IV.	Conclusion	20

Abstract. Published data now available on the use of correlation analysis in free-radical chemistry are discussed systematically. The scales of 'radical' σ-constants of substituents proposed previously are analysed. It is shown that none of them is applicable as a general scale because almost in all cases, it is impossible to separate correctly the proper radical and polar contributions to the overall effect of substituents. A new approach to the quantitative estimation of the relationship between the structure and reactivity of molecules in free-radical processes called r^{-2}-analysis is proposed. The bibliography includes 238 references.

I. Introduction

Correlation analysis is a widely used mathematical formalisation of the chemical similarity principle.

The foundations of the analysis were laid by Hammett, who discovered a correlation between the rate constants (k) or equilibrium constants (K) of reactions involving benzene derivatives and the ionisation constants of benzoic acids [1]

$$\log\frac{k_X}{k_H} = \rho\log\frac{K_X}{K_H} = \rho\sigma,$$

where the subscripts X and H refer to substituted and unsubstituted derivatives and ρ is the reaction constant for the given series. The reaction series of dissociation of benzoic acids in aqueous solutions at 25 °C was chosen as the reference series, described by $\rho = 1$, and the ratio

$$\log\frac{K_X}{K_H},$$

was introduced as the σ-constant, reflecting the influence of the substituent X in a set of similar reaction series. This empirical approach, which is also known as $\sigma\rho$-analysis, became one of the first quantitative methods for describing the structure – reactivity relationship for compounds and has served as the basis for the subsequent development of the general formal theory of the influence of substituents.

The principles of linear free energy (LFE) and polylinearity (PL) provide the physical grounds for this approach, according to which the increment of the Gibbs energy change (ΔG) in a reaction or of the activation energy caused by the introduction of a substituent is represented as the additive sum

$$\delta\Delta G = \delta\Delta G_I + \delta\Delta G_S + \delta\Delta G_R,$$

each of the terms reflecting a particular type of substituent effects, namely, inductive (I), steric (S) or resonance (R) effect. The multitude of inductive, steric and resonance constants determined from diverse experimental sources, together with some specific constants (for example, 'phosphorus' or 'silicon' constants) form dozens of scales which are widely used to describe the influence of substituents on the reactivity at the group level of additivity.

Various aspects of the determination and versatile practical application of steric and inductive constants of groups and the concept of electronegativity tightly connected to them have been described in detail in our previous reviews.[2–5] It should only be noted that modern correlation analysis has long overstepped the limits of a purely empirical approach. The group constants of substituents have provided the experimental basis for the physical interpretation and for the development of various quantitative models describing the steric and electronic effects.

Certainly, some key problems of the formal theory of interaction and correlation analysis are still to be ultimately solved. For example, the nature of the inductive effect and the mechanism of its transfer remain one of the most debatable and topical problems of physical chemistry [2] (the state-of-the-art in this line of research has been discussed comprehensively in recent review publications [5–8]). Nevertheless, it can be stated with confidence that the theoretical grounds of modern correlation analysis provide in general a clear picture and give good grounds for the extensive use of the substituent constants for description of the structure – property relationships in the chemistry of organic and heteroorganic compounds. Perhaps, the only field of chemistry in which the use of correlation analysis has not yet provided good results is free-radical chemistry. The application of LFE and PL principles in this field of chemistry is still limited to a rather narrow range of compounds (mainly, aromatics).

In this review, the current state of the use of correlation analysis for radical reactions is considered for the first time. In addition, we thought it necessary to present the generalising results obtained by the new approach to the estimation of the structure – reactivity relationship in free-radical reactions which we have developed and called 'r^{-2} analysis'.

II. Correlation analysis for reactions involving free radicals

1. Methods for the description of the effects of substituents in homolytic processes based on kinetic parameters. $\sigma^{\cdot}$-Scales

Despite the fact that the applicability of the Hammett equation to homolytic processes is sometimes debated,[9] there exist quite a few examples of successful use of various polar constants for the description of free-radical reactions.[10–28]

In addition to the proper Hammett σ-constants,[18–29] which reflect the overall effect of substituents in aromatic systems, so-called dual σ^+ and σ^- parameters of substituents, which imply direct polar (mesomeric) interaction of $^+$M or $^-$M substituents with the reaction centre, are also actively used in the analysis of homolytic processes.

The scale of σ^+-constants proposed by Brown and Okamoto,[30] which is based on the rates of solvolysis of *para*- and *meta*-substituted cumyl chlorides, is believed to be more adequate in describing the properties of aromatic radicals than the scale of Hammett σ-constants.[31] In our opinion, the use of σ^+-constants is really more effective as far as the properties of radical cations are concerned but this is not that obvious for neutral radicals. Nevertheless, radical bromination of substituted toluenes with bromine,[24] *N*-bromosuccinimide [24] and bromotrichloromethane [32] as well as the quantitative interpretation of abstraction of a hydrogen atom by alkoxy radicals,[11,12,33] chlorine atoms,[34] and peroxy radicals [34] have become classical examples of successful use of the σ^+ constants in free-radical chemistry. Experimental results obtained by one of the authors of this review have confirmed the exceptionally high efficiency of the σ^+ constants in correlations with single-electron reduction potentials of various aromatic molecules and radicals.[35–40]

Other researchers [18,41] have also considered the Brown–Okamoto scale to be the most suitable scale for the description of properties of free radicals; it is the scale of σ^+ constants that has served as the base for the introduction of several specific radical constants of substituents $\sigma^{\cdot}$ (they will be considered in detail in the subsequent sections of this review).

The σ^--constants found from the pK values for ionisation of substituted anilines, *N*,*N*-dimethylanilines and phenols [42,43] have also been used successfully to describe a number of radical processes.[29,44] However, polar constants are finding fairly limited application in free-radical chemistry. The scope of application of particular scales to the description of properties of free radicals remains obscure, identification of statistically significant correlations in each successful case being rather a matter of luck than of a systematic approach. Additional difficulties arise when the correlation analysis technique is employed to describe the properties of non-aromatic free radicals.

The main problem in the quantitative estimation of the effects of substituents in homolytic processes is, undoubtedly, the necessity of adequate description of their ability to delocalise the unpaired electron. Currently, this is one of the most topical and ambiguous problems in free-radical chemistry (see, for example, a monograph [45] and references therein).

There is a common opinion that both donors and acceptors are capable of stabilising a radical centre;[45] this is often used as an argument in favour of the introduction of special radical $\sigma^{\cdot}$ constants of substituents, which are expected to describe quantitatively the ability of substituents to delocalise spin density. The methods of determination of $\sigma^{\cdot}$-constants can be classified into three main types. The first type includes methods based on the use of kinetic parameters of homolytic processes; the second type comprises physicochemical methods which provide direct information on the spin density distribution in radicals; and thermodynamic approaches operating with energy characteristics belong to the third type. Below we consider the existing approaches in accordance with this classification.

The methods based on the kinetic parameters of homolytic processes are used most widely in determining the $\sigma^{\cdot}$-constants of substituents and are modifications of the classical correlation analysis, based on the use of the extended Hammett equation

$$\log\frac{k}{k_0} = \rho_1\sigma^{X} + \rho_2\sigma^{\cdot}. \qquad (1)$$

The essence of this approach is to separate the contribution of the proper radical stabilisation ($\sigma^{\cdot}$) from the polar effect (σ^{X}); hence, it requires selecting a model reaction series in which the latter contribution would be small and could be determined reliably in terms of polar constants. The most widely used reactions involving free radicals include electron transfer, free-radical transfer of a hydrogen atom and radical addition.

The kinetic approach to the description of the effects of substituents in radical reactions was first employed by Alfrey and Price [46] in a study of the reactivity of vinylic monomers in copolymerisation. The researchers [46] did not use the classical logarithmic form of Eqn (1); however, the capacity of substituents for stabilisation of radicals was estimated quantitatively for the first time in terms of group constants Q, whereas the polar component was taken into account by the parameter e (the Q constants are given in Table 1)

$$\frac{k_1}{k_2} = \frac{Q_1}{Q_2}\exp\left[-e_1(e_1 - e_2)\right]. \qquad (2)$$

A substantial disadvantage of this approach is the fact that the calculation of Q is based on the analysis of a set of data on copolymerisation, and introduction of new individual values requires a consistent procedure for recalculation of the whole array of Q.

Walling *et al.*[59] have critisised the theoretical substantiation of the Alfrey–Price approach, which ignores the possibility of resonance stabilisation of a radical transition state.

Later, the group parameters E_R have been introduced using the relative reactivity of monomers ($1/r$) in the radical copolymerisation of aryl-substituted methacrylates [47,48,60]

$$\log\frac{1}{r} = \rho\sigma + \gamma E_R\,, \qquad (3)$$

where the γ coefficient was taken to be 1, and the parameter E_R was interpreted as the resonance component of the substituent effect in free-radical processes. Subsequently,[49] this approach was subjected to severe criticism, the legitimacy of the E_R and γ values being prejudiced. The researchers [49] believed that the nature of E_R is rather complex; therefore they proposed adjusted values, E_R^n, free from the contribution of heterolytic resonance (see Table 1).

A similar scale of resonance constants E_D has been developed to describe the effects of *para*-substituents in the addition of trichloromethyl radical to substituted styrenes [53]

$$\log\frac{k_p}{k_H} = \rho\sigma_p^{+}(\rho\sigma_p) + E_D\,; \qquad (4)$$

in this case, the polar effect was taken into account by both the Brown–Okamoto constants and the Hammett σ_p-constants. Correspondingly, two sets of E_D parameters for *para*-substituents (MeO, Cl, CN, NO_2) in styrenes were obtained [$E_D(\sigma)$ and $E_D(\sigma^+)$ in Table 1]. The E_D constants of these substituents found using the σ^+ parameters are in good agreement with the Alfrey–Price Q constants.

A similar approach was used [54] to develop the τ scale, which reflects the conjugation effects in radical arylation of substituted benzenes

$$\log\frac{k_p}{k} = \rho\sigma_p + \tau_p\,, \qquad (5)$$

where k_p are the rate constants for the arylation into the *para*-position expressed in terms of the Hammett constants of *para*-substituents (σ_p) and the group parameters τ_p, which reflect the additional delocalisation effects of *para*-substituents. The ρ-constant appearing in Eqn (5) was determined on the basis of a similar reaction series of *meta*-arylation, the influence of substituents

Table 1. Constants characterising the radical-stabilisation properties of substituents (data of kinetic studies).

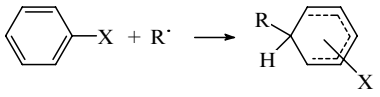
Note. The values which vary in original publications are given in parentheses.

[a] From Ref. 46; [b] from Refs 47, 48; [c] from Refs 49 – 52; [d] from Ref. 53; [e] from Ref. 54; [f] from Ref. 55; [g] from Refs 50 – 52; [h] from Ref. 56; [i] from Ref. 57; [j] from Ref. 58.

being entirely ascribed to the polar interaction. The parameters τ_o for *ortho*-substitution were introduced by a similar procedure. The 4-$XC_6H_4\dot{C}H_2$ radicals, where X = H, NO_2, Cl, Me, MeO, were investigated (regardless the nature of the attacking agent); in this case, the τ_p and τ_o constants decreased in the series $PhNO_2 \gg$ PhCl, PhOMe > PhMe (see Table 1). This model series has an important advantage: the measured kinetic parameters vary over a broad range due to the direct conjugation of para-substituents with a cyclohexadienyl radical.



However, it cannot be ruled out that, within the framework of the given reaction series, fairly reactive phenyl radicals would be involved with high probability in side homolytic properties.

The methodology of the above approaches is evidently similar to that used in the classical equations of correlation analysis, which determine the inductive and resonance constituents of the polar effect of substituents in terms of Taft,[42,61–63] Exner,[64–66] Yukawa–Tsuno,[67,68] Swain–Lupton,[69] Dewar–Grisdale,[70] Charton [71] and Palm [72,73] approaches. In all the studies described above, except for the study by Alfrey and Price,[46] the researchers dealt only with aromatic systems. Therefore, the radical constants τ, E_R and E_D are believed to contain a component due to the polar effect.

Fisher *et al.*[55,74,75] used radical bromination of 4-substituted 3-cyanotoluenes with *N*-bromosuccinimide as the model reaction to determine the 'extra-resonance' (this name was proposed by the authors), *i.e.*, the proper radical contribution (the polar contribution is minimised). When considering the possible canonical forms of the transition state of hydrogen abstraction *via* the reaction

$$YH + Z^{\cdot} \longrightarrow \left[\dot{Y}\,\dot{H}\,\dot{Z} \longleftrightarrow \underset{\mathbf{1a}}{Y^{+}\,\dot{H}\,Z^{-}} \longleftrightarrow \underset{\mathbf{1b}}{Y^{-}\,\dot{H}\,Z^{+}} \quad \underset{\mathbf{1c}}{}\right],$$

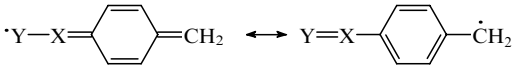
the researchers suggested that the high electronegativity of the attacking bromine atom Z precludes a substantial contribution of structure **1c**. In order to destabilise the polar form **1b** to decrease its contribution, the electron-withdrawing CN group was introduced in the *meta*-position relative to the methyl group (substrate YH) of the substituted toluene. The radical intermediate **1a** is stabilised additionally due to direct resonance. Assuming that the polar effects in the model system were thus minimised, Fisher *et al.*[55,74,75] proposed a scale of $\sigma^{\cdot}$ radical constants within the framework of a two-parameter equation including the Brown–Okamoto constant σ^{+}

$$\log\frac{k}{k_0} = \rho\sigma^{+} + \sigma^{\cdot}, \qquad (6)$$

in which the parameter ρ was determined on the basis of a similar reaction series of 4-substituted toluenes.

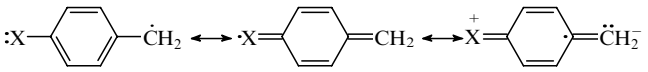
Fisher and Meierhoefer [55] did not use a series of *meta*-substituted toluenes as the standard for determining ρ on the ground that the corresponding parameter in Eqn (6) reflects, in their opinion, both the resonance and inductive polar effects. Thus, the differences between the effects of substituents in the free radical bromination of monosubstituted and 3-cyano-4-substituted toluenes by *N*-bromosuccinimide were attributed to the stabilisation of the structure **1a**; they were proposed as characteristics of the radical effects of *para*-substituents. In accordance with the results of this study, the ability of substituents to stabilise free radicals increases in the series F < OMe < Me < H < Cl < Ph < I < Br < NO_2 < N=NPh < CN < Ac, the $\sigma^{\cdot}$ constants for F and MeO being negative [$\sigma^{\cdot}$(F) = −0.25, $\sigma^{\cdot}$(MeO) = −0.12], which implies that these groups destabilise the radical reaction center (see Table 1).[55]

Meanwhile, it is obvious that the resonance stabilisatoion of substituted benzyl radicals by electron-withdrawing substituents (structures **2a** and **2b**) is similar to resonance delocalisation of the negative charge. This accounts for the most pronounced radical-stabilisation properties of substituents such as Ac, CN, N=NPh and NO_2, which also exhibit a negative mesomeric effect.



2a **2b**

In the case of stabilisation of the benzyl radical by the donor mesomeric effect of some substituents such as halogens (except for F), the researchers cited [55] discussed the formation of three contributing structures **2c**, **2d** and **2e**.



2c **2d** **2e**

Structure **2e** is characterised by substantial charge separation, which makes it energetically less favourable. The electrically neutral structure **2d** implies delocalisation of the unpaired electron because it has been added to the electron octet of the X atom. As Tsuno *et al.*[68] rightly noted, elements of Period II, O and F, are incapable of this type of interaction, which accounts for the negative values of the corresponding radical constants.

The presence of negative $\sigma^{\cdot}$ values in the Fisher–Meierhoefer scale hampers its quantitative comparison with other known scales, in most of which the radical constants can be only positive, implying that the radical reaction centres are stabilised by both donors and acceptors. It should also be noted that in the model system of disubstituted toluenes proposed, the possibility of resonance effect of *para*-substituents is retained, despite the minimisation of polar effects.

The search for standard reaction series with a clear-cut radical character of the transition state, which rules out a noticeable influence of polar interactions, has led Jackson *et al.*[50,51,56,76,77] to consideration of the thermal dissociation of dibenzylmercury derivatives in solution.

$$ArCH_2HgCH_2Ar \longrightarrow Ar\dot{C}H_2 + \dot{H}gCH_2Ar$$

$$\dot{H}gCH_2Ar \longrightarrow Hg + Ar\dot{C}H_2\,.$$

It was found that homolysis occurs in two stages. The first, rate-determining stage is generation of benzyl and benzylmercurio radicals;[52,78,79] it was suggested that in the transition state, one C–Hg bond has been cleaved almost completely, which corresponds to the formation of a nearly free benzyl radical.

The conventional $\sigma\rho$-analysis, which makes use of the first-order rate constants for the reaction under consideration and the Hammett σ-constants (subsequently, the σ^0 parameters were used), identified a linear correlation for *meta*-derivatives, whereas *para*-substituents of both electron-donating and electron-withdrawing nature accelerate homolysis, due to an additional stabilisation of benzyl radicals. In the equation

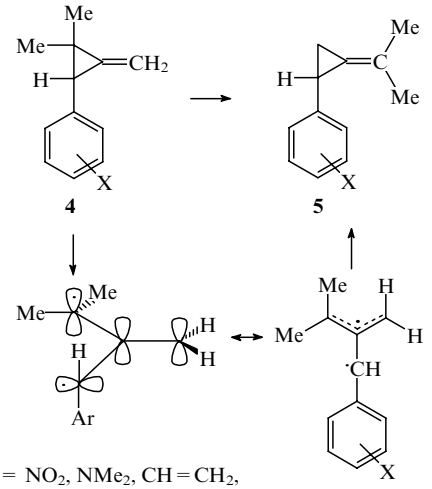
$$\log\frac{k}{k_0} = \rho\sigma + \rho^{\cdot}\sigma^{\cdot} \qquad (7)$$

resulting from the correlation procedure, the parameter $\rho^{\cdot}$ was taken to be unity for reactions giving rise to free benzyl radicals in the rate-determining step. In terms of the regression analysis performed, the constants which were later designated by $\sigma_J^{\cdot}$ (see Ref. 45) and which reflect the stabilising effect of substituents in the *para*-position of the benzyl radicals were determined from the deviations from the *meta*-correlation (see Table 1). The $\sigma_J^{\cdot}$ values were found to be in good agreement with the Q, τ, E_D and E_R scales (the correlation coefficients r varied from 0.83 to 0.92); as regards the Fisher–Meierhoefer constant ($\sigma_{FM}^{\cdot}$), only some qualitative correspondence was found in this case (r = 0.63).

It has been proposed [56] to use the $|\sigma^{\pm} - \sigma|/n$ scale, where $\sigma^{\pm}$ is the σ^{+} or σ^{-} constant, as a measure of radical stabilisation; for substituents containing a lone electron pair n = 2, while for groups with a multiple bond or any other π-system, n = 1. This

scale correlates well with the $\sigma_J^{\cdot}$ values. As drawbacks of this approach, the authors note the difficulty of preparing a broad range of dibenzylmercury derivatives and the limited solubility of these compounds in octanol, used as the reaction medium.

An attempt to select a perfect free-radical transition state is also the central point in Creary's approach,[57, 80–84] in which thermal rearrangement of 3-aryl-2,2-dimethylmethylenecyclopropanes **4** has been used as a standard reaction series to introduce the scale of radical constants $\sigma_C^{\cdot}$.



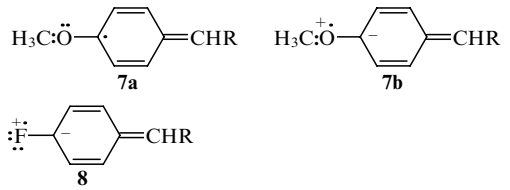
X = NO_2, NMe_2, $CH=CH_2$, $C(Me)=CH_2$, Ph, cyclo-C_3H_5, CH_2SiMe_3, $SiMe_3$, $SnMe_3$, HgCl, $B(OCH_2CH_2O)$.

The transition state of the rearrangement is of biradical nature; this has been confirmed in a series of studies.[85–94] Proceeding from the assumption that the biradical nature of the transition state rules out the possibility of substantial charge separation in it, Creary suggested using the logarithm of the relative rate constant for the reaction, k_{rel}, as a measure for the ability of substituents to stabilise the benzylic radical centre

$$\sigma_C^{\cdot} = \log k_{rel} . \quad (8)$$

The kinetic parameters of thermal rearrangement of 2-aryl-3,3-dimethylmethylenecyclopropanes **4** into 2-arylisopropylidenecyclopropanes **5** can be easily determined by gas chromatography or NMR; this permits determination of radical constants for *meta*- and *para*-substituents of the aromatic ring within the framework of this approach. It is also possible to evaluate the stabilising influence on the radical centre of heteroorganic substituents.[45]

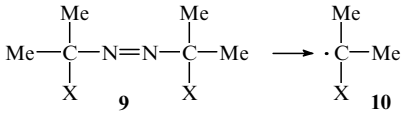
It was found [57, 84] that electronegative substituents in the *meta*-position retard the rearrangement, which might point to an electron-deficient character of the biradical transition state. Most *para*-substituents, both electron-donating and electron-withdrawing ones have positive values of $\sigma_C^{\cdot}$ constants. An exception is F, for which $\sigma_C^{\cdot} = -0.08$ (see Table 1); this was explained by the destabilising influence of F caused by the enhanced inductive effect. The influence of the *para*-methoxy group was regarded as stabilisation ($\sigma_C^{\cdot} = 0.24$), caused by the contribution of the canonical forms **7a**,**b**.



A similar structure for the *para*-fluorine-substituted system appears less favourable because of the high electronegativity of fluorine. From the molecular-orbital standpoint, the stabilising effect of the *para*-methoxy group can be due to the interaction of the radical centre with the filled non-bonding orbital of oxygen; however, the low energy of the filled 2*p* orbital of fluorine precludes manifestation of the effects of this type.

As has been noted in a monograph,[45] synthesis of a broad range of methylenecyclopropanes **4** is quite difficult; therefore, the reaction series proposed by Creary has no advantages in this respect over thermal dissociation of mercury dibenzyl derivatives. In addition, it is not quite clear to what extent the centre in the transition state **6** is a radical centre. Nevertheless, this approach has been successfully developed; it was shown in a recent publication [94] that the introduction of nitrogen-containing substituents into the *para*-position of the substrate **4** provides considerable radical stabilisation. Moreover, some substituents, for example, $CH=NNMe_2$, $N=NPh$, $N=N(O)Bu^t$ and $CH=N(O)Bu^t$ ($\sigma_C^{\cdot}$ = 0.92, 1.08, 1.08 and 1.13, respectively), displayed extraordinary radical-stabilisation capacity; they were called super-stabilisers.

A free-radical transition state in aliphatic systems [45, 95–100] has been modelled by pyrolysis of substituted azopropanes **9**.

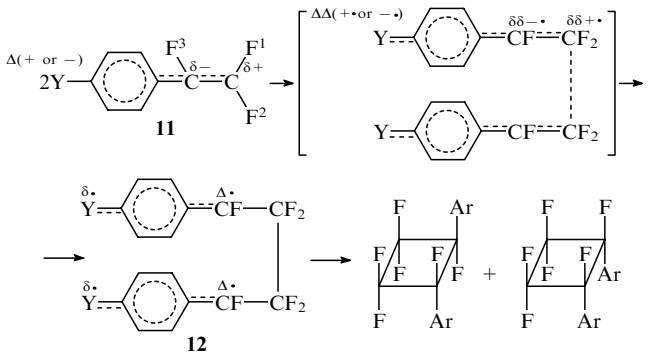


According to the researcher's assumption, this reaction series is characterised by slight steric and inductive interactions; therefore, the pronounced difference between the reaction rates (the range of variation of the rate constants is 10^9) is interpreted as being due exclusively to resonance stabilisation. Later, the kinetic characteristics of pyrolysis of the azopropanes **9** were found to be well correlated with the Creary radical constants $\sigma_C^{\cdot}$, despite the substantial difference between the structures of the radical substrates **6** and **10** and the fact that the extents of influence of substituents on the radical centres are difficult to compare.[83]

The series of model aryl-substituted azoalkanes has been markedly extended [101] by the inclusion of polycyclic azoalkane derivatives,[102] symmetrical azopropanes,[103, 104] azoethanes,[105, 106] azomethanes,[98] azoneopentanes [107] and 3,5-diaryl-1-pyrazolines,[98, 108] for which the kinetic parameters of pyrolysis have been found. It is worth mentioning that, only in terms of two-parameter correlations including polar constants σ, was it possible to attain satisfactory relationships between the experimental relative rate constants for the thermolysis of azo derivatives and the corresponding Creary parameters $\sigma_C^{\cdot}$.[84]

The equilibrium constant of the dissociation of substituted hexaarylethanes to triarylmethyl radicals has been used successfully as a measure of radical-stabilising capacity of substituents.[109]

An association reaction, namely, thermal [2 + 2]-cycloaddition of substituted α,β,β-trifluorostyrenes **11** [58] has been used as a model series for determination of spin-delocalisation group constants $\sigma_{JJ}^{\cdot}$ (see Table 1).



An advantage of this model reaction is that no side radical processes are involved. In addition, charge distribution in the transition state **12** is symmetric, which eliminates additional polar effects. Study of the kinetics of this reaction gave a two-parameter correlation equation

$$\log\frac{k_Y}{k_H} = \rho_{mb}\sigma_{mb} + \rho^{\cdot}\sigma^{\cdot}_{JJ}, \quad (9)$$

which was employed for the introduction of spin-delocalisation constants of substituents $\sigma^{\cdot}_{JJ}$. The σ_{mb} parameter in Eqn (9) is identical to the group constant proposed previously, which is determined on the basis of fluorine chemical shifts in the ^{19}F NMR spectra of compounds **11**.[58,110–113] The mb (multiple bond) subscript reflects the hypothetical additional repulsive component of interaction between the double bond and the electron lone pair or π-electrons in the Y substituent in the compound **11** (Jiang *et al.*[113] consider this to be a fundamental feature distinguishing the scale of σ_{mb} constants from the Brown–Okamoto σ^+ constants). Equation (9) provided the possibility of determining the $\sigma^{\cdot}_{JJ}$ constants for 32 substituents (see Table 1) at five different temperatures; this allowed the researchers to verify the adequacy of the correlation parameters proposed and to introduce an averaged scale.

By the use of the $\sigma^{\cdot}_{JJ}$ scale, together with the σ^+ parameters, the kinetic data underlying other scales of $\sigma^{\cdot}$ radical constants have been reproduced with rather high accuracy within the framework of a two-parameter equation. Assuming that the $\sigma^{\cdot}_{JJ}$ parameters reflect the real ability of substituents to delocalise spin density, Dust and Arnold[114] used the ratio of the coefficients of the two-parameter equations $\left|\frac{\rho}{\rho^{\cdot}}\right|$ as a measure of the relative contributions of radical effects in the corresponding model series. Thus it was shown that the ratio $\left|\frac{\rho}{\rho^{\cdot}}\right|$ for the reaction series of monosubstituted toluenes used by Fisher and Meierhoefer[55] to determine polar effects amounts to 4.8, whereas an analogous model series of substituted toluenes containing a cyano group in the *meta*-position is described by a ratio of polar to resonance effect equal to 1 : 1.51; in addition, the accuracy to which each contribution has been determined does not provide the possibility of their correct separation.

It should be noted that many researchers[4,52,77,114,115] proposed their own scales of $\sigma^{\cdot}$ constants which they considered to be the most suitable for estimating the radical character of transition states. For instance, Jackson *et al.*[56] used the $\sigma^{\cdot}_{J}$ scale and demonstrated that in the transition states of the model homolytic reactions that underlay the Fisher–Meierhoefer radical constants $\sigma^{\cdot}_{FM}$ and the E_R and E_D parameters, the fraction of structures corresponding to the proper benzyl radicals is not more than 50%.

The authors of most of the approaches discussed above have attempted to formulate the requirements to an ideal model system to be used for kinetic determination of radical constants.

1. The substituents should interact directly with the radical centre.

2. The mechanism of the model reaction should be as clear as possible.

3. Side reactions should be minimised.

4. Model systems should be preferred in which substituents have a strong influence on the reaction rate and for which accessible and precise methods for the determination of relevant kinetic parameters exist.

5. The polar effects should be either absent or minimised, or be reliably separated from the effect of radical stabilisation.

6. The model compounds should be readily available and should contain diverse substituents of both electron-donating and electron-withdrawing natures.

7. The role of other external and internal factors, for example, the solvent and the steric effect, should be minimised.

8. One of the most important features required for a free-radical reaction to be used as a model to describe the radical effects of substituents is that the nature of the transition state should be as radical as possible.

According to the Hammond postulate,[116] the last-mentioned condition (this is very important to emphasise) implies a late transition state of the process, which corresponds to a more endothermic generation of free radicals. This, in turn, stipulates a higher selectivity of the reaction.[117] Therefore, the radical effects of substituents (in particular, the captodative effect† of radical stabilisation) are often considered in the context of selectivity of free-radical processes (see, for example, Refs 45, 118).

It should be noted that in none of the above-listed approaches, the transition state can be considered completely radical — in any case, one should suggest the presence of charge separation and polar interactions. Therefore, the topicality of the question of to what extent a particular scale of radical constants is free from the polar constituent is beyond doubt. Apparently, the polar constituent can hardly be ruled out completely.

2. Spectroscopic determination of the capacity of substituents for delocalisation of spin density in free radicals

Physicochemical methods such as EPR spectroscopy permit direct investigation of the properties of free radicals.

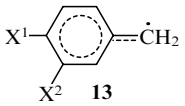
According to the McConnel equation

$$a_H = Q\rho^{\pi}_C,$$

the hyperfine splitting (HFS) constants a_H in the EPR spectra are directly proportional to ρ.[118]

For a number of compounds, the relative HFS constants have been found[119,120] to correlate with the σ and σ^- polar constants; it was concluded[119] that delocalisation of an electron pair is a more substantial stabilising factor than spin density delocalisation. A non-kinetic scale of the stability of alkyl radicals based on HFS constants of β-protons has been composed.[121]

The approach proposed by Arnold *et al.*[122–126] is best known of all; according to this approach, the HFS constants of α-protons are used as a measure of stabilisation energy, determined by delocalisation of spin density in substituted benzyl radicals **13** with respect to $PhC\dot{H}_2$.



13

This method has obvious advantages, which include the absence of side radical reactions and the relative ease of generation of the required free radicals.[45] In addition, the radical constants $\sigma^{\cdot}_{\alpha}$, defined by the equation

$$\sigma^{\cdot}_{\alpha} = 1 - \frac{a(H_X)}{a(H_0)}, \quad (10)$$

where $a(H_X)$ and $a(H_0)$ are the HFS constants of the α-protons in the substituted and unsubstituted radicals, respectively, can be considered to be free from the polar effects characteristic of radical-like transition states and do not correlate with the substituent effects in the corresponding diamagnetic initial compounds. The researchers[122] assumed that other factors which can potentially influence the HFS constants (hybridisation of the orbital bearing the unpaired electron, interaction with β-substituents, steric effects reflected in the geometry of benzyl radicals[118]) are insensitive to the substitution in the aromatic ring.

The $\sigma^{\cdot}_{\alpha}$ values thus obtained (Table 2) confirmed that the *meta*-substituents in the aromatic ring decrease delocalisation of the unpaired electron. The correlation established between the constants of *meta*-substituted benzyl radicals and the corresponding Hammett *meta*-constants (σ_m) made it possible to relate the destabilising effect of *meta*-substituents to their inductive electron-withdrawing effect.[45] However, it is not entirely clear why electronegative *meta*-substituents hamper delocalisation of spin density on the methylene carbon atom in the benzyl system.[124]

† Captodative effect is a joint influence of electron-donating and electron-withdrawing substituents on a radical reaction centre, resulting in a stabilisation greater than the sum of the two stabilising effects in the corresponding monosubstituted radicals.[45]

Note. E_d is the energy of homolytic dissociation of the C−X bond in substituted methanes.
[a] From Refs 114, 125; [b] from Ref. 127; [c] from Ref. 45; [d] from Ref. 115.

Presumably,[124, 128] a decrease in the electron density by the inductive mechanism prevents the effective overlap of the interacting sites, *i.e.*, of the orbital carrying the unpaired electron with the π-system of the benzene ring, or, in other words, it decreases the energy of the π-system and thus weakens the interaction between the CH_2-group carbon and the aromatic ring.

The effects of the OC(O)Me, CF_3 and F groups located in the *para*-position were found to destabilise the radical centre, whereas other *para*-substituents, according to the data obtained from EPR, favour spin density delocalisation.

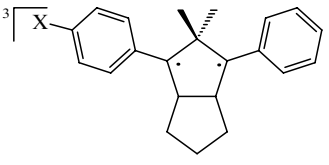
It has been suggested that a decrease in the spin density in the α-position of the benzyl radical would result in an increase in the π-resonance binding of the aromatic system with the methylene group and, correspondingly, in an increase in the barrier to rotation around the $C_{arom}-CH_2$ bond.[45, 124] The π-component of the stabilisation energy (E_s) of the π-radical was expressed *via* the rotation barriers of the CH_2 group in the $Z\dot{C}H_2$ radicals with or without spin density delocalisation

$$E_s = V_2(\dot{C}H_2) - V_2^*,$$

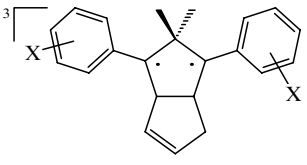
where the corresponding rotation barriers (V_2 and V_2^*) can be determined from EPR data.

Jackson [129, 130] has noted that the range of HFS constants considered by Arnold *et al.*[122–126] is rather narrow and some individual values were determined with substantial errors. Therefore, he developed a new approach that provided more accurate determination of the HFS constants $a(CH_2)$ in the EPR spectra of benzyl radicals.[116] The results [129, 130] are generally consistent with the $\sigma^{\cdot}_{\alpha}$ scale.

Yet another example of using quantitative parameters of EPR spectra is a study by Adam *et al.*,[127, 131–135] who made use of the electronic spin–spin splitting parameters *D*. The parameter *D* is a sensitive function of the averaged distance between the unpaired electrons in a biradical ($D \propto 1/r^3$) which is proportional to the product of local spin densities in the triplet biradicals **14** and **15**, chosen as the reference species to determine the capacity of the substituent X for spin density delocalisation.[130–132]



14



15

Proceeding from the assumption that specific electronic effects (captodative stabilisation, spin polarisation, *etc.*) are relatively insignificant in 1,3-biradicals,[136] Adam *et al.*[127, 132–134] proposed the scale of $\Delta D = D_H - D_X$ values (where H corresponds to the unsubstituted radical), which reflects delocalisation of the unpaired electron by the aryl group. Negative ΔD values, which should correspond to electron-donating groups, were found for all *meta*-substituents (including charged ones, *viz.*, NH_3^+, O^-) and for *para*-substituents such as F, OMe, OC(O)Me and OH. The *para*-substituents NO_2, CN, C(O)OMe, NH_2 and CF_3 exhibit the highest capacity for spin density delocalisation (see Table 1).

The additivity of ΔD values found for monosubstituted and symmetrically disubstituted triplet biradicals **14** and **15** served as the basis for the assumption that each of them can be represented as composed of two fixed fragments of the cumyl radical. Hence, the researchers suggested[127, 132] that the ΔD scale could also be used for adequate description of benzyl monoradicals. This suggestion is supported by the fact that the parameters D for triplet biradicals are correlated with the α-spin densities and the energies of resonance stabilisation of the corresponding cumyl radicals.[127, 132–134]

Comparison of the ΔD scale with known radical constants based on the properties of benzyl radicals revealed a relatively good correlation of this scale with the Fisher data (the correlation coefficient squared is $r^2 = 0.92$); however, the discrepancies with the $\sigma_J^{\cdot}$, $\sigma_C^{\cdot}$, and $\sigma_{JJ}^{\cdot}$ arrays are quite substantial ($r^2 = 0.33–0.60$). Subsequently, this approach has been extended to heteroaromatic π-systems such as pyridine and furan derivatives and some other.[135]

3. Thermodynamic approaches to the estimation of radical stabilisation. Bond energy as a measure of radical stabilisation

Study of the effects of substituents in free radicals is tightly connected with the problem of quantitative evaluation of the energies of dissociation of chemical bonds.

The energy of an R–R′ bond is known[136] to be determined by the enthalpy ΔH_1^0 of homolytic dissociation of this bond, giving rise to free radicals R$^{\cdot}$ and $\dot{R}'$

$$R-R' \longrightarrow \dot{R} + \dot{R}'.$$

In turn, the ΔH_1^0 value is determined by the standard enthalpies of formation of RR′, R$^{\cdot}$ and $\dot{R}'$

$$\Delta H_1^0 = \Delta H^0(\dot{R}) + \Delta H^0(\dot{R}') - \Delta H^0(RR').$$

Thus, the relative energies of the homolytic dissociation of bonds can serve as a measure of radicals stabilisation. On the basis of the foregoing, Benson and O'Neal[137, 138] have proposed estimating the stabilisation energy for π-resonance delocalised radicals R(π-$\dot{C}H_2$) as the difference between the dissociation energies E_d of the corresponding derivatives

$$E_s[R(\pi\text{-}\dot{C}H_2)] = E_d[R(CH_2-H)] - E_d[R(\pi\text{-}CH_2-H)].$$

Subsequently, the C–H bond energies have been widely used to estimate the stabilisation energies for carbon-centred radicals. For example, the resonance stabilisation energy of the benzyl radical can be represented as the difference between the energy of the benzylic bond in toluene and the energy of the C–H bond in ethane.[45, 139, 140] The enthalpy of dissociation of the C–H bond in the methane molecule $E_d(CH_3-H) = 439$ kJ mol^{-1} is used most often as the reference value.[140–145]

In one of the first studies dealing with this topic, the enthalpy of the isodesmic reaction (*i.e.*, a reaction in which the number and character of bonds do not change on passing from the initial compounds to the products)[146]

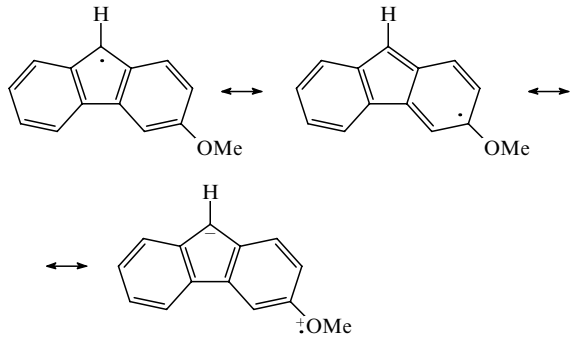
$$R^{\cdot} + CH_4 \longrightarrow RH + {}^{\cdot}CH_3$$

was identified as the stabilisation energy E_R of the R$^{\cdot}$ radicals[146]

$$E_R(R^{\cdot}) = \Delta H_2^0 = E_d(CH_3-H) - E_d(R-H).$$

Subsequently, stabilisation energies of radicals expressed in terms of E_d, *i.e.*, $E_s(R^{\cdot}) = E_d(CH_3-H) - E_d(R-H)$, have been widely used for various correlations.[138–145]

Bordwell *et al.*[147, 148] have proposed a scale of redox potentials I_{AO}, which is also actually based on the relative energies of dissociation of bonds in substituted fluorenes.



The potentials were determined using the thermodynamic cycle

HA	⟶	$H^+ + A^-$	(pK_a)
A^-	⟶	$A^{\cdot} + e^-$	(E^{ox})
$H^+ + e^-$	⟶	$H^{\cdot}$	(E^{red})
HA	⟶	$H^{\cdot} + A^{\cdot}$	(E_d),

in which the proton reduction potential E^{red} is a constant and the sum $pK_{HA} + E^{ox} = I_{AO}$ can be regarded as a measure of relative radical stability of the radical A$^{\cdot}$.

The oxidation potentials E^{ox} of substituted fluorenide ions were determined experimentally in DMSO solutions, and the pK values of the conjugate acids were established on the basis of their correlation with E^{ox}; this gave rise to a scale of I_{AO} values for a number of substituents at the 2-, 4- and 7-positions expressed in kJ mol^{-1} and reflecting the ability of these substituents to delocalise the unpaired electron in fluorenes.

The application of this approach to 9-substituted fluorenes and to 3- and 4-substituted phenylacetonitriles has made it possible to analyse a wide spectrum of radical-stabilisation and -destabilisation effects.[149, 150] Comparison of the I_{AO} values for 4-substituted arylacetonitriles with the $\sigma_{JJ}^{\cdot}$ constants within the framework of a two-parameter equation containing the σ^+-parameter showed that the contributions of the polar and radical constituents to I_{AO} are approximately equal.[58]

It has been proposed to use the E^{ox} oxidation potentials of 3- and 9-substituted fluorenes[150, 151] and of α-substituted acetone and acetophenone derivatives[152] in DMSO as the basis for determination of the stabilisation energies E_{RS} of the corresponding radicals

$$\Delta E_d = 1.37\Delta pK_{HA} + 23.1\Delta E^{ox}(A^-) = E_{RS}.$$

The resulting values point to a stabilising effect of substituents at the 3-position in substituted fluorenyl radicals, except for F and $PhSO_2$. Substitution into the 9-position both by donors and by acceptors results, as a rule, in system stabilisation. Most of 4-substituents (except for F and CF_3) also exhibit pronounced stabilising properties.[148] In general, it was concluded[150] that the majority of substituents play a dual role in the stabilisation of a free radical: they destabilise the radical due to the electron-acceptor influence and stabilise it due to delocalisation.

In some studies, the radical-stabilisation energy of substituent X was set identical to the covalent component of the dissociation energy of the XR–Z bond, where R is a permanent molecular fragment (for example, the aromatic ring), while R–Z is the 'indicator' bond.[140, 153–156] The notion 'indicator' bond was introduced back in Pauling's studies;[151] the stabilisation energy E_{RS} was defined *via* the relative dissociation energies of bonds in symmetrically substituted molecules

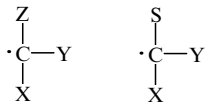
$$E_{RS} = 0.5\,E_d(XR-RX) - 0.5\,E_d(HR-RH).$$

A similar approach has been proposed by Leroy,[157, 158] who used the enthalpies of atomisation ΔH_a together with the standard bond energy E_{AB} to define the stabilisation energy E_s

$$E_s = \Delta H_a - \Sigma N_{AB} E_{AB},$$

where N_{AB} is the number of AB bonds. This procedure was applied successfully both to free radicals and to diamagnetic molecules.

Thermochemical and kinetic investigations of the rupture of the C—C bond have been employed to define the parameter E_{RS}, introduced to reflect the difference between the stabilities of the hydrocarbon radical **16a** and the corresponding substituted radical **16b**.[117, 156, 159–161]



16a **16b**

X, Y, Z are hydrogen atoms or alkyl substituents and S is a functional group.

A substantial drawback of the approaches in which the radical stabilisation is defined in terms of the relative bond energies and the reason why these approaches are severely criticised is the fact that the energy of homolytic dissociation of a bond is a relative value, *i.e.*, the difference between the energies of the molecule and the corresponding radicals; therefore, the substituent effect cannot be attributed to the properties of the free radical alone.[117, 143, 162, 163] It is well known that the dissociation energies of bonds depend on steric effects [116] and on polar effects;[164] the presence of numerous correlations between E_d(CH) and the 'ionic' constants of substituents σ^+ (see publications [23, 147, 165]) is common knowledge. In our opinion, this virtually rules out a legitimate separation of the polar and radical effects in this type of approach. Moreover, it was shown that in some cases, the effect of substituents can even prevail in the ground state; then the corresponding ΔE_d values reflect destabilisation of the molecule rather than stabilisation of the free radical.[163] It has been clearly demonstrated [143] using, among other reasons, vast literature data that relative bond energies cannot be related directly to the stability of radicals.

4. Calculation of the energies of stabilisation of radical centres

Apart from experimental methods, there also exist theoretical methods for the determination of group parameters of substituents reflecting their capacity for stabilisation of radical centres.

Modern quantum-chemical approximations permit direct calculation of quantitative characteristics of radicals such as the total energy, the standard enthalpy of formation, the energy of the orbital with the unpaired electron and the spin and charge density, which make it possible to judge the stabilising influence of substituents. Many quantitative parameters employed to determine the radical-stabilisation effects in terms of the experimental approaches described above such as the kinetic parameters of free-radical reactions and the overall thermodynamic characteristics, spin densities and rotation barriers in free radicals can be calculated quite reliably by quantum-chemical methods. Certainly, any general description of theoretical approaches requires separate consideration. Within the framework of this review, we shall dwell only on those of them that have served as the base for the introduction of sets (scales) of energetic parameters of substituents reflecting their radical-stabilisation influence and implying consistent utilisation of the LFE principle.

In studies by Pasto *et al.*,[166, 167] the change in the total energy of species participating in the free-radical transfer of a hydrogen atom has been identified with the stabilisation energy E_{RS} of the corresponding substituted methyl radical. The E_{RS} values were calculated for a large number of substituents. The captodative effect of radical stabilisation and the influence of the substituents attached to the reaction centre containing an unpaired electron were analysed from the additivity standpoint.[166] The comparison of the calculated E_{RS} values with the known scales demonstrated a relatively good quantitative agreement with the I_{AO} parameters for 3- and 9-substituted fluorenes and 4-substituted phenylacetonitriles,[148] with the relative constant of the thermal rearrangement of 3-aryl-2,2-dimethylmethylenecyclopropanes [57, 82, 83] and α-spin density in 4-substituted benzyl radicals.[114] Within the framework of this approach, it was found that the radical-stabilisation effect markedly increases on passing from F- to O- and N-containing substituents. In the series Cl, S, P, the capability for spin density delocalisation increases due to the decrease in the energy gap between the vacant MO of the methyl radical and the MO occupied by the unpaired electron. Study of the effects of substitution with charged ($^+NR_3$, $^+SR_2$, $^+PR_3$) or electronegative non-charged (CF_3, SOR, SO_2R) groups showed that they destabilised the radical. In addition, it was found that the energies of stabilisation of the radical centre calculated in terms of the approach proposed are exceptionally sensitive to the conformation of the free radical and the corresponding diamagnetic molecule.

Isodesmic reactions (see Section II.3) proved convenient for the calculation of $E_{RS}(R^{\cdot})$.[44, 144, 168–173] The enthalpy of hydrogen atom detachment in these reactions is a measure of the energy of stabilisation of the radical centre; the use of this value decreases the errors related to the basis set chosen and to electron correlation effects.[174]

The stabilisation energies of the radical centre E_{RS} correlated with the barriers to rotation around the C—C bond in benzyl radicals were calculated by quantum-chemical methods, as well as the difference between the energies of the conformers corresponding to angles of rotation around the σ-bond equal to 90° and 0°.[175–177]

$$E_{RS} = \Delta H_f(90) - \Delta H_f(0).$$

The E_{RS} values thus obtained are well correlated with the parameters D of the biradicals **14** and **15** determined experimentally by EPR.[127]

5. Critical analysis of the existing approaches

The attempts at systematisation of the existing radical scales of substituents made previously can be classified, in our opinion, into two main types, namely, the choice of the $\sigma^{\cdot}$-scale describing most accurately the standard homolytic reaction series and the development of a quantitative approach integrating the accumulated arrays of 'radical' constants and combining them into some universal scale.

We have already mentioned that the authors of many of the studies presented in the previous Sections proposed their own standard series; the corresponding arrays of the group parameters were regarded as most suitable for developing a scale that could be used as the reference in analogous approaches. However, the search for this optimal scale did not reveal obvious advantages of any of the known sets of radical parameters; therefore, in some cases, it was concluded [9] that development of universal radical constants $\sigma^{\cdot}$ is impossible in principle. The attempts to find multiparameter correlations with the use of various combinations of polar and radical scales did not produce a satisfactory general result either. Moreover, the methodology of using the extended Hammett equation for the description of radical-stabilisation effects has been criticised.[49]

In view of the difficulty of using group radical constants to describe homolytic processes, Hansch and Leo [178] proposed that the polar parameters σ should be used for this purpose whenever possible. Exner [179] also suggested that the σ_p^+ and $\sigma_{m,p}$ constants suffice for interpretation of the free-radical reactivity. In another study,[180] radical-stabilisation effects of substituents are described in terms of the quadratic function σ^2; this, in principle, contradicts the LFE formalism.

Several prominent researchers attempted, in a joint review,[45] to devise a universal scale of relative radical stabilisation (RRS), based on averaging of the above-mentioned scales of the Creary ($\sigma^{\cdot}_{C}$),[57,80–84] Jackson ($\sigma^{\cdot}_{J}$)[51,52,56,76–79] and Arnold ($\sigma^{\cdot}_{\alpha}$) constants,[114,122–125] the kinetic parameters of radical fragmentation of bis-azo derivatives[96–100] and a number of other analogous characteristics of free-radical reactions.[45,180–184] It was suggested that statistical averaging would eliminate the errors inherent in each of basic experimental approaches. In addition, the average group RRS parameters are expected to reflect the degree of additivity of the group influences upon multiple substitution at the carbon radical centre and to describe the effect of captodative radical stabilisation.

Positive averaged RRS_X values (see Table 2), which imply radical-stabilisation properties, were found for a large number of diverse substituents. The only exceptions were F and CF_3, for which the RRS_X(F) values were -1.4 and -0.3, respectively.

By means of the scale of averaged RRS_X, the researchers[45] were able to identify a number of interesting correlations which point, in particular, to underestimation of the radical-stabilisation properties of electron-withdrawing substituents and overestimation of the role of electron donors in terms of some $\sigma^{\cdot}$-approaches.

The averaged radical $\sigma^{\cdot}_{av}$ scale was based[115] on two sets of EPR characteristics of benzyl radicals taken from the literature[115,124] and on three 'kinetic' arrays, namely, scales of the $\sigma^{\cdot}_{C}$ (see Refs 57, 80–84) and $\sigma^{\cdot}_{J}$ (see Refs 50–52, 56, 76–79) constants and kinetic data taken from the literature.[101] The $\sigma^{\cdot}_{av}$ values (see Table 1) confirmed the radical-stabilisation properties of the vast majority of *para*-substituents including CF_3. Only the averaged constant for *p*-F was found to be negative ($\sigma^{\cdot}_{av} = -0.02$). This deviation was explained by assuming that, under the action of the electronegative F atom, hybridisation of the carbon atom at the 4-position changes somewhat towards sp^3; this disturbs the aromaticity of the benzene ring and, hence, destabilises the radical centre.

Each of the definitions of the radical $\sigma^{\cdot}$ constants characterised in this Section suffers from its own specific disadvantages. They were noted above whenever appropriate. In addition, the methods of description of the radical effects of substituent can be subjected to a common criticism. It is expedient to arrange critical remarks in accordance with the above classification.

1. Kinetic methods. It is known that the classical σ-constants of electron-withdrawing substituents, which stabilise an electron-enriched reaction centre, are positive, whereas electron-donating groups, which stabilise electron-deficient systems, have negative polar constants. In turn, the sign of the parameter ρ of the correlation equation reflects the character (either electrophilic or nucleophilic) of the reaction, while the magnitude of ρ shows the degree of charge separation in the transition state. It is commonly known that the polar constants of substituents correlate equally adequately with the properties of the transition state and the ground state (numerous polar scales are based on the physicochemical, for example spectroscopic, properties of neutral molecules). Thus, successful description of energy characteristics of heterolytic processes in terms of group constants is normally explained by assuming either that the substituent effects in the transition and ground states are correlated or that the latter can be neglected. The kinetic methods of determination of substituent effects in homolytic processes also deal with the difference between the energy of the ground and radical-like transition states. However, a significant specific feature of free-radical reactions is that the natures of the initial species (or products) and the transition state in any homolytic process are fundamentally different because of the presence of an unpaired electron; the effects of substituents on the energies of the ground and transition states differ not merely quantitatively, as in the case of heterolytic processes, but also qualitatively. Furthermore, the numerous examples cited in the preceding Sections point to the importance of substituent effects in the ground state of homolytic processes, which precludes the possibility of neglecting them. In addition, even if the polar interactions in the ground state are assumed to be proportional to those in the radical-like state, their role in delocalisation of the proper unpaired electron still remains obscure.

Strictly speaking, the magnitudes of radical $\sigma^{\cdot}$ parameters established by kinetic methods often reflect the differences between the influence of substituents on the initial and transition states of a particular reaction but not the effectiveness of delocalisation of the unpaired electron by one or another substituent. In this connection, the numerous examples of successful use of polar constants alone for the description of free-radical processes seem quite obvious and the lack of correlation between radical scales is quite logical. Thus, reasonable separation of the effects related to charge stabilisation and to delocalisation of the unpaired electron within the framework of kinetic approaches appears unlikely, if achievable at all.

It is also worthy of note that the role of other factors (steric effects and, especially, solvent effects) has been interpreted fairly arbitrarily in most of the approaches considered. As a rule, the authors assumed that the homolytic mechanism of the standard reaction allows the solvent effects to be completely neglected. However, as has already been noted, in reality, none of the kinetic approaches allows complete elimination of the influence of polar interactions (which can depend substantially on the properties of the medium); this casts doubt on the proper methodology of determination of many $\sigma^{\cdot}$-scales.

2. Spectroscopic methods. Methods based on the use of EPR for determination of the spin density distribution are free from the drawbacks associated with the substituent effects in the corresponding molecules. Meanwhile, the question of whether spin density delocalisation follows a linear correlation with the stabilisation energy of a free radical remains relevant. In addition, it is unclear to what degree the spin density distribution is governed by the delocalisation contribution and to what degree, by the spin-polarisation contribution.[45] And, finally, what is the role of polar effects (for example, resonance effects) in the spin density distribution? Is it proper to consider them insignificant and related exclusively to charge stabilisation?

In our opinion, the following circumstance is also rather important. Let us assume that the spectral $\sigma^{\cdot}$-constants do actually reflect the capacity of substituents for delocalisation of the unpaired electron. Then it is clear that valid considerations about the mechanisms of delocalisation of an unpaired electron by substituents can be constructed on their basis and the $\sigma^{\cdot}$ values can be used to verify the adequacy of similar approaches to the solution of problems for which the correlation analysis methods are meant. However, the scope of applicability of these spectral radical scales still remains vague, while their predictive capacity and practical application hardly possess considerable advantages. In any case, when describing real homolytic reaction series, the presence of polar interactions (which are always quite probable, as we have repeatedly emphasised above) implies the use of a two-parameter correlation equation containing both radical and polar constants. One or another polar scale can be preferred and the relationship between the polar and radical components of the stabilisation effect can be identified only on the basis of a statistical selection procedure. From a practical point of view, this brackets the $\sigma^{\cdot}$ constants obtained by spectroscopic methods with those determined by kinetic methods.

3. Thermodynamic methods. The approaches based on the use of thermodynamic methods are criticised especially vigorously. As has been mentioned above, determination of radical-stabilisation effects in terms of thermodynamic parameters (bond energies) corresponding to diamagnetic substrates does not permit one to rule out the substituent effects related to the molecules or to distinguish the proper radical stabilisation from polar or steric factors. Strictly speaking, these approaches are rather suitable for discussing the relative effects of substituents on the energies of covalent bonds; this, in itself, is a complex problem not ultimately solved. It is also noteworthy that, within the framework of

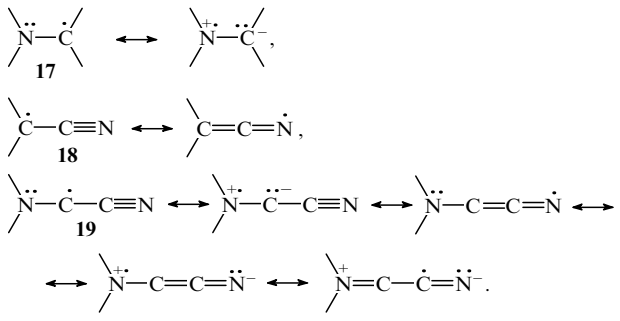
thermodynamic approaches, the radical stabilisation effect is largely replaced by the notion of radical stability. Strictly speaking, this is not the same; below we shall consider this point in more detail.

To conclude this section, it can be stated that none of the existing methods of $\sigma\rho$-description of substituent effects in free-radical processes is free from serious drawbacks and, as a rule, each method operates within a narrow reaction series. The lack of correspondence between radical scales and the different in kind interpretations of the radical-stabilisation properties of the same substituents in terms of different approaches make difficult the understanding of the physical meaning of radical constants and preclude the possibility of their joint application.

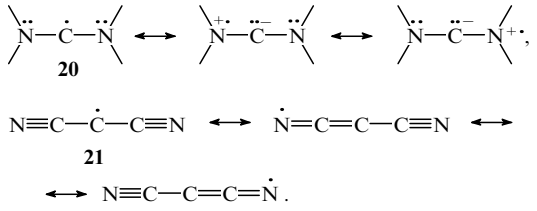
It cannot be ruled out that the correlation analysis formalism cannot, in principle, be applied in full measure to the description of homolytic processes because the additivity of group interactions is there violated. An especially clear example is the captodative stabilisation effect, or push – pull effect, repeatedly mentioned above.

4. Captodative effect. The existence of an extra-stabilisation effect peculiar to bifunctional radicals was first assumed by Dewar.[185] A quantitative proof of the unusual stability of these radicals was later presented in studies by Balaban *et al.*,[186, 187] who used the term 'push – pull resonance.' Later, Katritzky *et al.*[188 – 190] arrived at the conclusion that radical centres bearing simultaneously an electron-donating and an electron-withdrawing group are subject to an extra-stabilisation effect, which was called merostabilisation (later, captodative effect).[45,191 – 194]

A simple substantiation of the captodative stabilisation can be derived from the numbers of contributing structures [in the example presented below, there are two structures for the amino- (**17**) or the cyano-derivative (**18**)] corresponding to monosubstituted radicals and to a disubstituted radical containing both electron-donating and electron-withdrawing groups [five contributing structures are presented for the amino-cyano-substituted radicals **19**].



For disubstituted radicals containing either only amino- (**20**) or only cyano groups (**21**), three contributing structures can be proposed



Thus, stabilisation of these species due to delocalisation would be somewhat weaker than is expected based on the sum of the substituent effects in the monosubstituted analogues.

The over-additive stabilisation effect in radical species containing both electron-donating and electron-withdrawing groups has been repeatedly confirmed experimentally. The enhanced reactivity of captodative alkenes has been noted in radical [193 – 199] and [2 + 2]-cycloaddition [45, 199 – 202] reactions. The captodative acceleration was considered to be the reason explaining the results obtained in studies of cyclisation of 6-substituted hex-5-en-1-yl radical,[203] homosolvolysis of some alkyl bromides on treatment with di-*tert*-butylnitroxide,[204] thermal rearrangement of substituted 2-arylmethylenecyclopropanes,[205] isomerisation of diastereomeric substituted cyclopropanes [206, 207] and thermal homolysis of the C – C bond in hexa-1,5-dienes [207] and dibenzyls.[208, 209]

EPR data for substituted benzyl radicals point to enhanced stabilisation of those radicals that contain both electron-donating and electron-withdrawing substituents, whereas two identical substituents decrease radical stabilisation.[114] Analysis of the barriers to internal rotation and the energy barriers to *E*,*Z*-isomerisation of substituted allylic radicals determined from EPR data also attests in favour of captodative interactions.[210] Study of the barriers to rotation around the C – N bond in substituted aminoalkyl radicals has led to similar conclusions.[211] In several publications,[161, 212, 213] the captodative effect was substantiated from the standpoint of orbital views. Calculations of the stabilisation effects in free radicals also predict an enhanced stabilisation of captodatively substituted derivatives.[45, 163, 214, 215]

However, a number of experimental and theoretical studies have not elucidated any significant distinctive features of captodatively substituted radicals and demonstrated strictly additive influence of the corresponding substituents at a radical reaction centre.[216 – 219] Moreover, some researchers cast doubt on the existence of an additional captodative stabilisation. Within the context of the present consideration, we would only like to mention that, under the assumption of the existence of captodative stabilisation of free radicals, the use of additive correlation equations based on LFE and polylinearity principles to describe homolytic processes should be subject to certain, perhaps quite substantial, constraints.

Thus, analysis of the published data available to date provides grounds for the following conclusions.

1. The classical polar constants σ are not fully applicable to the description of free-radical processes and do not reflect the radical-stabilisation effects of substituents. In all probability, one can speak about a disproportion of substituent effects in heterolytic and homolytic processes. Although quite a few examples of successful use of polar constants in free-radical chemistry have been reported, the existing scales of specific radical constants $\sigma^{\cdot}$ are not general. The lack of correspondence between the scales and vagueness of their physical meaning might be due to the constrains inherent in the use of the LFE principles and correlation analysis in free-radical chemistry and violation of the additvity of the group influence in paramagnetic systems rather than to the drawbacks of the methods of their determination.

2. It is obvious that an approach, new in principle, to the description of substituent effects in free-radical systems needs to be developed. It is important that this approach should possess predictive capacity and provide a quantitative estimate of the character of interaction of substituents with the radical reaction centre. However, it is quite probable that the physical nature of this interaction would not be clarified completely but it would be possible to obtain a satisfactory quantitative description of the structure – reactivity relationship as applied to the chemistry of free radicals.

III. The use of r^{-2} analysis in free-radical chemistry

1. Modelling of inductive and steric effects

Previously, we have developed quantitative procedures for determination of the steric and inductive effects of substituents in terms of discrete atomic contributions. Detailed description and theoretical substantiation of the models proposed, aspects of their practical use and the inductive electronegativity concept based on them have been presented in our previous reviews.[2 – 6] In the context of this review, we considered it pertinent to mention the main theses of these approaches.

Steric interactions were determined in terms of the model of frontal steric effect in which the steric effect of a substituent is represented as a result of mechanical shielding of the reaction centre by the surrounding atoms

$$R'_S = \sum_{i=1}^{n} \frac{R_i^2}{4r_i^2}, \tag{11}$$

where R'_S is the steric constant, n is the number of atoms in the substituent, R_i is the radius of an ith atom and r_i is the distance from the ith atom to the reaction centre.

It should be emphasised that in terms of this approach, the steric effect of any substituent at any reaction centre can be predicted with high accuracy on the basis of only fundamental parameters (the size and the distance to the reaction centre) of the atoms forming the substituent. The R'_S parameters calculated for a broad range of the most frequently encountered groups follow a good correlation with the Taft steric constants ($N = 35$, $R = 0.9854$, $S = 0.141$).

In the model of inductive effect, the inductive constant σ^* of an n-atomic substituent was represented at the atomic additivity level

$$\sigma^* = \sum_{i=1}^{n} \frac{\sigma_{A(i)}}{r_i^2}, \tag{12}$$

where σ_A is an empirical constant introduced in the model of inductive effect and reflecting the ability of an atom to exhibit the inductive effect, which depends on the nature and valence state of the atom. The σ_A values have been established for a wide range of elements; the inductive constants calculated theoretically using these values (altogether 426 substituents) have formed a high-quality correlation with the corresponding experimental data ($N = 426$, $R = 0.9910$, $S = 0.190$).

The practical use of this additive approach in the description of reactivity and investigation of the mechanisms of reactions involving organic and heteroorganic compounds proved fairly successful. This has also contributed to the solution of a number of important theoretical problems related to inductive interactions such as the inductive effect of alkyl substituents, the presence or absence of linearity in the inductive effects of substituents on carbon and heteroatom reaction centres and some others. The models developed make it possible to describe quantitatively only the inductive and steric effects; no approach based on the modelling principle for estimation of resonance interactions has been devised yet. Nevertheless, as shown in our study,[4] the additive model of inductive effect describes rather adequately the electronic interactions in various conjugated systems and only some of them, subjected to the influence of direct polar conjugation, can provide exceptions.

2. Combinational approach. r^{-2}-Analysis. Ionisation energies of amines

The new topological approach developed on the basis of the above models, which allows the substituent effect to be expressed in terms of discrete atomic contributions, was first reported in our publication and called r^{-2}-analysis.[220]

Since both the steric and inductive constants were expressed in Eqns (11) and (12) as functions of $1/r^{-2}$, the two-parameter Taft equation

$$Y = \rho \sum_i \sigma^* + \delta \sum_i E_s \tag{13}$$

can be represented in terms of discrete atomic contributions

$$Y - Y^0 = \sum_{i \neq rc}^{N-1} \frac{e_i}{r_{rc-i}^2}, \tag{14}$$

where N is the number of atoms in the molecule, rc is the atom chosen as the reaction centre, r_{rc-i} is the distance between atom i and the reaction centre. The dependent parameter Y can be represented by any physical value which is used in terms of a general correlation equation (13) (the logarithm of the rate or equilibrium constant, the reaction or activation energy, *etc.*), Y^0 is the same parameter for a compound chosen as the standard in this reaction series, and e is a parameter reflecting the capacity of an atom of a definite type for exhibiting intramolecular effects determining the Y values.

The approximation we used permits one, first of all, to verify whether it is possible, in principle, to introduce the operational atomic constants e_i corresponding to atoms of different types and depending on the nature and the valence state. The next step is to determine their physical meaning. The formalism of this approach implies that each atom encountered in all the molecules of the reaction series can, in principle, be regarded as a hypothetical reaction centre. In this case, for each molecule contained in the reaction series, the other $N-1$ atoms are treated as a single sub-substituent.

After the reaction centre for a given series has been chosen, the matrix of sums

$$\sum_k \frac{1}{r_{rc-m_k}^2},$$

corresponding to the types of atoms present should be composed. A table should be made up, containing N vertical matrix elements (rows), where N is the number of molecules in the reaction series, and M horizontal elements (columns),where M is determined by the types of atoms represented in the molecules of the series. The k value in the matrix of sums corresponds to the number of atoms of type m in molecule n, and $r_{rc-m_k}^2$ are the distances between type m atoms and the reaction centre rc in molecule n. If no type m atoms are present in molecule n, the corresponding matrix element is taken to be zero. As an example, Table 3 gives the r^{-2}-matrix for the reaction series including the $MeH_2C^{\cdot}$, $ClH_2C^{\cdot}$, and $Me(NH_2)HC^{\cdot}$ radicals in which the carbon bearing the unpaired electron is chosen as the reaction centre. In real calculations, the number of horizontal elements should exceed the number of vertical elements; then the columns of this matrix can be regarded as sets of independent arguments and the $Y - Y^0$ array can be regarded as an array of dependent values of multiparameter linear regression (14).

Table 3. r^{-2}-Matrix for the reaction series containing the $MeH_2C^{\cdot}$, $ClH_2C^{\cdot}$ and $Me(NH_2)HC^{\cdot}$ radicals.

Radical	Type of atom			
	H	C(sp^3)	Cl	N(sp^3)
$MeH_2\dot{C}$	$\frac{2}{1.09^2} + \frac{3}{2.16^2}$	$\frac{1}{1.54^2}$	0	0
$ClH_2\dot{C}$	$\frac{2}{1.09^2}$	0	$\frac{1}{1.76^2}$	0
$Me(NH_2)H\dot{C}$	$\frac{1}{1.09^2} + \frac{3}{2.16^2} + \frac{2}{2.04^2}$	$\frac{1}{1.54^2}$	0	$\frac{1}{1.46^2}$

Thus, if the corresponding multiparameter correlation can be established with a satisfactory accuracy, its linear coefficients are the operational atomic constants e_i corresponding to particular types of atoms. It is clear that this scheme should be effective in the description of those reaction series that can be analysed quantitatively using inductive and steric group constants.

The method developed for the description of substituent effects has several obvious advantages over classical correlation analysis. First, it is free from the restrictions associated with the choice of an appropriate scale of substituents because it deals directly with interatomic distances and is conformationally sensitive. Second, the use of a simple mathematical apparatus allows one to analyse quickly and effectively indefinitely large sets of

parameters. Third, within the framework of this model, it becomes possible to consider all the potential reaction centres of the series, which can provide additional information on the mechanism of the process under study. This is important in those cases where interpretation of the mechanism does not appear unambiguous and variation of the reaction centre could permit decision in favour of one of the most probable mechanisms.

We implemented the algorithm outlined above as a product called RMATRIX, which was developed on the basis of the MATLAB program.[221] The RMATRIX program allows importing of intramolecular distances from HyperChem or from similar files containing data on the spatial structure of the molecules of a reaction series; then it composes the r^{-2}-matrix corresponding to the reaction centre chosen for each molecular series, and, finally, it establishes statistically the operational atomic increments e for the series.

3. The physical meaning of the operational atomic parameters

A drawback of r^{-2}-analysis is that it does not allow direct consideration of resonance interactions because they cannot be described certainly by any distance function. However, a more substantial problem is that the physical meaning of the operational atomic parameters e_i, defined by Eqn (14), remains vague and does not provide the possibility of resolving the substituent effects into the inductive and steric components. The analysis of the e_i values presented below is pertinent in this connection. The correlations established previously in terms of the steric and inductive models can serve as the basis for this consideration.

Thus it has been found[4] that the σ_A constants for a broad range of elements are correlated with the difference between Pauling's electronegativities $\Delta\chi_{i-rc}$ of a given element A and the atomic reaction centre (rc) (this difference reflects the ability of atom A to displace electron density) and with the squared covalent radius of the A atom (which reflects its capacity for charge delocalisation)[4, 5, 222]

$$\sigma_A = 7.84\Delta\chi_{i-rc}R_i^2 .$$

The back calculation of the χ values using this relation makes it possible to introduce a new scale of 'inductive' electronegativities, which is purely empirical because it is based on the inductive constants describing a huge array of reaction series.[4, 5] This scale is, by definition, in good agreement with Pauling's electronegativities, except that for carbon. According to the 'inductive' scale, the electronegativity of carbon is 2.1. This value appears to be more plausible than $\chi^P = 2.55$ proposed in the Pauling scale.[2, 223, 224] The latter value implies that carbon should be more electronegative than, say, phosphorus ($\chi^P = 2.2$) or iodine ($\chi^P = 2.4$), which is not the case in reality. The low polarity of the C—H bond also indicates that the Pauling χ^P value for carbon is overestimated. Subsequently, a scale of group inductive electronegativities and the concept of inductive chemical hardness, which interpret a number of widely used reactivity indices using simple geometrical characteristics of bonded atoms, have been developed in terms of this approach.[2] These concepts were considered in detail in our review [2] and in a number of publications.[223–231]

On the basis of established correlations, the Taft inductive constant can be expressed in terms of fundamental characteristics of the atoms of substituents and the reaction centre, namely, electronegativities, radii and interatomic distances

$$\sigma^* = 7.84\sum_i \frac{\Delta\chi R_i^2}{r_i^2} . \qquad (15)$$

By superposition of Eqns (11)–(14), the atomic parameters e_i can be represented as the sum of inductive and steric constituents

$$e_i = a\Delta\chi_{i-rc}R_i^2 + bR_i^2 . \qquad (16)$$

Evidently, if a satisfactory correlation of type (16) has been established, it becomes possible not only to calculate the unknown e_i values on its basis but also to express the dependent parameters Y in terms of inductive and steric Taft constants as an ordinary two-parameter equation (13). If the 'inductive' electronegativity of the reaction centre atom is unknown, the e value can be found using the two-parameter correlation

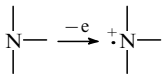
$$e_i = a'\chi_i R_i^2 + b'R_i^2 , \qquad (17)$$

where the coefficient b' includes the χ_{rc} value.

It should be emphasised that correct separation of the inductive and steric effects requires that the nature (electronegativity) of the reaction centre be known exactly and, in any case, it implies certain assumptions. Nevertheless, the corresponding atomic operational constants e_i still can be employed to predict the unknown Y values for related molecular systems consisting of atoms with known e_i even in those cases where correlations (15) and (16) cannot be established.

Except for the inapplicability for the description of the resonance effect, the method under discussion does not have any serious limitations and can be used successfully even in those cases where the standard empirical scales are ineffective. The quantitative description of the vertical and adiabatic ionisation potentials of amines performed in our study exemplifies the practical application of the r^{-2}-scheme.[221]

Previously, the dependence of the ionisation potentials of a limited range of amines on their structure has been interpreted with utilisation of a large number of independent parameters both those reflecting particular inductive, resonance and polarisation effects and those chosen rather arbitrarily.[232]



We attempted to consider the ionisation potentials of amines in terms of the unified approach developed and composed the corresponding r^{-2}-matrix in which the nitrogen atom was chosen as the reaction centre. The adiabatic and vertical ionisation potentials (I^{ad}, I^{vert}) of amines in the gas phase, taken from a publication,[233] were analysed in terms of the parameters of the basic equation (14). As a result, reliable multiparameter correlations were established for the sets of adiabatic and vertical potentials

$$I^{vert}_{R_3N} = \sum_i^{N-1} \frac{i_i^{vert}}{r_i^2} + \text{const}_1 \ (R = 0.954, S = 0.331, N = 287), \qquad (18)$$

$$I^{ad}_{R_3N} = \sum_{i=1}^{N-1} \frac{i_i^{ad}}{r_i^2} + \text{const}_2 \ (R = 0.960, S = 0.341, N = 231), \qquad (19)$$

where N is the number of atoms in the amine molecule and i_i^{vert} and i_i^{ad} are the operational atomic parameters reflecting the capacity of the atom of a definite type for participation in intramolecular interactions, which determine the I^{vert} and I^{ad} values, respectively.

The following fact attracts attention: although we analysed arrays of the absolute values of I^{ad} and I^{vert} not referred to any standard, the free terms of multiparameter correlations (18) and (19) determined statistically actually reproduced the corresponding ionisation potentials of the ammonia molecule.

The values of the $i^{ad/vert}$ parameters were then analysed using Eqn (16); the following correlations were identified:

$$i^{ad} = 4.55(\chi - 2.79)R^2, \qquad (20)$$

$$i^{vert} = 4.38(\chi - 2.98)R^2. \qquad (21)$$

Thus, the correlations found allow the calculation of the unknown parameters $i^{ad/vert}$ and, hence, the previously unknown ionisation potentials of amines from atom electronegativities and covalent radii. Moreover, if the role of steric effect during electron transfer is assumed to be insignificant (which appears quite reasonable), values of 2.79±0.7 and 2.98±0.7 found using these

relations are in a fairly good agreement with the inductive electronegativity of nitrogen (2.56, see Ref. 223).

4. Ionisation energies of free radicals

The possibility of quantitative determination of the energies of oxidation of amines to the corresponding radical cations using the approach we developed points to its adequacy and applicability to free-radical processes. As noted above, the examples of quantitative interpretation of the reactivity of free radicals currently available are limited, as a rule, to aromatic systems.

We attempted to apply the r^{-2}-analysis to electron transfer, which is one of the least studied homolytic reactions from the standpoint of 'radical' effects of substituents. We did not restrict ourselves to narrow series of aromatic compounds but considered single-electron processes involving diverse C-, N-, S- and O-centred radicals both belonging to aromatic and aliphatic series.[233, 234] The single-electron ionisation potentials of free radicals in the gas phase were taken from a database [235] and analysed in terms of our approach.

a. Carbon-centred radicals

In accordance with the approach developed, the ionisation potentials (I) and electron affinities (A_e) of carbon-centred radicals were analysed using the equations

$$I_{R^\cdot} - I_{Me^\cdot} = \sum_{i \subset R} \frac{e_i^+}{r_i^2} \text{ and} \tag{22}$$

$$A_e(R^\cdot) - A_e(Me^\cdot) = \sum_{i \subset R} \frac{e_i^-}{r_i^2}, \tag{23}$$

in which the I and A_e values for the methyl radical are included as reference values provided that the carbon atom bearing the unpaired electron is taken to be the reaction centre.

The multiparameter correlations (22) and (23) were established with high accuracy. The operational parameters e^+ and e^- found from relations (22) and (23) are presented in Tables 4 and 5 together with the corresponding values for the inductive electronegativities and the covalent radii of atoms. By comparing them in terms of a type (17) relation, we expressed the e^+ parameters in the form

$$e_i^+ = (1.09 \pm 0.33)\chi_i R_i^2 - (5.49 \pm 0.97) R_i^2 \tag{24}$$

(the O, N and S atoms were not included in the correlation) or

$$e_i^+ = 1.09(\chi_i - 5.04) R_i^2 .$$

Thus, the ionisation potentials of C-centred radicals in the gas phase can be expressed in terms of fundamental parameters of atoms

$$I = I_{Me^\cdot} + 1.09 \sum_{i=1}^{N} \frac{(\chi_i - 5.04) R_i^2}{r_i^2} . \tag{25}$$

Relations (24) and (25) demonstrate that the vast majority of atoms [except highly electronegative ones such as *sp*-hybridised N atom ($\chi = 6.76$)] introduced in the environment of the C$^\cdot$ reaction centre decrease the corresponding ionisation energy relative to that of the methyl radical. The deviation of the atomic parameters e^+ for O, N and S atoms from the general pattern of dependence is apparently due to the resonance effect, which cannot be described from the standpoint of the given approach, as has been repeatedly mentioned above. To elucidate the reasons for this deviation, a special detailed analysis is required; we plan to perform it subsequently. In addition, analysis of the predicted ionisation potentials demonstrates a substantial deviation of the I_{pred} value for the methyl radical, which is a typical problem for this type of approach. Since the methyl radical was chosen as the reference species ($\Delta I = 0$), its e^+ parameter should, by definition, be equal

or nearly equal to zero, which is not always fulfilled. The e^+(H) value found statistically is markedly smaller than zero, as well as the calculated $\Delta I(CH_3)$ value.

Taft [236] was faced with similar difficulties when using the methyl group as the reference for the scale of inductive constants σ^*. There are also other factors determining the so pronounced difference between the experimental and calculated ionisation potentials of methyl radicals in the construction of a scale of radical constants. Detailed analysis of these factors is beyond the scope of this review.

When considering the e^- parameters found from the electron affinities of carbon-centred radicals, the following correlation was established:

$$e_i^- = (1.64 \pm 0.43)\chi_i R_i^2 - (3.17 \pm 1.26)R_i^2 \quad (26)$$

or

$$e_i^- = 1.64(\chi_i - 1.93)R_i^2.$$

As for ionisation potentials, this correlation permits the electron affinity parameters of carbon-centred radicals to be expressed at the atomic level on the basis of fundamental atomic characteristics, namely, electronegativities, sizes and interatomic distances

$$A_e = A_e(Me^{\cdot}) + 1.64\sum_{i=1}^{N}\frac{(\chi_i - 1.93)R_i^2}{r_i^2}. \quad (27)$$

The ionisation potentials and electron affinities of carbon-centred radicals calculated from the atomic inductive electronegativities and covalent radii are listed in Tables 6 and 7; the statistical parameters of correlations are presented in Table 8, and the operational parameters e^+ and e^- are given in Tables 4, 5.

b. Deviations from the general dependence

As noted above, the presence of substantial resonance interactions in radicals can result in deviation of their characteristics predicted in terms of the additive scheme in question from the corresponding experimental values. An alternative and, perhaps preferable, explanation of most of the deviations observed in the description of redox properties of carbon-centred radicals is that in some radicals, the carbon atom bearing the unpaired electron is not the ionisation centre.

For example, in the case of ionisation potentials, the operational atomic parameters e^+ for S, N and O atoms deviate from the linear dependence (24), and the effects of the corresponding substituents observed experimentally exceed those predicted based on the e^+ values. The experimental values of the ionisation potential I_{exp} might correspond to the I value of a heteroatom (S, N, O) present in the carbon-centred radicals and having a lone electron pair rather than to the I value of the radical centre. A similar deviation from the linear dependence has been observed in a study of the single-electron reduction potentials of arylmethylchalcogenide radical cations in aqueous solutions.[40] In addition, electron-withdrawing substituents (NO_2, CN, Hal) are able to enter into reduction processes and, hence, only for some of the carbon-centred radicals considered, do the A_e values correspond completely to the ionisation of the radical centre. For some strong electron acceptors, a saturation effect also cannot be ruled out.

Thus, most of the observed deviations of the predicted ionisation potentials and electron affinities of substituted carbon-centred radicals are most likely due to non-homogeneity of the data arrays considered. It should also be borne in mind that the ionisation potentials and the electron affinities of radicals match the energy differences between the radical and the corresponding cation in the former case and between the anion and the radical in the latter case. Hence, the energy effects of substituents described by Eqns (22) and (23) can refer both to the radical and to the corresponding ion. The positive values of e^+ and e^- imply that the radical is stabilised by the substituent in question more efficiently than the cation as compared with the $\dot{C}H_3/CH_3^+$ pair (for ionisation potentials), and that the anion is stabilised by the given substituent more efficiently than the radical, compared with the $CH_3^-/\dot{C}H_3$ system (in the case of electron affinity). Note that, the use of the notion of relative stabilisation can also imply lesser

	A_e	6	0.9744	0.2179

destabilisation. In a published discussion[9–11] dealing with the influence of substituents on bond energies, similar considerations are presented concerning the situation where the effects observed can be attributed both to the RX molecule and the R˙ radical.

Equation (25) indicates that a substituent atom should have an abnormally high electronegativity ($\chi > 5.04$) to stabilise a radical more effectively than the corresponding cation. In turn, relation (27) illustrates the fact that for most of atoms ($\chi > 1.93$), stabilisation of anions predominates. Thus, it can be concluded that the described substituent effects which determine the electron potentials of free radicals refer to stabilisation of the corresponding ions. The role of steric interactions can be elucidated by comparing the adiabatic ionisation potentials, studied within the framework of the approach under discussion, with the corresponding vertical ionisation potentials.

The adiabatic potentials reflect the difference between the energies of the radicals and the cation having the most favourable (equilibrium) spatial structure, whereas vertical potentials imply identical geometries of these species. Thus, the difference between the adiabatic and vertical potentials can be attributed to structural reorganisation of a free radical caused by its oxidation.

The adiabatic and vertical potentials of the methyl radical are known to be equal. This is apparently due to the fact that both the radical and the cation are planar. The other primary, secondary and tertiary carbon-centred radicals are non-planar, unlike the corresponding cations. The difference between their adiabatic and vertical potentials remains approximately constant (0.3–0.4 eV) and does not change significantly on passing from primary to secondary or tertiary radicals, *i.e.*, the steric contribution to the adiabatic ionisation potentials is insignificant but they do contain a constant component due to the energy of spatial reorganisation. The absence of this component in the case of the methyl radical can be the main reason for the observed difference between the predicted and experimental $I(\dot{C}H_3)$ values.

The foregoing attests that steric interactions have no influence on the ionisation potentials and electron affinities of free radicals and the corresponding effect of substituents has a purely inductive nature.

It is common knowledge that cations are stabilised by electron-donating substituents and anions are stabilised by electron-withdrawing substituents. According to Eqn (15), the atomic inductive effect is proportional to the difference between the electronegativities of the given atom and the reaction centre. Hence, it is reasonable to assume that the electronegativity of the central atom (carbon) increases in the series anion < radical < cation, while the inductive effect of the substituent atoms switches from electron-withdrawing to electron-donating influence, and only in extreme cases [for example, for N(*sp*), which has $\chi_{ind} = 6.76$], is the effect of the atom adjacent to the cationic centre maintained as the electron-withdrawing influence. Thus, parameters of 5.04 and 1.93 in Eqns (24) and (26) can actually be taken as the inductive electronegativity of the reaction centre, *i.e.*, of positively and negatively charged carbon, respectively.

c. The group σ_+^C and σ_-^C scales

The empirical operational parameters e^+ and e^- established have also been used to introduce group scales called σ_+^C and σ_-^C, which make it possible to calculate the I and A_e values for carbon-centred radicals in terms of an additive scheme.[233]

$$I = I_0 + \sum \sigma_+^C$$

$$A_e = A_e^0 + \sum \sigma_-^C$$

These parameters were calculated for the most frequently encountered organic substituents with the assumption of the standard geometries and using the e^+ and e^- values for atoms contained in these substituents. These radical scales, based on electron transfer reactions and considering the substitution effect at the group level of additivity, reflect, as do the Hammett σ-constants, the overall influence of substituents on a radical reaction centre without separation of the inductive, resonance, and steric constituents. The use of group σ_+^C and σ_-^C scales simplifies the procedure of calculation of the ionisation energies of radicals and eliminates the necessity of determining interatomic distances.

Similarly, we calculated the ionisation energies of O-, S- and N-centred radicals in terms of the basic equation (14). The atomic operational parameters e^+ and e^- found in this way were then analysed using relation (16). The corresponding equations for radicals of various types are presented below in the same order which was accepted for carbon-centred radicals.[234]

d. Oxygen-centred radicals

For oxygen-centred radicals, the operational parameters e^+, which determine the relative contributions of atoms to the ionisation energy of the system, are described with high accuracy by means of atomic electronegativities and the covalent radii in accordance with Eqn (16)

$$e_i^+ = (3.94 \pm 1.01)\chi_i R_i^2 - (18.77 \pm 2.93)R_i^2$$

or

$$e_i^+ = 3.94(\chi_i - 4.76)R_i^2.$$

The corresponding atomic parameters e^- are determined in a similar way

$$e_i^- = (1.25 \pm 0.27)\chi_i R_i^2 - (2.31 \pm 0.79)R_i^2$$

or

$$e_i^- = 1.25(\chi_i - 1.84)R_i^2.$$

Thus, the ionisation energy of the alkoxy radicals $I(RO^{\cdot})$ can be presented by the relation

$$I(RO^{\cdot}) = I(HO^{\cdot}) + 3.94\sum_{i=1}^{N}\frac{(\chi_i - 4.76)R_i^2}{r_i^2}, \qquad (28)$$

and the electron affinity of oxygen-centred radicals is determined in terms of atomic parameters

$$A_e(RO^{\cdot}) = A_e(HO^{\cdot}) + 1.25\sum_{i=1}^{N}\frac{(\chi_i - 1.84)R_i^2}{r_i^2}. \qquad (29)$$

e. Sulfur-centred radicals

The atomic operational constants e^+ and e^- of sulfur-centred radicals determined from the ionisation potentials and the electron affinity correlate with the atomic electronegativities and atomic radii with a lower accuracy

$$e_i^+ = (1.71 \pm 2.19)\chi_i R_i^2 - (11.29 \pm 5.93)R_i^2$$

or

$$e_i^+ = 1.71(\chi_i - 6.61)R_i^2,$$

$$e_i^- = (-3.27 \pm 1.41)\chi_i R_i^2 + (6.84 \pm 3.68)R_i^2$$

or

$$e_i^- = -3.27(\chi_i - 2.09)R_i^2.$$

Nevertheless, the expressions obtained which relate the ionisation energies of sulfur-centred radicals to parameters of the atoms forming them appear well substantiated

$$I(\mathrm{RS}^{\cdot}) = I(\mathrm{HS}^{\cdot}) + 1.71\sum_{i=1}^{N}\frac{(\chi_i - 6.61)R_i^2}{r_i^2}. \quad (30)$$

The electron affinity of sulfur-centred radicals is found from the relation

$$A_e(\mathrm{RS}^{\cdot}) = A_e(\mathrm{HS}^{\cdot}) - 3.27\sum_{i=1}^{N}\frac{(\chi_i - 2.09)R_i^2}{r_i^2}. \quad (31)$$

f. Nitrogen-centred radicals

A similar correlation obtained for nitrogen-centred radicals is unsatisfactory because of the deficiency and great inaccuracy of the corresponding experimental data; therefore, the available data on the ionisation of N-centred radicals cannot serve as the base for discussion. Nevertheless, we thought it fit to present the relations determining the e^+ and e^- parameters for atoms making up N-centred radicals. As in the above cases, the electronegativities and the sizes of atoms forming the corresponding N-centred radical were used.

$$e_i^+ = (1.14 \pm 10.70)\chi_i R_i^2 - (12.01 \pm 24.9)R_i^2$$

or

$$e_i^+ = 1.14(\chi_i - 10.55)R_i^2,$$

$$e_i^- = (6.24 \pm 0.41)\chi_i R_i^2 + (13.76 \pm 0.92)R_i^2,$$

or

$$e_i^- = 6.24(\chi_i - 2.20)R_i^2.$$

The ionisation energies and electron affinities of nitrogen-centred radicals can be written as follows:

$$I(\mathrm{R_2N}^{\cdot}) = I(\mathrm{H_2N}^{\cdot}) + 1.14\sum_{i=1}^{N}\frac{(\chi_i - 10.55)R_i^2}{r_i^2}, \quad (32)$$

$$A_e(\mathrm{R_2N}^{\cdot}) = A_e(\mathrm{H_2N}^{\cdot}) + 6.24\sum_{i=1}^{N}\frac{(\chi_i - 2.20)R_i^2}{r_i^2}. \quad (33)$$

The ionisation potentials and the electron affinities of S-, N- and O-centred radicals calculated on the basis of the atomic inductive electronegativities and covalent radii are given in Tables 6 and 7. The electronegativities of ionic forms of the C, S, N and O atoms considered as reaction centres, obtained in accordance with the proposed procedure, are given in Table 9.

Table 9. Electronegativities and statistical parameters for correlations of type (16) determined for various types of free radicals.

Type of radicals	Parameter	χ_{rc}	N	R	S/ eV
C-centred	e^+	5.04	8 [a]	0.9509	0.266
	e^-	1.93	7 [b]	0.9502	0.328
S-centred	e^+	6.61	5	0.9368	1.3768
	e^-	2.09	5	0.8739	0.5329
O-centred	e^+	4.76	8	0.9891	0.7342
	e^-	1.84	7 [b]	0.9808	0.1975
N-centred	e^+	10.55	4	0.8393	1.9877
	e^-	2.20	3	0.9977	1.041

[a] Except for parameters for the O, N, S and N(sp) atoms; [b] except for parameters for the O atom.

The same Table contains the statistical parameters of the corresponding correlations of type (16) found for the the operational atomic parameters e^+ and e^- of the series studied.

5. The stability of free radicals in redox processes

We have already noted that the problem of radical stability, especially within the framework of the thermodynamic approaches proposed here, largely overlaps the problem of radical reactivity and is considered from the standpoint of the influence of substituents.

The stability of free radicals itself in terms of the relative energies of covalent bonds in the corresponding systems with filled electron shells is normally considered separately from the known effect of steric shielding of the unpaired electron by the molecular environment, decreasing the reactivity of the radical.[45, 114, 237] In our opinion, the concept of radical stability (reactivity) should be supplemented by one more type, namely, stability of free radicals in redox processes (subsequently referred to as redox stability).

As has already been noted, single-electron transfer is one of the most frequently encountered types of reaction in homolytic chemistry. Meanwhile, neither kinetic nor thermodynamic methods for the description of the radical effects of substituents take into account the redox stability of free radicals or provide the possibility of quantitative interpretation of the corresponding single-electron potentials. However, it is absolutely clear that the lower the ionisation potential and the higher the electron affinity of a free radical, the more easily it would enter into single-electron transfer reactions.

Thus, the redox stability of a free radical can be matched to its absolute chemical hardness (η)

$$\eta = \frac{I - A_e}{2},$$

where I and A_e are the single-electron ionisation potential and the electron affinity of the radical in the gas phase determined experimentally.

Let us consider carbon-centred radicals. Using relations (25) and (26), we express the relative chemical hardness of a carbon-centered radical (η) in terms of fundamental atomic characteristics used to describe its single-electron potentials

$$\eta(\mathrm{R}^{\cdot}) = \eta(\mathrm{Me}^{\cdot}) - 0.28\sum_{i=1}^{N}\frac{(\chi_i - 4.22)R_i^2}{r_i^2}.$$

This relation reflects the trend of the redox stability of C-centred radicals to decrease under the influence of the vast majority of atoms present in the environment of a carbon reaction centre; only the most electronegative elements increase the $\eta(\mathrm{R}^{\cdot})$ value with respect to the chemical hardness of the methyl radical $\eta(\mathrm{Me}^{\cdot})$.

As noted above, the stability of carbon-centred radicals is often expressed as a derivative of the dissociation energy of the C–H bonds. A lower energy implies higher radical stabillity. However, a low bond energy often corresponds to a low chemical hardness of the corresponding radical. In conformity with our approach, this, conversely, implies a lower redox stability of the radical. Hence, the criteria used to describe radical stability should be chosen with caution.

6. Energies of dissociation of C–H bonds

An attractive aspect of our approach is, in our opinion, the possibility of using it successfully to describe dissociation energies of bonds E_d. We demonstrated this taking carbon–hydrogen bonds as an example.[238]

We obtained a large array of E_d(CH) values using the following relation

$$E_d(\mathrm{R_3CH}) - E_d(\mathrm{CH_4}) = \sum_i \frac{d_i}{r_{\mathrm{C}-i}^2}. \quad (34)$$

Here $E_d(CH_4)$ is the energy of the C–H bond in the methane molecule, $E_d(R_3CH)$ is the energy of the C–H bond in the corresponding derivative; the correlation parameters are: $N = 72$, $R = 0.9773$, $S = 8.484$ kJ mol^{-1}.

Equation (34) allowed high-accuracy determination of atomic constants which were designated by d and corresponded to the operational parameters e_i in the base equation (14). We were unable to determine the parameters d using the inductive and steric constituents and a correlation of type (15). Thus, the relationship between the redox and thermodynamic [expressed in terms of relative $E_d(CH)$] stabilities of free radicals remains uncertain. Nevertheless, the operational values d can be used successfully to calculate unknown energies of the C–H bonds.

IV. Conclusion

To summarise, it can be stated that the use of polar constants for the description of the reactivity and physicochemical properties of free radicals is rather limited, although in some cases, it is quite successful. The scales of specific radical constants $\sigma^{\cdot}$ are not general either. The absence of coordination between them and the ambiguity of the physical meaning of the $\sigma^{\cdot}$ radical constants might be due not only to the drawbacks of methods of their determination but rather to the limitations of principle inherent in the application of the linear methodology of correlation analysis to the free-radical chemistry and to the violation of additivity of the group influence in paramagnetic systems.

Thus, the problem of using correlation analysis in the chemistry of free radicals is far from being solved; in this respect 'homolytic' chemistry is markedly inferior to the 'heterolytic' chemistry of organic compounds. The new approaches to the quantitative description of the structure–reactivity (property) relationships for the participants of homolytic processes which we propose give hope for elimination of this objectively formed unbalance and make the quantitative organic chemistry more harmonious in some respect.

The model we developed, based on the consideration of discrete contributions of atoms, depending on the remoteness, to the substituent effects makes it possible to predict with high accuracy the quantitative characteristics of free radicals obtained experimentally. The method implies taking account of the influence of the molecular environment on the reaction centre without preliminary resolution of the effect into electronic and steric constituents. This approach provides the possibility of analysing efficiently diverse experimental results, irrespective of the nature of reaction centres.

Within the framework of our approach, we have considered only one of the three main types of free-radical processes. The quantitative description of the ionisation potentials and the electron affinities of diverse C-, N-, S- and O-centred radicals and the ionisation energies of aliphatic and aromatic amines permitted us to identify the physical nature of the corresponding substituent effects and to demonstrate the versatility of this approach in interpretation of the results of quantitative investigations in the chemistry of organic and heteroorganic free radicals.

In our opinion, of fundamental importance is the established fact that the substituent effects determining the electronic potentials of free C-, N-, O- and S-centred radicals are correlated with the stability of the corresponding ions and can be regarded as purely inductive. Nevertheless, correct quantitative determination of these values requires that the electronegativities of the ionic forms of C, N, O and S acting as the reaction centres be established.

The σ_+^C and σ_-^C scales introduced on the basis of atomic operational parameters e^+ and e^-, which determine the overall effects of substituents in single-electron transfer reactions involving C-centred radicals, exhibit high predictive capacity, although they do not clarify the physical nature of the corresponding interactions.

The approaches that we developed provide the possibility of describing a large array of dissociation energies of the C–H bonds and of determining operational atomic constants d, which are applicable for predicting unknown $E_d(CH)$ values. The notion 'redox stability of free radicals' also appears useful. It interprets this type of stability in terms of absolute hardness, without resorting to the approach according to which the relative bond energies are used as a measure of radical stability and which is criticised in the literature.

Successful use of the developed approaches for the quantitative interpretation of the ionisation energies of free radicals and molecules with closed electron shells gives hope that they would also be employed to describe the effects of substituents in other types of free-radical processes.

Rotaxanes and polyrotaxanes. Their synthesis and the supramolecular devices based on them

I G Panova, I N Topchieva

Contents

II.	Rotaxanes	23
III.	Polyrotaxanes	30
IV.	Supramolecular devices based on rotaxanes and polyrotaxanes	41

Abstract. Various approaches to the synthesis of rotaxanes and polyrotaxanes are considered. The principles employed in the design of highly organised structures comprising rod-shaped polymeric molecules, *viz*., macromolecular inclusion complexes, are discussed. In addition to the conventional (step-by-step) methodology which consists of polymerisation of monomers in the presence of macrocycles, molecular self-assembly is gaining an ever increasing significance. The main emphasis is laid on the preparation and characterisation of inclusion complexes which are based on cyclodextrins and linear synthetic polymers. The bibliography includes 138 references.

I. Introduction

Supramolecular chemistry as a new line of research has evolved and has developed intensively in the past few years. This interdisciplinary science encompasses the chemistry of noncovalent interactions, molecular physics and molecular biology. Its main attention is focussed on the systems which are capable of self-organisation, *i.e*., spontaneous production of definite structures by self-assembly of constituents into supramolecular assemblies. The synthesis of such structures is based on the molecular recognition principle and is effected by the cooperation of various non-covalent interactions, *e.g*., electrostatic, hydrophobic, hydrogen bonding, *etc*.

The principle of molecular recognition can be exemplified in the formation of complexes of the 'host – guest' type. The role of 'hosts', *i.e*., receptors, is played by cyclic molecules, *e.g*., cryptands, crown ethers, cyclodextrins and calixarenes. The chemical nature of 'guests' is extremely diverse, they include both small particles (*e.g*., inert gas atoms, metal ions, *etc*.) and complex bulky molecules of the fullerene type. In the past few years, supramolecular chemistry has been enriched by systems with polymers as the 'guest' molecules, which underlies the supramolecular chemistry of polymers.

This approach has made it possible to obtain such compounds as polyrotaxanes, catenanes, 'molecular necklaces', dendrimers, *etc*., which possess novel, previously unknown structures and remarkable properties. This review is devoted to one type of polymeric supramolecular assemblies, *viz*., polyrotaxanes. In the latter, the macrocycles are 'threaded' onto a polymeric molecule with bulky terminal groups. In addition to polyrotaxanes, their topological analogues, *viz*., pseudopolyrotaxanes including 'molecular necklaces', are reviewed. Since these structures are synthesised using essentially the same procedures as for rotaxanes, the strategy of rotaxane synthesis is also discussed.

II. Rotaxanes

Rotaxanes (Rt) represent complexes comprising cyclic molecules (C) threaded onto linear molecules (L). Their characteristic feature is the lack of covalent binding between the components C and L. In order to prevent the dissociation of the complex into constituents, the 'stoppers' (S), *i.e*., bulky molecules which are covalently linked to the ends of linear molecules, are used (Fig. 1 *a*, *b*). Similar structures in which the molecules S are absent are called pseudorotaxanes (pseudo-Rt) (Fig. 1 *c*). The nomenclature used to describe such compounds takes account of the number of components involved in the complexation. Thus [2]-Rt (see Fig. 1 *a*) contains one L and one C molecule; [3]-Rt is comprised of one L and two C molecules (see Fig. 1 *b*), *etc*.

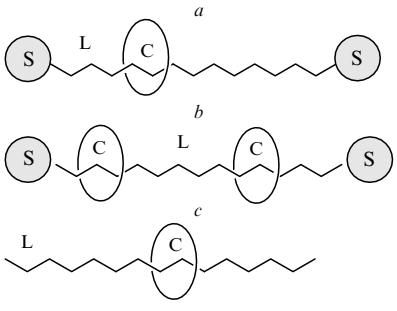

Figure 1. A schematic representation of rotaxanes: (*a*) [2]-Rt, (*b*) [3]-Rt, (*c*) pseudo-Rt.

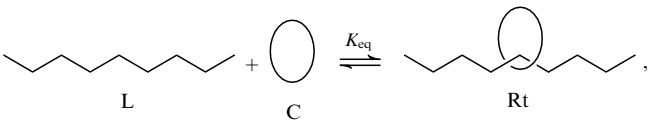
1. General approaches to the rotaxane synthesis

It should be noted that the threading of cyclic molecules onto linear components, which forms the basis for all the strategies of the rotaxane synthesis (Fig. 2), is a reversible process which is described by the equilibrium constant $K_{eq} = [Rt]/[L][C]$.



Therefore, the creation of conditions where the equilibrium of the reaction is shifted towards complex formation is the key event in the assembly of rotaxane molecules. Quantitatively, this process can be described by standard thermodynamic equations:

$$RT\ln K_{eq} = -\Delta G = -(\Delta H - T\Delta S), \quad (1)$$

$$\ln K_{eq} = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}. \quad (2)$$

As can be seen from Eqn (2), two extreme cases are thermodynamically possible. First, the so-called statistical threading, *i.e.*, a random collision and interaction of molecules of different nature (*e.g.*, L and C). The enthalpy of such a reaction, ΔH, is close to zero or is positive, *i.e.*, the threading is determined by the entropy factor. Second, template-directed threading, which is based on the principle of molecular self-assembly where the reaction is energetically favourable due to the existence of specific non-covalent interactions between the particles L and C ($\Delta H < 0$).

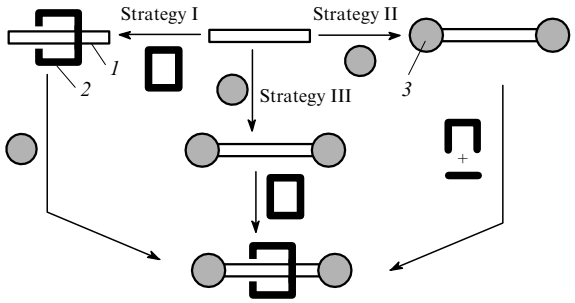


Figure 2. The strategies of the chemical synthesis of rotaxanes: (*1*) rod molecule, (*2*) macrocycle, (*3*) 'stopper'.

When considering the strategies of chemical synthesis of rotaxanes (see Fig. 2), one can distinguish three general approaches: [1]

(1) threading of a macrocycle onto a rod molecule and subsequent interaction of the complex formed with the blocking reagents (strategy I);

(2) cyclisation in the presence of compounds having a dumbbell-like structure (strategy II);

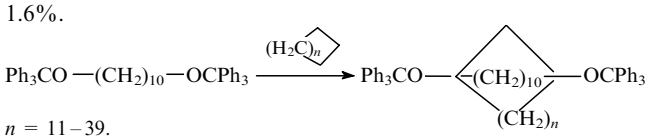
(3) temperature-induced 'slipping' of the macrocycle onto bulky terminal groups of the dumbbell-shaped molecule (strategy III).

2. The statistical approach to the rotaxane synthesis

The first attempts to synthesise rotaxanes were based on statistical threading of a cyclic component onto linear molecules. The first report on a successful synthesis of such complexes,[2] which consisted of random threading of a macrocyclic acyloin onto decane-1,10-diol using bulky trityl groups as stoppers, was published in 1967. After a 70-fold passage of the reaction mixture containing components L and S through a column with an immobilised cyclic component (C) and subsequent chromatographic separation of the eluate, the yield of rotaxane was as low as 6%. Further experiments [3,4] were aimed at establishing a correlation between the efficiency of statistical threading, the properties of the reactants C, L and S and reaction conditions.

The synthesis of rotaxanes from various dibenzocrown ethers, ethylene oxide oligomers (EOO) and trityl chloride by their joint fusion has been described.[4] In this case, the efficiency of threading depended on the size of the ring, the L : C ratio, the length of the chains of the L-molecules and the total volume of the reaction mixture, whereas temperature had no effect on the course of the reaction. The maximum degree of threading was achieved when a mixture of an ethylene oxide oligomer having a molecular mass (MM) of 1000 and crown ethers (on average, dibenzo-58.2-crown-19.4) is used. Mixing of EOO (MM = 400) with dibenzo-58.2-crown-19.4 at 130 °C and subsequent addition of triphenylchloromethane gave the corresponding [2]-Rt in 15% yield. The introduction of bromomethyl substituents into each phenyl group of the blocking reagent and the reaction in the presence of the Zn/Cu couple in DMF resulted in [4]-Rt in 8% yield.[5]

The experiments [3] with statistical threading of cyclic hydrocarbons onto 1,10-bis(triphenylmethoxy)decane at 120 °C revealed that only rotaxanes comprising C_{29} rings were more or less stable at this temperature, although their yields did not exceed 1.6%.



$n = 11-39$.

Later, it was found [4] that a macrocycle which has to be threaded onto the methylene groups should contain no less than 22 carbon atoms. It was shown also that terminal trityl groups can hold the rings which contained no more than 29 carbon atoms. Bulkier tris(*p*-butylphenyl)methyl groups prevent the dissociation of the rings containing 42 carbon atoms.

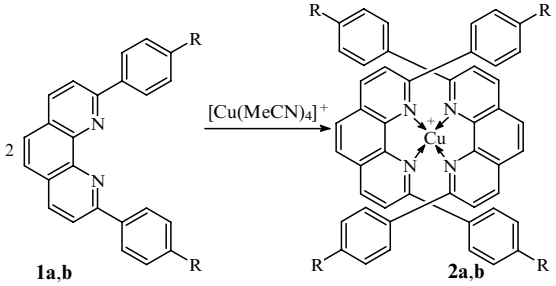
Thus, the statistical approach affords a mixture of starting compounds and rotaxanes; the isolation of the latter often presents a problem.[2–5] The efficiency of threading and the yields are controlled by varying the concentrations of the reactant and their molar ratios and by matching the geometric parameters of the molecules L, C and S. It is noteworthy that this approach gives relatively low yields of reaction products which at best do not exceed 15%. On the other hand, one of the benefits of the statistical approach to the rotaxane synthesis is the possibility of using a vast diversity of linear and cyclic molecules of different chemical nature which significantly expand the range of the structures that can be synthesised by this method.

3. Template synthesis of rotaxanes

Yet another approach to the rotaxane synthesis is based on the use of the fundamental principle of supramolecular chemistry, namely, the self-organisation of molecules due to specific non-covalent interactions. This approach is named template or directed synthesis, since in this case the process is directed by molecular recognition between two or more complementary fragments of the interacting molecules. Depending on the type of bonding, the following main routes to the rotaxane synthesis may be distinguished: (1) the formation of metal–ligand coordination bonds; (2) donor–acceptor interactions; (3) combined interactions which are observed in the formation of inclusion complexes based on cyclodextrins.

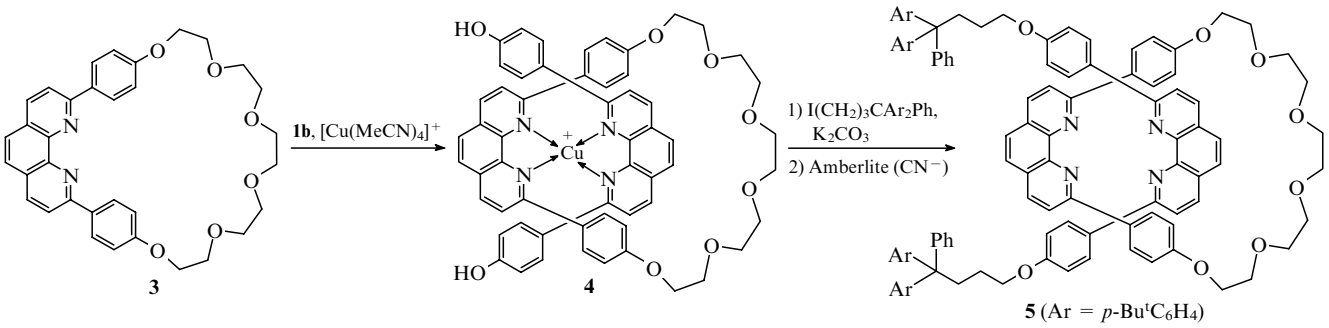
a. The synthesis of rotaxanes using transition metal ions

This strategy is based on the assembling and 'orientational' properties of transition metals. The complexation of two 2,9-disubstituted 1,10-phenanthrolines **1a**,**b** with the copper(I) ion was



R = OMe (**a**), OH (**b**).

Scheme 1

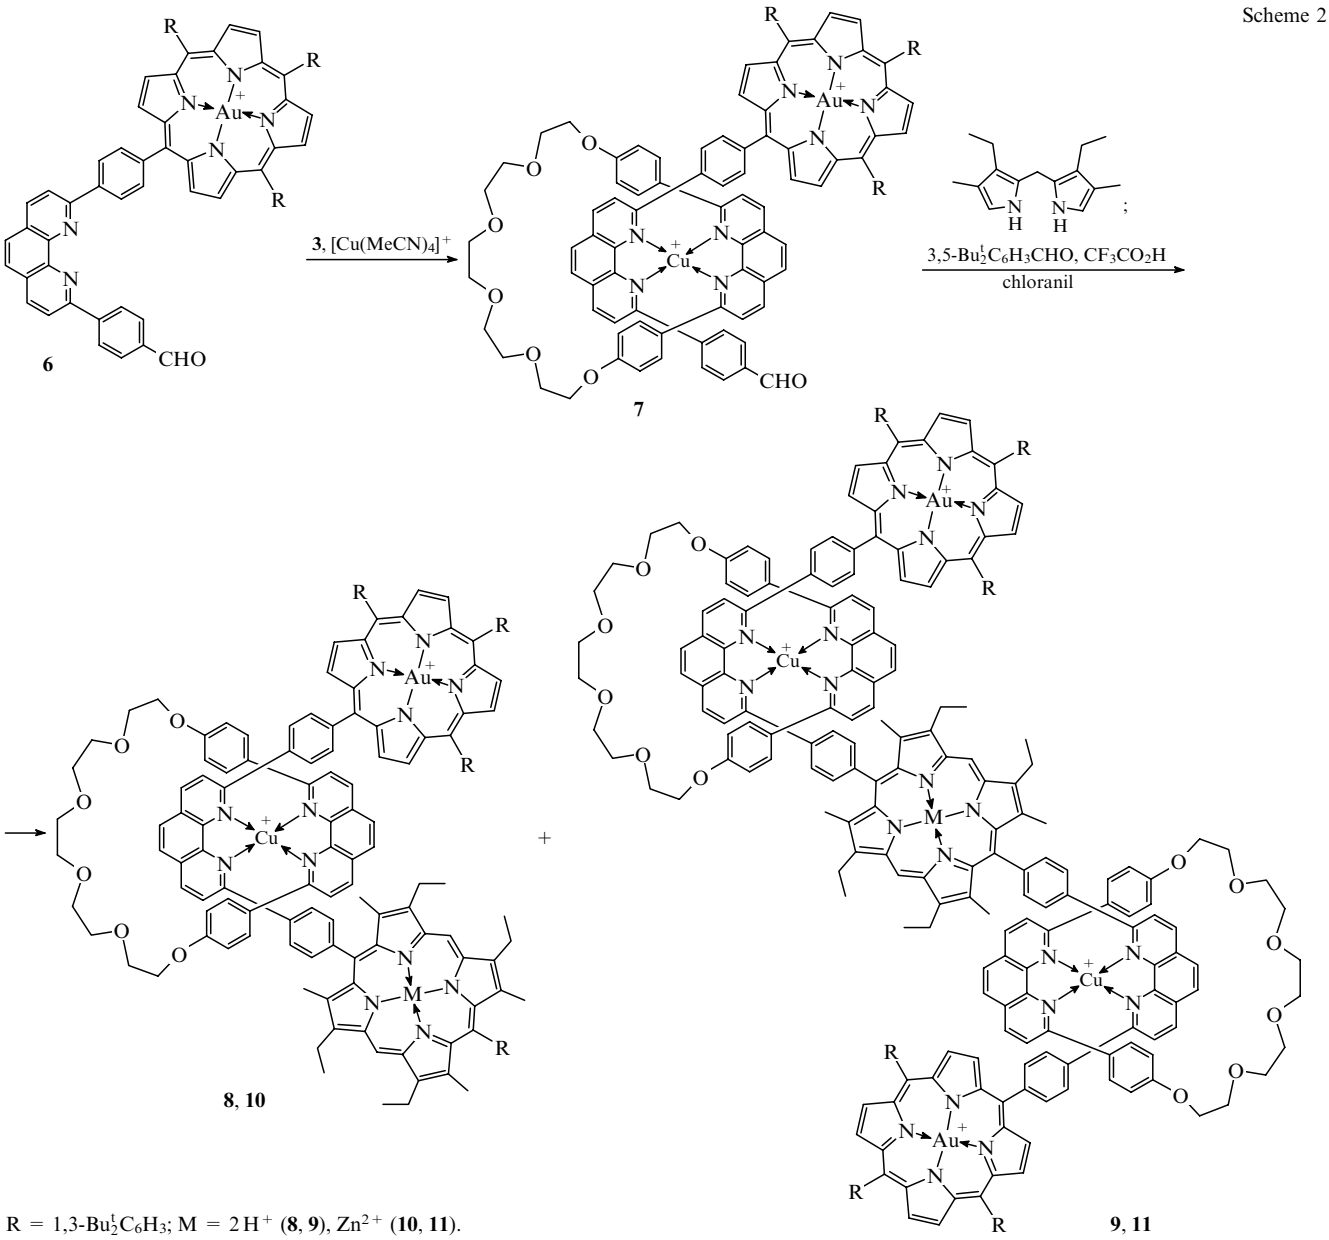


first proposed as the template-based reaction.[6] The complexes **2a**,**b** formed have an ideal spatial structure for the synthesis of rotaxanes based on them.

The synthesis of the macrocycle **3** incorporating one bidentate centre has been described.[7] The reaction of compound **3** with $[Cu(MeCN)_4]^+[BF_4]^-$ and 2,9-bis(4-hydroxyphenyl)phenanthroline **1b** affords the pseudorotaxane **4** (Scheme 1).[7] Reactive phenolic groups can react with different stoppers. Modification of the terminal groups of the complex **4** with alkyl iodide containing the bulky triarylmethyl group has led to [2]-Rt **5**.[8] In order to remove Cu^I, the complex formed was passed through an ion-exchange resin. The structure of the individual [2]-Rt **5** isolated in 21% yield was confirmed by ^1H NMR spectroscopy and mass spectrometry.

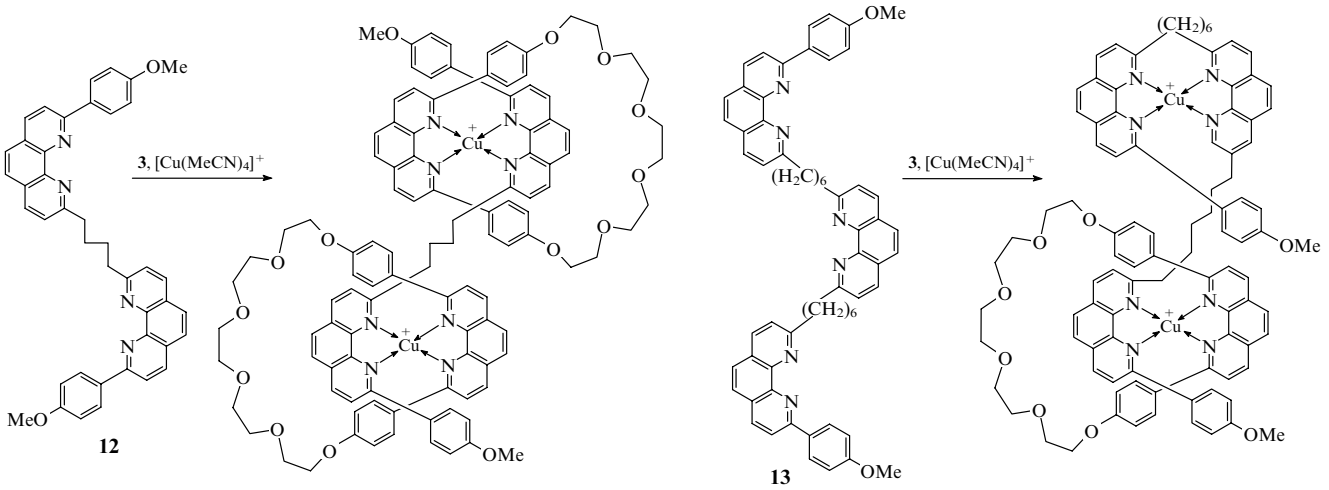
Later, data on the synthesis of porphyrin-containing rotaxanes have been documented (Scheme 2).[9–12] Initially, compound

Scheme 2



R = 1,3-$Bu^t_2C_6H_3$; M = $2H^+$ (**8**, **9**), Zn^{2+} (**10**, **11**).

Scheme 3



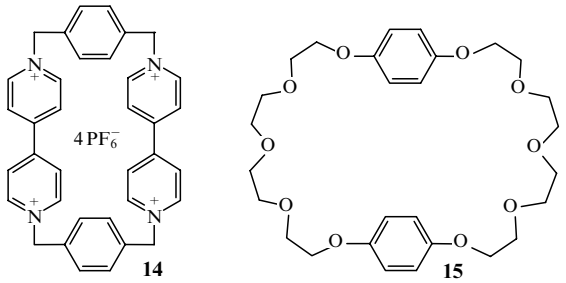
6 which contained a porphyrin–gold(III) complex as a stopper was prepared. This complex was added to the macrocycle **3** in the presence of a copper(I) complex. The intermediate product **7** formed reacted with 3,5-di-*tert*-butylbenzaldehyde and bis-(3-ethyl-4-methylpyrrol-2-yl)methane in the presence of trifluoroacetic acid. The intermediate porphyrinogen was oxidised with chloranil. Chromatographic separation gave [2]-Rt (**8**) and [3]-Rt (**9**) in 25% and 32% yields, respectively.[11] The rotaxanes **8** and **9** were converted into their Zn-analogues **10** and **11** by treatment with $Zn(OAc)_2 \cdot 2H_2O$. A ^1H NMR spectroscopic study showed that demetallation of the phenanthroline moiety of [2]-Rt by ion exchange with KCN changes its structure so that the phenanthroline fragment of the macrocycle lies outside the 'cleft' formed by the porphyrin fragments.[12]

Several modifications of this synthetic procedure are known. In one of them, the blocking groups are represented by fullerenes.[13]

It was suggested [14] to use linear molecules incorporating two (**12**) or three (**13**) 1,10-phenanthroline fragments for the synthesis of structurally more elaborate rotaxanes. Their interactions with the macrocycle **3** in the presence of $[Cu(MeCN)_4]^+ [BF_4]^-$ have been studied (Scheme 3). It was shown that [3]-pseudo-Rt formed on the basis of compound **12** has the composition $L : Cu^I : C = 1 : 2 : 2$. Compound **13**, which contains three phenanthroline fragments, yields a complex with the composition $L : Cu^I : C = 1 : 2 : 1$, *i.e.*, [2]-Rt in which two phenanthroline fragments of the rod molecule interact both with each other and with Cu^I, rather than the expected complex with a $L : Cu^I : C$ ratio of 1 : 3 : 3. This phenomenon was attributed to the flexibility of the stretched rod molecule. The ability for self-complexation must be taken into consideration in the synthesis of [3]- and [4]-Rt by this method.

b. Rotaxane syntheses based on donor-acceptor interactions of L and C molecules

This method consists in the interaction of electron-donor and electron-acceptor molecules or their fragments and results in π-bonding. Cyclobis(paraquat-*p*-phenylene) **14**,[15] which reacts with a variety of aromatic electron-donor substrates, and bis-*p*-phenylene-34-crown-10 (**15**),[16] which forms a complex with paraquat bis(hexafluorophosphate), have received especially wide acceptance as receptors. Using X-ray diffraction analysis, it was shown [17,18] that the complexes prepared on the basis of these compounds and the corresponding ligands have ordered structures both in solution and in the solid phase and represent pseudorotaxanes. The aromatic rings of the 'guest' molecules are accommodated inside the 'host' molecules between the rings of the receptor, which are stacked parallel to one another. The complexes have box-like structures, which are ideal for their conversion into rotaxanes.



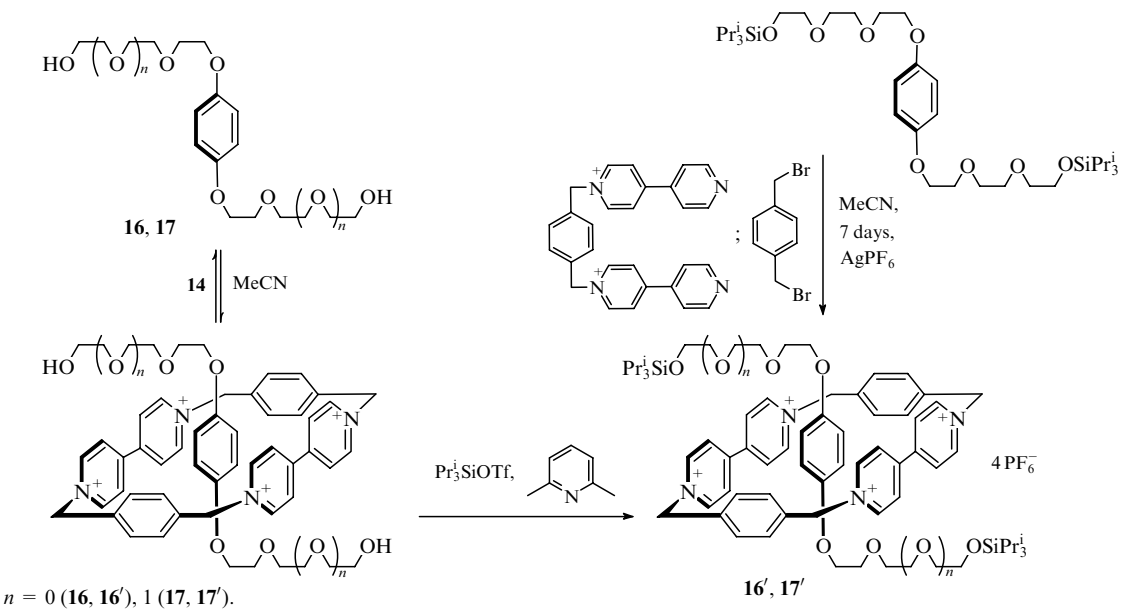
The interaction of compounds **16** and **17** (Scheme 4) with the macrocycle **14** in acetonitrile followed by a reaction with triisopropylsilyl triflate was studied.[19] After purification of the reaction mixture by column chromatography on silica gel, [2]-Rt **16′** and **17′** were isolated in equal yields (22%).

A similar compound, *viz.*, [2]-Rt **17′**, was obtained in 14% yield using strategy II (see Scheme 2, Fig. 2).[20] It was noted [19] that the reduction in the length of the oligoethylene oxide fragments of the rod molecules changes the arrangement of the *p*-dioxyphenylene fragments relative to the plane of cyclophane and results in the increase in the distance between the complementary aromatic fragments of the L and C molecules.

An increase in the number of electron-donor fragments in the rod molecule not only increases the yields due to the self-organisation of rotaxanes, but also enables the synthesis of the so-called molecular shuttles,[21–27] *viz.*, the complexes in which the macrocycle can migrate from one part of the rod molecule to another (the so-called translocation isomers). For the first time, such rotaxanes were synthesised in 1991 [21] by the reaction of the tetracationic cyclophane **14** with the dumbbell-shaped compound **18** (Scheme 5) containing two *p*-dioxyphenylene fragments. The corresponding rotaxane was obtained in 32% yield. A ^1H NMR spectroscopic study revealed that the cyclophane migrated between the two aromatic fragments of the L molecule at a rate of 500 s^{-1}. The activation free energy of the migration observed (ΔG) is $\sim$ 13 kcal mol^{-1}.

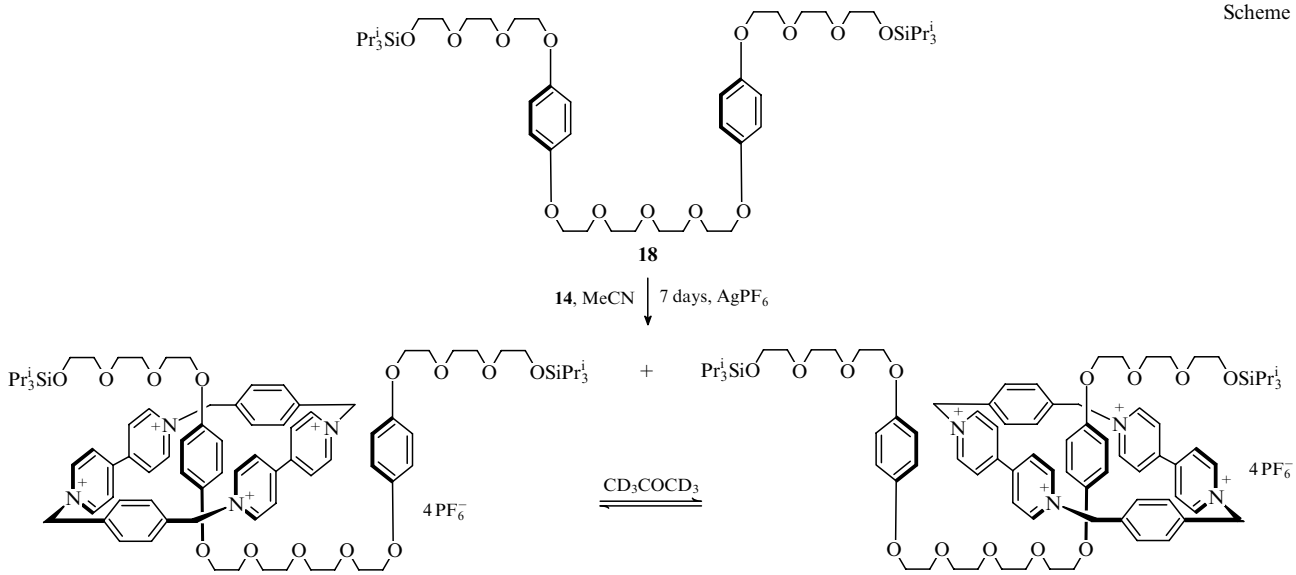
Strategy II was also used for the synthesis of a series of [2]-Rt **19–22** (yields 1%, 25%, 29% and 40%, respectively).[22] It is remarkable that in neither case [3]-Rt was obtained. Of the four rotaxanes isolated, only complex **22** exists in the form of two translocation isomers. Similar 'molecular shuttles' were obtained by substitution of electron-donor (*e.g.*, tetrathiofulvalene,[23–25] 4,4′-bisphenol, benzidine [26,27]) fragments for one of the *p*-dioxyphenylene fragments of the rod molecule; the yields of the isolated rotaxanes did not exceed 9%. Presumably, this can be attributed

Scheme 4

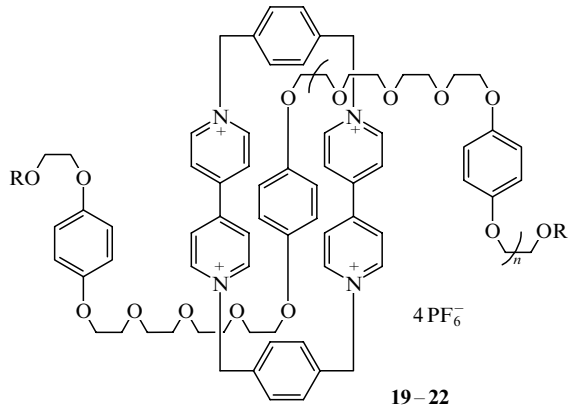


n = 0 (**16**, **16′**), 1 (**17**, **17′**).

Scheme 5



to the fact that in these cases the complexation largely involves one binding centre of the rod molecule.



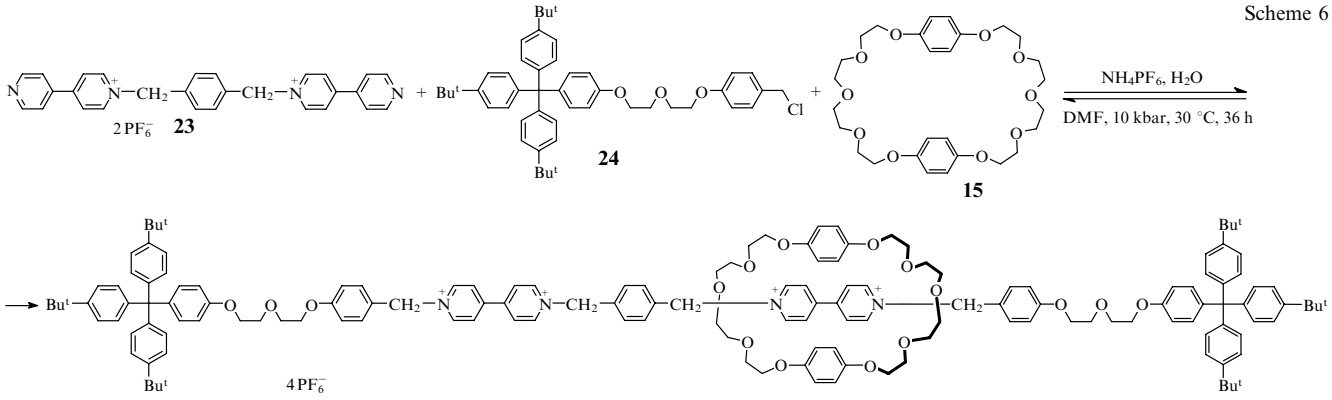
R =  ; n = 0 (**19**), 1 (**20**), 2 (**21**), 3 (**22**).

The synthesis of rotaxanes based on crown ether **15** was carried out using strategies I and III.[28] Thus the reaction of the dication **23** with the bulky blocking reagent **24** in the presence of an equimolar amount of the macrocycle **15** under high pressure (strategy I) (Scheme 6) has been described. The yield of the target product, *viz*., [2]-Rt, was 23%. Noteworthy, the rate of the translocation of the macrocycle between the two dications in this complex is $\sim 300\,000\ s^{-1}$, which markedly exceeds that of rotaxanes based on cyclobis(paraquat-*p*-phenylene).

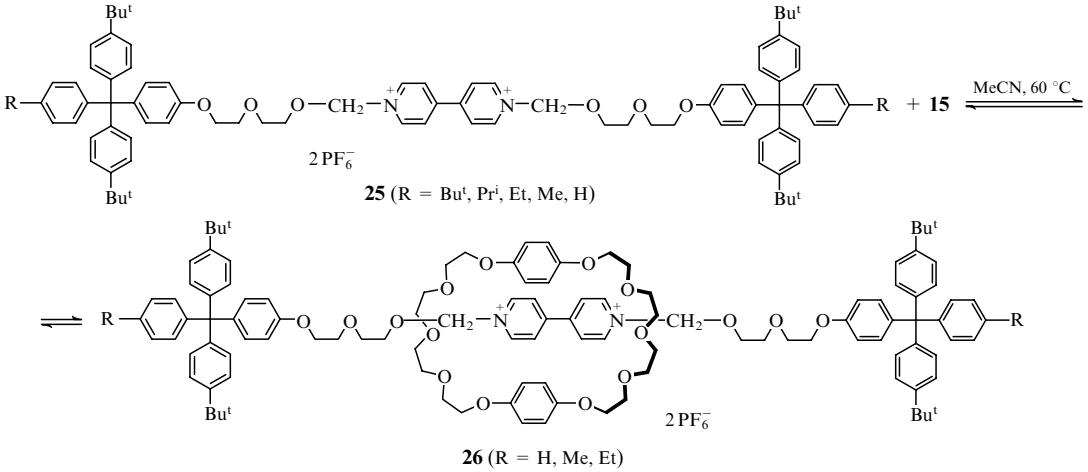
By varying the size of the blocking group in the dumbbell-shaped molecule **25** (Scheme 7), it became possible to synthesise rotaxanes using thermodynamically more favourable slipping of the macromolecule **15** onto the bulky terminal groups of compound **25** (strategy III, see Fig. 2). Compound **25** in which the terminal *tert*-butyl groups were replaced severally by isopropyl, ethyl and methyl groups as well as by hydrogen atoms were heated in acetonitrile with four equivalents of the macrocycle **15** at 60 °C.[29] This resulted in the self-organisation of [2]-Rt of the type **26** (see Scheme 7) in 47%, 45% and 51% yields for R = Et, Me and H, respectively. The isopropyl groups appeared to be too bulky for the slipping of the macrocycle. All the rotaxanes thus prepared were stable at room temperature.

Strategy III was also employed in the synthesis of [2]- and [3]-Rt containing two bipyridine fragments.[30] It should be noted that such rotaxanes cannot be synthesised using strategies I and II,

Scheme 6



Scheme 7



whereas slipping allows one to obtain them in 20% and 55% yields, respectively.

An illustrative example of a successful application of strategy III has been described.[31] Heating of a mixture containing compound **27** and the macrocycle **15** affords [2]-Rt **28** (yield 19%), [3]-Rt **29** (yield 41%) and [4]-Rt **30** (yield 22%) (Fig. 3). Such branched supramolecular assemblies are the first examples of dendritic rotaxanes.

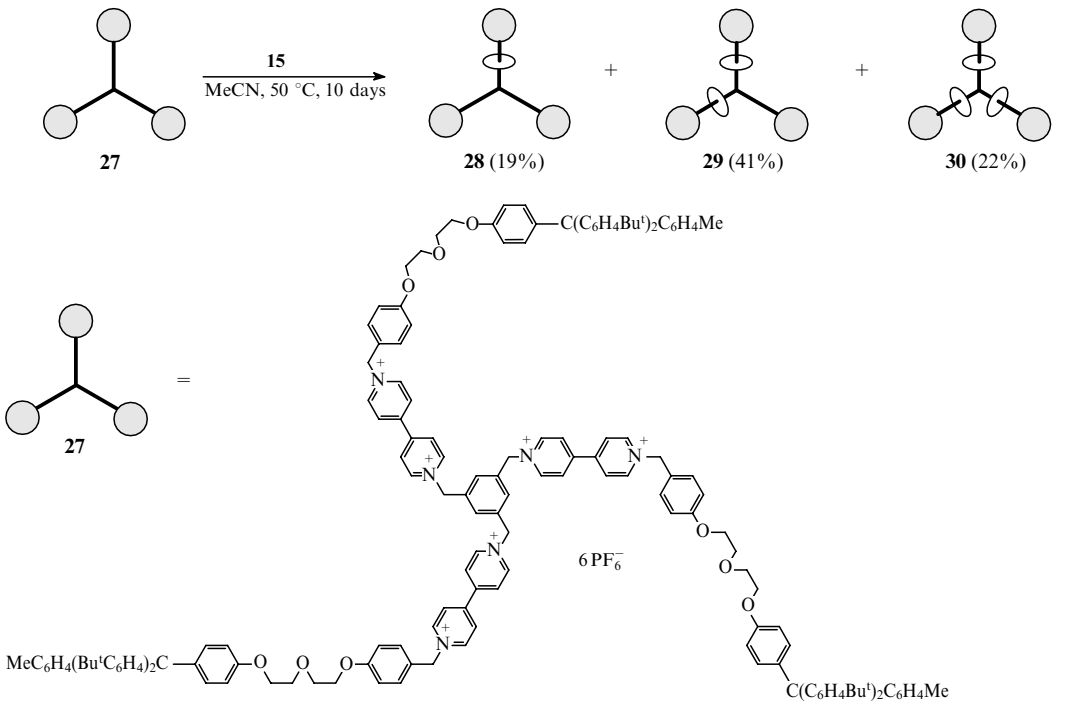


Figure 3. The synthesis of dendrimeric rotaxanes using strategy III.[31]

c. The synthesis of cyclodextrin-containing rotaxanes

The use of cyclodextrins (CD) as cyclic components has marked a new step in the synthesis of rotaxanes. These compounds were first discovered in 1891 [32] and represent cyclic oligosaccharides built up of D-glucopyranose units linked together by α-1,4-glucoside bonds. The shape of the cyclodextrin molecules resembles a torus. The structure of α-, β- and γ-cyclodextrins is schematically represented in Fig. 4. The presence of a cylindrical hydrophobic cavity determines the ability of cyclodextrins to form inclusion complexes with molecules of different chemical nature in aqueous solutions. The synthesis and characteristics of such complexes have been outlined in numerous reviews and monographs.[33–39] Suffice it to say that the driving forces of this complexation are Coulombic, dipole–dipole, hydrophobic and van der Waals interactions as well as hydrogen bonds between the CD and 'guest' molecules. Matching of the geometrical characteristics of the cyclodextrin cavity and those of the 'guest' molecule is an important prerequisite for the formation and stability of the inclusion complexes. The unique capacity of cyclodextrins to interact selectively with the substrate molecules which are complementary in size makes them attractive subjects of the supramolecular chemistry.

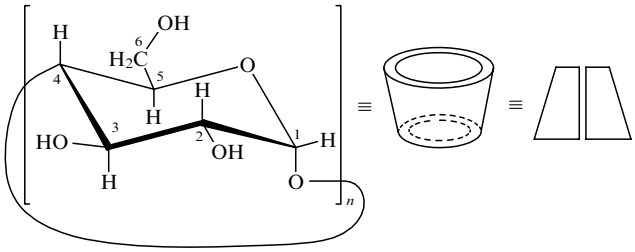

Figure 4. The structural formula of α- (n = 6), β- (n = 7) and γ-cyclodextrins (n = 8).

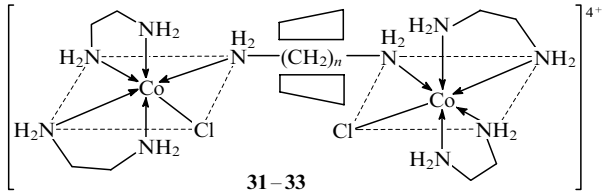
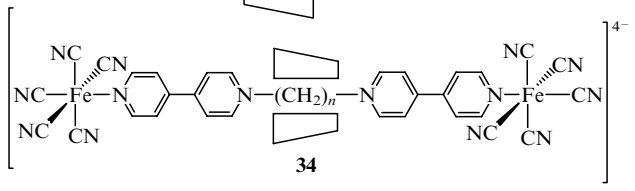
Initially, syntheses of cyclodextrin-containing rotaxanes were based on the ability of CD molecules to be threaded onto polymethylene chains. It should be noted that the cavity of one macrocycle accommodates approximately five methylene units. The blocking groups were introduced into pseudorotaxanes by the reaction with the terminal functional groups of the rod molecules. The role of stoppers was played by transition metal complexes. This approach was used in the synthesis of [2]-Rt **31**–**33** based on α- and β-CD.[40] The maximum yield of the rotaxanes (19%) was obtained for the systems comprising α-cyclodextrin and linear molecules whose alkyl chains contained 12 carbon atoms (n = 12). Similarly, [2]-Rt **34** was prepared by the reaction of the α-CD–1,1′-nonamethylenebis(4,4′-bipyridine) complex with cyanoferrate(II) in an aqueous solution.[41] The rotaxane formed was kinetically labile, so it could not be isolated from the solution.



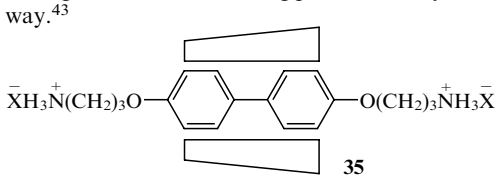
31–**33**

n = 8 (**31**), 10 (**32**), 12 (**33**); = α-CD, β-CD.

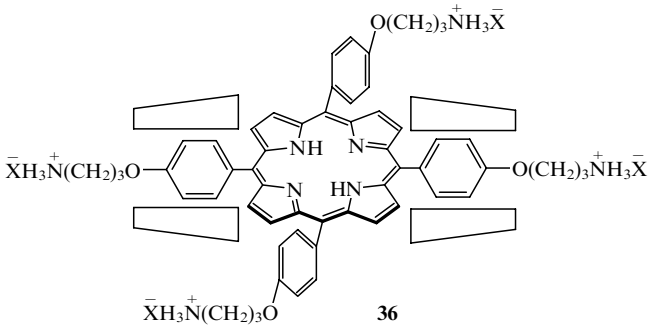


34

Ion-to-ion interactions were used to stabilise cyclodextrin-containing pseudorotaxanes.[42] The role of the thread was played by molecules carrying terminal ammonium groups, heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DM-β-CD) was used as the cyclic component. Pseudorotaxane **35** was precipitated from the solution by addition of tetraphenylborate; after isolation and purification, its yield was 71%. [3]-Rt **36** which can be regarded as an analogue of heme-containing proteins was synthesised in a similar way.[43]



35

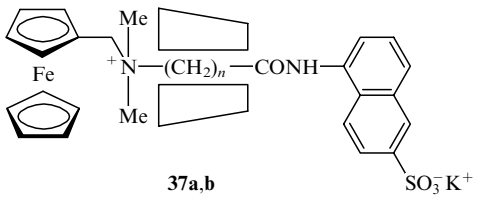


36

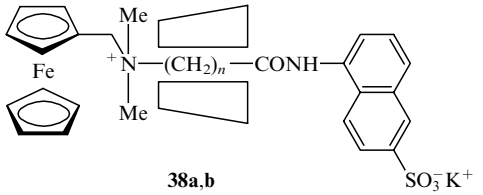
X = Ph_4B^-; = DM-β-CD.

Stable rotaxanes can only be obtained in those cases where stoppers are covalently bound to the termini of the 'guest' molecule. The main difficulty is related to the choice of a solvent which must serve as a suitable medium for the chemical reaction of the terminal groups of the pseudorotaxane and simultaneously ensure stabilities of the inclusion complexes. Water, which is the best solvent for the interaction of cyclodextrins with the substrate, is most often inappropriate for the introduction of terminal groups, since these reagents are usually poorly soluble in water or undergo hydrolysis. To overcome this problem, it was suggested [44] to use strong nucleophiles (*e.g.*, NH_2) as the functional groups of the stoppers and aliphatic carboxylic acid derivatives as the rod molecules.

This approach was used in the synthesis of two [2]-Rt, *viz.*, **37a**,**b**, and their orientational isomers **38a**,**b** in 15% yield.[45]



37a,**b**



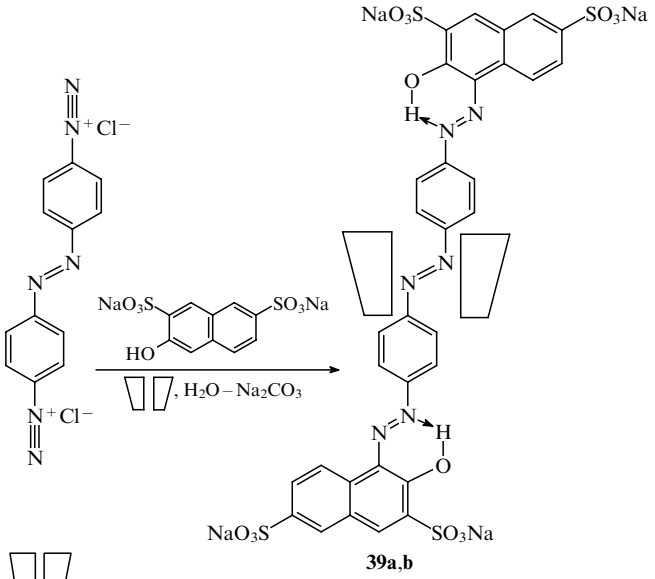
38a,**b**

n = 7 (**a**), 11 (**b**).

It is remarkable that the isomer **37a** remained stable, whereas the complex **38a** dissociated into constituents. This example illustrates the strong dependence of the stability of the rotaxanes on the spatial orientation of the CD molecules threaded onto the 'guest' molecules. A similar strategy of the rotaxane synthesis in aqueous solutions on the basis of rod molecules carrying terminal NH_2 groups and di-*O*-methyl- and tri-*O*-methyl-α-cyclodextrins

was used by Harada and Kamachi.[46] In this study, 1,12-diaminododecane complexes with methylated cyclodextrins reacted with an aqueous solution of trinitrobenzenesulfonic acid, which resulted in the corresponding rotaxanes isolated in 42% and 48% yields.

The formation of inclusion complexes based on cyclodextrins is often used for stabilisation of photosensitive compounds.[34–36] The conversion of such complexes into rotaxanes is a logical sequel of these studies. Thus an azo dye was synthesised from a bisdiazonium salt and a β-naphthol derivative in the presence of various cyclodextrins.[47] Rotaxanes **39a**,**b** were prepared from α- and β-CD in 12% and 15% yields, respectively. The formation of such water-soluble rotaxanes illustrates the possibility of an increase in the stabilities and solubilities of practically important synthetic dyes using this simple approach. It has thus been demonstrated that molecular self-assembly is an efficient tool for the design of new structures.



III. Polyrotaxanes

The strategies of rotaxane synthesis can also be applied to the development of procedures for the preparation of structurally more elaborate compounds, *viz*., polyrotaxanes (PRt or [*n*]-Rt) which represent supramolecular assemblies where multiple macrocycles are non-covalently bound with the polymeric chains. Two main types of such complexes are distinguished, *viz*., linear polyrotaxanes where the macrocycles are threaded onto the main chain (Fig. 5 *a*) and comb-like polyrotaxanes (Fig. 5 *b*).

There are several main approaches to the synthesis of polyrotaxanes, namely, the formation of a polymer in the presence of a macrocycle (method 1); the formation of a ring in the presence of a macromolecule (method 2); polymerisation or polycondensation of a stable pseudorotaxane (method 3); self-organisation of a pseudopolyrotaxane (pseudo-PRt) due to specific non-covalent interactions (method 4) and temperature-induced slipping of the macrocycles onto the stoppers, *viz*., terminal groups or those pertaining to the main chain (method 5). It should be noted that cyclisation is usually performed in dilute solutions. However, if polyrotaxanes are synthesised by the method 2, the Le Chatelier principle requires that the polymer was used as a solvent or was taken in excess. This results in a significant increase in the viscosity of the reaction mixture and, correspondingly, in a decrease in the rate of the reaction. For this reason, method 2 is virtually inapplicable to the synthesis of polyrotaxanes. The role of macrocycles is usually played by synthetic or natural cyclic molecules, *e.g*., crown ethers [48–59] or cyclodextrins.[60–117]

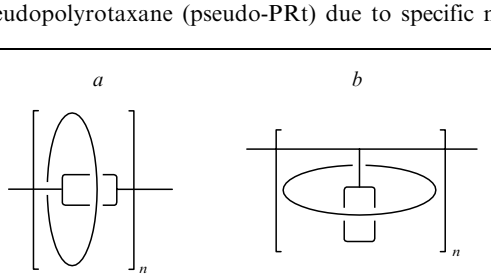


Figure 5. A schematic representation of polyrotaxanes: (*a*) linear, (*b*) comb-like.

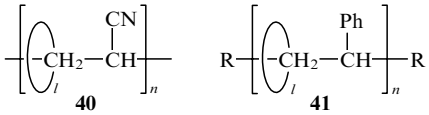
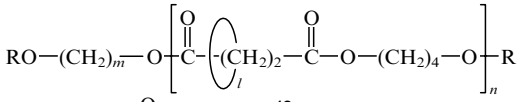
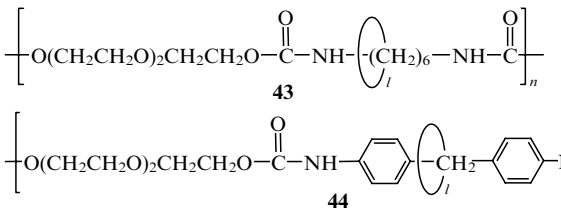
1. Linear polyrotaxanes based on crown ethers

The procedures used for the synthesis of polyrotaxanes which incorporate crown ethers have been studied in sufficiently great detail.[48–59] They are based on the statistical threading of macrocycles onto the rod molecule in the course of polymerisation (method 1). The possibility of the use of virtually all (as regards their chemical nature) linear molecules for the rotaxane synthesis allows the design of a great diversity of pseudopolyrotaxanes. 36-Crown-12, 42-crown-14, 48-crown-16 and 60-crown-20 are usually used as crown ethers.

Radical polymerisation was used for the synthesis of pseudopolyrotaxanes **40** based on polyacrylonitrile.[48,49,59] Polystyrene-based polyrotaxanes **41** were synthesised by anionic polymerisation of styrene in the presence of 36-crown-12 and 42-crown-14.[50] Pseudopolyrotaxanes and polyrotaxanes based on various polyesters (compound **42**) and polyurethanes (compounds **43** and **44**) were obtained by polycondensation and polyesterification.[51–58]



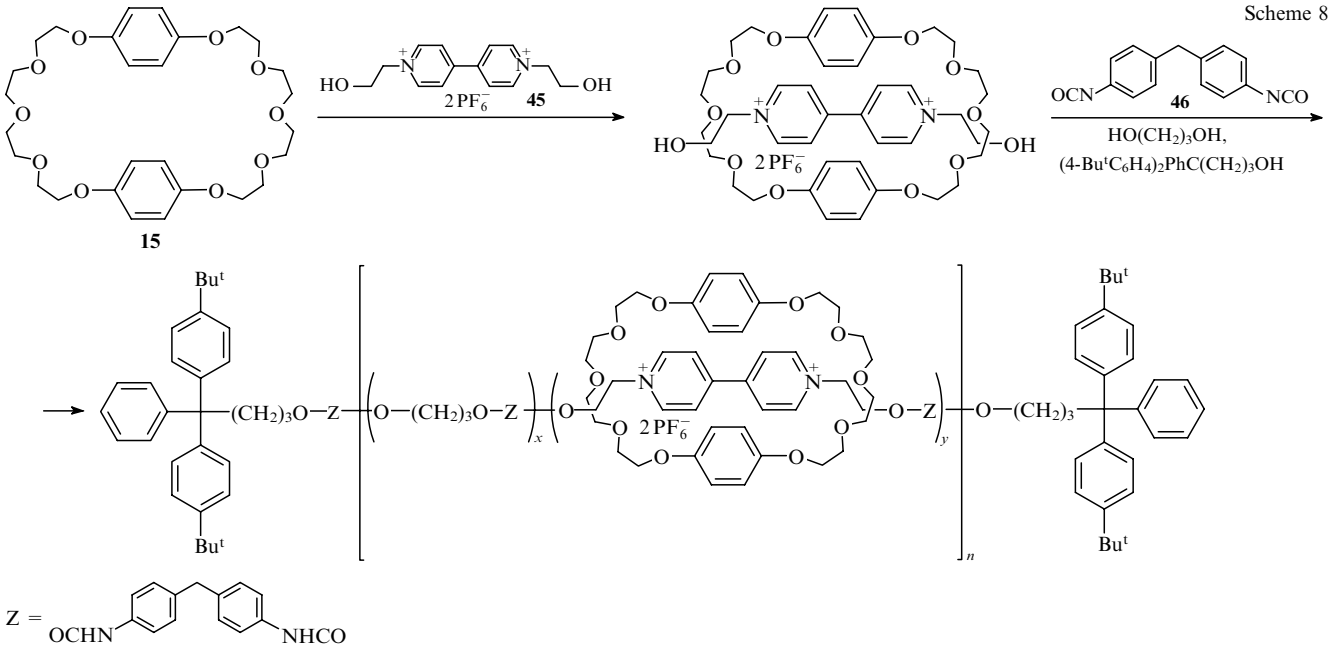




— 30-crown-10, 42-crown-14, 48-crown-16, 60-crown-20.

The isolation and purification of the polymers thus formed were carried out by multiple precipitation of the macrocycles using selective solvents. To ensure invariable composition, it is sufficient to repeat the procedure once or twice even in the case of pseudopolyrotaxanes. This suggests that the folded conformation of the macromolecules prevents the dissociation of the complex into the constituents. The properties of the polymers synthesised were studied by NMR spectroscopy, gel permeation chromatography (GPC), viscosimetry and differential scanning calorimetry (DSC). It was found that the molecular mass of the polyrotaxane formed and the degree of threading of the crown ether increase with an increase in the concentration of the macrocycle and depend on the ratio of the components in the original mixture. The maximum efficiency of threading of crown ethers is achieved where the latter are used as solvents or co-solvents for monomers in the course of polymerisation.

Scheme 8



The possibility of a template synthesis of polyrotaxanes was also studied using crown ether **15** as a template. Co-polymerisation of *N*,*N*′-bis(2-hydroxyethyl)-4,4′-bipyridinium bis(hexafluorophosphate) (**45**) with bis(*p*-isocyanatophenyl)methane (**46**) in the presence of the macrocycle **15** (Scheme 8) afforded a polyrotaxane with a high (54%) content of cyclic molecules.[51, 55] To increase the flexibility of the synthetic polymer, small amounts of an ethylene oxide oligomer were added to the reaction mixture. It was found that the molecular mass and the amount of the macrocycle in polyrotaxane depend on the ratio of the starting components as well as by the amount of the stopper added.

The incorporation of macrocycles into polymers causes significant changes in the physicochemical properties (*e.g.*, solubility, thermal and mechanical characteristics) of the rotaxanes formed in comparison with the starting compounds. Some authors [48–59] consider crown-ether-based polyrotaxanes as specific copolymers of the cyclic and linear components. The solubilities of polyurethane- and polyester-based rotaxanes depend on their composition as well as on the nature and size of the macrocycle. For example, the incorporation of 60-crown-20 increases the polarities of polyurethane-based rotaxanes so that these compounds, contrary to the original polymers, become soluble in polar solvents. In some cases, synthetic polyrotaxanes were water-soluble producing micellar structures.[55, 56] Treatment of polyurethane-based rotaxanes with solvents which are selective with respect to the incorporated polymer was accompanied by the aggregation and even crystallisation of the cyclic component which was attributed [55, 56] to the free migration of the crown ethers along the rod molecule.

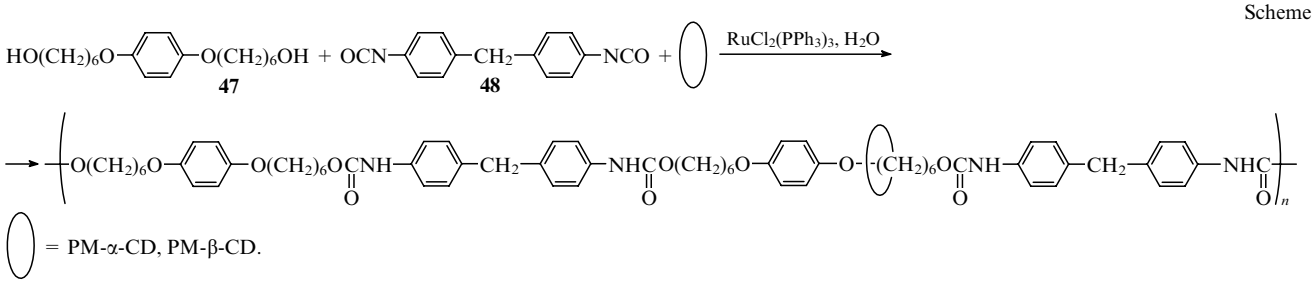
Studies of the thermal characteristics of polyrotaxanes by DSC revealed that phase-transition temperatures strongly depend on the nature of the interacting components and the composition of the supermolecules formed. For example, the polymer based on poly(butane-1,4-diyl sebaceate) and 60-crown-20 produced two endothermal peaks at 40 and 60 °C, which corresponded to the melting of the cyclic and linear components, respectively. These values are several degrees lower than those for the corresponding individual crown ethers and the polyester, which suggests a decrease in the crystallinity of each of the polyrotaxane components.[53] The glass transition of polyurethane-based rotaxanes is also observed at a lower temperature range in comparison with the glass transition temperatures for the original components.[59]

According to Gibson *et al.*,[48–59] the properties of polyrotaxanes formed by polymerisation of monomers can be changed directionally by varying their compositions. The feasibility of incorporation of crown ethers into polymers as plasticisers was also considered.[56]

2. Linear polyrotaxanes based on cyclodextrins

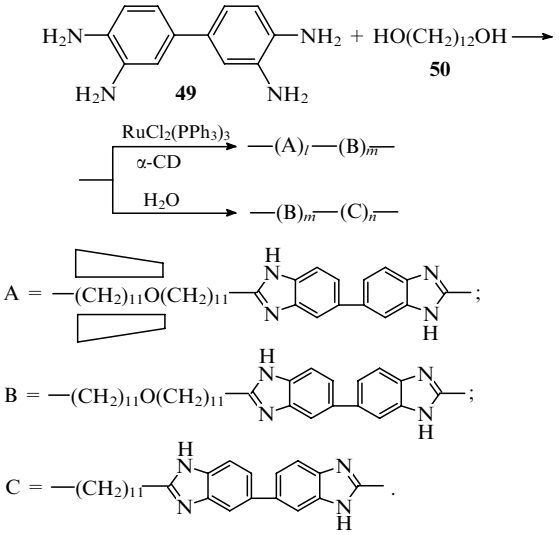
The procedure for the preparation of cyclodextrin-containing polyrotaxanes by the method 1 included polycondensation of 1,4-bis(ω-hydroxyhexyloxy)benzene (**47**) and 4,4′-methylenediphenylisocyanate (**48**) (Scheme 9) in the presence of permethylated α- and β-cyclodextrins (PM-α-CD and PM-β-CD).[60] This approach was used to synthesise a series of polyurethane-based pseudopolyrotaxanes in high yields (85% – 92%) with the starting components taken at different ratios. It was found that the compositions of the synthetic polymers depend on the PM-CD : monomer ratio. The maximum content of the macrocycles for PM-α-CD and PM-β-CD is one molecule of a cyclodextrin per four and five repeating fragments of the polymer, respectively. A ^{1}H NMR spectroscopic study revealed that in the polymers synthesised PM-α-CD fragments are accommodated on the polymethylene groups, whereas PM-β-CD, which has a larger cavity, is predominantly localised on the aromatic groups of the

Scheme 9



rod macromolecule. As in the case of the polyrotaxanes containing crown ethers, the glass transition temperature of cyclodextrin-based polyurethane pseudopolyrotaxanes was lower than that of the native polymer. This is attributed to partial destruction of polyurethane-specific intramolecular hydrogen bonds as a result of shielding of polar NH-groups of the polymer by the cyclic macromolecule.

A similar strategy was used in the polycondensation of monomers which contained either binding centres or blocking groups in the presence of a macrocycle.[61] It was shown that catalytic oxidative polycondensation of compounds **49** and **50** in the presence of α-CD resulted in the formation of irregular polyrotaxanes which comprised block copolymers incorporating the structural fragments A and B in a 16 : 84 ratio.



It is of note that the polyrotaxanes synthesised contain no structural fragments of the C type, whereas in the absence of cyclodextrin the polycondensation affords a polymer which contains ~ 20% of such blocks.

An alternative strategy of the polyrotaxane synthesis consisted in preliminary synthesis of inclusion complexes of a series of diamines with β-cyclodextrin and their subsequent polycondensation with isophthaloyl or terephthaloyl chlorides[62] (method 3). The conclusion concerning the formation of the macromolecular cyclodextrin – polymer complex was made on the basis of the results of elemental and differential thermal analyses. Radical polymerisation was used in the synthesis of cyclodextrin-containing homopolymers and copolymers based on inclusion complexes of β-CD with vinylidene chloride, allyl chloride, styrene and methyl methacrylate.[63] In this case, the reaction was accompanied by the chain transfer to cyclodextrin. The attempts to characterise unambiguously the compositions and structures of the resulting complexes failed owing to their poor solubilities and the presence of by-products.[62, 63] For this reason, the synthesis of supramolecular structures incorporating polymers and cyclodextrin from the inclusion complexes of the corresponding monomers did not acquire popularity.

a. Water-insoluble cyclodextrin-containing polyrotaxanes

Two independent groups of investigators[64–85] demonstrated the possibility of applying the molecular self-assembly principle (method 4) to the synthesis of polyrotaxanes. This method consists in the direct interaction of cyclodextrin and polymers in aqueous solutions.

A group of Japanese investigators[64–80] carried out a detailed study of interactions of poly(ethylene oxides) (PEO) with α-cyclodextrin. It was shown that mixing of aqueous solutions of the polymer and CD resulted in the precipitation of a weakly soluble product. It was assumed that in this case 'self-organisation' of the inclusion complex occurred in which cyclodextrin molecules are threaded onto the polymeric chain. This type of complexes have acquired the name of 'molecular necklaces' (MN). As a matter of fact, these structures represent pseudopolyrotaxanes which can be converted into polyrotaxanes by modification of their terminal groups.

Studies of complexation of poly(ethylene oxides) with α-cyclodextrin by the nephelometric method revealed that the lowest molecular mass of a polymer necessary for the formation of insoluble complexes is 300. However, in a more recent publication by these authors it was shown that 'molecular necklaces' can be prepared from tetra(oxyethylene) dibromide (MM = 176).[78] The rate of complexation reaches a maximum at the average molecular mass (M_n) of 1000 and shows a tendency to decrease with a further increase in M_n.[68] This result is attributed to a decrease in the number of terminal groups with an increase in the molecular mass of the polymer, which in its turn is due to the inclusion nature of the complexes. Evidence for the formation of MN can be obtained from the results of elemental and thermogravimetric studies as well as from ^{1}H and ^{13}C NMR spectroscopy and X-ray diffraction data. Thus ^{1}H NMR spectroscopy was used to determine the compositions of the complexes synthesised. Irrespective of the molecular mass of PEO and the molar ratios of the reagents, the complexes formed had strictly stoichiometric compositions where one molecule of α-cyclodextrin corresponded to two ethylene oxide units. Molecular simulation revealed that the diameter of the PEO chain matches perfectly the width of the inner cavity of α-CD, whereas the length of two ethylene oxide fragments is practically equal to the height of the cyclodextrin cone. Additional evidence in favour of MN formation can be derived from the fact that in the case where PEO molecules contained bulky terminal groups (2,4-dinitrophenyl or 3,5-dinitrobenzoyl groups), the sizes of which exceed that of the inner cavity of α-CD, cyclodextrin loses its ability to be threaded onto the polymeric chain and no inclusion complex is formed. It was suggested that the driving force of self-organisation of the complexes are hydrophobic interactions between the cyclodextrin cavity and the polymer fragments as well as the formation of hydrogen bonds between the OH groups of the neighbouring CD molecules.

Further studies showed that similar complexes could be prepared with other cyclodextrin – polymer pairs (Table 1). These data suggest that hydrophobic polymers can be used for complexation along with hydrophilic ones. Although the formation of complexes based on hydrophobic polymers takes much more time and requires preliminary sonication of the reaction mixture, the pseudopolyrotaxanes produced possess strictly stoichiometric compositions and they can be obtained in sufficiently high yields. It should be noted that the dependences of the yields of MN on the molecular mass of the polymer differ substantially for the complexes prepared from hydrophilic or hydrophobic polymers and cyclodextrin. Thus for the α-CD – PEO complex, this dependence is described by a curve which consists of two parts. First, the yield of the polymer increases with an increase in the molecular mass and then is independent of the molecular mass. For hydrophobic polymers, this dependence is bell-shaped;[65, 71, 74] in some cases, *e.g.*, for poly(isobutylene),[73] the product yield decreases monotonically. The observed regularities can be explained as follows. In aqueous solutions, hydrophobic polymers exist in an aggregated state. Since the tendency for aggregation increases with an increase in the molecular mass, the accessibility of the terminal groups of the polymer for the interaction with cyclodextrin is expected to decrease; therefore, only part of the macromolecules can find their 'partners'. Some polymers, *e.g.*, poly(oxytrimethylene), form pseudopolyrotaxanes with both α- and β-cyclodextrins (see Table 1), which was attributed[72] to different conformations of the polymer incorporated.

It was shown with the help of ^{1}H NMR spectroscopy and other analytical methods that the stoichiometric compositions of the complexes are usually independent of the molecular masses of the polymers in the MM range studied and are consistent with the results of molecular simulation studies.[64–68] Violations of this

regularity were observed only for the interaction of α- and β-cyclodextrins with poly(oxytrimethylene).[72] When polymers with MM $\leqslant$ 2000 were used, the compositions of MN remained constant and corresponded to one molecule of cyclodextrin per 1.5 – 2 or 2 – 2.5 monomeric units of the polymer for α- and β-CD, respectively. However, with an increase in the molecular mass of the rod macromolecule, the stoichiometry of the complex formed changed (see Table 1). Presumably, the increase in the hydrophobicity with an increase in MM prevents the diffusion of the polymer in the aqueous medium and the involvement of all of the macromolecules in the complex formation.[72] Probably, the precipitation of the complex is accompanied by co-precipitation of the free polymer; therefore, the composition of the pseudopolyrotaxane cannot be calculated exactly.

It was shown [69] that γ-cyclodextrin forms no stable complexes with unmodified PEO, although, like β-cyclodextrin, it forms a 2 : 1 complex with poly(propylene oxide) (PPO) (see Table 1). It was also found that poly(ethylene oxide) which contained bulky terminal substituents, *e.g.*, the 3,5-dinitrobenzoyl substituent, interacted with γ-cyclodextrin to form crystalline complexes in very high yields.[70] A ^{1}H NMR spectroscopic study revealed that the cavity of γ-CD accommodates four oxyethylene fragments, which suggests that γ-cyclodextrin is threaded simultaneously onto two polymeric chains. To corroborate this hypothesis, Harada *et al.*[69] obtained a fluorescently labelled polymer, *viz.*, bis(2-naphthylacetyl)poly(ethylene oxide). The MN prepared on the basis of this compound and γ-cyclodextrin also had a stoichiometric composition 1 : 4. Fluorescence spectroscopic studies revealed the presence of excimers, which suggests close contacts between the naphthyl residues and corroborates the hypothesis that the γ-cyclodextrin molecule incorporates two PEO chains (Fig. 6). Similar crystalline double-stranded inclusion complexes based on γ-cyclodextrin and PEO (MM = 1500) were obtained in high (~ 80%) yields;[86] in this case the complexation did not necessitate blocking of the chain termini by bulky substituents.

Later, a group of Japanese investigators synthesised a polyrotaxane **51** based on the molecular necklaces by the reaction of terminal amino groups of bisaminopoly(ethylene oxide) incorporated into α-cyclodextrin with fluoro-2,4-dinitrobenzene.[66] The yield of the reaction product after isolation and purification by GPC was 60%. Subsequent modifications of the polyrotaxane **51** allowed the authors to synthesise oligomers containing cross-linked cyclodextrins, the so-called 'polymeric tubes' (Fig. 7).[80] These compounds were synthesised by treatment of the polymer **51** in 10% NaOH with epichlorohydrin. Using GPC, it was shown that epichlorohydrin cross-linked CD molecules along the polymeric chain with the formation of hydroxypropylene bridges. The blocking groups were removed by hydrolytic cleavage with 25% NaOH which resulted in the release of the polymer enclosed inside the tube. The final product (yield 92%) represented a hollow tube which consisted of about 15 cross-linked cyclodextrin molecules (MM = 20 000) (**52**, see Fig. 7). Probably, such structures can be used for selective separation of substances.

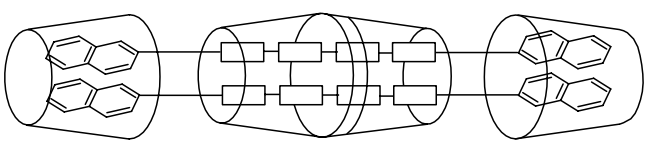

Figure 6. A schematic representation of an inclusion complex of γ-cyclodextrin with bis(2-naphthylacetyl)poly(ethylene oxide).[69]

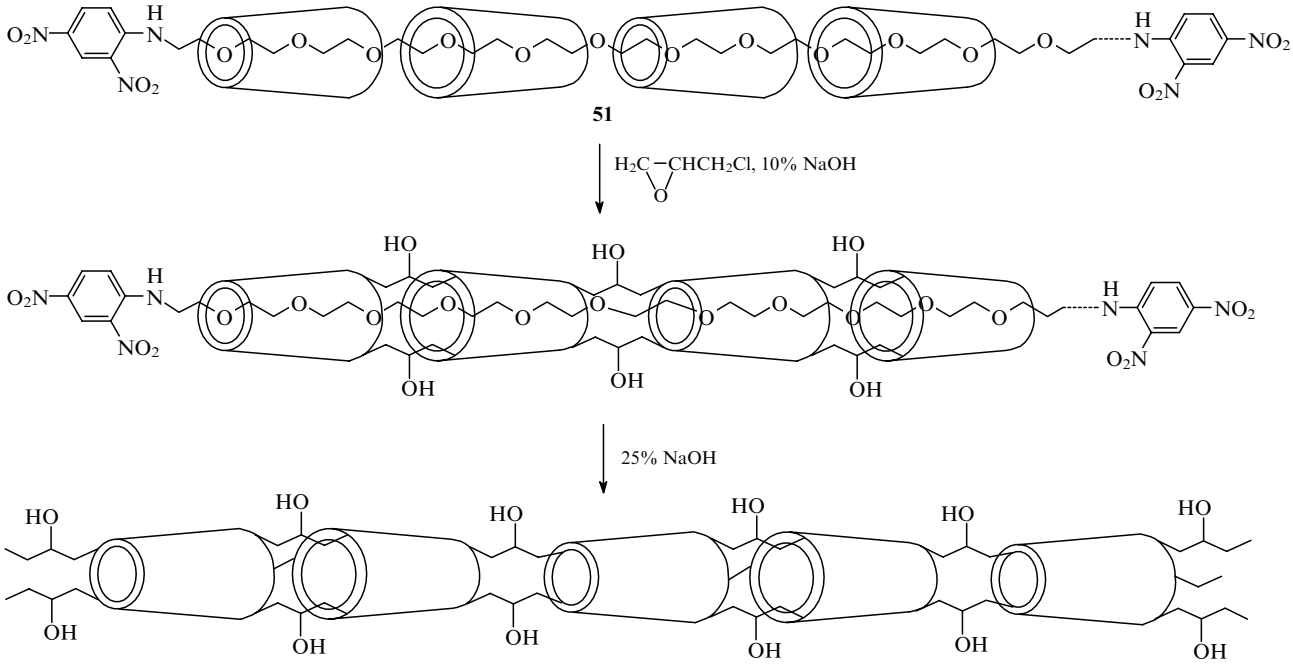

Figure 7. A scheme of synthesis of polymeric tubes from polyrotaxanes based on bisaminopoly(ethylene oxide) and α-cyclodextrin.[85]

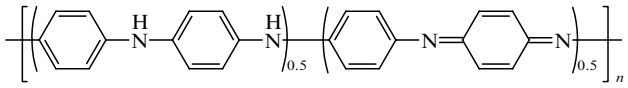
It was shown[87] that the reaction of cyclodextrin with the conjugated conducting polymer **53** (polyaniline), which contains emeraldine bases,



53

afforded a pseudopolyrotaxane in which the polymer was incorporated inside the cavity of the non-conducting cyclic molecules. These structures have been termed as 'insulating molecular wires'. This system was used to demonstrate that cyclodextrins prevent chemical oxidation of the rod macromolecule, *e.g.*, on doping of polyaniline with iodine.

The use of modified CD (particularly, of methylated macrocycles) as 'hosts' allows one to compare processes of molecular recognition involving native CD and their derivatives. Using ^{1}H NMR spectroscopy, it was shown than none of the methylated cyclodextrins form complexes with PEO as can be evidenced from the fact that no precipitation occurred even after 2-months' storage of their mixture. A different situation is observed in the interaction of these cyclodextrins with hydrophobic polymers. Complexes of PPO and poly(tetrahydrofuran) (PTHF) with heptakis- and hexakis-(2,6-di-*O*-methyl)cyclodextrins (DM-CD) as well as with heptakis- and hexakis-(2,3,6-tri-*O*-methyl)cyclodextrins (TM-CD) have been described in the literature.[79] It was shown that the addition of DM-β-CD first increases significantly the solubility of PPO in water and then a crystalline complex is formed. However, TM-α-CD, TM-β-CD and DM-α-CD neither favour the solubilisation of PPO in water nor form inclusion complexes. The solubility of PTHF in water increases in the presence of low concentrations of DM-β-CD and DM-α-CD. At high concentrations of these cyclodextrins, the solubility of PTHF decreases and inclusion complexes are precipitated. TM-β-CD also forms inclusion complexes with PTHF. The yields of PTHF – DM-β-CD complexes increase with an increase in the weight-average molecular mass (M_w), it is a maximum at $M_w = 1000$. The stoichiometric composition of PTHF – DM-β-CD complexes corresponds to one molecule of the macrocycle per 1.0 – 1.5 monomeric units of the rod macromolecule. Taking into account the number of atoms in the repeating fragment of the polymer per one CD molecule, it appears that the composition of the PTHF – DM-β-CD complex is consistent with the stoichiometric composition of the corresponding MN based on α-CD. The experimental data altogether suggest that hydrophobic interactions between methylated cyclodextrins and hydrophobic polymers make a weighty contribution to the process of molecular recognition.

Based on the geometrical correspondence of the CD molecules to polymeric 'guests', one can postulate the existence of ternary complexes which represent MN with low-molecular-weight 'guests' incorporated into them. Such complexes were obtained in PEO-β-CD – aromatic compound systems.[88] Benzene, its mono-, di- and tri-substituted derivatives were used as aromatic compounds. After mixing of these three components, a complex precipitated from the aqueous solution. Radiolabelled ^{3}H-PEO was used for quantitative determination of poly(ethylene oxide) content in the complexes. The content of β-CD was determined polarimetrically, while that of the aromatic compound was established by UV spectroscopy. The composition of the complexes corresponds to one β-CD molecule per two units of PEO and one molecule of the aromatic compound. The ternary complexes precipitate with benzene, benzoic acid and *p*-nitrophenol but do not precipitate in the presence of *o*-nitrophenol and 2,4-dinitrophenol. X-Ray diffraction studies have shown that the structures of the ternary complexes are identical with that of MN. Simulation of the ternary complexes demonstrated that the regular orientation of CD in MN is not disturbed upon incorporation of benzene and its monosubstituted derivatives into their cavities.

The molecular dynamics of MN based on α-CD – PEO[89] and β-CD – PPO[90] complexes has been studied. It was shown that the main driving force of molecular recognition are the van der Waals interactions. Hydrogen bonds provide arrangement of the CD rings in a 'head-to-head' and 'tail-to-tail' fashion. Cyclodextrins in polyrotaxanes exist in a more symmetrical and a less rigid conformation than in the individual state. The formation of polyrotaxanes is accompanied by the transition of the polymers to the stretched conformation due to an increase in the proportion

of *trans*-conformers in comparison with the state of the isolated polymeric chains. The structure- and energy-related reasons for the non-statistical distribution of CD in MN prepared on the basis of PEO – PPO block copolymers were established using the dynamic Monte Carlo method.[91] It was found that the stability of the complexes is determined by both hydrophobic interactions between the 'host' cavity and the 'guest' molecule and the hydrogen bonds between the cyclodextrin molecules.

It should be noted that the interest in MN is generated largely by fundamental problems. According to Tonelli *et al.*,[92–94] the polymeric inclusion complexes are convenient subjects for studying the behaviour of ordered and isolated polymeric chains, which simulates the state of oriented polymers in the crystalline phase.

It was also shown that macromolecular inclusion complexes can be used for the preparation of high-strength oriented fibres. Removal of cyclic molecules from the complexes was carried out by treatment of the polymers with a solvent which is selective with respect to cyclic compounds.[92] The selectivity of formation of crystalline polymeric inclusion complexes incorporating cyclodextrins served as a basis for the development of a new procedure for purification of polymeric materials under laboratory conditions, the so-called extractive crystallisation.[94]

b. Pseudopolyrotaxanes based on block copolymers

Considerable progress in the synthesis of supramolecular structures based on CD and polymers is associated with the use of block copolymers (BC) of ethylene oxide and propylene oxide (pluronics) as the 'guest' molecules. Pluronics differ in their compositions, number of blocks and mutual arrangements, which permits the synthesis of MN having different structures and properties. By varying the length of the free component of the complex based on a BC and cyclodextrin, one can obtain both water-insoluble [95–99] and water-soluble [100] polymeric inclusion complexes. For steric reasons, α-CD cannot interact with a poly(ethylene oxide) component of BC of the PPO – PEO – PPO type.

A systematic study of the reactions of α-, β- and γ-CD with different types of PEO – PPO block copolymers [95–99] has been carried out. Their characteristics are listed in Table 2. The interaction of α- and β-CD with BC I and BC II built up of poly(ethylene oxide) and poly(propylene oxide) blocks of virtually equal lengths has been studied.[95] It was found that the addition of solutions of block copolymers to aqueous solutions of the corresponding macrocycles results in the precipitation of water-insoluble complexes. Using the α-CD – BC I system as an example, it was shown that with an increase in the pluronic concentration the mass of the isolated complex increases at first and after reaching a certain maximum remains unchanged, which suggests the formation of a stoichiometric complex. Polarimetric and IR spectroscopic studies of these complexes as well as molecular simulation studies revealed that different pluronic blocks become involved in this process depending on the type of the cyclodextrin (α- or β-CD, which differ in the diameter of their inner cavity) used for the complexation. Thus, the interaction with α-CD involves

Table 2. Some characteristics of the block copolymers based on poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) used in the synthesis of pseudopolyrotaxanes.[95–99]

Block copolymer	Type of copolymer	MM	Content of PPO (%)	Degree of polymerisation	
				PEO	PPO
I	PEO – PPO	3000	50	30	28
II	PEO – PPO	2000	60	18	20
III	PEO – PPO – PEO	2700	45	18 [a]	19
IV	PEO – PPO – PEO	6000	23	52 [a]	24
V	PPO – PEO – PPO	3000	40	40	10 [a]

[a] The degree of polymerisation of one block.

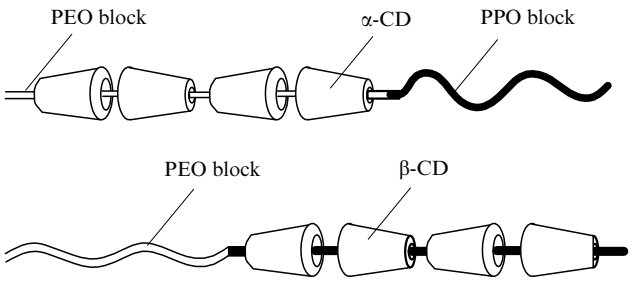


Figure 8. A schematic representation of α- and β-cyclodextrin complexes with ethylene oxide and propylene oxide diblock copolymers.[95]

only the PEO block, while the interaction with β-CD, only the PPO block. The stoichiometric compositions of the complexes are similar to those of MN based on homopolymers, *viz*., two monomeric units of ethylene oxide or propylene oxide per one α- or β-CD molecule, respectively. Thus the interactions of α- and β-CD with the PEO – PPO diblock copolymers result in the formation of new BC (Fig. 8) which consist of a rigid block, *viz*., a MN, and a free flexible poly(alkylene oxide).

A study of the interactions of cyclodextrins with PEO – PPO triblock copolymers III – V (see Table 2) revealed that the compositions of the crystalline complexes depend on the position of the interacting block and the reaction conditions.[96–98] If CD is threaded onto the inner block of the copolymer, the complex formed (**54**, Fig. 9) has a stoichiometric composition which is characteristic of cyclodextrin complexes with homopolymers and diblock copolymers. In those cases where CD is threaded onto the peripheral blocks, two types of block structures can be formed depending on the reaction conditions, *viz*., BC with a symmetrical position of MN (Fig. 9, complexes **55** and **56**) and non-symmetrical BC which are composed of three different blocks, one of them being MN (Fig. 9, complexes **57** and **58**). This depends on the concentration of the reagents in the solution. Thus in saturated solutions where the rate of complexation is comparable with the rate of crystallisation, it is the non-symmetrical complexes with one filled block that are formed. In dilute cyclodextrin solutions, *i.e*., under conditions where the rate of crystallisation is much lower than the rate of threading of CD onto the polymeric chains, both peripheral blocks of the complexes represent MN.

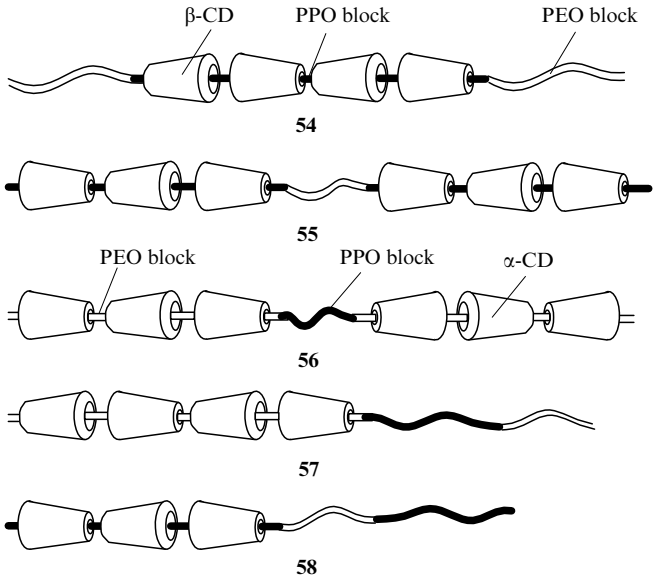

Figure 9. A schematic representation of α- and β-cyclodextrin complexes with ethylene oxide and propylene oxide triblock copolymers.

As has been noted above, two types of inclusion complexes of γ-cyclodextrin with poly(alkylene oxides) are possible. These comprise either one PPO chain or two PEO chains. The use of PEO–PPO block copolymers as 'guests' makes it possible to elucidate to which of these blocks γ-CD manifests higher affinity. To answer this question, the complexation of γ-CD with PEO–PPO diblock copolymers was studied where PEO and PPO blocks are sterically equally accessible for the interaction with cyclodextrin.[96–98] An analysis of the compositions of the complexes formed shed some light on the localisation of γ-cyclodextrins, since the number of γ-CD molecules that are threaded onto PEO and PPO blocks differs significantly for the given BC (I or II). It was shown experimentally that the number of γ-CD molecules per one copolymer molecule (r_{exp}) represents an intermediate value between the r_{theor} values calculated in the assumption that either PEO or PPO blocks take part in the complexation. This finding suggests that the interaction of γ-CD with PEO and PPO is nonselective.

The use of the γ-cyclodextrin–triblock copolymer couple opens up an opportunity for preparing new non-linear BC. Complexation of γ-CD with pluronics of the PEO–PPO–PEO type which contain peripheral ethylene-oxide blocks affords double-stranded inclusion complexes. It was found[97] that in saturated solutions the composition of the complex formed remains unchanged at any value of the γ-CD : BC IV ratio. This suggests that the interaction of γ-CD with the above block copolymer results in a stoichiometric complex, namely, a double-stranded inclusion complex in which two strands of PEO which belong to different copolymer molecules appear to be incorporated into the channel formed by the macrocycles. Taking account of different accessibility of the PEO blocks with respect to α-CD, it was demonstrated that the interaction of γ-CD with a triblock copolymer of the PEO–PPO–PEO type yields compound **59** (Fig. 10) which is characterised by nonsymmetrical distribution of the free PEO blocks. In dilute solutions, the complexation of γ-CD with the PEO–PPO–PEO copolymer results in pseudopolyrotaxane **60** in which both PEO blocks are coated with the CD molecules (see Fig. 10). Thus, the vast potentials in the design of pluronics and the ability of cyclodextrins to interact selectively with PEO and PPO blocks enable one to use them as a basis for the synthesis of inclusion complexes of different compositions and molecular architecture.

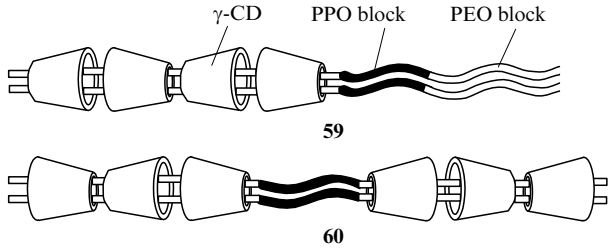

Figure 10. A schematic representation of γ-cyclodextrin complexes with the triblock copolymer IV.

c. The complexes of nonionic surfactants with cyclodextrins

Poly(ethylene oxide)-containing surfactants can be regarded as particular BC which comprise hydrophilic poly(ethylene oxide) blocks, whereas the hydrocarbon fragments play the role of their hydrophobic 'tails'. PEO surfactants of different chemical nature, *viz*., octylphenyl PEO ethers [Triton X-45 (**61a**) and Triton X-100 (**61b**)], polyethylene glycol-1000 monostearate (**62**) and dodecyl poly(ethylene oxide) ether (**63**) were used as 'guests'.[97, 99, 101, 102]

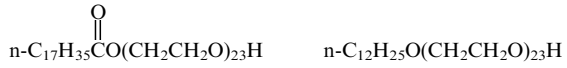
n = 5 (**a**), 10 (**b**)



62

63

Mixing of saturated aqueous solutions of poly(alkylene oxides) and α-CD resulted in the formation of a crystalline precipitate the structure of which is similar to that of MN based on PEO. The determination of the compositions of the complexes showed that one CD molecule corresponds to two monomeric units; thus, the α-CD molecules are selectively threaded onto the PEO fragments of surfactants. Important information about the type of interaction of PEO surfactants with cyclodextrins in dilute solutions can be derived from an analysis of colloidal and chemical properties of the surfactants, primarily, from the effect of CD on the critical micelle concentration (CMC). The dependences of CMC on the CD : surfactant molar ratio represent curves with saturation, which allows one to determine the stoichiometric compositions of inclusion complexes in solution. It is worth noting that the compositions of such complexes are identical both in solution and in the solid phase. The complexes formed by the interaction of the same surfactant with α-, β- and γ-CD differ drastically both in the structures and their colloidal and chemical properties.[101, 102] The chemical nature of the group linking together the hydrophilic and hydrophobic fragments of surfactants was found to affect critically the localisation and possible migration of CD molecules along the surfactant chains.

The covalent binding of poly(ethylene oxide) fragments to cyclodextrin molecules results in the formation of PEO–CD conjugates which represent bouquet-like structures endowed with amphiphilic properties (Fig. 11).[103–105] The conjugates have molecular masses of 3000–5500 and are characterised by narrow molecular mass distributions; the average degree of substitution is 8 to 12 ethylene oxide units per one glucose residue. A study of the complexation of the conjugates with Triton X-100 (**61b**) revealed that the pseudopolyrotaxanes formed have a stoichiometric composition, *i.e*., one molecule of the conjugate is threaded onto each hydrophilic fragment of the surfactant. These pseudopolyrotaxanes can form micellar structures in aqueous solutions. The architecture of the spherical molecular assemblies consisting of highly branched structural elements resembles that of dendrimers (Fig. 12).

Branched structures of yet another type were obtained[99, 106] as a result of interactions of star-shaped conjugates of PEO and PEO–PPO diblock copolymers with proteins, *e.g*., α-chymotrypsin (ChT). Such conjugates are formed as a result of one-point covalent attachment of the monofunctional derivatives of the polymers to the amino groups of the protein. Mixing of these compounds with cyclodextrin (PEO–ChT–CD and

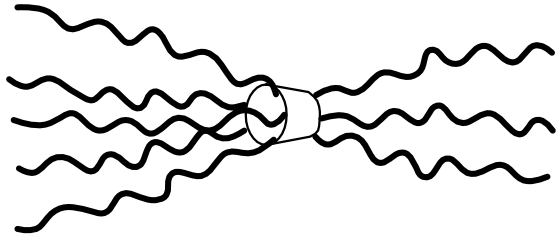


Figure 11. The structure of the poly(ethylene oxide)–cyclodextrin conjugate.[104]

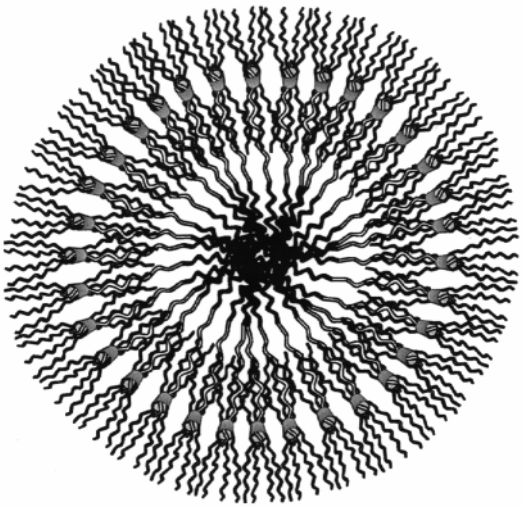

Figure 12. The hypothetical dendrimer-like structure based on the poly(ethylene oxide)–cyclodextrin conjugate and a micelle of Triton X-45.[105]

BC–ChT–CD conjugates) results in the formation of precipitates. The determination of their compositions revealed that they are similar to those of the complexes based on linear polymers and the corresponding CD. This implies that all the polymeric chains within the conjugates are accessible for the interaction with the CD. The crystalline structures of the resulting complexes are identical to those of MN. A decrease in the solubility of the complexes in water in comparison with the original polymer–protein conjugates or non-covalent polymer–protein adducts limits their application in biotechnology. The PEO–CD conjugates were used to confer solubility onto the complexes prepared on the basis of polymer–protein adducts and CD.[107, 108] The complexation between PEO chains, which are the components of covalent and non-covalent PEO–ChT and PEO–CD adducts, was studied using a kinetic method based on the analysis of enzymic properties of novel supramolecular structures incorporating these components.[107] For this purpose, the rate constants of thermoinactivation of ChT (k) in the adducts of PEO–ChT with PEO–β-CD were determined. A decrease in k suggests that complexation of the constituents occurs. The stoichiometric compositions of the complexes formed were determined from the dependence of k on the PEO–β-CD : $PEO_{(ad)}$ molar ratio, where $PEO_{(ad)}$ is the poly(ethylene oxide) that is involved in the adducts. It was shown that each of the polymeric chains of the PEO–ChT conjugates forms an inclusion complex with PEO–β-CD, whereas in the case of non-covalent PEO–ChT complexes only a half of the polymeric chains of $PEO_{(ad)}$ take part in the formation of the supramolecular structures. The hypothetical structures of supramolecular dendritic assemblies are depicted in Fig. 13.

d. Studies of the structural organisation of crystalline pseudopolyrotaxanes based on cyclodextrins

Supramolecular assemblies can be characterised both by the type of the intermolecular interactions which hold together their constituents and by their spatial configuration, *viz*., their architecture or 'suprastructure'. The phase state and the organisation of macromolecular inclusion complexes are studied using TGA, DSC, X-ray diffraction analysis as well as by optical, scanning electron and scanning tunnelling microscopy.

An X-ray diffraction analysis showed that the precipitates formed by poly(alkylene oxide)–cyclodextrin complexes have crystalline structures and differ from one another and from the original components in the type of the crystal lattice. It should be noted that the method which is commonly employed for the description of the structural organisation of 'molecular necklaces' is based on comparison of the diffractograms of MN and the complexes of the corresponding CD with various low-molecular-weight compounds. According to Saenger's classification,[34] the structures of the CD-based complexes can be divided into two main types, *viz*., cage-type structures in which cyclic molecules form brick network patterns and channel-type structures where the macrocycles are stacked sequentially in a pillar-like fashion. A comparative analysis of the diffractograms revealed [68, 71, 72] that MN belong to channel-like structures. However, this approach discloses only the qualitative differences but cannot provide quantitative evaluation of the parameters of the crystal lattices of macromolecular inclusion complexes.

Harada *et al*.[76, 77] have succeeded in growing single crystals of α-CD complexes with tetra- and hexa(ethylene oxide) and β-CD with poly(propylene oxide) (MM = 425), which mimic MN, and

the β-CD – poly(oxytrimethylene) complex (MM = 1400) and carried out their detailed X-ray diffraction analysis. It was found that in all these cases the macrocycles are arranged in a 'head-to-head' and 'tail-to-tail' fashion to form hydrogen bonds between all the secondary hydroxy groups of the large bases of the cyclodextrin torus. Water molecules are localised within the structure of α-CD-based [4]-Rt between the minor bases of the macrocycles. The β-CD dimers are shifted relative to one another due to the presence of only one hydrogen bond between the primary OH groups. Rod-like macromolecules are localised inside the narrow channels formed by cyclodextrins and exist in a *trans*-conformation.

The use of single crystals for the disclosure of the structural organisation of rotaxanes allows one to estimate, with a high degree of accuracy, the unit cell parameters, to determine the coordinates of all the atoms within the composition of the complex and to characterise the intermolecular contacts. However, this method has not received wide acceptance in structural studies of high-molecular-weight compounds because of the difficulty and sometimes impossibility of obtaining suitable large-sized single crystals. An approach to the description of the structural organisation of polymeric crystals consists in the use of oriented samples and in the recording and interpretation of X-ray fibre patterns. It was shown [86, 109] that in contrast to ordinary polymers whose orientation demands preliminary treatment, the formation of MN is accompanied by spontaneous formation of oriented structures. An X-ray diffraction analysis which includes a comparison of X-ray fibre patterns and diffractograms enables one to index the observed reflections, to determine the parameters of crystal lattices of the complexes formed and thus to characterise the structure of polymeric inclusion complexes at the molecular level. The results obtained suggest that crystallisation of MN results in the formation of structures in which cyclodextrin molecules are arranged one after another along a common symmetry axis. X-Ray diffraction data suggest the hexagonal, monoclinic and tetragonal packing of MN based on α-, β- and γ-cyclodextrins, respectively.

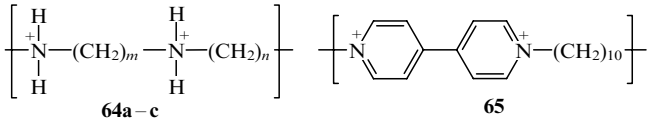
In order to obtain the information about the morphology of the crystallites formed by MN and the nature of their mutual packing in the course of precipitation, cyclodextrin complexes with poly(alkylene oxides) were studied by optical microscopy and scanning electron microscopy.[86, 109] The crystals of the β-CD – PPO complexes have the shape of sharply edged parallelograms, whereas those of the γ-CD – PEO complexes have the shape of rectangular parallelipipeds with an average facet size of the order of several microns, which is consistent with the results of an X-ray diffraction analysis of the symmetry of the crystal lattices of the complexes. The precipitates of cyclodextrin – poly(alkylene oxide) complexes represent lamellar structures the MN in which are located at right angles to the planes of the lamellae.

Isolated MN were visualised by scanning tunnelling microscopy. Japanese investigators [75, 87] have succeeded in photographing α-CD – PEO and β-CD – polyaniline complexes containing discernible rod-like structures. Their lengths correspond to the lengths of the extended molecule of the polymeric 'guest', while their widths match the diameter of the macrocycle.

These results are of fundamental importance for the understanding of the mechanism of the self-assembly of the supramolecular structures formed by polymeric inclusion complexes at different levels of their structural organisation. Three main stages in the formation of the nanostructures in such complexes can be distinguished. The first step consists in the threading of the macrocycles onto the polymeric chains. The driving forces of this process are the cooperation of the hydrophobic interactions between the nonpolar cavity of the cyclic molecule and the fragments of the polymeric 'guest' and the formation of hydrogen bonds between the hydroxy groups of the cyclodextrins. The second step is the crystallisation of MN and the formation of lamellar crystallites the inclusion complexes in which are located at right angles to the planes of the lamellae. In the third step, individual crystallites of the complex are aggregated to form an oriented precipitate. In the precipitation, the lamellae are aligned in parallel to the plane of the support to form an axial pattern of the precipitated material. Thus, polymeric cyclodextrin – poly(alkylene oxide) inclusion complexes can serve as a basis for the design of well-organised supramolecular assemblies.

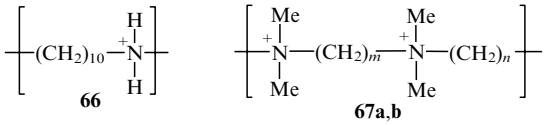
e. Water-soluble polyrotaxanes

Cyclodextrin-containing water-soluble pseudopolyrotaxanes were first synthesised by the interaction of CD with polyelectrolytes.[81 – 85] Self-assembly method was used to obtain inclusion complexes of the so-called poly(iminooligomethylenes) (**64a – c**),[81] *viz*., the polymers containing oligomethylene and quaternary ammonium fragments (**65**,[82] **66**,[83] **67a**,**b**[84, 85]), with α-cyclodextrin. In this case, the threading of CD molecules occurs by virtue of cooperation of hydrophobic and van der Waals interactions between the cyclodextrin cavity and the aliphatic sites of the polymers.



64a – c **65**

$m = n = 6$ (**a**); 11 (**b**); $m = 10$, $n = 3$ (**c**).

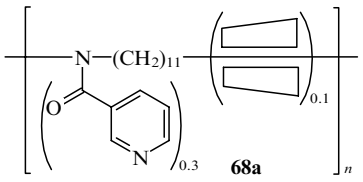


66 **67a**,**b**

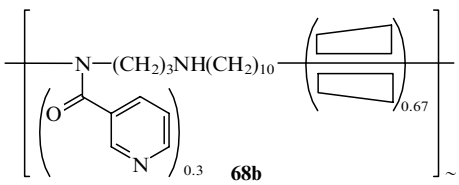
$m = n = 10$ (**a**); $m = 6$, $n = 10$ (**b**).

Using ^{1}H NMR spectroscopy, it was shown that α-CD molecules are localised on oligomethylene fragments containing no less than 10 units. Therefore, the short-chain polymer **64a** does not form any complex with α-CD. In contrast with poorly soluble MN, soluble complexes are formed at a very low rate at room temperature, this takes from several hours to several months and even years (in the case of compound **66**). Such a kinetics is attributed to the low rate of migration of CD molecules along the polymeric chain which in turn is due to steric hindrances created by bulky hydrate shells around the charged amino groups. At higher temperatures, slipping of the macrocycles over these 'barriers' occurs (method 5, Section III) resulting in a significant increase in the threading rate.[85]

Polyrotaxanes **68a**,**b** which are also readily soluble in water were prepared on the basis of MN consisting of polymers **64b**,**c** and α-CD, respectively.[81]



68a



68b

The binding of α-CD molecules to definite sites of the polymeric chain was achieved by acylation of the imino groups by nicotinyl chloride. Using polymers **64c** and **66** as examples, it was demonstrated that β-CD which has a larger cavity does not form any stable inclusion complexes. However, the use of an α- and β-CD mixture made it possible to prepare polyrotaxanes containing 60% β-CD and 7.5% α-CD in which β-CD was

blocked at the ends by α-CD molecules which slip off the chain at a very low rate.[83]

The possibility of formation of a water-soluble pseudopolyrotaxane was also demonstrated for the β-CD – triblock copolymer PEO – PPO – PEO.[100] It was found that the interaction of β-CD with block copolymers of the $PEO_n - PPO_m - PEO_n$ type gives either a crystalline precipitate ($n \ll m$) or a water-soluble complex ($n \gg m$) depending on the composition of the polymer used. The addition of cyclodextrin induces an upfield shift of the methyl and methylene proton signals in the ^1H NMR spectra. This suggests the complexation with block copolymers incorporated into the cavity of CD.

Amphiphilic DM-β-CD as a macrocycle and an analogous PEO – PPO – PEO copolymer with blocks of approximately equal sizes ($n \approx m$) were used to study the interactions of cyclodextrin with polymers in a monolayer. This study showed [100, 110] that the polymer passes from the coil to the rod-like conformation during complexation. Hence, one of the approaches to the synthesis of water-soluble MN consists in the introduction, into the starting polymer, of hydrophilic fragments which are not involved in the complexation.

Yet another approach to confer water solubility onto polymeric complexes is based on chemical modification of CD molecules in polyrotaxanes. The synthesis of water-soluble biodegradable polyrotaxanes was carried out by Ooya *et al.*[111–114] These authors used bis[aminopoly(ethylene oxide)] as the polymer and α-cyclodextrin as the cyclic compound. The terminal groups were blocked by an excess of L-phenylalanine (L-Phe) derivatives. The polyrotaxane formed was treated with propylene oxide which alkylated the OH groups of CD. The enhanced solubility of MN in water seems to be due to the destruction of hydrogen bonds. A three-step synthesis including removal of protective groups from the fragment of the stopper is depicted in Scheme 10. The results of light scattering studies [112, 113] suggest that the polyrotaxanes based on hydroxypropylated α-CD and PEO (MM = 2000 for **69a** and 4000 for **69b**) aggregate in aqueous solutions; the degree of aggregation of polyrotaxanes is much lower than that of the original PEO containing the same terminal fragments and is equal to 16 – 23 and 2 for the complexes **69a**,**b**, respectively. It was noted also that these polyrotaxanes preserve their rod-like conformation in solutions. It was found [112, 113] that enzymic hydrolysis of peptide bonds with papain which resulted in the cleavage of the stoppers brought about simultaneous supramolecular destruction of polyrotaxanes **69a**,**b**. This leads to complete dissociation of these polyrotaxanes into constituents irrespective of the degree of their aggregation (Fig. 14).

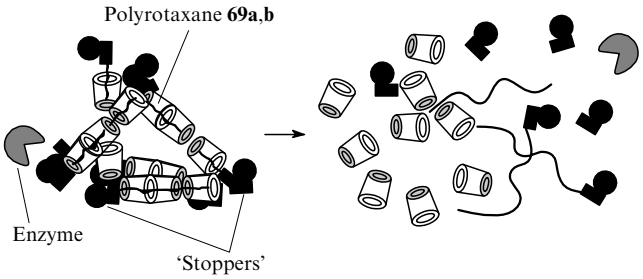


Figure 14. The destruction of the polyrotaxanes **69a**,**b** caused by enzymic hydrolysis of terminal L-Phe groups.[113]

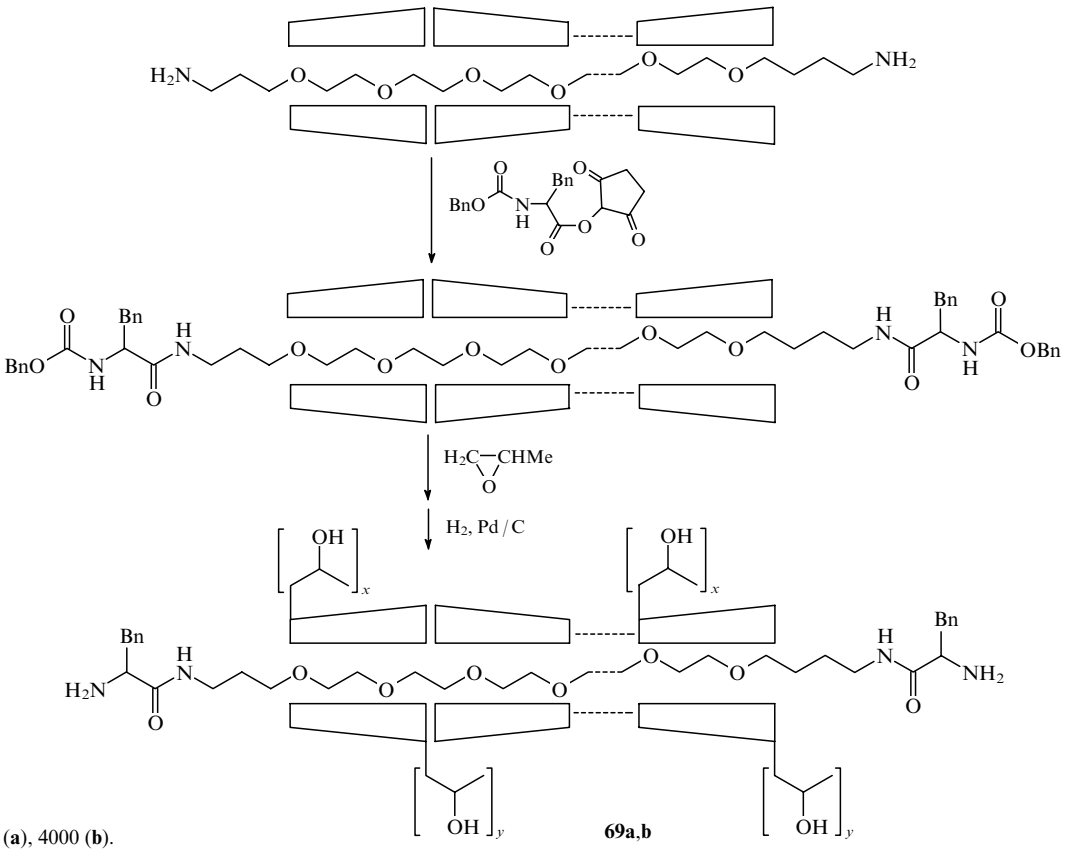
It was shown [116, 117] that polyrotaxanes of the type **69a**,**b** can be used in pharmacology and medicine as drug carriers and drug permeation enhancers. The interaction of these polyrotaxanes with blood cells was studied in detail; it was found that hydroxypropylated polyrotaxanes increase the fluidity of membranes and control the level of calcium by inhibiting platelet-induced elevation of Ca^{2+}.

The same group of investigators proposed to use this principle in the design of drug conjugates on the basis of polyrotaxanes and were the first to attempt to prepare such conjugates with insulin [112] and theophylline [115] which are covalently linked to CD molecules (Fig. 15).

Scheme 10



MM = 2000 (**a**), 4000 (**b**).

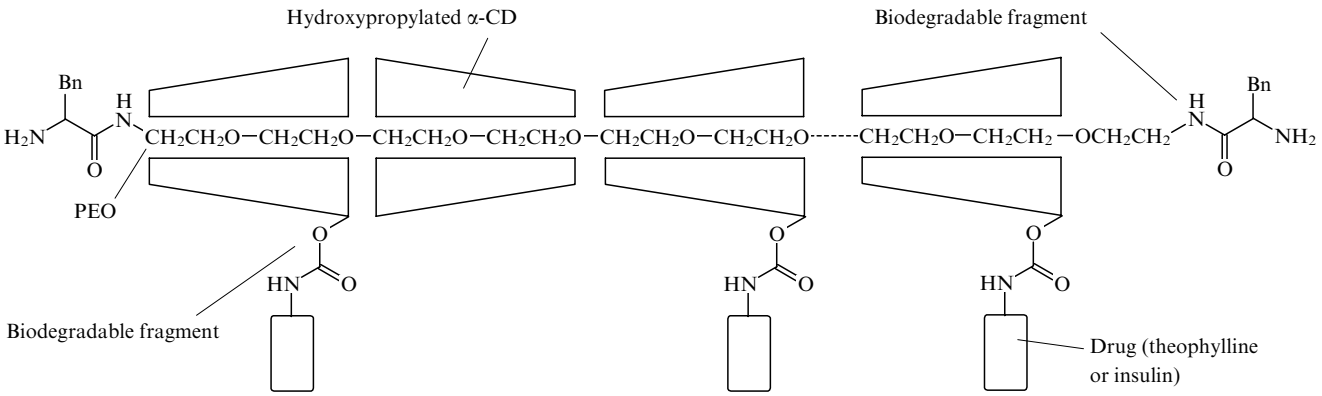


Figure 15. The drug–polyrotaxane complex prepared on the basis of poly(ethylene oxide) blocked by L-phenylalanine and hydroxypropylated α-cyclodextrin.

3. Comb-like polyrotaxanes

Non-covalent interactions of cyclodextrins with lateral fragments of comb-like polymers is yet another interesting example of molecular recognition. The determination of rate constants for the complexation of cyclodextrin with a series of copolymers of acrylamide with alkyl methacrylates (Table 3)[118] demonstrated the possibility of selective interaction of CD with comb-like polymers resulting in the formation of pseudopolyrotaxanes. In order to design true polyrotaxanes, Ritter *et al.*[119,120] proposed to use the strategy of covalent attachment of preformed pseudorotaxane **70** which is blocked at one end to the activated side fragments of the polymer (Scheme 11).

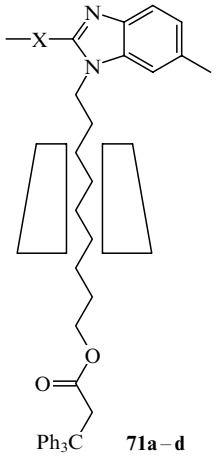
Table 3. The constants of complexation (K) of cyclodextrins and aliphatic fragments of water-soluble copolymers of acrylamide with alkyl methacrylates.[118]

Alkyl in alkyl methacrylate	K /litre mol^{-1}		
	α-CD	β-CD	γ-CD
Bu^n	55	–	–
Bu^t	–	340	57
Bu^i	36	–	–
n-C_6H_{13}	290	110	–
iso-C_8H_{17}	303	294	51
n-$C_{12}H_{25}$	990	660	245

A series of polyrotaxanes incorporating DM-β-CD have been synthesised.[119–123] It was found that these polyrotaxanes are less viscous than the starting polymers, apparently due to destruction of the hydrogen bonds between the fragments in the rod macromolecule.

The same group of investigators made an attempt to synthesise comb-like polyrotaxanes by radical polymerisation in aqueous solutions of the corresponding pseudorotaxanes based on β-CD, DM-β-CD and *N*-methacryloyl-11-aminodecanoic acid (method 2). However, this attempt was unsuccessful, since polymerisation was accompanied by elimination of the macrocycle from the side fragments of the polymer being formed.[124]

Alkylation of NH groups of poly(benzoimidazoles) with $Br(CH_2)_{12}OC(O)CH_2CPh_3$ in the presence of TM-β-CD resulted in comb-like polyrotaxane **71a–d**.[125]



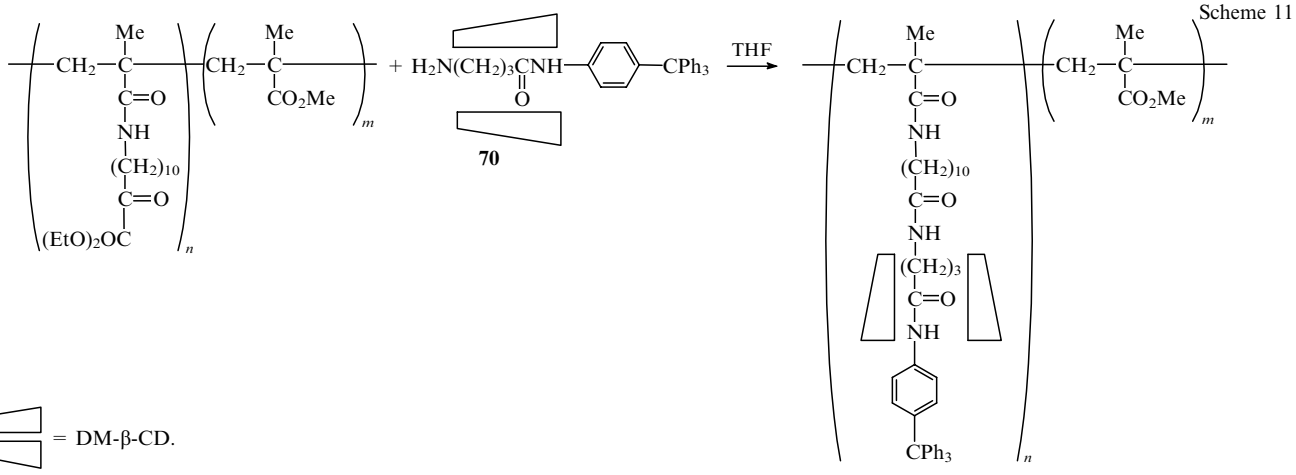
71a–d

X = *p*-C_6H_4 (**a**),
$(CH_2)_8$ (**b**),
$(CH_2)_{11}O(CH_2)_{11}$ (**c**),
$(CH_2)_{11}$ (**d**);

= TM-β-CD.

It was found that the degree of *N*-alkylation and the amount of the macrocycles incorporated depend on the lengths of the 'spacers' between the benzoimidazole fragments.

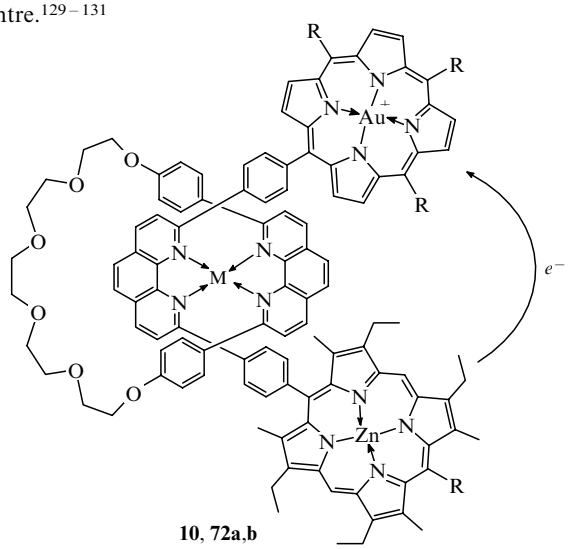
Scheme 11



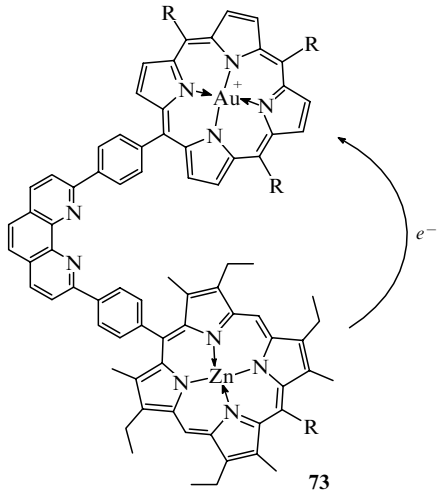
IV. Supramolecular devices based on rotaxanes and polyrotaxanes

Characteristic physicochemical properties of rotaxane-like structures are determined by both the unusual topology and the nature of their constituents. In the recent years, rotaxanes as molecular assemblies are considered as promising candidates for the construction of supramolecular devices which represent functional, structurally organised systems.[126–128] The feasibility of using rotaxanes in this area is due primarily to the ease of control over molecular directionality which determines the specific spatial configuration of their constituents. The introduction of photo-, electro- or ion-active groups into rotaxane molecules will allow the transfer of energy, electrons or ions as well as the transmission of signals and the storage of information.[12, 126–128]

Rotaxanes [2]-Rt which incorporate two different porphyrins as stoppers can serve as examples. The photophysical properties of [2]-Rt **10** and **72a**,**b** were studied [12, 129–131] and the rates of a photoinduced intramolecular electron transfer from the excited Zn-porphyrin to Au-porphyrin (1, 22 and 34 ps for complexes **10**, **72a** and **72b**, respectively) were compared to that in the dumbbell-shaped bisporphyrin **73** (55 ps). It was found that in the case of rotaxanes, the rate of the electron transfer increases significantly, the maximum increase being observed for complex **10**. This finding was attributed to the presence of copper(I) ions which play the role of mediators and to changes in the energy of the orbitals in the supermolecule under effect of the coordination centre.[129–131]



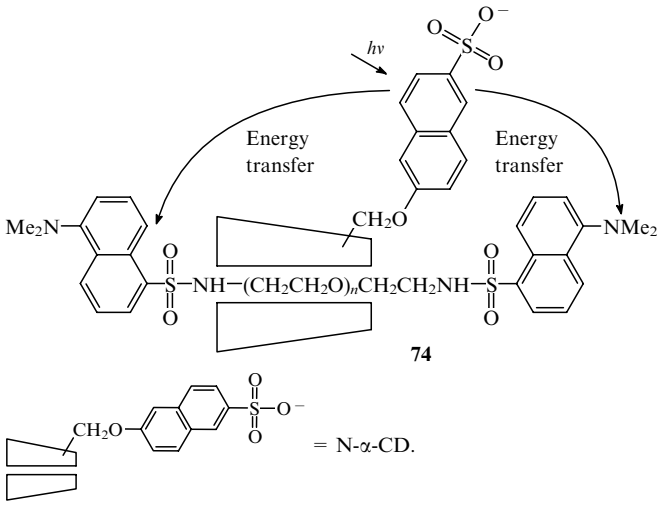
10, **72a**,**b**



73

M = Cu^+ (**10**), Zn^{2+} (**72a**), none (**72b**); R = 1,3-$Bu^t_2C_6H_3$.

The photosensitive rotaxane **74** was prepared on the basis of the naphthalene derivative of α-cyclodextrin (N-α-CD) and poly(ethylene oxide) with dansyl groups as stoppers.[132]



The fluorescence spectra of rotaxane **74** displayed a significant decrease in the intensity of signals elicited by the naphthalene fragments in comparison with the original N-α-CD which is due to the transfer of energy from the excited naphthalene groups of modified CD to the terminal dansyl groups of the rod molecule of PEO. The results of these studies are of interest for the construction of photochemical supramolecular devices which are able to effect directed transfer of electrons and energy.

Yet another promising line of investigations is the preparation of controlled 'molecular switches' (or 'shuttles' according to Stoddart). Molecular switch-on/off processes represent reversible transitions of one of the components between the two positions which differ either in structure or in conformation. The recently synthesised [2]-Rt **75** (Scheme 12) can serve as an example of an electrochemical (or chemical) 'molecular shuttle'.[127, 133] In this case, the migration of the macrocycle **14** occurs as a result of a redox reaction or protonation–deprotonation.

The synthesis of a photoreactive molecular switch prepared on the basis of CD-containing [2]-Rt **76** has been carried out (Fig. 16).[134] Here, azobenzene was used as a rod molecule, while 2,4-dinitrophenyl groups were used as stoppers. Irradiation of an aqueous solution of the complex **76** with UV light (λ = 360 nm) induced *trans*–*cis*-isomerisation of the azobenzene fragment. This reaction is reversible which was confirmed by the reverse reaction occurring upon irradiation of the solution in the visible region of the spectrum (λ = 430 nm). These changes in the configuration of the rod molecule induce the migration of the cyclodextrin molecule from one binding centre to another. A pH-sensitive 'molecular shuttle' was synthesised by self-organisation of aliphatic diamines and a triamine ligand.[135, 136]

Studies with polyrotaxanes based on β-CD and the PEO–PPO–PEO triblock copolymer showed that these polymers also manifest the properties of 'molecular switches'.[137, 138] The transition of polyrotaxanes from the insoluble into the soluble state can occur either upon a rise in the temperature or upon an increase in a pH above 12 due to the destruction of the hydrogen bonds between the CD molecules. As a result, the macrocycles migrate along the rod macromolecule. ^{1}H NMR studies of polyrotaxane solutions in 0.1 M NaOH showed that at room temperature CD molecules are distributed statistically along the whole polymeric chain, whereas upon heating the macrocycles are predominantly localised on PPO fragments (Fig. 17). Apparently, by changing such parameters as temperature and permittivity of the medium, one can govern the solubility of polyrotaxanes and the distribution of the CD molecules.

The design of photonic, electroninc and ionic switching devices based on molecular components and their incorporation

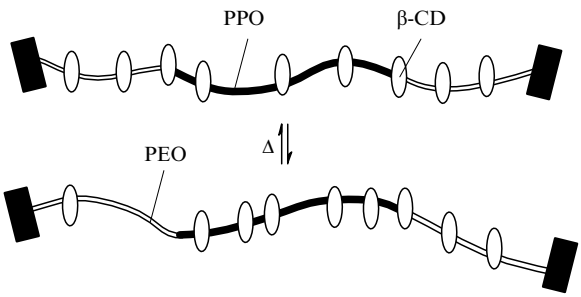

Figure 17. A mechanical 'molecular switch' based on polyrotaxane.

into well-organised assemblies is the next step in the development of functional materials on a nanoscale. Further studies in this field will inevitably culminate in the construction on their basis of multifunctional chemical 'machines' as the basis for the development of chemical informatics and an analysis of functioning of these devices in close conjunction with related biological processes.[126]

* * *

Thus, we are witnessing a revival of interest in rotaxane-like structures. New papers are being published and these are devoted to a search for their practical application. The literature data concerning polyrotaxanes consider them as a new type of regulatory polyfunctional rigid-chain polymers. It is these properties that determine the area of their further applications. New opportunities are emerging for the construction of complex polymeric structures which combine the blocks of 'molecular necklaces' with the flexible blocks of free polymers. Therefore, the fundamental problems related to the development of methods of synthesis of new supramolecular assemblies and investigation into their structural organisation and properties still remain in the focus of attention.

Abstract. The current state of studies on the mechanochemical synthesis of binary metallic systems is considered. It is shown that this method is suitable for the preparation of intermetallic compounds and solid solutions in concentration limits of equilibrium diagrams of many binary systems. The mechanochemical approach is demonstrated to exhibit the most promise for preparing intermetallic compounds in systems characterised by large differences in the melting points and in the densities of the initial components as well as phases with nanometer grain sizes and metastable phases. The major factors, which influence the concentration limits of existence of non-equilibrium solid solutions prepared by the mechanochemical method, are revealed. Using numerous examples, it is demonstrated that the formation of solid solutions may involve several stages. At the first stage, nanosized layered composite structures are formed with simultaneous dispersion of the initial components (the formation of a large contact area). The second stage involves the synthesis of intermetallic compounds in nanosized layered composites. At the third step, the intermetallic compounds are dissolved in a metal solvent to give a solid solution. The bibliography includes 397 references.

I. Introduction

Intermetallic compounds can exist only in the crystalline state. Individual molecules cannot be distinguished in these compounds and they cannot be melted or dissolved without the loss of individuality and do not exist in the gaseous phase. In addition, the physicochemical properties of intermetallic compounds differ substantially from those of their components.[1–3] Intermetallides with a particular composition differ in the chemical properties not only from the constituent metals, but also from intermetallides, which are characterised by the same elemental composition, and yet contain the components in a different ratio.[4,5]

Presently, a general theory, which would allow one to reveal factors stabilising particular intermetallic compounds, is lacking. A search for these factors was performed as follows. A group of systems in which the stability of intermetallic phases can be related to the effect of a particular factor was established after which the effect of this factor in other systems in which it was less evident was analysed. Three factors were revealed, *viz*., the ratio of the total number of valence electrons (e) to the total number of atoms per unit cell (a), the tendency for the maximum filling of space (*i.e*., for the formation of closest packing or structures with high coordination numbers) and the difference between the electronegativities of the components. The latter factor is of minor importance and is clearly manifested only in a small group of Zintl phases,[6] *viz*., in compounds of active metals (alkali metals, alkaline-earth metals, magnesium and aluminium) with germanium, tin, lead and bismuth.[7,8]

Hume-Rothery demonstrated[9] that phases with the same electron concentration (e/a) have similar crystal structures. In different systems, one of the following three types of structures is characteristic of phases with an electron concentration of 3/2, the so-called β phases: body-centred cubic (BCC) structures (the Cu – Zn, Cu – Al and Cu – Sn systems), structures of the β-Mn type (Cu – Si, Ag – Al and Au – Al) or hexagonal structures (Ag – Zn, Cu – Si and Ag – Sn). Phases with an electron concentration of 21/13 have complex cubic structures of γ-brass. In the case of $e/a = 7/4$, ε phases with hexagonal close-packed (HCP) structures are formed. The β, γ and ε phases have come to be known as electron compounds. In the case of a favourable dimension factor (more exactly, the number of electrons per unit cell), the electron concentration is of primary importance in the formation and stability of a particular crystal structure.

Compounds belonging to the $MgZn_2$, $MgCu_2$ and $MgNi_2$ structural types (the so-called Laves phases) are the most widespread intermetallides. For these compounds, the ratios between the atomic radii of the components (in addition to the above-mentioned stabilising factors) are also of great importance. The characteristic feature of Laves phases is that the smaller atoms (Zn, Cu and Ni) are grouped together to form tetrahedra linked to each other. The $MgZn_2$, $MgCu_2$ and $MgNi_2$ structures differ in the mode of arrangement of the tetrahedra. The bulkier magnesium atoms occupy the holes in the network of tetrahedra. As a result, very close packed structures are formed, the coordination number of the bulkier atoms being equal to 16. This value is larger than the coordination number (12) corresponding to the maximum density of packing of spheres of the same size. The

coordination numbers of the smaller atoms in these structure are equal to 12.[6]

The above-mentioned factors are responsible for the stability of solid solutions as one of the types of intermetallic compounds.[7] In the case of similar electronegativities of the elements and a favourable dimension factor, the electron concentration is the major factor affecting the limiting solubility. The quantitative theory of solubility of polyvalent elements in metals of the copper group is based on the concept of filling of the first Brillouin zone with electrons in the face-centred cubic (FCC) crystal structure.[8] Theoretically (taking into account the electron concentration), a solid solution can exist over wide concentration limits. However, the preparation of such solutions in these limits is determined primarily by the dimension factor. It was empirically established that if the atomic diameter of the element dissolved differs from the atomic diameter of the solvent by more than 14% – 15%, the dimension factor is unfavourable and the region of existence of the solid solution is limited.[9] No reliable theoretical explanation has been provided for the threshold value of 15%. Quantitative calculations were carried out within the framework of an elastic-sphere model. King [10] calculated the dimension factors for 469 substitution solid solutions and confirmed the above threshold value.

Therefore, the major factors influencing the formation and thermodynamic stability of intermetallic phases at equilibrium were revealed empirically.

Main procedures for the preparation of equilibrium intermetallic compounds involve alloying followed by homogenisation and sintering. Intermetallides with high formation enthalpies are generally prepared by the self-propagating high-temperature synthesis. Yet another procedure for the synthesis of intermetallic compounds, *viz*., the mechanochemical method, has been developed intensively in recent years. This method is promising in the synthesis of equilibrium and metastable phases, supersaturated solid solutions and amorphous phases and allows the preparation of intermetallides from components possessing high melting and boiling points (for example, $MoSi_2$) as well as from components characterised by large differences between these points (for example, the boiling point of magnesium in the Mg – Ti system is lower than the melting point of titanium). The mechanochemical procedure can be used for the introduction of the third component into a binary system to impart special properties to intermetallides.

Compounds prepared by the mechanochemical method are characterised by high dispersity (in most cases, nanosized particles are obtained), which affects the physicochemical properties of these compounds. Currently, one of the major problems with which researchers are faced in dealing with mechanochemical synthesis is to reveal the factors governing the formation and stability of phases prepared by this method.

In the present review, the experimental data on the problems of the mechanochemical synthesis in metallic systems published over the last 15 years are systematised. Earlier data, as a rule, are cited in the discussion of the general problems of metal deformation and mass transfer in the solid body.

II. Mechanochemical synthesis of intermetallic compounds and solid solutions at concentration limits of binary equilibrium diagrams

Analysis of the published data demonstrated that the mechanochemical method can be used for the synthesis of all major groups of intermetallic compounds, *viz*., of the following electron compounds: ε and β phases in the Zn – Ag [11] and Cu – Zn [12] systems, γ phases in the Cu – Zn system,[13] ε and η phases in the Cu – Sn system,[14] η (Cu_2Sb) and δ ($Cu_{4.5}Sb$) phases in the Cu – Sb system [15] and the Laves phases Fe_2Ti,[16] Mg_2Ni,[17–19] Mg_2Cu,[19] $MgZn_2$ [19] and Fe_2Tb.[20] The mechanochemical procedure for the synthesis of intermetallic compounds is most promising when the use of conventional metallurgical methods presents difficulties, in particular, in the synthesis of silicides of refractory metals. For example, the melting point of molybdenum (2620 °C) is virtually equal to the boiling point of silicon (2600 °C), whereas the densities of these elements differ by a factor of more than four (10.2 and 2.308 g cm^{-3}, respectively). In the case of silicon and tungsten, the difference between these parameters is even larger [T_{melt}(W) ≈ 3400 °C; ρ(W) = 19.35 g cm^{-3}]. Reactions of these elements can occur only through reactive diffusion at very high temperatures over a long period. However, it is very difficult to prepare monophase systems even under these conditions.[4]

Silicides of molybdenum,[21–27] tungsten [28] and tantalum [22,29,30] were synthesised by the mechanochemical method. The stoichiometric intermetallide $NbSi_2$ was prepared according to this method after continuous activation for 65 min.[31,32] The use of the mechanochemical method substantially simplified the preparation of iron silicides.[26,27,33,34] The boiling points of the first metals in the Mg – Ni, Mg – Ti, Mg – Si, Al – Nb, Al – Ru, Sn – Nb and Te – Cu binary systems are lower than the melting points of the second metals, but the mechanochemical approach allowed the preparation of the intermetallides Mg_2Si,[17,35,36] Mg_2Ni,[37] $NbAl_3$,[38] Nb_3Sn, Nb_6Sn_5,[39] AlRu [40] and Cu_2Te.[41]

Even more so, the synthesis of intermetallides according to conventional procedures presents technological problems due to a large difference between the melting points of the initial components. Hence, such intermetallides as FeSn, $FeSn_2$,[42–44] Ti_3Al,[38,45,46] TiAl,[45–51] $TiAl_3$,[41,45,46,52] AlPd,[53] Nb_3Ge, Nb_5Ge_2, $NbGe_2$,[39,54] ZrAl,[55] Ni_3Sn_2,[56] Ni_3Sn,[56] Ni_2Al_3,[57] NiAl,[57–65] VAl_3, V_5Al_8, V_4Al_2 and VAl_{10} [66] were prepared by the mechanochemical method.

The intermetallide Cu_7Hg_6, which is of practical importance, was prepared by mechanical alloying of copper with mercury.[67,68] These metals differ substantially in melting points. In addition, the vapour pressure of mercury at elevated temperature is very high.

Relushko *et al*.[69] studied the mechanochemical synthesis of iron aluminides in the Fe – Al system and revealed the sequence of formation of the Fe_2Al_5 and FeAl phases, *i.e*., the authors followed the stages of the synthesis of the intermetallides. The formation of the intermetallides in this system was also considered in more recent studies. Thus, Bonetti *et al*.[70] investigated Fe_3Al and FeAl and Morris and Morris [71] studied $FeAl_3$.

However, attempts to bring the mechanochemical synthesis to completion are not necessarily successful. In some cases, prolonged (during many hours) mechanochemical activation is required. It was found that mechanochemical treatment can substantially decrease the temperature of the subsequent thermal synthesis. Thus, preliminary mechanochemical activation of molybdenum and silicon powders for 2 h allowed the preparation of the intermetallide $MoSi_2$ at 800 °C.[72,73] After mechanochemical treatment of tungsten and silicon powders, the temperature of the synthesis of WSi_2 was 950 °C.[28] In the synthesis of β-$FeSi_2$, the duration of preliminary activation was decreased (50 h) by using brief mechanochemical treatment followed by annealing at 700 °C.[74] Conventional procedures for the synthesis required prolonged annealing at 982 °C;[75] however, the desired homogeneity of β-$FeSi_2$ was not achieved even in this case. Brief annealing of non-equilibrium systems obtained upon mechanochemical activation also afforded intermetallides, for example, Fe_3Al, FeAl, $FeAl_3$,[76] Fe_2Al_5,[76,77] γ-TiAl, $TiAl_3$ [51,52] and the corresponding compounds in the Co – Ti system.[78]

Systems characterised by large heats of formation of intermetallic compounds are worthy of particular consideration. Preliminary mechanochemical activation of these systems favours the subsequent self-propagating high-temperature synthesis. The new approach involving mechanochemical activation and self-propagating high-temperature synthesis extends the range of systems in which the latter can be performed,[79,80] expands the concentration limits of the synthesis and allows one to accelerate substantially the synthesis and to perform it in the solid-phase mode.[79,81] This approach was used for the preparation of the intermetallides NiTi,

NiAl, Ni_3Al, NiGe,[79–81] Ni_3Si,[82] $FeSi_2$,[75] $NbAl_3$,[83] FeAl[84–87] and $MoSi_2$.[86,88,89]

The mechanochemical method was employed for the synthesis of equilibrium solid solutions in systems characterised by continuous and very wide solubility ranges. Thus, Pavluykhin *et al.*[90] investigated the conditions of accelerated diffusion in binary metallic systems upon mechanochemical activation in centrifugal planetary mills and obtained solid solutions in the Fe–Cr system. Davis and Koch[91] were the first to examine the possibility of mechanical alloying of solid solutions consisting of fragile components. In the cited study, mechanical alloying of germanium with silicon (compositions containing 72 at.% and 50 at.% of Si) was investigated. Silicon and germanium are isomorphous and their unit cell parameters depend almost linearly on the concentration of the second element. The measured unit cell parameter of germanium was larger than that expected based on the Vegard rule, but this deviation virtually disappears in the case of specimens containing more than 72 at.% of Si. At lower concentrations of silicon, the deviation of the unit cell parameter persists even after annealing.

Yurchikov *et al.*[92,93] studied the formation of intermetallic compounds and solid solutions in the Fe–Cr and Fe–Si systems under high pressure on doubled Bridgman anvils with a rotating central part. Neverov *et al.*[94,95] prepared a large number of solid solutions on Bridgman anvils.

In the Fe–Co system, solid solutions with body-centred cubic structures were formed on mechanical alloying of mixtures containing less than 80 at.% of Co, whereas solid solutions with face-centred cubic structures were formed in the case of 90 at.% of Co.[96–99] In this system, the sizes of blocks of the body-centred cubic and face-centred cubic phases were 10–30 and 40–70 nm, respectively. Monophase solid solutions were obtained in the Fe–Ni system with the use of a planetary ball mill.[100]

All phase compositions in the Fe–Mn system were obtained in a high-energy ball mill. However, the concentration limits of the regions of solid solutions were substantially extended compared to those observed in the equilibrium diagram. The particle sizes were 20–80 nm.[101]

The mechanochemical synthesis of nanocrystalline solid solutions with body-centred cubic structures using high-energy mills was reported.[102–106] It was suggested that a solid solution of aluminium in iron became partially ordered on prolonged activation. Nanocrystalline solid solutions of iron containing 4 mass % (8 at.%) of Al were prepared in a high-energy SPEX 8000 ball mill (USA) during intervals from 10 to 60 min.[107]

Therefore, analysis of the published data demonstrated that the mechanochemical synthesis of equilibrium intermetallic compounds is most efficient in the cases of large differences between the melting points and between the densities of the initial components, high temperatures of the synthesis and, if required, in the preparation of phases with nanosized grains.† This method is used more widely in preparation for the subsequent thermal synthesis or for the self-propagating high-temperature synthesis.

III. Mechanochemical synthesis of non-equilibrium phases in bimetallic systems with negative mixing enthalpies

The mechanochemical synthesis of non-equilibrium phases can successfully compete with such methods for their preparation as superfast quenching and precipitation from the gaseous phase. Practical interest in metastable compounds (*i.e.*, in systems with an excessive free energy) arises from their high reactivities. These phases find wide application. It is evident that chemical activity of metastable phases depends substantially on crystal structure imperfection, which, in turn, is determined by the degree to which the phase is in non-equilibrium. Therefore, the major problem of the preparation of metastable phases is to achieve the maximum concentration deviation from the equilibrium state with retention of the crystal structure of the initial phase. As mentioned above, in equilibrium systems, the maximum concentration of an alloying (dissolved) element in solid solutions is determined by the electron concentration and the difference between the atomic radii, which should be no higher than 15%. Analysis of the published data demonstrated that mechanochemical synthesis leads to changes of priorities and variations in the above parameters. First, the mutual correlation between the crystal structures of the components assumes great importance. Second, the dimension factor is shifted to the region of 15%–28% to attain substantial concentration deviations.

Binary metallic systems in which the course of mechanochemical synthesis of non-equilibrium phases is governed by the difference between the atomic radii are listed in Table 1. It can be seen that metastable solid solutions characterised by a substantial deviation of the concentration form the equilibrium state can be synthesised by the mechanochemical method in systems in which the solubility of one element in another is limited by the dimension factor and in which the difference between the atomic radii is 15%–25%. The concentrations of such solid solutions are higher than both the low-temperature (in all the cases under consideration) and high-temperature (Cu–Hg, Ni–Sn and Fe–Sn) equilibrium limits. For the Cu–Sn system, these concentrations are also higher than the concentrations of solid solutions prepared by fast quenching, (in the latter case, these values amount to only 8 at.% of Sn; Fig. 1). Tianen and Schwarz[56] prepared supersaturated solid solutions of tin based on α-nickel with the lattice parameter $a = 0.3699$ nm, which is 5% larger than that of pure nickel.

Table 1. Differences between the atomic radii (ΔR) and the concentrations of equilibrium (C) and supersaturated solid solutions (c) prepared by the mechanochemical method in different systems.

System	ΔR (%)	C (at.% of the second element)		c (at.% of the second element)	Ref.
		I	II		
Cu–Sn	19	11.25 (852°C)	~0	10	108–111
Cu–Hg	20	5 (657°C)	0	17	111–113
Cu–In	23	10.8 (574°C)	>1	11	114–116
Ni–Sn	21	10.4 (1130°C)	0	17.7	117–119
Ni–In	25	14.5 (908°C)	0	14.5	117–119
Fe–Sn	20	9.8 (900°C)	>2	32	120–124
Ni–Bi	30	0.5 (>500°C)	0	3	125, 126

Note. The following notations are used: I is the concentration at high temperatures and II is the concentration at room temperature.

The limiting non-equilibrium concentration decreases as the difference between the atomic radii increases further. In the Ni–Bi system in which the difference between the atomic radii is 30%, the enthalpy of formation of solid solutions calculated by the Miedema method[127–129] has a small negative value. According to the equilibrium diagram,[108] this system contained two intermetallic compounds with the bismuth contents of 78.08 mass % (NiBi) and 91.44 mass % ($NiBi_3$), the solubility of bismuth in solid nickel being no higher than 0.5 at.%.[125] Solid solutions of bismuth in nickel with bismuth concentrations of up to 3 at.% were synthesised by the mechanochemical method.[126]

In systems in which the limiting solubility is determined by the electron concentration, the content of the alloying element exceeding the value allowed in this crystal structure is very difficult to achieve. In the Cu–Al system, the difference between the atomic radii is 11%. Taking into account the electron concentration under equilibrium conditions at room temperature, the limiting

† The term 'nanosized grain' used in many modern publications is generally related to the sizes of coherent-scattering regions.

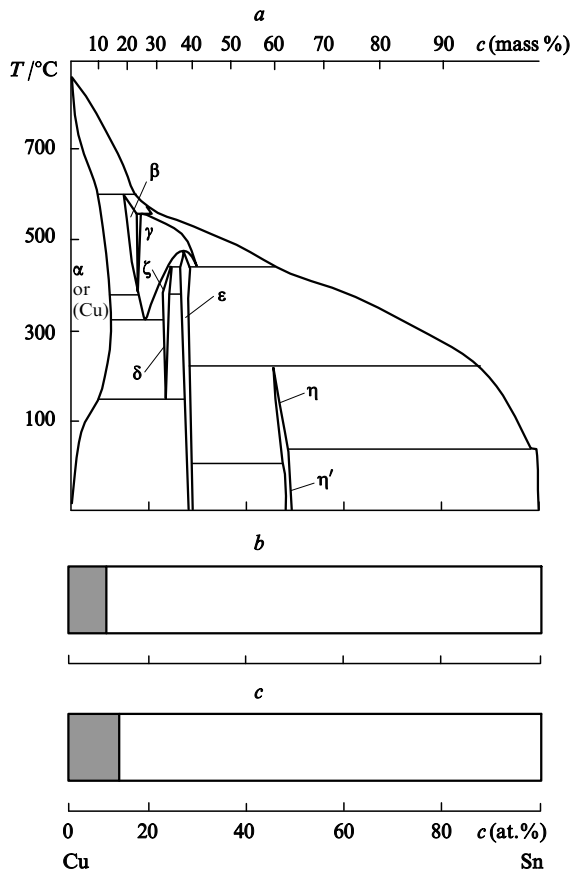

Figure 1. Equilibrium diagram of the Cu – Sn system (*a*) and the limiting concentrations of the solid solution prepared by fast quenching (*b*) and the mechanochemical method (*c*).

aluminium content in copper can be as high as 20 at.%. Solid solutions with a maximum aluminium content of up to 23 at.% were also prepared by the mechanochemical method.[111, 130, 131]

If there is structural compatibility between the metal serving as the solvent and the closest intermetallide and there is a favourable dimension factor, the resulting solid solutions are characterised by a very broad concentration range of supersaturation. In the Ni – Al system, the intermetallic compound Ni_3Al is structurally similar to nickel serving as the solvent.[132] According to the equilibrium diagram, the limiting solubility of aluminium in nickel is 13.5 at.% and 3.85 at.% at 1100 and 500 °C, respectively. At room temperature, the solubility is insignificant. The homogeneity region of the intermetallic compound Ni_3Al varies from 23 at.% to 27.5 at.% of Al.[108] Solid solutions of aluminium in nickel containing up to 28 at.% of Al were synthesised by the mechanochemical method.[111, 133]

The Ni – Ga system is characterised by an electron concentration identical to that observed in the Ni – Al system and by the favourable dimension factor ($\Delta R \simeq 10\%$).[134] The maximum gallium content in the equilibrium solid solution of gallium in nickel is 24.3 at.%. At the peritectic temperature of 1210 °C, the α' phase (Ni_3Ga) was formed. The solubility of gallium in nickel depends substantially on the temperature. For example, the solubility at 700 °C decreases to 15 at.% of Ga.[135] The system contained the β phase, *viz.*, the solid solution based on the intermetallide NiGa. The homogeneity region of the β phase falls in the concentration ranges of gallium from 36 at.% to 60 at.% and from 48.3 at.% to 53.3 at.% at high and low temperatures, respectively. At 1204 °C and a concentration of gallium of 29.4 at.%, the α' and β phases formed an eutectic. At 940 and 685 °C , two peritectoid reactions proceeded giving rise to new phases, *viz.*, γ and δ, respectively. The low-temperature γ' phase formed from the γ phases below 685 °C has the Ni_3Ga_2 composition and is characterised by a narrow homogeneity region. The Ni_3Ga phase (the Cu_3Au structural type) is structurally similar to β-nickel (the face-centred cubic structure). The succeeding Ni_3Ga_2 phase crystallises in the γ-Mn structural type, which can be described as a deformed structure of β-nickel, whereas the NiGa phase crystallises in the CsCl structural type (the body-centred cubic structure).[132] The mechanochemical method was used for the preparation of solid solutions of gallium in nickel with a Ga concentration of up to 50 at.%,[117, 133] *i.e.*, including the concentration range of existence of both structurally similar phases.

In the Ni – Ge system, the difference between the atomic radii of the metals is small,[134] but the region of existence of the solid solution, which is determined by the electron concentration, is noticeably narrower than that in the Ni – Ga system. According to the equilibrium diagram, the limiting solubility of germanium in nickel is 13.8 at.% at 1161 °C.[125] The solid solution is followed by the β phase, which is a solid solution based on the intermetallide Ni_3Ge. The β phase is homogeneous in the concentration range from 22.9 at.% to 24.8 at.% of Ge and has the cubic structure of the Cu_3Au type similar to that of β-nickel. The following ε phase is a solid solution based on Ni_2Ge with the hexagonal structure of the nickel-arsenide type, which differs substantially from the structure of the preceding phase. The mechanochemical method was used for the synthesis of non-equilibrium solid solutions whose homogeneity region extends to a concentration of 25 at.% of Ge.[133]

It is known that a solid solution of aluminium in α-iron was formed in the Fe – Al system at concentrations of aluminium varying from 0 at.% to 25 at.% (quenched alloys).[132] The further addition of aluminium led to a gradual ordering of the solid solution. Under favourable conditions, for example, upon annealing, ordering started even at 18 at.% of Al. At 25 at.% and 50 at.% of Al, the intermetallides Fe_3Al and FeAl, respectively, were formed. Solid solutions of aluminium in iron with an aluminium content of up to 50 at.% were prepared by the mechanochemical method.[136 – 138]

Therefore, the mechanochemical method enables one to extend substantially the concentration range of existence of solid solutions toward the non-equilibrium region if the intermetallic compounds closest to the metal, which serves as the solvent, are structurally similar.

Metastable solid solutions can be prepared by the mechanochemical method from powders of metals in different systems among which are systems characterised by large differences between the melting points and between the densities of the initial components, by high melting points of the resulting intermetallic compounds and by narrow homogeneity regions of the equilibrium chemical compound. In the synthesis of supersaturated solid solutions, as in the synthesis of intermetallides, systems with very large differences between the melting points of the initial components attract particular attention. Among these are systems containing tungsten ($T_{melt} \approx 3400$ °C) and tantalum ($T_{melt} = 3015$ °C) whose melting points are higher than boiling points of many metals.

In the Ni – W system, the boiling point of nickel (2900 °C) is lower than the melting point of tungsten and hence compounds are difficult to prepare from these elements by conventional procedures. According to the equilibrium diagram, this system contained (*a*) the α phase, *viz.*, a solid solution of tungsten in nickel with a homogeneity regions from 0 at.% to 35 at.% of W at 900 °C and from 0 at.% to 41.5 at.% of W at temperatures from 1000 °C to the melting point, (*b*) the β phase, *viz.*, the intermetallic compound Ni_4W, and (*c*) the γ phase, *viz.*, a solid solution of nickel in tungsten containing ~4 at.% of Ni.[125] Solid solutions of tungsten in nickel were synthesised from a mixture of these metals by the mechanochemical method.[139]

An analogous ratio between the melting points of the initial components is observed in the Fe – W system. According to the

equilibrium diagram, the system contained two intermetallides, *viz*., Fe_2W and Fe_3W_2. At 1520 °C and at room temperature, the solubility of tungsten in iron is 33 mass % (13 at.%) and 8 mass % (3 at.%), respectively. At 1640 °C, the solubility of iron in tungsten in the solid state is only 0.8 mass % (2.6 at.%).[125] The solid-phase synthesis in this system was carried out by the mechanochemical method to produce solid solutions.[140]

In the Cu – Ta system, the mixing enthalpy is close to zero, the difference between the atomic radii is large (~ 25%), the initial components belong to different structural types, and the boiling point of copper is almost 600 °C lower than the melting point of tantalum. According to the published data,[108, 141] the solid-phase solubility of tantalum in copper is virtually absent. At 1200 °C, only 0.009 at.% of Ta was dissolved in copper and no other metallic compounds were formed. Supersaturated solid solutions of tantalum in copper were prepared by the mechanochemical method.[142]

In the Cu – Nb system, the difference between the melting points of the initial components is also large. According to the equilibrium diagram, the system contained only two phases, *viz*., solid solutions based on copper (α) and niobium (β). The solubility of niobium in copper at 1100 and 20 °C is 1.66 mass % (1.14 at.%) and 0.2 mass % (0.13 at.%), respectively. The solubility of copper in niobium at high temperatures and at 700 °C amounts to ~2 at.% and 0.07 at.%, respectively.[141] Solid solutions with concentrations of each component up to 10 mass % (7.05 at.%) were prepared by the mechanochemical method.[143, 144]

The limiting solubilities (~10 at.%) both of niobium in a solid solution of nickel (a face-centred cubic structure) and of nickel in a solid solution of niobium (a body-centred cubic structure) were achieved in the Ni – Nb system by the mechanochemical method.[145] For comparison, is should be noted that the equilibrium solubilities are 4.2 at.% of Nb (at 987 °C) and 3.5 at.% of Ni (at 1000 °C).[146]

Solid solutions of aluminium based on different metals are of particular interest in materials technology. These compounds differ sharply from the starting compounds in chemical properties. The concentration of aluminium introduced has a pronounced effect on the properties. Gerasimov *et al*.[147] observed the formation of supersaturated solid solutions based on α-titanium for the compositions $Ti_{100-x}Al_x$ ($x < 60$ at.%). The solutions were formed even if the equilibrium phases Ti_3Al and TiAl were used as the starting components. The authors believed that the intermetallides can decompose and tribochemical equilibrium was established in the course of mechanical alloying giving rise to metastable phases. Solid solutions in the Ti – Al system were prepared in a planetary ball mill using the Ti_xAl_{100-x} compositions (x = 75 at.%, 50 at.% and 35 at.%). In none of the compositions examined did amorphisation occur. In all cases, the formation of solid solutions was observed, *viz*., the hexagonal Ti(Al) solid solution in the cases of $Ti_{75}Al_{25}$ and $Ti_{50}Al_{50}$ and a mixture of hexagonal Ti(Al) and cubic Al(Ti) solid solutions in the case of $Ti_{35}Al_{65}$. Variations in the conditions of activation led to a change in the quantitative ratio between the hexagonal and cubic phases.[148]

It is known that the equilibrium concentration of aluminium in niobium is less than 10 at.% at 1000 °C.[149] The use of the mechanochemical method allowed an increase in the concentration to 30 at.%.[150]

Supersaturated solutions were formed in the Zr – Al system containing up to 15 at.% of Al, the lattice parameters a and c of zirconium being decreased from 0.3235 to 0.3200 and from 0.5196 to 0.5148 nm, respectively.‡ After mechanochemical activation for 12 h, the particle size was ~ 12 nm.[55]

‡ Here, the first and second values correspond to the lattice parameters of zirconium and of the solid solution of aluminium in zirconium, respectively.

Solid solutions with an Al content of up to 50 at.% were formed in the Al – Pd system in which the equilibrium solubility of aluminium in palladium is 15 at.%.[53]

The mechanochemical method was used for the synthesis of solid solutions Al – 10 at.% of X (X = Ti, Zr or Hf) from powders of the metals.[151] Supersaturated solid solutions containing up to 13 at.% of Sb with a grain size of 10 nm were obtained in the Cu – Sb system.[152] The maximum concentration of 2.1 at.% of Sb was achieved in the Fe – Sb system.[153] In the Fe – Tb system, the mechanochemical method made it possible to attain a solubility of 36 at.% of Tb.[20] Metastable solid solutions W – 25 mass % (25 at.%) of Re with nanosized grains were also prepared by this method.[154]

Systems in which the absence of solubility of one element in another one is associated neither with the difference between the atomic radii nor with the difference in the structural type, but is most probably determined by the electron concentration are a special case. For example, the difference between the atomic radii in the Ge – Sn system is ~ 12%.[134] The face-centred cubic structure of germanium is similar to the tetragonal structure of β-Sn.[125] However, the equilibrium concentration of germanium in solid tin falls in the concentration range of 0.001% – 0.1% (see Ref. 125) and the formation of intermetallides was not observed. Solid solutions with a substantial deviation from the equilibrium state containing 12 at.% – 24 at.% of Sn were synthesised by the mechanochemical method.[155] These concentrations of tin are substantially higher than its concentrations in solid solutions prepared by fast quenching.[156] The non-equilibrium solubility of germanium in tin is achieved if the particle sizes of germanium are no larger than 10 nm.

In the Ge – Al system in which the initial elements belong to the same structural type and the difference between the atomic radii is very small (only ~3%), no intermetallides are formed. At 424 °C and 54 mass % (30.3 at.%) of Ge, the eutectic consisting of two solid solutions appeared. The germanium content in a solid solution based on aluminium decreased from 5.1 mass % (~2 at.%) at the eutectic temperature to 0.3 mass % (> 0.1 at.%) at 20 °C.[125] Metastable intermetallic compounds were obtained by quenching from the liquid state.[42, 157] Structurally similar metastable intermetallides were also synthesised by the mechanochemical method.[158, 159]

Analysis of the experimental data demonstrated that systems in which the atomic radius of the alloying element is larger than that of the metal serving as the solvent are characterised by higher equilibrium solubilities than those observed in systems with other ratios between the atomic radii. For example, the solubilities of aluminium (R = 0.143 nm) in nickel (R = 0.124 nm), iron (R = 0.126 nm) and copper (R = 0.128 nm) amount to tens of atomic percent, whereas the solubilities of iron, nickel and copper in aluminium are close to zero. The use of the mechanochemical method allowed a substantial extension of the region of existence of such solid solutions. Thus, metastable solid solutions based on aluminium with Cu and Fe contents of up to 33 at.% (see Ref. 160) and 10 at.%, respectively, were prepared.[161 – 163] Pekala and Oleszak[164] prepared a solid solution with composition $Fe_{10}Al_{90}$ in a horizontal low-energy ball mill after activation for 200 h. The average size of crystallites of the solid solution was ~7 nm. It was found that the mechanochemical formation of the solid solution in the course of activation was preceded by the short-duration formation of the intermetallide $FeAl_3$ from powders of iron and aluminium. Dunlap *et al*.[165] compared the microstructures of supersaturated solid solutions of iron in aluminium synthesised by the mechanochemical method and fast quenching and demonstrated that alloys with composition $Al_{98}Fe_2$ prepared by fast quenching occurred as monophase supersaturated solid solutions. In the initial stage of the mechanochemical synthesis, a supersaturated solid solution whose microstructural properties are similar to those of quenched alloys was formed. Further activation led to a decrease in the grain size and gave rise to an amorphous phase.

Supersaturated solutions with a magnesium content of up to 45 at.% were synthesised in the Al – Mg system by the mechanochemical method. The particle sizes were in the range of 2 – 10 nm.[166]

In the case of intermetallides with low enthalpies of formation or with enthalpies close to mixing enthalpies, supersaturated solid solutions can be prepared not only by mechanochemical synthesis from powders of the initial elements, but also on mechanochemical activation of intermetallides resulting in disordering of the equilibrium intermetallic phases synthesised by other methods. For example, the intermetallides Nb_3Al,[167] V_3Ga,[168] Nb_3Au,[169 – 171] Ni_3V,[172, 173] $Cr_{53}Fe$ [174] and Fe_3Ge [176] were transformed into solid solutions with body-centred cubic structures, whereas $NbAl_2$ (see Ref. 172) and $TiAl_3$ (see Ref. 175) were transformed into solid solutions with face-centred cubic structures upon mechanochemical activation. As a result of disordering of equilibrium intermetallides, solid solutions also formed in the Ni – Al system.[177]

Supersaturated solid solutions of tin in iron characterised by a substantial deviation from the equilibrium state can be prepared using mechanochemical activation both of a monophase intermetallide and a mixture of intermetallic compounds.[178 – 180]

Therefore, the mechanochemical method allows the preparation of supersaturated solutions in systems with negative enthalpies of mixing of the components. For most systems, the degree of supersaturation depends on the difference between the atomic radii of the initial elements, their structural compatibility and the electron concentration.

IV. Mechanochemical synthesis of supersaturated solid solutions in systems with positive mixing enthalpies

Of systems with positive mixing enthalpies, the Fe – Cu system has received the most study. If the concentrations of the components are equal to 50 at.% each, the mixing enthalpy calculated by the Miedema method [127 – 129] is 22 kJ mol^{-1}. It is believed that one of the reasons for the immiscibility of these metals in the solid state is the difference in their structural types. Thus, copper has the face-centred cubic (FCC) lattice and α-iron has the body-centred cubic (BCC) lattice. However, it is known that the structural type of iron changes as the temperature is increased: α-Fe (BCC) → β-Fe (BCC) at 770 °C → γ-Fe (FCC) at 920 °C. Hence, the possibility of dissolution is higher at high temperatures. At 1094 °C, the equilibrium solubilities of iron in copper and copper in γ-iron are 3.8 mass % (4.2 at.%) and ~8 mass % (~7.1 at.%), respectively.[108, 125] Solid solutions, which are non-equilibrium at room temperature, can be prepared by quenching from vapour or liquid phases. For example, solid solutions based on iron (BCC lattice) in the concentration range of up to 15 mass % (13.5 at.%) of Cu and based on copper (FCC lattice) in the concentration range of up to 20 mass % (22 at.%) of Fe were obtained from melts by quenching.[181] Supersaturated solid solutions in a wider concentration range were prepared by precipitation from the vapour phase *in vacuo* on a support at room temperature. It was demonstrated [182] that solutions had BCC structures if the copper content was lower than 50 mass % (47 at.%) and FCC structures if the copper content was higher than 70 mass % (68 at.%). Solutions with concentrations of copper in the range of 50 mass % – 70 mass % were not prepared. Supersaturated solid solutions in a wide concentration range were also synthesised by quenching from the vapour phase. Solid solutions based on iron existed up to 40 mass % (37 at.%) of Cu. Solid solutions based on copper with a FCC structure occurred up to 60 mass % (57 at.%) of Cu.[183]

Benjamin [184] was the first to report the results of mechanochemical alloying of the components in the Fe – Cu system. He obtained the homogeneous mixtures 80 mass % (82 at.%) of Fe – 20 mass % (18 at.%) of Cu and 50 mass % (24 at.%) of Pb – 50 mass % (76 at.%) of Cu in a high-energy laboratory mill. Metallographic studies of a specimen of the Cu – Fe system confirmed its homogeneity. It was also noted that the colour changed from red (the colour of copper) to grey (the colour of steel). Neverov *et al.*[94, 185] obtained solid solutions on a Bridgman anvil. The concentrations of copper in iron and iron in copper reached 40 mass % and 10 mass %, respectively. Gusev [186] demonstrated that solid solutions based on copper (FCC lattice) with compositions up to $Cu_{40}Fe_{60}$ and solid solutions based on iron (BCC lattice) with compositions up to $Cu_{30}Fe_{70}$ can be obtained in a centrifugal planetary ball mill. Kaloshkin *et al.*[187, 188] prepared supersaturated solid solutions $Fe_{100-x}Cu_x$ ($x = 20 – 80$) from powders of iron and copper in a planetary ball mill. The mechanochemical formation of solid solutions was completed in 30 min. It was also established that the FCC phase of the solid solution, the BCC phase of the solid solution and a mixture of these phases were formed at $x = 40$ at.% – 80 at.% of Cu, $x = 20$ at.% of Cu and $x = 30$ at.% of Cu, respectively. In studies of structural changes occurring in the course of mechanical alloying, Barro *et al.*[189] observed the formation of solid solutions in the Fe_xCu_{100-x} system ($x = 5$, 10 and 20). Uenishi *et al.*[190] performed mechanical alloying of the solid solution $Fe_{1-x}Cu_x$ and prepared also monophase compositions with BCC (if $x < 40$ at.%) and FCC (if $x > 40$ at.%) structures. Yavari *et al.*[191] confirmed that the lattice parameters in these compositions were increased. Eckert *et al.*[192, 193] prepared solid solutions Fe_xCu_{100-x} in a SPEX 8000 ball mill. It was demonstrated that monophases with FCC and BCC structures exist at $x \leqslant 60$ and $x \geqslant 80$, respectively, whereas solid solutions with FCC and BCC structures coexist in the range of $60 \leqslant x \leqslant 80$. The formation of solid solutions starts when grains reach nanometer sizes.

Jiang *et al.*[194, 195] also observed the formation of solid solutions in the Cu – Fe system and detected small amounts of γ-Fe (a FCC structure) in all specimens subjected to mechanochemical treatment for more than 10 h. Supersaturated solid solutions in the Cu – Fe system were also prepared in SPEX 8000 ball mills in more recent studies (see, for example, Refs 196 – 206). It was established by different methods that monophase supersaturated solid solutions were formed in mixtures containing more than 80 mass % or less than 60 mass % of copper, whereas two phases coexisted in the region with a copper content from 50 mass % – 60 mass % to 80 mass %.

Therefore, the mechanochemical method allows the preparation of supersaturated solid solutions throughout the concentration range of existence of a binary system with a high positive heat of mixing of the initial components (Fig. 2).

The Cu – Co system also has a positive mixing enthalpy (~20 kJ mol^{-1} for the equiatomic composition). According to the data reported by different researchers, the concentration of cobalt in a solid solution based on copper (β phase) at 1100 °C changes from 5.2 mass % to 8 mass % (from 5.6 at.% to 8.5 at.%) and the concentration of copper in a solid solution based on cobalt at the same temperature changes from 12 mass % to 14 mass % (from 11.2 at.% to 13.1 at.%). At temperatures below 500 °C, the mutual solubility of one element in another is no higher than 0.1%.[108] The low mutual solubility is attributable to the difference in the structural types of these elements. However, it is known that α-Co (the hexagonal close-packed structure) is transformed into β-Co at 350 – 470 °C. The latter, like copper, has a FCC structure. The high mutual solubility of these elements is quite possible due to the insignificant difference between their atomic radii. Fast quenching made it possible to dissolve up to 20 mass % of Co and less than 25 mass % of Cu in cobalt. The mechanochemical method was used for the preparation of solid solutions with FCC structures throughout the concentration range of existence of this binary system.[197, 199, 207 – 213] In a number of studies, it was found that phase transformations of cobalt occurred upon mechanochemical activation in ball mills.[214 – 216]

The Cu – Cr system is also characterised by a positive mixing enthalpy (~20 kJ mol^{-1} for the equiatomic composition). In this

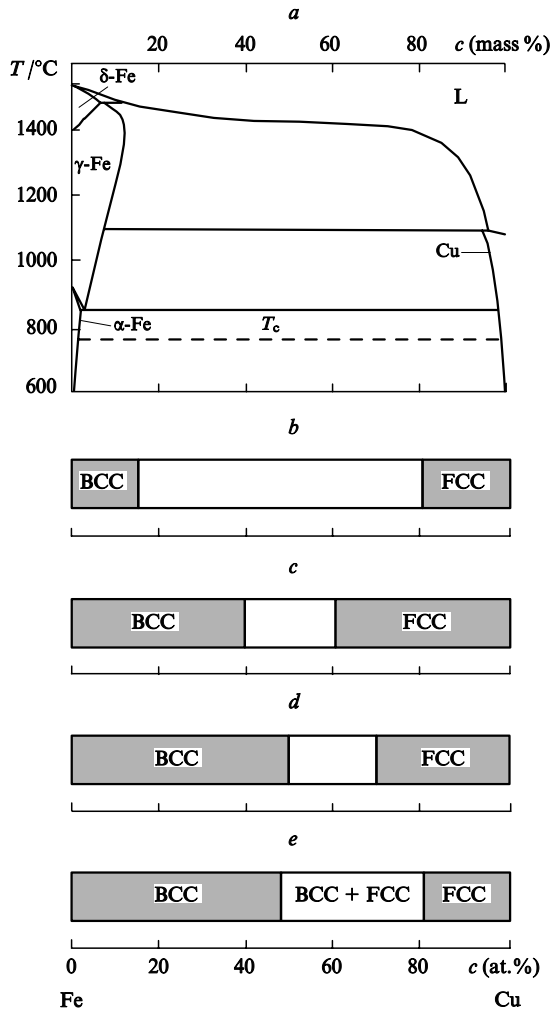

Figure 2. Equilibrium diagram of the Fe – Cu system (*a*) and the regions of existence of solid solutions synthesised by quenching from a melt (*b*), quenching from the vapour phase (*c*), precipitation from the vapour phase (*d*) and the mechanochemical method (*e*).

system, as in the above-considered one, the difference between the atomic radii of the initial metals is insignificant, but their structural types differ substantially (BCC and FCC structures, respectively). The solubility of chromium in copper varies from 1.25 mass % to 0.5 mass % (from 1.5 at.% to 0.6 at.%) at 1050 °C and it is less than 0.03 mass % at 400 °C. The solubility of copper in chromium is 0.16 at.% and 0.085 at.% at 1300 °C and 1150 °C, respectively.[141] Chromium has several crystal modifications, *viz*., α-Cr (BCC structure), β-Cr and γ-Cr. Supersaturated solid solutions characterised by substantial deviations from the equilibrium state were prepared by the mechanochemical method.[217–220]

In the Cu – V system, the atomic radii of the initial metals have close values, whereas their structural types are different (FCC and BCC structures, respectively). According to the equilibrium diagram, solid solutions based on copper (α) and vanadium (β) are formed in the system. The maximum solubility of vanadium in copper is 0.8 at.% at 1120 °C (0.1 at.% at 20 °C) and the maximum solubility of copper in vanadium is 8 at.% at 1530 °C.[141] A wide range was found in which the components in the liquid state were immiscible (the range from 4.0 at.% to 84.6 at.% of V). Solid solutions both with BCC and FCC structures were prepared on mechanochemical activation.[218,221] It was demonstrated [221] that the particle sizes of the components should be no larger than 30 nm for solid solutions to be prepared.

In the Cu – Ag system, both components have FCC lattices, the difference between the atomic radii is ~11% and the melting points of the components have close values. However, according to the equilibrium diagram of this system, the components have limited solubilities in the solid state at the eutectic temperature (~780 °C). At this temperature, the solubility of silver in copper is 8.0 mass % (4.9 at.%) and the solubility of copper in silver is 8.8 mass % (14.1 at.%). Quenching at a rate of cooling of 10^7 deg s^{-1} afforded a continuous series of solid solutions. On cooling at lower rates, a continuous series of solid solutions was not detected. Depending on the conditions, solid solutions with different contents of the second element can be synthesised by the mechanochemical method throughout the concentration range of this system.[42,186,222–225]

In the Pb – Al system, both elements also have FCC structures, the difference between their atomic radii is ~18% and both metals are rather low-melting. However, the system is characterised by a positive mixing enthalpy. The metals do not form intermetallides and mutual solubility is absent. Supersaturated solid solutions were prepared in this system by the mechanochemical method.[226]

The Fe – Ag system is characterised by a very high positive mixing enthalpy, the initial elements have different structural types (BCC and FCC, respectively) and the mutual solubility of the components is limited even in the liquid state. The solubility of silver in solid iron is no higher than 0.01% and the solubility of iron in solid silver is 0.0006%.[125] Solid solutions are difficult to synthesise by the mechanochemical method.[227–230] Only very thin dispersions of iron in a silver matrix were obtained; the average radius of iron particles was equal to several nanometers.[230]

In systems with positive mixing enthalpies, a low mutual solubility of one component in another may be associated with a large difference between the atomic radii of the initial elements. For example, this difference in the Cu – Bi system is ~30% and the solubility of bismuth in copper in the solid state is only 0.003 at.% at 800 °C, the solubility of copper in bismuth being insignificant.[231] The formation of the metastable intermetallide with composition Cu_5Bi_2 was observed in this system.[232] The mechanochemical method was used for the preparation of supersaturated solid solutions of bismuth in copper with a concentration of bismuth of up to 4 at.%; the average grain size was ~10 nm.[233]

The Fe – In system is also characterised by a positive mixing enthalpy and the difference between the atomic radii of ~23%. In the equilibrium state mutual solubility is completely absent. Solid solutions of indium in iron with rather low concentrations of indium were prepared by the mechanochemical method.[234]

In solid solutions prepared by the mechanochemical method in systems characterised by positive mixing enthalpies and large differences between the atomic radii, the maximum solubilities of one element in another are rather low compared to those in systems in which the differences between the atomic radii of the initial elements are smaller and the elements can adopt similar structures due to phase transitions on mechanochemical activation.

The use of the mechanochemical synthesis for the preparation of intermetallides and solid solutions in immiscible systems with a large difference between the melting points of the initial components, in particular, in systems in which the melting point of one component is higher than the boiling point of another one, is of most practical interest. For example, the Mg – Ti system is characterised by a positive mixing enthalpy (12 kJ mol^{-1}). In this system, the difference between the atomic radii is ~9%, the components belong to the same structural type and the melting point of titanium is ~500 °C higher than the boiling point of magnesium. Hence, solid solutions are difficult to prepare by conventional methods (probably, they can be synthesised by precipitation from the vapour phase). Solid solutions of titanium in magnesium with concentrations of up to 20 mass % of Ti were synthesised by the mechanochemical method.[235] Moritaka *et al*.[236] examined the Ti – *x*Mg system (*x* = 10 at.%, 20 at.%,

30 at.%, 40 at.%, 50 at.%, 60 at.%, 70 at.%, 80 at.% and 95 at.%). Mechanical alloying was carried out in a Frich ball mill (P-7 type). Supersaturated solid solutions were detected at a magnesium content of $\geqslant 60$ at.%. In the range from 70 at.% to 80 at.% of Mg, the coexistence of solid solutions based both on titanium and magnesium was observed. The sizes of crystallites were larger and nonuniform distortions of the lattices of solid solutions based on magnesium were more substantial than those observed in the case of nanocrystalline solid solutions based on titanium.

The Cu–W system is characterised by a very high positive mixing enthalpy (35 kJ mol^{-1}). In this system, the difference between the atomic radii is $\sim 8\%$, the structural types of the initial metals are different (FCC and BCC, respectively) and the boiling point of copper is lower than the melting point of tungsten. Solid solutions were synthesised in this system by the mechanochemical method.[237,238] Raghu *et al.*[239] performed mechanical alloying in the systems Cu–5 mass % (1.9 at.%) of W and Cu–15 mass % (5.2 at.%) of W and demonstrated that nonequilibrium solubilities both of copper in tungsten and tungsten in copper occurred.

Therefore, the use of mechanochemical synthesis in systems which are immiscible in the equilibrium state allows the preparation both of metastable intermetallic compounds and non-equilibrium solid solutions. In systems in which the atomic radii of the initial components have close values and their structural types become similar due to phase transitions, the concentration ranges of existence of supersaturated solid solutions prepared by the mechanochemical method are extended most significantly compared to those of analogous solutions prepared by quenching. If the immiscibility in the equilibrium state is dictated by the difference between the atomic radii of the initial components, a substantially lower solubility is attained. In the latter case, rarely, if ever, can supersaturated solid solutions be prepared by quenching, whereas a particular solubility is achieved using the mechanochemical method, but this solubility is substantially lower than that in systems in which the difference between the atomic radii is small.

V. Quasicrystals and amorphous alloys

Follstaedt and Knapp[240] were the first to use solid-phase diffusion for the synthesis of icosahedral phases in the Al–Ru and Al–Mn systems. The melting point of ruthenium is substantially higher than that of aluminium and an alloy of these elements is difficult to prepare by quenching. Hence, the search for new procedures for the synthesis of these alloys is a topical problem. The formation of an icosahedral phase in experiments on heterophase diffusion signifies that nuclei of this phase are formed and grow more rapidly than the crystalline phase with the corresponding composition and a lower free energy in the solid state. This may be due to the fact that the fragments characterised by the short-range icosahedral order are more ordered in the crystal structure. Taking into account the results of experimental investigation of heterodiffusion and assuming that the mechanism of formation of amorphous alloys and supersaturated solid solutions on mechanical alloying is also associated with the process of heterodiffusion, Follstaedt and Knapp suggested that an icosahedral phase can also be prepared by mechanochemical alloying. Independently, Ivanov *et al.*[241] were the first to synthesise the icosahedral phases $Mg_{32}(Zn, Al)_{49}$ and $Mg_{32}(Cu, Al)_{49}$ from elements by the mechanochemical method and performed structural transformations of the corresponding Frank–Casper cubic phases into icosahedral phases by mechanochemical activation. The synthesis of the icosahedral phase $Mg_{32}(Zn, Al)_{49}$ from the elements involved an intermediate step giving rise to an amorphous phase. Apparently, clusters possessing short-range icosahedarl order were formed in this step. Then an icosahedral phase arose. This phase appeared to be rather stable and remained unchanged in the course of further treatment in a ball mill. The authors demonstrated that the synthesis of the icosahedral phase on mechanical alloying of metallic powders was accompanied by intermediate formation of an amorphous phase. Mechanochemical treatment of the cubic phase led to gradual broadening and then disappearance of a series of X-ray diffraction reflections belonging to this phase, whereas the remaining reflections were shifted so that they corresponded to the icosahedral phase. The X-ray diffraction reflections of the final product are broadened compared to those of quenched specimens. The metastable icosahedral phase was transformed into the cubic phase upon heating. According to the data of differential scanning calorimetry, this transformation was accompanied by three exothermic effects. The first of these effects most probably corresponds to annealing of defects in the icosahedral phase, which is confirmed by the fact that the X-ray diffraction reflections corresponding to this phase were narrowed after annealing of a specimen at the temperature of the first exothermic peak.

Eckert *et al.*[242] synthesised quasicrystals of $Al_{65}Cu_{20}Mn_{15}$ from the elements by mechanochemical activation in a planetary ball mill for 90 h. This phase also appeared to be stable to mechanochemical treatment. Thus, the X-ray diffraction pattern remained virtually unchanged in the course of grinding during 160 h. Unlike the authors of the above-considered study, Eckert *et al.* did not observe the formation of an intermediate amorphous phase and suggested that the formation of the icosahedral phase proceeded by a mechanism of heterodiffusion at the expense of heat, which was released upon dissipation of the kinetic energy of colliding balls. More recently (see, for example, Ref. 243), the icosahedral phase $Al_{70}Cu_{20}Fe_{10}$ has been synthesised from a mixture of metallic powders by the mechanochemical method. Local icosahedral symmetry was observed in alloys of aluminium with molybdenum after their mechanical grinding.[244]

The investigation performed by Schwarz and Johnson,[245] who demonstrated that amorphous alloys can be formed through heterodiffusion in a layered composite, has stimulated increased interest in the preparation of amorphous alloys in solid-phase processes. More recently, Schultz[246] has prepared a voluminous amorphous nickel–zirconium alloy by the annealing of a repeatedly rolled layered specimen. These facts suggested that the preparation of amorphous alloys by mechanical alloying occurred as a solid-phase process. During the last decade, a rich variety of amorphous alloys both in binary and multicomponent metallic systems, including systems characterised by large differences in the melting points and in the densities of the initial components, have been synthesised by mechanical alloying of powders of elements. For example, it was demonstrated that amorphous alloys can be prepared in the Ni–Mg system by the mechanochemical method (this process depends substantially on the blend composition). In addition, the formation of an amorphous alloy in magnesium-rich compositions was preceded by the formation of the intermetallic compound Mg_2Ni, whereas amorphous alloys were formed immediately from metallic powders in compositions with high nickel contents in spite of the fact that, according to the equilibrium diagram, the intermetallide Ni_2Mg existed in this concentration range.[247]

Nanosized amorphous alloys were also prepared in the Cu–Zr system.[248] The amorphous alloys Al_x-Zr_{100-x},[249] $Fe_{50}-Ta_{50}$,[250] Ni_xTa_{100-x},[251] Cu–Ti,[252] $Fe_{75}Zr_{25}$[253] and $Fe_{66.7}Zr_{33.3}$[254] were synthesised. In the Ti–Fe system, the formation of amorphous alloys was preceded by the formation of the supersaturated solid solutions β-Ti(Fe) and α-Fe(Ti) and the intermetallides FeTi and Fe_2Ti.[255] Amorphous phases were prepared in the systems Fe–6 mass % (11.3 at.%) of Si (see Ref. 256) and Se–As.[257] In the Fe–Cr system, amorphous alloys containing only 28 mass % (26.5 at.%) and 45 mass % (43 at.%) of Fe were prepared.[258] Multicomponent systems containing boron, phosphorus, silicon, carbon and other elements, for example, $Ni_{50}Pd_{40}Si_{10}$ (see Ref. 259) and YNi_2B_2C,[260] have received much consideration. In the latter system, the formation of nanocrystalline or amorphous phases is determined to a large extent by the

activation parameters (an amorphous phase appeared only after prolonged activation). Amorphous phases with composition $Cu_{86-x}Sn_xP_{14}$ ($x = 2-15$) can be prepared from powders of the initial elements, the time of the preparation of the amorphous phase depending on the tin content in the mixture. Thus, the duration of activation was 28, 20, 12 and 32 h at $x = 4, 5, 8$ and 10, respectively.[261] The alloy $Fe_{39}Ni_{39}Si_{10}B_{12}$ can be prepared both in the amorphous and nanocrystalline states.[262] An amorphous alloy with composition $(Zr_{0.65}Al_{0.075}Cu_{0.175}Ni_{0.1})_{100-x}Fe_x$ ($x \leqslant 20$) was synthesised from powders of the initial elements.[263]

Ermakov *et al.*[264–267] were the first to perform amorphisation of intermetallic compounds by the mechanochemical method. They carried out the structural transformation of the intermetallic compounds X–M, where X = Y, Gd or Tb and M = Fe or Co, from the crystalline to amorphous state in a wide concentration range by mechanical grinding. In the late 1980s, investigations of this process have been started by many researchers.[268–272] Amorphisation of intermetallides was examined in the Sn–Nb, Ge–Nb,[39,269] Cr–Ti, Cu–Ti, Fe–Ti, Mn–Ti, Co–Ti, Ni–Ti, Cu–Cr, Ni–Zr, Mn–Si[270] and Ni–Al[271,272] systems. Koch[13] was the first to initiate the process of amorphisation of intermetallides and called it 'mechanical grinding' rather than 'mechanical alloying' from the initial elements. In the last decade, this process has been studied intensively. Amorphisation of the Laves phases Fe_2Sc and Fe_2Y was investigated.[273,274] It was demonstrated that vigorous mechanical grinding of the intermetallide Fe_2Sc led initially to partial chemical disordering followed by amorphisation, whereas Fe_2Y was transformed into the amorphous state without preliminary disordering. Amorphisation of the intermetallides $Ni_{10}Zr_7$ and $NiZr_2$ was also studied.[275–277] Skakov *et al.*[278] investigated the process of amorphisation in the Ni–Nb system. An amorphous phase with composition $Fe_{78}P_{22}$ was prepared by mechanical grinding.[279] Poon *et al.*[280] succeeded in transforming supersaturated solid solutions based on titanium into amorphous phases.

For some systems, amorphisation upon mechanical grinding occurred as a cyclic process. For example, investigations of the structural evolution of powders of elements upon mechanical grinding of the $Co_{75}Ti_{25}$ and $Co_{50}Ti_{50}$ mixtures[281–283] demonstrated that the formation of amorphous alloys with these compositions occurred rather rapidly, but these alloys were transformed into Co_3Ti and CoTi (both compounds have BCC structures) on further mechanical treatment. These intermetallides were thermally stable and were not transformed into other phases upon heating to 1300 K. However, further grinding again afforded the amorphous compositions $Co_{75}Ti_{25}$ and $Co_{50}Ti_{50}$. Surinach *et al.*[284] observed the transformation of an amorphous phase into a nanocrystalline phase in the $Fe_{77.5}Cu_1Nb_3Si_{9.5}B_9$ system and determined the activation energy of the nanocrystalline transformation.

Amorphous structures can also be prepared according to the mechanochemical method by grinding intermetallides together with metallic powders. Thus, an amorphous phase in the Cu–Cd system was prepared by grinding the equilibrium δ phase together with a copper powder.[285] It should be noted that attempts to obtain an amorphous structure in this system either by mechanical alloying of powders of copper and cadmium or by grinding of the single δ phase failed.

Amorphous phases in the Mg–Ni and Mg–Ni–V systems were synthesised upon mechanical grinding of the Mg_2Ni alloy with powders of nickel and vanadium, respectively.[286] An amorphous phase was formed by mechanical grinding of the intermetallide $EuFe_2$ as well as by its grinding with powders of europium and iron.[287] More complex amorphous phases were also synthesised in such a manner. The amorphous compositions $Mg_2Ni_1M_{0.1}$ (where M = Ni, Ca, La, Y, Al, Si, Cu or Mn) can be prepared by mechanochemical grinding of the binary system of the intermetallide $Mg_2Ni_{0.9}M_{0.1}$ and a powder of nickel.[288]

The regions of existence of amorphous alloys synthesised by the mechanochemical method were calculated and determined experimentally in a large number of studies (see, for example, Refs 289–295).

VI. Phase and structural transformations in the mechanochemical synthesis of intermetallic compounds

Benjamin[184,296,297] considered mechanical alloying of metallic powders in attritors as a repeated process of cold welding under pressure and grinding. He believed that a metal particle is flattened upon its initial collision with balls, *i.e.*, the ratio of the surface area of the particle to its volume increases, surface films of adsorbed impurities being disrupted. Flattened metal particles contact with each other through the freshly formed surfaces giving rise to a layered composite of powdered particles (Fig. 3). The layers in this composite become thinner as welding and grinding are continued. The formation of layered composites was detected in many systems.[13,230,247,298,299] There are five typical stages of evolution of a mixture of powders of two plastic metals (Fig. 4).

The formation of layered composites from mixtures of metallic powders is accompanied by their intensive dispersion as evidenced by the results of investigations on deformation of metals. Initially, the so-called elementary structure of slip bands appears upon deformation of pure metals even without the use of activators and mills.[300] This band consists of thin slip lines, which

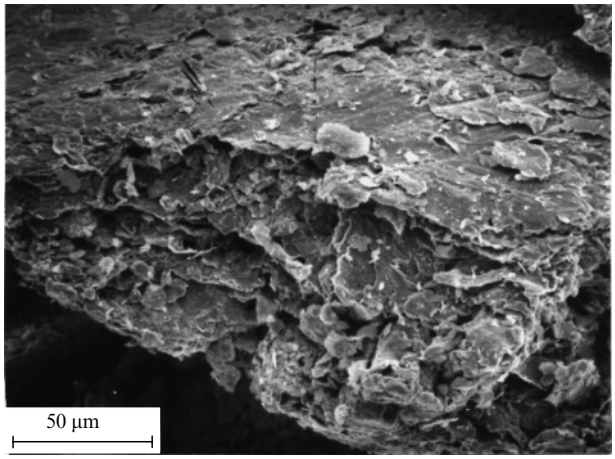

Figure 3. Microphotograph of a cross-cut cleavage of the layered composite (the system Ni–14 at.% of Al, mechanochemical activation for 30 s).[80]

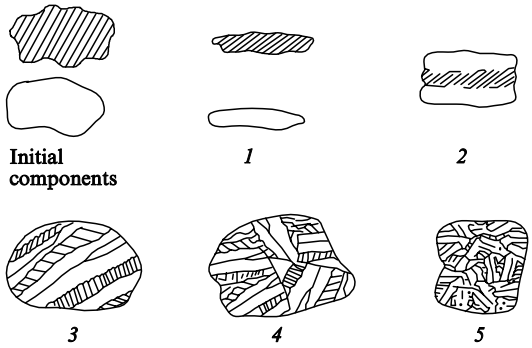

Figure 4. Typical stages of evolution of plastic powders in the course of mechanochemical activation;[84]
(*1*) plastic deformation of the initial particles (flattening), (*2*) the formation of new contacts between the initial elements, (*3*) accumulation of dislocations and breakage of layers into blocks, (*4*) and (*5*) subsequent stages of mixing and diffusion giving rise to the product.

cover the crystal surface uniformly. As plastic deformation is developed, packets of slip bands arise and deformation is distributed less uniformly throughout the bulk of the crystal. More in-depth investigation demonstrated that crystals were broken up into blocks, which were slightly disordered with respect to each other, even in the initial stage of deformation. At this stage, the appearance of dislocation networks was observed in studies of a thin foil by electron microscopy. Further development of plastic deformation led to roughening of the dislocation network to form an irregular cellular structure, the density of dislocations at the interface of the cells being substantially higher than the average density throughout the bulk. At this stage, the growth of disordered blocks was observed.[300] The mechanism of formation of the cellular structure is not entirely known. However, it is assumed that processes of polygonisation associated with dislocation climb and rearrangement are of great importance in this mechanism. Since dislocation climb can occur only under the action of very large stresses or through diffusion inflow of point defects,[301] the formation of the cellular structure is estimated taking into account these factors. At rather high temperatures (close to the temperature of recrystallisation), the formation of a cellular structure is promoted by a high rate of migration of vacancies. The concentration of vacancies in plastically deformed metal is also high. Thus, it is believed that this concentration and the equilibrium concentration of point defects at temperatures close to the melting point are of the same order of magnitude. According to van Bueren,[302] after low-temperature deformation, which leads to a change in the linear dimensions of the specimen by only 10%, the concentration of point defects reaches $10^{19}-10^{20}$ cm^{-3}. Apparently, the high concentration of point defects upon low-temperature deformation is responsible for the formation of a cellular structure. In addition, low-temperature deformation is favourable for a decrease in the cell dimensions.[303] Rapid deformation also influences the cell dimensions, *viz*., it causes the formation of extremely small cells.[303, 304] The formation of cellular structures characterised by the disordered arrangement of the adjacent cells and substantial deformations were observed for chromium,[303] iron,[305] copper,[306] tantalum,[307] molybdenum and its alloys [308–312] and for a number of other metals and alloys.[313–316]

Therefore, domains of the crystal lattice are rearranged in the course of plastic deformation. This effect was revealed both for metals and their alloys in wide ranges of temperature, stresses and rates of deformation. The fragment-boundary angles depend on the degree of deformation and can be as large as several tens of degrees. The boundaries are either small-angle walls and networks or grain boundaries of a deformation nature.

Plastic deformation arising under the joint action of high pressure and shear on mixtures of metals leads to a decrease in the dimensions of coherent-scattering regions compared to the analogous regions for individual compounds treated analogously.[317–321] Positron studies of structural defects in metals subjected to high pressure and shear deformations demonstrated that vacancy clusters with sizes of up to 0.5 nm were formed in these specimens. In addition, specimens were intensively saturated with dislocations as the degree of deformation increased.[319]

Therefore, plastic deformation leads to the formation of non-equilibrium point defects and their clusters and to a high density of dislocations. As the degree of deformation increases, a cellular structure is developed followed by fragmentation. In the case of plastic deformation of heterogeneous mixtures, blocks become smaller and interactions at the boundaries of dissimilar blocks occur.

Processes of grinding and formation of layered composites occur more vigorously in planetary ball mills because rapid shear deformations are realised on collisions in such mills. The dynamics of grinding, the microstructure and the sizes of the particles formed depend both on the conditions of mechanical treatment and on the properties of metals as exemplified by copper, nickel, iron and germanium.[320–326]

The process leading to a decrease in the grain size in ball mills involves three steps.[326]

1. Initially, deformation is localised in slip bands consisting of a series of high-density dislocations.

2. When a particular degree of deformation is achieved, annihilation and recombination of these dislocations take place within small-angle grain boundaries separating individual grains. The grain sizes thus obtained are 20–30 nm.

3. The orientation of individual crystalline grains with respect to the adjacent grains becomes totally random.

These stages are typical of deformation processes, which involve metals with BCC lattices and intermetallic compounds and which occur at high rates of deformation.

Eckert *et al*.[327] found that the minimum grain size of nanocrystalline metals (generally, 6–22 nm) is achieved if two competitive process take place, *viz*., substantial plastic deformation caused by mechanical treatment in a ball mill and relaxation of the material. Moreover, it was found that the minimum grain size of metals with FCC lattices is in inverse proportion to the melting point.[328, 329] Fecht *et al*.[328] demonstrated that the average grain sizes of metals with BCC lattices and hexagonal close-packed lattices are decreased to 9 and 13 nm, respectively.

The initial step of the mechanical synthesis in metallic systems involves the formation of layered composite structures accompanied by simultaneous dispersion of the initial components to nanosized grains. The formation of such layered composites results in an increase in the contact area between the initial components. It is known that heterogeneous solid-phase reactions can proceed only at the regions of tight contacts of the reacting phases. At these regions, a layer of the product arises and the further course of the reaction depends on the mechanism of diffusion of the reacting compounds through this layer. Solid-phase compounds are transferred primarily through diffusion whose rate depends on the mobility of lattice defects (their mobility is particularly high at the crystal surface even at low temperature).[330]

Pavlyukhin *et al*.[90] studied the formation of solid solutions in the Fe–Cr system and demonstrated that accelerated diffusion can proceed in binary metallic mixtures upon their mechanical activation in centrifugal planetary mills. Based on the results of Mössbauer spectroscopy, the authors estimated the diffusion coefficient (D) for the system containing spherical particles of radius R under conditions of activation. The determined value $D \simeq 10^{-5}-10^{-7}$ cm^2 s^{-1} is seven orders of magnitude larger than the diffusion coefficient of chromium in iron at 1600 K ($10^{-12}-10^{-14}$ cm^2 s^{-1}). A change in the microstructure of the alloy, which is generally observed in the initial step of mechanical alloying, was ignored in calculations. However, since the thickness of layers changes substantially in the course of mechanical alloying, the radius of the initial species is not the only factor determining the diffusion path.

In the case of plastic deformation of metals, diffusion can be substantially accelerated due to destruction and generation of dislocations [331] along which the rate of diffusion in metals is several orders of magnitude larger than along other directions.[332–339] In addition, it was demonstrated [340–345] that the diffusion coefficient is linearly proportional to the rate of deformation. Therefore, solid-phase dissolution of elements can be substantially accelerated on rapid plastic deformation. If this process is accompanied by the formation of layered composites, mass transfer can be promoted, on the one hand, due to short diffusion distances, and, on the other hand, due to acceleration of diffusion upon rapid plastic deformation.

Clemens [346] found parallels between mechanochemical synthesis and solid-phase transformations in layered film systems. He believed that the role of mechanical activation consists in the formation of a composite from disperse particles of the initial components and promotion of diffuse mixing due to generation of non-equilibrium defects.

Hellstern and Schultz[347] considered phase formation taking into account solid-phase diffusion. In the cited study, mechanical mixing of pure powders of iron and chromium was performed in a ball mill under argon. The authors believed that mechanical treatment afforded a layered microstructure consisting of two elements and the layers became thinner in the course of treatment. Since this system possesses a substantial chemical driving force, which favours diffusion between layers, the process occurs through the mechanism of a solid-phase diffusion reaction. An analogous viewpoint was also followed in a more recent study.[348] In the latter study, it was demonstrated that particles with a typical layered structure were formed in Ni–Zr and Fe–Zr systems at the initial stage of mechanical treatment of initially crystalline powders in a mill. Further mechanical treatment afforded composites consisting of ultrathin layers in which solid-phase diffusion proceeded. Samwer suggested[349,350] that amorphous alloys are formed in the course of solid-phase diffusion and this process occurs at low temperature due to rapid diffusion of one component into another one. As a result of mechanical treatment, particles of the components adopt a 'multilayer-sandwich' form and a negative heat of mixing is the driving force for the process. Koch *et al.*[271] also believed that mechanochemical reactions are accompanied by the formation of ultradisperse composite particles, solid-phase diffusion occurs in these particles and a negative mixing enthalpy is the driving force for diffusion.

Most researchers attributed fast mass transfer in mechanochemical reactions characterised by negative mixing enthalpies to a large contact area and a high rate of solid-phase diffusion at high rates of plastic deformation of metals.

A large number of experimental studies of spontaneous diffusion arising when particles of the initial components (which are in intimate contact) become nanosized, have been carried out in recent years.

In many systems, non-equilibrium solid-phase solubility of one element in another one is readily realised when grains become nanosized. It was found that extremely high diffusion rates are characteristic of highly disperse nanosized particles.[351–353] It was found that copper immediately dissolved in nanosized gold particles at room and lower temperatures.[354] Fast spontaneous alloying afforded the intermetallides $AuSb_2$, InSb and AlSb.[355–357] It was demonstrated that every pair of elements is characterised by its own critical grain (particle) size at which spontaneous alloying starts at room temperature. The critical size of the initial particles increases as the heat of alloy formation increases. In the Au–Cu,[358] Au–Zn[353] and Au–Al[359] systems, the mixing enthalpies are negative and spontaneous alloying takes place even in the case of a rather large critical particle size. In the Au–Ni system, the enthalpy is positive and spontaneous alloying at room temperature occurs only if grains are very small. In the In–Al system, the mixing enthalpy is substantially larger than zero and hence, spontaneous alloying was not achieved (Fig. 5). Phase diagrams for systems consisting of nanosized particles differ substantially from standard diagrams and the solid-phase solubility of one element in another increases essentially (reaches several tens of percent) even if the elements virtually do not form solid solutions.[361] It was assumed that relaxation of lattice distortions, which may be caused by a dissolved atom, proceeds much more readily in nanosized particles than in bulkier particles because the lattice becomes more mobile (Fig. 6).[362,363]

Therefore, mass transfer in layered composite structures containing nanosized grains, which are formed in the first step in metallic systems with negative mixing enthalpies, proceeds through spontaneous diffusion. This diffusion can take place at room temperature because the critical grain size at which it starts depends on the mixing enthalpy, *viz.*, the larger the (negative) mixing enthalpy the larger the appropriate grain size. In systems in which intermetallides with high heats of formation (or, at least, in which the heats of formation of intermetallic compounds are substantially larger than the heats of mixing of solid solutions), these intermetallic compounds are formed first. Examination of

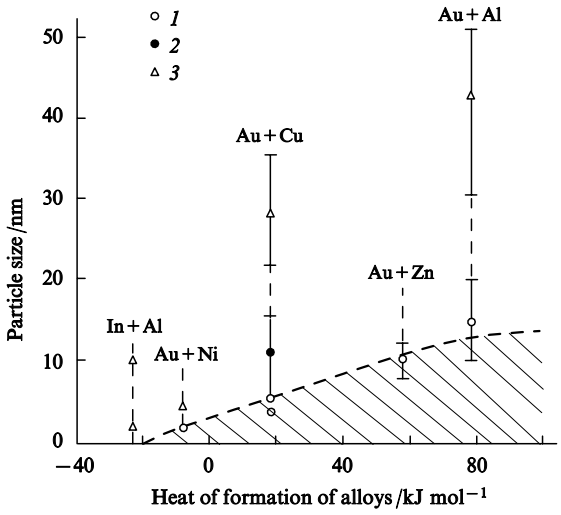

Figure 5. Dependence of the critical sizes of the initial particles on the heat of formation of alloys in different systems at 300 K;[360] (*1*) complete spontaneous alloying at 300 K, (*2*) partial spontaneous alloying, (*3*) alloying does not occur.

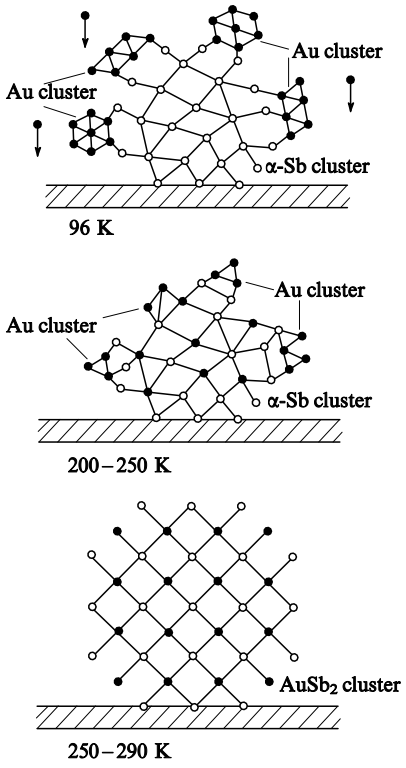

Figure 6. Scheme of spontaneous alloying of gold and antimony particles.

the mechanochemical synthesis of solid solutions demonstrated that in layered composites, intermetallides are actually formed first. In the second step of the mechanochemical synthesis, intermetallides characterised by a high heat of formation and a high content of the alloying element arise in the Ni–Ge, Ni–Al, Ni–Si, Ni–Bi, Ni–Sn, Ni–In, Ni–Ga, Cu–Sn, Cu–In, Cu–Ga and Fe–Sn systems.[111,113,115–119,121–124,126,132,364] X-Ray diffraction data corresponding to the phase formation in the course of the mechanochemical synthesis of solid solutions of bismuth in nickel are shown in Fig. 7. In this system, two intermetallic compounds, *viz.*, NiBi (78.8 mass % Bi) and $NiBi_3$

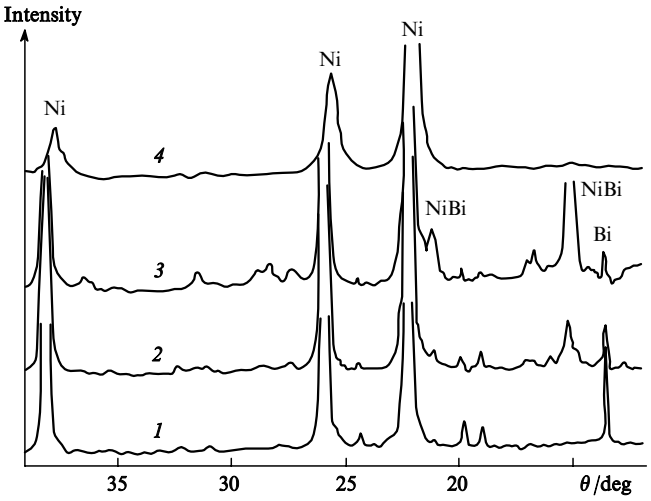

Figure 7. X-Ray diffraction patterns of the products of mechanical alloying of nickel with 10 mass % of bismuth. The activation time (min): (*1*) 1, (*2*) 3, (*3*) 10, (*4*) 90.[126]

(91.44 mass % Bi), exist.[108] The enthalpies of formation of these compounds calculated by the Miedema method[127–129] are approximately -4 kJ mol^{-1} for NiBi and -2 kJ mol^{-1} for $NiBi_3$. In the course of the mechanochemical synthesis of solid solutions in this system, the formation of layered composites is followed by the formation of the intermetallide NiBi (see Fig. 7). It is worthy of note that the above-mentioned phase can be formed under equilibrium conditions only if the bismuth content is 78 mass % and the mixture subjected to mechanical activation contains only 10 mass % of Bi. As the time of activation was increased, the intensities of reflections of the NiBi phase increased (see Fig. 7, curves *2* and *3*), the lattice parameter of nickel remaining the same. The growth of the NiBi phase proceeded until the bismuth was completely consumed. Only further activation of the resulting intermetallide with unconsumed nickel led to a decrease in the intensities of reflections of the intermetallide NiBi, broadening of the diffraction peaks of nickel and their shift to the small-angle region (see Fig. 7, curve *4*), which is indicative of the formation of a solid solution. Analogous changes in the diffraction patterns were observed for other systems. The dynamics of changes in the phase composition of the mixture can be followed using the Fe–Sn system as an example (Fig. 8). Thus, the amount of the intermetallic compound $FeSn_2$ increased and then decreased upon mechanochemical dissolution of $FeSn_2$ in iron to form a solid α-solution of tin in iron. Mechanochemical activation led to a decrease in the grain size of α-Fe to 10–20 nm and the resulting intermetallide $FeSn_2$ also contained nanosized particles (Fig. 8 *b*). It should be noted that the intensive formation of the solid solution α-Fe(Sn) was observed only if the grain sizes of the phases α-Fe and $FeSn_2$ reached 3–8 nm. These values agree well with other data on the mechanochemical synthesis of solid solutions in this system.[122]

Investigations demonstrated that the dynamics of formation of intermediate intermetallic compounds in the second step of the mechanochemical synthesis of solid solutions in metallic systems characterised by negative enthalpies of formation correlates with the enthalpies of formation of equilibrium intermetallic compounds.[365–368]

Comparative studies of mechanochemical synthesis from a mixture of metallic powders and from a mixture of a metal serving as the solvent and intermetallic compounds, whose phase compositions are identical to those of substances which are formed in the intermediate stage of the mechanochemical reaction of the metallic powders, demonstrated that the dynamics of formation of the solid solution is virtually the same in both cases.[369]

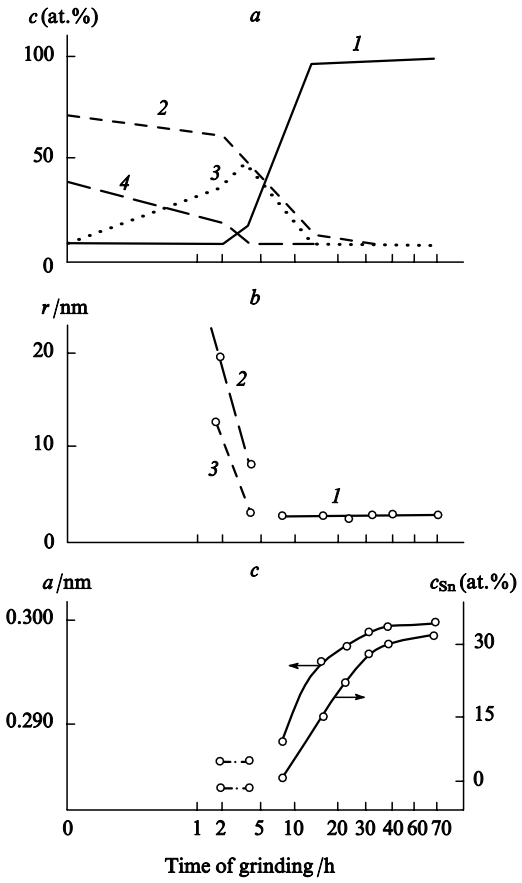

Figure 8. Dependences of the phase composition (*a*), the average size of crystallites (*b*), the lattice parameter of the resulting BCC phase and the concentration of tin (*c*) on the time of grinding in a Pulverizette-5 mill;[123] (*1*) α-Fe(Sn), (*2*) α-Fe, (*3*) $FeSn_2$, (*4*) β-Sn.

Therefore, the synthesis of solid solutions in metallic systems characterised by negative mixing enthalpies may involve the following stages.

1. The formation of layered composite structures with simultaneous dispersion of the initial components to nanosized particles (a sharp increase in the contact area between the initial components).

2. The formation of intermetallic compounds in nanosized layered composites.

3. Dissolution of intermetallic compounds in the metal acting as the solvent to form a solid solution.

Most of researchers assumed that the process of formation of amorphous alloys from metallic powders involves two steps. In the first step, layered composites containing nanosized grains are formed. The formation of an amorphous alloy in the second step proceeds through diffusion in a heated specimen. It is believed that the specimen is heated at the expense of the energy of collision of balls and the temperature increases to hundreds of degrees, but it does remain inadequate to attain crystallisation of an amorphous alloy. This point of view was confirmed by Petzoldt *et al.*[370] The authors observed amorphous interlayers between layers of nickel and niobium by electron microscopy. These interlayers are analogous to those between layers of nickel and zirconium observed by Meng *et al.*[371] in experiments on annealing of sputtered films.

In a number of studies, the formation of intermetallic phases before amorphisation was detected. This fact seems to be quite reliable because amorphous alloys in many systems were prepared by mechanical grinding of intermetallides. The formation of intermetallic compounds involves, most probably, two steps

because intermetallides can arise immediately in layered composite structures.

In layered composite structures, which are formed in metallic systems, spontaneous diffusion of the initial compounds can proceed at room temperature due to the thermodynamic driving force for the process. In analogous layered composites formed in systems characterised by a positive mixing enthalpy, this driving force is absent. It can be suggested that the formation of solid solutions under conditions of mechanochemical activation proceeds, most probably, through quenching from the liquid state because, first, the temperatures of phase transitions, including the solid phase → liquid phase transition, sharply decrease compared to those in a bulky material as the sizes of the initial particles decrease to several nanometers,[372–376] and, second, sharp local increases in temperature and pressure can take place in activators.

Bowden *et al.*[377–379] gained experimental evidence for the existence of local heating and revealed their sites, which arise at the contacts between particles of solid compounds on their mechanical treatment. The authors established that the area of heating sites is, on the average, 10^{-2} cm^2, the time of their existence is 10^{-5}–10^{-3} s and the temperature jumps at the sites of heating can be as large as 800–1000 K and sometimes even larger. According to the hypothesis proposed by Dubnov, Sukhikh and Tomashevich,[380] individual dislocation pairs with antiparallel Burgers vectors in the regions of intensive shear can annihilate with restoration of a perfect structure and liberation of the dislocation energy, which, according to estimates made by Cottrell,[381] is ~1 eV. Since the atomic forces act only through very short distances, the region of energy liberation is limited to a radius of about one interatomic distance. In this case, local heating is $\sim 10^3$ K.

Avvakumov[321] also concluded that local sites of heating limited by the melting point of particles being treated can arise in the mechanochemical processes.

Urakaev and Avvakumov[382] calculated the thickness of the molten zone. They believed that this value can reach 5×10^{-7} cm if the size of rubbing particles is $\sim 10^{-4}$ cm and the sites of local heating (taking into account the possibility of melting of particles treated) are limited by their melting points. Kopylov *et al.*[383] suggested that intermetallic compounds can be synthesised in a planetary mill due to short-period local heating on friction of the particles. Based on the results of calculations, it was concluded[384–387] that high local temperatures and pressures can arise in the course of mechanochemical activation.

Dannik[388] solved the problem of collision of two particles taking into account frictional forces on interaction of rigid bodies. Based on Dannik's equations, Urakaev[389] calculated the temperatures at the contacts between inorganic particles rubbed in drums of centrifugal planetary mills. The maximum local temperature at the rubbing surface of the particles is ~1030 K and the lifetime of this temperature is 10^{-9} s.

Ermakov, Yurchikov and Barinov[390] also considered the problem of the effect of the temperature on processes occurring in mechanochemical activators. They believed that substantially heated and rapidly cooled local regions (hot spots) can appear at the surface of the particles. The lifetime of hot regions of sizes 1–10 nm 'heated' almost to the melting point is 10^{-3}–10^{-6} s. The authors also estimated the rate of cooling of these regions at 10^6–10^9 deg s^{-1}. The appearance of hot sites has also been observed in more recent studies. For example, the intermetallide SnTe was synthesised at room temperature by repeated cold pressing of granulated tin and powdered tellurium.[391] The system consisted of the initial elements until the pressing action provided an adequate mechanical energy. Hot regions of diameter 1–2 nm were observed at the metal surface with particle sizes of 10–15 nm. In these regions, 0.25%–0.35% of the total deformation energy was accumulated after 30-fold pressing (1.25 g of a mixture of Sn and Te, 343 MPa).

Eckert *et al.*[392] also calculated the high local temperatures arising at contact sites. The experiments were carried out using a 'Pulverizette-5' planetary ball mill (Frich, Germany) at the ball rates of 2.5, 3.6 and 4.7 m s^{-1}. The temperatures at the contact sites, which are shifted with respect to each other due to deformation caused by colliding balls, were calculated as described by Schwarz and Koch.[393] The following values were obtained: at the rate of 2.5 m s^{-1}, $\Delta T = 80$ deg; at the rate of 3.6 m s^{-1}, $\Delta T = 167$ deg; at the rate of 4.7 m s^{-1}, $\Delta T = 287$ deg. The authors believed that the average temperature of the drum, which was 50, 80 and 120 °C, respectively, in the case of the above-mentioned rates, should be added to the temperature developed due to collisions.

Zalkin[394] concluded that molten zones can arise at temperatures, which are substantially lower than the melting point of a low-melting element; in this case, diffusion has virtually no effect on the onset of melting.

Experimental investigations aimed at direct measurement of local temperatures are many fewer in number compared to studies in which local temperatures were calculated. Changes in the temperature are sometimes determined on vibrating mills with the use of thermocouples. A thermocouple is attached to the outer wall of the drum and the temperature can be monitored throughout the process. In this case, it is assumed that the temperatures of the drum, balls and the material under treatment are equal or differ insignificantly. Kimura *et al.*[395] used this procedure for the measurements of the temperature of the drum wall depending on the rate of the stirrer of the attritor and demonstrated that the temperature of powders reached 573 K.

The AGO planetary ball mills are characterised by very high energies and the input power of ~1 W per cm^3 of the drum volume.[396] The temperature of balls can amount to 500 °C increasing very rapidly.[397] Hence, not only dispersion of the initial components, but also substantial temperature jumps, which arise upon contact of the material treated with balls, should be taken into account in mechanochemical synthesis in high-energy mills.

Analysis of the published data demonstrated that mechanochemical synthesis of non-equilibrium solid solutions in metallic systems characterised by a positive mixing enthalpy involves two steps. In the first step, layered composite structures containing nanosized grains of the initial components are formed. In the second step, solid solutions arise. The second step can proceed through quenching of the liquid phase in which, apparently, mixing of the components occurs. The liquid phase is formed both due to a sharp decrease in the temperature of phase transition to the liquid state when grains become nanosized and due to local temperature jumps in the contact region at the instant grinding particles collide.

In the case of metallic systems with a positive mixing enthalpy, it seems reasonable to speak about mechanical alloying rather than about the mechanochemical synthesis of non-equilibrium solid solutions. Unfortunately, the term 'mechanical alloying' is assigned in the literature both to systems in which chemical reactions proceed and to systems in which components are only mixed.

The formation of intermetallic compounds upon liquid-phase contact interaction in metallic systems, which are characterised by a negative mixing enthalpy and which contain a low-melting component, should also be taken into account. The presence of layered composites in metallic systems containing nanosized grains in which the melting temperature is sharply decreased with simultaneous existence of rather high temperature jumps at sites of contacts with grinding particles can ensure contact melting of the components and their chemical reaction in the liquid phase.

Presently, there is no agreement regarding the nature of mechanochemical synthesis, *viz.*, the question of whether it is a solid-phase process or it proceeds in the liquid phase remains open. A large number of calculations and experimental studies available in the literature indicate that substantial temperature jumps can occur in activators. However, the direct mechanochemical synthesis from components with high melting temperatures and the fact that mechanochemical synthesis can be performed on

Bridgman anvils and in low-energy ball mills in which high temperatures are difficult to attain provide evidence in favour of the solid-phase nature of the processes.

In the present review, various opinions as to the mechanisms of processes occurring in mechanochemical synthesis in metallic systems are surveyed. It should be noted that most researchers consider the preparation of amorphous alloys and supersaturated solid solutions by the mechanochemical method as the process of disordering of equilibrium phases.

Abstract. Chemical modification and blending of polymers in an extruder reactor are discussed. Relationships between the parameters affecting the reaction kinetics, *viz*., mixing time, duration of a chemical reaction and the residence time of the system in the extruder reactor, and the structure of the materials produced are analysed. The mechanisms of (i) grafting of low-molecular-mass compounds onto polymers; (ii) reactions between terminal groups of different polymers and (iii) transesterification and interchange reactions are considered. The factors affecting the mechanism of dynamic vulcanisation and the properties of thermoplastic elastomers are identified. Solid-phase reactions of polysaccharides in an extruder are discussed. The priority aspects of studies on the chemical modification and blending of polymers are noted. The bibliography includes 90 references.

I. Introduction

Polymeric composites are currently widely used and actively studied. Particular interest has been shown in multicomponent polymer blends and alloys. The creation of such polymeric materials entails the possibility of combining attractive qualities of each component of the polymer blend in the end product.[1–3] Useful properties of polymer blends are affected by such characteristics as the nature of the dispersed and dispersion phases, the volume ratio of the phases, the sizes and size distributions of the particles of the dispersed phase, and interfacial adhesion.

Much attention is paid by investigators to the processes of preparation of materials by blending components in which chemical reactions proceed.[4,5] Such processes are called 'reactive blending' or 'reactive extrusion'. Only a few polymers are thermodynamically compatible and form blends with homogeneous morphology at a molecular level. The majority of polymers exhibit limited compatibility or are incompatible and their blends possess heterogeneous morphologies.

Reactive blending extends the possibilities of controlling the phase structures of multicomponent polymeric materials. Not only does the technology for reactive blending of polymers open new ways for the employment of polymeric products already available but also permits the creation of blends, the preparation of which by other methods has been economically unfavourable. Application of methods of organic chemistry and reactive blending allows preparation of diverse modified polymers and polymer blends based on a a small number of industrially produced polymers.[4]

II. Characteristic features of reactive blending processes

1. Blending condition

Blending of polymers is an intricate physicochemical process, which proceeds under the action of mechanical and temperature fields. If blending of polymers is accompanied by chemical reactions, their rates are determined by the character of blending, temperature gradients and by diffusion of the reagents and products. These characteristics can be controlled if reactive blending is carried out in extruder reactors.

Currently, continuous extruder reactors (Fig. 1) are available. Extrusion is used for the preparation of products or semifinished items of desired shape by forcing polymer melts through an exit (a shape-forming orifice).[6–8] Extrusion processing of plastics is effected by using mainly single-screw and twin-screw extruders. Technologies with employment of extruder reactors combine the processes that are usually separated, *e.g*., blending, chemical reactions and moulding. Here, new problems arise associated with, *e.g*., changes in the viscosity during the reaction or heat removal. Some lines of attacking such problems, as applied to polymerisation reactions, have been considered.[5,9] It was found that in the case of chemically reacting systems twin-screw extruders are preferable to single-screw extruders owing to more efficient mixing and heat removal. However, the complexity of chemical and physical processes proceeding in an extruder reactor hampers the choice of the moulding parameters and equipment.

This requires experimental and theoretical studies on the evolution of the structure and properties of polymers during the preparation of materials using extruder reactors.[10–13] However, experimental investigation of the polymer structure is a complicated multiparameter problem. On the other hand, only a few

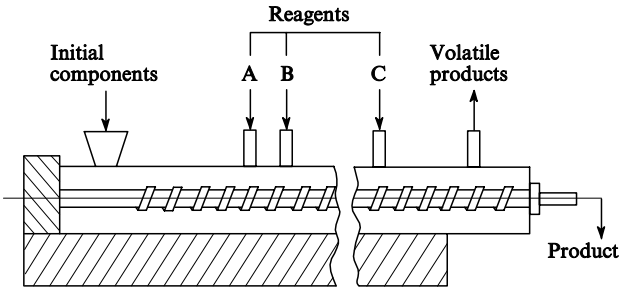

Figure 1. A scheme of an extruder reactor.

theories which allow qualitative description of the changes in the polymer structures after completion of the chemical reactions in the system have been developed.[14–16] This can be illustrated as follows. If a reaction proceeds in the melt, the reaction rate can be strongly affected by diffusion. Changes in the blend composition during the reaction can in turn affect the diffusion processes. Therefore, a theory is required which describes the evolution of the structure of a polymer blend taking into account the mutual influence of the chemical reaction and diffusion.[17]

Changes in the structure of a model heterogeneous blend, in which the copolymer AB is an intermediate of a polymeranalogous reaction A → B have been considered.[18] It was shown that diffusional mixing has a pronounced effect on the reaction kinetics. This effect manifests itself if the characteristic time of the chemical reaction,

$$\tau_r = \frac{1}{k},$$

(k is the rate constant of the chemical reaction) is shorter than, or comparable with, the mixing time τ_m. The mixing can be considered efficient if

$$\tau_m < \tau_r. \qquad (1)$$

This condition holds well for the alcoholysis of poly(ethylene-*co*-vinyl acetate) with aliphatic alcohols (octan-1-ol, 2-ethylhexan-1-ol, 3-phenylpropan-1-ol) in the bulk and in solution (dodecan-1-ol) with dibutyltin dilaurate as catalyst.[19] The bulk reaction was carried out in a Haake Rheochord mixer (Germany).

It was shown [19] that the reaction in solution and in the bulk follows the same mechanism, which is independent of the nature of the alcohol. The equilibrium constants of the reactions in solution and in the bulk were equal. The reaction rates were of the second order with respect to the concentrations of reagents. The viscosities of the systems in solution and in the bulk differed by five orders of magnitude. Based on the results of analysis of the kinetic data, it was suggested that (i) the reaction rate is substantially lower than the diffusion rate and (ii) mechanical mixing is necessary only for the homogenisation of the reaction system in the initial stage of the reaction (once this is achieved, mixing is of no significance during the reaction).

However, the differences between the limiting degrees of conversion have not been discussed.[19] From the plots reported in this study it follows that the limiting degree of conversion in the bulk at 180 °C is ~ 65% while that in solution at 170 °C is ~ 90%. This is most likely due to the change in the viscosity of the reaction system.

Usually, the viscosity of the medium increases during the reaction, thus hampering homogenisation of the reaction system and leading to the formation of structurally inhomogeneous material. Changes in the viscosity during the ionic and radical polymerisation reactions have been analysed [9, 20] and a theoretical approach to quantitative estimation of these changes has been considered.

During the reaction, the system can become heterogeneous and the reaction kinetics can in turn change. The kinetics of the chemical reactions in homogeneous and heterogeneous polymer melts have been analysed taking the esterification reaction between 1-naphthylacetic acid (NAA) and a random ethylene/ethyl acrylate/glycidyl methacrylate (E–EA–GMA) terpolymer as an example.[21] Being initially homogeneous, the system NAA–E–EA–GMA became heterogeneous upon addition of an inert polymer, *viz*., polystyrene (PS). Polystyrene and E–EA–GMA are immiscible, whereas NAA can be mixed with both polymers in the concentration and temperature ranges studied. It was shown that the mechanisms of these reactions are identical and that the rate of NAA diffusion is much higher than the reaction rates in both systems.

Thus, preparation of materials with homogeneous distribution of submicroscopic particles of the dispersed phase requires that the condition (1) be met.

2. Effect of the residence time of a system in an extruder reactor

The reaction in an extruder reactor goes to completion if

$$\tau_r \ll \tau_f, \qquad (2)$$

where τ_f is the mean residence time of the reaction system in the extruder reactor (hereafter, the residence time). This time depends on the ratio of the extruder length, l, to the longitudinal component of the flow rate, V,

$$\tau_f = \frac{l}{V}. \qquad (3)$$

Generally, the residence time is determined by some distribution function.[22] The distribution functions, f(τ), for a ZSK-30 co-rotating twin-screw extruder (Werner and Pfleiderer, Germany; screw length-to-diameter ratio, $l/d = 42$) are shown in Fig. 2*a*. Proceeding to the dimensionless time

$$\theta = \frac{\tau}{\tau_f},$$

where τ is the current residence time of the reaction system in the extruder reactor, gives the residence time distribution function, f(θ), shown in Fig. 2*b*. As can be seen, the f(θ) curves are shifted to a short-time domain when the feed rate Q and screw speed N increase, *i.e*., τ_f shortens and the f(θ) curves match one another. It is believed that the mechanical mixing intensity does not vary much upon varying Q and N at a constant Q/N ratio. On the other hand, the residence time distribution function, which characterises macromixing, changes. The ratio between the convection mass transfer in a flow and free molecule diffusion is characterised by the Peclet number (criterion), Pe (Ref. 24)

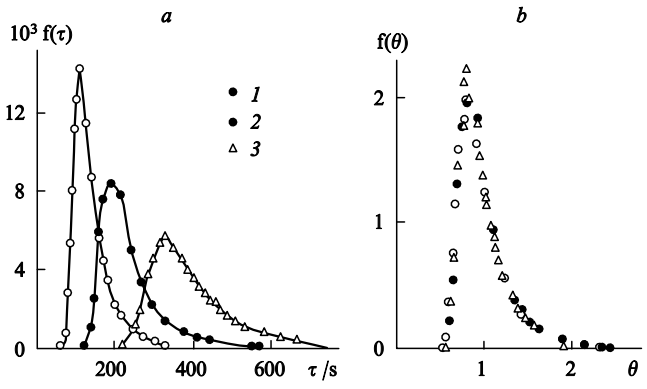

Figure 2. Residence time distribution function in dimensional (*a*) and dimensionless form (*b*) as a function of the feed rate Q and screw speed N at a constant Q/N value of 1/43 kg min h^{-1} rev^{-1};
(*1*) Q = 5.6 kg h^{-1}, N = 240 rev min^{-1}; (*2*) Q = 3.5 kg h^{-1}, N = 150 rev min^{-1}; (*3*) Q = 2.1 kg h^{-1}, N = 90 rev min^{-1}.[24]

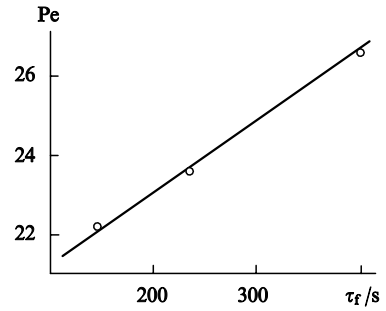

Figure 3. Dependence of the Peclet number on the residence time.

$$\mathrm{Pe} = \frac{Vl}{D},$$

where D is the diffusion coefficient. The dependence of the Peclet number on τ_f is shown in Fig. 3. As can be seen, the Pe number increases as τ_f increases. This plot was constructed using the results obtained by Sun *et al.*[23] Unfortunately, they reported no numerical data for the calculation of the Peclet numbers. At small Pe values, free molecule diffusion predominates, while convection mass transfer is predominant at large Pe values. Hence, the contribution of the convection mass transfer increases with lengthening of the residence time τ_f, (*i.e.*, with a decrease in the feed rate Q and screw speed N).

The residence time was found to be the main parameter which controls the degree of grafting (q) of, *e.g.*, GMA onto polypropylene (PP). As Q and N decrease, τ_f and q (Fig. 4) increase. On the other hand, the degree of grafting decreases with increase in the energy supplied per unit mass of the reacting system U (Fig. 5).

Thus, the degree of grafting is mainly determined by the mixing mechanism rather than energy expenditure.

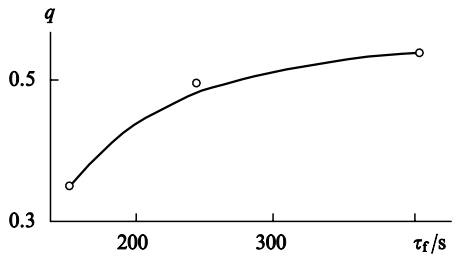

Figure 4. Dependence of the degree of grafting of GMA onto PP (q) on the residence time at $l/d = 42$, $Q/N = 1/43$ kg min h^{-1} rev^{-1}.

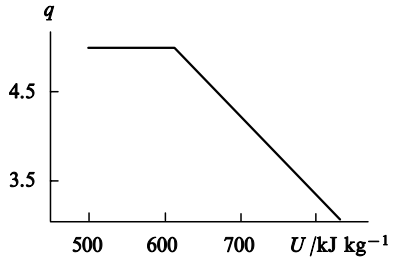

Figure 5. Dependence of the degree of grafting on the energy supplied per unit mass of the reaction system at $Q/N = 1/43$ kg min h^{-1} rev^{-1} (see Ref. 24).

III. Grafting of low-molecular-mass compounds onto polymers

1. Grafting onto polypropylene

Modification of polymers is carried out for compatibilisation of polymer blends. This is achieved by using block and graft copolymers.[25] Preparation of diverse polymer blends by reactive blending has been reported.[4] The synthesis of graft copolymers of polyalkenes by reactive extrusion has been reviewed [26] and the mechanisms of grafting and structures of graft copolymers depending on the reaction conditions have been analysed.

Polypropylene is one of the intensively studied polymers. Grafting of GMA onto PP proceeds by a radical mechanism. The limiting degree of grafting increases with increase in the peroxide concentration [23] as well as upon introduction of styrene as the second monomer. In the latter case, $\overline{M}_w$ increases from 220 000 in the absence of styrene to 350 000 in the presence of styrene.

The stage that follows grafting is blending of polymers. Here, reactions of graft polymers with other blend components take place. These reactions result in improvement of interfacial adhesion. Problems arising where two processes, *viz.*, functionalisation and chemical mixing, are carried out in one extrusion step have been considered.[27, 28]

In situ compatibilisation of PP and poly(butylene terephthalate) (PBT) blends (PP : PBT = 70 : 30) was carried out by one-step reactive extrusion in a ZSK-30 co-rotating twin-screw extruder (Werner and Pfleiderer, Germany) ($d = 30$ mm, $l/d = 42$).[27] Possible screw configurations are schematically represented in Fig. 6.[28] The extruder is divided into two functional zones: grafting of GMA onto PP is carried out in the first part of the extruder and the reaction between the GMA-*g*-PP and the carboxy group of the PBT is carried out in the second part of the extruder.

It was found that changes in the compatibility of the PP – PBT blend are accompanied by changes in its morphology. In the mechanical blend of the initial components, the particle size of the dispersed phase (PBT) was larger than in the blend of grafted PP and PBT. In the latter case, the interfacial adhesion was also improved.

The plot of the residence time distribution function in the reaction of PP with PBT [27] is similar to that considered above (see Fig. 2 *a*). As the feed rate Q and screw speed N increase, the residence time distribution function curve is shifted to the short-

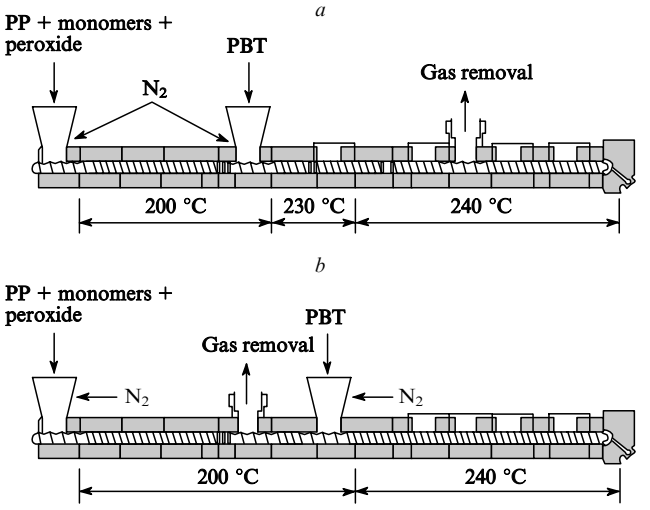

Figure 6. Examples of screw configurations for combining the modification of PP and its blending with PBT.[28]

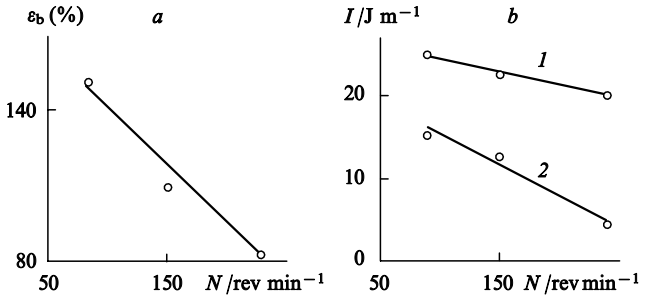

Figure 7. Dependence of the elongation at break (*a*) and impact strength (*b*) on the screw speed at $Q/N = 1/30$ kg min h^{-1} rev^{-1} (see Ref. 27). Temperature: (*1*) 0 and (*2*) 720 °C.

time domain. In dimensionless coordinates, the plots of these functions match one another (see Fig. 2*b*).[24] The elongation at break and the impact strength depend on the residence time of the system in the extruder. With a decrease in Q and N, the residence time lengthens and, correspondingly, the elongation at break (ε_b) and the impact strength (I) increase (Fig. 7).

The effects of the chemical nature and concentration of compounds subject to grafting onto PP, the concentration of the initiator (peroxide) and some other parameters on PP modification have been studied.[28] Among the three compounds studied, namely, acrylic acid (AA), maleic anhydride (MA) and GMA, the last-named compound was found to be the most efficient for the modification of PP–PBT blends. After optimisation of the reaction conditions, the elongation at break and impact strength of the modified PP–PBT blend (PP : PBT = 70 : 30) increased 15- to 20-fold as compared with the corresponding parameters for the mechanical blend. Further increase in the PBT concentration leads to a decrease in the elongation at break and impact strength of the modified PP–PBT blend. This is probably due to cross-linking reactions.

Comparison of the properties of the polymer blends prepared by one-step reactive extrusion[27] and by conventional two-step technique showed that the elongations at break and impact strengths of the blends prepared by the former method are higher.[8]

Numerous studies have been concerned with grafting of MA onto PP.[29–34] It was shown[29] that if the reaction was carried out with 2,5-dimethyl-2,5-bis(*tert*-butylperoxy)hexane as the initiator, the dependence of the degree of grafting on the MA concentration passes through a maximum. This is due to the fact that the PP–MA system becomes a two-phase system with an increase in the MA concentration and, hence, the effective concentrations of the MA and peroxide decrease. In this case, the grafting reaction was carried out in a batch mixer at 215–220 °C at a rotor speed of 64 rev min^{-1} over a period of 15 min. If grafting is carried out in a twin-screw extruder (200 °C, $\tau_f = 3$ min, screw speed = 75 rev min^{-1}), the degree of grafting increases; however, intense degradation of the extrudate is observed.

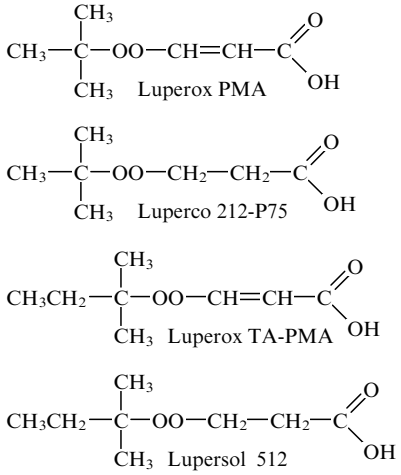
Modification of PP is accompanied by its degradation. An important problem is to reduce the degree of polymer degradation during the grafting. It was found[23] that introduction of an electron-donor monomer (*e.g.*, styrene) causes an increase in the degree of grafting of MA onto PP and substantially inhibits degradation.

Similar results were obtained by Bettini and Agnelli[30,31] who studied the effect of content of MA and a 46.5% concentrate of 2,5-dimethyl-2,5-bis(*tert*-butylperoxy)hexane in $CaCO_3$, the rotor speed and duration of the reaction on the degree of grafting of MA onto PP and on changes in the molecular mass (MM). Blending was carried out in a System 90 torque rheometer (Haake, Germany) equipped with a Rheomix 600 mixer. It was found that an increase in the peroxide concentration leads to an increase in the degree of grafting and to a decrease in the MM. The dependence of the degree of grafting on the MA concentration passes through a maximum, the position of which is determined by the rotor speed and duration of the reaction. Degradation of PP is a complex function of the MA concentration: at high MA concentration, the melt flow index (MFI) decreases, *i.e.*, the degradation of PP is retarded.

Grafting of MA onto PP of different stereoregularity in melt and in solution in the presence of dicumyl peroxide has been compared.[32–34] Similarly to the reactions discussed above, the dependence of the degree of grafting on the MA and peroxide concentrations was also found to pass through an extremum. The degree of grafting in the melt was higher than that in solution (with xylene and decalin as solvents). The maximum degree of grafting onto atactic PP was found to be higher than onto isotactic PP. However, the modified atactic PP was more compositionally heterogeneous.

Different types of peroxides were used as radical initiators of the grafting reactions. Naturally, the question arises: how does the chemical nature of the peroxide affect the grafting kinetics?

A number of functional peroxides (peroxy esters) has been studied.[35] The structures of functional nonsymmetric peroxides and the corresponding trade names are shown below.



Blending of PP and peroxides was carried out in a Rheochord 90 counter-rotating, twin-screw extruder (Haake, Germany). The screw speed was 15 rev min^{-1}, which corresponded to a residence time of ~ 7 min. The reactions were carried out in a N_2 atmosphere. It was assumed that the residence time is sufficient for the peroxides to decompose completely.

The degree of grafting of a carboxylic acid onto PP and degradation of PP has been studied.[35] Grafting reactions carried out in the presence of peroxides which decompose to give methyl radicals were found to be more efficient than those in the presence of peroxides which decompose to give ethyl radicals. The increase in the concentration of polymeric radicals leads to an increase in the degree of grafting and to greater degradation of PP. A similar effect was also observed upon the formation of radicals with double bonds.

Thus, varying the molecular structure of the peroxide allows the degree of grafting of functional groups onto PP to be changed.

Grafting of MA onto PP can also be carried out using not only radical reactions accompanied by intense degradation of PP but also other types of reactions. The degradation upon radical modification of PP can be reduced and the process becomes controllable if a 'specific' functionalisation, *viz.*, the reaction of the terminal vinylidene groups with various compounds, is carried out. Among possible reactions, the Alder ene addition seems to be the most convenient to be performed in an extruder reactor.[36] The reaction rate depends on the acidity and basicity of the ene moiety and enophilic fragments and on the reaction conditions; it increases in the presence of Lewis acids.

Grafting of MA onto PP in the presence of Lewis acids ($SnCl_2$, $RuCl_2$) in an LSM 30.34 co-rotating twin-screw extruder (Leistritz, Germany; $d = 34$ mm; $l/d = 42$) has been studied.[36]

Grafting of MA onto PP using the Alder ene reaction was shown [36] to proceed without considerable degradation of PP. An increase in the reaction temperature and the MA concentration leads to an increase in the degree of grafting, which also increases with improved mixing. For this reaction, $RuCl_2$ was found to be a more efficient catalyst than $SnCl_2$.

2. Grafting onto polyethylene

Polyethylene (PE) is yet another polymer which is widely used in polymer blends. The number of different types of PE is larger than that of PP. Therefore, it is of interest to analyse the effect of grafting onto PE as function of its structure. Grafting of diethyl maleate (DEM) onto high-density polyethylene (HDPE) and linear low-density polyethylene (LLDPE) in two co-rotating twin-screw extruders, namely, a ZSK-30 extruder (Werner and Pfleiderer, Germany) and a ECS-2E25 extruder (Berstorff, Germany) has been studied.[37] Screw configurations, extrusion conditions and the order of introduction of the components into the extruder were varied. The effects of different parameters on the residence time distribution function were analysed. As for PP, the efficiency of grafting was determined by the residence time. When the transport delay time and the mean residence time exceeded certain critical values, the concentration of free radicals decreased owing to secondary reactions (*e.g.*, thermal oxidation, mechanochemical degradation and/or chain branching, *i.e.*, the formation of long branches for LLDPE), which resulted in a decrease in the degree of grafting.

An increase in the degree of grafting with increase in the initiator concentration was independent of the screw configuration and extruder type. The molecular mass distribution (MMD) of the DEM graft LLDPE was virtually the same as that of the initial sample. However, $\bar{M}_w$ of the DEM graft HDPE decreased and the MMD became narrower. Hence, the degree of grafting onto PE is determined by the residence time of the system in the extruder while the MMD is determined by the type of the PE.

Rosales *et al.*[37] also studied the influence of chemical nature of the peroxide by comparing the effects of a 90% solution of 2,5-dimethyl-2,5-bis(*tert*-butylperoxy)hexane and dicumyl peroxide. The second initiator was found to be less efficient.

A study of the effect of the degree of grafting on the rheological and thermal properties has been reported.[38] It was shown that the rheological properties are more sensitive to the changes due to grafting than the structural parameters determined from the measurements of thermal behaviour. An increase in the dynamic viscosity with increase in the degree of grafting was observed at low frequencies of strain sweep. Mention was made that the blends obtained possess enhanced compatibility with polyamides and polyesters.

Compared to the molecular structure characteristics, the rheological properties of the modified LLDPE are also more sensitive to the changes due to reactions at low peroxide concentrations.[39, 40] LLDPE was extruded in the presence of the initiator, 2,5-dimethyl-2,5-bis(*tert*-butylperoxy)hexane, in a co-rotating twin-screw extruder (Leistritz, Germany; $d = 34$ mm, $l/d = 35$). The screw configuration was varied. The peroxide concentration was low in order to prevent cross-linking. In this case, the MMD broadened owing to an increase in the percentage of the high-molecular-mass fraction, which increased with increase in the peroxide concentration.

The proportion and lengths of the side groups were determined by different methods (size-exclusion liquid chromatography, nuclear magnetic resonance, differential scanning calorimetry). It was found that the proportion of unsaturated terminal units in the modified LLDPE diminished. Based on the results obtained, a reaction mechanism was proposed.

The authors established that an increase in the complex viscosity at low frequencies of strain sweep is due to the formation of a small number of long-chain branches. Changes in the molecular parameters of the modified LLDPE affected not only the shear characteristics of the flow but also the flow characteristics in the longitudinal direction. The modified LLDPE had higher viscosity in the longitudinal direction. However, this was accompanied by a decrease in the tensile deformability. Swelling of the extrudate decreased with increase in the peroxide concentration. The efficiency of the LLDPE modification in the extrusion strongly depended on the temperature and quality of mixing.

The influence of extrusion on the cross-linking and degradation of PE has been studied.[41] Cross-linking of HDPE in the presence of a peroxide, 1,3-bis(*tert*-butylperoxyisopropyl)benzene (system 1), and mixtures of this peroxide with coagents, *viz.*, trimethylolpropane triacrylate (TMPTA) (system 2) and *para*-benzoquinone (PBQ) (system 3), in the extrusion in a twin-screw extruder ($d = 25$ mm; $l/d = 30$) at 230 °C has been studied.

It was shown that the MFI decreased rapidly as the peroxide concentration increased in system 1, more smoothly in system 2 and showed a slight increase in system 3. The last-named effect was probably due to degradation of HDPE.

Thermal properties of the modified HDPE depend on the peroxide concentration in a complex manner. The melting temperature, T_m, and the crystallisation temperature, T_{cr}, increase with increase in the peroxide concentration. On the other hand, T_m decreases while T_{cr} increases as the concentration of the peroxide–TMPTA initiator increases. Initially, the heat of melting increases and then decreases with increase in the concentration of the initiator.

The effect of the peroxide and TMPTA concentrations on the mechanical properties can be followed from the data listed in Table 1. As can be seen, the impact strength increases by ~ 7-fold as compared to that of the initial HDPE.

Table 1. The effect of the peroxide and TMPTA concentrations on the mechanical properties of cross-linked HDPE.

[Peroxide] [a]	[TMPTA] [a]	MFI /g/10 min	D	I	E	σ_y	ε_b
–	–	4.74	61	148	1290	27.5	600
0.05	–	1.62	62	576	1290	30.0	20
–	0.3	0.95	62	1084	1400	37.5	30

0.02	0.2	0.13	62	1016	1420	38.5	20

Note. The following notations are used here and in Tables 2–5: D is the hardness (arbitrary units), I is the notched Izod impact strength (J m^{-1}), E is the flexural modulus (MPa), σ_y is the yield stress (MPa) and ε_b is the elongation at break (%).

[a] The concentrations of peroxide and TMPTA are given in mass parts per 100 mass parts of HDPE.

3. Grafting onto an ethylene/propylene terpolymer and polylactide

Grafting of MA onto ethylene/propylene/ethylidenenorbornene terpolymer (EPDM, with ethylene and ethylidenenorbornene concentrations of 56 mass % and 5.7 mass %, respectively) in a Rheomix 750 mixer (Haake-Buchler, Germany) at ~ 160 °C with dicumyl peroxide as the initiator has been studied.[42] It was shown that the amount of the gel fraction initially increases up to 4 mass % with an increase in the MA concentration and then decreases. On the other hand, the amount of the gel fraction increases monotonically with increase in the peroxide concentration.

As in the case of polyalkenes, the dependence of the degree of grafting onto EPDM on the MA concentration increases as the MA concentration increases up to 3 mass % and then decreases, thus passing through an extremum. The degree of grafting

increases with increase in the peroxide concentration. The reaction is accompanied by cross-linking and degradation of the terpolymer.

Introduction of an electron donor (*e.g.*, stearamide) into the reaction system inhibits side reactions, *viz.*, cross-linking and degradation. The optimum content of stearamide was found to be $\sim$ 20 mass %.

Grafting of MA onto other types of polymers has also been studied. In particular, a study on the grafting of MA onto polylactide in a co-rotating twin-screw extruder (Baker Perkins, United Kingdom) with 2,5-dimethyl-2,5-bis(*tert*-butylperoxy)-hexane as the initiator has been reported.[43] Polylactide is a biodegradable polymer widely used in medicine. It was shown that the degree of grafting increases with increase in the initiator concentration, while MM decreases (the MFI increases). The ratio of the weight-average molecular mass to the number-average molecular mass, $\bar{M}_w/\bar{M}_n$, remained virtually constant. It was found that even a small amount of the MA graft onto polylactide essentially improves the interfacial adhesion in the polylactide-based blends and composites.

IV. Reactions between terminal groups of polymers

Chain extension in PBT owing to the reactions of the epoxy groups of diglycidyl tetrahydrophthalate with the terminal hydroxy and carboxy groups of PBT has been studied.[44]

The synthesis of high-molecular-mass PBT is a rather complicated problem. Industrially, PBT with an MFI greater than 20 g/10 min can be produced, while the PBT with relatively low MM possesses poor mechanical properties. Therefore, the problem of chain extension is topical. One of the possible ways of solving this problem is to carry out reactions of bifunctional compounds with terminal groups of PBT. Guo and Chan[44] carried out the reaction of epoxy groups with the carboxy and hydroxy groups of PBT in a Rheomix 600 mixer (Haake, Germany). The rotor speed was varied from 30 to 120 rev min^{-1} and the temperature was varied from 230 to 280 °C. As the temperature was raised and the rate of shear increased, the duration of the reaction of the terminal groups of PBT with the epoxy groups decreased owing to an increase in the rate of diffusion of the epoxy groups. The duration of the reaction was found to be $\sim$ 3 min at 260 °C. Therefore, this reaction can be performed in both single-screw and twin-screw extruders.

The results of mechanical and rheological tests of the PBT thus obtained are listed in Table 2. As can be seen, the MFI value decreases rapidly with increase in the concentration of epoxy groups, while the notched Izod impact strength and the elongation at break increase. The PBT thus obtained was found to be more thermally stable.

Table 2. The effect of the concentration of epoxy groups [E] on the mechanical properties of PBT.[41]

[E] (mass %)	σ_b /MPa	ε (%)	σ_{bn} /MPA	I /J m^{-1}	MFI /g/10 min
0	53.7	50.2	88.6	19.9	35.4
0.4	54.4	62.3	91.2	20.2	29.8
0.5	53.9	76.9	91.7	22.9	23.5
0.7	52.3	101.8	93.2	23.2	17.8
0.8	52.6	130.4	89.3	24.1	15.4
0.9	52.3	267.7	93.3	25.7	13.1
1.0	53.5	262.5	92.1	26.3	10.3
1.2	53.0	278.5	92.5	34.4	8.4
1.3	53.0	329.2	93.0	39.2	5.0
1.4	52.9	360.1	92.4	51.9	3.6
1.6	52.1	360.0	92.2	49.5	2.6

Note. The following notations are used: σ_b is the tensile strength and σ_{bn} is the bending strength.

On the other hand, the reaction considered above can be accompanied by cross-linking; the longer the chain the higher the degree of cross-linking. Cross-linking begins as the concentration of epoxy groups exceeds 1.2 mass %; the amount of the gel fraction was 7.97 mass % at an epoxy group concentration of 1.4 mass %.

Compatibilisation of PP and a liquid-crystal copolyester Vectra A900 (LCC) following the reactions between the epoxy groups of poly(ethylene-*co*-GMA) (EGMA) containing 12% GMA with the hydroxy and/or carboxy groups has been studied.[45] It was found that the EGMA graft LCC is formed at the PP – LCC interface and the surface tension decreases. Blending was carried out in a co-rotating twin-screw extruder (d = 30 mm) in the temperature range 265 – 290 °C. The PP – LCC blends thus obtained possessed higher elongations at break and impact strengths. The LCC domains were found to be of smaller size and the crystallinity of the modified PP was lower than that of the blends prepared by conventional (mechanical) technique. The use of ethyltriphenylphosphonium bromide as a catalyst improves the blend compatibility owing to grafting.

A broad class of polymer blends based on polyamides (PA) was obtained.[1] Compatibilisation by the strengthening of the interaction between the blend components is a major way of modification of toughened materials.

Kudva *et al.*[46] studied blends of Nylon-6 with acrylonitrile/butadiene/styrene terpolymer (ABS) and poly(styrene-*co*-acrylonitrile) (SAN) using copolymers of GMA with methyl methacrylate (MMA) as compatibilisators. The GMA molecules contain epoxy groups which can react with the terminal groups of PA, while poly(methyl methacrylate) (PMMA) can be mixed with the SAN phase of ABS at any concentration of acrylonitrile. Blends were prepared in a Killion single-screw extruder (Germany) (d = 25.4 mm; l/d = 30) at 240 °C and a screw speed of 40 rev min^{-1} or in a Baker-Perkins co-rotating twin-screw extruder at 240 °C and a screw speed of 170 rev min^{-1}.

The dependence of the mass-average size of the SAN particles ($\bar{d}_w$) on the GMA concentration in poly(GMA-*co*-MMA) is shown in Fig. 8. The complex shape of the curve describing the variation of $\bar{d}_w$ is due to chemical reactions between the epoxy groups and the amino and carboxy terminal groups of Nylon-6 at the interface (Fig. 9). Owing to the nature of the PA, the interdomain space is filled with loop-like and bridging structures.

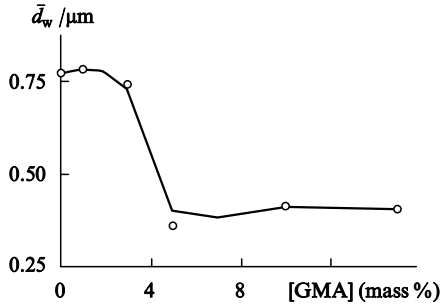

Figure 8. Dependence of the mass-average size of SAN particles on the GMA content in poly(GMA-*co*-MMA).
The blend ratio was Nylon-6 : SAN : poly(GMA-*co*-MMA) = 75 : 20 : 5. The SAN copolymer contained 25% of acrylonitrile. In the absence of poly(GMA-*co*-MMA), a blend with the ratio Nylon-6 : SAN = 75 : 25 was studied.[43]

It was found that the notched Izod impact strength decreases upon introduction of the copolymer containing 3 mass % of GMA (Fig. 10). When the GMA content was 5 mass % and 10 mass %, the impact strength increased. More intense mixing using a twin-screw extruder resulted in a substantial decrease in

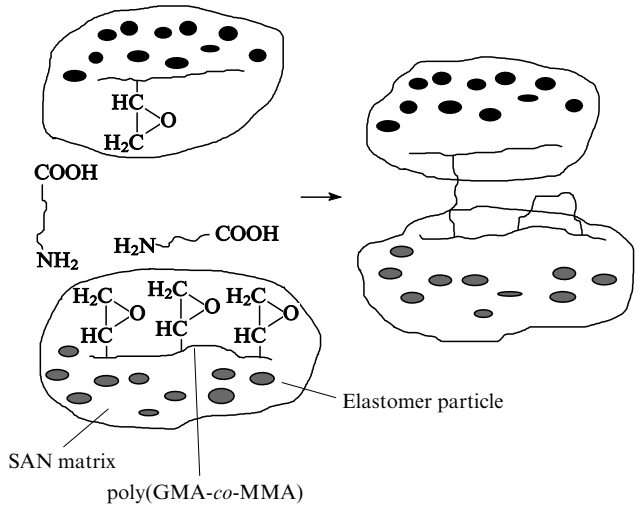

Figure 9. A scheme of the reaction between Nylon-6 and poly(GMA-*co*-MMA) in the Nylon-6 – ABS – poly(GMA-*co*-MMA) blend.[43]

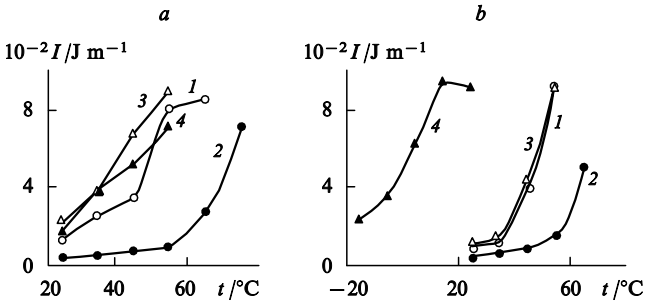

Figure 10. Temperature dependences of the notched Izod impact strength for Nylon-6 – ABS blend (*1*) and ternary blends Nylon-6 : ABS : (GMA – MMA) = 47.5 : 47.5 : 5.0 at a GMA content of 3% (*2*), 5% (*3*) and 10% (*4*) in single-screw (*a*) and twin-screw (*b*) extruders.[43]

the domains of the dispersed phase and in an increase in the impact strength.

V. Transesterification reactions and interchange processes

The kinetics of the transesterification reaction between poly(ethylene terephthalate) (PETP) and co[poly(PETP – *p*-hydroxybenzoate)] copolyesters (PHB – PETP) at blend ratios of 85 : 15, 70 : 30 and 50 : 50 in a Brabender Plasticorder mixer (Germany) at 275, 285 and 293 °C has been studied taking two types of the PHB – PETP copolyesters, with a PHB : PETP ratio of 40 : 60 (P46) and 60 : 40 (P64), as examples.[47] It was shown that the reaction is described by a second-order kinetic equation and the effective rate constant of the reaction depends on the blend ratio and temperature.

Yet another type of reaction, namely, interchange processes between a polyhydroxyether of bisphenol A and a segmented copolyetherester Hytrel, has been studied.[48] The copolyester is a thermoplastic elastomer comprising rigid crystallisable tetramethylene terephthalate blocks and flexible polytetramethylene – ether glycol – terephthalate blocks. Mixing of the components was carried out in a Brabender Plasticorder mixer. The kinetics of the interchange reactions was studied by tracing the torque variations. After mixing for 15 min, the interchange processes are completed to yield mainly branched and cross-linked products. The induction period was independent of the blend ratio and always exceeded 15 min at 240 °C.

Owing to specific interactions, the components of this blend are miscible at any ratios. Because of this, only one glass transition temperature is observed.

VI. Preparation of thermoplastic elastomers by dynamic vulcanisation

Among reactive blending processes in an extruder reactor, dynamic vulcanisation is the most promising for industrial use.[49] Thermoplastic elastomers (TPE), prepared from polymer blends by dynamic vulcanisation, are a specific class of materials which, on the one hand, can be processed in the molten state as thermoplastic polymers and, on the other hand, possess the properties of vulcanised elastomers at operating temperatures. Since they are quite competitive with conventional rubbers in the market, interest in these materials is currently increasing.[50]

The merit of TPE is their ability to be reprocessed. The properties of TPE do not change essentially upon reprocessing. This allows complete recycling and waste utilisation. Creation of polymer blends which can be non-waste processed is an important ecological problem due to the increasing accumulation of plastics waste and environmental protection demands.[51]

The history of the creation of different types of TPE up to the year 1987 has been considered in a comprehensive review by Legge.[52] Technological fundamentals of the preparation of modern types of TPE have been developed by Coran.[49] An *in situ* dynamic vulcanisation technique has been proposed, where vulcanisation of an elastomer proceeds simultaneously with its mixing with a thermoplastic polymer. This allows the preparation of blends with unique morphology characterised by 'dispersion' of the particles of the vulcanised elastomer in a continuous thermoplastic matrix. This technique permits the production of materials with excellent operating characteristics and these materials can be readily non-waste reprocessed.[53]

Polymeric compositions based on 11 different elastomers and 9 thermoplastic polymers have been considered.[49] Combining these elastomers and plastics allowed the preparation of more than 75 types of TPE.

1. The mechanism of dynamic vulcanisation

The properties of TPE depend on many parameters such as blend composition, the nature of vulcanising agents, blending conditions, temperature – time superposition during the formation of network structure of the elastomer, *etc.*

The preparation of TPE with improved mechanical properties requires mixing of dispersions of submicron sizes.[49, 50, 53] In particular, the tensile strength and elongation at break of the PP – EPDM-based blends (PP : EPDM = 40 : 60) increase with the decrease in the domain size (Fig. 11). In this case, mixing is superimposed on the cross-linking reaction which causes changes

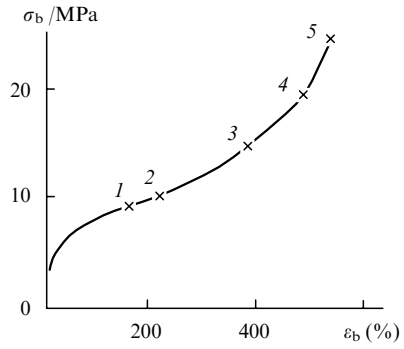

Figure 11. 'Stress – strain' diagrams for PP – EPDM blends (PP : EPDM = 40 : 60) with different domain size of the elastomer phase (× denotes a break).[49]
Number-average domain size /μm: (*1*) 72, (*2*) 39, (*3*) 17, (*4*) 5.4, (*5*) 1 – 1.5.

in the morphology of the elastomer phase, thus resulting in an increase in the viscosity of the medium and hampering the blend homogenisation. Therefore, efficient blending leading to a material with homogeneous submicroscopic distribution of the particles of the dispersed phase requires that the condition (1) be met.

The plots shown in Fig. 12 illustrate the effect of the density of cross-links, v_e, on the tensile strength σ_b and tension set ε_∞ of TPE. As can be seen, σ_b monotonically increases with increasing v_e, whereas ε decreases rapidly even at small v_e values. It is noteworthy that the rigidity of the material varies only slightly in this case.

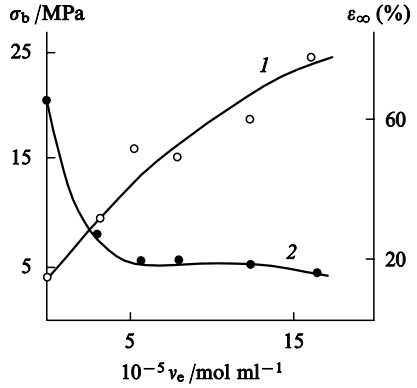

Figure 12. The effect of the density of cross-links v_e on the tensile strength σ_b (*1*) and tension set ε_∞ (*2*).[47]

Polypropylene-based TPE are usually prepared at temperatures above 180 °C. Degradation of TPE, which occurs at this temperature, detracts from the properties of the PP and elastomer phase.[54] If peroxides are used as vulcanising agents, degradation is accompanied by cross-linking. Therefore, the preparation of TPE with optimum properties requires knowledge of the parameters of temperature – time superposition during the formation of a network structure of the elastomer in the blend. Additionally, if the process is performed in the presence of peroxides, one should know the kinetics of (i) degradation and cross-linking of PP and (ii) the formation of interfacial polymer – elastomer links.

Regularities in the cross-linking and degradation of a polyisoprene elastomer SKI-3℗ at 190 °C have been reported.[55] The content of the sol fraction and its MMD was studied as function of the duration of vulcanisation at different concentrations of tetramethylthiuram disulfide (TMTD) and sulfenamide C (SA) used as vulcanising agents. Figure 13 presents typical gel chromatograms of the sol fractions of the SKI-3℗ elastomer cross-linked at different TMTD : SA ratios. After heating the main peak on the chromatogram of the elastomer is shifted towards the low MM region due to the depletion of the rubber fractions with the highest molecular masses. As can be seen, the rates of vulcanisation and degradation depend on the ratio of the components of the vulcanising system. For instance, for the same vulcanisation time of 3.5 min the system with the ratio TMTD : SA = 2 : 0 exhibits a bimodal distribution (Fig. 13 *a*), the system with the ratio TMTD : SA = 1 : 1 exhibits a shoulder (Fig. 13 *b*) while the system with the ratio TMTD : SA = 0 : 2 exhibits a broad unimodal distribution, which also covers the region of the initial molecular masses (Fig. 13 *c*). The existence of the limiting MM value of the sol fraction of the cross-linked elastomer was established [55] and it was found that this value remains virtually the same at any ratio of the vulcanising agents in the system. A similar picture was also observed in the case of prolonged vulcanisation carried out for 14 min (see Fig. 13, curves *3*).

The kinetics and mechanism of degradation of an elastomer – polymer blend can be significantly different. It was shown [56] that the induction period for the oxidation of PP – EPDM blends at

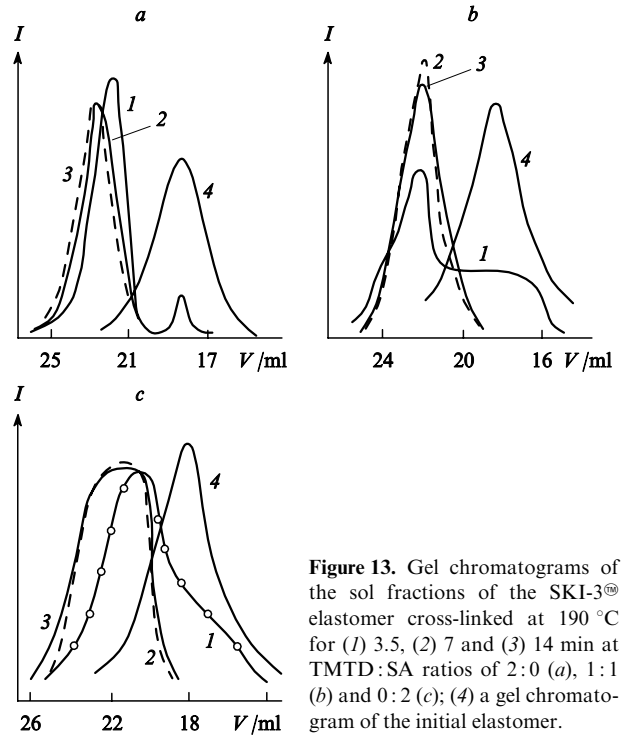

Figure 13. Gel chromatograms of the sol fractions of the SKI-3℗ elastomer cross-linked at 190 °C for (*1*) 3.5, (*2*) 7 and (*3*) 14 min at TMTD : SA ratios of 2 : 0 (*a*), 1 : 1 (*b*) and 0 : 2 (*c*); (*4*) a gel chromatogram of the initial elastomer.

110 °C is longer than that for the oxidation of the initial PP and can even be longer than the induction period for the oxidation of EPDM at a particular blend ratio. Upon introduction of vulcanising agents the oxidation resistance of the material increases and depends on the type of the vulcanising system of the rubber. Degradation products changes the blend morphology, thus changing the properties of TPE. This effect was particularly pronounced in the case of dynamic vulcanisation of ternary PE – PP – EPDM blends in the presence of peroxide as the vulcanising agent.[57,58] It was found that the tensile strength σ_b and modulus of elasticity E decrease with increase in the peroxide concentration in the blends with high PP content, whereas in the blends with high EPDM content these parameters increase under the same conditions. George *et al.*[59] showed that the cross-linking reaction dominates over degradation in the PP – nitrile elastomer blend in the presence of dicumyl peroxide.

The effect of the chemical nature and concentration of the vulcanising system on the properties of an EPDM – HDPE blend was studied.[60] The vulcanising systems investigated exhibited different induction periods and rates of EPDM vulcanisation. The sulfur-containing vulcanising system exhibited the shortest induction period and the highest rate of vulcanisation, whereas the resin-based system exhibited the longest induction period and the lowest rate of vulcanisation.

Studies on the kinetics of vulcanisation of systems with different concentrations of vulcanising agents showed that the rates of vulcanisation remain virtually constant irrespective of the chemical nature of the vulcanising system as the concentrations of these agents is doubled or halved. On the other hand, the induction period lengthens as the concentration of the sulfur-based vulcanising system decreases and remains the same if the resin-based system is used.

It was shown [61] that the dependence of the density of cross-links in the ethylene/propylene/vinylnorbornene terpolymer on the peroxide concentration passes through an extremum.

Vulcanised EPDM samples exhibited the greatest tensile strength in the presence of the sulfur-containing system, while the largest elongation at break and tension set were attained if the resin-based system was used as the vulcanising agent. The tensile strength increased to some extent with increasing concentration of activators (the sulfur-containing system). A decrease in the con-

centration of the vulcanising agents caused some deterioration of the stress–strain properties and an increase in the elongation at break and tension set. Mechanical properties of the vulcanisates remained virtually unchanged in the presence of the resin-based system.

For TPE samples, the concentration of vulcanising agents had almost no effect on the rebound elasticity and hardness. The strain–strength properties of TPE improved with the increase in the concentration of the sulfur-containing system and deteriorated as the concentration of the resin-based system increased. A decrease in the concentration of the vulcanising agents caused a decrease in the tensile strength, while the elongation at break and tension set at break increased.

The effect of the chemical nature of the vulcanising system on the physical properties of the TPE based on the EPDM–PP blends can be followed from the data listed in Table 3.[62] As can be seen, TPE prepared with the use of the phenolic system exhibit better characteristics (especially, swelling in oil and tension set at compression).

Table 3. The effect of the chemical nature of the vulcanising system on the properties of TPE based on SKEPT℗–PP blends [EPDM : PP = 60 : 40 (mass %)].[62]

Property	Vulcanising agent		
	sulfur-containing system	dimethylol-alkylphenol	peroxide
D (arbitrary units)	43	44	39
σ_b /MPA	24.3	25.6	15.9
$\sigma_{\varepsilon = 100\%}$ /MPa	8.00	9.72	8.07
ε_b (%)	530	350	450
H (%)	194	109	225
ε'_∞ (%)	43	24	32

Note. The following notations are used: D is the Shore hardness; $\sigma_{\varepsilon = 100\%}$ is the stress at 100% elongation; H is the swelling in oil and ε'_∞ is the tension set upon compression (22 h, 100 °C).

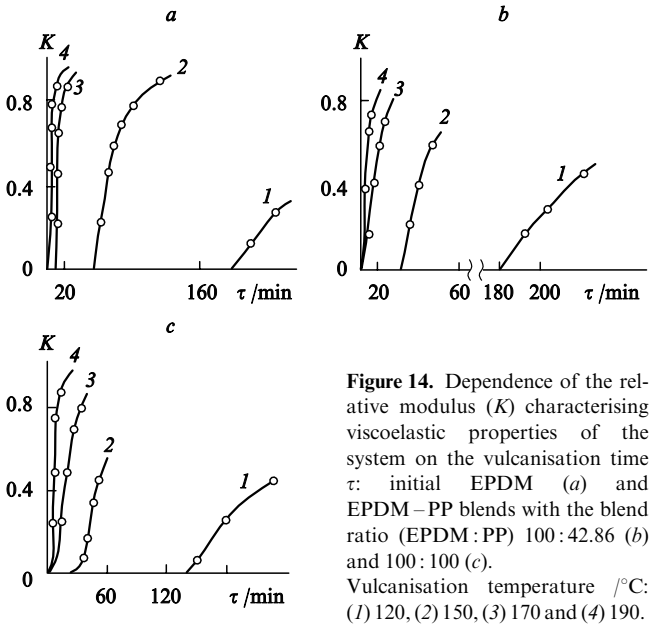

Figure 14. Dependence of the relative modulus (K) characterising viscoelastic properties of the system on the vulcanisation time τ: initial EPDM (*a*) and EPDM–PP blends with the blend ratio (EPDM : PP) 100 : 42.86 (*b*) and 100 : 100 (*c*).
Vulcanisation temperature /°C: (*1*) 120, (*2*) 150, (*3*) 170 and (*4*) 190.

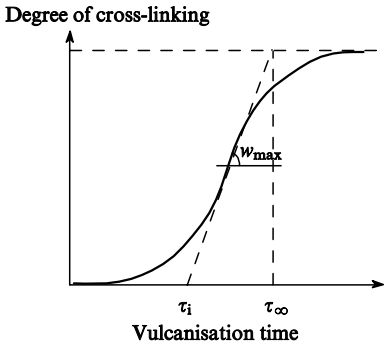

Figure 15. A schematic representation of the vulcanisation curve.

Does the thermoplastic polymer affect the kinetics of vulcanisation of the elastomer? Sengupta and Konar[63] studied this problem taking the vulcanisation of EPDM–PP blends in the presence of a sulfur-containing vulcanisation accelerator in the temperature range from 120 to 190 °C as an example. The blend ratio was varied from EPDM : PP = 100 : 0 to EPDM : PP = 100 : 100. Analysis of the vulcanisation curves revealed three time intervals corresponding to the main stages of vulcanisation (Fig. 14), *viz*., the induction period of the vulcanisation, the network formation period and the reversion period, respectively. The effective activation energy of vulcanisation varies only slightly, being equal to 8.85 kcal mol^{-1} for the initial elastomer and lying between 7.11 and 11.17 kcal mol^{-1} for the EPDM–PP blends. On the other hand, the induction period and the rate constant of the vulcanisation change.

Figure 15 presents a general pattern of a vulcanisation curve. In the second stage of vulcanisation, the degree of cross-linking, q, can be to a first approximation written as the following linear relation:[64]

$$q = w_{max}(\tau - \tau_i), \tag{4}$$

where w_{max} is the maximum vulcanising rate, τ is the vulcanising time and τ_i is the induction period. Preparation of a material with homogeneous submicroscopic distribution of the particles of the dispersed phase requires that the following condition [see the inequality (1) above] be met

$$\tau_m < \tau_i . \tag{5}$$

The time taken to reach the limiting degree of cross-linking (τ_∞) can be determined from the relation (4)

$$\tau_\infty = \tau_i + \frac{q_\infty}{w_{max}}, \tag{6}$$

where q_∞ is the limiting degree of cross-linking.

As to degradation, it has no pronounced effect on the material structure if

$$\tau_f < \tau_d , \tag{7}$$

where τ_d is the induction period of degradation.

The limiting degree of cross-linking should be reached during the time τ_f, therefore

$$\tau_\infty \ll \tau_f . \tag{8}$$

Based on the inequalities (5)–(8), a criterion for the choice of optimum temperature–time superposition during dynamic vulcanisation can be written as follows:

$$\tau_m \leqslant \tau_i \leqslant \tau_\infty \ll \tau_f < \tau_d . \tag{9}$$

The vulcanising agents and temperature-time superposition during the formation of TPE are chosen taking into account relations (9) and the criteria (10a)–(10c)

$$\tau_i \geqslant \frac{R^2}{6D}, \tag{10a}$$

$$w_{max} \geqslant \frac{1}{l/V - \tau_i} \quad (10b)$$

or

$$w_{max} \geqslant \frac{1}{\tau_d - \tau_i}, \quad (10c)$$

where R is the radius of the extruder and D is the effective diffusion coefficient.[64] These conditions hold if the vulcanising agents are introduced into the initial elastomer prior to blending.

The problem of the order in which the blend components are fed into the extruder reactor is also topical. For instance, by varying the order of the introduction of carbon black in TPE one can change the resistivity of the end product from 3.7×10^{13} to 2.5 Ω cm.

The knowledge of the order in which the components are fed into the extruder reactor and employment of the criteria (10a)–(10c) allowed the development of one-step dynamic vulcanisation.[65]

2. Structure and properties of thermoplastic elastomers

Thermoplastic elastomers represent two-phase systems in which cross-linked elastomer particles of size ~1 to 2 μm are uniformly distributed in the polymer matrix.[49, 50, 53]

Dynamic vulcanisation has been carried out in either a Brabender mixer or a Berstorff twin-screw extruder.[65] The temperature-time superposition as well as the type and order of feeding the blend components into the extruder were chosen with account taken of the criteria for the formation of TPE [relationships (10a)–(10c)]. Table 4 lists the results of mechanical and rheological tests of the TPE obtained upon varying the blend ratio. As can be seen, the rigidity and tension set of the TPE increase with the increase in the PP content, *i.e.*, the elastomeric properties of the TPE diminish. On the other hand, the rheological properties of the TPE are improved (the MFI increases). As the oil content increases, the rheological characteristics are also improved, while the strength characteristics deteriorate. Similar results have also been reported by Coran.[49]

Table 4. Effect of the TPE composition on their mechanical and rheological properties.

TPE composition			E_0 /MPa	E_{100} /MPa	σ_b /MPa	ε_b (%)	MFI[a]	D	ε_∞ (%)
[PP] (vol.%)	[EPDM] (vol.%)	M							
40	60	100	67	4.5	5.7	270	20.2	86	20
35	65	100	55	3.8	5.9	345	17.5	80	15
30	70	100	42	3.6	6.2	380	11.1	69	7
25	75	100	36	3.4	7.8	452	2.3	65	5
30	70	20	58	4.4	12.8	685	0.8	80	16
30	70	30	52	4.2	9.7	500	4.3	72	9
30	70	40	47	3.9	8.2	446	6.2	69	7

Note. The following notations are used: M is the oil content (in mass parts per 100 mass parts of the elastomer), E_0 is the initial modulus of elasticity, E_{100} is the modulus of elasticity at 100% elongation, D is the Shore hardness (in arbitrary units) and ε_∞ is the tension set.
[a] In g/10 min.

3. Deformation of thermoplastic elastomers

Deformation mechanisms of TPE have been poorly studied as yet.[66] It is unclear so far why the mechanical properties of TPE at room temperature are determined by the properties of the dispersed phase rather than of the matrix.[67, 68]

Figure 16 presents the stress–tensile strain diagrams of TPE in the coordinates $\sigma-\varepsilon$ at a tensile strain rate of 2.4×10^{-4} s^{-1} and different temperatures.[66] Similar patterns of the stress–tensile strain diagrams were also observed for other tensile strain rates. No 'neck' formation was observed in all cases. At $\varepsilon > 3\%$, the $\sigma-\varepsilon$ diagrams are well linearised in the coordinates $\sigma-(\lambda-\lambda^{-2})$, where $\lambda = 1 + \varepsilon$ (Fig. 16 *b*). At small elongations ($\varepsilon < 3\%$), a rapid increase in σ (a jump) was observed. The results obtained can be described by the following equation

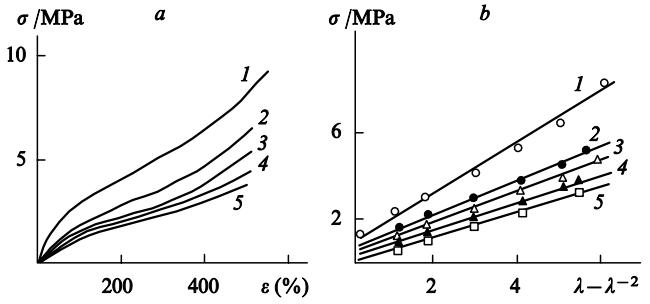

Figure 16. Stress–tensile strain diagrams $\sigma-\varepsilon$ (*a*) and $\sigma-(\lambda-\lambda^{-2})$ (*b*). The λ values at a tensile strain rate of 2.4×10^{-4} s^{-1} are given for 20 (*1*), 50 (*2*), 75 (*3*), 100 (*4*) and 125 °C (*5*).

$$\sigma = \sigma_0 + G(\lambda-\lambda^{-2}), \quad (11)$$

where σ_0 is the jump magnitude and G is the modulus determined from the slope of the straight line.

Thus, the overall stress is determined by the sum of two contributions, *viz.*, the stress which rapidly increases with the tensile strain and reaches the σ_0 value and the stress which linearly depends on $\lambda-\lambda^{-2}$. It was found that the jump magnitude, σ_0, decreases linearly with the increase in the temperature and is independent of the tensile strain rate (Fig. 17). At $T \to 145$ °C, $\sigma_0 \to 0$. This temperature corresponds to the onset of the melting of PP. Therefore, it was assumed that σ_0 is determined by the tensile strain of PP. The modulus G increases as the tensile strain rate increases and decreases with the increase in temperature.†

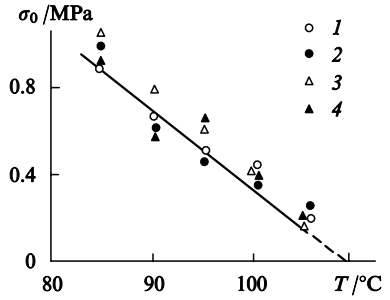

Figure 17. Temperature dependences of the σ_0 jump at tensile strain rates of 2.4×10^{-4} (*1*), 2.4×10^{-3} (*2*), 2.4×10^{-2} (*3*) and 9.5×10^{-2} s^{-1} (*4*).

The dependences of the tensile strength σ_b and elongation at break ε_b on the tensile strain rate $\dot{\varepsilon}$ and temperature are shown in Fig. 18. As can be seen, ε_b is temperature independent. As $\dot{\varepsilon}$ increases, the elongation at break decreases rapidly and then varies only slightly. The tensile strength, σ_b, is a linear function of $\log\dot{\varepsilon}$. The straight lines obtained for different temperatures are parallel to one another. The slope of the straight lines $\sigma_b - \log\dot{\varepsilon}$ is very small, which means that σ_b depends only slightly on the tensile strain rate.

Based on the results obtained, a structural model and a deformation mechanism were proposed for TPE.[66] At high PP

† Similar results for other types of TPE were recently obtained by S I Volfson, R R Grabdrashitov and K S Minsker *Russ. Polym. News* **5** (3) 1 (2000).

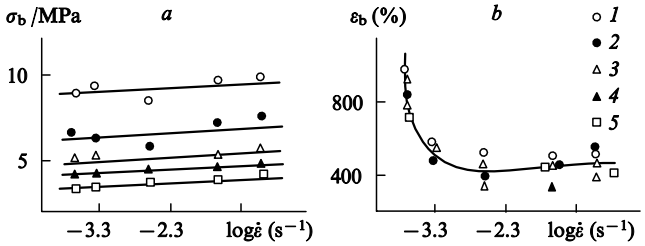

Figure 18. Dependences of the tensile strain (*a*) and elongation at break (*b*) on $\log\dot{\varepsilon}$ at 20 (*1*), 50 (*2*), 75 (*3*), 100 (*4*) and 125 °C (*5*).

content in the blend, the cross-linked EPDM domains are linked by the PP chains; at high EPDM content, they are linked by the elastomer chains. The space between the EPDM domains and the links is filled with oil and PP spherolites (Fig. 19). Initially, only the PP matrix undergoes deformation, thus being responsible for the initial jump, σ_0. In further stages, deformation of the PP matrix occurs simultaneously with that of the dispersed EPDM phase.

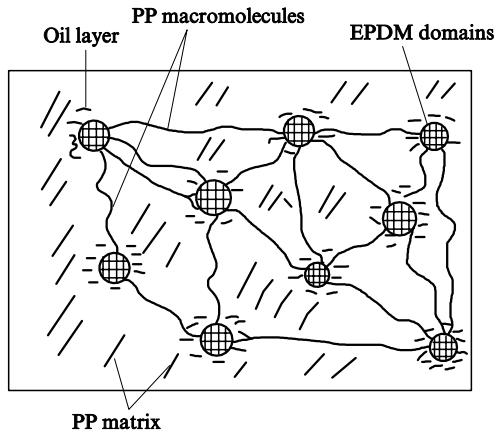

Figure 19. A scheme of the TPE structure.

4. Processing of thermoplastic elastomers

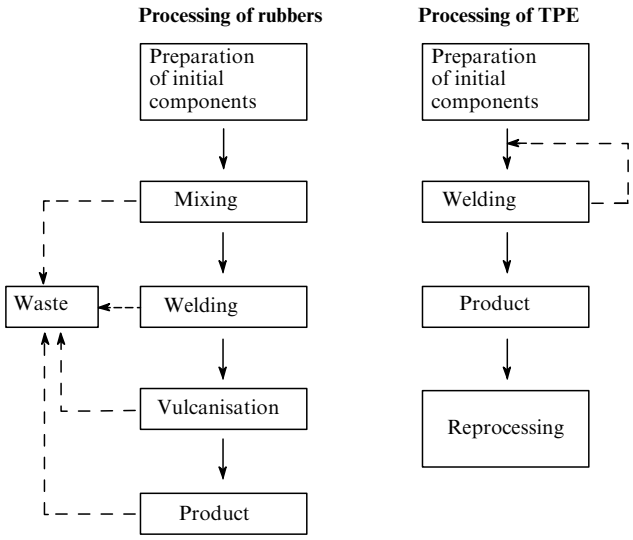
The processability of TPE depends on their rheological properties. Chung *et al.* showed [69] that in the molten state thermoplastic elastomers behave like the melts of filled polymers or rubber-modified plastics.

The properties of TPE allow their processing in the same manner as thermoplastic polymers, *i.e.*, by compression moulding, blow moulding, extrusion welding, calendering and thermoforming. Comparison of the production processes designed for rubbers and TPE (Scheme 1) reveals the major advantages of TPE, namely, easy processing, the possibility of re-moulding, multiple waste recycling, *etc*.

In the case of TPE, the process parameters are determined by the composition of the TPE and preparation conditions. The structure of the TPE specimens obtained by injection moulding has been studied [70] as a function of the radii of the specimens. It was found that the surface layers are highly oriented. A decrease in the process temperature leads to the formation of a disordered smectic structure in several TPE specimens and to a change in the EPDM : PP ratio in the layers owing to the orientation of the PP phase.

Yet another advantage of TPE as compared to the initial component (PP) is an increase in the highest operating temperature. It was shown [71] that at 280 °C the thermo-oxidative stabilities of the blends of PP with rubbers of different nature are higher and the mass losses are ~5 to 20 times smaller than those

Scheme 1



of the virgin PP (Fig. 20). Thermal stability of the polymer blends is independent of the blend ratio and is not determined by the thermal stability of the initial rubber (polyisoprene rubber SKI-3™, butadiene–nitrile rubber SKN-40™ or EPDM). It was also found that the thermal stability increases in the order PP–SKN-40™ < PP–SKI-3™ < PP–EPDM and is independent of the degree of vulcanisation of the elastomer.

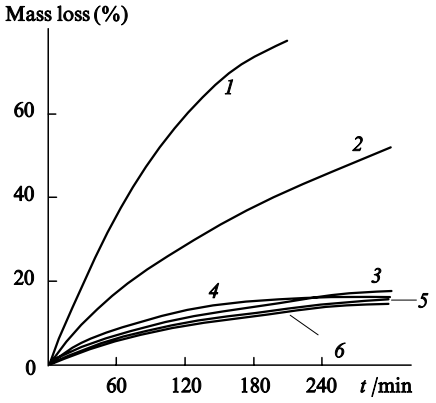


Figure 20. Isothermal TGA curves obtained at 280 °C in air for PP (*1*), EPDM (*4*) and PP–EPDM blends of compositions (PP : EPDM) (mass %) 95 : 5 (*2*), 20 : 80 (*3*), 50 : 50 (*5*) and 80 : 20 (*6*).

Replacement of traditionally used rubbers by TPE will make it possible to reduce the environmental pollution during their processing. These materials seem to be among the most promising materials to be used in the XXIst century and the areas of application of TPE are intensively expanded.

VII. Solid-phase reactions in an extruder reactor

Investigations into the solid-phase reactions in extruder reactors date back to the studies carried out by Academician N S Yenikolopyan at the N N Semenov Institute of Chemical Physics.[72] Solid-phase modification of polymers has an advantage over conventional modification techniques because it is more efficient and ecologically safe and permits substantial reduction of the cost of the end product.

1. Modification of polyalkenes

In studies on the solid-phase modification of isotactic PP and low-density polyethylene (LDPE) in the presence of maleic acid and its derivatives (maleic anhydride and sodium maleate) in an extruder reactor it was found that grafting depended only slightly on the presence of a radical initiator, *viz*., azoisobutyronitrile (AIBN).[73–77] The amount of the graft compound was found to be dependent on the intensity of mechanical treatment and the total mechanical energy supplied. The best result ($\sim$1.5 mass %) was obtained using the extruder reactor equipped with a set of cams which permitted the highest compression and shear stress of the materials. During processing, the particles of the PP phase undergo plastic deformation and breakdown.[78]

Mechanical properties of the solid-phase modified polyalkenes are much the same as those of the initial polymers. The modified polyalkenes exhibit adhesion to aluminium foil, which is more than an order of magnitude higher even at low degree of grafting (0.1 mass % to 0.2 mass %).[79,80] Degradation of the solid-phase modified polyalkenes is reduced as compared to the melt modified polyalkenes.

2. Modification of polysaccharides

The interest in natural polymers (in particular, polysaccharides) is due to the need for rational use of these materials and to the design of new ecologically safe processes. The most abundant natural polysaccharides are cellulose and chitin containing in the shells of crustacean and insects and in mushrooms.

Natural cellulose is widely used in the production of artificial fibres and films and in the textile industry.

Chitin and its deacetylated derivative, chitosan, are of considerable interest because they possess film-forming and fibre-forming properties and are biologically active compounds. Chitin and its derivatives are thought to be promising materials for biotechnological processes that use immobilised enzymes, for the creation of ion-exchange membranes for ultrafiltration and dialysis and for use as sorbents and ion-exchange resins. The complex-forming abilities of these polymers and their derivatives containing ionogenic groups can be used for selective extraction of metals from sea water.

Systematic studies on the solid-phase modification of natural polysaccharides under the joint action of high pressure and shear strain using different types of equipment[81] showed that under such conditions the polymers pass to the plastic flow state, which is accompanied by changes in their morphologies. This leads to a substantial enhancement of the reactivities of the polymers. These conditions have been employed to prepare three most abundant cellulose derivatives (alkali cellulose, carboxymethyl cellulose and cellulose acetate), chitosan (from chitin) and a number of its derivatives.

3. Modification of cellulose

The formation of alkali cellulose under the action of concentrated NaOH solutions on cellulose (mercerisation of cellulose) is one of the main stages of the process of viscose fibre production. Industrially, cellulose sheets are treated with a large excess of 18% aqueous NaOH (usually, the ratio of the volume of the liquid to the mass of cellulose varies from 20 to 40). This ratio is dictated by the necessity of complete and uniform swelling of cellulose. The large amount of waste water substantially detracts from the ecological characteristics of this process.

If mercerisation of cellulose is carried out in an extruder reactor, cellulose sheets are preliminarily milled and then the milled cellulose is treated with alkali solutions at a minimum volume of water. Depending on the initial concentration of alkali, the alkali cellulose thus formed differs in the degree of substitution of hydroxy groups, degree of polymerisation and some other characteristics.

Using the joint effect of shear strain and pressure on a mixture of cellulose with alkali allows the preparation of alkali cellulose with preset characteristics and improved properties, which is due to higher homogeneity of the product. Since in this case the amount of liquid is minimal, the process does not include the stage of removal of excess alkali solution. Here, water consumption reduces by an order of magnitude while alkali consumption reduces threefold as compared to the corresponding parameters of conventional procedures for the modification of cellulose. This to a great extent improves the ecological characteristics of the process.

Carboxymethyl cellulose (CMC) is one of numerous and valuable cellulose derivatives. Water-soluble CMC is widely used in the food, cosmetic and petroleum refining industry and in pharmacy.

Usually, CMC is obtained by treatment of cellulose with monochloroacetic acid (MCAA) in the presence of NaOH in an aqueous or aqueous-organic medium. However, this is accompanied by a side reaction (alkaline hydrolysis of MCAA) which nearly halves the efficiency of the procedure employed.

The ratio of the contributions of these reactions to the overall process can be changed by excluding water or any other dispersion medium from the reaction volume, *i.e*., by carrying out a solid-phase reaction under the conditions of shear strain.[82]

The yield of CMC increases with increase in the initial concentrations of MCAA and alkali in the blend. The degree of substitution varies in parallel and can be as high as 0.94. The efficiency of MCAA increases (up to 60% to 70%, *cf*. 50% for the conventional process); however, it decreases with increase in the MCAA concentration in the initial blend. Finely milled cellulose is much more reactive than coarsely milled cellulose and the CMC obtained from the former possesses a higher degree of substitution and solubility.

Cellulose acetates are used in the manufacture of artificial fibres, film, lacquers and plastics, so production quantities of cellulose acetates are rather large. Usually, acetylation of cellulose is carried out with acetic anhydride as the acetylating agent and with an acid (*e.g*., sulfuric acid) as the catalyst at 35–40 °C over a period of 4 to 6 h. It is known that cellulose acetates with a high degree of substitution cannot be obtained by treatment of cellulose with acetic acid. Strong intermolecular interaction in solid cellulose due to the formation of hydrogen bonds is the main factor precluding the esterification of the hydroxy groups of cellulose by acetic acid.

Figure 21 presents the dependences of the degree of substitution of hydroxy groups on the concentration of H_2SO_4 in the blend in the acetylation of cellulose by different acetylating agents under normal conditions and under the conditions of joint action of high pressure and shear strain. Acetylation by acetic acid under normal conditions results in the formation of cellulose acetates with a low

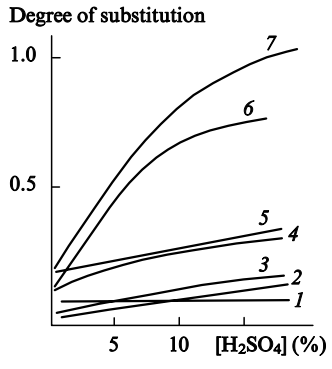

Figure 21. Effect of the concentration of H_2SO_4 on the degree of substitution of the hydroxy groups of cellulose in acetylation under normal conditions (the duration of the acetylation reaction was 4 h, at 20 °C) (*1–3*) and under plastic flow conditions (p = 1 GPa) (*4–7*).
(*1*, *5*) Cellulose : CH_3COOH = 1 : 3, (*2*, *7*) cellulose : CH_3COOH (glacial) = 1 : 3, (*3*, *6*) cellulose : $(CH_3CO)_2O$ = 1 : 1.5, (*4*) cellulose : : CH_3COOH (glacial) = 1 : 1.5.

degree of substitution. Treatment of cellulose with acetic anhydride yields cellulose acetates with higher degrees of substitution.[83]

If the process is performed under the conditions of plastic flow and high pressure, the degrees of substitution for all acetylating agents are higher than those observed under normal conditions.

4. Delignification of wood

Wood is a multicomponent polymeric system. The existing technologies for chemical processing of wood with the aim of cellulose production have some drawbacks. The loss of the wood content in the course of processing is nearly 50% and the amounts of toxic wastes and waste gases are large. Purification of these wastes presents severe difficulties. Modification of the technologies for wood processing to obtain wood pulp in such a way that the yield of the end product be 90% to 95% would allow substantial reduction of toxic waste and waste gases.[84]

A study on the model processes of delignification of wood and mercerisation of cellulose using Bridgman anvils has been reported.[85] The specimens were exposed to the joint action of high pressure and shear strain. It was found that under these conditions the above-mentioned processes proceed without an activation barrier. The activation energy for the delignification of wood by means of alkali cooking was found to be 32 kcal mol^{-1}.[86]

Delignification of wood in an extruder reactor resulted in products with fibrous structures. The reason is that the plastic flow of wood under the joint action of pressure and shear strain occurs mainly along the boundaries of strong, rigid fibres. This results in cleavage of the inter-fibre links and, correspondingly, in degradation of the wood. The fibrous products obtained in the extruder reactor exhibited improved mechanical properties as compared to those of the products prepared by conventional methods.

5. Preparation of chitosan and its derivatives

Chitin is less reactive than cellulose. This is due to specific features of its molecular and supramolecular structure, strong hydrogen bonding and a less active surface.

Chitosan is usually obtained by long-term treatment of chitin with concentrated NaOH solution at elevated temperatures. The existing technology for the production of chitosan is rather inefficient and requires high energy expenditures, the use of a large excess of aqueous alkali solutions and subsequent utilisation of alkali waste and waste water. It was shown [87] that the grinding of chitin and chitosan in a solvent in an extruder reactor leads to partial breakdown of the crystal structure. This appreciably enhances their reactivities towards etherification and leads to some decrease in MM.

Deacetylation of chitin in the temperature range 25 – 200 °C has been studied.[88] An increase in the excess of NaOH favours an increase in both the degree of deacetylation and solubility of the products obtained. The preparation of nearly completely deacetylated product with a solubility of 90% requires only a fivefold molar excess of NaOH, whereas conventional procedures for the preparation of chitosan require at least 10 moles of NaOH per 1 mole of chitin. Both the degree of deacetylation and solubility of the product can be increased by lengthening the residence time of the reaction system in the extruder reactor. Experimental studies showed that raising the temperature from 25 to 200 °C at the mole ratio chitosan : alkali = 1 : 5 results in an increase in the degree of deacetylation from 0.33 to 0.98 and in a substantial decrease in MM.

Conventional procedures for the preparation of chitin and chitosan carboxymethyl ethers are inconvenient since they are time-consuming, proceed as multistage reactions and require large consumption of reagents.[89]

A recently developed solid-phase method [90] for the preparation of these compounds allows improvement of ecological characteristics of the process owing to the absence of solvents and shortening of the reaction time from several hours to several minutes. The reaction was carried out in a Berstorff twin-screw extruder reactor. In the first stage, a mixture of chitin and solid NaOH was extruded at different ratios of the components. Alkali chitosan thus obtained was mixed with an alkylating agent (*e.g.*, MCAA dissolved in isopropyl alcohol or solid sodium monochloroacetate) and again fed into the extruder reactor (stage 2). The residence time in the extruder reactor was 3 to 5 min.

The effect of the reaction conditions on the properties of the reaction products can be followed from the data listed in Table 5. As can be seen, an increase in the concentration of MCAA and alkali leads to an increase in the degree of substitution, which reaches a maximum value of 1.4.

Table 5. Effect of the reaction conditions on the properties of the reaction products.

Specimen number	A	T_{react} /°C		P	$10^{-3} M$ (see note [a])	$x_1 + x_2$	z
		stage 1	stage 2				
1	1 : 4.25 : 2.0	absent	80	48	–	0.90	0.10
2	1 : 2.60 : 2.3	absent	80	20	47	0.40	0.62
3	1 : 4.80 : 2.3	180	120	30	5	0.51	0.32
4	1 : 5.25 : 2.5	100	100	70	82	0.70	0.35
5	1 : 5.25 : 2.5	200	100	68	6	0.68	0.29
6	1 : 8.40 : 2.9	120	120	65	70	1.02	0.25
7	1 : 8.40 : 4.0	80	60	70	90	1.40	0.20
8	1 : 2.60 : 2.3	100	100	46	62	0.65	0.45
9	1 : 4.40 : 4.0	100	100	58	45	0.87	0.27

Note. The following notations are used: A denotes the chitin : NaOH : MCAA mole ratio; P is the solubility in water (in mass %); x_1, x_2 and z are the degrees of substitution as regards the *O*-carboxymethyl, *N*-carboxymethyl and *N*-acetyl groups, respectively. Specimen 1 was obtained from chitosan and specimens 2 – 9 were obtained from chitin. Specimens 4 – 7 were obtained using a 40% solution of MCAA in isopropyl alcohol and specimens 8 and 9 were obtained using solid sodium monochloroacetate as the alkylating agent.

[a] The molecular mass of the soluble fraction of the end product.

The specimen prepared from chitosan in one extrusion step (see Table 5, specimen 1) exhibited a relatively high degree of carboxymethylation (0.9) at smaller consumption of MCAA. The molecular mass decreased dramatically as the temperature increased. This feature is common to solid-phase extrusion-modified polymers.

Solid-phase reactions of chitosan with a higher fatty acid (stearic acid) and with dicarboxylic acids (oxalic, malonic and succinic acids) in a twin-screw extruder have been studied.[82] The residence time of the reaction system in the extruder was 3 to 5 min.

Reaction products of chitosan with higher fatty acids combine the properties of polymeric substances (film-forming, fibre-forming, thickening properties, *etc.*) and surfactants. They can be of interest as amphiphilic materials for the preparation of solid and hydrogel membranes. Modification of chitosan by lipophilic compounds with the aim of enhancement of both the surfactant properties and the ability not only to thicken but also stabilise the food and cosmetic compositions containing oils and lipids is also topical.

The addition of stearic acid to chitosan proceeds mainly by an ionic mechanism. Reactions of chitosan with dicarboxylic acids occur as both the ionic and covalent linking. Studies on the reactions of chitosan with phthalic, succinic and maleic anhydrides showed [89] that these compounds react mainly with the amino groups of chitosan and that the degree of conversion increases with increase in temperature.

Abstract. The results of studies in the field of rigid-rod poly(benzobisazoles) and molecular composites based on them are analysed and generalised. Poly(benzobisazoles) are most promising candidates for high-strength and high-modulus polymeric materials, while the molecular composites based on them can be employed in the synthesis of polymeric materials with a broad spectrum of mechanical properties. The bibliography includes 101 references.

I. Introduction

Rigid-rod polymers began to attract the keen attention of investigators after two main hypotheses had been put forward,[1] namely:

1. Those materials which possess high rigidity manifest the highest deformation strengths. In terms of their moduli of elasticity (E) the polymers, all the macromolecules in which are straightened in the same direction, can be equivalent to steel.

2. The polymers with relatively low densities possess high mechanical characteristics. This suggests that the values of specific moduli of rupture and deformation strengths of the straightened macromolecules can be very high.[2]

These statements have predetermined the increased interest of synthetic chemists in the construction of macromolecules which display maximum thermodynamic rigidities.[3]

High deformation strengths and rigidities of polymers are provided by covalent bonds between the macromolecules which should manifest high levels of straightness and contain predominantly aromatic rings. These properties also determine the thermal stabilities of the polymers.[3,4]

High levels of molecular straightness are more effectively achieved in fibres than in bulk products; therefore, special attention to the design of high-strength fibres for composite materials was given.[3–5]

The first steps in these investigations were aimed predominantly at the preparation of fibres based on aromatic polyamides devoid of non-symmetrical fragments and 'hinge' groups, *e.g.*, poly(*p*-benzamide) and poly(*p*-phenyleneterephthalamide).[6–12]

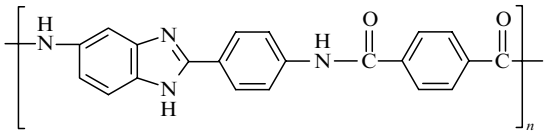
The latter polymer, which is commonly known under the commercial name Kevlar, and its different modifications are used as the basis for the preparation of high-modulus and high-strength polymeric materials.

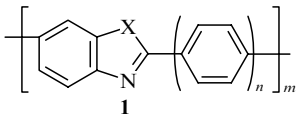
In addition to aromatic polyamides synthesised from carbocyclic diamines and dicarboxylic acids, polyamides based on heterocyclic monomers, *e.g.*, poly[(2-phenylbenzoimidazole-5,4′-diyl)terephthalamide], are of considerable interest.[10]



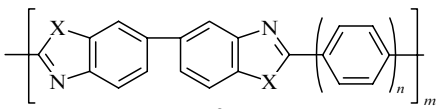
It should be noted however that the presence of amide groups in the macromolecules of these polymers limits their thermal and thermohydrolytic stabilities. Hence, in the second step of investigations in this field, the main attention was focused on rigid-rod polymers which contain only aromatic carbo- and heterocycles,[13–18] the so-called rigid-rod poly(heteroarylenes).

II. Rigid-rod poly(benzazoles)

In the series of rigid-rod polyheteroarylenes, the poly(benzoazoles) (PBAz) **1** and **2** and, particularly, poly(benzobisazoles) (PBBAz) **3a–c** or isomeric structures have been studied in especially great detail.[17–23]

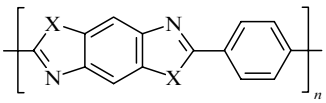


1



2

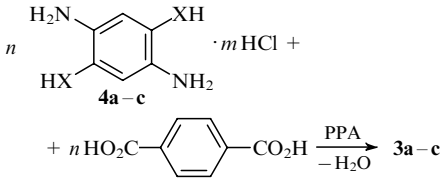
X = NH, NPh, O; n = 1, 2.



3a–c

X = NH (**a**), O (**b**), S (**c**).

High-temperature polycyclocondensation of 1,2,4,5-tetraaminobenzene-,[26] 4,6-diaminodihydroxybenzene-[27] and 2,5-diaminobenzene-1,4-dithiol hydrochlorides[28,29] with terephthalic acid in polyphosphoric acid (PPA)[23–25] is the most popular procedure for the synthesis of the polymers **3a–c**.



4a–c

m = 4, X = NH (**a**); *m* = 2: X = O (**b**), S (**c**).

If the synthesis is performed at polymer concentrations which are high enough for the formation of anisotropic solutions, the resulting polymeric solutions can be used directly for the preparation of high-modulus fibres[29,30] and films.[31]

Because of high oxidisability of the tetrafunctional nucleophilic monomers **4a–c**, these are used in the form of hydrochlorides or other salts rather than as free bases. The process is performed in two steps. In the first step which is carried out at 60–80 °C, the nucleophilic monomers are subjected to dehydrochlorination; in the second step, terephthalic acid is added, the mixture is slowly heated to 190–200 °C and stirred at this temperature for 8–10 h.

In the course of polycyclocondensation, the content of P_2O_5 in PPA decreases, and its properties as the solvent, catalyst and cyclodehydrating agent deteriorate. The addition of P_2O_5 to the solutions results in both acceleration of the polycyclodehydration reaction and an increase in the molecular mass of the target polymers.[32–35] In addition to dicarboxylic acids, the respective acid chlorides are also used for the synthesis of PBBAz in a PPA medium.[36] Since the glass transition temperatures of PBBAz often exceed their decomposition temperatures,[14] the fibres and films are usually prepared directly from the solutions of these polymers.

Poly(benzobisazoles) are soluble in strong acids, *e.g.*, PPA, methanesulfonic acid, chlorosulfonic acid, 100% H_2SO_4 and Lewis acids (*e.g.*, $BiCl_3$ or $SbCl_3$). Recently,[37] it was shown that poly(benzobisthiazole) (PBBT **3c**) forms liquid-crystalline solutions in nitromethane containing $AlCl_3$ or $GaCl_3$. Liquid-crystalline solutions of PBBAz yield high-strength and high-modulus films and fibres. Very often, the deformation strength characteristics of PBBAz fibres even surpass those of Kevlar polyamide fibres which is attributed, in particular, to the greater values of the Kuhn segments in PBBAz (see Table 1 and Fig. 1).[38–45]

Table 1. The ultimate rupture strength (σ), the modulus of elasticity (E), the elongation at rupture (ε) and values of the Kuhn segment (A) of fibres based on rigid-rod polymers.

Polymer	σ/GPa	E/GPa	ε(%)	A/Å	Ref.
 (Nomex)	0.70	17.3	22	47	9
 (Kevlar 29)	2.64	58.9	4	300	38
 (Kevlar 49)[a]	2.64	127.5	2.4	300	39
 (PBBT **3c**)[b]	0.5–2.2	50–76	4.5	1060	40, 41
 (PBBT **3c**)[a]	0.8–2.5 (4.2)	76–265 (< 300)	1.0–1.5	1060	42
 (PBBO **3b**)[a]	2.8–3.4	467		–	34, 44

[a] Heat-treated; [b] freshly formed.

The films with controlled planar orientation based on PBBT and PBBO have specific strengths of 2 GPa and moduli of elasticity of 270 GPa.

Poly(benzobisazoles) are distinguished by extremely high thermal stabilities, *viz.*, under conditions of a dynamic thermogravimetric analysis in air (ΔT = 10 deg min^{-1}), they begin to lose weight at temperatures above 600 °C (Fig. 2).[18] Under conditions of an isothermal analysis in circulating air at 371 °C, their thermal characteristics markedly exceed those of poly(*p*-benzamide), PBBT **3c** being much more resistant to heating than PBBO **3b** (Fig. 3).[46]

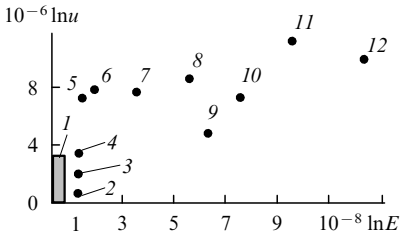


Figure 1. The specific moduli of elasticity (E) and the specific strains (u) of some materials;[45]
(*1*) organic compounds, (*2*) aluminium, (*3*) steel, (*4*) 'E'-glass, (*5*) 'S'-glass, (*6*) Kevlar 29, (*7*) Kevlar 49, (*8*) freshly formed poly(benzobisoxazole) (PBBO **3b**) fibre, (*9*) boron fibre, (*10*) freshly formed poly(benzobisthiazole) (PBBT **3c**) fibre, (*11*) heat-treated PBBT **3c** fibre, (*12*) heat-treated PBBO **3b** fibre.

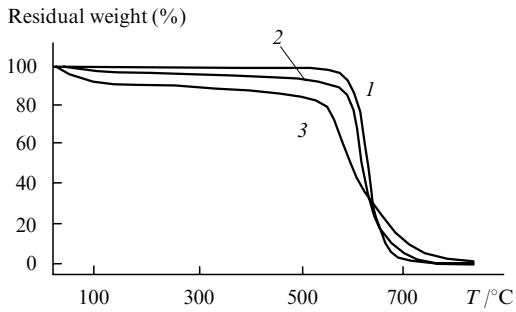

Figure 2. Thermogravimetric analysis of PBBAz in air (the rate of heating is 10 deg min^{-1});[18] (*1*) PBBT, (*2*) PBBO, (*3*) poly(benzobisimidazole) (PBBI **3a**).

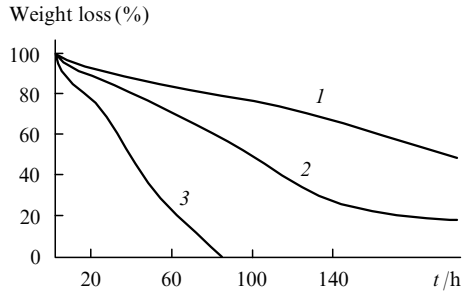

Figure 3. Isothermal ageing in circulating air at 371 °C; (*1*) PBBT **3c**, (*2*) PBBO **3b**, (*3*) poly(benzamide).

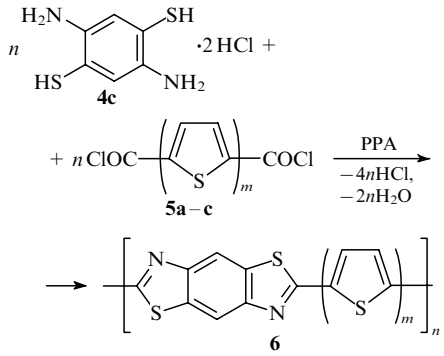
A significant disadvantage of all PBBAz is their low compression strength. Modification of the basic chains of their macromolecules and the introduction of bulky substituents into macromolecules were undertaken in order to enhance this parameter, to improve the solubility of PBBAz and to impart specific properties to these systems.

Thus the *p*-phenylene residues of terephthalic acid in the basic chains of PBBAz were replaced by thiophene-2,5-diyl,[47–49] fluorene-2,7-diyl,[50] adamantanediyl,[51] bicyclo[2.2.2]octanediyl [52,53] and 2,2′-bipyridinediyl [54] fragments. In particular, the reaction of the 2,5-diaminobenzene-1,4-dithiol dihydrochloride (**4c**) with thiophene- (**5a**), bithiophene- (**5b**) and terthiophenedicarbonyl (**5c**) dichlorides afforded PBBT **6** soluble in methanesulfonic and sulfuric acids.[47]



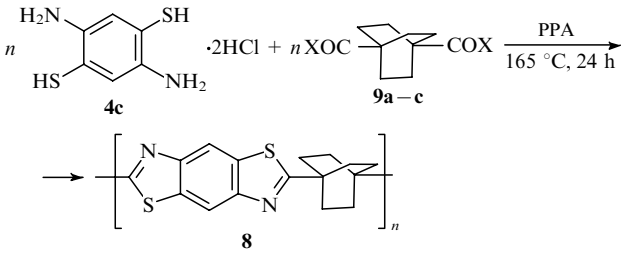
m = 1 (**5a**), 2 (**5b**), 3 (**5c**).

A similar approach was used for the synthesis of a thiophene-containing PBBO.[49] Although PBBT and PBBO are characterised by much lower values of the Kuhn segment than those of the analogous polymers based on terephthalic acid, the majority of their solutions in various acids manifest liquid-crystalline properties.

A certain deviation from a strictly straightened chain was also observed in the case of PBBT **7** prepared from the dihydrochloride **4c** in PPA after partial substitution of fluorene-2,7-dicarbonyl dichloride for the terephthaloyl dichloride (Scheme 1).[50]

Polycyclocondensation at 165 °C results in the formation of high-molecular-weight polymers which are completely soluble in methanesulfonic and sulfuric acids. At higher temperatures, this reaction is accompanied by the formation of insoluble polymers which can be due to the five-membered ring opening in the fluorene fragment.

The colourless PBBT **8** was obtained by the reaction of the dihydrochloride **4c** with bicyclo[2.2.2]octane-1,4-dicarboxylic acid (**9a**), its dimethyl ester (**9b**) or the dichloride (**9c**) in PPA.[52,53]



X = OH (**9a**), OMe (**9b**), Cl (**9c**).

The resulting polymer is soluble in methanesulfonic and sulfuric acids. In terms of thermal stability, the rupture strength and modulus of elasticity, the polymer **8** ranks below PBBT **3** based on terephthalic acid but considerably surpasses it in compression strength.

Poly(benzobisoxazoles) and poly(benzobisthiazoles) containing 2,2′-bipyridinediyl residues were obtained by the reaction of 2,2′-bipyridine-4,4′- or -5,5′-dicarboxylic acids with various mononuclear diaminodiols and diaminodithiols (Scheme 2).[54]

The 4,4′-substituted PBBAz **11** and **12** are soluble in methanesulfonic, sulfuric, trifluoroacetic and formic acids as well as in a mixture of nitromethane with $AlCl_3$. They form strong films. The 5,5′-substituted polybenzazoles **13** and **14** are soluble only in methanesulfonic acid and in a mixture of nitromethane with $AlCl_3$. The solutions of PBBAz **14** form lyotropic mesophases in methanesulfonic acid.

The poly(benzobisazoles) **12a**,**b** and **13a**,**b** manifest extremely high thermal stabilities in inert media and in air (Table 2).

Table 2. Some characteristics of the PBBAz **12** and **13**.[54]

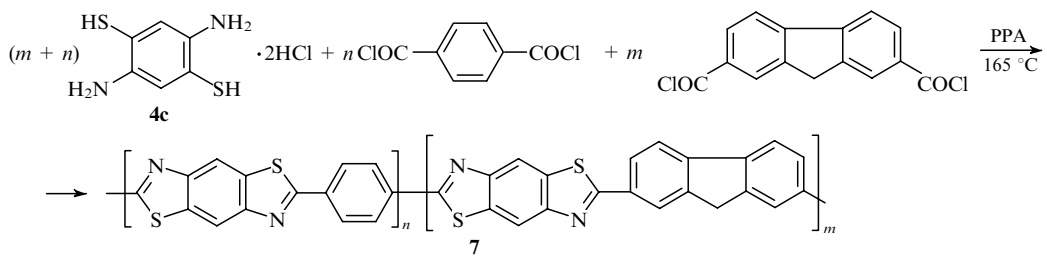
Compound	η_{log} (see [a])	T_{destr} /°C		Yield (%)
		in air	in N_2 atmosphere	
13b	3.1	591	668	82
13c	3.7	537	585	83
12b	1.7	586	648	86
12c	2.1	569	597	87

[a] $MeSO_3H$, 30 °C, c = 0.25 g dl^{-1}.

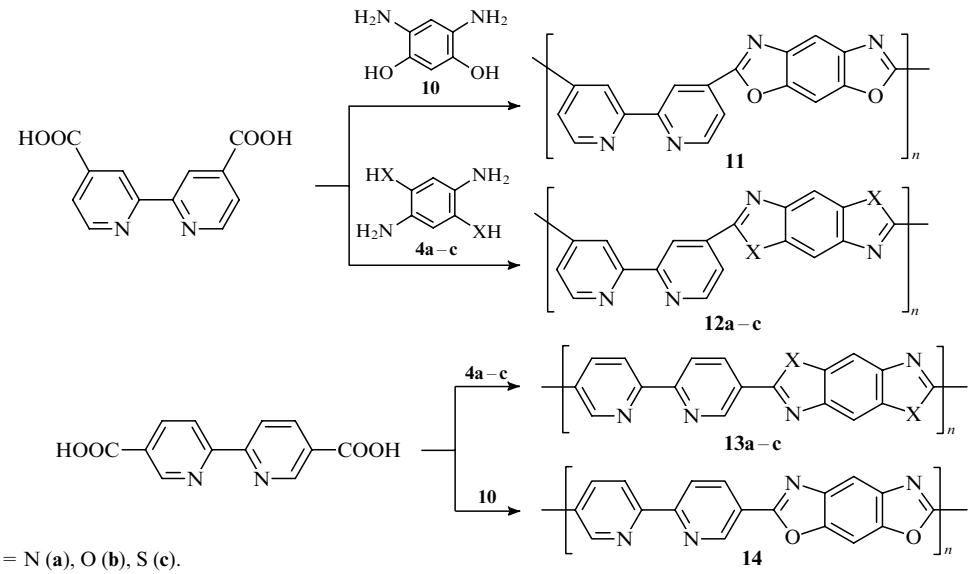
The synthesis of the phenyl-substituted poly[benzo(*N*-phenyl)bisimidazole] **15** [55,56] was carried out in two steps. In the first step, 4,6-dianilinobenzene-1,3-diamine **16** reacted with terephthaloyl dichloride in *N*-methylpyrrolidone (NMP); in the second step, the poly(dianilino)amide **17** formed is cyclodehydrated in PPA to PBBAz **15**.

Poly[benzo(*N*-phenyl)bisimidazole] **15** is one of the first rigid-rod PBBAz. It is soluble in methanesulfonic, sulfuric and formic

Scheme 1



Scheme 2

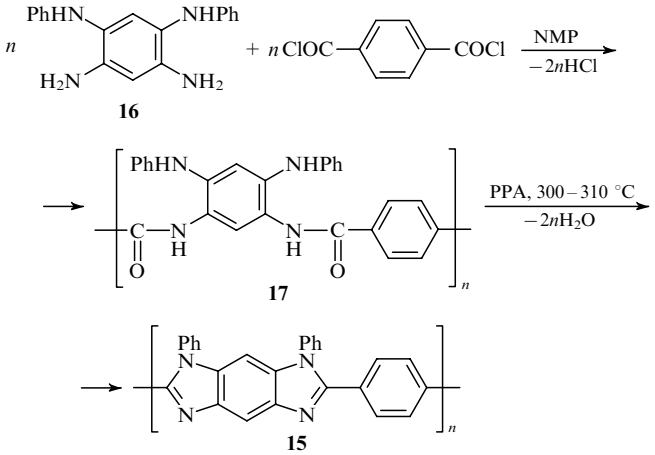


X = N (**a**), O (**b**), S (**c**).

acids as well as in a tetrachloroethane – phenol mixture (3 : 1). This corroborates the hypothesis [57] that the phenyl substituents in the heterocyclic fragment improve the solubility of polyheteroarylenes.[57]

The polymer **15** has a specific viscosity of 9.9 dl g^{-1} and a glass transition temperature (T_g) at 380 °C; at 450 °C, it loses 5% of its mass. Casting of the polymeric solutions was used to obtain films with a rupture strength of 135 MPa.

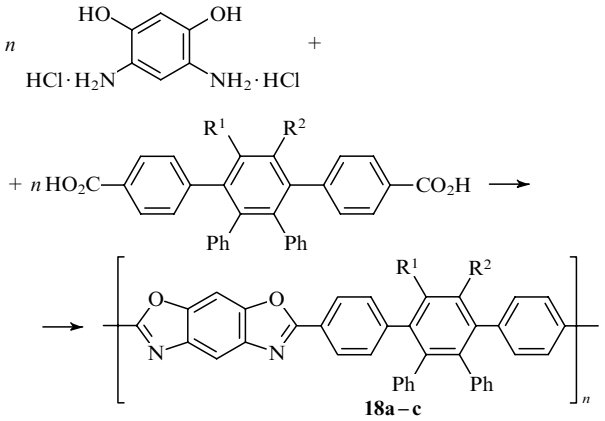
It should be noted that in contrast to other PBBAz, poly-[benzo(*N*-phenyl)bisimidazole] **15** is not formed by direct reaction of 4,6-dianilinobenzene-1,3-diamine **16** with terephthalic acid or its dichloride in PPA.



Much attention has been given to the synthesis of PBBAz with bulky substituents in the carbocyclic fragments of the macromolecules. Such structures are usually synthesised by polycyclocondensation of dicarboxylic acids or their derivatives containing the corresponding substituents.

Wolfe and Arnold [27] were among the first who have synthesised PBBO **18a** – **c** based on di-, tri- and tetraphenyl-*p*-terphenyldicarboxylic acids.

The solubilities of the phenyl-substituted polymers **18a** – **c** exceeds markedly that of the unsubstituted PBBO. In addition to methanesulfonic and chlorosulfonic acids, they are soluble in benzenesulfonic acid and a 7 : 3 mixture of *m*-cresol with dichloroacetic acid as well as in a 9 : 1 mixture of dichloroacetic acid with methanesulfonic acid.



$R^1 = R^2 = H$ (**a**), $R^1 = H$, $R^2 = Ph$ (**b**), $R^1 = R^2 = Ph$ (**c**).

An analysis of the thermal stabilities of PBBO **3b** and the polymer **18b** containing a triphenyl-substituted central fragment revealed that the latter is more resistant to isothermal ageing at 316 °C than PBBO **3b**, but is decomposed more rapidly at 371 °C (Fig. 4) due to the splitting of the phenyl groups.

The poly(benzobisoxazoles), poly(benzobisthiazoles) and poly(benzobisimidazoles) **19a** – **f** containing benzooxazol-2-yl or benzothiazol-2-yl substituents in the phenyl fragment were obtained using the corresponding substituted terephthalic acids **20**.[58 – 61]

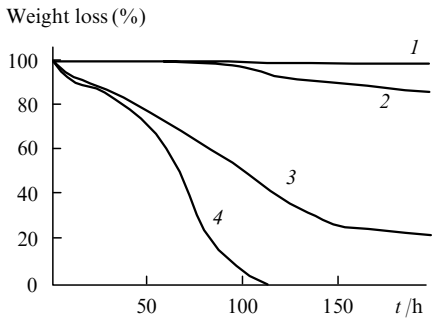


Figure 4. Isothermal ageing of PBBO **3b** and the polymer **18b** powders in circulating air;[27] (*1*) polymer **18b** at 316 °C, (*2*) PBBO **3b** at 316 °C, (*3*) PBBO **3b** at 371 °C, (*4*) polymer **18b** at 371 °C.

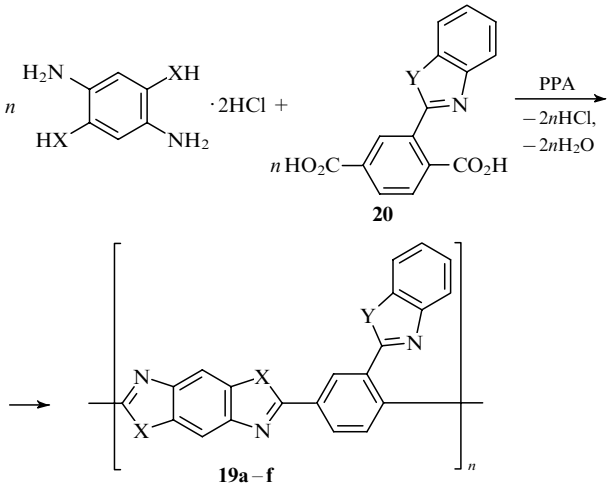


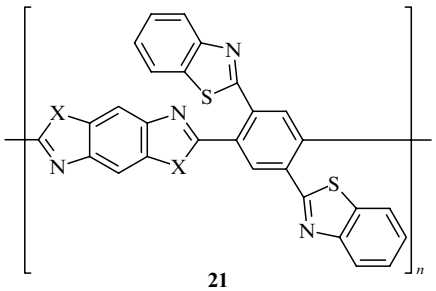
20

19a – f

X = Y = O (**19a**); X = O, Y = S (**19b**); X = Y = S (**19c**);
X = S, Y = O (**19d**); X = NH, Y = O (**19e**); X = NH, Y = S (**19f**).

The PBBAz **19a – f** thus formed were soluble in sulfuric and methanesulfonic acids; the specific viscosities of their solutions in methanesulfonic acid varied from 4 to 19 dl g^{-1}. The anisotropic polymeric solutions (10%, w/w) were used to obtain fibres. The fibres from PBBT **19c** manifested the most valuable properties, *viz*., stability of 2.4 GPa and specific modulus of elasticity of 172 – 207 GPa. Their compression strengths (380 MPa) exceed that of the unsubstituted PBBT **3c**.

2,5-Di(benzothiazolyl)terephthalic acid was used together with 2-benzoazolylterephthalic acids **20** in the synthesis of PBBAz, which afforded PBBAz **21**.[61]



21

Dicarboxylic acids **22a – d** were used as acid components in the synthesis of PBBT and PBBO in order to achieve an even greater disturbance of the close packing of PBBAz and to increase the compression strength.[62, 63]

It should be noted that high-molecular-weight PBBAz **23a – d** were obtained only in those cases where polycyclocondensation was carried out at very low concentrations of the monomers in PPA ($\leqslant$ 1%), whereas with an increase in their concentration to 10% only low-molecular-weight oligomers could be isolated from their solutions (Scheme 3).[62]

The poly(benzobisazoles) **23a – d** are soluble in sulfuric, methanesulfonic and trifluoromethanesulfonic acids. The intrinsic viscosities, [η], of the polymers **23a – d** measured in methanesulfonic acid at 30 °C were equal to 12.0, 7.7, 11.4 and 8.7 dl g^{-1}, respectively.

The presence of extended side groups in the PBBAz synthesised prevents the straightening of the basic chains of the macromolecules and the formation of anisotropic solutions as a result of which the attempt to prepare high-quality fibres based on them failed.

The introduction of insignificant amounts (1 mol.% – 2 mol.%) of benzothiazolylphenyl-substituted *p*-terphenyldicar-

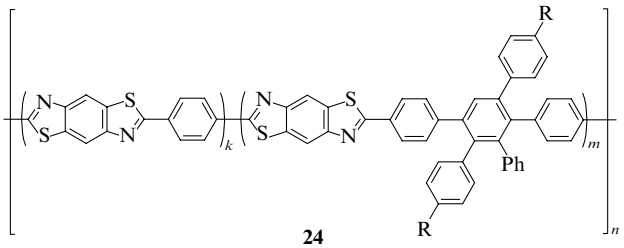
boxylic acid as a co-monomer to terephthalic acid results in the copolymers **24**.[64]



24

The polycyclocondensation at the concentrations of 10% (w/w) yielded copolymers with intrinsic viscosities of 20 to 28 dl g^{-1}. The fibres prepared from the copolymers **24** manifested a specific strength of 2.5 GPa, a modulus of elasticity of 193–283 GPa and compression strengths of 344 to 482 MPa.

The poly(benzobisazoles), *e.g.*, **25** and **26**, with aryloxide and arylthio substituents were obtained[65] by the reactions of 4,6-diaminoresorcinol, 2,5-diaminohydroquinone-, 4,6-diaminobenzene-1,3-dithiol and 2,5-diaminobenzene-1,4-dithiol hydrochlorides with 4,8-diaryloxy(arylthio)naphthalene-2,6-dicarboxylic acids in PPA.[65]

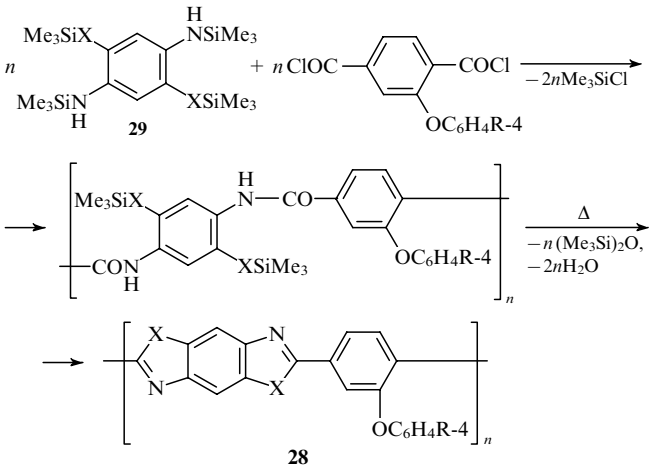
26

X = O, S, NH; Ar = 
R = H, Me, Et, Pr^n, Pr^i; Y = O, S.

In addition to a single-step synthesis of PBBAz in PPA, two-step synthetic procedures have been developed which yield prepolymers in the first stage under mild conditions. Their subsequent solid-phase cyclisation yields poly(benzobisazoles).

Thus the polymers **28** which are soluble in mixtures of dichloromethane chloride with methanesulfonic and trifluoroacetic acids have been synthesised from the silyl derivatives **29** and aryloxy-substituted terephthaloyl dichlorides by Kricheldorf *et al.*[66–70]

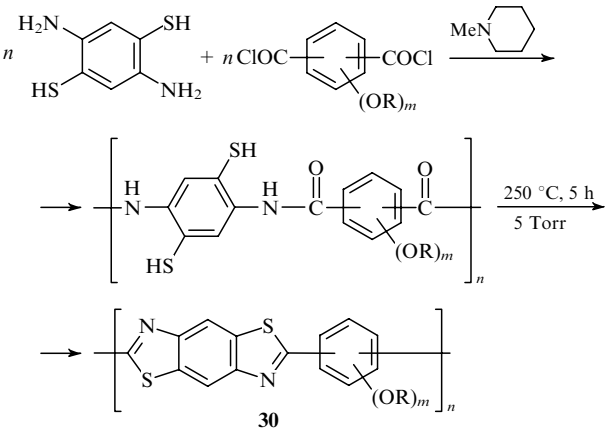


29 **28**

X = O, S; R = Ph, OPh, Bu^t, Cl, Br.

The use of silylated monomers makes it possible to increase the nucleophilicity of the nitrogen atom, as a result of which the reaction with acid chlorides proceeds more selectively and does not affect the trimethylsilyloxy(thio) groups.[71–74]

Kimura *et al.*[75] used a stepwise procedure for the synthesis of the alkoxy-substituted PBBT **30**.



30

R = Bu^n, n-C_6H_{13}, n-C_8H_{17}, n-$C_{10}H_{21}$, n-$C_{12}H_{25}$; m = 1, 2.

Nearly all the PBBT **30** were able to form anisotropic melts in the temperature range from 280 to 450 °C.

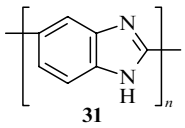
On the whole, it should be noted that most PBBAz can successfully be used for the preparation of high-quality fibres and films; however, bulk products can hardly be obtained, since their glass transition temperatures exceed their decomposition temperatures. This problem was solved, to a large extent, within the framework of a new concept in materials technology, namely, the construction of molecular composites.[76]

III. Molecular composites

The term molecular composites is usually applied to describe systems which consist of rigid-rod molecules dispersed in matrices of flexible-rod molecules at the molecular level; in this case, rigid-rod molecules play the role of reinforcing elements.

Molecular composites can be prepared both by mixing rigid- and flexible-rod polymers at the molecular level and by synthesising block and graft copolymers containing rigid- and flexible-rod fragments.

Among the first molecular composites were those based on PBBT **3c** as a rigid-rod component and polybenzoimidazole (**31**, ABPBI) as a flexible-rod component.[77–79]



31

Poly(benzoimidazole) (**31**) was obtained by homocondensation of 3,4-diaminobenzoic acid in PPA.[80,81]

Mixtures of these polymers at the molecular level were prepared from solutions with concentrations below those required for precipitation.[78,79] The mechanical properties of PBBT – ABPBI molecular composites (both as fibres and as films) are listed in Table 3. As can be seen from the Table 3, the introduction of 30% PBBT into the matrices of ABPBI enhances significantly the deformation strength characteristics of the material. The results of morphological studies of these mixtures, *viz*., low- and wide-angle X-ray scattering, optical microscopy and scanning electron microscopy suggest the absence of phase separation.[77,82,83]

[a] Freshly formed; [b] heat-treated; [c] heat-treated at 427 °C; [d] heat-treated at 525 °C; [e] heat-treated at 540 °C.

The processability of molecular composites could be improved using thermoplastic polymers, *e.g*., amorphous and partially crystalline polyamides,[84,85] poly(phenylquinoxalines)[86] and poly(ether ether ketones)[87] as flexible-rod matrices. The mechanical characteristics of the molecular composites based on thermoplastic polymers and PBBT are listed in Table 4. Thus the mechanical properties of the PBBT – Nylon system exceed those of a monoaxially oriented fibrous composite with identical composition by 50% – 300%.

As well as the construction of composites at the molecular level, the design of molecular composites by the synthesis of block and graft copolymers has become a very popular approach. Whereas in the molecular composites prepared by mechanical mixing of flexible- and rigid-rod components the reinforcing

Table 4. Mechanical characteristics of PBBT – thermoplastic molecular composites.

macromolecules are bound to the matrices exclusively due to physical interactions, in block copolymer-based molecular composites the flexible- and rigid-rod fragments are linked by covalent bonds. As a result, the transfer of strains from the rigid-rod fragments to the flexible-rod matrices occurs more effectively, hence, the block copolymer-based molecular composites manifest higher deformation strengths and dimensional stabilities.

The block copolymers **32** of the ABA type[88] which contain rigid-rod blocks B and flexible-rod blocks A[88] were synthesised as model systems. Macromolecules of PBBT **33** with carboxy terminal groups ($[\eta] = 10-24$ dl g^{-1}) used as rigid-rod blocks were introduced into co-polycondensation with 3,4-diaminobenzoic acid hydrochloride, which resulted in the formation of benzoimidazole rings and simultaneous binding of the individual blocks (Scheme 4).

The compositions of the blocks were varied by changing the content of 3,4-diaminobenzoic acid used for co-polycondensation. As can be seen from Table 5, the moduli of elasticity of the block-copolymeric molecular composites are comparable with those of the dynamic mixtures; their magnitudes depend on the ratios of the rigid- and flexible-rod components. The values of the moduli suggest that the reinforcement does not necessarily require highly extended macromolecules of PBBT **32**. Comparison of the breaking strengths (see Table 5) points to a much higher (up to

Table 5. Some characteristics of the block copolymers and mixed molecular composites.[88]

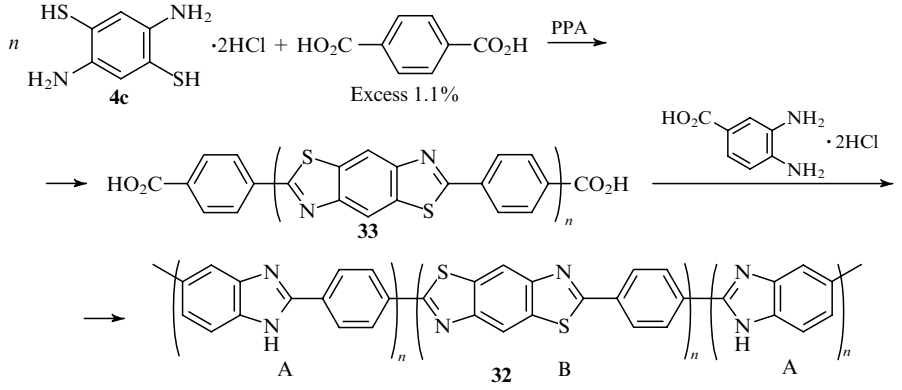
Scheme 4



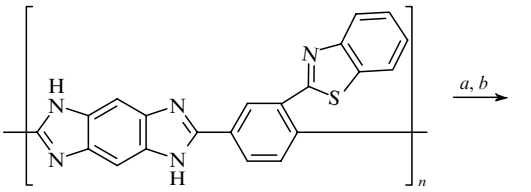
33%) deformation strength of the block-copolymeric molecular composites compared with the materials prepared from mechanical mixtures.

The polybenzobisthiazoles carrying terminal carboxy groups were introduced into the Friedel–Crafts polycondensation reaction with *m*-phenoxybenzoic acid in a P_2O_5–$MeSO_3H$ mixture.[89] This reaction yielded block copolymers of the ABA type which contained flexible-rod polyether ketone blocks and rigid-rod PBBT blocks.

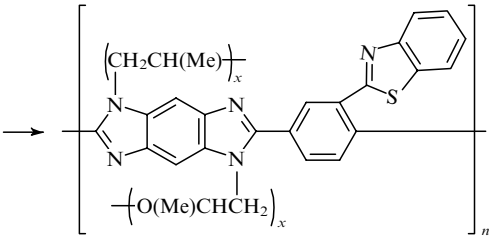
In addition to block-copolymeric molecular composites, much attention has been given to the synthesis of molecular composites based on graft copolymers containing rigid- and flexible-rod macromolecules. In particular, benzothiazol-2-yl-substituted PBBI **34** was metallated using NaH in DMSO with subsequent treatment with acrylamide[90] or, which is especially important, with propylene oxide.[90–92]

The grafted copolymer **35** is soluble in methanesulfonic, 97% formic and trifluoroacetic acids much more easily than PBBI **34**.

Although the softening of these polymers could not be detected by differential scanning calorimetry, their solid melts could be obtained by compaction at 190–232 °C. The introduction of polypropylene oxide side chains is accompanied by a significant decrease in their thermal stabilities in comparison with that of the starting compound, *viz*., PBBI **34**.



34



35

(*a*) NaH, DMSO, (*b*) Me–CH(O)–CH_2.

Of special interest is the synthesis of molecular composites based on grafted copolymers with heat-resistant side chains. Since rigid-rod PBBAz are soluble only in acidic solvents, the set of reactions used for the grafting is rather limited. Evers *et al*.[93,94] used the Friedel–Crafts reaction of *m*-phenoxybenzoic acid with poly(benzobisthiazole) in $MeSO_3H$–P_2O_5 (10 : 1, w/w) for the synthesis of grafted copolymers of the AB type. Thus the reaction of the polybenzobisthiazole copolymer **36** containing 4,4′-(*o*-diphenoxyphenylene) groups which are distributed statistically among the fragments of the rigid-rod PBBT with *m*-phenoxybenzoic acid afforded the copolymer **37** (Scheme 5).[95]

Compaction at high temperatures and pressures (285 °C, 6.9 MPa) is employed for the preparation of bulk products possessing isotropic properties. The main disadvantage of this approach is the low elasticity of the grafted fragments.

An alternative approach is based on the use of polybenzobisthiazole copolymers containing 2,6-dimethylphenoxide side groups as the basic macromolecular chains.[96,97] Treatment of these systems with *m*-phenoxybenzoic acid in P_2O_5–$MeSO_3H$ was accompanied by the formation of the grafted copolymers **38** (Scheme 6).

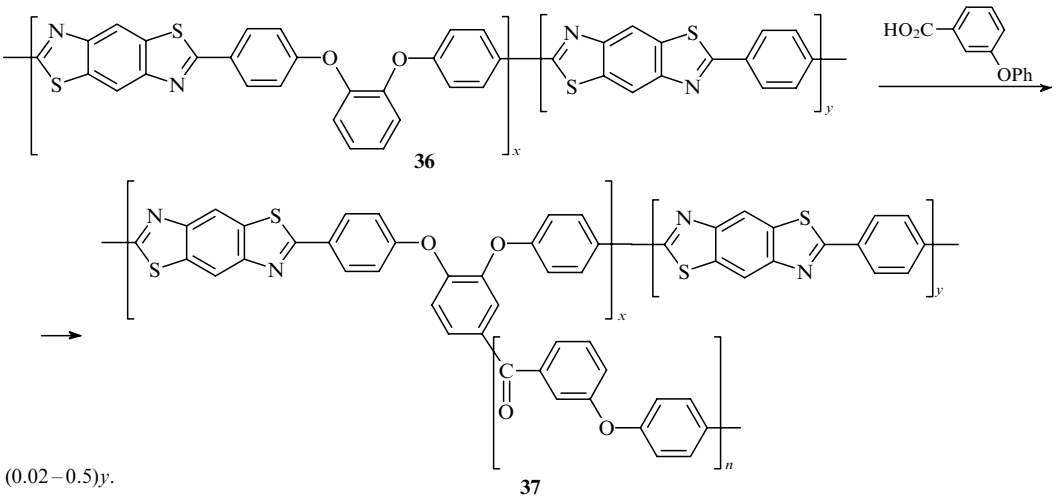
According to the dynamic mechanical analysis data, the softening of the grafted copolymers **38** occurs at 180–265 °C depending on the value of y.[98] Their secondary processing into bulk products is carried out at pressures up to 40 MPa and at temperatures which are 40 to 50 °C higher than the softening temperature. A specimen containing 46% (w/w) of PBBT **3c** and 54% (w/w) of the copolymer **38** manifests a rupture strength of 40 MPa and modulus of elasticity of 9.7 GPa.

IV. Conclusion

Rigid-rod PBBAz are the most promising materials in those fields where small weight, high deformation strength, rigidity, thermal and chemical stability as well as radiotransparency are the critical factors. The latter property is especially important, and in this respect PBBAz fibres have an indisputable advantage over graphite fibres. PBBAz fibres manifest greater elongation at rupture in comparison with graphite fibres and possess higher thermal and thermooxidative stabilities in comparison with Kevlar fibres. This altogether demonstrates their usefulness for aeronautical, aerospace and electronic engineering. Yet another field of application in which PBBAz have obvious advantages over glass, Kevlar fibres and coal plastics are thermostable membranes and filters. Further progress in this area will largely depend on the cost of the monomers and the 'cost–property' ratios of these systems.

The main drawback of the materials based on PBBAz is their low compression stability. This review considers the individual approaches to the solution of this problem which are based on structural modifications of these polymers. In recent years, increasing attention has been given to the construction of

Scheme 5



36

37

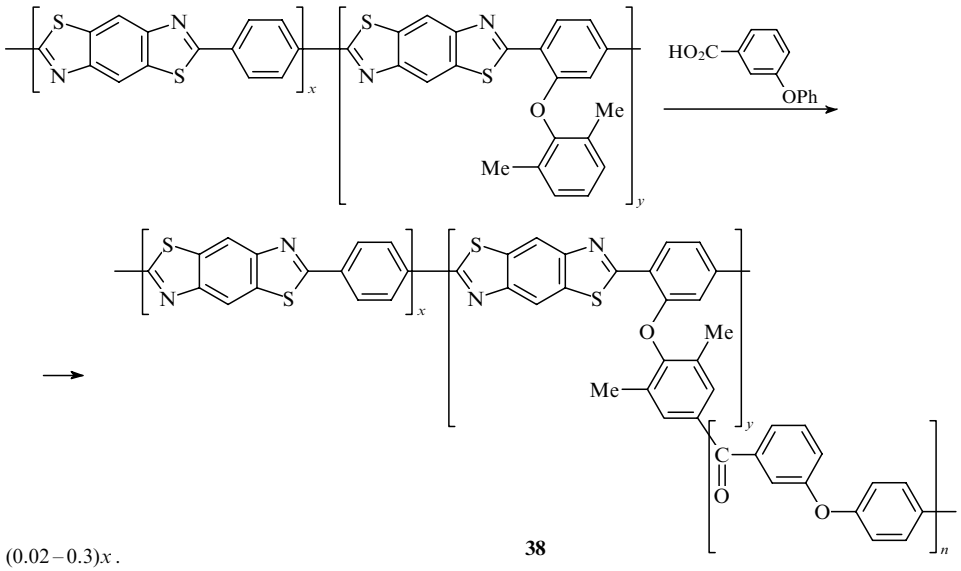
Scheme 6



$y = (0.02-0.3)x$.

38

PBBAz that can be cross-linked to form three-dimensional structures.[99–101] Further developments in this field will obviously be aimed at the construction of systems whose solidification is not accompanied by the evolution of volatile by-products.

Abstract. Modern trends of the chemistry of nitrous oxide are discussed. Data on its structure, physical properties and reactivity are generalised. The effect of N_2O on the environment and the possibility of its utilisation are considered. Attention is focused on the processes in which the oxidising potential of nitrous oxide can be employed. The bibliography includes 329 references.

I. Introduction

Nitrous oxide was discovered by J Priestley in 1772. After experiments performed by H Davy in 1799, N_2O received the name 'laughing gas' from its action. In the mid-nineteenth century, N_2O assumed importance and found wide application as a soft anaesthetic. Presently, nitrous oxide is used in medicine primarily in mixtures with other more powerful inhalation anaesthetics.[1] Since nitrous oxide is non-toxic and readily soluble in lipophilic media, it finds use in food industry as a foaming agent. Nitrous oxide is one of three compounds containing N–O bonds which were discovered in interstellar space.[2]

In the last two decades, the chemistry of nitrous oxide has been substantially developed. In one aspect or another, N_2O was mentioned in a large body of research. In the present review, the abundant data on nitrous oxide are surveyed. Particular attention is given to studies in which N_2O was described as the reagent. The role of N_2O in the destruction of the ozone layer giving rise to the so-called 'greenhouse' effect is also considered.

II. Atmospheric nitrous oxide

1. Sources of atmospheric N_2O and its environmental effects

The environmental effects of nitrous oxide have been the subject of much attention of ecologists over the last several decades. This interest is primarily associated with the fact that the role of 'laughing gas' (previously, it had been thought that this gas was quite harmless) in the atmospheric processes is beginning to emerge. It was realised that nitrous oxide plays a role in destruction of the ozone layer and gives rise to the greenhouse effect.

It was demonstrated that the average residence time of nitrous oxide in the lower layers of the atmosphere is about 120 years due to the lack of processes necessary for chemical conversions of N_2O.[3] Nitrous oxide gradually diffuses from the troposphere to the stratosphere, where it decomposes partly through photolysis and partly in reactions with reactive O and $^{\bullet}OH$ species formed upon photolysis.[4]

$$N_2O \xrightarrow{h\nu} N_2 + O(^1D),$$

$$N_2O + O(^1D) \longrightarrow 2\,NO,$$

$$N_2O + O(^1D) \longrightarrow N_2 + O_2,$$

$$N_2O + {}^{\bullet}OH \longrightarrow N_2 + HO_2^{\bullet}.$$

Nitric oxide (NO), in turn, reacts with ozone to form O_2 and NO_2. The latter undergoes disproportionation to give NO and O under the action of solar radiation, this process occurring repeatedly.[5]

Nitrous oxide is the third most abundant minor component of the atmosphere, exceeded in amount only by carbon dioxide and methane. It is believed that these gases along with ozone and Freons are of importance in processes providing thermal balance of the Earth. Their molecules adsorb heat given up by the Earth as infrared radiation resulting finally in a noticeable increase in the temperature of the troposphere and the greenhouse effect.[6, 7] Although the contribution of N_2O to the total greenhouse effect is evaluated at 6%, the 'greenhouse-forming' power of nitrous oxide is approximately 260 times larger than that of carbon dioxide.[4, 5] Taking into account the residence time of nitrous oxide in the atmosphere and the fact that its discharge to the atmosphere from anthropogenic sources cannot be terminated immediately, ecologists have expressed serious concern over the contribution of N_2O to the greenhouse effect.

Analysis of air samples taken from cavities in land ice in Greenland demonstrated that the nitrous oxide content of the

atmosphere remained rather constant ($\sim$ 280 ppb) over the last thousand years.[8] Beginning in the mid-eighteenth century, the growth in industry was accompanied by a progressive increase in the N_2O content in the atmosphere. Presently, the concentration of N_2O in the Northern Hemisphere reaches $\sim$ 314 ppb and continues to increase at a rate of $\sim 0.5-0.9$ ppb per annum. Thus, the nitrous oxide content of the atmosphere increases by 0.2% – 0.3% annually. The same trends are true for the Southern Hemisphere.

Identification of all sources of discharge of nitrous oxide to the atmosphere and quantitative estimation of the contributions of these sources are stubborn problems. For various reasons, the scatter in the data obtained by different researchers is very wide.[4,9] However, the available models are steadily improved with the aim of gaining reliable information on the processes influencing the total balance of emission of N_2O to the atmosphere and its decomposition.[10]

In 1990, emission of nitrous oxide to the atmosphere was $\sim$ 12.7 million tons [11] of which about 35 percent were of anthropogenic origin. Processes of nitrification and denitrification in soils of tropical and temperate regions and in oceanic waters are the major natural contributors of N_2O. It is assumed with a rather low accuracy that these processes are responsible for 45%, 25% and 30% of all natural emission of N_2O, respectively. Heating and power plants,[12,13] motor transport (18%),[14,15] some industrial chemical processes (12%) [16] and agriculture (70%) [17] are recognised to be the major sources of N_2O of anthropogenic origin.

One cannot say that no efforts are being undertaken to decrease the discharge of nitrous oxide to the atmosphere. Thus, the largest world's manufacturers of adipic acid ($\sim$ 5% – 8% of the total anthropogenic emission of N_2O) concluded an agreement [18] and committed themselves to supply plants with special technological cycles and to reduce the amount of N_2O exhausted into the atmosphere by more than 90% by 2000. New catalysts and catalytic processes for decomposition of N_2O are being developed.[19,20] However, agriculture remains the major contributor of nitrous oxide. The amount of nitrous oxide can be reduced by decreasing the use of nitrogen-containing fertilisers and by reducing flooded areas under rice crops where anaerobic processes of N_2O formation occur. However, it is difficult to accomplish this goal because the growth of population generates a need for the solution of food problems, while modern highly productive agricultural crops require the intensive use of nitrogen fertilisers.

Therefore, it was predicted that the N_2O content in the atmosphere will be increased by 0.2% – 0.3% annually in the coming years, as has been observed in recent years.[11,21]

2. Catalytic purification of waste gases from N_2O

Presently, a number of catalytic processes for the neutralisation of pollutants are available and successfully used.[22] Purification of waste gases from N_2O is one of the steps aimed at reducing its discharge to the atmosphere. Apparently, the optimum procedure involves catalytic decomposition of nitrous oxide.

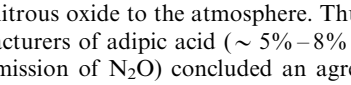
For a long time, investigations in this field were carried out from the standpoint of fundamental science.[19] The available systems often did not satisfy strict requirements imposed upon industrial catalysts for gas purification. More recently, many available catalytic systems have been reinvestigated under 'pseudoindustrial' conditions, *viz*., in the presence of complex gas mixtures, at temperature modes typical of heating furnaces and at high flow rates.[23,24] The world's large manufacturers of adipic acid, for example, DuPont (the catalyst is $CoO-NiO/ZrO_2$), BASF and Asahi (the catalyst is Cu/Al_2O_3), developed new technologies for the utilisation of N_2O.[25,26] However, the available catalytic compositions are far short of optimum. In addition, a wide variety of industrial sources of N_2O emission as well as operating conditions varying over a wide range call for a search for new more perfect catalysts. In addition, it was established that installations used for the neutralisation of NO and NO_2 can serve as sources of nitrous oxide.[25] Denitrification of waste gases in industrial scrubbers is generally performed using selective high-temperature reduction of nitrogen oxides NO_x with ammonia or hydrocarbons in the presence of a catalyst.[27] The conditions and parameters of the reactions of N_2O with reducing agents [RH,[28–33] NH_3 (see Refs 34 and 35) or CO [36–38]] have also been studied extensively. Since the maximum conversions of NO and N_2O into N_2 are achieved at different temperatures, the possibility of the simultaneous removal of these gases is an important criterion for the estimation of the efficiency of catalysts used for the purification of waste gases from nitrogen oxides.[39–41]

It should be mentioned that catalytic procedures for the purification of waste gases from nitrogen oxides are generally more favourable both from the economical standpoint and from the viewpoint of the efficiency of a reduction in the amount of NO_x to the maximum permissible concentrations. The adsorption methods can also be employed for the solution of this problem. Thus Centi *et al.* [42] demonstrated that Ba – ZSM-5 zeolites can be used for the selective removal of nitrous oxide from gas flows containing 0.1% – 0.2% of N_2O, and mixtures enriched with nitrous oxide (5%) can be either utilised as an oxidant or directed to refineries for subsequent decomposition.

III. Structure and properties

1. Structure of the nitrous oxide molecule

Generally, the structure of the nitrous oxide molecule (the symmetry group $C_{\infty v}$) is described by the resonance forms **A** and **B**.



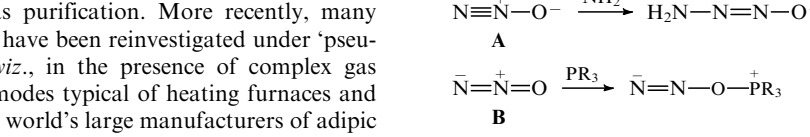
A **B**

It is believed that the *N*-oxide form **A** makes the major contribution to the geometric and electronic structure of the molecule. The total effective charges on the atoms in the form **A** are given below:

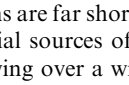
Calculation procedure	q_N	$q_{N(O)}$	q_O	Ref.
CNDO/2	−0.14	0.47	−0.33	43
4-31G	−0.07	0.62	−0.55	44
MP3	−0.11	0.44	−0.33	45

The opposite charge distribution in the resonance forms **A** and **B** accounts for the relatively low dipole moment of the molecule (0.161 D).[46] The N – N bond (1.128 Å) in nitrous oxide is substantially shorter than the standard N = N bond (1.24 Å, MeN = NMe) and is only insignificantly longer than the N ≡ N bond (1.10 Å, N_2). The N – O bond (1.184 Å, N_2O) is quite similar to the standard N = O double bond (1.21 Å, MeN = O).[47] Therefore, the N – N and N – O bond orders in nitrous oxide are estimated at 2.73 and 1.61, respectively.[48]

It is easy to see that the representation of the N_2O molecule by the resonance forms **A** and **B** formally assumes the presence of ambidentate properties, which can be manifested in the reactions of nitrous oxide both with electrophilic [49] and nucleophilic [50] agents.



The zwitterionic resonance forms **A** and **B** can be supplemented with the form **C** (1,3-dipole)

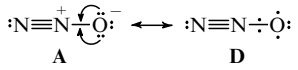


C

which can be involved in cycloaddition.

Data on the formation of stable five-membered rings in the reactions of N_2O with dipolarophiles are lacking. The theoretical possibility of this cycloaddition was discussed.[51,52] Bridson-Jones *et al.*[53] suggested that dihydro-1,2,3-oxadiazoles can be formed as intermediates in high-temperature oxidation of alkenes with nitrous oxide.

It should be noted that the non-classical representation of the nitrous oxide molecule as a biradical **D**[47,54] also allows an adequate description of the behaviour of N_2O in chemical reactions.



A **D**

Within the framework of the molecular orbital method, this description implies that one-electron delocalisation of the $2p\pi_x$ and $2p\pi_y$ orbitals of O^- results in the fact that electrons occupy the π_x and π_y bonding molecular orbitals which form one-electron π_x(NO) and π_y(NO) bonds and weak partial π_x(NN) and π_y(NN) bonds.

2. Brønsted basicity

Based on the data on the equilibrium constants of several tens gas-phase reactions

$$B_1H^+ + B_2 \rightleftharpoons B_2H^+ + B_1$$

the absolute gas-phase basicity scale for a wide range of compounds from N_2 to *tert*-butylamine was proposed.[55] According to this scale, the proton affinity of nitrous oxide (137.8 kcal mol^{-1}) is comparable with those of methane (130.2 kcal mol^{-1}) and carbon monoxide (141.9 kcal mol^{-1}). Olah *et al.*[44] prepared (and characterised) $MeON_2^+$ by the reaction

$$N_2O + MeF \xrightarrow[-80\ ^\circ C]{SO_2F_2,\ SbF_5} MeON_2^+SbF_6^-,$$

However, the authors did not detect the hydroxydiazonium ion $NNOH^+$ in the reaction of N_2O with superacids.

The protonated form of nitrous oxide in the gas phase was detected by IR spectroscopy.[56] The spectral characteristics were not unambiguously assigned to particular isomers, *viz.*, to $NNOH^+$ or ^+HNNO. Calculations[57,58] demonstrated that protonation of the oxygen atom is more favourable than protonation of the nitrogen atom. However, the results of these calculations depend substantially on the electron correlation methods applied.[59]

3. Physical properties

Nitrous oxide is a colourless diamagnetic gas with a weak pleasant odour and sweetish flavour. It is incombustible but can maintain burning. The nitrous oxide molecule is very stable. In the absence of a catalyst at 400–530 °C, thermal decomposition of N_2O is insignificant (0.22%–0.23%)[60]

$$2N_2O \longrightarrow 2N_2 + O_2.$$

The activation energy E_a of this non-adiabatic spin-forbidden process is ~ 59 kcal mol^{-1}.[61]

Nitrous oxide possesses a high critical temperature. At room temperature under high pressure (50.1 atm, 21 °C), it can exist as a liquid and can be stored in steel cylinders. In laboratory conditions, N_2O is generally prepared either by thermal decomposition of ammonium nitrate or by the reaction of potassium nitrosyl sulfate with sulfuric acid.[61] The physical properties of nitrous oxide are given below.[62–64]

Melting point /°C	−90.86
Boiling point /°C	−88.48
Critical pressure /atm	71.7
Critical temperature /°C	36.5
Critical density /g cm^{-3}	0.452
Density of N_2O (liq) at −88.48 °C /g cm^{-3}	1.226
Density of N_2O (g) at 0 °C /mg cm^{-3}	1.997
Enthalpy of formation ($\Delta_fH^0_{298}$) /kcal mol^{-1}	19.6
Free energy of formation ($\Delta_fG^0_{298}$) /kcal mol^{-1}	24.6
Entropy (S^0) /cal K^{-1} mol^{-1}	52.52
Thermal capacity (C^0_p) /cal K^{-1} mol^{-1}	9.19

IV. Decomposition of nitrous oxide

1. Thermal decomposition

Homogeneous thermal decomposition of nitrous oxide is one of the most extensively studied chemical reactions.[65,66] This process is often used as a model for testing new theories and experimental systems[67] and it is also widely employed for the preparation of atomic oxygen $O(^3P)$.[68]

The following most important elementary stages resulting in decomposition of N_2O are distinguished:

$$N_2O + M \longrightarrow N_2 + O + M, \quad (1)$$

$$N_2O + O \longrightarrow N_2 + O_2, \quad (2)$$

$$N_2O + O \longrightarrow NO + NO, \quad (3)$$

$$N_2O + H \longrightarrow N_2 + {}^{\bullet}OH, \quad (4)$$

$$N_2O + {}^{\bullet}OH \longrightarrow N_2 + HO_2^{\bullet}. \quad (5)$$

From the above-listed equations it can be seen that decomposition of nitrous oxide can occur either as a result of collisions with the third body M [reaction (1)] or through secondary reactions with the oxygen atom or with radical species [reactions (2)–(5)]. The nature of the species M and the character and concentrations of the radical species have an essential effect on this process.

In most of the early investigations, the kinetics of decomposition of nitrous oxide was examined in the presence of argon or nitrogen at 850–1300 °C. However, the formation of nitrous oxide in industrial apparatuses used for denitrification of waste gases and in heating and power plants, which are important anthropogenic contributors of N_2O,[9] occurs at moderately high temperatures (600–900 °C) in complex gas mixtures. The necessity of gaining an insight into the kinetics of these processes gave impetus to investigations of thermal decomposition of N_2O at 600–900 °C in the presence of carbon dioxide, water vapour, hydrogen, methane, oxygen and other gases.[69–71]

2. Heterogeneous catalytic decomposition

A search for new alternative oxidants, on the one hand, and the necessity of the environmental protection aimed at reducing industrial discharge of nitrous oxide to the atmosphere, on the other hand, gave impetus to the development of efficient procedures for catalytic decomposition of nitrous oxide. These procedures were devised primarily by large manufacturers of adipic acid. Thus the BASF, Bayer, DuPont and Asahi companies use catalytic systems for decomposition of N_2O in waste gases,[72] whereas the Solutia company employs recirculation of N_2O to the technological cycle and utilises it as an oxidant for the direct preparation of phenol from benzene.[73]

Problems of a search for efficient catalysts of decomposition of nitrous oxide were covered in an excellent review[25] in which the data on decomposition of N_2O with the use of different heterogeneous catalysts published up to 1996 inclusive have been surveyed and analysed. In the cited review, the mechanism and kinetics of decomposition of N_2O were considered, the role of different oxygen forms occurring on the surface of catalysts was discussed and the problem of catalyst poisoning was touched on. However, a body of the published data in this field increases very rapidly and we believe that it is necessary to survey the data published in 1997–2000 (Table 1).[74–106]

The discovery of isothermal oscillation of concentrations of N_2O, N_2 and O_2 upon decomposition of nitrous oxide on the

$(Mg_xCo_{1-x})Co_2O_4$		106

Cu–ZSM-5 zeolite catalyst [107] was mentioned in a review.[25] Later, a mechanism was proposed according to which the concentrations of the components change in a wave-like fashion due to cyclic oxidation–reduction of active copper(I) centres responsible for decomposition of N_2O.[108–110] Recently, oscillation of nitrous oxide on the Rh/ZrO_2 (Ref. 111) and Fe–ZSM-5 (Ref. 112) catalysts was observed.

3. Photochemical decomposition

Photochemical decomposition of nitrous oxide affords N_2, O_2, NO and NO_2.[113] Spin-forbidden primary processes (6) and (7) occurring under exposure to light ($\lambda \approx 250$ and 200 nm, respectively) are convenient procedures for the preparation of atomic oxygen in investigations of the kinetics of different reactions in the gas phase.[114, 115]

$$N_2O \xrightarrow{h\nu} N_2 + O(^3P) \quad (6)$$

$$N_2O \xrightarrow{h\nu} N_2 + O(^1D) \quad (7)$$

In recent years, considerable attention has been paid to electronic, vibrational and rotational states of both photofragments, *viz*., N_2 and O,[116, 117] with the aim of giving a comprehensive description of N_2O photolysis.

Great interest was also expressed in photochemical reactions of nitrous oxide in the atmosphere [4] because photolytic decomposition of N_2O is the key process in the conversion of nitrous oxide in the stratosphere.

4. Photocatalytic decomposition

Presently, photocatalysis is the most vigorously evolving line of photochemistry,[118, 119] and this method can be successfully used for decomposition of nitrous oxide. Thus photodecomposition of N_2O under irradiation with UV light ($\lambda < 300$ nm) at room temperature readily proceeds on the surfaces of ZnO,[120] TiO_2,[25] Pt/TiO_2 [121] or Cu–ZSM-5.[122] Copper(I) compounds applied to inert supports,[123] Ag, Cu/TiO_2 [124] or ions of different transition metals in zeolite matrices [125] exhibit high catalytic activities. Possible mechanisms of decomposition, in particular, on zeolites ZSM-5, were discussed.[126, 127] Based on the data from IR and UV spectroscopy, it was concluded [127] that the reaction of N_2O with the Ag^+–ZSM-5 system afforded the Ag^+–N_2O complex whose photoactivation resulted in decomposition of nitrous oxide into N_2 and O_2.

Photodissociation of nitrous oxide on heterogeneous catalysts may be very useful not only in denitrification but also in oxidation or destruction of organic compounds. Photocatalytic degradation of salicylic acid [128] in saturated aqueous solutions of N_2O in the presence of ZnO or ZnO/TiO_2 is an example.

V. Chemistry of nitrous oxide

1. Thermodynamical analysis of the use of N_2O as an oxidant

A change in the Gibbs free energy Δ_rG^0 can be used as a criterion for the possibility of a particular reaction occurring. Thus the reactions can take place and proceed spontaneously if Δ_rG^0 (in kcal mol^{-1}) < 0, whereas in the range of 0–10 kcal mol^{-1}, the reactions are unlikely. This situation calls for further investigation. If $\Delta_rG^0 > 10$ kcal mol^{-1}, the reactions cannot proceed; however, special conditions can help in performing these processes. The Δ_rG^0 value at which the reaction under consideration cannot be carried out depends on many factors and the above-mentioned values can be considered only as a very rough estimate.

The thermochemical data for hypothetical and actual reactions of N_2O with the reagents X or HX, which were calculated as differences between the total changes of the enthalpies ($\Delta_fH^0_{298}$) or the Gibbs free energies ($\Delta_fG^0_{298}$) of formation of the final and starting compounds, are given in Tables 2–5.

$$X + N_2O\,(g) \longrightarrow XO + N_2\,(g),$$

$$2XH + 3N_2O\,(g) \longrightarrow 2XO + 3N_2\,(g) + H_2O\,(g).$$

The required thermodynamical properties of individual compounds were taken from handbooks.[129–133] It should be emphasised once again that the data in Tables 2–5 serve only as a qualitative estimate of the possibility for the reaction to occur. In addition, the above-mentioned data should be compared with each other with caution because the compounds exist in different

physical states and the determined Gibbs energies and enthalpies of the initial and final compounds may be inexact.

Therefore, N_2O is potentially a powerful oxidant. However, only the data on high-temperature oxidation of organic substrates on heterogeneous catalysts and several examples of oxidation of some substrates in homogeneous reactions catalysed by transition-metal complexes are available in the literature. Evidently, this inertness is associated with the high activation energy of decomposition of nitrous oxide. Apparently, this problem can be solved by searching for suitable catalysts.

2. The use of N_2O in oxidative catalysis

Considerable progress has been achieved in oxidative catalysis over the latter part of the twentieth century;[134] however, the advances in oxidative hydroxylation of paraffins and aromatic compounds are still poor. Generally, the reactions using atmospheric or molecular oxygen as an oxidant proceed with low selectivity (sometimes these reactions lead to complete oxidation of the substrate). Presently, several major approaches to the solution of this problem are available, *viz*., the employment of membrane-type reactors,[135, 136] the separate performance of reduction and reoxidation of catalyst's surface (two-step process) [137] or the use of alternative oxidants. In the latter case, major hopes are placed on the use of hydrogen peroxide on titanium silicate catalysts [138] and nitrous oxide on ZSM-5 zeolite catalysts.[139]

Two main lines of investigation, *viz*., selective oxidation of aliphatic (aromatic) hydrocarbons and oxidative condensation of lower alkanes, were mentioned in reviews [139, 140] devoted to the employment of N_2O as an oxidant under conditions of heterogeneous catalysis. However, in spite of a large number of studies,[141–151] the latter reaction is, in Krylov's opinion,[152] substantially less useful than other oxidative conversions of hydrocarbons. Actually, direct oxidation reactions of benzene to phenol or of methane to methanol are of importance. Phenol is still prepared by the oxidation of cumene, and methanol is prepared by the conversion of the synthesis gas. A multitude of catalytic systems, including those involving N_2O as an oxidant, *viz*., various metal oxides (mixed solid solutions doped with ions of other metals fixed on inert supports), heteropolyacids and their salts, zeolites, *etc*., were examined in direct oxidation reactions of benzene and methane.[139, 140] Some catalysts of hydroxylation of methane and benzene with nitrous oxide are listed in Table 6. However, attempts to perform the selective conversion of methane to methanol failed.

Table 6. Catalysts of oxidative hydroxylation with the use of nitrous oxide.

Hydrocarbon	Catalytic system	Ref.
Benzene	Fe–Si, $FePO_4$, H–Ga–FER	153, 154
	H, Na, H–[Al], Fe–ZSM-5	156–159
Methane	Fe–Si, $FePO_4$, H–Ga–FER	155
	H, Na, H–[Al], Fe–ZSM-5	160–162
	Sr- or Ca-hydroxyapatites	163, 164
	Mo/SiO_2	165
	12-phosphomolybdic acid	166

The major progress has been achieved in performing the oxidation of benzene to phenol.[167] A new procedure for the synthesis of phenol, which is based on the use of Fe-containing ZSM-5 zeolites and is characterised by high selectivity with respect to both phenol (97%–98%) and nitrous oxide (85%), was developed by researchers from the G K Boreskov Institute of Catalysis of the Siberian Branch of the Russian Academy of Sciences in cooperation with the Solutia company (USA). Successful tests of a pilot plant were performed and the construction of the industrial plant (Pensacola, Florida) rated at 140 thousand tons of phenol per annum is being brought to completion.[168] It should be noted that the results of many investigations in this field were covered by patents.[169–176]

The nature of high catalytic activity of zeolites in oxidation of benzene is the matter of vivid debates. Presently, two major hypotheses are available. One of them is based on a conventional view of zeolites as acid catalysts whose activity is associated with Lewis [156, 159, 177] and (or) Brønsted [178, 179] acidic centres. However, a special investigation [180] did not confirm the hypothesis based on the concept of Brønsted centres.

The second hypothesis was proposed by Panov *et al*.[139, 181] These authors believed that the interaction of N_2O with the surface of Fe-ZSM-5 zeolites afforded a special form of surface oxygen arbitrarily called α-oxygen. In its properties, α-oxygen differs substantially from the known surface forms of oxygen.[182, 183] α-Oxygen cannot be formed upon adsorption of molecular O_2. It was assumed that α-oxygen resembles somewhat active oxygen of monooxygenases for which hydroxylation of C–H bonds is a typical reaction. Quantum-chemical calculations

of the thermodynamical and geometric parameters of the formation of α-oxygen and its successive reactions with benzene or methane were performed.[184, 185]

It was demonstrated[162] that CH_4 reacted virtually quantitatively with the α-form of oxygen, which arose as a result of decomposition of N_2O on Fe-ZSM-5 zeolite, at room temperature. However, the resulting methanol was strongly bound to the zeolite surface and its desorption into the gas phase did not occur. An increase in the temperature to 250–300 °C led to vigorous CO evolution due to secondary conversion of the product.

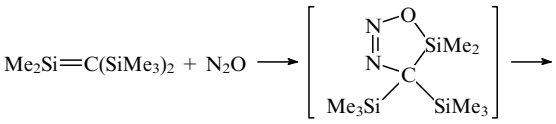
A search for possible catalysts of selective oxidation of hydrocarbons is not restricted to zeolites. Different research groups made efforts to search for a means of activation of C–H bonds.[186] Wang *et al.*[187] succeeded in performing oxidative carbonylation of methane on $Rh/FePO_4$ at 300–400 °C in the presence of CO and nitrous oxide to form MeOH, $MeCO_2H$ and $MeCO_2Me$. Partial oxidation of methane with nitrous oxide under conditions of plasma discharge[188] gave rise to HCHO and MeOH in a total yield of 10%, which is comparable with the results obtained with the use of the best catalytic systems.

On the whole, the problem of direct oxidation of methane to form methanol, in spite of efforts made, is still far from solution.

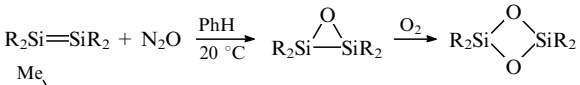
3. Oxidation reactions involving N_2O

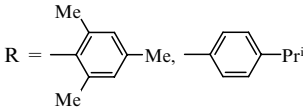
As mentioned above, nitrous oxide is a potentially strong oxidant, but it is very inert for kinetic reasons. Under mild conditions, N_2O reacts only with highly reactive compounds, such as organoboranes,[189] silaethenes[190] or disilenes.[191]

$$BEt_3 + N_2O \xrightarrow[-15\ ^\circ C]{C_6H_{14}} N_2 + (Et_2B)_2O + C_2H_4 + H_2O$$

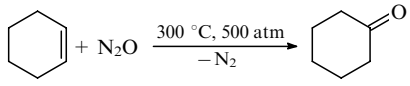


$$\longrightarrow (Me_2SiO)_n + (Me_3Si)_2CN_2$$



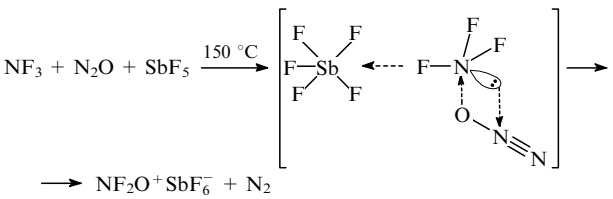


In the absence of a catalyst, N_2O does not react with alkanes, arenes, amines, esters and aliphatic alcohols even at 200–300 °C and 100–500 atm.[53] Under these conditions, alkenes and alkynes form predominantly carbonyl compounds.[192, 193]



The reactions of nitrous oxide with a solution of triethyl phosphite or cyclohexyl isocyanide in benzene (20 atm, 130 °C) afforded triethyl phosphate (80%) or cyclohexyl isocyanate (20%), respectively.[194] A series of oxides of tertiary phosphines were prepared in quantitative yields[195] with the use of nitrous oxide in the supercritical state (100–140 atm, 60–100 °C).

The reaction of N_2O with nitrogen trifluoride in the presence of an excess of SbF_5 gave rise to $NF_2O^+Sb_2F_{11}^-$ whose vacuum pyrolysis afforded NF_3O.[196] Until recently, procedures for the preparation of NF_3O by direct chemical oxo transfer from an O-donor to NF_3 were lacking.



Oxidation of aqueous solutions of alcohols, amines and ethers with nitrous oxide in the presence of Pt or Pd black proceeds according to a radical mechanism.[197] It is assumed that reductive decomposition of N_2O adsorbed on platinum gives rise to N_2 and the $Pt(^{\bullet}OH)$ radicals, which are strong electrophilic oxidants.

$$Me_2CHOH + Pt(^{\bullet}OH) \longrightarrow Me_2\dot{C}OH + H_2O + Pt,$$

$$Pt(N_2O) + Me_2\dot{C}OH \longrightarrow N_2 + Me_2CO + Pt(^{\bullet}OH).$$

On the whole, activation of N_2O is generally a necessary condition for its involvement in oxidation as the oxo donor.

4. Reactions with nucleophilic reagents

The reactions of N_2O with melts of amides of alkali metals and alkaline-earth metals giving rise to the corresponding azides are among the most important reactions of nitrous oxide with nucleophilic reagents.[50] Since sodium azide is rather stable, it serves as the starting compound for the preparation of other azides, and this reaction provides the basis for the industrial production of NaN_3.[198]

$$2NaNH_2 + N_2O \longrightarrow NaN_3 + NaOH + NH_3.$$

Sodium azide is also formed in the reaction of N_2O either with Na in liquid ammonia

$$4Na + 3N_2O + NH_3 \longrightarrow NaN_3 + 3NaOH + 2N_2,$$

or with sodium oxide[61]

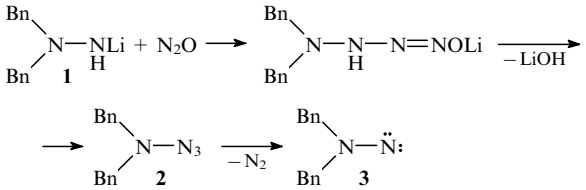
$$2Na_2O + N_2O + NH_3 \xrightarrow{110-190\ ^\circ C} NaN_3 + 3NaOH.$$

The reaction of N_2O with ammonia over the $Ni-Al_2O_3$ catalyst afforded ammonium azide[63]

$$2NH_3 + N_2O \xrightarrow{Ni-Al_2O_3} NH_4N_3 + H_2O.$$

Diazo transfer from nitrous oxide to anions of different anilines was carried out (2–5 atm, 20 °C)[199] and the corresponding aryl azides were isolated (10%–35%).

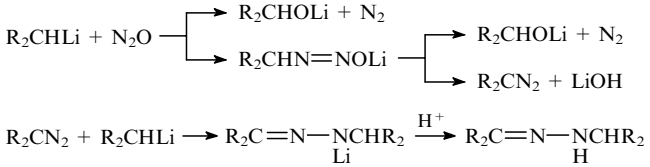
The reaction of N_2O with the monolithium derivative of 1,1-dibenzylhydrazine (**1**) proceeded successively through the formation of *N*-azidoamine **2** and *N*-nitrene **3**.[200]



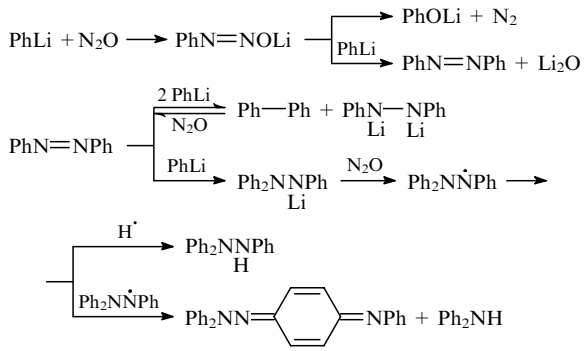
1,2-Diphenylethane (12%) and *N*,*N*-dibenzylbenzalhydrazone (11%) were identified as the major products of the above reaction.

The reactions of N_2O with phosphorus ylide $Ph_3P^+CH_2^-$ (see Ref. 201) or with MeLi[202] gave rise to diazomethane (in 25% or 70% yields, respectively). It should be noted that, with rare exceptions, the reactions of nitrous oxide with anions of organolithium compounds afforded mixtures of *N*- and *O*-products due to the ambidentate character of the former. In addition, the possibility of direct oxidation of organometallic compounds with nitrous oxide must not be ruled out. Based on the results of investigations into the reactions of N_2O with different organolithium compounds, two pathways were proposed.

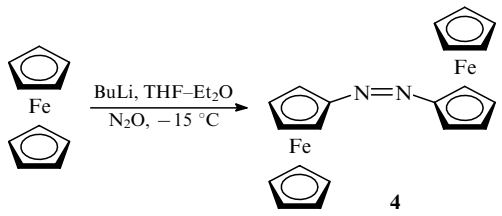
Pathway *a* (see Ref. 203)



Pathway *b* (see Refs 204, 205)



To our knowledge, the procedure for the preparation of diazoferrocene (**4**) (the yield was 25%) developed by Nesmeyanov *et al.*[206] is the only example of the successful application (from the synthetic standpoint) of diazo transfer involving nitrous oxide.



4

Recently, this procedure was used for the preparation of N=N-bonded ferrocene oligomers.[207, 208]

Grignard reagents, unlike organolithium compounds, do not react with nitrous oxide.[203] However, it was demonstrated [209] that the reaction of PhMgBr with N_2O in the presence of CuCl (10 mol.%) afforded small amounts of PhN=NPh (2%) and Ph_2NH (1%). Previously, it has been found [210] that organocalcium analogues of Grignard reagents, for example, PhCaI, reacted with N_2O to yield azobenzene (8%), biphenyl (10%) and traces of benzidine, phenol and hydrazobenzene.

The potential of this reaction as a new procedure for the formation of C–N bonds was examined. [211] It appeared that the yields and the ratio of the reaction products depend substantially on the solvent and the type of substitution in the benzene ring. The maximum yield of azobenzene (60%) was achieved in dimethoxyethane. However, substantial amounts of biphenyl obtained as a by-product impair the synthetic significance of this reaction. The reaction of N_2O with Ph_2Ca afforded azobenzene as the major product (10%).[211] This provides evidence that PhN=NPh can be formed by the direct insertion of N_2O at the R–M–R bond, and not just by the reaction of diazotate R–N=N–OM with the second R–M molecule, as has been suggested previously.[210]

5. Reactions with metal-complex compounds

Nitrous oxide can act as the oxo donor in reactions with metal-complex compounds. The pioneering studies in this field were performed by Bottomley *et al.*[212–218] The authors used N_2O as an oxidant for the synthesis of a series of oxometallocenes with terminal and(or) bridging oxygen atoms, such as oxocyclopentadienyl derivatives of titanium,[213, 214] chromium [215, 216] and vanadium.[217, 218]

Generally, the reactions of low-valence cyclopentadienyl derivatives of transition metals with N_2O afford oxometallocenes containing the central metal atom in an intermediate oxidation state, whereas the reactions with O_2 give rise to oxo clusters containing the metal atoms in the highest oxidation state.[212] Thus oxidation of dicyclopentadienylchromium with oxygen [212] or nitrous oxide [216] afforded two different derivatives, *viz.*, **5** and **6**, respectively.

$$2(\eta\text{-}C_5Me_5)_2Cr + 2O_2 \longrightarrow [(\eta\text{-}C_5Me_5)Cr(O)(\mu\text{-}O)]_2 + (C_5Me_5)_2,$$

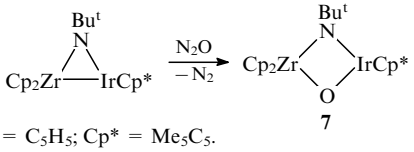
5

$$4(\eta\text{-}C_5Me_5)_2Cr + 4N_2O \longrightarrow [(\eta\text{-}C_5Me_5)Cr(\mu_3\text{-}O)]_4 + 4N_2 + 2(C_5Me_5)_2.$$

6

From Bottomley's standpoint [212] this fact cannot be explained only by thermodynamical reasons [the energy of the N–O (D^0_{298}) bond in N_2O is ~ 40 kcal mol^{-1} and the energy of the O–O bond in O_2 is 119 kcal mol^{-1}].[133] The difference in the structures of oxometallocenes should be determined by the reaction mechanisms, which are poorly understood so far because of their complexity. The reactions of titanocene and vanadocene [219] with nitrous oxide proceeded through the formation of the monomers $[(\eta\text{-}C_5Me_5)_2]M(O)$ (M = Ti or V) whose decomposition afforded the oxo clusters $[(\eta\text{-}C_5Me_5)M_4(\mu\text{-}O)_6]$.

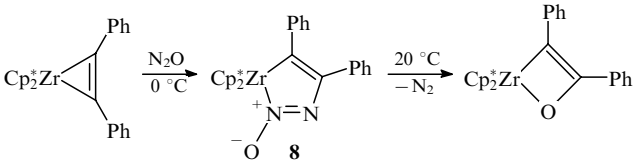
More recently, many researchers used nitrous oxide along with conventional oxo donors (PyO, $OPPh_3$, Me_2SO or O_2) for the preparation of different terminal (bridging) oxo metal complexes. Thus the reactions of N_2O with the tetraaza[14]annulene–Sn(II) complex,[220] $U(OC_6H_3Bu^t_2\text{-}2,6)_3$ (see Ref. 221) and $V[(Me_3SiNCH_2CH_2)_3N]$ [222] were reported. Cyclopentadienyl derivatives of uranium,[223] samarium,[224] zirconium [225, 226] and hafnium [227] also reacted with nitrous oxide to give oxo compounds. The heterobinuclear zirconium–iridium oxo complex **7** was prepared.[228]



7

Cp = C_5H_5; Cp* = Me_5C_5.

The reactions of N_2O with metal complexes can be accompanied by insertion of the former at the $(L_n)M-R$ bond. Generally, these reactions afford compounds of the $(L_n)MOR$ type as the final products. However, intermediate complexes **8** containing the nitrous oxide molecule were isolated and characterised in the case of titano- [229] and zirconocene [230, 231] systems.

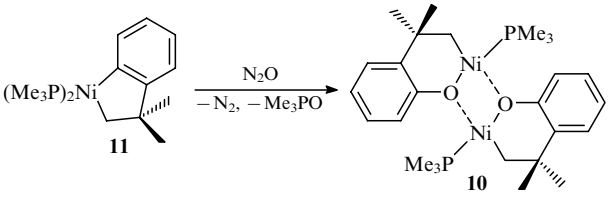


8

Nickel compounds reacted with N_2O to form stable alkyl(aryl)oxy complexes **9** and **10**.[232–234]

9

bipy is 2,2′-bipyridyl.

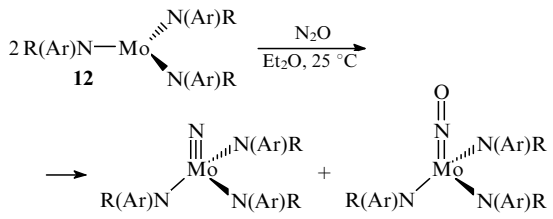


11 **10**

It was proposed [232] that the reaction with nickel complex **11** proceeded *via* intermediates analogous to the zirconium complexes **8**.

The insertion of N_2O at the $(L_n)M-R$ bond giving rise to the $(L_n)MOR$ compounds was described for the complexes of Hf [235] and Ru.[236, 237]

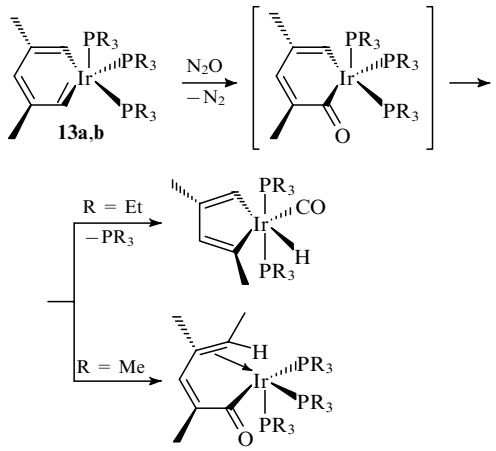
The reactions of nitrous oxide with some metal complexes proceed according to unique mechanisms. Thus the molybdenum complex **12** is the only known metal complex, which can cleave the N–N bond in the N_2O molecule.[238]



R = $C(CD_3)_2Me$; Ar = $C_6H_3Me_2$-3,5.

Based on the results of calculations, it was suggested [239] that the reactions of this complex with N_2O and N_2 proceed by different mechanisms, *viz*., by bimolecular and monomolecular mechanisms in the cases of nitrous oxide and N_2, respectively.

Two different complexes were obtained in the reactions of iridabenzenes **13a**,**b**, which differ by the substituents in the phosphine ligands.[240]



R = Et (**a**), Me (**b**).

It was found [241] that the reactions of the $[Cr(OCP)Li_2(THF)_4]$ complex (OCP is octaalkylcalix[4]pyrrole) with N_2O gave rise to two different oxygen-containing products depending on the solvent used.

6. Metal-complex catalysis of oxo transfer

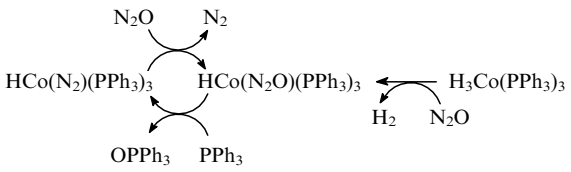
Apparently, the high activation energy of decomposition of N_2O (E_a = 59 kcal mol^{-1}) [61]

$$N_2O\,(g) \longrightarrow N_2\,(g) + O\,(g)\,(^1D), \quad \Delta H^\circ = 85 \text{ kcal mol}^{-1},$$

$$N_2O\,(g) \longrightarrow N_2\,(g) + O\,(g)\,(^3P), \quad \Delta H^\circ = 40 \text{ kcal mol}^{-1},$$

is the only factor that prevents the wide use of nitrous oxide as an oxo donor. Powerful inexpensive nitrous oxide, which can be readily removed from the reaction medium and does not introduce impurities, could be a valuable oxidant. A search for suitable catalysts of N_2O decomposition seems to be the most promising way of solving this problem. Oxo transfer from the reagent to the substrate under the action of metal-complex catalysts is used in various reactions.[242] Acyl(alkyl) peroxides, molecular oxygen, amine *N*-oxides, hydrogen peroxide and aryliodoso compounds are most popular oxo donors. Attempts to use nitrous oxide have also been undertaken, but no noticeable success has been achieved. Generally, elimination of the O atom from N_2O either gives rise to oxo derivatives of complexes which cannot participate in the catalytic cycle for various reasons, or leads to the oxidation of ligands involved in the coordination sphere about the metal atom.

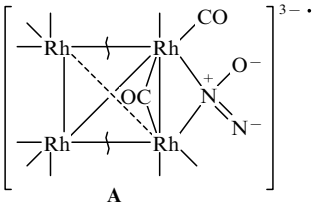
Thus the use of N_2O in the catalytic cycle of oxidation of PPh_3 to form Ph_3PO in the presence of $HCo(N_2)(PPh_3)_3$ was reported.[243] The following reaction scheme was proposed:



Oxidation of carbon monoxide is catalysed by carbonyl complexes of Rh,[244] Ru, Os or Fe.[245]

$$N_2O + CO \xrightarrow{cat} N_2 + CO_2.$$

It was suggested [245] that the reactions in the [Rh]–CO–N_2O and [Fe]–CO–N_2O systems proceeded through different mechanisms. In the case of rhodium complexes, the catalytic cycle involves one-electron transfer from $[Rh(CO)]^-$ to N_2O yielding $N_2O^{-\bullet}$, its capture by the $[Rh_4(CO)_{11}]^{2-}$ anion and subsequent elimination of N_2 and CO_2 (the fragment **A** of the resulting cluster **14** is shown).



A

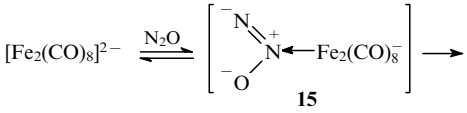
$$[Rh(CO)_4] + N_2O \rightleftharpoons [Rh(CO)_4]^\bullet + N_2O^{-\bullet}$$

$$[Rh_4(CO)_{11}]^{2-} + N_2O^{-\bullet} \longrightarrow [Rh_4(CO)_{11}(N_2O)]^{3-\bullet} \longrightarrow$$

14

$$\longrightarrow [Rh_4(CO)_{10}]^{3-\bullet} + N_2 + CO_2$$

In the presence of iron carbonyls, the nucleophilic attack of N_2O on the reactive intermediates occurs giving rise to an intermediate adduct **15**.

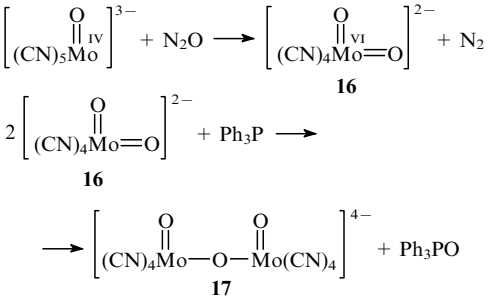


15

$$\longrightarrow [Fe_2(CO)_7]^{2-} + CO_2 + N_2$$

It should be mentioned that molecules which are incorporated into complexes and can regenerate these complexes in the catalytic cycle serve as substrates in the above-considered oxidation reactions involving N_2O. These reactions are not versatile, which impairs their practical significance. Oxidation of CO [246, 247] and PR_3,[248] which are incorporated into metal complexes, with nitrous oxide beyond the catalytic cycle is also documented. The reactions of nitrous oxide with cyclopentadienyl complexes of cobalt at 130 °C resulted in their decomposition to form the corresponding furans and but-2-ene-1,4-dials.[249]

Oxo transfer from N_2O to triphenylphosphine in the presence of $[(CN)_5Mo(O)](PPh_4)_3$ proceeded through the formation of $[(CN)_4Mo(O)_2]^{2-}$ (**16**), the latter serving as an oxidant.[250]



16

17

However, the reaction of the dioxo complex **16** with the substrate afforded compound **17**, which cannot be involved in subsequent reactions, and these reaction cannot be performed in the catalytic mode. Triphenylphosphine was oxidised with nitrous oxide in an autoclave at 80 °C in the presence of phthalocyanine complexes of Al and Cu.[251]

In the studies cited, the possibility of the use of N_2O as the oxo donor in reactions catalysed by metal complexes was merely mentioned. However, a series of investigations in which N_2O was used in the catalytic cycle were published in recent years. Thus it was demonstrated [252] that Ru(II)(TMP)$(THF)_2$ (TMP is tetramesitylporphyrin) reacted with nitrous oxide under mild conditions. The reaction of the resulting complex, *viz.*, of *trans*-Ru(VI)$(O)_2$(TMP), with styrene afforded finally the starting Ru(II) complex and oxirane, thus closing the catalytic cycle. Yamada *et al.*[253] examined the possibility of activation of nitrous oxide with some low-valent transition-metal complexes. Oxidation of PPh_3 was used as the model reaction in the presence of acetylacetonates of the corresponding metals as precatalysts. It was found that Co- and Ni-containing compounds exhibit high activities. The reactions were carried out in the presence of 20 mol.% of metal acetylacetonate and 40 mol.% of diisobutylaluminium hydride under atmospheric pressure of N_2O.

$$Ph_3P \xrightarrow[N_2O,\ 20\ ^\circ C,\ PhMe]{M(acac)_n,\ Bu^i_2AlH} Ph_3PO$$

$M(acac)_n$	$Co(acac)_2$	$Ru(acac)_3$	$Fe(acac)_3$	$Pd(acac)_2$	$Ni(acac)_2$
Yield Ph_3PO (%)	98	43	18	0	89

VI. Applied aspects of the chemistry of nitrous oxide

1. Reduction in protic media

Reduction of nitrous oxide with a copper-containing enzyme, *viz.*, N_2O reductase, is one of the stages of microbiological denitrification [254]

$$NO_3^- \longrightarrow NO_2^- \longrightarrow NO \longrightarrow N_2O \longrightarrow N_2,$$

which, in turn, together with nitrogen fixation and nitrification comprise the global biogeochemical cycle of nitrogen in nature. At the same time, nitrous oxide can serve as a substrate both for natural nitrogenases [255,256] and for synthetic protic nitrogen-fixing systems.[257]

$$N_2O + 2e^- + 2H^+ \longrightarrow N_2 + H_2O.$$

It was demonstrated [258] that N_2O reacts also with aprotic synthetic nitrogen-fixing compositions.

$$Li-Me_3SiCl-MCl_n + N_2O \xrightarrow[-LiCl]{THF,\ 20\ ^\circ C,\ 24\ h} \longrightarrow [M{-}N(SiMe_3)_n] + (Me_3Si)_3N + Me_3SiOSiMe_3$$

M = Cr, Fe, Co, Ti.

A number of other metal-containing enzymes (CO dehydrogenase [259] and methionine synthetase [260]) also react with nitrous oxide.

Aqueous solutions of strong reductants, such as $CrCl_2$, can also reduce nitrous oxide [261] although this reduction proceeds very slowly. The rate constant of this reaction increases more than 10^8 times if nitrous oxide is present as a ligand in the $[Ru(NH_3)_5(N_2O)]^{2+}$ complex.[262] This complex, which was isolated in its individual state as salts with PF_6^- or BF_4^-,[263] is presently the only known stable metal complex containing N_2O as a ligand. The mode of coordination of nitrous oxide in this complex is not finally established;[264] however, according to calculations,[265] the Ru–NNO mode of bonding is preferential.

The reactions of N_2O with solutions of some transition-metal compounds were investigated.[266] In particular, it was demonstrated that the reduction of N_2O in aqueous solutions with potassium borohydride was catalysed by cobalt complexes $Co(bipy)_3(ClO_4)_3$ and $Co(DMG)_2PyCl$ (DMG is dimethylglyoxime) and by vitamin B_{12}.

$$Co(I) + N_2O \longrightarrow Co(II) + N_2.$$

In the absence of a reductant, vitamin B_{12} is oxidised by N_2O according to the following scheme

$$Cob(I)alamin + N_2O + H_2O \longrightarrow Cob(III)alamin + N_2 + 2OH^-,$$

$$Cob(I)alamin + Cob(III)alamin \longrightarrow 2Cob(II)alamin.$$

The discovery of this reaction, which proceeds both *in vitro* and *in vivo*, was of importance for anaesthetics and hematology.[267]

Tetraaza[14]annulene compounds of Ni(I) and Cu(I) also proved to be capable of reducing N_2O in the two-electron mode.[268] The Ni(II)Ann complex (Ann is tetraaza[14]annulene) was subsequently used as a catalyst of electrochemical reduction of nitrous oxide and showed high efficiency and chemical stability.[269]

Reduction of N_2O in aqueous solutions is a thermodynamically favourable process. However, in most cases the reactions in the absence of a catalyst proceed very slowly for kinetic reasons.

2. Electrocatalytic reduction

Presently, electrochemical processes are successfully used both in the synthesis of a great variety of compounds and in environmentally safe technological processes.[270,271] It is known that N_2O along with Freons plays a crucial role in the destruction of stratospheric ozone and hence maximum effort is expended to decrease its discharge to the atmosphere. As mentioned above, high-temperature catalytic processes are most often used for the neutralisation of nitrogen oxides. However, electrochemical reduction of nitrous oxide has advantages over thermal destruction because the former process is not accompanied by the formation of by-products, *viz.*, NO_x. Reduction of N_2O to molecular nitrogen is thermodynamically favourable.

$$N_2O + 2H^+ + 2e^- \longrightarrow N_2 + H_2O,\ E^\circ = +1.77\ V.$$

The kinetics of electrochemical reduction on platinum electrodes in alkaline [272] and acidic [273,274] solutions was examined by cyclic voltammetry. A model was proposed [273,274] according to which adsorbed hydrogen plays the key role in reduction of N_2O.

$$N_2O\ (ads) + H\ (ads) \longrightarrow N_2\ (g) + OH\ (ads).$$

On the other hand, Ahmadi *et al.*[275] believed that decomposition of adsorbed nitrous oxide is the limiting stage of this process.

$$Pt-N_2O\ (ads) \longrightarrow N_2\ (g) + Pt-O.$$

The stage of subsequent reduction on the electrode, on the contrary, proceeds very rapidly.

$$Pt-O + 2H^+ + 2e^- \longrightarrow Pt + H_2O.$$

Electrochemical reduction of N_2O on other metal [276,277] and semiconducting oxide [278,279] electrodes was investigated. With Au, Pd, Cu, Ag, ZnO or In_2O_3, high current efficiency was achieved.

Tetraaza[14]annulene-nickel complexes,[269,280] cobalt porphyrins,[281,282] myoglobin [283] and iron–molybdenum complexes [284] fixed on graphite electrodes can be used as catalysts of electrochemical reduction of nitrous oxide.

A possibility of performing the destruction of NO_x on a cathode under conditions of a gas diffusion electrode seems to be promising. Both platinum [285] (or modified platinum [286,287]) electrodes and electrodes prepared from other transition metals [288] are employed as cathodes. In all cases, reduction of N_2O to N_2

proceeds smoothly without the formation of by-products. In addition, it was demonstrated [285] that N_2O-H_2 (1 M KOH) fuel cells can be used as chemical sources of electrical current.

Catalytic reduction of N_2O with atomic hydrogen was successfully carried out in a special electrochemical membrane-type reactor.[289] Reduction of nitrous oxide with carbon monoxide was also performed in an electrolytic cell supplied with a solid oxide electrolyte.[290]

Considerable attention is given to the development of electrochemical methods for the analysis of nitrous oxide in liquids.[291, 292] These methods, unlike chromatographic methods, allow one to monitor changes in the N_2O content on-line. Undoubtedly, these gas analysers will find wide use in medicine, food industry and systems of environmental monitoring.

3. Radiation-induced reactions in aqueous media

Ionising radiation in water induces processes giving rise to radicals, ions and stable species:[293]

Product of water radiolysis	$^{\bullet}OH$	$^{\bullet}H$	e^-_{aq}	H_2	H_2O_2	H_3O^+
Radiochemical yield G /μmol J^{-1}	0.29	0.06	0.29	0.04	0.08	–

In aqueous solutions saturated with N_2O, solvated electrons e^-_{aq} react with nitrous oxide to give the $^{\bullet}OH$ radicals, the total radiochemical yield [$G(^{\bullet}OH)$] of the latter being increased to ~ 0.58 μmol J^{-1}.

$$N_2O + e^-_{aq} \longrightarrow {}^{\bullet}OH + N_2 + OH^-.$$

This procedure for the generation of hydroxyl radicals, which are powerful electrophilic oxidants, is rather widely used in the laboratory practice.[294, 295] In addition, the ability of N_2O to react with solvated electrons attracts attention of researchers engaged in the application of ionising radiation to purification of sewage. It is well known that radiation treatment (cathode-ray or gamma radiation) in combination with other chemical or biological methods for the purification of liquid waste often proves to be convenient for the decomposition of harmful impurities.[296] The efficiency of this purification can be improved by introducing compounds which transform water radiolysis products to radicals acting as reductants (oxidants).[297, 298] Bubbling of nitrous oxide through sewage may improve the efficiency of the purification process.[299] However, the presence of N_2O sometimes substantially impairs the efficiency of this process.[298]

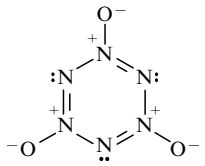
Not only gamma radiators or cathode-ray accelerators, but also ultrasonic probes and UV lamps can be employed as sources of ionising radiation. Thus photoinduced oxidation of aqueous solutions of Am(III),[300] Np(IV), Pu(IV),[301] aliphatic alcohols [302] and amino acids [303] saturated with nitrous oxide was reported. Shilov *et al.*[304] demonstrated that $\sim 35\%$ of Np(V) existing as a suspension of its hydroxide in 1 M LiOH solution saturated with N_2O was converted into Np(VII) upon sonication (44 KHz) for 40 min.

Oxidation of organic substrates with nitrous oxide under the action of ionising radiation can occur both in the gas phase [305] and in non-aqueous media.[306]

4. Nitrous oxide oligomers as potential high-energy materials

Semiempirical calculation procedures are finding increasing application in the search for new high-energy fuels and explosives. Before proceeding to the development of procedures for the synthesis of this type of compound, calculations are performed to elucidate whether conditions necessary for the preparation of the desired high-energy compound are fulfilled.

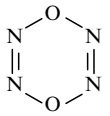
In a series of studies, calculations for hypothetical nitrous oxide oligomers were performed. Thus, Vol'pin *et al.*[307] examined the possibility of the existence of the cyclic trimer $(N_2O)_3$ (**18**). The heats of its formation (ΔH_0) calculated by different methods are given in Table 7.



18

The potential barrier to the $(N_2O)_3 \rightarrow 3\,N_2O$ decomposition reaction of the benzene-like molecule **18** (the ΔE_a value varies from 33 to 85 kcal mol^{-1}) is rather high, and it could exist due to kinetic stability.

Selected geometric and thermodynamical parameters (see Table 7) of the hypothetical cyclic structure N_4O_2 (**19**) were discussed.[308, 309]



19

Jones [308] believed that the N_4O_2 molecule is planar (the symmetry group D_{2h}). However, Manaa and Chabalowski [309] reasoned that this conformation is only intermediate one between two equivalent boat conformations (the symmetry C_{2v}). According to the calculations performed by these authors, the potential barrier to this transformation is approximately 7–10 kcal mol^{-1}.

Table 7. Heat of formation ΔH_0 of nitrous oxide cyclic oligomers.

Oligomer	ΔH_0 /kcal mol^{-1}						Ref.
	MINDO/3	MNDO	AM1	DZPSCF	MP_2	QCSISD	
18	−17	−48	−155				307
19	−48.5	−3.2	−82.0				308
				−86.3	−100.5	−78.5	309

The assumed structures and properties of open-chain,[310] crown-like [311] and $(NO)_3$-grafted [312] nitrous oxide oligomers were considered with the use of *ab initio* calculations. Jones and Csizmadia [310–312] believed that the occurrence of such metastable compounds is quite possible. The authors reasoned that high pressures, which have become accessible in recent years, can provide a decrease in the activation energy necessary for polymerisation of nitrous oxide and favour the formation of these unusual structures.

It should be noted that the $(N_2O)_n$ polymers in the form of ionic clusters [313, 314] or weakly bound complexes [315, 316] have long been known. However, these systems are of no interest as high-energy compounds. Thus the trimer of nitrous oxide, which has been observed in a molecular beam by IR spectroscopy,[315] exists as a non-planar acyclic weakly bound molecular complex characterised by the energy of dissociation into monomers equal to ~ 3.5 kcal mol^{-1}.

5. Nitrous oxide in the supercritical state

In the late 1980's, liquids in the supercritical state rekindled interest owing to their unique properties and unusual sensitivity with respect to small changes in the state parameters. The major fields of their application are supercritical liquid extraction,[317] chromatography [318] and synthetic chemistry.[319, 320]

Nitrous oxide in the supercritical state [N_2O(sc)] is more polar than CO_2(sc), which allows one to use the former with greater success both for extraction of different organic compounds [321, 322] and as a mobile phase in chromatography.[323, 324] In the synthetic chemistry, N_2O(sc) can be employed either as a reagent [195] or as a solvent.[325] Oxidation of tertiary phosphines with N_2O(sc) or with

the $N_2O(sc)/CO_2(sc)$ mixture was performed.[195] However, attempts to oxidise other classes of organic compounds, including compounds sensitive to oxidation by atmospheric oxygen, such as aldehydes, failed.[195] Poh *et al*.[195] reported that secondary alcohols can be oxidised under analogous conditions in the presence of palladium black. In addition, in some cases[326, 327] the use of $N_2O(sc)$ in the presence of rather low concentrations of organic compounds led to explosions. This is a serious obstacle to the wide application of $N_2O(sc)$ as a reagent. However, it is believed that the use of co-solvents, two-phase systems or carefully selected conditions can make these reactions less dangerous.

VII. Conclusion

Analysis of the data published over the last fifteen years demonstrated that the majority of studies concerned in one way or another with nitrous oxide have been carried out within the framework of either the environmental chemistry or heterogeneous catalysis. It should be noted that these lines of investigation are closely related.

On the one hand, there is a need to diminish the emission of nitrous oxide by 70% – 80% to stop an increase of its content in the atmosphere. This aim should be aided by employing new selective catalysts of decomposition of nitrous oxide in motor vehicles, heating and power plants and industrial processes. On the other hand, there are grounds to believe that N_2O will be used as one of the major oxidants in industry. Presently, procedures for the preparation of nitrous oxide by direct oxidation of ammonia over a catalyst are being developed.[167, 328, 329]

In our opinion, in the coming years the major efforts will go into the solution of problems associated with catalytic activation (destruction) of N_2O and ecological monitoring of nitrous oxide in the atmosphere.

Abstract. The results of studies on the synthesis, structure, thermochemistry and oxidising capacity of organic hydrotrioxides are generalised. Particular emphasis is placed on the analysis of thermal and catalytic decomposition of ROOOH and on generation of free radicals and singlet molecular oxygen. Problems concerning the mechanisms of formation and decomposition of organic hydrotrioxides are also considered. The bibliography includes 154 references.

I. Introduction

The chemistry of trioxides, *viz*., compounds with a $-O-O-O-$ fragment, has been a matter of considerable interest during recent decades.[1–5] The family of trioxides comprises hydrogen trioxide HOOOH, organic hydrotrioxides ROOOH, dialkyl- and diaryltrioxides ROOOR. Primary ozonides (1,2,3-trioxolanes) and transannular ozonides can be considered as cyclic analogues of dialkyl- and diaryltrioxides. Phosphite ozonides [*e.g*., $(RO)_3PO_3$], ozone–arene complexes $ArX \cdot O_3$ as well as alkali metal and ammonium ozonides also belong to trioxides.

The nomenclature of compounds with the general formula RO_nR' has not been settled yet. For $n = 2$, this formula corresponds to the class of peroxides, the simplest representative of which is hydrogen peroxide (or hydrogen dioxide), HOOH. Extension of the oxygen chain by an O atom gives compound HOOOH, which by analogy should be named 'hydrogen trioxide'. Replacement of H atoms by organic radicals leads to 'hydrotrioxides' (HTO), ROOOH, and 'trioxides', ROOOR. 'Tetraoxides' RO_4R are formed in the radical-chain oxidation of organic compounds, in the stage of quadratic termination of the oxidation chain induced by peroxyl radicals $ROO^{\bullet}$. Hydrotrioxides of different classes of organic compounds have the general formula ROOOH and should probably be named by analogy with hydroperoxides ROOH. For instance, the term 'acylhydrotrioxides' refers to aldehyde hydrotrioxides.

In this review, we analyse the publications devoted to the synthesis, structure and decomposition of HTO and their use as oxidants of various organic compounds. The latest review concerning this topic was published by Plesničar in 1992.[4] Since then, numerous papers dealing with various aspects of the chemistry of HTO have appeared and a considerable body of new information on their structures and reactivity has been obtained. Progress in the studies of HTO necessitates generalisation of these data, refinement or even revision of some statements in Plesničar's review [4] concerning, *e.g*., the efficiency of generation of $^1O_2$ in the decomposition of HTO. In addition, the kinetics of the synthesis of ROOOH, the synthesis of ROOOH on surfaces, thermochemistry of HTO and related compounds, radical and catalytic decomposition of HTO, the use of HTO as oxidants of unsaturated, organophosphorus, nitrogen- and sulfur-containing organic compounds are considered in detail in the present review. We also present comprehensive information on the kinetics of thermal decomposition of HTO and report a critical analysis of the data on the efficiency of generation of singlet molecular oxygen in the thermal decomposition of ROOOH. In his review,[4] Plesničar did not dwell on these problems or only briefly outlined them.

Finally, it should be noted that studies carried out by the researchers from the Russian Federation have been incompletely covered in that review.[4] Therefore, we deemed it our duty to consider in the present review not only the results of studies carried out during the last eight years but also those reported before 1992.

For a rather long time, HTO were thought of only as hypothetic labile intermediates in the studies of the mechanisms of ozonisation of saturated organic compounds. However, once the fact that hydrotrioxides are stable at low temperatures had been revealed, the chemistry of HTO has progressed rapidly. Methods for the synthesis of HTO have been developed which allow the preparation of HTO at concentrations as high as ~ 1 mol litre^{-1}. Organic HTO appeared to be both efficient oxidants in reactions with various organic substrates and convenient chemical sources of singlet molecular oxygen in organic media.

A hypothesis that hydrotrioxides are formed as intermediates in the ozonisation of certain organic compounds RH was first put forward independently by Price and Tumolo [6] and by White and Bailey [7] to rationalise the results obtained in studies of the reactions of ozone with ethers [6] and aromatic aldehydes.[7] Rapidly, this hypothesis has gained acceptance and was nearly simultaneously used by different authors in their studies on ozonisation of saturated hydrocarbons,[8–10] alcohols,[9] acetals [11] and silanes.[12]

Murray *et al.*[13–15] were the first who have provided strong experimental evidence for the existence of HTO. They have shown that unstable peroxide compounds **1a**, **2** and **3a** (Table 1) accumulated in the reaction medium during the low-temperature ozonisation of benzaldehyde, 2-methyltetrahydrofuran and isopropyl methyl ether, respectively. A signal at δ 13.1 was present in the ^{1}H NMR spectra of compounds **1a**, **2** and **3a**, which was tentatively assigned to the OOOH proton.

In further studies, ^{1}H NMR spectroscopy has become the basic method for identification and quantification of HTO in solution. Table 1 lists hydrotrioxides derived from aromatic aldehydes, ethers, linear and cyclic acetals, alcohols and ketones and Table 2 presents hydrotrioxides derived from hydrocarbons known to date. Organic compounds of other carbon subgroup elements also form hydrotrioxides upon oxidation by ozone. Hydrotrioxides of organosilicon and organogermanium com-

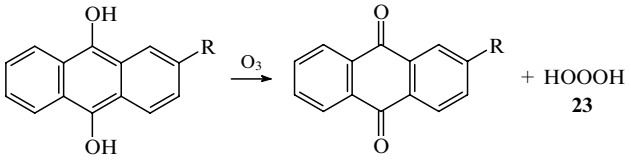
II. Synthesis of hydrotrioxides

It was only recently that the methods for the synthesis of the simplest trioxide, HOOOH (**23**), have been proposed. Hydrogen trioxide **23** is formed upon oxidation of 9,10-dihydroxyanthracene, 2-ethyl-9,10-dihydroxyanthracene or hydrazobenzene by ozone (−78 °C, acetone-d_6 or methyl acetate).[34]



R = H, Et.

Hydrogen trioxide **23** is also formed in the decomposition of silane hydrotrioxides.[33, 34]

All HTO listed in Tables 1–3 can be synthesised using a rather simple and virtually identical procedure consisting of bubbling a cooled O_3-O_2 or O_3-N_2 gas mixture through a liquid substrate RH or its solution at reduced temperature (−20 to −78 °C). After completion of the reaction, the unconsumed ozone is removed by blowing air or (if necessary) an inert gas and then the concentration of HTO in the solution is determined by NMR spectroscopy. The yield of ROOOH with respect to the consumed RH depends on the substrate structure and varies from 1%–2% for cumene hydrotrioxide **8** to 70%–90% for acetal, alcohol and silane hydrotrioxides.

A modified procedure for the synthesis of HTO involves ozonisation of organic compounds on the surface of silica gel (the so-called 'dry' ozonisation).[18, 31, 32, 38, 39] It was used to obtain the hydrotrioxides **11** and **15**–**19**, which could not be prepared in the liquid-phase ozonisation.[18, 31, 32] Highly polar silica gel surface stabilises the ionic intermediates of the ozonisation reaction, thus favouring the formation of ROOOH even from non-activated hydrocarbons. It can be hypothesised that 'dry' ozonisation will also be convenient for the synthesis of other HTO which cannot be obtained by liquid-phase ozonisation.

The kinetics of formation of compounds **3m**,[16] **4h**,[21] **6d**,[25] **6f**[16] and **7b**[27] have been studied. At sufficiently low temperatures where thermal decomposition of HTO can be ignored the kinetic curves of accumulation of HTO have the shape of saturation curves, which means that the yield of ROOOH (α) calculated with respect to the ozone consumed decreases with an increase in conversion. The extent of the reaction is related to the amount of the ozone absorbed $\Delta(O_3)$ and the yield of ROOOH is calculated by the formula

$$\alpha = \frac{[ROOOH]}{\Delta(O_3)}.$$

The yield calculated with respect to the ozone consumed (α_0) is obtained by extrapolating the value of α to the zero time [$\Delta(O_3) = 0$].

The α_0 values for a number of HTO are listed in Table 4. The decrease in the yield with the increase in the extent of the reaction is explained by consumption of the HTO in the reactions with ozone.

The rate constants for the first (k_1) and second (k_2) stages of ozonisation of 1,1-diethoxyethane at −60 and −80 °C are $k_1 = 6.8 \times 10^{-4}$ and 2.5×10^{-5} litre mol^{-1} s^{-1} and $k_2 = 3.0 \times 10^{-3}$ and 1.2×10^{-4} litre mol^{-1} s^{-1}, respectively.[21]

III. The structure, thermochemistry and spectroscopy

1. The structure

a. Equilibrium molecular geometry of hydrotrioxides

Experimental data on the spatial structure of HTO are lacking and this was established only from the results of semiempirical (EHT, CNDO/2, MINDO/3, AM1)[40–43] and *ab initio* quantum-chemical calculations.[33, 44–54]

Ab initio calculations of the equilibrium molecular geometry of HOOOH have been carried out at different levels of theory, from simple calculations in the one-determinant approximation with the STO-2G basis set to sophisticated calculations with different TZP basis sets augmented with diffuse functions and intensive treatment of electron correlation. Both partial[44–48, 50] and full optimisation of the molecular geometry[33, 49, 51, 52, 54] were employed. Tables 5 and 6 present the results of *ab initio* calcu-

lations [53] of the molecular structures of HOOOH, H_3COOOH and $H_3SiOOOH$ with full geometry optimisation.

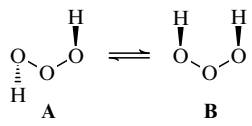
The data listed in Tables 5 and 6 reveal salient features of the molecular geometry of hydrotrioxides.

1. The r(O−O) distances in trioxides are close to those in peroxides. Blint and Newton [46] found that the O−O bond length can be calculated with a reasonable accuracy using the empirical Pauling equation

$$r_e = r_e^s - \alpha \ln(n), \quad (1)$$

where r_e is the equilibrium bond length (Å); r_e^s is the equilibrium length of a bond with the order of unity; $\alpha = 0.351$ Å is the empirical constant; and n is the bond order. According to calculations with the 4-31G basis set, r(O−O) ≈ 1.41 – 1.44 Å in polyoxides. The O−O bond in HOOOH is 0.03 to 0.04 Å shorter than in HOOH. A similar tendency of changes in the O−O bond length is observed for the pairs H_3COOOH/H_3COOH and $H_3SiOOOH/H_3SiOOH$,[54] which seems to be a general feature.

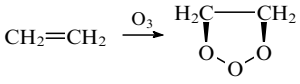
2. The torsion (dihedral) angle φ in the HTO molecules characterises the positions of the substituent atoms with respect to the plane passing through three O atoms. According to the most sophisticated calculations,[49, 54] $\varphi \approx 75 – 80°$. The calculations revealed two stable conformations, *anti* (**A**) and *syn* (**B**), for the hydrogen trioxide molecule, which differ in positions of the H atoms with respect to the trioxide plane.



A **B**

The assumption of the existence of stable *anti* and *syn* conformations of hydrogen trioxide molecule (**23**) is indirectly confirmed by the results of IR and microwave spectroscopic studies of hydrogen trisulfide, a close analogue of HOOOH.[55] According to the results of quantum-chemical calculations carried out at the MP2/TZ+P and QCISD/TZ+P levels of theory, the *anti* conformation of HSSSH molecule is 0.25 kcal mol^{-1} (87 cm^{-1}) more stable than the *syn* conformation.

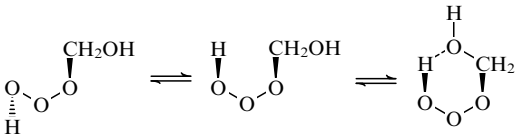
For the HOOOH molecule, conformation **A** is more energetically favourable (by 3.5±1.0 kcal mol^{-1}) than conformation **B** (see Refs 43, 44, 46, 49). This gives a rationale of the low stability of 1,2,3-trioxolanes, which are intermediates of the ozonolysis of alkenes, compared to linear trioxides. The molecule of primary ozonide (1,2,3-trioxolane **24**) adopts an 'envelope' conformation [56, 57] in which the positions of methylene groups formally correspond to the *syn* conformation of the trioxide.



24

Hence, the energy of conformational transition and strain energy in the five-membered ring [∼6 kcal mol^{-1} (see Ref. 58)] contribute to the destabilisation of the primary ozonide. As a consequence, the activation energy of further transformations of compound **24** is ∼10 kcal mol^{-1} lower than those of thermal decomposition of dialkyl trioxides.[5]

Hydrotrioxides derived from alcohols, ethers and acetals can form intramolecularly hydrogen-bonded structures only if these molecules adopt the *syn* conformation.[13, 14, 16, 17, 19, 20, 24]



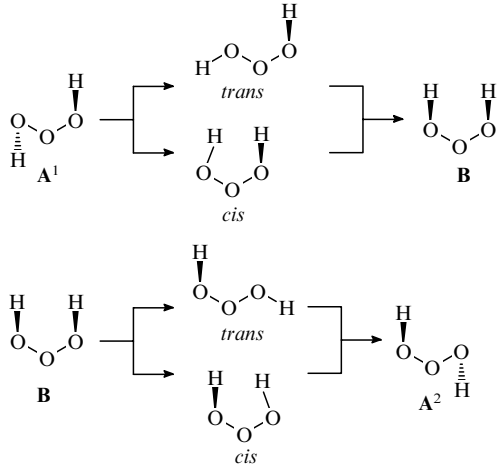
Hence, the enthalpy of formation of a hydrogen bond, $\Delta H°$, includes the *anti*–*syn* interconversion energy.[18] Radical decomposition of the cyclic intermediate removes the conformational strain, thus decreasing the activation energy for this process.

3. The H−O−O and C−O−O bond angles (see Tables 5 and 6, respectively) in hydrotrioxide molecules are somewhat larger than in the corresponding hydroperoxides. The O−O−O bond angles in different HTO (104 – 107°) are in good agreement with the IR spectroscopic estimate.[59]

4. Conformational analysis of the HOOOH molecule has been carried out.[49] The potential energy surface for simultaneous

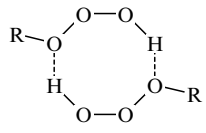
rotation of the OH groups about the O—O axes in the molecule was calculated. Analogous semiempirical AM1 calculations were carried out for hydrogen trioxide and tetraoxide.[43] The nature of the barriers to rotation was interpreted based on the results of the Fourier analysis of the conformational potential of the polyoxides. The conformational behaviour of polyoxides is dominated by the repulsion between the lone electron pairs of the neighbouring oxygen atoms and by stabilisation of the hydropolyoxide owing to delocalisation of the lone electron pair (n_O) over the σ*-antibonding orbital of the neighbouring O—O bond (or O—C and O—H bonds).[18, 54] The latter effect provides an explanation for the shortening of the r(O—O) distance in trioxides compared to peroxides, since the stabilising effect of hyperconjugation $n_O - \sigma^*_{O-O}$ on the trioxide molecule is more pronounced than that of hyperconjugation $n_O - \sigma^*_{O-OH}$ on the peroxide molecule, thus favouring a decrease in the O—O bond length.[54]

Analysis of the potential surface for internal rotation of hydrogen trioxide suggests that the most favourable conversional process between two global energy minima (**A**[1] and **A**[2]) for the *anti* conformation of HOOOH involves a two-step flip-flop rotation rather than simultaneous rotation of the OH groups.[43, 49]



b. Association of hydrotrioxides

The binding energies of the intermolecularly hydrogen-bonded dimers were calculated taking dimerisations of HOOOH, H_3COOOH and $H_3SiOOOH$ as examples.[33, 53]

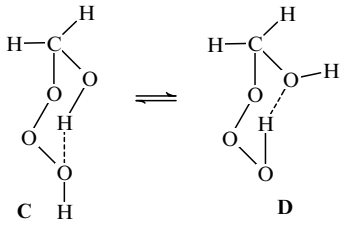


R = H, CH_3, SiH_3.

Relatively high binding energies (E = 6–8 kcal mol^{-1} per O—H bond) are close to the hydrogen bond energy in cyclic dimers of carboxylic acids.[60, 61] This confirms the assumption that self-association is a salient feature of HTO molecules. It should be noted, however, that the computational method (RHF/6-31G) employed by Plesničar *et al.*[33, 53] overestimates the energies of hydrogen bonds. Indeed, augmentation of the basis set with *p*-polarisation functions for hydrogen and *d*-polarisation functions for other atoms leads to more realistic results, *viz*., the binding energy of H_3COOOH in the eight-membered dimer is 4.5 kcal mol^{-1} per hydrogen bond.[18]

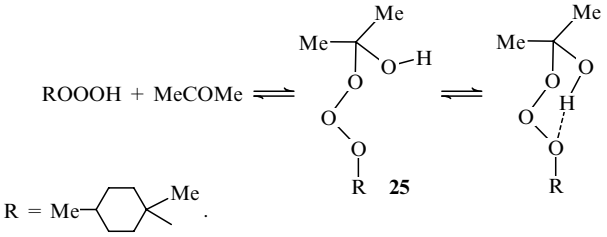
The effect of water on the decomposition of HOOOH has been studied.[52, 54] The water molecule acts as a bifunctional catalyst, thus facilitating the decomposition of hydrogen trioxide into H_2O and $^1O_2$. This reaction is preceded by the formation of a six-centred hydrogen-bonded complex. The binding energy in this complex is 1.5 kcal mol^{-1} lower than in the cyclic dimer of HOOOH. The calculated height of the potential barrier to decomposition of hydrogen trioxide (15.1 kcal mol^{-1} relative to noninteracting reagents) is in good agreement with the experimentally found effective activation energies for the decomposition of HOOOH.[34, 52, 62]

Ab initio calculations of intramolecularly hydrogen-bonded structures ROOOH have been carried out taking methanol hydrotrioxide (**6a**) as an example.[18] The most stable conformers of the molecule are the *anti* (**C**) and *syn* (**D**) conformers with nearly equal energies.



The *anti* conformer **C** is stabilised by the hydrogen bond between the H atom of the alcoholic hydroxy group and the most distant (from the carbon atom) O atom of the trioxide fragment. The *syn* conformation **D** favours the formation of a hydrogen bond between the OOOH hydrogen and alcoholic O atom. The binding energies of structures **C** and **D** calculated at the MP2//RHF/6-31G** level of theory are 2.2 and 5.4 kcal mol^{-1}, respectively.

In conclusion, mention should be made that HTO can form associates with carbonyl compounds.[18] In addition to the signal at δ = 13, the ^{1}H NMR spectrum of 1,4-dimethylcyclohexyl hydrotrioxide (**16**) in acetone exhibits two peaks at δ = 4.15 and 4.35 which disappear irreversibly upon heating. It is well known that hydrogen peroxide[63] and hydroperoxides[64, 65] readily react with aliphatic and alicyclic ketones to give α-hydroxy hydroperoxides and α-hydroxy peroxides. Presumably, a similar reversible reaction occurs in the system HTO **16** – acetone resulting in a derivative of 2-R-trioxy-2-hydroxypropane **25**.[18] Compound **25** exists in two forms, which accounts for the presence of two OH proton resonance peaks in its ^{1}H NMR spectrum.



2. Thermochemistry

In this Section, we outline briefly the possibilities of estimation of the enthalpies of formation and bond dissociation energies in hydrotrioxides. For more detailed data, see a recent review.[66]

The experimentally determined thermodynamic characteristics of HTO (enthalpies of formation and of phase transitions, entropies, *etc*.) are lacking. Therefore, thermochemical calculations of the thermal effects of the reactions involving ROOOH were carried out using approximate computational schemes, in particular, the approach of additivity of thermochemical increments developed by Benson *et al.*[58, 67, 68] In the framework of Benson's scheme, the enthalpies of formation of hydropolyoxides are related by simple relationships

$$\Delta_f H^\circ(\text{ROOOH}) = \Delta_f H^\circ(\text{ROOH}) + \Delta_f H^\circ[\text{O}-(\text{O})_2], \quad (2)$$

$$\Delta_f H^\circ(\text{ROOOOH}) = \Delta_f H^\circ(\text{ROOOH}) + \Delta_f H^\circ[\text{O}-(\text{O})_2], \quad (3)$$

where the second term in the right side of Eqns (2) and (3) is the polyoxide group increment, which characterises the enthalpy contribution of the central O atom of the trioxide fragment. As will be shown below, the assumption that the enthalpy of formation changes linearly in the order ROOH—ROOOH—

ROOOOH is rough and leads to substantial discrepancies between the results of thermochemical studies carried out by different authors.

Practically, the most convenient way of calculating the $\Delta_f H^\circ$(ROOOH) values is to use Eqn (2). A number of experimentally determined enthalpies of formation of hydroperoxides has been reported.[69] Good agreement with experimental $\Delta_f H^\circ$(ROOH) values is also observed when using the method of isodesmic reactions as well as *ab initio* calculations with extended basis sets and inclusion of electron correlation (CI or perturbation theory).[70, 71] Unfortunately, high computational cost of real-time calculations of $\Delta_f H^\circ$(ROOH) allows them to be carried out only for the simplest substituents R. Thermochemistry of peroxides has been analysed using a large body of experimental data on the enthalpies of formation (see Ref. 72 and references cited theirein), increments for calculating $\Delta_f H^\circ$(ROOH) in both the gas phase and condensed phase were proposed.

The polyoxide group increment, $\Delta_f H^\circ[O-(O)_2]$, which plays the key role in calculations of the enthalpies of formation of hydrotrioxides, cannot be calculated from the available experimental data on $\Delta_f H^\circ$ and bond dissociation energies in related compounds. Since the accuracy of indirect estimates is insufficient, the numerical value of $\Delta_f H^\circ[O-(O)_2]$ has been the subject of systematic revisions.[70, 73–77]

a. Comparison of the enthalpies of formation

The first estimates of $\Delta_f H^\circ[O-(O)_2]$ (25±6 and 19±4 kcal mol^{-1}, see Refs 73 and 74, respectively) were made based on the assumption that thermodynamic properties change linearly in the order $ROR'-ROOR'-ROOOR'$ and from comparison of the enthalpies of formation for pairs of compounds H_2O and H_2O_2,[73, 74] MeOH and MeOOH and MeOMe and MeOOMe.[74] This approach was found to be very rough. In particular, the results obtained suggested that tetraoxides can be synthesised at temperatures below 80–100 K.[74] Later, it has been shown[78–80] that tetraoxides ROOOOR (R = *tert*-Alk, ArAlk) are rather stable at $T \leqslant 170$ K, which indicated overestimation of the $\Delta_f H^\circ[O-(O)_2]$ value reported in earlier studies.[73, 74]

b. Comparison of thermal effects of reactions

Another procedure for the calculation of the polyoxide group increment was used by Nangia and Benson.[75] Based on the reaction equations

$$Bu^tOOOOBu^t \longrightarrow 2\,Bu^tOO, \quad (4)$$

$$Bu^tOOOBu^t \longrightarrow Bu^tO + Bu^tOO, \quad (5)$$

$$Bu^tOOBu^t \longrightarrow 2\,Bu^tO \quad (6)$$

with the known thermal effects $\Delta H^\circ(4) = 9.0\pm1.5$[78, 79] and $\Delta H^\circ(6) = 38.0\pm1.0$ kcal mol^{-1} (see Ref. 81) and using the additivity rule, according to which

$$\Delta H^\circ(5) = 0.5[\Delta H^\circ(4) + \Delta H^\circ(6)],$$

they found that $\Delta H^\circ(5) = 23.5\pm0.8$ kcal mol^{-1} and $\Delta H^\circ(6) - \Delta H^\circ(5) = \Delta H^\circ(5) - \Delta H^\circ(4) = 14.5\pm0.8$ kcal mol^{-1}. By representing the enthalpies of formation of the molecules under study as the sums of the enthalpies of formation of the thermochemical groups, one can readily obtain the expression for the calculation of the polyoxide group increment

$$\Delta H^\circ(6) - \Delta H^\circ(5) = \Delta_f H^\circ(RO) - \Delta_f H^\circ(ROO) + \Delta_f H^\circ[O-(O)_2]. \quad (7)$$

Using the known values of the enthalpies of formation of the $MeO^\bullet$ and $MeOO^\bullet$ radicals, the new polyoxide group increment $\Delta_f H^\circ[O-(O)_2]$ was found to be 16.8±2.2 kcal mol^{-1} (see Ref. 75). A year later, Nangia and Benson corrected this estimate and reported that $\Delta_f H^\circ[O-(O)_2] = 14.8$ kcal mol^{-1}.[76] This approach has a drawback consisting of the assumption of linear changes in the ΔH° of the reactions (4)–(6). Recent experiments showed that $\Delta H^\circ(5) = 20-21$ kcal mol^{-1} (see Refs 18, 82, 83). Mention has been made of the nonlinear character of changes in the enthalpies of formation in the order 'peroxide–trioxide–tetraoxide'.[84]

c. Quantum-chemical calculations of the enthalpies of formation

The use of quantum-chemical methods has opened new possibilities for the thermochemical analysis of the reactions of HTO and higher polyoxides.[44, 46, 50, 70, 71, 77, 82, 84–87] However, direct calculations of the enthalpies of formation of polyoxides can lead to large errors owing to incomplete inclusion of electron correlation in the *ab initio* computational schemes and inadequate parametrisation of semiempirical methods. This can be illustrated as follows. The enthalpy of formation of MeOOOH obtained from MP4SDTQ/6-31G*//MP2/6-31G* calculations is −22.2 kcal mol^{-1} and must correspond to the energy of dissociation of the weakest O–O bond, D(MeO–OOH); however, D(MeO–OOH) = 35.8 kcal mol^{-1} (see Ref. 70). The value cannot be regarded as realistic despite the high level of quantum-chemical calculations. It is only 2 to 3 kcal mol^{-1} lower than the corresponding bond dissociation energies in peroxides. However, the temperature intervals of stability of these compounds are not comparable: peroxides are rather stable at room temperature, while the lifetimes of HTO under these conditions are within several minutes. Therefore, the numerical estimates of the polyoxide group increment obtained from both semiempirical MNDO[77] and *ab initio*[70] calculations of $\Delta_f H^\circ$ of polyoxides {$\Delta_f H^\circ[O-(O)_2]$ = 13.1±1.5 and 9.6±0.1, respectively} should be used with caution.

d. Quantum-chemical calculations of bond dissociation energies

The best results can be obtained from calculations of bond dissociation energies (strengths). This is due to mutual cancellation of the errors of calculations of $\Delta_f H^\circ$ for polyoxide and its decomposition products. Systematic studies of the O–O and O–H bond dissociation energies in organic polyoxides (see Table 7) have been carried out.[18, 82, 84–86] This allowed calculations of the enthalpies of formation for a number of peroxides, trioxides and tetraoxides. It was found that the difference $\Delta_f H^\circ(ROOR') - \Delta_f H^\circ(ROR')$ is 5 to 8 kcal mol^{-1} larger than $\Delta_f H^\circ(ROOOOR') - \Delta_f H^\circ(ROOOR')$. The reason for this discrepancy was explained based on the results of analysis of the conformational potentials of polyoxide compounds H_2O_x (x = 2,

Table 7. Bond strengths D (kcal mol^{-1}) in organic hydropolyoxides.

Bond type	D	Ref.

[a] R = Alk. [b] R is unsubstituted, halo-, hydroxy- or alkoxy-substituted alkyl. [c] R = Me. [d] R is unsubstituted, halo-, hydroxy- or alkoxy-substituted alkyl, H, HCO or MeCO.

3, 4).[43] It was shown that the enthalpies of formation in the series 'peroxide – trioxide – tetraoxide' do not change linearly as it would follow from the additivity method owing to additional stabilisation of peroxides by the dipole – dipole interaction between the alkoxy groups. Therefore, the $\Delta_f H^\circ[O-(O)_2]$ group increment can be calculated as the difference between the enthalpies of formation of a trioxide and tetraoxide with the same substituents. Calculations of the enthalpies of formation of trioxides from the corresponding peroxides should be carried out with inclusion of the energy of conformational rearrangement of the molecule (~ 5 kcal mol^{-1}).

For practical calculations of $\Delta_f H^\circ$ values in polyoxides we recommend the following relationships

$$\Delta_f H^\circ(\mathrm{ROOOR}') = \quad (8)$$
$$= \Delta_f H^\circ(\mathrm{ROOR}') + (17.6 \pm 1.6) \text{ kcal mol}^{-1},$$
$$\Delta_f H^\circ(\mathrm{ROOOOR}') = \quad (9)$$
$$= \Delta_f H^\circ(\mathrm{ROOOR}') + (11.1 \pm 1.0) \text{ kcal mol}^{-1}.$$

Calculations using Eqns (8) and (9) allow correct reproduction of the intervals of thermal stability of trioxides and tetraoxides and give the bond dissociation energies that are close to the activation energies for decomposition of polyoxides (provided that E_a is corrected for the normal value of the pre-exponential factor).

3. Spectroscopic studies

a. UV, IR and Raman spectra

Scarce experimental data indicate that the electronic spectra of HTO are similar to those of related peroxide compounds. The optical spectrum of HOOOH obtained in the pulse radiolysis experiments is similar to that of hydrogen peroxide and exhibits a somewhat larger molar extinction, $\varepsilon \approx 100$ litre mol^{-1} cm^{-1} ($\lambda = 240$ nm).[62] Weak absorption at $\lambda > 320$ nm in the spectrum of benzaldehyde hydrotrioxide (**1a**) can be assigned to the S_1 ($\pi^*_{O-O} \rightarrow \sigma^*_{O-O}$) transition. The position and spectral features of this signal are similar to those of aromatic endoperoxides.[89] Thus, the UV spectra of HTO exhibit no characteristic bands suitable for identification and determination of the concentration of ROOOH. Since almost any reaction of the synthesis or decomposition of HTO proceeds to give peroxides as side or major products, one can conclude that investigations into the chemical nature of organic HTO based on the UV spectra is hardly probable.

Specific features of the IR spectra of hydrogen and deuterium trioxides and tetraoxides allowed Giguere and Herman [59] to relate the observed frequencies to vibrations of the zigzag chain of the O atoms linked by single bond. They estimated the O – O bond length at ~ 1.5 Å and the O – O – O bond angle at 100 to 120 ° and concluded that internal rotation of the OH groups in free molecules is only weakly hindered, whereas in the solid state their orientation will be strongly dependent on the possibility of hydrogen bonding, as in hydrogen peroxide. More recently,[90] normal coordinate analyses for HOOOH and HOOOOH molecules were performed. Nonplanar hydrogen polyoxide structures exhibited fairly good correspondence between the calculated frequencies and experimental IR spectrum and the existence of several spatial isomers was suggested. Further quantum-chemical studies have confirmed in general the above-mentioned conclusions [59, 90] (see Table 3).

Raman spectra of hydrogen polyoxides have been studied.[91, 92] The fundamental skeletal vibrations of the HOOOH and HOOOOH molecules and their deuterated analogues were identified and interpreted (Table 8). The frequencies observed are consistent with the C_2 symmetry of the molecular structure in the form of a skew chain of O atoms linked by single bonds.

Vibrational spectra of organic hydroperoxides have not been studied as yet.

Table 8. Vibrational spectra of hydrogen polyoxides.[92]

b. NMR studies

Organic HTO can be conveniently identified by NMR spectroscopy owing to the presence of characteristic signals of the hydrotrioxide fragment. Resonance absorptions of other groups are less characteristic. The chemical shifts of the ^{1}H, ^{13}C and ^{29}Si nuclei in the NMR spectra of a number of HTO and related compounds [17, 29, 33] are listed in Tables 9 and 10.

Typical of HTO is the signal of the OOOH proton at $\delta \sim 13$ in the ^{1}H NMR spectra, the position of the signal being virtually independent of the nature of ROOOH.[13 – 17, 19 – 21, 23 – 30, 33, 34, 36, 37] In the series ROH – ROOH – ROOOH, the chemical shift of H increases from δ 0.5 – 5.5 for ROH to δ 7.6 – 9.2 for ROOH [93] and δ 12 – 14 for ROOOH. Unlike alcohols and hydroperoxides,[93] dilution of HTO solutions has little effect on the chemical shift of the trioxide proton. Based on these observations, it was concluded that hydrotrioxides form strong intramolecularly hydrogen-bonded complexes.[13, 14]

A peculiarity of the ^{1}H NMR spectra of hydrotrioxides is the appearance, in some cases, of the splitting of the OOOH proton signal into two signals.[14, 16, 17, 19, 20, 24] The chemical shifts of these signals also show little change with dilution. Heating of the samples results in broadening and coalescence of the lines. The coalescence temperature depends on the chemical nature of both ROOOH and the solvent. For instance, two peaks in the ^{1}H NMR spectrum of 2-methyltetrahydrofuran hydrotrioxide (**2**) coalesce at -27 °C.[14] For hydrotrioxide **3b** obtained from methyl α-methylbenzyl ether in Freon 11/12, two peaks appear in its ^{1}H NMR spectrum only at -50 °C and lower temperatures, whereas no peak coalescence is observed in diethyl ether, acetone-d_6 and ethyl acetate even at -10 °C.[17] The origin of two resonance signals for the OOOH proton is still to be clarified. This can be due to either the 'chair – boat' conformational transition of the six-membered ring resulting from the formation of intramolecular hydrogen bond or the presence of two conformations with the R group at the O atom in either axial or equatorial position. Hydrotrioxides derived from cyclic acetals [19, 20] can form various complexes owing to nonequivalence of the two acetal O atoms with respect to the OOOH group.

Studies of the ^{1}H NMR spectra of hydrotrioxides in different solvents [17] showed that though the chemical shifts of two peaks vary insignificantly, their relative intensities can vary over a rather wide range (see Table 9). In diethyl ether, the more intense low-field peak of the hydrotrioxide **3b** disappears upon heating with a somewhat higher rate compared with the high-field signal. The

possibility of assigning the weaker signal to the ROOOH formed from the solvent was rejected.[17]

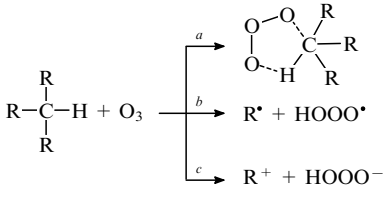
Based on the results of the concentration dependence and temperature variation studies, Plesničar *et al.*[17] concluded that HTO can form either intramolecularly hydrogen-bonded structures or rather strong eight-membered intermolecular associates.

In conclusion mention may be made of the first identification of isopropyl alcohol hydrotrioxide (**6f**) and hydrogen trioxide (**23**) by ^{17}O NMR spectroscopy.[94,95] The experimental results are in reasonable agreement with those of the *ab initio* GIAO/MP2/6-311++G** calculations of the ^{17}O chemical shifts. For HO(1)O(2)O(3)H (**23**), the experimental and calculated chemical shifts for the O(2) atom are 421 and 433 ppm, respectively, while δ[O(1,3)] = 305 (*cf.* the calculated value δ = 306). Hydrotrioxide $Me_2C(OH)$[O(1)O(2)O(3)H] (**6f**) is characterised by δ[O(1)] = 368, δ[O(2)] = 445 and δ[O(3)] = 305 (relative to $H_2{}^{17}O$). Probably, ^{17}O NMR spectroscopy of hydrotrioxides would serve as the basis for a breakthrough in understanding of the structure of organic HTO in the condensed phase.

IV. The mechanism of formation of organic hydrotrioxides

1. Experimental results

The reactions of ozone with C–H bonds of organic compounds leading to hydrotrioxides have been proposed to follow three main mechanisms, *viz*., a concerted 1,3-dipolar insertion of ozone (route *a*),[6,8,11,96,97] homolytic abstraction of an H atom by ozone followed by cage recombination of the radical pair (route *b*)[9,10,96,98] and ionic (molecular) mechanism (route *c*).[10,11,76,98]



Obviously, the variety of transformations of organic compounds in the reactions with ozone to give HTO cannot be described by a common mechanism. In this connection, the

study by Giamalva, Church and Pryor[99] is remarkable. They proposed that the reactions of O_3 with a number of cage hydrocarbons proceed by the insertion mechanism (route *a*) with the feasible transition states considered to be a set of resonance structures including both the radical (route *b*) and ionic (route *c*) mechanisms as the limiting cases.

The dominating reaction mechanism depends on the nature of the substrate and oxidation conditions. Let us consider the experimental grounds that serve as the basis for inferences about the most plausible mechanism of the ozone reaction with the C–H bond.

a. Reaction kinetics

The pre-exponential factors for the reaction RH + O_3 (Table 11) are 2 to 3 orders of magnitude lower than those of typical radical abstraction reactions of the H atom.[101] The estimate $\log A \approx 6.5$ obtained for the 1,3-addition reaction (route *a*) (see Ref. 76) is close to the activation parameters listed in Table 11; however, the experimental activation energies are incompatible with the energies of formation of pentacoordinated carbon. Taking into account the strain energy in the five-membered ring in the transition state of the 1,3-addition reaction, the expected E_a value must lie between 20 and 26 kcal mol^{-1} (see Ref. 76).

Table 11. Activation parameters of the reactions of organic compounds with ozone.[100]

Substrate	Solvent	$\log A$ /litre mol^{-1} s^{-1}	E_a /kcal mol^{-1}
cyclo-C_6H_{12}	cyclo-C_6H_{12}	7.71	13.7
$PhPr^i$	$PhPr^i$	6.4	8.7
EtOH	EtOH	4.88	7.3
	MeCOOH	6.15	9.1
	CCl_4	6.81	10.0
cyclo-$C_6H_{11}OH$	CCl_4	6.26	7.9
MeCOEt	CCl_4	10.7	18.5

b. Kinetic isotope effect

Relatively high k_H/k_D values (see Table 12) indicate substantial weakening of the C–H bond in the transition state of the reaction RH + O_3. A large kinetic isotope effect is evidence for the linear transfer of a proton and its symmetric localisation in the transition state.[102] This conclusion contradicts the mechanism of 1,3-cycloaddition and precludes linear arrangement of the C, H and O atoms.

Table 12. Kinetic isotope effect in the oxidation of organic compounds by ozone.[10, 96, 100]

Substrate	Solvent	T/K	k_H/k_D
cyclo-C_6D_{12}	cyclo-C_6H_{12}–cyclo-C_5H_{10}	295	4.1–4.5
$PhCD_2OCMe_3$	Freon 11	273	3.8–4.1
$MeCD_2OCMe_3$	Me_2CO	273	2.4–4.5
$MeCD_2OH$	CCl_4	293	5.9

c. Relative reactivity

Ozone exhibits a much higher selectivity toward primary, secondary and tertiary C–H bonds (0.003 : 1 : 87) as compared to alkoxyl (0.08 : 1 : 33.7) and peroxyl (0.024 : 1 : 10) radicals.[4]

d. Structure of a substrate

It is remarkable that compounds used as substrates in the liquid-phase ozonisation to give HTO, *viz*., oxygen-containing compounds (acetals, ethers, alcohols), hydrocarbons (cumene, cage compounds, including those containing the cyclopropane fragment) and silanes exhibit a common feature consisting of the possibility of effective stabilisation of the derived carbocation. Ozone was found to react with the benzylic C–H bond of fluorene at a much lower rate than with the analogous bond in diphenylmethane and 9,10-dihydroanthracene derivatives.[103] The low reactivity of fluorene is due to the fact that the formation of a carbocation from fluorene is less energetically favourable than from the other two compounds.[103]

Studies within the same class of compounds showed that electron-donor substituents accelerate the reaction of the RH + O_3 type and that the apparent rate constant for the reaction series for substituted toluenes ($\rho = -2.07$) substantially differs from the ρ values for peroxyl (-0.76) and alkoxyl (-0.34) radicals.[4]

e. Solvent effect

The yields of HTO in the oxidation of aliphatic and aromatic acetals by ozone in polar solvents (acetone, diethyl ether) are much higher than in dichloromethane and pentane.[4, 19, 20]

f. Formation of charge-transfer complexes

Taking into account the high electron affinity of ozone, one can assume that the reaction with the appropriate substrate will proceed with partial transfer of the electron density to the O_3 molecule. Indeed, the reaction of ozone with alkylaromatic compounds (*e.g*., cumene) results in a charge-transfer complex, which was proved by spectroscopic methods.[104–107] Further nonradical transformation of the complex results in the hydrotrioxide. This is confirmed by a substantial increase in the yield of the hydrotrioxide **8** upon irradiation of the reaction mixture by light in the spectral region corresponding to absorption of the charge-transfer complex;[28, 29] the absence of kinetic isotope effect in the reaction of ozone complex with toluene-d_8[108] and by acceleration of the decomposition of ozone–arene complexes in polar solvents.[109]

2. Thermochemical analysis of the mechanisms of formation of ROOOH

Thermochemistry of the reactions of ozone with the C–H bonds was investigated taking the reaction with ethanol as an example. Detailed kinetic studies[24, 100] of the reaction revealed its first order with respect to both reagents, the rate constants were determined over a wide temperature range (see Table 11) and the dependence of the rate constant on the chemical nature of solvent was investigated.

At $T = 293$ K, the rate constant for the gas-phase reaction EtOH + O_3 is 0.72±0.06 litre mol^{-1} s^{-1}.

Let us consider a feasible mechanism for this reaction. α-Hydroxyethyl hydrotrioxide **6b** was reliably established[24, 100] to be the major product. As mentioned above, the mechanism of 1,3-dipolar insertion (route *a*), for which $\log A \approx 6.5$ and $E_a \approx 20-26$ kcal mol^{-1}, is inconsistent with the observed Arrhenius parameters (see Table 11).

The enthalpies of the reactions proceeding by routes *b* and *c* can be calculated using the following values (in kcal mol^{-1}): $\Delta_f H^\circ$(EtOH) = −56.1,[110] $\Delta_f H^\circ(O_3)$ = 34.0,[110] $\Delta_f H^\circ$(MeĊHOH) = −14.5±3,[111] $\Delta_f H^\circ$(MeC$^+$HOH) = 139±3[111] and $\Delta_f H^\circ$(HOOO$^\bullet$) = 15.3.[18] The $\Delta_f H^\circ$(HOOO$^-$) value can be found using the gas-phase acidity of HOOOH (352 kcal mol^{-1} obtained from the *ab initio* MP4//MP2/6-31++G* calculations[52]) and $\Delta_f H^\circ$(HOOOH) = −12.2 kcal mol^{-1} (see Ref. 18). Thus we get $\Delta_f H^\circ$(HOOO$^-$) = −25.9 kcal mol^{-1}.

The activation energy of the gas-phase reaction of ethanol with ozone was estimated using the experimental rate constant $k = 0.72$ litre mol^{-1} s^{-1} provided that $A = 1 \times 10^8$ litre mol^{-1} s^{-1} (see Ref. 112); this gives $E_a = 10.9$ kcal mol^{-1}.

The enthalpy of a reaction proceeding by the radical route *b* is

$$\Delta H^\circ(b) = \Delta_f H^\circ(\mathrm{MeC\dot{H}OH}) + \Delta_f H^\circ(\mathrm{HOO\dot{O}}) - \\ - \Delta_f H^\circ(\mathrm{EtOH}) - \Delta_f H^\circ(\mathrm{O_3}) = \\ = 15.3 - 14.5 - 34.0 + 56.1 = 22.9 \text{ kcal mol}^{-1}.$$

Comparison of the $\Delta H^\circ(b)$ and E_a values suggests that the homolytic mechanism for the formation of the hydrotrioxide **6b** is energetically unfavourable. In addition, both thermochemical estimates [18, 66] and quantum-chemical calculations [70, 71, 113] predict that the radical $HOOO^\bullet$ is less stable compared to its decomposition products ($HO^\bullet$ and O_2) and decomposes almost barrierlessly. This reduces the role of the radical $HOOO^\bullet$ in the formation of HTO from saturated organic compounds to a minimum. Thus, the homolytic mechanism (route *b*) is inconsistent with thermochemical estimates.

The enthalpy of the gas-phase reaction of the hydride ion transfer (route *c*) can be calculated using the following equation

$$\Delta H^\circ(c) = \Delta_f H^\circ(\mathrm{MeC^+HOH}) + \Delta_f H^\circ(\mathrm{HOOO^-}) - \\ - \Delta_f H^\circ(\mathrm{EtOH}) - \Delta_f H^\circ(\mathrm{O_3}) + E_q\,.$$

Here, E_q is the energy of the Coulomb interaction within the ion pair ($-e^2/r$), where r is the inter-charge separation. Assuming that $r = 2.65 \pm 0.05$ Å,[76] we get

$$\Delta H^\circ(c) = 139 - 25.9 - 34.0 + 56.1 - 125 = 10.2 \text{ kcal mol}^{-1}.$$

As can be seen, the calculated E_a value is in good agreement with $\Delta H^\circ(c)$.

Calculations of $\Delta H^\circ(c)$ values for liquid-phase reactions face considerable difficulties owing to the lack of reliable methods for calculating the solvation energies of reactants, $\Delta H^\circ(\mathrm{solv})$. A qualitative estimate, $\Delta H^\circ(\mathrm{solv}) < 0$, can be obtained by simply reasoning that the ionic character of the transition state will favour its solvation compared to the electrically neutral EtOH and O_3. It is also clear that $\Delta S_0(\mathrm{solv}) < 0$. Therefore, the $\log A$ and E_a values for the liquid phase will be smaller than those obtained for the gas phase, which is consistent with the experimental results (see Table 11). Nangia and Benson [76] used the Kirkwood formula for calculating the change in the Gibbs free energy of solvation. However, it was noted [100] that this approach *a priori* implies too strong a dependence of the rate constant for the reaction on the dielectric constant of the medium. We believe that a consistent explanation is that the actual transition state is not purely ionic but includes to a great extent the contribution of charge transfer from MeC^+HOH to $HOOO^-$.

3. Formation of hydrotrioxides in the ozonisation of hydrocarbons

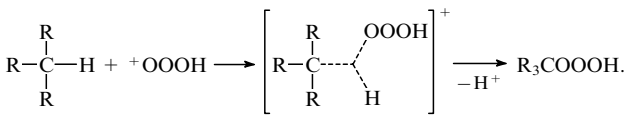
Experiments show that the most plausible mechanism for the reaction of ozone with the C–H bonds of organic compounds involves a hydride transfer of hydrogen to ozone followed by cage recombination of the ion pair (route *c*). The reaction is favoured by some factors responsible for the stabilisation of the carbocation formed: the structure of the substrate, polar substituents in the substrate, the presence of electron-donor substituents at the reaction centre.

In the absence of these factors the most plausible mechanism for the reaction $RH + O_3$ involves a homolytic abstraction of a H atom by the ozone molecule. The energy profiles of the reactions of ozone with the C–H bonds of methane, ethane, propane and isobutane have been studied.[113] In the transition state, the H atom is nearly orthogonal to the plane passing through three oxygen atoms, which indicates the involvement of the π-MO of ozone in the formation of a new bond. The C–H–O angle is rather large (167 to 174°) and the C–H and H–O distances are close (1.28 and 1.25 Å for methane and 1.27 and 1.34 Å for isobutane, respectively). This is consistent with the results obtained in studies of the kinetic isotope effect (see Section IV.1). According to quantum-chemical calculations, all the localised transition states have large contributions of biradical structures. The radical $HOOO^\bullet$ formed in the reaction is extremely unstable and decomposes into the oxygen molecule and the hydroxyl radical

$$RH + O_3 \longrightarrow R^\bullet + HOOO^\bullet \longrightarrow R^\bullet + O_2 + {}^\bullet OH.$$

Thus, the probability of the homolytic mechanism of the ozonisation of hydrocarbons containing non-activated C–H bonds in the gas phase (or in non-polar solvents) is very low.

On the other hand, the contribution of radical structures to the transition state decreases as the number of alkyl substituents in the α-position relative to the C–H bond involved in the reaction increases.[113] Hence under specific conditions (*e.g.*, with appropriate substituents and medium) the ionic mechanism can become even more energetically favourable. This can occur in the ozonisation of alkanes in superacidic solutions at −78 °C.[114, 115] The reaction proceeds *via* a transition state with the 3c-2e bond between the protonated ozone, $HOOO^+$, and the C–H bond. The pentacoordinated carbonium ion either undergoes further decomposition or loses a proton to give the corresponding hydrotrioxide:



Yet another specific procedure for the preparation of hydrotrioxides of non-activated organic compounds is 'dry' ozonisation, *i.e.*, the reaction of ozone with hydrocarbons adsorbed on a polar surface. The synthesis of HTO **11** and **15**–**19** by 'dry' ozonisation of aliphatic, alicyclic and alkylaromatic hydrocarbons on silica gel has been reported.[18, 31, 32]

$$RH \xrightarrow[-70\ ^\circ C]{O_3,\ SiO_2} \underset{\mathbf{11,\ 15-19}}{ROOOH}.$$

It was also noted in these studies that hydrotrioxides **11** and **15**–**19** cannot be obtained by conventional liquid-phase oxidation.

Triphenylmethylhydrotrioxide **18** can be prepared not only by 'dry' ozonisation but also in solution. However, low solubility of triphenylmethane at temperatures near −70 °C precludes the synthesis of Ph_3COOOH in solution. In addition, this synthesis requires thermal activation or photoactivation of the intermediate complex $ArH \cdot O_3$, as in the case of cumyl hydrotrioxide.[28, 29] In 'dry' ozonisation, the polar surface acts as an activator.

We can distinguish several factors responsible for the differences between the low-temperature ozonisation of hydrocarbons on the surface and the ozonisation in solution. First, the concentrations of reagents on the surface of the adsorbent can be very high, which cannot be achieved in solution at low temperature. As a result, ozonisation on the surface proceeds much faster.[116] Second, low mobility of the adsorbed reagents, intermediates and products reduces the probability of side reactions and, hence, increases selectivity of the process. Finally, the surface of silica gel is a highly polar anisotropic medium, which stabilises the ionic intermediates. Thus, the formation of hydrotrioxides ROOOH by 'dry' ozonisation is yet another argument in favour of the ionic mechanism of the reactions of ozone with the C–H bonds of saturated organic compounds.

V. Decomposition of hydrotrioxides

1. Reaction products. Chemiluminescence

The thermolysis products of hydrotrioxides **1a**, **2**, **3d**, **3m**, **4h**, **5a**,**b**, **8** and **20a** are presented in Table 13. It should be noted that with a few exceptions (see notes to Table 13) the decomposition products were analysed together with the products formed in the synthesis of ROOOH; because of this, the yields of each of the products were calculated with respect to ozone consumed to give the

Table 13. Thermal decomposition products of ROOOH.

ROOOH	Solvent	Product	Yield [a] /mol mol^{-1}	Ref.
 (**1a**)	RH	$PhCO_2H$	0.96	14

Note. Hydrotrioxides ROOOH were obtained by oxidation of the corresponding substrates RH. [a] The yields are given with respect to ozone consumed in the reactions, $\Delta(O_3)$. [b] The product undergoes further cyclisation and dehydration to give 2-methyl-4,5-dihydrofuran. [c] The yields are given with respect to HTO. [d] The yield is given with respect to Δ[ROOOH]; decomposition of the hydrotrioxide **8** in the presence of ionol results in $PhMe_2COH$ as the only reaction product.

particular product, $\Delta[P]/\Delta(O_3)$. All the reactions are accompanied by evolution of molecular oxygen including $^1O_2$.

According to the data listed in Table 13 thermal decomposition reactions of the hydrotrioxides derived from benzaldehyde (**1a**), acetals (**4h**, **5a**,**b**), cumene (**8**) and dimethylphenylsilane (**20a**) in which the reaction products are formed in nearly 100% yields exhibit the highest selectivities. As was mentioned above, silane-derived hydrotrioxides decompose to give, in particular, HOOOH.[33,34] Taking hydrotrioxide **6b** as an example, it was shown that the yields of the major decomposition products, *viz*., $\Delta[P]/\Delta(O_3) = 0.30\pm0.04$ for MeCHO, 0.56 ± 0.03 for MeCOOH, 0.11 ± 0.03 for HCOOH and 0.57 ± 0.03 for H_2O_2, are virtually independent of temperature in the range between -78 and 0 °C.[25]

Decomposition of HTO is accompanied by chemiluminescence in the visible spectral region.[16,21,27,117–119] The chemiluminescence spectra of compounds **8**, **6d**, **6f**, **6e**, **7a**, **3m** and **1** exhibit maxima (λ) at 425, 425, 405, 405, 405, 405 and 515 nm, respectively. No chemiluminescence was observed in the thermolysis of the hydrotrioxide **6b**. Based on comparison of both the fluorescence and phosphorescence spectra of the carbonyl compounds which resulted from decomposition of ROOOH and the chemiluminescence spectra in the visible spectral region it was concluded that the emitters of chemiluminescence are excited carbonyl groups ($>C=O^*$).

One of the most interesting and important properties of hydrotrioxides is their ability to generate $^1O_2$ during thermal decomposition.[13,14,16,17,19–21,27,31–33,35,52,89,117,118,120–122] The formation of singlet molecular oxygen was proved by carrying out specific reactions of singlet oxygenation of unsaturated organic compounds (see Section VII.1). Yet another convincing proof of the formation of $^1O_2$ is intense chemiluminescence in the IR spectral region with a maximum at $\sim$1270 nm, which is typical of O_2 ($^1\Delta_g$).[123]

Chemiluminescence in the visible and IR spectral regions has also been observed in the decomposition of adamantyl hydrotrioxide **15** on the surfaces of silica gel and alumina.[32,39] Spectral characteristics of chemiluminescence were found to be identical with those observed in the liquid phase. The yield of singlet molecular oxygen was determined by three methods.

The first method involved measurements of the amount of the $^1O_2$ acceptor consumed (1,3-diphenylisobenzofuran, 1,2-dimethylcyclohexene or tetraphenylcyclopentadienone).[13–15,17,19,20,28,29,35] The yield of singlet molecular oxygen ($\Phi_0 = \Delta[^1O_2]/\Delta[ROOOH]$ /mol mol^{-1}) was calculated based on the assumption that the amount of $^1O_2$ that evolved in the reaction ($\Delta[^1O_2]$) is equal to the amount of acceptor consumed ($\Delta[A]$). However, this approach provides only semiquantitative data on the yield of $^1O_2$,[124] so it is not surprising that the results obtained in the experiments with different $^1O_2$ acceptors differ substantially. For instance, the $\Delta[^1O_2]/\Delta[ROOOH]$ values for 1,1-diethoxyethane-derived hydrotrioxide (**4h**) found using tetraphenylcyclopentadienone and 1,3-diphenylisobenzofuran were $20\pm5\%$ and $54\pm5\%$, respectively.[20] Quantitative determination of the yield of $^1O_2$ requires a kinetic approach based on rigorous analysis of all possible consumption channels for the $^1O_2$ acceptor, hydrotrioxide and singlet molecular oxygen. The drawback of this method is that the acceptor of singlet molecular oxygen can be oxidised by the hydrotrioxide, which leads to overestimation of the results of measurements of the Φ_0 values.

Generation of $^1O_2$ in the decomposition of ROOOH, its deactivation and quenching by acceptors A was found [16] to follow a mechanism similar to that of the thermolysis of organic phosphite ozonides [124]

$$ROOOH \xrightarrow{k_0} P_0 + O_2,\ ^1O_2,$$

$$^1O_2 \xrightarrow{k_d} O_2, h\nu,$$

$$^1O_2 + A \xrightarrow{k_r} AO_2,$$

$$^1O_2 + A \xrightarrow{k_q} A + O_2,$$

where k_0, k_d, k_r and k_q are the rate constants for thermal decomposition of the hydrotrioxide, radiative deactivation of singlet molecular oxygen and chemical and physical quenching of $^1O_2$ by the acceptor A, respectively; and P_0 is the decomposition product of the hydrotrioxide.

Based on this mechanism, for the steady state we get

$$\ln\left(\frac{I_0}{I_t}\right) = k_0 t, \tag{10}$$

$$\frac{I_0}{I_A} = 1 + k\tau_d[A], \tag{11}$$

$$\frac{[A]_0 - [A]_\infty}{[ROOOH]_0} = \Phi_0\Phi_r - (k\tau_d)^{-1}\left\{\frac{\ln([A]_0/[A]_\infty)}{[ROOOH]_0}\right\}. \tag{12}$$

Here I_0 and I_A are the initial intensities of chemiluminescence in the absence and in the presence of the acceptor A, respectively; I_t is the current intensity of chemiluminescence in the absence of the acceptor; t is time; $k = k_r + k_q$; $\tau_d = 1/k_d$ is the lifetime of $^1O_2$ in the solvent specified; $[A]_\infty$ is the concentration of the acceptor in the reaction mixture after complete decomposition of ROOOH ($t \to \infty$); and $\Phi_r = k_r/(k_q + k_r)$.

Equation (10) can be used to follow the kinetics of the overall decomposition of ROOOH in the absence of the acceptor A. The Stern–Volmer equation (11) allows determination of the parameter $k\tau_d$ and calculation of the overall rate constant for quenching of singlet molecular oxygen by the substrate A provided that τ_d is known. This approach was used [120–122] for calculations of the k values for quenching of $^1O_2$ that evolved during the decomposition of hydrotrioxides **4h**, **6b**,**f** and **7b** by alkenes, dienes, phenols, glycosides and flavonoids.

The yield of $^1O_2$ can be determined from Eqn (12) using the Φ_r and $(k\tau_d)^{-1}$ values that can be found experimentally. Preference should be given to those acceptors which are characterised by high k_r values and $\Phi_r \approx 1$ (*e.g.*, 1,3-diphenylisobenzofuran). The results obtained by this method for hydrotrioxides **3m**, **4h** and **6b**,**f** are listed in Table 14. This approach is appropriate in the case of systems with relatively low concentrations of the acceptor (10^{-5} to 10^{-3} mol litre^{-1}). If the initial concentrations of the acceptor ($[A]_0$) are high, account must be taken of the reaction of the acceptor with HTO.

Yet another procedure for the determination of Φ_0 involves measurements and comparison of total light emissions for the reactions of thermal decomposition of ROOOH under study and a standard source of $^1O_2$ (*e.g.*, triphenyl phosphite ozonide).[18] This method has been employed for the determination of Φ_0 in the recombination of peroxyl radicals [125] and decomposition of di(*tert*-butyl) trioxide in various solvents.[126] The Φ_0 values were calculated using Eqn (13)

$$\Phi_0 = \Phi_{st}\frac{S_{ROOOH}}{S_{st}}\frac{k_d}{k_d^{st}}\frac{k_r^{st}}{k_r}\frac{[(PhO)_3PO_3]_0}{[ROOOH]_0}, \tag{13}$$

where Φ_0 is the yield of singlet molecular oxygen per 1 mol of HTO decomposed; $\Phi_{st} = 1$ (see Ref. 124) is the yield of singlet molecular oxygen in the decomposition of the standard source of $^1O_2$ (triphenyl phosphite ozonide); and S_{ROOOH} and S_{st} are the areas under the chemiluminescence decay curves for the decomposition of ROOOH and the standard source of $^1O_2$, respectively.

The Φ_0 values for a number of HTO are listed in Table 14. In all cases, except for hydrotrioxide **6f** in propan-2-ol, methods A and D give close Φ_0 values which are much smaller than the yields of $^1O_2$ calculated by methods B and C. This suggests that HTO are efficient sources of singlet molecular oxygen, though their efficiency has sometimes been overestimated.

Table 14. The yield of singlet molecular oxygen upon thermolysis of hydrotrioxides.[14, 16, 18, 20, 89]

Hydrotrioxide	Solvent	T /°C	Φ_0 (%)	Method of determination of Φ_0 [a]

	CD_3COCD_3	⩾ −78	25	C

Note. Hydrotrioxides ROOOH were obtained by oxidation of the corresponding substrates RH. [a] For methods A and D, the yield of $^1O_2$ was determined from Eqn (10) and Eqn (12), respectively; for methods B and C, the Φ_0 value was determined by following the consumption of the acceptors of singlet molecular oxygen, *viz*., 1,3-diphenylisobenzofuran (B) and tetraphenylcyclopentadienone (C). [b] The HTO was decomposed by a light pulse (λ = 266 nm), the Φ_0 value was determined from the relative intensity of chemiluminescence at λ = 1270 nm.

The influence of the reaction conditions on the yield of singlet molecular oxygen has been studied.[16, 18] It was found that the Φ_0 value decreases as the initial concentration of hydrotrioxide **3m** ([**3m**]$_0$) increases. This effect was explained by an increase in the contribution of 'blank' decomposition (without production of $^1O_2$) of ROOOH induced by free radicals with an increase in [**3m**]$_0$.[18] Taking hydrotrioxides **6f** [16] and **6b** [18] as examples, it was shown that the increase in temperature leads to a decrease in Φ_0. For compound **6b**, the temperature dependence of Φ_0 is satisfactorily described by the Bagdasaryan equation.[127] It seems likely that singlet molecular oxygen can be produced either by molecular conversion of ROOOH or as a result of disproportionation of the solvent-caged radical pair, [RO$^{\bullet}$ $^{\bullet}$OOH]. In a recent study,[18] preference has been given to the latter mechanism for the formation of ROOOH.

Table 15. Effect of solvents on the rate constant for decomposition and on the yield of singlet molecular oxygen in thermolysis of the hydrotrioxide **6b** {5 °C, [MeCH(OH)OOOH] = 0.011 mol litre^{-1}}.

Solvent	$10^3 k$ /s^{-1}	Φ_0 (%)	Solvent	$10^3 k$ /s^{-1}	Φ_0 (%)
$CFCl_3$	47.7	18.1	$C_6D_5CD_3$	21.4	13.6
CCl_4	57.4	10.1	$PhCH_2Cl$	10.6	10.4
$CHCl_3$	42.5	15.2	$PhCH_2OH$	40.0	1.6
CH_2Cl_2	31.5	13.3	PhEt	22.6	7.6
$C_2H_4Cl_2$	22.7	11.6	$PhPr^i$	32.8	5.6
PhH	28.9	8.0	Me_2CO	3.6	14.6
PhCl	34.0	6.4	MeCN	9.0	12.7
PhMe	24.4	13.0	$MeNO_2$	22.0	0.9

Solvent has a pronounced effect on Φ_0 in the case of thermal decomposition of the hydrotrioxide **6b** (Table 15). Using the Koppel – Palm correlation equation, the yield of $^1O_2$ was analysed as the function of the properties of the solvent and it was found that the yield of singlet molecular oxygen, Φ_0, increases as the solvent polarity increases, whereas enhancement of specific solvation in the transition state leads to a decrease in Φ_0.[18]

2. The kinetics of overall decomposition of hydrotrioxides

The kinetics of overall decomposition of HTO is studied by ^{1}H NMR spectroscopy (as the basic method) and chemiluminescence technique. Within the limits of experimental errors, both methods give usually the same results. Decomposition of ROOOH proceeds as a first-order reaction [14 – 21, 23, 24, 26 – 29, 31, 33, 35, 89, 119, 128]

$$-\frac{d[ROOOH]}{dt} = k_0[ROOOH].$$

The available rate constants k_0 and activation parameters of the reaction are collected in Table 16. The $\log A_0$ and E_0 values are related by a linear dependence (the compensation effect):

$$\log A_0 = -3.5 + 0.95\,E_0\,.$$

This dependence holds for a very broad range of changes in E_0 (from 1.7 to 25.1) and $\log A_0$ (from 0.2 to 21.6). It covers almost all available experimental data (Fig. 1) and suggests a common mechanism for the decomposition of ROOOH. The linear dependence between $\log A_0$ and E_0 indicates that the linear free energy relationship and the correlation equations based on it which relate the reactivity of HTO to their structure and to the physicochemical properties of the medium should also hold in the case of thermal decomposition of ROOOH in the liquid phase.

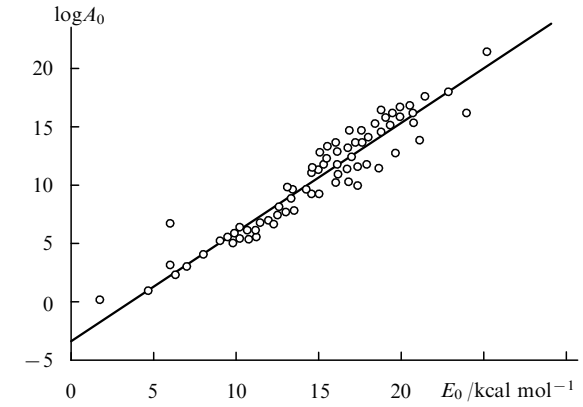

Figure 1. Compensation effect in the thermal decomposition of hydrotrioxides.

Table 16. Kinetic parameters of the overall decomposition of hydrotrioxides.

Note. The A_0 and k_0 values are given in s^{-1}; the $\Delta G^{\neq}$, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values were calculated using the data taken from the corresponding references (−20 °C). Hydrotrioxides ROOOH were obtained by oxidation of the corresponding substrates RH. [a] In the presence of 2,6-di-*tert*-butyl-4-methylphenol. [b] The addition of 2,6-di-*tert*-butyl-4-methylphenol has no effect on k_0. [c] In the presence of 2,6-di-*tert*-butyl-4-methylphenol. [d] The rate constant depends on the initial concentration of hydrotrioxide which was varied between 2×10^{-3} and 8×10^{-3} mol litre^{-1}. [e] Calculated from $\tau_{1/2}$. [f] The thermodynamic parameters are given for $T = -50$ °C.

Indeed, analysis of the kinetics of decomposition of hydrotrioxides derived from benzaldehydes **1b**–**f**, acetals **4b**–**g**, benzyl methyl ethers **3b**–**g**, alcohols **6b**–**j** and silanes **20a**–**d** using the Hammett – Taft equation shows that the rate constant for thermal decomposition of ROOOH increases as the electron-acceptor properties of substituent R become stronger [16, 17, 20, 33] and its polarity increases.[26]

The effect of the solvent nature on the rate constant of the overall decomposition has been studied taking hydrotrioxides **6b**,**f** (see Table 16) as examples.[26] Both dependences can be described using the Koppel – Palm correlation equation:

$$\log k_0 = \log k_0^0 + yY + pP + eE + bB,$$

where Y, P, E, B are empirical parameters which describe the polarity, polarisability, specific electrophilic solvation ability and specific nucleophilic solvation ability of the solvent, respectively.

However, the regression coefficients at the parameters Y, P, E and B differ appreciably for the two structurally similar HTO.

Presumably, this points to a formal type of description of the dependence of the rate constant for thermal decomposition of ROOOH on the chemical nature of the solvent rather than a real influence of different solvation mechanisms on the reactivity of HTO.

The activation parameters of the overall decomposition of ROOOH in the presence of inhibitors of radical-chain processes are listed in Table 16. The rate constant for decomposition of the hydrotrioxide **8** substantially decreases in the presence of ionol.[28,29] In other cases, inhibitors have little or even no effect on the rate constant.

3. Radical decomposition of hydrotrioxides

ESR studies showed that free radicals are generated only in the decomposition of cumyl hydrotrioxide (**8**).[29] The ESR spectrum is a single line with $g = 2.0151$, which is typical of peroxyl radicals. Some other examples of detection and identification of free radicals in the presence of spin traps have been reported.[130] Decomposition of HTO synthesised from methyl oleate, 2-methyl-1,3-dioxolane, propan-2-ol, 1,1-diethoxyethane, diisopropyl ether, benzaldehyde, methyl α-methylbenzyl ether and dimethylphenylsilane was studied and the spin traps used were 2-methyl-2-nitrosopropane, *C*-phenyl-*N*-*tert*-butylnitrone and methyl-*N*-(2,3,5,6-tetramethylphenyl)nitrone. Spin trap technique has also been used to identify alkyl, acyl, alkoxyl and peroxyl radicals.[17,21,22,131]

It should be noted that this method does not allow unambiguous inference about the initial products of radical decomposition of HTO. First, spin trap technique allows detection of only those radicals which form stable adducts. Second, not only the primary reaction products but also the radicals formed in the secondary reactions (reaction with the solvent, transformation of an adduct into another one[130]) are trapped in this case. Third, the spin trap is often oxidised by the hydrotrioxide to give a paramagnetic adduct.

The ratio of the radical and non-radical routes of decomposition of ROOOH was determined[21,128,129] taking the decomposition of HTO in the presence of di(*p*-methoxyphenyl)nitroxyl (an acceptor of free radicals) as an example (Table 17). The contribution of radical decomposition, k_r/k_0, varies from 0 (**6f**, EtOH : H_2O = 1 : 4) to ~23% (**1a**, PhCHO). The contribution of homolytic decomposition of ROOOH depends on the structure of HTO and temperature. For the hydrotrioxide **6f**, $\log k_r = (16.7\pm0.9)-(25.2\pm2.5)/\theta$ ($\theta = 2.303RT$/kcal mol^{-1}).

The nature of the solvent has a pronounced effect on the rate constant for radical decomposition. However, the ratio of radical and non-radical routes of decomposition remains virtually constant (see Table 17).

Table 17. Kinetic parameters of the radical decomposition of hydrotrioxides.[21,129]

Hydrotrioxide	Solvent	T/°C	$10^5 k_r$/s^{-1}	$10^2(k_r/k_0)$

4. Catalytic decomposition of hydrotrioxides

Acid- and amine-catalysed decomposition of HTO is of interest since it allows both extension of the temperature range in which these compounds can be used for generation of singlet molecular oxygen (Section V.1) and free radicals (Section V.3) and controllability of the rate of these reactions. Catalytic effect of organic acids and amines on the decomposition of HTO has been studied.[132,133] Catalytic effects of strong mineral acids (H_2SO_4 and $HClO_4$) on the decomposition of HOOOH[134] and of *N*,*N*-dimethylacetamide on the decomposition of hydrotrioxides derived from alkyl α-methylbenzyl ethers[17] have also been reported.

a. Amine-catalysed overall decomposition of organic hydrotrioxides

The kinetics of decomposition of hydrotrioxides **1a**, **3m**, **4h** and **6f** in the presence of amines (triethylamine; pyridine; 2-methylpyridine; 3-methylpyridine; 4-methylpyridine; 2-bromopyridine; 2,4-dimethylpyridine; 2,6-dimethylpyridine and quinoline) has been studied by ^{1}H NMR spectroscopy and chemiluminescence method.[132]

In the presence of amines, the rate constant for the decomposition of the hydrotrioxide **6f** increases. A similar effect is also observed upon addition of triethylamine and pyridine to benzaldehyde-derived hydrotrioxide (**1a**). However, the addition of pyridine [$(4-50)\times10^{-3}$ mol litre^{-1}] to hydrotrioxides **3m** and **4h** has no catalytic effect on their decomposition.

Catalytic decomposition in the presence of amines seems to follow a complex mechanism. On the other hand, the main channels of consumption of the ROOOH and amine can be described by a simple scheme:

$$\mathrm{ROOOH} \xrightarrow{k_0} \mathrm{P_0}\,,$$

$$\mathrm{ROOOH} + \mathrm{Am} \xrightarrow{k_{1.1}} N\text{-oxide} + \mathrm{P_{1.1}}\,,$$

$$\mathrm{ROOOH} + \mathrm{Am} \xrightarrow{k_{1.2}} \mathrm{P_{1.2}}\,,$$

where k_0, $k_{1.1}$, $k_{1.2}$ are the rate constants for the overall thermal decomposition, formation of *N*-oxide and catalytic decomposition of ROOOH, respectively; Am is amine; and P_0, $P_{1.1}$ and $P_{1.2}$ are the reaction products.

According to this scheme, the overall rate constant for the consumption of ROOOH is given by the formula

$$k = k_0 + (k_{1.1} + k_{1.2})[\mathrm{Am}]_0\,. \qquad (14)$$

Almost no *N*-oxides are formed at low concentrations of amine. This allows determination of k_0 and $k_{1.2}$ using Eqn (14) (Table 18). The temperature dependence of the rate constant for pyridine-catalysed decomposition of the hydrotrioxide **6f** is described as follows

$$\log k_{1.2} = (12.6\pm1.1) - (15.9\pm2.0)/\theta,$$

where $\theta = 2.303RT$ kcal mol^{-1}.

Linear correlation between the $\log k_{1.2}$ values and pK_a of amines is in good agreement with the Brønsted relationship for the general acid-base catalysis.[135] Thus, the kinetic data provide

Table 18. Kinetic parameters of decomposition of the hydrotrioxide **6f** in the presence of amines in isopropyl alcohol.

Amine	T/°C	$10^3 k_0$/s^{-1}	$k_{1.2}$/litre mol^{-1} s^{-1}
Pyridine	−26	0.177	0.03
	−14	0.417	0.16
	−1	1.45	0.69
2-Bromopyridine	−2	1.32	0.0005
Quinoline	−2	1.32	0.33
2-Methylpyridine	−2	1.32	0.93
3-Methylpyridine	−2	1.32	0.95
4-Methylpyridine	−1	1.45	1.34

an explanation for low yields of *N*-oxide in the oxidation of amines by hydrotrioxides (see Section VII.2): ROOOH is not only consumed in the oxidation reaction but also undergoes conversion following other routes, *e.g.*, thermal and amine-catalysed decomposition. As the amine basicity increases, the rate of catalytic process also increases with concomitant decrease in the yield of the corresponding *N*-oxide.

b. Acid catalysis of the overall decomposition of organic hydrotrioxides

Formic, acetic, monochloroacetic, trichloroacetic, trifluoroacetic and butyric acids were found to accelerate the decomposition of hydrotrioxides **3m** and **6f**.[133]

Acid-catalysed decomposition of hydrotrioxides is described by a first-order equation, the effective rate constant being proportional to the concentration of the acid (HA)

$$k = k_0 + k_{cat}[HA].$$

The rate constants for noncatalytic (k_0) and catalytic (k_{cat}) reactions are listed in Table 19.

Table 19. Kinetic parameters for the overall decomposition of the hydrotrioxide **6f** catalysed by carboxylic acids (in isopropyl alcohol).

Acid	T /°C	$10^3 k_0$ /s^{-1}	$10^2 k_{cat}$ /litre mol^{-1} s^{-1}
HCOOH	0	1.29	1.76
$MeCO_2H$	0	1.44	1.90
$ClCH_2CO_2H$	0	1.34	4.00
Cl_3CCO_2H	0	1.89	11.00
F_3CCO_2H	0	1.70	14.60
	−10	0.74	11.00
	−20	0.16	5.40
	−32	0.09	1.90
	0	11.18 [a]	11.50 [a]
$BuCO_2H$	0	1.27	2.15

[a] The data for the hydrotrioxide **3m** in diisopropyl ether.

The temperature dependences of the rate constants k_0 and k_{cat} for decomposition of the hydrotrioxide **6f** catalysed by CF_3CO_2H are as follows:

$$\log k_0 = (7.3 \pm 1.7) - (12.6 \pm 2.0)/\theta,$$

$$\log k_{cat} = (6.1 \pm 0.9) - (8.6 \pm 1.0)/\theta,$$

where $\theta = 2.303RT$ kcal mol^{-1}.

As for amines, the $\log k_{cat}$ values and the pK_a of the acids are related by a linear dependence, which is in agreement with the Brønsted relationship for acid catalysis.[135]

We cannot perform a detailed analysis of the mechanism of consumption of ROOOH in the presence of acids based on the knowledge of the formal kinetics of the process. It can be assumed that the decomposition of the hydrotrioxides can be accelerated owing to, in particular, the formation of associates ROOOH···HA, which leads to polarisation of the O−O bond, thus facilitating thermolysis of ROOOH. Such a 'through-the-H-bond' association followed by decomposition of the associates with cleavage of the O−O bond was found in the hydroperoxide–carboxylic acid system.[136, 137]

VI. The mechanism of thermal decomposition of hydrotrioxides

Thermal decomposition of HTO can follow several routes:

$$ROOOH \longrightarrow RO^{\bullet} + {}^{\bullet}OOH, \quad (15)$$

$$ROOOH \longrightarrow ROO^{\bullet} + {}^{\bullet}OH, \quad (16)$$

$$ROOOH + X^{\bullet} \longrightarrow ROOO^{\bullet} + XH \longrightarrow RO^{\bullet} + O_2 + XH, \quad (17)$$

$$ROOOH \longrightarrow \text{molecular products}. \quad (18)$$

In reaction (17), X represents a radical which escaped from the solvent cage, thus initiating induced decomposition of HTO.

The thermal effects of reactions (15) and (16) are equal to the dissociation energies of the corresponding O−O bonds. By substituting the data listed in Table 7 we get $\Delta H^{\circ}(15) \approx 20-21$ kcal mol^{-1} and $\Delta H^{\circ}(16) \approx 26-27$ kcal mol^{-1}. Therefore, it seems likely that reaction (16) can be ignored in the case of homolytic decomposition of ROOOH. The exothermicity of reaction (17) is equal to the difference between the dissociation energies of the ROOO−H (see Table 7) and X−H bonds. If X = ROO, the reaction (17) can be considered thermally neutral since $\Delta H^{\circ}(17) \approx -5 \pm 3$ kcal mol^{-1}. If X = RO, the reaction (17) is exothermic [$\Delta H^{\circ}(17) \approx 20$ to 25 kcal mol^{-1}].

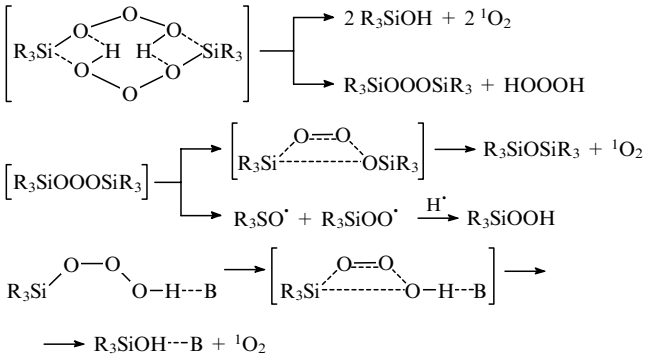
The enthalpy of the reaction of molecular decomposition of ROOOH depends on the chemical nature of both R and products formed but, as a rule, it is much less than zero. For instance, decomposition of cyclohexyl hydrotrioxide into cyclohexanol and singlet molecular oxygen is characterised by $\Delta H^{\circ}(18) = -55$ kcal mol^{-1} and the formation of cyclohexanol and hydrogen peroxide is characterised by $\Delta H^{\circ}(18) = -75.5$ kcal mol^{-1}.

Taking into account the experimental activation energies of thermal decomposition of ROOOH (see Table 16), we can conclude that virtually all mechanisms for the decomposition of ROOOH, *viz.*, reactions (15), (17) and (18), are possible. Large values of the pre-exponential factors for the rate constant of thermal decomposition of several HTO often make the radical mechanism preferable. Solvation of polar transition state can change the log A and E values in the 'compensating' manner. The fact that this dependence holds for almost all compounds ROOOH (see Fig. 1) suggests a common mechanism of the decomposition of HTO with different structures.

Our thermochemical analysis of possible channels of the decomposition of ROOOH is consistent with the experimental results. The particular route of thermal decomposition is determined by the structure of HTO and reaction conditions. This is illustrated below taking different classes of hydrotrioxides as examples.

1. Silane-derived hydrotrioxides

Plesničar *et al.*[33] reported a detailed study of the mechanism of decomposition of silane-derived hydrotrioxides taking dimethylphenylsilyl hydrotrioxide (**20a**) as an example. They determined the kinetic and activation parameters of the reaction (in particular, large negative entropy of activation), revealed a pronounced substituent effect, found that the rate constant for decomposition depends on the solvent polarity and showed that the radical inhibitor, 2,6-di-*tert*-butyl-4-methylphenol (ionol), has no effect on the kinetics of decomposition. Based on these results, the authors suggested the molecular route as the major channel of decomposition of silane-derived hydrotrioxides.[33]



The formation of dimethylphenylsilyl hydroperoxide at $T > -50$ °C indicates some contribution of the radical reaction to the overall mechanism; however, Plesničar *et al.*[33] concluded that homolytic processes are a minor channel (< 10%) under the conditions investigated.

2. Cumyl hydrotrioxide

Cumyl hydrotrioxide (**8**) is a carbon analogue of dimethylphenylsilyl hydrotrioxide; the kinetics of its decomposition have been studied by ^{1}H NMR spectroscopy.[28,29] It was found that thermal decomposition of **8** at $T > -40$ °C (E_a = 16.0±0.1 kcal mol^{-1} and log A = 10.4±0.1) is substantially retarded in the presence of ionol. Correspondingly, the activation parameters of the reaction change (E_a = 23.9±0.1 kcal mol^{-1} and log A = 16.4±0.1). In the absence of the inhibitor, the reaction results in 2-phenylpropan-2-ol (the major product), acetophenone and cumyl hydroperoxide.

$$PhCMe_2OOOH \longrightarrow PhCMe_2O^{\bullet} + {}^{\bullet}OOH,$$

$$PhCMe_2O^{\bullet} ({}^{\bullet}OOH) + PhCMe_2OOOH \longrightarrow$$
$$\longrightarrow PhCMe_2OH\ (HOOH) + PhCMe_2OO^{\bullet},$$

$$PhCMe_2OO^{\bullet} \longrightarrow PhCMe_2O^{\bullet} + O_2,$$

$$PhCMe_2O^{\bullet} \longrightarrow PhCOMe + Me^{\bullet},$$

$$PhCMe_2O^{\bullet} + PhCHMe_2 \longrightarrow PhCMe_2OH + Ph\dot{C}Me_2,$$

$$Ph\dot{C}Me_2 + O_2 \longrightarrow PhCMe_2OO^{\bullet},$$

$$PhCMe_2OO^{\bullet} + PhCHMe_2 \longrightarrow PhCMe_2OOH + Ph\dot{C}Me_2.$$

In the presence of ionol, induced decomposition is inhibited and 2-phenylpropan-2-ol is virtually the only organic reaction product.[28,29]

$$PhCMe_2O^{\bullet} ({}^{\bullet}OOH) + ArOH \longrightarrow PhCMe_2OH\ (HOOH) + ArO^{\bullet},$$

$$PhCMe_2O^{\bullet} ({}^{\bullet}OOH) + ArO^{\bullet} \longrightarrow \text{non-radical products}.$$

3. Hydrotrioxides derived from oxygen-containing compounds

The kinetic parameters of thermal decomposition of hydrotrioxides derived from oxygen-containing compounds are listed in Table 16 and the reaction products are presented in Table 13.

We will consider the decomposition derived from hydrotrioxides of oxygen-containing compounds taking ethanol-derived hydrotrioxide (**6b**) as an example. Despite the fact that HTO derived from alcohols, ethers, acetals, *etc*., can form intramolecularly hydrogen-bonded structures [based on this, the molecular route of decomposition (Scheme 1, route *a*) was proposed [13]], the experimental results are altogether in better agreement with the radical mechanism for decomposition of ROOOH, the first stage of which involves homolysis of the RO–OOH bond (Scheme 1, route *b*).

Low yields of radicals escaped from the solvent cage are due to self-association of ROOOH and the formation of intermolecular hydrogen bonds (HTO dimers, association with the solvent molecules).[128,129] Yet another factor which stabilises the transition state of the reaction that follows route *b* is an increase in the proton acidity and, hence, strengthening of the hydrogen bond [pK_a(HOOOH) ≈ 9.5,[62] whereas pK_a of the decomposition product, *i.e*., the hydroperoxyl radical, is 4.4 [134]].

The hydrotrioxide **6b** decomposes into acetaldehyde, water, acetic acid and hydrogen peroxide (see Table 13). The first pair of products is formed as a result of disproportionation of the radical pair **A** (Scheme 1, route *c*). The second pair, $MeCO_2H$ and H_2O_2, are formed [76] owing to rotation about the C–O bond in the oxyl radical **A** followed by disproportionation of the radical pair **B** (Scheme 1, route *d*).

The formation of small amounts of organic peroxide products is due to homolytic oxidation reactions which proceed involving free radicals escaped from the solvent cage into the bulk.

4. Factors responsible for the mechanism of thermolysis

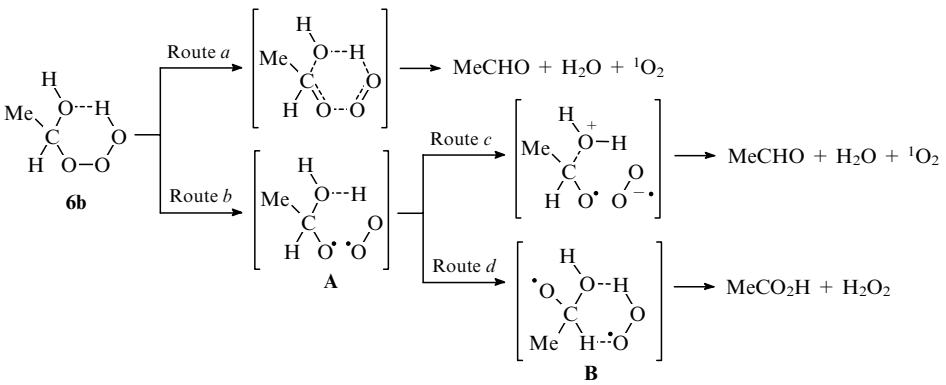
As was shown above, thermal decomposition of ROOOH can follow several pathways. The contribution of each mechanism (radical, induced or molecular decomposition) can vary depending on the experimental conditions. A number of factors determining the direction of decomposition of hydrotrioxides can be distinguished.

1. The nature of the atom bonded to the hydrotrioxide group. The larger the difference between the electronegativities of the X and O atoms in the hydrotrioxide $R^1R^2R^3XOOOH$ the more polar the X–O bond. Because of this, one should expect a larger contribution of the molecular channel of the reaction for silane-derived hydrotrioxides (X = Si). Comparison of the mechanisms for decomposition of hydrotrioxides **8** and **20a** which differ only in the nature of the atom X (see Sections VI.1 and VI.2) confirms this assumption. Koenig *et al.*[36] suggested that in the case of hydrotrioxides derived from organogermanium and organotin compounds (X = Ge, Sn) the molecular mechanism for decomposition is even more pronounced.

2. Temperature. Hydrotrioxides are typical peroxide compounds. By analogy with the latter, the increase in temperature causes a relative increase in the contribution of radical processes characterised by higher activation energies and pre-exponential factors. At low temperatures, polar rearrangements without formation of radical intermediates are more probable. This is confirmed by the results obtained by Plesničar *et al.*[33] who have found that $PhCMe_2OOH$, a typical product of radical transformation, is formed only at relatively high (as regards decomposition of dimethylphenylsilyl hydrotrioxide **20a**) temperatures ($T > -50$ °C) under conditions of fast warmup procedure.

3. Solvent. As was shown in Section V.2, the rate constant for decomposition of hydrotrioxides is affected by both specific and non-specific solvation of HTO and the transition states.[18,26] Polar solvents accelerate the molecular decomposition of ROOOH. For the hydrotrioxide **20a**, the effect of solvent decreases in the order: acetone-d_6 > methyl acetate > dimethyl ether.[33] The solvent polarity has a less pronounced effect on homolysis of the O–O

Scheme 1



bond: hydrotrioxides **3b** and **6k** decompose in acetone, ethyl acetate and diethyl ether with nearly the same rate.[17] Specific interactions (*e.g.*, the formation of hydrogen bonds) cause an increase in the viscosity of HTO solutions and in the degree of association of HTO molecules in solution.

Correspondingly, the amount of radicals escaping from the solvent cage decreases. As a result, the radical mechanism becomes a 'hidden-radical' one, which is virtually indistinguishable from the molecular mechanism under the experimental conditions. We believe that 'hidden-radical' processes make a rather large contribution to the decomposition of HTO of oxygen-containing organic compounds and, hence, the initiating ability of ROOOH is low[129] owing to large cage effect and despite the formally radical type of decomposition.

4. The presence of a heteroatom in the ROOOH molecule. On the one hand, the O atom in α-position relative to the hydrotrioxide group stabilises the positive charge on the carbon atom in the formation of ROOOH (see Section IV.1). On the other hand, this structure of the oxygen-containing compound is extremely favourable for the formation of an intramolecular hydrogen bond. Self-association of ROOOH molecules also decreases the yield of radicals into the bulk, which manifests itself in low initiating ability and the absence of the effect of radical inhibitors on the kinetics of thermal decomposition. This type of HTO decomposes following a non-chain radical route. If the ROOOH molecules contain no heteroatom appropriate for the formation of hydrogen bond, they decompose to give high yields of radicals that initiate an induced decomposition of the HTO.[29]

5. Formation of electronically excited products

As was shown above (Section V.1), decomposition of ROOOH is accompanied by chemiluminescence in the visible and IR spectral regions. The radical mechanism for the decomposition of HTO provides better explanation for the appearance of chemiluminescence in the visible spectral region.

$$ROOOH \longrightarrow RO^{\bullet} + {}^{\bullet}OOH,$$

$$RO^{\bullet}({}^{\bullet}OOH) + RH\,(SolvH) \longrightarrow R^{\bullet}(Solv^{\bullet}) + ROH\,(HOOH),$$

$$R^{\bullet}(Solv^{\bullet}) + O_2 \longrightarrow ROO^{\bullet}(SolvOO^{\bullet}),$$

$$ROO^{\bullet} + ROO^{\bullet}(SolvOO^{\bullet} + SolvOO^{\bullet}) \longrightarrow \rangle C{=}O^{*} + \ldots$$

Solv — solvent.

Emitters of the chemiluminescence are the excited carbonyl compounds that are formed in the recombination of peroxyl radicals.[138] It is believed that the source of peroxyl radicals is the solvent SolvH (or RH if hydrotrioxides are synthesised in the bulk).

An increase in the cage effect makes the role of free-radical processes less significant and reduces the probability of the formation of triplet excited carbonyl compounds. Indeed, thermal decomposition of hydrotrioxide **6b** proceeds without formation of free radicals[128] and is not accompanied by luminescence in the visible spectral region.

Luminescence in the IR spectral region is caused by singlet oxygen $^1\Delta_g$. The mechanism for its formation has been less studied. The yield of $^1O_2$ determined using polyaromatic acceptors of singlet molecular oxygen was found to be nearly equal for both silane-derived hydrotrioxide **20a** (25% – 60%)[33] which decomposes following the molecular route and the hydrotrioxide **3b** (25% – 45%)[17] which mainly undergoes homolytic decomposition. A drawback of this procedure for the determination of the yield of $^1O_2$ is that the acceptor can be simply oxidised by the hydrotrioxide, which can introduce large errors into the results of measurements. However, the yield of $^1O_2$ in both processes is nearly the same. Thermochemically, the formation of singlet molecular oxygen in the reaction

$$ROOOH \longrightarrow ROH + O_2$$

is quite possible. It is known[69] that the enthalpies of formation of alcohols ROH and corresponding hydroperoxides are related by a simple relationship

$$\Delta_f H^{\circ}(ROOH) = \Delta_f H^{\circ}(ROH) + 19.2 \text{ kcal mol}^{-1}. \quad (19)$$

Taking into account Eqn (11), we get

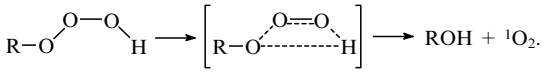
$$\Delta_f H^{\circ}(ROOOH) = \Delta_f H^{\circ}(ROH) + 36.8 \text{ kcal mol}^{-1}. \quad (20)$$

Thus, according to Eqn (20), the thermal effect of the reaction of decomposition of ROOOH into ROH and O_2 molecule (the barrier height is $\sim 10 + 36.8$ kcal mol^{-1}) is sufficient for populating the $^1\Delta_g$ singlet level of molecular oxygen (22.5 kcal mol^{-1}). It is reasonable that singlet molecular oxygen can also be efficiently generated following the radical mechanism to give the same products (however, in this case the activation energy is higher).

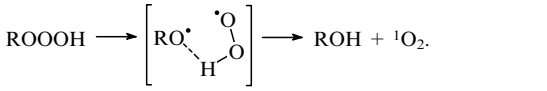
It should be noted that, despite the absence of free radicals and chemiluminescence in the visible spectral region, decomposition of the hydrotrioxide **6b** is accompanied by bright chemiluminescence in the IR spectral region.[16, 18] This indicates the formation of $^1O_2$ in the 'hidden-radical' reactions.

It seems likely that generation of singlet molecular oxygen can proceed by several mechanisms simultaneously.

Route *a* (molecular)



Route *b* ('hidden-radical')



Route *c* (radical-chain)

$$ROOOH \longrightarrow RO^{\bullet} + {}^{\bullet}OOH,$$

$$RO^{\bullet}({}^{\bullet}OOH) + RH\,(SolvH) \longrightarrow R^{\bullet}(Solv^{\bullet}) + ROH\,(HOOH),$$

$$R^{\bullet}(Solv^{\bullet}) + O_2 \longrightarrow ROO^{\bullet}(SolvOO^{\bullet}),$$

$$ROO^{\bullet} + ROO^{\bullet}(SolvOO^{\bullet} + SolvOO^{\bullet}) \longrightarrow {}^1O_2 + \ldots$$

Undoubtedly, the mechanisms of the formation of singlet molecular oxygen in the thermal decomposition of HTO are still unclear and deserve further investigation.

VII. Organic hydrotrioxides as oxidants

It is well known that peracids and hydroperoxides ROOH (R is alkyl, aryl, acyl) containing active oxygen are highly reactive compounds.[139, 140] Hydrotrioxides containing two active oxygen atoms are highly active oxidants of unsaturated (alkenes, dienes, acenes) and heteroorganic compounds (amines, phosphines, phosphites, sulfides, sulfoxides, sulfur ylides). A salient feature of hydrotrioxides is that both the ROOOH molecule and singlet molecular oxygen generated in the decomposition of ROOOH can act as the oxidants.

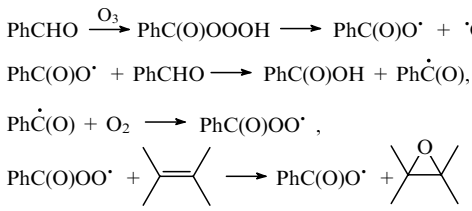
1. Oxidation of unsaturated compounds

Depending on the structure of the substrate, the reactions of ROOOH with unsaturated compounds can result in epoxides, hydroperoxides, endoperoxides, 1,2-dioxetanes (or products of their transformations in the reaction medium).

a. Preparation of epoxides

Epoxidation of alkenes at -50 °C in $CHCl_3$ under the action of ROOOH has been studied taking the reactions of 4-trimethylsilylcyclohexene with hydrotrioxides **1a** and **6f**,**h** as examples (the yields of 4-trimethylsilyl-1,2-epoxycyclohexane calculated with respect to Δ[ROOOH] were ~60%, 13% and 6%, respectively).[141]

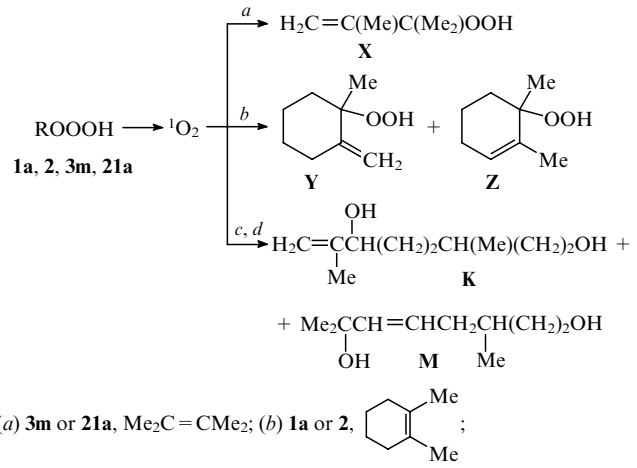
It seems likely that epoxidation by hydrotrioxide **1a** proceeds analogously to the Prilezhaev reaction.[139] In addition, since the radical mechanism contributes largely to the overall decomposition of the hydrotrioxide **1a** (see Table 17), one cannot rule out the contribution of the corresponding channel to the overall reaction of the synthesis of epoxide.[137, 142]



b. Preparation of hydroperoxides

Hydroperoxides can be prepared by oxidation of unsaturated compounds by singlet molecular oxygen generated in the decomposition of hydrotrioxides. Treatment of hydroperoxides with reducing agents results in the corresponding alcohols. This procedure is employed in the synthesis of natural compounds. The oxidation of tetramethylethylene by hydrotrioxides **3m**[13] and **21a**[35] and the oxidation of 1,2-dimethylcyclohexene by hydrotrioxides **1a** and **2** follow this pathway (Scheme 2).[14]

Scheme 2



(*a*) **3m** or **21a**, $Me_2C=CMe_2$; (*b*) **1a** or **2**, ;

(*c*) **21a**, $Me_2CH=CH(CH_2)_2CH(Me)(CH_2)_2OH$; (*d*) $NaBH_4$, EtOH.

The yields of compounds **X**, **Y**, **Z**, **K** and **M** are presented in Table 20. It should be noted that in both cases the oxidation of 1,2-dimethylcyclohexene results in the products **Y** and **Z** in the ratio ~9 : 1, which is typical of the oxidation of this substrate by singlet molecular oxygen.[143] If hydroperoxides obtained upon oxidation of citronellol by hydrotrioxide **21a** are reduced by sodium borohydride (Scheme 2), a 1 : 1 mixture of diols **K** and **M** is formed (see Table 20).[35]

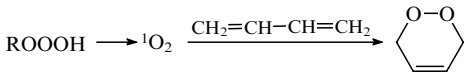
Table 20. The yields of compounds **X**, **Y**, **Z**, **K**, **M**.

Reagent	T /°C	Solvent	Yield (%)				Ref.
			X	**Y**	**Z**	**K**, **M**	
3m	−10 – 5	CH_2Cl_2	61 [a]				13
21a	−78	CH_2Cl_2	40 [b]				35
1a	23	RH	51.3 [a]	51.3 [a]	5.8 [a]		14
2	23	RH		39.7 [a]	3.5 [a]		14
21a	−78	CH_2Cl_2				25 [b, c]	35

[a] Calculated with respect to $\Delta[O_3]$. [b] Calculated with respect to Δ[A]. [c] The ratio **K** : **M** was 1 : 1.

c. Synthesis of endoperoxides

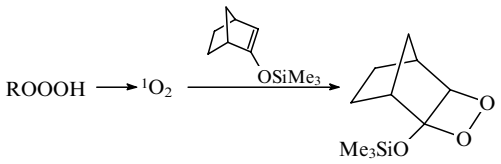
The reaction proceeds by the mechanism of [4 + 2]-cycloaddition of the singlet molecular oxygen generated to conjugated carbo- and heterodienes.



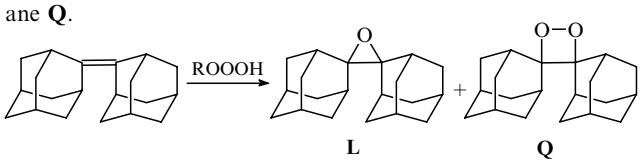
This reaction has been studied in most detail. The corresponding results are presented in Table 21.

d. Synthesis of 1,2-dioxetanes

Oxidation of 2-(trimethylsilyloxy)bicyclo[2.2.1]hept-2-ene into the corresponding dioxetane under the action of hydrotrioxide **21a** (−78 °C, CH_2Cl_2) also follows the mechanism of [2 + 2]-cycloaddition of singlet molecular oxygen evolved in the decomposition of ROOOH to the C = C bond of the substrate. The yield calculated with respect to Δ[A] is 50%.[35]



The reactions of adamantylideneadamantane with hydrotrioxides **1a**, **3m**, **4h** or **6f** in the $RH-CHCl_3$ medium at −78 °C proceed to give a mixture of the epoxide **L** and the 1,2-dioxetane **Q**.



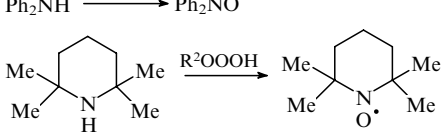
This reaction is an interesting example of dual reactivity of hydrotrioxides. Here, the role of oxidants is played by both the HTO which reacts to give the epoxide **L** and the singlet molecular oxygen which enters into the [2 + 2]-cycloaddition reaction to give the dioxetane **Q**.

Depending on the structure of the hydrotrioxide and composition of the reaction mixture, the reaction can be shifted towards the formation of either the epoxide **L** or the 1,2-dioxetane **Q**. The highest yield of dioxetane **Q** (~85% with respect to Δ[A]) was attained with the hydrotrioxide **4h** taken in the equimolar ratio to the substrate. The most efficient epoxidising agents are hydrotrioxides **1a** and **3m**; if the substrate and oxidant are taken in 1 : 10 ratio, the yield of the epoxide **L** calculated with respect to Δ[A] is 84% for **1a** and 88% for **3m**.[118, 144]

2. Oxidation of nitrogen-containing compounds

a. Secondary amines

Reactions of hydrotrioxides **1a**, **4h**, **6b**,**f** with diphenylamine or 2,2,6,6-tetramethylpiperidine (−20 °C, the substrate : oxidant ratio is 20 : 1) result in diphenylnitroxyl and 2,2,6,6-tetramethylpiperidin-1-oxyl, respectively.[145]



R^2OOOH = **1a**, **4h**, **6b**,**f**.

The yield of nitroxyl radicals calculated with respect to the hydrotrioxide consumed is low (~2%). This is likely due to either a fast reaction of the radicals with the HTO [129] or amine-catalysed decomposition of the HTO that proceeds concurrently (see Section V.4.a).

Table 21. Oxidation products of conjugated carbo- and heterocyclic dienes by hydrotrioxides.

Substrate	Reaction product	Hydrotrioxide	Temperature /°C	Solvent	Yield (%)	Ref.
		**1a**	−50	$RH-CH_2Cl_2$	96 [a]	14
		2	−70	$RH-Me_2CO$	80 [a]	14
		3a	−23	RH	30 [a]	14
		3b	−40 to −10	Me_2CO	45 [a]	17
				$MeCO_2Et$	–	17
		4f	−50 to −40	$MeCO_2Et$	55 [a]	20
		4h	−50 to −40	RH	54 [a]	20
		5a	−50 to −40	$MeCO_2Et$	46 [a]	20
		5d	−50 to −40	$MeCO_2Et$	85 [a]	20
		6k	−40 to −10	Me_2CO	60 [a]	17
				$MeCO_2Et$	60 [a]	17
		20a	−70 to −40	CD_3COCD_3	65 [a]	33
		21a	−78	CH_2Cl_2	45 [a], 91 [b]	35
		**3m**	−10–5	$RH-CH_2Cl_2$	38 [a]	13
		21a	−78	CH_2Cl_2	62 [b]	35
		**3m**	−10–5	$RH-CH_2Cl_2$	47 [a]	13
		**21a**	−78	CH_2Cl_2	90 [b]	35
		**21a**	−78	CH_2Cl_2	92 [b]	35
		**21a**	−78	CH_2Cl_2	46 [b]	35

[a] Calculated with respect to the amount of ozone [$\Delta(O_3)$] consumed in the synthesis of ROOOH. [b] Calculated with respect to the substrate.

b. Tertiary amines

At −80 to −50 °C, tertiary amines undergo selective oxidation to give the corresponding *N*-oxides.[132, 146]

$$R^1_3N \xrightarrow{R^2OOOH} R^1_3N{\rightarrow}O$$

R^1_3N R^1_3 — pyridine, 2-methylpyridine, 2,4-dimethylpyridine, 2,6-dimethylpyridine, quinoline, 7-nitroquinoline;

R^2OOOH = **4h**, **6b**,**f**.

The yields of *N*-oxides calculated with respect to $\Delta[R^2OOOH]$ increase as the ratio $[R^1_3N]_0 : [R^2OOOH]_0$ increases. For instance, the yield of pyridine *N*-oxide in the oxidation of pyridine by the hydrotrioxide **6f** is ~27% if the reagents are taken in ~2 : 1 ratio and 60% if this ratio is 20 : 1. The nature of the HTO has little effect on the yield of *N*-oxides. As the basicity of the amine increases, the ratio $\Delta R^1_3[NO]/\Delta[R^2OOOH]$ decreases, which is due to the amine-catalysed decomposition of the hydrotrioxide (see Section V.4.a).

3. Oxidation of phosphorus-containing compounds

a. Phosphines

At −78 °C, hydrotrioxides **6b**,**f** oxidise triphenylphosphine into triphenylphosphine oxide nearly quantitatively, the reaction being completed during the mixing time of the reactants.[147] As the ratio of the initial concentrations, $[Ph_3P]_0 : [ROOOH]_0$, changes from 1 : 1 to 1 : ⩾ 2, the ratio $\Delta[Ph_3P] : \Delta[ROOOH]$ increases from 1 to 2. The change in the stoichiometric coefficient is thought to be due to the reduction of a hydroperoxide by triphenylphosphine.

$$ROOOH \xrightarrow{Ph_3P} ROOH \xrightarrow{Ph_3P} ROH.$$

Fast and nearly quantitative reduction of HTO with an excess of triphenylphosphine serves as the basis for the method for quantitative determination of HTO by analysing the unconsumed Ph_3P.[147]

Pryor *et al.*[29] used the reaction of Ph_3P with the hydrotrioxide **8** in acetone at −73 °C for identification of the HTO **8**.

b. Phosphites

Hydrotrioxides **1a**, **4a**,**h**, **5a**, **6b**,**d**,**f** oxidise phosphites into the corresponding phosphates (at −78 to −50 °C) in nearly quantitative yields.[148–150]

$$(R^1O)_3P \xrightarrow{R^2OOOH} (R^1O)_3P{=}O$$

R^1 = Me, Et, Pr^i, Bu^n, $CH_2{=}CHCH_2$, Ph, 2-MeC_6H_4;

R^2OOOH = **1a**, **4a**,**h**, **5a**, **6b**,**d**,**f**.

Aromatic phosphites are oxidised somewhat slower than the aliphatic phosphites.[149] The reactivities of phosphites towards the hydrotrioxide **6f** have been studied by the method of competing reactions (at −50 °C in propan-2-ol) with $(EtO)_3P$ as the reference compound:

$$n_r(R^1O)_3P + R^2OOOH \xrightarrow{k_r} n_r(R^1O)_3PO,$$

$$n_0(EtO)_3P + R^2OOOH \xrightarrow{k_0} n_0(EtO)_3PO,$$

where k_r and k_0 are the rate constants for the oxidation of the phosphite under study and triethyl phosphite, respectively, and n_r and n_0 are the stoichiometric coefficients of the corresponding reactions.

If $[R^2OOOH]_0 \ll [(R^1O)_3P] = [(EtO)_3P]_0$ and the stoichiometric coefficients $n_r \approx n_0 \approx 2$, for the relative rate constant we get

$$k_r/k_0 = [(R^1O)_3PO]/[(EtO)_3PO].$$

A correlation was found between the $\log(k_r/k_0)$ value and the sum of the Kabachnik constants ($\Sigma\sigma^{\Phi}$) of the substituents at the phosphorus atom

$$\log(k_r/k_0) = -0.87 - 0.96\,\Sigma\sigma^{\Phi}.$$

At low $[(R^1O)_3P]_0/[R^2OOOH]_0$ ratios, the stoichiometric coefficient $\Delta[(R^1O)_3P]/\Delta[R^2OOOH] \approx 1$. As the phosphite concentration increases, this coefficient also increases approaching a value of 2. It seems likely that here, as in the preceding case, not only the hydrotrioxide but also the hydroperoxide acts as the oxidant. Probably, the reactions of phosphites with hydroperoxides occur during the warmup of the reaction mixtures.

Chemical polarisation of ^{31}P nuclei in $(PhO)_3PO$ observed in the *in situ* reaction of triphenyl phosphite with the hydrotrioxide **6f** carried out in an NMR tube (in propan-2-ol at ~40 °C) indicates the presence of radical species.[149] It is essential that the ^{31}P nuclei in the major product, phosphate, are strongly polarised. This system differs from the phosphite–hydroperoxide system in which the atomic nuclei in the molecules of the minor products are strongly polarised whereas a very weak or even no chemical polarisation is observed for the major product, *viz*., phosphate.[151] The addition of styrene (a free radical acceptor) does not lead to disappearance of chemical polarisation. It thus follows that the polarised phosphate molecules are formed as a result of recombination of the geminate radical pair without exit of the radicals into the bulk.

Taking the oxidation of triphenyl phosphite by hydrotrioxides **1a**, **4h** and **6f** (−26 °C, CH_2Cl_2) as an example, it was found that the reactions are accompanied by chemiluminescence in the visible and IR spectral regions.[144] Maxima in the spectra of chemiluminescence in the visible spectral region are observed at $\lambda = 460\pm20$ nm. It is assumed [144] that the emitter of chemiluminescence is the triplet excited phosphate (the phosphorescence spectrum of triphenyl phosphate exhibits a maximum at $\lambda = 465$ nm), as in the case of the oxidation of phosphites by hydroperoxides. The emitter of luminescence in the IR spectral region is the singlet molecular oxygen generated in the thermal decomposition of ROOOH that proceeds in parallel.

4. Oxidation of sulfur-containing compounds

a. Sulfoxides

Oxidation of dimethyl sulfoxide and dibutyl sulfoxide by hydrotrioxides **1**, **3m**, **4h** and **6b**,**f** (−78 to −50 °C, $[R^2OOOH]_0:[R^1SOR^1]_0 \approx 1-10$, 10–12 h) results in the corresponding sulfones in nearly 100% yields.[152]

$$R^1SOR^1 \xrightarrow{R^2OOOH} R^1SO_2R^1$$

R^1 = Me, Bu^n; R^2OOOH = **1a**, **3m**, **4h**, **6b**,**f**.

The most efficient oxidants are hydrotrioxides **1a** and **6f**. Complete conversion of sulfoxides into sulfones requires a threefold to fivefold excess of these reagents.

The yields of sulfones calculated with respect to $\Delta[R^2OOOH]$ are, as a rule, 5% to 30%; the higher the thermal stability of the HTO the higher the yield of the sulfone. Thus, the oxidation of sulfoxides is accompanied by thermal decomposition of the hydrotrioxide which proceeds concurrently at a rather high rate; singlet molecular oxygen thus formed is inactive in the reaction with sulfoxides under these conditions. Otherwise, one would expect an increase in the yield of sulfones with the increase in the rate of decomposition of such an efficient source of $^1O_2$, as, *e.g*., the hydrotrioxide **6f**.

It was shown [33] that the transfer of oxygen from the hydrotrioxide **20a** to the substrates, $4\text{-}XC_6H_4S(O)Me$ (X = MeO, Me, H, Cl), follows the electrophilic mechanism ($\rho = -1.1$, −78 °C, Me_2CO).

b. Sulfides

Depending on the composition of the initial reaction mixture and the reaction time, sulfides undergo selective oxidation into either sulfoxides or sulfones (at T from −78 to −40 °C).[23, 144, 153]

$$R^1SR^1 \xrightarrow{R^2OOOH} R^1SOR^1,$$

$$R^1SR^1 \xrightarrow{R^2OOOH} R^1SO_2R^1$$

R^1 = Me, Pr^n, Bu^n, n-C_6H_{13}, n-C_7H_{15}; R^2OOOH = **1a**, **4h**, **5a**,**b**, **6b**,**f**,**h**.

The first reaction proceeds at the ratio of the initial concentrations $[R^2OOOH]_0:[R^1SR^1]_0 \leqslant 1$ (the reaction goes to completion within 15 to 30 min).[144, 153] The yields of sulfoxides calculated with respect to sulfides consumed are close to 100%. If hydrotrioxides **1a** and **6f** are used, the yields calculated with respect to the HTO consumed in the reaction are also close to 100%. On the other hand, if $[\mathbf{6f}]_0:[R^1SR^1]_0 = 2$, the yields of sulfoxides decrease down to 50%, which indicates that the reaction is accompanied by thermal decomposition of the excess HTO which proceeds concurrently and that $^1O_2$ evolved in the reaction with the sulfide is inactive.

Oxidation of R^1SR^1 into $R^1SO_2R^1$, which seems to proceed *via* the corresponding sulfoxide R^1SOR^1, is observed if the HTO is taken in large excess and the reaction takes a long time. This indicates a relatively low reactivity of sulfoxides towards hydrotrioxides. For instance, a nearly quantitative conversion of dibutyl sulfide into dibutyl sulfone under the action of hydrotrioxides **1a** or **6f** requires that the following conditions be met for the ratios of the initial concentrations, $[\mathbf{1a}]_0:[R^1SR^1]_0 \geqslant 15$ or $[\mathbf{6f}]_0:[R^1SR^1]_0 \geqslant 4$; the yields of the sulfones calculated with respect to $\Delta[R^2OOOH]$ were ~7% and 25%, respectively.

The oxidation of sulfides $4\text{-}XC_6H_4SMe$ (X = MeO, Me, H, Cl) by hydrotrioxides **20a**,**b** and **23** in acetone, methyl acetate and n-pentane at −78 °C has been studied.[33, 34] The reactions resulted in the corresponding sulfoxides as the major products (the yields are 70% to 80%); sulfones are not formed in large amounts, since the reactivities of the sulfides are much higher than those of the sulfoxides. The Hammett ρ constants for the oxidation of these aryl methyl sulfides by hydrotrioxides **20a**,**b** and **23** in different solvents are listed in Table 22. An electrophilic nature of the oxidant was revealed.

Table 22. The Hammett ρ constants for the oxidation of aryl methyl sulfides by hydrotrioxides.

Hydrotrioxide	Solvent	ρ	Ref.
20a	Me_2CO	−1.99	33
	$MeCO_2Me$	−1.59	33
	n-C_5H_{14}	−1.65	33
20b	Me_2CO	−1.83	33
	$MeCO_2Me$	−1.77	33
	n-C_5H_{14}	−1.53	33
23	MeCOMe	−1.9	34
	$MeCO_2Me$	−1.9	34

c. Sulfur ylides

Oxidation of the ylide $Me_2\overset{+}{S}-\overset{-}{C}HCO_2Et$ by the excess of the hydrotrioxide **6f** results in a mixture of the oxidation and decomposition products, *viz*., $Me_2S(O)CHCO_2Et$, $EtOC(O)CHO$, Me_2SO and Me_2SO_2, in 2.1 : 4.5 : 1.8 : 1.0 ratio (−78 to −60 °C, $[ROOOH]_0 : [ylide]_0 \approx 4.5$).[154]

* * *

Summing up, mention may be made that hydrotrioxides have found wide use in organic synthesis. They can be used as oxidants, sources of singlet molecular oxygen and initiators of free-radical reactions. Reactions of organic HTO proceed under mild conditions, which extends the possibilities for the synthesis of many valuable compounds. It is hoped that as new experimental information will be available, the use of organic hydrotrioxides will rank high among other synthetic methods.

Hydrogen-containing carbon nanostructures: synthesis and properties

B P Tarasov, N F Goldshleger, A P Moravsky

Contents

I. Introduction 131
II. Synthesis of hydrofullerenes 131
III. Properties of hydrofullerenes 135
IV. Sorption of hydrogen by carbon nanotubes and graphite nanofibres 138
V. Conclusion 143

Abstract. Data on the interaction of carbon nanomaterials (fullerenes, carbon nanotubes, graphite nanofibres and their metal-doped modifications) with hydrogen are surveyed. New results on the preparation and properties of hydrofullerenes are presented. The prospects for the use of carbon nanomaterials as reversible hydrogen sorbents are discussed. The bibliography includes 183 references.

I. Introduction

Hydrogen has indisputable advantages over other energy carriers as it is a versatile, highly efficient and environmentally safe energy carrier. This provides good prospects for its wide application in power engineering, especially as a fuel for vehicles transport.[1] However, there is a very serious problem hampering the use of hydrogen as a fuel, namely, hydrogen storage and transportation. None of the currently available methods for the storage of hydrogen (in the gas state under high pressure, in the liquid state, as metal hydrides and hydrides of intermetallic compounds, or in the adsorbed state at low temperatures, see Table 1) meets the requirements imposed on hydrogen storage systems, *e.g.*, by the US Department of Energy (DOE) Hydrogen Plan (content of hydrogen $\geqslant 6.5$ mass % or $\geqslant 63$ kg m^{-3})[2] and by the International Energy Agency (content of hydrogen $\geqslant 5$ mass %, release of hydrogen at temperatures below 373 K).[3] Therefore, the development of new, more efficient methods for the storage and transportation of hydrogen is still an important task the success of which will determine, in many respects, further progress in the development of the 'hydrogen' technology and power engineering.

Hydrogen accumulation based on the reversible sorption of hydrogen is one of the most promising and popular methods for the storage of hydrogen. The most popular sorbents include hydride-forming metals and intermetallic compounds[4,5] as well as active carbons prepared by various methods.[6–9] Fullerenes and their derivatives, carbon nanofibres and nanotubes have been suggested repeatedly over recent years as hydrogen-accumulating substrates.[2,6,10,11] In the present review, we consider the data on the interaction of molecular hydrogen with these carbon nanomaterials (NM) and the prospects for their application as reversible sorbents for the storage of hydrogen.

Table 1. Traditional hydrogen storage methods.[3]

Method and conditions for hydrogen storage	Hydrogen content in the sorbent (mass %)	Hydrogen volume content /kg m^{-3}	Drawbacks of the method
Gaseous H_2 (300 K, 10 MPa)	100	7.7	heavy containers, small volume capacity
Liquid H_2 (20 K)	100	71	high losses, high cost
Metal-hydride			
TiH_2	4.0	150	insufficient
MgH_2	7.6	120	capacity; necessity
$LaNi_5H_{6.7}$	1.4	85	of heating;
$TiFeH_2$	1.9	95	sensitivity
Mg_2NiH_4	3.7	80	to admixtures
Cryoadsorption activated carbon (155 K, 6.9 MPa)	0.05 – 2	~1 – 2	necessity of cooling and compression

II. Synthesis of hydrofullerenes

The presently known methods for the preparation of hydrofullerenes,† such as the Birch – Hückel reduction of fullerenes, hydroboration, catalytic hydrogenation of fullerenes, reduction of fullerenes based on non-catalytic transfer of hydrogen from a donor to an acceptor, *etc.*, have been surveyed in detail in several reviews.[12–14] However, the rapid development of studies in this field requires a continuous analysis of the newly appearing methods for the synthesis of hydrofullerenes, especially because no ideal procedure for the preparation of hydrofullerenes with reliably controlled composition is yet available.

† Hydrofullerenes are also called fullerene hydrides or hydrogen-containing fullerene compounds; sometimes they are also called hydrofullerites in order to emphasise the solid state of the product.

1. Hydrogenation of fullerites and metal fullerides with molecular hydrogen

Chemical transformations occurring in mechanical mixtures of powders of a fullerite (C_{60}, C_{60}/C_{70}) and hydrogen-sorbing metals and intermetallic compounds (Pd, V, $LaNi_5$, $LaNi_{4.65}Mn_{0.35}$, $CeCo_3$) under the action of molecular hydrogen or deuterium have been studied in a wide pressure and temperature range.[15–19] It has been found that hydrogenation at 1.0–5.0 MPa and 573–673 K results in mixtures of metal hydrides MH_y and hydrofullerenes $C_{60}H_x$:

$$\{C_{60} + M\} + H_2 \longrightarrow \{C_{60}H_x + MH_y\}.$$

Heating of the resulting mixture $\{C_{60}H_x + MH_y\}$ in an inert atmosphere results first in dehydrogenation of the metal hydride and then (at 800 K) dehydrogenation of the hydrofullerene to give hydrogen and fullerene–metal compositions.‡

$$\{C_{60}H_x + MH_y\} \xrightarrow[-H_2]{<600\ K} \{C_{60}H_x + M\} \xrightarrow[-H_2]{\sim 800\ K} \{C_{60} + M\}.$$

Hence, we are dealing with a system which can accumulate hydrogen under certain conditions and release it under other conditions. This reaction cycle can be repeated many times, but the side reactions, such as polymerisation and carbide formation, restrict the prospects of application of these systems for hydrogen accumulation.

Depending on the temperature, the reaction of the pre-synthesised fullerides $C_{60}Pt$ and $C_{60}Pd_{4.9}$ with hydrogen (the H_2 pressure being 1–3 MPa) results either in hydrogen compounds of metallofullerides $<C_{60}MH_x>$ or in mixtures of hydrofullerenes $C_{60}H_x$ ($x = 2–26$) with Pt or PdH_y, respectively.

$$C_{60}Pt + H_2 \xrightarrow{400–550\ K} <C_{60}PtH_x>$$
$$C_{60}Pt + H_2 \xrightarrow{600–700\ K} C_{60}H_x + Pt$$

$$C_{60}Pd_{4.9} + H_2 \xrightarrow{400–550\ K} <C_{60}Pd_{4.9}H_x>$$
$$C_{60}Pd_{4.9} + H_2 \xrightarrow{600–700\ K} C_{60}H_x + PdH_y$$

Upon heating to 800 K, almost all the hydrogen is evolved from the reaction products, and the resulting mixture of the fullerite with the metal (Pd, Pt) can be hydrogenated again in the temperature range from 400 to 700 K to give mixtures of the hydrofullerene with PdH_y or Pt.[20–22]

The source of gaseous hydrogen and its purity affect considerably the hydrogenation of solid fullerenes and the state of the reaction products. For example, the hydrogenation of crystalline fullerene (fullerite) with hydrogen evolved upon the decomposition of hydrides of intermetallic compounds results in crystalline hydrofullerenes containing from 10 to 30 hydrogen atoms per fullerene molecule.[23,24] The content of hydrogen in the product increases with the number of the 'heating to 673 K–cooling to 300 K' cycles. The thermal cyclic hydrogenation mode not only provides a deeper process but also gives samples with a more homogeneous distribution of the components over the volume. The IR spectra of the resulting hydro- or deuteriofullerenes show intense absorption bands in the regions of C–H (2800–3000 cm^{-1}) and C–D (2050–2200 cm^{-1}) stretching vibrations. The relative intensities of the absorption bands of the starting C_{60} decrease abruptly (Fig. 1).

X-Ray diffraction analysis of the reduction product shows that hydrofullerene $C_{60}H_x$ (or deuteriofullerene $C_{60}D_x$) retains the crystal structure of the parent fullerite; the a_0 parameter of the face-centred cubic (FCC) lattice increases monotonically with the amount of hydrogen (or deuterium) in the hydrofullerene (Fig. 2).§

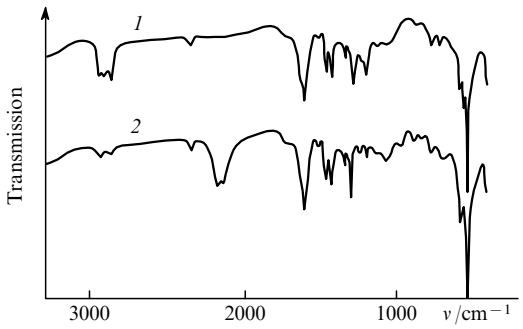

Figure 1. IR spectra of hydro- (*1*) and deuteriofullerenes (*2*) $C_{60}H(D)_{18–24}$.[24]

Heating of the hydrides synthesised by this method to 800 K results in intense evolution of hydrogen. The IR spectrum of the solid product of the thermal decomposition of hydrofullerene manifests bands corresponding to C_{60} and a series of bands the positions of which are close to those of the photo- or thermobarically polymerised C_{60} with the cyclobutane rings between the fullerene molecules,[26] which indicates that thermal dehydrogenation is accompanied by polymerisation of the fullerene cages.

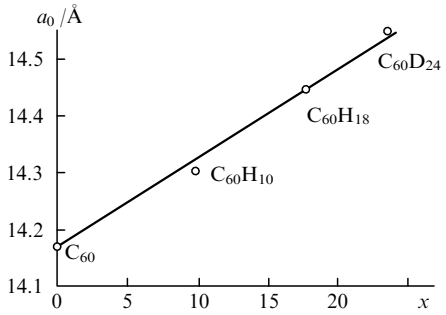

Figure 2. Dependence of the FCC lattice parameter a_0 of hydro- and deuteriofullerenes $C_{60}H(D)_x$ on the number of hydrogen and deuterium atoms.[25]

The samples dehydrogenated at 800 K can be hydrogenated again, but repeated 'hydrogenation–dehydrogenation' cycles result in the accumulation of polymerised fullerene.[25] The addition of NH_3, HI or C_2H_5I (5 mass %–10 mass %) to the hydrogen evolved from a metal-hydride accumulator accelerates considerably the hydrogenation of the fullerite but also increases the degree of polymerisation of the fullerene molecules formed upon the dehydrogenation of the hydrofullerene.[3]

Studies of the magnetic properties of hydrofullerenes prepared by hydrogenation of fullerene with hydrogen liberated from an accumulator based on hydrides of intermetallic compounds of nickel and rare-earth metals [23] showed that the samples contained ferromagnetic particles; this was explained by the gas-phase transfer into the reactor of traces of metal or metal hydride particles by hydrogen which has evolved from the accumulator. One could assume that fine particles of nickel and/or nickel–rare-earth metal intermetallides act as catalysts of the solid-phase hydrogenation of fullerene. The use of a nickel catalyst for hydrogenation of solid fullerite, *e.g.*, by controlled addition of volatile nickel compounds to the gas fed into the reactor, could

‡ In certain cases, heating above 950 K results in irreversible formation of metal carbides.

§ According to the reported data,[25] the lattice parameters for $C_{60}H_x$ and $C_{60}D_x$ are similar for equal x values.

provide more efficient reversible systems for hydrogen accumulation.

The solid-phase hydrogenation of fullerenes continues to attract the attention of scientists from the viewpoint of both practical application (hydrogen storage) and synthesis of individual hydrofullerenes. For example, solid-phase deuteration of C_{60} at 373–773 K and p_{D_2} = 15 MPa gave deuterides with the compositions $C_{60}D_8$, $C_{60}D_{18}$ and $C_{60}D_{36}$ (FCC structure, a_0 = 1.423, 1.448 and 1.500 nm, respectively).[27] Controlled doping of fullerene with palladium decreases (down to 373 K) the temperature of hydrogen or deuterium sorption relative to that for the undoped C_{60} sample at a gas (H_2 or D_2) pressure of 100 MPa.[28] A neutron diffraction study of palladium-doped fullerene showed no characteristic peaks of metallic Pd. Similarly, these peaks were not observed in the samples treated with hydrogen. Treatment of fullerene-containing carbon black by hydrogen plasma gives hydrofullerenes with low hydrogen content (x = 1–6).[29] Prolonged treatment does not increase the amount of sorbed hydrogen.

Progress is also observed in the field of liquid-phase hydrogenation of fullerenes. Cheaper heterogeneous catalysts have been developed and methods for more selective and extensive hydrogenation have been found. For example, the hydrogenation of C_{60} on the Ni/Al_2O_3 catalyst[30] occurs under milder conditions (toluene, 423–523 K, 2.5–7.5 MPa) than the hydrogenation on the Ru/C catalyst.[31] The reaction occurs selectively to give $C_{60}H_{36}$. The reaction selectivity can primarily be accounted for by the high dispersion of nickel deposited onto Al_2O_3.¶ A decrease in the reaction temperature decreases the selectivity (similarly to the reduction of C_{60} with dihydroanthracene in the presence of an organic catalyst[32]).

Liquid-phase hydrogenation of C_{60} with hydrogen (at atmospheric pressure, in the presence of 4% Pd/SiO_2, 5% Ru/Al_2O_3 or 5% Rh/Al_2O_3) or with hydrogen donors (cyclohexane, decalin, *etc.*) at 323–343 and 348–433 K, respectively, results in hydrofullerenes $C_{60}H_x$.[33] In some experiments, Pd/SiO_2 was used as the catalyst for the hydrogenation of fullerene by hydrogen transfer from a donor (cyclohexane, cyclohexene) to the acceptor (C_{60}). Titration of the hydrogen peroxide formed due to the oxidation of $C_{60}H_x$ with 2-ethylanthraquinone in the presence of O_2, chemical determination of hydrogen in $C_{60}H_x$, as well as IR and NMR spectra indicate that the C_{60} reduction products have the composition $C_{60}H_{42-46}$.[33] Unfortunately, the results of mass spectrometric determination of the hydrofullerenes formed have not been reported; this might provide direct information on the composition of $C_{60}H_x$.[33]

In a search for systems for the hydrogenation of fullerenes and dehydrogenation of hydrofullerenes which would comply with the requirements for the practically applicable hydrogen accumulators, Loutfy *et al.*[34] have examined whether soluble catalysts could be employed for hydrogenation of the C=C bonds and if salt melts could be used as the reaction media for hydrogenation. They also studied the effect of modification of the fullerene electronic structure on the hydrogenation process. This approach was based on the achievements in studies of the activation of the C–H bonds by metal complexes,[35] on the one hand, and on the data on the efficient catalytic hydrogenation of the C=C bonds with hydrogen in the presence of Cs_6C_{70},[36] on the other hand. Alkoxy compounds of the Group IV metals were found to be efficient as the soluble catalysts for fullerite hydrogenation and hydrofullerite dehydrogenation. This study[34] has shown that the use of certain soluble catalysts made it possible to decrease considerably the activation energy of hydrogenation and the temperature of the process. For example, the dehydrogenation of $(C_{60}/C_{70})H_{36}$ occurred at 573 K (6 h) to give $(C_{60}/C_{70})H_{22}$ (the loss of 1.74 mass % H_2), while the repeated hydrogenation of $(C_{60}/C_{70})H_{22}$ occurred at 423 K (12 h, 3.6 MPa) to give $(C_{60}/C_{70})H_{\sim 45}$. It has also been shown that doping of fullerene by an alkali metal facilitated markedly the fullerene hydrogenation. The dehydrogenation in this system occurs at considerably lower temperatures than the non-catalytic dehydrogenation of solid hydrofullerites.

The use of operating temperatures below 400 K is important for hydrogen-accumulating systems, hence these results[34] demonstrate that an almost acceptable temperature range can be achieved.

2. Reduction of fullerenes in the 'metal–hydrogen donor' system

The reduction of fullerenes is carried out using many traditional methods of organometallic chemistry (see, *e.g.*, the review[37]). For example, lithium in liquid ammonia in the presence of Bu^tOH was used for the reduction of C_{60}.[38]

$$C_{60} \xrightarrow{Li,\ NH_3\,(liq),\ Bu^tOH} C_{60}H_{2n}\,.$$

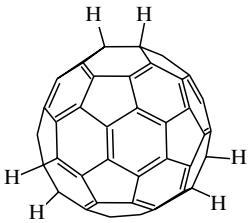
The process stopped in the step of the formation of $C_{60}H_{32-36}$ (see Refs 12 and 13). The products with a lower hydrogen content, *e.g.*, $C_{60}H_{32}$, were probably formed during the analysis or storage of the samples. The composition $C_{60}H_{36}$ of the reduction product of C_{60} fullerene with lithium in liquid ammonia has also been confirmed by other researchers.[39]

Polyfullerenes obtained by photo-induced and radical polymerisation of C_{60} cages (the radical polymerisation is preferable for the synthesis of polyfullerenes) are also reduced according to the Birch–Hückel method to give hydropolyfullerenes with a mean hydrogen content of ~3.5 mass % (for $C_{60}H_{36}$, 4.76 mass % H_2).[40] Hydropolyfullerenes, unlike monomeric hydrofullerenes with an equal hydrogen content, are almost insoluble in CS_2. This implies that the reduction at low temperatures does not involve cleavage of the C–C bonds between the fullerene cages in the polymers; this has been confirmed by gel-permeation chromatography. The IR spectra of hydropolyfullerenes contain intense bands in the region of C–H stretching vibrations. The ^1H and ^{13}C NMR spectra indicate structural similarity between polymeric and monomeric hydrofullerenes (the positions of the hydrogen atoms in the fullerene cage). The use of polyfullerenes does not increase the degree of hydrogenation of the fullerene cage, and hence, the amount of stored hydrogen. Thus, polyfullerenes are not superior to C_{60} molecules in hydrogenation and dehydrogenation reactions.

The reaction of C_{60} with $EtAlCl_2$ and activated magnesium [C_{60} : Al : Mg = 1 : (50–150) : (30–50); 293–295 K] in a THF–toluene mixture in the presence of Cp_2TiCl_2 (1 mol.%–3 mol.%) results in fullerene-containing aluminacyclopropane (yield 75%–90%), hydrolysis of which in D_2O results in a partially deuterated fullerene derivative.[41] Metallation of C_{60} with an excess of Et_3Al in the presence of Cp_2ZrCl_2 gives 2,3-fullerenoaluminacyclopentanes, hydrolysis of which results in mixtures of hydrogen-containing ethylfullerenes of the type $H_mC_{60}Et_m$ (m = 1–12).[42]

The reduction of C_{60} and C_{70} in the 'metal (M)–proton donor' system, where M = Zn (E° = −0.76 V), Ti (E° = −1.63 V), Al (E° = −1.66 V) or Mg (E° = −2.37 V), was also studied.[43–46] It was shown that the reaction of C_{60} with the Zn/Cu redox couple and a proton donor in toluene , unlike the reaction of C_{60} with Zn dust,[43] results in a more efficient fullerene reduction which occurs *via* the consecutive formation of $C_{60}H_2$, $C_{60}H_4$, and finally, $C_{60}H_6$; the target compounds can be isolated in each step.[44–47] Prolonged heating of a C_{60}–Zn/Cu–H_2O mixture in toluene results in two $C_{60}H_6$ isomers in the ratio 6 : 1, these amount to 30%–40% with respect to the starting C_{60}. The ^1H and ^{13}C NMR data show 1,2,33,41,42,50-$C_{60}H_6$ to be the main reaction product.[44,45]

¶ The results obtained[30] agree with the conclusion on the possible involvement of highly-dispersed nickel particles in the solid-phase hydrogenation of C_{60}.[23,24]



The hydrogen atoms in 1,2,33,41,42,50-$C_{60}H_6$ are not exchanged with deuterium atoms from D_2O on the NMR time scale, *i.e.*, the pK_a of $C_{60}H_6$ is much higher than that of $Bu^tC_{60}H$, which rapidly exchanges protons with the medium.[48] An attempt to isomerise 1,2,33,41,42,50-$C_{60}H_6$ in the presence of a Pd/C or Pt/C catalyst (as has been done for 7,8-$C_{70}H_2$, *cf.* Ref 49) resulted in rapid dehydrogenation of hydrofullerene instead of the expected reaction.[44]

The reaction in the $C_{70}-Zn/Cu-H_2O$ system under certain conditions results in preferential formation of $C_{70}H_{10}$, 7,8,19,26,33,37,45,49,53,63-$C_{70}H_{10}$ being the major isomer.[50] For various reasons (the presence of an oxide film, difficult separation of the products from the reaction mixture, *etc.*), efficient and selective reduction of fullerenes in the presence of other metals (Ti, Al, Mg)[44,46] was found to be impossible.

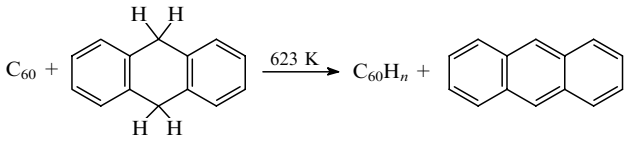
Water is the most suitable proton donor for the preparation of reduced fullerene derivatives in the $C_n-Zn/Cu-H_2O$ systems (n = 60, 70). Hydrofullerenes with low hydrogen content, *viz.*, $C_{60}H_2$, $C_{60}H_4$, $C_{60}H_6$ and $C_{70}H_{10}$, were obtained in good yields.[44,50] The isomer distribution is controlled by the reduction kinetics. The use of strong acids as proton donors for the reduction of fullerenes gives hydrofullerenes with higher hydrogen content.[51]

In toluene, the reduction of the fullerene cage in the $C_{61}H_2$ fulleroid in the presence of Zn/Cu occurs more slowly than that of fullerene,[52] but the reaction in *o*-dichlorobenzene occurs quite efficiently to give three isomeric compounds $C_{61}H_4$ which are light- and air-sensitive even at low temperatures. The reaction of sodium naphthalenide with C_{60} in THF gives 1,1′,2,2′-tetrahydro-bi[60]fulleren-1-yl $C_{120}H_2$ together with other products (including 1,2-dihydrofullerene).[53] Compound $C_{120}H_2$ is also formed upon hydrolysis of the salt $(Me_2NC_6H_4)_3C^+[C_{60}]^{-\bullet}$ obtained by the reduction of C_{60} with the crystal violet radical.[54]

The reaction of C_{60} with dilithiumacetylenide results in bis(hydrofullerenyl)acetylene $C_{122}H_2$ (yield 6.6%).[53] It should be noted that deprotonation of $C_{120}H_2$ is accompanied by fast dissociation of the transient C_{120}^{2-} dianion to the C_{60}^{-} monoanion, whereas deprotonation of $C_{122}H_2$ results in the C_{122}^{2-} dianion.[53]

3. Reduction of fullerenes by organic compounds

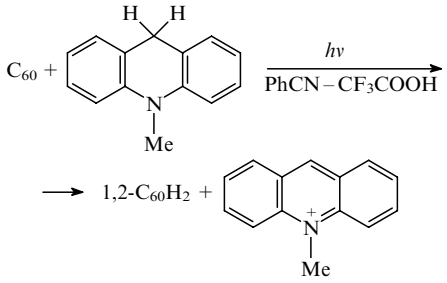
The reduction of fullerenes based on non-catalytic hydrogen transfer from a donor (*e.g.*, dihydroanthracene) to an acceptor (*e.g.*, C_{60} fullerene) results in selective formation of $C_{60}H_{36}$ † or $C_{60}H_{18}$, depending on the reaction conditions.[55,56]



The hydrogenation of C_{70} with dihydroanthracene results in a series of hydrofullerenes $C_{70}H_n$ (n = 36–46), $C_{70}H_{36}$ being the major product.

Anhydrous hydrazine in benzene reduces C_{60} and the endohedral compound $^3He@C_{60}$ into the lower hydrides $C_{60}H_2-C_{60}H_8$ and $^3He@C_{60}H_2-{}^3He@C_{60}H_8$; their compositions and structures were determined using ^1H and ^3He NMR spectroscopy (in the case of $^3He@C_{60}$). At high hydrazine concentrations, the reaction mixture also contained higher hydrofullerenes, *viz.*, $C_{60}H_{18}$ and $C_{60}H_{36}$.[57]

Photoinduced electron transfer (PET) plays an important role in the reduction and oxidation of fullerenes. Since the one-electron oxidation potential of the triplet-excited state of C_{60} is 1.14 V (relative to the saturated calomel electrode),[58] electron donors having less positive oxidation potentials can be used for the photoreduction of C_{60}. For example, the photoreduction of C_{60} with allyltributyltin in the presence of CF_3COOH results in the selective formation of 1-allyl-1,2-dihydrofullerene, C_{60}-1,2-(H)C_3H_5,[59] while the reaction of C_{60} with tributyltin hydride in benzene occurs (under irradiation[59] or at elevated temperatures[60]) to give C_{60}-1,2-(H)$SnBu_3$. If 10-methyl-9,10-dihydroacridine is used as a hydrogen donor in the presence of $PhCN-CF_3COOH$ in photoreduction of C_{60} (λ > 540 nm), fullerene is reduced selectively to give 1,2-$C_{60}H_2$ (70%).[59]

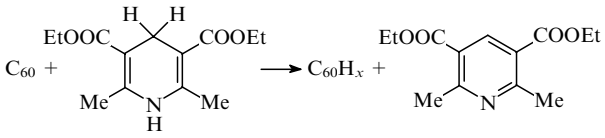


This photoreduction reaction of C_{60} is superior to, *e.g.*, the hydroboration of C_{60} (see Ref. 61) because of its selectivity and because mild reducing agents are used. However, in the absence of irradiation this reaction does not occur even at 373 K.

The bimolecular rate constant for quenching of the triplet-excited C_{60} ($^3C_{60}$) by 10-methyl-9,10-dihydroacridine (k_q = 4.3×10^9 litre mol^{-1} s^{-1}) and the mechanism of the photoreduction of C_{60} have been determined.[62]

Similarly to the two-electron reduction of C_{60} in the presence of 10-methyl-9,10-dihydroacridine, the one-electron reduction of C_{60} involving 1-benzyl-1,4-dihydronicotinamide and its dimer occurs through photoinduced electron transfer from the electron donor to $^3C_{60}$.[63,64] The difference between the redox and acid-base properties of the radical cations formed upon PET can define the reaction pathway.

Heating (100 °C, toluene) or pulse photolysis (Nd^{3+} : YAG laser, λ = 532 nm, benzonitrile) of a mixture of C_{60} with the Hantzsch ester (diethyl 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate) under anaerobic conditions result in fullerene hydrogenation products and diethyl 2,6-dimethylpyridine-3,5-dicarboxylate (the dehydrogenation product of the Hantzsch ester).



The progress of the dehydrogenation of the Hantzsch ester with the fullerene was monitored by ^1H NMR spectroscopy and a signal at δ 5.93 characteristic of 1,2-$C_{60}H_2$ could be detected if the reaction was carried out at room temperature. Heating of the reaction mixture in the presence of excess Hantzsch ester results in hydrofullerenes with the composition $C_{60}H_x$ (x = 2, 4, 6) identified by mass spectrometry.[65,66]

Illumination of the same mixture by visible light under aerobic conditions (room temperature), in agreement with the known data[67] on the sensitising effect of C_{60}, completely converted the Hantzsch ester in the presence of fullerenes to give the correspond-

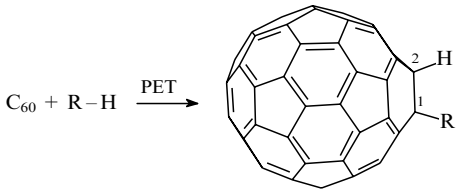
† Lobach *et al.*[56] paid much attention to standardisation of the conditions for the preparation of $C_{60}H_{36}$ because the synthetic procedure affects considerably the properties and structures of hydrofullerenes.

ing pyridine derivative; the concentration of C_{60} remained unchanged.[65]

Tertiary amines are widely used in the photoreduction of fullerenes. Prolonged irradiation (λ = 350 nm, N_2) of a mixture of C_{60} with tertiary amines $RNMe_2$ (R = Ph, Me) gives 1,2-$C_{60}H_2$ along with a pyrrolidine derivative of C_{60} (fullereno[C_{60}]pyrrolidine).[68]

The ESR method was used to study many photoreduction reactions of C_{60}. For example, it was found that the $C_{60}^{-\bullet}$ radical anion is formed in the presence of photo-activated TiO_2[69] or triethylamine[70] in a mixture of organic solvents[69,70] and in an aqueous solution.[71] The photochemical reduction of C_{60} in the presence of TiO_2 or ascorbic acid was studied.[72] It was found that the C_{60} fullerene is reduced photochemically by triethylamine to give $C_{60}^{-\bullet}$. Prolonged irradiation of the reaction mixture results in $C_{60}H^-$ (the C_{60}^{2-} protonation product) which is decomposed to $C_{60}^{-\bullet}$ in a dark reaction.[73]

Irradiation of C_{60} in the presence of certain acceptor-type photosensitisers (9,10-dicyanoanthracene, 1,4-dicyanonaphthalene, *N*-methylacridinium and 2,4,6-triphenylpyrylium hexafluorophosphates) results in 1-substituted 1,2-dihydro[60]fullerenes following introduction of proton donors such as *N*,*N*-dimethylformamide, 1,3-dioxolane, phenylacetaldehyde, methyl formate, *tert*-butyl alcohol, propionic acid, *etc*.[74,75]



Co-sensitisers, *e.g*., biphenyl, are used in order to increase the yield of the products. The $C_{60}^{+\bullet}$ radical cation formed was shown to possess electrophilic character.

$$C_{60} \xrightarrow[\text{PET}]{h\nu} C_{60}^{+\bullet},$$

$$C_{60}^{+\bullet} + RH \longrightarrow H-C_{60}^{+} + R^{\bullet},$$

$$H-C_{60}^{+} + R^{\bullet} + e^- \longrightarrow H-C_{60}-R.$$

4. Other methods for the preparation of hydrogen-containing fullerene derivatives

Dihydrofullerene $C_{60}H_2$ was obtained in low yield upon sonication of C_{60} solutions in decahydronaphthalene.[76] The formation of dihydrofullerene $C_{60}H_2$ upon electrochemical hydrogenation of C_{60} in 30% aqueous KOH was also reported.[77] The electrolytic hydrogenation of C_{60} and dehydrogenation of $C_{60}H_2$ are reversible.[77]

$$C_{60} + xH_2O + x\,e^- \rightleftharpoons C_{60}H_x + xOH^-.$$

Mechanochemical reactions involving fullerenes and graphite have been studied.[78–81] Mechanochemical treatment of graphite in an atmosphere of hydrogen (1 MPa) at room temperature results in nano-structured graphite which adsorbs hydrogen both physically and chemically.[81] The method of 'high-speed vibration milling' (under these conditions, crystalline C_{60} is pulverised into particles with sizes smaller than 1 μm) was found to be highly efficient for the supramolecular complexation of fullerenes and their derivatives with γ-cyclodextrin and sulfocalixarene.[79] The yields of [4 + 2]-cycloaddition products of fused aromatic compounds (anthracene, tetracene, pentacene and naphtho[2,3-*a*]pyrene) to C_{60} obtained according to this procedure are higher than the yields of the same products obtained by heating the components in solution.[80] The solid-phase reaction of C_{60} with KCN, unlike the homogeneous reaction, gives the C_{120} dimer.[82] This reaction also occurs in the presence of other salts (K_2CO_3, AcOK), metals (Li, Na, K, Mg, Al and Zn) and organic bases (4-dimethylamino- and 4-aminopyridine).[82] It is probable that the mechanochemical method can also be applied for the synthesis of hydrogenated fullerene derivatives ‡ (similarly to the hydrogenation of organic compounds with hydrogen[84]).

III. Properties of hydrofullerenes

1. The state of hydrogen in solid hydrofullerenes

In the majority of experiments on the reduction of C_{60} and C_{70}, mixtures of fullerene hydrides are obtained. Solid samples of hydrofullerenes with the same molecular formula but prepared by different methods differ strongly in their solubilities, light and air resistances, abilities to withstand prolonged storage and in other properties (see, *e.g*., Refs 13, 51, 85).

Of hydrofullerenes, $C_{60}H_{36}$ has been studied most thoroughly. Electron-impact and field-desorption mass spectrometric analysis showed that $C_{60}H_{18}$ is the first stable thermal decomposition product of $C_{60}H_{36}$ prepared under the conditions of non-catalytic transfer of hydrogen from a donor to an acceptor.[56] The intermediate hydrides $C_{60}H_n$ (n = 33–35) are much less stable than $C_{60}H_{36}$. Intense peaks of $C_{60}H_{18}$ and C_{60} appearing in the mass spectrum of a sample of $C_{60}H_{36}$ after its prolonged storage indicate that $C_{60}H_{36}$ undergoes decomposition; the presence of the C_{60} peak is evidence of possible reversible addition of hydrogen to fullerene. The formation of $C_{60}H_{36}$ as the only reduction product of C_{60} under non-catalytic hydrogen transfer conditions is also confirmed by the spectra obtained using matrix-assisted laser desorption ionisation mass spectrometry (MALDI-MS): the most abundant peak is that of $C_{60}H_{35}^+$, the fragmentation is insignificant, the intensities of the satellite peaks corresponding to the oxidation products $C_{60}H_xO^+$ are much lower than in the case of the $C_{60}H_{36}$ obtained by the Birch reduction.[39]

As noted above, solid hydrofullerenes decompose at temperatures above 800 K in an inert or in a hydrogen atmosphere to give hydrogen and fullerenes.[23,86] The thermal decomposition product of crystalline $C_{60}D_{24}$ at 823 K mainly consists of fullerene (Fig. 3)

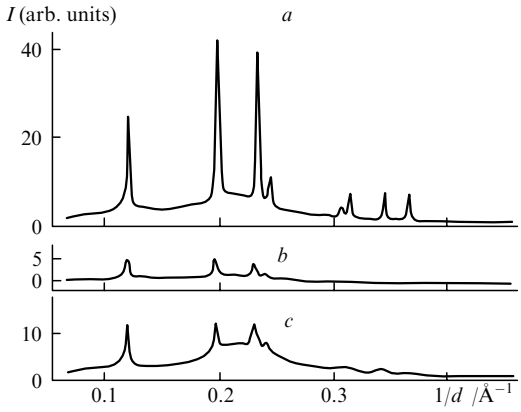


Figure 3. Diffractograms of the parent fullerene (*a*), fullerene deuteride $C_{60}D_{24}$ (*b*) and the product of thermodecomposition of the deuteride (*c*).[25]

with the distance between the C_{60} molecules considerably exceeding that in the parent fullerene (the a_0 constants of the FCC lattice of the decomposition product and C_{60} are 1.452 and 1.417 nm, respectively). Presumably, the increase in the fullerene crystal lattice constant resulting from hydrofullerene decomposition can be useful in the synthesis of alkali metal fullerides with superconducting properties.[86] The position of the C1*s* peak maximum in the X-ray photoelectron spectrum of the $C_{60}D_{24}$ deuteride is shifted towards lower bond energies in comparison with that of C_{60}, which makes it possible to conclude that a small positive charge exists on the deuterium atoms. The peak becomes narrower

‡ Apparently, the microwave irradiation method[83] can also be used for the preparation of hydrogenated fullerene derivatives.

as the deuteride undergoes thermal decomposition, and its 'centre of gravity' shifts to higher bond energies.[86]

Particular interest in the fundamental and applied aspects is felt in the synthesis of hydrofullerenes in which the hydrogen atoms are located both outside and inside the fullerene cage. This is a way to increase the hydrogen capacity of fullerenes. Therefore, studies of the properties of individual hydrogen molecules located in a closed space are also of interest. For example, it was found that compounds $C_{60}H_{52}$ and $C_{60}H_{48}$ fluoresce in the long-wave region. This phenomenon was interpreted taking account of the possibility of penetration of hydrogen molecules into a closed hydrofullerene cavity.[87] Hydrofullerites obtained under ultrahigh hydrogen pressures, $p_{H_2} = 0.6$ and 3.0 GPa, were studied by inelastic neutron scattering (INS) spectroscopy.[88] The spectra showed that the synthesis of $C_{60}H_x$ ($p_{H_2} = 0.6$ and 3.0 GPa, 620 K, 24 h) followed by cooling the sample to 77 K under a high pressure of H_2 is accompanied by the formation of a solid solution of hydrogen in the $C_{60}H_x$ lattice ($x \approx 24$ and 32–46 for $p_{H_2} = 0.6$ and 3.0 GPa, respectively).[88,89] The main features of the INS spectrum of $C_{60}H_{32}$ obtained at $p_{H_2} = 3.0$ GPa [90] are similar to those for $C_{60}H_{\sim 23}$ obtained at $p_{H_2} = 0.6$ GPa.[91] Presumably, a considerable fraction of hydrogen (~ 3 H_2 molecules per C_{60} molecule) are located as H_2 molecules in the interstices of the $C_{60}H_x$ lattices. Upon heating to 293 K, the H_2 molecules leave the sample with heat evolution. Dissolved molecular hydrogen is detected by the rotational transition peaks in the H_2 molecule (~ 15 and 30 meV) in the difference INS spectra between the 'quenched' (H_2-containing) and heated (H_2-free) products. The possibility of polymeric binding of the $C_{60}H_{32}$ hydrofullerite at high H_2 pressure (3.0 GPa) is suggested by the presence of a peak near 13 meV in its INS spectrum. The low-energy part of the INS spectrum (< 9 meV) for $C_{60}H_{32}$ is believed to indicate [88,89] the presence of an endohedral hydrogen atom unbound with carbon.

Hydrofullerites obtained at $p_{H_2} = 0.6$ and 3.0 GPa and $T = 520$–620 K and then quenched at $T < 120$ K exhibited ferromagnetic properties up to $T \approx 300$ K. Their magnetisation was as high as $M = 1.2$ emu g^{-1} at $H = 1$ T.[92] According to analytical data, the concentration of ferromagnetic admixtures in hydrofullerenes is insignificant. Magnetisation which disappears upon heating of the samples above 340 K or upon prolonged storage at room temperature is a property inherent in hydrofullerites obtained by various methods.[92,93] Probably, their magnetisation is caused by the presence of unstable transient radical-type electronic states. The penetration of hydrogen inside the cage, polymerisation of the fullerene cages upon dehydrogenation and other high-energy transformations of the C–C and C–H bonds in sterically hindered fullerene lattices could be the reasons for the generation of quasistable carbon atoms with unsaturated valence or delocalised unpaired electrons.

2. Thermodynamic analysis of the dehydrogenation of hydrofullerenes

The thermodynamic properties of the $C_{60}H_{36}$ hydrofullerene obtained by non-catalytic hydrogen transfer [56] have been studied in the temperature range from 4.8 to 340 K.[94,95] The following values of thermal capacity, enthalpy, entropy and Gibbs free energy were found for the hydrofullerene obtained at $T = 298.15$ K and $p = 101.325$ kPa:

$$C_p^\circ(298.15) = 690 \text{ J K}^{-1} \text{ mol}^{-1};$$

$$H^\circ(298.15) - H^\circ(0) = 84.94 \text{ kJ mol}^{-1};$$

$$S^\circ(298.15) = 506 \text{ J K}^{-1} \text{ mol}^{-1};$$

$$-[G^\circ(298.15) - H^\circ(0)] = 66.17 \text{ kJ mol}^{-1}.$$

High temperature is required for the dehydrogenation of hydrogen-containing fullerene derivatives. Quantum-chemical calculations of the C–H bond energy in fullerene hydrides performed by the semi-empirical AM1 method gave the values of 306.27, 298.32, 295.80 and 293.72 kJ mol^{-1} for $C_{60}H_{12}$ (T_h), $C_{60}H_{18}$ (C_3) and $C_{60}H_{36}$ (T and T_h), respectively.[96] Heating of $C_{60}H_{36}$ under isothermal conditions (594 and 610 K, 20 h) results in dehydrogenation of the sample and evolution of gaseous H_2. In this case, the composition of the solid residue is '$C_{60}H_6$': $C_{60}H_{36} \rightarrow C_{60}H_{18} \rightarrow$ '$C_{60}H_6$'. The dehydrogenation occurs stepwise [97] and is accompanied by sublimation of $C_{60}H_{36}$ and $C_{60}H_{18}$. The estimated saturated vapour pressures of $C_{60}H_{36}$ and $C_{60}H_{18}$ at 594 K are 9.8×10^{-9} and 5.4×10^{-9} MPa, respectively.

3. Specific features of hydrofullerene structures

The $C_{60}D_{24}$ deuteride obtained by deuteration of crystalline fullerene with gaseous D_2 is a crystalline powder with an FCC lattice ($a_0 = 1.455$ nm) [23] and a crystallite size of 51–56 nm.[25] The synthesis of $C_{60}D_{36}$ with an FCC lattice ($a_0 = 1.500$ nm) has been reported.[27] On the other hand, $C_{60}H_{36}$ samples obtained by hydrogenation under high pressure [98] or in the presence of iodine [99] have body-centred cubic (BCC) lattices.[100]

Theoretical and experimental studies of the structures of the most stable (T, T_h, S_6 and two D_{3d}) isomers of the $C_{60}H_{36}$ hydrofullerene have been carried out.[99–103] Comparison of the experimental ^1H and ^{13}C NMR spectra of the solid $C_{60}H_{36}$ (see Ref. 99) with the calculated ones [104] made it possible to assume a structure with the T symmetry [105] for $C_{60}H_{36}$ obtained by non-catalytic hydrogen transfer.[56] According to X-ray emission and photoelectron spectral data, quantum-chemical calculations and electrochemical behaviour, the most probable structure for the $C_{60}H_{36}$ hydrofullerene is that with the T symmetry and with four isolated benzenoid (non-hydrogenated) rings located on the surface of the $C_{60}H_{36}$ hydrofullerene in the vertices of an imaginary tetrahedron (Fig. 4).[103,106,107]

Comparison of the CK_α spectra of C_{60}, $C_{60}H_{36}$ and C_6H_6 prompts the conclusion that the π-electron systems of hydrofullerenes and benzene are similar; the localisation of the HOMO electron density of the $C_{60}H_{36}$ hydrofullerene on the benzenoid rings allows one to assume that η^6 metal complexes based on $C_{60}H_{36}$ can be synthesised.[106,108] Studies of the electrochemical behaviour of the $C_{60}H_{36}$ hydrofullerene indicates that $C_{60}H_{36}$ is a rather 'hard' molecule with low reactivity in redox reactions. The electrochemical electronegativity decreases in the series $C_{60} > C_{60}H_2 > C_{60}H_{36} \approx C_6H_6$. The approximate equivalence of the electronegativities of the two latter compounds can also be evidence in favour of the T-symmetrical structure of $C_{60}H_{36}$.[107]

The presence of a large number of reaction centres in the fullerene molecules results in a large number of possible isomers of hydro- and fluorofullerenes. Based on a combination of the MO LCAO method with molecular mechanics, Breslavskaya and D'yachkov [109] predicted the structures of the most stable C_nX_k

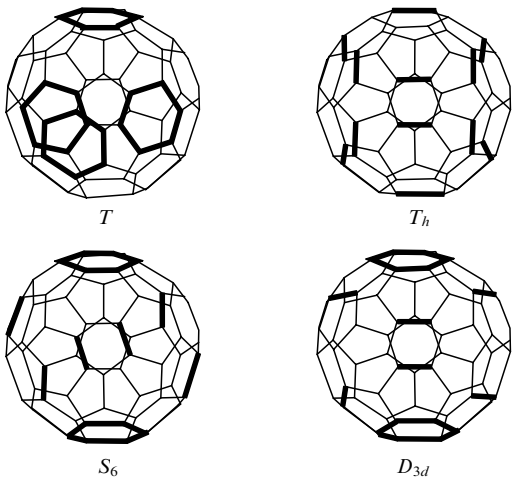

Figure 4. The most stable $C_{60}H_{36}$ isomers (one of the two D_{3d} is shown).[103] The thick lines denote the non-hydrogenated C–C bonds.

isomers with high hydrogen and fluorine contents (X = H, F; n = 76, 78, 84) and compared the theoretical data with the available experimental results. According to the neutron diffraction structural data[110] for $C_{60}D_{36}$ prepared according to a reported method[99] by deuteration of C_{60} at 623 K and a D_2 pressure of 3.4 MPa in the presence of iodine as a promoter, the structure with the T symmetry is most stable for this deuteriofullerene as well [a structure with the T symmetry has been suggested previously[99] as the most stable one for $C_{60}H_{36}$ (IR and ^{13}C NMR spectral data)].

Billups *et al.*[111] studied the ^3He spectra of $^3He@C_{60}H_{36}$ samples prepared by reduction of $^3He@C_{60}$ with lithium in liquid ammonia[38] and by non-catalytic hydrogen transfer.[55] The ^3He NMR spectra of both $^3He@C_{60}H_{36}$ samples contain peaks at δ −7.7 and −7.8; the third peak at δ −16.45 was assigned to the chemical shift of the $^3He@C_{60}H_{18}$ hydrofullerene. Comparison of the experimental spectra[111] with the calculated chemical shifts for the most stable $^3He@C_{60}H_{36}$ isomers [δ −10.8 (T), −7.7 ($D_{3d'}$), −6.1 (S_6), −3.4 (T_h) and −5.6 (D_{3d})][104] makes it possible to assume that the $D_{3d'}$ isomer is formed in both cases. In addition, based on the ^3He NMR spectra of the sample prepared by reduction of $^3He@C_{60}$ with lithium in liquid ammonia, the conclusion was made as to the low probability of the formation of the isomer with the T_h symmetry which had previously been suggested[38] for a $^3He@C_{60}H_{36}$ sample. According to the reported data,[112] the isomer with the S_6 symmetry (see Fig. 4) is the most stable $C_{60}H_{36}$ hydride, though the difference between the energies of the ten most stable isomers is less than 62.76 kJ mol^{-1}. In the previous studies by the same authors, isomers with the T and D_{3d} symmetries were noted as the most stable ones of the large number of possible structures suggested for the $C_{60}H_{36}$ fullerene hydride.[101]

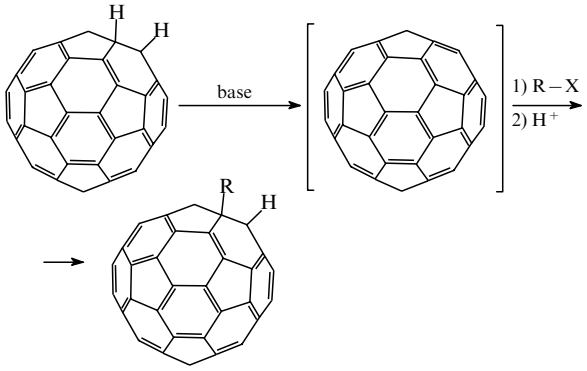
Thus, it has been shown for $C_{60}H_{36}$ that not only different chemical methods can result in isomers with different symmetries, but also products with different isomer compositions can be formed within a single procedure (see, *e.g.*, Refs 85 and 106). In the case of the $C_{60}H_{36}$ molecule, the problem of the most stable structure remains open and requires more accurate theoretical calculations. It is quite possible that certain methods for the synthesis of $C_{60}H_{36}$ can produce thermodynamically unstable isomers (*e.g.*, due to kinetic factors). In order to verify the validity of this assumption, one has to perform in-depth experimental and theoretical studies, including the isomerisation of $C_{60}H_{36}$. A reliable determination of the $C_{60}H_{36}$ structure is also interesting from the practical respect. For instance, the knowledge of its exact structure is very useful when one plans the syntheses based on this hydrofullerene.

4. The reactivities of hydrofullerenes

According to the reported data,[113] a hydride with the net composition $C_{60}H_{18.7}$ with a_0 = 1.476 nm is stable up to 703 K in an Ar atmosphere. Further increase in the temperature results in hydrogen evolution and is accompanied by decomposition of part of the fullerene molecules and formation of graphite platelets and methane.§ The use of catalytic amounts of ruthenium or platinum did not decrease the temperature of hydrofullerene dehydrogenation.

The dehydrogenation of $C_{60}H_{36}$ on treatment with a strong hydrogen acceptor, *viz.*, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, which is widely used in the analysis of hydrofullerenes, was found to be non-quantitative, since in addition to C_{60}, its derivatives were also formed.[56] Thermogravimetric (TG) and differential thermogravimetric (DTG) studies of $C_{60}H_{36}$ in the presence of oxygen were carried out.[30] It was found that $C_{60}H_{36}$ is partially oxidised at 550 K to give $C_{60}H_{36}O_x$ ($x \approx 4.8$) and that its combustion occurs at 745 K. As it might have been expected, these temperatures are much lower than the temperatures of partial oxidation and combustion of C_{60} (705 and 888 K, respectively).[30] Complexes of polyaromatic compounds and fullerene with platinum immobilised on silica exist in the temperature range 323–373 K and can be repeatedly hydrogenated and dehydrogenated.[114] It is these properties that are required for practically usable systems for the storage of hydrogen: good reproducibility of hydrogenation–dehydrogenation cycles in a temperature range as low as possible.

Deprotonation of 1,2-$C_{60}H_2$ in the presence of Bu_4NOH (benzonitrile, anaerobic conditions) is accompanied by the formation of the C_{60}^{2-} dianion which quickly reacts with a number of alkyl halides to give mono- and dialkylfullerenes.[115]



Ph_2CHBr, $PhCH_2Br$, MeI, propargyl bromide and allyl bromide are used as the alkylating reagents. However, attempts at alkylation of the C_{60}^{2-} formed with octyl bromide failed. Analysis of the absorption spectra for mono- and dialkylated C_{60} derivatives shows that the sp^3 carbon atoms in the monoalkyl derivative are in the 1,2-position, while in dialkyl-C_{60} derivatives, they are in the 1,4-position. Fukuzumi *et al.*[116] studied the mechanisms of formation of R_2C_{60} and $R(R')C_{60}$ dialkylfullerenes from chemically obtained C_{60}^{2-} and various alkyl halides (RX and R′X) differing both in the nature of the R and R′ radicals and of the halogen atom. In the first step, transfer of one electron from the C_{60}^{2-} dianion to an alkyl halide occurs to give RC_{60}^-, which is transformed to R_2C_{60} or $R(R')C_{60}$ according to the S_N2 mechanism.

It was shown that protonation of $Bu^tC_{60}^-$ with trifluoroacetic acid initially gives 1,4-$Bu^tC_{60}H$; the latter is then quickly transformed to 1,2-$Bu^tC_{60}H$ which is more stable thermodynamically. Photoinduced transfer of an electron from a soft reducing agent, 1-benzyl-4-*tert*-butyl-1,4-dihydronicotinamide, to triplet-excited C_{60} results eventually in selective two-electron reduction of C_{60} to give $Bu^tC_{60}^-$, which reacts with $PhCH_2Br$ or Bu^tI in the next step to give 1,4-$Bu^t(PhCH_2)C_{60}$ (see Ref. 63) or $Bu^t_2C_{60}$ (see Ref. 117), respectively. Photoalkylation of C_{70} occurs similarly to give $Bu^tC_{70}^-$ (and $Bu^tC_{70}H$ after protonation); the formation of five regioisomers is possible for $Bu^tC_{70}^-$, unlike $AlkC_{60}^-$ which gives only one product.[118]

The reactivities of the $C_{60}^{-\bullet}$ radical anion or the C_{60}^{2-} dianion manifest themselves not only in reactions with alkyl halides. The higher C–H bond strength in lower hydrofullerenes in comparison with the higher ones results in the possibility of the transfer of a hydrogen atom onto these anions from higher hydrofullerenes. It was shown by cyclic voltammetry that the reaction between C_{60} and $C_{60}H_{36}$ in a propylene carbonate–toluene mixture is induced by electron transfer and eventually involves transfer of a hydrogen atom from $C_{60}H_{36}$ to the fullerene.[119] The pathway according to which the $C_{60}^{-\bullet}$ radical anion and the C_{60}^{2-} dianion electrogenerated from C_{60} react with $C_{60}H_{36}$ was considered as the most probable variant of the transformation; this reaction involves the transfer of a hydrogen atom from $C_{60}H_{36}$ and results in $C_{60}H_2$ (proton transfer is impossible since the calculated[120] pK_1 for $C_{60}H_{36}$ is 31.35 and $C_{60}H_2$ is a rather strong acid[121,122] with pK_1 = 4.7 and pK_2 = 16). In order to estimate the possibility of formation of

§ Presumably, the character of thermal decomposition and the crystal lattice parameters of hydrofullerenes depend considerably on the conditions of fullerene hydrogenation.

$C_{60}H_2$ from C_{60} and $C_{60}H_{36}$, Tkachenko *et al.*[119] calculated the mean C–H bond energies in hydrofullerenes $C_{60}H_2$ and $C_{60}H_{36}$, which were found to be 295 and 279 kJ mol^{-1}, respectively. Thus, cleavage of a C–H bond in $C_{60}H_{36}$ with subsequent formation of a C–H bond in $C_{60}H_2$ is energetically favourable.

The relatively week C–H bond strength in higher hydrofullerenes enables its homolytic cleavage by other relatively weak acceptors as well. Elimination of a hydrogen atom from $C_{60}H_{36}$ under mild conditions can also be carried out by treatment with the 2-(*p*-fluorophenyl)hexafluoroisopropyl radical.[123] Heating (353 K) of hydrofullerenes $C_{60}H_x$ ($x = 6-18$) with $Hg[N(SiMe_3)_2]_2$, $Ti[N(SiMe_3)_2](NEt_2)_3$ and other metal complexes also results in elimination of a hydrogen atom from $C_{60}H_x$ and formation of fullerene-containing oligomers, *e.g.*, $-[(C_{60}H_n)Hg_2]_m-$.[124]

$$mC_{60}H_x + 2mHg[N(SiMe_3)_2]_2 \longrightarrow$$
$$\longrightarrow -[(C_{60}H_n)Hg_2]_m- + 2mHN(SiMe_3)_2.$$

IV. Sorption of hydrogen by carbon nanotubes and graphite nanofibres

Much attention has been given recently to the sorption of hydrogen by such carbon nanostructures as carbon nanotubes, graphite nanofibres and their metal-doped modifications.

Carbon nanotubes (NT) with low-defect structures were found in 1991 in the products of electric-arc evaporation of graphite.[125] However, long before that, similar NT¶ with a high content of structural defects have repeatedly been detected in solid products of hydrocarbon pyrolysis on metal catalysts.[126] Owing to its high efficiency, the catalytic pyrolysis of hydrocarbons is still widely used for the practical production of long (up to millimetres) carbon nanostructures, including NT and the so-called vapour-grown carbon fibres (VGCF).

A graphene sheet rolled in a seamless cylinder is the main element of carbon NT. Multi-walled nanotubes (MWNT) consisting of graphene sheets rolled as a cylindrical spiral also exist.

Vapour-grown carbon nanofibres can consist of parallel-sided graphene platelets perpendicular to the fibre axis (platelet-type VGCF), of nested graphene cones (herring-bone VGCF), of truncated cones (conical layer nanotubes, CLNT), *etc*.

Single-walled nanotubes (SWNT) are closed networks built of quasi-sp^2-hybridised carbon atoms. The network consists of hexagonal cells on the side surface of the cylinder. Open and closed SWNT exist; in the latter, the cylinder ends are closed by hemispheres ('fullerene halves') consisting of hexagonal and pentagonal cells. The SWNT diameter ranges within 0.8–5 nm (most often, 1–2 nm) and its length is 1–500 μm (most often, 5–50 μm). Carbon SWNT have a rather narrow diameter distribution, in contrast to activated carbons in which the sizes of macro-, meso- and micropores differ by a factor of several hundred.[127]

A typical feature of SWNT is the formation of rather strong molecular aggregates (named as bundles, strands, ropes, braids, *etc*.), in which the axes of separate SWNT are parallel to each other. The shortest distance between the carbon skeletons of the adjacent SWNT in the bundles is 0.32 nm. This value is close to the size of the van der Waals distance between graphene layers in graphite and can be changed by introduction of inorganic or organic intercalants, surfactants or by chemical modification of the cylindrical surface of the NT.

Ideal (defect-free) multi-walled nanotubes (MWNT) are built of SWNT inserted one into another. Ideal MWNT are formed in a carbon arc if no metal catalyst is added to the graphite to be vaporised. The distances between the layers in MWNT are close to the interlayer distance in graphite. The outer diameters of electric-arc MWNT are 5–40 nm (most often 15 nm), the inner diameters are 0.8–5.0 nm (mostly 1–2 nm), and the lengths are 0.5–70 μm.

¶ These nanotubes were called tubular graphite fibres.

The synthesis of SWNT and MWNT is accompanied by the formation of other carbon modifications: fullerenes, multilayer polyhedral nanoparticles, graphite microcrystals and amorphous carbon. Furthermore, mixtures of products obtained by the catalytic method contain metal particles. The content of carbon NT in the synthesis products does not exceed 20%–70% (for different methods), therefore in all cases purification from admixtures is the most laborious stage in the preparation of pure carbon NT.

Many publications (see, *e.g.*, the corresponding reviews[128–133]) report the state-of-the-art of the methods for the preparation and study of the properties of carbon nanostructures and their use.

1. Sorption of hydrogen by single-walled carbon nanotubes

The carbon material obtained by the electric-arc method and containing single-walled carbon NT (in the form of bundles containing 7–14 NT), amorphous carbon and particles of a catalyst (for example, Co) adsorbs 5 mass %–10 mass % H_2 (with respect to the pure SWNT) at 273 K and 300 Torr followed by cooling to 90 K.[134] According to the temperature-programmed desorption (TPD) data,[134] hydrogen is desorbed from nanotubes and activated carbon at 133 K. However, if a sample containing SWNT is preliminarily subjected to a treatment which opens the 'plugs' at the tube ends, a second peak almost at room temperature (290 K) appears on the TPD curve. This peak is explained by the evolution of hydrogen adsorbed inside the SWNT due to the penetration of H_2 molecules through the open tube ends. No high-temperature peak of this type is observed in the desorption of hydrogen from activated carbon samples or from fullerene soot obtained in the absence of a catalyst. It is believed[134] that in the carbon material obtained by the electric-arc method, the 'high-temperature' hydrogen is mainly located in the SWNT channels, whereas the 'low-temperature' hydrogen is adsorbed on amorphous carbon, on the outer surface of the SWNT and/or in the intertube space of the SWNT bundles.

The amount of adsorbed hydrogen (99.9999% purity) for relatively pure carbon SWNT obtained by the laser method (see Refs 135 and 136) exceeds 8 mass % H_2 at 10–12 MPa and 80 K.[137] In this case, the mean diameter and the specific surface of a separate SWNT are ~ 1.3 nm and 1300 $m^2\ g^{-1}$, respectively. The diameters of the SWNT bundles are ~ 6–12 nm. The outer specific surface of the bundles measured by the BET method is 285±5 $m^2\ g^{-1}$. The amount of adsorbed hydrogen depends on the number of 'sorption–desorption' cycles. For freshly prepared samples of pure SWNT, the C : H ratio of ≈ 1 (~ 8.25 mass % H_2) is achieved at 80 K and 7 MPa of H_2 (Fig. 5, curve *1*).

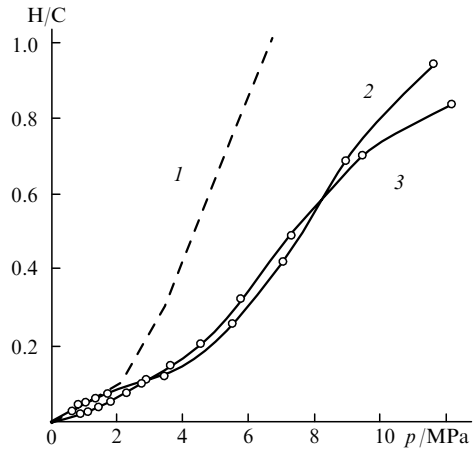


Figure 5. Dependence of the amount of hydrogen adsorbed by an SWNT at 80 K on pressure in the first (*1*) and subsequent cycles (*2* and *3*).[137]

Hydrogen is initially adsorbed on the outer surface of an SWNT bundle. An increase in pressure to 12 MPa during subsequent cycles increases the amount of absorbed H_2, which is attributed to the penetration of H_2 molecules into the intertube space of the bundles. As a result, the intertube space increases and the bundle breaks into separate SWNT; the outer SWNT surfaces are completely covered and the inner surfaces are partially covered by H_2 molecules (Fig. 5). The increase in the intertube distance inside the SWNT bundle can be detected by X-ray diffraction and NMR spectroscopy.[138] It has been shown that an SWNT bundle expands after immersing a carbon SWNT sample in a nitric acid solution and shrinks to the original configuration after deintercalation of HNO_3, *i.e.*, this change is reversible.

Liu *et al.*[139] synthesised carbon SWNT by the electric arc method (the production rate of SWNT was 2 g per hour) in the presence of hydrogen [a nickel–cobalt–iron powder (Ni : Co : Fe = 3 : 0.75 : 0.75) was used as the catalyst, and FeS was used as the SWNT growth accelerator]. The content of SWNT in the carbon material obtained by this method was ~ 60%, the mean SWNT size was 1.85 nm, the diameter of the SWNT bundles was about 20 nm. Upon treatment of the SWNT samples, which included, in particular, heating at 770 K, the amount of adsorbed hydrogen (room temperature, 10 MPa) reached 4.2 mass %, which corresponded to the ratio H : C = 0.52. Up to 78% of the adsorbed hydrogen desorbed under standard conditions. The remaining hydrogen (from 0.52 mass % to 0.95 mass % H_2 for different SWNT specimens) desorbed on heating the sample to 423 K.

Studies of the hydrogen-sorbing properties of a carbon material obtained by the electric-arc method [140] and containing ~ 70 mass % SWNT showed that it adsorbs about 3.5 mass % H_2 at 10 MPa and with multiple repetition of the cycles 'cooling to 77 K – heating to 300 K'.[3, 6] Interesting results were reported [141] that up to 6.5 mass % – 7.0 mass % of hydrogen was absorbed by an SWNT at room temperature and 0.1 MPa.

The specific surface and the gas-sorbing capacity of carbon materials depend considerably on the preliminary thermal treatment. It was shown [142] that heating of an SWNT sample, which has preliminarily been acid-etched, above 600 K *in vacuo* results in the liberation of different gases (CH_4, CO, CO_2 and H_2). After thermal pretreatment, SWNT adsorb a considerably greater amount of xenon at 95 K: the SWNT samples annealed at 1073 K absorbed 20 times more Xe than the samples heated to 623 K. The increase in the adsorption capacity of SWNT was explained by the effect of high-temperature annealing, which removes the carboxyl groups blocking the ends and defects of the NT walls (Fig. 6). Apparently, such a thermal treatment should also affect the hydrogen adsorption capacity of NT.

Hydrogen can also be stored in SWNT using an electrochemical process which is reversible. The relatively low but quite reliably measured hydrogen capacity in the process

$$HT + x\,H_2O + x\,e^- \xrightarrow{\text{charge}} (HT + x\,H) + x\,OH^-$$

is about 0.4 mass % for a number of SWNT specimens. In this case, SWNT/Au is the negative electrode, Ni is the positive electrode, $Hg/HgO/OH^-$ is the reference electrode, and 6 M KOH is the electrolyte. The capacity decreases by only 30% after 100 charge–discharge cycles.[143]

The maximum content of hydrogen in carbon NT specimens reduced with dihydroanthracene at 623 K or with lithium under modified Birch conditions corresponds to the '$C_9H-C_{10}H$' and 'C_8H' compositions, respectively;[144, 145] this is several times less than in the systems using physical hydrogen adsorption at high pressures. The desorption of hydrogen from such hydrogen-containing nanotube derivatives occurs only at 773 K, which implies that hydrogen is chemically bound.[145]

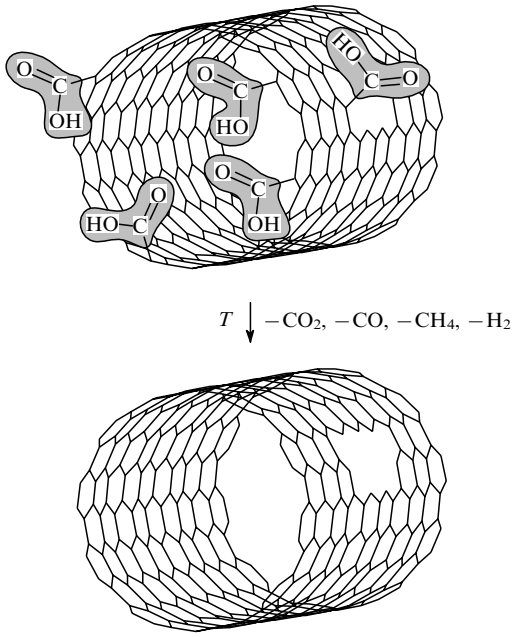

Figure 6. Schematic drawing of chemically treated single-walled NT before and after heating above 600 K.[142]

2. Sorption of hydrogen by graphite nanofibres

Inconsistent data on the hydrogen-sorbing properties have been reported for vapour-grown carbon fibres (VGCF). The highest hydrogen-sorbing capacity of VGCF (11 mass % – 67 mass % H_2) has been reported by Chambers *et al.*[146] The graphite nanofibres were obtained by catalytic pyrolysis of carbon-containing gases on the nanoparticles of a metal catalyst containing iron, nickel and copper, and then purified from the catalyst particles. The VGCF with a length of 10 – 100 μm and a diameter of 3 – 50 nm obtained by this method can be assigned to the platelet-type or conical layered structures.[146] In a favourable conformation, the distance between the graphene sheets is 0.337 nm, while the gas-kinetic molecular diameter of hydrogen is 0.289 nm. The sorption of hydrogen at 12 MPa and 298 K was studied on a Sieverts-type apparatus.

In a series of studies,[147, 148] attention was drawn to the necessity of careful preparation of the samples intended for the H_2 sorption capacity measurements. It was noted that VGCF having developed systems of slit-shaped nanopores with a great number of open edges have a perfect configuration for hydrogen adsorption. Owing to this unique VGCF structure, the hydrogen molecules interact not only with the graphene sheet surface but also with the adjacent H_2 molecules; it is believed that this may result in the capillary condensation of hydrogen at anomalously high temperatures.[146] Moreover, the sorption of H_2 is accompanied by the expansion of pores (crevices), which can also result in polymolecular sorption of hydrogen. Comparison of X-ray diffraction spectra of VGCF samples before and after hydrogen adsorption indicates that the interlayer distance d between separate graphene sheets increases to 0.347 nm after H_2 adsorption (d = 0.340 nm for the initial VGCF). As the adsorbed H_2 is removed from the sample, the parameter d returns to the original value (0.340 nm).[147, 148]

The results on the hydrogen sorption by VGCF reported by Chambers *et al.*[146] have evoked both much interest and many critical comments,† as all attempts to reproduce this experiment failed.[6, 149, 150] Moreover, the reported high values of H_2 absorption considerably exceed even the highest theoretical estimates.[2, 151]

† It may well be that an error was made in the evaluation of the amount of hydrogen adsorbed by the VGCF. For example, the same study [146] reported data on the sorption of hydrogen by palladium and intermetallic compounds which were much higher than the generally accepted values.

Stöbel *et al.*[150] studied the adsorption of hydrogen on two types of carbon materials: on various specimens of amorphous high-porosity activated carbon and on VGCF synthesised in the presence of a catalyst. The adsorption of H_2 by activated carbon measured at 296 K and an H_2 pressure of 12 MPa was 1.6 mass %, which is in good conformity with calculations on the physical adsorption of hydrogen. Under these conditions, the adsorption of H_2 by VGCF did not exceed 1.2 mass %. The authors [150] did not obtain high H_2 absorption on carbon nanofibres with parallel-laminated structure prepared by them; however, they noted an unusual behaviour of the material in a hydrogen atmosphere, which may be due to the fibre nanostructure.

The hydrogen-sorbing properties of a lithium- and potassium-doped carbon material prepared by catalytic decomposition of methane have been studied. After removal of the catalyst, the material contained up to 90% VGCF ‡ with an outer diameter of 25–35 nm, with mainly platelet or conical-layered structures.[152] Doping with lithium or potassium [Li(K) : C ≈ 1 : 15] occurred under conditions of the solid-phase reaction between VGCF and Li(K)-containing compounds such as carbonates and nitrates. Hydrogen uptake reaches 20 mass % for the Li-containing VGCF at 653 K and 14 mass % for the K-containing VGCF at room temperature, which amounts to ~ 160 and 112 kg (H_2) m^{-3}, respectively.[152] Multiple repetition of the H_2 absorption–desorption process results in an insignificant (~ 10%) loss of the sorption capacity of the material. The specimens doped with lithium had higher chemical stabilities under ordinary conditions than those doped with potassium. The high sorption capacity of Li(K)-doped VGCF is attributed to the layered VGCF structure with large interlayer clearance (0.347 and 0.335 nm for VGCF and graphite, respectively) between the small-size (50 nm and less) graphene sheets in the VGCF, as well as to the presence of an alkali metal. Without alkali doping, the absorption of H_2 by the VGCF decreases abruptly.

Chen *et al.*[152] have also obtained anomalously high values of H_2 sorption by graphite doped with Li and K [up to 35%–70% of the sorption capacity of Li(K)-VGCF at 473–673 K and p_{H_2} = 0.1 MPa]. The high hydrogen sorption by VGCF doped with alkali metals was explained by possible dissociative hydrogenation of the carbon sorbent, in which the alkali metal is a catalytic active centre. This hypothesis is supported by the fact that a band characteristic of the Li–H bond vibrations (~ 1420 cm^{-1}) appears in the IR spectrum of a Li-doped VGCF specimen upon treatment with H_2. In the temperature range from 473 to 673 K, the intensity of the Li–H vibrations correlates with the hydrogen absorption. Subsequently, the hydrogen atoms are transferred to the carbon network and add to carbon atoms. The appearance of an absorption band in the region of the C–H stretching vibrations confirms the dissociative mechanism of VGCF interaction with hydrogen. An increase in temperature causes the desorption of hydrogen and, correspondingly, disappearance of the bands assigned to vibrations of the C–H bond. Thus, systems based on Li(K)-VGCF can store hydrogen at elevated temperatures.

While recognising the validity of the qualitative dependences of hydrogen sorption by carbon nanomaterials doped with alkali metals,[152] Yang [153] assumed that these results might have been affected by the presence of moisture in the hydrogen used. Comparative experiments on the absorption of extremely pure (99.999%) absolutely dry and moist hydrogen by the lithium-doped VGCF obtained using the above technique [152] have shown that the adsorption was 2 mass % and 12 mass % H_2, respectively. It was assumed [153] that the anomalously high hydrogen sorption (up to 20 mass %) by the VGCF doped by Li and K [152] can be due to the formation of alkali metal hydroxides and hydrates in a humid atmosphere.

The graphite nanofibres obtained by pyrolysis of CO in the presence of Co/La_2O_3 also absorb H_2;[154] preheating of the samples at 1173 K is necessary in order to provide a high sorption efficiency (see also Ref. 148). The samples preheated at 673 K absorbed much less H_2, whereas graphite was found to be completely inert under identical conditions.

The effect of thermal treatment of a carbon material surface on the adsorption of hydrogen is shown by the data listed in Table 2. It was found that etching followed by treatment of carbon nanostructures increased their specific surfaces and the hydrogen-sorbing capacities, which resulted in the stable absorption of 5 mass % H_2 by the samples treated with a NaOH solution.[155] The VGCF-containing carbon soot obtained by catalytic pyrolysis of ethylene on nickel at 900 K adsorbs about 2.5 mass % of hydrogen at 5–7 MPa and with repetition of the cycles 'cooling to 77 K – heating to 300 K'.[3, 6]

Table 2. Effect of pretreatment of carbon nanotubes on hydrogen adsorption at p_{H_2} = 10 MPa and T = 293 K.[155]

Conditions of NT pretreatment	H_2 (mass %)
Mechanochemical treatment (30 min), etching (65% HNO_3, 72 h)	2.67
Mechanochemical treatment (30 min), etching (65% HNO_3, boiling)	1.16
Heating with NaOH (3 mol $litre^{-1}$, 1 h), washing with H_2O, drying at 373 K (2 h), calcination at 823 K (1 h), treatment with H_2SO_4 (15%, 1.5 h), heating at 373 K (10 min), washing with H_2O, drying at 373 K	5.15

Catalytic decomposition of acetylene at 1173 K in the presence of Co/SiO_2 results in the formation of carbon nanofibres.[156, 157] The sorption capacities of such metal-free carbon fibres at 10 MPa hydrogen pressure is ~ 1 mass % H_2. Although the structure of the carbon material obtained by Klyamkin *et al.*[156, 157] is similar to that of the VGCF obtained by Chambers *et al.*,[146] their sorption capacities differ strongly (1 mass % H_2 [156] and 67 mass % H_2 [146]), despite the similar behaviour of the specimens in the stage of hydrogen desorption. According to the reported data,[158] multi-walled carbon NT absorb up to 1 mass % H_2 at 10 MPa and 298 K. The amount of adsorbed H_2 increases with an increase in pressure in the range of 10–200 MPa.

The $CO : H_2$ ratio affects the specific surface of the nanocarbon fibre obtained upon pyrolysis of CO in the presence of a Fe–Ni–Cr alloy and its sorption capacity with respect to H_2: the hydrogen uptake by the VGCF decreases with an increase in the H_2 content in the starting mixture.[159]

High-precision calorimetric methods [160] were used to study the adsorption capacity of a number of carbon materials, including VGCF obtained according to the reported technique,[161] and commercial SWNT. The materials studied were found to be poor H_2 adsorbents under the experimental conditions (H_2 adsorption at 303 K, H_2 desorption at 373 K), and their adsorption capacities did not exceed that of activated carbon, which disagrees with other reported data.[146]

Ozaki *et al.*[162] compared the adsorption of hydrogen on platinum-coated carbon fibres prepared by two methods. The first method involved the preparation of a homogeneous mixture of a polymer with a metal complex followed by high-temperature carbonisation of the specimen. High-temperature activation of this specimen in water vapour or in CO_2 resulted in the migration of the metal particles to the outer surface of the carbon carrier. The second method employed a mixture of polymers, *viz.*, one

‡ Chen *et al.*[152] relate this material, which contains layered truncated graphene cones, to carbon nanotubes. In accordance with the terminology accepted by Dresselhaus [2] and by us, it should be attributed to graphite nanofibres.

which underwent pyrolysis and one which underwent carbonisation. The addition of a metal (Pt) compound to the pyrolysable polymer made it possible to deposit the metal on the walls of the pores formed upon pyrolysis. The H_2 adsorption for the material obtained according to the second method depends on the amount of platinum added: a small amount of platinum favours H_2 spillover and higher H : Pt ratios. A decrease in the H : Pt ratio with increase in the platinum concentration is due to an increase in the metal particle sizes.[162]

It was shown that thermal treatment of carbon nanofibres prepared by pyrolysis of ethylene in the presence of a Fe—Ni—Cu alloy (Fe : Ni : Cu = 85 : 10 : 5) in argon at 1273 K resulted in a noticeable increase in the amount of the stored hydrogen (up to 6.5 mass % H_2).[163] The importance of pretreatment of a specimen before hydrogen sorption has also been noted in other studies [148, 154] where the necessity of a special thermal treatment of VGCF in order to remove the chemisorbed gases has been shown. By analogy with NT (see Refs 142, 155), it may be surmised that chemical treatment of VGCF and their subsequent high-temperature annealing increase the specific surface of a VGCF and its activity with respect to H_2 adsorption. After an appropriate treatment, VGCF and NT obtained under catalytic pyrolysis conditions (carbon source: benzene or methane; precursor of the catalytically active species: ferrocene) can adsorb up to 4.0 mass % – 5.7 mass % H_2.[164] The absorption of pure hydrogen (99.999%) by graphite fibre with a parallel-laminated structure (98% of VGCF in the mixture) starts immediately without an induction period to reach 10 mass % – 13 mass % H_2 in the first cycle (Table 3). The H_2 adsorption and desorption rates are high.[166] Upon repeated adsorption – desorption cycles, the sorption capacity of the material decreases to approximately 70% of the original value, which is thought to be due to the destruction of the graphite fibre structure. The graphite nanofibre obtained by pyrolysis of acetylene and ethylene at 873 K in the presence of Ni adsorbs up to 10 mass % H_2 following keeping for 16 h at room temperature at 12 MPa. After a decrease in pressure, almost all hydrogen is released (Fig. 7).[166]

Table 3. Effect of pretreatment of a graphite nanofibre on hydrogen adsorption at p_{H_2} = 11 MPa and T = 373 K.[165]

Mean VGCF diameter /nm	Conditions of VGCF pretreatment	H_2 (mass %)
80	evacuation, 5 h, 373 K	12.38
90	treatment with 37% HCl, washing with H_2O, evacuation, 5 h, 373 K	12.82
100	dispersion in ethanol, treatment with 37% HCl, washing with H_2O, evacuation, 5 h, 373 K	10.03
125	dispersion in ethanol, treatment with 37% HCl, washing with H_2O, evacuation, 5 h, 373 K	10.1

Note. The graphite nanofibre was obtained by pyrolysis of benzene at 1373 – 1473 K in the presence of Fe and S.

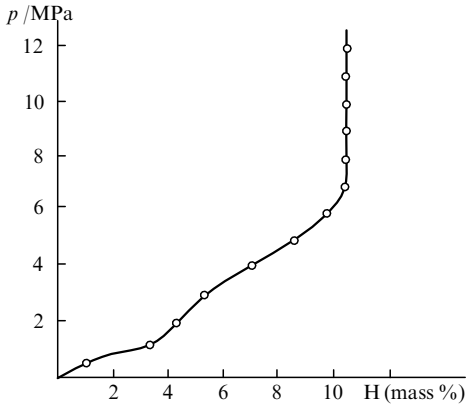

Figure 7. Hydrogen desorption isotherm at 300 K.[166]

Despite the observed discrepancies in the available experimental data (*cf.*, *e.g.*, Refs 148, 150, 158, 165), it is obvious that NT and VGCF are actually characterised by high capacities with respect to hydrogen.

3. Sorption of hydrogen by nanostructured graphite

The sorption of hydrogen on activated carbons at 133 K and p_{H_2} = 2 MPa is 0.5 g H_2 per 1 kg of C (Ref. 8) and 2 mass % at 155 K and p_{H_2} = 6.9 MPa.[150] A uniquely high, though hard to explain, hydrogen-sorbing capacity was observed for carbon of AX-21 grade with 3000 $m^2\ g^{-1}$ overall material surface and 700 – 1800 $m^2\ g^{-1}$ micropore surface; the mass and volume densities of H_2 at 77 K and 5.0 MPa were 100 g H_2 per 1 kg of the adsorbent and 32 kg H_2 per 1 m^3, respectively.[9]

The relationship between the sorption capacity and the volume of micropores has been analysed for a series of activated carbons. It has been found that a pore size optimal for the adsorption of hydrogen exists.[167]

Thermal desorption spectroscopy was used to study the sorption of hydrogen by nanoporous carbon (NPC).[168] It was shown that the maximum amount of H_2 that can be adsorbed by NPC is 15.6 at.% at 266 MPa and 773 K. Mechanochemical treatment of graphite in an extra-pure hydrogen atmosphere (99.9999%) at room temperature and starting hydrogen pressure of 1.0 MPa results in nanostructured graphite which adsorbs H_2 well.[81] After milling for 80 h, the maximum amount of adsorbed H_2 for such a sample is 7.4 mass % ($CH_{0.95}$). This value is comparable to the values of H_2 absorption reached for nanotubes and superactive carbon at temperatures below 100 K and H_2 pressures of about 5 MPa.

Enoki *et al.*[169] studied the properties of nanostructured graphite and its intercalated compounds. The composites prepared by mechanical grinding of Mg and graphite in the presence of organic additives (THF, cyclohexane, benzene) were found to be efficient hydrogen-adsorbing materials.[170, 171] The introduction of an organic additive is necessary for the composite structure to form and its hydrogen-adsorbing properties to appear.

4. Theoretical calculations of hydrogen adsorption by carbon nanomaterials

The mechanism of the uniquely high hydrogen sorption by carbon NM has not yet been clarified. Different variants have been considered: physical adsorption and chemisorption of H_2 molecules on the graphene sheet surface; the arrangement of more than one layer of H_2 molecules between the graphene planes; capillary condensation of hydrogen inside the nanotubes and in the space between the graphene sheets at anomalously high temperatures; the charge state of hydrogen in carbon nanomaterials. Therefore, the calculated maximum hydrogen capacities of NM differ strongly as well.

The Monte-Carlo method was used [172] to calculate the adsorption capacities of carbon materials with crevice-shaped and cylindrical pores with respect to gaseous H_2 at various temperatures and pressures. The calculated values of H_2 sorption were compared to the experimental results obtained for the specially prepared microporous activated carbon (AC). A linear relationship between the adsorption capacity of hydrogen and the specific surface of AC was found. The best AC samples had a specific surface of 2290 $m^2\ g^{-1}$; the corresponding maximum amount of adsorbed H_2 was 0.6 mass %. This value is in good agreement with the calculated value of 0.7 mass % H_2 for ideal slit-shaped pores with S = 2600 $m^2\ g^{-1}$ at 300 K and p_{H_2} = 6 MPa.

According to the reported data,[172] carbon materials with slit-shaped pores ($d = 0.7$ nm) are the optimum H_2 adsorbents at room temperature and $p_{H_2} = 10$ MPa. The highest calculated H_2 volume density is equal to 14 kg m^{-3} (mass content equal to 1.3 mass % H_2). According to the data of Rzepka *et al.*,[172] the sorption capacities of carbon materials with slit-shaped pores are higher than those of materials with cylindrical pores over practically the entire temperature and pressure range studied. It was noted that polymolecular (two-layer) sorption of hydrogen can be observed at 77 K in pores with $d = 1.0$ nm even at low H_2 pressures; this corresponds to the gravimetric capacity of the carbon material equal to ~ 2.0 mass % and 5.5 mass % H_2 for cylindrical and slit-shaped pores, respectively. Therefore, the observed high values of H_2 uptake by single-walled nanotubes (5 mass % – 10 mass % H_2 at room temperature)[134] cannot be explained by pure physical adsorption occurring in SWNT due to strong capillary forces.

Calculations[172] of physical H_2 adsorption at room temperature and $p_{H_2} = 11$ MPa on carbon material with slit-shaped pores with $d = 0.34$ nm corresponding to the interlayer distance in VGCF[146] imply that hydrogen cannot be adsorbed by this material. Since under these conditions the gravimetric capacity of a microporous carbon material with $d = 0.7$ nm is as low as 1.3%, the increase in d observed for VGCF in the course of hydrogen adsorption cannot result in adsorption equal to 11% – 67% reported in Ref. 146. Using the model of VGCF structure with sorbed hydrogen shown in Fig. 8 for the calculation of H_2 adsorption, it has been shown[173] that the distance of 0.34 nm between the graphene layers is insufficient for the incorporation of hydrogen molecules. Moreover, a graphite nanofibre with $d = 0.9$ nm can adsorb as low as 0.46 mass % – 1.6 mass % H_2 at 298 K and $p_{H_2} = 5 – 11.2$ MPa.

Analysis of H_2 adsorption on a graphite surface taking into account the real sorption conditions and the geometric parameters of the hydrogen molecule and the graphite layer gives the value of ~ 2.8 mass % H_2 for one H_2 layer adsorbed on a separate graphene sheet.[2] In real systems, the intermolecular forces, the interaction of the H_2 molecules with the material surface and the presence of surface defects can result in the formation of additional sites for H_2 adsorption. Considering the possible formation of the second hydrogen layer, the value of H_2 sorption on the carbon surface was assessed to be ~ 4.1 mass %.

Doping of graphite with K, Rb and Cs increases slightly its sorption capacity with respect to H_2; the H_2 content due to chemisorption corresponds to the $C_8KH_{2/3}$ composition, and the H_2 content due to physical adsorption corresponds to the $C_{24}KH_2$ composition. However, the hydrogen content is small in both cases (see Ref. 2 and the references therein). On the other hand, for VGCF doped by a metal, high H_2 absorption was obtained even at a low metal : carbon ratio (1 : 15), apparently because of partial reduction of carbon in the graphite layer due to the catalytic effect of alkali metals.[152] However, other researchers are skeptical about the high values of H_2 adsorption obtained[152] (see, for example, Refs 153 and 174), despite the elegant hypothesis put forward by Chen *et al.*[152] for the explanation of the absorption of hydrogen by nanomaterials doped by alkali metals.

Two geometrical models have been suggested for hydrogen sorption by carbon NT bundles.[2] In the first one, hydrogen is considered as a liquid capable of filling the free space unoccupied by the carbon atoms of the nanotube. The use of density values of 0.071 and 2.26 g cm^{-3} for liquid hydrogen and carbon atoms, respectively, results in the H_2 adsorption equal to 2.3 mass %. According to the second model which accounts for the adsorption of hydrogen molecules with a gas kinetics diameter of 0.289 nm both inside the SWNT and in the inter-tube space of SWNT bundles (Fig. 9), the overall H_2 adsorption for a (10,10)NT bundle§ (the NT diameter being 1.38 nm) was found to be 4.0 mass % H_2. Of these, 3.3 mass % H_2 corresponds to the adsorption inside the tubes and 0.7 mass % H_2, to adsorption between the NT in the bundle. Under high-pressure conditions, the compressibility of hydrogen and intermolecular interaction might result in a denser packing of the hydrogen molecules and hence in an increase in its adsorption on carbon NT. In order to confirm this assumption, a detailed calculation has been carried out[175] which has shown that the density of hydrogen in this case can be, in fact, higher than follows from purely geometrical considerations.

Computer simulation of hydrogen adsorption by SWNT and a carbon material with idealised slit-shaped pores has also been carried out.[151] The hydrogen – hydrogen and hydrogen – carbon interactions were simulated using the Silvera – Goldman and Crowell – Brown potentials, respectively; quantum effects were also taken into account. Adsorption of hydrogen inside the NT, between the tubes in the bundles and on the outer SWNT surface was assumed in the calculations. The computer simulation of hydrogen absorption by SWNT and activated coal is in favour of SWNT but does not confirm the high values of hydrogen adsorption for SWNT and VGCF found experimentally.[134, 146]

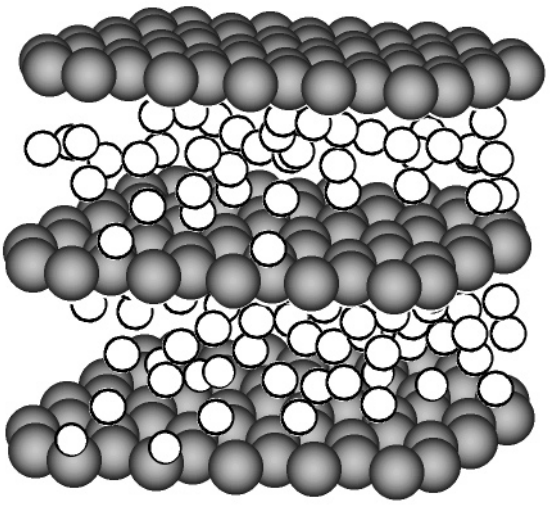

Figure 8. Cell model for the calculation of hydrogen adsorption by a platelet-type graphite nanofibre (pore diameter 0.9 nm). The dark and light circles indicate the carbon atoms and hydrogen molecules, respectively.[173]

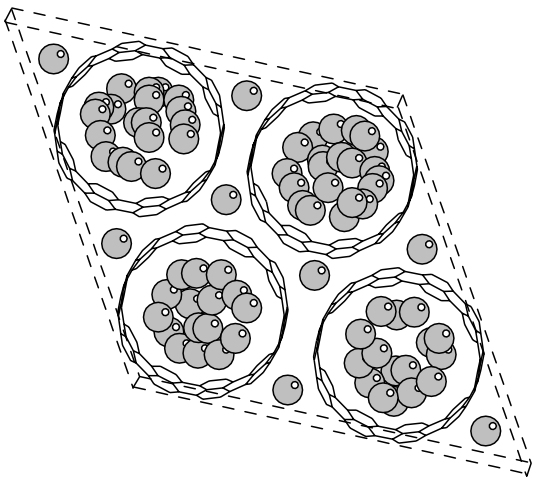

Figure 9. A typical arrangement of H_2 molecules adsorbed on triangularily packed carbon nanotubes.[2]

§ The numbers in parentheses indicate the indices used for the description of the nanotube structures; they are related directly to the NT diameter and the chiral angle.

Calculations of H_2 adsorption in SWNT bundles show [151] that the dense packing of SWNT results in lower gravimetric and volume densities of hydrogen even at sufficiently high adsorption potentials. Low adsorption can result from the surface inaccessibility in dense SWNT bundles.

The results of calculations using the Monte-Carlo method carried out for bundles of parallel SWNT demonstrate a strong dependence of the gravimetric adsorption of hydrogen on the bundle diameter, *i.e.* on its specific surface.[176] At 77 K and p_{H_2} = 10 MPa, the adsorption of H_2 for isolated (10,10)NT and for bundles consisting of three and seven (10,10)NT were 9.6 mass %, 7.0 mass % and 5.5 mass %, respectively. A dependence of the gravimetric capacity of NT on the inter-tube distance in a bundle was also noted.

The increase [138] in the inter-tube distance inside the SWNT bundles observed upon their treatment with nitric acid allows one to assume that the parameter $g = a - d$ (where g is the van der Waals gap, a is the lattice spacing, d is the NT diameter) used in the calculations of H_2 adsorption can be optimised.[177] Optimisation of the packing geometry (the g parameter) for SWNT has been carried out in order to obtain the maximum hydrogen adsorption on SWNT at 298 and 77 K. With this purpose, a series of NT have been studied, *viz*., (9,9)NT with d = 1.22 nm, (12,12)NT with d = 1.63 nm and (18,18)NT with d = 2.44 nm. It has been found that the optimum g value is a function of temperature and equals 0.6 and 0.9 nm at 298 and 77 K, respectively.

It has been shown that none of the SWNT packing geometries studied (the triangular and square ones) can provide high hydrogen adsorption at room temperature. Hydrogen adsorption capacity approximating that recommended by the International Power Agency can be obtained on carbon NT with d = 1.22 nm and g = 0.9 nm only at 77 K and $p_{H_2} > 5$ MPa.

Calculations for charged carbon NT by the Monte-Carlo method have confirmed their somewhat higher ability to adsorb H_2 in comparison with uncharged NT: the presence of a charge results in an increase in H_2 adsorption by 10% – 20% and 15% – 30% for 298 and 77 K, respectively.[178] However, the hydrogen mass and volume densities at 298 K are still too small even for charged tubes.

Calculations using the density functional theory performed in order to search the optimum conditions of hydrogen sorption by SWNT showed that there are two types of H_2 chemisorption sites on the outer and inner NT surfaces.[179] Hydrogen is sorbed in the atomic state on the outer and inner SWNT surfaces, and also in the molecular form ¶ inside the SWNT channel.[181] The emergence of a new absorption band at 4226 cm^{-1} in the Raman spectrum of NT samples after their electrochemical charging (for gaseous H_2, 4161 cm^{-1}) assigned to the absorption of molecular hydrogen was considered as proof of the presence of adsorbed hydrogen. The H_2 capacity of cylindrical channels of carbon SWNT increases linearly with the NT diameter in accordance with the expression: c_{H_2}(mass %) $\geqslant 14.3(d/d_0)$ [where 14.3 is the amount of H_2 (in mass %) adsorbed by (10,10)NT, d_0 is the diameter of (10,10)NT]. The maximum H_2 storage capacity of carbon NT is limited by the energies of intermolecular repulsion between hydrogen molecules located in the inner SWNT cavity and those between H_2 molecules and SWNT walls.

Lee *et al*.[181] calculated the sorption of hydrogen by multilayer carbon nanotubes. Hydrogen atoms were found to be preferentially adsorbed on the outer NT surface and the sorption capacities of MWNT with respect to H_2 were found to be independent of their diameters.[181] The maximum capacities of (5,5)@(10,10)MWNT and (10,10)SWNT are 7.7 mass % and 14.3 mass % H_2, respectively.[179, 181]

¶ The inelastic neutron scattering spectra of SWNT after hydrogen adsorption on them display a peak at *ca.* 14.5 meV corresponding to rotational transitions in the H_2 molecule. The presence of this peak indicates that physical adsorption of H_2 occurs under the experimental conditions; the peak intensity decreases with a temperature increase in the range of 25 – 40 K.[180]

V. Conclusion

Carbon nanomaterials attract interest as promising materials for the development of hydrogen accumulators.

Theoretically, fullerene can be hydrogenated to $C_{60}H_{60}$ without destruction of the fullerene skeleton; this corresponds to 7.7 mass % H_2 (0.92 m^3 of H_2 per 1 kg of $C_{60}H_{60}$). However, attempts at synthesis and characterisation of the hydrofullerene with this composition have failed so far. Compound $C_{60}H_{60}$ should be extremely unstable; the excessive strain of this molecule stems from the appreciable deviation of the configuration of bonds between the carbon atoms from the most stable tetrahedral configuration. According to molecular mechanics calculations, the strain in the $C_{60}H_{60}$ molecule can be decreased if at least ten hydrogen atoms in the $C_{60}H_{60}$ molecule are bound endohedrally (this is the most stable conformation for the $C_{60}H_{60}$ composition).[182]

The methods used in practice for the reduction of fullerenes give $C_{60}H_x$ compounds with 4.5 mass % – 6.0 mass % H_2. Their preparation requires high temperatures and H_2 pressures or reactive reducing agents (see, *e.g*., Refs 12 and 13). Analysis of numerous studies on the synthesis, structures and reactivities of hydrofullerenes shows that the practical applications of fullerenes and their metal derivatives as hydrogen sorbents require that the actual sorption capacities are increased, the hydrogenation is accelerated, the dehydrogenation temperature is decreased and the hydrogenation – dehydrogenation reversibility is ensured. In addition, side reactions should be eliminated.[3] Nevertheless, $C_{60}H_x$ and $C_{70}H_x$ hydrofullerenes have already been suggested, for example, as modifying additives for the carbon anodes of reversible Li-batteries.[183]

Other carbon nanostructures, such as single-walled carbon nanotubes and vapour-grown carbon fibres, as well as their metal-doped modifications, are quite promising as hydrogen-storage media. This is evident from Table 4 which shows generalised data on the hydrogen-sorption capacities of SWNT and VGCF, which in certain cases exceed considerably the values required for mobile hydrogen-storage systems. However, the data on the amount of hydrogen accumulated by carbon NM obtained by different authors differ considerably. The reasons for the discrepancies lie in the absence of reliable methods for the preparation of pure SWNT and VGCF and the absence of generally accepted techniques for their certification, for example, with respect to purity, degree of their 'openness', nanotube diameter and interlayer distances, and the amount of metal catalysts. In addition, the

Table 4. Sorption characteristics of various carbon nanomaterials.

Material	Maximum capacity (mass %)	T /K	p_{H_2} /MPa	Ref.
SWNT	8.25	80	7.18	137
SWNT	5 – 10	90	0.04	134
SWNT	4.2	300	10 – 12	2, 139
SWNT	6.5 – 7	300	0.1	141
SWNT	1.1 – 5.2	293	10	155
SWNT	3.5	77 ↔ 300 [a]	5 – 10	3
VGCF	11 – 67	300	11	146
VGCF	0.4	298 – 773	0.1	152
VGCF	10 – 12	373	11	166
VGCF	2.5	77 ↔ 300 [a]	5 – 10	3
Li-VGCF	20	473 – 673	0.1	152
K-VGCF	14	473 – 673	0.1	152
VGCF	10	300	12	167

[a] 'Cooling to 77 K ↔ heating to 300 K' process.

hydrogen-sorbing capacity depends crucially on the pretreatment of carbon nanomaterials and the purity of hydrogen used. Therefore, the results obtained in the studies on hydrogen sorption characterise only a particular material and cannot as yet be used for comparison of the efficiencies of different types of carbon NM. The mechanism of the uniquely high hydrogen sorption by carbon nanomaterials is not clear, either. Nevertheless, the existence of high hydrogen capacities in nanocarbon materials is obvious. This allows one to hope that nanocarbon materials (provided that they are accessible) can be used in actual hydrogen-storage systems.

The experimental and theoretical materials presented in this review testify to a significant increase in the scope of research on the synthesis and hydrogen-sorbing properties of carbon nanostructures aimed both at the solution of fundamental scientific problems and at the development of mobile hydrogen-storage systems. This is also evident from presentations submitted at various conferences on carbon nanomaterials, hydrides and hydrogen power engineering.

Metallic nanosystems in catalysis

V I Bukhtiyarov, M G Slin'ko

Contents

I.	Introduction	147
II.	Physicochemical properties of nanostructures	147
III.	Reactivities and catalytic properties of nanostructures	150
IV.	The prospects for the application of nanostructures in catalytic processes	154
V.	Conclusion	157

Abstract. The reactivities of metallic nanosystems in catalytic processes are considered. The activities of nanoparticles in catalysis are due to their unique microstructures, electronic properties and high specific surfaces of the active centres. The problems of increasing the selectivities of catalytic processes are discussed using several nanosystems as examples. The mutual effects of components of bimetallic nanoparticles are discussed. The prospects for theoretical and experimental investigations into catalytic nanosystems and the construction of industrial catalysts based on them are evaluated. The bibliography includes 207 references.

I. Introduction

Metallic catalysts supported on various carriers (*e.g.*, SiO_2, α- and γ-Al_2O_3, zeolites, magnesium and chromium oxides, carbonaceous materials, *etc*.) are widely employed in chemical, petrochemical and oil-refining industries as well as for purification of gaseous industrial wastes and motor transport exhausts from toxic components. The production of efficient industrial catalysts includes selection of inert carriers of definite porous structures, their coating with particles of active metals of predetermined compositions, sizes and structures and the most efficient unimodal distribution of these particles over the carrier surface.

Catalytic reactions occurring on the catalyst's surface consist in adsorption of molecules of the starting compounds, their migrations, chemical conversions of adsorbed substances and subsequent desorption of the products formed. The gas-phase components are dissolved in the near-surface layers of the catalyst thus changing its reactivity. In some cases where a certain degree of coating of the catalyst's surface with the adsorbed molecules is achieved, its spontaneous and adsorption-induced reconstruction takes place. The energies of lateral interactions of the adsorbed species, their mobilities and the energies of binding of the interacting molecules to the catalyst are the crucial factors which determine the rates of the elementary catalytic steps mentioned above. The efficiency of a catalyst depends on how fast and concertedly do the active sites on the catalyst's surface adsorb the reacting species, retain them during the chemical conversions and liberate the reaction products to be recovered for the next catalytic cycle. The maximum reaction rate is reached when the adsorption, reaction and desorption possess the optimum energies of binding of molecules to the catalyst (the Sabatier – Balandin principle).

The rates of individual elementary stages depend differently on the size of the active metal particles; hence, the total rate of the reaction varies with a change in the particle size. The knowledge of the structure and properties of the active sites and their distribution over the catalyst's surface is of primary importance for establishing a correlation between the structure and properties of the catalyst's surface and the particle size. It is also desirable to establish the number of adsorbed reacting species and metal atoms involved in an elementary catalytic act.

II. Physicochemical properties of nanostructures

The intermediate position occupied by nanoparticles between the metals in bulk and individual atoms predetermines the deviation of their physicochemical properties from those of bulk metals, on the one hand, and those of isolated atoms, on the other hand. Such characteristics of nanoparticles with the sizes ranging from several tens to units of nanometres are affected as the electronic, magnetic, optical properties and many others. The changes in the surface structures and electronic properties of metallic nanoparticles present the greatest interest for specialists in catalysis, because these characteristics determine primarily specific interactions of the reactants with the surface of the active component, the nature and reactivities of the adsorbed species and eventually the activities and selectivities of the nanosystems in heterogeneous catalysis.

1. The structure and geometry of the surface

The atoms inside bulk crystals have optimum chemical bonds with all adjacent atoms. If the number of metal atoms in the particle (N) is less than 13, it has a close packing in which each atom represents a surface atom. For $N \geqslant 13$, two kinds of atoms exist, *viz*., the inner and surface ones. The proportion of surface atoms in a cluster † depends on the total number of atoms.

† Many investigators believe that in contrast to particles, clusters comprise a strictly definite number of atoms and thus represent nearly monodisperse structures with sizes less than 10 nm.

Number of atoms in a cluster	13	55	147	349	561
Proportion of surface atoms (%)	92	76	63	52	45

These data refer to clusters with 'shell' structures which are characterised by close packing of their metal atoms (see below). For $N = 13$, such clusters have only one inner layer (consisting of only one atom, whereas for $N = 55$ and $N = 147$, these have two and three inner layers of atoms, respectively. Then, the particle size increases from 0.8 to 2 nm. In particles with sizes of 2–10 nm, the numbers of surface and inner atoms are comparable, whereas in particles with sizes > 30 nm the fraction of surface atoms is less than 2%. Hence, the proportion of surface atoms decreases with an increase in the particle size, their coordination properties with respect to the reactants change too. Small particles form many different faces; their number and parameters depend on the method used for their preparation. The properties of the particles approach those of bulk crystals with an increase in the particle size.

The surface structures of metallic particles are studied by theoretical and experimental methods.[1–4] The theoretical approach is based on the analysis of the equilibrium form of crystals [1] determined by the minimum value of Gibbs' free energy. The total energy depends on the thermodynamic properties of the bulk phases, the contribution of the planar surface and the plane intersection energy, which corresponds to the contribution of curved or rough surfaces. Obviously, the surface structures of nanoparticles are determined by the ratio of contributions of planar and rough surfaces, which in turn depends on the particle size. For large particles, the contribution of rough surfaces is insignificant and the equilibrium form of a crystal is determined by the minimum surface energy. The contribution of the curved surface increases with a decrease in the particle size. Hence, the surface of nanoparticles contains predominantly planar, planar and rough or predominantly rough areas depending on their sizes.

Experimental studies of surface structures are complicated, since the methods employed should ensure resolution at the atomic level. Transmission electron microscopy (TEM) is one such method. Studies of nanoparticles using TEM corroborated the presence of planar and rough surface areas and made it possible to follow their alterations with a change in the nanoparticle size.[3,4] Thus a combination of TEM with computer simulation of surface structures showed that the surface of platinum particles (~ 8 nm) consists of (111) faces (~ 37%), (100) faces (28%) and rough areas (35%).[4] It is noteworthy that the rough areas contain faces with higher Miller's indices, *e.g.*, (001), (113), (012) and (133) faces. The results of computer simulation studies of rough areas and of platinum particles as a whole are presented in Fig. 1.

In recent years, scanning tunnelling microscopy (STM), which ensures resolution at the atomic level, has been widely used for the study of surface structures of metallic nanoparticles.[5–9] It was found that surface structures of small (1–2 nm) metallic particles are determined by their shapes which in turn strongly depend on the nature of the support. At the same time, such low coordinated sites as edges and kinks strongly affect the interaction of a surface with adsorbed species. The use of STM for the analysis of surface structures of metallic nanoparticles seems promising, since in contrast to TEM this method allows *in situ* analysis of surface structures, *i.e.*, in the course of a catalytic reaction.

An alternative procedure is based on the adsorption of molecules the spectral characteristics of which are sensitive to the structure of the adsorption centre. Successful application of this method entails the choice of a suitable molecular probe and measurements of its spectral characteristics in the adsorption on single crystals with different surface structures. Like STM, this method permits one to obtain information *in situ*, which is extremely important in studies of catalytic reactions, especially those where the molecular probe is one of reactants. NMR and IR spectroscopic studies of CO adsorption on platinum and palladium clusters supported on SiO_2 is an example.[10–12] It was shown

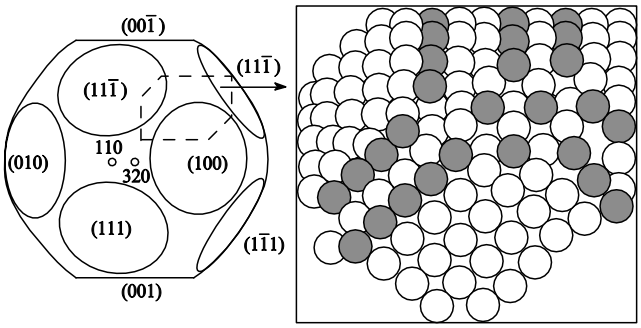

Figure 1. The types of faces on the surface of a platinum particle (8 nm) and a structural model of a site marked by a dashed line.[4] The light and dark circles designate the atoms localised at different levels.

that part of the ^{13}CO is adsorbed on platinum catalysts in a linear rather than a bridge-like form, the proportion of the linear fraction being increased with an increase in the degree of platinum dispersion from 16%–19% to 56%.[10] This effect was attributed to the fact that the surfaces of smaller platinum particles contain more low-coordinated sites. A similar conclusion was made by Xu *et al.*[11] who showed that the major part of the CO is adsorbed on small palladium particles in a linear rather than in a bridge-like form. This points to a higher concentration of defect/edge sites in small nanoparticles in comparison with large ones.

An analysis of spectra of the O 1*s* core level recorded after low-temperature adsorption of O_2 was proposed by us for investigation of surface structures of supported silver. This approach is based on the previously established regularity, *viz.*, the greater the number of defects on the silver surface the lower the minimum temperature needed for dissociation of oxygen molecules.[13–15] In other words, the amount of atomic oxygen after low-temperature adsorption correlates with surface defects of the supported silver particles. Studies of low-temperature ($T = 140$ K) adsorption of O_2 on silver particles deposited onto a graphite surface revealed that the form (atomic or molecular) of the chemisorbed oxygen depends on the sizes of the silver particles. The molecular form is absent in the case of small (< 10 nm) particles which suggests a high degree of defectiveness of their surface structures, while this is present with an increase in the particle sizes to 20–40 nm. The latter circumstance points to the formation of (111) and (110) low-index faces. It is worth noting that the dimension-dependent effect is manifested in the epoxidation of ethylene on silver catalysts in the range of particle size from 40 to 50 nm.

These data altogether suggest that the surfaces of small clusters do not exclusively contain low-index faces, such as (111), (110) or (100) faces. The greater part of the surface, which increases with a decrease in the nanoparticle size, is occupied by curved areas. This circumstance is of crucial importance for the catalysis by nanoparticles, since the adsorption properties of rough surface defects (*e.g.*, angles, steps, edges, *etc.*) differ from those of flat surfaces. Therefore, simple extrapolation of experimental data obtained for single crystals to real catalytic systems is impossible. In this connection, studies of reactivities of metallic nanoparticles become especially urgent.

2. Electronic properties

As the number of atoms in nanoparticles is limited, their electronic structures occupy an intermediate position between the discrete energy levels of free atoms and continuous energy bands of the bulk metal. The dependence of electronic structures of metallic particles on their sizes was studied in particular by Kubo,[16] who suggested that the spectrum of the energy levels of nanometre particles should resemble that of a large molecule rather than that of a bulky solid. The electronic levels of atoms in a large metallic particle are close to one another and eventually overlap to form energy bands. The expression:

$$h = \frac{E_F}{N}, \quad (1)$$

where E_F is the Fermi level energy and N is the number of atoms in a metallic particle, was proposed to evaluate the distance between the neighbouring energy levels (h). Estimation of the maximum size of a particle where changes in its electronic properties can occur as calculated by this simple formula gives the value of ~ 2 nm. Presumably, this is the threshold size where significant changes in the electronic properties of supported metallic nanoparticles are observed. This hypothesis was confirmed by experimental data. It was found that the properties of nanoparticles change so drastically in the size range of 2–5 nm that a 'metal–non-metal' transition becomes very likely. This conclusion is based on the increase in the binding energy of electrons (E_b) at core levels [16] [the binding energy was measured by X-ray photoelectron spectroscopy (XPS)] with a decrease in the sizes of metallic nanoparticles.

In the general case, the changes in ΔE_b are due to the contribution of the following terms:

$$\Delta E_b = \Delta E + \Delta E_R + \Delta E_F, \quad (2)$$

where ΔE is the 'true chemical shift' equal to the difference between the energies of different initial states of the element under study,‡ ΔE_R is the change in the relaxation energy and ΔE_F is the difference between the Fermi level energies.

The last two terms in equation (2) are determined by the effects of the final state as a result of photoelectron emission, *viz*., the ΔE_R value reflects the changes in the relaxation energy upon the screening of photoelectron vacancies caused by redistribution of electrons in the solid, whereas ΔE_F reflects possible changes in the Fermi level of a sample relative to that of the spectrometer.§ If the conductivity of the sample is high enough, an electrochemical equilibrium is established between the sample and the spectrometer. In this case, the positive charge induced by photoelectron emission is neutralised due to the transition of electrons from the 'earth' to the sample and the contribution of ΔE_F to the total change in ΔE_b will be insignificant. If the electronic conductivity of the sample is not high enough to compensate for the charge due to photoemission, the positive charge is accumulated on the surface of the sample. The electrons passing through this positively charged layer lose their kinetic energies, which results in the overestimation of the apparent binding energy. This suggests that the Fermi levels of the sample and the spectrometer are no longer at equilibrium, which results in the charging effect due to accumulation of unknown surface potential.

The subdivision into terms proved to be useful for establishing the reasons for the change in ΔE_b with a decrease in the metallic nanoparticle sizes. It was suggested (see, *e.g*., Refs 17 and 18) that it is the relaxation effect that underlies the positive shift of the binding energy in small metallic nanoparticles (2–3 nm) by 0.5–1.0 eV in comparison with the binding energy of the bulk metal. However, studies of alloys [19,20] and those employing isochromatic spectroscopy [21,22] revealed that the observed shift in the binding energy cannot be attributed to the relaxation effect alone. It was concluded that the changes in the initial state of atoms in metal clusters with particle sizes of less than 2–3 nm are due to the 'metal–non-metal' transition. This conclusion is of fundamental importance, since the changes in the initial states of atoms in small clusters should influence (and they do influence, as will be shown below) their reactivities with respect to the gases to be adsorbed. It is evident that the catalytic properties of clusters cannot remain unchanged under these conditions.

In contrast to the initial-state and relaxation effects, the contribution of the charging effect to total changes in ΔE_b was not taken into consideration by the majority of authors who dealt with studies of electronic properties of metal clusters. Such an approach is justified with respect to homogeneous insulator specimens where the magnitude of the charging potential is identical for all inner levels and can be easily taken into consideration in the analysis of XPS spectra by the internal standard method. The situation is more complicated in heterogeneous systems where different phases are characterised by different conductivities. In this case, the surface charges are different in individual phases of the specimen, which generates the so-called differential charging of the more conducting phase in comparison with the less conducting one. Apparently, this situation is quite realistic in the case of heterogeneous catalysts which contain metallic nanoparticles supported onto the surface of dielectric substrates (Al_2O_3, SiO_2, *etc*.). Indeed, it was demonstrated [23,24] that metallic crystallites with the sizes ranging from five to several tens of nanometres manifest the properties of conducting metals by providing more efficient compensation of the surface charge in comparison with the surface of insulating substrates. As a result, the charge potential on metallic particles is lower than that of the dielectric substrate, and the corresponding lines of the substrate in the XPS spectra manifest a greater shift in the binding energy (ΔE_b) than those of the supported metal. Then, the shift of the spectra by a value equal to the charge of the substrate, the lines of which are generally used as internal standards in calibration of XPS spectra, will produce an apparent negative shift in the lines of the corresponding spectra of the metals.

The latter effect is manifested exclusively upon photoemission; however, it can be of tremendous importance for characterisation of reactivities of various particles including silver particles. The hypothetical role of the conductivity electrons in the formation of chemical bonds between the metal surface and chemisorbed molecules which was put forward as early as 1937,[25] was corroborated later by quantum-chemical calculations.[26] The role of the conductivity electrons in the formation of chemical bonds was confirmed experimentally by the presence of the Knight shift in the ^{13}C NMR spectra of carbon oxide adsorbed on supported metallic particles.[27,28]

The effects of differential charging can be taken into account with the help of those parameters of XPS spectra which do not depend on the surface charge. One of them is the modified Auger parameter α, which represents the sum of the binding energies of the most intense line in the XPS spectrum of the element under study and the kinetic energy of the corresponding Auger peak.[29] Since the charge potential increases the binding energy of the core level and decreases the corresponding kinetic energy of the Auger peak by the same value, their sum is not changed with changes in the charge. With the use of the Auger parameter we have demonstrated that it is the differential charging of supported nickel and silver particles that is responsible for the changes in the binding energies of their core levels ($2p_{3/2}$ and $3d_{5/2}$, respectively) in catalysts (both fresh and treated with the reaction mixture) for butadiene hydrogenation (Ni/C) and ethylene epoxidation (Ag/Al_2O_3).[30–32]

Treatment of nickel particles supported onto carbon filaments with the reaction mixture causes a shift in the overall Ni spectrum ($2p_{3/2}$) by 1.1 eV towards higher values of E_b with a simultaneous decrease in the Ni : C ratio.[30] The constancy of the parameter α and the absence of a shake-up satellite in the Ni $2p_{3/2}$ spectrum indicate that both fresh and treated samples contain metallic nickel, whereas the shift in the Ni spectrum $2p_{3/2}$ is due to the differential charging.

Studies of Ag/Al_2O_3 catalysts where the sizes of silver particles vary from 10 to 100 nm revealed a negative shift in the Ag $3d_{5/2}$ spectra by 0.3–0.4 eV for particles with the sizes above 50 nm.[31,32] In this case, the parameter α was constant for all

‡ The XPS method owes its second name which is widely used by researchers *viz*., 'electron spectroscopy for chemical analysis' (ESCA), to the term ΔE.

§ 'The Fermi level of spectrometer' is a popular term used to define the Fermi level of the material (mostly, gold) of which the energy analyser of the spectrometer is made.

specimens and equal to 726.2 eV. Comparison of this parameter with the known values of α for metallic silver (726.0 – 726.3 eV) and silver oxides (724.0 – 724.5 eV) suggests that the samples under study contain particles of metallic silver. This conclusion was confirmed by the results of an X-ray phase analysis and scanning tunnelling microscopy, which have demonstrated the presence of the α-Al_2O_3 phase and metallic silver in the specimens.[33]

The observed change in E_b(Ag $3d_{5/2}$) is determined by the effect of a differential charging of the supported silver, which in turn is due to the inner conductivity of large silver particles and the lack of conductivity of the surface of the non-conducting substrate.[31] This conclusion is in good agreement with the results of NMR studies of silver catalysts[34,35] according to which the Knight shift of the ^{147}Ag signal disappears if the size of silver particles is less than 50 nm. Since the Knight shift is determined by hyperfine interactions of silver nuclei with the conductivity electrons, it is clear that the size of several tens of nanometres is critical with respect to the conductivities of supported silver particles. The great importance of such changes in the properties of silver conductivity electrons for catalysis is illustrated in Fig. 2. As can be seen, the rate of ethylene epoxidation decreases more than 10-fold with a decrease in the sizes of silver particles below 50 nm. It will be shown below that this correlation depends on the form of oxygen adsorbed on silver.

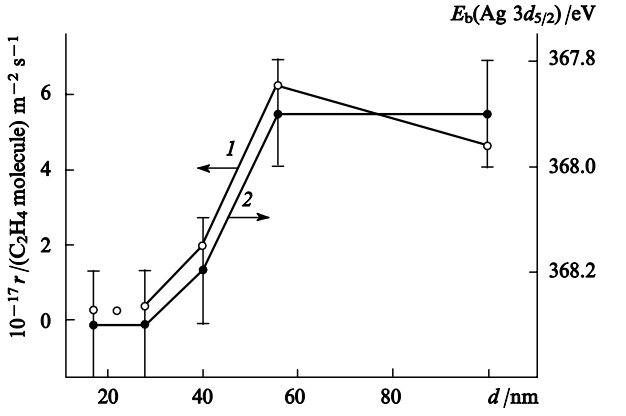

Figure 2. The dependence of the rate of ethylene epoxidation (*1*) and the binding energy E_b(Ag $3d_{5/2}$) (*2*) on the average size of silver particles in non-promoted Ag/Al_2O_3 catalysts.

A correlation was also found[36–38] between the deviation of electronic properties of supported nanoparticles from those of bulk metals and the catalytic activities of nanoparticles.

III. Reactivities and catalytic properties of nanostructures

The existence of size effects in electronic and structural properties of nanostructures implies that their reactivities with respect to gaseous molecules also differ from those of bulk metals, this difference being more pronounced in smaller particles. The first evidence for such dependence was obtained in catalytic studies which demonstrated that the rates of numerous reactions catalysed by metallic nanoparticles vary in the same range[39] as their electronic and structural properties.[10–12,19–21,40–42] Catalytic reactions usually occur on the catalyst's surface. Therefore, the activities of catalysts are conventionally referred to unit surface area. This quantity, which is termed 'specific catalytic activity' (SCA), is determined by the chemical composition, sizes of crystallites, structures of surface faces, structural irregularities and miscellaneous defects. Therefore, the knowledge of changes in the catalytic properties of the catalyst's surface caused by changes in both the sizes of crystallites and surface structures of their faces is of fundamental importance for the theory and practice of catalysis. Although the structures of nanocrystals can differ from those of macroscopic crystals due to exposure of other types of faces on their surface,[43] we thought it appropriate to analyse, at least briefly, the results of investigations of applied single crystals with different surface orientations as the subjects. This is especially important, because the results of such studies are very often used as references for illustrating the dependence of reactivities of metallic nanoparticles on their sizes, as will be shown below.

1. The reactivities and catalytic properties of single crystal faces

The properties of atoms in the crystal lattices of metals are determined by their specific atomic environment, *i.e.*, the number of adjacent and more remote neighbours, and the sizes of the corresponding coordination zones. Therefore, the reactivity of a surface depends essentially on the localisation of atoms on one or another crystallographic face and the parameters of their atomic environment. A correlation between the orientation of the crystal faces and their catalytic activities was established by A A Balandin as early as 1929.[44] In the past years, the number of investigations of this kind has increased manifold.

The rates of carbon monoxide oxidation on (111), (100), (410) and (210) faces of the single crystal $Pt_{0.25}Rh_{0.75}$ at different temperatures, total pressure of 2×10^{-7} mbar and the $CO:O_2$ ratio of 2 : 1 differ markedly.[45] On heating, the reaction rates on different planes increase rapidly but differently in the range of 400 – 500 K and then decrease slowly after reaching a certain maximum. The higher the strength of lateral interactions of the CO molecules, the higher the temperature at which the maximum rate is achieved. The oxidation of CO on the faces of Pt, Pd, Ir, Rh and Ru crystals proceeds in a similar way.

The catalytic activity of the (111) face of iron in the synthesis of ammonia from nitrogen and hydrogen is about 430 times higher than that of the closely packed (110) face and 13 times higher than that of the (100) face.[46] It is also known that aromatisation and cyclisation of hydrocarbons occur on the (111) face of platinum, whereas the (100) face is responsible for their isomerisation and hydrogenolysis. The presence of curved areas, *e.g.*, (10 8 7) favours the formation of undesired products, such as propane and ethane.

The atoms in the surface layer can be at equilibrium with the atoms in the second layer. Since the bonds of the surface atoms are not compensated, their equilibrium positions can differ from their positions in the bulk. Such 'surface reconstruction' was observed in the CO oxidation catalysed by platinum and some other metals. For example, the reaction occurring on the (110) face of platinum single crystals is accompanied by spontaneous reconstruction of the surface from the (1×1) state into the (1×2) state. Surface rearrangements are due to interactions between the platinum atoms, CO molecules and oxygen atoms.[47–49] The higher reactivity of the (110) face of platinum in comparison with other faces can be the reason for autooscillations of the reaction rate.[48–54] On this face, spatial-temporal self-organisation in the form of progressive spiral and stationary reaction waves and chaotic regimes were observed in the nano- and micrometre ranges. On the other hand, the oxidation of carbon monoxide by oxygen on the (111) face of platinum at low partial pressures of CO and O_2 and at 300 – 700 K was unaccompanied by changes in the surface structure and, correspondingly, by autooscillations of the reaction rate.

The activation energy of a catalytic reaction depends on the coverage of the catalytic surface with oxygen and carbon monoxide.[47] The adsorbed oxygen atoms increase the reaction rate, while adjacent CO molecules decrease it. The distribution of atoms and molecules adsorbed on the surface of a catalytic species influences substantially the dependence of the rates of elementary stages of the catalytic reaction on the degree of coverage of the catalytic surface.

Spatial-temporal self-organisation was also observed in a nanometre range in the interaction of NO and H_2 on the (110) face of rhodium single crystals at partial pressures of nitrogen

oxide and hydrogen of 10^{-6}–10^{-4} mbar and at temperatures on the catalyst's surface of 300–800 K.[55–58] Phase transitions of the 'order–disorder' type and various superstructures of adsorbed hydrogen atoms were found. The nitrogen atoms initiated the rearrangement of the original surface resulting in the appearance of the (3×1)–N superstructure recorded by low energy electron diffraction. This was transformed into the (2×1)–N superstructure with an increase in the degree of coverage of the catalyst's surface with the adsorbed nitrogen.[59] Lateral interactions of adsorbed particles and their mobilities exert a crucial effect on the formation of structures on a nanometre range. The NO + H_2 system on Rh(110) was also characterised by anisotropy of the near-surface layer and the presence of unusual reaction autowaves of different shapes. Non-linear phenomena, *e.g.*, spatial-temporal self-organisation in nanosized particles, significantly influence both the spatial structure of the reaction autowaves at the meso level and the rate of the catalytic reaction.

The effects of the structural factor on SCA can also be explained by assuming that the surface of small metallic clusters contains many more low-coordinated atoms than that of bulk metals.[60] Indeed, the proportion of surface atoms, particularly those localised in the apices as well as on the boundaries and faces and characterised by lower coordination numbers than atoms localised inside the crystals, increases essentially in crystallites the sizes of which exceed 5 nm. If this is true, SCA will depend on the changes in the crystallite sizes in the range of not more than 1–5 nm, whereas the catalytic activities of larger crystallites will be determined by the structures of the faces exposed on the surface of the nanoparticles.

2. The reactivities and catalytic activities of nanostructures

The first attempts to establish a correlation between the rate of a catalytic reaction and the particle size of the active component were undertaken by Kobozev in the late 1930's.[61] These investigations were continued in the early 1950's by Boreskov *et. al.*[62, 63] who have formulated a rule of relative stability of SCA of catalysts having identical chemical compositions. A similar conclusion was made later by Boudart *et al.*[64, 65] who have named this kind of reaction 'structure-insensitive reactions'. However, the rates of many reactions do depend on the degree of dispersion of the active component, and these reactions have been named 'structure-sensitive reactions'. Further studies of the dependence of catalytic activities of metals on the particle size have revealed [66–76] that all metal-catalysed reactions can be classified into four main groups, *viz.*,

(a) SCA depends only weakly on the size of the supported metal particles (structure-insensitive reactions);

(b) SCA drops with a decrease in the particle size (the so-called negative size effect);

(c) SCA increases with a decrease in the particle size (the positive size effect);

(d) maximum SCA is characteristic of particles of intermediate sizes.

Seemingly, in the case of structural insensitivity or a positive dimensional effect the sizes of nanoparticles of the active component in certain systems can be minimised, thus affecting favourably the economical parameters of the industrial process. Unfortunately, this assumption was refuted by some examples.[77, 78] It was shown [77] that the rate of even such structure-insensitive reactions as the hydrogenation of hydrocarbons decreases by more than two orders of magnitude in those cases where iridium nanoclusters ($d \approx 2$–3 nm) supported on MgO were used instead of conventional Ir/MgO catalysts, whereas the tenfold increase in the activity of the Ir_n/γ-Al_2O_3 catalyst in the hydrogenation of toluene is explained [78] by the formation of iridium agglomerates during the annealing of fresh samples in hydrogen at 573 K.[78]

Obviously, such drastic differences in the behaviour of SCA as a function of the particle size are due to changes in the reactivities of the particles with respect to the participants of the catalytic reaction. This accounts for a great number of publications devoted to the analysis of reactivities of nanoparticles. However, real specimens used in catalytic studies appeared to be unsuitable subjects for establishing an exact correlation between the changes in the catalytic properties and reactivities. Progress in this field could be achieved, if model systems were used. These were prepared by covering flat samples of a substrate with metal particles using physical (*e.g.*, deposition of bulk metals in high vacuum) or chemical methods (*e.g.*, introduction of chemical compounds of a metal followed by reduction and/or calcination).

For the first time, the reactivities of metallic clusters were studied in detail using the oxidation of CO on platinum metals as an example.[79–82] This choice has been made owing to the large body of experimental material obtained in precision studies of this reaction on bulk metals.[83–86] These results could be used for the analysis of reactivities of nanostructures supported on metals.

Thus the earlier established mechanism of this reaction carried out on the (111) face of palladium [83] was used to explain the peculiarities of CO oxidation on palladium clusters supported on α-Al_2O_3.[79, 80] The threefold increase in the rate of CO_2 formation at temperatures > 500 K upon a decrease in the sizes of palladium clusters from 4.9 to 1.5 nm was attributed to the increased coefficient of CO adhesion to edge and corner palladium atoms the number of which increases with a decrease in the particle size.[79] This explanation was corroborated by experiments [87] in which the reactivities of palladium clusters with respect to CO were studied by temperature-programmed desorption (TPD). It was shown that the TPD spectra of CO molecules adsorbed on palladium with the particle size of 27 nm and on the (111) face of palladium single crystals coincide, whereas the corresponding spectra of desorption of CO with a particle size of 2.5 nm display an additional peak at lower temperatures. Similar TPD spectra were recorded by following the CO desorption from palladium with a particle size of < 5 nm supported on mica. This suggests that the formation of weakly bound forms of carbon monoxide is characteristic of small palladium particles and does not depend on the nature of the substrate.[88] Presumably, it is the appearance of a weakly bound adsorbed form of CO that is responsible for the increased rate of CO_2 formation with a decrease in the sizes of palladium nanoparticles.[79, 80]

Quite opposite regularities were observed by following the temperature-programmed desorption of CO molecules from platinum particles supported on Al_2O_3 (Ref. 89) and mica (Ref. 90), *viz.*, the intensity of the low-temperature peak of the CO desorption decreased with a decrease in the size of the platinum particles (> 4 nm). It was thus concluded that CO molecules are more strongly adsorbed on small particles, which can account for the decrease in the rate of CO oxidation on small (< 2.5 nm) platinum particles.[81]

Comparison of CO adsorption on supported platinum and rhodium particles revealed that the ratio of low- and high-temperature components in the TPD spectra of rhodium particles (in contrast to the corresponding parameters in the TPD spectra of platinum particles), only weakly depends on the size of the metal particles.[91] Presumably, this peculiarity of CO adsorption on rhodium is the reason for the structure-insensitivity of the CO oxidation on Rh-containing catalysts.[82]

These data suggest that a correlation exists between catalytic activity in the CO oxidation on various platinum metals and the strength of the CO–metal bond despite significant differences in the manifestations of the size effect. The fact that the structure-insensitivity of the CO oxidation on rhodium, its negative sensitivity on palladium and its positive sensitivity on platinum could be explained on the basis of 'single crystal data' gave impetus to the studies of the behaviour of nanoparticles in other catalytic systems.[82, 92, 93] For example, the results of TPD studies of NO molecules [92] provided an explanation for the 45-fold decrease in the rate of the CO + NO reaction with a decrease in the size of rhodium particles on Rh/α-Al_2O_3 from ~ 70 to 1 nm (see Ref. 82). According to these data, the major part of the nitrogen

is desorbed from large particles at 463 K and only a small part is desorbed at 553 K. The amount of nitrogen adsorbed at high temperatures increases with decrease in the particle size. Stronger adsorption of nitrogen on the surface of small rhodium particles can be responsible for the structure-sensitivity of the CO + NO reaction on rhodium.[82] It is of note that the nature of the support (α-Al_2O_3, θ-Al_2O_3, SiO_2) has practically no effect on the activity of rhodium particles in this reaction.

Yet another example is the $CH_4 + O_2$ reaction and O_2 adsorption on Pt/Al_2O_3 catalysts with average sizes of platinum particles of < 2 and 20 nm.[94] It was found that the catalysts with larger particle sizes are ninefold more active in the methane oxidation, these are characterised by lower heats of oxygen adsorption (250 kJ mol^{-1} instead of 280 kJ mol^{-1} for smaller particles) and the oxygen adsorbed on them is more reactive with respect to hydrogen. The latter assumption is based on the fact that the oxygen adsorbed on a platinum catalyst with a particle size of 20 nm is totally desorbed by hydrogen at 195 K, whereas in the case of smaller platinum particles it does not react with hydrogen at temperatures up to 276 K. These findings point to a weakening of the bond between the platinum surface and the adsorbed oxygen with an increase in the particle size and a concomitant increase in the reaction rate.[94]

Studies aimed at establishing a relationship between the changes in the reactivities of nanoparticles and their electronic and structural properties are of fundamental importance.

The discovery of a dependence of the heat of desorption of CO on the crystallographic orientation of platinum faces[95–97] aroused debates concerning the effect of the structural factor on the heat of CO adsorption with changes in the particle size.[94] It is known that the spectra of the temperature-programmed desorption of carbon monoxide from the closely packed (111) face of platinum have the main peak at 400 K,[95] whereas its desorption from the more open (110) face of platinum or from platinum foil is accompanied by the appearance of an additional peak at 510 K, the relative intensity of the high-temperature peak being increased with an increase in the densities of the monoatomic steps.[96,97]

Comparison of spectra of temperature-programmed desorption of CO molecules from platinum single crystals and Pt/Al_2O_3 particles revealed that the weakening of the CO–Pt bond on large particles is due to predominant localisation on their surface of terraces the structure of which is identical with that of the (111) face, whereas small particles contain a large number of coordinatively unsaturated sites, which favours strengthening of this bond.[89] The presence of such low-coordinated sites was related to possible dissociation of the CO molecules on small platinum particles.[87] Their structure was simulated as a (100) step separating the (111) terraces. It was suggested that the repulsion of carbon atoms adsorbed on such sites from the CO molecules adsorbed on the (111) face of platinum weakens the CO–metal bond.[89]

The expediency of the structural approach is also confirmed by the fact that the shape of TPD spectra of the CO molecules did not depend on the orientation of the faces of Rh single crystals,[98,99] which is in complete agreement with the structure-insensitivity of the $CO + O_2$ reaction on rhodium-containing catalysts. The decrease in the heat of adsorption of oxygen and the corresponding increase in its reactivity with an increase in the size of platinum nanoparticles supported on alumina was attributed to the increased number of smooth areas on the catalyst's surface.

The electronic approach to rationalise unusual reactivities of metallic clusters was largely developed in studies with the use of methods suitable for the analysis of the nature of adsorbed particles together with the electronic properties of metal atoms.[10,100–103] Studies of CO adsorption on palladium, copper and nickel clusters supported on graphite revealed that a 'metal–dielectric' transition and strengthening of the CO–M bond with a decrease in the cluster size are observed within the same range of particle sizes.[103] It was found that in small particles the decrease in the intensity of the C 1*s* signal which is associated with the adsorbed CO (E_b = 285.9 eV) occurs at higher temperatures. Moreover, the strengthening of the CO–M bond on nickel particles results in the dissociation of CO as can be evidenced from the appearance, in the TPD spectrum, of a C 1*s* signal with E_b = 284.2 eV characteristic of elemental carbon, after heating of the sample to 300 K. It was assumed that the observed increase in the reactivities of small nickel particles with respect to the CO oxidation is accounted for by closeness of the 3*d*-levels of Ni and the $2\pi^*$-orbital of CO.

If the sizes of palladium and nickel nanoparticles are less than 3 nm, their metallic properties are weakened, which correlates with an increase in their reactivities towards oxygen[101] and hydrogen sulfide,[102] respectively. The conclusion about the strengthening of the O–Pd bond was based on data from microcalorimetry according to which the heat of adsorption of O_2 remains unchanged ($Q \approx 210$ kJ mol^{-1}) for particle sizes ranging from 1000 to 3 nm, but increases drastically (up to 335 kJ mol^{-1}) for smaller particles.[101] The nature of the support does not influence the heat of adsorption of O_2 on palladium particles sprayed over SiO_2, η-Al_2O_3 and SiO_2–Al_2O_3. The conclusion about enhanced dissociation of H_2S on smaller nickel clusters is based on the increase in the relative intensity of the S 2*p* line (E_b = 162.0 eV) characteristic of S^{2-} ions in comparison with the line (E_b = 164.5 eV) related to hydrogen sulfide adsorbed as a molecule with a decrease in the particle size.[102]

One should not rule out the possibility that the proportion of rough surfaces in particles with sizes varying from 3 to 5 nm is greater, since they contain a large number of low-coordinated atoms on the steps, in the edges, *etc*. Apparently, the electronic and structural factors are closely interrelated and their effects on the reactivities of metallic clusters cannot be differentiated. The correctness of this statement can be illustrated by the results of experiments carried out by Zilm *et al*.[10] Comparison of ^{13}C NMR spectra of adsorbed CO molecules recorded with and without magic angle spinning allowed the authors to suggest that the significant decrease in the diffusion rates of carbon monoxide on the surface of small palladium particles is due to stronger binding of CO to these particles. It was concluded that strongly bound CO with a lowered ability for diffusion is linearly adsorbed on edge and corner palladium atoms the proportion of which increases with a decrease in the particle size. Moreover, comparison of the Knight shift for the linear and bridge-like forms of CO demonstrated that these low-coordinated sites are characterised by electron deficiency resulting from changes in their Fermi levels relative to those of the bulk metal.

It is worth noting that the differences in the properties of the conductivity electrons of supported nickel[30] and silver[31,32] particles, on the one hand, and those of the corresponding bulk metals, on the other hand, also correlate with changes in the surface structures of the particles, which become more defective after their treatment with the reaction medium. In the case of Ni–C catalysts for butadiene hydrogenation, this conclusion was based on TEM data, whereas for silver particles active in ethylene epoxidation it was based on the disappearance, from the XPS spectra, of the O 1*s* line characteristic of the adsorbed oxygen.

The variations in the routes of NO decomposition and the CO + NO reaction with a decrease in the size of palladium particles supported on silica was explained by the effect of low-coordinated sites, with lower electron density on the NO adsorption.[103] The strengthening of the NO–Pd bond in such low-coordinated sites the existence of which was confirmed by comparison of infrared absorption spectra of CO molecules adsorbed on palladium particles and on (111) and (110) faces of palladium single crystals,[104,105] favours the dissociation of NO into nitrogen and oxygen atoms. In the absence of NO adsorbed as molecules on the surface of small palladium particles, N_2O cannot be formed as was demonstrated using the temperature-programmed reaction (TPR).

As mentioned above, the number of papers which attribute the changes in selectivity caused by a decrease in the size of metallic

nanoparticles to changes in the chemical nature of their surface adsorption in comparison with adsorption on bulk metals will unquestionably be increasing. The above-cited NMR studies of CO adsorption on palladium supported on SiO_2 represent a first step in this direction.[10] It was shown that two types of CO molecules on the surfaces of small palladium particles differ in the degree of mixing of their electronic levels with the electronic zones of the metal.

The correlation between the nature of the adsorbed molecules and the catalytic properties (in the first place, selectivities) of supported nickel and silver particles has been demonstrated.[30, 31, 106] The TPD spectra of hydrogen following its adsorption for 2 min on two catalysts of selective hydrogenation of butadiene differing in their Ni : C ratios are depicted in Fig. 3. The selectivity of butadiene hydrogenation to butene on a catalyst with a low carbon content (Ni : C ratio of 0.4) was 45%, whereas that on a catalyst with a higher carbon content (Ni : C ratio of 0.1) reached 95%.[30] As can be seen from Fig. 3, the more selective catalyst gives one TPD peak at 320 K, whereas the TPD spectrum of the less selective specimen contains a weakly expressed additional peak corresponding to more strongly bound hydrogen (at 360 K). These peaks were assigned based on the TPD data and work function measurements of hydrogen adsorption on specimens of bulk nickel (single crystals and foil) obtained in earlier studies.[107, 108] In experiments where hydrogen exposure varied, it was established that hydrogen in a high-temperature form is initially adsorbed on the nickel surface and the work function increases markedly. The TPD peak at 360 K was ascribed to the negatively charged hydrogen ions, H^-. The intensity of the high-temperature peak becomes constant with an increase in the hydrogen exposure, whereas the 320 K peak continues to increase gradually. The work function did not change in the studied range of coverage of the nickel surface with hydrogen, which points to the absence of a charge on the low-temperature form of hydrogen.[107] High reactivity of hydride ions is a possible reason for non-selective hydrogenation of butadiene on specimens with high Ni : C ratios (~ 0.4). The lack of this form in specimens with the Ni : C ratio of ≈ 0.1 (see Fig. 3) is the reason for increased selectivity. Unfortunately, these conclusions cannot be corroborated by XPS, since hydrogen does not generate a photoelectron spectrum.

This approach is quite useful in studies of different forms of oxygen adsorption on silver. The screening of O 1*s* signals from the adsorbed oxygen by the oxygen of the substrate (α-Al_2O_3) used in industrial catalysts of ethylene epoxidation was eliminated by replacing the latter with a model substrate (graphite).[106] The oxygen adsorbed on the surface of silver particles with the sizes of 10 nm produces one peak with $E_b = 530.5$ eV, while larger particles produce an additional peak with $E_b = 528.5$ eV. Comparison of these values with the E_b values for oxygen adsorbed on bulk silver specimens prompted a conclusion about the formation

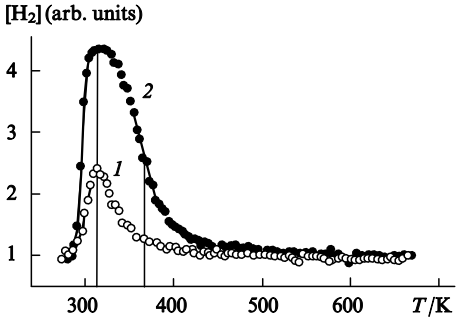

Figure 3. The TPD spectra of hydrogen after its 2-min adsorption at $P = 10$ Pa and $T = 270$ K on Ni–C catalysts with the Ni : C ratio of 0.1 (*1*) and 0.4 (*2*).

of two forms of oxygen adsorbed as atoms, *viz*., the peak with a lower binding energy is related to nucleophilic oxygen (O^{2-}), while the second peak is related to the electrophilic form ($O^{\delta-}$). It was shown [109, 110] that the formation of ethylene oxide requires the co-existence of these two forms of the adsorbed oxygen on the silver surface: the electrophilic oxygen participates in the formation of ethylene oxide directly by reacting with ethylene, while the nucleophilic oxygen serves as a source of surface Ag^+ ions (surface silver oxide), which are the sites of adsorption of ethylene molecules. The key step of the ethylene epoxidation can be presented as follows:

$$O^{\delta-}_{ads} + C_2H_{4\,ads}(Ag^+) \longrightarrow C_2H_4O.$$

With account taken of the sharp drop in the concentration of nucleophilic oxygen with a decrease in the size of the silver particles in the range of 50–20 nm, the mechanism proposed provides an explanation for the sharp decrease in the rate of epoxidation on silver catalysts with a particle size of less than 50 nm.[76] The reaction rate decreases as a result of less effective adsorption of ethylene on small particles which contain no Ag^+ sites. Since the nucleophilic oxygen is active exclusively in complete oxidation of ethylene, its disappearance due to a decrease in the size of the catalyst's nanoparticles will increase the selectivity of ethylene oxide formation. This suggestion has been confirmed experimentally by Verykios *et al.*[111] who have observed a continuous increase in the selectivity with a decrease in the size of silver particles from 50 to 20 nm. These data and the results of other investigations [109, 110] suggest that this size range is an optimum for particles of highly reactive and highly selective silver catalysts for ethylene epoxidation.

Studies of the dependence of selectivities of chemical reactions on the average sizes of coated nanoparticles of the active components revealed both positive and negative effects and, in some cases, their independence of the particle size (see, *e.g.*, Refs 112–114). We shall consider only the results of several experiments which are promising for use in practical catalysis.

The dependence of selectivities of the synthesis of higher hydrocarbons from CO and H_2 on Co–MgO and Co–ZnO catalysts on the sizes of coated cobalt particles was established.[115] The smaller the average sizes of cobalt nanoparticles, the higher the selectivity expressed by the Anderson–Schulz–Flory distribution coefficient (α). It was suggested that the amount of dissolved hydrogen responsible for complete hydrogenation of hydrocarbon intermediates decreases with a decrease in the particle size, eventually resulting in the formation of heavier hydrocarbons. The selectivity of hydrodesulfurisation of thiophene increased with a decrease in the sizes of ruthenium nanoparticles supported on alumina.[116] Comparison of Co/Al_2O_3 catalysts accelerating steam conversion of ethanol and prepared from different Co-containing precursors revealed that the selectivity of this reaction decreases in the following order: Co (carbonyl) > Co (chloride) > Co (acetate) > Co (nitrate).[117] Since the sizes of metal particles increase in the reverse order, the observed decrease in selectivity was attributed to the enlargement of cobalt nanoparticles. And, finally, it was found [118] that the selectivity of n-pentane hydrogenolysis on Pt/Y-zeolite catalysts increases linearly with decrease in the size of the metallic nanoparticles.

Even these few examples illustrate the remarkable effects of the average sizes of active metal nanoparticles on the relative rates of individual steps of multiroute catalytic reactions which influences the selectivities of formation of the reaction products. The catalytic activities manifested by nanosystems in reactions in which bulk specimens or even supported large crystallites are virtually inactive corroborate this statement. Gold nanoparticles which, in contrast with the bulk metal, manifest catalytic activity in certain reactions including those promising for industrial use, provide an illustrative example. In the 1980's, Japanese investigators succeeded in demonstrating that Au nanoparticles supported on Fe_2O_3 or Co_3O_4 represent active catalysts for low-temperature oxidation of CO.[119] This finding has stimulated the

appearance of numerous publications devoted to the analysis of the catalytic properties of these systems. The dependence of their catalytic properties on the nature of the substrate, size of gold particles and further treatment of freshly prepared specimens was studied.[120–125] It was shown that the size of gold nanoparticles is the key factor which determines the activity of a catalyst in CO oxidation; this activity changes 2–3-fold with different substrates (TiO_2, Al_2O_3, SiO_2), whereas the reaction rate increased by one and even two orders of magnitude with a decrease in the gold particle sizes below 4 nm.[120–122] The maximum catalytic activity was observed in particles with a size of 3.2 nm.[123] It is of note that gold-containing catalysts manifest high activity even at low temperatures (250–270 K), whereas such a catalytically active metal as platinum is inactive at these temperatures due to the blocking of its surface by adsorbed CO molecules.[126]

The range of reactions catalysed by gold nanoparticles appeared to be rather broad. It was demonstrated that impregnated Au/SiO_2 and Au/Al_2O_3 catalysts manifest high selectivities in the hydrogenation of buta-1,3-diene to butene.[127] The selectivity of hydrogenation of diene mixtures into alkenes on Au/ZrO_2 catalysts reached 100%.[128] Studies into hydrogenation of CO_2 on Cu-, Ag- and Au-containing catalysts supported on ZrO_2 revealed that these metals are catalytically active in methanol synthesis.[129] Gold nanoparticles used as catalysts for low-temperature reduction of NO with propene have certain advantages.[130] Unlike Rh-,[131] Pt-[132] and Pd-containing[133] catalysts with which N_2 is formed instead of N_2O at temperatures above 570 K, the formation of nitrogen on Au/Al_2O_3 proceeds efficiently even at 370 K.

The use of gold nanoparticles as catalysts of propene epoxidation provides a more interesting example. The gas-phase oxidation of propene by an oxygen–hydrogen mixture on Au/TiO_2 catalysts ensures nearly 100% selectivity of propene oxide formation at a 1% conversion of C_3H_6.[134] A detailed study of various factors revealed that the selectivity of this reaction depends critically both on the nature of the substrate and the size of gold nanoparticles. If the particle size is less than 2 nm, the reaction performed on gold catalysts changes its route in such a way that propane is formed with nearly 100% selectivity.[135] This finding is in good agreement with the high activity of the low-percentage Au/SiO_2 catalyst in the hydrogenation of alkenes.[136] It may thus be concluded that gold nanoparticles with sizes ranging from 2 to 4 nm catalyse propene epoxidation, whereas smaller particles catalyse its hydrogenation. It was found that the selectivity of formation of some industrially important products increases considerably with a decrease in the particle size.[137,138] For example, Pt_n clusters within the structure of the zeolite LTL provided a nearly 100% selectivity of dehydrogenation of n-hexane to benzene.[137]

A vast variety of physical instrumental methods, such as molecular beam technique, low energy electron diffraction, electronic Auger spectroscopy, photoelectron X-ray spectroscopy, vacuum tunnelling microscopy, nuclear magnetic resonance, electron spin resonance, Raman spectroscopy, calorimetry, TPR, TPD, infrared spectroscopy, EXAFS, Mössbauer spectroscopy, *etc*., came into use in the last decades of the XXth century for studying surfaces of heterogeneous catalysts at the molecular level. However, despite the high precision achieved in the techniques for measuring and the control of the state of the catalytic surfaces, the 'cognitive' potential of the experimental results is rather limited because these measurements are usually indirect and the information derived from them demands quantitative processing and interpretation. This can be done only with the use of mathematical models. It is clear that successful interpretation of the results obtained requires that the mathematical models and the methods employed for their analysis provide an accurate description of the whole body of experimental results.[139–146]

The lattice gas model is an example. The main difference between ordinary and lattice gases is that in the former case a particle can have any coordinates, whereas molecules of lattice gases occupy definite positions in space, *viz*., those in the knots of a certain regular lattice where elementary processes can occur. These processes are described either by computational methods conventionally used in statistical physics (*e.g*., the Monte-Carlo and cellular automaton methods) or by using cluster approximations, which allow simple estimation of thermodynamic parameters of a system and the rates of elementary surface acts based on the classical transition state theory developed by M I Temkin for heterogeneous catalysis.

Sequential implementation of a series of elementary steps results in changes in the state of the lattice cells and the evolution of the system. The Monte-Carlo method considers evolution as a random Markovian chain of elementary events occurring in the lattice cells. The cellular automaton approach also represents an effective tool for simulating the dynamics of elaborate spatially distributed systems based on the analysis of their local behaviour. To obvious disadvantages of stochastic methods, one can relate the large body of calculations, whereas their main advantage is the possibility of precise control over the position of a particle on the surface of a catalyst. The deterministic approach entails the solution of systems of nonlinear differential equations derived from the main kinetic equation using certain approximations.

The energy of lateral interactions of the adsorbed species involved in reactions and their mobilities are the main parameters which characterise their surface layer. The latter represents an open, non-ideal, non-linear system which exchanges mass and energy with the environment. The use of the non-linear dynamics method made it possible to gain considerable experience in mathematical simulation of catalytic systems starting at the molecular level.[143–146] Non-linear events, such as self-organisation, the appearance of chemical turbulence, *etc*., have also been studied. However, the attempts to simulate the effects of the particle size on such events have not been undertaken yet.

IV. The prospects for the application of nanostructures in catalytic processes

1. Ligand-stabilised transition metal clusters

The catalytic properties of supported particles can differ essentially from those of bulk metals; therefore, new routes of catalytic processes should not be ruled out. It can thus be assumed that the advantages of nanostructures prepared by conventional methods as highly selective catalysts cannot always be realised due to the broad size distribution of particles and their sintering in the course of the catalyst's operation. In supported metallic catalysts obtained by industrial synthesis, which includes impregnation of substrate granules with solutions of active metal compounds followed by calcination and/or reduction, strong interactions between metallic nanoparticles and the substrate surface are usually absent, which results in the statistical distribution of particles according to their sizes and also facilitates their sintering.

There are several ways to solve this problem, namely, modification of the support aimed at generating a sufficient number of centres for nucleation of metallic particles,[147] the choice of materials (a substrate and an active component) providing the epitaxial growth of nanoparticles owing to the structural matching of parameters of crystal lattices,[148] the use of novel substrates with an original geometry of the pore volume,[149] *etc*. The size homogeneity of nanostructures can be achieved through the use of ligand-stabilised metallic clusters.[150,151] Isolated transition metal nanoclusters which are the most commonly used as active components of supported metal catalysts, are prepared by the following techniques: (1) reduction of transition metal salts; (2) reduction and removal of ligands from organometallic compounds; (3) electrochemical synthesis.[151] Studies into the kinetics of growth of nanoclusters revealed that clusters containing the so-called magic number of atoms are characterised by regular geometry of the outer surface and manifest enhanced stabilities. The other name of these clusters, *viz*., 'full-shell clusters', reflects the presence of fully packed layers surrounding the central metal atom. The number of

the metal atoms (N) in the nth-layer is determined by the equation:[151]

$$N = 10n^2 + 2 \ (n > 0). \quad (3)$$

Thus, full-shell clusters contain 13 (1 + 12); 55 (13 + 42); 147 (55 + 92); 309 (147 + 162), *etc*., atoms (see Section II.I). The enhanced stabilities of these clusters stem from their closely packed structures which ensure the formation of the maximum number of metal–metal bonds and, as a consequence, the minimum surface energy.

An excellent survey of growth mechanisms of nanoclusters has been given in reviews.[152–154] It was shown that the formation of iridium nanoclusters stabilised by the $P_2W_{15}Nb_3O_{62}^{9-}$ polyoxoanion follows an autocatalytic surface growth mechanism, which provides an explanation for the formation of isolated full-shell clusters in a kinetically controlled regime of synthesis. Experimental evidence for these conclusions can be derived from the formation of nearly monodisperse rhodium nanoclusters ($d = 4\pm0.6$ nm) in the reduction of polyoxoanionic Rh(I) complexes with hydrogen in acetone.[154]

The nature of nanoclusters stabilised by ligands entails the possibility of their additional stabilisation by electrostatic and steric interactions. Electrostatic or inorganic stabilisation is achieved by adsorption of ions on the electrophilic surface of a metal.[155] Such adsorption results in the appearance, on the surface of nanoclusters, of a double electrical layer which provides Coulombic repulsion of like-charged individual species. Steric or organic stabilisation is provided by the surrounding of the metal centre of the nanocluster with a layer of bulky structures,[155] such as polymeric units[156] or surfactants.[157] The geometric sizes of these adsorbates favour the formation of a steric barrier which prevents the contacts between the metal centres of nanoclusters. It is evident that some of the stabilising agents, *e.g*., polyoxoanions, combine electrostatic and steric functions.[151, 158] Stabilisation of nanoclusters with ligands presents substantial interest as regards the synthesis of supported catalysts characterised by enhanced stabilities and homogeneous size distribution of metal particles. In addition, this makes the use of metallic nanoclusters promising for homogeneous catalysis, as will be shown below.

The catalytic properties of metallic nanoclusters have been studied by several groups of investigators (for a review see Ref. 151). In 1981, Schmid *et al*.[159] succeeded in synthesising a cluster with the composition $Au_{55}(PPh_3)_{12}Cl_6$ by passing B_2H_6 through a solution of PPh_3AuCl in benzene. Later, $Rh_{55}(PPh_3)_{12}Cl_6$, $Ru_{55}(PBu^t_3)_{12}Cl_{20}$, $Pt_{55}(AsBu^t_3)_{12}Cl_{20}$ clusters were synthesised using diborane as the reductant.[160, 161] Substitution of hydrogen for diborane made possible the synthesis of $Pt_{\sim309}phen_{\sim36}O_{\sim30\pm10}$ and $Pt_{\sim561}phen_{\sim36}O_{\sim190-200}$ clusters.[162, 163] As can be seen, all these clusters are 'magic' ones, which provides additional evidence in favour of enhanced stabilities of the full-shell nanostructures cited above. First attempts at using Ru clusters as catalysts in homogeneous hydrogenation reactions were unsuccessful because of their rapid decomposition.[163] Therefore, further efforts of this research group were directed to the use of nanoclusters for the synthesis of supported heterogeneous catalysts. It was shown that palladium clusters with sizes of 3–4 nm stabilised by ligands manifest high activities and selectivities in the hydrogenation of hex-2-yne into *cis*-hex-2-ene. It was shown that the activity of a catalytic system depends on the nature of the stabilising ligands, while the selectivity is always equal to 100%. Rhodium and palladium nanoclusters supported on TiO_2 and Al_2O_3 appeared to be highly efficient catalysts of hydroformylation[164] and hydrogenation[165] reactions.

Unlike the authors of the above-cited papers, in the early 1980's Vargaftik, Moiseev *et al*.[166] carried out a successful synthesis of ligand-stabilised clusters which are active and stable in homogeneous catalysis. The $Pd_{\sim561}phen_{\sim60}(OAc)_{\sim180}$ and $Pd_{\sim561}phen_{\sim60}O_{\sim60}(PF_6)_{\sim60}$ clusters catalysed oxidative acetoxylation of a series of light organic compounds, *e.g*., of ethylene into vinyl acetate, of propene into allyl acetate and of toluene into benzyl acetate, with 95%–98% selectivity. Moreover, these catalysts effected the oxidation of primary alcohols into ethers and aldehydes and of secondary alcohols into ketones.[166] Yet another example of a successful application of metallic nanoclusters in homogeneous catalysis is the use of rhodium clusters stabilised by polyoxoanions, which manifested high selectivities in the hydrogenation of cyclohexene.[154] This was ascribed to the double stabilisation (both electrostatic and steric) of the clusters by polyoxoanions.[167]

Notwithstanding, the majority of successful applications of metallic nanoclusters as catalysts is connected with the use of systems fixed or immobilised on the surface of porous and non-porous supports, *e.g*., SiO_2, Al_2O_3 or TiO_2. It was shown, in particular, that 5% colloidal rhodium supported on activated charcoal with a narrow size distribution of clusters (1.2–2.2 nm) was nearly 3 times more active in the hydrogenation of butyronitrile than the corresponding industrial catalyst which also contains 5% Rh on activated charcoal with a greater scatter of particle sizes (1–5 nm).[168] In catalysts stabilised by ligands, the size of rhodium particles varies from 1.2 to 2.0 nm, whereas standard catalysts contain predominantly large crystallites, while the fraction of small particles (1–5 nm) is small. A representative list of reactions which are efficiently catalysed by clusters stabilised by ligands is given in a review.[151] This list includes various reactions of enantioselective hydrogenation,[169] hydrosilylation,[170] hydropyrolysis and hydrogenolysis,[171] CO and CO + H_2 oxidation,[172] cycloaddition reactions,[173] *etc*.

This can be supplemented with examples of enhanced stabilities of catalysts based on clusters stabilised by ligands under conditions of a catalytic reaction. Thus the 'lifetime' of a catalyst containing palladium nanoclusters in the reaction of cyclooctene hydrogenation was 96 000 turnovers, whereas that of an industrial catalyst (*e.g*., palladium on activated charcoal) was 38 000 turnovers.[168] The $Ir_{\sim300}$ nanoclusters did not change their activities after 3200 ± 1000 hydrogenation turnovers, which is comparable with the corresponding value (3950 ± 1000 turnovers) for the industrial catalyst (7.9% Ir/γ-Al_2O_3) and markedly exceeds the 'lifetime' of Ir/η-Al_2O_3 ('Exxon', USA) equal to 1740 ± 250 turnovers.

Ligand-stabilised metallic clusters are extremely interesting subjects for the development of fundamental concepts of catalysis by nanostructures, since it allows one to control precisely the size distribution of nanoparticles, to establish relationships between their sizes and catalytic properties and even to govern the activities and selectivities of catalysts based on them. However, the high cost of such catalysts in comparison with ordinary specimens is an obstacle to their wide industrial application. Only electrochemical synthesis makes it possible to prepare relatively large (*e.g*., hundreds of milligrams) amounts of catalysts based on metal clusters stabilised by ligands. Therefore, industrial applications of such nanoclusters in large-scale catalytic processes is hardly probable. However, their use in fine organic syntheses where high selectivity of formation of the target product is the main requirement imposed on a catalyst can be of considerable practical interest. It is anticipated that the attainment of 100% selectivity will become one of the main challenges to catalytic science in the next few decades.[174] This can be exemplified by successful recent applications of clusters stabilised by ligands in various hydrogenation reactions including enantioselective hydrogenation.[175, 176]

2. Bimetallic clusters: molecular design of active centres

Studies into bimetallic systems have the same long history as studies of individual metals. This is primarily due to the search for the ways of increasing the activities, selectivities and stabilities of monometallic catalysts. The first patents which suggested the use of Pd–Au catalysts for hydrocarbon conversions instead of palladium ones appeared in the 1960's.[177] In the past years, the number of investigations (including those having industrial applications) which demonstrate the advantages of bimetallic catalysts

over monometallic ones has increased manifold.[178–184] Most of these studies dealt with the dependences of catalytic activities related to the surface metal atoms and their selectivities on the ratios of metals. For example, the maximum activity of Pt–Re/SiO_2 catalysts containing 75% rhenium exceeds those of individual platinum and rhenium supported on SiO_2 by more than two orders of magnitude.[180] Rubidium, palladium or platinum additives increased the activities of nickel-containing zeolites in butyronitrile hydrogenation in both gas and liquid phases.[181] The steady-state activity of Pd–Re/Al_2O_3 catalysts in the hydrogenolysis of 2,2-dimethylpropane passes through an obvious maximum at a rhenium content of 50 at.%.[182] Examples of enhanced selectivity in the formation of various products through multiroute catalytic reactions are even more impressive. The above-cited patent[177] claims that the selectivity of n-heptane isomerisation increases from 66.9% to 81.3% with a change in the Pd : Au ratio of Pd–Au/Al_2O_3 catalysts from 6 : 1 to 1 : 2 (mass %). The selectivity of monometallic palladium and gold catalysts is equal to 50% and ~ 25%, respectively. The selectivity of 1% Ru/SiO_2, which is a catalyst of cyclohexane dehydrogenation to benzene, increases, following introduction of inactive copper and silver (1 mass %), from 76% to 94% and 87.9%, respectively.[183] The enhanced selectivity of nitrogen formation and decreased yields of ammonia were observed in the reduction of NO with hydrogen with an increase in the rhenium content in bimetallic Pt–Re/SiO_2 catalysts.[184] Modification of platinum nanoparticles on silica with tungsten made it possible to reach 99.2% selectivity of methanol formation in the reaction of CO_2 with hydrogen, the conversion being 2.6%.[185] It is of note that platinum alone catalyses the formation of CO with nearly 100% selectivity, whereas tungsten is inactive in this reaction. It was shown[181] that all M–Cu/NaY catalysts (M = Ru, Rh, Pd, Pt) manifest high selectivities in the formation of tertiary amines from acetonitrile.

The unusual properties of bimetallic catalysts gave impetus to the studies of their surface using model systems and sensitive physical methods. The experimental results have been generalised in the reviews.[186, 187] It was found that the introduction of a second metal influences the catalytic properties of the first metal through the following mechanisms:

(1) by changing the electronic properties of the first metal atoms (as has been shown previously, the electronic properties of metals influence the nature and reactivities of adsorbed particles);

(2) by changing the number of identical atoms within the structure of the adsorption centre (as is known, adsorption of molecules from the gas phase often requires a combination of specifically arranged atoms rather than a single 'landing' site).

In the first case, we deal with an electronic (ligand-associated) effect, whereas in the second case the multiplet ensemble effect is manifested.[178, 186, 187] With regard to real catalysts, this is, most probably, artificial, therefore, the existence of such effects has been demonstrated using only model systems.

Direct evidence for the electronic effect was obtained in experiments with adsorption of simple gases on the surface of a metal single crystal covered with a monolayer of atoms of another metal. Concrete systems for such experiments were selected on the basis of structural matching of this monolayer and the plane of a metal substrate.[188–191] For example, a palladium monolayer was deposited onto the (110) face of tungsten the hexagonal structure of which ensured a practically complete coincidence of Pd–Pd distances in the monolayer (0.2740 nm) and onto the (111) face of the bulk Pd single crystal (0.2751 nm).[188] The activation energy of desorption of CO molecules from the surface of Pd/W(110) appeared to be by 85 kJ mol^{-1} smaller than that from the surface of the Pd(111) single crystal. In addition, the preexponential factor in the equation of CO desorption rate increased by five orders of magnitude. Combined use of both factors caused a decrease in the desorption temperature from 510 K on Pd(111) to 330 K on the monolayer of Pd/W(110) in the case of a low degree of coverage by CO. A similar effect was observed when palladium was deposited onto the surface of the Re(0001) hexagonal face.[189] An analysis of UV photoelectron spectra of the palladium monolayer on the (110) faces of tantalum[190] or niobium[191] revealed that the densities of filled electronic states of palladium near the Fermi levels in these systems are significantly decreased in comparison with that on Pd(111). As a result, the electronic structure of the surface layer of palladium becomes similar to that of the Group IA metals characterised by weak chemosorption bonds with CO. This can be explained by the formation of covalent bonds between palladium and niobium due to rehybridisation of *d*- and *sp*-orbitals, although a small charge transfer can also take place. Alloys with high negative enthalpies of formation are related to the systems in which the electronic effect plays a crucial role.[187]

Depending on the strength of the interaction between the main and incorporated metals, the ensemble effects are conventionally divided into simple and mixed ones.[186, 187] Simple effects are largely manifested in systems where a reactive metal is mixed with an inert one. For example, the multibound state of CO on platinum and nickel is not realised following their fusion with copper.[192, 193] The triply bound form of NO which predominates on the (111) face of platinum is not detected on the surface of the (3×3)-$SnPt_2$/Pt(111) alloy where triatomic platinum multiplets are completely absent.[194] Decisive evidence for the existence of a mixed ensemble effect was obtained in the study of a copper monolayer deposited onto the (111) face of nickel single crystals.[195, 196] Despite the higher strength of binding of the bridge-like form of CO to the nickel surface in comparison with the linear form, the latter was exclusively formed at low coverage of carbon monoxide. This was inferred from the results of high-resolution electron energy loss spectroscopy (HREELS) which point to the absence of Ni—Ni couples on the surface of this bimetallic system. However, a bridge-like form was also detected at higher degrees of CO coating, which is due to the presence of Ni—Cu couples.[196]

The mutual effects of individual components are characteristic of many bimetallic systems. Therefore, several attempts have been undertaken to use these regularities for the directed synthesis of bimetallic catalysts with predetermined properties. Thus Besenbacher *et al.*[197] proposed to introduce atoms of gold into a nickel-containing catalyst of the steam conversion of methane in order to reduce the rate of its coking. The choice of gold was based on the results of fundamental investigations of single crystals and porous specimens of the catalyst using physical methods and quantum-chemical calculations of activation energies of the abstraction of the first hydrogen atom from the methane molecule and carbon atom adsorption on pure and modified nickel surfaces. The conditions for gold introduction were also established. This resulted in the synthesis of an Au—Ni bimetallic catalyst, which, in contrast to the nickel catalyst, preserved its activity in n-butane conversion due to the absence of graphite deposits on its surface.

The most remarkable achievements in the design of bimetallic catalysts can be expected from the use of nanoclusters which allows molecular design of active centres. There exist several synthetic routes which ensure control over the composition and properties of the nanostructures formed,[198] *viz.*, combined or sequential reduction of metal salts, electrochemical synthesis and reduction of double complexes. Studies of synthetic nanoclusters by physical methods aimed at elucidating their structures acquires special importance, since in addition to the crystal structure of the bulk alloy, bimetallic nanoclusters contain unusual structures which have no analogues among bulk materials. These include two types of structures, *viz.*, 'core–shell' and 'cluster-in-cluster' types.

Core–shell structures were detected in Pd—Pt clusters stabilised by poly(*N*-vinyl-2-pyrrolidone) (PVP) with a Pd : Pt ratio of 4 : 1; they were prepared by the reduction of a H_2PtCl_6—$PdCl_2$ mixture.[199–201] Elucidation of exact structures of these nanoclusters required the use of a combination of methods, *e.g.*, X-ray phase analysis, TEM, XPS, UV-visible absorption spectroscopy (UV-Vis) and EXAFS. Analysis of the UV-Vis spectra and X-ray diffractograms confirmed the formation of bimetallic nanoclus-

ters. Using the TEM approach, it was shown that the Pd–Pt clusters formed are homogenous according to their sizes (the mean size was 1.5 nm) and belong to 'magic' clusters with $N = 55$.[169] A conclusion about the saturation of the nanocluster surface with palladium was inferred from the quantitative XPS data.[202] And, finally, the coordination numbers for palladium and platinum were determined using EXAFS. Comparison of experimental results with the values calculated for two models, *viz*., a model with inner platinum nuclei and a statistical distribution model, revealed that the former best fits the experimental results.[199] The experimental data altogether allowed one to propose a structural model of a Pd–Pt nanocluster in which a monolayer of 42 palladium atoms covers a nucleus consisting of 13 platinum atoms.[198] Later, bimetallic nanoclusters containing core–shell structures could successfully be obtained by stabilisation of Pd–Au, Pt–Au and Rh–Pt systems by polyvinylpyrrolidone.[203, 204]

In bimetallic nanosystems of the 'cluster-in-cluster' type, the atoms of one component form a cluster, whereas the atoms of the other component cover only some of its planes (not necessarily as a monolayer) to form an intertwining structure. The fact that such structures are formed in Pd–Au clusters with a change in the Pd : Au ratio from 4 : 1 to 1 : 1,[203] implies that it can represent a modified structure with an inner nucleus. Additional evidence in favour of this suggestion can be derived from the transformation of Pd–Pt nanoclusters with inner nuclei into 'cluster-in-cluster' structures in their application onto inorganic materials.[205] Without going into details about the similarities and differences of these two structures, it should be noted that the surface of nanoclusters of the 'cluster-in-cluster' type contains some centres which consist of two kinds of atoms, *i.e*., the ensemble effect is possible, whereas only the electronic (ligand) effect is *a priori* possible in structures with inner nuclei.

It is the ligand effect that is responsible for the enhanced catalytic activities of PVP-stabilised Pd–Pt clusters in the hydrogenation of cycloocta-1,3-diene into cyclooctene. Indeed, the maximum increase in activity (more than twofold in comparison with pure palladium) was observed for the Pd : Pt ratio of 4 : 1,[200] *i.e*., under conditions where palladium atoms completely covered the inner platinum nucleus. A similar dependence was observed in the case of Pd–Au nanoclusters.[203] The fourfold increase in the catalyst's activity in comparison with those of individual components was observed in the hydrogenation of cyclopentadiene into cyclopentene on Pd–Rh nanoclusters.[198]

Yet another example of the ensemble effect is the reaction of selective hydration of acrylonitrile to acrylamide:

$$CH_2=CH-CN + H_2O \longrightarrow CH_2=CH-CONH_2$$

on bimetallic Cu–Pd nanoclusters stabilised by PVP.[206] It was found that this reaction occurs on two adjacent palladium and copper atoms: the coordination of the C=C bond takes place on the palladium atom, which brings the C≡N bond close to the adjacent copper atom which effects hydration. This results in the enhancement of activity and nearly 100% selectivity of the amide synthesis. It was shown also that the supported Pd–Mo/SiO_2 catalyst based on a bimetallic precursor manifests higher activity in the CO + NO + O_2 reaction than analogous specimens synthesised from individual organometallic complexes.[207]

V. Conclusion

The fundamental knowledge of catalytic properties of nanosystems at the molecular level and practical application of their peculiarities largely determine progress in industrial catalysis and, correspondingly, the economic potential of certain branches of the chemical industry and the environmental situation.

The unique microstructures of nanosystems in comparison with ordinary metals and chemical compounds confer novel properties on them. The characteristic features of nano- and microgeometry of nanosystems and their high specific surfaces open up new opportunities for the design of highly selective and highly reactive perfect catalysts. Some of these features can be synergistic, *e.g*., in bimetallic clusters where one component influences the properties of the adjacent component. Detailed investigations into such interactions will allow the synthesis of novel selective catalysts with predetermined properties. It is the selectivity that is the key problem in the theory and practice of catalysis. And if the problems of sizes and compositions of nanoclusters which ensure their optimum selectivity, detailed electronic structures of cluster complexes, *etc*., are solved, surface reactivity will be put under control.

Nanosystems are a 'natural bridge' between homogeneous and heterogeneous catalysis. Many metals, especially Group VIII metals, which manifest the highest activity as heterogeneous catalysts form numerous cluster compounds endowed with unique catalytic properties. The chemistry of these elements has been studied in sufficiently great detail and the dependence of physicochemical properties of the corresponding clusters on their sizes has been established. However, in more general terms the state-of-the-art in the studies of catalytic activities of nanosystems can be characterised as 'abundance without order'. The main task for the next few years is to combine experimental studies aimed at the construction of new active catalysts based on nanosystems with theoretical (including quantum-mechanical) calculations and more extensive use of physical (both instrumental and diagnostic) methods as well as kinetic studies and mathematical simulation.

Abstract. The model concepts for the mechanisms of formation of electrochemically active species and multielectron processes in ionic nitrate-, carbonate-, boron- and titanium-containing fluoride melts are generalised. The fundamental importance of the acid-base properties of a melt in the mechanism of formation of electrochemically active species is shown for nitrate- and carbonate-containing melts. This fact is confirmed by electrochemical measurements and by calculations of force constants for oxyanions. The optimum form of electrochemically active species has been established; their reduction abilities depend on the cationic composition of a melt, the adsorption properties of the electrode surface and the electric field strength. The bibliography includes 218 references.

I. Introduction

Complex multicomponent systems containing ions of polyvalent metals are used as reaction media in the preparation of inorganic and organic compounds by high-temperature electrochemical synthesis, for the implementation of processes in high-temperature current sources, in electrometallurgy, in electroplating and other areas where a specific approach to the control of chemical processes in melts is required. Molten salts are widely used in practice, that is why the study on their structures, chemical and electrochemical properties is an issue of current interest.[1–3]

This review covers the state-of-the-art of a fundamental problem of electrochemistry of ionic melts, *viz*., determination of the nature of electrochemically active species (EAS) involved in electrochemical reactions and the conditions required for multielectron transformations at electrode – electrolyte interfaces. The electrochemically active species are groups of ions formed in a melt due to acid-base interactions and possessing the highest abilities to accept electrons in the double electric layer. To date, this problem got both the theoretical background and was confirmed comprehensively by experiment for not-too-complicated electrochemical systems with simple one-element ions. If the components of a system arise from complexes, the electrode reactions are supposed to involve multiple-charged ions with complex compositions. Such systems can exist both in aqueous electrolytes and in ionic melts. The problem of theoretical description of multielectron electrochemical reactions in ionic melts has not been solved unambiguously so far. In order to describe experimental results on multielectron transformations at interfaces of electrochemical systems, one mainly uses the concepts on acid-base equilibria and the concepts on electron density redistribution mechanisms during the formation of new chemical bonds or under the influence of the outer-sphere cations and anions on the intracomplex bonds.

The concepts of the mechanism of formation of electrochemically active species in ionic melts based on the analysis of thermodynamic and kinetic parameters are phenomenological. The lack of systematic studies on the relationship between chemical reactions of EAS formation in the bulk melt and their electrochemical reduction and on the effect of the adsorption properties of electrode surfaces and the external electric field on the acid-base interactions in ionic melts not only predetermines the existence of controversial results in the interpretation of the relationships obtained experimentally but also prevents the formulation of basic principles of EAS formation and control of electrochemical processes. The most abundant information on the interaction between the species in a melt and on the processes of their electrochemical reduction can be obtained from data on the changes in the electronic state of the species.[4–7] Therefore, it seems expedient to use the results of both theoretical and modern experimental research methods for the substantiation of EAS formation mechanisms in ionic melts. Once this mechanism has been established, it will be possible to develop a theoretical basis for creating the general principles for control over multielectron processes.

In ionic liquids (ionic melts), the acid-base interactions manifest themselves explicitly,[8,9] but it is difficult to conceive their mechanisms because of their complexity. A cation – anion interaction model is used for the description of this mechanism. In accordance with this model, the acid-base properties of a medium with respect to a particular anion are changed by addition of different types of cations to a dilute solution. Let us consider how this model 'operates' for such anions as NO_3^-, CO_3^{2-}, TiF_6^{2-}, BF_4^-, WO_4^{2-} and MoO_4^{2-} (hard bases) and such cations as Cs^+, Rb^+,

K^+, Na^+, Li^+, Pb^{2+}, Ba^{2+}, Sr^{2+}, Ca^{2+}, Mg^{2+}, Be^{2+} (hard acids) in nitrate-, carbonate-, boron- and titanium-containing fluoride melts that are widely used in practice.[2–4]

II. Model concepts on the structures of ionic melts

The physicochemical properties of ionic melts containing polycoordinated anions, *viz*., NO_3^- and CO_3^{2-}, are determined by the electronic structures of the oxygen-containing anions and the character of their interactions with the melt cations. There is only the near-range order in ionic liquids, which creates problems both for the interpretation of the experimental relationships and for the theoretical descriptions of the melt structures. This can explain the existence of various model concepts as to the structures of ionic melts.

Studies on the changes in the intra-anion bonds depending on the cationic environment (changes in the force constants of the bonds and in bond angles were analysed) in melts of monovalent metal nitrates have led to the conclusion that contact cation–anion pairs exist in these melts.[10, 11] Based on this conclusion, a model of an ion pair was built. This model has been used, *e.g*., for the explanation of the features of IR and Raman spectra of $LiNO_3$ and alkaline-earth nitrate melts, namely, the low-frequency component of the spectrum resulting from the M–O vibrations and splitting of one of the frequencies in the NO_3^- spectrum.

The quasi-lattice model of the melt structure accounts for the concerted vibrational movement of the ions. Considering the mean statistical distribution of the inter-ion potential, the existence of two sublattices, namely, cationic and anionic, was assumed.[12, 13] This model denies the existence of ion pairs due to the comparability of lifetimes of the vibrational levels and the diffusional migration of species. Based on this quasi-lattice model, the existence of $[M(NO_3)_4]^{3-}$ complexes was assumed;[14] this was confirmed by spectroscopic data.[15]

The Kucharski–Flengas quasi-chemical model[16] and the three-sphere Ferland model[17] account for the statistical exchange of cations in sublattices of mixed nitrate melts. Complex ions existing in the melt are regarded as fragments of the ionic structure rather than isolated species of an anionic sublattice.[16] The asymmetry of the cation-anionic environment and the existence of independent kinetic species are explained[18] by effects of various cations, in agreement with the assumptions made elsewhere.[10, 11]

For objective reasons, the above models cannot claim to provide full description of the structures of ionic melts, but each of them states unambiguously that the structure depends significantly on the cationic compositions. This dependence has been confirmed by spectroscopic data for systems with polycoordinate anions, *viz*., complexation products. In fact, the geometries and types of complex species in melts containing insignificant amounts of transition metal salts as well as in melts with oxygen-containing anions have been established based on spectroscopic data.[19] Analysis of the spectra of sulfate melts revealed a considerable contribution of π-interactions to the chemical bonds of the metal complexes studied.[15] The characteristic vibration frequencies were found to depend on the cationic composition for individual and mixed melts containing molecular ions as the starting structural elements. In many cases, C–O and S–O vibration frequency shifts for outer-sphere cations $Cs^+ > K^+ > Na^+ > Li^+$, accompanied by band broadening due to the polarising effect of the cations, were observed in carbonate- and sulfate-containing solutions.[15]

However, the reasons for the frequency shifts in the spectra of melts were explained either qualitatively[20, 21] or on the basis of various model assumptions on the melt structures (the quasi-lattice model,[13] the ion-pair model,[10, 11] *etc*.). In addition, mutually exclusive interpretations of the same data can be found as well.

The use of spectroscopic methods for the study on dilute oxygen-containing melts encounters considerable difficulties in the interpretation of the bands because of their low intensities. On the other hand, information on the acid-base interactions in ionic liquids can be obtained by studying electrode processes. Let us consider certain specific features of electrode processes in melts, in particular those containing nitrate and carbonate ions.

Neglecting of the role of acid-base properties of the medium has traditionally led researchers to mutually exclusive conclusions in the explanation of the same features of electrode processes. For example, Delimarskii *et al*.[22, 23] showed that a cathodic process with a 100% yield of carbon was possible in the electrolysis of a molten equimolar mixture of lithium and potassium carbonates. They noted a specific feature of the voltammetric curves, *viz*., the existence of a region with a distinct limiting current at potentials 0.4–0.5 V, and considered that this region corresponded to the evolution of carbon preceding that of the alkali metal.[23] The existence of limiting currents in voltammograms has also been reported in other studies on cathodic processes in molten carbonates (see, *e.g*., Refs 24–27), but these features have been interpreted differently by different authors. Studies on the possibility of carbon evolution preceding the discharge of alkali metal cations[28, 29] showed that cathodic carbon evolution depends on the electrolyte cationic composition and can occur not only from carbonates but also from chlorides, either supplemented with thermally unstable carbonates or saturated with gaseous CO_2. The dependence of the amount of carbon evolved on the cationic composition of the carbonate electrolyte showed the dominating role of the reducing ability of CO_2 formed in the redox reaction

$$(2/m)\,M^{m+} + CO_3^{2-} \rightleftharpoons M_{2/m}O + CO_2\,. \qquad (1)$$

As in the case of carbonate-containing melts, the development of concepts on the mechanism of formation of electrochemically active species in nitrate-containing melts was facilitated by the existence of many different interpretations of the features of cathodic processes. In fact, the nature of the electrode process preceding the electrochemical reduction of alkali metals, which has first been reported by Lyalikov and Karamzin,[30] was interpreted in different manners. Rust and Duke,[31] who studied acid-base equilibria, assumed that it is the dissociation product of the anion, *viz*., the nitronium ion NO_2^+, that is reduced in electrochemical and chemical reactions. A similar conclusion was reached by Delimarskii *et al*.[32] However, no direct measurements could prove the existence of NO_2^+ in nitrate melts. It was also found[33] that noticeable amounts of NO_2^+ cannot be formed in the presence of strong acids; instead, a compound is formed the properties of which coincide with those of NO_2. This subsequently undergoes one-electron reduction into nitrite. Usanovich[34] believes that $[H_2NO_3]^+$ ions rather than NO_2^+ exist in aqueous melts.

A different viewpoint regarding the nature of the electrode process preceding the alkali metal evolution was given by Delimarskii *et al*.:[35] this process results from direct NO_3^- reduction, irrespective of the electrolyte cationic composition. A similar interpretation has been given in other studies,[36–38] but the reasons for the direct electrochemical nitrate ion reduction have not been explained.

The currently available experimental results on electrode processes in molten salts, particularly in nitrate melts, are used as a base for the simulation of various schemes of formation of electrochemically active species and the corresponding electrode processes. Let us consider some of the models.

Tkalenko *et al*. applied the regularities of the electrochemical reduction of NO_3^- in aqueous solutions[39] to melts;[40–43] this allowed them to propose a model scheme of the cathodic process in concentrated nitrate melts. According to this scheme, the NO_3^- ion in the bulk melt is an ellipsoid with the negative charge distributed over the periphery. Near the electrode surface, the ion is subjected to a combined effect of the cation and electrode fields, therefore its state differs from that in the bulk. It is believed that at negative potentials (cathodic polarisation) the NO_3^- ions are polarised additionally by the electrode force field in such a way that the positively charged nitrogen atom is displaced towards the

electrode relative to the oxygen atoms. The nitrate ion polarised by the electrode field is regarded as an activated complex. Species that form activated complexes under the action of both the electrode field and cation field in the double electric layer are considered electrochemically active.[43] It is the NO_3^- ions that undergo discharge upon cathodic polarisation, hence they can be regarded as electrochemically active species.

We feel that the above scheme of the formation of electrochemically active species has a number of drawbacks. First, though the authors do not deny the effect of the electrolyte cationic composition, they believe that the cation–anion interaction is limited to indirect anion polarisation (through variation of the field potential). They rule out the formation of metal complexes as electrochemically active species; this disagrees with the concept on the chemical interaction of species in melts. In addition, this assumption contradicts the results of studies on the electrochemical reduction of oxygen-containing anions [4, 44, 45] and spectroscopic data.[15, 19, 46] Second, the unreasonable overestimation of the electrode field effect requires a thorough consideration. And, finally, while noting the possible effect of both the electrode field and cations, the authors do not estimate the contributions of each of the effects to the formation of the activated complex.

A different model of the formation of electrochemically active species in melts has been proposed by Chernukhin *et al.*[47, 48] The model is based on the concept on inter-species interactions in condensed media. It was suggested [48] that inter-species interactions result in concerted groups of ions consisting of one anion and surrounding cations. The anion can be transformed to the activated state and undergo electrochemical transformation. In their study on electrode processes in ternary mixtures, Chernukhin *et al.* assumed that the inter-species interactions in the double electric layer and in the melt bulk have similar natures.

Within the framework of the concept that melts are dynamic systems † and based on the results reported by Belen'kaya *et al.*[50] (see footnote ‡), it was assumed [48] that the state of an anion depends on the concerted action of the ionic environment. The activation of anion discharge was explained by the polarising action of the electrode field resulting in a definite anion orientation and, subsequently, localisation of its pairwise inter-species interactions, preferably with cations having the strongest polarising effect. This enhances the non-equivalence of the N–O bonds and prolongs considerably the life-time of the group consisting of the anion and the first-sphere cations. Such a group has been called the activated complex.[48] For example, the formation of an activated complex is given by the following scheme for a binary melt containing potassium and calcium:

$$K^+_{n-x}Ca^{2+}_{x-1}\{Ca^{2+}[ONO_2]^-\} \xrightarrow{-E} K^+_{n-x}Ca^{2+}_{x-1}\{Ca^{2+}...O...[(NO_2]^+\}, \quad (2)$$

where n is the coordination number (c.n.) of the anion during discharge, which is constant irrespective of the cationic composition; $K^+_{n-x}Ca^{2+}_{x-1}\{Ca^{2+}[ONO_2]^-\}$ is the binary melt formula which emphasises the polarising effect of the cation on the NO_3^- anion by designating the anion as $[ONO_2]^-$. Within the scope of Scheme (2), the electrode reaction has the form:

$$Ca^{2+} + NO_3^- \xrightarrow{-E} \{Ca^{2+}...O...[NO_2]^+\} \xrightarrow{2e^-} CaO + NO_2^- . \quad (3)$$

For similar lithium-containing melts, an intermediate compound LiO^- can be formed:

$$Li^+ + NO_3^- \xrightarrow{-E} \{Li^+...O...[NO_2]^+\} \xrightarrow{2e^-} LiO^- + NO_2^- . \quad (4)$$

Based on the above model for the formation of electrochemically active species, the appearance of additional cathodic waves in the voltammograms upon addition of strongly polarising cations, *e.g.*, in melts of sodium and potassium nitrates, can be explained by an increase in anion asymmetry. The shift of the reduction wave upon addition of strongly polarising cations to the melt occurs due to the gradual replacement of the background cations in the nitrate ion environment by cations with a higher polarising strength. This scheme, unlike that proposed by Tkalenko,[43] is generally consistent with the concept on the chemical interactions between species in melts and with the data of numerous spectroscopic studies on concentrated nitrate melts. However, certain aspects of the mechanism discussed above are debatable.

Shapoval *et al.*[4, 44] generalised their own results and other data and explained some features of the electrochemical reduction of oxygen-containing anions. It was assumed that electrode processes in molten salts with oxygen-containing anions are limited by a preceding chemical reaction. For example, the formation of electrochemically active species in the reduction of the carbonate ion in lithium-containing melts was represented by the scheme:

$$n\,Li^+ + CO_3^{2-} \rightleftharpoons [Li_nCO_3]^{n-2} \rightleftharpoons Li_nO^{n-2} + CO_2 . \quad (5)$$

A similar scheme of the preceding acid-base reaction has been proposed for nitrate-containing melts based on data for NO_3^- reduction in a KCl–LiCl eutectic as the background:[45]

$$2\,Li^+ + NO_3^- \rightleftharpoons [Li_2NO_3]^+ \rightleftharpoons Li_2O + NO_2^+ . \quad (6)$$

As follows from Eqns (5) and (6), it is not anions but their reaction products with cations of the molten media that are electrochemically active species.

The proposed anion–cation interaction scheme agrees most closely with the concepts on the chemical reactions of species in ionic melts, but this has a phenomenological character.[51] The anion–cation interaction mechanism can be comprehended more precisely by studying it at an electronic level with the use of quantum-chemical calculations and by comparing them with experimental data. The CO_3^{2-} and NO_3^- anions which are most sensitive to variations of the acid-base properties of a melt are most convenient for the comparison of the electrochemical reduction characteristics.

The scheme for the formation of electrochemically active species in oxygen-containing melts proposed by Shapoval *et al.*[4, 44] does not account fully for the function of cations as acids which, like protons in aqueous media, can add to anions and thus accelerate electrochemical reduction. The complex nature of interaction between species in ionic media creates difficulties for their theoretical description. Therefore, it is expedient to consider a model scheme of cation–anion interaction which makes it possible to change the acid-base properties of the medium with respect to a selected anion by gradual accumulation of cations in the anion's first solvation shell (cationised anion).[52] The cation–anion interaction for carbonate- and nitrate-containing melts can be represented as follows:

$$n\,M^{m+} + CO_3^{2-} \rightleftharpoons \begin{matrix} \{M_n^{m+}[CO_3]^{2-}\}^{(mn-2)+} \\ \rightleftharpoons \\ M_{2/m}O + CO_2 + (n-2/m)M^{m+} \end{matrix} , \quad (7)$$

$$n\,M^{m+} + NO_3^- \rightleftharpoons \begin{matrix} \{M_n^{m+}[NO_3]^-\}^{(mn-1)+} \\ \rightleftharpoons \\ M_{2/m}O + NO_2^+ + (n-2/m)M^{m+} \end{matrix} , \quad (8)$$

where m is the cation charge, n is the reaction order with respect to the cation (coordination number). Thus, cation–anion interaction can result either in cationised anions (metal complexes) or in anion dissociation (both under direct influence of cations and *via* intermediate formation of 'short-lived' metal complexes).

Earlier quantum-chemical calculations [53] and electrochemical data [51, 54] showed that cation–anion interactions in nitrate-containing melts result mostly in nitrate metal complexes, whereas in carbonate-containing melts, two mechanisms of the EAS formation in accordance with Scheme (7) are equally probable. On the

† These views have later been generalised by Delimarskii *et al.*[49]

‡ Belen'kaya *et al.*[50] used Raman spectroscopy to study the changes in the geometry and the potential function of nitrate ion in molten alkali nitrates. It was shown that the bond lengths and strengths in molecular ions can be changed with strengthening of inter-species interactions in the melt. Therefore, the reactivities of species in molten media can be controlled directly by varying their compositions.

other hand, the model proposed, which is valid in dilute melts as the background, does not account for the effects of the electrode surface adsorption properties and the electric field on the character of acid-base interactions and on the charge transfer elementary act.

A calculation of the total energies, charges and populations for carbonate ions showed [55] that the presence of uncharged electrode surface atoms (this surface was simulated by a linear cluster of three carbon atoms) favours the electron density redistribution in an isolated CO_3^{2-} anion according to the σ,π-mechanism (where the σ-component predominates), which, in turn, weakens the intra-anion bonds. Estimates of contributions from the electrode surface and from the cation field to the changes in the C–O bond energy showed that the latter contribution predominates, *i.e.*, the electrode surface does not affect in principle the mechanism of the EAS formation within this model. This mechanism is primarily determined by the melt cationic composition.

The cation–anion interactions are affected considerably not only by the adsorption effects but also by electric fields.[56] Comparison of the energy characteristics and atomic charges and orbital populations in an isolated CO_3^{2-} anion and in an anion located near the electrode surface under the effect of the cation field and an external electric field ($E = 2 \times 10^{10}$ V m^{-1}) showed that cleavage of C–O bonds occurs with formation of CO_2. It is believed [57] that the effect of the electrode surface lowers the activation barriers for two- and four-electron CO_3^{2-} reduction in comparison with the similar magnitudes for an isolated anion. The additional effect of the electric field increases the effect discovered (by a factor of ~2) and favours the direct discharge of the CO_2 molecule

$$CO_2 + 4e^- \longrightarrow C + 2O^{2-} . \quad (9)$$

The geometric sizes of metal complexes resulting from cation–anion interactions in nitrate-containing melts are much larger than that of the linear cluster of three carbon atoms mentioned above. This fact prompted a search for new clusters simulating the electrode surface.[58] The optimum four-cluster variant selected is an aromatic system of 12 carbon atoms (48 basis orbitals) which ensures an adequate representation of the donor-acceptor properties of an uncharged electrode surface. Interaction of a surface cluster with an NO_3^- anion initiates the electron density redistribution in it according to the σ,π-mechanism (with the σ-component predominating) which weakens the intra-anion bonds. An additional influence of the field from the melt cations, *e.g.*, Li^+ and Be^{2+}, on the NO_3^- anion results in a considerable (three- to fourfold) increase in the N–O bond energies. In this case, the π-component predominates in the σ,π-mechanism. Both of these factors increase the N–O bond energy. The trend towards strengthening the N–O bonds is preserved as the c.n. of the cation is increased. Solov'ev *et al.*[59] emphasised that the overall effect of the electrode surface and melt cations on the EAS formation mechanism is determined by competition of two opposite trends in electron density redistribution in NO_3^- and concluded that the electrode surface effect on the mechanism of formation of EAS, such as metal complexes $\{M_n^{m+}[NO_3]^-\}^{(mn-1)+}$, is insignificant within the framework of Scheme (8).

Calculations carried out by Solov'ev *et al.*[60] showed that the external electric field (2×10^{10} V m^{-1}) imposed on a cationised nitrate ion located near the electrode surface virtually does not change the energy of N–O intra-anion bonds against the background of the rather strong interaction of NO_3^- with Li^+ or Be^{2+}. It was found that the contributions of both electric field and electrode surface do not greatly affect the cation–anion interaction.

It has been found [58] (from activation barrier calculations) that the effect of the electrode surface increases considerably the reactivity of metal complexes with respect to two-electron reduction. This effect increases with increase in the cation specific charge and coordination number. The trend towards lowering of activation barriers is preserved under an external electric field. An estimate of the electrode surface effects, the cation field and the external electric field on the elementary charge transfer act showed that the adsorption properties of the electrode surface play the most significant role in these processes. The optimum coordination numbers were found to be 2 for NO_3^- surrounded by Li^+ cations and 3 for the same anion surrounded by Be^{2+} cations. Taking electrochemical measurement data into account,[61] electrochemical reduction can be represented as follows

$$\{M_n^{m+}[NO_3]^-\}^{(mn-1)+} + 2e^- \longrightarrow NO_2^- + n M_{2/m}O + (n-2/m) M^{m+} . \quad (10)$$

Experimental studies [62] not only confirm the formation of EAS according to Scheme (8) but also suggest unambiguously the catalytic nature (caused by the depolariser regeneration) of nitrate reduction waves in the presence of strongly polarising cations. An excess of the latter is believed to result in regeneration of the original EAS

$$3NO_2^- \xrightarrow{M^{m+},\ -E} NO_3^- + 2NO + O^{2-} . \quad (11)$$

The possible realisation of Scheme (11) follows from quantum-chemical calculations of interactions between $M_n^{m+} \cdots NO_2^-$ ($M = Li^+, Be^{2+}$) in an electric field with a strength of $E = 0$; 0.2; 2×10^{10} V m^{-1} (see Ref. 55). Similar calculations showed the priority of cation–anion interactions in the EAS formation in ionic melts. This fact was confirmed in IR and Raman spectroscopic studies on the effect of the melt cationic composition on the force constants of the N–O, C–O, W–O and Mo–O bonds in NO_3^-, CO_3^{2-}, WO_4^{2-} and MoO_4^{2-} anions. The force constants calculated for the $[MNO_3]^0$ and $[M_2CO_3]^0$ systems ($M = Cs^+$, Rb^+, K^+, Na^+, Li^+) suggest [53, 62] a trend towards an increase in the stretching force constants of the N–O and C–O bonds compared with the same bonds in isolated NO_3^- and CO_3^{2-} anions as the cation specific charge increases in the series from Cs^+ to Li^+. The observed effect of the increase in the N–O bond strength due to anion cationisation was confirmed by quantum-chemical calculations and by analysis of electronic absorption spectra.[15, 19] In carbonate melts containing the Cs^+, Rb^+ and K^+ cations, the C–O force constants tend to increase, which also agrees with quantum-chemical calculations.

Calculations of force constants for $[MEO_4]^0$ systems ($M = Na_2^+, Li_2^+, Pb^{2+}, Ba^{2+}, Sr^{2+}, Ca^{2+}$; E = W, Mo) showed [61] that the E–O bond stretching force constants and the deformation force constants in EO_4^{2-} increase with the increase in the cation specific charge. The increase in the force constants of these interactions is believed to result from an increase in the degree of delocalisation of the valence electrons of the EO_4^{2-} anion on the cation orbital. In turn, this stabilises the electronic energy levels of the inner shells in EO_4^{2-}.

III. Structures, chemical and electrochemical properties of titanium-containing fluoride melts

To date, data on the structure of dilute titanium-containing melts in fluoride–chloride systems are very scarce, therefore even the simplest models of the structures of these melts are unavailable. However, there are a number of publications devoted to the studies of these melts.

Analysis of the electronic absorption spectra of the fluoride-containing system KCl–NaCl–NaF with the use of the ligand field theory [63] revealed transient coordination forms of the Ti^{3+} ion resulting from mixed coordination with Cl^- and F^- anions. In the presence of a 100-fold excess of F^- with respect to TiF_3, the formation of a trigonally distorted complex was detected. Complexation of lower titanium compounds with fluoride ions in KCl–NaCl melts was reported [64–66] and it was noted that the c.n. with respect to the F^- ligand in the complexes formed is 3–4.

The existence of $[TiF_4Cl_2]^{2-}$ complexes, presumably with distorted octahedral symmetry, in K_2TiF_6–NaF melts was stated.[67] The possible formation of titanium tetrafluoride in these melts was also reported by Rolin.[68] The formation of poorly soluble compounds $MTiF_4$ in titanium-containing melts cannot be ruled out.[69, 70]

Thus, based on the results of the few studies on the structure of titanium-containing fluoride–chloride melts, one can assume that they contain the mixed $[TiF_4Cl_2]^{2-}$ complex and that the interaction mechanism of the melt species, which results in the compounds $MTiF_4$, depends considerably on the cationic composition.

The electrochemical reduction of titanium-containing fluorides in the presence of chlorides was studied by Smirnov *et al.*[70] The steady-state polarisation curve method was used to study the reduction of Ti^{4+} in the 0.14 K_2TiF_6–0.86 NaCl melt at 1033 K. The titanium deposition mechanism was studied by recording the potentiometric voltammetric characteristics of electrochemical reduction on steel, graphite and titanium electrodes (tetravalent titanium ions were assumed to be the EAS). A polarographic study on the electrochemical reduction of K_2TiF_6 with a KCl–NaCl melt as the background was first carried out by Vitlaci and Nechel[71] who have established the two-electron nature of the charge transfer to the TiF_4^{2-} anion.

Analysis of results reported in these studies[70, 71] suggests unambiguously the possibility of formation of new titanium-containing species upon dissociation of the original complex, *viz.*, chloride–fluoride titanium complexes with titanium in various valent states and cationised titanium-containing anions. These species can react with the melt components. In such cases, a multistep electrode process is observed, and the transfer act can involve several species.

A higher level of experimental data interpretation (with calculation of diagnostic criteria of electrochemical reduction) distinguishes a series of studies[65, 66, 72] which served as a basis for the assumption on the formation of TiF_4 molecules from the original species TiF_6^{2-} and the cationised anion $\{M_n^{m+}[TiF_6]^{2-}\}^{(mn-2)+}$. However, the studies discussed above and those by Juman and White[73] do not report any quantitative data on the electrochemical reduction kinetics and merely suggest the electrode reaction mechanisms.

The most comprehensive data on the electrochemical properties of titanium-containing fluoride melts have been obtained in the studies on the electrochemical reduction of the TiF_6^{2-} anion with a KCl–NaCl melt as the background.[74–76] The possible formation of new EAS, *viz.*, dissociation products of the original complex, was also reported in these studies. Three reduction waves were found in the cathodic polarisation curves. The first wave was interpreted as a result of charge transfer to the dissociation product, *i.e.*, the TiF_4 molecule, and the second one, as a result of four-electron charge transfer directly to the complex anion. The third wave could not be interpreted on the basis of the experimental data.

The authors of the majority of studies discussed above did not relate the results obtained to the effect of the melt cationic composition on the EAS formation mechanism. It seems most reasonable to study this mechanism with the use of quantum-chemical methods which enable the simulation of EAS formation at the electronic level by relating it to electron transfer during electrochemical reduction.

The successful application of the cation–anion interaction model to the studies on carbonate- and nitrate-containing melts stimulated the use of this model for the study on melts containing complex anions. A scheme of the cation–anion interaction in titanium-containing fluoride melts was represented as follows:[77]

$$n\mathrm{M}^{m+} + \mathrm{TiF}_6^{2-} \rightleftharpoons \{\mathrm{M}_n^{m+}[\mathrm{TiF}_6]^{2-}\}^{(mn-2)+} \rightleftharpoons \mathrm{TiF}_4 + 2\mathrm{F}^- + n\,\mathrm{M}^{m+}. \quad (12)$$

According to this scheme, the cation–anion interaction can involve the formation of cationised anions (metal complexes) $\{M_n^{m+}[TiF_6]^{2-}\}^{(mn-2)+}$ or dissociation of the TiF_6^{2-} anion to give titanium tetrafluoride.

Calculations showed[78] that dissociation of an isolated TiF_6^{2-} anion is impossible for energetic reasons: comparative analysis of atomic orbital populations in an isolated TiF_6^{2-} anion and that in cationic environment showed that electron density redistribution cannot result in cleavage of the Ti–F bond in this anion. Reactions of the Na^+ or Li^+ cations with the TiF_6^{2-} anion yield metal complexes with coordination numbers equal to 2, 4 and 6. The Ti–F bond energies decrease with the increase in the c.n. under the influence of cations, whereas the energies of the cation–anion bonds increase. The interaction between Mg^{2+} cations and TiF_6^{2-} at c.n. = 2 results in cleavage of two Ti–F bonds. Further increase in the number of Mg^{2+} cations in the first solvate shell results in further dissociation of the TiF_6^{2-} anion.

Weakening of Ti–F bonds due to the cation–anion interaction results from electron density redistribution in the TiF_6^{2-} anion according to the σ,π-mechanism. The electron density redistribution increases with the increase in both c.n. and the cation specific charge.

It was noted[79] that the cation–anion interaction lowers the activation barriers for two- and four-electron reduction of metal complexes of the TiF_6^{2-} anions and titanium tetrafluoride molecular associates in comparison with the corresponding values for isolated TiF_6^{2-} and TiF_4. Predominance of four-electron reduction was established for metal complexes; on the contrary, two-electron charge transfer predominates for isolated TiF_4.

Volkov[80] does not rule out that the EAS formation mechanism is affected by chloride anions of the background electrolyte. The existence of stable ion-molecular associates $\{Cl_2^-[TiF_4]^0\}^{2-}$ in the melt bulk is probable. This follows from an estimate (based on quantum-chemical calculations) of the interaction of Cl^- ions with the TiF_4 molecule. The activation barriers for two- and four-electron reduction of TiF_4 increase considerably in the presence of chloride anions. Hence, anionic environments (unlike cationic ones) do not increase the reducing ability of EAS.

It has been shown[81] that the electrode surface effect results in electron density redistribution in cationised TiF_6^{2-} anions and in TiF_4 molecular associates, as well as in isolated TiF_4, according to the σ,π-mechanism with predominance of the σ-component. Hence, the electrode surface does not affect considerably the EAS formation mechanism but only enhances the cation–anion interaction effect. Comparative analysis of atomic charges and atomic orbital populations[82] showed that the electric field initiates electron density redistribution in the TiF_6^{2-} anion with predominance of the σ-component and in TiF_4 with predominance of the π-component. The combined effect of the electrode surface and the electric field results in considerable lowering of the activation barrier for EAS four-electron reduction. A TiF_6^{2-} anion surrounded by six cations and a TiF_4 molecule surrounded by four alkali metal cations have the optimum reducing ability. In our opinion, these results are in full compliance with the idea of outer-sphere cationisation in melts containing anions with complex compositions[3, 44, 45] confirmed by electrochemical studies on tungstate- and molybdate-containing systems.[83]

IV. Structures, chemical and electrochemical properties of boron-containing fluoride melts

Much less data are currently available on the structures and properties of boron-containing fluoride melts than on titanium-containing fluoride melts; these data have almost not been interpreted.

Raman spectroscopic studies on the $NaBF_4$ and $NaF–NaBF_4$ melts[84] showed that the structure of the BF_4^- anion remains unchanged at temperatures up to 880 K. A similar conclusion was made by Prostakov *et al.*[85] who also noted that various complex associates can exist in $KBF_4–KF–CsF$ melts. Pirina and

Prostakov[86] used data on the specific densities and electric conductivities of the $KBF_4-KF-CsF$ system to calculate the stabilisation energies of these complex associates. They also stated that complex anions $[M(BF_4)_4]^{3-}$ with tetrahedral configurations were formed predominantly and noted that mixing of salts having the same cation resulted in gradual substitution of anions to give mixed complexes of the types $[MF_4]^{3-}$, $[M_4F]^{3+}$, $[M(BF_4)_4]^{3-}$, $[M(BF_4)_6]^{3-}$, $[M(BF_4)_3F]^{3-}$ and $[M(BF_4)_2F_2]^{3-}$.

A study on solubility of BF_3 in $KCl-KF$ melts at 870–970 K showed[87] that after dilution of the melt with respect to fluoride or after addition of strongly polarising cations (Li^+, Mg^{2+}, Ba^{2+}, Ca^{2+}), the system contains (in addition to the BF_4^- species) mixed fluoride–chloride boron complexes and BF_3 molecules in equilibrium with halide ions. Based on data on boron equilibrium potentials in $KCl-KF-KBF_4$ melts,[88,89] it was concluded that the majority of boron ions exist as higher fluoride and fluoride–choride complexes, *viz*., $[BF_4]^-$ and $[BF_3Cl]^-$, respectively. It was assumed[90] taking account of viscosity and specific density data for $NaCl-NaBF_4$ and $NaCl-RbBF_4$ melts that the structures of tetrafluoroborate melts comply with the model of 'solids' (with retention of the short order arrangement of species).

The ambiguous interpretation and scantiness of data on the structures and physicochemical properties of boron-containing melts often result in conflicting concepts on the electrochemical reduction processes in these melts. Studies on the cathodic process in the $LiF-KBF_4-KF$ system showed that reduction of the BF_4^- anion involves simultaneous transfer of three electrons.[91] It was assumed that diffusion of the BF_4^- anions from the melt bulk is not a limiting step of electrochemical reduction, and this is an indication of the process complexity. Myshalov[92] who studied the electrochemical reduction in boron-containing melts concluded that boron reduction follows a two-step mechanism. Vasil'eva *et al*.[93] studied the possibility of electrochemical preparation of boron from borax-containing melts; they detected several waves on the polarisation curves originating from the stepwise reduction of the oxygen-containing anion.

The reduction kinetics of boron compounds in fluoride-containing melts have been studied most thoroughly by Tsiklauri *et al*.[94–96] Analysis of reduction chronovoltammograms and interpretation of the spectral characteristics of the ternary molten system $KCl-NaCl-KBF_4$ suggest that the chloride–fluoride melt contains several boron-containing equilibrium forms. Reduction of three of them, *viz*., BF_4^-, BF_3Cl^- and BF_3, is believed to account for two waves in the voltammetric curves. This conclusion does not contradict the data by Zarutskii *et al*.[97] On the other hand, the EAS formation mechanism was not related to the melt cationic composition[98] which is important in EAS formation in the melt bulk.

The EAS formation scheme in fluoride boron-containing melts is represented as follows:[99]

$$n\,M^{m+} + BF_4^- \rightleftharpoons \begin{matrix} \{M_n^{m+}[BF_4]^-\}^{(mn-1)+} \\ BF_3 + F^- + n\,M^{m+} \end{matrix} \qquad (13)$$

Preliminary calculations showed that dissociation of an isolated BF_4^- anion is impossible for energetic reasons. It was found that the interaction of this anion with Na^+ and Mg^{2+} cations demonstrates a trend towards a decrease in the intra-anion bond energies, while the interaction with the Li^+ cations, the trend is towards their increase. Distribution of atomic charges and populations of the atomic orbitals of these systems indicates strengthening of the B–F bonds in metal complexes of the anion with Li^+ cations due to predominance of the π-component in the σ,π-mechanism of electron density redistribution in BF_4^-. In metal complexes with Na^+ and Mg^{2+} cations, the σ-component was found to predominate.

The possible dissociation of the BF_4^- anion upon cation–anion interaction cannot be ruled out. The interaction of one of the products of reaction (13), *viz*., the BF_3 molecule, with the melt cations has been studied.[100] Analysis of the interaction energies of BF_3 with Na^+ or Li^+ for the cases where the coordination numbers of these cations are equal to 1, 2 and 3 showed that cleavage of the B–F bonds does not occur, though they are weakened considerably. On the other hand, interaction of two Mg^{2+} cations with BF_3 results in decomposition of the BF_3 molecule; in this case, the formation of $\{Mg_2^{m+}[BF_3]^0\}^{2m+}$ associates in the melt bulk is possible.

It was noted[101] that the cationic environment lowers the activation barriers for two- and four-electron reduction of the products of reaction (13), *i.e*., metal complexes of the BF_4^- anion and associates of the BF_3 molecule, in comparison with the corresponding values for the isolated BF_4^- and BF_3 species. Predominance of two-electron reduction over four-electron reduction is observed both for cationised anions and for BF_3.

Spectroscopic studies on the molten ternary system $KCl-NaCl-KBF_4$ suggest that mixed chloride–fluoride complex ions $[BF_{4-x}Cl_x]^-$ exist in the melt.[102] Analysis of the effect of the background electrolyte chloride anions on the interaction of the BF_4^- species with one or two lithium cations (carried out by quantum-chemical calculations) showed the possible formation of both $[BF_{4-x}Cl_x]^-$ complexes and their associates in the cationic environment. The $\{[BF_3]^0Cl^-\}^-$ species is the most reduction-stable. The activation barrier for two-electron reduction of these associates is lower than that of the BF_4^- anion without the cationic environment. The maximum decrease is achieved for the $\{Li^+[BF_3Cl]^-\}^0$ system. However, though the effect of the activation barrier decrease for BF_4^- and BF_3 in a cationic environment is greater than that for the $\{Li^+[BF_3Cl]^-\}^0$ associate, one cannot rule out a possible decrease in the latter.

Solov'ev[103] assumed that the effect of the electrode surface in boron-containing fluoride melts causes electron density migration in EAS according to the σ-mechanism, resulting in an insignificant weakening of the B–F bonds. It was therefore concluded that, within the model scheme selected, the electrode surface does not affect greatly the EAS formation mechanism.

Imposed electric field ($E = 2\times10^{10}$ V m^{-1}) enhances the trend towards weakening of the B–F bonds in $\{M_n^{m+}[BF_4]^-\}^{(mn-1)+}$ and strengthens slightly these bonds in other EAS.[104] On the other hand, the decrease in the activation barriers for reduction due to the surface and electric field effects results in a considerable increase in the reducing ability of cation–anion interaction products. Taking this into consideration, the following EAS forms can be assumed: $\{M_4^{m+}[BF_4]^-\}^{(4m-1)+}$, $\{M_2^{m+}[BF_3]^0\}^{2m+}$, BF_3, $\{M^+[BF_3Cl]^-\}^0$. Thus, the EAS formation mechanism was complemented as follows:

$$n\,M^{m+} + BF_3 \rightleftharpoons \{M_n^{m+}[BF_3]^0\}^{mn+}, \qquad (14)$$

$$n\,M^{m+} + [BF_{4-x}Cl_x]^- \rightleftharpoons \{M_n^{m+}[BF_{4-x}Cl_x]^-\}^{(mn-1)+}. \qquad (15)$$

Analysis of electrochemical measurements of BF_4^- and BF_3 reduction with the $KCl-NaCl$ melt as the background has been carried out by Tsiklauri *et al*.[95,96] without interpretation of the EAS reduction waves. Based on the calculations, the existence of an additional EAS (besides BF_3 and associates of chloride–fluoride complexes) was assumed,[104] namely, $\{M_n^{m+}[BF_3]^0\}^{mn+}$; the probability of its reduction is higher than that of mixed chloride–fluoride associates.

V. Effect of cations on the mechanisms of chemical and electrochemical reactions in ionic melts

The effect of the solvent nature on the mechanism and rate of chemical reactions in ionic melts was first discovered by Rust and Duke[31] in a study on acid-base equilibria in nitrate-containing melts. It was shown that replacement of a solvent with weakly polarising cations by a solvent with strongly polarising cations accelerates the reactions. This effect was explained by activation of the reacting molecules by the cationic environment. In other studies, the role of the melt cationic composition was ignored. For example, in studies on the electrochemical reduction of oxygen-

containing anions [26, 35, 36] it was assumed that, irrespective of the electrolyte cationic composition, the anions themselves participate in the cathodic reaction. The specific features of the cathodic reduction of anions in the presence of cations were explained by various factors excluding the acid-base interaction.

Certain model concepts used in studies on aqueous solutions were applied to ionic melts. In an analysis of the possible direct discharge of the nitrate ion in aqueous solutions, Lopatin[105] used the 'cationic bridges' concept which makes it possible to explain the effect of the solution cations on the cathodic process. Having studied the anion discharge kinetics near the zero charge potential of the electrode, he explained the effect of cations on the discharge rate by a decrease in the negative reduction potential of the nitrate ion with increase in the concentration and the cation charge. The possibility of direct discharge of the nitrate ion has also been noted.[106] Kvaratskheliya [39] studied the effect of the cation nature on the shift of NO_3^- cathodic reduction waves in aqueous electrolyte solutions. In his opinion, one of the reasons for the effect of salts with polyvalent cations on the positive shift of the cathodic wave is the formation of cation–anion pairs in which one of the N—O bonds is weakened under the effect of the cationic environment.

In studies on electrode processes in melts of individual nitrates with various cationic compositions,[40–42] it was concluded that the activity of the nitrate ion is determined by its environment and hence depends on the acid-base properties of the melt. Differences in the positions of the NO_3^- electrochemical reduction wave were explained by the different charge densities of the cations whose force field affects both the NO_3^- anions and the O^{2-} ions formed in the cathodic process. Attempts were made to find an empirical relationship between the composition of a nitrate-containing melt and the reactivities of its components. For example, Fletcher *et al.*[107] reported an inverse dependence of the isobaric potential of activation of NO_3^- electrochemical reduction on the solvent cation radius.

In a study on the self-diffusion and charge transfer in carbonate- and nitrate-containing melts, the existence of metal complexes such as MCO_3^-, MNO_3^- and $M_2NO_3^+$ (the latter being most probable for the lithium cation) in the melt was assumed and the possibility of the following elementary chemical reactions in a melt was noted:[108]

$$M^{n+} + \text{base} \rightleftharpoons \text{acid}. \qquad (16)$$

Of interest are the studies by Shams El Din *et al.*[109, 110] reporting a comparative estimate of the acidities of alkali and alkaline-earth metal cations. According to these data, the acidity changes in the series of cations: $Ca^{2+} > Li^+ > Sr^{2+} > Ba^{2+} > Na^+, K^+$.

One of the first theoretical studies on the effect of the medium on the elementary act of chemical reactions in the condensed phase can be found in a series of works.[98, 111–113] They considered certain classes of chemical and electrochemical processes and calculated the kinetic parameters of the elementary act of charge transfer, the mechanism of which being dynamically affected by the macroscopic medium. In their opinion, the dynamic effect is determined by fluctuations or changes in the ionic environment surrounding the reacting species; chemical reactions are assumed to occur in a polar liquid and to be accompanied by a considerable charge density redistribution in the reacting species.[110] It was noted [111] that short-range effects predominate in reactions in ionic melts.

Proof that the cationic composition of the medium affects the mechanisms of electrochemical reactions in nitrate-containing melts was obtained in a series of studies [47–49] where a different scheme for the EAS formation mechanism in such melts was suggested (see Section II). However, we feel many statements of this scheme to be debatable because of the doubtful assumption that the nature of inter-species interactions in the electric double layer is the same as in the melt bulk. The electrochemical reaction mechanisms have also been found to be affected by cations for titanium-[66, 69, 70] and boron-containing [84–86, 97] halide melts. Unfortunately, the results obtained were not accompanied by conclusions or generalisations.

The results of experimental studies [28–30, 44, 45] on the kinetics of electrode processes with conjugate acid-base reactions in oxychloride molten salts demonstrate that the cationic composition of the melt affects the rate and mechanism of the reactions occurring in the melt. These studies are based on the idea that the electrochemical activities of oxygen-containing anions originate from the cation–anion mechanism of the EAS formation specific for molten salts (see Section II). This mechanism can be regarded as acid-base interaction where the decisive role belongs to the acid properties of the cations. The formation of EAS and their reactions in the near-electrode layer occur at a limited rate since these processes involve complete restructuring of the reacting species.

The assumption on the cation–anion interaction in molten electrolytes was confirmed in studies on the electrochemical reduction kinetics of oxygen-containing anions in chloride and oxide melts. Detailed studies on the electrochemical reduction of WO_4^{2-} with an equimolar KCl–NaCl melt as the background [4] and of a sodium tungstate melt [114] showed that the tungstate ion itself is not an electrochemically active species but it can generate such species. Owing to the cation–anion interaction, a sufficient excess of strongly polarising cations results in outer-sphere cationisation of the WO_4^{2-} anion to give symmetrically cationised species. Thus, the electrochemical reduction of oxygen-containing anions in the presence of molten chlorides as the background is preceded by a slow acid-base reaction which is the rate-determining step of the electrode process. The EAS are formed due to the interaction of the oxygen-containing anion with the molten electrolyte according to the cation–anion interaction mechanism determined by the acid-base properties of the medium.

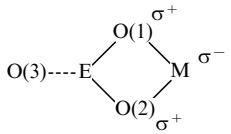
VI. Theoretical and experimental studies of cation–anion interactions in nitrate- and carbonate-containing melts

The results of experimental studies discussed above [28–30, 39–42, 44–49, 108–110] suggest that the reduction of oxygen-containing anions depends on the cationic composition of the melt. Hence, it is necessary, first, to estimate the possibility of the formation of cationised anions (metal complexes) in principle and second, to study the effect of cations on the reducing abilities of anions. In application to nitrate- and carbonate-containing melts, the cation–anion interaction was represented by Schemes (7) and (8).

The CO_3^{2-} anion, the CO_2 molecule and their complexes with the lithium cations (up to five-coordinate complexes) were selected as model compounds for preliminary quantum-chemical calculations. A preliminary energy-based estimate of cation–anion interaction pathways for carbonate-containing melts based on a semiempirical calculation showed [115, 116] the possibility of formation of a broad spectrum of metal complexes of the CO_3^{2-} anion with lithium cations and the effect of the cation nature on the increase in the reducing ability of cation–anion interaction products.

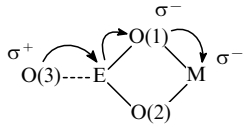
Analysis of the energy profiles of potential surfaces of the interaction of NO_3^- and CO_3^{2-} with Li^+ or Be^{2+} showed that the interaction of cations preferentially occurs along the bisecting line of any bond angle of the anion; there are local energy minima in the monodentate position of the cation with respect to the anion.[117, 118] If interaction between cations and anions is sufficiently strong (it is more efficient in the case of Be^{2+}), the weakening of N—O intra-anion bonds under the effect of the cation was found to differ noticeably from that of C—O bonds. As calculations showed, bidentate interaction of an anion with a cation results in electron density migration from the $2s$, $2p_x$ and $2p_y$ orbitals of the O(1) and O(2) atoms to the corresponding

cation orbitals with formation of σ-bonds. As a result, an effective positive charge σ^+ is transferred to the oxygen atoms.



(17)

In turn, this favours the electron-donating effect of the $2p_2$ orbitals of O(3)



(18)

with formation of π-bonds.

In complexes formed by the nitrate ion, electron density redistribution along the π-bonds under the effect of cations occurs within the NO_3^- anion and causes strengthening of the N—O bond. On the contrary, the σ-mechanism of electron density redistribution predominates in the carbonate ion and in the corresponding complexes, resulting in a considerable weakening of the C—O bonds. Thus, the role of metal cations is to effect the polarisation of an anion as a whole according to the σ,π-interaction mechanism with predominance of one of the interaction types in the isoelectronic ions NO_3^- and CO_3^{2-} (see Refs 119, 120). The results of semiempirical and *ab initio* calculations coincided qualitatively, which afterwards permitted the use of semiempirical calculations which are less laborious.

The gradual increase in the number of the first solvate shell cations, results in the weakening of C—O bonds in CO_3^{2-} with an increase in the coordination number. For the coordination number equal to 2, cleavage of one C—O bond occurs. Conversely, a trend towards strengthening of the N—O bonds is observed for NO_3^-. This conclusion was confirmed by data on charge transfer and electron density migration within anions for the entire coordination number range and by spectroscopic data.[121]

Analysis of the energies of the frontier molecular orbitals showed that the ability of NO_3^- to undergo reduction is higher than that of CO_3^{2-}. Cationisation results in a decrease in the energy gap between the highest occupied and lowest unoccupied molecular orbitals in these anions, which suggests that the cation–anion interaction has a favourable effect on the ability of anions to undergo reduction.[122, 123] Comparison of the reduction activation barriers for NO_3^- and CO_3^{2-} and their metal complexes also indicates an increase in the ability of anions to undergo reduction due to the cation–anion interaction. This interaction decreases the reduction activation barriers for the entire series of complexes.[123]

Electric field is one of the most important factors affecting the reduction in melts. The results of quantum-chemical calculations were used to estimate the effect of the electric field on the acid-base interaction and on the elementary charge transfer act. A uniform electric field was simulated by a system of opposite charges located symmetrically at a long distance from the molecule. The calculations were carried out using a programme developed for this purpose.[124] It was shown[125] that a field which enhances the specificity of cation–anion interaction (predominantly, σ-type in carbonate ion and π-type in nitrate ion) affects considerably the reducing ability of the interaction products; specifically, it lowers the activation barrier.

Shapoval *et al.*[126] reported the results of an experimental examination of the acid-base interaction mechanism by determining a number of electrochemical parameters of the electrode process affected most strongly by the acidity of the melt. The model, Scheme (8), determined the choice of the starting system for the study on cation–anion interaction in melts. Studies on NO_3^- electrochemical reduction in a K, Na, Cs/Cl eutectics as the background (T = 793 K) showed that, like the K, Na, Rb/Cl eutectics, it is weakly acidic with respect to the NO_3^- anion and is suitable for studies on NO_3^- anions with strongly polarising cations. Introduction of Mg^{2+}, Ca^{2+} or Li^+ cations to a nitrate-containing chloride melt at concentrations no higher than a two-, four- and hundred-fold excess, respectively, with respect to NO_3^- shifted the electrochemical reduction wave towards negative potentials.[127–129] Further increase in the concentration of the added anions shifted the discharge potential to more positive region. Analysis of the chronovoltammograms for the NO_3^- anion in the presence of, *e.g.*, a strongly polarising Ca^{2+} cation suggested unambiguously the catalytic character of nitrate reduction waves in the presence of excess Ca^{2+}. It was shown[127, 129] that the excess of these cations is not only consumed in the formation of qualitatively new electrochemically active species, *viz.*, metal complexes, but also results in regeneration of the depolariser in agreement with the experimental Scheme (11).

The coordination number of the Ca^{2+} cations determined in the presence of a considerable excess of these cations equalled 2, while that in the case of excess magnesium cations equalled 3. Calculations of heterogeneous rate constants of charge transfer and regeneration of the original EAS indicate that introduction of cations to the melt catalyses the overall process,[127, 130] while the EAS formation during the electrochemical reduction of NO_3^- in the presence of Li^+, Ca^{2+}, Mg^{2+} occurs according to the cation–anion interaction mechanism in accordance with Scheme (8).

Experimental studies on the cation–anion interaction of CO_3^{2-} with strongly polarising cations[131–133] indicate that this can be described by Scheme (7).

Experimental studies confirmed certain regularities obtained from quantum-chemical calculations.[134] For example, an increase in the rate constants of charge transfer and regeneration of the original EAS with an increase in the specific charges and concentrations of cations in a melt corresponded to a decrease in the activation barrier for EAS reduction. The reduction potential shift by more than 0.6 V upon replacement of Na^+ by Mg^{2+} correlated with the calculated changes in the N—O bond energies in metal complexes formed by the nitrate ion. The absence of electrochemical activity in CO_3^{2-} in the presence of weakly polarising cations in a melt correlates with high activation barriers of two- and four-electron reduction. The experimentally found reduction of CO_3^{2-} in the same potential range in the presence of cations with various polarising strengths correlates with the calculated data, according to which CO_3^{2-} is characterised by a trend towards dissociation. Similar results were also obtained in other studies[51, 135] on the electrochemical reduction of CO_3^{2-} in tungstate melts with various cationic compositions.

The results of a theoretical and experimental study on the mechanism of cation–anion interaction in carbonate and nitrate-containing melts were reviewed by Solov'ev.[136] It is generally acknowledged that this mechanism includes the formation of cationised anions (metal complexes) $[M_nNO_3]^{(mn-1)+}$ and dissociation of CO_3^{2-} under the effect of cationic environment. However, this mechanism being applied to dilute melts did not account for the effect of the electrode surface and the electrical field on both the character of cation–anion interaction and the elementary charge transfer act.

The electrochemical reduction characteristics measured depend on a combination of various factors. The adsorption properties of the electrode surface (together with the temperature mode and the electrical field) affect strongly the character of electrochemical reduction in melts. Considering the surface of a solid electrode as possessing a discrete structure and the differences in the structures of the melt–electrode interfaces (at zero charge potential) caused by individual features of the electrode and melt surfaces, one should take into account the interaction of the surface atoms with adsorbed species of the melt. In accordance with the general physical concepts, this results in changes in the electronic properties of the interface. A preliminary estimate (quantum-chemical calculations) of the electrical field effect on the reactivity of cation–anion interaction products[125] agrees with

real processes of electrochemical reduction in melts. Such processes occur on electrode – melt interfaces where a certain potential gradient exists. Electrochemical reduction and cation – anion interaction are influenced not only by adsorption effects but also by the electrical field (external field and double layer field). Therefore, more detailed studies of the field effect on electrochemical reduction (on the energy parameters of cation – anion interaction products and on their reactivities) are necessary.

Thus, three basic factors should be taken into account in the analysis of the EAS formation mechanism and electrochemical reduction in nitrate- and carbonate-containing melts, *viz*., the acid-base properties of a melt, the electrode surface properties and the effect of the electric field.

VII. Multielectron electrochemical reduction of oxoanions of high-melting metals and non-metals in ionic melts

Multielectron electrochemical discharge – ionisation reactions can occur with simultaneous charge transfer or through a number of consecutive steps, with transfer of one or several electrons involved in each of the steps. It was noted [137–139] that the mechanisms of these reactions can be described by determining experimentally the effective transfer factors or the stoichiometric factors of the elementary steps. However, due to the diversity of ionic states in electrolytes and structures of cathodic deposits, it is unlikely that a general (common) mechanism for the electrochemical deposition of polyvalent metals and non-metals will ever be established.[140, 141] One can govern the reactivities, solubilities and electrochemical properties of the starting and transient forms by changing, *e.g*., the temperature and electrolytes.

There are several viewpoints on the mechanisms of electrochemical reduction of high-melting polyvalent metals from ionic melts. According to one of them (*cf.* Ref. 141), electrochemical reactions result in cathodic deposition of high-melting metals as solid oxygen-containing compounds (oxides and bronzes). A different viewpoint was expressed by Spitsyn *et al*.[142] who believe that the deposits in question consisted of products of electrochemically initiated polymerisation of high-melting metal ions. At the moment, it is hardly possible to prefer the involvement of one particular species over another in reduction. However, there is no doubt that after multicharged species obtain the first electrons, they become reactive and initiation of polymerisation of the species becomes possible. In this case, the situation resembles that observed in aqueous solutions.[141] It is believed that the alkali metal acts as the reduced state stabiliser in melts and in non-aqueous solutions; in aqueous solutions, this role is played by hydrogen. However, the mechanism suggested is questionable, especially in the case where solid oxygen-containing compounds are not formed on the cathode.

It was assumed in certain publications (see, *e.g*., Refs 143 and 144) that the discharge and ionisation of polyvalent metals in aqueous solutions occur *via* transient ions with intermediate valence, the kinetic and thermodynamic stabilities of which depend on the nature of the metal and the electrolyte. Many of the intermediates formed in the bulk of the near-electrode layer possess high reactivities; they react with each other (disproportionation) and with the solution components (redox reactions). As a consequence, the life-times of these ions are small. It is a matter of discussion whether these concepts can be applied to ionic melts.

Polyakov [145] analysed the studies on the electrochemical behaviour of niobium in chloride, oxochloride, chloride – fluoride, oxochloride – fluoride, chloride and oxofluoride melts. It was concluded that both multistep discharge (according to virtually every possible scheme for pentavalent metals, including the transient formation of clusters and intermediates) and single-step discharge of niobium-containing ions are possible. It is generally acknowledged that niobium is reduced in two or three steps in chloride – fluoride electrolytes. The number of steps of niobium reduction in oxochloride – fluoride melts depends on the O : Nb ratio (for $O : Nb \leqslant 1$, a single-step process is observed).

The diversity of niobium oxofluoride and fluoride complexes existing in melts based on NaCl – KCl and the variety of mechanisms of their electrochemical reduction have been noted in a number of studies.[146–151] To date, much remains unclear in the chemistry and electrochemistry of niobium in salt melts.[145] A general problem, as in studies on other metals, is the establishment of correlations between the data from physicochemical and spectroscopic studies and the results of electrochemical measurements obtained by linear voltammetry, chronopotentiometry and other related methods. In addition, discharge of different-ligand complexes and release of their anionic shells in the near-cathode layer can involve the formation of species with compositions other than those of species in the melt bulk.

The laws of electrochemical behaviour of tantalum resemble those of niobium in similar melts.[147]

In their surveys Kuznetsov *et al*.[152, 153] noted diverse views on the electrochemical reduction mechanism of zirconium in fluoride, chloride, fluoride – chloride and oxofluoride melts. Some researchers consider that discharge of ZrF_6^{2-} to give the metal is preceded by various intermediate steps (formation of complex fluorides $n\,MF \cdot ZrF_2$, poorly soluble complex salts $MZrF_4$, *etc*.). Others believe that the reduction of ZrF_6^{2-} is a multistep (involving two or even three steps) or a one-step process. The existing disagreement can be explained by differences in the experimental conditions and in techniques for the interpretation of results.[154, 155] It is presently believed [155, 156] that the electrochemical reduction of zirconium in chloride – fluoride melts occurs either according to the auto-inhibition scheme or with four-electron reversible single-step charge transfer, depending on the concentration of the F^- ion.

Of particular interest are theoretical studies on the stepwise character of charge transfer. For non-adiabatic reactions, the discharge of polyvalent ions is usually represented by a sequence of single-electron charge transfer steps with concomitant intervalent interactions, which are also considered to be one-electron processes.[157, 158] However, a series of studies on the features of electrochemical reduction of the elements in question did not reveal any steps in the discharge of the corresponding oxo, oxohalide and halide complexes. Studies on adiabatic electrochemical electron transfer reactions showed [157, 158] that at a certain ratio between the energy of environment reorganisation accompanying the electron transfer and the Coulombic interaction energy of valence electrons in the reagent, the consecutive single-electron discharge can become multi-electron discharge. In this case, the elementary charge transfer act can be compared to a continuous stream of electrons which cannot be separated into separate steps.

To date, the stepwise character of multielectron processes could not be detected by methods of electrochemical analysis. The use of quantum-chemical methods was suggested for this purpose.[57, 79, 101, 104] A specially developed technique was used for comparison of the activation barriers of multi- and single-step electrochemical EAS reduction with optimal compositions and forms in carbonate-, nitrate-, boron- and titanium-containing melts.[57, 104] For boron-containing melts it was found [57, 101] that the activation barriers for two-step reduction of BF_4^- anions and BF_3 molecules are lower than those for single-step reduction. This law is no longer valid in the case of boron-containing metal complexes. It was concluded for titanium-containing fluoride melts [57, 79] that single-step reduction is more favourable than multi-step reduction.

Thus, no common mechanism of electrochemical reduction of multivalent metals and non-metals has been established to date. Different states of the ions of these metals in electrolytes, structures of cathodic deposits and conditions of the process (temperature and the nature of the electrolyte) can favour one or another electrochemical reduction mechanism. The ambiguity

and diversity of electrochemical reduction mechanisms of EAS can also be due to differences in the melt compositions (different anionic and cationic compositions, admixtures) and in features of experimental techniques (for example, electrode polarisation rates, purity of reagents, materials of electrodes and atmosphere in voltammetry). The possible 'masking' of the apparent stepwise mechanism by autoinhibition should also be noted. Therefore, in each particular case of single-step electrochemical reduction, one should speak of a narrow potential range, which practically cannot be resolved by the existing methods.

The processes of electrochemical evolution of high-melting metals and non-metals from ionic melts underlie a new promising method for the preparation of carbides, borides and silicides of Group IV–VIA metals, *i.e.*, high-temperature electrochemical synthesis.[3, 159] It should be noted that there is as yet no generally accepted opinion on the mechanism of EAS formation involving these compounds. In this Section, we survey the results of experimental studies on the mechanisms of formation and structures of the EAS of high-melting metals.

1. MoO_4^{2-} and WO_4^{2-} anions with chloride melts as the background in the presence of strongly polarising cations

Systematic studies on the electrochemical behaviour of molybdate and tungstate ions in oxohalide electrolytes were carried out by many research groups. Electrochemists from the Sverdlovsk scientific school studied the electrochemical deposition from melts based on alkaline-earth metal chlorides. It was found[160] that anodic dissolution of molybdenum in $CaCl_2$–CaO melts produces MoO_4^{2-} ions; if an admixture of MoO_3 is present, the formation of $Mo_2O_7^{2-}$ ions is more probable. Depending on the melt temperature on the cathode, either molybdenum oxide Mo_2O_3 or metallic molybdenum are deposited.[161] Deposition of molybdenum occurs from electrolytes with acidic properties caused by the presence of calcium cations.[160–162]

It has been shown by electrochemists from the Kiev scientific school[163, 164] that EO_4^{2-} anions (E = Mo, W) in an equimolar KCl–NaCl melt as the background (973–1073 K) do not manifest electrochemical activity up to decomposition potentials of the background electrolyte. The equilibrium potential of molybdenum (tungsten) is not reached in these systems, as noticeable metallic corrosion occurs. The acidic character of alkali and alkaline-earth metal cations (Li^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Al^{3+}) was established.[165, 166] Introduction of cations with high polarising strength (Li^+, Ba^{2+}, Ca^{2+}) to melts containing EO_4^{2-} anions gives rise to a reduction wave at more positive potentials than the decomposition potential of the background electrolyte.[167, 168] Acidification of the melt results in a considerable increase in the reduction wave of molybdate (tugstate) ions and its displacement to the positive range of potentials. If the melt is acidified with a small concentration of Ca^{2+} cations, one wave is observed; two waves are observed at $[Ca^{2+}] \approx (4-5)\,[WO_4^{2-}]$: the first wave reaches a maximum, and a second wave appears at more negative potentials. Upon acidification with Li^+, Ba^{2+} or Ca^{2+} cations, the WO_4^{2-} reduction waves maintain their kinetic nature. This follows from the absence of a linear dependence of the limiting current on the cation concentration and from the activation energy of the limiting current (88.2 kJ mol^{-1} for $[Ca^{2+}] \to 0$). As the melt is acidified, the surface kinetic constant increases by an order of magnitude and reaches the values comparable to the diffusion constant, while the activation energy of the limiting current decreases to 12.4 kJ mol^{-1} (see Ref. 169).

If a 3.5–4.0-fold excess of Mg^{2+} cations with respect to EO_4^{2-} is introduced, an almost proportional relationship between the limiting current of the reduction waves and the concentration of these cations is observed.[170, 171] The maximum limiting current is reached at $[Mg^{2+}] \approx 4\,[EO_4^{2-}]$. Under these conditions, the mass transfer rate constant $[(1.5-2.0)\times 10^{-3}$ cm s$^{-1}]$ is comparable to the diffusion constant; this suggests the diffusion nature of the steady-state waves.

Introduction of Al^{3+} cation also resulted in a proportional dependence of the limiting current on the concentration of this cation. At $[AlCl_3] > 0.5\,[EO_4^{2-}]$, strong evolution of gases (chlorine, chlorine oxides) and a decrease in the limiting current were observed.

In a chloride melt as the background, the electrochemical reduction of MoO_4^{2-} and WO_4^{2-} anions to the metals in the presence of various cations (Li^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Al^{3+}) occurs at various potentials. On going from Li^+ to Al^{3+}, the reduction potentials are shifted in the positive direction by more than 1 V. The limiting current of MoO_4^{2-} and WO_4^{2-} electrochemical reduction is reached at a non-equivalent concentration of cations. The shift of the reduction half-wave potentials ($E_{1/2}$) upon a ten-fold increase in cation concentration is 0.2–0.4 V. Such a significant $E_{1/2}$ shift upon changing the concentration and the cation polarising strength results from the different compositions of the electrochemically active species due to changes in the acid-base properties of the melt. As Shapoval *et al.*[170, 171] report, this shows that, first, variations of the acid strength and the cation concentration change the acid-base reaction stoichiometry, which cannot be described by dissociation of the anion; second, it cannot be described by a reaction resulting in the complete loss of oxygen ions by the metal.

The EAS formation mechanism in melts with various cationic compositions can be presented by the following scheme:

$$xM^{z+} + EO_4^{2-} \rightleftarrows \begin{matrix} \{M_x^{z+}[EO_4^{2-}]\}^{zx-2} \\ \rightleftarrows \\ EO_{4-x}^{2(x-1)} + xM^{z+}O^{2-} \end{matrix}, \qquad (19)$$

where E = Mo, W; $M^{z+} = Li^+$, Ba^{2+}, Ca^{2+}, Mg^{2+}, Al^{3+}.

The direction of shift of equilibrium (19) is determined by the polarising strength and concentration of the cation and by the anion strength. In any case, the cation–anion interaction occurs through a step of the formation of metal complexes.

Acidification of a melt containing MoO_4^{2-} or WO_4^{2-} by Li^+, Ba^{2+}, Ca^{2+} or Mg^{2+} cations results in outer-sphere cationisation of anions giving metal complexes $\{M_x^{z+}[EO_4^{2-}]\}^{(xz-2)+}$. Acidification of the same melts by the Al^{3+} cation results in decomposition of the anions to give $EO_{4-x}^{2(x-1)-}$ species.

The outer-sphere cationisation of WO_4^{2-} anion by the Ca^{2+} cation was studied by IR emission spectroscopy.[172] It was shown that at $[Ca^{2+}] > [WO_4^{2-}]$, symmetric cationisation occurs to give the $\{Ca_4^{2+}[WO_4^{2-}]\}^{6+}$ species.

Shapoval *et al.*[170, 171] also observed an increase in the electron-accepting properties of molybdate and tungstate ions with increase in their degree of cationisation and increase in the acid strength of the cation. This indicates that multielectron processes might have occurred. Apparently, the specific features of multielectron processes are caused by the particular structure of the cationised EAS. For example, in the case of Ca^{2+} and Li^+ cations, two electrons are transferred in the electrode process

$$\{Ca_x[WO_4^{2-}]\}^{2(x-1)} + 2e^- \rightleftharpoons WO_2 + x\,CaO + (2-x)\,O^{2-}, \qquad (20)$$

where $1 \leqslant x \leqslant 2$.

For $x = 4$ in the presence of Mg^{2+}, Al^{3+} in the melt, transfer of six electrons occurs in a practically unresolvable range of potentials. The multielectron electrochemical processes are described by the following overall reactions:

$$\{Li_4^+[EO_4^{2-}]\}^{2+} + 6e^- \longrightarrow E + 2\,Li_2O + 2O^{2-}, \qquad (21)$$

$$\{Ca_4^{2+}[EO_4^{2-}]\}^{6+} + 6e^- \longrightarrow E + 4\,CaO, \qquad (22)$$

$$\{Mg_4^{2+}[EO_4^{2-}]\}^{6+} + 6e^- \longrightarrow E + 4\,MgO. \qquad (23)$$

In the case of acidification by the Al^{3+} cations

$$AlO_2Cl_{2+x}^x + 6e^- \rightleftharpoons Al + 2\,O^{2-} + (2+x)\,Cl^-. \qquad (24)$$

2. CO_3^{2-} anions with chloride and carbonate melts as the background

The cathodic evolution of carbon upon electrolysis of molten carbonates has first been reported by Haber and Tolloczko [173] who obtained carbon deposits from a $BaCl_2-BaCO_3$ melt at 853 K. Systematic studies on electrolysis and electrode processes involving carbonates have been carried out by electrochemists from the Kiev and Sverdlovsk scientific schools. Delimarskii *et al.*[22] have found that graphite powder is the only cathodic product in the electrolysis of an equimolar $Li_2CO_3-K_2CO_3$ mixture at 853–873 K (current efficiency ~100%); carbon dioxide and oxygen (in 2:1 ratio) are the anodic products. The cathodic process is believed [174, 175] to include the reaction

$$CO_3^{2-} \rightleftharpoons CO_2 + O^{2-} \quad (25)$$

and reaction (9), while the anodic process includes the reactions

$$CO_3^{2-} \longrightarrow CO_2 + (1/2)O_2 + 2e^- , \quad (26)$$

$$O^{2-} \longrightarrow (1/2)O_2 + 2e^- . \quad (27)$$

The ratio of the parallel reactions (26) and (27) is determined by the current density. It has been noted that carbon is not formed in the electrolysis of pure K_2CO_3. If this melt is saturated with CO_2 (under pressure), carbon is precipitated on the cathode. Shapoval *et al.*[176, 177] concluded that a certain CO_2 concentration is required for carbon deposition from molten chlorides; it can be achieved by addition of thermally unstable carbonates or by saturation of the melt with gaseous carbon dioxide.

Trunov and Stepanov [178, 179] showed that a platinum electrode which contacts with a mixed stream of carbon dioxide and oxygen is reversible with respect to a carbonate melt. They believe that an equilibrium (between carbonate ions and molecules of CO_2 and O_2) is established on the electrode. Smirnov *et al.*[180] studied the polarisation of platinum and nickel electrodes in a melt of alkali metal carbonates. It was shown that, depending on the current density, various electrode reactions occur resulting in formation of carbides, evolution of free carbon and carbon(II) oxide, as well as discharge of alkali metal cations. The polarisation depends on the concentration of carbonate ions and is due to their diffusion from the bulk melt to the surface. The mechanisms of anodic processes in chloride–carbonate melts in various atmospheres (He, CO, CO_2 or $2CO_2 + O_2$ mixture) have been studied in detail.[181]

Bartlett and Johnson [27, 182] calculated the decomposition potential of alkali and alkaline-earth metal carbonates and considered all possible variants in the reduction of carbonate ions. Based on the calculations, it was concluded that the precipitation of the alkali metal is energetically more favourable at all temperatures for K_2CO_3; for Na_2CO_3, the evolution of carbon is possible up to 1143 K, while that of sodium is possible above 1143 K. Reduction of lithium, calcium, magnesium and barium carbonates gives carbon.

In a series of studies,[183–187] the formation of new species upon dissolution of carbon dioxide in molten $Li_2CO_3-Na_2CO_3-K_2CO_3$ eutectics was reported. The formation of dicarbonate ions was confirmed by potentiometric titration, by structural studies on a melt and by determination of the free energy ($\Delta H = -142$ kJ mol^{-1}) of the reaction between CO_2 and CO_3^{2-} to give $C_2O_5^{2-}$ (see Ref. 183). The possible existence of such species as CO_4^{2-} (see Refs 184, 185), $C_2O_6^{2-}$ (see Ref. 184), $C_2O_4^{2-}$ (see Ref. 186) and CO_2^{2-} (see Ref. 187) was noted.

In K, Na, Rb/Cl melts as the background, the carbonate ion does not show electrochemical activity.[188] An increase in temperature to 700 °C does not favour the electrochemical reduction of CO_3^{2-} either. The addition of a 500-fold excess of LiCl with respect to CO_3^{2-} does not produce a wave on the voltammograms. As the Li^+ concentration is increased, a small wave of CO_3^{2-} electrochemical reduction stretched along the potential axis is observed in the potential range from 0.7 to 0.9 V. The Ca^{2+} cation affects the electrochemical reduction of CO_3^{2-} more strongly than Li^+ does. A noticeable wave is observed even with a 200-fold excess of Ca^{2+}. The waves in the presence of Ca^{2+} are also extended along the potential axis. The wave heights were not found to depend explicitly on the cation concentration. The effect of the Mg^{2+} cation was found to be most pronounced. A distinct wave appears even with a four-fold excess of Mg^{2+}. Further increase in the Mg^{2+} concentration increases the wave height, and it reaches a maximum with a 100-fold excess of Mg^{2+}. Evacuation of the system after reaching the maximum wave height decreases the latter. The addition of Mg^{2+} after evacuation increases the wave again.

It should be noted that the electrochemical reduction of CO_3^{2-} in molten chlorides as the background occurs in the same potential range, irrespective of the polarising force of the cation. Hence, the electrode processes in melts with different cationic compositions involve the same species, namely, CO_2. The electrochemical reduction of CO_3^{2-} under the action of strongly polarising cations occurs at much lower temperatures than the thermal decomposition temperatures of the corresponding carbonates. Hence, the formation of CO_2 does not result from thermal decomposition but is a consequence of the polarising effect of cations.

3. MoO_4^{2-}, WO_4^{2-} and CO_3^{2-} anions in oxide melts as the background in the presence of strongly polarising cations

It is known [189–192] that polytungstate and polymolybdate melts $Na_2EO_4-EO_3$ (E = Mo, W) can be considered as melts of eutectic mixtures $Na_2EO_4-Na_2E_2O_7$ containing the Na^+, EO_4^{2-} and $E_2O_7^{2-}$ ions. The ratio between the concentrations of EO_4^{2-} and $E_2O_7^{2-}$ ions is determined by the equilibrium

$$2\,EO_4^{2-} \rightleftharpoons E_2O_7^{2-} + O^{2-} . \quad (28)$$

Presumably, the introduction of Li_2WO_4 or $ZnWO_4$ as well as of WO_3 in a sodium tungstate melt complicates the structure of tungsten–oxygen groups, for example, owing to the reaction

$$2\,WO_4^{2-} + x\,Li^+ \longrightarrow Li_xO^{(2-x)-} + W_2O_7^{2-} . \quad (29)$$

However, if this concept is applied to molten $M^{I}EO_4-M^{II}EO_4$ mixtures (M^{I} = Li, Na, K; M^{II} = Ca, Zn, Ba, Sr, Mg, Al), some contradictions arise. First, if the equilibrium (28) took place upon introduction of tungstates of strongly polarising cations, *e.g.*, $CaWO_4$, in a sodium tungstate melt, this would have occurred in melts containing an excess of the Ca^{2+} cation with formation of the tungstate ion dimer. However, studies on the electrochemical behaviour of the $CaCl_2-CaWO_4-CaO$ system at high temperatures [152] and the IR spectra of a $KCl-NaCl-Na_2WO_4-CaCl_2$ melt (for $[Ca^{2+}] > [WO_4^{2-}]$) [14] indicate that the tungstate ion retains its tetrahedral structure. Second, the solubility of tungstates (molybdates) with strongly polarising cations in sodium or potassium tungstate (molybdate) decreases with the increase in the cation specific charge.[193] These facts can imply that the strength of $M^{z+}-EO_4^{2-}$ interaction increases with increase in the specific charge and that the concentration of oxygen ions in the molten mixtures decreases.

In our opinion, the cationic composition of tungstate and molybdate mixtures, like that of oxochloride melts, should affect considerably the EAS composition and the parameters of the electrode process. Kushkhov *et al.*[194, 195] studied the melts of $Na_2WO_4-MEO_4$ mixtures (M = Li, Ca, Zn, Ba, Sr, Mg, Al; E = Mo, W). The addition of tungstates and molybdates with strongly polarising cations shifts the oxygen electrode potential towards more positive values, *i.e.*, decreases the activity of the O^{2-} ion. An increase in the cation specific charge in the series Ba^{2+}, Sr^{2+}, Li^+, Mg^{2+}, Al^{3+} leads to a more significant shift. In the cases of addition of aluminium tungstate (molybdate) and tungsten (molybdenum) trioxide, the concentration dependences of the oxygen electrode potential practically coincide. It can thus be assumed that if a strongly polarising cation is present in a melt, an acid-base reaction of the molybdate (tungstate) ion with the Al^{3+} cation is possible

$$2\,Al^{3+} + 3\,EO_4^{2-} \longrightarrow 3\,EO_3 + Al_2O_3\,. \quad (30)$$

According to reactions (28) and (29), the parameters (potentials, rates) of electrochemical evolution of tungsten and molybdenum should be virtually identical in melts with identical acidities, irrespective of the cationic composition. However, an increase in the cation specific charge shifts the electrochemical reduction wave towards more positive potentials. For example, the shift upon transition from Na^+ to Al^{3+} is $\sim$1.0 V.

This fact cannot be explained using the viewpoint that EAS are formed in melts of sodium tungstate containing molybdates and tungstates of strongly polarising cations according to reaction (28). In melts with equal acidities, the specific charge on cations affects considerably the electrochemical reduction potential. In fact, the electrochemical reduction potentials of tungstate ion in the presence of barium, magnesium and aluminium cations are within 1.8–1.9, 1.5–1.7 and 1.0–1.2 V, respectively. A similar situation is observed for molybdate ion.

The acid-base (cation–anion) interactions occurring in a melt of sodium tungstate upon addition of the carbonate ion are judged by changes in the e.m.f. of a cell with oxygen electrodes.[135] Upon addition of carbonates, the oxygen electrode potential is shifted towards negative values, indicating an increase in the oxygen ion activity in the melt. The addition of lithium carbonate shifts the oxygen electrode potential much more strongly than that of sodium carbonate. This is due to the fact that the stability constant of sodium carbonate is higher than that of lithium carbonate.[196] For the same reasons, a melt of sodium tungstate containing lithium carbonate has a lower pCO_2.

The electrochemical reduction of carbonate ion in sodium tungstate as the background can be detected only upon addition of lithium carbonate. The absence of a linear dependence of the reduction wave current on the lithium carbonate concentration and the decrease in the diagnostic criterion $j_p/V^{1/2}$ (where j_p is the peak current density, V is the potential sweep rate) with an increase in the polarisation rate implies the kinetic nature of electrochemical reduction waves of carbonate ion. Electrochemically active CO_2 species are formed as a result of cation-anionic interaction of the strongly polarising Li^+ cation with the carbonate ion. The formation of CO_2 can be described by the above scheme [see Eqn (5)]. The addition of sodium carbonate increases pCO_2 considerably, therefore the CO_2 reduction wave is not observed in the voltammetric curves.

4. Effect of PO_3^- anions on the formation of electrochemically active species in the presence of MoO_4^{2-} and WO_4^{2-} anions

Introduction of PO_3^- in $KCl-NaCl-Na_2WO_4$ (Na_2MoO_4) melts gives two waves on the voltammograms.[197, 198] An increase in PO_3^- concentration within $0.01 < [PO_3^-]/[EO_3^{2-}] < 0.2$ increases the current of the second wave, whereas the potentials and currents of the first wave remain unchanged. The current of the second wave is proportional to the PO_3^- concentration. Potentiostatic electrolysis of molybdate (tungstate)-containing melts with the specified concentration ratio of molybdate (tungstate) and metaphosphate anions gives a deposit of the corresponding high-melting metal on the cathode.

Our assumption on the participation of the dimeric ionic forms of molybdenum and tungsten in the electrode processes in question is based on the following data. It has been shown [199] that introduction of sodium metaphosphate in a purely tungstate melt shifts the potential of the tungsten electrode from -1.8 to -1.0 V. It is at -1.0 V that discharge of $W_2O_7^{2-}$ ions occurs; the existence of these ions has been proven both electrochemically [200] and by high-temperature radiography.[201]

Based of voltammetric data,[197, 198] the effect of PO_3^- on the electrochemical reduction of MoO_4^{2-} and WO_4^{2-} can be interpreted as follows. The role of PO_3^- involves the formation of two EAS forms according to the scheme

$$PO_3^- + 2EO_4^{2-} \rightleftharpoons \begin{matrix} E_2O_7^{2-} + PO_4^{3-} \\ 2EO_3 + PO_4^{3-} + O^{2-}\,. \end{matrix} \quad (31)$$

The formation of ditungstate ions in a sodium tungstate melt in the presence of PO_3^- anions has also been reported by Malyshev.[202]

5. Effect of neutral MoO_3, WO_3 and B_2O_3 molecules on the formation of electrochemically active species in the presence of MoO_4^{2-} and WO_4^{2-} anions

The effect of tungsten trioxide on the electrode processes in tungstate melts has been studied in detail by a research group directed by Academician A N Baraboshkin.[189, 191, 200] Contradictory opinions on the ionic composition of tungstate melts exist at present. It has been noted above that the melts of the $Na_2WO_4-WO_3$ system can be regarded as melts of the $Na_2WO_4-Na_2W_2O_7$ eutectic mixture and that they mostly consist of a mixture of Na^+, WO_4^{2-} and $W_2O_7^{2-}$ ions.

The discharge of $W_2O_7^{2-}$ occurs more easily than that of the tungstate ion. This is evident from a thermodynamic calculation of the decomposition potentials of the corresponding compounds [203, 204] and from experimental data:[190, 191] introduction of small amounts of WO_3 increases abruptly the potential of tungsten evolution and decreases the decomposition potential of polytungstate melts.

The effect of MoO_3 on electrode processes in the sodium tungstate melt and the EAS formation mechanism were studied by potentiometric and voltammetric measurements (a cell with oxygen electrodes was used).[205, 206] Measurements of the equilibrium potentials of the oxygen electrode showed that in the presence of up to 2 mol.% – 3 mol.% MoO_3 in the sodium tungstate melt, the pre-logarithmic factor of the dependence of the oxygen electrode potential on MoO_3 concentration is 0.120 V. This means that in this concentration range molybdenum exists mainly as MoO_4^{2-} ions. The pre-logarithmic factor of this dependence at concentrations 7 mol.% – 20 mol.% is 0.112 V. Hence, molybdenum is present mainly as dimolybdate ions $Mo_2O_7^{2-}$ in this concentration range. The experimental dependences match the calculated ones, which confirms the validity of the chosen model of the ionic composition of the melt.

Measurements of the potential of a molybdenum electrode *versus* MoO_3 concentration showed the existence of two equilibria.[206, 207] At MoO_3 concentration up to 4 mol.% – 5 mol.%, metallic molybdenum is in equilibrium with a melt containing $Mo_2O_7^{2-}$ ions. The concentration dependence of the equilibrium potential is well described by the Nernst equation. The number of electrons per one electroactive species calculated from the slope of the plot of the molybdenum electrode potential against MoO_3 concentration, ($dE/d\log[MoO_3]$), equals 1.5. This value is consistent with the equilibrium

$$4\,Mo_2O_7^{2-} + 6\,e^- \rightleftharpoons Mo + 7\,MoO_4^{2-}\,. \quad (32)$$

At high MoO_3 concentrations (> 5 mol.%), the activity of $Mo_2O_7^{2-}$ increases, and a tungstate–molybdate melt is in equilibrium with the dioxide MoO_2 rather than with metallic molybdenum

$$2\,Mo_2O_7^{2-} + 2\,e^- \rightleftharpoons MoO_2 + 3\,MoO_4^{2-}\,. \quad (33)$$

The number of electrons per one electroactive species, also calculated from the slope $dE/d\log[MoO_3]$, equals 1. This value describes the equilibrium (33).

The formation of dimolybdate and ditungstate ions in tungstate–molybdate melts in the presence of B_2O_3 was noted.[208, 209]

6. Effect of fluoride and fluoroaluminate ions on the formation of electrochemically active species in the presence of CrO_3, MoO_3, WO_3, CrO_4^{2-}, MoO_4^{2-} and WO_4^{2-} in chloride–fluoride melts

Tungsten and molybdenum trioxides can be stabilised in chloride melts by binding them in oxofluoride complexes which are more

stable. Such complexes have been described in the literature; they are obtained by treatment of tungstates and molybdates with hydrofluoric acid. We were able to find data on the existence of these compounds in melts in only one publication.[210]

The composition range of oxohalide melts where tungsten and molybdenum exist as stable oxofluoride complexes was determined by studying $KCl-NaCl-NaF-EO_3$ melts (E = Mo W) with different [NaF]/[EO_3] concentration ratios.[211,212] Based on the results of these studies, the overall electrode process of electrochemical reduction of the oxofluorotungstate complex can be presented as follows:

$$[WO_2F_4]^{2-} + 6e^- \rightleftharpoons W + 2O^{2-} + 4F^- , \quad (34)$$

$$2O^{2-} + [WO_2F_4^-]^{2-} \rightleftharpoons WO_4^{2-} + 4F^- , \quad (35)$$

$$2[WO_2F_4]^{2-} + 6e^- \rightleftharpoons W + WO_4^{2-} + 8F^- . \quad (36)$$

As noted above, MoO_4^{2-} and WO_4^{2-} in melts of chlorides of weakly polarising cations (Na^+, K^+) as the background manifest no electrochemical activity up to decomposition potentials of the background electrolyte. The addition of fluoride ion to a sodium chloride melt containing molybdate and tungstate ions does not change the shapes of the voltammetric curves. The molybdate and tungstate ions are stable in NaCl–NaF melts; the O^{2-} is not replaced by F^- with the formation of oxofluoride complexes, and they do not manifest electrochemical activities up to decomposition potentials of the background electrolyte.[213,214]

It is known that aluminium fluoride complexes possess acceptor properties with respect to O^{2-} ions and hence can be used for controlling the acid-base properties. On introduction of AlF_6^{3-} in a sodium chloride melt containing MoO_4^{2-} and WO_4^{2-} anions, waves at 0.7–1.0 V appear on the voltammetric curves.[163,164] Acid-base interaction of EO_4^{2-} with AlF_6^{3-} is accompanied by replacement of F^- by O^{2-} in the aluminium environment to give $AlOF_x^{1-x}$ complexes ($x = 2-5$), while EO_4^{2-} is bound in oxofluoride complexes. For example, for $x = 2$

$$EO_4^{2-} + 2AlF_6^{3-} \longrightarrow EO_2F_4^{2-} + 2AlOF_2^- . \quad (37)$$

The proof that tungsten and molybdenum are evolved from oxofluoride complexes in the $NaCl-Na_3AlF_6-Na_2EO_4$ systems is as follows. First, the deposition potentials of tungsten and molybdenum from these systems correlate well with the deposition potentials of these elements from WO_2F_2, MoO_2F_2 relative the oxygen electrode calculated from thermodynamic data.[203,204] Second, the deposition potential of tungsten (molybdenum) from the system in question coincides with the deposition potential of tungsten (molybdenum) from the $NaCl-KCl-NaF-EO_3$ system, in which the high-melting metal exists as $EO_2F_4^{2-}$ (see Refs 215, 216). The formation of $EO_2F_4^{2-}$ and its subsequent electrochemical reduction to the metal in a $KF-MoO_3-B_2O_3$ melt was assumed by Japanese researchers.[213] The electrochemical reduction waves recorded for a $NaCl-Na_3AlF_6$ melt containing EO_3 and Na_2EO_4 both separately and simultaneously are virtually identical. Hence, the reaction between tungstate (molybdate) and fluoroaluminate ions results in $EO_2F_4^{2-}$ and $AlOF_x^{1-x}$.

Taking into account the linear dependences of the reduction wave peak current on the EO_3 (EO_4^{2-}) concentration and on the polarisation rate and using the mass transfer constant of $(5-6)\times10^{-3}$ cm s^{-1}, Malyshev *et al.*[214] reached a conclusion on the diffusion nature of the limiting current. The dependence of the potential of molybdenum or tungsten electrode in a $NaCl-Na_3AlF_6$ melt on the EO_3 or EO_4^{2-} concentration *vs.* the Pt, O_2/NaCl–0.05 Na_2MO_4 half-cell is well described by the Nernst equation. The number of electrons per one electroactive species calculated from the slope of plots of the metal electrode potential against the EO_3 (or EO_4^{2-}) concentration equals 5.8±0.2. For these melts, the polarisation curves of the molybdenum and tungsten electrodes are characterised by low overvoltage; the cathodic and anodic segments of polarisation curves are symmetric up to the overvoltage of 0.35 V. Based on the slopes of the polarisation curves in the current–overvoltage coordinates, the number of electrons participating in the electrode process was found to be 5.5–6.1. These data suggest the reversibility of the charge transfer step. The overall electrochemical reaction can be represented as follows:

$$EO_2F_4^{2-} + 2AlF_6^{3-} + 6e^- \rightleftharpoons E + 2AlOF_4^{3-} + 8F^- . \quad (38)$$

Several studies[214,217,218] deal with the effect of fluoride complexes AlF_6^{3-} and SiF_6^{2-}, manifesting acid properties with respect to O^{2-} ions on the electrochemical reduction of CrO_4^{2-} in K, Na/Cl, F melts as the background. The chromate ion in halide melts as the background with weakly polarising cations, such as Na^+ and K^+, does not manifest electrochemical activity up to the decomposition potentials of the support electrolyte. The formation of EAS can be represented by an equation analogous to Eqn (38). The Cr_2O_3 formation potential coincides with its evolution potential from $CrO_2F_4^{2-}$ *vs.* the oxygen electrode calculated from thermodynamic data.[203,204] The dependence of the chromium electrode potential in a $NaCl-Na_3AlF_6$ melt (50 mass % : 50 mass %) on CrO_4^{2-} concentration at 1173 K obeys well the Nernst equation with the number of electrons per EAS equal to 3.0±0.1. The electrochemical deposition of Cr_2O_3 occurs without a noticeable overvoltage; analysis of polarisation curves gives 5.7–6.1 electrons. These data suggest the reversibility of the charge transfer step. The overall electrochemical equilibrium can be expressed as follows:

$$2CrO_2F_4^{2-} + AlF_6^{3-} + 6e^- \rightleftharpoons Cr_2O_3 + AlOF_4^{3-} + 10F^- . \quad (39)$$

Studies on the electrochemical reduction of oxoanions of high-melting metals in the presence of chloride, chloride–fluoride and oxide melts with various acid-base properties made it possible to reveal three mechanisms of EAS formation:[3,4] anion cationisation with formation of $\{M_x^{z+}[EO_{n/2+1}]^{2-}\}^{(xz-2)+}$ species, oxoanion decomposition to give $\{EO_{[(n+2(1-x)]/2}Hal_{2(x-1)+y}\}^{y-}$ oxohalide complexes, formation of $[E_{(1+x)}O_{n(1+x)/2+1}]^{2-}$ dimer complexes where E = Cr, Mo, W, C; M = Li^+, Ba^{2+}, Sr^{2+}, Mg^{2+}, Zn^{2+}, Al^{3+}.

The direction of EAS formation is determined by the acid properties and the concentration of M^{z+}, EO_n, PO_3^-, F^- and the stability of the EO_n^{2-} anion.

One can create conditions enabling various multielectron electrochemical processes to favour a particular reduction mechanism in ionic melts, by constructing electrochemically active species with various structures and compositions (in other words, by controlling the cation–anion interactions).

II.	Synthesis and classification of nanoclusters and nanocluster structures	177
III.	Properties of isolated nanoclusters	179
IV.	Cluster nanosystems and nanostructures	185
V.	Conclusion	206

Abstract. Data on the structures and properties of nanoclusters and nanocluster systems are analysed. A classification of nanoclusters and nanosystems based on the method of their preparation is proposed. Methods for assembling nanoclusters to give nanostructures, the main principles of assembling and the types of nanosystems are described. The appearance of new properties upon combination of nanoclusters into a nanosystem is noted. The bibliography includes 274 references.

I. Introduction

The properties of a material are known to change significantly on passing from macrostructures to the microstructures the size of which lies in the nanometer range. Thus the crystal lattice parameters, the heat capacity, the melting point and the electrical conductivity of nanoclusters in the condensed state differ from those of the corresponding macrocrystals. In addition, they acquire new optical, magnetic, and electronic characteristics; their reactivity and catalytic properties also change.[1–10] The properties of nanostructures are determined by not only the cluster size but also the mode of their organisation or self-organisation into a nanocluster structure in which the clusters act as separate atoms. Nanostructures, in turn, can form supramolecular structures.

The ways of assembly of nanoclusters into nanostructures depend not only on the properties of separate nanoclusters and intercluster interactions but also on the methods used to prepare nanoclusters. Thus, several main trends can be distinguished in research on nanoclusters and cluster nanosystems

— methods for the preparation and classification of nanoclusters;
— properties of isolated nanoclusters;
— ways of assembly (self-assembly) of cluster nanosystems;
— properties of nanocluster systems.

Great progress in studies of nanoclusters and nanostructures has been achieved in the last decade. An enormous number of publications have appeared, devoted both to fundamental research on nanoclusters and nanostructures and to the ways of using them in nanotechnologies (design of magnetic recording devices, nanodiodes, nanowires, and single-electron transfer devices tuned by changing the size of the nanolaser; production of new nanomaterials with specific mechanical, thermal, electronic, optical, and magnetic properties).

In this review, we present data on nanoclusters and nanostructures obtained both by methods of inorganic, physical, and solid-state chemistry and by methods of condensed-state physics and the physics of gases, using diverse calculation procedures and experimental equipment. We have not intended to give an exhaustive review on the published data concerning all the properties of nanoclusters, but considered only those of them that are of fundamental importance in the formation of cluster systems. Some of the problems considered in the review related to the interpretation of experimental facts and, especially, classification of clusters and nanoparticles are debatable. In addition, not all the cluster effects are considered. Nevertheless, we hope that the information we present would be of interest for researchers engaged in the chemistry or nanotechnologies and in physics.

II. Synthesis and classification of nanoclusters and nanocluster structures

As noted above, many properties of nanoclusters and nanosystems depend on the method used to prepare them. Therefore, we attempted to classify the clusters in terms of the method of synthesis. With this empirical approach, the diversity of properties of clusters and cluster systems can be represented on the basis of their origin. In terms of the preparation method, clusters can be classified into six groups: molecular, gas-phase, colloid, solid-state, matrix and film clusters. Isolated nanoclusters can be prepared by chemical reactions (molecular clusters), laser vaporisation (gas-phase clusters) or by matrix isolation (solid-state and colloid syntheses). Nanosystems are mainly formed in solid-state and colloid syntheses.

1. Molecular ligand metal clusters

Molecular metal clusters are multinuclear complex compounds the molecular structure of which is based on a core (cell) of metal atoms (their number should be greater than two) bound directly to one another and surrounded by ligands. The metal–metal distances in these clusters are usually shorter than those in the bulk metal.[11] The metal core consists of chains of different lengths and different branching types, rings or polyhedra or combinations of these structural units. Both homo- and heterometallic clusters are known.

Uspekhi Khimii **70** (3) 203 – 240 (2001); translated by Z P Bobkova

Molecular ligand metal clusters are produced from metal complexes upon various chemical reactions. An enormous number of publications have been devoted to the synthesis, structure and properties of molecular metal clusters (see, for example, a monograph [11] and references therein).

2. Gaseous ligand-free clusters

Ligand-free clusters of metals or metal oxides can be prepared, for example, by laser vaporisation of metals from a substrate followed by separation according to size (or weight) in a time-of-flight mass-spectrometer. The clusters formed upon vaporisation are fixed in traps (or on substrates) and then their electronic, optical, and other properties are studied.[12] The clusters obtained in this way contain from several dozens to several hundreds of atoms. The synthesis of big nanoclusters ($\geqslant 100$ nm) is performed by heating and vaporisation of metals in a radio-frequency electromagnetic field *in vacuo* or under an inert gas followed by deposition of clusters onto a substrate or a filter.[13] The use of a substrate is necessary because nanoparticles are highly reactive and stick together upon collisions, while the substrate stabilises them.

Yet another method for the preparation of gas-phase metal clusters is vaporisation of metals in an inert gas followed by the formation of metal clusters in a low-temperature matrix (cryochemical method).[14]

Gas-phase methods of synthesis are also used for the preparation of carbon clusters (in particular, fullerenes). Thus C_{60} fullerene was prepared for the first time by laser vaporisation of graphite in 1985.[15] Fullerenes with the compositions C_{36}, C_{70}, C_{82}, C_{84}, C_{90} and C_{96} have also been synthesised.[16–19]

Among other gas-phase ligand-free clusters, van der Waals clusters of noble gases and water should be mentioned.

The evaporation–condensation technique allows the preparation of the purest metal particles; therefore, nowadays, this method is still finding application. However, when using this method, it is difficult to control the size of the resulting metal clusters. The clusters obtained in this way are characterised by broad size distributions.

3. Colloid clusters and nanosystems

Colloid solutions containing metal nanoclusters and their compounds have long been known; however, in connection with the task of preparing assembled nanostructures, it became necessary to synthesise monodisperse colloid systems with a controlled cluster size. Monodisperse colloid systems are usually synthesised using sol–gel technology,[20] which includes preparation of a sol and its transformation into a gel. Sols are prepared using dispersion and condensation (physical and chemical) methods. Thus hydrolysis of metal salts or metal alkoxides gives rise to sols of metal oxides or hydroxides characterised by high excess energy. Owing to the excess energy, aggregation of sols takes place in these systems, accompanied by the formation of a gel. This process affords nanostructures with a size of up to 100 nm.

In recent years, the use of microemulsion systems (direct and reverse micelles) for the preparation of nanoclusters with a narrow size distributions of particles has started.† Many metal clusters with particle size of 1 to 10 nm have been prepared in this way.[21,22]

4. Solid-state clusters

Solid-state clusters are formed as a result of diverse transformations of the solid phase: chemical reactions in the solid phase, crystallisation of an amorphous phase, mechanochemical transformations, *etc*.[23] Many chemical reactions in the solid state for example, thermal decomposition of metal salts and complexes are accompanied by the formation of metal or metal oxide nuclei, which then grow due to sintering. The size of nanoclusters thus formed varies over a very broad range — from one to hundreds of nanometers.

Crystallisation is employed to prepare nanoclusters from amorphous alloys. The crystallisation conditions are maintained in such a way as to generate as many crystallisation centres as possible; the growth of nanoclusters should occur at a low rate.

Solid-state nanoclusters can also be prepared *via* photochemical reactions, for example, those involving silver halides. These reactions, too, start with the formation of nuclei, which are then enlarged giving rise to nanoclusters with sizes ranging from tens to hundreds of nanometers.[7]

Apart from chemical reactions in solids, mechanochemical transformations can also be used to prepare solid-state clusters. Thus mechanical grinding of a bulk solid permits one to prepare nanoclusters the size of which does not exceed several nanometers. Due to the activation of the newly formed surface, new nanocluster compounds differing from the initial ones can arise.[6,8]

Yet another method for the preparation of solid-state nanoclusters consists in nanostructurisation of a material on exposure to pressure with shear.[6] By increasing pressure to 5 GPa and shear to 1000 °C, one can prepare nanoclusters with a grain size reaching several nanometers the properties of which differ sharply from those of the initial material. Nanoclusters are also produced when other methods of plastic yield are employed.

5. Matrix clusters

Methods for the preparation of nanoclusters which make use of various inorganic and organic matrices and matrix isolation constitute a self-dependent group, although they can include some features of the gas-phase, solid-state and other methods. The point is that nanoclusters prepared using matrix methods differ from those formed, for example, in solid-state chemical reactions because they are isolated from one another by the matrix and, therefore, heating of the whole nanosystem does not result in an increase in the cluster size due to sintering. The originality of this approach is that it provides the possibility of restricting size dispersion of the nanoclusters and of changing the intercluster interactions in a required manner. Thus microencapsulation of nanoclusters in inert gases at low temperatures is used to prepare gas-phase metal clusters.

Clusters and cluster systems are often prepared by chemical reactions in solution followed by precipitation of the resulting compounds in the pores of a solid. Nanoclusters and nanosystems can also be prepared by impregnating porous matrices with solutions and performing chemical reactions in the pore acting as a micro- or a nanoreactor. This procedure is used, for example, to prepare metal and metal oxide clusters in zeolites, the cluster size being determined by the size of zeolite cells (1–2 nm). In this case, aluminosilicates promote the formation of assembled cluster structures.

Broad opportunities for the variation of the size and composition of clusters are provided by using inorganic and organic sorbents (for example, silica gels and aluminogels, ion exchange resins and polysorbs).[3] In this case, the change in the cluster size and cluster organisation takes place due to both the change in the pore size and the variation of the surface hydrophilicity (or hydrophobicity), the concentration of initial components, temperature, *etc*.

6. Nanofilms

When nanoclusters are formed in nanofilms, the mechanism of nucleation and growth differs from those in the formation of solid-state clusters because the synthesis is related to the surface chemistry (the formation of two-dimensional structures). Epitaxial nanofilms on an oriented crystalline surface are prepared using laser vaporisation and molecular beams.[17]

In recent years, the CVD method has started to be widely used to apply nanocluster nanofilms on the surface.[24] According to this

† Procedures for the synthesis of ultradisperse particles based on the sol–gel method and microemulsion systems are described in the recent review by B D Summ, N I Ivanova *Usp. Khim.* **69** 995 (2000). [*Russ. Chem. Rev.* **69** 911 (2000)]

method, the initial substances are first evaporated and then transferred through the gas phase and deposited in a required proportion onto a chosen substrate.

To produce molecular layers with controlled composition and thickness, the method of molecular layering is used, the essence of which is to induce surface chemical reactions separated in space and time.[25–27] Nanofilms containing one to ten monolayers have been prepared in this way.

The technology of synthesis of Langmuir–Blodgett films, which has been developed in recent years, makes it possible to introduce metal ions and metal complexes into the surfactant film being formed on the surface of water and thus to prepare nanoclusters. The use of this approach results in the formation of Langmuir–Blodgett films with an ordered monolayer of clusters, which can then be applied onto a solid substrate using a special technique. This procedure can be repeated thus forming multilayer films and superstructures.[28]

III. Properties of isolated nanoclusters

Clusters occupy an intermediate position between separate molecules and macro-solids. Therefore, the properties of a single isolated cluster can be compared both with the properties of separate atoms or molecules and with the properties of a bulk solid.

The notion 'isolated cluster' is rather abstract because it is virtually impossible to obtain a cluster not interacting with the environment. In addition, when investigating the properties of isolated clusters, one should take into account their interaction with the measuring instrument, which can change the properties of the cluster during the measurements. This is especially true for contact techniques of measurement (for example, tunnelling microscopy). However, these changes are relatively insignificant and we shall not consider this type of interaction in this review. Since molecular metal clusters, van der Waals noble gas and water clusters, gas-phase metal clusters, and fullerenes are subject only to weak intercluster interactions, they can conventionally be considered as isolated clusters.

In this Section, we shall consider the structure, the atomic dynamics, and the electronic, optical, and magnetic properties of isolated clusters.

1. Molecular ligand clusters in solutions

Molecular clusters are important objects of coordination, inorganic and structural chemistry. The unusual features of their structures and properties caused by the presence of a core of metal atoms have stimulated the development of a separate branch of science — cluster chemistry — possessing its own calculation, synthesis and investigation methods. Since the number of metal atoms forming the cluster core can vary from a few to hundreds or even thousands, a specific approach to the choice of the investigation method for each particular cluster is required. The methods range from those designed for separate atoms (for example, atomic molecular spectroscopy), used in the case of small clusters, to those developed to study the collective and dynamic properties, which are used for big clusters.

In this Section we consider specific quantum-size properties of molecular clusters, which display themselves when the size of the metal core of the cluster ranges from 1 to 3 nm. The properties of bigger clusters (3 to 20 nm) are discussed in the Section devoted to colloid clusters.

The core of a molecular cluster is formed in accordance with the close-packing pattern of metal atoms, similarly to the bulk metal.[29,30] The number of metal atoms in a close-packed core constructed as a regular 12-vertex polyhedron (cubooctahedron, icosahedron, or anticubooctahedron) can be found from the formula

$$N = \frac{1}{3}(10n^3 + 15n^2 + 11n + 3),$$

where n is the number of layers around the central atom. Thus, the smallest close-packed core contains 13 atoms: one central atom and 12 first-layer atoms. This gives a set of 'magic' numbers $N = 13, 55, 147, 309, 561, 923, 1415, 2057, 2869$, *etc*. corresponding to the most stable cores of metal clusters. Indeed, the following clusters are known: 13-atomic (single-layer) clusters $[Au_{13}(diphos)_6](NO_3)_4$ (diphos is $PPh_2CH_2CH_2PPh_2$)[31] and $[Rh_{13}(CO)_{24}H_3]^{2-}$ (see Ref. 32) with icosahedral and cuboocta-hedral cores, respectively, 55-atomic (two-layer) clusters $Au_{55}(PPh_3)_{12}Cl_6$,[33,34] $Rh_{55}(PPh_3)_{12}Cl_6$, $Pt_{55}(AsBu^t_3)_{12}$,[35,36] $Ru_{55}(PBu^t_3)_{12}Cl_{20}$ (see Ref. 37) with cubooctahedral cores, a 309-atomic (four-layer) cluster $Pt_{309}Phen'_{36}O_{30\pm10}$ [Phen′ is the sodium salt of 4,7-bis(phenylsulfate)-1,10-phenanthroline] with a cubooctahedral core,[38] a 561-atomic (five-layer) cluster $Pd_{561}Phen_{60}(OAc)_{180}$ (Phen is phenanthroline) with an icosahedral core,[39,40] 1415-atomic (seven-layer) cluster $Pd_{1415}Phen_{60}O_{\sim1100}$ and a 2057-atomic (eight-layer) $Pd_{2057}Phen_{84}O_{\sim1600}$ cluster.[10] It should be noted that, in addition to stable clusters, with 'magic' numbers of metal atoms, intermediate clusters with other numbers of atoms are also inevitably formed.

For the Au_{55} and Pd_{561} clusters, electrical conductivity, heat capacity, and magnetic susceptibility were measured. These characteristics proved to differ substantially from those of the bulk metal. The electrons of the metal atoms forming the cluster core are not delocalised, unlike the collectivised electrons in a bulk metal sample; instead, they form discrete energy levels differing from molecular orbitals. On passing from the bulk metal to a cluster and then to a molecule, delocalised *s*- and *d*-electrons forming the conduction band in the bulk metal are replaced by non-delocalised electrons, which form discrete energy levels in a cluster, and then by molecular orbitals.

The appearance of discrete electron bands in metal clusters with a size ranging from 1 to 4 nm should be accompanied by the appearance of single-electron transitions. An efficient technique for observing effects of this type is tunnelling microscopy (TM), which provides voltammetric characteristics when the tip of the microscope is fixed on a molecular cluster. Upon transition from the cluster to the tip of the tunnelling microscope, an electron overcomes a Coulomb barrier the height of which is equal to the electrostatic energy $\Delta E = e^2/2C$ (C is the nanocluster capacity proportional to its size). For small clusters, the electrostatic energy of an electron becomes greater than its kinetic energy kT; therefore, steps corresponding to the single-electron transition appear on the voltammetric curve $U = f(I)$. Thus, a decrease in the cluster size and in the temperature of the single-electron transition results in violation of the linear dependence $U = f(I)$, typical of the bulk metal. A stepwise dependence has been observed for the $Au_{55}(PPh_3)_{12}Cl_6$ molecular cluster with a size of 1.4 nm even at room temperature.[41] As the temperature further decreases to 90 K, several Coulomb steps appear on the voltammetric curve (Fig. 1 *a*,*b*).

Quantum-size effects were observed in the measurements of the magnetic susceptibility and the heat capacity of the molecular clusters $Pd_{561}Phen_{60}(OAc)_{180}$, $Pd_{561}Phen_{36}O_{200}$, $Pd_{1415}Phen_{54}$. O_{1000} and $Pd_{2057}Phen_{78}O_{1600}$ (see Ref. 42) at ultralow temperatures. Bulk Pd exhibits Pauli paramagnetism, which is provided by electrons with an energy E_F near the Fermi energy; therefore, its magnetic susceptibility barely depends on the temperature down to the liquid-helium temperature.

Calculations show that on passing from Pd_{2057} to Pd_{561}, *i.e*., as the size of Pd clusters diminishes, the density of states near E_F decreases, resulting in a change in the magnetic susceptibility. The calculation predicts that upon a decrease in the temperature ($T \to 0$), the susceptibility should either drop to zero or increase to infinity for even and odd numbers of electrons, respectively. Since the study was performed for clusters containing an odd number of electrons, the magnetic susceptibility was actually found to increase. The increment is substantial for Pd_{561} (with a maximum at $T < 2$ K) and slight for Pd_{1415}. In the case of Pd_{2057}, virtually no temperature variation is observed, which is typical of

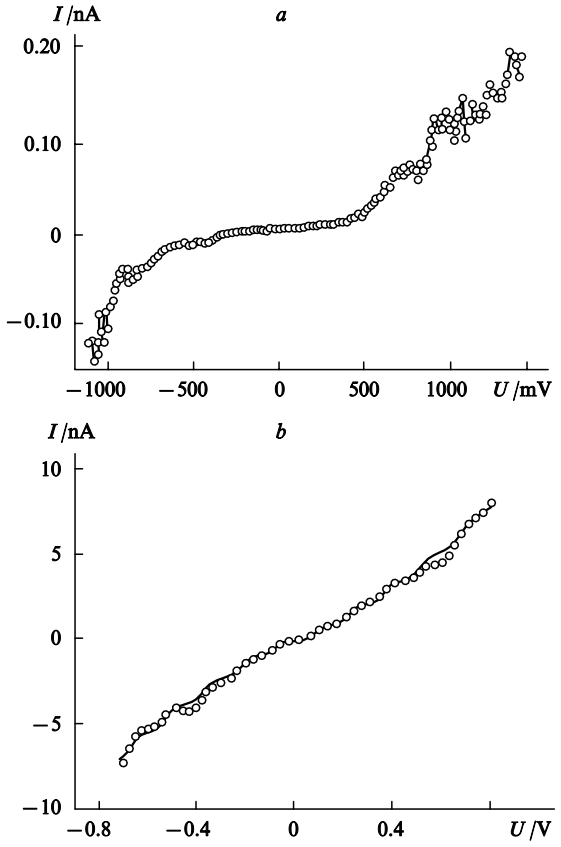

Figure 1. Voltammetric characteristics of the $Au_{55}(PPh_3)_{12}Cl_6$ cluster at $T = 300$ (*a*) and 90 K (*b*).[41]

bulk Pd, although, as noted above, the values of magnetic susceptibility found for Pd_{2057} are much lower than those for bulk Pd.

Heat capacity measurements for giant Pd molecular clusters have revealed equally interesting features. Bulk solids are characterised by a linear temperature dependence of electron heat capacity, $C \sim T$. The transition from the bulk solid to nanoclusters gives rise to quantum-size effects,[42] which are manifested as a deviation of the $C = f(T)$ plot from linearity following a decrease in the cluster size. Thus the greatest deviation from the linear dependence is observed for Pd_{561}. With a correction for the ligand dependence ($C \sim T^3$), a $C \sim T^2$ dependence was obtained for nanoclusters at ultralow temperatures $T < 1$ K. The heat capacity of a cluster is known to be $C = kT/\delta$ (δ is the mean distance between energy levels, $\delta = E_F/N$, where N is the number of electrons in the cluster). Calculations of the δ/k value carried out for Pd_{561}, Pd_{1415} and Pd_{2057}, and for the colloid Pd cluster with a size of $\sim$15 nm, gave values of 12, 4.5, 3.0 and 0.06 K, respectively. Thus, the unusual $C \sim T^2$ dependence in the region of $T < 1$ K indicates that quantum-size effects are involved. Note that the $C \sim T^2$ dependence is also typical of amorphous solids and is attributable to tunnelling effects.[43]

Quantum-size effects have also been observed in non-metal and metal oxide and chalcogenide ligand clusters.[44–46] The internal metallic core in the molecular cluster $[Mn_{12}(CH_3COO)_{16}.(H_2O)_4O_{12}]\cdot 2CH_3COOH\cdot 4H_2O$ (Mn^*_{12}) has a tetragonal two-layer structure: the Mn^{4+} atoms of the inner cubane structure of Mn_4O_4 have total spin $S = 3/2$, and the eight outer Mn^{3+} atoms have spin $S = 2$.[45] The exchange interactions within the cluster stabilise the ferromagnetic ground state with a collective spin $S = 10$ (parallel and antiparallel alignment of the individual spins of Mn^{4+} and Mn^{3+}). A single crystal constructed from Mn^*_{12} clusters was placed in an external magnetic field ($H = 5$ T) and its magnetisation at $T = 1.55 - 3.2$ K was measured.[45]

The Mn^*_{12} cluster with the spin $S = 10$ forms energy levels in an external magnetic field. Electronic transitions between these levels can be either induced by thermal fluctuations or occur *via* quantum tunnelling. A thermally activated transition can be due to superparamagnetism (superparamagnetic relaxation), when the total magnetic moment of the cluster fluctuates as a whole. In this case, the magnetisation curves vary smoothly. For a single crystal constructed from Mn^*_{12} clusters, unusual 'stepwise' hysteresis curves (Fig. 2) resembling single-electron conductivity curves have been obtained. A magnetisation curve has steps in the case where the quantum mechanism of tunnelling is involved. This effect takes place when the magnetic field strength is such that the energy levels coincide. At these H values, the relaxation by a tunnelling mechanism from one spin state to another is accelerated compared to the superparamagnetic relaxation. As a consequence, at low temperatures, discontinuous changes in the magnetisation by $H_{n+1} - H_n = \Delta H = 0.44$ T are observed in the region of H from 0 to 2.64 T, in accordance with quantisation of the spin levels in a magnetic field.

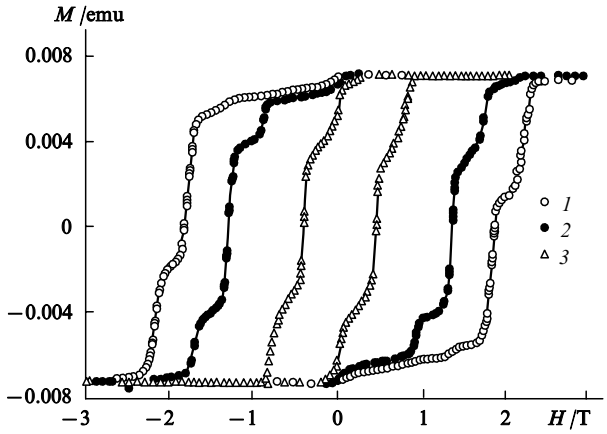

Figure 2. Magnetisation curves for a single crystal of the Mn^*_{12} acetate cluster at different temperatures.[45]
Temperature /K: 1.77 (*1*), 2.10 (*2*) and 2.64 (*3*).

Semiconductor molecular clusters also exhibit a number of remarkable properties. Since semiconductor clusters acquire discrete energy levels in the valence band and in the conduction band, and the energy gap between them increases (with respect to that in the bulk sample), the optical transitions between these levels are characterised by greater energies. The smaller the cluster, the greater the energy of optical transitions. This is the so-called blue shift of the radiation frequency observed upon a decrease in the cluster size. A similar effect has been observed for the $Cd_{32}S_{17}(SC_6H_5)_{36}(DMF)_4$ clusters with a semiconductor CdS nucleus having a size of $\sim$1.5 nm.[46] The increase in the radiation frequency is accompanied by an increase in the oscillator strength, which is now concentrated on several transitions.

A decrease in the cluster size also restricts the wavelength of carriers in semiconductors. The appearance of discrete levels in the clusters characterises them as quantum dots with zero dimensionality.

Examples of semiconductor clusters with specific optical properties will be considered in the Section devoted to colloid clusters.

Thus, the molecular ligand clusters of metals and metal oxides and chalcogenides possessing quantum-size properties can underlie the design of materials with new electronic, magnetic, and optical properties.

2. Gaseous ligand-free clusters

Ligand-free clusters are devoid of a ligand shell influencing the properties of the surface atoms of the core; in this respect, they

differ from molecular clusters. Ligand-free clusters have been obtained for almost each element of the Periodic System. Several groups of ligand-free clusters possessing characteristic properties can be distinguished: alkali metal clusters, carbon clusters, rare gas clusters and van der Waals clusters.

a. Alkali metal clusters

The properties of alkali metal clusters are well described in terms of the jellium model or, what is the same, the drop shell model. According to this model, a cluster is considered as two subsystems: positively charged ions forming the core and delocalised *s*-electrons, which can form shells similar to the electron shells in atoms. The electron shell in an atom is occupied by the numbers of electrons $n_e = 2, 8, 18, 20, 34, 40$, *etc*., which corresponds to the filling of 1*s*, 1*p*, 1*d*, 2*s*, 1*f*, 2*p*, *etc*. shells.[47,48] The number of metal atoms in a cluster that corresponds to the number of electrons in the filled shells is called the 'magic' number. The 'electronic magic numbers'‡ correspond to the most stable electronic configurations of clusters with filled shells. They were discovered experimentally during measurements of ionisation potentials and electron affinities.[49]

Calculations carried out in terms of the jellium model made it possible to explain the shell structure of the clusters. The classical expression for the electron work function in the jellium model (drop model) of the cluster[50]

$$W(R,z) = W_\infty + \frac{(z + 3/8)e^2}{R}, \qquad (1)$$

[W_∞ is the electron work function for the bulk metal, z is the charge of the cluster (spherical), and R is the cluster radius] predicts higher ionisation potentials for clusters compared to bulk solids. In the case of nanoclusters, a stepwise dependence of the ionisation potential on the number of atoms is observed (the steps occur at points corresponding to 'magic' numbers). The stability of charged clusters is determined by the dissociation energy. Thus the dissociation energies for Na_n^+ and K_n^+ pass through maxima at $n = 9$ and 21, which corresponds to filled shells containing 8 and 20 electrons.[51,52]

The quantum-size effects manifest themselves in the optical properties of clusters, which is expressed as the appearance of a discrete structure and broadening of spectral lines.[53] An interesting effect is giant resonance associated with oscillations and polarisability of the cluster electrons. Similar giant resonance effects have also been observed for atomic nuclei, in which they are related to the collective motion of protons relative to neutrons. The optical absorption in a cluster is calculated using the Mie equation,[54] derived for a spherical cluster. According to Mie, light absorption cross-section (σ) has a resonance form

$$\sigma = \frac{ne^2}{mc\Gamma\varepsilon_0} \frac{\omega^2}{\omega^2 - \omega_0^2 + (\omega\Gamma)^2}, \qquad (2)$$

where n is the number of electrons, e and m is the charge and the mass of an electron, c is the velocity of sound, Γ is the damping coefficient for the oscillation of electrons in an electromagnetic field (line width), ε_0 is polarisability in vacuum, ω is the oscillation frequency, and $\omega_0 = \omega_p/\sqrt{3}$ is the resonance oscillation frequency constituting a part of the plasmon frequency (ω_p) of electron oscillations in the bulk metal ($\omega_p = e^2/4\pi\varepsilon_0 V$, $V = 4/3\pi r_s^3$, r_s is the Wigner – Seitz radius).

Calculation of the cluster polarisability in terms of the jellium model predicts that the cluster polarisability $\alpha = (ne^2/m\varepsilon_0)\omega_0^2$ should be greater than that of a bulk sample, which is actually observed for Na and K clusters with $n \leqslant 40$.[55] Ellipsoidal clusters have two resonance frequencies, longitudinal and transverse ones; this makes it possible to estimate the cluster shape. Figure 3 shows

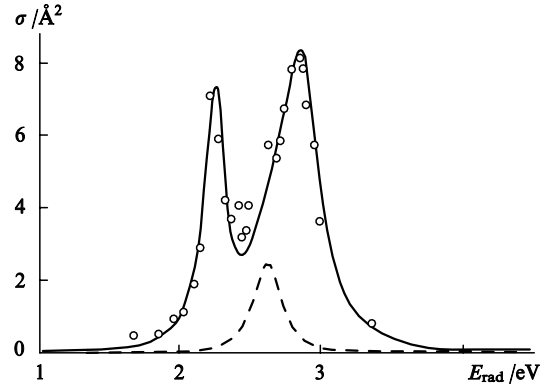

Figure 3. Giant resonance for ellipsoidal Na_{11}^+ clusters.[56] The lower-energy peak corresponds to vibrations along the ellipsoid axis and the higher-energy peak corresponds to perpendicular vibrations. The dashed line corresponds to spherical Na_9^+ clusters.

the resonance dependences of absorption cross-sections on the radiation energy for the ellipsoidal Na_{11}^+ and spherical Na_9^+ clusters.[56] The two resonance peaks on the curve for the ellipsoidal Na_{11}^+ cluster imply that the oscillation frequencies along (low energies) and across (high energies) the cluster axis are different.

A shell electronic structure was also found for noble metal clusters. Although the valence bands in Cu and Ag clusters are almost twice as wide as those in alkali metal clusters, their electronic structures are similar. Due to stronger bonding of Ag atoms, the shell effects are more pronounced in the Ag cluster. The shell structure of Ag_n^- clusters ($n = 3$ to 21) was studied by photoelectron spectroscopy.[57] The greatest Ag – Ag energy was found for the Ag_{17}^- cluster, which corresponds to a filled 18-electron shell. Quantum-mechanical calculations carried out in the same study demonstrated the legitimacy of using the shell model for virtually any Ag_n^- cluster, except for Ag_7^- and Ag_9^-, which might be due to the shape of these anions.

b. Transition metal clusters

In this Section, the attention is focused on the stability and reactivity of transition metal clusters and their magnetic properties. It has been noted previously that the stability and reactivity of clusters are due to two series of 'magic' numbers, one of them being related to the geometric factor (close packing), as in ligand metal clusters, and the other being related to the electronic shell structure, as in alkali metal clusters. The properties of most ligand-free clusters of transition metals are determined by both electronic and geometric factors. In addition, for ligand-free transition metal clusters, the ability of metal atoms to exist in different oxidation states becomes especially significant; therefore, the properties of these clusters cannot be characterised by the simple shell model, as were the properties of alkali metal clusters. Exceptions are provided by Cu, Ag and Au atoms in which the *d* shell is filled and compressed, so that only *s* electrons are involved in binding.

One of the important characteristics of metal nanoclusters is ionisation energy. According to the drop model, it should increase with a decrease in the cluster size according to the $1/R$ law. However, the ionisation energy of Fe_n, Co_n and Nb_n clusters calculated using this model proved to be markedly lower than the value obtained in experiments. In addition, for small clusters with $n < 25$, the ionisation energy was shown to vary irregularly with size: the ionisation energies for clusters with even numbers of atoms are greater than those for odd numbers of atoms. The deviation from the drop model points to a difference between the electron *d* bands formed during the variation of n (even or odd).[58,59]

Let us follow the variation of the properties of a cluster depending on its size and structure taking niobium clusters as

‡ Of course, the 'electronic magic numbers' do not coincide with the Kini 'magic' numbers[29] (see above).

examples. The reactivity of Nb_n clusters was studied in the reactions with N_2 and D_2.[60] Among niobium clusters with $n < 21$, Nb_8, Nb_{10} and Nb_{16} were the most stable, which correlates with minima of the ionisation potential. It was found that some Nb clusters can exist as several geometric isomers differing in reactivity.[61] The geometric structure influences most substantially the reactivity of Nb_n clusters with $n = 3-35$.[62] However, the reactivity of Nb_n clusters with $n = 2-20$ is still governed by the electronic structure. Thus the photoelectron spectra of Nb_n^- clusters ($n = 6-17$) with even numbers of electrons differ from the spectra of Nb_n^- clusters with odd numbers of electrons,[63] which is related to the occupation of the electron shells. The highest transition energies were found for Nb_8, Nb_{10} and Nb_{16}.

A number of ligand-free copper sulfide clusters $[Cu_nS_m]^-$ with $n = 6-45$ and $m = 4-23$ have been prepared by laser vaporisation.[64] Different reactivities of $[Cu_{10}S_6]^-$ and $[Cu_6S_4]^-$ were noted. The former cluster is inert in gas-phase reactions with RSH (R = H, Pr, Ph), while the latter reacts with them to give addition products.[64]

The stability of the clusters was also estimated from their trend to decompose, undergo fission or store energy. The Coulomb fission (induced by repulsion of two charged clusters) and vaporisation of the Sb_n^+ and Sb_n^{2+} clusters ($5 \leqslant n \leqslant 80$) have been studied.[65] The results were interpreted using two models — the drop model taking into account vaporisation of fragments and the Coulomb model. Decomposition of a cluster depended on its charge. For Sb_n^+ clusters with $5 \leqslant n \leqslant 8$, decomposition with vaporisation of neutral dimers was observed, while for Sb_n^+ clusters with $n \geqslant 8$, decomposition with vaporisation of Sb_4 took place. The fragmentation of Sb_n^{2+} clusters followed a different route: for Sb_n^{2+} with $26 \leqslant n \leqslant 36$, asymmetric fission with evolution of Sb_5^+ and Sb_7^+ occurred, whereas for Sb_n^{2+} with $n > 40$, the fission was more symmetric ($Sb_n^{2+} \rightarrow Sb_{n-p}^+ + Sb_p^+$), the masses of the fragments differing by less than 30%. The rate of fission of Sb_n^{2+} clusters with $n < 36$ depends on the type of decomposition and varies according to the $1/n$ pattern, which is in line with the drop model. For larger clusters with $n > 40$, the decrease in the fission rate no longer obeys the $1/n$ law, indicating a deviation from the drop model. In this case, fission occurs simultaneously with vaporisation of Sb_4 fragments.

The variation of the magnetic moment of a substance on passing from an atom to a solid has been followed in relation to gas-phase ligand-free clusters of transition and rare earth metals. The magnetic moment of an isolated transition metal atom differs from the value found for a bulk sample. This is due to the facts that the bulk metal has a *d* conduction band and that the *d* electrons in delocalised states undergo exchange interactions known as itinerant exchange interactions. Thus the magnetic moment of an iron atom in mono- and binuclear iron compounds amounts to $6\,\mu_B$, while the magnetic moment of an iron atom in a bulk ferromagnet is $2.2\,\mu_B$. The magnetic moments of metal atoms and the magnetic properties of a cluster depend on the number of metal atoms in the cluster and vary over a broad range. This may be due to the possible rearrangement of the crystal lattice consisting of clusters, which does not coincide with the crystal lattice of the bulk sample. The determination of magnetic properties during cluster formation can occur in accordance with either the geometric close-packing model, as in the case of molecular ligand clusters with the 'magic' numbers 13, 55, 147, 304, 561, *etc.*, or the structure of the electron shell, as in the case of alkali metal clusters.

For Fe, Co and Ni clusters, the magnetic moments of the metal atoms in the core were found to increase with respect to the values for the same atoms in the bulk sample.[66,67] Thus the Fe magnetic moment increased to $3.2\,\mu_B$; this was accompanied by fluctuations of the magnetic moment depending on the number of metal atoms in the cluster (Fig. 4*a*), which may be due to the geometric filling of close-packed layers. The value $\mu = 2.2\,\mu_B$, typical of Fe atoms in a bulk sample, is attained when the number of atoms (n) in the cluster has increased to 500. For Ni atoms, the lowest magnetic moments were found in the Ni_{13} and Ni_{55} clusters, which corresponds to the 'magic' numbers of close packing.[68] However, when measuring the magnetic properties, the electronic properties of the cluster and the itinerant magnetism should be taken into account. A decrease in the cluster size not only increases the magnetic moments of the atoms forming it but also gives rise to a magnetic moment of the cluster as a whole, which was observed for clusters of non-magnetic Rh (Fig. 4*b*).[69]

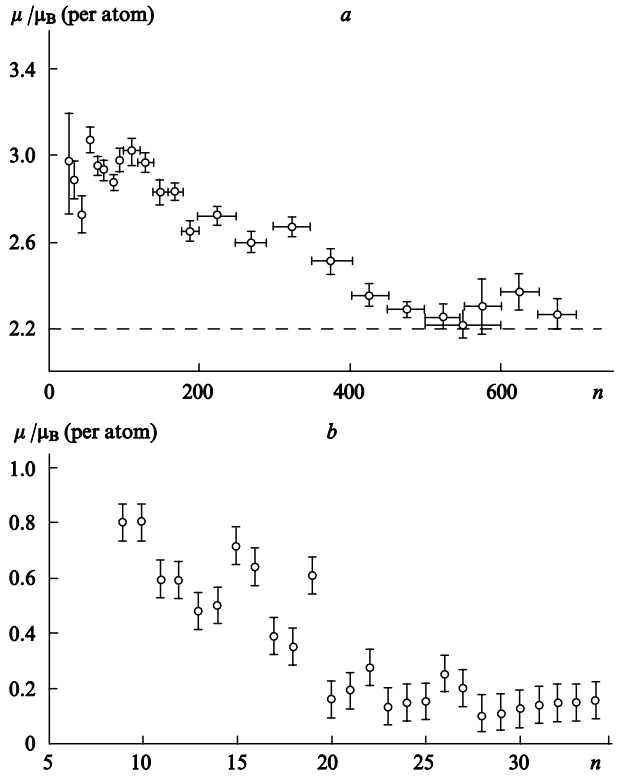

Figure 4. Magnetic moments (per atom) for Fe (*a*)[66] and Rh (*b*)[69] clusters of various sizes. The dashed line corresponds to the magnetic moment $\mu = 2.2\,\mu_B$ of bulk Fe; n is the number of metal atoms in the cluster.

c. Carbon clusters

Carbon atoms readily form clusters. They are usually prepared by laser vaporisation of a graphite target. Their mass distribution is normally studied using mass spectrometry. The mass spectrum of these species has a bimodal divergence. Among small carbon clusters with $n < 24$, clusters with odd 'magic' numbers (3, 7, 11, 19, 23) of carbon atoms were the most stable, while among big clusters (fullerenes), the most stable species are those with even numbers of carbon atoms.

Small carbon clusters display enhanced stabilities when $n = 7$, 11, 15, 19 and 23, which is related to 'magic' numbers corresponding to close packing of atoms.[70,71] The fragmentation of carbon clusters is accompanied by detachment of C_3 and C_5 fragments, pointing to high stability of these fragments. The reasons for the formation of stable carbon clusters include easy *sp*-hybridisation of carbon atoms and high strength of π-bonds.

Quantum-mechanical calculations for the molecular orbitals in carbon clusters indicate that clusters with $n \leqslant 10$ tend to have a linear structure. As the number of carbon atoms increases, the linear structure is replaced by a ring structure.[72] Thus both chain and ring species were found for the C_7^+ clusters.[70] However, the ring structure is subject to additional strain, which increases the total energy of the cluster; therefore, it is more favourable for big clusters. For C_{20}, a three-dimensional structure also becomes possible. Clusters with mixed structures were also detected. Small positively charged carbon clusters react with various diatomic molecules in the gas phase,[70,73] and also with small

hydrocarbon molecules such as C_2H_2 ($C_n^+ + C_2H_2 \rightarrow C_{n+2}H_2$)[74] and HCN ($C_n^+ + HCN \rightarrow HC_nCN^+$).[75]

The first representatives of big carbon clusters, C_{60} and C_{70} fullerenes, were discovered in 1985 based on the mass spectra;[15] as soon as 1990, the method of fullerene preparation by vaporisation of graphite electrodes in an electric arc was developed.[16] This technique was used to prepare diverse fullerenes, which triggered extensive studies on their physical and chemical properties.

The best studied fullerene is C_{60}, shaped like a truncated icosahedron in which the pentagonal cells are coupled with hexagonal ones. This fullerene is the most symmetrical among all the fullerenes prepared. The unique feature of C_{60} is that it is the only structure in which all the carbon atoms in the five- and six-membered rings are equivalent (*i.e.*, the strain is uniformly distributed). In addition, in this fullerene, the five-membered rings are all separated from one another.

How does the so well-organised and symmetrical molecule arise? Calculations using simple kinetic models[76] describing the nucleation and growth of carbon clusters from the carbon atoms produced upon laser-induced vaporisation of graphite electrodes showed that the formation of a linear chain is energetically the most favourable. These chains interact with one another in a plasma giving rise to aggregates of 20–30 carbon atoms. During aggregation, aromatic rings or graphene layers are formed as a result of fluctuations. If the density of carbon atoms is rather high, the rings become twisted to give carbon black particles. There exists, however, a large probability that the opposite edges of the rings would meet; this yields fullerene.

The symmetrical closed structure of C_{60} and C_{70} fullerenes produces an impression that they should have low reactivity. However, a tremendous number of fullerene compounds are known. Various atoms and molecules can be attached to the carbon atoms of the fullerene cage (exohedral fullerenes); foreign atoms and molecules can be introduced inside the fullerene cage (endohedral fullerenes); the carbon atoms in the cage can be replaced by other atoms (substitution fullerenes).

The following substitution fullerenes are known: $C_{59}B$, $C_{69}B$,[77] $C_{59}N$ and $(C_{59}N)_2$.[78] The cage can also incorporate silicon and niobium atoms.[79–82] Fullerenes containing transition metal atoms $C_{59}M$ and $C_{69}M$ (M = Fe, Co, Ni, Rh, Ir) have been synthesised.[83] This was done by mixing metal and fullerene vapours. The formation of $C_{59}M$ and $C_{69}M$ fullerenes was detected in the mass spectra after photoionisation of the clusters. Substitution fullerenes have also been obtained by photoionisation of the exohedral fullerenes $C_{60}M_x$ and $C_{70}M_x$ ($x = 0–30$) with metal atoms on the surface of the cluster. It was found that, after crossing the photoionisation threshold, the metal atoms passed from the cluster surface (exohedral position) into the fullerene cage (substitution fullerenes).

Among exohedral fullerenes, fluorinated fullerenes, $C_{60}F_{60}$, are the most interesting.[84] These clusters and materials based on them are suggested to act as 'molecular ball bearings' and superlubricants. The $C_{60}M_x$ and $C_{70}M_x$ fullerenes with exohedrally attached alkali metal atoms have found extensive use. Of considerable interest are not only the structure and reactivity of these compounds but also the high-temperature superconductivity arising in them. Thus C_{60} fullerenes with a Cs/Rb component ($T_c = 33$ K) and with a Rb/Tl component ($T_c = 43$ K) have been prepared.[85] It is expected that fullerenes with an I_2 component would have $T_c = 70$ K.

The first endohedral fullerene La@C_{60} has been synthesised simultaneously with the discovery of fullerenes themselves.[86] Endohedral fullerenes can be prepared either during the fullerene synthesis by vaporisation of graphite electrodes containing a particular metal or by introducing atoms of inert gases inside the fullerene cage at high pressures and temperatures.[87,88] The size of the fullerene inner cavity increases with an increase in the number of carbon atoms; a larger fullerene cavity can accommodate several metal atoms. For example, evidence for the insertion of the La_3 cluster inside C_n fullerenes with $n \geqslant 88$ has been obtained.[89] Study of the photofragmentation of fullerenes containing K and Cs atoms showed that the minimum C_n clusters whose cavity can accommodate K and Cs atoms are C_{44} and C_{48}, respectively.[88,90]

d. Van der Waals clusters of inert gases and other small molecules

The properties of clusters formed by atoms of inert gases are dictated by weak van der Waals interactions. The stability of these clusters, like that of molecular ligand metal clusters, is associated with the 'magic' numbers characterising the geometric close packing. Clusters of inert gases with $n = 3$ are shaped like triangles, those with $n = 4$ are tetrahedra, the clusters with $n = 7$ are pentagonal pyramids, and starting with $n = 13$, the icosahedral geometry appears. The next icosahedra are formed for $n = 55$, 147, 309, 561, *etc.*, that is, for n values equal to the 'magic' numbers. For clusters with $n > 800$, a face-centered cubic packing becomes favourable.[91,92]

For rare gas clusters, effects related to photoabsorption, fluorescence, photoionisation and photofragmentation thresholds, as well as to the formation and relaxation of excitons have been studied. Fluorescence was excited by synchroton radiation.

The exciton transitions in krypton clusters have been studied. Various Kr_n clusters, atomic Kr, and a bulk sample were used (Fig. 5).[93] The Kr atomic spectrum (Fig. 5 *a*) contains two narrow bands caused by the $4p^6 \rightarrow 4p^5 5s$ transition (spin–orbit splitting). The spectra of Kr_n clusters (Fig. 5 *b–e*) exhibit lines corresponding to exciton transitions. Excitation of an electron in the Kr atom gives rise to a positive charge (hole). The electron and the hole form a series of hydrogen-like states, which are manifested in the fluorescence spectra as broadening, displacement, and additional lines.

Apart from the differences between the spectra of atoms, clusters, and bulk materials, differences between the spectra of atoms located on the surface and inside the cluster are also observed. For example, the spectra of Xe_mAr_n clusters ($n = 1000$) were found to contain lines corresponding to the Xe atoms located on the surface and inside the Ar_n clusters and also incorporated in the cage made of Ar atoms.[94]

In charged rare gas clusters, the charge is not delocalised over the whole cluster, as, for example, in Na_n^+, but is located on a small structural fragment (dimer, trimer, or tetramer), the rest of the cluster remaining neutral, as, for example, in $(Ar_x^+)Ar_{n-x}$ ($x = 3$, 4).[95]

Van der Waals clusters formed by H_2O, CO_2, SF_6 and C_6H_6 molecules able to form weak van der Waals polarisation contacts and hydrogen bonds are also known. For example, for the $(CO_2)_n$, $(SF_6)_n$ and $(C_6H_6)_n$ clusters, the van der Waals bonding energy is lower than 0.1 eV; for $(HF)_n$, $(H_2O)_n$ and $(CH_3OH)_3$, this value is lower than 0.3 eV.[96] Clusters with relatively small numbers of molecules, $n < 5$, can have ring structures. Small clusters with $5 < n \leqslant 20$ are non-symmetrical because side chains are attached to the ring structure, the whole cluster looking like a fragment of an amorphous or liquid structure. This trend is retained until the cluster size reaches $n = 20$. Then switching to ordered structures typical of big clusters takes place. The structures of molecular clusters are characterised by fast dynamic transitions between various conformations. The changes in the widths and positions of bands in the IR spectra of these clusters attest to the change in the number of molecules forming the clusters.[97]

Of special interest are water clusters that constitute liquid water and ice. They also participate in the formation of clouds and rains. The progress in laser spectroscopy and molecular dynamics made it possible to determine a number of properties of water clusters caused by their dynamic structure. Data on the geometric structure and hydrogen bond tunnelling in water tri-, tetra-, penta- and hexamers have been obtained.[98] Calculations[99,100] predict a planar structure for the tri-, tetra- and pentamers and a three-dimensional structure for the heptamers and larger clusters of water. The optimal configuration is characterised by the maximum number of hydrogen bonds and the minimum geo-

metric strain. IR-spectroscopic data confirm these assumptions.[98] Frequencies equal to 206, 304 and 658 cm^{-1} corresponding to the barriers to the rearrangement of the hydrogen bond configurations were found for three-, tetra- and pentamers, respectively. Water clusters are also formed upon hydration of gas-phase and colloid clusters, in particular, upon the hydration of macromolecules and proteins.

3. Colloid clusters

Colloid clusters are formed in solutions upon chemical reactions; their sizes range from 1 to 100 nm. They can exist in the liquid phase for long periods without being precipitated or coagulated, owing to weak intercluster interactions, charge repulsion and surface passivation. In terms of their behaviour towards the liquid medium, colloid clusters can be divided into two groups: lyophilic (hydrophilic) and lyophobic (hydrophobic) clusters.

Lyophilic clusters can sorb molecules from the environment and form strong solvation complexes with them. Clusters of this type are surrounded by a liquid shell, which is partially retained upon coagulation of separate clusters or on passing into a gel nanosystem. The most typical representatives of hydrophilic clusters are those formed by silicon and iron oxides and other metal oxides.

Lyophobic clusters do not adsorb solvent molecules on their surface. However, the surface can be modified by ions from solution, thus acquiring a positive or a negative charge. The giant Pd clusters the structure and the properties of which were considered in Section III.1 can be classified as colloid clusters in terms of the preparation method and the size (1.4–2.0 nm).

Normally, colloid clusters of metals are passivated with various ligands to prevent sticking together. Compounds suitable as these ligands are, for example, thiols, triphenylphosphine and its derivatives, phenanthroline.[101] Colloid clusters of semiconductors such as CdS, CdSe, CdTe, SnO_2, TiO_2, Fe_2O_3, MoS_2, HgS, InAs, GaP, GaAs, BiI_3, *etc* have been prepared.[7, 101, 102]

The weak intercluster interaction in solutions of colloid clusters does not preclude investigation of their individual properties. Among the optical properties peculiar to colloid clusters, the shift of the absorption frequency and the change in the oscillator strength following the change in the cluster size are the most impressive. As the size of the nanocluster decreases, the bands corresponding to the electronic excitation shift to higher energies and the oscillator strength is concentrated on several transitions. These effects are due to the replacement of the band spectrum corresponding to transitions between the conduction and valence bands in the bulk sample by the line spectrum of a cluster. It has also been reported that a decrease in the cluster size results in shorter lifetimes of excited states.

An expression for the calculation of the transition energy as $E \approx 1/R^2$ (R is the cluster radius) can be deduced from the quantum-size dependence $\Delta p \Delta x \geqslant h$ (p is the momentum, x is the coordinate) with the assumption that $\Delta x = R$. For semiconductors, the absorption and emission of energy are related to the formation and decomposition of the exciton (hydrogen-like bound state of a conduction electron and a hole); hence, the energy of exciton excitation is written in the form

$$E_n = \frac{h^2 n^2}{3R^2 m^*_{ef}},$$

where n is an integer, R is the cluster radius, m^*_{ef} is the effective mass of the exciton. Figure 6 shows the variation of the coefficient of light absorption by CdS colloid clusters with sizes from 6.4 to 48 nm *vs*. wavelength.[102] It can be seen that an increase in the

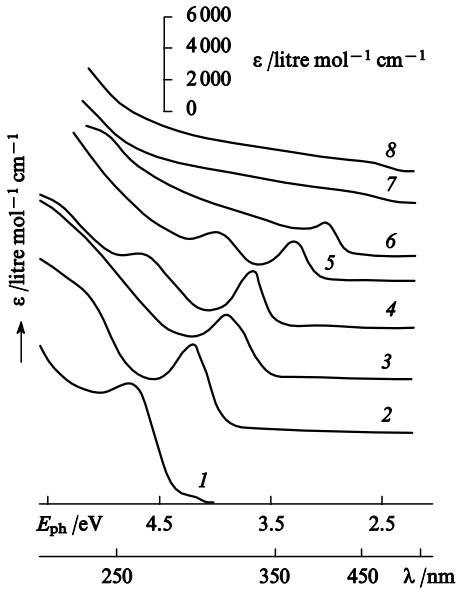

Figure 6. Absorption of light by CdS clusters *vs*. cluster size ('blue shift').[102]
Cluster size /nm: 6.4 (*1*), 7.2 (*2*), 8.0 (*3*), 9.3 (*4*), 11.6 (*5*), 19.4 (*6*), 28.0 (*7*), 48.0 (*8*). E_{ph} is the phonon energy.

cluster size entails a displacement of the absorption peak toward shorter wavelengths ('blue shift'). Similar shifts have also been observed for CdSe clusters.[103]

In the luminescence of nanoclusters caused by charge generation on exposure to light, a shift to shorter wavelengths following a decrease in the cluster size also takes place. Luminescence was observed for the ZnO, ZnS, CdS and CdSe clusters.[104–110] The change in the wavelength in the light absorption and emission spectra following a change in the cluster size can be employed in the design of frequency-tuned lasers on the basis of InAs and CdS.[111, 112]

The accumulation of the oscillator strength in several narrow bands or an increase in the oscillator strength normalised to the volume with a decrease in the cluster size should also be classified as quantum-size effects. This is caused by the increase in the overlap integral of the electron and hole wave functions. The oscillator strength corresponds to the radiation lifetime of the excited state at low temperature, while the oscillator strength normalised to the volume corresponds to the light absorption coefficient. For bulk semiconductors, the width of the exciton band is 0.15–0.3 eV; however, in clusters, the width of transitions decreases to 0.1–0.5 meV as a result of quantum restriction, which leads to the accumulation of the integral oscillator strength and to substantial growth of the exciton absorption of nanoclusters.[103, 113]

For clusters, the radiation lifetime of fluorescence was found to decrease with a decrease in the cluster size.[114] For instance, the lifetime of a Eu^{2+} tracer in clusters of alkali metal halides and chalcogenides[115, 116] and in ZnS[117] was found to decrease by almost five orders of magnitude with respect to the lifetime of Eu^{2+} in the bulk material. However, in another study,[118] no decrease in the lifetime was observed for Eu^{2+} in a 4-nm ZnS cluster. Thus, the data for the Eu^{2+} tracer lifetime in ZnS clusters are contradictory. This interesting phenomenon requires further studies and collection of experimental data both for the elucidation of the quantitative relationships between the cluster size and the optical characteristics and for the production of new optical materials.

IV. Cluster nanosystems and nanostructures

In this Section, we discuss the principles and approaches to the formation of nanosystems from clusters, from separate clusters and matrices, and from a bulk material. The properties of nanostructures to be considered include the intracluster, atomic, and intercluster dynamics, structural and mechanical properties, electrical conductivity, and optical and magnetic properties.

1. The formation of nanostructures. Assembly and self-assembly

Assembly and self-assembly of nanoclusters to nanostructures is an important problem the solution of which would contribute to the design of a new generation of materials with unique properties. The properties of materials can be changed in two ways: by changing the size of nanoclusters and by changing the intercluster interactions. The assembly of a nanostructure from nanoclusters follows the same laws as the formation of crystals from atoms; however, clusters differ substantially from atoms because they have a real surface and real cluster boundaries.§ Therefore, the formation of nanosystems from nanoclusters is accompanied by generation of numerous defects and stresses, resulting in fundamental changes in the properties of the nanosystem.

Nanostructures and nanosystems can be formed from clusters of any type. However, before proceeding to consideration of the processes of formation of nanosystems from solid-state and matrix clusters, it is necessary to consider the primary cluster nucleation processes because the properties and structure of these clusters depend markedly on their interaction with the matrices.

a. Nanosystems based on solid-state clusters

Let us consider the formation of nanosystems from solid-state nanoclusters using thermal decomposition of iron salts as an example. Decomposition of iron salts at a temperature above some critical (or threshold) value starts with the formation of a mobile active reaction medium in which nucleation of iron oxide nanoclusters occurs.[119] The process of cluster formation can be compared with seed formation in a confined space in a solution or in a melt (a cage or a pore). In this case, the role of this confinement can be played by diffusion restriction, which prevents the perturbation of the concentration of the mother medium caused by the change in the cluster size from migrating over the nucleation time (t_n) by a distance longer than $L \approx (Dt_n)^{1/2}$ (D is the diffusion coefficient). It is this distance that determines the size of the cage surrounding the cluster beyond which components of the mother medium cannot migrate. For a system of non-contacting clusters, the dependence of the Gibbs energy (ΔG_f) on the cluster radius (R) for one cluster is described by the formula ¶

$$\Delta G_f = 4\pi R^2\alpha - \frac{4}{3}\pi R^3\rho\Delta\mu, \tag{3}$$

where α is the density of the surface energy of the cluster (α = const), ρ is the substance density in the cluster (the number of atoms in 1 m^3), $\Delta\mu$ is the change in the chemical potential of the system caused by the transfer of a single iron atom from the medium to the cluster. If the cluster and the surrounding medium contain N atoms of any type of which n_0 are iron atoms (n iron atoms being contained in the cluster), then for $N \gg n_0 > n$

$$\Delta\mu = \Delta\mu^0 + \ln\frac{n_0 - n}{N}. \tag{4}$$

Here $\Delta\mu^0$ is the change in the standard chemical potential upon the transfer of one iron atom from the medium to the cluster structure expressed in kT units. At the initial stage, clusters do not contact one another. Since the volume of this cluster is $V_f = (4/3)\pi R^3$ and the surface area is $S_f = 4\pi R^2$, relation (3) can be written in the form

$$\Delta G_f = \alpha S_f - \left(\Delta\mu^0 + \ln\frac{n_0 - n}{N}\right)\rho V_f. \tag{5}$$

The function ΔG_f passes through a maximum at $R = R_{cr}$ (R_{cr} is the critical radius of seeds in the nucleation) and through a minimum at $R = R_{max}$ (R_{max} is the cluster radius corresponding to a stable equilibrium state of the system) (Fig. 7).

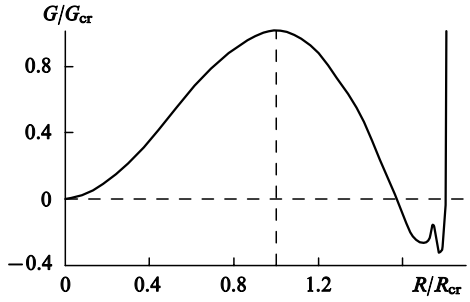

Figure 7. Change in the Gibbs energy G/G_{cr} upon nucleation, cluster growth and cluster sintering according to relations (5) and (7) in R/R_{cr} units.

§ The same boundaries appear on grinding of a bulk sample, for example, using mills or by plastic deformation.

¶ It should be noted that the thermodynamic approach is used in relation to ensembles of atoms or clusters which contain a large number of particles. However, this approach also proved effective (as will be shown below) for a limited number of particles.

Expression (5) characterises the stages of nucleation and the growth of a cluster in the system of weakly interacting non-contacting clusters. Upon further growth of clusters, they come into contact and the boundaries between them vanish (sintering). The onset of cluster sintering corresponds to a discrete transition from isolated clusters first, to weakly interacting and then, to strongly interacting clusters. If half of the distance R_t between the cluster centres at the stage of sintering is equal to R_t = const, the surface area (S_s) and the volume (V_s) of the cluster which has formed contacts with k neighbours can be calculated fairly accurately using the expressions

$$S_s = 4\pi R^2 + k2\pi R(R_t - R), \tag{6}$$

$$V_s = \frac{4}{3}\pi R^3 + k\frac{1}{3}\pi(-2R^3 + 3R^2R_t - R_t^3).$$

Correspondingly, the change in the Gibbs energy at the stage of sintering, *i.e.*, when $R > R_t$, is

$$\Delta G_s = \alpha S_s - \left(\Delta\mu^0 + \ln\frac{n_0 - n}{N}\right)\rho V_s. \tag{7}$$

Thus, the profile of the variation of free energy of the system per one cluster over the whole range of R is determined by relation (5) for $R < R_t$ and by relation (7) for $R > R_t$. As an example, Fig. 7 presents the $\Delta G(R/R_{cr})$ plot for $R_t = 1.75\,R_{cr}$. The curve given in the Figure has three minima separated by two maxima. The first minimum at the point $R = 0$ corresponds to the initial state of the mother medium; the second minimum at $R = R_{max}$ matches the first stable state, namely, the equilibrium state of the cluster having formed but not contacting (this is possible when $R_{max} < R_t$); the third minimum matches a system of sintering clusters each of them having k contacts. Correspondingly, the first maximum at $R = R_{cr}$ corresponds to the potential barrier to nucleation, while the second one corresponds to the potential barrier to sintering. Figure 8 shows the shape of the potential barrier to sintering for $k = 6$ and for different R_t. In a system densely populated by clusters, at $R_t \leqslant 1.7\,R_{cr}$, sintering occurs without a barrier; in a system less densely populated by clusters, at $R_t = 1.75R_{cr}$, the transfer to sintering requires overcoming a potential barrier, and in an even less densely populated system, at $R_t = 1.8R_{cr}$, sintering does not occur at all because in this case, this process is associated with an increase in the free energy.

The differential thermal analysis (DTA) and differential thermal gravimetry (DTG) curves recorded during thermal decomposition of iron oxalate $Fe_2(C_2O_4)_3 \cdot 5\,H_2O$ in air exhibit two minima at T_d = 200 and 260 °C.[120] The first minimum in both curves corresponds to dehydration of the iron complex with its partial decomposition giving rise to CO and CO_2. When $T_d > 200$ °C, a mobile medium starts to form, in which nucleation and growth of iron oxide clusters takes place. The second minimum is apparently due to further removal of CO and CO_2 and the onset of sintering of iron oxide clusters. The cluster size can be estimated from the specific surface area (BET) or using data of X-ray diffraction analysis, atomic force microscopy (AFM) and Mössbauer spectroscopy. The AFM images of iron oxide-based cluster systems formed at T_d = 265 °C are shown in Fig. 9 *a*,*b*. The contacting clusters which undergo sintering can be readily seen in Fig. 9 *a*.

Figure 10 shows how the thermodynamic model of nucleation and cluster growth and sintering (the upper section of the Figure)

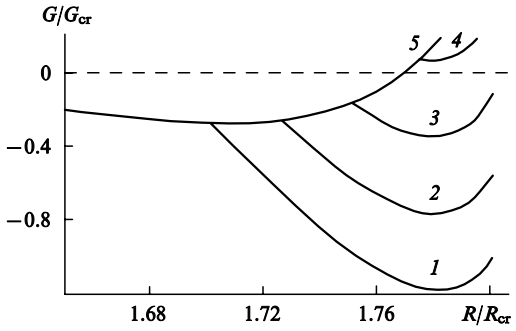

Figure 8. Change in the Gibbs energy G/G_{cr} in the region of the onset of cluster sintering *vs.* R/R_{cr} at different R_t values (which is half the distance between the cluster centers).
$R_t = 1.7R_{cr}$ (*1*), $1.73R_{cr}$ (*2*), $1.75R_{cr}$ (*3*), $1.77R_{cr}$ (*4*), $1.78R_{cr}$ (*5*).

The line is 14 nm long; the maximum relief depth is 6.4 nm.

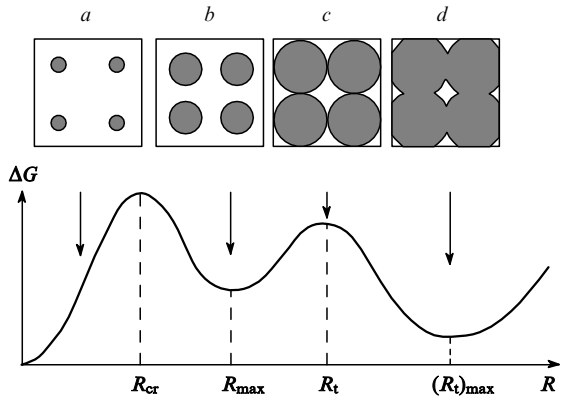

Figure 10. Scheme of cluster formation, growth and sintering; (*a*) formation of seeds, (*b*) maximum size (5–6 nm) of a stable cluster in a weakly interacting system of clusters, (*c*) onset of sintering; (*d*) formation of a system of strongly interacting clusters. The arrows match steps *a*–*d* to the curve for the change in the Gibbs energy obtained upon thermal decomposition of iron oxalate.

interprets the experimental data on iron oxalate thermolysis (the low section of the Figure). The subcritical range of cluster sizes ($R < R_{cr}$) corresponds to the stage of fluctuation nucleation of clusters; in this range, the function $\Delta G(R)$ increases (Fig. 10 *a*). In the region of $R > R_{cr}$, the enlargement of clusters is accompanied by a decrease in the free energy; it proceeds spontaneously and ends in the formation of a stable cluster with the size $R_{max} = 5-6$ nm and a nanosystem formed by weakly interacting clusters (Fig. 10 *b*). When the distance between the centres of neighbouring clusters ($2R_t$) approaches the value $2R$, sintering starts (Fig. 10 *c*). In the region of $R_{max} < R < R_t$, the function $\Delta G(R)$ increases, which forms a potential barrier to the sintering with a maximum at $R = R_t$. With further increase in R ($R > R_t$), sintering occurs spontaneously and is accompanied by a decrease in the Gibbs energy. The second potential well in the $\Delta G(R)$ curve corresponds to a system of strongly interacting clusters (Fig. 10 *d*). When $R > (R_t)_{max}$, the potential well disappears and further sintering becomes impossible because it would be accompanied by an increase in the Gibbs energy ($\Delta G > 0$). Since the R_{max} and R_t values are dictated by experimental conditions, the outcome of the topochemical reaction depends on the reactor temperature, duration of sintering and the previous history of the sample.

Thus, the formation of a nanosystem includes two main stages: first, a nanosystem of weakly interacting clusters is formed (this stage starts with nucleation and ends in cluster sintering) and subsequently it is converted into a nanosystem of strongly interacting clusters (this stage starts with cluster sintering). Figure 9 *a* corresponds to a nanosystem formed by strongly interacting clusters† with sizes of 20–50 nm. The appearance of strong intercluster interaction and the sintering bring about substantial interfacial stresses. These stresses (p) are generated by the 'neck' formed due to the surface tension (the region where the clusters are contacting):[121] $p = 2\alpha/x$ (α is the surface tension, x is the radius of the neck formed upon cluster sintering). Assuming that $\alpha = 1\ \mathrm{N\,m^{-1}}$ for iron oxide[122] and $x \approx 1$ nm, we obtain $p \approx 10^9-10^{10}$ Pa.

Excessive pressure also develops due to the presence of defects and dislocations at the interface; for ~10-nm clusters, it reaches 10^9 Pa.[6,123–125] The stress and pressure developing in a system of strongly interacting nanoclusters are important factors determining the formation and properties of the nanostructure.

A system of strongly interacting solid-state clusters can also arise upon mechanical treatment of bulk samples. Thus plastic deformation of Ni and Cu bulk samples gave nanosystems of Ni and Cu clusters with an average size of 100 and 50 nm, respectively.[126–128] Titanium nanoclusters with sizes of up to 30–40 nm[129] have been prepared by imposing pressure with shear on the titanium carbide $TiC_{0.62}$.

Crystallisation of multicomponent alloys is of considerable interest. Thus crystallisaton of amorphous Fe–Cu–Nb–Si–B alloys at 700–900 K affords a cluster system consisting of an amorphous matrix with 10-nm α-Fe clusters and ~1-nm Cu clusters uniformly distributed in the matrix.[130,131] Crystallisation conditions can be altered by preliminary treatment of the alloy. In this case, α-Fe clusters with sizes of up to 5 nm were obtained.[130,131] Crystallisation of rapidly solidifying amorphous alloys Al–Cr–Ce–M (M = Fe, Co, Ni, Cu) with Al concentrations of more than 90% yields icosahedral Al nanoclusters, which occur in an amorphous matrix.

b. Nanoclusters prepared using matrices

In this Section, we shall find out how a matrix influences the properties of nanoclusters formed in it. The formation of nanocluster seeds from a supercooled liquid or a supersaturated solution in an infinite space has been extensively studied and discussed, in particular, from the thermodynamic standpoint.[132–134]

The Gibbs energy for this process is calculated using an equation[132–134] similar to equation (3) introduced for solid-phase reactions

$$\Delta G = 4\pi\alpha R^2 - \frac{4}{3}\pi R^3 \rho \Delta\mu. \qquad (8)$$

For a solution with the finite concentration $c = n_0/N$ (n_0 is the number of atoms of a dissolved substance, *e.g.*, iron, N is the number of solvent atoms), the $\Delta\mu$ value is found from the relation

$$\Delta\mu = \Delta\mu^0 + \ln\frac{n_0}{N} = \Delta\mu_0\,. \qquad (9)$$

Thermodynamic estimation of the influence of a pore on the features of the formation of a nanocluster in it has been reported.[135] For a closed pore in which a cluster of n atoms is formed,

$$\Delta\mu = \Delta\mu^0 + \ln\frac{n_0 - n}{N}, \qquad (10)$$

where $\Delta\mu^0 = \mu_l - \mu_s$ is the difference between the chemical potentials of the liquid and solid standard states. Thus, the Gibbs energy for cluster formation in a closed pore can be written as

$$\Delta G = \frac{4}{3}\pi\rho R^3\left[\frac{3\alpha}{\rho R} - \left(\Delta\mu_0 + \ln\frac{n_0}{n_0 - n}\right)\right]. \qquad (11)$$

The pattern of the $\Delta G(n)$ dependences describing the formation of a cluster in an infinite space and in a closed pore is shown in Fig. 11. The curves describing the change in the Gibbs energy upon the formation of nanoclusters in an infinite space have a maximum at the points n_{min} corresponding to the critical volume of formation of a stable cluster seed (Fig. 11, curves *1*, *2*). For a supersaturated solution (Fig. 11, curve *1*) or a supercooled melt, the n_{min} value is found from Eqn (8). As the initial concentration n_0/N decreases, the n_{min} value shifts to greater n [$(n_{min})_2$ in curve *2*].

The formation of a cluster in a closed pore is illustrated by curves *3* and *4* (Fig. 11). The limited concentration of the solute inside the pore entails the existence of a limiting volume of the cluster n_{max}; after this volume has been reached, cluster growth becomes energetically unfavourable and ceases. One more important factor influencing cluster formation and growth in a pore is pore heterogeneity. Heterogeneity of a pore changes the condi-

† The change in the type of intercluster interaction changes many properties of the nanosystem; this will be discussed in the Section dealing with the properties of nanostructures.

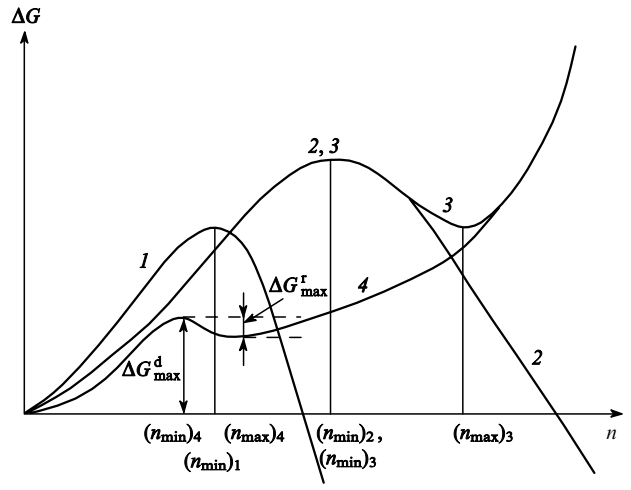

Figure 11. Funcion $\Delta G = f(n)$ characterising the growth of a cluster with an increase in n;
(*1*) in a supersaturated solution having a macrovolume, (*2*) in a solution with finite concentration c, (*3*) in a pore; (*4*) in a pore with allowance for the heterogeneity factor K.

tions of cluster formation and decreases the energy barrier to the formation of a stable seed of a cluster having the critical volume.[135]

Now we shall consider the variation of ΔG_{max} as a function of cluster size (n). In the region of $n \ll n_0$,

$$n_{min} = \frac{32\alpha^3}{3\rho^2\Delta\mu_0^3}. \quad (12)$$

It follows from Eqn (11) that an increase in the concentration n_0/N decreases the cluster critical volume (size). The height of the energy barrier to the formation of a stable cluster equals

$$\Delta G_{max} = \frac{16\pi\alpha^3}{3\rho^2\Delta\mu_0^2}. \quad (13)$$

However, in the region of $n_{min} \ll n < n_0$

$$n_{max} = n_0 \frac{\Delta\mu_0}{2 + \Delta\mu_0}. \quad (14)$$

Thus, the maximum size of the clusters (n_{max}) in a pore is always smaller than n_0 and, for a constant concentration, it increases with an increase in the pore size. When estimating n_{max}, one should take into account the influence of pore heterogeneity and the fact that the probability of formation of several clusters in one pore increases with an increase in the pore size from 10 to 100 nm and further; naturally, this results in smaller n_{max} (in large pores, $n_{max} \ll n_0$).

As noted above, pore heterogeneity decreases the energy barrier to cluster formation. The Gibbs energy of both the formation (ΔG^d_{max}) and decomposition (ΔG^r_{max}) of clusters can be considered. With allowance for the heterogeneity factor K ($K < 1$), which depends on the contact angle between the cluster and the pore surface,

$$\Delta G^d_{max} = \frac{16\pi\alpha^3 K}{3\rho^2\Delta\mu_0^2}. \quad (15)$$

The pore also influences the ΔG^r_{max} value, *viz*., decreases it. As a consequence, with a decrease in n_{max} (especially for pores of $\sim$10 nm), $\Delta G^r_{max} < \Delta G^d_{max}$.

The surface and the volume of a pore influence as well the rate of cluster formation, which increases due to a decrease in the energy barrier and the heterogeneity factor.[134, 135]

The nucleation and the formation of iron hydroxide clusters in organic sorbents — styrene and divinylbenzene copolymers (polysorbs) with a specific surface area of up to 1000 $m^2\ g^{-1}$ and a pore size of 7 to 50 – 100 nm have been investigated.[135, 136] The pore surface in polysorbs bears no functional groups; therefore, the influence of chemisorption on cluster formation can be neglected. Polysorbs were impregnated with ferric chloride solutions with different concentrations and purged with air containing an ammonia admixture (0.008% – 0.08%). As a result the irreversible chemical reaction

$$FeCl_3 + H_2O + NH_3 \longrightarrow Fe(OH)_3 + NH_4Cl + NH_4OH,$$

resulting in the formation of iron hydroxide took place in the polysorb pore. This changed the pH of the medium and induced the growth of insoluble iron clusters in the pore.

Changes in the intensity (ε) of spectral lines in the Mössbauer spectra of iron hydroxide clusters were used to investigate the influence of various parameters (pore size, concentration of ammonia in air, concentration of $FeCl_3 \cdot 6\,H_2O$) on the size of the resulting clusters. Figure 12 shows the dependence of ε on the size (d) of the pore in polysorb at different ammonia concentrations in air.[135] It was found that a decrease in the pore size results in a corresponding decrease in the cluster size [*e.g*., according to Eqn (14)] and, hence, in a decrease in the intensity of spectral lines. For large pores, a decrease in ε with an increase in the iron chloride concentration was also observed, which can be due to the formation of several smaller clusters within one pore. A substantial increase in the rate of cluster formation with respect to that in a macro-volume was noted, which is consistent with the heterogeneity factor and Eqn (15).

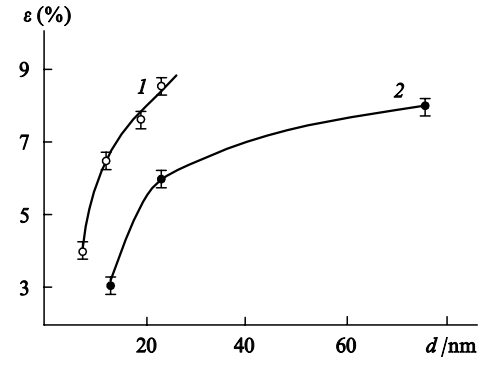

Figure 12. Line intensity in the Mössbauer spectrum of iron oxide clusters formed in the polysorb pores *vs*. pore diameter ($T = 300$ K) at an ammonia concentration in air of 0.08% (*1*) and 0.008% (*2*).

Yet another active matrix widely used to prepare nanoclusters is porous active carbon. The deposition of metal salts, for example, iron oxalate $Fe_2(C_2O_4)_3 \cdot 5\,H_2O$, on an active carbon substrate followed by annealing and reduction under a hydrogen atmosphere gives rise to a mixed heterogeneous system of Fe_3O_4, γ-Fe_2O_3 and metallic iron clusters on a carbon substrate. Depending on the duration of the reduction with hydrogen, the size of oxide clusters ranges from 7 to 12 nm, and the size of iron (α-Fe) clusters is 3 – 7 nm.[137] It is noteworthy that a nanosystem of these clusters possesses a self-forming property: the reduction by hydrogen is accompanied by hydrogenation (carbon burning) accompanied by an increase in the pore size. The size and composition of nanoclusters are also markedly affected by the nature of the carbon surface.[138, 139]

c. Colloid nanosystems

Nanostructures prepared from colloidal solutions and sols by sol – gel technology can be used in conductive systems, optics and catalysts. Systems consisting of zirconium, titanium or aluminium alkoxides [$Zr(OPr^i)_4$, $Ti(OBu^i)_4$, $Al(OPr^i)_3$] and iron or cobalt complexes are fairly promising.[140] Based on them, supported catalysts represented by nanocluster systems have been prepared, for example, FeO/ZrO_2, FeO/TiO_2, FeO/Al_2O_3. The cluster size was varied by changing the concentrations of components and the heating temperatures. However, clusters prepared by sol – gel technology are unsuitable for the design of assembled nanostructures because of the large scatter in the nanocluster size. It is more promising to assemble nanostructures from clusters prepared using direct and reverse micelles.[21, 22, 141, 142] These clusters are distinguished by narrow size distributions.

Since reverse microemulsions are characterised by high mobility and great interfacial surface area, they can act as a universal medium for numerous chemical syntheses including those giving rise to metal, metal sulfide and other clusters. In a microemulsion, drops constantly collide due to the Brownian motion, coalesce and again split, which results in the continuous exchange of their contents.

Thus Ag_2S clusters are prepared using mixtures of two types of reverse micelles, the aqueous phases of which contain Na_2S and Ag-surfactant, respectively. Upon collision, these micelles coalesce, which is accompanied by the exchange of the contents of the aqueous media. This exchange yields solid Ag_2S particles. The size of a new-phase particle is limited by the size of the drop. The size of Ag_2S clusters was found to increase from 3.0 to 5.8 nm with an increase in the size of water drops.[21] In this case, the model of nucleation in a pore considered in Section IV.1.b is also valid. To release the nanoclusters from the micelle, the micelle is destroyed by thiols, the resulting nanoclusters are dissolved in an appropriate solvent, the solution is filtered, and the solvent is evaporated. This procedure permits preparation of nanoclusters with a size of up to 10 nm passivated by thiols (*e.g.*, dodecanethiol). Two- and three-dimensional nanostructures are formed from these clusters on various substrates.

Characteristic features of the formation of nanostructures from Ag_2S clusters have been described.[141, 142] The researchers observed the self-assembly of clusters to give ordered two- and three-dimensional structures. Organised nanostructures have also been obtained from metallic Ag, Co, Au and semiconductor nanoclusters.[143 – 147] Alkanethiols, alkylphosphines and dithiols were used as nanocluster surface passivators.

Figure 13 presents two photomicrographs of the Ag_2S nanostructure prepared from passivated nanoclusters with a size of 5.8 nm. The photomicrograph shown in Fig. 13 *b* clearly demonstrates that the nanoclusters are strictly assembled to give a nanostructure rather than arranged randomly. Like conventional crystals, this structure can contain dislocations and defects (they are marked by arrows in photomicrograph 13 *a* obtained with a smaller magnification).

Two-dimensional nanostructures (2D structures) are closely packed monolayers, while 3D structures have a face-centred cubic (FCC) lattice.

The procedure for the preparation of monodisperse nanoclusters using microemulsion systems makes it possible to vary the size of the initial nanoclusters, a sort of 'atoms'. Figure 14 presents three photomicrographs of the nanostructures prepared from Ag_2S nanoclusters with a size of 3.0 (*a*, *b*), 4.0 (*c*, *d*) and 5.8 nm (*e*, *f*). Despite the difference in the shape of the aggregated nanostructures (Fig. 14 *a*,*c*,*e*), the type of organisation is the same

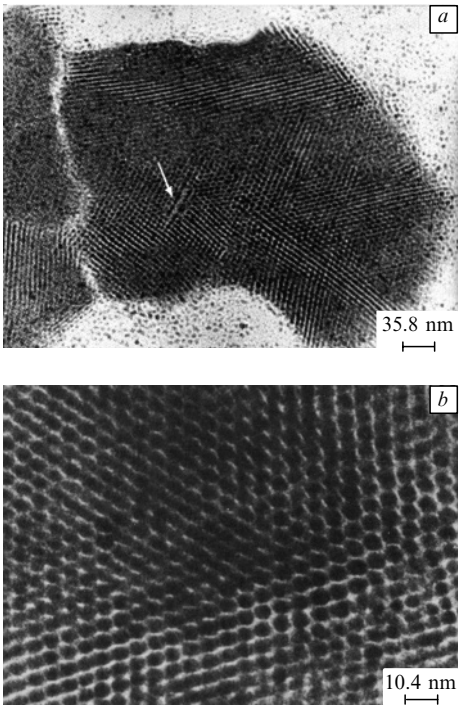

Figure 13. Photomicrographs of Ag_2S nanocluster structures with a resolution of 35.8 (*a*) and 10.4 nm (*b*). The white arrow marks a defect in the nanostructure 'crystallinity'.[21]

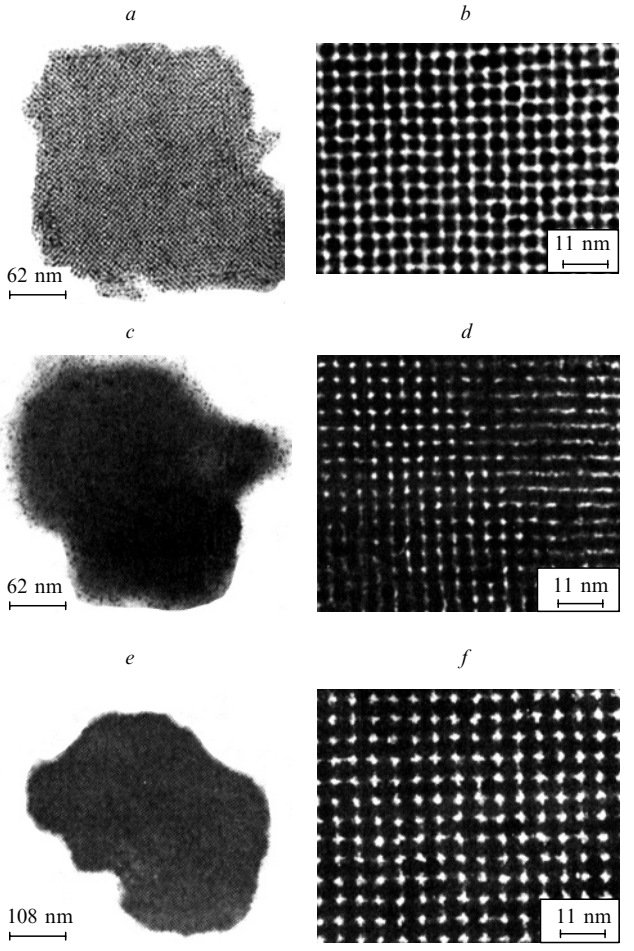

Figure 14. Photomicrographs of nanocluster structures formed from Ag_2S clusters with different sizes: 3.0 (*a*, *b*), 4.0 (*c*, *d*) and 5.8 nm (*e*, *f*).[21]

and corresponds to the body-centred cubic (BCC) lattice (Fig. 14 *b*,*d*,*f*).

In this case, assembly and self-assembly of nanoclusters to give a BCC crystal lattice is induced, apparently, by van der Waals forces acting between separate nanoclusters having a nearly spherical shape.

d. Assembling of fullerenes, fullerides, fullerene-like structures and nanotubes

Fullerenes are fairly convenient structural materials for the formation of nanostructures because they are perfectly monodisperse and spherical. The organisation and self-organisation of colloid and gas-phase fullerenes to nanostructures (fullerides) is induced by heating, pressing, *etc*. In aqueous solutions, the star hexaanion derivatives $C_{60}[(CH_2)_4SO_3]_6^-$ form spherical aggregates comprising four molecules.[148] The shape, the size and the structure of aggregates were studied by small-angle neutron and X-ray scattering. An unusual stability of these aggregates was noted: their volume and shape do not depend on the fullerene concentration or on the inter-aggregate interaction.

Larger aggregates were formed from colloid solutions of C_{60} fullerene in benzonitrile at C_{60} concentrations of more than 100 μmol litre^{-1} (at lower C_{60} concentrations, only separate fullerene molecules are present in the solution).[149] In this case, the average size of the aggregate reached $\sim$250 nm. These aggregates, existing as dynamic systems,‡ were detected using picosecond photolysis. No aggregates of this type are formed in benzene or decalin up to concentrations of 500 μmol litre^{-1}. Apparently, the formation of aggregates is influenced by solvent polarity and the symmetry of the molecules being joined. Indeed, the non-symmetrical C_{70} molecule does not form aggregates either in polar benzonitrile or in nonpolar benzene or decalin.

The preparation and study of the nanocrystals of fullerene fluorides $C_{60}F_x$, $C_{60}F_{36}$ and $C_{60}F_{48}$ present considerable interest.[84, 150, 151] It was found that at room temperature, the crystals of $C_{60}F_{36}$ have a BCC lattice, while those of $C_{60}F_{48}$ crystallise with a body-centred tetragonal lattice. The data of high-temperature (T = 353 K) X-ray diffraction *in situ* point to a phase transition in a $C_{60}F_{48}$ nanocrystal: the body-centred tetragonal lattice is transformed into a face-centred cubic lattice.

The parameters governing the formation of fullerene nanostructures (crystals) are the pressure and the temperature. Thus crystallisation of C_{60} fullerene at 1.56 GPa and 423 K affords a crystal lattice the structural elements of which are dumb-bell-shaped $C_{60}-C_{60}$ dimers.[152] (This reaction is similar to the mechanochemical reaction of C_{60} with KCN.[153]) An increase in the temperature induces decomposition of the dimers to give an orthorhombic polymeric structure of C_{60} molecules, which is converted into a polymeric tetragonal structure at $T \approx 723$ K.

Carbon nanotubes (NT) are also used for the formation of nanostructures. A nanotube is a graphene sheet rolled into a hollow cylinder. The chirality and the diameter of this tube can be characterised by the vector $\mathbf{c} = n\mathbf{a} + m\mathbf{b}$, ($\mathbf{a}$, $\mathbf{b}$ are the unit vectors of the hexagonal cell and m and n are integers). Depending on the mode of rolling, nanotubes can be either achiral zigzag-like (two sides of each hexagon are parallel to the NT axis, $m = 0$), or armchair-like (two sides of each hexagon are normal to the NT axis, $n = m$), or chiral helix-like (each pair of the hexagon sides is arranged at an angle other than 0 or 90 ° to the NT axis). The form of the nanotubes influences substantially the properties of nanostructures (metallic or semiconducting). By varying and combining two types of nanotubes, for example, zigzag and armchair nanotubes, one can create single-electron devices with different conductivities, for example, diodes.[154] The size (length) of nanotubes also influences the properties of nanostructures formed from them. Depending on the nanotube size, the properties of nanosystems vary from semiconductor properties with a real forbidden gap (quantum dots, 0D) to metallic properties for a unidimensional system (quantum wire, 1D). According to quantum-mechanical calculations, transition from (0D) to (1D) structures takes place if the nanotube becomes more than 10-nm long.

‡ Aggregates of C_{60} are unstable and undergo constant assembly and destruction of the type $nC_{60} \leftrightarrows (C_{60})_n$.

e. Nanofilms

Nanofilms are two-dimensional structures. There exist numerous expedients for film deposition or growth on metallic, oxide, chalcogenide and other substrates. The method used most widely to prepare organised films is deposition of atoms or molecules from the gas phase onto the surface of a single crystal and design of epitaxial or polycrystalline atomic or molecular layers from them.

Considerable progress has been attained in the synthesis of films from fullerenes on substrates of various materials including metals,[155, 156] semiconductors,[157–159] layered materials,[160, 161] insulators,[162] *etc*. However, the question of what factor dictates the type of the structure being formed (face-centred, hexagonal or close-packed) still remains open. It can only be concluded that weak interaction of the fullerene molecules with the substrate favours the formation of an ordered layer of C_{60} molecules, whereas strong chemisorption of C_{60} on the substrate surface gives rise to a disorganised, disordered structure. The structure of a thin film of fullerene molecules formed on the graphite surface has been studied.[163] It was shown by computer simulation that the C_{60} film supported on graphite has a hexagonal structure.

The films deposited on a substrate can also have a nonuniform, islet structure. The formation of films of gas-phase clusters on a substrate depends on the time, temperature and deposition velocity. The final state of the film is determined by the average size and density of the cluster islets: the larger the islets, the smaller the density.

The rate of atom diffusion is known to be low at low temperatures; therefore, relatively small clusters with high density are formed. The same considerations are valid for the formation of films from clusters. The formation of nanostructures from antimony clusters on the amorphous surface of carbon has been studied as a function of the number of Sb atoms in the cluster (n = 4–2200).[164] (The antimony clusters were prepared by condensation of antimony vapour in a helium cell cooled with liquid nitrogen.) The dependence of the average size (N) of the cluster islet structure on the average size (n) of the primary antimony cluster passes through a minimum at $n = 350 \pm 50$. This was interpreted as being due to the fact that the size distribution of the islet structure becomes narrower as the cluster size approaches the optimum value ($n = 350 \pm 50$). As the size of the primary antimony cluster increases, the rate of its diffusion over the substrate surface decreases; hence, the probability of coalescence of the primary clusters to an islet nanostructure also decreases. Each large primary cluster (from $n > 400$ to $n = 2200 \approx N$) is adsorbed on the surface and retained unchanged for some densities of the primary beam. From small clusters with $n < 350$, it is possible to form islet structures with large N (> 3000), owing to higher diffusion rates.

An effective method for the formation of nanofilms from clusters is deposition from plasma as well as chemical and physical vapour deposition (CVD and PVD).[8, 165] In plasma deposition, the film thickness and the size of crystallites are controlled by variation of the gas pressure and discharge parameters. Dudko *et al*.[166] and Barg [167] prepared chromium films on a copper substrate with an average size of crystallite clusters of $\sim$20 nm. The increase in the film thickness to 500 nm resulted in its crystallisation. The ion-plasma deposition of titanium carbide and nitride also results in the formation of nanocrystalline films.[165] The use of magnetron sputtering of the initial substances allows the substrate temperature to be decreased by 100–200 °C; this extends the scope of the preparation of nanotubes. This procedure was employed to produce Ni_3Al films with a crystallite size of 20 nm.[168]

The preparation of nanofilms from colloid solutions has been considered in the previous Section in relation to the formation of silver sulfide-based nanostructures.[21] It has been noted [21] that hexagonal ordering of clusters (3 – 5 nm) is observed even within a monolayer. Generally, to prepare assembled nanofilms from colloid solutions, it is necessary to have monodisperse nanoclusters, which are self-assembled into a film due to weak van der Waals intercluster interactions.

In recent years, a procedure has been developed for the formation of films on a liquid surface (Langmuir – Blodgett) and transferring them onto a solid surface. This method permits the formation of superlattices and nanometer layers of organic molecules with a specified pattern of layer alternation.

The organisation of nanofilms by chemical assembling and molecular layering methods has been described.[27] In the synthesis of highly organised structures by the chemical assembling method, the key role is played by the chemical reactions taking place between the functional groups located on the surface of a solid (substrate) and the adsorbed molecules with specified composition. This procedure is used, for example, to apply organised layers of metal oxide clusters.

f. Compacted nanosystems

Compacting of gas-phase, colloid or molecular clusters by pressing followed by the high-temperature sintering of nanoclusters gives rise to nanosystems.[169, 170] The most densely organised nanostructures are produced from the smallest monodisperse clusters. Thus a nanostructure based on titanium nitride were prepared by pressing nanoclusters with a size of 8 – 25 nm with subsequent sintering.[171] To preserve a small size of crystallites in nanosystems, low sintering temperatures and doping additives hampering the crystal growth are required. An example is provided by WC – Co nanocrystalline solid alloys, which consist of WC nanoclusters (50 nm) dissolved in a Co matrix.[172, 173] Tungsten carbide (up to 1 mass %) is added to retard the crystal growth.

A magnetic-pulse method is also used to compact nanosystems.[174] In this case, pressing occurs on exposure to pulse compression waves and is accompanied by local heating due to the fast energy evolution upon the friction of particles during packing. The magnetic-pulse pressing allows the generation of pulse compression waves with an amplitude of up to 5 GPa and a duration of several microseconds. The use of pulse pressures results in a higher compaction density compared to that reached by static pressing. Apparently, this is due to the generation of intercluster pressures, which enhance the intercluster interactions. The magnetic-pulse method was used, for example, to press Al_2O_3 [175] and TiN [176] nanoparticles. An increase in the temperature of magnetic-pulse pressing was found to be more efficient than an increase in the pressure (cold pressure). With a pulse pressure of 4.1 GPa and a temperature of 870 K, nanosystems with a grain size of 80 nm and a density of 83% of the theoretical one were prepared. Upon a decrease in the temperature to 720 K, the density decreased to 81%.

2. The properties of nanocluster systems

As noted above, isolated nanoclusters possess unique properties related to their nanometer size. However, in most cases, nanoclusters are interacting with one another; this can not only induce a quantitative change in their properties but also provoke the appearance of new properties. The assembly and self-assembly of clusters to give nanocluster systems changes many properties of the clusters. The most vivid properties of nanosystems such as structural phase transitions (in particular, in ferroelectrics and fullerenes) and optical, electric and magnetic (giant magnetoresistance, quantum magnetic tunnelling, magnetic phase transitions) properties are related to the atomic and cluster dynamics.

It is pertinent to consider both the intracluster atomic dynamics and the intercluster dynamics in a nanosystem where the cluster moves as a a single whole.

a. Intracluster atomic dynamics

The intracluster atomic mobility (in relation to the melting dynamics) is studied using microscopic and quantum-statistical methods as well as methods based on the use of thermodynamic models and computer simulation of motions (molecular dynamics and Monte Carlo method). The most important and characteristic parameters of motion are the mean square displacements of atoms in the cluster

$$\langle \bar{r}^2(t)\rangle = \frac{1}{N}\langle [x(t) - x(0)]^2\rangle \tag{16}$$

$\{\langle [x(t) - x(0)]^2\rangle$ is the mean-square displacement along the x axis in which the displacement is time averaged$\}$ and the diffusion coefficient

$$D = \frac{1}{6}\,\frac{\mathrm{d}\langle \bar{r}^2(t)\rangle}{\mathrm{d}t}\,.$$

At longer times, $\langle \bar{r}^2(t)\rangle = 6Dt$.

Before we proceed to the consideration of the microscopic approach, it is necessary to discuss two points: (i) whether the concept of phonons determining the dynamics of solids is applicable to clusters and (ii) what changes in the vibrational and rotational spectra would occur upon a decrease in the nanocluster size. The point is that in crystals constructed of nanoclusters, the lattice is not strictly periodical, unlike that in molecular crystals (because the substantial influence of the surface should be taken into account for clusters); therefore, phonons cannot be considered as plane waves with the energy E and momentum q. However, a cluster can be regarded as a single giant molecule with $3N$ degrees of freedom (N is the number of atoms in the cluster). All the natural frequencies ω corresponding to the vibrations of this 'molecule' and eigenvectors can be found. Thus, the vibrational states can be numbered in terms of frequencies ω_i rather than momenta. The mean square displacement of an atom can be found from the formula [119]

$$\langle r^2\rangle = \frac{\hbar}{NM}\sum_i \frac{\bar{n}_i + 1/2}{\omega_i}\,, \tag{17}$$

where M is the atom mass, $\bar{n}_i$ is the averaged number of vibrations.

For large clusters, the density of phonon states $\rho(\omega)$ should be introduced and the summation over frequencies should be replaced by integration. In this case, we obtain

$$\langle r^2\rangle = \frac{\hbar}{NM}\int\left(\frac{1}{2} + \frac{1}{\exp(\hbar\omega/kT) - 1}\right)\frac{\rho(\omega)}{\omega}\,\mathrm{d}\omega\,. \tag{18}$$

The form of the function $\rho(\omega)$ depends on the phonon spectra and on the model of the atomic cluster mobility chosen. In the case of the Debye model,

$$\rho(\omega) = \frac{9N\omega^2}{\omega_{\max}^3}$$

and

$$\langle r^2\rangle = \frac{9\hbar^2}{4Mk\theta_{\mathrm{D}}}\left(1 + \frac{4T^2}{\theta_{\mathrm{D}}^2}\int_0^{\theta_{\mathrm{D}}/T}\frac{u\,\mathrm{d}u}{\exp(u-1)}\right), \tag{19}$$

where θ_{D} is the Debye temperature, $u = \hbar\omega/kT$. At high temperatures, $T \gg \theta_{\mathrm{D}}$

$$\langle r^2\rangle = \frac{9kT}{M\omega^2}\,, \tag{20}$$

$$\langle x^2\rangle \approx \frac{3kT}{M\omega^2}\,.$$

For the Einstein model,

$$\rho(\omega) = 3N\delta(\omega - \omega_{\mathrm{E}})$$

(δ is the δ function, ω_{E} is the Einstein frequency) and

$$\langle x^2\rangle = \frac{\hbar}{2M\omega_t}\mathrm{cth}\left(\frac{\hbar\omega_E}{2kT}\right). \quad (21)$$

Before we consider the phonon spectra of small particles, it is necessary to calculate the density of states function $\rho(\omega)$ for the vibrations in clusters. Specific features of the spectra of clusters are due to the presence of a large number of surface atoms. It is known that atoms on the cluster surface are more weakly attached to the lattice and, hence, their vibration frequencies are lower. Therefore, the vibrational spectrum of the cluster exhibits a large number of low-energy vibrations, which results, in accordance with (18)–(21), in an increase in $\langle r^2\rangle$. However, clusters are characterised by limiting phonon wavelengths stipulated by the cluster size, *i.e.*, the phonon spectrum loses some of the low-frequency vibrations, and $\langle r^2\rangle$ decreases. Thus, the phonon spectrum of the cluster becomes discrete. However, if the Debye dependence is assumed for the contribution of the density of phonon states [$\rho(\omega) \sim \omega^2$], the effect of cutting of the phonon spectrum would be insignificant, and the overall effect for the isolated clusters would still be related to an increase in $\langle r^2\rangle$.

Even a simple model of the atomic cluster mobility predicts unusual cluster properties. If a cluster is regarded as a sphere consisting of two parts — the surface layer and the inner core — a characteristic Einstein frequency and the mean square displacement of atoms can be attributed to each part, $(\omega_E)_s$ and $\langle x^2\rangle_s$ for the surface and $(\omega_E)_i$ and $\langle x^2\rangle_i$ for the inner core. In this case,

$$\langle x^2\rangle_s = \frac{\hbar}{2M(\omega_E)_s}\mathrm{cth}\left[\frac{\hbar(\omega_E)_s}{2kT}\right]$$

and

$$\langle x^2\rangle_i = \frac{\hbar}{2M(\omega_E)_i}\mathrm{cth}\left[\frac{\hbar(\omega_E)_i}{2kT}\right].$$

According to the Lindemann criterion, melting of a substance starts when $\langle x^2\rangle_m \simeq 0.1a^2$ (a is the average distance between the atoms); the difference between melting of the surface layer and the inner core of the cluster should be taken into account because $\langle x^2\rangle_s$ is greater than $\langle x^2\rangle_i$ owing to the decrease in the number of atomic bonds for the surface atoms.[177] Figure 15 shows the temperature dependences of $\langle x^2\rangle_s$ (curve *1*) and $\langle x^2\rangle_i$ (curve *2*). Due to the difference between the $\langle x^2\rangle_s$ and $\langle x^2\rangle_i$ values, the $\langle x^2\rangle_m$ point where melting starts would be matched by different melting points for the surface $(T_m)_s$ and internal $(T_m)_i$ atoms. Moreover, apart from the regions corresponding to the solid and liquid states of the system, a transient region appears corresponding to the solid and liquid states existing simultaneously (see Fig. 15).

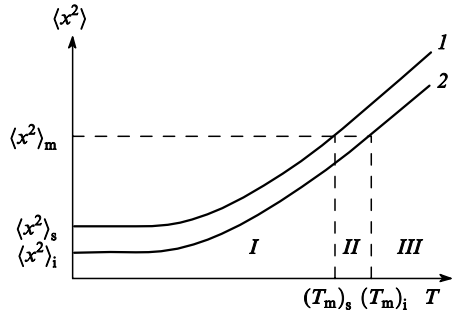

Figure 15. Temperature dependence of $\langle x^2\rangle$ for atoms on the cluster surface (*1*) and inside the cluster core (*2*). The subscripts s and i denote the surface and the cluster core, $\langle x^2\rangle_m$ are the mean-square displacements corresponding to the Lindemann criterion, $(T_m)_s$ and $(T_m)_i$ are the melting points of the surface layer and the cluster core; (*I*) is the region corresponding to the solid, (*II*) is the region corresponding to the solid–liquid transition state, (*III*) is the region corresponding to liquid.

Now we shall consider the quantum-statistical method for the investigation of the atomic mobility.

The change in the thermodynamic state of a cluster can be described by the free energy function $\Delta G = \Delta E - T\Delta S$ (E is the internal energy of states of the cluster, S is entropy). The entropy of the cluster can be calculated from the formula

$$S = -kT\ln Z,$$

where $Z = \sum g_i \exp(E_i/kT)$ is the function of distribution of states (here, g_i and E_i are the degeneracy and the energy of an ith level). Numerous studies have been devoted to the calculation of the Z value by quantum-statistical methods (see, for example, a number of studies [178–180]). The energy distribution of states for a solid cluster differs substantially from that for a liquid. At low temperatures, the density of states is greater for a solid than for a liquid; however, at high temperatures, the situation is reversed; as a consequence, the temperature of the equilibrium transition (T_{eq}) from the solid to the liquid state appears. Thus, at low temperatures, the energy change ΔE is determined by the vibrational and rotational energy levels of a solid. As the temperature increases, the entropy factor, *i.e.,* the disorder of motions, starts to play the crucial role, which is typical of a liquid. The T_{eq} value (or the melting point of the cluster) depends on the model chosen for the calculation of states for the solid and the liquid and on the number of states, *i.e.*, on the cluster size. When $T = T_{eq}$, the system contains both the solid and liquid phases.

The degree of disorder of the solid or liquid state can be characterised, for example, by the non-rigidity parameter (γ).[181] The variation of the Gibbs energy $G(T,\gamma)$ of a cluster system as a function of γ showed that the freezing point (T_f) and the melting point (T_m) of a cluster system do not coincide, *i.e.*, there is a region of coexistence of the solid and liquid states.

Yet another approach to the study of the dynamics of cluster melting is based on computer simulation of melting using Monte Carlo or molecular dynamics methods.[182–184] To determine the $\langle r^2\rangle$ and $\langle x^2\rangle$ parameters, one should solve a set of equations for the movement of clusters in a field with a specified attraction potential between atoms or molecules. The calculations can be carried out for a constant energy or temperature. In addition to the $\langle r^2\rangle$ and $\langle x^2\rangle$ parameters, this approach gives the time-averaged mean kinetic energy (temperature) over all the degrees of freedom of the cluster atoms

$$T = \frac{2\bar{E}}{(3N-6)k}$$

and the relative averaged change in the bond length (δ)

$$\delta = \frac{2}{N(N-1)}\sum_{ij}\frac{(\langle r_{ij}^2\rangle - \langle r_{ij}\rangle^2)^{1/2}}{\langle r_{ij}\rangle}.$$

By analysing these values, one can draw a conclusion about the cluster dynamics, in particular, about the melting–freezing phase transition. Figure 16 presents the computer simulation data for the Ar_{13} cluster.[185] The temperature at which δ sharply increases, which is interpreted as melting of the cluster in accordance with the Lindemann criterion, can be clearly seen in the Figure. The dependence of $\langle T\rangle$ on the system energy in the solid and liquid states indicates that the melting E_m and freezing E_f energies of the Ar_{13} cluster are different. The results of calculations of $\langle r^2\rangle$ for Ar_{13} also point to a substantial difference between the solid and liquid states. For the solid state, $\langle r^2\rangle$ reaches a flat plateau after 100 time intervals of simulation, whereas for the liquid state, $\langle r^2\rangle$ increases in accordance with the diffusion equation.

The organisation of the $(C_{60})_n$ structure on a graphite substrate and phase transitions in it have been studied by computer simulation.[163] A nanosystem in the ground state consists of hexagonal monolayers parallel to the substrate surface. The most stable structures were formed for n = 7, 19, 37, 61. Raising

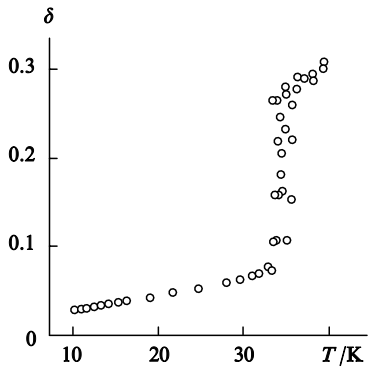

Figure 16. Temperature dependence of the mean-square change in the distance (δ) between the closest neighbours in the Ar_{13} cluster.[185]

the temperature had induced sublimation of C_{60} before the system passed into the state where the solid and the liquid phase coexisted. Study of the thermal stability of the $(C_{60})_{55}$ nanosystem near the graphite substrate demonstrated that, due to the low mobility of C_{60} clusters, this system did not undergo noticeable structural changes prior to the onset of sublimation.

Melting of clusters can also be considered within the framework of the thermodynamic formalism.[177, 186–191] The state of the clusters formed during solid-state reactions or from solutions and melts is determined by the free energy $G = f(\alpha,\mu,R)$ [see Eqns (3) and (8)]. The difference between the free energies of the cluster in the liquid and solid states is

$$\Delta G = 4\pi R^2\Delta\alpha + \frac{4}{3}\pi R^3\rho\Delta\mu, \tag{22}$$

where $\Delta\alpha = \alpha_l - \alpha_s$ is the difference between the surface energies, $\Delta\mu = \mu_l - \mu_s$ is the difference between the chemical potentials for the liquid and solid states of the cluster. It is obvious that for melting, $\Delta\alpha < 0$ and $\Delta\mu > 0$. The $\Delta G(R)$ curves are shown in Fig. 17. The critical cluster size corresponding to the transition from the solid to liquid state ($\Delta G = 0$) is calculated from the formula

$$R_{cr} = \frac{3\Delta\alpha}{\rho\Delta\mu}. \tag{23}$$

When $R < R_{cr}$, a cluster occurs in the liquid state. It follows from Eqn (23) that the solid–liquid transition state cannot be realised for separate atoms in a matrix (for $\Delta\alpha = 0$), when a cluster has not yet formed. Meanwhile the $\Delta\alpha$ value should be the greatest for a free cluster. Any intercluster interactions would decrease this

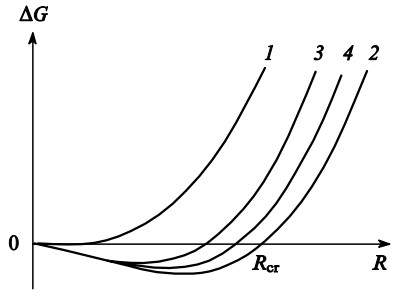

Figure 17. Change in the Gibbs energy for an ensemble of separate atoms in a solid (*1*), for an isolated cluster (*2*) and for a system of interacting clusters (*3*, *4*) occurring in the solid and liquid states *vs*. cluster size.
(*3*) Clusters interacting with one another, (*4*) clusters after treatment with surfactants.

value and, hence, the R_{cr} value, which determines the region of possible fluctuations of the solid and liquid states.

Cluster stability can be characterised by the change in the pressure $\delta p = p_0 - p$ or temperature $\delta T = T_0 - T$ which corresponds to a given difference between the chemical potentials $\Delta\mu = f(p,T)$ and brings the phases to equilibrium at a specified cluster size (p_0 and T_0 are the pressure in the medium and the melting point for the bulk material).

If the function $\Delta\mu = f(p,T)$ is replaced by its series expansion in terms of δp at the point p_0, then, with allowance for the fact that $\partial\mu_l/\partial p = V_l$, $\partial\mu_s/\partial p = V_s$ (V_l and V_s are the molecular volumes of the cluster in the liquid and solid states),[192] we have

$$\Delta\mu \approx -(V_l - V_s)\delta p. \tag{24}$$

Using the Clapeyron–Clausius formula

$$\frac{\delta p}{\delta T} = \frac{q}{T_0}(V_l - V_s),$$

where q is the latent heat of the phase transition, we obtain

$$\Delta\mu \approx -\frac{q\delta T}{T_0}. \tag{25}$$

Substitution of Eqn (25) into Eqn (23) gives a hyperbolic variation of the phase transition temperature for a cluster *vs*. its radius

$$\frac{\delta T}{T_0} \approx -\frac{3\Delta\alpha}{\rho q R}. \tag{26}$$

Dependence (26) indicates that the melting point of a cluster decreases with a decrease in the cluster size. Dependence (22) shown in Fig. 17 allows one to conclude that at a given temperature and pressure of the medium, the initially stable structure of the cluster ($\Delta\mu > 0$) becomes metastable with respect to the liquid phase at $R < R_{cr}$.

Analysis of the experimental data on the atomic dynamics of clusters attests mainly to an increase in the mean square displacements in the metal and oxide clusters compared with the displacements in bulk samples.[119] Thus a decrease in the probability of the Mössbauer effect and an increase in the mean square displacements of atoms $\langle r^2\rangle$ was observed for the W, β-Sn, Fe and α-Fe_2O_3 clusters.[119] An exception is provided by the Au clusters with a size of 6–20 nm for which the probability of the Mössbauer effect was found to increase and $\langle r^2\rangle$ was found to decrease with a decrease in the cluster size; this was explained by the long-wavelength restriction of the phonon spectrum. Study of thin oxide films on the surface of β-Sn and Fe clusters also points to an increase in $\langle x^2\rangle$ for atoms located on the surface.[119] Apart from the increase in the $\langle x^2\rangle$ values, an important feature of atomic dynamics on the surface is the anisotropy of the atomic vibrations. Anisotropy of the atomic vibrations along the surface and normal to the surface has been observed for iron and tin atoms deposited on the extensive surface of η-Al_2O_3, silica gels and zeolites.

A decrease in the melting point (down to room temperature) with a decrease in the cluster size has been observed for gold, tin and CdS nanoclusters.[193–195] An electron microscopy study of tin films[194] has also revealed the separation of the melting and freezing points and the existence of a specific solid ⇌ liquid state in which clusters possess an enhanced mobility in the transient temperature range.

In several publications, melting of iron oxide nanoclusters has been studied.[135, 190, 191] It was noted that melting of these clusters is accompanied by an increase in the mean square displacements of atoms. Figures 12 and 18 present the Mössbauer spectroscopy data for iron hydroxide clusters formed in polysorbs with pore diameters of 7.5 to 0.75 nm and for the nanosystem formed from the iron oxide clusters prepared by thermal decomposition of iron oxalate. For iron hydroxide clusters (see Fig. 12), the intensity of

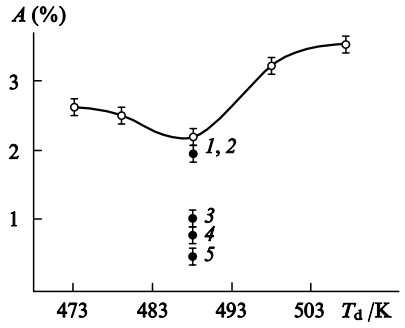

Figure 18. Spectral surface area of the Mössbauer spectrum of a nanosystem formed from iron oxide clusters prepared by decomposition of iron oxalate *vs*. temperature of thermal decomposition T_d.
The light dots are experimental data. The dark dots correspond to the surfactants: (*1*) ethanol, (*2*) isopropanol, (*3*) the surfactant Twin-65, (*4*) butanol, (*5*) SDS.

the spectral line sharply decreased upon an increase in the polysorb pore size. According to nucleation conditions [135] [see Eqn (13)–(15)], a decrease in the pore size leads to a decrease in the cluster size in the pore. The curve shown in Fig. 12 corresponds to the onset of cluster melting, which is attributable to an increase in the intracluster atomic mobility. For the γ-Fe_2O_3 nanocluster system, the dependence of the spectral surface area A on the temperature of thermal decomposition of iron oxalate (T_d) has a minimum at $T_d \approx 488$ K (Fig. 18). According to Mössbauer spectroscopy, the T_d value is related to the mean size of the γ-Fe_2O_3 cluster prepared by decomposition of iron oxalate. It was found that the cluster size increases from 2 to 4 nm as the temperature T_d changes from 488 to 508 K. The right-hand branch of the curve in Fig. 18 is related to a decrease in A (following an increase in T_d) and an increase in the atomic mobility in the γ-Fe_2O_3 cluster, similarly to the observed decrease in A in the iron hydroxide clusters formed in polysorb pores. It should be noted that the Mössbauer spectra of iron hydroxide and iron oxide clusters contain no 'broad component' corresponding to the movement of the cluster as a whole, which is due to the restricted diffusion of clusters in the pores. This will be discussed in the Section 'intercluster dynamics.' Thus, changes in the spectral surface area are associated with the change in the atom mobility within the cluster.

The left-hand ascending branch in the curve $A = f(T_d)$ (Fig. 18) is related to further decrease in T_d and, correspondingly, to a decrease in the size of clusters down to their disappearance to give separate atoms, dimers and trimers of Fe^{3+} (see Fig. 17, curve *1*). Thus, the minimum in the $A = f(T_d)$ curve observed at $T_d = 488$ K appears to be due to the onset of formation of an iron oxide cluster.

As noted above, the atomic cluster mobility is strongly influenced by the intercluster interactions. They decrease the surface energy. However, the intercluster interactions and strain can be reduced due to the action of surfactants or mechanochemical treatment. It can be seen from Fig. 18 that the spectral surface area markedly decreases after the action of surfactants. Thus, weakening of the intercluster interaction results in an increase in the intracluster atomic mobility and in a decrease in the melting point. Relation (26) can be used to estimate the R_{cr} value, corresponding to the onset of melting of γ-Fe_2O_3 clusters and to compare it with the $R(V)$ value observed experimentally from Mössbauer spectra. Using the values $\rho = 5.18 \times 10^6$ g m^{-3} (see Ref. 196), $\Delta\alpha \approx 1$ J m^{-2} (see Ref. 197) and $q \approx 2 \times 10^{-19}$ (see Ref. 136), we obtain

$$R = \frac{aT_0}{\delta T},$$

where $a = 0.1-1.0$ nm. As a result, for $T_m = 300$ K, we have $R \approx 0.1-1.2$ nm, which is in good agreement with the value $d = 2$ nm found from the Mössbauer spectrum.

It is also noteworthy that the existence of the specific solid–liquid transition state in which atoms possess enhanced mobility can provide an interpretation for the effect of adsorption decrease in the material strength (Rehbinder effect)[198] at the atomic-molecular level due to wetting and deformation of its surface under the action of a surfactant.

For nanosystems prepared by compacting, changes in $\langle r^2 \rangle$ and in the heat capacity were noted. Thus the low-temperature heat capacity in the region of T from 0.06 to 10 K for a compacted nanosystem of copper clusters with nanocluster sizes of 6.0 and 8.5 nm was 5–10 times higher than the heat capacity of bulk copper. An increase in the heat capacity of a nanostructured copper [199] is attributable to an increase in $\langle r^2 \rangle$ on the surface of nanoclusters.

Study of the phonon spectra of a compacted system of Ni clusters with a size of 10 nm prepared by neutron scattering showed an increase in the density of phonon states at low frequencies (below 14 MeV) [200] with respect to coarsely crystalline Ni. Calculation of the heat capacity based on these data demonstrated its increase (1.5–2-fold) for a nanosystem with respect to the bulk material. A Ni nanosystem formed from 70-nm clusters [130, 201] also has a higher heat capacity (by 10%–25%) up to 600 K, which is attributed to a decrease in the Debye temperature.

A model calculation of nanosystems with cluster sizes of 1.1, 2.0 and 2.8 nm using the Lennard-Jones potential showed [202] diffusion of the phonon spectrum to both high- and low-frequency regions, most of the additional vibrational modes being located at grain boundaries. The results point to a substantial increase in the heat capacity with a decrease in the cluster size in the region of $T \approx 100$ K, which is due to the predominant contribution of the low-frequency vibrations at grain boundaries.

Thus, joining of nanoclusters into a nanosystem smoothes only partially the dynamic characteristics of nanoclusters.

b. Intercluster dynamics

Convenient nanosystems for study of the movement of a cluster as a whole are represented by cation exchange resins, for example, styrene–divinylbenzene copolymers with different degrees of cross-linking (1%, 2% and 12% — samples A, B and C, respectively) and different sets of nanopores containing iron oxide nanoclusters with a size of 3 nm.[203–205] Due to the cross-links, which restrict the diffusion of iron hydroxide nanoclusters in the copolymer, nanoclusters are placed in cages with a varied size. The Mössbauer spectra of iron hydroxide clusters in polymeric systems with different degrees of cross-linking are presented in Fig. 19. These spectra in the velocity range of ± 100 mm s^{-1} exhibit a narrow component and a broad component.

The movement of iron hydroxide clusters can be described in terms of the model of limited diffusion of particles in the field of a potential. The form of the potential and the diffusion rate can be found from the temperature dependence of the surface area of the narrow component and from the shape of the broad component.[206] The Mössbauer spectrum consists of Lorentzian components with non-broadened (narrow) lines having the intensity

$$A_0 = z^{-2}\left|\int \exp(i\mathbf{k}^*\mathbf{R}) \exp\left(-\frac{U(\mathbf{R})}{kT}\right) d^3\mathbf{R}\right|^2.$$

Here $z = \int \exp(U(\mathbf{R})/kT) d^3\mathbf{R}$, $\mathbf{k}^*$ is the radiation wave vector, $\mathbf{R}$ is the cluster radius.

Analysis of the $A = f(T)$ function provides the possibility of reproducing the movement potential $U(\mathbf{R})$. Study of the temperature dependence $A_0 = f(T)$ for a sample with 2% cross-linking (sample B) gives $A_0 = 0.06$ ($T = 264-243$ K) and the potential form as a square (spherical) well with elastic walls (Fig. 20). If we

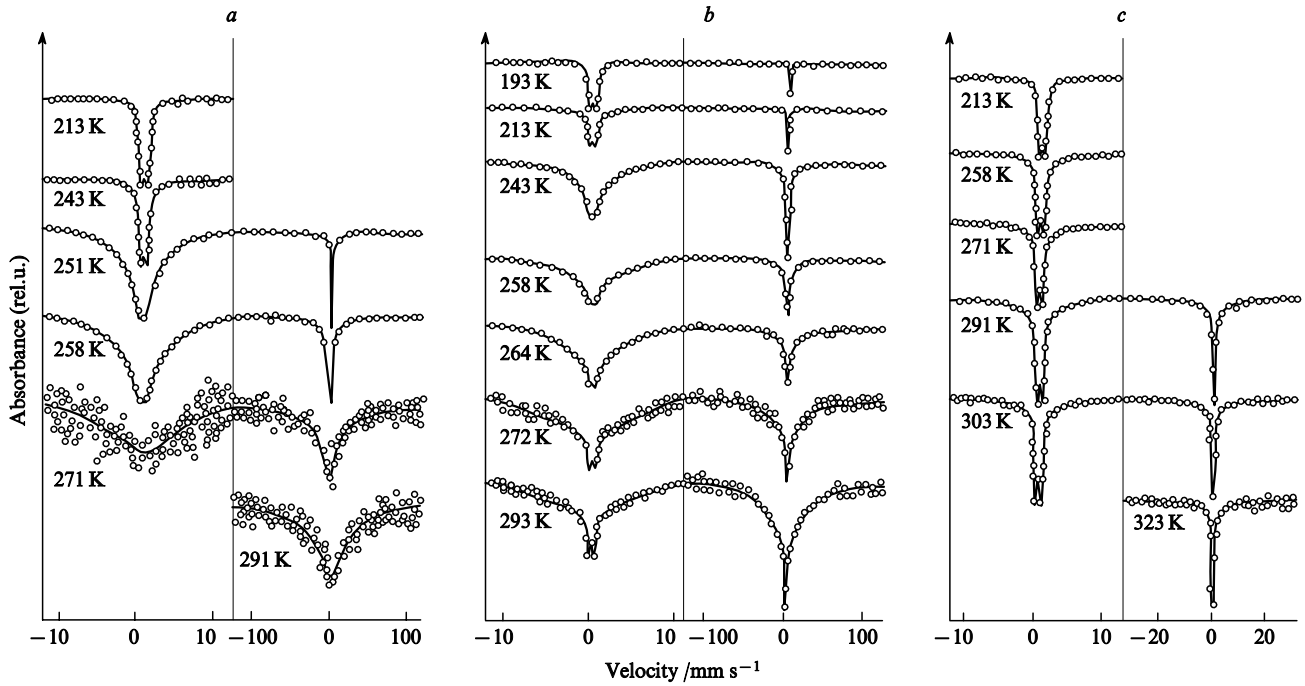

Figure 19. Mössbauer spectra of iron hydroxide in an ion exchange sulfo resin at different temperatures; (*a*) 1% (sample A), (*b*) 2% (sample B), (*c*) 12% of cross-linking (sample C).

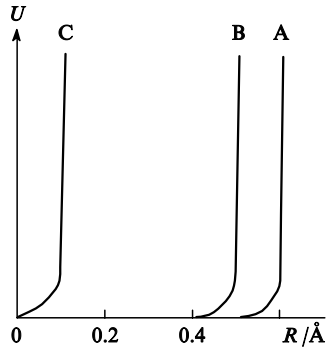

Figure 20. Shape of the potential well describing the movement of iron hydroxide clusters in samples A, B and C (see the notation to Fig. 19).

assume that in a spherical cage with radius b, only the diffusion coefficient is temperature-dependent, then

$$A_0 = \frac{g(\sin kb - kb\cos kb)^2}{(kb)^6}.$$

For $kb = 3.6$, the radius of the potential well is 0.5 Å. The spectrum calculated using these parameters is in good agreement with the experimental one.[203–205] An increase in the size of the cage (sample A) increases the well radius to 0.62 Å, while a decrease (sample C) arrests completely the cluster movement. Thus, the maximum clearance between the cluster and the network is equal to 0.62 Å. This type of motion with limited diffusion is observed for iron oxide hydroxide FeO(OH) clusters in an iron accumulating protein, ferritin.[206]

c. Structural features of nanosystems. The role of defects and stresses

Combination of clusters into a nanosystem gives rise to numerous phase boundaries and dislocations and a corresponding intercluster stress. The phase boundaries play a crucial role in considering many mechanical properties, heat conductivity, electrical conductivity and magnetic characteristics of nanostructures. The size effects and intercluster interactions also influence the structural phase transitions. The phase transitions related to the movement of atoms in a cluster were considered in the previous Section. Now we shall discuss the structural changes in a nanosystem induced by variations of the cluster size, intercluster interactions, defects and dislocations.

The intercluster interactions create stresses, excess energy and excess pressure at the cluster boundaries. The excess energy per dislocation is calculated from the formula [207]

$$E_d = \frac{Gb^2}{4\pi(1-v)}\ln\frac{r}{r_0}, \qquad (27)$$

where G is the shear modulus, b is the Burgers vector characterising the magnitude of the shift of an edge dislocation, $b = a_0/\sqrt{2}$ (a_0 is the lattice constant), v is the Poisson coefficient (usually 0.3), r is the maximum distance at which the influence of dislocations is still retained, r_0 is the minimum dislocation size. With the assumption that the concentration of dislocations in a cluster is determined by the ratio of the cluster surface area to the cluster volume, the excess energy density of the cluster ε_d is

$$\varepsilon_d = \frac{Gb^2}{4\pi(1-v)}\frac{1}{R}\ln\frac{r}{r_0}. \qquad (28)$$

Thus, the excess energy density decreases as the cluster size R increases and approaches zero for a bulk material. It should be noted that the applicability of this approach to small nanoclusters is restricted by the thickness of the surface layer of the cluster (a), *i.e.*, Eqn (28) can be used only to calculate the excess energy of clusters with $R > a$.

When considering the influence of defects and dislocations on the properties of nanosystems constructed from nanoclusters of arbitrary sizes, one should proceed from the thermodynamic concentration of defects and dislocations, which takes into account the chemical potential and the excess energy of the cluster surface. The excess energy gives rise to excess pressure, which is equal to $\sim 10^9$ Pa for 1-nm clusters. If the pressure drop between the cluster bulk and the cluster surface is neglected, the concen-

tration of defects in the cluster (c_s) can be calculated from the relation

$$c_s = \frac{a(3R^2 - 3aR + a^2)}{R^3}, \quad (29)$$

where a is the thickness of the surface layer. It can be assumed that in the absence of pressure drop, *i.e.*, when the influence of defects inside the cluster is counterbalanced by the influence of defects on its surface, the difference between the chemical potentials in the cluster and on the surface is equal to zero

$$\Delta\mu^0(0) + kT\ln\frac{c_s}{c_0} = 0, \quad (30)$$

where c_0 is the defect concentration on the surface.

Naturally, the allowance made for the pressure drop shifts the equilibrium by

$$\Delta\mu^0(\delta p) = \Delta\mu^0(0) + V\delta p, \quad (31)$$

where V is the volume of a defect, $\delta p = 2\alpha/R$ (α is the surface tension). In this case, the new equilibrium of the system is determined by the expression

$$\Delta\mu^0(0) + V\delta p + kT\ln\frac{c}{c_0} = 0. \quad (32)$$

By solving the set of equations (30) and (32), we obtain

$$c = c_s\exp\left(-\frac{2\alpha V/R}{kT}\right). \quad (33)$$

The dependence of c on the cluster size in the R/a units is shown in Fig. 21. The maximum in the $c = f(R/a)$ curves is located at $R/a = 25$, which corresponds to $R = 10-50$ nm. It is the 10–50-nm clusters, having the maximum defect concentration and the highest excess energy, that are involved in the formation of nanosystems. This is important for the understanding of the reasons for the appearance of new properties in nanosystems. In nanostructures formed by molecular clusters from CO_2, N_2 and SF_6, an increase in the stress with an increase in the cluster size was observed.[208] Numerous studies of nanosystems by X-ray diffraction methods point to the influence of the cluster size and interfacial stresses on the structure of a nanosystem.[209] Analysis of nanocrystalline Al, Ru, Cu and AlRu systems[210,211] showed that the mean square deformation of these systems is equal to 1%–3%, which is markedly greater than the deformation of coarse-grain metals. Meanwhile, by modelling X-ray diffraction of clusters of different size,[212] it was shown that small clusters do not contribute to the elastic distortions of the crystal lattice caused by dislocations at phase boundaries. The major contribution is made by larger nanoclusters. Thus, there exists a transient region of nanocluster sizes in which the effect of stresses at phase boundaries is a maximum; this complies with the conclusions based on the thermodynamic model for the influence of defects [see relations (29) and (33)].

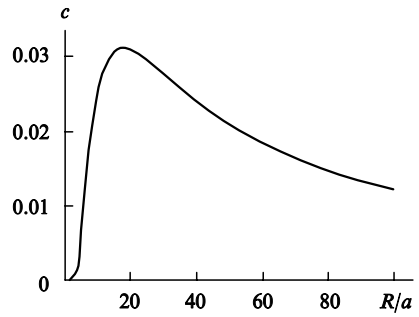

Figure 21. Density of defects c in the cluster *vs*. the cluster size (in the R/a units).

The excess stresses result in a change in the crystal lattice constant. In most cases, the lattice parameters decrease, which is attributed to the generation of additional energy at phase boundaries, to the change in the specific volume and to the appearance of excess pressure.[213–215]

Nanosystems are characterised by unusual mechanical properties: microhardness and superplasticity. At room temperature, microhardness of nanosystems is 2–7 times higher than that of the corresponding bulk materials. According to a publication,[216] the Vickers microhardness of a cluster

$$H_v \approx H_0 + k_0 d^{-1/2}$$

increases with a decrease in the cluster size. The results of microhardness measurements for nanosystems formed by Ag, Cu, Pd, Se, Fe and Ni metal clusters have been reported.[217] It was found that a decrease in the cluster size is accompanied by an increase in the nanosystem hardness. In addition, microhardness of a nanosystem depends on the conditions of its treatment. These conditions influence the structure of interfaces, cluster interactions and the cluster size. For example, relaxation and annealing of defects at the phase boundaries of the $Al_{98.5}Mg_{1.5}$ clusters, with the cluster size remaining invariant ($d \approx 150$ nm),[218] decrease the microhardness from 1.7 to 1.45 GPa. However, the cluster size is affected by annealing to a markedly greater extent. Thus annealing of a nanosystem formed by Pd clusters at 475–600 K brings about an increase in the cluster size and, hence, an almost threefold decrease in the system microhardness. Upon annealing of nanosystems of Ag ($d \approx 10$ nm) and MgO ($d \approx 10$ nm) clusters, their microhardness changed in different ways: the microhardness of the metallic nanosystem decreased[219] (apparently, due to an increase in the size of Ag clusters), while the microhardness of the oxide system remained constant up to 870 K.[220]

Yet another remarkable feature of nanosystems is superplasticity: upon stretching, the sizes of samples can increase by factors of dozens without fracture. For example, the Ni and Ni_3Al nanosystems were found to exhibit low-temperature superplasticity at $T_s = 470$ and 450 °C, respectively (these temperatures are almost three times as low as the melting point).[221] The superplasticity of oxides and ceramics presents considerable interest from both theoretical and practical standpoint. The results of a study[222] indicate that the superplasticity of nanosystems manifests itself for cluster sizes from 1 nm to 1 μm; the cluster size should not change on thermal treatment. For example, in two-phase systems, the growth of clusters of one phase caused by heat treatment is suppressed due to the presence of the other phase. It is also believed that the system superplasticity is affected by the presence of the amorphous phase.[223]

The high strength and the superplasticity of nanosystems can be explained by using the extremal dependence of the defect density and excess energy on the nanocluster size which we obtained. Indeed, nanosystems composed of small nanoclusters with sizes $d < 10$ nm contain few defects and dislocations and display exceptionally high hardness. Meanwhile, in nanosystems formed by clusters with intermediate size ($10 < d < 100$ nm), the number of dislocations is maximal, which ensures their record plasticity.

Thus, superhard materials can be produced by using nanosystems composed of nanoclusters with $d < 10$ nm, while manufacture of superplastic materials requires nanosystems composed of nanoclusters with $10 < d < 100$ nm.

The stresses arising at phase boundaries play one more important role — they act as growth stimulators for assembled nanosystems. The self-assembly and the growth of superlattices of the $Si_{0.84}Ge_{0.16}$ alloy under the action of stress induced by alternating absorption of layers of silicon and germanium atoms at the Si(001) plane at 380 °C has been considered.[224] Computer simulation using an elastic field of stress forces arising on the layer surfaces showed that the stresses are different for the layers formed by atoms differing in size. The superlattice $Si_{0.84}Ge_{0.16}$

formed under the action of stresses had equal distances between the layers (*i.e.*, a regular alternation of layers was observed) and a regular arrangement of atoms within a layer. The period of the $Si_{0.84}Ge_{0.16}$ superlattice was 3 nm.

Considerable interest is also aroused by structural phase transformations in nanosystems. It was found that the nanometer size results in stabilisation of many non-equilibrium structures. Thus nanoclusters with a size of several nanometers constructed from unstable Fe(C) and γ-Fe phases are known. They are stable even at room temperature, whereas in the bulk materials, these phases are stable only at temperatures of 800 and 1000 °C, respectively.[225] Stable CdS nanoclusters with the rock salt structure are also known, whereas bulk CdS can be stabilised only at high pressures.[226] The stabilisation of structures not equilibrated at a given temperature due to the formation of small clusters with $d < 10$ nm can be explained by the action of the surface energy and pressure created by the surface tension, which reaches a value of several Gigapascals for 1–2-nm clusters.

Non-equilibrium states of a cluster system can also be stabilised by external pressure. The phase transitions induced by high pressure (1.5 GPa) in the crystal of C_{60} (fullerite) but absent at normal pressure have been studied.[152] It was found that crystallisation of C_{60} at room temperature yields a crystal lattice with dumb-bell-shaped $(C_{60})_2$ dimers in the lattice points.§ An increase in the temperature (> 423 K) gives an orthorhombic C_{60} structure, which passes into a tetragonal structure at 723 K.

Now we shall consider one more example of phase transitions in nanocrystalline ferroelectrics. A ferroelectric transition accompanied by a first-order structural phase transition was observed in $BaTiO_3$ [227] and $PbTiO_3$ [228] crystals. This transition is characterised by a critical temperature T_C (similar to the Curie point for ferromagnets) above which the substance passes into the paraelectric state. Spontaneous polarisation in ferroelectrics results from first-order phase transitions, due to the tetragonal distortion of the crystal lattice (change in the $c:a$ ratio). At temperatures above T_C, the tetragonal crystal lattice is transformed into a cubic lattice; then $c:a \to 1$.¶

The influence of the cluster size on the ferroelectric transition was studied in relation to the $PbTiO_3$ nanosystem. This system was prepared by precipitation from a solution of clusters with sizes of 20–100 nm. For the $PbTiO_3$ crystal, the effect of the cluster size on the temperature and character of the phase transition was studied by X-ray diffraction analysis and differential scanning calorimetry (DSC). The X-ray diffraction study (Fig. 22 *a*) showed that the $c:a$ ratio changes upon phase transition. It was found that, as the cluster size decreases, the $c:a$ ratio decreases; however, even for the smallest of the clusters studied (with $d = 23$ nm), the $c:a$ ratio does not reach unity. The extrapolation $c:a \to 1$ gives the d_{cr} value, *i.e.*, the cluster size at which the spontaneous polarisability disappears, the lattice symmetry becomes cubic, and the nanosystem passes into a paraelectric state. The DSC data indicate that the phase transition temperature (T_C) decreases as the cluster size decreases from 80 to 30 nm (Fig. 22 *b*), the phase transition is gradually smeared and for clusters with $d = 26$ nm, no phase transition is observed. The decrease in T_C amounted to 20 °C. Despite the absence of obvious indications of the transition, in the case of the crystal consisting of clusters with $d = 26$ nm, one should still assume the presence of a residual smeared ferroelectric transition, which cannot be observed, apparently, due to the scatter of particles over sizes and the diffusion character of the transition itself.† It should be noted that the T_C value is also influenced by the intercluster interaction, which determines not only the T_C value but also its scatter.

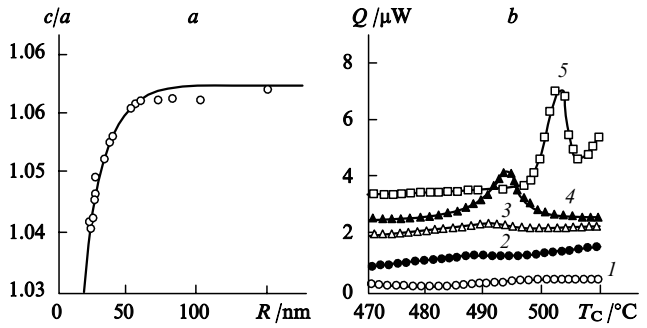

Figure 22. Ratio c/a (tetragonal distortion) (*a*) and temperature of phase transition (*b*) in the crystal of the $PbTiO_3$ ferroelectric *vs.* the cluster size.[228]
(*a*) X-Ray diifraction data; (*b*) differential scanning calorimetry data (scanning 5 K/min) obtained for clusters with $R = 26$ (*1*), 31 (*2*), 39 (*3*), 57 (*4*) and 81 nm (*5*).

The structure-magnetic properties of nanocluster systems depend largely on the presence of defects and dislocations. As noted above, the formation of a nanosystem is accompanied by the appearance of interfaces (or phase boundaries). Under some conditions, these phase boundaries can participate in the nucleation of nanoclusters. Thus the magnetic properties of cluster nitride phases arising upon nitriding of an iron catalyst in a flow of ammonia at 200–350 °C were studied by Mössbauer spectroscopy. When the nitrogen concentration in the cluster catalyst is 1 mass % – 2 mass %, phases of defect ε-iron nitride are formed in the catalyst. During low-temperature annealing (200 °C) in air, the nitrogen atoms are segregated at phase boundaries, resulting in a decrease in T_C of the nitride phase. Nitrogen is accumulated on the defects. An increase in the temperature of annealing to 400 °C results in normal gradient concentrational diffusion of the nitrogen atoms over the cluster, resulting in their uniform distribution and an increase in T_C. The equilibrium segregation of nitrogen atoms near the phase boundaries decreases the magnetic stability of the defect regions and serves as a peculiar method for 'magnetic decoration' of the stress fields by defects.[230]

Let us consider yet another example of the influence of phase boundaries and defects on the magnetic properties of the copper nanostructure with an admixture of iron atoms. Plastic deformation of the copper samples with iron dissolved therein [231] afforded copper clusters with a size of 130–150 nm and ~3-nm iron clusters.‡ The annealing of this system at a temperature of < 1000 K results in the diffusion of iron atoms along the grain boundaries and in enlargement of iron clusters; simultaneously, the magnetic properties of the system change. As the temperature rises (> 1000 K), the solubility of iron in copper increases, and normal concentrational diffusion starts; this results in vanishing of the clusters and uniform dissolution of iron atoms in copper.

The magnetic susceptibility of paramagnetics is influenced by the presence of vacancies in the crystal lattice. For nanocrystalline Pd prepared by plastic deformation (pressure with shear),[6] the magnetic susceptibility was found to increase, which was attributed to an increase in the density of electronic states at the Fermi level. This increase is possible due to the presence of vacancies in the lattice formed by palladium clusters.

d. Optical and electric properties of nanocluster systems

Specific optical and electric properties arise in nanocluster systems owing to the effects associated with the restriction of the electron

§ The same dimers are formed in the mechanochemical reaction.[153]

¶ As noted above, nanosystems composed of clusters with $d < 10$ nm contain fewer defects and dislocations. The minimisation of the crystal lattice energy with a decrease in the cluster size results in the transition from a crystal lattice with lower symmetry to a lattice with higher symmetry.[229]

† The residual smeared ferroelectric transition appears to occur also in the crystals formed from clusters smaller than 26 nm, down to 7 nm.

‡ Iron clusters can be located, for example, at grain boundary junctions.

free path (quantum restrictions) and with the appearance of discrete energy levels in the valence band and the conduction band, which changes the selection rules for optical transitions. It is possible to create one-electron nanocluster systems in which the number of discrete energy levels increases, as the cluster size decreases; in this case, the energy of electron transition from one electronic level to another increases according to the relation $e^2/2c$ ($c \approx d$). This energy can become greater than the kinetic energy of an electron (kT) and thus stimulate tunnel transitions. The development of these systems provides new potentialities for the manufacture of rectifier devices, diodes, *etc*.

It has already been noted that the nanocluster semiconductors CdS, CdSe and InP exhibit a 'blue shift' of frequency. For example, in the case of CdSe, the energy of electron transition changes from 1.7 eV (red region) to 2.4 eV (green region) as the cluster size diminishes from 20 to 2 nm.

The preparation of light-tunable diodes based on CdSe nanoclusters has been described.[232,233] In one study,[232] CdSe nanoclusters were assembled as a thin film on the surface of a luminescent polymer (poly-*p*-phenylenevinylene, PPV). The polymer was grown on an indium oxide–tin layer able to let carriers as holes pass through. In addition, a nanocrystalline CdSe layer was coated with a Mg–Ag film for electron injection. When a voltage was applied to this system, electroluminescence was observed. The electroluminescence wavelength can be changed by varying the size of nanoclusters.

An increase in the oscillator strength and a decrease in the de-excitation time typical of some nanoclusters may lead to the design of non-linear optical nanosystems, for example, optical switches which modulate a laser beam from a high-power laser by weak, non-resonant pulses.

Light absorption and emission by porous silicon is attributed to the appearance of new optical transitions. In bulk silicon, electronic transitions between the excited state of the conduction band and the ground state of the valence band are forbidden. Only non-radiative transitions involving phonons are possible. In nanocrystalline silicon, non-radiative transitions are also retained but their contribution is insignificant. Radiative electronic transitions are more characteristic in this case.[234,235]

In addition to the 'blue shift', a 'red shift' can also be observed in nanosystems. This occurs in semiconductors with a broad forbidden band. For example, a decrease in the absorption edge energy by 0.2 eV ('red shift') has been observed for the γ-Fe_2O_3 nanoclusters with $d \sim 8.5$ nm residing in the pores of a polymeric ion exchange sulfo resin.[236] The most probable reason for the 'red shift' is the appearance of strains and stresses on the surface of the clusters (due to surface tension) which form the lattice of the solid. Indeed, in a 5-nm γ-Fe_2O_3 cluster, the internal pressure ($p = 2\alpha/R$) equals 0.4 GPa.

X-Ray diffraction studies demonstrated a 0.35% decrease in the lattice volume for γ-Fe_2O_3 nanoclusters. If the compression modulus for γ-Fe_2O_3 is taken to be equal to that for Fe_3O_4, then a 0.35% compression of the γ-Fe_2O_3 lattice brings about an internal pressure of 0.35 GPa, which is in agreement with the calculated value, equal to 0.46 GPa, derived from the estimates of the influence of the surface tension. The action of pressure is known to induce a phase transition of a semiconductor to the conducting state. Thus, when magnetite Fe_3O_4 is kept under a pressure of 5 GPa, it passes to the conducting state. Since the forbidden gap (E_g) for γ-Fe_2O_3 is 2.1 eV and that for Fe_3O_4 is 2 eV, then the decrease in the width of the forbidden gap in γ-Fe_2O_3 induced by high pressure is 0.15 eV, which is in good agreement with the results obtained in the optical experiment.

The optical properties of a nanosystem depend on its organisation and on the intercluster interaction. Light absorption by silver nanoclusters prepared using reverse micelles has been studied.[142] This procedure yields nanoclusters with a very narrow size distribution (2 to 8 nm), the surface of which can be stabilised by thiols, and then they can be used for assembling two- and three-dimensional structures. Nanosystems incorporating silver nanoclusters with sizes of 4.5, 5.2 and 6.1 nm were prepared. Two- and three-dimensional systems were formed on a graphite substrate by applying a drop or several drops of a colloid solution of silver nanoparticles in hexane. It was found that coating of the surface of silver nanoclusters by dodecanethiols influences their optical properties: the absorption band of the plasmon peak shifts to lower energies (from 2.85 to 2.73 eV) and its width increases (from 0.9 to 1.3 eV). These data were interpreted on the basis of the model of light absorption by clusters proposed in a study.[54] The shift of the absorption band was attributed to the electronic plasmon absorption inside the cluster, while band broadening was ascribed to the change in the dielectric constant of the medium (intercluster absorption). Simulation of the absorption spectra of a 2D nanosystem showed that a decrease in the cluster size in an isolated medium (reverse micelle) results in a substantial increase in the width of the absorption band due to the restriction of the electron free path, while placing the clusters in media with different dielectric constants ε_m stimulates the shift of the absorption band, an increase in ε_m resulting in a substantial decrease in the absorption energy. Thus, the shift of the absorption band observed for silver nanoclusters can be explained by the increase in the dielectric constant upon the assembly of a 2D hexagonal network of silver clusters.

Optical investigations (Fig. 23) of the nanosystems formed show that their properties depend on the degree of structure perfection and the preparation procedure. Application of one drop of a colloid solution on the substrate gives rise to a 2D nanosystem with a hexagonal network of silver clusters (Fig. 23, curve *2*). The absorption spectrum of nanoclusters in this system differs from the spectrum of these clusters in solution: the plasmon absorption band shifts by 0.27 eV and its width increases from 0.8 eV (in solution) to 1.0 eV (in the nanosystem).

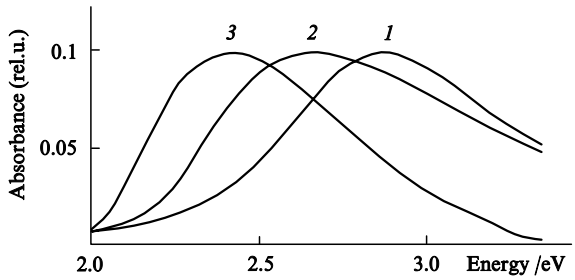

Figure 23. Variation of the plasmon absorption width and peak shift in a colloid solution and in nanosystems containing 4.5-nm silver clusters formed on a carbon substrate.[142]
(*1*) Initial colloid solution with $[Ag_n] = 2.5 \times 10^{-3}$ mol litre^{-1}; (*2*) two-dimensional cluster system formed on a substrate after deposition of one drop of a colloid solution; (*3*) three-dimensional cluster system formed after deposition of three drops of a colloid solution.

An increase in the concentration of nanoclusters in a colloid solution or deposition of several drops of the colloid solution on a graphite substrate afford a more perfect, three-dimensional, face-centred cubic structure.

For the 3D structure (Fig. 23, curve *3*), further shift (by 0.47 eV with respect to that in solution) of the absorption band toward lower energies is observed; however, the width of the plasmon peak diminishes to 0.7 eV. The narrowing down of the absorption band is a result of the increase in the electron free path. This implies that an electron penetrates the barrier between the nanoclusters (a ~2-nm thick coating). The possibility of electron tunnelling between metal surfaces by such a long distance[237] is an important feature for the design of new materials for lasers, optics and electronics.

The restriction of the electron free path in small clusters and the presence of intercluster boundaries impart new electric properties to nanosystems obtained on the basis of nanoclusters. For

example, metals or semiconductors pass into a non-conductive state. This transition is due, first, to a decrease in the carrier density as a result of the restriction of the electron wavelength and the appearance of discrete electronic levels and, second, to a decrease in the conductivity as a result of electron scattering at phase boundaries and generation of dielectric charges. Indeed, a 7–20-fold increase in the electric resistance was observed for nanocrystalline copper in the region of $T < 275$ K.[238] The high resistivity of cobalt films (2- to 50-nm thick) was mainly attributed [239] to the effects of electron localisation. The influence of the phase boundaries between nanoclusters on the electric properties of nanosystems may be due to long-range stress fields and to the dynamic state of the atoms.

In recent years, substantial progress in the fabrication of 3D, 2D and 1D electronic nanosystems (see, for example, Ref. 41) used to produce single-electron transitions, unidimensional nanowires, *etc.* has been made. The 3D organisation of nanoclusters is the most obvious. The 3D nanosystems are prepared by crystallisation of clusters (instead of atoms). For example, nanocrystalline copper was prepared in this way. However, the researchers were able to crystallise only large copper clusters (~40 nm) passivated by thiols.[143] Crystallisation of copper selenide clusters $Cu_{146}Se_{75}(PPh_3)_{10}$ was also performed.[240] The crystals thus obtained can be used in semiconductor devices. The idea of producing an organised 3D cluster structure from clusters linked by spacer molecules proved fruitful. The spacers allow one to control the distance between the clusters; this can be accompanied by spontaneous crystallisation. An advantage of this approach is that it provides the possibility of changing the energy barrier to passage of an electron through the cluster. Figure 24 shows the change in the Coulomb barrier between the Au_{55}^* clusters depending on the spacer length and nature.[41]

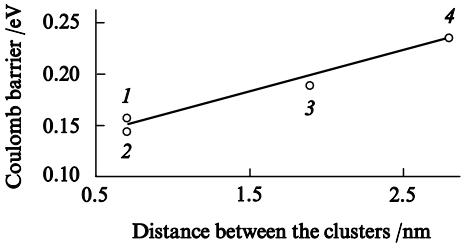

Figure 24. Coulomb barrier *vs.* distance between the clusters.[41]
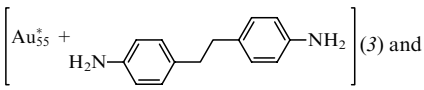
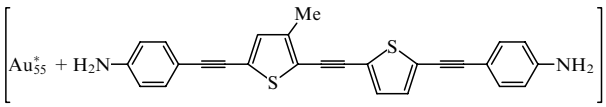
The dots on the straight line correspond to the $Au_{55}(PPh_3)_{12}Cl_6$ (Au_{55}) (*1*) and $Au_{55}(PPh_2C_6H_4SO_3Na \cdot H_2O)_{12}Cl_6$ (Au_{55}^*) (*2*) clusters and the systems



(*3*) and



(4).

Two-dimensional cluster structures are usually assembled using molecular clusters stabilised by ligands. Perfect layers of gold clusters with alkanethiol coatings which virtually did not interact with the substrate and were self-assembled due to van der Waals forces have been prepared.[241] If the interaction of the clusters with the substrate is enhanced, the structure loses its perfection. However, 2D cluster structures cannot be used in conducting devices or in a tunnelling microscope without proper fixing on the substrate. Study of Au and Pd clusters on various substrates (gold, mica, glass, silicon) demonstrated that chemical fixing of clusters on the support can be easily attained, whereas a perfect organisation of the 2D structure is achieved with difficulty.[41] The point is that self-assembly requires that the building blocks be free and mobile; however, when the clusters are attached to the substrate surface, the mobility decreases. The binding between the adsorbed cluster and the substrate can be weakened by treating the substrate with a surfactant. Thus deposition of the $Au_{55}(Ph_2PC_6H_4SO_3H)_{12}Cl_6$ clusters onto a single-crystal Au(111) surface modified by aminothiols improved the ordering of the 2D layer.

The assembly of the 2D layers for electronic devices is performed in the presence of spacer molecules, which allow one to control the distances between the clusters. These nanostructures are prepared by dissolution of clusters with appropriate spacers in Langmuir–Blodgett films; the cluster ligands and the spacer molecules should be complementary.

Of great interest from the practical standpoint are unidimensional cluster structures, nanowires. They are formed as whiskers at atomic steps of the surfaces. A nanowire from gold clusters was prepared using porous membranes based on alumina with 7-nm channels in which clusters consisting of Au_{55} cores stabilised by ligands were placed.[242]

Nanowires are also prepared from carbon nanotubes. The conduction of nanotubes can be switched (from the metallic to the semiconductor type) by changing their helical structure.[154] Electronic devices are assembled by combining nanotubes with different structures. The combination of carbon nanotubes in pairs of 'armchair' (A) and 'zigzag' (Z) types was considered.[154] Calculation of the switching from the metallic type of conduction (A state) to the semiconductor type (Z state) showed an asymmetry along the tube axis, which provides a rectifier effect. This result is in line with experimental data [243] on the rectifying effect of nanotubes.

e. Magnetic properties

The magnetic properties of nanocluster systems are influenced by both size effects and intercluster interactions and the cluster organisation. One of the best known and well-studied phenomena is superparamagnetism, *i.e.*, the change in the direction of the magnetic moment of the cluster as a whole due to thermal fluctuations without losing the magnetic ordering. The formation of magnetic domains in cluster systems depends on both the individual properties of the clusters (magnetic anisotropy) and the intercluster interactions. Therefore, magnetisation processes in these systems depend appreciably on the defectiveness of the cluster structure and on phase boundaries.

The magnetic quantum tunnelling effects and giant magnetoresistance also present interest. The new effects include the first-order magnetic phase transitions in nanoclusters and nanocluster systems in which the magnetic ordering and magnetisation disappear by a jump upon an increase in the temperature or a decrease in the cluster size.

Superparamagnetism. The phenomenon of superparamagnetism consists in the generation of measurable thermal fluctuations of the magnetic moment of the cluster upon a decrease in the cluster size to 1–10 nm. The fluctuation time ($\tau = 10^{-9}$–10^{-10} s) can be calculated using a simple equation

$$\tau = \tau_0 \exp\left(\frac{K_a V}{kT}\right), \qquad (34)$$

where K_a is the magnetic anisotropy constant of the cluster, V is the cluster volume. The observation of superparamagnetism depends on the time of measurement (τ_{meas}) of the magnetic characteristics, namely, magnetisation and magnetic susceptibility. If $\tau < \tau_{meas}$, the system is referred to as a superparamagnetic system. If $\tau > \tau_{meas}$, the superparamagnetic state cannot be detected. In this connection, Mössbauer spectroscopy with a characteristic time of measurement $\tau_{meas} = 10^{-8}$ s (the time of Larmor precession of the ^{57}Fe nuclear spin in the magnetic field) has become a unique method for the investigation of superparamagnetism. The superparamagnetic relaxation of the magnetic moment with $\tau \approx 10^{-8}$–10^{-10} s causes line broadening in the Mössbauer spectra and disappearance of the magnetic hyperfine

structure. Mössbauer spectroscopy makes it possible to estimate the relaxation times in the range of $10^{-8}-10^{-10}$ s and cluster sizes in the range from several nanometers to tens of nanometers.

One more important characteristic of a nanosystem is the magnetic anisotropy constant. This value is related to the magnetic structure and the shape of the cluster. In addition, it characterises the state of the surface, defects and intercluster interactions. Thus for γ-Fe_2O_3 nanoclusters formed in the pores of a sulfo resin with a size of ~ 7 nm, the magnetic anisotropy [236] is 4.4×10^5 J m^{-3}, which is much higher than the value $K_a = 4.7\times10^3$ J m^{-3} for a bulk sample.

It is known that ferromagnets have a magnetic domain structure below the critical temperature. In the absence of an external magnetic field, a system formed from ferromagnetic clusters has a minimum magnetic energy (E_m), which consists of the exchange and dipole energies and the energy of magnetic anisotropy

$$E_m = E_{ex} + E_d + E_{an}\,.$$

The exchange interaction (E_{ex}) lines up the magnetic moments parallel to one another; it is responsible for the uniform magnetisation of domains, and the dipole interaction (E_d) induces antiparallel arrangement of the magnetisation vectors of neighbouring domains, thus decreasing E_m.

As the cluster size decreases below some critical value, the fragmentation of a cluster into domains becomes energetically unfavourable; in this case, a system of single-domain clusters with single-phase magnetisation is formed. Transition of a ferromagnetic cluster from the single-domain state with single-phase magnetisation into a multidomain state changes superparamagnetic properties.[244, 245] When the cluster size increases ($R > R_{cr}$), the energy of anisotropy $U = E_{an} = K_aV$ decreases to zero, which is accompanied by a corresponding decrease in the relaxation time τ and the change in the superparamagnetic properties.

A cluster having the critical size R_{cr} occurs in a state of uniform magnetisation, its magnetic moment being constant over the whole volume $\mathscr{M}(r,\theta,\varphi) = \mathscr{M}_0$ (r is the radial coordinate, θ and φ are the polar and azimuthal angles). When $R > R_{cr}$, the uniform magnetisation state is no longer energetically the most favourable, and rearrangement of $\mathscr{M}$ over the whole particle bulk takes place. It was found [244, 245] that

$$R_{cr} \simeq 2.085\sqrt{\frac{3I}{4\pi}}\,,$$

where I is the exchange integral. The height of the potential barrier was calculated [244] using the formula

$$U = \frac{K_a}{2}\int\left(\cos^4\omega - 3\cos^2\omega\sin^2\omega + \frac{3}{8}\sin^4\omega\right)\mathrm{d}V, \qquad (35)$$

where ω is the function $\omega(R,\theta)$, characterising the deviation of the magnetic moment of the cluster from the uniform magnetisation state. For a nanosystem with a cubic symmetry ($\omega \ll 1$),

$$U_{cub} = \frac{K_a}{2}\int(1-5\omega^2)\mathrm{d}V. \qquad (36)$$

If one compares expressions (35) and (36) with the relation for the calculation of the total moment of the cluster

$$\mathscr{M} = \mathscr{M}_0\int\cos\omega\;\mathrm{d}V \approx \mathscr{M}_0\int\left(1-\frac{\omega^2}{2}\right)\mathrm{d}V, \qquad (37)$$

it turns out that a minor deviation of $\mathscr{M}$ from $\mathscr{M}_0$ (by $\omega^2/2$) gives an order of magnitude higher change in the energy of the anisotropy of the potential barrier. Note that for clusters with a uniaxial symmetry, in which the magnetisation state deviates from the uniform state, the U value does not decrease sharply with the cluster size

$$U_{rel} = \frac{K_a}{2}\int\left(1-\frac{3}{2}\sin^2\omega\right)\mathrm{d}V. \qquad (38)$$

The superparamagnetic behaviour of a nanocluster system formed by Fe–Ni and Fe clusters with a size of 10–25 nm has been studied.[244, 245] To separate the clusters and to weaken the magnetic dipole interaction between them, clusters with a filler and with a content of iron clusters equal to 10% were studied. The data of Mössbauer spectroscopy indicate that the superparamagnetic relaxation time for 11.5-nm clusters is shorter than the relaxation time of 10.5-nm clusters; subsequently, τ increases in proportion with K_aV, which is consistent with the beginning of the deviation from uniform magnetisation.

Magnetisation and quantum magnetic tunnelling. The state of the cluster surface, cluster shape and intercluster interaction influence substantially the magnetisation curves of a nanosystem and the coercive force. Calculations of the relaxation time upon transition of the system into the state with uniform magnetisation show an increase in the energy of anisotropy and the related coercive force following a decrease in the cluster size.[244] The magnetic hysteresis curves for nanocrystalline Ni and Co [246] indicate that the coercive force H_c in cluster nanosystems subjected to plastic deformation is several times as great as H_c for bulk materials. Low-temperature annealing leads to a decrease in H_c with the cluster size remaining invariant, due to the annealing of defects, while high-temperature annealing results in lower H_c and larger clusters. Thus, the increased coercive force of nanocrystalline metals and alloys is related to the stresses and defects at the cluster boundaries and to the single-domain state of the clusters.

The influence of arrangement of Co nanoclusters on the magnetisation curves has been investigated.[22] The colloid Co clusters with sizes of 5.8–8.0 nm were arranged into a 2D hexagonal lattice on a graphite substrate. Studies of the superparamagnetic properties of this system demonstrated shifting of the blocking temperature § of the assembled structure ($T_b = 63$ K) towards higher values with respect to T_b for the colloid solution ($T_b = 58$ K). The increase in T_b is due to the increase in the energy barrier K_aV as a result of intercluster interactions. The total saturation magnetisation of the nanocrystalline system was found to decrease to $M_s = 80$ emu g^{-1} with respect to that of bulk cobalt ($M_s = 162$ emu g^{-1}). The decrease in M_s is due to the presence of the stabilising ligand layer around the Co clusters, which decreases the total magnetic moment of the cluster due to the exclusion of electrons of the Co atoms located on the surface. Attention is drawn to the difference between the magnetisation curves and hysteresis loops for colloid solutions of clusters and organised nanosystems (Fig. 25). Magnetic saturation is achieved for the fields $H = \sim 2$ T only in the case of the organised nanosystem, which implies collective rotation of the magnetic moments of nanoclusters.

The superparamagnetic behaviour of nanoclusters has been considered so far as a thermally activated process with an energy barrier of about K_aV. However, in organised nanosystems, quantum-tunnelling transitions accompanied by a discrete change in the magnetisation of the whole nanocluster system are also possible. These effects were observed for the $[Mn_{12}(CH_3COO)_{16}\cdot(H_2O)_4O_{12}]\cdot 2\,CH_3COOH\cdot 4\,H_2O$ single crystal, which is constructed from acetylacetonate manganese nanoclusters (Mn_{12}^*) with identical sizes.[45] This nanosystem exhibits unusual magnetisation and magnetic hysteresis curves (see Fig. 2). The hysteresis loop is stepwise and consists of vertical and flat sections. In the flat sections of the hysteresis loop, the relaxation time of the magnetic moment is longer than the time of the measurement ($\tau_{meas} \approx 600$ s). In the sloping sections, the relaxation time is close to the time of measurement, which gives rise to several

§ Blocking temperature is the temperature at which no thermal fluctuations take place over the period of magnetisation measurement.

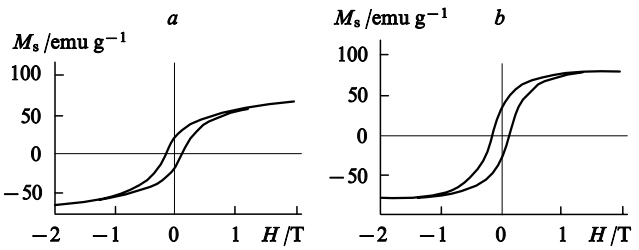


Figure 25. Magnetisation curves for Co nanoclusters with $d = 5.8$ nm; (*a*) a colloid solution in pyridine ($T = 3$ K), (*b*) a nanosystem organised on the graphite surface.[22]

minima in the curves for the dependence of τ on the external magnetic field (Fig. 26*a*). The dependence of $\Delta M/\Delta H$ on H provides exact magnitudes of the fields at which the relaxation times have a minimum. The relaxation time oscillates with respect to the applied field with a minimum corresponding to the steps in the hysteresis loop. Figure 26*b* gives the experimental τ values obtained at different temperatures for the H_0 values corresponding to the minima in the $\tau = f(H)$ curve (Fig. 26*a*): H_0 varies from 0 to 2.64 T with the step $H_{n+1} - H_n = \Delta H = 0.44$ T. At these points discontinuous change in τ is observed. They correspond to the sequence of intersection of electron levels with the spin $S = 10$. Calculation using the formula $\Delta H = D/g\mu_B = 0.44$ T (D is splitting of the level in the crystal field, g is the gyromagnetic ratio) gives $D = 0.60$ K, which coincides with the value $D = 0.61$ K,

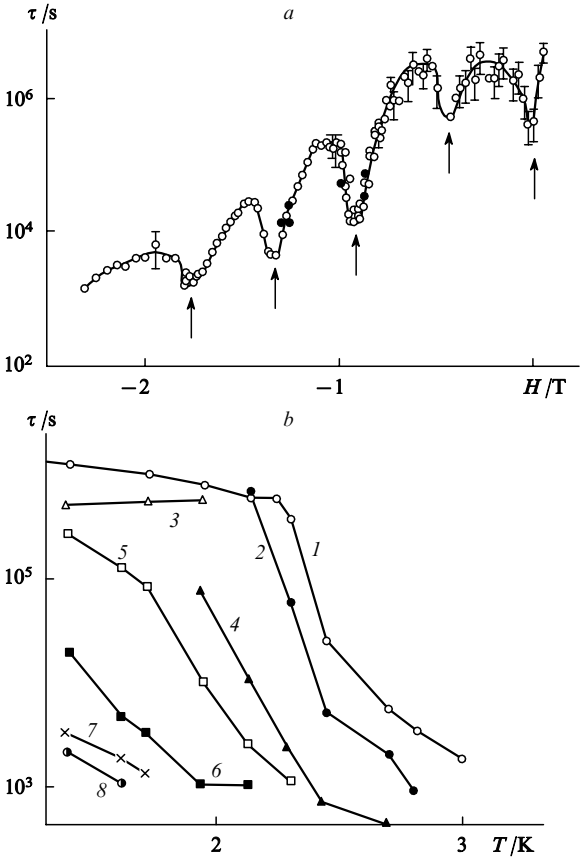

Figure 26. Relaxation time of the magnetic moment of the Mn_{12}^* cluster *vs.* the strength of the external magnetic field (*a*) and *vs.* temperature at different H_0 values (*b*).[45] The measurements were carried out at $T = 2.1$ K; (*a*) the arrows mark the H_0 values at which the steps are observed when the electron levels coincide; (*b*) H_0 values (in T): (*1*) 0, (*2*) 0.44, (*3*) 0.60, (*4*) 0.88, (*5*) 1.32, (*6*) 1.76, (*7*) 2.20, (*8*) 2.64.

reported in a study.[247] Thus, relaxation of the magnetic moment is accelerated when tuning by the magnetic field results in coincidence of the electron levels. This is indicative of quantum tunnelling in the magnetic cluster system, which is possible only when the levels of all clusters contained in the molecular crystal strictly coincide. The decrease in the relaxation time with an increase in temperature (Fig. 26*b*) is apparently due to the electron tunnelling through excited levels with lower Boltzmann occupancy. The probability of tunnelling depends on the width and the height of the barrier. Each minimum of the relaxation time corresponds to the resonance tunnelling from a given level with a time of the order of the measurement time.

An attempt has been made[248] to find out whether quantum tunnelling occurs in large clusters, for example in iron oxide hydroxide clusters, which constitute the core of the protein ferritin. The superparamagnetism phenomenon in such a large cluster (maximum size 6 nm) is usually observed at temperatures above 10 K (depending on the size of the ferritin core). Nevertheless, at low temperatures (5 and 12 K), the hysteresis curve for magnetisation of this cluster in the field with $H = 0$ also displays a step. It is obvious that for this system, coincidence of levels upon tuning by a magnetic field is impossible, which precludes quantum tunnelling. However, at one point ($H = 0$) with doubly degenerate levels, tunnelling is still possible. In addition, the blocking temperature of this system depends on the external magnetic field according to a non-trivial pattern. The temperature increases for low fields, passes through a maximum and decreases for high fields with $H > 0.3$ T. The increase in T_b for low fields is attributed to the violation of the quantum tunnelling condition at $H \neq 0$, while the decrease observed at high fields is ascribed to the decrease in the activation barrier to thermal fluctuations. It should be noted that in this experiment, the $\Delta M/\Delta H = f(H)$ curves have a standard shape, pointing to the absence of the quantum character of transitions.

Giant magnetoresistance effects. The giant magnetoresistance effect (GMR) in clusters is a great decrease in the resistance of the cluster material (by 1000%) when it has been inserted in a magnetic field, whereas the magnetoresistance of a bulk sample changes slightly (for example, the resistance of permalloy, 80% Ni–20% Fe, increases by 3% in a magnetic field). The GMR effects were observed in a study of the magnetic properties of various metallic[249–252] and oxide[253–257] nanosystems, the mechanisms of GMR origination for nanocrystalline metals and metal oxides being different.

Magnetic nanoclusters are prepared by dissolving one metal (for example, Fe or Co) in the matrix of another (conducting) metal (for example, Cu or Ag); these two components should be poorly soluble in each other. In a nanosystem consisting of a conducting metallic matrix and magnetic clusters, the conduction electrons of the matrix are scattered on the magnetic moments of the clusters. When a magnetic field is applied, the direction of the magnetic moments of the clusters changes; this changes their interaction with the conduction electrons of the metallic matrix and, hence, the conductivity. The magnitude of the GMR effect is determined by the ratio of the electron free path (l) to the distance between the neighbouring magnetic clusters, which depends on the concentration of the dissolved metal. When the free path is long, an electron undergoes numerous scattering events before it enters into interaction with the magnetic cluster (the direction of the cluster magnetic moment does not influence the electron scattering and no GMR is observed). If the free path is relatively short, magnetic clusters can be involved in the percolation processes of the matrix and can interact strongly with one another, which also eliminates GMR.

For a system consisting of Co clusters dissolved in an Ag matrix,[251] the change in the Co concentration from 10% to 50% is accompanied by a substantial change in the electric resistance of clusters in the magnetic field (Fig 27). The most pronounced effect is observed when the Co concentration is $\sim 20\%$, which is

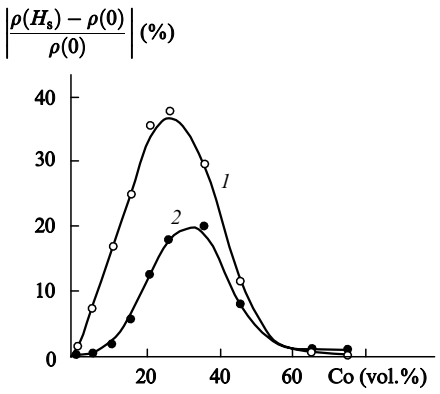

Figure 27. Giant magnetoresistance effect in the Co–Ag nanosystem *vs.* the Co concentration at $T = 5$ (*1*) and 300 K (*2*) in a 0.5-T magnetic field.[251]

attributed to the optimal size of the Co clusters in the Ag matrix. The GMR effect increases with a decrease in temperature.

To interpret the appearance of GMR, the two-current model is used. According to this model, electron scattering on the cluster magnetic moment in a disordered system is equivalent in two directions (for example, up and down). In a system ordered by a magnetic field, one direction, namely, that along the field, has a lower resistance than the other direction; this results in an overall decrease in the resistance. The change in the resistance ($\Delta\rho$) correlates with the change in the size of the magnetic cluster (d): $\Delta\rho \sim 1/d$.

Nanosystems that contain magnetic clusters are promising for controlling the magnetic field of conduction valves. A model system with epitaxially deposited Co(2.5 nm)–Cu(2.2 nm) nanofilms and with a Pb monolayer as an interlayer [252] demonstrated high sensitivity with respect to relatively weak fields (up to 0.05 T), which is of interest for practical purposes.

An even more pronounced effect (decrease of resistance by several orders of magnitude) was observed for perovskite structures of manganites.[253] These are ceramic samples, and, at first sight, in is difficult to distinguish a nanostructure in them. However, as will be shown below, the results of magnetic measurements in this type of system are interpreted resorting to cluster models. The results of studies of the $La_{0.67}Ca_{0.33}MnO_x$ films on $LaAlO_3$ substrates [253] are shown in Fig. 28. In the manganite,

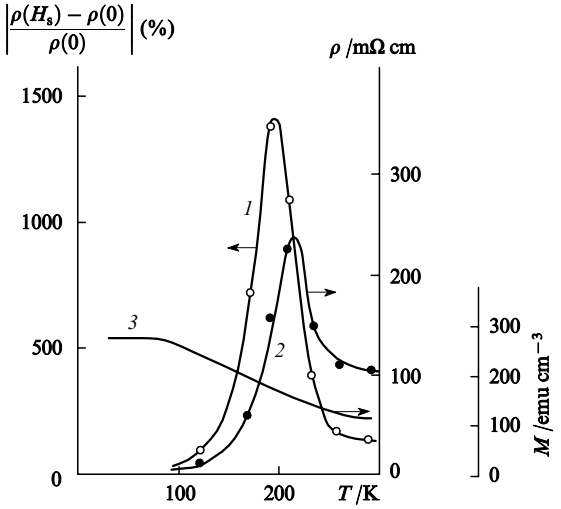

Figure 28. Temperature dependence of the giant magnetoresistance $|\rho(H_s)-\rho(0)/\rho(0)|$ (curve *1*), the resistance (ρ) (curve *2*) and magnetisation (M) (curve *3*) for $La_{0.67}Ca_{0.33}MnO_x$.

unlike metals or alloys, GMR does not cover the whole range of temperature measurement but occurs only in the vicinity of the phase transition from the semiconductor to metallic state (at $T = 220$ K). The most pronounced GMR effect induced by switching on a magnetic field with $H = 4-6$ T is achieved at $T \approx 190$ K, *i.e.*, near the point of transition to the metallic state. However, the temperature dependence of the magnetic moment of the manganite indicates that no sharp magnetic phase transition occurs at $T = 190-220$ K, magnetisation decreasing from the maximum value (saturation at $T = 100$ K) to $M \approx 100$ emu cm^{-3} (at room temperature). This indicates that the GMR is mainly influenced by the semiconductor–metal phase transition rather than the magnetic phase transition.

The GMR value is sensitive to the temperature of annealing and to the concentration of oxygen. Thus GMR measurements for a film prepared at 640 °C gave a smeared GMR peak with a maximum $\Delta\rho/\rho = 500\%$ at $T = 100$ K; for a film annealed at 700 °C in an O_2 atmosphere for 0.5 h, the peak $\Delta\rho/\rho = 1400\%$ was observed at $T \approx 200$ K; further increase in the annealing temperature to 900 °C resulted in a shift of the $\Delta\rho/\rho$ maximum to $T = 280$ K. The giant magnetoresistance observed in ceramics will undoubtedly find practical application.

The mechanism of the formation of GMR in ceramics differs apparently from that for metals. The spin dynamics in manganites of the $La_xCa_yMn_zO_3$ type in which the Mn atoms have been partly replaced by Fe has been studied by Mössbauer spectroscopy.[254–257] A $La_{0.75}Ca_{0.25}Mn_{0.98}Fe_{0.02}O_3$ sample prepared by sintering of salts and oxides was employed.[254] Figure 29 shows the Mössbauer spectra of this compound at different temperatures. Typically, in the region of GMR, the spectrum is separated into the paramagnetic central doublet and the magnetic HFS.[253] Broadening of the HFS lines points to a relaxation type of behaviour of the magnetic moment in the compound $La_{0.75}Ca_{0.25}Mg_{0.98}Fe_{0.02}O_3$, which is similar to the superparamagnetism observed for cluster nanosystems. However, ceramics consist of coarse grains, whose size is beyond the nanometer range.

Data on inelastic neutron scattering (INS) [258] attest that this compound is a ferromagnet at low temperatures; however, when the temperature rises, an inelastic component appears in the INS spectra. As the point of transition of the ceramics from the metallic to the paramagnetic state ($T_c = 250$ K) is approached, this component starts to predominate. This result suggests that in the region of transition of the ceramics from the semiconductor to metallic state, the GMR arises due to the appearance of fluctuating nano-sized regions, which possess ferromagnetic ordering. The size of these regions increases as the temperature decreases. An increase in the size of the region in which the ceramic passes from the paramagnetic to the metallic state is accompanied by an increase in the superparamagnetic relaxation time and the ultimate transition to the magnetically ordered, ferromagnetic state. The temperature range in which this magnetic transition takes place covers tens of degrees but it is in this region that the scattering of conduction electrons changes and the GMR effect arises due to the change in the relaxation time of the magnetic moment, the distances between the fluctuating clusters, and the cluster size (at temperatures below the phase transition temperature, there are no ferromagnetic nano-sized regions, whereas at high temperatures, there is no metallic electrical conductivity).

Magnetic phase transitions. In isolated nanoclusters and nanosystems, magnetic phase transitions are observed; usually, they are second-order phase transitions.¶ The magnetic phase transitions are characterised by Langevin dependences of magnetisation,[259] by disappearance of the magnetic order and spontaneous magnetisation at the Curie (T_C) and Neel (T_N) temperatures, respectively, and by smooth curves for the variation of the magnetisation with temperature. (Nanosystems can also possess superparamagnetism, resulting in an effective lowering of T_C and T_N.)

¶ These transitions are similar to those observed in bulk magnets.

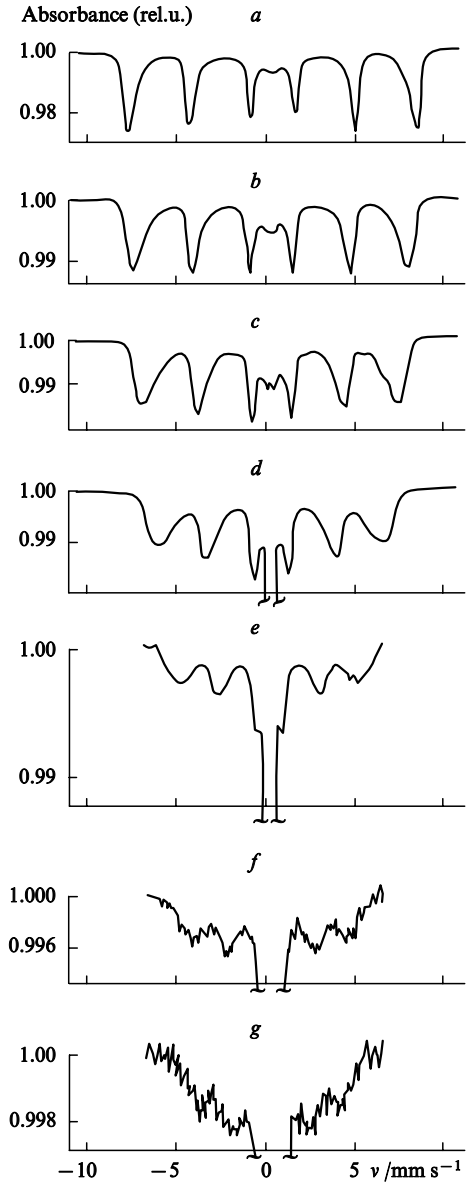

Figure 29. Mössbauer spectra ($a-g$) of a ceramic $La_{0.75}Ca_{0.25}Mn_{0.98}$-$Fe_{0.02}O_3$ sample at different temperatures.[254]
Temperature /K: 78 (*a*), 100 (*b*), 120 (*c*), 150 (*d*), 185 (*e*), 200 (*f*) 210 (*g*).

For several metal oxide clusters, in addition to second-order magnetic phase transitions, first-order magnetic phase transitions were also observed. In this case, a nanosystem lost abruptly the spontaneous magnetisation at some temperature T_{cc} or at some critical cluster size, below which the cluster passed into the paramagnetic state (not the superparamagnetic state). It is difficult to observe the first-order magnetic phase transitions in clusters by magnetisation measurements due to the scatter of clusters over sizes (this scatter results inevitably in smooth variations of the nanosystem magnetisation, and it is difficult to distinguish it from the superparamagnetic behaviour). However, Mössbauer spectroscopy can draw a distinction between the paramagnetic and magnetically ordered states; therefore, it is widely used to study the magnetic phase transitions.

The stepwise magnetic phase transitions were observed for iron oxide-based nanoclusters and nanosystems.[120,260–263] Note that first-order magnetic phase transitions also take place in some bulk transition metal and rare earth metal oxides and alloys.[259] They are interpreted using a thermodynamic model.[264]

A thermodynamic model for magnetic phase transitions in nanoclusters has been proposed.[261] A cluster is assumed to exhibit a pronounced magnetostriction effect, *i.e.*, to change its volume on passing from the magnetically ordered to the paramagnetic state. Meanwhile, the Curie point of a substance depends on its volume

$$T_C = T_0\left(1 + \beta\frac{V - V_0}{V_0}\right), \tag{39}$$

where β is the magnetostriction constant of a substance, V and V_0 are molecular volumes of a substance in the magnetically ordered and paramagnetic states. The change in the Gibbs energy density on passing from the magnetically ordered state to the paramagnetic state is written in the form

$$\Delta G_V = -\frac{1}{2}NkTm^2 + \frac{1}{2}\eta\left(\frac{V - V_0}{V_0}\right)^2 + 2\frac{\alpha}{R}\frac{V - V_0}{V_0} + \frac{1}{2}NkT\left(\ln\frac{1 - m^2}{4} + m\ln\frac{1 + m}{1 - m}\right), \tag{40}$$

where N is the number of atoms with the spin 1/2, $m = M/M_s$ is the relative magnetisation value (M_s is the saturation magnetisation), η is the volume compressibility, and α is the surface tension. The first term in Eqn (40) corresponds to the exchange energy density in the molecular field approximation, the second term reflects the deformation energy, the third term corresponds to the surface energy, and the fourth one matches the entropy term for the temperature dependence of magnetisation.

Minimisation of the free energy and solution of the set of equations $d\Delta G_V/dV = 0$, $d\Delta G_V/dm = 0$ gives

$$\frac{T}{T_{c0}} = m\left(\frac{1}{3}\gamma m^2 + 1\right)\left(\frac{1}{2}\ln\frac{1 + m}{1 - m}\right)^{-1}, \tag{41}$$

where $T_{c0} = T_0(1 - \beta\eta p)$ shows the change in T_0 due to pressure ($p = 2\alpha/R$), $\gamma = (3/2)NkT_0\eta\beta^2(1 - \beta\eta p)^{-1}$.

Figure 30 presents the temperature dependence $m = f(T/T_{c0})$ for different values of the parameter γ, which determines the character of the magnetic phase transition. For $\gamma < 1$, the phase transition corresponds to a second-order magnetic transition and when $\gamma \geqslant 1$, it is a first-order magnetic transition. The γ value can be represented as $\gamma = T_{cc}/T_{c0}$, where $T_{cc} = (3/2)NkT_0^2\eta\beta^2$. If the cluster size $R \leqslant R_{cr}$, then for $\gamma \geqslant 1$, the cluster passes from the magnetically ordered to the paramagnetic state upon a first-order phase transition.

$$R_{cr} = \frac{2\alpha\beta\eta}{1 - T_{cc}/T_{c0}}. \tag{42}$$

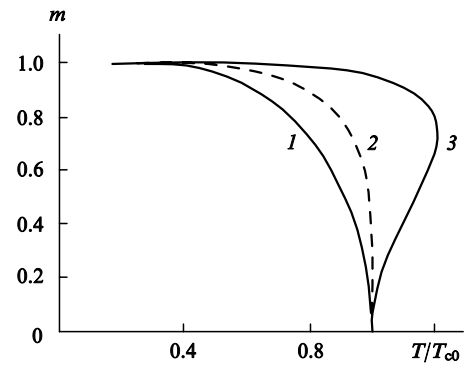

Figure 30. Temperature dependence of the cluster magnetisation for different γ (see the text).
(*1*) $\gamma < 1$, (*2*) $\gamma = 1$, (*3*) $\gamma > 1$.

For larger clusters, only the second-order phase transition can take place. It can also manifest itself as superparamagnetism at temperatures $kT > K_aV$.

The first- and second-order magnetic transitions were observed, for example, for the ferrihydrite $Fe_5HO_8 \cdot 4H_2O$ clusters formed in the polysorb pores.[261] The matrix method allows two cluster systems to be produced, namely, a system with isolated clusters and that with clusters interacting with one another (if several clusters occur in a pore). Figures 31 and 32 show the Mössbauer spectra of the ferrihydrite clusters obtained in 13- and 20-nm polysorb pores. The spectrum recorded at 4.2 K corresponds to a quadrupole doublet and consists of two parts — the central component and the magnetic hyperfine structure with relatively narrow lines (with allowance for the disorder of the cluster structure). As the temperature is raised, some of the HFS of the spectrum is converted into a paramagnetic doublet, without entering the intermediate states corresponding to the superparamagnetic behaviour. The results presented in Figs 31 and 32 suggest that a jumpwise first-order magnetic phase transition occurs in ferrihydrite clusters in the temperature range of 4.2–6 K. An increase in the iron concentration results in an increase in the cluster size; nevertheless, the spectral pattern at 4.2 and 6 K does not change.

In the spectra recorded at 10 K (Fig. 32 *c*) for large clusters ($c = 1.2 \times 10^{-3}$ mol litre^{-1}) formed in a 13-nm pore, the absorption line is broadened, which corresponds to the intermediate forms (between the quadrupole doublet and HFS), peculiar to superparamagnetism. Thus, at 10 K, a second-order magnetic transition is observed for large clusters, in addition to the first-order phase transition. For smaller clusters ($c = 1.2 \times 10^{-3}$ mol litre^{-1}, Fig. 31 *b*), line broadening is barely observed and the second-order magnetic transitions (superparamagnetism) do not show themselves. The appearance of superparamagnetism at 10 K made it possible to estimate the critical cluster size from the broadening of the HFS lines in the spectrum (Fig. 32 *c*), using relation (34): $R_{cr} \approx 2$ nm.

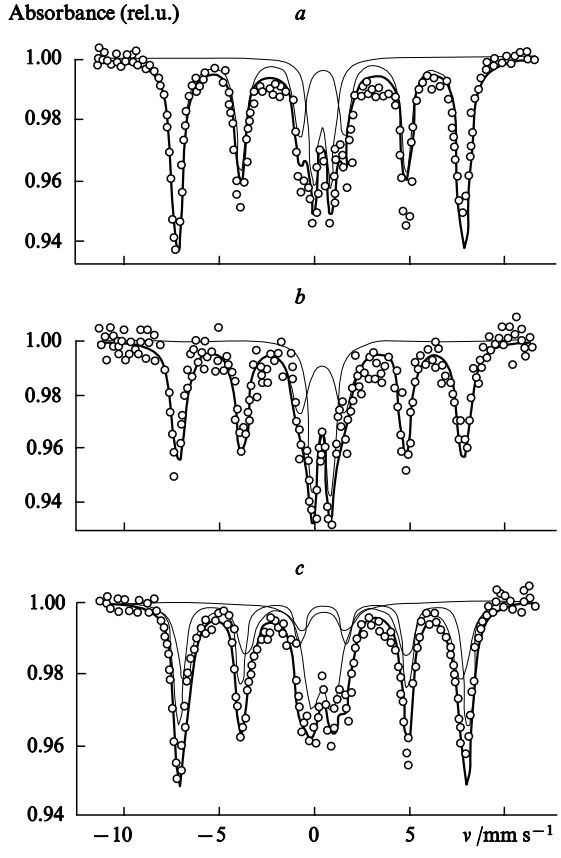

Figure 31. Mössbauer spectra of ferrihydrite clusters ($c = 1.2 \times 10^{-3}$ mol litre^{-1}) in polysorb pores with sizes of 13 (*a*, *b*) and 20 nm (*c*). Here and in Figs 32 and 33, the thick lines show the results of computer processing of the spectrum and the thin lines show its separation into components.
Temperature /K: (*a*) 4.2, (*b*) 10, (*c*) 42.

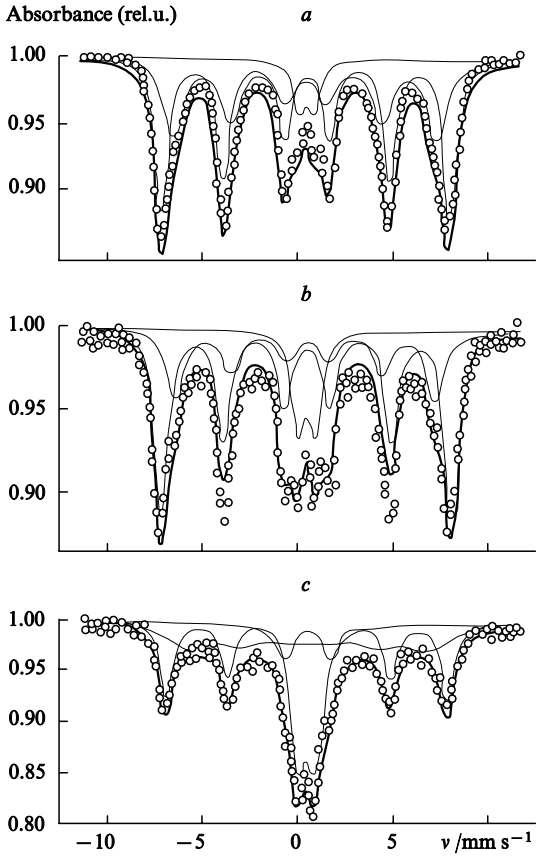

Figure 32. Mössbauer spectra of ferrihydrite clusters ($c = 1.2\,10^{-2}$ mol litre^{-1}) obtained in polysorb pores with a size of 13 nm at different temperatures.
Temperature /K: (*a*) 4.2, (*b*) 6, (*c*) 10.

Estimation of the size of the cluster formed in a pore from the concentration of iron atoms ($c = 1.2 \times 10^{-3}$ mol litre^{-1}) gives the value $R \approx 1-2$ nm (for an isolated cluster). Thus, these data and the data obtained on the basis of superparamagnetic relaxation can be used to estimate the R_{cr} value ($R_{cr} \approx 1.5-2$ nm).

Further growth of clusters and enhancement of their interactions is accompanied by appearance of second-order magnetic transitions: the HFS lines are markedly broadened and the first-order phase transition can no longer be distinguished against the background of the second-order transitions. Estimation of the R_{cr} size using relation (42) gives $R_{cr} \approx 1$ nm, which coincides in order of magnitude with the results obtained in experiments.

The effects similar to a first-order magnetic phase transition were also observed in the α-Fe_2O_3 nanoclusters,[265] in the α-FeOOH – α-Fe_2O_3 system,[266, 267] and in proteins, ferritin and hemosiderin, which include the magnetic core $(FeOOH)_8 \cdot (FeOOPO_3H)$.[268]

Yet another parameter determining the character of the magnetic phase transition is the external excess pressure. It has been noted above that the critical temperature of phase transition decreases upon an increase in pressure due to the change in the surface tension. A change in the external pressure by Δp entails a change in the magnetic transition temperature for the cluster by the value

$$\frac{\Delta T_{c0}}{T_0} = \frac{\Delta p}{2\alpha/R - 1/\beta\mu}. \quad (43)$$

Thus, a decrease in T_{c0} increases the probability of the first-order magnetic phase transition. A study of two nanosystems, namely, an ion exchange sulfo resin (sulfo cation exchange resin) incorporating iron hydroxide clusters with a size of 3 nm and a globular protein (ferritin) incorporating iron hydroxide clusters with a size of 6 nm has been reported.[262] In these systems, the interaction of clusters with the polymeric and biopolymeric networks changed due to hydration. The excess pressure on the cluster was determined from the deformation of the polymeric matrix [from the increase in the water volume which accompanied its crystallisation (freezing)]. This pressure is calculated from the expression

$$\Delta p = \frac{1}{\eta_m}\frac{\Delta V}{V}. \quad (44)$$

For $\Delta V/V = 0.09$ (for water) and $1/\eta_m = 5-10$ GPa,[196] it was found that $\Delta p = 0.45-0.9$ GPa, which is comparable in magnitude with the surface pressure in a 1.5-nm cluster (~ 1 GPa). Using relation (43), one can estimate the decrease in T_{c0} under the action of pressure. Assuming that $p = 1$ GPa, $\beta = 10^2$, $\mu = 10^{-11}$ m^2 J^{-1} and $1/N \sim 10^{-28}$ m^3 (the data were taken from publications [196, 261]), we have $\Delta T_{c0} = (0.1-1.0)T_{c0}$. Thus, ΔT_{c0} can reach a value of the order of T_{c0}.

The ΔT_{c0} value was estimated from the Mössbauer spectra of the sulfo cation exchange resin (in the range of $T = 4.2-30$ K) and ferritin (in the range of 4.2–78 K).[262] Hydration followed by freezing was found to be accompanied by a decrease in T_{c0}. This value was determined from spectra in which the paramagnetic state and the magnetic HFS of the spectra were equal. The following values were obtained: T_{c0}: 9–10 K for the hydrated sulfo cation exchange resin, 13–14 K for the dry cation exchanger, 30 K for hydrated ferritin, and 30–34 K for dry ferritin. Comparison of the T_{c0} values for the dry and hydrated samples provides the temperature shift $\Delta T_{c0} \approx 3-4$ K, which is in line with thermodynamic estimates.

The first-order magnetic phase transitions induced by intercluster stresses and defects can also arise in nanosystems containing larger nanoclusters (20–50 nm). These systems are formed in solid-phase chemical reactions (see Fig. 9),[263] for example, in cluster sintering, and are subject to substantial intercluster interactions. The phase transitions observed in these systems are similar to those in the ferrihydrite clusters (1–3 nm) in a polymeric matrix. Figure 33 shows the Mössbauer spectra of the α-Fe_2O_3–γ-Fe_2O_3 nanosystem. The spectra indicate that jumpwise magnetic transitions from the magnetically ordered state (magnetic HFS) to the paramagnetic state (central doublet) can take place in this system. These magnetic transitions take place at distributed critical temperatures $T_{c0} = 120-300$ K, which are lower than the temperatures T_{c0} for bulk samples of α- and γ-Fe_2O_3 (856 and 965 K, respectively). The decrease in T_{c0} cannot be due to superparamagnetism because of the large cluster size (see Fig. 9); therefore, the calculation using relation (34) affords relaxation times several orders of magnitude longer than τ_{meas}. As a consequence, magnetisation disappears abruptly, which is related to the transformation of the magnetic HFS of γ-Fe_2O_3 into a paramagnetic doublet (Figs 33 and 34 *a*).

The presence of the first-order magnetic phase transition in the α-Fe_2O_3–γ-Fe_2O_3 nanosystem is related to the strong intercluster interactions, which bring about substantial stress in the nanosystem. This stress results in the generation of enormous pressures (up to several Gigapascals). The pressures arise during sintering [121] of the α- and γ-Fe_2O_3 clusters, the unit cells of which have different specific volumes,† and under the action of defects

† The α-Fe_2O_3 clusters have an rhombohedral structure of the corundum type and γ-Fe_2O_3 has a spinel type cubic structure.

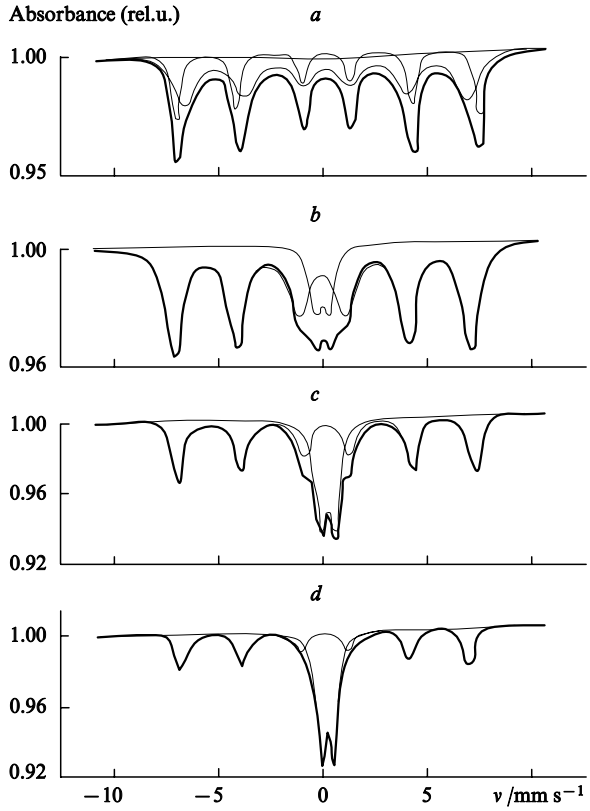

Figure 33. Mössbauer spectra of the α-Fe_2O_3–γ-Fe_2O_3 nanosystem (see Fig. 9) at different measurement temperatures.
Temperature /K: (*a*) 77, (*b*) 120, (*c*) 160, (*d*) 300.

and dislocations. As has been shown above (see Fig. 21), the density of defects has a maximum at a cluster size of exactly 20–30 nm. Further increase in the cluster size is accompanied by a decrease in the fraction of phase boundaries and defect density; thus, the cluster properties approach the properties of a bulk substance.

In addition to the first-order magnetic phase transition in this nanosystem, two more phase transitions were observed in this system, namely, a weak ferromagnetic–antiferromagnetic transition and a collective magnetic phase transition to give twined nanostructures.

Transitions from weak ferromagnetism (non-collinear antiferromagnetism) to antiferromagnetism (collinear antiferromagnetism) were observed for the α-Fe_2O_3 crystals. Weak ferromagnetism is also typical of $MnCO_3$, $CoCO_3$, MnF_2 and orthorhombic $MFeO_3$ crystals (M is a rare earth metal).[259] Weak ferromagnetism is found for antiferromagnetics with some small extent of non-collinearity of sublattice magnetisation. The non-collinearity of the magnetisation of sublattices in antiferromagnetic structures arises upon an increase in the temperature as a consequence of the instability of compensated antiferromagnetism.[269]

For bulk α-Fe_2O_3, a magnetic phase transition, known also as the Morin transition, takes place at $T_M \approx 260$ K; in this transition, the type of magnetic ordering changes jumpwise. When $T_M < 260$ K, collinear antiferromagnetism exists, while at $T > 260$ K, non-collinear antiferromagnetism (weak ferromagnetism) is observed. This transition is due to the internal symmetry of the crystal, which allows distortions in the crystal lattice at higher temperatures; this is accompanied by the rotation of spins through 90 °. The collinearity–non-collinearity phase transition for the magnetic moments of sublattices can be traced in the Mössbauer spectra as the change in the sign and the magnitude of the quadrupole splitting of the spectrum (ΔE_Q) possessing a magnetic HFS

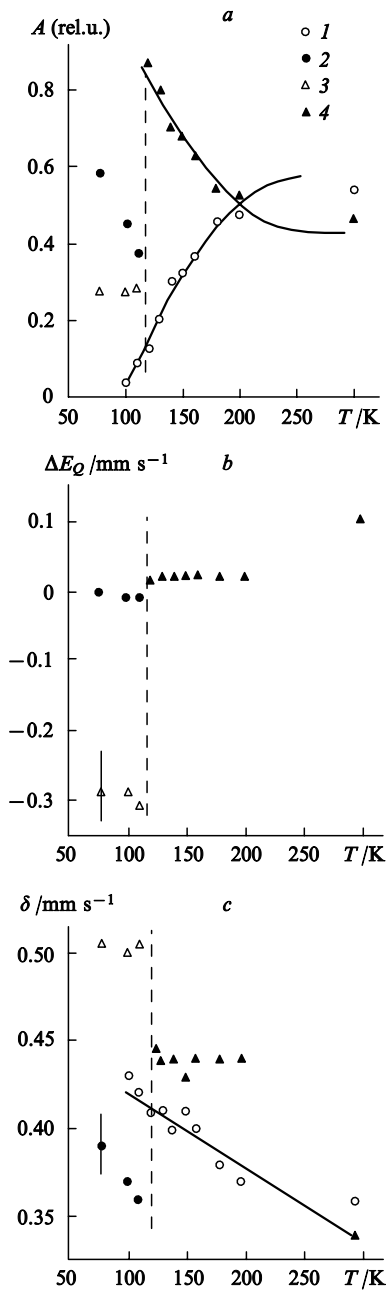

Figure 34. Results of computer simulation of the Mössbauer spectra of the α-Fe_2O_3–γ-Fe_2O_3 nanosystem: temperature dependences of the spectral surface areas (A) for various iron species (a), the quadrupole shift ΔE_Q of the magnetic HFS (b) and the isomer shift δ (c).
(1) Paramagnetic component (quadrupole doublet), (2) the magnetic component of γ-Fe_2O_3, (3) the magnetic component of α-Fe_2O_3, (4) the component corresponding to the twinning structure. The dashed line designates the region of the Morin phase transition.

$$\Delta E_Q = \frac{1}{8} e^2 q Q (3\cos^2\theta - 1),$$

where e is the electron charge, q is the crystal field gradient, Q is the quadrupole moment of the ^{57}Fe nucleus, θ is the angle between the directions of the atom spin and the electric field gradient on the nucleus. The high-temperature α-Fe_2O_3 phase is responsible for $\Delta E_Q = 0.2$ mm s^{-1}, and for the low-temperature phase, $\Delta E_Q = -0.3$ mm s^{-1}.

Now we shall consider specific features of this phase transition in the α-Fe_2O_3–γ-Fe_2O_3 nanosystem (Fig. 34 b). The low-temperature α-Fe_2O_3 phase ($\Delta E_Q = -0.3$ mm s^{-1}), exhibiting collinear antiferromagnetism at $T < 120$ K, passes into a state of non-collinear antiferromagnetism with $\Delta E_Q = 0-0.1$ mm s^{-1} at $T = 120$ K (high-temperature phase). Thus, in the nanosystem, the temperature of the Morin transition decreases to 120 K and the high-temperature phase has a lower ΔE_Q. The decrease in T_M is related to the magnetic dipole energy E_M and the exchange energy E_{exc} by a simple relation. As the cluster size decreases, the E_{exc} value decreases (because the T_{c0} value for Fe_2O_3 diminishes), and the probability of existence of the non-collinear antiferromagnetism increases. Similar examples of decrease in T_M following a decrease in the cluster size have been reported in other studies.[270, 271]

Yet another important circumstance should be mentioned. Despite the broad size distribution of nanoclusters, the phase transition in a nanosystem occurs at a fixed temperature $T_M = 120$ K. This attests to a collective transformation of the whole nanosystem, where the phase transition in one cluster initiates the phase transition in the whole sample. This type of phase transition with instantaneous collective phase transformations of the whole sample was also observed for the transformation of austenite into martensite in carbon steels (martensite transitions).[272]

Let us consider the temperature behaviour of the α-Fe_2O_3–γ-Fe_2O_3 nanosystem (from the Mössbauer spectroscopy data). At low temperatures ($T < 120$ K), both phases, α-Fe_2O_3 and γ-Fe_2O_3 exist in the system; at $T > 120$ K, the α-Fe_2O_3 and γ-Fe_2O_3 phases are converted into one common structure with the ΔE_α parameter corresponding to the α-phase, the crystal lattices of both phases being retained (X-ray diffraction data). The temperature dependence of the isomer shift δ (Fig. 34 c) demonstrates a sharp change in δ at 120 K: for the α-phase, δ decreases, while for the γ-phase, it increases jumpwise to an average value of 0.45 mm s^{-1}. These data point to collective transformations of the γ- and α-phases into an α-like phase; the retention of the crystal lattices of both phases can be explained by assuming the formation of a twinned nanostructure. Twinned structures are often formed upon crystallisation induced by mechanical deformations and during seed sintering. Twinning also occurs upon fast thermal expansion or compression and on heating of deformed crystals.[273, 274]

During the formation of the α-Fe_2O_3–γ-Fe_2O_3 nanosystem, sintering of iron oxide seeds takes place, resulting in the formation of strongly interacting clusters. It is strong intercluster interaction that appears to be responsible for the twin collective transitions in a nanosystem. As a consequence, the two-phase heterogeneous ($\alpha-\gamma$)-iron oxide nanosystem undergoes a sort of a phase temperature transition into a one-phase twinned nanostructure in which the γ-phase is attached to the α-phase. This transition is accompanied by the transfer of an electron from the γ-phase to the α-phase, which shows itself as an increase in the isomer shift.

This transition is a new feature of a heterogeneous nanosystem in which the generator of the transition, a cluster possessing a first-order collinear phase transition, induces the collective transition of the system to a twinned nanostructure. Indeed, the temperature of the twinning phase transition ($T_t = 120$ K) for this nanosystem coincides with the temperature of the antiferromagnetic–weak ferromagnetic phase transition ($T_M = 120$ K).

V. Conclusion

The unusual properties of nano-sized cluster systems have been attracting the attention of researchers for many years, and the interest in these systems has not abated. It is noteworthy that substantial progress in the study of nanoclusters and nanocluster systems has been achieved in recent years. This is due to the fact that the modern level of experiment permits not only the preparation of separate nanocluster particles but also investigation of their properties.

The main advances achieved in the design of new nanocluster systems are listed below:

— methods for the preparation of monodisperse nanoclusters and ordered nanosystems have been developed;

— ways of controlling cluster size, intercluster interaction and intercluster stress, permitting the formation and variation of the properties of nanosystems have been found;

— methods of stabilisation of nanocluster systems *via* passivation of isolated clusters have been proposed;

— methods for the production of ordered layers and superlattices using film and matrix relaxation and by the introduction of spacers have been developed.

Further progress in nanocluster chemistry would involve the synthesis of new nanostructures, creation and development of theoretical and experimental approaches to the study of mechanical, elastic, thermal, electronic, optical and magnetic properties of nanoclusters and nanosystems. The sequence nanocluster – nanosystem – nano-device should be adhered to.

The ordered systems and cluster nanocrystals manufactured on the basis of molecular clusters, fullerenes and colloid clusters can be used in nanotechnology for the design of single-electron devices, optical switches and non-linear systems, lasers with frequency tuned by changing the cluster size and quantum magnetics.

Fullerenes can be employed to manufacture unidimensional wires, rectifiers, diodes, electroluminescent light sources, field-emission cathodes and flat displays.

There appeared the possibility to produce superplastic materials by varying the mechanic properties.

The development of ordered nanolayers and superlattices opens the way to the development of single-electron devices, holographic images and superhigh-density magnetic recording.

The authors are grateful to Academician I I Moiseev, who initiated writing of this reviews and to Academicians V I Gol'dansky and L A Piruzyan, Doctors of Science V N Buravtsev and Yu M Maksimov for useful remarks.

Abstract. Data on the structures and reactivities of nitrosonium complexes of organic compounds are systematised and generalised. The characteristic features of the electronic structure of the NO^+ cation are responsible for a wide structural variety of nitrosonium complexes. Reactions of nitrosonium complexes are described. The bibliography includes 172 references.

I. Introduction

Nitrosonium complexes of organic compounds have been extensively studied over many years. The continuing interest in these complexes stems from the fact that they are intermediates in a series of reactions, including nitrosation of aromatic compounds,[1] nitrosohalogenation of alkenes,[2–4] *etc*.[5] Recently, interest in these complexes has increased due to the discovery of the unique role of the NO molecule in biochemical processes.[6–15] It is assumed that the nitrosonium cation and some molecules generating the nitrosonium ion are involved in processes of neurotoxic and neuroprotective actions of nitric oxide[16,17] (*cf*. Refs 18–20)† and participate in cross-linking of DNA.[21,22]

Investigations of the structures and reactivities of nitrosonium complexes are essential to the understanding of the role of the NO^+ cation in various chemical processes (from ionospheric[23,24] to biochemical[9,16–19]) giving rise to different classes of organic compounds.

In the present review, the data on the structures and reactivities of nitrosonium complexes published over the last 10–15 years are analysed and systematised. The results of earlier studies are cited if they are necessary for an understanding of the problem and for elucidation of new trends in this area of exploration.

† Hereinafter, the reader is referred to studies, which are either indirectly associated with the problem under consideration or even contradictory.

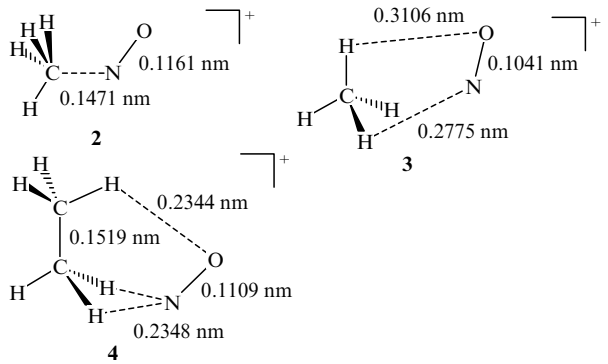
II. Complexes of the nitrosonium ion with alkanes

Electrophilic substitution in the aliphatic series of compounds lies at the basis of one of the procedures for the functionalisation of alkanes.[25–27] Weak electrophiles, in particular NO^+, can be involved in electrophilic aliphatic substitution reactions along with strong electrophiles, such as H^+ and Alk^+. Nitrosonium salts react with adamantane in the presence of HF, oxygen or nitriles to form 1-fluoroadamantane,[28] 1-nitroadamantane[29] or *N*-(1-adamantyl)amides,[30] respectively. Generally, it is assumed that the attack of the electrophile E^+ in electrophilic aliphatic substitution reactions occurs at the C–H bond to give intermediates of the type **1** characterised by the two-electron three-centre mode of bonding of the E, H and C atoms (3X-2e-intermediates)[25–27] (*cf*. Ref. 31).

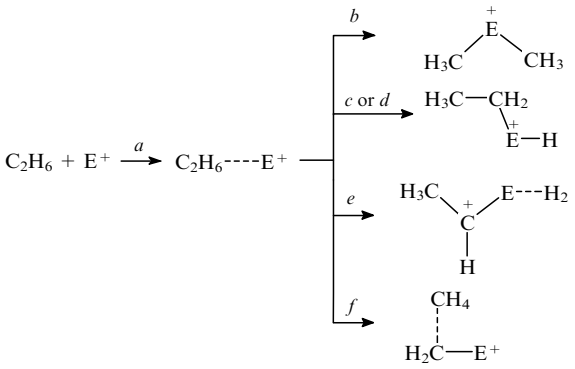
$$HCR_3 + E^+ \longrightarrow \underset{\mathbf{1}}{\overset{E^+}{H\cdots CR_3}} \longrightarrow CR_3E + H^+$$

According to high-level *ab initio* calculations for the reactions of the NO^+ cation with methane and ethane,[32,33] the mechanism of the reactions of the nitrosonium cation with alkanes might differ from that described above. Thus, the NO^+ cation attacks the methane molecule at the carbon atom to form complex **2** whose precursor is unstable complex **3** [$\Delta H_0 = -15.5$ kJ mol^{-1}, where ΔH_0 is the relative energy of the complex taking into account the zero-point energy; the results of calculations by the MP4SDTQ/6-31 + G(dp)/MP2/6-31 + G(dp) + ZPVE//MP2/6-31 + G(dp) method]. An alternative path involving the attack of the NO^+ cation at the C–H bond is less favourable (by 60.2 kJ mol^{-1}).



Analogously, unstable complex **4** {$\Delta H_0 = -16.7$ kJ mol^{-1}; calculations by the CISD + Q/TZP + //MP2/6-31G(dp) + ZPVE[MP2/6-31G(d)] method} is initially formed in the reaction with ethane. In the latter complex, the NO^+ cation is bound to the ethane molecules *via* polarisation and Coulomb interactions.[33] Subsequent conversions of this complex are shown in Scheme 1.

Scheme 1



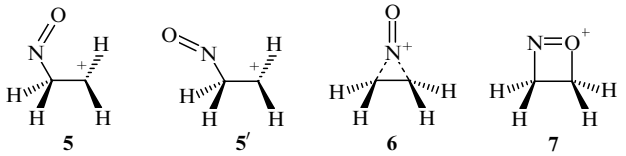
(*a*) $\Delta H_0 = -17.2$ kJ mol^{-1}; (*b*) insertion of E^+ at the C–C bond; $\Delta H_0 = -118.8$ kJ mol^{-1}; (*c*) insertion of E^+ at the C–H bond, $\Delta H_0 = -84.5$ kJ mol^{-1}; (*d*) elimination of H^-, addition of EH, $\Delta H_0 = -84.5$ kJ mol^{-1}; (*e*) elimination of H_2, $\Delta H_0 = 119.2$ kJ mol^{-1}; (*f*) elimination of CH_4, $\Delta H_0 = 39.7$ kJ mol^{-1}.

Although the attack of the NO^+ cation at the C–C bond is thermodynamically favourable (see Scheme 1), Schreiner *et al.*[33] believed that the attack on the C (to form a complex of the type **2**) and H atoms is kinetically more favourable. Elimination of the H_2 molecule is also unlikely because this path is thermodynamically unfavourable ($\Delta H_0 = 119.2$ kJ mol^{-1}). Attempts to isolate the transition states in these reactions failed. The activation barriers to elimination of methane and the hydride ion giving rise to nirosomethane and nirosoethane, respectively, have similar values (140.2 and 130.1 kJ mol^{-1}, respectively).

III. Complexes of the nitrosonium ion with alkenes

In a series of investigations, alkene–NO^+ complexes were proposed as intermediates of reactions of alkenes with nitrosyl halides[2–4] and $[NO]^+X^-$ salts (see Refs 34–37). These reactions are of importance in the synthesis of halonitroso- and halonitroorganic,[1–4,38] N,O-heterocyclic[34–36,39] and some other organic compounds.[37,40–42]

The energy profiles of fluoronitrosation of ethylenes were calculated by the MINDO/3 and UMINDO/3 quantum-chemical methods.[43] The facts that the NO^+ cation approaches the ethylene molecule at an angle to the symmetry plane of the latter and attacks the carbon atom to form σ-complex **5** are attributed to a strong $\pi_\sigma - \pi_\sigma$ interaction between the unoccupied e(π*)-MO of the NO^+ cation and HOMO of ethylene.



According to the results of MINDO/3 calculations, the isomeric form **5′** is less favourable than the structure **5** ($\Delta\Delta H_f = 22.2$ kJ mol^{-1}, where ΔH_f is the enthalpy of complex formation). The open cation **5** is rearranged into isomeric cyclic structures **6** and **7**, the activation energies (E_a) of these rearrangements being low ($E_a = 5.0$ and 14.2 kJ mol^{-1}, respectively). Among the structures **5**–**7**, the π-complex **6** is the most stable.

Ab initio calculations (the STO-3G basis set) predicted that the structure **7** should be the most stable.[43] Higher-level *ab initio* quantum-chemical calculations (MP4/6-31G + D) also provided evidence for higher stability of the structure **7** (Table 1).[44] In addition to the π-complex **6** in which the NO group is located in proximity to the ethylene fragment [the distance from the N atom to the C–C bond (*d*) is 0.1272 nm], more favourable (within the framework of the MP4 method) 'loose' π-complex **9** was found. In the latter, the distance *d* is substantially larger (0.1978 nm) and the NO group is located at an angle to the plane passing through the C, C and N atoms (Fig. 1, see Table 1).

Table 1. Relative energies (E_{rel} /kJ mol^{-1}) of the structures **7**–**10** obtained by *ab initio* quantum-chemical calculations.[44]

Structure	Basis set	E_{rel} [a] calculated by the method				
		HF	MP2	MP3	MP4	CCD + ST(4)
7	STO-3G	−335.6	–	–	–	–
	6-31G	−77.4	76.6	−36.8	43.1	–
	6-31G + D	−75.3	−16.3	−75.7	−33.1	–
8	STO-3G	−223.8	–	–	–	–
	6-31G	−89.1	31.0	−79.5	17.6	5.0
	6-31G + D	−35.1	−15.9	−60.7	−11.7	−13.8
9	STO-3G	−132.6	–	–	–	–
	6-31G	−65.7	−10.5	−76.1	−31.8	−38.1
	6-31G + D	−30.1	−41.4	−61.9	−49.4	−50.2
10	STO-3G	−139.7	–	–	–	–
	6-31G	−49.4	59.4	−27.2	22.2	13.4
	6-31G + D	5.4	33.1	−2.9	7.9	6.7

[a] The total energy of the C_2H_4 molecule and the NO^+ cation was taken equal to zero.

The σ-complex **10** is substantially less stable than the π-complexes **8** and **9** (see Table 1, Fig. 1). The C–N bond in the cation **10** is unusually long, which indicates that the C and N atoms are weakly bound together[44] (*cf.* Refs 37 and 43).

The structural and energy characteristics of the nitrosonium complexes with cyclobutadiene were calculated by the MINDO/3 and *ab initio* methods (the STO-3G basis set).[45] Qualitative analysis of orbital interactions revealed five structures with attractive interactions of the $\pi_\sigma - \pi_\sigma (p_\sigma - \pi_\sigma)$ type between the NO^+ cation and the ring. In the complexes **11** and **12**, the nitroso group is located parallel to the plane of the carbon ring above its centre and above one of the double bonds, respectively.

In the structures **13**–**15**, the NO group is perpendicular to the plane of the ring. Interactions between the orbitals of the nitroso group and the π orbitals of one of the double bonds occur in the isomers **13** and **15**, whereas interactions between the orbitals of the nitroso group and all π orbitals of the ring take place in the pyramidal structure **14**. The energy characteristics of the cations **11**–**13**, **15**, **17** and **18** are given in Table 2. According to calculations by the MINDO/3 method, the azapyrylium cation **18** is the most stable one in the above-mentioned series.

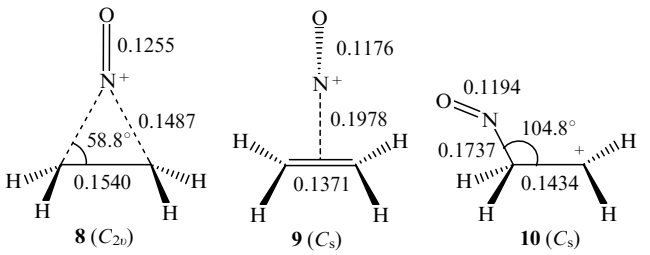


Figure 1. Geometric parameters of the π-complexes **8** and **9** and the σ-complex **10** obtained by *ab initio* calculations (the STO-3G basis set).[44] The bond lengths are expressed in nm; the symmetry is given in parentheses.

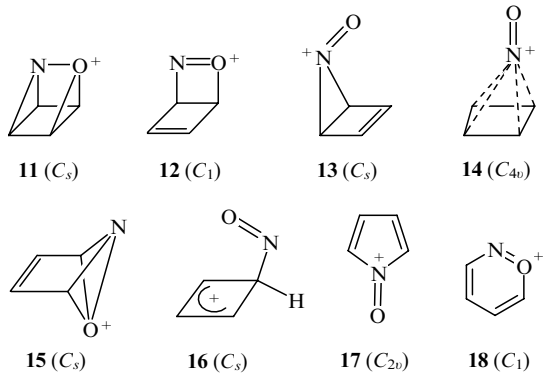
Table 2. Enthalpies of formation (ΔH_f), total energies (E_{tot}) and relative energies (E_{rel}) of the structures **11**–**13**, **15**, **17** and **18**.[45]

Parameter	**11**		**12**		**13**		**15**	**17**	**18**
	MINDO/3	STO-3G	MINDO/3	STO-3G	MINDO/3	STO-3G	MINDO/3		
ΔH_f /kJ mol^{-1}	1036.0	–	1016.3	–	1044.7	–	885.8	931.4	681.6
E_{tot} /a.u.[a]	–	−279.1292	–	−279.1439	–	−279.0593	–	–	–
E_{rel} /kJ mol^{-1}	354.4	38.6	334.7	0	363.1	222.1	204.2	249.8	0

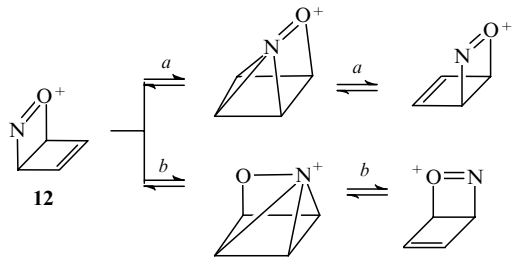
[a] 1 a.u. = 2625.5 kJ mol^{-1}.



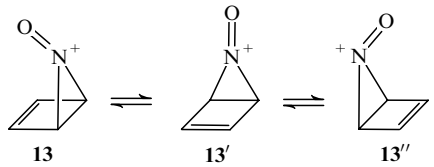
Ab initio calculations (the STO-3G basis set) for the structures **11**–**13** predicted the higher stability of the cation **12**. In the case of the pyramidal structure **14**, no minimum was found on the potential energy surface (PES).‡ The conversion of this structure into the structure **13** is barrierless, the latter being the only η^n structure ($n = 1-4$) corresponding to a local minimum. There is also no minimum on the potential energy surface corresponding to the σ-complex **16**. Minkin *et al.*[45] believe that attempts to generate the nitrosocyclobutenyl cation in the gas phase or in a weakly solvating solvent will fail.

Calculations by the MINDO/3 method for the structure **12** predicted that the nitroso group can either migrate parallel to the plane of the cyclobutadiene ring (Scheme 2, path *a*) or rotate about the C–O bond (Scheme 2, path *b*).[45]

Scheme 2



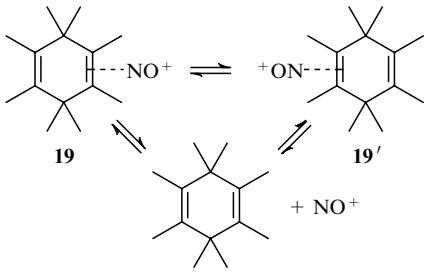
For the η^2-isomer **13**, the rotational-type rearrangement **13** ⇋ **13′** ⇋ **13″** with the low energy barrier (E_a = 46.9 kJ mol^{-1}) involving cation **16** as the transition state was revealed.[45]



‡ *Ab initio* calculations taking into account the electron correlation (MP2/6-31G*+ZPE) also demonstrated that the structure **14** does not correspond to the minimum on the PES.[46]

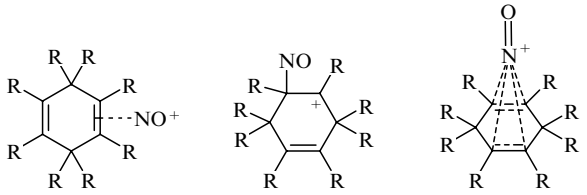
It should be noted that the above-considered topomerisation reactions of the structures **12** (see Scheme 2) and **13** are, apparently, of only theoretical interest because these complexes are kinetically unstable and are converted into the structures **18** and **17**, respectively, with low energy barriers (E_a = 14.2 and 16.7 kJ mol^{-1}, respectively).[45]

Until recently, experimental data on π-complexes of alkenes with the nitrosonium cation were lacking in the literature. Attempts to synthesise complexes of this type by reactions of $[NO]^+[BF_4]^-$ with ethylene or 2,3-dimethylbut-2-ene failed. In the former case, the reaction did not proceed, whereas the latter reaction afforded exclusively polymeric products.[47] Olah *et al.*[47] believed that the reaction of $[NO]^+[BF_4]^-$ with adamantylideneadamantane gave rise to either a dynamical σ-complex or a π-complex. However, the authors failed to choose between these complexes. The first reliable data on the synthesis of an alkene–NO^+ complex were obtained in a study by Borodkin and coworkers.[48] According to the results of ^{1}H, ^{13}C and ^{27}Al NMR spectroscopy using the isotope perturbation method, the complex of 1,2,3,3,4,5,6,6-octamethylcyclohexa-1,4-diene with the NO^+ cation is a η^2-type π-complex (structure **19**).[48,49] It appeared that this complex underwent degenerate π,π-rearrangement **19** ⇋ **19′** (in the $SO_2-SO_2ClF-CD_2Cl_2$ system), rapid within the NMR time scale even at low temperature (−80 to −90 °C), the rate of intramolecular transfer of the NO^+ group being higher than the rate of intermolecular transfer.



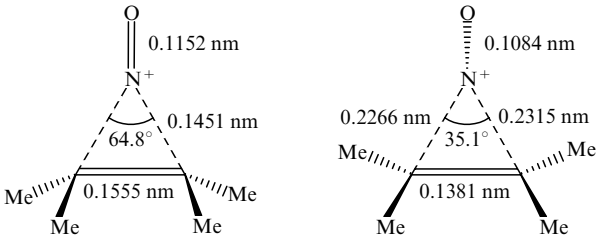
The rate of the intermolecular rearrangement increases on going from the $SO_2-SO_2ClF-CD_2Cl_2$ system to the $SO_2-CD_2Cl_2$ system.[48,49]

The results of quantum-chemical calculations for the nitrosonium complexes with cyclohexa-1,4-diene and 1,2,3,3,4,5,6,6-octamethylcyclohexa-1,4-diene by the MINDO/3 and MNDO/PM3 methods indicate that η^2-type π-complexes (**20** and **21**) are more stable than the corresponding σ-complexes (**22** and **23**) and η^4-type π-complexes (**24** and **25**)[48,49] through which intramolecular transfer of the nitroso group apparently proceeds.



R = H (**20**, **22**, **24**), Me (**21**, **23**, **25**).

As mentioned above, *ab initio* calculations provided evidence for the existence of two types of ethylene complexes with the NO^+ cation (**8** and **9**). These complexes differ in geometry and, primarily, in the distance between the nitrogen atom and the C=C bond (d = 0.1272 and 0.1978 nm, respectively).[44] The structure of the nitrosonium complex with 2,3-dimethylbut-2-ene was analysed in detail by ^1H and ^{13}C NMR spectroscopy using the isotope perturbation method and by *ab initio* quantum-chemical (6-31G* basis set) and IGLO calculations.[50] As in the case of the ethylene–NO^+ isomers, the calculations predicted the existence of two types of complexes characterised by the symmetry C_{2v} (**26**) and the approximate symmetry C_s (**27**). In these complexes, the distances from the N atom to the C=C bond are 0.1225 and 0.2183 nm, respectively.

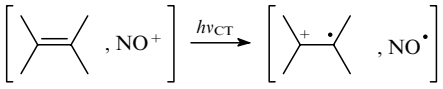


26 (C_{2v}) **27** ($\sim C_s$)

In the complexes **26** and **27**, the energies of binding of the nitrosonium cation with 2,3-dimethylbut-2-ene are 93.7 and 117.6 kJ mol^{-1}, respectively, which is indicative of higher stability of the complex **27**. The experimental chemical shifts of the C(2) and C(3) atoms (190.2 ppm) are substantially closer to those calculated by the IGLO(DZ) method for the complex **27** (δ_C 183.4 and 189.8, respectively) than to those for the complex **26** (δ_C 67.2). The equivalence of the C(2) and C(3) atoms and the equivalence of the carbon atoms of the methyl groups observed in the ^{13}C NMR spectrum of the complex **27** were attributed either to the inversion of the nitrogen atom or to the rotation of the NO group about the axis passing through the nitrogen atom perpendicular to the C(2)–C(3) bond as well as to the high rate of migration of this group.[50]

Complexes of different alkenes with the $[NO]^+[BF_4]^-$ and $[NO]^+[PF_6]^-$ salts and with other sources of the nitrosonium cation ($RONO-CF_3CO_2H$, $NOCl-CF_3CO_2H$ and $N_2O_4-SbF_5$) were investigated.[51] At low temperature, the electronic spectra of 2,3-dimethylbut-2-ene, 2,3,4-trimethylpent-2-ene and adamantylideneadamantane have charge-transfer bands. The reactions of other alkenes, such as 2,5-dimethylhex-2-ene, 2,4,4-trimethylpent-2-ene, 1-methylcyclohexene, cyclohexene, 2,3,3-trimethylbut-1-ene, norbornene, 3,3-dimethylbut-1-ene and hex-1-ene, with the above-mentioned salts either afforded slightly coloured solutions or did not give coloured solutions corresponding to the formation of charge-transfer complexes at all. These differences in the behaviour of alkenes containing the completely substituted C=C bond and those with the partially substituted C=C bond were attributed to the difference in the oxidation potentials (E_{ox}) of these alkenes.[51] Thus the oxidation potentials of 2,3-dimethylbut-2-ene and 2,3,4-trimethylpent-2-ene (E_{ox} = 1.6 V) are substantially smaller than those of 2-methylbut-2-ene and but-2-ene ($E_{ox} \approx$ 2.0 and 2.4 V, respectively). The thermal and photochemical behaviour of the alkene–NO^+ complexes is explained by the formation of charge-transfer complexes.

The photochemical activation of these complexes leads to generation of the corresponding radical cations. Thus irradiation of 2,3-dimethylbut-2-ene and N_2O_4 in a matrix at the frequency corresponding to the charge-transfer band (ν_{CT}) at 75 K afforded a pair of the type **28**.

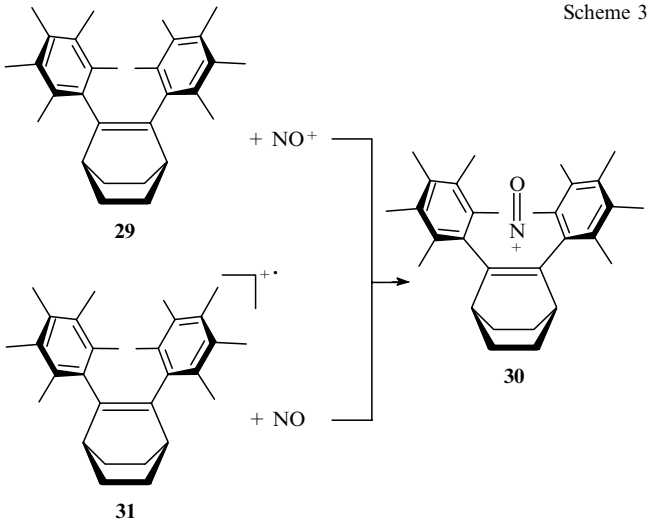


28

The subsequent reaction of the radical cation of 2,3-dimethylbut-2-ene with nitric oxide gave rise to the 1-nitroso-2,3-dimethylbut-2-yl cation, which reacted with the NO_3^- anion to form nitrosonitrate.[51,52]

The reaction of 1,2-bis(pentamethylphenyl)bicyclo[2.2.2]oct-2-ene (**29**) with the nitrosonium cation in CH_2Cl_2 at 25 °C afforded π-complex **30**. The characteristic feature of the latter complex is the fact that the NO group in this complex can interact with both the double bond and the aromatic rings (Scheme 3).[53]

Scheme 3

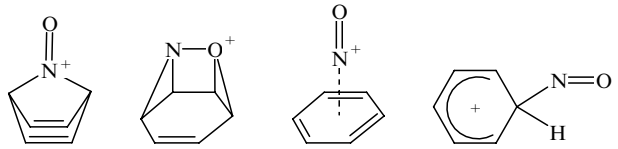


Electrochemical oxidation of the alkene **29** gave rise to the corresponding radical cation **31** whose reaction with gaseous nitric oxide afforded the same π-complex **30**[53] (*cf.* Ref. 54). X-Ray diffraction analysis of the π-complex **30** (with the $SbCl_6^-$ counterion) revealed the presence of noncovalent bonding of the NO^+ cation with the aromatic rings (the average distance to the plane of the rings is ~0.25 nm) and with the double bond, the positive charge being primarily localised at the aromatic and alkene carbon atoms, respectively.[53] The C(1)=C(2) bond length in the complex **30** (0.137 nm) is larger than that in the precursor **29** (0.133 nm) and is virtually identical to the above-mentioned C=C bond lengths in the complexes **9** and **27** determined by *ab initio* calculations. The strong bond between the NO^+ group and the unsaturated system in the complex **30** is consistent with its high formation constant ($> 3 \times 10^6$ litre mol^{-1}).[53]

IV. Nitrosonium complexes of aromatic compounds

Nitrosonium complexes of monocyclic aromatic compounds have been investigated in sufficient detail.[44,55–90] These complexes attract the attention of organic chemists primarily because they are analogues of intermediates of such important reactions as diazotisation, C-nitrosation and nitration proceeding through nitrosation of aromatic compounds[1,90–95] (*cf.* Ref. 96). In addition, it is known that the NO^+ cation catalyses bromination of aniline derivatives[97] and proton exchange in the *N*,*N*-dimethylanilinium ion,[98] which was assigned to the formation of the corresponding arene–NO^+ complexes.

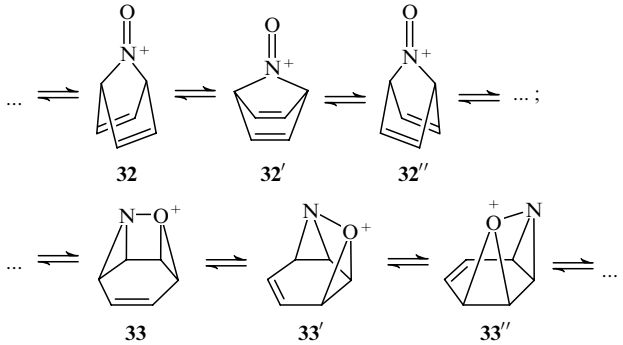
The nitrosation of benzene was investigated by quantum-chemical methods.[70] Thus, the pathway of electrophilic replacement of the hydrogen atom in the benzene ring by the NO^+ cation was calculated by the MINDO/3 method. Initially, the electron is transferred from the frontier orbital of the benzene molecule to the π* orbital of the nitrosonium cation to form π-complexes **32** and **33**. The enthalpies of their formation are 1017.1 and 959.0 kJ mol^{-1}, respectively.



32 (C_{2v}) **33** (C_1) **34** (C_{6v}) **35** (C_s)

According to the rule of electron counting for pyramidal structures,[99–101] the π-complex **34** with the symmetry C_{6v} is unstable (ΔH_f = 1031.8 kJ mol^{-1}) and corresponds to a peak top on the potential energy surface. A shallow minimum on the PES (8.4 kJ mol^{-1}) corresponds to the structure of σ-complex **35** (ΔH_f = 928.8 kJ mol^{-1}), which indicates that it is not detectable experimentally.

Calculations for the π-complexes **32** and **33** provided evidence for the occurrence of a sixfold-degenerate rearrangement with a low energy barrier (E_a < 12.6 kJ mol^{-1}) caused by 'switching' of the C–N bond in the complex **32** and migration of the nitroso group over the plane of the ring in the structure **33**:

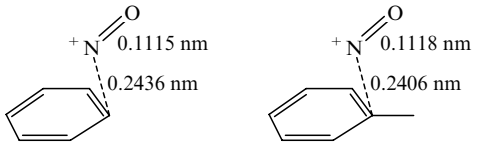


32 **32′** **32″**

33 **33′** **33″**

The $\Delta\Delta H_f$ value (relative to the C_6H_6–NO^+ system) found by higher-level quantum-chemical calculations (*ab initio*, MP2/6-31G+D)[44] for the centrosymmetrical structure **34** is −189.1 kJ mol^{-1}, which is close to the experimental value for the gas phase (−172±21 kJ mol^{-1}).[44,64] The corresponding σ-complex is substantially less stable ($\Delta\Delta H_f$ = −23.4 kJ mol^{-1}).

Ab initio B3LYP/6-31G(d) calculations revealed stable π-complex **36** with the symmetry C_1. The energy of its formation from benzene and the NO^+ cation is −220.5 kJ mol^{-1}.[89] In addition, the calculations gave local minima for the π-complexes **32** and **33** whose relative energies are 163 and 201 kJ mol^{-1}, respectively, smaller than that in the case of the π-complex **36**.



36 **37**

According to the results of quantum-chemical calculations, the π-complex of toluene with the NO^+ cation (**37**) is more stable than the π-complex **36** (ΔE_{rel} = 17.6 kJ mol^{-1}). The stretching vibration frequency of the NO group calculated for the complex **37** (2087 cm^{-1}) is smaller than that for the complex **36** (2110 cm^{-1}), which is indicative of a higher degree of electron density transfer from the aromatic ring to the NO group in the cation of the complex **37**.[89]

The first experimental data on the formation of ArH–NO^+ π-complexes were obtained by electronic spectroscopy of nitrosonium complexes of benzene and its derivatives.[58,59] Shortly thereafter, π-complexes of the NO^+ cation with benzene derivatives were investigated by Allan *et al.*[60,61] More recently, NMR spectroscopy along with electronic and IR spectroscopy were employed for studying cationic π-complexes. The available spectral data for the nitrosonium π-complexes of benzene and its derivatives are summarised in Tables 3–5. The formation of π-complexes leads to characteristic changes, in particular, to downfield shifts of the signals in the ^{1}H and ^{13}C NMR spectra (see Tables 3 and 4, respectively), to the appearance of charge-transfer bands in the electronic spectra and to a decrease in the stretching vibration frequency of the NO group in the complexes compared to those in $[NO]^+X^-$ salts (see Table 5). Apparently, all the above-mentioned changes are caused by the electron density transfer from the aromatic moiety of the complex to the nitroso group.

Table 3. ^{1}H NMR spectral data for the π-complexes of benzene and its derivatives with the nitrosonium cation (the molar ratio ArH : $[NO]^+X^-$ = 1 : 1).

[a] The differences between the chemical shifts of the signals for the protons in the spectra of the π-complex and its precursor are given in parentheses. [b] Either $NOBF_4$ or $NOPF_6$ was used as the salt. [c] Either CD_3CN or CD_3NO_2 was used as the solvent. [d] The ArH : $[NO]^+X^-$ molar ratio was 2 : 1. [e] The reaction temperature was 35 °C; in all other cases, the temperature was not reported.

Table 4. ^{13}C NMR spectral data for the π-complexes of benzene and its derivatives with the nitrosonium cation (the molar ratio ArH : $[NO]^+X^-$ = 1 : 1).

[a] The ArH : $[NO]^+X^-$ molar ratio was 2 : 1. [b] The λ_{max} value is given only for the long-wavelength band (at −78 °C). [c] At −78 °C. [d] In KBr pellets. [e] Mineral oil mull. [f] Spectra of the crystalline form. [g] Shoulder. [h] At −40 °C.

The degree of electron density transfer can be estimated from ^{13}C NMR spectral data. It is known that the chemical shifts of the sp^2-hybridised carbon atoms in charged π-electron systems correlate linearly with the π-charges on these atoms.[102, 103] Assuming that the degree of electron density transfer to the nitroso group in the π-complex depends on the ionisation potential of the aromatic substrate (I_p), one would expect a relationship between the positive π-charges (q_π^+) and the ionisation potentials of the aromatic donor.[78] Actually, a linear correlation between these characteristics takes place in the case of the nitrosonium π-complexes of benzene and alkylbenzenes [78] (Fig. 2) from which it can be seen that an increase in the donating ability of the aromatic substrate leads to an increase in the degree of charge transfer.

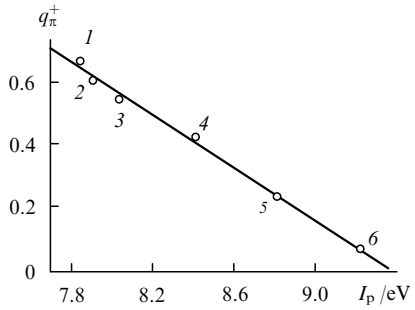

Figure 2. Correlation between the positive π-charges (q_π^+) on the aromatic fragments in the nitrosonium complexes with benzene and alkylbenzenes and the ionisation potentials (I_p) of the aromatic donors:[78] (*1*) hexamethylbenzene, (*2*) pentamethylbenzene, (*3*) durene, (*4*) mesitylene, (*5*) toluene, (*6*) benzene ($r = -0.998$). The q_π^+ values were calculated using the differences between the chemical shifts of the complexes and their precursors determined in the study;[78] the value of 160 ppm was taken per unit π-charge.

It was demonstrated[78] that the degree of charge transfer in π-complexes can be estimated by IR spectroscopy. Thus a linear correlation between the ionisation potentials of the aromatic substrate and the degree of charge transfer (Z) was found for benzene and its derivatives. The degree of charge transfer was determined from the following formula:

$$Z = (\nu_{NO^+}^2 - \nu_\pi^2)/(\nu_{NO^+}^2 - \nu_{NO}^2),$$

where ν_{NO^+}, ν_π and ν_{NO} are stretching vibration frequencies of the NO group in the NO^+ cation, the π-complex and nitric oxide, respectively (Fig. 3).[78]

X-Ray diffraction studies provide the most reliable information on the structures of cationic complexes. The first data on the structures of nitrosonium complexes of aromatic compounds obtained[68,69] for the complex of hexamethylbenzene with the NO^+ cation disclosed that the conventional view (*cf.* Refs 61 and 64) that π-complexes of aromatic compounds with electrophilic agents are highly symmetrical systems should be revised.[104] According to the X-ray diffraction data,[68,71] the normal (which passes through the nitrogen atom of the NO group) to the plane of the core of this complex is displaced from the centre of the aromatic ring and the nitroso group is located at an angle of ~50° (the structure **38**), the nitrogen atom being rather far removed from the ring (by 0.21 nm).

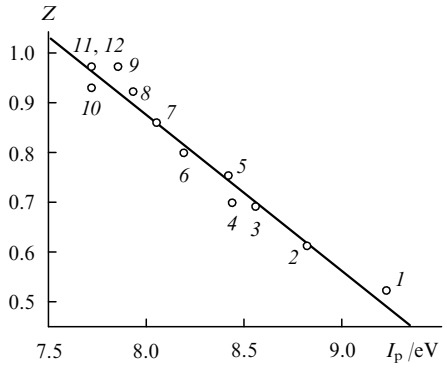

Figure 3. Correlation between the degree of electron transfer (Z) in nitrosonium complexes with benzene and alkylbenzenes and the ionisation potentials (I_p) of the aromatic donors: (*1*) benzene, (*2*) toluene, (*3*) 1,2-dimethylbenzene, (*4*) 1,4-dimethylbenzene, (*5*) 1,3,5-trimethylbenzene, (*6*) 1,3,5-tri(*tert*-butyl)benzene, (*7*) 1,2,4,5-tetramethylbenzene, (*8*) pentamethylbenzene, (*9*) hexamethylbenzene, (*10*) hexaethylbenzene, (*11*) 1,4-di(neopentyl)-2,4,5,6-tetramethylbenzene, (*12*) 1,3-di(neopentyl)-2,3,5,6-tetramethylbenzene ($r = -0.987$).[78]

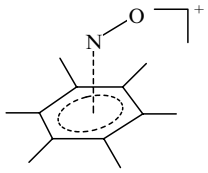
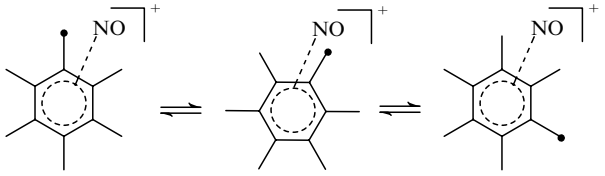


38

The nitrosonium complexes of toluene,[73] mesitylene,[78] durene,[71] hexaethylbenzene,[88] 2,3-dimethyl-2,3-diphenylbutane,[81] 1,2,3,4,5,6,7,8,9,10,11,12-dodecahydro-1,4;5,8;9,12-triethanotriphenylene[88] and octamethyl-9,10-dihydro-9,10-ethanoanthracene[105] have analogous structures. A comparison of the structures and geometric parameters of nitrosonium complexes of arenes and alkenes disclosed that these complexes are somewhat similar, *viz.*, the NO group is located at an angle to the plane of the core and the distances from the nitrogen atom to this plane have close values.

According to the results of CNDO/2 calculations with the use of the real geometry of the hexamethylbenzene complex with the nitrosonium cation, the positive charges on the aromatic carbon atoms of the same type differ substantially from those on the carbon atoms of the methyl groups.[71] Nevertheless, two rather narrow singlets are observed in the ^{13}C NMR spectra recorded both for solutions (in the HSO_3F-SO_2ClF mixture, −130 °C)[75] and for the solid phase,[71] which is attributable to the π,π-rearrangement, rapid within the NMR time scale.



38 **38′** **38″**

The mechanism of this rearrangement involves either the migration of the NO group over the plane of the ring or the rotation of this ring about its 'normal' followed by 'switching' of the $C_{arom}-N$ bonds, the latter situation being more probable for the complex in the crystalline state.[71,75] The results of studies of the isotope effects of deuterium manifested in the ^{13}C NMR spectra of nitrosonium π-complexes with $C_6(CD_3)_m(CH_3)_{6-m}$ compounds do not contradict the conclusion that these complexes undergo rapid π,π-rearrangement in solutions.[80] The kinetic parameters of this rearrangement ($E_a = 42.7\pm2.5$ kJ mol^{-1}, $\log A = 13.9\pm0.3$) for the crystalline complex were determined by relaxation NMR spectroscopy.[75]

According to the ^1H and ^{13}C NMR spectral data, analogous π,π-rearrangements occur, apparently, in the nitrosonium complexes of benzene,[72,73,78] alkylbenzenes,[62,72–74,76,78] chlorobenzene,[72] anisole,[87] 2,3,5,6,8,9-hexahydro-1,2;3,4;5,6-tris(cyclopenta)benzene,[106] [2.2]paracyclophane[107] and triptycene.[107]

To reveal the contributions of the intermolecular and intramolecular mechanisms of rearrangements of nitrosonium complexes, it is important to elucidate the influence of the structure of the aromatic substrate on the formation constants of these complexes (K):

$$ArH + NO^+ \overset{K}{\rightleftharpoons} ArH-NO^+.$$

The quantitative data on the constants K for the π-complexes of benzene and its derivatives were obtained[76,78,81,84,88] by processing electronic absorption spectra using the Benesi–Hildebrand method. A linear correlation between the logarithms of the formation constants of the π-complexes and the ionisation potentials of the corresponding aromatic hydrocarbons was found[76] (Fig. 4). The point corresponding to 1,3,5-tri(*tert*-butyl)benzene deviates from the dependence presented in Fig. 4[76] due, appa-

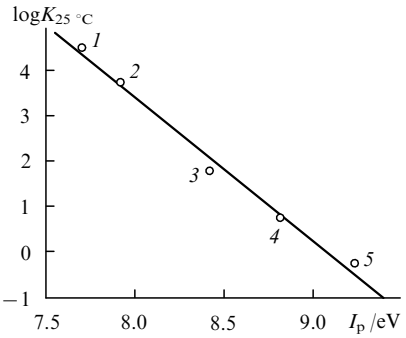


Figure 4. Dependence of the logarithms of the formation constants ($\log K$) of the $ArH-NO^+$ complexes (BF_4^- as the anion) in MeCN at 25 °C on the ionisation potentials (I_p) of the aromatic donors: (*1*) hexamethylbenzene (*2*) pentamethylbenzene (*3*) mesitylene (*4*) toluene (*5*) benzene ($r = -0.995$).[76]

rently, to steric inhibition of the donor-acceptor interaction between the aromatic substrate and the nitrosonium cation (*cf.* Ref. 88).

The high degree of charge transfer in the ground state of nitrosonium complexes of aromatic compounds containing donor substituents agrees well with the chemical behaviour of these complexes. The key stage of these reactions involves the transfer of one electron from the aromatic donor to the NO^+ group giving rise to a radical cation, which undergoes further transformations:

$$ArH + NO^+ \rightleftharpoons [ArH, NO^+],$$

$$[ArH, NO^+] \rightleftharpoons [ArH^{+\bullet}, NO^{\bullet}],$$

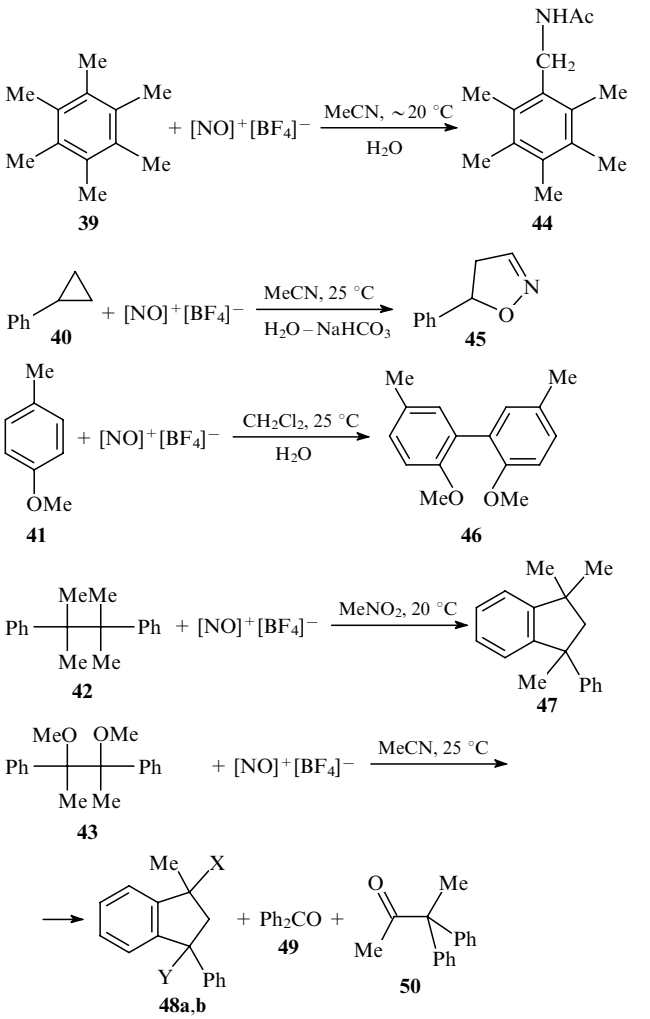
$$[ArH^{+\bullet}, NO^{\bullet}] \longrightarrow \text{products}.$$

This general scheme can be exemplified by the conversions of aromatic compounds **39**–**43** into products **44**–**50** (Scheme 4). In these processes, $ArH-NO^+$ π-complexes are, apparently, generated at the initial stage (see Refs 78 and 81).

All the above-considered calculated and experimental data provide evidence that the reactions of the nitrosonium cation with monocyclic aromatic compounds generally afford π-complexes rather than σ-complexes. In this connection, it is of interest that investigation of the kinetics of nitrosodeiodination of 4-iodoanisole by electronic absorption spectroscopy [63] provided evidence for the formation of the σ-complex, *viz.*, the 1-iodo-4-methoxy-1-nitrosobenzenonium ion (*cf.* Ref. 91). Recently, the nitrosonium σ-complexes with benzene, mesitylene, hexamethylbenzene and other aromatic compounds have been detected by this method using the femtosecond laser technique at low temperature.[90] However, it is known that information on the structures of cationic complexes of aromatic compounds obtained by electronic absorption spectroscopy is less reliable than that provided by NMR spectroscopy.[103] The more reliable NMR spectral data demonstrated that the reactions of anisole [87] and hexamethylbenzene [80] with $[NO]^+[AlCl_4]^-$ in the $SO_2-CD_2Cl_2$ system at low temperature afforded π-complexes (*cf.* Refs 68 and 71–76).

The nitrosonium cation is a strong oxidising agent [108, 109] (*cf.* Refs 55 and 56). Generally, its reactions with bi- and polycyclic arenes possessing, as a rule, low ionisation potentials [110] give rise to the corresponding radical cations or their reaction products.[55, 78, 109] Thus, the reactions of naphthalene with nitrosonium salts in trifluoroacetic acid at ~20 °C afforded initially a monomeric radical cation, followed by the formation of a dimeric radical cation and, finally, of a mixture of hydrocarbons $C_{10}H_7-(C_{10}H_6)_m-C_{10}H_7$.[109, 111, 112] Most likely, the transfer of one electron from the aromatic substrate to the NO^+ cation is preceded by the formation of the $ArH-NO^+$ π-complex. In spite of the importance of the data on the structures and reactivities of nitrosonium complexes with polycyclic aromatic compounds,

Scheme 4



48a: X = OMe, Y = Me;
48b: X = Y = OMe.

attempts to generate these complexes have long been unsuccessful.[61, 76, 113–117]

The first data on the formation of nitrosonium π-complexes with fused arenes were obtained for derivatives of naphthalene,[113, 114] fluorene [113] and acenaphthylene [114] (*cf.* Refs 55 and 76). The reactions of $[NO]^+[AlCl_4]^-$ with methylnaphthalenes **51a**–**i** in SO_2 at low temperatures (from −70 to −80 °C) afforded cationic π-complexes **52a**–**i**, respectively.[115, 116]

Table 6. Parameters of the ^{13}C NMR spectra (δ_C) of the complexes **57a**,**c**–**f** [117, 119] and the charges q_π^+ on the C(3)–C(8b) atoms.

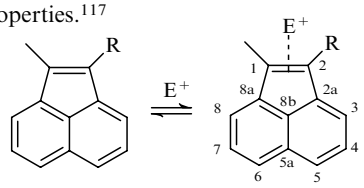
Complex	System or solvent	Temperature /°C	$\delta_{C(1)}$, $\delta_{C(2)}$ (see [a])	$\Delta\sum\delta_{C(3)-C(8b)}$ (see [b])	q_π^+ (see [c])
57a	HSO_3F-SO_2	−70	170.8	33.9	0.21
		−40	171.3	35.4	0.22
57c	SO_2-SO_2ClF	−95	153.6, 168.0	–	–
57d	SO_2	−80	150.6, 166.4	41.6	0.26
57e	CD_2Cl_2	−80	80.8	10.1	0.06
57f	HSO_3F-SO_2ClF	−50	98.3	17.4	0.11

[a] The chemical shifts are given relative to Me_4Si; CD_2Cl_2 was used as the internal standard (δ 52.9). [b] The difference between the total chemical shifts of the signals for the C(3)–C(8b) atoms in the spectra of the π-complex and its precursor. [c] In calculations, the value of 160 ppm was taken per unit π-charge.[102]

The structures of these complexes were confirmed by the results of ^1H, ^{13}C and ^{15}N NMR spectroscopy using the isotope perturbation method.[116] The equivalence of the methyl groups in the π-complexes **52f**–**i** observed in the ^1H NMR spectra was attributed [116] to the rapid (within the NMR time scale) intra- and(or) intermolecular migration of the NO group from one aromatic ring to another.

Apparently, analogous rearrangements occur in the nitrosonium complexes of fluorene (**53**),[113] [2.2]paracyclophane (**54**),[107] triptycene (**55**) [107] and corannulene (**56**) [118] (Scheme 5).

Unlike the complexes of the nitrosonium ion **52**–**56**, the nitrosonium complexes with 1-R-2-methylacenaphthylene (R = Me, CH_2D, CH_2Cl or Br) **57a**–**d** do not exhibit dynamical properties.[117]



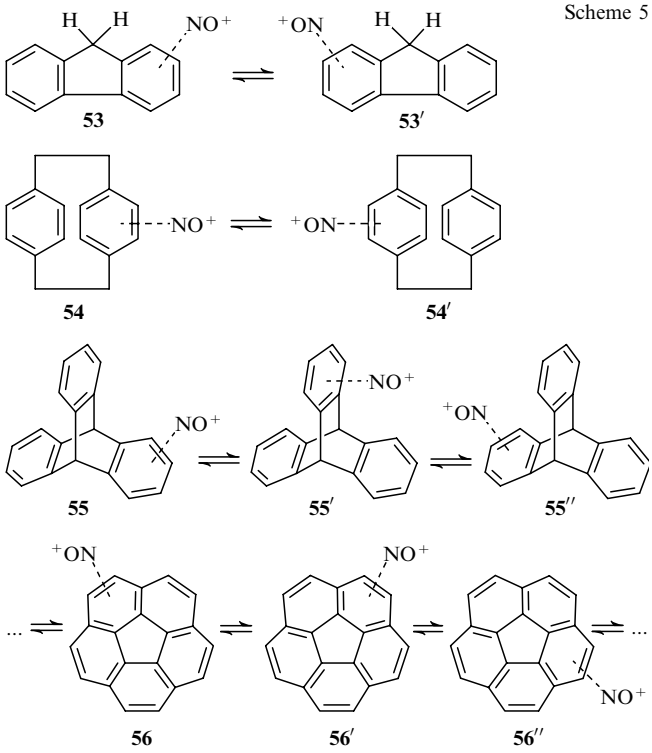
57a–**f**

Compound **57**	E	R
a	NO	Me
b	NO	CH_2D
c	NO	CH_2Cl
d	NO	Br
e	MeS	Me
f	PhS	Me

This is evidenced by the ^1H, ^{13}C and ^{15}N NMR spectral data and by the results obtained by the isotope perturbation method.[117] The fact that the signals for the C(1) and C(2) atoms in the π-complexes **57a**–**d** are shifted downfield compared to those of their analogues, *viz*., the episulfonium ions **57e**,**f** [119] (Table 6), was taken [117] as convinicng evidence for the preferential localisation of the NO group at the C(1)–C(2) bond assuming that the C(1) and C(2) atoms have nearly sp^2-hybridisation.

Substantial electron density transfer from the aromatic fragment to the NO^+ group is observed in the complexes of acenaphthylene and naphthalene derivatives (Table 7, see Table 6), as in nitrosonium complexes of monocyclic aromatic compounds containing donor substituents.[78] The greater the number of methyl groups in the rings of the complexes **52a**–**i**, the higher the degree of transfer.[116, 117] In addition, judging from the difference between the total chemical shifts of the signals for the C(1)–C(4) and C(5)–C(8) atoms in the ^{13}C NMR spectra of the π-complex and its precursor, the positive charge is localised predominantly at the methylated aromatic ring. Interestingly, an approximate linear correlation between the total positive π-charges on the core (q_π^+) and the oxidation potentials of the precursors ($E_{1/2}$) is observed for the nitrosonium complexes of naphthalene and its derivatives (Fig. 5, see Table 7). As expected, a decrease in the oxidation potential of the aromatic hydrocarbon leads to an increase in the positive π-charge on the aromatic fragment of the π-complex **52**.

Scheme 5



As mentioned above, naphthalene is oxidised by the nitrosonium cation at room temperature to form the corresponding

Table 7. Parameters of the ^{13}C NMR spectra of the complexes **52a**–**i** (SO_2, −70 °C) [116] and the oxidation potentials of their precursors **51a**–**c**, **e**–**i**.

Compounds **51** and **52**	$\Delta\sum\delta_{C(1)-C(4)}/\Delta\sum\delta_{C(5)-C(8)}$ [a]	q_π^+[C(1)–C(8a)] [b]	$E_{1/2}$ /V [c]

h	32.7 / 32.7 [e]	0.42	1.30
i	47.2 / 16.8	0.42	1.44

[a] The ratio of the differences between the total chemical shifts of the signals for the C(1)–C(4) and C(5)–C(8) atoms in the spectra of the complexes **52a**–**i** and their precursors. [b] In calculations, the value of 160 ppm was taken per unit π-charge.[102] [c] The data were reported in Ref. 120. [d] At −75 °C. [e] At −80 °C.

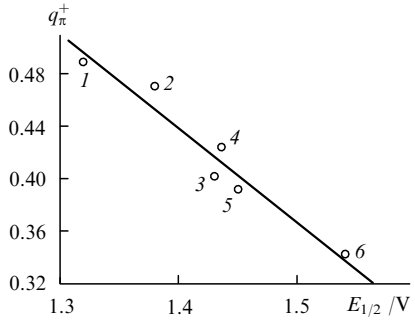

Figure 5. Correlation between the q_π^+ values for the π-complexes **52a**–**c**,**e**,**f**,**i** and the oxidation potentials ($E_{1/2}$) of their precursors **51a**–**c**,**e**,**f**,**i**:[120] (*1*) 1,4-dimethylnaphthalene, (*2*) 1,3-dimethylnaphthalene, (*3*) 1-methylnaphthalene, (*4*) 2,3-dimethylnaphthalene, (*5*) 2-methylnaphthalene, (*6*) naphthalene ($r = -0.970$). The data for the π-complexes **52g**,**h** were not taken into consideration because the q_π^+ values for the latter complexes were determined from ^{13}C NMR spectra measured at different temperatures.

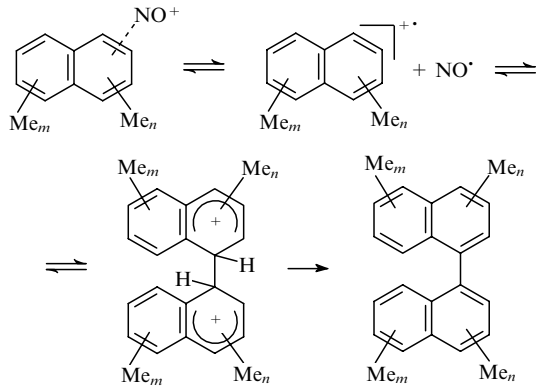
radical cation.[109, 111, 112] In the case of methylnaphthalenes, an analogous process takes place at low temperature. As the temperature increases from −60 or −70 °C to −30 or −50 °C, the signals in the ^1H NMR spectra of the complexes **52a**–**i** become broader (up to their 'disappearance'), which was explained [116] by the one-electron transfer between the aromatic core of the complex and the NO group.

Dimerisation of the resulting radical cations is one of the possible conversions of these compounds.[116] Actually, storage of solutions of the complexes **52b**,**d**,**e**,**h** at −20 to −30 °C for 1–2 h followed by their treatment with water afforded 4,4′-dimethylbinaphthyl, 3,3′,4,4′-tetramethylbinaphthyl, 2,2′,4,4′-tetramethylbinaphthyl and 4,4′,5,5′-tetramethylbinaphthyl, respectively, in ~20% yields. Analogous reactions proceeded with the participation of 2-methyl-, 1-ethyl-, 2-ethyl-, 1,6-dimethyl-, 2,3-dimethyl-, 2,6-dimethyl-, 2,7-dimethyl-, 1-methoxy-, 2-methoxy-, 1-bromo- and 2-hydroxynaphthalenes (the yields of the dimeric products were 25%–95%).[121, 122]



$m = 0, 1; n = 0–2$.

V. Complexes of the nitrosonium ion with nitrogen-containing organic compounds

In a number of studies it has been suggested that nitrosonium complexes of amines and N-heterocyclic compounds are intermediates in diazotisation,[1] nitrosation of amides [1] and N-heterocyclic compounds,[123, 124] the formation [1, 125] and denitrosation [126] of nitrosoamines and other reactions involving the nitrosonium cation.[1, 127–130]

According to the results of quantum-chemical calculations [131–133] and experimental data for the gas phase,[66, 134] N-bases possess high affinities for the NO^+ cation. Thus according to the results of *ab initio* calculations [HF/6-31 + G(d)], the energy of binding of the NO^+ cation with the methylamine molecule is 127.7 kJ mol^{-1} (*cf.* Ref. 133). The data on the binding energies (E_b) of the NO^+ cation with nitriles, pyridine and the derivatives of the latter [134] were obtained by ion-cyclotron resonance and in studies of the fragmentation of $L^1(NO^+)L^2$ dimers by kinetic methods (Table 8). A linear correlation between the E_b values for alkylnitriles RCN and Taft's σ*-constants of the substituents [135] was revealed (Fig. 6). Consequently, the inductive effect of the substituents R is the major factor responsible for the stability of the $RCN-NO^+$ complexes (*cf.* Ref. 66).

Table 8. Energies of binding (E_b) of the NO^+ cation with N-bases.[134]

Compound	E_b /kJ mol^{-1}	Compound	E_b /kJ mol^{-1}
$CH_2(CN)_2$	82.0	PhCN	121.3
MeCN	110.5	*o*-MeC_6H_4CN	123.4
EtCN	115.5	3-FC_5H_4N	156.1
Pr^nCN	117.2	4-ClC_5H_4N	162.3
Pr^iCN	118.8	C_5H_5N	167.8
Bu^tCN	121.3	3-MeC_5H_4N	172.0

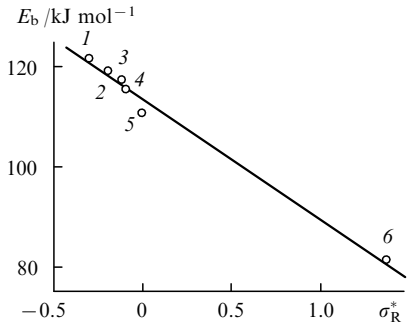


Figure 6. Correlation between the energies of binding (E_b) of the NO^+ cation with nitriles RCN [134] and the σ*-constants of the substituents R (σ_R^*),[135] where R = Bu^t (*1*), Pr^i (*2*), Pr^n (*3*), Et (*4*) or Me (*5*) and RCN = $CH_2(CN)_2$ (*6*) ($r = -0.995$).

A linear correlation between the E_b values [134] and the σ-constants of the substituents X [135] observed for pyridine and its derivatives XC_5H_4N (Fig. 7) indicates that both the inductive and resonance effects are of considerable importance.

The reaction of the $[NO]^+[BF_4]^-$ salt with pyridine in polar solvents (MeCN, $MeNO_2$, SO_2 or sulfolane) was examined by ^1H NMR and IR spectroscopy.[136] The results obtained in the

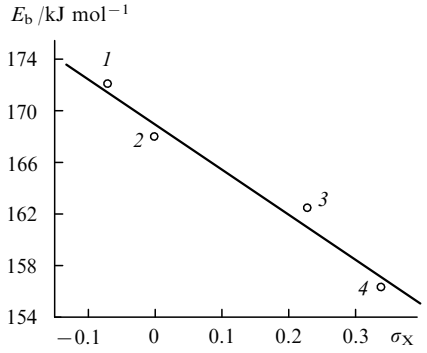

Figure 7. Correlation between the energies of binding (E_b) of the NO^+ cation with the XC_5H_4N compounds [134] and the σ-constants of the substituents X (σ_X),[135] where X = 3-Me (*1*), H (*2*), 4-Cl (*3*) or 3-F (*4*) ($r = -0.984$).

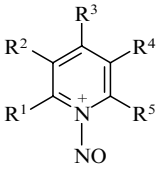
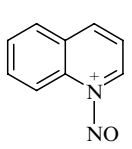
cited study provided evidence for the formation of the $C_5H_5N-NO^+$ *n*-complex (*cf.* Refs 76, 82 and 137). It should be noted that the transfer of the NO group from the nitrogen atom to the carbon atom of the ring was not observed even under the conditions of thermal decomposition of the $[C_5H_5N-NO]^+[BF_4]^-$ salt.[136]

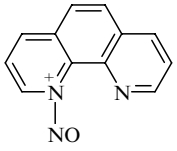
The reactions of pyridine, its derivatives, quinoline and 1,10-phenanthroline with $[NO]^+[BF_4]^-$ in $(CD_3)_2SO$ at 20 °C or with $[NO]^+[AlCl_4]^-$ in SO_2 at −60 °C afforded complexes **58a–d**, **59** and **60** whose structures were confirmed by ^1H and ^{13}C NMR spectroscopy.[138,139]



58a–d



59



60

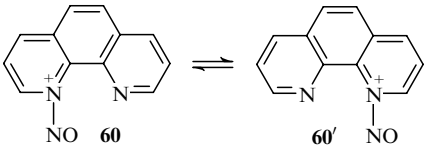
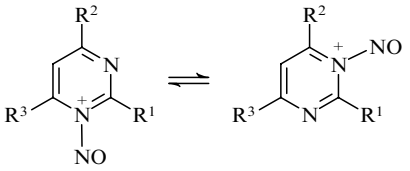
c	H	H	CHO	H	H
d	Me	H	Me	H	Me

The ^1H and ^{13}C NMR spectra of the complex **60** are indicative of a degenerate rearrangement rapid within the NMR time scale, which proceeds through the intra- and(or) intermolecular transfer of the NO group.



60 **60′**

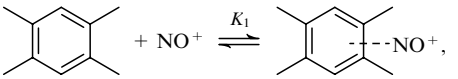
Nitrosonium complexes of pyrimidine derivatives (**61** and **62**) undergo analogous rearrangements persisting even at −70 °C.[140]

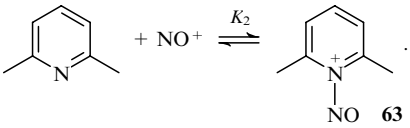


61, **62**

61: R^1 = Me, R^2 = R^3 = Ph; **62**: R^1 = PhO, R^2 = R^3 = Me.

According to the experimental data for the gas phase, pyridine derivatives and alkylbenzenes possess similar affinities for the NO^+ cation.[134] The formation constant of the 2,6-dimethylpyridine complex with the nitrosonium cation in MeCN was determined by the competitive method.[82] On gradual addition of 2,6-dimethylpyridine to a solution of the durene complex with $[NO]^+[BF_4]^-$ in acetonitrile, the intensity of the charge-transfer band for the durene–NO^+ complex decreases monotonically, while the intensity of the corresponding band for the nitrosonium complex with 2,6-dimethylpyridine increases due to the following reactions:



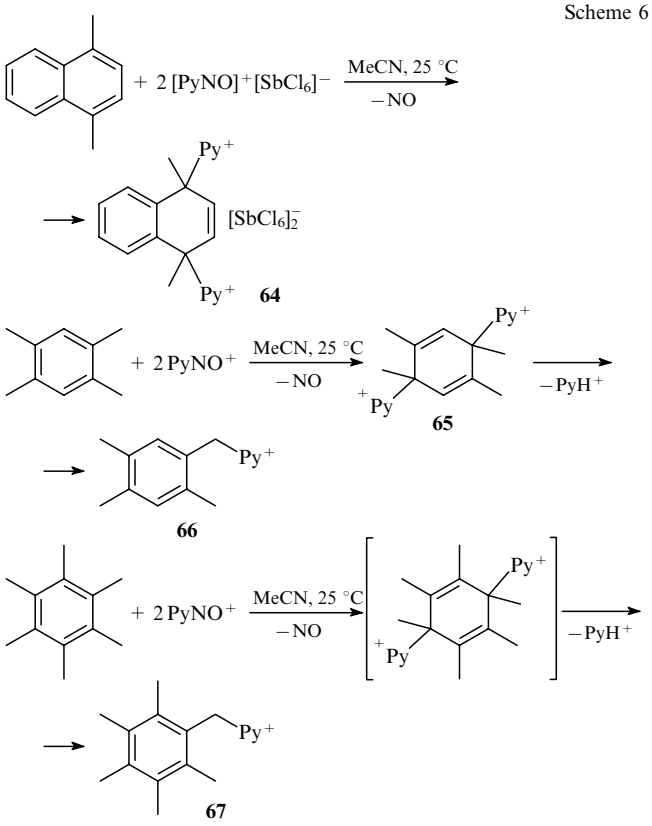


63

The equilibrium constant, K_2, of the reaction of NO^+ with 2,6-dimethylpyridine [$K_2 = (3\pm2)\times10^3$ litre mol^{-1}] was determined[82] from the equilibrium constant of the reaction of durene with the NO^+ cation (K_1 = 450 litre mol^{-1}) estimated previously. A somewhat different value was obtained for electrochemical reduction of complex **63**, ($K_2 \approx 500$ litre mol^{-1}). This difference in the constant determined by different methods is due partially to salt effects.[82]

Intensely coloured solutions of complexes of aromatic compounds with $C_5H_5N^+-NO$ ($PyNO^+$) in acetonitrile are decolourised in the presence of alkyl derivatives of benzene or naphthalene at room temperature in the dark, the rate of this process being decreased in the series 1,4-dimethylnaphthalene > hexamethylbenzene > durene ≫ *p*-xylene > toluene.[82] The chemical conversions responsible for decolouration of the complexes under the action of 1,4-dimethylnaphthalene, durene and hexamethylbenzene are shown in Scheme 6.[82]

Scheme 6



64

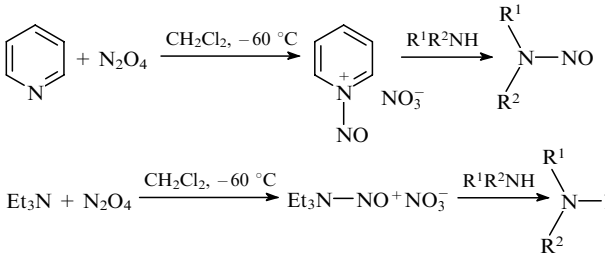
65

66

67

The structures of complexes **64–67** were established by ^1H NMR spectroscopy. The structure of the complex **65** (with the $SbCl_6^-$ anion) was additionally confirmed by X-ray diffraction analysis. Interestingly, the reaction of durene with the $[PyNO]^+[SbCl_6]^-$ salt afforded exclusively the *trans*-adduct **65**, while the reaction with the $[PyNO]^+[BF_4]^-$ salt gave rise to an equimolar mixture of the *trans*- and *cis*-adducts.[82]

N-Nitrosation reactions of secondary amines with complexes synthesised by the reactions of N_2O_4 with pyridine or triethylamine have been examined.[137]



Analogous N-nitrosation reactions of amino acids containing secondary amine groups under the action of a mixture of nitro-

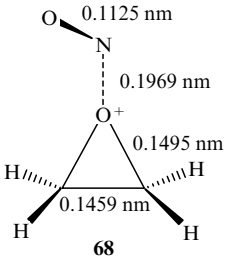
sonium tetrafluoroborate and pyridine have been described[141] (*cf.* Ref. 127). Apparently, the $[PyNO]^+[BF_4]^-$ complex served as an active nitrosating agent in these reactions.[141]

VI. Complexes of the nitrosonium ion with organic compounds containing Group VI elements

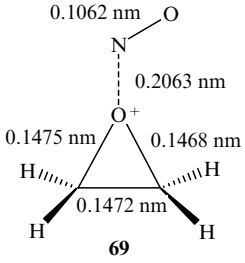
Complexes of the nitrosonium ion with compounds of the R^1ER^2 and $R^1R^2C=E$ types (E is the Group VI element) were considered as intermediates in many liquid-phase reactions of O-bases (alcohols,[1,142,143] ketones,[144–146] *etc.*[1,92–94]) and S-bases (desulfofluorination of thioesters,[147] conversions of thioketones and thioamides giving rise to ketones and amides of acids, respectively,[148] *etc.*[149–151]).

According to the results of quantum-chemical calculations[133,152–154] and experimental data for the gas phase obtained by the ion-cyclotron resonance[66,134] and kinetic methods,[134] O-bases possess rather high affinities for the NO^+ cation.

Calculations based on thermochemical data demonstrated that the energy of the nitrosonium complex with ethylene oxide (**68**) is 112.5 kJ mol^{-1} lower than those of the initial reagents.[152]

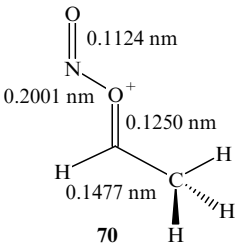


68

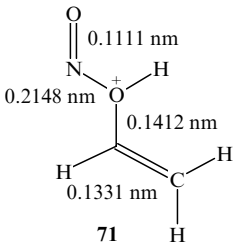


69

Ab initio calculations (SCF/MP2) demonstrated that the planar analogue of this complex (**69**) is somewhat energetically less favourable (ΔE_{rel} = 15.1 kJ mol^{-1}), the latter being a transitional structure between two equivalent forms **68**. According to the results of *ab initio* calculations (MP2/6-31+G*), the energy of the nitrosonium complex with acetaldehyde (**70**), which is isomeric with structure **68**, is 115.5 kJ mol^{-1} lower than those of the initial reagents, whereas the nitrosonium complex with the enol form of acetaldehyde (**71**) is energetically less favourable than the complex **70** (ΔE_{rel} = 105.0 kJ mol^{-1}).[152]



70



71

Analogously, *ab initio* calculations [HF/6-31+G(d)[133] and G2[154]] gave rather high affinities of the NO^+ cation for methanol (97.3 and 105.9 kJ mol^{-1}, respectively).

The *ab initio* energies of binding of the NO^+ cation with acetaldehyde and methanol are very close to the experimental values determined for the gas phase (Table 9).[134]

The energies of binding of the NO^+ cation with O-bases were analysed within the framework of Taft's equation.[66] Linear correlations were revealed for each class of compounds (MeCOR, where R = H, Me or Et; ROAc or RCHO, where R = Me, Et or Pr^i; and ROH, where R = Me, Et or Pr^i). Analogous relationships are true for the compounds of the $RONO_2$ and RNO_2 types (Fig. 8).

As mentioned above, nitrosonium complexes with O-bases were postulated for many liquid-phase reactions. However, the data on generation of these complexes in solutions are scarce.[77,155–159]

Table 9. Energies of binding (E_b) of the NO^+ cation with O-bases.[134]

Compound	E_b /kJ mol^{-1}	Compound	E_b /kJ mol^{-1}
H_2O	77.4	MeCHO	115.5
MeOH	97.5	Me_2CO	130.1
CH_2O	112.5	$MeCO_2Et$	131.4
$MeONO_2$	86.6	MeCOEt	134.3
$EtONO_2$	95.0	Et_2CO	136.8
Pr^iONO_2	101.7	Pr^iCOMe	138.1
$MeNO_2$	104.2	Bu^tCOMe	140.2
$EtNO_2$	112.5	Bu^t_2CO	141.0
Pr^nNO_2	115.9	Pr^i_2CO	142.3
Pr^iNO_2	118.0	PhCOMe	146.9
Bu^nNO_2	116.7	$(C_3H_5)_2CO$	152.7
Bu^tNO_2	123.4	Ph_2CO	160.2
$MeCOC(OMe)_2Me$	154.8	$(PhCH_2)_2CO$	165.3
$MeCO_2Bu^t$	141.0		

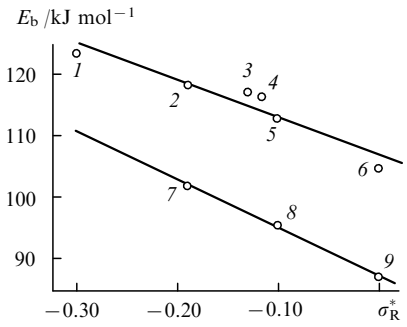


Figure 8. Correlation between the energies of binding (E_b) of the NO^+ cation with the RNO_2 (*1–6*) and $RONO_2$ compounds[134] (*7–9*) and the σ^*-constants of the substituents R (σ^*_R),[135] where R = Bu^t (*1*), Pr^i (*2*, *7*), Bu^n (*3*), Pr^n (*4*), Et (*5*, *8*) or Me (*6*, *9*) (r = −0.955 and −0.999, respectively).

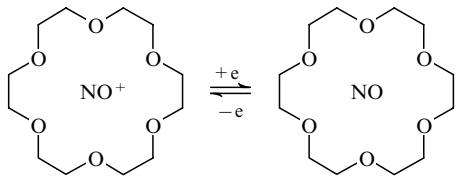
Thus, the reactions of the $[NO]^+[BF_4]^-$ and $[NO]^+[PF_6]^-$ salts with 18-crown-6, 15-crown-5 and 12-crown-4 in dichloromethane, acetonitrile and nitromethane were studied by ^{1}H NMR and IR spectroscopy and conductometry.[155] The reactions of 18-crown-6 and 12-crown-4 with $[NO]^+X^-$ afforded the 1:1 and 2:1 complexes, respectively. In the case of 15-crown-5, the 1:1 stoichiometry was observed if the reaction was performed in MeCN or $MeNO_2$, whereas the 2:1 stoichiometry was achieved in CH_2Cl_2. The addition of the $[NO]^+X^-$ salt to a solution of a complex always leads to a downfield shift of the signal of the crown ether in the ^{1}H NMR spectrum, one narrow singlet being observed due to the rapid (within the NMR time scale) exchange between the free crown molecule and the molecule involved in the complex. New absorption bands at 1850–1852 and 1876 cm^{-1} appeared in the IR spectra of solutions of 18-crown-6, 15-crown-5 and 12-crown-4 in CH_2Cl_2 and MeCN, respectively, upon the addition of the $[NO]^+X^-$ salts, which indicates that the NO^+ cation is covalently bonded to the crown molecule.[155] It should be noted that the positions of the bands in the IR spectra are virtually independent of the nature of the counterion.[155]

The reaction of 18-crown-6 with the NO^+ cation (BF_4^- as the counterion) was examined by ^{1}H and ^{13}C NMR, IR and Raman spectroscopy.[156] The ^{1}H and ^{13}C NMR spectra of the 1:1 complex have singlets at δ 3.67 and 70.327, respectively. The ^{13}C chemical shift changes only slightly (by 0.428 ppm) on going from free 18-crown-6 to the ether involved in the complex. The IR spectrum of the [18-crown-6–NO]$^+[BF_4]^-$ salt (in hexachlorobutadiene) has an absorption band of the NO group at 2274 cm^{-1} the position of which differs substantially from those observed in the spectra of this complex in CH_2Cl_2 or MeCN (see above).

Analogous results were obtained in another study.[157] It was suggested that the band at 2250 cm^{-1} in the IR spectrum of a solution of the [18-crown-6–NO]$^+$[BF_4]$^-$ complex in CH_2Cl_2 and the charge-transfer band of this complex (λ_{max} = 300 nm) be used for the detection of an impurity of the [NO]$^+$[BF_4]$^-$ salt in the [NO_2]$^+$[BF_4]$^-$ specimen.[77] A polycrystalline specimen prepared by the reaction of N_2O_4 with 18-crown-6 was studied by Raman spectroscopy.[158] The Raman spectrum of the salt [18-crown-6–NO]$^+$H$^+$[NO_3^-]$_2$ has an intense band at 2270 cm^{-1} belonging to the stretching vibration of the NO^+ group bound to the crown ether. No explanation was provided for the above-mentioned differences in the stretching vibration frequency of the NO group.[156–158] Apparently, these differences are associated with a change in the mode of bonding of the NO^+ cation with 18-crown-6.

The complex of 18-crown-6 with [NO]$^+$[BF_4]$^-$ in MeCN was examined by cyclic voltammetry.[77] The complexation constant ($K > 10^4$ litre mol^{-1}) was estimated based on the oxidation and reduction potentials. Reduction of the complex **72** gave rise to the compound **73**. On oxidation of the latter, NO molecules were only partially converted into NO^+ cations and its complex with the crown ether.



72 **73**

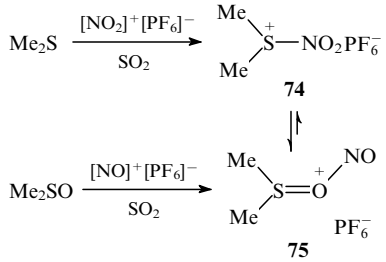
The reversible reduction potential of the complex **72** in MeCN ($E_{red} \approx 0.9$ B) is smaller than the E_{red} values determined for the hexamethylbenzene complex with the NO^+ cation (E_{red} = 1.02 V) and for NO^+ (E_{red} = 1.28 V).[77]

The reactivity of the nitrosonium cation changes substantially on the involvement of the [NO]$^+$[BF_4]$^-$ salt in the complex with 18-crown-6.[156] Thus the [18-crown-6–NO]$^+$[BF_4]$^-$ complex did not react with benzamide in MeCN at low temperature, whereas the amide was rapidly converted into acid under the action of [NO]$^+$[BF_4]$^-$ in the absence of the crown ether.[156]

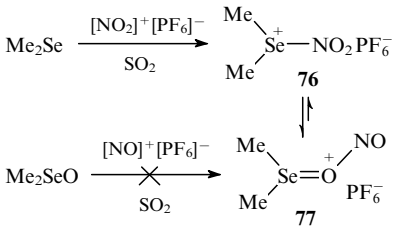
The nitrosonium cation vigorously reacts with ketones in the gas phase[66, 134] to give the [R^1R^2C=ONO]$^+$ complexes (see Table 9). Analogous complexes were obtained in the reactions of the NO^+ cation with compounds of the ArN=O and R_2S=O types in the liquid phase.[93, 94, 159]

Kinetic studies of the mechanism of nitrosation of aromatic compounds provided evidence for the formation of [ArNO–NO]$^+$ complexes in which the nitrosonium cation is bound to the oxygen atom of the NO group in the ArNO molecule.[92–94] The formation constants of the complex of the NO^+ cation with 4-nitrosotoluene and 1,3-dimethyl-4-nitrosobenzene in trifluoroacetic acid are 58 000 and 38 000 litre mol^{-1}, respectively.[93]

Studies by ^{1}H, ^{13}C and ^{15}N NMR spectroscopy showed[159] that the reaction of [NO]$^+$[PF_6]$^-$ with dimethyl sulfoxide in SO_2 or the reaction of [NO_2]$^+$[PF_6]$^-$ with dimethyl sulfide in SO_2 at low temperature gave rise to nitrosonium complex **75** (existing in equilibrium with complex **74**).

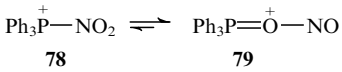


Analogously, the reaction of [NO_2]$^+$[PF_6]$^-$ with dimethyl selenide in SO_2 at −78 °C afforded nitrosonium complex **77** along with complex **76**.[159]



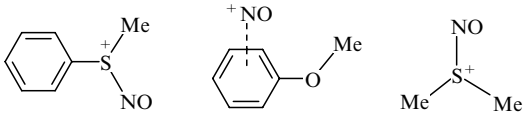
However, all attempts to generate the complex **77** by the reaction of [NO]$^+$[PF_6]$^-$ with dimethyl selenoxide failed because the latter readily underwent Pummerer fragmentation.[159]

The ambident reactivity of the NO_2^+ cation (the competitive O- or N-reactions) is manifested in its reactions with triphenylphosphine. In this case, as in the case of the S- and Se-analogues, the equilibrium **78** ⇋ **79** is shifted toward the nitritophosphonium complex **79**.[159]



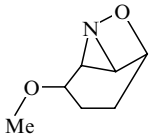
78 **79**

Investigations of the interaction of the NO^+ cation with O- and S-anions using perturbation theory demonstrated that the nitrosonium cation acts as a soft acid [160] (*cf.* Ref. 161). According to the Pearson concept,[162] the complexes of the NO^+ cation with S-bases should be more stable than those with O-bases. This statement can be exemplified by the fact that the reaction of thioanisole with [NO]$^+$[$AlCl_4$]$^-$ in the SO_2–CD_2Cl_2 system at −70 °C afforded an *n*-complex (**80**), whereas the reaction of anisole under these conditions gave rise to π-complex **81**, the oxygen atom of the anisole remaining unbound.[87]

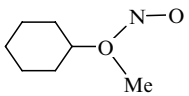


80 **81** **82**

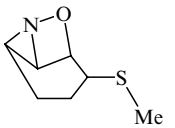
The structures of these complexes were confirmed by ^{1}H, ^{13}C and ^{15}N NMR spectroscopy. In particular, the fact that the cation **80** belongs to an *n*-complex is witnessed by the close values of the corresponding chemical shifts in the ^{15}N NMR spectra of this complex and Me_2S^+–NO (**82**) [HSO_3F–SO_2, δ(−70 °C) 291.6 and 258.6, respectively].[87] The results of quantum-chemical calculations by the MINDO/3 method confirmed that of the *n*-, π- and σ-complexes, the *n*-complex of thioanisole and the π-complex of ansiole are more stable.[87]



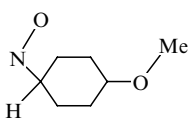
ΔH_f = 643.9 kJ mol^{-1}



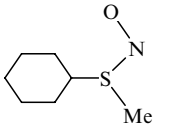
ΔH_f = 761.5 kJ mol^{-1}



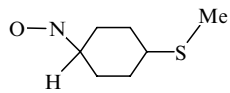
ΔH_f = 832.6 kJ mol^{-1}



ΔH_f = 663.6 kJ mol^{-1}



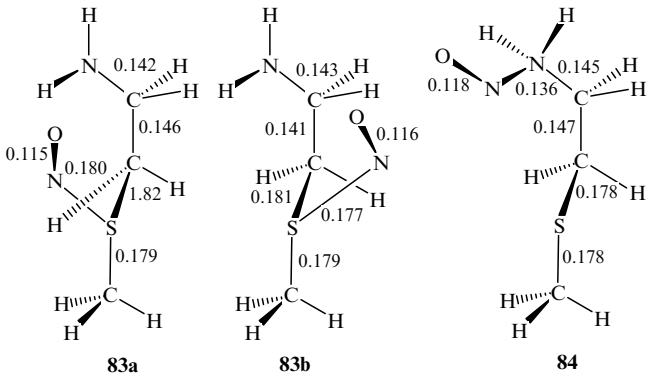
ΔH_f = 788.3 kJ mol^{-1}



ΔH_f = 854.0 kJ mol^{-1}

The preferential binding of the NO^+ cation at the sulfur atom rather than at the oxygen atom in the PhEMe compounds (E = O or S) was attributed [87] to the lower electronegativity of the S atom and a greater *p*,π-conjugation of the aromatic fragment with the MeO group compared to that with the MeS group. It was suggested [163] that binding of the nitrosonium cation in the case of thioanisole, occurs preferentially at the S atom due to the fact that the HOMO of thioanisole has the highest coefficient at the sulfur atom.

Ab initio (the 4-31G basis set), CNDO and INDO quantum-chemical calculations were performed with the aim of studying the reaction of 2-(methylthio)ethylamine with the NO^+ cation.[164] The structures of the complexes **83a**,**b** and **84** optimised by the CNDO and INDO methods are shown in Fig. 9. Analysis within the framework of perturbation theory demonstrated that the NO^+ cation acts as a soft acid, *i.e.*, it is bound primarily to the sulfur atom rather than to the nitrogen atom, the energy of the N-complex **84** being 50 kJ mol^{-1} higher than the energy of the stable *syn*-complex **83a**.[164]

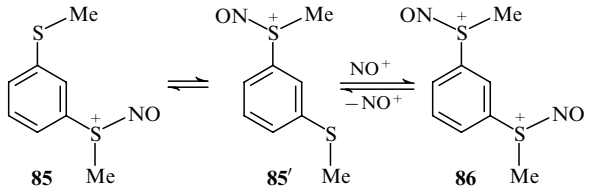


83a **83b** **84**

Figure 9. Geometric parameters of the *n*-complexes **83a**,**b** and **84** calculated by the CNDO and INDO methods.[164] The bond lengths are given in nm.

The reaction of 1,3-dimethylthiobenzene with $[NO]^+[AlCl_4]^-$ in the $SO_2-CD_2Cl_2$ system at −70 °C produced *n*-complex **85**, which underwent degenerate rearrangement, rapid within the NMR time scale (Scheme 7).[165]

Scheme 7



85 **85′** **86**

The structure of the complex **85** was confirmed by ^1H, ^{13}C and ^{15}N NMR spectroscopy. As expected, the ^{15}N chemical shift for the complex **85** (δ_N 267.1 relative to $MeNO_2$, −70 °C) is similar to that observed in the spectrum of the nitrosonium complex with thioanisole (δ_N 291.6 relative to $MeNO_2$, −70 °C).[87] The signals for the protons of the aromatic ring and methyl groups and the signals for the C(2), C(4), C(5) and C(6) atoms are shifted downfield as the 1,3-dimethylthiobenzene : $[NO]^+[AlCl_4]^-$ ratio changes from 1 : 1 to 1 : 2 due, apparently, to the shift of the equilibrium **85′** ⇌ **86** (see Scheme 7) to the dication **86**. A further increase in the amount of the salt (to 1 : 5) has no effect on the positions of the above-mentioned signals.

The complexes of dialkyl, alkylaryl and diaryl sulfides with $[NO]^+[BF_4]^-$ or N_2O_4 in CH_2Cl_2 were studied by electronic spectroscopy.[86] At low temperature, the spectra have charge-transfer bands whose positions depend only slightly on the nature of the counterion (NO_3^- or BF_4^-) (Table 10). It was demonstrated

Table 10. Parameters of electronic absorption spectra (λ_{CT} /nm) of the nitrosonium complexes with the R^1R^2E compounds (E = S or Se) in CH_2Cl_2 at −78 °C.[86, 166]

R^1	R^2	λ_{CT} (E = S)		λ_{CT} (E = Se)	
		A	B	A	B
Me	Me	390	393	–	–
Bu^n	Bu^n	400	400	–	–
Me	$PhCH_2$	406	406	426	424
Me	Bu^t	396	400	–	–
$(CH_2)_4$		387	386	–	–
Bu^t	$Me(CH_2)_{17}$	–	408	–	–
Me	Ph	502	500	494	498
Et	Ph	500	500	–	–
Pr^i	Ph	494	494	500	496
Me	*p*-ClC_6H_4	510	512	–	–
Me	*p*-MeC_6H_4	514	514	–	–
Me	*p*-$MeOC_6H_4$	542	542	–	–
Me	*p*-$Bu^tC_6H_4$	514	517	–	–
$PhCH_2$	$PhCH_2$	–	–	452	444
Ph	$PhCH_2$	506	–	508	506
Ph	Ph	558	563	–	–

Note. A and B are the complexes with the $[NO]^+[BF_4]^-$ salt and N_2O_4, respectively.

that low-temperature irradiation of the $[R^1R^2SNO]^+[NO_3]^-$ complexes at the frequency corresponding to the charge-transfer band afforded sulfoxides. The complexation constants for dialkyl and alkylaryl sulfides (K_1 and K_2, respectively) were estimated by the competitive method.

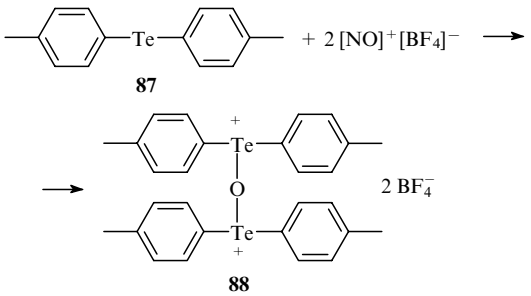
$$R_2S + [NO]^+[BF_4]^- \overset{K_1}{\rightleftharpoons} [R_2S, NO]^+[BF_4]^-$$

$$R_2S + [ArH, NO]^+[BF_4]^- \overset{K_2}{\rightleftharpoons} [R_2S, NO]^+[BF_4]^- + ArH$$

The complexation constant (K_1) for Bu^n_2S in CH_2Cl_2 at −78 °C is similar to that for hexamethylbenzene ($K_1 \approx 3 \times 10^4$ litre mol^{-1}), whereas ethylphenyl sulfide possesses a somewhat lower affinity for the NO^+ cation ($K_1 \leqslant 3 \times 10^3$ litre mol^{-1}).

Analogously, the reactions of dialkyl and alkylaryl selenides with $[NO]^+[BF_4]^-$ or N_2O_4 in CH_2Cl_2 at −78 °C gave rise to the nitrosonium complexes $R^1R^2SeNO^+$ (see Table 10).[166] As can be seen from Table 10, the positions of charge-transfer bands in the spectra of the nitrosonium complexes R^1R^2S and R^1R^2Se are rather close. Low-temperature irradiation of the complex $[PhMeSeNO]^+[NO_3]^-$ at the frequency ν_{CT} gave rise to the corresponding selenoxide PhSe(O)Me.[166]

The reactions of nitrosonium salts with diaryl tellurides, unlike those with S- and Se-containing aromatic compounds, did not produce nitrosonium complexes.[167] Thus treatment of bis(4-methylphenyl) telluride (**87**) with the $[NO]^+[BF_4]^-$ salt in the CH_2Cl_2-MeCN system at −40 °C under an atmosphere of argon afforded dication **88**.

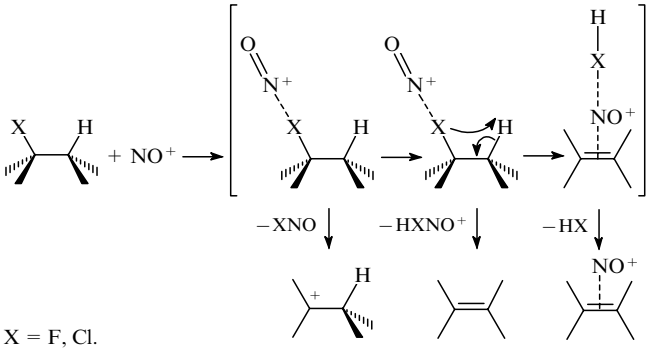


87 **88**

It was found that the oxygen atom in the dication **88** was derived from the nitrosonium salt.[167]

VII. Complexes of the nitrosonium ion with halogen-containing organic compounds

The reactions of the nitrosonium cation with organic halogen derivatives RX in the gas phase generate chemically active species, which can dissociate to form carbocations, nitrosyl halides and nitrosonium complexes of alkenes.[168]



X = F, Cl.

The latter react with alkyl halides yielding halonitrosonium complexes. Thus the reactions involving Pr^iCl or Pr^iF proceeded as follows:[168]

$$(MeCH{=}CH_2)\cdot NO^+ + Pr^iX \longrightarrow Pr^iX\cdot NO^+ + C_3H_6$$

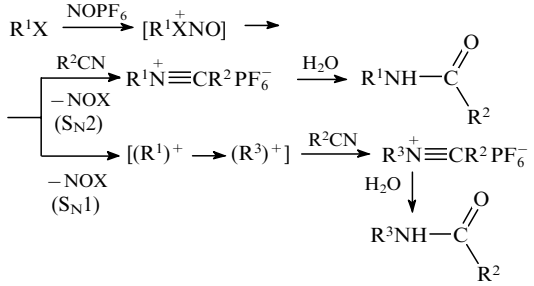
X = F, Cl.

It is assumed that analogous ion-molecular reactions take place upon interaction of the vibrationally excited NO^+ cation with different alkyl halides (see Ref. 169 and references cited therein).

The data on the energies of binding of the NO^+ cation with alkyl chlorides RCl (R = Me, Et or Pr^i; E_b = 77.4, 82.0 and 89.5 kJ mol^{-1}, respectively) were determined by the ion-cyclotron resonance and kinetic methods.[134] The following correlation between the E_b values for aryl chlorides and Taft's σ^*-constants was deduced: [135]

$$E_b = (76.8 \pm 1.3) - (63.4 \pm 10.7)\,\sigma^*,\ r = -0.986,\ s = 1.4.$$

To our knowledge, the data on generation of long-lived nitrosonium complexes of halogen-containing organic compounds in solutions are lacking. However, such complexes can be generated in different reactions of alkyl and aryl halides with salts of the nitrosonium cation.[170, 171] Thus, a new procedure was developed [170] for the preparation of amides by the reactions of alkyl or aryl halides with nitriles in the presence of the $[NO]^+X^-$ salts. The assumed mechanism involves the formation of a nitrosonium *n*-complex *via* the lone electron pairs of the halogen atom followed by nucleophilic substitution (of the S_N1 or S_N2 type) of nitrile for the XNO^+ group.[170]



R^1 = Alk, $ArCR^2R^3$; R^2 = Me, Et, Pr, Ph, $PhCH_2$;
$(R^3)^+$ — isomer $(R^1)^+$; X = F, Cl, Br.

Analogous results were obtained in another study. [172]

* * *

To summarise, abundant data on the structures and reactivities of different classes of nitrosonium organic complexes have been accumulated due to the extensive use of modern physical and quantum-chemical methods. In the present review, we generalise the results of recent studies in this area. The necessity of summarising these data stems from the fact that investigations aimed at refining the theoretical notion of the processes, which involve nitrosonium complexes and include both classical organic and biochemical reactions, are progressing rapidly.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 99–03–32878).

Abstract. The published data on the synthesis and chemical transformations of xenon derivatives are generalised and analysed. The bibliography includes 489 references.

I. Introduction

Xenon derivatives were obtained for the first time in 1962 by Bartlett [1] who used elementary xenon and PtF_6 as the oxidant to synthesise a xenon-containing salt.

$$Xe + PtF_6 \longrightarrow XePtF_6$$

Further studies showed that xenon compounds can be synthesised from elementary xenon and other oxidants. For example, the oxidation of elementary xenon by AgF_2 in anhydrous HF in the presence of BF_3 (see Ref. 2) results in XeF_2, whereas in the presence of AsF_5 the cation $Xe_2F_3^+$ is formed (see Refs 2 – 5).

$$2AgF_2 + 2BF_3 + Xe \xrightarrow{HF(liq)} 2AgBF_4 + XeF_2$$

$$4AgF_2 + 5AsF_5 + 2Xe \xrightarrow{HF(liq)} 4AgAsF_6 + Xe_2F_3^+AsF_6^-$$

Mass-spectrometric studies of the reaction of xenon with SiF_4 in the gas phase revealed the presence of the cation F_3SiXe^+ (see Ref. 6), whereas the formation of the cations $C_2H_4Xe^+$ and $C_2H_4XeF^+$ was established in reactions where the cations Xe_2F^+ or XeF_2^+ were generated in the presence of ethene (see Ref. 7). These reactions present substantial theoretical interest, since they illustrate the high synthetic potential of xenon.

At present xenon chemistry rests predominantly on fluorinated derivatives of xenon, such as xenon tetrafluoride and particularly xenon difluoride, the latter being produced by different manufacturers. The methods for the direct synthesis of XeF_2 and XeF_4 from fluorine and xenon at elevated temperatures were published in the early 1960's independently by several groups of investigators.[8,9] Further studies [10] were mostly directed at the elaboration of more convenient and simpler procedures for the preparation of xenon derivatives. A variety of inorganic xenon derivatives, both unstable and sufficiently stable in a broad temperature interval, were synthesised within a relatively short period of time. The first xenon derivatives containing Xe – N (see Ref. 11), Xe – B (see Ref. 12) and Xe – C bonds (see Ref. 13) were also prepared.

The interest in xenon chemistry stimulated the appearance of numerous reviews. Some of those [14 – 35] dealt with the discovery of noble gases, the chemistry of inorganic xenon derivatives and their applications in the fluorination of unsaturated and aromatic compounds. The physical and chemical properties of noble gas derivatives have been documented.[22 – 24] In some publications (see, *e.g.*, Refs 26, 27 and 32), xenon chemistry is considered in only a little detail and mostly in connection with other fields of chemistry, *e.g.*, the synthesis of organofluorine compounds, *etc.* All of these reviews generalised the literature data published before the early 1990's.

The aim of this review is to systematise, analyse and generalise the literature data concerning the synthesis and chemical properties of xenon derivatives with special emphasis on the chemistry of xenon difluoride and its derivatives.

II. Synthesis and properties of xenon difluoride-based reagents

At present, xenon difluoride is the only commercially available xenon derivative. A characteristic feature of this reagent is that it behaves as a radical fluorinating agent in the gas phase or under irradiation and as an electrophilic agent under other conditions. It is of note that the reactivity of XeF_2 increases dramatically in the presence of Lewis acids, apparently due to ionization of the XeF_2 molecule resulting in the formation of $XeF^+MF_n^-$ or $Xe_2F_3^+MF_n^-$ salts which are both strong oxidants.[35,36]

Some properties of xenon difluoride, *e.g.*, melting point, enthalpy of formation, critical parameters, solubility, maximum permissible concentrations, *etc.*, have been documented in earlier publications.[3,20 – 24,29,30,36 – 39]

The methods used for the synthesis of inorganic xenon derivatives can arbitrarily be divided into two main groups, *viz*., reactions of elementary xenon with various oxidising systems and synthesis of fluorinated xenon derivatives directly from xenon and fluorine. Xenon difluoride, -tetrafluoride and -hexafluoride were obtained in good yields by varying xenon and fluorine ratios as well as by selecting appropriate reaction conditions (pressure, temperature).[40–43] A photochemical method was developed in addition to the thermal procedure. Thus UV irradiation of a xenon–fluorine mixture results in xenon fluorides in satisfactory yields.[44–48] By virtue of their simplicity, thermal and photochemical methods are especially popular. These methods allow the synthesis of xenon difluoride with 99% purity. Other fluorinating reagents (with the exception of elementary fluorine) can also be used for the fluorination of elementary xenon. Thus the more readily available and safe ClF_3 was successfully used in the synthesis of large amounts of xenon difluoride,[49] whereas O_2F_2 was used in the synthesis of xenon tetrafluoride and -hexafluoride.[50] Other examples of xenon fluoride synthesis by oxidation of elementary xenon [13–23], *e.g*., irradiation of crystalline xenon by a flux of fluorine atoms, thermocatalytic synthesis,[51,52] γ-irradiation of a fluorine–xenon mixture [53] and electrochemical fluorination, have also been described.[54]

Other xenon halides, *e.g*., xenon chlorides [55,56] and -bromides,[57] are also known, but these compounds are difficult to access due to their low stabilities and are therefore virtually noninvestigated.

Some xenon compounds are synthesised by substitution of ligands for fluorine in the corresponding fluorides. For example, the reaction of xenon fluorides with oxygen-containing substrates yields compounds containing covalent Xe–O or Xe=O bonds.[58] The formation of the Xe=O bond usually occurs upon hydrolysis of xenon fluorides. The hydrolysis of xenon difluoride which gives xenon and hydrogen peroxide has been studied in detail. The Appelman hypothesis [59] about the formation of the oxidising species Xe=O in the first step of hydrolysis was corroborated by other authors.[60–64]

Aqueous solutions of XeF_2 oxidise both inorganic [58–60] and organic compounds.[61–64] The reactions of xenon difluoride with alcohols give reactive alkoxyxenonium fluorides ROXeF which manifest pronounced electrophilic properties (see Section III).

Hydrolysis of xenon hexafluoride by two equivalents of water results in xenon oxytetrafluoride $XeOF_4$ (**1**);[65] the highly explosive xenon trioxide XeO_3 is formed in the presence of excess water, apparently, *via* xenon dioxydifluoride (**2**). Compound **2** reacts with AsF_5 to yield the cation $[XeO_2F]^+$ (compound **3**) or the bridged cationoid structure **4**.[66,67]

$$XeF_6 + 2H_2O \longrightarrow \underset{\mathbf{1}}{XeOF_4} + 2HF$$

$$\underset{\mathbf{2}}{XeO_2F_2} + AsF_5 \xrightarrow{HF} \underset{\mathbf{3}}{[XeO_2F]^+AsF_6^-}$$

$$\underset{\mathbf{2}}{2XeO_2F_2} + AsF_5 \xrightarrow{HF} \underset{\mathbf{4}}{[FO_2XeFXeO_2F]^+AsF_6^-}$$

Xenon oxytetrafluoride $XeOF_4$ (**1**) is formed upon reactions of xenon hexafluoride with SeO_2F_2,[68] $NaNO_3$ [69–71] and TcO_3F.[72] However, these methods have some limitations connected with the use of toxic reagents and the possibility of formation of the explosive xenon trioxide as a by-product. These problems can be overcome by carrying out the reaction with phosphorus oxyfluoride. This reaction proceeds with a nearly quantitative yield; XeO_3 is not formed.[73]

$$XeF_6 + POF_3 \longrightarrow \underset{\mathbf{1}}{XeOF_4} + PF_5$$

Xenon oxytetrafluoride (**1**) can form complexes with alkali metal fluorides [74,75] which are attractive as regards their structural parameters and salts of the $[XeOF_5]Y$ type, *e.g*., where $Y = NO^+$ (see Refs 76–80).

$$XeOF_4 + ONF \longrightarrow NO^+XeOF_5^-$$

Perxenonates pertaining to octavalent xenon derivatives can be obtained by the following scheme:[81]

$$XeF_6 \xrightarrow{HOPOF_2} XeO_3 \xrightarrow{NaOH} Na_4XeO_6 + Xe.$$

Perxenonates are the starting compounds in the preparation of perxenates [82,83] and hydroxenates.[84] Perxenates of virtually all alkali metals,[85] alkaline-earth metals and actinide elements have presently been synthesised.[35] All of them are potent oxidants.[86]

Xenon fluorides react with various oxo acids to give compounds rather stable at low temperatures.[87–95] These reactions have been especially well studied for XeF_2 which forms mono- (**5a–j**) or diesters (**6a–j**) depending on the reagent ratio (Scheme 1).

Scheme 1

$$XeF_2 \xrightarrow[-78\ ^\circ C]{CH_2Cl_2} \begin{cases} \xrightarrow{HOR} \underset{\mathbf{5a-j}}{FXeOR} + HF \\ \xrightarrow{2\,HOR} \underset{\mathbf{6a-j}}{Xe(OR)_2} + 2\,HF \end{cases}$$

Compounds **5** and **6**	R	Ref.
a	OSO_2F	87, 88
b	OSO_2CF_3	89
c	OSO_2Me	89
d	$OCOCF_3$	89–91
e	$OPOF_2$	92
f	$OIOF_4$	93, 94
g	$OClO_3$	87–89
h	$OSeF_5$	95, 96
i	$OTeF_5$	90, 97–99
j	ONO_2	88

The Xe–O bond can also be formed through insertion of XeF_2 into the E=O bond. This approach was used in the reaction of XeF_2 with SO_3 [100] and resulted in mono- (**5a**) or difluorosulfate (**6a**) depending on the reagent ratio.

$$XeF_2 \begin{cases} \xrightarrow{SO_3} \underset{\mathbf{5a}}{FXeOSO_2F} \\ \xrightarrow{2\,SO_3} \underset{\mathbf{6a}}{Xe(OSO_2F)_2} \end{cases}$$

XeF_2 or the monoesters **5a**,**f** react with iodine trifluorodioxide analogously.[94]

$$XeF_2 + IO_2F_3 \xrightarrow[BrF_5 \text{ or } CFCl_3]{SO_2ClF} \underset{\mathbf{5f}}{FXeOIOF_4}$$

$$\underset{\mathbf{5a,f}}{FXeR} + IO_2F_3 \xrightarrow[BrF_5 \text{ or } CFCl_3]{SO_2ClF} \underset{\mathbf{6f,k}}{RXeOIOF_4}$$

R = OSO_2F (**5a**, **6k**), $OIOF_4$ (**5f**, **6f**).

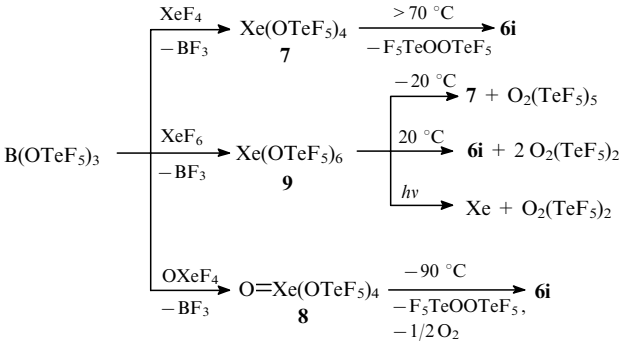
Exchange of ligands (other than fluorine) at the xenon atom is also possible, although this reaction has not been well studied yet.[94]

$$\underset{\mathbf{6i}}{Xe(OTeF_5)_2} + 2\,HOIOF_4 \xrightarrow{CFCl_3} \underset{\mathbf{6f}}{Xe(OIOF_4)_2} + 2\,HOTeF_5$$

In some cases, synthesis of bivalent xenon derivatives is accompanied by the formation of undesirable side products directly from acids and XeF_2. Hydrogen fluoride liberated can be bound by $(Me_3Si)_2NH$ or its formation can be prevented by boric anhydrides of the type $B(OR)_3$ (R = SO_2CF_3, $C(O)CF_3$).[101]

$$XeF_2 \begin{cases} \xrightarrow{B(OSO_2CF_3)_3} \underset{\mathbf{5b}}{FXeOSO_2CF_3} \\ \xrightarrow{2/3B(OC(O)CF_3)_3} \underset{\mathbf{6d}}{Xe(OCOCF_3)_2} + BF_3 \end{cases}$$

The ligands $OTeF_5$ and $OSeF_5$ manifesting pronounced electron-withdrawing properties and maximum stabilising effect in comparison with other known oxygen ligands are the most suitable for the synthesis of tetra- and hexavalent xenon derivatives containing covalent Xe–O bonds.[102,103] The Xe(IV) **7**[104–108] and Xe(VI) **8** and **9**[106–109] derivatives were obtained using $OTeF_5$ as the ligand.



The synthesis of bis(pentafluorotellurium) xenonate (**10**) and tetrakis(pentafluorotellurium) xenonate (**8**) made use of the corresponding boric anhydride.[110]

$$3XeO_2F_2 + 2B(OTeF_5)_3 \longrightarrow 3(F_5TeO)_2XeO_2 + 2BF_3$$
2 **10**

$$3XeOF_4 + 4B(OTeF_5)_3 \longrightarrow 3OXe(OTeF_5)_4 + 4BF_3$$
8

The reaction of xenon with O_2BF_4 results in the evolution of O_2 and F_2 and the formation of white crystals with the composition $FXeBF_2$ (see Ref. 11). This is the only currently known compound containing a Xe–B bond. At 243 K, it decomposes to yield an equimolar mixture of Xe and BF_3.

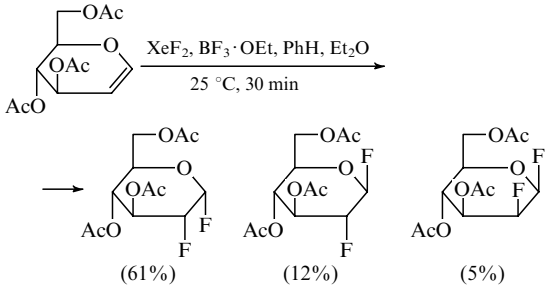
$$Xe + O_2BF_4 \longrightarrow FXeBF_2 + O_2 + F_2$$

III. Reactions of xenon difluoride and its derivatives with unsaturated compounds

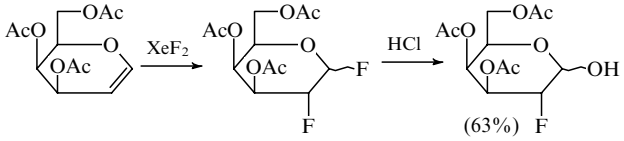
Reactions of XeF_2 with alkenes, alkynes and dienes have been described in detail in reviews.[20,30–33] In the general case, XeF_2 reacts with ethylene and terminal alkenes to afford mixtures of the addition products to the double bond and of the substitution products of fluorine for an alkene hydrogen atom.[111–113] This reaction occurs more selectively in the presence of HF, *viz.*, the addition products to the double bond are formed in up to 95% yields.[114–119] In addition to fluorine derivatives, the reaction of alkenes with XeF_2 in CF_3CO_2H also gives the corresponding trifluoroacetates.[120] 1-Phenyl-substituted cycloalkenes react with XeF_2 in the presence of HF to give a mixture of *cis*- and *trans*-difluorides (in up to 90% yields); the isomer ratio depends on the ring size.[121,122] Fluorohalogenation of the substrate occurs in the presence of a chlorine or a bromine source.[122] The reaction of XeF_2 with acenaphthylene, indene, 1,2- and 1,4-dihydronaphthalenes,[123,124] norbornene[125–130] and norbornadiene[125,130,131] results in the corresponding difluorides. The reaction of aliphatic 1,3-dienes with XeF_2 in the presence of $BF_3 \cdot Et_2O$ gives 1,2-addition products (75%–100%).[132] The reaction of enols with XeF_2 results in α-fluorocarbonyl compounds.[133–140] The reaction of diphenylacetylene with XeF_2 catalysed by trace amounts of HF gives 1,2-diphenyltetrafluoroethane in 50% yield.[141]

The fluorination of acetyl derivatives of D-fucal, D-glucal and D-galactal by XeF_2 has been described.[142–144]

Thus tri-*O*-acetyl-D-glucal reacts with XeF_2 in the presence of $BF_3 \cdot OEt_2$ to give a mixture of 2-fluoroglycosyl fluorides.[142]



The fluorination of tri-*O*-acetyl-D-galactal by XeF_2 in $CFCl_3$ and subsequent hydrolysis of the reaction product with hydrochloric acid affords 2-deoxy-2-fluoro-D-galactose.[144]



A versatile procedure for chemical doping of π-conjugated polymers, *e.g.*, polyacetylene and poly(*p*-phenylene), has been developed which allows introduction of various anions (A^-) into the polymer. The polymer is treated with xenon difluoride used as the oxidant and the corresponding acid, *e.g.*, HA (XeF_2 : HA = 1 : 2) in liquid HF or CH_2Cl_2.[145] Such a modification of polymers is not accompanied by incidental formation of degradation or fluorination products.

$$P + 1/2n\,XeF_2 + 1/n\,HA \longrightarrow P^{n+}(A^-)_n + 1/2n\,Xe + 1/n\,H$$

where P is the elementary unit of the polymer (CH or C_6H_4), *n* is the degree of doping, A = BF_4, AsF_6, SbF_6, OSO_2F, OSO_2Me or $OCOCF_3$.

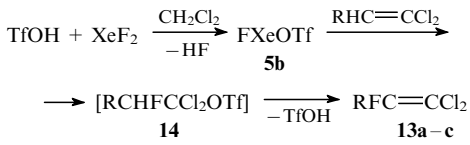
The degree of doping of the polymers under study by the XeF_2–2HA system increases with increase in the reaction time and the reagent : polymer molar ratio. The doping ability of anions decreases in the following order: $SbF_6^- > AsF_6^- \geqslant BF_4^- \geqslant OSO_2F^- > OSO_2Me^- > OCOCF_3^-$, which correlates with the order of the relative withdrawing capacity of the corresponding acids in reactions with XeF_2.[22] The maximum degree of doping of poly(*p*-phenylene) (0.97) is achieved with the anion SbF_6^-. This is probably due to the generation of the active species XeF^+ [its electron affinity is 10.4 eV (see Ref. 3)] as a result of complete ionisation of the XeF_2–2HA complex and the formation of $XeF^+SbF_6^-$ (see Ref. 146). It should be noted that the oxidising system XeF_2–2 HA allows variations of the anion A in a broad range, which makes this system superior to oxidants of the AsF_5 and I_2 type.[145]

Reactions of alkenes of different structures with other xenon derivatives including fluoroxenon triflate (**5b**), fluorosulfate (**5a**) and nitrate (**5j**), have been studied.[147–150] These reagents appeared to be more reactive than XeF_2. Xenon bis(fluorosulfate) (**6a**) reacts explosively with ordinary unsaturated hydrocarbons even at low temperatures. On the other hand, electron-deficient alkenes (**11**) yield covalent bis(fluorosulfonates) **12**.[149]

$$Cl(R)C{=}C(R)Cl + Xe(OSO_2F)_2 \xrightarrow[-Xe]{\text{Freon 113, } -10\ ^\circ C} (FSO_2O)Cl(R)CC(R)Cl(OSO_2F)$$
11 **6a** **12**

R = H, Cl, F.

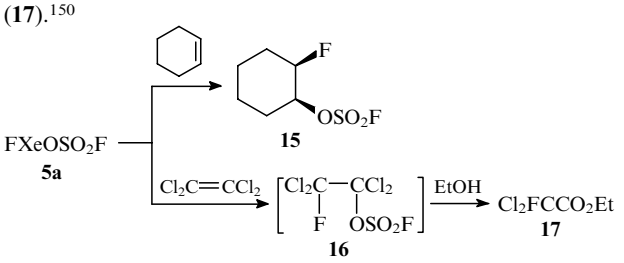
A one-step procedure for the preparation of fluorohalogenoalkenes using the reagent **5b** has recently been proposed.[151] Thus mixing of equimolar amounts of XeF_2 and CF_3CO_2H in anhydrous CH_2Cl_2 and subsequent addition of 1,1-dichloroalkene results in fluorodichloroalkenes **13a–c**, *viz.*, the products of formal substitution of fluorine for the vinylic hydrogen atom.[151] This approach is an alternative to the Swarts fluorination.[152]



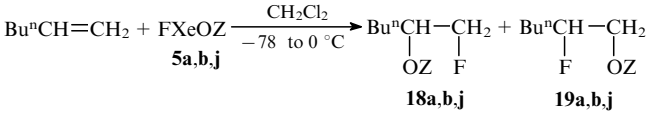
Tf = CF_3SO_2; R = H (**13a**, 65%), Me (**13b**, 66%), Et (**13c**, 63%).

The addition of the reagent **5b** follows the Markownikoff rule and yields the adducts **14**. Spontaneous elimination of trifluoromethanesulfonic acid from the adducts **14** can be attributed to the fact that the easily leaving triflate group and two electronegative chlorine atoms are localised at the same carbon atom.

cis-β-Fluorocyclohexyl fluorosulfate (**15**) was obtained as the main product in 50% yield in the reaction of xenon fluorosulfonate fluoride (**5a**) with cyclohexene; the reaction with tetrachloroethylene gave the adduct **16**, which was unstable at room temperature and could be identified as ethyl dichlorofluoroacetate (**17**).[150]

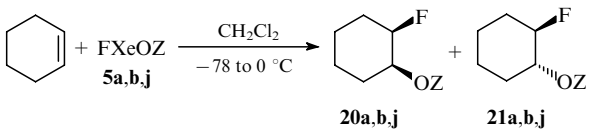


The reactions of compounds **5a**,**b**,**j** with hex-1-ene result in β-fluoroalkyl sulfonates or nitrates **18** and **19** with the predominance of the Markownikoff regioisomers **18a**,**b**,**j**.[148,149]



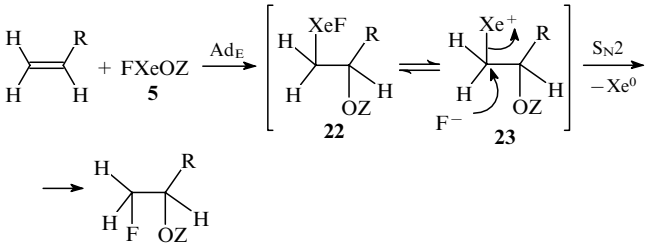
Reagent	Z	Yield (%)	
		18	**19**
5a	SO_2F	34	17
5b	Tf	48	15
5j	NO_2	18	9

Analogous reactions with cyclohexene yield predominantly *cis*-adducts. Thus *cis*-2-fluorocyclohexyl triflate **20b** is exclusively formed in 75% yield when the reagent **5b** is used. The reagent **5a** reacts with cyclohexene to give a mixture of the *cis*- and *trans*-isomers **20a** and **21a** in a 3 : 1 ratio (the total yield is 64%). The reaction of cyclohexene with the reagent **5j** gives a mixture of the isomers **20j** and **21j** in a total yield of 25%.[148,150]



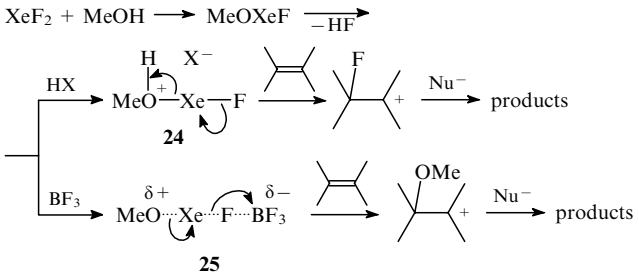
Z = OSO_2F (**a**), OTf (**h**), ONO_2 (**j**).

Earlier, it was assumed[20,30–34] that the addition of the reagents **5a**,**b**,**j** to alkenes occurs by a carbocationic mechanism involving the 'electrophilic' fluorine. However, the selective formation of *cis*-adducts in the reaction with cyclohexene cannot be rationalised within the framework of this mechanism. Based on the fact that the addition of triflates and perchlorates of trivalent iodine to alkenes also results in *cis*-adducts[153–162] and taking into account the isoelectronic nature of I(III) and Xe(II) derivatives, a reaction mechanism was proposed[148] which includes electrophilic addition of the reagents **5** to the double bond and the formation of the intermediate **22**.

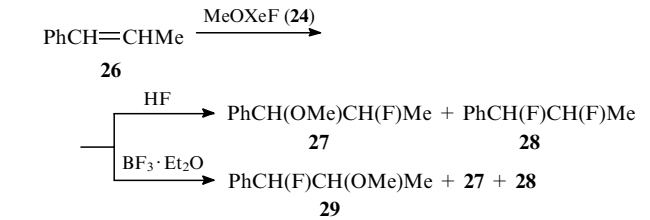


This reaction occurs in a *trans*-selective manner as in the case of trivalent iodine compounds.[153–162] Its second step includes stereospecific nucleophilic substitution of fluorine for xenon by the S_N2 mechanism, which is accompanied by an inversion of configuration and the formation of the *cis*-product.[163] Additional evidence in favour of the intermediate formation of the organoxenon compounds **22** and **23** containing the C–Xe bond in these reactions will be given in Section VI.

The reaction of XeF_2 with alkenes in the presence of aliphatic alcohols has been studied.[164–169] It was shown that methanolysis of XeF_2 yields an unstable electrophilic intermediate with hypothetical composition MeOXeF, which generates a potential electrophilic fluorine donor **24** in the presence of HX. MeOXeF reacts with boron trifluoride to give the positive oxygen electrophile **25**. The reaction of the intermediates **24** or **25** with alkenes results in carbocations containing F or OR in the α-position.[164]



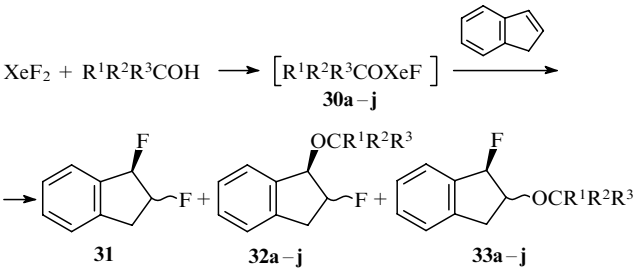
It was found[164] that the reaction of XeF_2 with alkenes in methanol involves MeOXeF rather than MeOF[170] the formation of which requires a stronger oxidant than XeF_2 (*e.g.*, F_2). In the absence of alkenes, MeOXeF disproportionates quantitatively with the formation of HF, Xe and CH_2O. The presence of an acid catalyst strongly affects the regioselectivity of the reaction. In the presence of hydrogen fluoride, MeOXeF reacts with *cis*- and *trans*-1-phenylpropenes **26** to give the final Markownikoff products **27** and **28**, whereas in the presence of BF_3 (in Et_2O or MeOH) the anti-Markownikoff products **29** predominate in the reaction mixture.[164,165]



Catalyst	Yield of **27** (%)		Yield of **28** (%)		Yield of **29** (%)	
	erythro	*threo*	*erythro*	*threo*	*erythro*	*threo*
cis-**26** as the substrate						
HF	0	25	2	73	0	0
$BF_3 \cdot Et_2O$	0	1	3	26	27	43
trans-**26** as the substrate						
HF	0	2	2	96	0	0
$BF_3 \cdot Et_2O$	1	0	3	29	20	47

^1H and ^{13}C NMR spectroscopy and mass spectrometry were used to study the regio- and stereochemistry of reactions of indene

with the unstable intermediates **30a–j** formed upon the reaction of XeF_2 with the corresponding alcohols.[164–166, 169]



31 **32a–j** **33a–j**

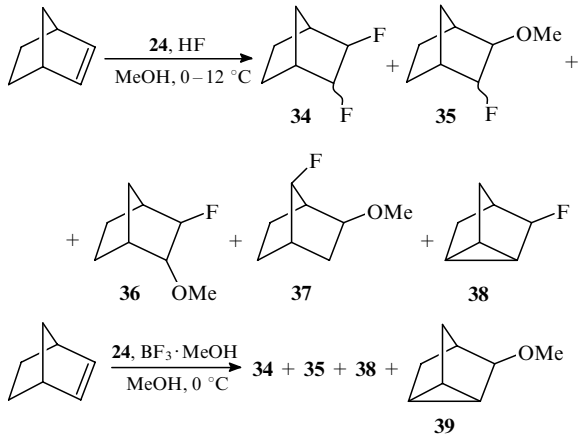
$R^1 = R^2 = R^3 = H$ (**a**); $R^1 = R^2 = Me$, $R^3 = H$ (**b**); $R^1 = R^2 = R^3 = Me$ (**c**); $R^1 = ClCH_2$, $R^2 = R^3 = H$ (**d**); $R^1 = FCH_2$, $R^2 = R^3 = H$ (**e**); $R^1 = CF_3$, $R^2 = R^3 = H$ (**f**); $R^1 = R^2 = R^3 = CF_3$ (**g**); $R^1 = CF(NO_2)_2$, $R^2 = R^3 = H$ (**h**); $R^1 = C(NO_2)_3$, $R^2 = R^3 = H$ (**i**); $R^1 = MeC(NO_2)_2$, $R^2 = R^3 = H$ (**j**).

The reaction with xenon methoxyfluoride (**30a**) in the presence of HF (MeOH, 0–12 °C) gives predominantly a mixture of *cis*- and *trans*-isomers of the methoxy fluoride **32a** (52% and 46%, respectively); the yield of yet another reaction product, *viz*., the difluoride *cis*-**31**, is 2%.

The anti-Markownikoff adducts **33** (26% of the *cis*-isomer and 52% of the *trans*-isomer) are the main products of the reaction carried out in the presence of $BF_3 \cdot Et_2O$ (MeOH, 0 °C).[164, 165]

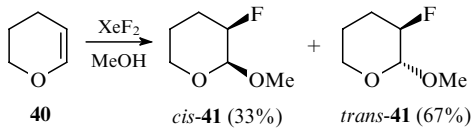
Alkoxyfluorides **32b**,**c** (*cis*- and *trans* isomers) are the main reaction products formed in the presence of protic catalysts (HF generated *in situ*) in Pr^iOH or Bu^tOH. Alkoxy fluorides **33b**,**c** (*cis*- and *trans*-isomers) are formed first in the presence of $BF_3 \cdot OEt_2$. In both cases, *cis*- and *trans*-difluoroindanes **31** are formed as admixtures. Compounds **33b**,**c** rearrange under the reaction conditions into the thermodynamically more stable adducts **32b**,**c**. In the absence of $BF_3 \cdot Et_2O$, the rearrangement occurs more slowly, *viz*., within several days. Reactions with alcohols containing electron-withdrawing substituents occur faster due to their higher acidities. The product yields in CF_3CO_2H decrease owing to the polymerisation of indene.[166, 169]

The nortricyclane derivatives **38** and **39** were also identified in reactions with norbornene along with the isomeric difluorides **34** and the methoxy fluorides **35**, **36** and **37**.[164, 165]



The reaction of 1,3-dimethylbuta-1,3-diene with XeF_2 in methanol in the presence of a catalyst (HF or $BF_3 \cdot MeOH$) affords a mixture of various 1,2- and 1,4-adducts, *viz*., difluorides and methoxy fluorides. The addition occurs both according to the Markownikoff rule and against it.[165]

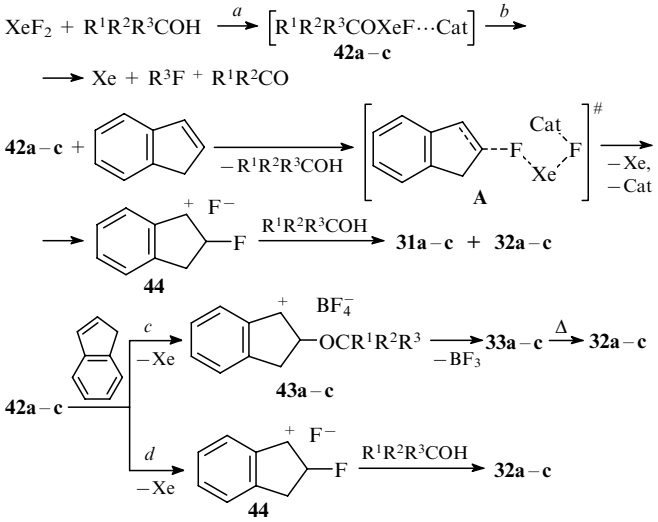
In the absence of a catalyst, dihydropyrane (**40**) reacts with XeF_2 and MeOH to give *cis*- and *trans*-isomers of the adduct **41**.[165]



40 *cis*-**41** (33%) *trans*-**41** (67%)

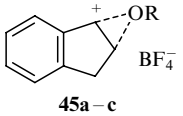
It is of note that hex-1-ene, buta-1,3-diene and methyl crotonate do not react with MeOXeF; in this case, the latter rapidly disproportionates to afford formaldehyde quantitatively.[165]

Shellhamer *et al*.[166] studied the mechanism of the reaction of alkenes with XeF_2 in the presence of alcohols using indene as an example.



(*a*) Cat, slow step; (*b*) fast step; (*c*) BF_3, fast step; (*d*) HF, fast step.

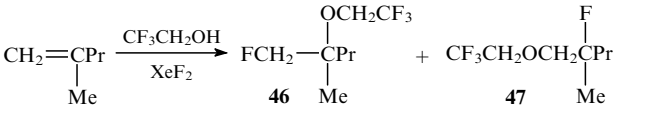
In the absence of alkenes or in the case of their low reactivities, alcohols undergo oxidation into aldehydes or ketones with the concomitant formation of alkyl fluorides and evolution of elementary xenon (routes *a* and *b*). It is believed that the complexes **42a–c** of xenon alkoxy fluorides **30a–c** with the catalyst are the intermediate products of this reaction. The intermediates **42a–c** are trapped by highly reactive alkenes (*e.g*., indene) to give complexes **A**; further conversions depend on the nature of the alcohol and the catalyst. In the presence of BF_3, xenon alkoxy fluorides **30a–c** react with indene as positive oxygen electrophiles to give, after elimination of xenon, 2-alkoxyindan-1-ylium tetrafluoroborates (**43a–c**). Their stabilisation is accompanied by the liberation of BF_3 and the formation of compounds **33a–c** (route *c*). The latter rearrange into more stable isomers **32a–c**. The intermediates **42a–c** act as electrophilic fluorine donors in the reaction with protic catalysts (HF); after the intermediate 2-fluoroindan-1-ylium fluoride **44** has been formed, they give compounds **32a–c** (route *d*).[166] The dependence of the direction of the reaction on the nature of the alcohols used (*e.g*., their acidity) is explained in the following way. In the presence of alkoxy substituents containing electron-withdrawing groups (CF_3CH_2, CF_3) in the intermediates **42**, they react as open ions (route *d*), whereas in the presence of electron-donor groups in alkoxy substituents they react with indene to afford the soft bridged intermediates **45a–c**. The reaction of these intermediates with the tetrafluoroborate anion results in the predominant formation of the *trans*-adducts **33a–c** which are transformed into compounds **32a–c** under the reaction conditions.[166]



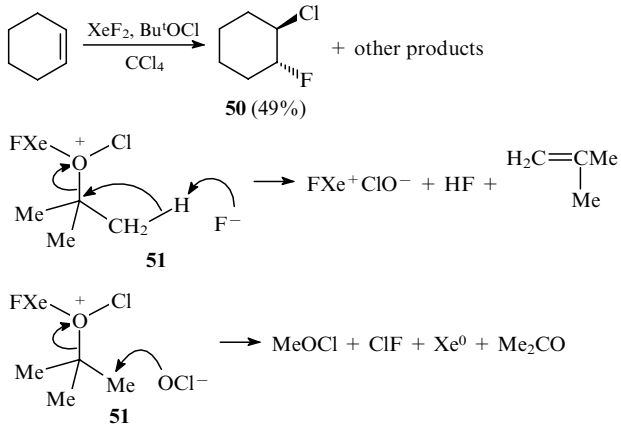
45a–c

R = Me (**a**), Pr^i (**b**), Bu^t (**c**).

The reaction of 2-methylpent-1-ene with XeF_2 in CF_3CH_2OH at 0–25 °C yields the alkoxy fluorides **46** (route *c*) and **47** (route *d*) in a total yield of 76% and in a *ca.* 1 : 1 ratio (these compounds were isolated by preparative GLC). Only the difluorides **48** and **49** could be prepared from hex-1-ene under analogous conditions, which corresponds to direct fluorination (route *d*).



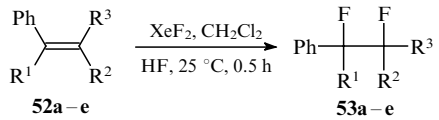
tert-Butyl hypochlorite and XeF_2 react with cyclohexene in CCl_4 to give a complex mixture of compounds with *trans*-1-chloro-2-fluorocyclohexane (**50**) as the main product.[171]



In this case, the lack of selectivity is attributed[171] to the formation of an intermediate complex of xenon fluoride with ButOCl (**51**), which generates various reactive species upon decomposition. It should be noted that *tert*-butyl hypochlorite and XeF_2 do not react with cyclohexene when used separately.[171]

This reaction was extended to other hypohalites (MeOX, ButOX, where X = Cl, Br).[171,172] It is assumed that the reaction of hypohalites with XeF_2 gives the corresponding interhalides HalX (Hal = Br, Cl), which are weaker electrophilic reagents than Cl_2 or BrCl. Therefore, they react more selectively with electron-enriched unsaturated and aromatic compounds to give the corresponding difluorides in high yields. Cyclohexene, methylenecyclohexane, hex-1-ene, hept-1-ene, hex-3-yne, 3,4-dihydro-2*H*-pyran, anisole, *etc*., were used as substrates.[171,172]

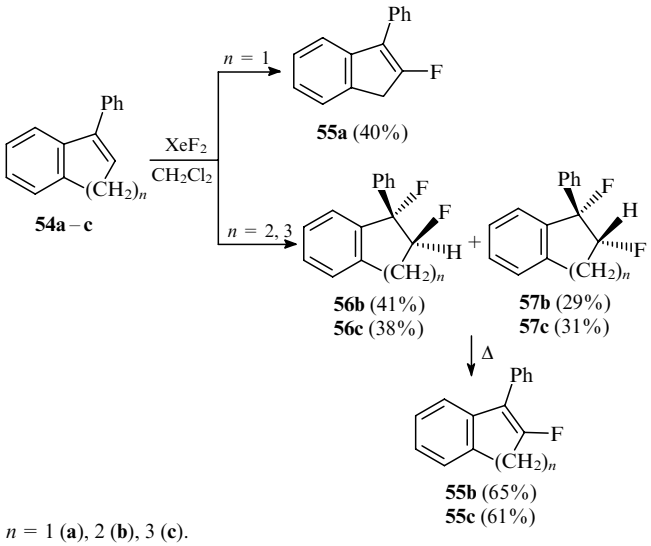
The fluorination of the phenyl-substituted alkenes **52a–e** with XeF_2 in the presence of 0.1–0.2 equiv. of anhydrous HF results in the difluorides **53a–e**.[173]



52a–e **53a–e**

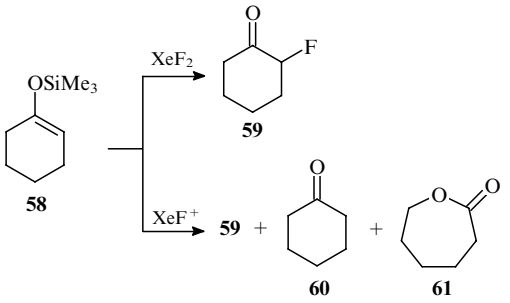
$R^1 = R^2 = R^3 = H$ (**a**); R^1 = Me, $R^2 = R^3 = H$ (**b**); R^2 = Me, $R^1 = R^3 = H$ (**c**); R^1 = Ph, $R^2 = R^3 = H$ (**d**); R^1 = Ph, R^2 = Me, $R^3 = H$ (**e**).

The reaction of XeF_2 with 3-phenyl-1*H*-indene (**54a**) affords 3-phenyl-2-fluoro-1*H*-indene (**55a**) as a result of addition–elimination. The fluorination of 4-phenyl-1,2-dihydronaphthalene (**54b**) and 9-phenyl-6,7-dihydro-5*H*-benzocycloheptene (**54c**) by XeF_2 yields diastereomeric pairs of the vicinal difluorides **56a**,**b** and **57a**,**b**. They are unstable on heating and eliminate HF at 200 °C, being converted into 3-fluoro-4-phenyl-1,2-dihydronaphthalene (**55b**) and 8-fluoro-9-phenyl-6,7-dihydro-5*H*-benzocycloheptene (**55c**).[173]



n = 1 (**a**), 2 (**b**), 3 (**c**).

The reaction of enol trimethylsilyl ethers with XeF_2 has recently been studied.[174] Thus 1-trimethylsilyloxycyclohexene (**58**) reacts with XeF_2 to give α-fluorocyclohexanone (**59**) in a quantitative yield. In the case of XeF^+, this reaction gives a mixture of three products (**59**–**61**); their formation is interpreted in terms of a single-electron transfer mechanism.[174]



IV. Reactions of xenon derivatives with aromatic and polyfluoroaromatic compounds

Xenon difluoride is a convenient fluorinating agent for the preparation of fluorine-containing mono- and polycyclic aromatic compounds. The reaction of aromatic and polyfluoroaromatic hydrocarbons with XeF_2 has been described in detail in reviews,[20,30–33] therefore, in Table 1 we shall cite only the most common reactions. Special attention will be given only to those papers which have not been surveyed in the literature.

Several papers are devoted to the reactions of functional derivatives of aromatic hydrocarbons with XeF_2. Thus the reaction of XeF_2 with anisole and 1,2-dimethoxybenzene gives 4-fluoroanisole and 4-fluoro-1,2-dimethoxybenzene (yields 72% and 37%, respectively).[198] The reaction of phenol with XeF_2 in CH_2Cl_2 yields a mixture or isomeric fluorophenols (47%);[198] in water, phenol is oxidised into *p*-benzoquinone.[63,199,200] Hydroquinone and 4-*tert*-butylcatechol are oxidised by XeF_2 into benzoquinone derivatives,[201] whereas catechol affords 4-fluorocatechol in 38% yield.[198] The initially proposed structure of the reaction product of pentafluorophenol with XeF_2 ($C_6F_5OOC_6F_5$)[202] was later refuted;[203] it was shown that this reaction yielded perfluoro-4-phenoxycyclohexa-2,5-dienone and perfluorocyclohexa-2,5-dienone. The reaction of (perfluoroaryl)-trimethylsilanes (Ar_F = C_6F_5, 4-$CF_3C_6H_4$, 4-C_5F_4N) with XeF_2 results in desilylation and formation of perfluorobiaryls.[204,205]

The fluorination of the aromatic nucleus of L-3-methoxy-4-hydroxyphenylalanine[206,207] used in the synthesis of L-6-fluorodihydroxyphenylalanine-[^{18}F] occurs smoothly.[207]

Table 1. The reaction products of aromatic compounds with xenon difluoride.

Starting compound	T/°C	Solvent	Catalyst	Reaction products	Yield (%)	Ref.
PhH	165			mixture of mono-, di and trifluorobenzenes		175
	145			the same		175
	25	CCl_4	HF	C_6H_5F	68	176 – 178
PhMe	25	CCl_4	HF	C_6H_4FMe (mixture of *o*-, *m*- and *p*-isomers)	32	177, 179, 180
PhCl	25	CCl_4	HF	C_6H_4FCl (mixture of *o*-, *m*- and *p*-isomers)	65	177, 179, 180
PhF	25	CCl_4	HF	$C_6H_4F_2$ (mixture of *o*-, *m*- and *p*-isomers)	47	177, 179, 180
$PhCF_3$	25	CCl_4	HF	$C_6H_4FCF_3$ (mixture of *o*-, *m*- and *p*-isomers)	75	177, 179, 180
PhOMe	20	CCl_4	HF	$C_6H_4(OMe)F$ (mixture of *o*-, *m*- and *p*-isomers)	65	177, 179, 180
$PhNO_2$	120			mixture of *o*-, *m*- and *p*-nitrofluorobenzenes		175
	167			the same	81	177, 179, 180
1,4-$F_2C_6H_4$	100			1,2,4-$C_6H_3F_3$: 1,2,4,5-$C_6H_2F_4$ = 8 : 1		175

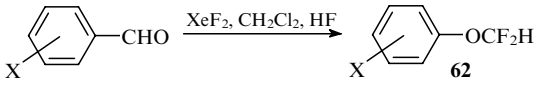
[a] At 10^{-6} mm Hg; [b] at 10^{-5} mm Hg.

Aromatic aldehydes react with XeF_2 in CH_2Cl_2 in the presence of HF to give the ethers **62** in 67% – 86% yields, the maximum yields being achieved with 4 – 5 equiv. of HF.[208, 209]

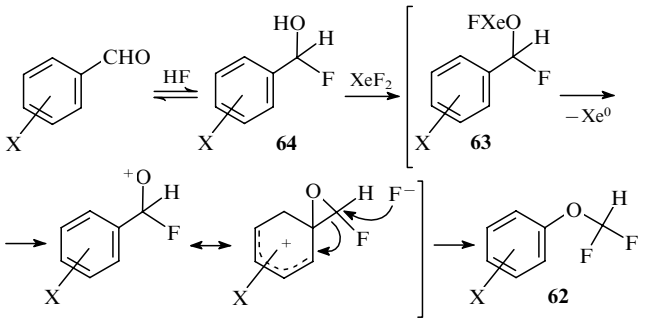


62

X = H, 4-Me, 4-Cl, 4-OMe, 4-OC_5H_{11}, 4-CO_2H, 4-CO_2Me, 2-NO_2, 3-NO_2, 4-NO_2, Ts.

The difluoromethoxylation of aromatic aldehydes carrying electron-donor substituents, such as acetamido- and methoxy groups, is accompanied by fluorination of the aromatic ring.[208]

The difluoromethyl ethers **62** are formed as a result of rearrangement which probably occurs *via* the intermediates **63** in the reaction of the fluorohydrins **64** with XeF_2.[208]



The aryl ketones **65** and **66a–c** react with XeF_2 in a similar way to give the fluorinated phenol ethers **67** and **68a–c** in low yields with considerable recovery of the starting compounds.[141,210,211]

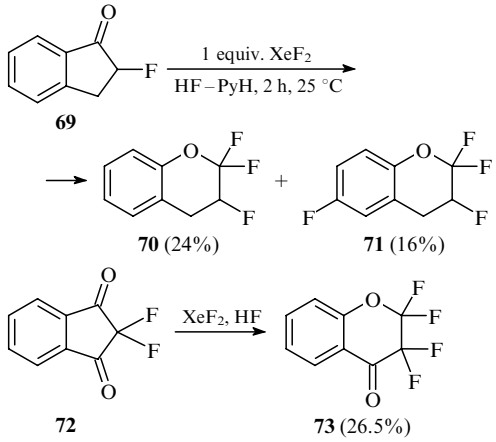
$$\underset{\mathbf{65}}{ArCOCH_2X} \xrightarrow[24\ h,\ 25\ ^\circ C]{1\ equiv.\ XeF_2,\ HF,\ CH_2Cl_2} \underset{\mathbf{67}}{ArOCF_2CH_2X}$$

Ar = Ph, C_6F_5, 2-$NO_2C_6H_4$; X = H, F.

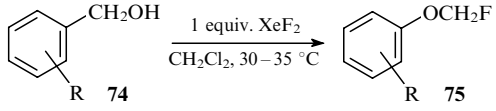
$$\underset{\mathbf{66a-c}}{Ar^1COAr^2} \xrightarrow[24\ h,\ 25\ ^\circ C]{1\ equiv.\ XeF_2,\ HF,\ CH_2Cl_2} \underset{\mathbf{68a-c}}{Ar^1OCF_2Ar^2}$$

$Ar^1 = Ar^2$ = Ph (**a**); Ar^1 = Ph, Ar^2 = 4-$NO_2C_6H_4$ (**b**);
$Ar^1 = Ar^2 = C_6F_5$ (**c**).

2-Fluoroindan-1-one (**69**) reacts with 1 equiv. of XeF_2 in HF–Py to give 2,2,3-trifluoro-3,4-dihydro-2*H*-benzo[*b*]pyran (**70**) and 2,2,3,6-tetrafluoro-3,4-dihydro-2*H*-benzo[*b*]pyran (**71**) as the main products.[210] 2,2-Difluoroindanedione **72** yields tetrafluorobenzopyrone **73** with XeF_2 in the presence of HF.

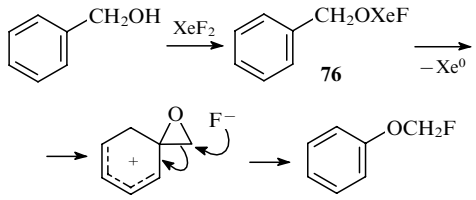


The reactions of the benzyl alcohols **74** with XeF_2 afforded the aryl fluoromethyl ethers **75** in high yields.[212] The yield of the main product increases in the presence of electron-withdrawing substituents, *e.g.*, for R = 3-NO_2, it reaches 85%. Fluorinated ethers are not formed if benzyl alcohols contain hydroxy-, alkoxy- or alkylamino groups.[212]

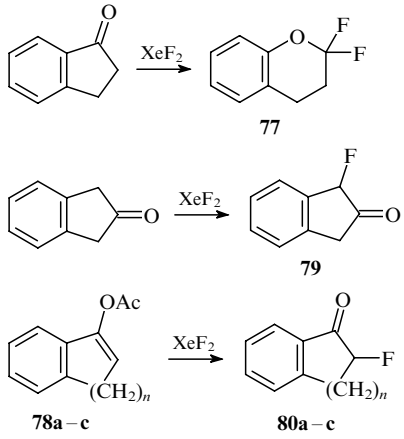


R = H, 2-NO_2, 3-NO_2, 4-NO_2, 4-Me, 3-F.

Presumably, this reaction occurs *via* the intermediate **76** and according to the same mechanism as does the synthesis of the difluoromethyl ethers **62** from aldehydes. The reaction is probably catalysed by HF; therefore, on the whole, it represents an autocatalytic process.[212]

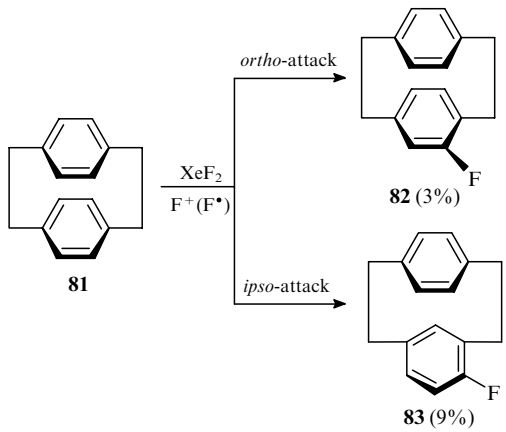


The reaction of indan-1-one with XeF_2 is accompanied by ring expansion resulting in the difluoro-substituted dihydrobenzopyran **77**. The α-fluoroketones **79** and **80a–c** are formed in the reaction of indan-2-one and the enol acetates **78a–c** with XeF_2. The fluorination products of the aromatic ring have not been found in either case.[211]



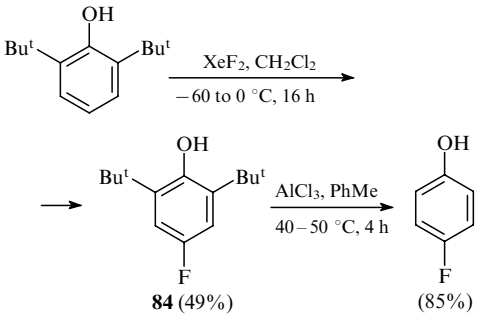
n = 1 (**a**), 2 (**b**), 3 (**c**).

The [2.2]metaparacyclophane system contains two types of aromatic rings, *viz.*, *para*- and *meta*-substituted ones. Reutov *et al.*[213] proposed a method for selective introduction of functional groups into this compound based on the use of XeF_2. It was shown that two cyclophane derivatives (**82** and **83**) containing a fluorine atom in the *para*- and *meta*-substituted benzene rings are formed from non-substituted [2.2]paracyclophane (**81**) after addition of an equimolar amount of XeF_2. Mixing of the reaction components in a Teflon vessel with CH_2Cl_2 did not result in any reaction between them, at least within one hour. The reaction could be initiated only after addition of an equimolar amount of CF_3CO_2H.



As mentioned above, the reaction of phenol with XeF_2 is nonselective.[198] 4-Fluorophenol was obtained from 2,6-di-*tert*-butylphenol in high yield using a two-step synthesis, *viz.*, fluorination by XeF_2 at low temperatures and subsequent treatment of the monofluoride **84** with $AlCl_3$ resulting in the elimination of

isobutylene and the formation of *p*-fluorophenol.[214] It is of note that fluorination of phenols can also be achieved through the use of *N*-fluoropyridinium triflate.[215, 216]

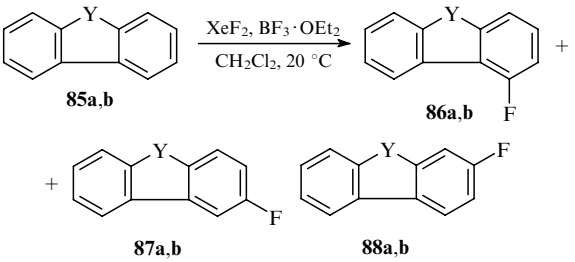


It is known [217] that XeO_3 and XeF_2 decompose in the presence of water to form a vast array of products, *e.g.*, HO$^{\bullet}$ radicals, hydrogen peroxide, molecular oxygen, XeO and the superoxide ion. It can be assumed that these products will effectively hydroxylate arenes. Indeed, heating or irradiation of a XeO_3 solution with a high-pressure mercury lamp at 20 °C in aqueous acetonitrile in the presence of benzene results in hydroxylation of the latter. The induction period of this reaction can be significantly reduced by addition of a catalytic amount of CrO_3.[218, 219] Xenon difluoride in aqueous acetonitrile is a more efficient hydroxylating reagent. In this case, the induction period is small, the initial rate of the reaction and the yield of phenol being strongly dependent on the concentration of water in the solution. HOXeF is a likely intermediate.[219]

Ethylbenzene is slowly oxidised by XeO_3 to acetophenone in the presence of the tetraphenylporphyrin manganese complex (TPP)MnOAc (TPP is tetraphenylporphyrin) in aqueous acetone. In this case, XeO_3 acts as an oxygen donor and is transferred by the metal-porphyrin catalyst to the substrate containing C–H bonds.[218]

A method for iodination of aromatic compounds by a mixture of XeF_2 with iodine or *N*-iodosuccinimide has recently been described.[172, 220] It is noteworthy that the same mixture was used for iodofluorination of alkenes. The IF generated from xenon difluoride is less reactive than that synthesised from I_2 and F_2. Presumably, in this case we deal with the reaction of an IF–XeF_2 complex with alkenes and aromatic compounds.[206]

The reaction of fluorene (**85a**) or dibenzofuran (**85b**) with XeF_2 in the presence of $BF_3 \cdot OEt_2$ gives a mixture of the monofluorides **86a**,**b**–**88a**,**b**.[221]



Y = CH_2 (**a**), O (**b**).

The reaction of XeF_2 with 1-R-2,3,4,5-tetrafluorobenzene (R = H, F, Br, NO_2) or 1-R-2,3,4,6-tetrafluorobenzene (R = H, CF_3) in HF or CH_2Cl_2–$BF_3 \cdot OEt_2$ results in the substitution of F for the hydrogen atom in the aromatic ring.[222] Only the addition reaction occurs in 1-R-2,3,5,6- (R = H, Br, CF_3) or 1-bromo-2,3,4,6-tetrafluorobenzenes under these conditions. The role of radical cations as intermediate compounds has been discussed.[222]

V. Reactions of xenon difluoride with organic acids and their derivatives

Earlier, it was shown (see Section II) that the reaction of XeF_2 with protic oxygen-containing acids gives unstable compounds of the FXeOR and $Xe(OR)_2$ types, which manifest strong electrophilic properties with respect to unsaturated and aromatic compounds. The reaction of benzoic acid with XeF_2 in an excess of benzene which gives phenyl benzoate in up to 70% yield is an example.[223, 224]

$$PhCO_2H + PhH + XeF_2 \longrightarrow PhCO_2Ph + 2\,HF + Xe$$

Biphenyl (1%–5%) is formed along with phenyl benzoate. Kinetic studies have shown that this reaction occurs *via* the formation of $PhCO_2XeF$ or $(PhCO_2)_2Xe$ with their subsequent reactions with benzene.[224]

For different benzoic acid derivatives, the yields of phenyl esters depend essentially on the structure of the original acid.[225] In the case of *p*-fluorobenzoic acid, the yield of the corresponding phenyl ester reached 68%, whereas for *o*-toluic acid it was as small as 3%, which can be due to steric hindrances preventing the formation of the intermediate compound.

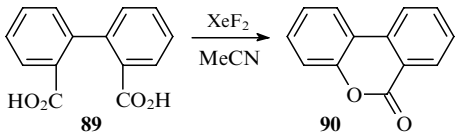
$$RC_6H_4CO_2H + XeF_2 \longrightarrow RC_6H_4CO_2XeF + HF$$

$$RC_6H_4CO_2XeF + PhH \longrightarrow RC_6H_4CO_2Ph + HF + Xe$$

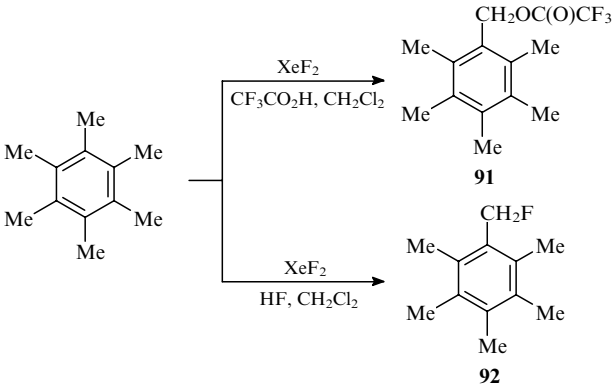
R = H, 2-NO_2, 3-NO_2, 4-NO_2, 2-Me, 3-Me, 4-Me, 4-Br, 4-F, 4-Cl.

The possibility of incorporation of benzoyloxy groups into toluene, fluoro-, chloro-, bromo- and nitrobenzene using the XeF_2–$PhCO_2H$ system has been studied.[226] The kinetic data and the isomeric composition of the reaction products suggest that the benzoyloxy group is introduced into *o*- and *p*-positions of toluene, chloro- and bromobenzene. The nitro group deactivates the nucleus so that no esters are formed. The relative rates of acyloxylation of benzene derivatives in the presence of XeF_2 decrease in the following order: $MeC_6H_5 > ClC_6H_5 > BrC_6H_5 > NO_2C_6H_5$. The experimental data suggest the electrophilic type of this reaction. The electrophilic reagent PhCOOXeF is deficient of electrons on the xenon atom and therefore attacks the positions with increased electron density in substituted benzenes.[226] Kinetic studies of the reaction of benzene with Ph[^{14}C]OOH revealed that benzoic acid is involved in the formation of phenyl benzoate and is not decarboxylated with the liberation of radiolabelled carbon dioxide.[227]

Aromatic dicarboxylic acids can be dehydrated by XeF_2 or undergo more profound conversions. The reaction of phthalic acid with XeF_2 (1 : 2) results in phthalic anhydride in 26% yield. Under the same conditions, 2,2′-diphenic acid (**89**) generates 3,4-benzocoumarin (**90**) in 30% yield along with a small amount of the anhydride.[228] The formation of compound **90** is due to partial decarboxylation of the intermediate with subsequent intramolecular acyloxylation.



The reaction of fluoroxenon trifluoroacetate (**5d**) with aromatic derivatives has also been studied. It was shown in particular that hexamethylbenzene reacts with the *in situ* generated compound **5d** to give pentamethylbenzyl trifluoroacetate (**91**) in good yield, while the reaction with XeF_2 in the presence of HF in CH_2Cl_2 gives pentamethylbenzyl fluoride (**92**) in 72% yield.[182]



91 **92**

Acids react with one equivalent of XeF_2 in dichloromethane or chloroform to give alkyl fluorides in 20% to 95% yields.[229, 230] This reaction, like other reactions occurring in the presence of XeF_2, is catalysed by HF and thus represents an autocatalytic process. This conversion is a method for carbon chain shortening by one atom as a result of the halodecarboxylation reaction.

$$RCO_2H + XeF_2 \xrightarrow{25\ ^\circ C,\ 8-16\ h} RF + Xe + HF + CO_2$$

R = $PhCH_2$ (76%), $Ph(CH_2)_2$ (76%), $Ph(CH_2)_3$ (60%), $Me(CH_2)_8$ (54%), Ph_2CHCH_2 (63%), $Me(CH_2)_{14}$ (62%), $MeC(O)CH_2CH_2$ (82%), 2-norbornyl (74%), 1-adamantyl (82%), $PhOCH_2$ (64%), 2,4-$Cl_2C_6H_3OCH_2$ (84%), Ph_3C (65%), $PhC(OMe)CF_3$ (95%), $PhCH_2$ (76%), $PhCH(CH_2CO_2H)CH_2$ (60%), $PhCH_2CHCO_2H$ (68%), Ph (20%), $Br(CH_2)_3$ (91%).

Alkanoic and arylalkanoic acids containing primary radicals, aryloxyacetic and dicarboxylic acids are highly susceptible to fluorodecarboxylation. Carboxylic acids containing secondary radicals form fluoro derivatives in low yields, whereas carboxylic acids with tertiary radicals react as smoothly as the acids with primary radicals. Those acids which contain other protic functional groups, *e.g.*, amino acids, cholic acid, *etc.*, as well as cinnamic acid do not enter into this reaction. Benzoic acid yields benzoyl fluoride in a low yield.

The proposed mechanism [230] of fluorodecarboxylation entails the intermediate formation of xenon carboxylates.[91, 116, 182, 226]

$$RCO_2H \xrightarrow[-HF]{XeF_2} [RCO_2XeF] \xrightarrow[F^-]{a} RF + Xe + HF + CO_2$$

$$[RCO_2XeF] \xrightarrow{b} RCO_2^{\bullet} + Xe + F^{\bullet}$$

$$RCO_2^{\bullet} \xrightarrow[-CO_2]{} R^{\bullet} \xrightarrow[-Xe,\ -F^-]{XeF^{\bullet}} R^+ \xrightarrow{F^-} RF$$

According to Patrick *et al.*,[230] the reaction follows both ionic (route *a*) and radical mechanisms (route *b*). Acids containing primary and secondary radicals react by route *a*, whereas acids containing tertiary radicals and arylalkanoic acids react by route *b*. Route *a* is realised when the reaction is carried out in the presence of $[Bu_4^nN]^+[^{18}F]^-$. This made it possible to obtain 2-phenyl-1-[^{18}F]fluoroethane and 3-bromo-1-[^{18}F] fluoropropane in high radiochemical yields [230, 231] and opened a possibility of replacing the carboxy group by substituents other than the fluorine atom.[230]

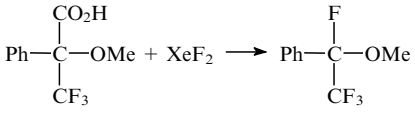
$$PhCH_2CH_2CO_2H + XeF_2 + [^{18}F]^- \longrightarrow PhCH_2CH_2[^{18}F]\ (40\%)$$

$$Br(CH_2)_3CO_2H + XeF_2 + [^{18}F]^- \longrightarrow Br(CH_2)_3[^{18}F]\ (78\%)$$

The reaction with 3-phenylpropionic acid affords no elimination side products or those involving the aromatic ring. 4-Phenylbutyric acid also reacts smoothly with XeF_2 and undergoes no intramolecular rearrangements characteristic of radical processes,[230] which makes it different from the reaction with $Pb(OAc)_4$, which results in cyclisation.[232]

It could be expected that 1,2-diphenylethane would be the main reaction product of XeF_2 with 3,3-diphenylpropionic acid, since such rearrangement is well known for phenylethyl radicals.[233] However, 2,2-diphenyl-1-fluoroethane is formed instead. Presumably, this reaction is in some respect analogous to the Borodin – Hunsdiecker reaction [234, 235] where the rearrangement products are not detected either, which makes it different from the Kochi reaction.[236, 237]

Racemic 1-methoxy-1-phenyl-1,2,2,2-trifluoroethane (**94**) was obtained in 95% yield by fluorodecarboxylation of the optically active (+)-α-methoxy-α-trifluoromethylphenylacetic acid (**93**). In the presence of $[Bu_4^nN]^+[^{18}F]^-$, this reaction gave compound **94**-[^{18}F] in 65% radiochemical yield.[230]



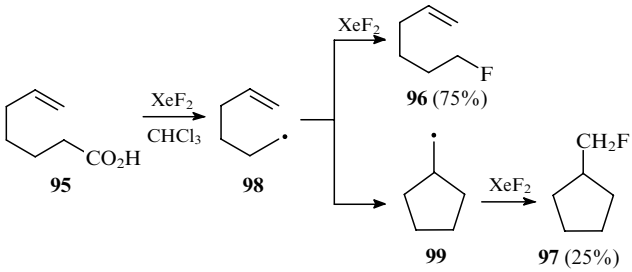
93 **94**

Pyridylacetic acid reacts with XeF_2 in the presence of HF in dichloromethane to give products the compositions of which are typical of a radical reaction.[238]

$$PyCH_2COOH \xrightarrow[CH_2Cl_2]{XeF_2,\ HF} PyCH_2CH_2Py + PyMe + PyCH_2F + PyCHCl_2 + PyCH_2Cl$$

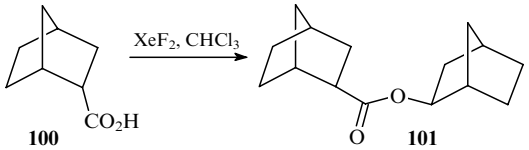
(58%) (10%) (<1%) (17%) (11%)

The reaction of hept-6-enoic acid (**95**) with XeF_2 gives 6-fluorohex-1-ene (**96**) and fluoromethylcyclopentane (**97**).[238, 239] Fluorocyclohexane was not detected. In this case, the feasibility of a radical mechanism was unambiguously confirmed by direct EPR identification of the alkyl radicals **98** and **99** (trapped by α-phenyl-*N*-*tert*-butylnitrone). Additional experiments demonstrated the impossibility of interconversion of the fluorides **96** and **97**. The rate constant for the second-order reaction ($k = 1.1 \times 10^6$ litre mol^{-1} s^{-1}) was determined at 25 °C.[239]



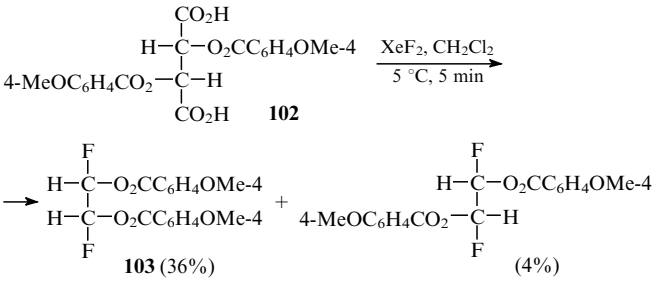
95 **98** **96** (75%) **99** **97** (25%)

endo-Norbornane 2-carboxylic acid (**100**) does not afford fluoro derivatives in the reaction with XeF_2, but rather gives 2-*exo*-norbornyl *endo*-norbornane-2-carboxylate (**101**) in 72% yield. The *exo*-position of the alcoholic function is explained by the generation of the 2-norbornyl cation, which reacts with nucleophiles to give exclusively products with an *exo*-configuration of the substituents.[238]

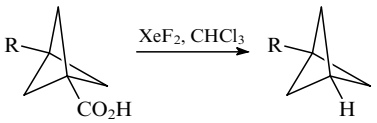


100 **101**

The reaction of the L-tartaric acid derivatives **102** with XeF_2 is non-stereospecific. The *meso*-difluoro derivative **103** (yield 36%) was isolated as the main product.[238]

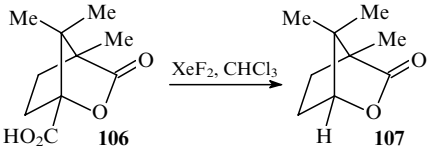


Patrick *et al.*[230] suggested that the reaction of 3-phenylbicyclo[1.1.1]pentane-1-carboxylic acid (**104a**) with XeF_2 generates a dimer; however, later it was shown [238] that this reaction yields the hydrocarbon **105a**. 3-Methoxycarbonylbicyclo[1.1.1]pentane-1-carboxylic acid (**104b**) and (−)-camphanic acid **106** are also decarboxylated by XeF_2 to give compounds **105b** and **107** in 80% and 85% yields, respectively.[239]

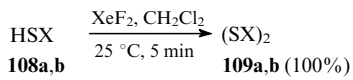


104a,**b** **105a**,**b**

R = Ph (**a**), CO_2Me (**b**).

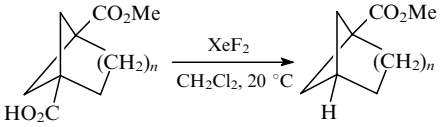


The reaction of XeF_2 with the carboxylic acids **108a**,**b** containing a thiol group gives the disulfides **109a**,**b** in a quantitative yield,[238] which is consistent with the data described in Section VIII.2.

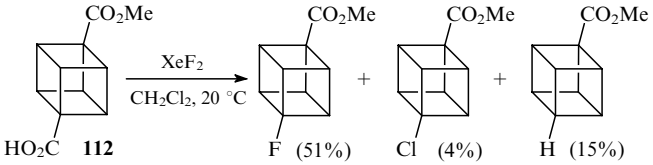


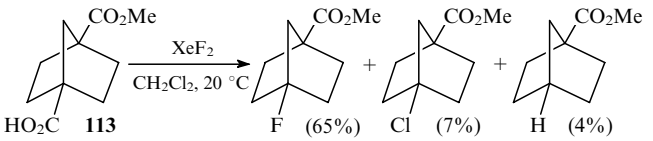
X = CH_2CO_2H (**a**), $CH_2CH_2CO_2H$ (**b**).

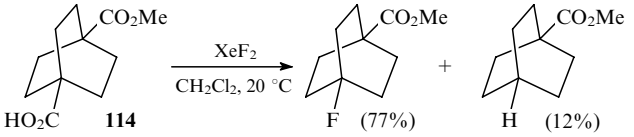
Fluorodecarboxylation with 1.5 equiv. of XeF_2 in dichloromethane was successfully employed for the synthesis of bridged cage fluorides.[238, 240]



n = 0 (**104b**, **105b**); 1 (**110**, **111**).



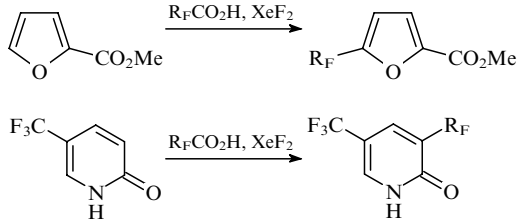




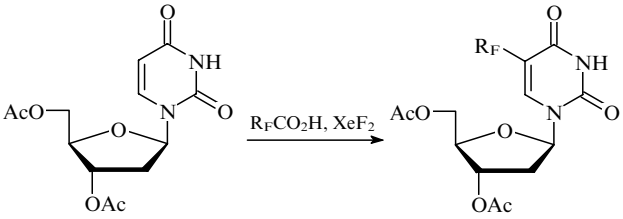
The yields and the compositions of the reaction products depend on the cage compound used. For example, 3-methoxycarbonylbicyclo[1.1.1]pentane-1-carboxylic (**104b**) and 3-methoxycarbonylbicyclo[2.1.1]hexane-1-carboxylic (**110**) acids yield exclusively the reduced decarboxylation products **105b** and **111**, whereas the monoester of a dicarboxylic acid of the cubane series (**112**) and 4-methoxycarbonylbicyclo[2.2.1]heptane-1-carboxylic acid (**113**) afford a mixture of fluorides, chlorides and reduction products. 4-Methoxycarbonylbicyclo[2.2.2]octane-1-carboxylic acid **114** forms no chlorination products under these conditions.[240]

Decarboxylation of some carboxylic acids by XeF_2 is accompanied by the formation of free radicals and can be used for their generation. Halogenocarboxylic acids, particularly trifluoroacetic acid, are especially prone to such reactions. The reaction of trifluoroacetic acid with the corresponding substrate in the presence of XeF_2 was used by Tanabe *et al.*[241] for the incorporation of the trifluoromethyl radical into aromatic and heterocyclic compounds. The reaction with benzene gives trifluoromethylbenzene in 33%–38% yield. An analogous reaction takes place in the case of other perfluorocarboxylic acids.[241]

Ar = Ph, 1,4-$Cl_2C_6H_4$, 4-$ClC_6H_4CO_2Me$, 4-ClC_6H_4NHAc, 3,5-$Cl_2C_6H_3NHAc$, 2,5-$F_2C_6H_3NHAc$.



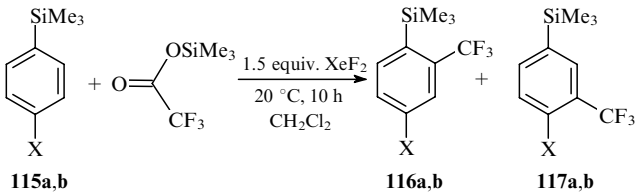
R_F = CF_3, C_2F_5, C_3F_7.



R_F = CF_3, C_2F_5.

If a heterocyclic compound contains a thiol group, perfluoroalkylation occurs exclusively at the sulfur atom.[242] In this case, disulfides are formed as side products in the same manner as in the case of acids containing a thiol group.[238]

The trifluoromethylation [243] was extended to trimethylsilyl derivatives of arenes.[241] Thus the reaction of compounds **115a**,**b** with trimethylsilyl trifluoroacetate yields a mixture of the regioisomers **116a**,**b** and **117a**,**b**. The products of *ipso*-substitution of the trimethylsilyl group were not detected.[241]



115a,**b** **116a**,**b** **117a**,**b**

Compound	X	Yield (%)	
		116	**117**
115a	Cl	9	34
115b	NHAc	8	29

Perfluorodicarboxylic acids can generate biradicals in the reaction with XeF_2. Thus the reaction of perfluoroglutaric acid (**118**) with XeF_2 in benzene results in 1,3-diphenylhexafluoropropane (**119a**) (yield 47%). 1,3-Bis(*p*-tolyl)- (**119b**) and 1,3-bis-(4-fluorophenyl)hexafluoropropane (**119c**) are formed in toluene or fluorobenzene in 62% and 65% yields, respectively.[244] The reaction of the dicarboxylic acid **118** with XeF_2 in the presence of elementary chlorine or bromine was used to prepare 1,3-dichloro- or 1,3-dibromohexafluoropropanes.

$$HO_2C(CF_2)_3CO_2H + XeF_2 \longrightarrow$$

118

ArH, 15–20 °C → $Ar(CF_2)_3Ar + HF + CO_2 + Xe$ (**119a–c**); Ar = Ph (**a**), MeC_6H_4 (**b**), FC_6H_4 (**c**)

Cl_2 or Br_2, 0–5 °C → $X(CF_2)_3X + HF + CO_2 + Xe$; X = Cl (54%), Br (71%)

The reaction of XeF_2 with the corresponding aromatic substrate in the presence of carboxylic acids containing different functional groups allows the introduction of polyfunctional substituents into the molecule of an aromatic compound. The high value of this reaction was demonstrated using chlorofluoro- or difluoronitroacetic acid as examples.[245]

$$O_2NCF(R^1)CO_2H + 1/2\ XeF_2 + PhR^2 \longrightarrow$$

120

R^1 = Cl → $O_2NCFClC_6H_4R^2$ (**121a–c**)

R^1 = F → $O_2NCF_2C_6H_4R^2$ (**121d–f**) + $O_2NCF_2CO_2C_6H_4R^2$ (**122d–f**)

R^1 = Cl: R^2 = H (**a**), Me (**b**), F (**c**); R^1 = F: R^2 = Me (**d**), F (**e**), H (**f**).

It was found that the structures of the reaction products depend on the substituent R^1 in the original acid **120**. Thus for R^1 = Cl, the reaction gives the alkylation products **121a–c**, whereas for R^1 = F, aryl difluoronitroacetates **122d–f** are formed in addition to compounds **121d–f**, which is probably due to the higher stability of the intermediate difluoronitroacyl radical.[245]

In contrast with non-substituted carboxylic acid, the reactions of the halogeno nitro carboxylic acids **123a,b** with XeF_2 yield halogenodinitromethanes.[246]

$$O_2NCFXCO_2H \xrightarrow{XeF_2}$$

123a,b

X = F → $CF_2(NO_2)_2 + CF_4 + CO_2 + Xe + HF$

X = Cl → $CFCl(NO_2)_2 + CFCl_2NO_2 + CF_4 + CO_2 + Xe + HF$

X = F (**a**), Cl (**b**).

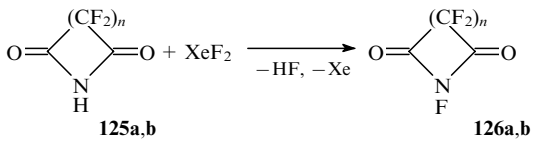
If this reaction is carried out in the presence of chlorine, bromine or nitrogen oxides, the carboxy group in fluorochloro- (**123a**) or difluoronitroacetic acids (**123b**) can be replaced by the corresponding functional groups; compounds **124** are formed in satisfactory yields.[247] If the reaction is carried out in aromatic solvents, they undergo alkylation.[245, 248]

$$O_2NCF(X)CO_2H + XeF_2 \xrightarrow{Y_2} O_2NCFXY + CO_2 + Xe + HF$$

123a,b → **124a–f**

$Y_2 = Cl_2, Br_2, N_2O_4$; X = F, Y = Br (**a**); X = Cl, Y = Br (**b**); X = F, Y = NO_2 (**c**); X = Cl, Y = NO_2 (**d**); X = F, Y = Cl (**e**); X = Y = Cl (**f**).

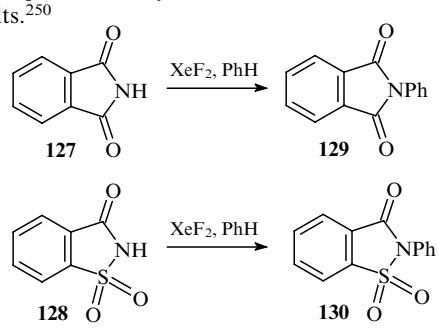
Xenon difluoride reacts with carboxylic acid imides. Thus the reaction of perfluorosuccinimide (**125a**) and -glutarimide (**125b**) with XeF_2 gives *N*-fluoroimides (**126a,b**).[249]



125a,b → **126a,b**

n = 2 (**a**), 3 (**b**).

The reactions of phthalimide (**127**) and saccharin (**128**) or their potassium salts with XeF_2 in dry benzene result in the *N*-phenyl derivatives of the corresponding imides **129** and **130** in 14% – 22% yields. In addition to *N*-phenyl derivatives, biphenyl is formed as a side product; its yield is lower in the reactions of potassium salts.[250]



127 → **129**; **128** → **130**

The reaction of trimethylsilyl arenecarboxylates **131** with XeF_2 in dichloromethane or hexaflurobenzene results in the aryloxycarbonyl fluorides **132**. Arenes or aryl fluorides generated from the corresponding aryl radicals are the main reaction products in acetonitrile.[251]

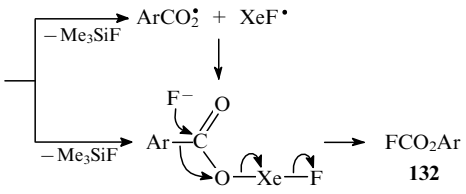
$$ArCO_2SiMe_3 \xrightarrow{XeF_2} \begin{cases} \xrightarrow{C_6F_6 \text{ or } CH_2Cl_2} FCO_2Ar + Xe + Me_3SiF \\ \xrightarrow{MeCN} ArF + Xe + Me_3SiF + CO_2 \end{cases}$$

131 → **132**

Ar = 4-$Bu^tC_6H_4$, 4-MeC_6H_4, 3-ClC_6H_4, 4-$MeOC_6H_4$, 4-$CF_3C_6H_4$.

The transformation of compounds **131** into compounds **132** is the first example of the $R^1CO_2R^2 \rightarrow R^2CO_2R^1$ rearrangement. A mechanism for this reaction has been proposed, which includes one-electron oxidation and the formation of a radical cation and a radical anion.[251]

$$(ArCO_2SiMe_3)^{+\bullet} + (XeF_2)^{-\bullet} \longrightarrow$$



132

Using this approach, the electron-enriched centre, *i.e.*, the oxygen atom of the carbonyl group, can be converted into an electron-deficient centre using a temporary group. This is an example of so-called Umpolung.[251]

VI. Organic xenon(II) compounds containing the C–Xe bond

The chemistry of organoxenon compounds has been developing intensively in the past two decades. This trend was initiated by the appearance of a report [13] on the synthesis of $Xe(CF_3)_2$ (**133**). This compound is sublimed in *vacuo*, is stable at low temperatures and can be stored for two weeks at liquid nitrogen temperature. Upon decomposition, it gives XeF_2 and a mixture of fluorocarbons.

$$C_2F_6 \xrightarrow{\Delta} 2\dot{C}F_3 \xrightarrow[-F_2]{XeF_2} Xe(CF_3)_2$$

133

This experiment and the results of ion cyclotron resonance studies of the reaction mixture containing H_2, Xe and MeF [253,254] which were aimed at the determination [252] of the strength of the Xe–C bond (43±8 kcal mol^{-1}) gave impetus to further investigations into the synthesis of new compounds containing Xe–C bonds. Thus the formation of the methylxenon(II) cation was established in an equilibrium reaction which included a transfer of methyl cation from Me_2F^+ to Xe. The physicochemical characteristics of the equilibrium ($K = 0.16\pm0.05$, $\Delta G^\circ = 1.1\pm0.2$ kcal mol^{-1}, $\Delta S^\circ = 9.6\pm1.0$ kcal mol^{-1} K^{-1}, $S^\circ(MeXe^+) = 60.5$ cal mol^{-1} K^{-1}, $\Delta H^\circ = 4.0\pm0.5$ kcal mol^{-1}) confirmed [255] the earlier obtained [252] data on the strength of the Xe–C bond in $MeXe^+$ (55.2±2.5 kcal mol^{-1}).

Compound **133** had long been the only genuine organic xenon derivative. Further developments in the chemistry of organoxenon compounds confronted the task of creating stable xenon derivatives by a correct choice of ligands linked to xenon atoms. For xenon compounds, as for any other hypervalent compounds,[153,154,256] fluorine-containing ligands are the most suitable ones. However, despite the presence of fluorine-containing ligands in compound **133**, its stability was insufficient even for conducting routine spectral analyses.[257–259] It was suggested [260–262] that perfluorinated compounds containing a Xe–C bond have been formed as intermediates. These conclusions were inferred from the structures of the reaction products assuming that they might be formed exclusively as a result of incorporation of xenon into the C–E bond (E is an element). These investigations provided a basis for the development of a methodology of synthesis of stable organic xenon derivatives.

This approach was realised almost simultaneously by Naumann and Tyrra,[263] and Frohn and Jacobs and coworkers.[257,264,265] A procedure for the preparation of stable organic compounds with a covalent Xe–C bond, *e.g.,* of the $[Xe(C_6F_5)]^+X^-$ type, was proposed based on the cleavage of the C–B bond. Thus the low-temperature reaction of tris(pentafluorophenyl)boron with XeF_2 in CH_2Cl_2 gives the pentafluorophenylxenon salt **134a** (yields 40% [257] and 92% [266]) which separates from the reaction mixture as a colourless precipitate and could be recrystallised from acetonitrile. This compound is stable in the crystalline state for a long time at −60 °C; its solutions in acetonitrile are unstable at room temperature. A similar reaction in acetonitrile gives the pentafluorophenylxenon salt **134b**.[263]

$$B(C_6F_5)_3 + XeF_2 \xrightarrow[-30\ ^\circ C]{CH_2Cl_2} \underset{\mathbf{134a}}{[C_6F_5Xe]^+[C_6F_5BF_3]^-}$$

$$B(C_6F_5)_3 + XeF_2 \xrightarrow[0\ ^\circ C]{MeCN} \underset{\mathbf{134b}}{[C_6F_5Xe]^+[(C_6F_5)_3BF]^-}$$

Presumably, the boron compounds $B(C_6F_5)_3$, $[B(C_6F_5)_3F]^-$, $BF_3\cdot MeCN$ and BF_4^- identified by ^{11}B NMR spectroscopy could be formed by dismutation of a putative intermediate **135**.[263]

$$\underset{\mathbf{135}}{B(C_6F_5)_{3-x}} + XeF_2 \longrightarrow (3-x)\,B(C_6F_5)_3 + x\,BF_3$$

$x = 1, 2.$

It should be noted that the dismutation results also in the formation of a weak BF_3–XeF_2 complex [267] which readily reacts with pentafluorobenzene derivatives to give 1-R-heptafluorocyclohexa-1,4-dienes (R = H, F, Cl, Br, C_6F_5).[193] Heptafluorocyclohexa-1,4-diene and octafluorocyclohexa-1,4-diene were identified as the side products [263] using ^{19}F NMR.

The structures of compounds **134a**,**b** were established from NMR [268–270] and X-ray diffraction data.[263,271]

Some chemical properties of compounds **134** have been studied. Thus the reaction of the salts **134a**,**b** with water or D_2O is accompanied by the formation of C_6F_5H or C_6F_5D.[257,263] The salt **134a** reacts with halide ions in acetonitrile with the liberation of xenon and the formation of halopentafluorobenzene;[257,263] the salts **134a**,**b** form the corresponding adducts **136**–**139** with halopentafluorobenzenes,[257,263] tellurium-[263] or phosphorus-containing compounds.[257]

$$\underset{\mathbf{134b}}{[C_6F_5Xe]^+[(C_6F_5)_3BF]^-} \xrightarrow{KF} C_6F_6 + Xe + K[(C_6F_5)_3BF]$$

$$\xrightarrow{Te(C_6F_5)_2} \underset{\mathbf{136}}{[(C_6F_5)_3Te]^+[(C_6F_5)_3BF]^-} + Xe$$

$$\xrightarrow{C_6F_5I} \underset{\mathbf{137}}{[(C_6F_5)_2I]^+[(C_6F_5)_3BF]^-} + Xe$$

$$\underset{\mathbf{134a}}{[C_6F_5Xe]^+[C_6F_5BF_3]^-} \longrightarrow$$

$$\xrightarrow[Hal = I, Br]{[R_4N]^+Hal^-} C_6F_5Hal + Xe + R_4N^+[C_6F_5BF_3]^-$$

$$\xrightarrow{(4\text{-}CF_3C_6H_4)_3P} \underset{\mathbf{138}}{[C_6F_5(p\text{-}CF_3C_6H_4)_3P]^+[C_6F_5BF_3]^-} + Xe$$

$$\xrightarrow{C_6F_5Hal} \underset{\mathbf{139}}{[(C_6F_5)_2Hal]^+[C_6F_5BF_3]^-} + Xe$$

The pentafluorophenylxenon cation in compound **134a** reacts with benzylcyanide and triphenylmethane containing activated C–H bonds to give the nitriles **140** and **141** in the former case and tetraarylmethane **142** and the biphenyl derivative **143** in the latter case.[264,265]

$$\mathbf{134a} \xrightarrow[-Xe,\ -HF]{PhCH_2CN} \underset{\mathbf{140}}{Ph(C_6F_5)CHCN} + \underset{\mathbf{141}}{Ph(C_6F_5)_2CCN} + (C_6F_5)_2BF$$

$$\mathbf{134a} \xrightarrow[-Xe,\ -HF]{Ph_3CH} \underset{\mathbf{142}}{Ph_3CC_6F_5} + \underset{\mathbf{143}}{C_6F_5C_6H_4(Ph_2)CC_6F_5} + (C_6F_5)_2BF$$

The reaction of compound **134a** with bis(pentafluorophenyl)-cadmium results in perfluorobiphenyl (**144**) and pentafluorobenzene (**145**). The same products are formed in the reaction of XeF_2 with one equivalent of $Cd(C_6F_5)_2$.[266] Both reactions seem to occur *via* the intermediate **146**, which eliminates xenon to generate the radical $^\bullet C_6F_5$.

$$\underset{\mathbf{134a}}{[C_6F_5Xe]^+[(C_6F_5)_2BF_2]^-} + Cd(C_6F_5)_2 \longrightarrow \underset{\mathbf{146}}{[C_6F_5XeC_6F_5]} \xrightarrow{-Xe} \cdots$$

$$XeF_2 + Cd(C_6F_5)_2 \xrightarrow{-CdA_2}$$

$$\cdots \longrightarrow {}^\bullet C_6F_5 \longrightarrow \underset{\mathbf{144}}{C_6F_5C_6F_5}$$

$$\xrightarrow[-Solv^\bullet]{SolvH} \underset{\mathbf{145}}{C_6F_5H}$$

A = F or $[(C_6F_5)_2BF_2]^-$; SolvH is solvent.

The anion in compound **134b** can be replaced by using AsF_5.[258,272]

$$\underset{\mathbf{134b}}{C_6F_5Xe^+[(C_6F_5)_3BF]^-} + AsF_5 \xrightarrow[-20\ ^\circ C]{MeCN} \underset{\mathbf{134c}}{C_6F_5Xe^+AsF_6^-} + B(C_6F_5)_3$$

The salt **134c** formed is stable at temperatures up to 125 °C. Its chemical properties have been investigated.[272,273] The reaction with halide anions in acetonitrile yields different products depending on the nature of the anion. Thus the reaction with the fluoride anion which is a hard nucleophile yields a C_6F_5H–$C_6F_5C_6F_5$ mixture, whereas the reactions with I^-, Br^- and Cl^- anions give C_6F_5X (X = I, Br, Cl). The reactions with compounds containing the HF_2^- anion gives a mixture of C_6F_6, C_6F_5X and $C_6F_5C_6F_5$.[273] The salt **134c** was further used for the synthesis of the organoxenon compound **147** by anionic exchange with an aqueous solution of cesium pentafluorobenzoate. Compound **147** is thermally stable up to 85±3 °C ($T_{1/2} \approx 3$ h at 35 °C).[272,274,275]

$$C_6F_5Xe^+AsF_6^- + C_6F_5CO_2Cs \xrightarrow{D_2O} C_6F_5XeOCOC_6F_5$$
134c **147**

The structure of compound **147** was established by X-ray diffraction analysis.[275] The length of the C–Xe bond (2.122 Å) is larger than that in the cation $[MeCN\cdots XeC_6F_5]^+$ (2.092 Å), whereas the Xe–O bond (2.367 Å) is much longer than those in other known xenon derivatives (2.12–2.21 Å).[87,89,276–279] It should be noted that the Xe–O bond in compound **147** cannot be regarded as a purely ionic bond because of the essential differences in the lengths of the C–O bonds (1.171 and 1.220 Å) in the C_6F_5COO group,[275] which is inconsistent with an ionic carboxylate (1.26 Å).[280]

The reaction of XeF_2 with arylboranes gave the arylxenonium salts **134d**,**e**.[257,263,271,281–284]

$$(3\text{-}CF_3C_6H_4)_2BF + XeF_2 \longrightarrow [3\text{-}CF_3C_6H_4Xe]^+[3\text{-}CF_3C_6H_4BF_3]^-$$
134d

$$(4\text{-}FC_6H_4)_3B + XeF_2 \longrightarrow [4\text{-}FC_6H_4Xe]^+[(4\text{-}FC_6H_4)_2BF_2]^-$$
134e

The synthesis of organoxenon compounds from arylboranes can be carried out in the presence of boron trifluoride.[257,266,271,281,285,286] The resulting salts **134f**,**g** are obtained in good yields.

$$BAr_3 + 3\,XeF_2 + 2\,BF_3 \longrightarrow 3\,ArXe^+BF_4^-$$
134f,**g**

Ar = C_6F_5 (**f**), 2,4,6-$F_3C_6H_2$ (**g**).

The structure of compound **134g** was established by ^{129}Xe, ^{19}F, ^{13}C and ^1H NMR spectroscopy. The absolute value of $^1J(^{129}Xe-{}^{13}C)$, equal to 103.6 Hz (see Ref. 271), is much smaller than that in the cation $C_6F_5Xe^+$ [$^1J(^{129}Xe-{}^{13}C)$ = 119 Hz],[257,263] which suggests the existence of short and, as a consequence, strong bonds and the relative stability of compound **134g**. Some reactions of compounds **134f**,**g** have been studied.[271]

134f,**g** → ($Te(C_6F_5)_2$, 20 °C) $[Te(C_6F_5)_2Ar]^+BF_4^- + Xe$

134f,**g** → (KCl) $ArCl + Xe + KBF_4$

134f,**g** → (IC_6F_5, 60 °C) $Xe + [C_6F_5IAr]^+BF_4^-$

Compounds **134f**,**g** are inert with respect to atmospheric oxygen and water and can be stored in dry air for 21 days without any visible alterations, while their hydrolysis in aqueous acetonitrile is completed within 7 days.

Cyclic voltammograms of compounds of the X^+Y^- type, where X = C_6F_5Xe, $C_6F_5N_2$, C_6F_5Br, C_6F_5I and $(C_6F_5)_4P$, were obtained in 0.1 M solution of Bu_4NBF_4 in MeCN.[287] The minimum and maximum values of electroreduction potentials were obtained for $C_6F_5Xe^+$ and $(C_6F_5)_4P^+$ cations, respectively. The attachment of the first electron to the cations $C_6F_5Xe^+$ and $C_6F_5N_2^+$ is accompanied by the evolution of Xe or N_2 and the generation of the $^{\bullet}C_6F_5$ radical, which either undergoes dimerisation or abstracts hydrogen from MeCN. The first step in the electroreduction of other cations is followed by the liberation of pentafluorophenyl derivatives, *e.g.*, C_6F_5Br, C_6F_5I or $(C_6F_5)_3P$, which undergo further reduction.[287]

XeF_2 was used in the synthesis of new organoxenon compounds.[288,289] The reaction of stoichiometric amounts of XeF_2 and trifluoroacetic acid in CCl_3F at −20 °C gives xenon bis(trifluoroacetate) **6d**,[89–91] which further reacts with trifluoromethanesulfonic acid at −40 °C. This can be accompanied by the formation of the intermediate **148**; indirect evidence can be derived from the appearance of a singlet in the ^{129}Xe NMR spectrum at δ = 400 and the generation of signals at δ = −69.1 ($OCOCF_3$) and −75.6 (OSO_2CF_3) in the ^{19}F NMR spectrum. Compound **148** reacts with fluorine-containing arenes to give the arylxenon triflates **134h**–**k**.[288]

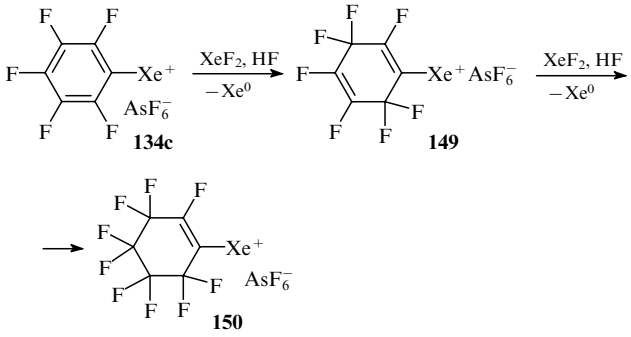
$$XeF_2 + 2\,CF_3CO_2H \xrightarrow[-40\ ^\circ C]{CCl_3F} Xe(OCOCF_3)_2 \xrightarrow{TfOH}$$
6d

$$\longrightarrow [Xe(OCOCF_3)OTf] \xrightarrow{ArH} ArXeOTf$$
148 **134h**–**k**

Ar = 2,4,6-$F_3C_6H_2$ (**h**), 3,5-$(CF_3)_2C_6H_3$ (**i**), 1-F-3-$(CF_3)C_6H_3$ (**j**), 2-F-5-$NO_2C_6H_3$ (**k**).

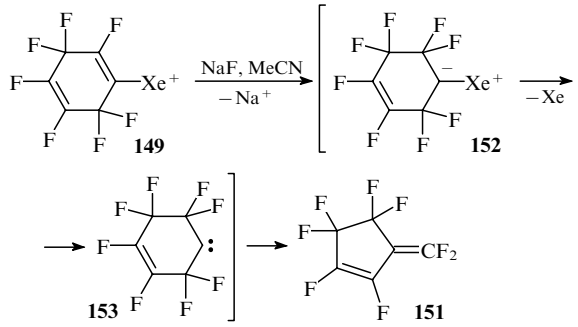
It is noteworthy that this reaction does not occur if FXeOTf (**5b**) is used as a starting material, while the reaction of 1,3-$F_2C_6H_4$ with the intermediate **148** gives a mixture of Xe(2,4-$F_2C_6H_3$)(OTf) and Xe(3,5-$F_2C_6H_3$)(OTf) (10 : 1) (^{129}Xe NMR data) and several side products. The reaction of 1-F-3-$(CF_3)C_6H_4$ with the intermediate **148** gives compound **134j** and some non-identified products, whereas 1,3,5-$(CF_3)_3C_6H_3$ does not react at all. The addition of arenes devoid of a fluorine, chlorine or trifluoromethyl substituent to the reaction mixture results in immediate decomposition.[288]

A method for the synthesis of cycloalkenylxenon(II) salts by the reaction of (pentafluorophenyl)xenon(II) hexafluoroarsenate **134c** with XeF_2 in HF has been developed.[273,274,290–295] Thus the reaction of the salt **134c** with XeF_2 results in the addition of two or four fluorine atoms to the aromatic ring to afford the salts **149** or **150**.[290]



Compounds **149** and **150** are white crystalline substances stable at room temperature and soluble in MeCN. Their structures were established on the basis of ^{19}F, ^{13}C and ^{129}Xe NMR spectral data and chemical transformations.

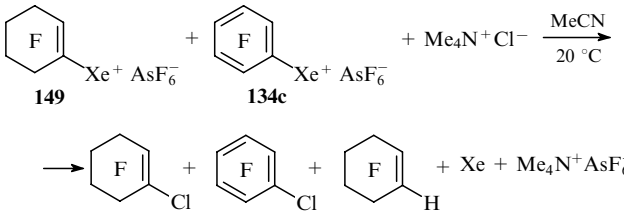
The salts **149** and **150** react with the bromide anion or benzene in acetonitrile to give products with composition 1-R-1,4-C_6F_7 or 1-R-C_6F_9 (R = Br, Ph), respectively.[296,297] The reaction of the salt **149** with sodium fluoride in acetonitrile results in a ring contraction and the formation of perfluoro-3-methylenecyclopentene (**151**).



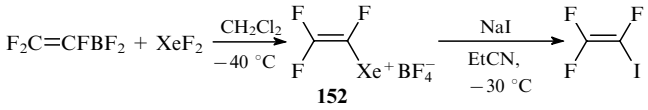
The diene **151** was the main product in the reaction mixture and was unambiguously identified on the basis of ^{19}F NMR spectra (see Ref. 291). Its formation can be interpreted in terms of the HSAB concept. Being a hard base, the nucleophilic fluoride

anion predominantly attacks the hard electrophilic centre of C(2) rather than the soft electrophilic centre of xenon(II). Elimination of xenon from the intermediate **152** results apparently in the carbene **153**, which is further transformed into the reaction product **151**.[291]

The relative reactivities of alkenyl- and arylxenon(II) derivatives were studied in a competitive reaction with tetramethylammonium chloride in acetonitrile. The conversion of the salt **149** was 67% and that of the salt **134c** was 19%. These results and the compositions of the reaction products demonstrate the high electrophilicity of the xenon atom linked to the perfluorocyclohexen-1-yl group.[295]

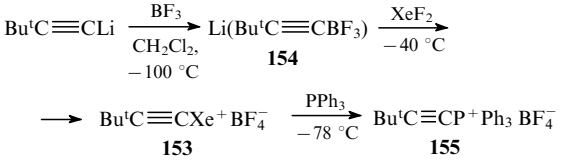


A method for the synthesis of trifluorovinylxenon(II) tetrafluoroborate (**152**) by the reaction of trifluorovinylboron difluoride with XeF_2 in CH_2Cl_2 at −40 °C has been developed recently. The salt **152** is a white solid, which decomposes at temperatures above 0 °C. Its solution in anhydrous HF is stable at 20 °C for several hours but rapidly decomposes in MeCN.[298]



The reaction of the salt **152** with an excess of sodium iodide in EtCN at −30 °C results in trifluoroiodoethylene, which is an indirect proof of the structure of compound **152**.[298]

The alkynylxenon fluoroborate **153** was synthesised using a similar approach.[299] The borofluoride complex **154** generated from lithium *tert*-butylacetylide and BF_3 reacts with XeF_2 in CH_2Cl_2 at −40 °C to give the salt **153** the structure of which was established by NMR and IR spectroscopy. Compound **153** is relatively stable in chloroform at −30 °C, but slowly decomposes at room temperature.[299]



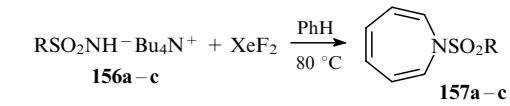
The salt **153** reacts with nucleophiles, *e.g.*, triphenylphosphine, at −78 °C to give the stable phosphonium salt **155**,[299] which confirms its structure.

The attempts to prepare xenon-containing salts from other alkynes were unsuccessful. However, some organoxenon tetrafluoroborates could be detected by ^{129}Xe NMR (see Ref. 299).

VII. Reactions of xenon difluoride with nitrogen-containing compounds

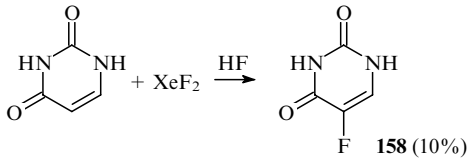
Considerable experience has been gained in the study of reactions of xenon derivatives with nitrogen-containing compounds.

Earlier it was shown[300] that aniline and benzylamine are fluorinated with XeF_2 in the absence of a catalyst without involving the NH-bonds. Unlike benzene derivatives, pyridine easily reacts with XeF_2 in the absence of a catalyst to give 2-fluoro- (35%), 3-fluoro (20%) and 2,6-difluoropyridines (11%).[300] 8-Hydroxyquinoline is converted into 5-fluoro-8-hydroxyquinoline (35%) under the action of XeF_2.[300] On the other hand, imidazo[1,2-*b*]pyridazine is not fluorinated by XeF_2.[301] The reaction of XeF_2 with tetrabutylammonium salts of arenesulfamides **156a–c** in benzene yielded *N*-sulfoazepines **157a–c** presumably formed as a result of generation and subsequent incorporation of nitrene into the benzene ring.[302,303] The yields of the azepines **157a–c** increase as the temperature increases.

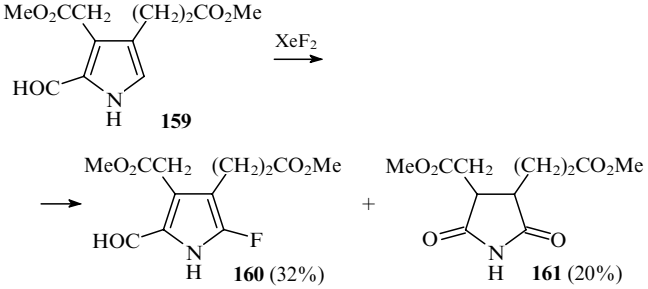


Compound **157**	R	Yield (%)
a	Ph	47
b	Me	41
c	4-MeC_6H_4	42

The reaction of uracil with XeF_2 in hydrofluoric acid or anhydrous hydrogen fluoride results in 5-fluorouracil (**158**) in small yield.[304]

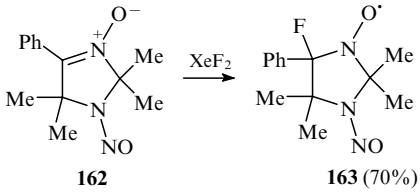


The reaction of the substituted pyrrole **159** with XeF_2 in acetonitrile at 20 °C results in the fluoride **160** and the imide **161**.[305] If the reaction was carried out in dichloromethane, 3-methoxycarbonylmethyl-4-methoxycarbonylethyl-2-formyl-5-chloropyrrole was isolated in 24% yield; its formation is explained by the involvement of the solvent in the reaction.

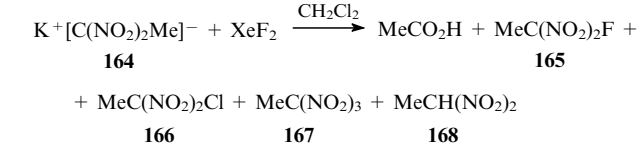


It should be noted that XeF_2 was found to be a most suitable reagent for the fluorination of pyrroles containing electron-withdrawing groups.[305]

The nitrone **162** reacts with XeF_2 to generate a stable nitroxyl radical **163**,[306] which can be converted into an ammonium salt by a reaction with ammonia.



The reaction of aliphatic nitro compounds with xenon difluoride has been studied in detail.[307–313] Thus it was shown that the potassium salt of 1,1-dinitroethane (**164**) reacts with XeF_2 in CH_2Cl_2 to give a mixture of compounds.[307]



When this reaction was carried out in dry dichloromethane, 1,1-dinitro-1-fluoroethane (**165**) was the main product, whereas the chlorodinitro derivative **166** was predominantly formed in

CH_2Cl_2 saturated with water. The addition of nitrogen oxides to the reaction mixture increases the yield of 1,1,1-trinitroethane (**167**) to 22%. When this reaction is carried out in dry CH_2Cl_2, the addition of KCl and Na_2CO_3 does not influence the ratios of the reaction products. However, the yield of compound **166** in aqueous CH_2Cl_2 increases after addition of KCl, whereas 1,1-dinitroethane (**168**) is not formed in the presence of sodium carbonate. Compound **168** does not react with XeF_2 in CH_2Cl_2 at room temperature. As the reaction mixture contains simultaneously 1,1-dinitroethane and its salt, one can anticipate the formation of a self-condensation product of compound **168**, *viz*., 2,5,5-trinitro-3-aza-4-oxa-hex-2-ene, which was in due course detected. The data obtained suggest[307] that this reaction occurs by a radical or a radical-ion mechanism.

The reaction of dinitromethane, trinitromethane and phenyldinitromethane salts with XeF_2 in different solvents (CH_2Cl_2, MeCN, CCl_4) have also been studied.[308, 309] In this case, the formation of fluorination products, *e.g*., fluorodinitromethyl compounds, was accompanied by the formation of reaction products involving solvent molecules, *viz*., dinitromethyl compounds in CH_2Cl_2 (CH-form) and chlorodinitromethyl compounds (in CH_2Cl_2 and CCl_4) Acetonitrile was found to be resistant to XeF_2 and intermediate radical species. The fluorination of 1,1-dinitroethane and phenyldinitromethane in acetonitrile occurs with high selectivity.[308]

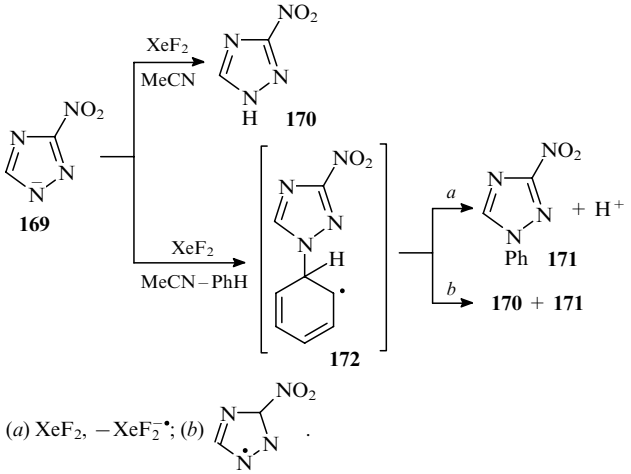
The reaction of the potassium salt of nitroform with XeF_2 in acetonitrile containing 50 vol.% of benzene or THF is accompanied by the formation of a complex mixture of products.[309]

$$^{-}C(NO_2)_3 + XeF_2 \xrightarrow[MeCN]{PhH} FC(NO_2)_3 + HC(NO_2)_3 + PhNO_2 + PhC(NO_2)_3 + PhF + PhPh + FCH(NO_2)_2 + PhC(NO_2)_2F$$

$$^{-}C(NO_2)_3 + XeF_2 \xrightarrow[MeCN]{THF} FC(NO_2)_3 + HC(NO_2)_3 + FCH(NO_2)_2 + \text{(O)}C(NO_2)_3 + \text{(O)}CF(NO_2)_2$$

It is of note that the side fluorination products of anions of dinitromethyl compounds with XeF_2 in various solvents are similar to the reaction products of dinitromethyl radicals, generated by electrochemical oxidation of polynitroalkane anions, with solvents. This similarity can be explained by the identity of the intermediate species.[309]

Xenon difluoride can play the role of a single-electron oxidant with respect to both 1,1-dinitrocarbanions and the difficultly oxidisable nitroazole anions.[310] Thus the reaction of the potassium salt of 3-nitro-1,2,4-triazole (**169**) with XeF_2 in acetonitrile results in the non-ionised 3-nitro-1,2,4-triazole (**170**) (yield 70%–80%). A 3:2 mixture of 3-nitro- (**170**) and 1-phenyl-3-nitro-1,2,4-triazoles (**171**) is formed in the MeCN–PhH system.



(*a*) XeF_2, $-XeF_2^{-\bullet}$; (*b*)

Presumably, compound **171** is formed as a result of generation of the radical **172**. The latter can be rearomatised by two equally probable routes, *viz*., by single-electron oxidation and deprotonation (route *a*) and by abstraction of the hydrogen atom by the 3-nitro-1,2,4-triazole radical (route *b*).[310] However, the latter route is less probable, since benzene has a much higher oxidation potential ($E_{1/2}$ = 2.02 V[314]) than the triazole anion [$E_{1/2}$ = 1.77 V (see Ref. 315)].

The reactions of potassium salts of 1,1-dinitrobut-2-enonitrile (**173a**) and the respective amide (**173b**) with XeF_2 were studied in order to compare the reactivities of the dinitromethyl group and the double bond. These reactions give the fluorination products **174a**,**b** in high yields.[311]

$$[RCH{=}CHC(NO_2)_2]^{-}K^{+} + XeF_2 \xrightarrow{MeCN} RCH{=}CHCF(NO_2)_2 + KF + Xe$$

173a,**b** **174a**,**b**

R = CN (**a**), $CONH_2$ (**b**).

Selective fluorination of the dinitromethyl anion without affecting the double bond can be explained by the absence of a catalyst (HF), since the reaction was carried out in a vessel made of ordinary silicate glass which is known to be an effective chemical acceptor of HF. According to ^{1}H NMR and GLC data, this reaction gives < 5% admixtures. When the fluorination was performed in a reactor made of a fluoropolymer resistant to HF, this resulted in a mixture of products, which can be assigned to the occurrence of HF-catalysed side reactions, *e.g*., the fluorination of the double bond.[311]

The kinetics of fluorination of salts of dinitromethyl compounds by XeF_2 has been studied.[312, 313] The kinetics is described by second-order equations, first-order with respect to each reagent. The nature of the cation in the salt does not influence the value of the fluorination rate constant in the concentration range from 10^{-3} to 10^{-5} mol litre^{-1}. The thermodynamic activation parameters ($\Delta H_{298}^{\neq}$ = 30–60 kJ mol^{-1}, $\Delta S_{298}^{\neq}$ = -60 to -130 J mol^{-1} K^{-1}) lie in the range characteristic of an S_N2 reaction.

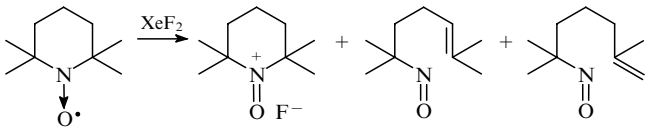
A mechanism of the reaction of dinitro compounds with XeF_2 has been proposed.[307, 309, 310, 313] Its first step probably includes single-electron oxidation of the dinitro compound anion by XeF_2. The reaction products result from the reaction of the solvent molecules with the radical species formed in the first step. The CH_2Cl_2 molecules serve as the source of chlorine and hydrogen atoms, whereas the radical of the original dinitro compound serves as the source of NO_2.

$$R\dot{C}(NO_2)_2 + F^{-} \longrightarrow [RC(NO_2)_2F]^{-\bullet} \xrightarrow{XeF_2\,(\dot{X}eF)} RC(NO_2)_2F$$

$$[RC(NO_2)_2]^{-} + \dot{N}O_2 \longrightarrow [RC(NO_2)_3]^{-\bullet} \xrightarrow{XeF_2\,(\dot{X}eF)} RC(NO_2)_3$$

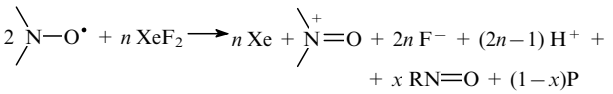
The rates of the reaction of XeF_2 with salts of *ortho*-, *meta*- and *para*-substituted aryldinitromethanes in MeCN were measured by spectrophotometric methods.[313] The relationship between the structures of the substrates and their reactivities with respect to XeF_2 is described by linear free energy equations using inductive, resonance and steric constants of the substituents. For the overwhelming majority of dinitromethyl compounds, it was found that the rate of fluorination of the corresponding dinitrocarbanion decreases with the increase in the CH-acidity.

Xenon difluoride acting as a single-electron oxidant converts the nitroxyl radicals **175** into the oxoammonium fluorides **176**, nitroso compounds **177** and **178** and the products of more profound oxidation.[316]



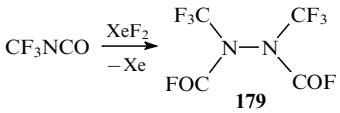
175 **176** **177** **178**

The general stoichiometric equation for the oxidation was derived from the kinetic data.[316]

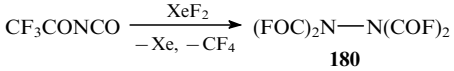


P are reaction products.

A convenient procedure for the synthesis of fluorocarbonyl-substituted hydrazines **179** and **180** in the reaction of XeF_2 with isocyanates has been developed.[317] The reaction of XeF_2 with perfluoroazapropene yields tetrakis(trifluoromethyl)hydrazine **181**.[317]



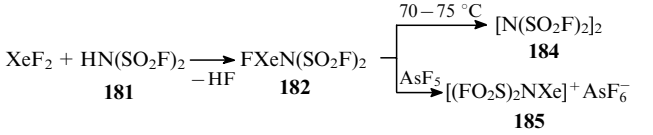
179

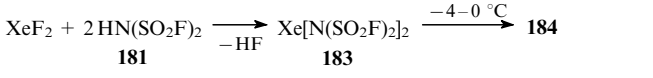


180

181

A compound containing the Xe–N bond was first synthesised by the reaction of XeF_2 with di(fluorosulfuryl)imide (**181**).[318–320]



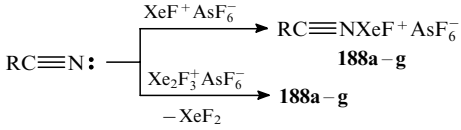


Mono- (**182**) or bis[*N*,*N*-di(fluorosulfuryl)imido]xenon fluorides **183** can be obtained depending on the reagent ratio. The structures of compounds **182** and **183** were confirmed by X-ray diffraction analysis.[321–323] The magnitude of the angle C–Xe–N (174.5°) corresponds to the structure of a distorted trigonal bipyramid with the substituents in the axial positions. The length of the Xe–C bond (2.092 Å) is comparable with that of the C–I bond.[153] The coordinate bond Xe–N (2.681 Å) in compounds **134a**,**b** is much longer than the covalent bond Xe–N.[323, 324] The decomposition of compounds **182** and **183** is accompanied by the formation of the dimer **184**. The intermediate radical $^{\bullet}N(SO_2F)_2$ was detected by EPR. The reaction of compound **182** with AsF_5 gives the salt **185**.[319, 322, 324]

N-Trimethylsilyl(trifluoromethylsulfonyl)amine (**186**) was used as the starting material for the preparation of bis[bis(trifluoromethylsulfonyl)imido]xenon (**187**), which is a stable compound and decomposes only at 72 °C to generate the radical $^{\bullet}N(SO_2CF_3)_2$.[325]

186 **187**

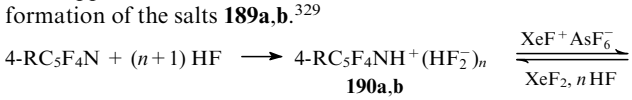
The attempt to prepare compounds containing a Xe–C bond by the reaction of HCN with XeF_2 was unsuccessful. However, the fact that xenon-containing cations manifest the properties of Lewis acids[326] made it possible to synthesise xenon derivatives containing the Xe–N bond from HCN.[327–330] The first adiabatic ionisation potential of HCN (13.80 eV) was determined from photoionisation data.[331] The electron affinity of the XeF^+ cation is 10.9 eV. It may therefore be assumed that HCN will be resistant to the oxidative attack of XeF^+, and $HC{\equiv}NXeF^+$ should manifest satisfactory thermal stability. Indeed, compounds **188a–g** containing covalent Xe–N bonds were synthesised by the reaction of $XeF^+AsF_6^-$ or $Xe_2F_3^+AsF_6^-$ with HCN or nitriles.[327–330]

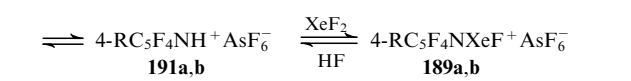


R = H (**a**), Me (**b**), CH_2F (**c**), Et (**d**), C_2F_5 (**e**), C_3F_7 (**f**), C_6F_5 (**g**).

Compounds **188a–g** were characterised by spectral methods.[328] The reaction product with hydrogen cyanide (**188a**) is a white crystalline substance stable below −60 °C. The derivatives **188e–g** containing perfluoroalkyl radicals are even less stable; they were characterised by spectral methods without being isolated from the reaction mixtures. The nature of the bond in the cation $HC{\equiv}NXeF^+$ has been discussed.[328] It is of note that the corresponding fluorokrypton salts were synthesised by an analogous scheme in the reaction of the cation KrF^+ with nitriles (the electron affinity of the cation KrF^+ is 13.2 eV).[330, 332]

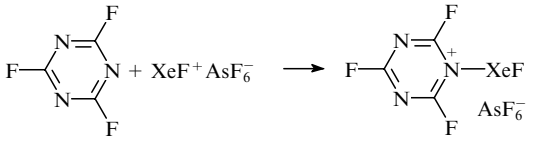
Equimolar amounts of $XeF^+AsF_6^-$ and perfluoropyridine (I_p = 10.08 eV) react in anhydrous HF at −20 to −30 °C to give the salts **189a**,**b** containing the Xe–N bond. Removal of the solvent (HF) at −50 °C leads to the formation of a white solid substance which represents a mixture of XeF_2 with the salts **190a**,**b** and **191a**,**b** containing no xenon (data from the Raman spectra). BrF_5 appeared to be a more suitable solvent than HF in the formation of the salts **189a**,**b**.[329]





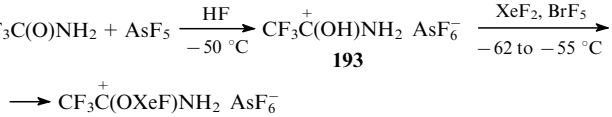
R = F (**a**), CF_3 (**b**).

The reaction of trifluoro-*s*-triazine (I_p = 11.50 eV) with $XeF^+AsF_6^-$ (1 : 1) for 4 h at room temperature gives the crystalline compound **192** which is stable at room temperature; this compound was characterised by spectral methods.[330]



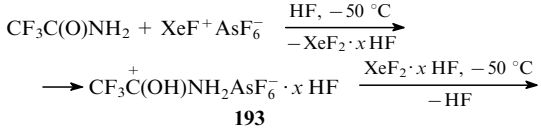
192

The reaction of the salt **193**, prepared by the reaction of trifluoroacetamide (I_p = 10.77 eV) with AsF_5, with xenon difluoride resulted in the organoxenon compound **194**.[333] The salt **193** was isolated in the crystalline state. At 0 °C, it rapidly decomposes to give gaseous products.



193 **194**

Rapid removal of HF from a solution containing $XeF^+AsF_6^-$ and $CF_3C(O)NH_2$ at −50 °C affords a white precipitate of composition identical to that of compound **195**; the salt **194** was not detected.[333]



193

$$\longrightarrow CF_3\overset{+}{C}(OH)NH_2AsF_6^- \cdot XeF_2 \cdot x\,HF$$
195

A detailed study of the reaction of xenon difluoride with HN_3, NaN_3 and NaOCN in H_2O, anhydrous HF and SO_2ClF has been published.[334] An analysis of reaction products made it possible to suggest the formation of $FXeN_3$ (**196**) and FXeNCO (**197**) as intermediates, which react according to the following schemes:

$$[FXeN_3] \xrightarrow[-HF,\ -Xe]{H_2O} [HON_3] \xrightarrow{-N_2} [HON] \xrightarrow{-N_2}$$
196

$$\longrightarrow HON{=}NOH \xrightarrow[-H_2O]{} N_2O,$$

$$[FXeNCO] \xrightarrow[-HF,\ -Xe]{H_2O} [HONCO] \xrightarrow{2\,H_2O} HONH_2 + H_2O + CO_2.$$
197

Ab initio quantum-chemical calculations of the structural parameters of both intermediates have been made.[334] The data obtained suggest that the Xe–F bond in the intermediates **196** and **197** (2.051 and 2.024 Å, respectively) is longer than that in bis[(difluorosulfuryl)imido]fluoroxenon **182** (1.97 Å) and in XeF_2 (1.977 Å).[318, 320, 322–325, 328] The calculated length of the Xe–N bond (2.21 Å) in compound **197** is comparable with the experimentally determined value (the length of the corresponding bond in compound **182** is 2.20 Å). The Xe–N distance (2.32 Å) in compound **196** is much longer (2.318 Å).[328] The thermodynamic possibility of formation of the intermediates **196** and **197** was demonstrated using an energy cycle for gas-phase reactions. The enthalpies of the reactions were calculated on the basis of the literature data.[334]

$$XeF_2\,(gas) + NH_3\,(gas) \longrightarrow$$
$$\longrightarrow FXeN_3\,(gas) + HF\,(gas)\ (\Delta H^\circ < -12.1\ kcal\ mol^{-1}).$$

$$XeF_2\,(gas) + HNCO\,(gas) \longrightarrow$$
$$\longrightarrow FXeNCO\,(gas) + HF\,(gas)\ (\Delta H^\circ < -12.1\ kcal\ mol^{-1}).$$

The synthesis of $NO^+XeF_5^-$ and $NMe_4^+XeF_5^-$ in the reaction of XeF_4 with NOF or $Me_4N^+F^-$ (see Ref. 335) and the synthesis of $NF_4^+XeF_7^-$ from XeF_6 and $NF_4^+HF_2^-$ were documented.[336]

VIII. Oxidative fluorination of organoelement compounds by xenon difluoride and its derivatives

Oxidative fluorination of organoelement compounds by xenon difluoride and its derivatives presents theoretical and practical interest. The first reports on the feasibility of oxidative fluorination of iodine to IF_5 (see Ref. 29) and of SO_2 to SO_2F_2 (see Refs. 29 and 337) appeared in the late 1960's to early 1970's. Later, the reactions of other elements, their oxides, halides and carbonyls with XeF_2 were also studied, which demonstrated convincingly the high potentials of the oxidative fluorination.[338]

The transformations of organoelement compounds under the action of XeF_2 are extremely diverse and depend on the structures of the radicals linked to the heteroatom, the degree of oxidation of the heteroatom, the reaction conditions, the nature of the solvent, *etc*. The examples of the application of XeF_2 for fluorination of the majority of classes of organoelement compounds are now available.

1. Reactions of XeF_2 with Group VII organoelement compounds

a. Reactions of organoiodine compounds with XeF_2

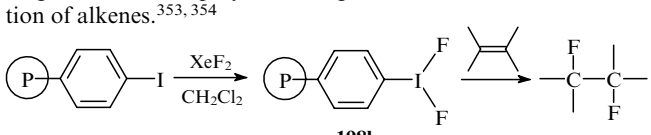
Organoiodine compounds are among the first to have been subjected to oxidative fluorination by XeF_2. These studies were aimed at a search for convenient methods for the preparation of difluoro-λ^3-iodanylalkenes (arenes) used for fluorination of unsaturated compounds.[339–342] The first report on the oxidative fluorination of methyl iodide by XeF_2 was published in the early 1970's. The difluoro-λ^3-iodanylalkene synthesised (**198a**)[339] was rather unstable and could only be characterised by spectral methods. However, despite its low stability this compound was used for iodofluorination of alkenes.[343–346]

Later, this method of the synthesis of difluoro-λ^3-iodanylalkanes (arenes) was extended to a vast variety of alkyl- and aryl iodides. Iodobenzene,[347] substituted aryl iodides[348] as well as perfluoroalkyl- and perfluoroaryl iodides[349] are easily fluorinated by XeF_2. In the case of 1-iodo-3,5-dichlorobenzene and iodopentafluorobenzene, the excess of XeF_2 converts difluoro-λ^3-iodanylarenes into tetrafluoro-λ^5-iodanylarenes in quantitative yields,[349] while the reaction of difluoro-λ^3-iodanylbenzene (**198b**) with XeF_2 results in the fluorination of the aromatic nucleus and the formation of tetrafluoro-λ^5-iodanylbenzene.[349, 350]

$$RI + XeF_2 \xrightarrow{20\ ^\circ C} RIF_2 + Xe$$
198a–k

R = Me (**a**), Ph (**b**), CF_3CH_2 (**c**), C_6F_5 (**d**), 3,5-$Cl_2C_6H_3$ (**e**), 2-$CF_3C_6H_4$ (**f**), 3-$MeOC_6H_4$ (**g**), 4-$MeOC_6H_4$ (**h**), 3-ClC_6H_4 (**i**), 4-ClC_6H_4 (**j**), 3-$NO_2C_6H_4$ (**k**).

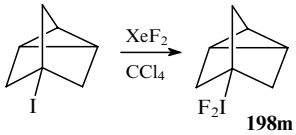
Difluoro-λ^5-iodanylbenzene (**198l**) immobilised on a polymeric support was synthesised using XeF_2 as a soft fluorinating reagent.[351, 352] The polymeric reagent was used for the fluorination of alkenes.[353, 354]



198l

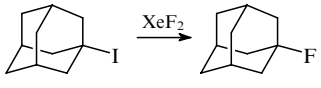
(P) is polymeric support.

In the majority of cases, (difluoro-λ^3-iodanyl)alkanes are unstable.[339] However, treatment of a solution of 4-iodotricyclene in tetrachloromethane with a sixfold excess of XeF_2 and subsequent removal of the solvent and the excess of XeF_2 yield a light-yellow solid stable product **198m**.[355]

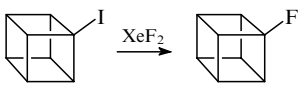


198m

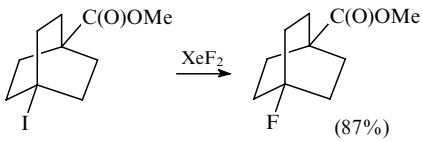
In some cases, the reaction of iodoalkanes with XeF_2 results in the substitution of fluorine for iodine instead of oxidation. This takes place in the reaction of XeF_2 with polycyclic bridged iodides. Fluorinated bicycloalkanes and polycycloalkanes are formed in high yields.[240, 356]



(85%)



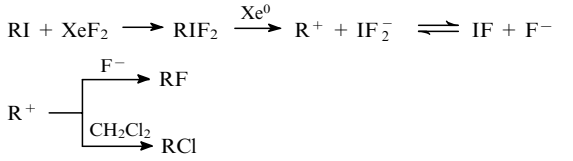
(80%)



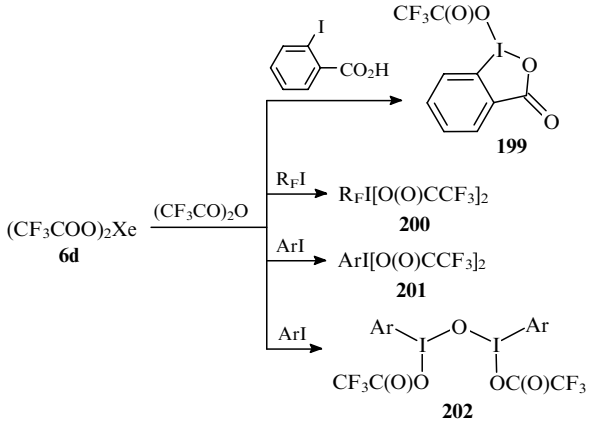
(87%)

It is assumed that this reaction occurs by a carbocationic mechanism. Initially, the difluoro-λ^3-iodanylalkanes generated undergo heterolytic cleavage of the C–I bond to give IF_2^- and the carbocations containing a cationic centre at the head of the bridge.[343] The carbocation can further react either with the fluoride anion to give a fluoride or with CH_2Cl_2 to give a chloride.

Stable cations usually generate fluorides, whereas highly reactive cations, such as cubyl or norbornyl cations, react nonselectively to give chlorides. Their content in the reaction mixture correlates with the calculated values of the carbocation energies.[356]

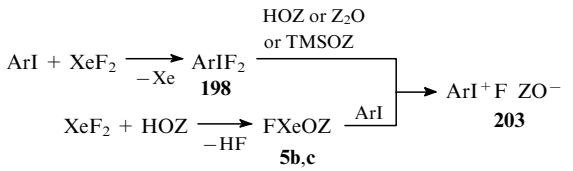


Recently, divalent xenon derivatives other than XeF_2, *e.g.*, xenon bis(trifluoroacetate) (**6d**),[89–91] xenon fluoro(triflate) (**5b**)[89] and xenon fluoro(mesylate) (**5c**),[89] came into use. Thus the reagent (**6d**) obtained *in situ* from XeF_2 and trifluoroacetic acid in the presence of trifluoroacetanhydride reacts with aryl iodides to give bis(trifluoroacetoxy)-λ^3-iodanylarenes **199**–**201**.[357] In the absence of trifluoroacetanhydride, this reaction affords μ-oxobis-[trifluoroacetato(aryl)] iodides (**202**) the structure of which was established by X-ray diffraction analysis.[357, 358]



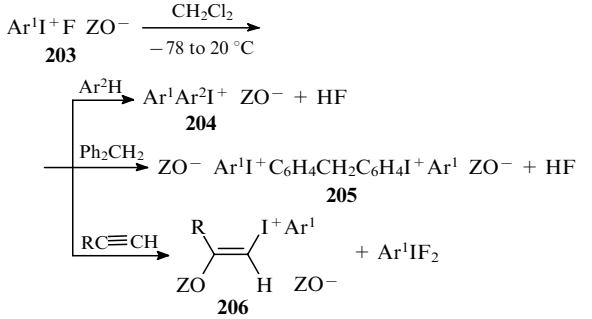
Ar = Ph, 4-MeC_6H_4, 2-MeC_6H_4, 4-PhC_6H_4, 4-[$MeC(O)O]C_6H_4$, 4-$NO_2C_6H_4$, 3-$NO_2C_6H_4$, 2-Me-4-$NO_2C_6H_3$; R_F = C_3F_7, C_4F_9.

A one-step procedure for the generation of iodanylarenes directly from aryl iodides[359–367] is based on their oxidation by xenon fluorosulfonate which gives salts of the type **203**.



Z = Tf (**b**), Ms = SO_2Me (**c**); TMS = Me_3Si.

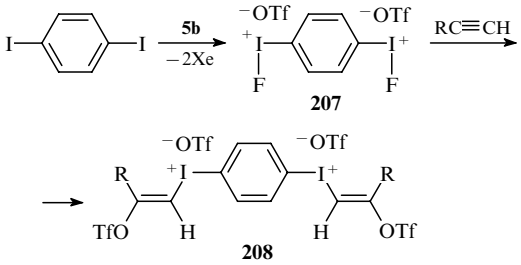
The interest in the sulfonates **203** is due to the fact that they can react with aromatic compounds and terminal alkynes to give the corresponding diaryliodonium (**204**, **205**) and alkenyl(aryl)-iodonium salts **206**.[359, 363, 365]



Z = Tf, Ms; Ar^1, Ar^2 = Ph, 4-MeC_6H_4, 2-MeC_6H_4, 4-$NO_2C_6H_4$;
R = H, Pr^n, Bu^n, n-C_8H_{17}, CH_2OH, CH_2OMe, CH_2Cl, $(CH_2)_2OH$.

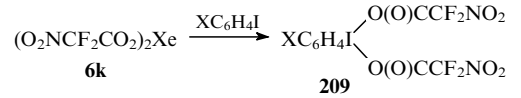
It is noteworthy that in earlier studies the alkenyl(aryl)iodonium sulfonates **206** were obtained by electrophilic addition of [PhIO–HOTf] to alkynes.[368–373] The use of xenon derivatives **5b**,**c** for the synthesis of the salts **203** allows one-pot synthesis of β-functionalised vinyliodonium salts from iodobenzene and terminal acetylenes.

The reagent **5b** oxidises 1,4-diiodobenzene resulting in the bistriflate **207** which reacts with terminal alkynes to yield (*p*-phenylene)alkenyliodonium salts **208**.[364, 365]



R = H, Me, Et, Ph, Pr^n, n-C_8H_{17}, CH_2Cl.

The oxidation of iodoarenes by bis(nitrodifluoroacetoxy)xenon (**6k**) yields the iodonium salts **209** in 65%–80% yields.[374, 375]



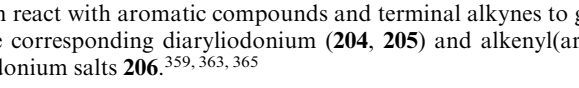
X = H, 4-Me, 4-F, 4-MeO, 3-CF_3, 4-NO_2, 4-Cl.

The reaction of $XeF^+AsF_6^-$ with HI in solution has been studied.[376]

According to *ab initio* calculations, the enthalpy of the reaction of XeF_2 with HI is equal to -63.4 kcal mol^{-1} (see Ref. 376).

b. Reactions of organobromine compounds with XeF_2

Nesmeyanov *et al.*[377] have demonstrated that bromine can in principle be oxidised in mononuclear bromoarenes. However, this is possible only with XeF_2. The difluorides **210** formed react with different arenes in the presence of boron trifluoride etherate to give the diarylbromonium salts **211**, their structures were confirmed by independent syntheses, *viz.*, by decomposition of arenediazonium tetrafluoroborates in the presence of the corresponding bromoarenes. In some cases, the formation of bromonium salts could be detected using ^{19}F NMR spectra. The yields of the salts **211** do not exceed 5%. Fluorination and oxidation of aromatic nuclei is the main route of this reaction even at -70 °C.



Ar^1 = 4-FC_6H_4, 4-ClC_6H_4, 4-MeC_6H_4, 2-$MeO_2CC_6H_4$;
Ar^2 = Ph, 4-FC_6H_4, 4-ClC_6H_4, 4-MeC_6H_4.

2. Reactions with Group VI organoelement compounds

a. Reactions of organosulfur compounds with XeF_2

Owing to the high oxidation potential of XeF_2, its reaction with sulfur-containing compounds occurs vigorously at low temperatures. Oxidative fluorination of sulfur-containing compounds, *viz.*, methyl phenyl sulfide, tetrahydrothiopyrones and thiochromanone, by XeF_2 was carried out for the first time in 1976 by Zupan.[378] The reaction of XeF_2 with diaryl or alkyl aryl sulfides results in the formation of sulfur(IV) and sulfur(VI) compounds;

the structures of the original sulfides influence the direction of the reaction. The nature of substituents at the α-carbon atom is the most important factor. The sulfides containing no α-hydrogen atoms are smoothly converted into difluorosulfuranes.[379] The presence of Me, CH_2 and CH fragments vicinal to the sulfur atom results in the formation of α-fluoro sulfides. For example, methyl phenyl sulfide is oxidised to fluoromethyl- (**212**) or difluoromethyl phenyl sulfide (**213**) depending on the amount of XeF_2 used.[378, 379]

$$PhSMe + XeF_2 \xrightarrow[25\ ^\circ C]{HF,\ CH_2Cl_2} \underset{\mathbf{212}\ (67\%)}{PhSCH_2F} \xrightarrow[25\ ^\circ C]{XeF_2\cdot HF,\ CH_2Cl_2} \underset{\mathbf{213}\ (58\%)}{PhSCHF_2}$$

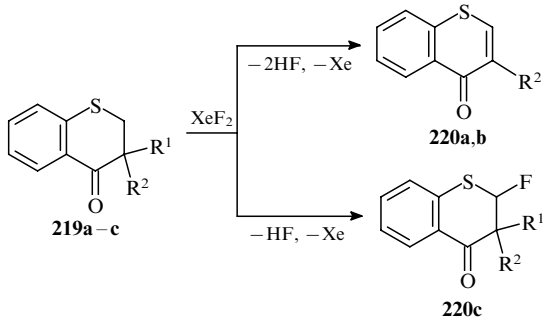
Sometimes, the reaction of alkyl aryl sulfides with XeF_2 gives unsaturated sulfides. This is due to the low stability of α-fluoroalkyl sulfides and their proneness to eliminate HF. Thus the reaction of isopropyl phenyl sulfide with XeF_2 at −10 °C gave the fluorination product **214**, whereas isopropenyl phenyl sulfide (**215**) was obtained at 0 °C.[379]

$$PhSCHMe_2 \xrightarrow{XeF_2} \begin{cases} \xrightarrow[-10\ ^\circ C,\ 30\ min]{MeCN} \underset{\mathbf{214}\ (>90\%)}{PhSCFMe_2} \\ \xrightarrow[0\ ^\circ C,\ 2\ min]{MeCN} \underset{\mathbf{215}\ (>90\%)}{PhSC(Me)=CH_2} \end{cases}$$

The reaction of XeF_2 with diphenyl sulfide and subsequent hydrolysis of the reaction products afford diphenyl sulfoxide or sulfone. Presumably, diphenyldifluoro- (**216**), diphenyldifluorooxo-λ⁴-sulfanes (**217**) and diphenyltetrafluoro-λ⁴-sulfane (**218**) are formed as the intermediate products.[380]

$$Ph_2S \xrightarrow[HF]{XeF_2} \underset{\mathbf{216}}{[Ph_2SF_2]} \begin{cases} \xrightarrow{OH^-} Ph_2SO \xrightarrow[HF]{XeF_2} \underset{\mathbf{217}}{Ph_2S(O)F_2} \xrightarrow{OH^-} Ph_2SO_2 \\ \xrightarrow[HF]{XeF_2} \underset{\mathbf{218}}{Ph_2SF_4} \xrightarrow{OH^-} Ph_2SO_2 \end{cases}$$

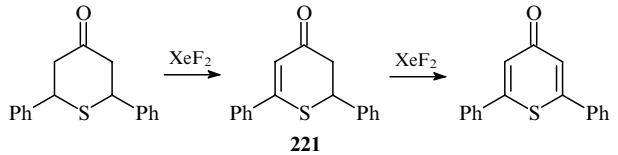
The fluorination of thiochroman-4-one (**219a**) or its 3-bromo derivative (**219b**) results in thiochromen-4-ones (**220a**,**b**), whereas the reaction of 3,3-dibromothiochroman-4-one (**219c**) gives 3,3-dibromo-2-fluorothiochroman-4-one (**220c**).[378, 380]



219a–c **220a**,**b** **220c**

R^1, R^2 = H (**a**); R^1 = H, R^2 = Br (**b**); R^1 = R^2 = Br (**c**).

The reaction of thio-4-pyrone with XeF_2 gives dihydro-2,6-diphenylthio-4-pyrone (**221**) which is dehydrogenated by XeF_2.[378]



221

The reaction of dimethyl sulfide with XeF_2 has been studied in detail. In the absence of a solvent, this reaction is explosive. Dilution of the reaction mixture with trichlorofluoromethane results in FCH_2SMe which further reacts with the excess of dimethyl sulfide to give the salt **222**.[381] It is of note that the reaction of dimethyl sulfide with XeF_2 in the presence of BF_3 or AsF_5 is not accompanied by fluorination of the methyl group but the salts **223** are formed instead.

$$Me_2S \xrightarrow{XeF_2} MeSCH_2F \xrightarrow[HF]{Me_2S} \underset{\mathbf{222}}{[Me_2SCH_2SMe]^+[F(HF)_n]^-}$$

$$Me_2S \xrightarrow[A]{XeF_2} \underset{\mathbf{223}}{[Me_2SF]^+[AF]^-}$$

A = BF_3, AsF_3.

The intermediate formation of the salts **223** in this reaction was confirmed by ^{19}F NMR spectral data and independent synthesis. The cation $[Me_2SCH_2SMe]^+$ is generated only in the presence of a protic acid. It is suggested[381] that $R_2S^+X^-$ or $R_2S^+XeFX^-$ are formed as intermediates. The latter are used[382] for the fluorination of carbanions.

The reactions of sodium derivatives of diethyl malonate or of substituted malonates with XeF_2 in CH_2Cl_2 result in the dimers **224**. The fluorination products **225** were isolated in the presence of $BF_3\cdot Et_2O$. The methylthio derivatives of the malonates **226** are formed along with the fluorination products **225** after addition of dimethyl sulfide to the reaction mixture.[382] It is interesting to note that the reaction of diethyl nitromalonate with XeF_2 gives only a dimer of the type **224**.

$$RC^-(CO_2Et)_2Na^+ \xrightarrow{XeF_2} \underset{\mathbf{224}}{\left[(EtO_2C)_2C(R)\right]_2} \quad (CH_2Cl_2)$$

$$RC^-(CO_2Et)_2Na^+ \xrightarrow[CH_2Cl_2,\ BF_3\cdot Et_2O]{XeF_2} \underset{\mathbf{225}}{RC(F)(CO_2Et)_2}$$

$$RC^-(CO_2Et)_2Na^+ \xrightarrow[BF_3\cdot Et_2O,\ Me_2S]{XeF_2,\ CH_2Cl_2,} \mathbf{225} + \underset{\mathbf{226}}{RC(SMe)(CO_2Et)_2}$$

R = H, Me, Et, C_5H_{11}, Bn, NO_2.

The highest yields of the reaction products are obtained for equimolar ratios of the reagents and at low temperatures (−78 °C).[382]

The reaction of XeF_2 with fluorinated sulfides generated easily hydrolysable aryl trifluoromethyl difluorosulfuranes **227**.[383]

$$4\text{-}RC_6H_4SCF_3 + XeF_2 \xrightarrow{HF} \underset{\mathbf{227}}{4\text{-}RC_6H_4SF_2CF_3} + Xe$$

R = H, Cl, NO_2.

Thus, the reaction of sulfides with XeF_2 affords three main types of reaction products, *viz*., α-fluoroalkyl sulfides, dehydrofluorination products and sulfoxides or sulfones. A mechanism of this reaction has been proposed.[384]

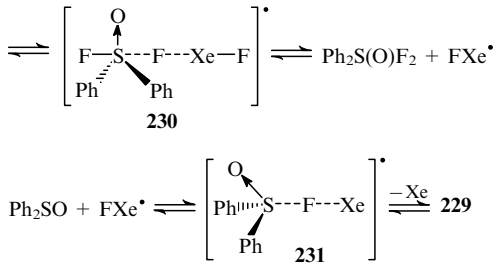
The reaction of Ph_2SO with XeF_2 in the presence of ~1% solution of Et_4NCl in CH_2Cl_2 at 20 °C results in the difluoride **217** in quantitative yield.[385]

$$Ph_2SO + XeF_2 \xrightarrow[CH_2Cl_2]{Et_4NCl} \underset{\mathbf{217}}{Ph_2S(O)F_2} + Xe$$

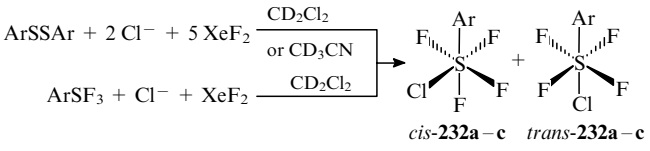
In the absence of Cl^-, the reaction is sluggish (2–6 days). Apparently, the chloride anion promotes the generation of the fluoride anion, which behaves as a strong base in CH_2Cl_2 in the absence of HF.[386, 387] The reaction mechanism proposed by Ou and Janzen[385] which includes the formation of the anion **228** and its oxidation to the radicals **229**–**231** is corroborated experimentally by the identification of the radical XeF• (spectroscopic data).[388]

$$2Cl^- + XeF_2 \longrightarrow 2F^- + Cl_2 + Xe$$

$$Ph_2SO \underset{}{\overset{F^-}{\rightleftharpoons}} \underset{\mathbf{228}}{Ph_2S(O)F^-} \overset{e^-}{\rightleftharpoons} \underset{\mathbf{229}}{Ph_2S(O)F^\bullet} \overset{XeF_2}{\rightleftharpoons}$$

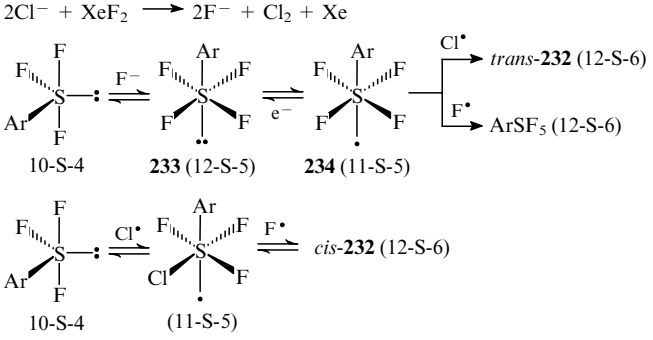


Compounds **232a–c** (*cis*- and *trans*-isomers) were synthesised in the reaction of XeF_2 with ArSSAr or $ArSF_3$ in the presence of a chloride anion source, *viz*., Et_4NCl.[389] Individual isomers can be obtained by varying the reaction conditions and the ratios of the reagents. The maximum yield of the *trans*-**232a** (89%) is achieved for the $Ph_2S_2 : Et_4NCl : XeF_2$ ratio of 1 : 2 : 8, that of the *cis*-**232c** (83%), for the $(4\text{-}O_2NC_6H_4)_2S_2 : Et_4NCl : XeF_2$ ratio of 1 : 2 : 6. In each case, the formation of side products ($ArSF_5$ and $ArSOF_3$) and fluorination of the solvent took place.

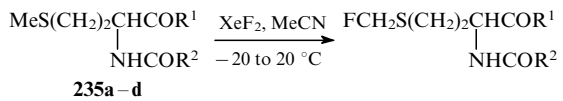


Ar = Ph (**a**), 4-MeC_6H_4 (**b**), 4-$O_2NC_6H_4$ (**c**).

A scheme with the nomenclature N-X-L (where X is the central atom, N is the number of valent electrons and L is the number of ligands)[390] illustrates the mechanism of this reaction which includes the formation of the anion **233**, its oxidation to the radical **234**[391] and subsequent recombination.[389] With a decrease in the content of the radical Cl•, the concentration of $ArSF_5$ should increase, which was confirmed experimentally.[389]



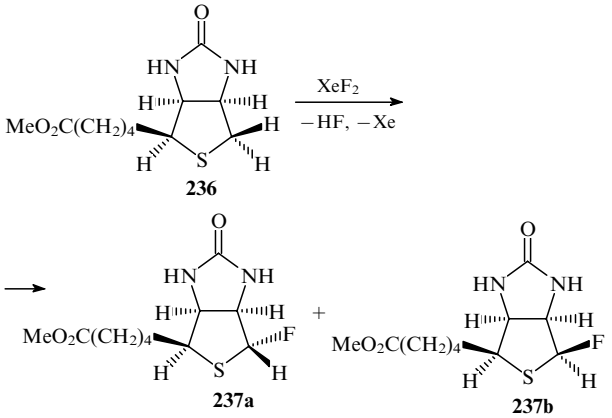
The highly selective oxidative fluorination of sulfides by XeF_2 was used for incorporating one or two fluorine atoms into the carbon chains of biologically active substances. For example, the fluorination of the methionine derivatives **235a–d** by XeF_2 (−20 to 20 °C) occurs regiospecifically and involves the MeS group.[392, 393]



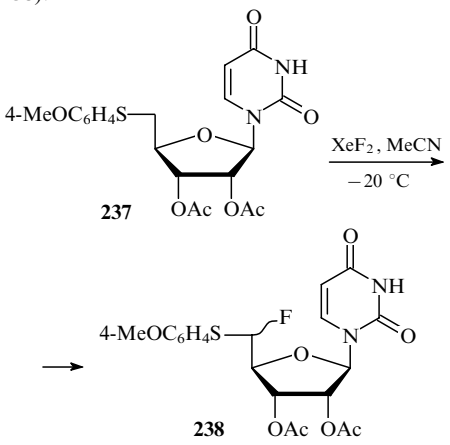
235a–d

R^1 = OMe, R^2 = CF_3 (**a**); R^1 = $OC_6H_4NO_2$-4, R^2 = OBu^t (**b**);
R^1 = $OC_6H_4NO_2$-4, R^2 = CF_3 (**c**); R^1 = $NHCH_2C(O)OEt$,
R^2 = OCH_2Ph (**d**).

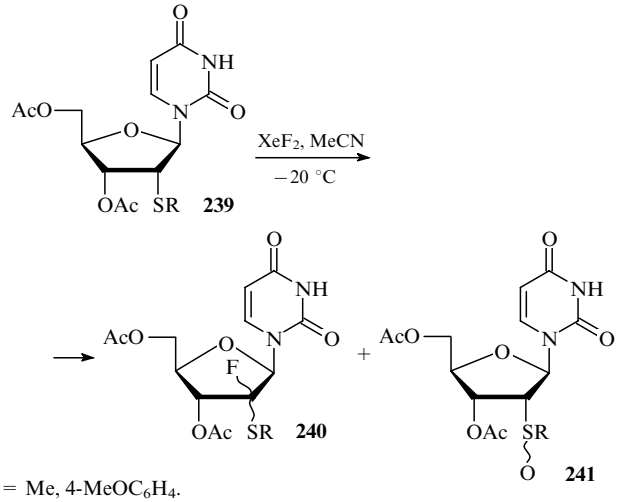
The reaction of XeF_2 with methyl ester of β-biotin (**236**) results in the diastereomers of 6-fluorobiotin methyl ester **237a**,**b**.[394]



The reaction of 2′,3′-di-*O*-acetyl-5′-*S*-(4-methoxyphenyl)-5′-thiouridine (**237**) with XeF_2 yields a mixture of diastereomeric 2′,3′-di-*O*-acetyl-5′-fluoro-5′-*S*-(4-methoxyphenyl)-5′-thiouridines (**238**).[395]



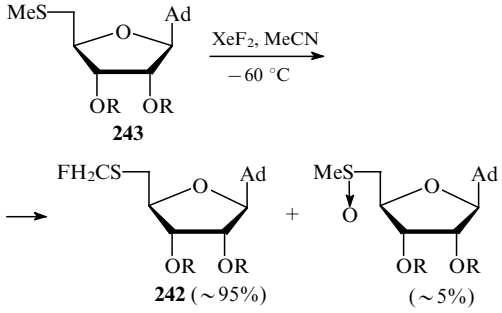
Xenon difluoride was also used for the fluorination of 3′,5′-di-*O*-acetyl-2′-*S*-alkyl(aryl)-2′-thiouridines. Thus the reaction of compound **239** with XeF_2 affords a mixture of diastereoisomeric 3′,5′-di-*O*-acetyl-2′-*S*-alkyl(aryl)-2′-fluoro-2′-thiouridines **240** in 22% yield.[396] This reaction is accompanied by partial oxidation of the sulfur atom in the initial sulfides **239** and the formation of the sulfoxides **241**.



R = Me, 4-$MeOC_6H_4$.

A convenient method for the synthesis of 5′-(fluoromethylthio)adenosine derivatives (**242**) (yield 70%) by regioselective fluorination of 5-methylthioadenosine derivatives **243** by XeF_2 has been proposed.[397] In this case, as in the fluorination of the

5′-arylthioadenosine,[398] methionine [392] and biotin derivatives,[394] the reaction occurs at the least substituted carbon atom.



R = Bz, Ac; Ad is 9-adenine.

In contrast to sulfides, thiols and thiophenols are not fluorinated by XeF_2, but are usually oxidised to disulfides in quantitative yields. The structure of the radical at the sulfur atom and the thiol : XeF_2 ratio do not influence the direction of this reaction.[379]

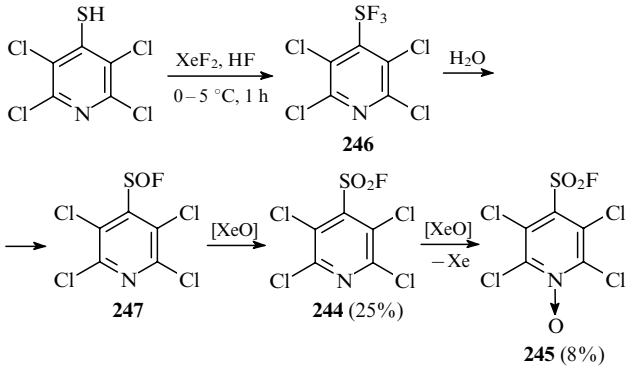
$$2\,RSH + XeF_2 \longrightarrow RSSR + 2\,HF + Xe$$

R = Me, Pr^i, Bu^t, Ph.

Under drastic conditions, disulfides also react with XeF_2. Thus, fusion of bis(pentafluorophenyl) disulfide with XeF_2 at 85 °C in a sealed tube for 3 h yields a mixture of $C_6F_5SF_3$ and C_6F_5SOF which are identified by their ^{19}F NMR spectra (see Ref. 20).

$$C_6F_5SSC_6F_5 + XeF_2 \xrightarrow[-Xe]{} C_6F_5SF_3 \xrightarrow{H_2O} C_6F_5S(O)F$$

The use of XeF_2 in reactions with polychloropyridinethiols allowed one to develop new methods for perfluoroalkylation and oxyfluorination of thiol groups as well as for the oxidation of polychloropyridines to *N*-oxides. Thus the reaction of 2,3,5,6-tetrachloropyridine-4-thiol with XeF_2 in HF gave 4-fluorosulfonyl-2,3,5,6-tetrachloropyridine (**244**) and 4-fluorosulfonyl-2,3,5,6-tetrachloropyridine *N*-oxide (**245**).[399,400] This reaction is accompanied by oxidation of the original thiol into bis(2,3,5,6-tetrachloro-4-pyridyl) disulfide.



A reaction scheme which allows one to get insight into the mechanism of formation of the fluorosulfonyl fragment has been suggested.[400] Initially, the thiol group is fluorinated by XeF_2 in the presence of HF to the derivative **246** which is easily hydrolysed to the sulfoxide **247** and the sulfonylfluoride **244**. The latter can be converted into compound **245** by oxidation with [XeO] species formed in the hydrolysis of XeF_2 (the bonding energy of Xe—O is 7 kcal mol^{-1} which corresponds to the weakly bound atomic oxygen).[62–64]

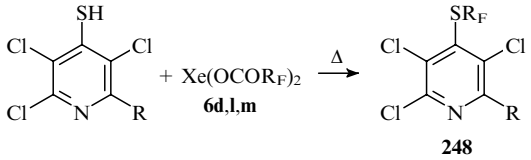
A new method for perfluorination of polychloropyridinethiols which is based on the thermolysis of the xenon bisperfluorocarboxylates **6d**,**l**,**m** in the presence of thiols has been described.[242, 399–404]

Table 2. Perfluoroalkylation of pyridinethiols.

Reagent (method of generation)	Compound **248**	R	R_F	Yield (%)	Ref.
6d (A)	**a**	Cl	CF_3	66	242
6d (B)	**a**	Cl	CF_3	36.5	242, 399
6d (A)	**b**	CCl_3	CF_3	45	242
6d (A)	**c**	CN	CF_3	50	242
6l (B)	**d**	Cl	C_3F_7	85	242, 399
6m (B)	**e**	Cl	C_2F_5	85	404

Thermolysis is carried out either using the preformed reagents **6d**,**l**,**m** (method A) or with the simultaneous *in situ* generation of the xenonates **6d**,**l**,**m** (method B).

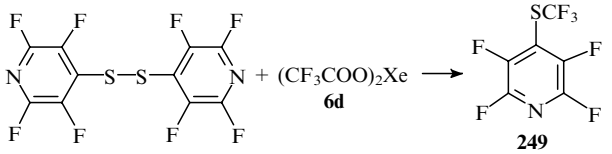
This reaction yields the polychloroperfluoroalkylthiopyridines **248**; their yields depend on the mode of generation of the xenonates **6d**,**l**,**m** (Table 2). It was found that the reactivity of the thiol group decreases with an enhancement of the acceptor properties of the substituent R.[242, 399–404]



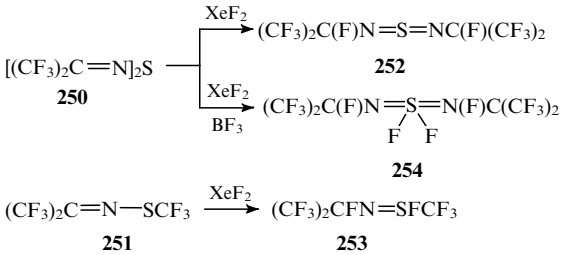
R_F = CF_3 (**d**), C_2F_5 (**l**), C_3F_7 (**m**).

This method allows direct perfluoroalkylation of thiols including those containing substitution-sensitive groups.[405]

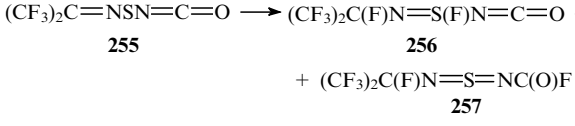
4-Trifluoromethyl-2,3,5,6-tetrafluorothiopyridine (**249**) is formed upon the *in situ* generation of the xenonate **6d** in the presence of di(1,3,5,6-tetrafluoro-4-pyridyl) disulfide with simultaneous thermolysis at 50–60 °C (yield 41%).[242, 406]

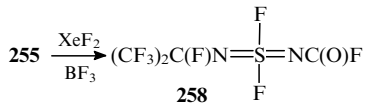


Xenon difluoride selectively oxidises the sulfur atom in compounds containing the S—N bond and the S—N bond is retained. Thus the S(IV) derivatives **252** and **253** containing the imidosulfenyl group are formed from compounds **250** and **251** in the absence of a catalyst, whereas compound **252** is further oxidised into S(VI) compound **254,** when BF_3 is used as a catalyst.[407]



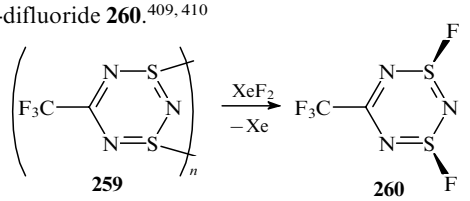
The pseudo-triene system of the isocyanate **255** undergoes 1,3- and 1,5-difluorination by XeF_2 in the absence of a catalyst resulting in compounds **256** and **257**. The N^1-(heptafluoroisopropyl)-N^2-(fluorocarbonyl)-*S*,*S*-difluorosulfodiimide (**258**) is formed in the presence of BF_3.[408]





255 $\xrightarrow[BF_3]{XeF_2}$ $(CF_3)_2C(F)N{=}S(F){=}NC(O)F$ **258**

The oligomeric di-λ^4-thiatriazine **259** is easily fluorinated by XeF_2 with the preservation of the ring and the formation of the *cis*-difluoride **260**.[409,410]



259 $\xrightarrow[-Xe]{XeF_2}$ **260**

N-Sulfinylperfluoroalkylamines **261** are converted into *N*-perfluoroalkyl-*S*,*S*-difluorosulfoximides **262** by XeF_2 in perfluorodecalin.[411]

$$R_FNSO + XeF_2 \xrightarrow[-Xe]{20\ ^\circ C} R_FNSOF_2$$

261 **262**

R_F = CF_3 (54%), C_2F_5 (50%).

The synthesis of sulfonyl fluorides from sulfonyl chlorides is effected by direct substitution of fluorine for chlorine. For example, the reaction of XeF_2 with methane-, benzene-, *p*-toluene- and pentafluorobenzenesulfonyl chlorides affords the corresponding sulfonyl fluorides as the main products upon heating for 4–10 h (yields 20%–80%). This reaction is carried out in acetonitrile or without the solvent. In some cases, fluorination of the aromatic nucleus takes place.[412]

$$RSO_2Cl \xrightarrow{XeF_2} RSO_2F$$

R = Me, Ph, C_6F_5, *p*-MeC_6H_4.

Recent reports suggest the use of $XeF^+MF_6^-$ salts (M = As, Sb) as the oxidants. It was shown in particular that $XeF^+MF_6^-$ reacts with the sulfides R^1SR^2 ($R^1 = R^2 = C_6F_5$;[413] $R^1 = CF_3$, $R^2 = Me$;[414,415] $R^1 = R^2 = Me$[381,414,415]) and thiols RSH [R = Me, CF_3 (see Ref. 416)] to give the fluorosulfonium cations of the type $R^1R^2S^+(F)MF_6^-$ and with disulfides R^1SSR^2 [$R^1 = R^2 = CF_3$; $R^1 = Me$, $R^2 = CF_3$; $R^1 = R^2 = Me$;[417] $R^1 = R^2 = Cl$ (see Ref. 418)] to give the sulfonium salts $[R^1SS(F)R^2]^+MF_6^-$. The reaction of the λ^4-sulfanes **263** with $XeF^+MF_6^-$ (M = As, Sb) gives the corresponding fluorosulfonium salts **264** and XeF_2[418] which cannot convert S(IV) into S(VI) due to its lower oxidation capacity in comparison with the cation XeF^+ (see Ref. 326).

$$R_nSF_{4-n} + XeF^+MF_6^- \longrightarrow R_nS^+F_{3-n}MF_6^- + XeF_2$$

263 **264**

R = CF_3; *n* = 0, 1, 2; M = As, Sb.

It should be noted that in the case of the λ^4-sulfanes **263**, $XeF^+MF_6^-$ salts behave as Lewis acids rather than oxidants. Their oxidative properties are manifested in the reaction with trifluoromethane sulfinyl fluoride. The S–F bond in $CF_3S(O)F$ is relatively strong as can be judged from its length (1.591 Å).[419] Depending on the nature of the element, this reaction affords either (trifluoromethyl)difluorosulfinyl hexafluoroantimonate (**265**) or the adduct **266**.[419] The reaction with dimethyl sulfoxide gives similar adducts.[419]

$$XeF^+MF_6^- \xrightarrow{CF_3S(O)F} \begin{cases} M = Sb: & Xe + [CF_3S(O)F_2]^+SbF_6^- \ (\mathbf{265}) \\ M = As: & CF_3S(O)F\cdot AsF_5 + XeF_2 \ (\mathbf{266}) \\ Me_2SO: & Me_2S(O)F\cdot MF_5 + XeF_2 \end{cases}$$

M = As, Sb.

The reaction of bis(trifluoromethyl) sulfoxide with $XeF^+SbF_6^-$ yields the salt **267** which was identified by spectral methods.[419,420] It is assumed that its first step involves a cationic attack of the sulfoxide oxygen atom by XeF^+, whereas the second step consists in the intramolecular migration of the fluoride anion to the sulfur atom. The second step seems to be hindered by steric shielding of the reaction centre by two CF_3 groups.[327]

$$(CF_3)_2SO + XeF^+SbF_6^- \longrightarrow [(CF_3)_2SOXeF]^+SbF_6^-$$

267

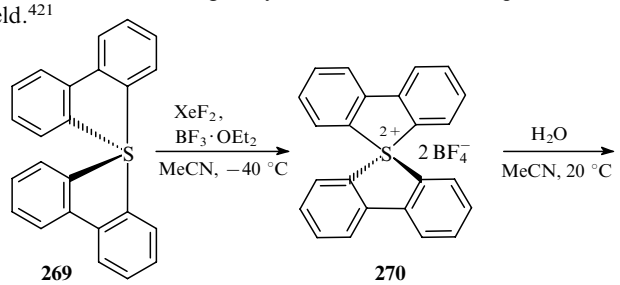
The reaction of thionyl chloride with $XeF^+MF_6^-$ is accompanied by the elimination of Xe and the formation of the salt **268**.[419]

$$2OSCl_2 + 3XeF^+MF_6^- \longrightarrow 2[OSClF_2]^+MF_6^- + Cl_2 + MF_5 + 3Xe$$

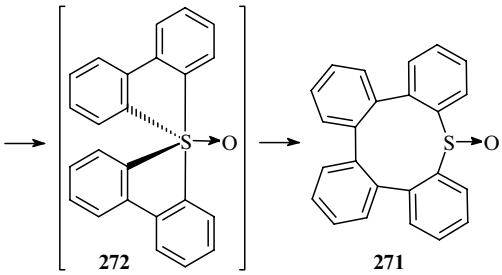
268

M = As, Sb.

The reaction of bis(2,2′-biphenylyl)-λ^4-sulfane **269** with 1 equiv. of XeF_2 in the presence of $BF_3\cdot OEt_2$ gives the bis(tetrafluoroborate) **270** which reacts with excess water or a dilute solution of an alkali to give cyclic sulfoxide **271** in a quantitative yield.[421]



269 **270**



272 **271**

The formation of the sulfoxide **271** is associated with the C–C ligand coupling in the oxide **272**.[422]

The first compound containing the Xe–S bond, *viz*., HXeSH, was studied by spectral methods.[423,424] It was generated by photolysis of H_2S in a xenon matrix at 7.5 K and represents a particular case of a compound with the general formula HXY, where X = Xe, Kr, and Y is the fragment with a higher electron affinity (H, Cl, Br, I, CN, NC).[425–428]

b. Reactions of organoselenium compounds with XeF_2

For selenium, the transition into a four-coordinated state occurs much easier than for sulfur. Aryl trifluoromethyl selenides form more stable fluorides with XeF_2 than the corresponding sulfides. Thus compounds **273** react with XeF_2 in the presence of HF to give aryl trifluoromethyl difluoro-λ^4-selanes **274** in quantitative yields.[429] Bis(pentafluorophenyl) diselenide forms the pentafluorophenyl trifluoro-λ^4-selane (**275**) with XeF_2.

$$4\text{-}RC_6H_4SeCF_3 \xrightarrow[HF]{XeF_2} 4\text{-}RC_6H_4SeF_2CF_3$$

273 **274**

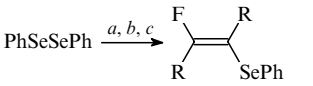
R = H, Cl, NO_2.

$$C_6F_5SeSeC_6F_5 \xrightarrow[HF]{XeF_2} C_6F_5SeF_3$$

275

An efficient procedure for vicinal fluoroselenenation of alkynes by addition of synthetic equivalents of the selanyl fluoride

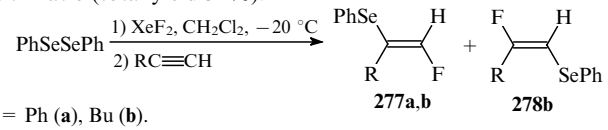
RSeF generated *in situ* from XeF_2, diaryl, dibenzyl or dialkyl diselenides has been developed.[430] The direction of this reaction depends on the structures of the alkyne and the diselenide. Thus symmetric dialkylacetylenes react smoothly with XeF_2 and diphenyl diselenide to give the vicinal (fluoroalkenyl)phenyl selenides **276** in high yields.[430]



276 (72% – 87%)

R = Me, Et, Pr, Bu; (*a*) XeF_2, CH_2Cl_2, −20 °C, 15 min;
(*b*) RC≡CR, −20 °C, 0.5 h, (*c*) 20 °C, 1 h.

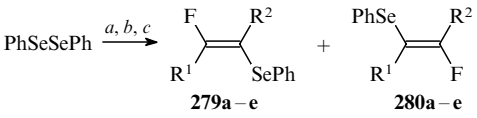
Terminal alkynes do not react with PhSeBr and AgF (sonication);[431] phenylacetylene forms the adduct **277a** with XeF_2 and diphenyl diselenide in 27% yield. Under these conditions, hex-1-yne affords a mixture of *E*-isomers of the adducts **277b** and **278b** in a 3 : 1 ratio (total yield 31%).[430]



277a,**b** **278b**

R = Ph (**a**), Bu (**b**).

The reaction of asymmetrical inner alkynes with XeF_2 and $(PhSe)_2$ also results in the vicinal fluoroselenenation products **279a**–**e** and **280a**–**e** (total yield 26% – 83%).[430]

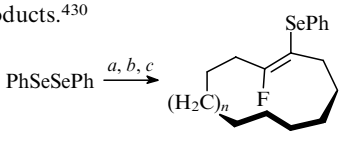


279a–**e** **280a**–**e**

R^1 = Ph, R^2 = Me (**a**); R^1 = Bu, R^2 = Me (**b**); R^1 = Bu, R^2 = Et (**c**);
R^1 = Bu, R^2 = Pr^i (**d**); R^1 = Bu, R^2 = Bu^t (**e**);
(*a*) XeF_2, CH_2Cl_2, −20 °C, 15 min;
(*b*) $R^1C{\equiv}CR^2$, −20 °C, 0.5 – 2 h; (*c*) 20 °C, 1 – 2.5 h.

Compounds **279** or a mixture of the selenides **279** and **280** are exclusively formed depending on the nature of the substituent in the alkyne. Thus 1-phenylpropyne and the sterically hindered 2,2-dimethyloct-3-yne react with XeF_2 and $(PhSe)_2$ to give exclusively the isomers **279a**,**e**, while hept-2-yne and oct-3-yne give a mixture of the isomeric selenides **279b**,**c** and **280b**,**c** in a *ca.* 1 : 1 ratio. The proportion of the isomer **279d** increases significantly in the case of 2-methyloct-3-yne.[430]

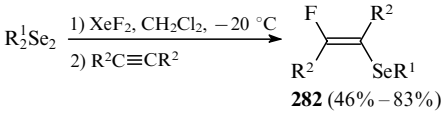
It can be expected that cycloalkynes will behave similarly in reactions with XeF_2 and $(PhSe)_2$. However, it was found that only cycloundecyne and cyclododecyne react selectively to give the adducts **281a**,**b** (yields 68% and 80%, respectively), whereas cyclooctyne and cyclodecyne yield a mixture of non-identified products.[430]



281a,**b**

n = 1 (**a**), 2 (**b**); (*a*) XeF_2, CH_2Cl_2, −20 °C, 15 min; (*b*)  , −20 °C, 1 h; (*c*) 20 °C, 1 h.

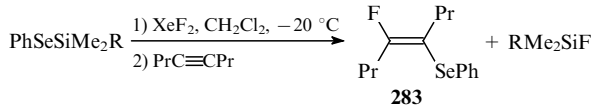
The reactions of other diselenides with XeF_2 and alkynes including functionally substituted ones have been studied.[432] These reactions resulted in the adducts **282**.[430, 432]



282 (46% – 83%)

R^1 = Me, Et, Pr^i, Bn, Bu^t, 2-$NO_2C_6H_4$, $CH_2CH(OMe)_2$, $(CH_2)_3CO_2Et$, $(CH_2)_3CO_2H$, $(CH_2)_2NMe_2$, CH_2SiMe_3; R^2 = Me, Et, Pr, Bu.

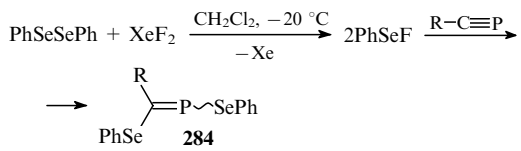
Trimethylphenylselanylsilane and *tert*-butyldimethylphenylselanylsilane react with oct-4-yne under analogous conditions to give the adducts **283** (yields 73% and 82%, respectively). Contrary to expectations, alkynes do not react with the PhSeNCO – XeF_2 system.[430]



283

R = Me, Bu^t.

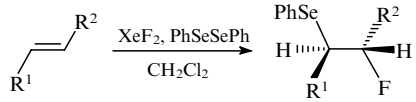
The fluorophenylselenenation of various phosphaalkynes resulting in the adducts **284** has been studied.[433]



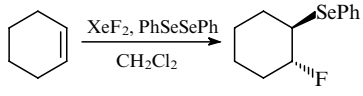
284

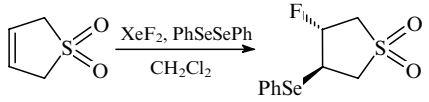
R = Bu^t, adamantyl.

Alkenes also react with XeF_2 and $(PhSe)_2$ in CH_2Cl_2 to give readily hydrolysable vicinal phenylselanylfluoroalkanes. The yields of the products depend on the reaction conditions and decrease dramatically with an increase in temperature.[434]



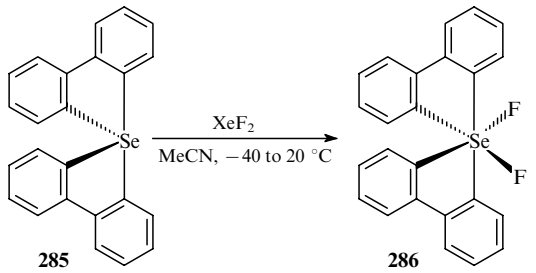
R^1 = H, Me, Bu, CH_2CN; R^2 = H, CH_2CN, CO_2Me, SO_2Ph.





The *in situ* generated PhSeF is more reactive than PhSeCl or PhSeBr; it reacts even with electron-deficient alkenes and 2,5-dihydrothiophene 1,1-dioxide. Since the Se – F bond is more polar than the Se – Cl and Se – Br bonds, the PhSe fragment in PhSeF bears a higher positive charge than that in PhSeBr and PhSeCl and is therefore more electrophilic. Indirect evidence in favour of this assumption was obtained from spectral data.[434]

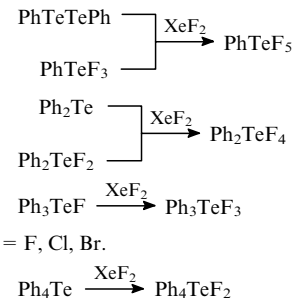
Bis(2,2′-biphenylene)-λ^4-selane (**285**) reacts with XeF_2 in acetonitrile at −40 °C to give the bis(2,2′-biphenylene)difluoro-λ^6-selane (**286**) in 54% yield.[435]



285 **286**

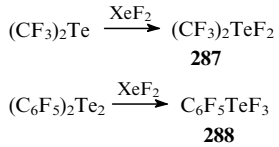
c. Reactions of organotellurium compounds with XeF_2

Organotellurium compounds react smoothly with XeF_2 to give derivatives of Te(IV) and Te(VI). XeF_2 was successfully used for the synthesis of a vast variety of aryltellurium(VI) fluorides from diaryl tellurides or Te(IV) derivatives.[389, 436]

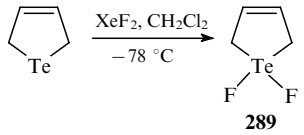


X = F, Cl, Br.

Bis(trifluoromethyl)tellurium difluoride **287** was synthesised by fluorination of bis(trifluoromethyl) telluride by XeF_2 in an acetonitrile–Freon-11 mixture.[437] Bis(pentafluorophenyl) ditelluride reacts with XeF_2 to give the pentafluorophenyltellurium trifluoride (**288**) with the cleavage of the Te–Te bond and the oxidation of Te(II) to Te(IV).[429]



The oxidative fluorination of 2,5-dihydrotellurophene by xenon difluoride results in 2,5-dihydrotellurophene 1,1-difluoride (**289**).[438]

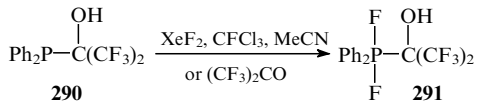


Special mention should be made of an unsuccessful attempt at the fluorotellurination of oct-4-yne by the Ph_2Te_2–XeF_2 or $PhTeSiMe_3$–XeF_2 systems.[430]

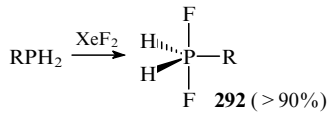
3. Reactions of XeF_2 with Group V organoelement compounds

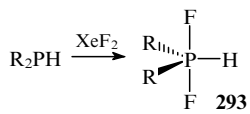
a. Reactions of organophosphorus compounds with XeF_2

Xenon difluoride smoothly oxidises phosphorus(III) to phosphorus(V) in various phosphorus derivatives. Under these conditions, other functional groups present in the molecule are not involved as a rule. Thus the oxidation of (1-hydroxyhexafluoroisopropyl)diphenylphosphine (**290**) yields the pentavalent phosphorus derivative **291**.[439]



High selectivity is also observed in the oxidation of compounds containing a P–H bond. Thus the reaction of primary and secondary phosphines with XeF_2 gives the corresponding difluorides **292** and **293** in high yields.[347,440]



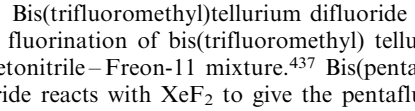


R = Ph, CH_2CH_2CN.

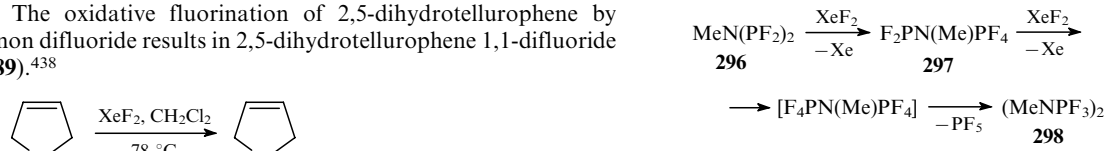
Oxidative fluorination also takes place in reactions with arylchlorophosphines **294** where it occurs simultaneously with the substitution of fluorine for chlorine. Triphenylphosphine (**294d**) is quantitatively converted into triphenyldifluorophosphorane **295d**,[347] whereas the chlorine-containing phosphines **294a–c** react with XeF_2 to give the fluoro-substituted phosphoranes **295a–c** in quantitative yields. No intermediate formation of chlorofluorophosphoranes was detected.[353]

n = 0 (**a**), 1 (**b**), 2 (**c**), 3 (**d**).

The fluorination of four-coordinated phosphorus derivatives containing P–H bonds results in fluorides.[441]

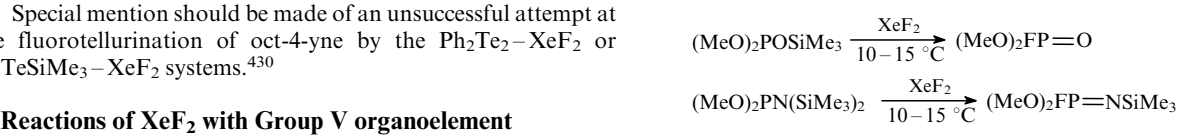


The oxidation of organic derivatives of phosphorus(III) containing P–N, P–S or P–O bonds is complicated due to easy elimination of PF_5 which is accompanied by the formation of compounds containing a P = X fragment (X = N, O, S). For example, the fluorination of bis(difluorophosphino)methylamine (**296**) by XeF_2 gives difluorophosphino(tetrafluorophosphoranyl)methylamine (**297**), which undergoes dimerisation to give compound **298**.[442]

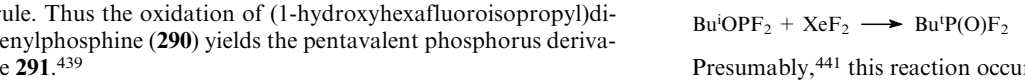


The oxidation of organic derivatives of phosphorus(III) containing P–N, P–S or P–O bonds is complicated due to easy elimination of PF_5 which is accompanied by the formation of compounds containing a P = X fragment (X = N, O, S). For example, the fluorination of bis(difluorophosphino)methylamine (**296**) by XeF_2 gives difluorophosphino(tetrafluorophosphoranyl)methylamine (**297**), which undergoes dimerisation to give compound **298**.[442]

Silyl esters and silyl-substituted amides of trivalent phosphorus acids are oxidised by XeF_2 to dialkylphosphofluoridates or dialkyl fluorophosphazenes, respectively.[441]



An unusual reaction takes place on the interaction of isobutyl phosphodifluoridite with catalytic amounts of XeF_2. In this case, the *tert*-butylphosphonic difluoride was isolated as the main product in 50% yield.[441,443]



Presumably,[441] this reaction occurs through the formation of alkoxytetraphenylphosphorane, which disproportionates with the formation of the isobutyl cation.[443] The latter undergoes isomerisation and reacts with the original phosphite to afford the final product.

b. Reactions of organoarsenic derivatives with XeF_2

The reactions of XeF_2 with organoarsenic derivatives were studied in the single example.[351]

It is quite probable that in other cases the behaviour of As(III) compounds in the reaction with XeF_2 will also not be different from that of P(III) derivatives.

c. Reactions of organoantimony compounds with XeF_2

To date, reactions of XeF_2 with antimony derivatives have been studied relatively little.

Xenon difluoride fluorinates aromatic derivatives of trivalent antimony in quantitative yields under mild conditions. Trifluorodiphenylantimony and difluorotriphenylantimony were prepared from fluorodiphenylstibine (or trifluorodiphenylacetoxystibine) and triphenylstibine, respectively.[444] Tris(pentafluoro-

phenyl)stibine yields difluoro tris(pentafluorophenyl)antimony in its reaction with XeF_2.[262]

$$Sb(C_6F_5)_3 \xrightarrow{XeF_2} Sb(C_6F_5)_3F_2 + Xe$$

d. Reactions of organobismuth compounds with XeF_2

Oxidative fluorination of triphenylbismuth with XeF_2 is the most convenient and available method for the preparation of trisubstituted bismuth difluoride[445] which is interesting as a fluorinating reagent.[446, 447]

$$Ar_3Bi + XeF_2 \longrightarrow Ar_3BiF_2 + Xe$$

Ar = Ph, C_6F_5.

However, tris(trifluoromethyl)bismuth yields the bismuth trifluoride, CF_4 and Xe even at -60 °C. Their formation is attributed either to the trifluoromethylation of the XeF^+ intermediate or the degradation of the pentavalent bismuth derivative.[445]

$$Bi(CF_3)_3 + 3\,XeF_2 \longrightarrow BiF_3 + 3\,CF_4 + 3\,Xe$$

The reactions of XeF_2 or $XeF^+MF_6^-$ (M = As, Sb, Ta) with tris(pentafluorophenyl)bismuth have been studied.[448] In both cases, $(C_6F_5)_3BiF_2$ was isolated from the reaction mixture with trace amounts of pentafluorobenzene which provides indirect support for the formation of xenon compounds, such as C_6F_5XeF or $C_6F_5Xe^+MF_6^-$.[262]

4. Reactions of XeF_2 with Group IV organoelement compounds

a. Reactions of organosilicon compounds with XeF_2

Reactions of organosilicon compounds with XeF_2 were studied for compounds containing Si–Cl, Si–H, Si–C, Si–O, Si–S and Si–N bonds.

The reactions of XeF_2 with chlorosilanes are completed within several minutes. However, the yields of fluorosilanes depend on the number of chlorine atoms to be substituted in the original molecule. Mono- and dichlorosilanes are easily fluorinated to give fluoro- and difluorosilanes.[440]

$$2R_3SiCl + XeF_2 \xrightarrow{MeCN} 2R_3SiF + Xe + Cl_2$$

$$Me_2SiCl_2 + XeF_2 \xrightarrow{MeCN} Me_2SiF_2 + Xe + Cl_2$$

R = Me, Et, Ph.

If the molecule contains a hydrogen atom, difluorosilanes are formed in satisfactory yields. A stepwise mechanism of this reaction which includes initial fluorination of the Si–H bond has been proposed.[440]

$$R_2SiHCl \xrightarrow{XeF_2} R_2SiHF \xrightarrow{Cl_2} R_2SiClF \xrightarrow{XeF_2} R_2SiF_2$$

R = Ph, Me.

Triarylchlorosilanes yield products of more profound conversions.[440]

The reaction of allylchlorodimethylsilane with XeF_2 is accompanied by the cleavage of the Si–C bond to afford difluorodimethylsilane in a quantitative yield.[440]

Compounds containing alkoxy groups at the silicon atom react with XeF_2 at a very slow rate (within 4–5 days).[399] On the other hand, the reaction of XeF_2 with *tert*-butylthiotrimethylsilane in acetonitrile occurs easily and affords di-*tert*-butyl disulfide and flurotrimethylsilane in high yields.[347]

$$Me_3SiSBu^t + XeF_2 \xrightarrow{MeCN} Bu^tSSBu^t + Me_3SiF + Xe$$

Bu^tSSSBu^t and Bu^tSH are formed as side products. In the absence of a solvent, this reaction yields a mixture of products.[347]

The reaction of XeF_2 with nitrogen-containing silanes is accompanied by the cleavage of Si–N bonds resulting in the formation of fluorotrimethylsilane in > 90% yield. Presumably, this reaction occurs by a radical mechanism. The formation of $FXeNR_2$ (see Ref. 423) and FXeSR (see Refs. 318–321) as intermediate products was proposed.

$$Me_3SiNR_2 + XeF_2 \xrightarrow{MeCN} Me_3SiF + Xe + R_2\dot{N}$$

$$R_2\dot{N} \xrightarrow{R = Me} MeN{=}CH_2 \longrightarrow \text{polymer}$$

$$R_2\dot{N} \xrightarrow{MeCN} R_2NH$$

The ability of XeF_2 to cleave smoothly the Si–N bonds in polyfunctional compounds was used in the synthesis of the hexamethyltriamido-*N*-fluorophosphazene (**299**) from hexamethyltriamido-*N*-trimethylsilylphosphazene (**300**).[449]

$$\underset{\mathbf{300}}{(Me_2N)_3P{=}NSiMe_3} + XeF_2 \xrightarrow[-15\ ^\circ C]{MeCN} \underset{\mathbf{299}}{(Me_2N)_3P{=}NF} + Me_3SiF + Xe$$

An attempt to synthesise a compound containing the Xe–N bond by the reaction of XeF_2 with $Me_3SiN{=}C(CF_3)_2$ was unsuccessful. This reaction gave Xe, Me_3SiF and $(CF_3)_2C{=}NH$.[347]

It was found that trimethylpentafluorophenylsilane (**301a**) does not react with XeF_2 in acetonitrile at 20 °C. However, the addition of a catalytic amount of anhydrous CsF to the reaction mixture results in the formation of pentafluorobenzene and decafluorobiphenyl in 58% and 11% yields, respectively. In acetonitrile, this reaction is completed within 15–20 min, but in $CFCl_3$ or SO_2FCl trimethylpentafluorophenylsilane (**301a**) does not react with XeF_2 even in the presence of CsF, apparently due to the low solubility of the latter.[450–452]

$$\underset{\mathbf{301a-d}}{ArSiMe_3} + XeF_2 \xrightarrow[10-20\ ^\circ C]{CsF,\ MeCN} ArH + ArAr + Xe + Me_3SiF$$

Ar = C_6F_5 (**a**), 4-$CF_3C_6F_4$ (**b**), 4-C_5F_4N (**c**), 4-$CF_3C_6H_4$ (**d**).

Arylsilanes **301a**,**b** react similarly with XeF_2 in the presence of anhydrous KF and RbF.[450]

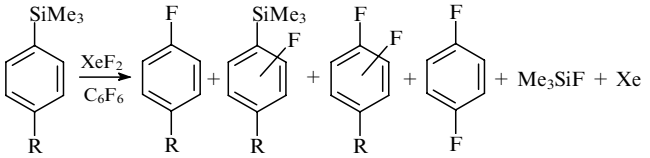
Trimethyl-4-tetrafluoropyridylsilane (**301c**) reacts with XeF_2 very slowly in the absence of a catalyst and within several minutes in the presence of CsF.[450]

In contrast to fluorinated arylsilanes, their hydrocarbon analogues (phenyl-, 4-tolyltrimethylsilane, tetraphenylsilane) do not enter into the reaction with XeF_2 and CsF even on heating at 40–60 °C for several hours.[451] The presence of the electron-withdrawing CF_3 group in (4-trifluoromethylphenyl)trimethylsilane (**301d**) increases its reactivity in comparison with trimethylphenylsilane. It reacts with XeF_2 to give benzotrifluoride and 4,4′-bis(trifluoromethyl)biphenyl, although the conversion is low.[450]

^{19}F CIDNP was used to establish a radical mechanism of the Si–C bond cleavage.[450] This reaction seems to be convenient for generating polyfluoroaryl and polyfluorohetaryl radicals under mild conditions. Chemical reactions occurring in the arylsilane–XeF_2–CsF system and the CIDNP data offer the most probable mechanism for this reaction.

$$C_6F_5SiMe_3 \overset{F^-}{\rightleftharpoons} \left[C_6F_5SiFMe_3\right]^- \xrightarrow[-XeF^{\bullet}, -F^{\bullet}]{XeF_2} \left[C_6F_5SiFMe_3\right]^{\bullet} \xrightarrow[-Me_3SiF]{} [C_6F_5]^{\bullet} \longrightarrow C_6F_5H + C_{12}F_{10}$$

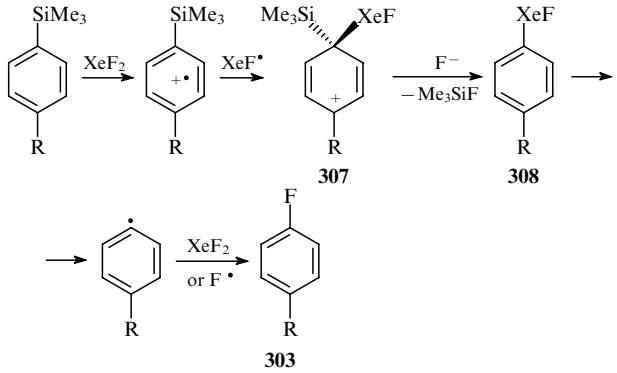
A radical mechanism has also been proposed for the reaction of aryltrimethylsilanes **302a**–**d**.[453] It was shown that compounds **302a**–**d** react with two equivalents of XeF_2 to give the *para*-fluoro derivatives **303**. Moreover, this reaction gives the isomeric monofluoroarylsilanes **304**, the difluorides **305** and 1,4-difluorobenzene (**306**) as is the case with the reaction involving acetyl hypofluorite, the well-known radical fluorinating agent.[453]



302a–d **303a–d** **304a–d** **305a–d** **306**

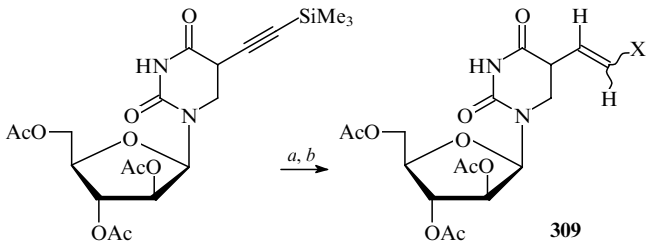
Compounds **302**	R	Yield (%)			
		303	**304**	**305**	**306**
a	H	65	0	0	35
b	Bu^t	86	8	6	0
c	OMe	61	39	0	0
d	Cl	82	12	6	0

This reaction occurs through the formation of the cationoid intermediate **307**, which is stabilised not only due to the β-effect of the silyl substituent but also due to the interaction of the cationic centre with the non-bonding molecular orbital of the hypervalent xenon.[453]



The subsequent reaction with the fluoride anion results in the intermediate **308** (see Section VI) which further yields the aryl fluorides **303a–d**.

Xenon difluoride is a convenient reagent for converting vinyl silanes into vinyl halides. This reaction was used in particular in the synthesis of 5-(2-halovinyl) derivatives of the pyrimidine nucleosides **309**.[454]



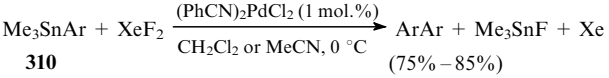
X = $SiMe_3$, I, Br, Cl;

(*a*) $Pd/CaCO_3$, , AcOEt; (*b*) XeF_2, MX (MX = LiCl, LiBr, NaI), PhH.

b. Reactions of organotin compounds with XeF_2

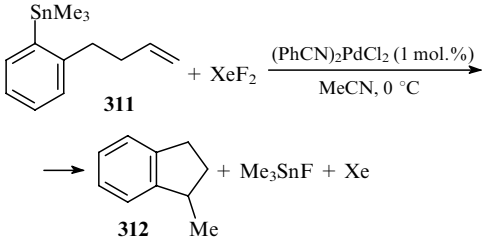
Aryltrimethylstannanes react with XeF_2 with cleavage of the C–Sn bond and can be used for the generation of aryl radicals. Thus trimethyl(phenyl)stannane reacts with XeF_2 rather slowly, *viz*., the conversion of the original compound reaches 80% after 12 h. In the presence of $BF_3 \cdot Et_2O$ as the catalyst, this reaction is strongly accelerated but yields a complex mixture of products.[455]

XeF_2 reacts with aryltrimethylstannanes more selectively in the presence of catalytic amounts of a palladium benzonitrile complex. Thus biaryls are formed in good yields from the aryltrimethylstannanes **310**; the yields of side products (benzene, chlorobenzene) do not exceed 1%–2%.[455]

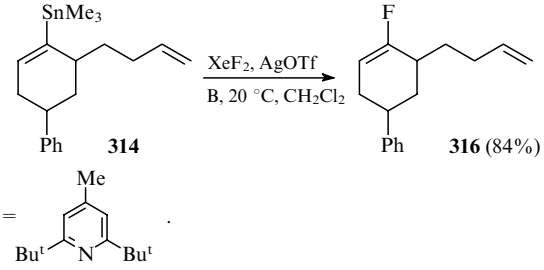


Ar = Ph, 1-naphthyl.

If a molecule contains a functional group which can react with the radical, cascade reactions may be triggered. Thus the reaction of 2-trimethylstannyl(but-3-enyl)benzene (**311**) with XeF_2 in the presence of a Pd complex results in 1-methylindan (**312**) in a satisfactory yield. In this case, no homocoupling reaction occurs.[455]

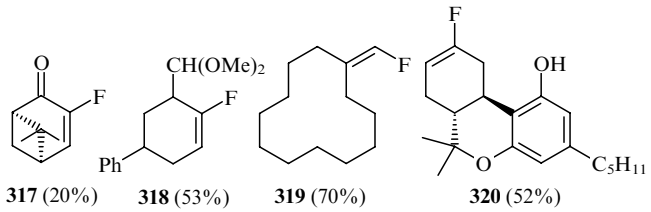


Organotin compounds can be used for the synthesis of organofluorine derivatives.[456–462] Thus the reaction of the vinylstannanes **313** and **314** with XeF_2 in the presence of silver triflate (~1:1.5) and a catalytic amount of 2,6-di-*tert*-butyl-4-methylpyridine in dichloromethane results in the vinyl fluorides **315** and **316**.



It should be noted that in contrast to compound **311**, the stannane **314** does not undergo cyclisation.[463]

Diverse functional groups in the vinylstannane molecule do not inferfere with this reaction. Thus this approach was used for the synthesis of the vinyl fluorides **317–320**.[460–462]



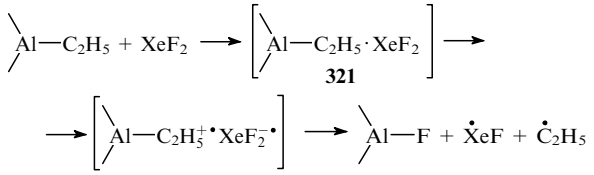
317 (20%) **318** (53%) **319** (70%) **320** (52%)

5. Reactions of XeF_2 with organoaluminium compounds

The oxidation of organoaluminium compounds (OAC) by XeF_2 is an exothermic reaction. Any contact of even small amounts of the reagents in the absence of a solvent brings about an explosion. Oxidation in solutions (toluene appeared to be the most suitable one) is associated with chemiluminescence,[261] which is similar to that observed on oxidation of OAC by oxygen.[464] It was found that this reaction involves exclusively the C–Al or the H–Al bond. The reactions of Et_3Al, $(EtO)_2AlEt$, Et_2AlCl and Bu^i_2AlH with XeF_2 gave Et_2AlF, $(EtO)_2AlF$, EtAlClF and Bu^i_2AlF (yields 95%, 97%, 80% and 79%, respectively). In addition to the above-mentioned products, Xe and C_2H_6 are formed as the main products, while C_2H_4 and C_4H_{10} are formed as admixtures. The AOC : XeF_2 ratio of 2:1 ensures the reaction of XeF_2 with the

most reactive substituent (H, Alk, Cl) bound to Al. The reactivities of the substituents decrease in the following order: H > Alk > Cl.[465]

The mechanism of the reaction of OAC with XeF_2 in toluene was studied in the example of a model compound $(EtO)_2AlEt$ containing only one non-oxidised Al–C bond.[465,466] The redox reaction begins with the formation of the intermediate complex **321** in which the electron is transferred from the OAC to the electrophilic XeF_2.[467] The reactive intermediates, *viz*., $^{\bullet}C_2H_5$ radicals, are converted through three main routes, *viz*., they react with each other to give ethane, ethylene and butane; they attack toluene at the side chain to give bibenzyl or at the aromatic ring to give ethyl-, diethyltoluenes and bitolyls. Chemiluminescence is evoked as a result of excitation and generation of the $^{\bullet}XeF$ radicals formed in the reaction of polarised ethyl radicals with XeF_2.[466,467]

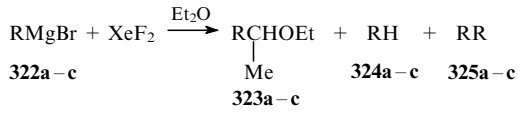


The effects of luminescence activators, *viz*., 9,10-dibromoanthracene, pyrene, *p*-terphenyl and the $[Ru(bipy)_3Cl_2\cdot(OAC)_n]$ complex (bipy is 2,2′-bipyridyl) on the chemiluminescence of the reaction of $(EtO)_2AlEt$ with XeF_2 in solution have been studied.[468] It was shown that enhanced luminescence is a result of involvement of the activator in the oxidation–reduction process.[468]

6. Reactions of XeF_2 with Group II organoelement compounds

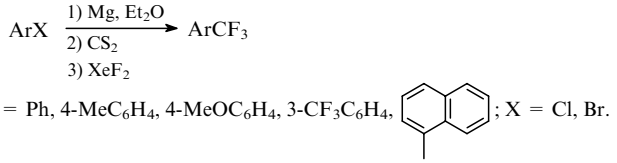
a. Reactions of organomagnesium compounds with XeF_2

The direction of the reactions of the Grignard reagents **322a–c** with XeF_2 in diethyl ether at 20 °C depends on the structure of the substrate. Thus decylmagnesium bromide reacts with XeF_2 to give 2-ethoxydecane (**323a**), decane (**324a**) and eicosane (**325a**) in a total yield 98%. In the case of benzylmagnesium bromide, the total yield of the three main reaction products **323b–325b** is 80%; benzyl bromide was detected among side products. The composition of the reaction mixture is even more complicated in the reaction of phenylmagnesium bromide with XeF_2. In this case, the main products **323c–325c** are formed in a total yield 70% (the side products include bromobenzene, bromophenyl, mono- and dibromoacetophenone, *etc*.).[469]



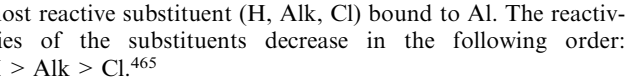
R = n-$C_{10}H_{21}$ (**a**), Bn (**b**), Ph (**c**).

A method for incorporating a trifluoromethyl group into the molecules of aromatic compounds has been proposed[470,471] which includes the conversion of aryl halides (more preferably, bromides) into the corresponding Grignard reagents and their subsequent reaction with carbon disulfide and XeF_2.



b. Reactions of organomercury compounds with XeF_2

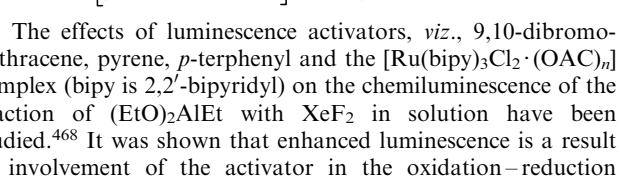
The C–Hg bond in the reaction of XeF_2 with the mercury derivatives R_2Hg is cleaved to yield a mixture of products, such as RHgF (or RHgF + HgF_2), RF, RR, *etc*.[260,472]



R = 4-$MeOC_6H_4$, 4-$Me_2NC_6H_4$, Bn, 4-$EtO_2CC_6H_4$, PhC≡C.

This reaction is carried out in an argon atmosphere to avoid the formation of oxygen-containing products. In the case of di(phenylethynyl)mercury, PhC≡CF is unstable and could not therefore be detected in the reaction mixture. However, indirect evidence for the formation of this compound was obtained upon treatment of the reaction mixture with tetraethylammonium bromide after complete liberation of xenon eventually resulting in PhC≡CBr in 43% yield.[472]

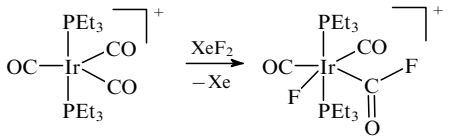
The efficiency of this reaction is judged by the temperature at which the liberation of xenon occurs. The reactivities of R_2Hg were found to decrease in the following order depending on R: $PhCH_2$ > *p*-$Me_2NC_6H_4$ > PhC≡C > *p*-$MeOC_6H_4$ > *p*-EtO_2C–C_6H_4. Hence, XeF_2 acts as an electron acceptor, while R_2Hg acts as an electron donor. Presumably, this reaction is a radical process involving an initial transfer of an electron from R_2Hg to XeF_2. The absence of R_2Hg fluorination products in the reaction mixture suggests that the C–Hg bond is cleaved by XeF_2 more easily than the C–H or C–C bond.[260,472]



It should be noted that XeF_2 also reacts readily with mercury dihalides to give mercury difluoride in a quantitative yield. This reaction occurs especially easily with HgI_2.[472]

7. Reactions of other organometallic compounds with XeF_2

Many metals, *e.g*., iridium, react with XeF_2 to yield metal fluorides.[473] The high oxidation potential of XeF_2 allows the oxidation of carbonyl complexes of some metals. Thus the cationic complex tricarbonylbis(triethylphosphine)iridium(I) **326** reacts with XeF_2 to give the complex **327**.[474]



This approach can be used for preparing fluorinecarbonyl complexes of other metals.

The reactions of $[M_2(CO)_{10}]$ (M = Mn, Re) with $Xe(OTeF_5)_2$ at −78 °C in CH_2Cl_2,[475] and the reactions of $[Os_3(CO)_{12}]$,[476] $[Ir_4(CO)_{12}]$[421,477,478] and $[Ru_3(CO)_{12}]$[479] with XeF_2 in the presence of HF have been studied.

IX. Miscellaneous reactions

It was shown that the fluorination of polyethylene with XeF_2 in liquid media follows a radical mechanism.[480] The oxidation of methane by XeF_2 in aqueous media at 10–25 °C gives a mixture of MeOH (8%), MeF (2%) and CO_2 (50%).[481] The reaction of $CF_3COOXeF$ and $(CF_3COO)_2Xe$ with adamantane and its 1-halogeno (Cl, Br) derivatives results in a mixture of isomeric trifluoroacetoxyadamantanes.[482] The use of a new reagent, *viz*., I_2–XeF_2, has been documented recently.[483] Its application allows one to convert terminal alkenes into geminal difluorides.[484–486] The hypothetical mechanism of this reaction is discussed.[486]

A new line of research in the chemistry of fullerenes associated with their fluorination has evolved and is developing actively.[487] It was found that noble gas fluorides, particularly xenon difluoride, can be successfully used for the fluorination of fullerenes.[487–489]

* * *

The data discussed in the review provide convincing evidence that xenon chemistry is developing successfully and XeF_2 is applicable to miscellaneous synthetic tasks. The reagents based on the xenon derivatives considered in the review surpass well-known classical reagents and can often replace them.

II.	Size effects in single-component systems	266
III.	Heterogeneous multicomponent solid-phase systems (composites)	271
IV.	Mechanochemical synthesis of nanocomposites and nanoparticles	278
V.	Chemical properties of nanoscale systems	280
VI.	Conclusion	282

Abstract. Size effects in single-component and multicomponent solid-phase systems are discussed. Peculiarities of the size effects in microcrystalline and nanoscale systems are analysed. Methods for mechanochemical synthesis of nanoparticles are considered. Chemical properties of nanoscale systems are analysed. Particular attention is paid to the results of studies of the properties of nanocomposites and nanoparticles. Problems concerning their stability and the possibility of mechanochemical synthesis of these systems are discussed. The bibliography includes 175 references.

I. Introduction

The understanding of basic principles and the development of new methods for the synthesis of functional materials with unusual and valuable properties is a key problem of solid state chemistry. Currently, 'dry' (*i.e.*, partially or completely solvent-free) technologies are known to be the most efficient and ecologically safe way to carry out chemical reactions.[1]

Mechanochemical processes meet this requirement. A mechanochemical reaction is a multistage process proceeding by a complex mechanism, which requires that many factors be taken into account when optimising the conditions for mechanical activation of reactants. The mechanism of a mechanochemical reaction involves the following main stages: initial deformation of the crystal structures of reactants; formation and accumulation of both point and linear defects and interaction between them; dispersion of the reactants into blocks; formation of intermediate metastable states in the regions of phase contacts and, finally, chemical homogenisation of the reaction product followed by its relaxation to reach a thermodynamically equilibrium state.

These processes have been best studied for metals where mechanochemical reactions proceed with relative ease. However, the results of recent investigations showed that ionic and molecular crystals are also promising objects for studying mechanochemical processes. In ionic crystals, the charge and potential of the double electrical layers on the phase boundaries have a pronounced effect on the interphase interaction. In molecular crystals, there is a broad spectrum of chemical bonds differing in nature, direction and energy and each type of these bonds is characterised by a specific response to mechanical treatment. By varying the type and positions of functional groups in the molecules of the crystal one can control the mechanism of mechanochemical reactions, which is of great importance for the synthesis of advanced materials.

Mechanical activation of heterogeneous mixtures allows preparation of nanocomposites with unusual properties, including supramolecular systems. Supramolecular nanoscale systems comprise chemically active components (substrates) bound to particular atoms or molecular groups of the carrier matrices (receptors) by non-covalent interactions. Such systems have been poorly studied as yet; however, a novel class of materials based on them has been designed. Unique properties of these materials are due to both specific types of intramolecular and intermolecular interactions in the bulk of the substrate and the character of the receptor – substrate interactions. Here, the role of receptor can be played by either the molecular fragments or by a particular sublattice in the crystal structure of the reactant (intercalated compounds or 'guest – host' inclusion compounds), or by active groups on the surface of heterogeneous inclusions, which favour the formation of, *e.g.*, Langmuir films or other surface layers.

A salient feature of supramolecular heterogeneous systems is the strong interface interaction, which depends on many interrelated factors including chemical, structural, morphological and thermodynamic ones. This interaction is responsible for the structural rearrangement in the substrate and for the changes in its thermodynamic, transport and chemical properties. In certain systems, the cationic or protonic conductivity of an ionic salt (substrate) can increase by several orders of magnitude and unusual phases can be stabilised in the receptor – substrate contact region. For instance, composites of the ionic salt – oxide type are candidates for the synthesis of supramolecular solid electrolytes based on them. Of considerable interest are also heterogeneous systems of the molecular crystal – oxide type.

Theoretical analysis of the mechanism of the surface interaction between different phases is a complicated problem. Currently, the properties of intergrain and phase boundaries in metals have been fairly well investigated. However, the ionic crystal – oxide or molecular crystal – oxide interfaces are still inadequately explored both experimentally and theoretically. Experimental studies are hampered by the problems of controlling the morphol-

ogy of the composite, which leads to irreproducibility of the results obtained. Modern calculations require the inclusion of the contributions of not only covalent, hydrogen and van der Waals interactions but also long-range Coulomb and dipole–dipole interactions, which makes them rather difficult. Moreover, consideration of characteristic features of real interface structures is also of great importance. Nevertheless, one can carry out trial calculations of the energetically favourable surface configurations for systems of the molecular crystal (substrate)–oxide (receptor) type using the known model interaction potentials. Such estimates would be useful for targeted search of a substrate for a particular receptor.

Since the action range of surface forces is confined to a thin near-surface layer, one can expect that nanocomposites will hold the greatest promise for the synthesis of supramolecular systems. Nanocomposites are heterophasic systems, which represent dense aggregates of nanoparticles of both phases, which are uniformly distributed in the bulk. The particle size of a nanocomposite does not exceed 10 nm. In nanocomposites, virtually the whole bulk of the substrate is in the interface region, which allows experimental investigations of its physicochemical properties at the nanoscale level. To date, the properties of nanocomposites have been poorly studied, since the preparation of these systems by conventional methods is an extremely complicated task. Mechanical activation facilitates considerably the grinding of the active component and its spreading over the oxide (receptor) surface, thus favouring strong adhesive interaction.

It is known that the physical and chemical properties of solids change as the particle size decreases. These types of phenomena are usually called size effects. Numerous papers dealing with theoretical and experimental studies of size effects have appeared (see, *e.g.*, reviews [2–13]). Currently, it has been reliably shown that size effects are inherent in all solids; some phenomenological models have been proposed for qualitative or semiquantitative description of these effects.

Size effects have been best studied for metals and to a lesser degree for ionic crystals. For many materials, size effects are observed at relatively large grain size. For instance, the diffusion coefficient, conductivity and mechanical properties of a material become dependent on the average grain size (L) for $L \sim 10^3 - 10^4$ nm; as L reduces to $10 - 10^2$ nm, the melting temperature decreases and a change in the crystal lattice parameter of the material is observed. Size effect is most pronounced in nanoscale dispersed systems with a characteristic particle size in the range from 1 to 10 nm. In this case, the properties of the material can change basically, *e.g.*, it can undergo a transformation into a high-temperature phase or another high-energy state, which cannot be realised under standard conditions.

In heterogeneous systems, size effects depend on some additional factors such as the chemical nature of the components of the heterogeneous mixture, the particle morphology (spatial distribution of the components in the bulk of the composite) and the interface interaction. Consideration of these factors is a complicated problem and no satisfactory theoretical model for the description of size effects in composites has been proposed so far. The most pronounced changes in the properties are observed in both pure substances (undoped homogeneous individual compounds) and nanocomposites if the average particle size in these systems is less than 10 nm.

Recently, the interest increased in the studies of unusual effects observed in nanoscale systems. This is not surprising since the processes proceeding in such systems serve as the basis for future solid-state nanotechnologies. However, chemical reactions in solid-phase mixtures are still the least investigated aspect of solid state chemistry. This is to a great extent due to the necessity of taking into account specific features of small particles involved or formed in the reactions. For instance, the reaction system can become a nanocomposite where the properties of reactants differ substantially from those at equilibrium in the stage of nucleation of the reaction product phase. In this review, we tried to describe the most plausible mechanisms of the influence of size effects on the course of physicochemical (including mechanochemical) processes in heterogeneous solid-phase systems. In presenting the material, we pass from simple systems to more complex ones. First, size effects in isolated particles of simple substances are considered. Then, we discuss size effects in ensembles of small particles, in heterogeneous systems of different morphologies and in the nanoparticles formed in the initial stages of heterogeneous chemical reactions and prepared by mechanical activation.

II. Size effects in single-component systems

Size effects can be arbitrarily divided into two types. Weak effects where insignificant changes in the physicochemical properties of a substance are observed with an increase in the specific surface area (*i.e.*, with reduction of the particle size) belong to the first type of size effects. Here, all the changes observed can be explained by surface effects. As a rule, these effects are usually observed in crystals with a characteristic size exceeding 10 nm. These systems will be referred to as microcrystalline ones.

Strong effects where dramatic changes in the properties of a substance cannot be interpreted in terms of conventional surface phenomena belong to the second type of size effects. Most often, they are observed for very fine particles with a characteristic size of less than 10 nm. These systems will be referred to as nanoscale ones.

In this review, we will compare these two types of size effects and follow a gradual transformation of microcrystalline systems into nanoscale ones.

1. Microcrystalline systems

It has been experimentally shown that physicochemical properties of substances change noticeably as the particle size changes in the range from 10 to 100 nm. As mentioned above, the effects observed in this case are explained by the influence of the surface on the properties of crystals. As L decreases, the fraction of surface atoms increases. A 10 nm isotropic crystal of a simple substance has $\sim 1\% - 5\%$ of the atoms on the surface. The classical Gibbs thermodynamics treats all the excess thermodynamic characteristics of such fine particles, which differ from the corresponding bulk values, as being due to surface effects.

Let us consider a small particle of a substance. Ignoring adsorption, the excess Gibbs free energy, ΔG, per unit area of the tension surface is the surface tension γ of the substance. For an isotropic medium (*e.g.*, a liquid), γ equals the surface energy of the substance, σ. If the particle size (here, the diameter of a drop of the liquid) is much larger than the characteristic molecular size, the tension surface virtually matches the geometric surface of the particle. For a spherical particle, the excess energy is

$$G_s = \gamma A = \sigma A = \sigma \frac{6V}{L}, \tag{1}$$

where A, V and L are the surface area, volume and diameter of the particle, respectively. Generally, the surface tension, $\hat{\gamma}$, of a phase in an anisotropic medium is a tensor quantity. For a slightly curved surface, it is defined as the difference between the proper local value of the stress tensor, $\hat{E}$, and its bulk value, $\hat{E}_\alpha$, extrapolated to the same point and is found by integration

$$\hat{\gamma} = \int_{-\infty}^{\infty} (\hat{E} - \hat{E}_\alpha) \mathrm{d}z, \tag{2}$$

where z is the coordinate normal to the surface of the layer. The absolute value of γ is defined as half the spur (trace) of the surface tension tensor

$$\gamma = \frac{1}{2} \mathrm{Tr} \langle \hat{\gamma} \rangle = \frac{1}{2} (\gamma_{11} + \gamma_{22}). \tag{3}$$

For a liquid or an isotropic medium, $\gamma = \gamma_{11} = \gamma_{22}$ and expression (1) holds. In the crystalline phase, the surface area

can be increased in two independent ways, *viz*., by increasing the number of surface atoms and by elastic deformation of a crystal. A specific feature of a solid is the presence of an immobile structural component, the chemical potential of which is considered to be a tensor quantity.[14,15] Nonuniformity of the chemical potential distribution over the surface layer of the crystal can lead to substantial difference between the surface tension at and surface energy of different surface areas. Owing to anisotropy of the crystal lattice, each face of the crystal is characterised by its own values of the surface tension and surface energy. In addition to the crystal faces, some contribution to the excess energy of the crystal also comes from the excess energy due to the presence of edges and vertices. Assuming an ideally smooth surface, the surface tension of *i*th crystal face is related to the surface energy by the following relationship

$$\gamma_i = \sigma_i + A_i \frac{\mathrm{d}\sigma_i}{\mathrm{d}A_i}. \tag{4}$$

The effective surface energy of a crystal with N faces, M edges and Z vertices equals [16]

$$\sigma = \left(\sum_i^N \sigma_i A_i + \sum_j^M k_j l_j + \sum_k^Z \varepsilon_k \right) A^{-1}, \tag{5}$$

where k_j is the energy of formation of the jth edge, l_j is the length of the jth edge, ε_k is the energy of formation of the kth vertex (these parameters depend on the crystal shape) and $A = \sum A_i$ is the total tension surface area. The terms in formula (5) describe the contributions of crystal faces, edges and vertices to the excess energy of the crystal ignoring surface stress. For a crystal with an equilibrium shape,

$$\sigma \approx \frac{3V}{A} \frac{\sigma_i}{h_i},$$

where h_i is the distance from the Wulf point to the ith crystal face. It is appropriate to choose the parameter [16]

$$L = \frac{6V}{A} \tag{6}$$

as the characteristic crystal size.

If the parameters σ and L of a crystal are defined by formulae (5) and (6), an additional term can be entered into Eqn (1) and it can be rewritten in the form

$$G_\mathrm{s} = \gamma A = \sigma A + \Delta G_\mathrm{e} = \sigma \frac{6V}{L} + \Delta G_\mathrm{e}, \tag{7}$$

where ΔG_e is the elastic strain energy

$$\Delta G_\mathrm{e} \approx \sum A_i \frac{\mathrm{d}\sigma_i}{\mathrm{d}A_i}.$$

In real microcrystals, the ΔG_e value depends on many factors such as the crystal shape, the tension surface area A, the type of lattice symmetry, presence of defects in the crystal, *etc*. Estimation of the elastic strain energy in real crystals is a complicated problem. Expression (7) holds for both the liquid and crystalline phases (note that the contribution of elastic strain energy is nonzero only in crystals, since for liquid $\Delta G_\mathrm{e} = 0$).

As follows from the general thermodynamic expression for the Gibbs free energy,

$$G(P,T,A) = U + PV - TS + \sigma A + \Delta G_\mathrm{e}(A), \tag{8}$$

where U, V, S are the internal energy, volume and entropy of a crystal at a pressure P and temperature T, the surface area of the crystal plays the role of an additional external parameter that defines the thermodynamic properties of the material.

If the substance is highly dispersed, the contributions of the surface-dependent terms become noticeable. This leads to specific size effects such as changes in the crystal lattice parameters, low-temperature (at temperatures close to 0 K) heat capacity, the Debye temperature, phase transition temperatures and stabilisation of unusual phases. The electronic structure of the substance also changes, which is responsible for unusual optical, electrical and magnetic properties.

Among all the size effects, the effect of a decrease in the phase transition (*e.g*., melting) temperature, T_t, of small particles has been studied in most detail. Transition temperatures are determined assuming that the corresponding phases have equal Gibbs energies. In the framework of the classical Thomson model for an isolated particle, the relative change of T_t is a linear function of $1/L$ (see Refs 17–19).

$$\frac{T_\mathrm{t}}{T_\mathrm{t}^0} = 1 - \frac{6(\gamma_\alpha V_\alpha - \gamma_\beta V_\beta)}{H_\mathrm{t}} \frac{1}{L}, \tag{9}$$

where T_t^0 and H_t are the temperature and enthalpy of the phase transition from the high-temperature α-phase to the low-temperature β-phase, respectively; γ_α and γ_β are the surface tensions of the α- and β-phases at temperature T_t, respectively; and V_α and V_β are the molar volumes of the α- and β-phases, respectively. Deviation of the experimental dependences of $T_\mathrm{t}/T_\mathrm{t}^0$ on $1/L$ from linear ones can be explained by the formation of a thin film of the liquid phase on the surface of a crystal owing to melting of small particles,[20] by the dependence of γ_α and γ_β on the particle size [21] or by the contribution of elastic strain energy $\Delta G_\mathrm{e}(A)$.[11] In the last-mentioned case, Eqn (9) can be represented in the form

$$\frac{T_\mathrm{t}}{T_\mathrm{t}^0} = 1 - \frac{6(\sigma_\alpha V_\alpha - \sigma_\beta V_\beta)L^{-1} + \Delta G_\mathrm{e}(L)}{H_\mathrm{t}}, \tag{10}$$

where σ_α and σ_β are the specific surface energies of the α- and β-phases, respectively. From Eqn (10) it follows that the transition temperature depends not only on the particle size and specific surface energy, but also on the change in the molar volume, the elastic strain energy difference between two phases, $\Delta G_\mathrm{e}(L)$, and the enthalpy of the phase transition. In the case of melting, the term $\Delta G_\mathrm{e}(L)$ includes the contribution of elastic strain energy of the crystalline phase at the melting temperature.

Neglecting the ΔG_e contribution allows construction of the phase diagrams of a substance in the T–$(1/L)$ coordinates. They can be used not only for the estimation of changes in the transition temperatures, but also for the prediction of the phase size effect with a decrease in the crystal size below a certain critical value.[6,7,13] This effect manifests itself in, *e.g*., stabilisation of new phases which are atypical of the macrocrystal. Currently, numerous experimental studies have confirmed the existence of phase size effects in both films [6,7] and polycrystalline samples.[11,13] For instance, the equilibrium crystal structure of Al_2O_3 was found to be dependent on particle size. If the radius of alumina particles does not exceed 35 nm, the γ-phase is stable; if the particle size increases, γ-Al_2O_3 undergoes transformations into β-, ε-, θ- and α-Al_2O_3.[8] The formation of amorphous phases in a number of systems can also be due to size effects.[7,22,23]

In the early studies on size effects, changes in the crystal structure of small particles were explained by the effect of excess pressure,

$$\Delta p = \frac{4\gamma}{L},$$

produced owing to surface tension.[2,4] Indeed, isolated particles of many metals, alkali metal halides, oxides and nitrides exhibit a monotonic decrease in the lattice parameter with a decrease in L, which corresponds to positive Δp values. However, the unit cell parameters of nanocrystals (*e.g*., Si, Se, Cr and Pd) increase as the particle size decreases.[3] Most often, a decrease in L leads to stabilisation of high-temperature modifications rather than high-pressure phases. An explanation [24] of this fact involves the assumption of the effective negative pressure in small particles, so that the classical concept of the Laplacian pressure cannot be generally used to describe their properties.

Recently, intensive research has been carried aimed at the synthesis of highly dispersed materials such as metals, oxides, ceramics and high-melting compounds. Currently, substances with the characteristic particle size of less than 100 nm are usually classified as nanocrystalline materials.[25,26] Most of the systems studied to date are characterised by a grain size, L, ranging from 10 to 100 nm and their properties differ insignificantly from those of large crystallites. Hence, they should be considered as microcrystalline rather than nanoscale systems. As will be shown below, the systems with a particle size smaller than 10 nm can be classified as nanoscale ones. Diverse morphologies of, *e.g.*, the particles of ceramic materials complicate the problem of description of their physical properties using a unified approach. Particular effects, such as the appearance of additional contribution to the heat capacity, a decrease in the Debye temperature, an increase in the coefficients of thermal expansion and enhanced diffusion depend on the state of intergrain boundaries and can be described in the framework of an additive model which takes into account the contributions of the bulk and the surface to the physical properties of a material. In this case, the intergrain boundaries and pores in the material can be considered as specific metastable phases, the concentrations of which increase as L decreases. On the other hand, such characteristics as the magnitude of microstresses or elastic properties of the materials under study are strongly dependent on the prehistory of a sample (*viz.*, on the procedure for its preparation and heat or mechanical pretreatment). For samples with relatively large grain size, these properties can be satisfactorily described using the Hall–Petch model. As the grain size becomes less than 10 nm, the response of the dislocation structure, formed owing to the presence of intergrain boundaries, to mechanical action becomes hardly predictable;[8,12,27] however, this can also be due to inadequate experimental procedures employed in studies of these materials.

2. Nanoscale systems

Numerous experimental studies have shown that if the particle size is less than the critical size $L_c \sim 10$ nm, the bulk properties of materials change noticeably. A particle of size $L \approx 10$ nm contains 10^4-10^5 atoms, of which 1%–5% are on the surface of the particle and contribute largely to the physicochemical properties. Ensembles of such particles form nanoscale (nanocrystalline) systems in which the following characteristic effects are observed.

1. Structural changes. If $L < L_c$, the average interatomic distance in the crystal changes dramatically and the crystal lattice parameter a becomes dependent on L. In the near-surface layer, the interplanar spacings along the normal to the surface are smaller than in the bulk of the crystal,[3,4] which is due to the nonsymmetrical action of interatomic forces on the near-surface atoms. High-resolution electron microscopy (HREM) studies have shown that the region of noticeable changes in the lattice parameter is confined to five or six atomic planes and has a characteristic size $\lambda_s \sim 1-3$ nm. The same values have been obtained in calculations on alkali halide crystals.[28,29] The λ_s value can be considered as the action range of surface forces or the effective thickness of the crystal surface. The entire near-surface region of thickness λ_s is in the state that is characteristic of the surface and the crystal structure of this region depends on particular characteristics of the surface. In this connection, mention may be made that the structure of, *e.g.*, nanoscale particles of metal glasses, which is experimentally determined from the radial distribution functions, differs from the structure of the same glasses in bulk specimens.[10]

2. Changes in thermodynamic properties. In nanocrystalline systems, the Debye temperature decreases and an additional contribution to the low-temperature heat capacity of the material appears, which increases as the particle size decreases.[2,11,12,30] These effects can be explained by changes in the vibrational states of the nanocrystal,[3,4,12] namely, by 'softening' of the spectrum (an increase in the number of low-frequency modes owing to a decrease in the number of high-frequency modes) with a decrease in L. Qualitatively, 'softening' of spectra can be explained by the action of the pure surface effects: the atoms on the surface of a bulk crystal are characterised by increased amplitudes and lower vibration frequencies. However, analysis of the behaviour of the atomic Debye–Waller factors using the data of X-ray diffraction study has shown[3] that changes in the Debye temperature in nanocrystals cannot be explained only by the contribution of the vibrations of the surface atoms since a decrease in L causes a stronger lattice 'softening' than it could be expected. This means that not only the vibrational frequencies of the surface atoms, but also those of the atoms in the bulk of the nanocrystal are lowered. Yet another interesting feature of nanocrystals is that both the entropy of melting and the melting temperature decrease as L decreases.[11] Since changes in the vibrational entropy makes the major contribution to the entropy of melting, this effect is also explained by the 'softening' of the lattice of the nanocrystal with the decrease in its size.

3. Phase size effect. This is an example of a specific type of manifestation of structural and thermodynamic changes in materials. Phase size effect is most pronounced in nanoscale systems. A decrease in L down to 10–100 nm leads to stabilisation of high-temperature phases in both nanocrystals and microcrystals. In some instances, phases that are not characteristic of a given substance (including the amorphous phase) can be formed.[2,6,7,8] Structural data for even smaller particles are lacking; however, numerous theoretical studies suggest that simple substances (metals, inert gases) occur in the form of polyatomic clusters as the particle size reduces to several nanometres.[3,4,31,32]

4. Changes in the electronic properties of materials. Among the effects experimentally observed in nanoscale systems, the quantum size effect[4,7,33,34] seems to be the most interesting for chemistry. If the size of a crystal is comparable with the de Broglie wavelength of elementary excitations, the quantisation conditions of electron energy are changed and the energy bands split into a system of energy levels (Fig. 1). In semimetals, this effect leads to the appearance of low-temperature oscillations of the kinetic coefficients and optical absorption with a decrease in the thickness of specimens (films).[7] In wide-band semiconductor crystals, electronic excitation results in the formation of loosely bound electron–hole pairs. In this case, the quantum size effect manifests itself markedly as changes in the optical spectra, namely, reduction of L leads to an increase in both the energy at the maximum of the absorption band and the exciton peak intensity and to a shift of the luminescence spectrum towards the short-wavelength region. The pattern of the absorption spectrum becomes similar to that of the spectra of individual macromolecules. Semiconductor nanocrystals possessing these properties are called 'quantum dots'; they can be used in optoelectronics and are currently

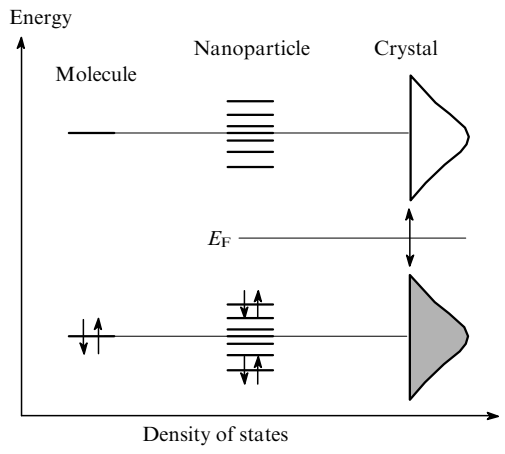

Figure 1. Electronic spectra of an isolated molecule, a nanoparticle and a semiconductor crystal. E_F is the Fermi level.

intensively studied.[33,34] As the size of ferromagnetic crystals reduces to $\sim 10-100$ nm, the coercive force increases and a decrease in the Curie temperature is observed. However, further decrease in the particle size causes a decrease in the coercive force and disappearance of ferromagnetic properties owing to the effect of superparamagnetism.[4] Ferromagnetic clusters with sizes of the order of several nanometres or layered structures with the layer thicknesses of the same order of magnitude possess abnormally high magnetoresistance coefficients.[35–37]

The above-mentioned effects can hardly be explained in the framework of the commonly accepted theory of surface phenomena. A correct mention has been made [3] that the concept of surface tension loses its meaning in the case of nanocrystals since all atoms can be treated as surface ones. Changes in the interatomic distances in small particles are mainly due to the decrease in the number of atoms in the particle,[3] which means that the size effect is a collective property of all the atoms constituting the particle. Therefore, it is helpful to follow the changes in the properties of materials on going from molecules to clusters, then to nanocrystals and, finally, to conventional bulk crystals in order to gain a deeper insight into the phenomena observed.

Let us consider pure substances with a Lennard-Jones potential of the interatomic interaction. If the number of atoms in a particle, N, is small ($N \leqslant 7$), regular polyhedral clusters are formed. If $7 < N < 13$, a large number of isomeric forms of the clusters exists, the energies of the isomers being only slightly different. If $N = 13$, a relatively stable icosahedral cluster is formed. Using this cluster as a 'seed', one can obtain larger icosahedral clusters with $N = 55$, 147, 309, 561, *etc*., by building up the atomic layers on the cluster faces.[3,4,31,32] Seldom, can large crystals of the icosahedral phase (quasicrystals) be obtained.[38,39] In addition to icosahedral clusters, pentagondodecahedral ones are also relatively stable. Owing to the presence of the five-fold symmetry axes, an increase in the cluster size should inevitably result in the development of elastic strain. According to theoretical estimates, the icosahedral and dodecahedral structures become unstable for $N \approx 500$, which corresponds to the particle size $L > \sim 2$ nm. In this case, the particle is broken into tetrahedral blocks with a close-packed, face-centred cubic (fcc) structure separated by defect domains such as systems of twin boundaries, dislocations and disclinations.[4,40] These defects provide the thermodynamic stability of the particle; in other words, small crystalline particles with imperfect structure are in the thermodynamically equilibrium state. Further increase in N leads to stabilsation of the defect-free Wulf polyhedra, the shape of which is determined from the minimum condition for the surface energy of the crystal.

Thus, each substance is characterised by two 'threshold' lengths denoted as L_1 and L_2. If the particle size of a substance is less than L_1, the particle spontaneously breaks down into nanocrystalline blocks. If $L < L_2$, a phase transition into an X-ray amorphous phase (ensemble of clusters) occurs in the particle. It should be mentioned that for small particles there is a great number of different atomic configurations with close energies.[41] This makes the concept of the equilibrium state of a particle ambiguous and is responsible for a gradual, diffuse character of phase transitions in the nanoscale systems. In particular, melting of clusters is considered as a dynamic equilibrium between the 'solidlike' and 'liquidlike' clusters that coexist at any temperature.[41,42]

On going from individual clusters to ensemble of nanoparticles, the effect of intergrain boundaries on the physicochemical properties of the ensemble becomes noticeable. Since the number of surface atoms in a nanoparticle is comparable with that in the bulk, in the case of random packing of particles the structure of each crystallite is 'tuned' to correspond to the local environment, which leads to effective broadening of the intergrain boundaries. Information on the structure of intergrain boundaries in nanoscale materials is contradictory. Both strongly disordered boundaries with a loose amorphous structure [9,10] and the boundaries with relatively high concentration of atoms (typical of bulk polycrystals) are observed.[12] In a 10 nm nanocrystal with an intergrain boundary width of 0.5–1 nm, the fraction of the atoms situated on these boundaries reaches 15%–30% of the total number of atoms.[10,12] Depending on the conditions for the preparation and annealing of ceramic nanoparticles, the structures of the intergrain boundaries can be different. Freshly prepared specimens have more disordered structures compared to either sintered or simply stored specimens in which the boundary atoms are ordered to form conventional intergrain boundaries. This is accompanied by the growth of crystallites owing to a decrease in the concentration of disordered boundary atoms. According to molecular dynamics calculations of model ensembles using the Coulomb or Lennard-Jones interatomic potentials,[43,44] these relaxation processes should be observed after intense mechanical deformation of nanoscale systems.

3. Transport properties of microcrystals and nanocrystals

Polycrystalline materials are characterised by increased mobility of atoms. This has been confirmed in studies on the kinetics of sintering and recrystallisation,[45] diffusion of radioactive isotopes [46] and ionic conductivity.[47,48] In bulk crystals, diffusion and mass transfer occur by migration of point defects which has an activation character. Earlier, enhanced diffusion in fine crystallites was thought to be due to changes in the concentration of vacancies caused by curvature of the crystallite surface. In fact, the expression for the excess concentration of point defects in a metal near the curved surface, $[V_M]$, obtained using the Thomson–Kelvin equation for the equilibrium of vacancies in crystal, has the form [45]

$$[V_M] = [V_M]_\infty \exp\left(-\frac{2\gamma\upsilon}{RkT}\right) = [V_M]_\infty \exp\left(-\frac{Q}{kT}\right), \qquad (11)$$

where $[V_M]_\infty$ is the concentration of defects in the bulk and R is the radius of curvature. If $\gamma = 100$ erg cm^{-2} and $\upsilon = 10$ cm^3 mol^{-1}, the curvature of the surface makes an additional contribution, Q, of 0.003 eV ($R = 10$ nm) and 0.03 eV ($R = 1$ nm) to the energy of formation of defects. This effect can lead to a noticeable increase in the concentration of defects only in very fine particles with the size of about 1 nm.

Currently, it is accepted that the activation energy of grain boundary diffusion in metals is lower than that of bulk diffusion; this is explained by the relatively loose local grain boundary structure and by high concentration of boundary defects.[10,46] The formation of a defect in the bulk of a metal involves two stages,[49] namely, the formation of a pair comprising an excess atom above the surface and a vacancy in the surface layer and detachment of the vacancy from the surface followed by its diffusion into the interior of the metal. This is illustrated in Fig. 2 in which the plots of changes in the free energy of the crystal upon the formation of a surface vacancy and its diffusion into the bulk of the metal are also presented. In the first stage, surface disordering occurs: the metal atom M goes out of the surface layer on the outer surface of the crystal, which leads to the formation of a pair of defects, *viz*., the adatom, M_s, and a vacancy in the surface layer, V_{Ms}. The concentration of defects on the surface, $[V_{Ms}]$, and in the bulk, $[V_M]_\infty$, are determined by the corresponding energies of formation (g_s and g_0, respectively)

$$[V_{Ms}] = [M_s] = \exp\left(-\frac{g_s}{2kT}\right), \qquad (12)$$

$$[V_M]_\infty = \exp\left(-\frac{g_0}{kT}\right). \qquad (13)$$

Surface diffusion can occur owing to both migration of atoms over the outer surface and migration of vacancies within the surface layer. In polycrystals, the role of the outer surface is played

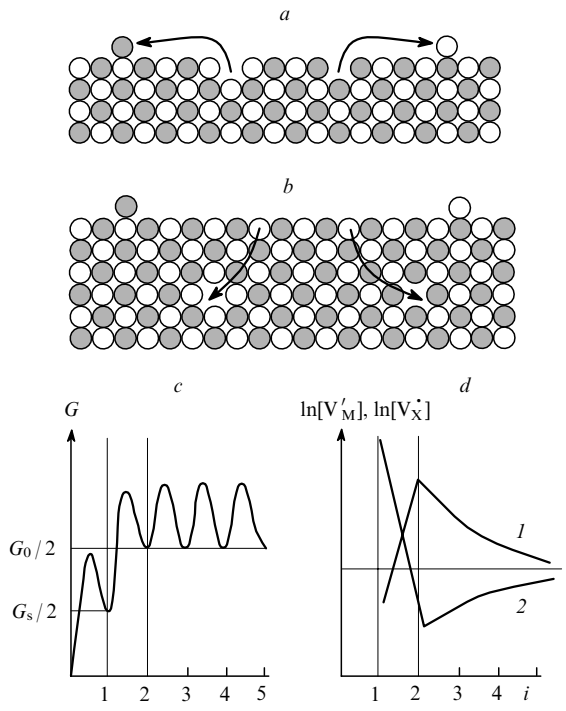

Figure 2. Schematic representation of the elementary act of surface disordering (*a*) and the formation of a Schottky defect in the bulk of a crystal (*b*) as well as change in the Gibbs free energy of the crystal upon the formation of a defect (*c*) and the spatial distribution of defects in the near-surface layer of the ionic crystal of the MX type (*d*).
$[V'_M]$ is the concentration of cationic vacancies (*1*), $[V^{\bullet}_X]$ is the concentration of anionic vacancies (*2*); *i* is the order number of the near-surface layer along the normal to the surface directed into the interior of the crystal ($i = 1$ corresponds to the outer surface of the crystal).

by the intergrain boundaries; in this case, $[M_s] \approx 1$ and surface disordering is described by the equation

$$[V_{Ms}] = \exp\left(-\frac{g_s}{kT}\right). \tag{14}$$

The energy of formation of a defect and, hence, the concentration of defects in the bulk of the crystal are determined by the fundamental properties of matter rather than surface disordering. On the contrary, the g_s value can vary between 0 and g_0 depending of many factors such as orientation of the surface, the type of intergrain boundary, adsorption of impurities on the surface, *etc*.[50] Hence, the activation energy of surface diffusion should depend on the procedure for the preparation of a given material.

In ionic crystals of the MX type, surface disordering is accompanied by the formation of the electrical double layer since both cationic (V'_{Ms}) and anionic ($V^{\bullet}_{Xs}$) vacancies within the surface layer can be formed independently in accordance with the equations of quasichemical reactions

$$0 \rightleftarrows V'_{Ms} + M^{\bullet}_s, \tag{15}$$

$$0 \rightleftarrows V^{\bullet}_{Xs} + X'_s \tag{16}$$

(here, zero corresponds to a perfect crystal).

As in the case of metals, the concentration of uncharged surface defects should be completely determined by the energy of formation of these defects

$$g_s = (g_{V_M})_s + (g_{V_X})_s.$$

However,

$$(g_{V_M})_s \neq (g_{V_X})_s,$$

hence, an excess surface charge and the corresponding surface potential φ_s appear. The magnitude of φ_s depends on the energy difference between the quasichemical surface disordering reactions:[50]

$$\varphi_s = \frac{(g_{V_X})_s - (g_{V_M})_s}{2e}. \tag{17}$$

The concentration of the Schottky defects in the bulk of a crystal is determined by the equilibrium constant of a quasichemical reaction involving the formation energy of bulk defects of g_0,

$$0 \rightleftarrows V'_{M\infty} + V^{\bullet}_{X\infty}. \tag{18}$$

The concentrations of defects on the surface,

$$[V'_{Ms}] = [V'_{M\infty}] \exp\left(\frac{g_0 - g_s}{2kT} + \frac{e\varphi_s}{kT}\right), \tag{19}$$

$$[V^{\bullet}_{Xs}] = [V^{\bullet}_{X\infty}] \exp\left(\frac{g_0 - g_s}{2kT} - \frac{e\varphi_s}{kT}\right) \tag{20}$$

depend on both the surface potential (17) and the additional contribution of the surface disordering. In the absence of the latter, (*i.e*., in a particular case $g_0 = g_s$), Eqns (19) and (20) coincide with the expressions obtained in the framework of Frenkel's model.[51, 52] Analogous expressions can also be obtained for crystals with Frenkel defects.

The parameter φ_s can be considered as the potential jump at the crystal – vacuum interface; this takes into account the properties of the surface, in particular, specific adsorption of charged particles (vacancies) on the surface. The defects localised on the surface can form a dense diffusion layer. At low concentrations of defects, the properties of this layer (or the space charge region) are described in the framework of the Gouy – Chapman model. The concentration of defects in the diffusion layer is calculated using the Poisson – Boltzmann equation which relates the space charge to the potential. The simplified expression for the ionic conductivity due to the electrical double layer has the form [53]

$$\varkappa = \frac{B}{L} T^{-1/2} \exp\left[\left(-\frac{h_0}{4} + \frac{e\varphi_s}{2} - E_m\right)(kT)^{-1}\right], \tag{21}$$

where B is the constant which includes all temperature-independent terms, h_0 is the enthalpy of formation of the defect, E_m is the migration energy of the defects that form the electrical double layer; for simplicity, the entropy contribution to φ_s is taken as zero. The expression for the conductivity of the diffusion layer written in the coordinates of the Arrhenius equation has the form:

$$\log(\varkappa T^{1/2}) = \log\frac{B}{L} - \frac{E_a}{kT},$$

where the activation energy of conductivity is

$$E_a = \frac{h_0}{4} - \frac{e\varphi_s}{2} + E_m.$$

Two regions corresponding to the high-temperature and low-temperature conductivities can be seen on the plot of experimental temperature dependence of the conductivity of a polycrystalline ionic salt. The former corresponds to the intrinsic conductivity, while the latter is due to the contribution of surface defects and is described by Eqn (21).

The mobility and transport properties of atoms in small crystals or in clusters have not been studied so far. Nevertheless, computer simulation predicts high mobilities of the atoms and points out that a distinctive feature of the mechanism of migration is its collective character.[3, 54] This has been confirmed by the results of experimental studies of nanocrystalline powders of pure substances.[55–57] For instance, the coefficient of self-diffusion in

copper nanocrystals at 271 K is 14 to 20 orders of magnitude greater than in conventional bulk copper.[55] An analogous effect was also found in studies of bulk diffusion in nickel nanocrystals.[56]

However, one should treat the interpretation of the results obtained in studies of self-diffusion with caution. A critical analysis [58] of the experimental results obtained in a study of diffusion in Cu, TiO_2 and Pd nanocrystals [57] has shown that correct consideration of the diffusion 'suction' into the bulk of the crystal makes the coefficient of surface diffusion in Cu nanocrystals typical of polycrystalline copper rather than abnormally high. It has also been mentioned [58] that the coefficients of oxygen diffusion in TiO_2 nanocrystals are 5–6 orders of magnitude greater than in bulk crystals and that the coefficients of diffusion of the dissolved hydrogen in palladium nanocrystals are greater than in the bulk specimen.

III. Heterogeneous multicomponent solid-phase systems (composites)

Generally, a solid-phase composite is a complex, heterogeneous multicomponent system which comprises several real solid phases considered as components. By a real solid phase is meant a totality of single crystals of different sizes, which contain impurities, point lattice defects, dislocations and pores as well as free surfaces (*e.g.*, cracks, intergrain and outer boundaries). Many properties of composites depend on their morphologies, namely, the particle size distribution of each phase and mutual spatial arrangement of monophasic domains. From the standpoint of connectivity of their components, composites can be divided into (i) three-dimensional random mixtures of different phases, (ii) layered and (iii) columnar structures.[59,60] Film and porous structures can also be considered as composites. Real heterogeneous systems are usually characterised by mixed morphologies.

When studying composites, one should take into account both the properties of each individual phase and those of interphase boundaries. If different phases interact with one another, the interfaces can exhibit specific properties that are characteristic of neither of the individual phases. It is appropriate to use the thermodynamic approach to describe the properties of heterogeneous systems and find the conditions for their stability. We will restrict ourselves to consideration of two possible types of the surface interaction (a weak interaction and a strong one) between components of a simple system taking a two-phase composite as an example.

1. Interface interaction and sintering of composite

For a two-phase composite composed of macrocrystalline phases (phase 1 and phase 2) with weak interaction between them, the Gibbs energy, G, can be thought to be approximately equal to the sum of the Gibbs energies of the pure components:

$$G = G_1 + G_2 .$$

In real polycrystalline specimens, the energies G_1 and G_2 depend not only on the bulk parameters but also on a number of additional factors such as the presence of (i) dislocations and corresponding elastic strain, (ii) point defects, (iii) interfaces and outer surfaces, *etc*. Assuming that the largest contribution to the total excess Gibbs energy of the real pure components comes from their surface energies, one can write:

$$G = G_1 + G_2 + G_s = (G_1^\circ + G_2^\circ) + (G_{s1} + G_{s2}). \qquad (22)$$

Here, G_1° and G_2° are the standard Gibbs energies and G_{s1} and G_{s2} are the surface energies of the components, which are defined for each component by expression (7).

Long-term heat treatment of such a composite leads to conventional sintering accompanied by growth of crystallites of both phases and annealing of dislocations.[45] After sintering, the Gibbs energy of each phase becomes close to its bulk value, G_1° and G_2°, and the system reaches a thermodynamic equilibrium. If the mixture was mechanically treated in such a manner that the particle sizes of one or both components decreased substantially, a post-annealing phase separation will occur in the composite to give a mixture of the initial macrocrystalline phases (Fig. 3 *a*).

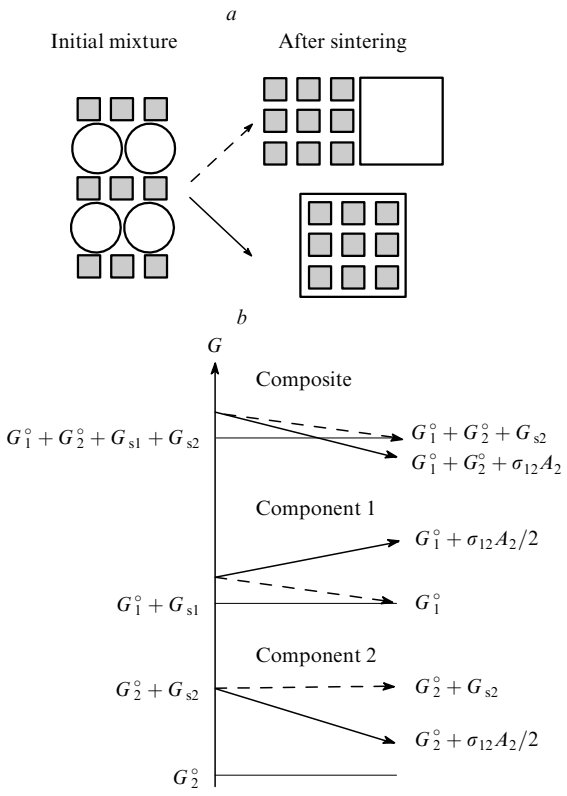

Figure 3. Schemes of sintering (*a*) and changes in the Gibbs energy of a composite (*b*) in the absence of adhesion between the components (dashed arrows) and in the case of strong adhesion (solid arrows).

Let us consider the case where the rates of recrystallisation and annealing of the component 1 are much higher than those of the component 2. The expression for the Gibbs energy of the composite annealed at the sintering temperature of the component 1 can be written in the form

$$G = G_1^\circ + G_2^\circ + \sigma_2 A_2 + \Delta G_{e2} . \qquad (23)$$

After sintering, the component 1 reaches an equilibrium state ($G_1 = G_1^\circ$), though the entire system remains thermodynamically nonequilibrium since the component 2 remains dispersed. Changes in the Gibbs energy of the composite are schematically shown in Fig. 3 *b*.

If surface interaction occurs between the constituent phases of the composite, an additional term, G_{s12}, appears in the expression for the Gibbs energy; this term represents the total change in the Gibbs energy of a heterogeneous system owing to the appearance of interphase contacts

$$G = G_1 + G_2 + G_{s12}. \qquad (24)$$

The G_{s12} is calculated as follows

$$G_{s12} = \sigma_{12} A_{12} ,$$

where σ_{12} is the specific surface energy of the interface and A_{12} is the interface area between the components 1 and 2. The contribution of the elastic strain energy should be taken into account by introducing additional terms, ΔG_{e1} and ΔG_{e2}. The total Gibbs energy of the composite with inclusion of surface interaction is

$$G = (G_1^\circ + \sigma_1 A_1 + \Delta G_{e1}) + (G_2^\circ + \sigma_2 A_2 + \Delta G_{e2}) + \sigma_{12} A_{12} . \qquad (25)$$

The expression for the Gibbs energy of the component 2 of the composite can be obtained from Eqn (25)

$$G_2 = G_2^\circ + \sigma_2 A_2 + \sigma_{12}\frac{A_{12}}{2} + \Delta G_{e2}, \quad (26)$$

assuming that the interface energy is evenly distributed between the components 1 and 2. The contribution of the elastic strain energy, ΔG_{e2}, to the total energy of the phase 2 is mainly determined by the elastic strain energy due to the crystal lattice misfit at the phase 1 – phase 2 interface and by the energy of misfit dislocations formed in the near-interface regions.[6–8] Calculations of G_e values are very complicated even for simple thin film morphology, which make estimation of this contribution in composites difficult. Nevertheless, irrespective of the character of elastic strain (a dilation or compression strain), the contribution ΔG_{e2} is always positive and should increase with an increase in A_{12}. Thus, the third and fourth terms in expression (26), which determine the energy of the phase 2, depend on the interface area in the composite.

Sintering of a mixture of a low-melting component 1 with the greater self-diffusion coefficient with nanoparticles of a high-melting compound 2 can lead to both a decrease and an increase in the interface area A_{12}. In the former case, sintering results in conventional recrystallisation of the phases. In the latter case, which is of particular interest for solid state chemistry, the formation of the interface is thermodynamically favourable if

$$\frac{dG}{dA_{12}} < 0.$$

Sintering is accompanied by an increase in the interface area A_{12}. Neglecting the dependences of the specific surface energies and elastic strain energy on the surface area (or particle size) and expressing σ_{12} in terms of the free energy of adhesion (σ_a),

$$\sigma_{12} = \sigma_1 + \sigma_2 - \sigma_a,$$

one can write

$$\frac{dG}{dA_{12}} = \sigma_1\frac{dA_1}{dA_{12}} + \sigma_2\frac{dA_2}{dA_{12}} + \sigma_1 + \sigma_2 - \sigma_a. \quad (27)$$

The formation and growth of the interface (the so-called 'sticking') have been considered in detail.[45, 61, 62] The mechanism and kinetics of 'sticking' are different in two cases defined by the conditions

$$\sigma_a < 2\sigma_1, \quad (28)$$

$$\sigma_a > 2\sigma_1. \quad (29)$$

If condition (28) is met, a 'neck' is formed between two particles of the composite. The shape and size of the 'neck' depend on the shapes and sizes of the particles and on σ_1, σ_2 and σ_a. Inequality (29) is known as the Gibbs – Smith condition for ideal wetting of films. If this condition is met, phase 1 completely covers the particle of the phase 2 after sintering.

Inequalities (28) and (29) also determine the growth mechanism of the films of the phase 1 on a support formed by the phase 2. Growth of island films according to the Volmer – Weber mechanism is observed in the former case while a steady layer-by-layer growth of films according to the Franck – van der Merve mechanism is observed in the latter case.[6, 63] The inequality (29) follows from expression (27) if

$$\frac{dG}{dA_{12}} < 0, \quad \frac{dA_1}{dA_{12}} \approx 1, \quad \frac{dA_2}{dA_{12}} = -1,$$

i.e. if a decrease in the free surface area of the component 2 (the support) leads to the formation of an equivalent free surface area of the component 1 (the film). Considering the general case of an arbitrary morphology of the initial mixture of the components 1 and 2, one can see that the newly formed free surfaces of the component 1 can overlap if the distance between the surfaces of the phase 2 is sufficiently short (see Fig. 3 *b*). Complete overlap of these free surfaces makes the derivative dA_1/dA_{12} close to zero and, assuming that the following conditions are met,

$$\frac{dG}{dA_{12}} < 0, \quad \frac{dA_1}{dA_{12}} = 0, \quad \frac{dA_2}{dA_{12}} \approx -1$$

from Eqn (27) it follows that

$$\sigma_a > \sigma_1. \quad (30)$$

This inequality determines the condition for spreading of the component 1 over the surfaces of the phase 2 in the composite. Comparison of inequalities (30) and (29) (the condition for ideal wetting or epitaxy in films) shows that the surface interaction in composites must be much stronger and requires a lower adhesion energy than in conventional film structures. It is known that roughness of a surface improves its wetting and that the roughness factor can vary between 0 and 1. Inequality (30) corresponds to the limiting case where the coefficient of roughness of the surface of the phase 2 is equal to unity.

If condition (29) or (30) is met, a spontaneous increase in the interface area or 'wetting' of the well-developed surface of the component 2 with the component 1 occurs in the system. If compound 2 is in the nanocrystalline state, the effective particle size of the phase 1 can be substantially reduced. In other words, an unusual effect, *viz.*, self-dispersion of the component 1 to give a two-phase nanocomposite, will be observed. Self-dispersion is an indicator of a strong interface interaction in the system. This interaction will occur during the long-term sintering of the composite until the entire surface of the component 2 will be covered with the component 1. In this limiting case, $A_{12} \approx A_2$ and the system reaches the state of metastable equilibrium, where

$$G = (G_1^\circ + G_2^\circ) + \sigma_{12} A_2 + (\Delta G_{e1} + \Delta G_{e2}), \quad (31)$$

$$G_1 = G_1^\circ + \sigma_{12}\frac{A_2}{2} + \Delta G_{e1}(A_2). \quad (32)$$

The effect of self-dispersion was experimentally observed in, *e.g.*, solid-phase sintering of composites $AgCl - Al_2O_3$ (see Ref. 64), $AgI - Al_2O_3$ (see Ref. 65) and $Li_2SO_4 - Al_2O_3$ (see Ref. 66). An analogous effect was detected in the heterogeneous systems based on alkali nitrates and halides such as $LiNO_3 - Al_2O_3$ and $NaNO_3 - Al_2O_3$ (see Ref. 67), $RbNO_3 - Al_2O_3$ and $CsNO_3 - Al_2O_3$ (see Ref. 68), $NaCl - Al_2O_3$, $KCl - Al_2O_3$ and $RbCl - Al_2O_3$ (see Ref. 53). This is indicative of strong adhesion of ionic salts to the alumina surface.

Analysis of expression (32) shows that the properties of an ionic salt depend not only on the standard thermodynamic parameters of the material, but also on the contribution of the energy of interface interaction, which increases as the oxide surface area increases. If the components are taken in a 50 : 50 (vol.%) ratio and mixed uniformly and an ideal wetting of the entire surface of the oxide with the MX component is achieved, the effective MX grain size is nearly equal to half the particle size of the oxide. In the composites with nanoscale oxide particles ($\sim$10 nm), the size of the MX particles becomes sufficiently small to provide noticeable size effects.

2. Adhesion energy and formation of point defects at the interface

Stable interphase contacts require that the energy of adhesion be sufficiently high. Generally, the mechanism of adhesion depends on the character and strength of the interaction between the atoms arranged on the contacting surfaces. The authors of classical monographs on adhesion [69–71] have studied the systems in which the major contribution to the surface interaction comes from the dispersion forces. In this case, the energy of adhesion can be calculated using the Hamaker – de Buhr theory

$$\sigma_a = 2(\sigma_{d1}\sigma_{d2})^{1/2} + \sigma'_{12}, \quad (33)$$

where σ_{d1} and σ_{d2} are the contributions of the dispersion forces to the surface energies of the components 1 and 2, respectively, and the last term includes the contributions of the non-dispersion interactions, *viz*., the ion–ion, donor–acceptor, dipole–dipole interaction, *etc*. In composites of the ionic salt–oxide type, it is the last term of expression (33) that makes the largest contribution to the energy of adhesion. In the absence of the electrical double layers, the σ_a value can be approximately estimated using the model of 'weak boundary layers',[72] according to which the work of adhesion is equal to the geometric mean of the works of cohesion of the components

$$\sigma_a \approx (W_1 W_2)^{1/2} = 2(\sigma_1 \sigma_2)^{1/2}. \quad (34)$$

From relationships (34), (29) and (30) it follows that self-dispersion should occur if $\sigma_2 > \sigma_1$ and be enhanced with a decrease in σ_1. Among alkali halides, lithium salts are characterised by the highest specific surface energies σ, while cesium salts are characterised by the lowest ones, the σ values being monotonically decreased on going from fluorides to iodides.[29] Therefore, self-dispersion should proceed most easily in the composites based on cesium iodide and have the lowest rate in the systems based on lithium fluoride. However, it was noted [70] that the model of 'weak boundary layers' [72] does not take into consideration specific characteristics of the interface in composites (its morphology and the presence of surface-active centres), which prevents a correct separation of the contributions of different types of interactions to the surface energies of the components, and does not assume the formation of the double surface layers.[72] Therefore, this model allows only qualitative estimation. To carry out more reliable calculations, one should take into account the structure of the contact surface and the potentials of the ion–ion interactions at the ionic crystal–oxide interface, which represents an extremely complicated problem that has not been solved so far. Approximate estimates of the surface energy using the Harkins 'broken bond' method have shown [13, 69, 73] that σ increases in proportion to the crystal lattice energy for isostructural compounds, the coefficient of proportionality being dependent on the type of the corresponding crystallographic plane. Comparison of the σ values for alkali halides [29] with the corresponding values for oxides Al_2O_3, FeO, MgO and SiO_2 (100–300 and 600–1200 erg cm^{-2}, respectively) [13, 69] shows that the wetting condition (30) should be met for the composites based on ionic halides and high-melting oxides including alumina.

Physically, a tendency of the components of composites of the ionic salt–oxide type to decrease the surface energy owing to the ion–ion interaction at the interface is the reason for rerrangement of surface layers. To a first approximation, the MX–A interface energy (MX is the ionic salt and A = Al_2O_3)

$$G^s_{MX-A} = \sigma_{MX-A} A_{MX-A} \approx \approx E_{M-Al} + E_{Al-X} + E_{M-O} + E_{X-O} \quad (35)$$

is determined by the sum of the energies of the cation–cation ($M^+ - Al^{3+}$), cation–anion ($Al^{3+} - X^-$ and $M^+ - O^{2-}$) and anion–anion ($X^- - O^{2-}$) interactions. For the sake of simplicity, let us assume that strong interfacial interaction provides a structural correspondence between the crystal lattices of the MX and A phases. Since the energies E_{M-Al}, E_{X-Al}, E_{M-O} and E_{X-O} differ from one another, an ideal structure of the boundary layer of each phase will be distorted to provide an additional gain in the surface energy owing to the mutual approach (or removal) of different surface ions. The magnitudes of the displacements of the ions from ideal positions are determined by the balance of energies E_i. Since the sizes of the anions of alumina and most of MX salts are larger than those of the cations, one can expect that, provided that both contacting phases are close-packed, the cations at the interface are displaced to longer distances than anions. As a result, an intermediate, positively charged layer enriched with cations is formed between the surface layers of the components (Fig. 4) and

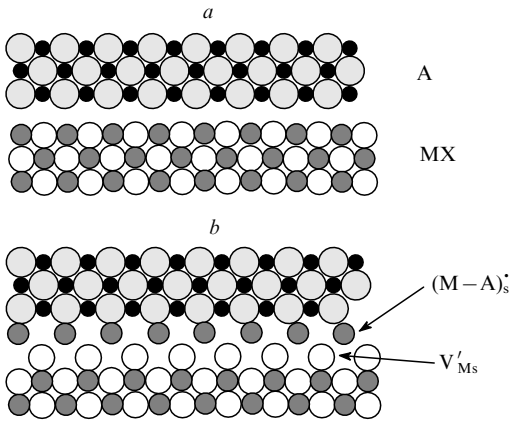

Figure 4. A scheme for the formation of defects at the interface between two binary ionic compounds.
Initial surfaces (*a*) and interface (*b*).

a layer of cationic vacancies (V'_{Ms}). Such a structural relaxation can be represented as the following quasichemical reactions:

$$0 \rightleftarrows V'_{Ms} + (M-A)_s^{\bullet}, \quad (36)$$

$$0 \rightleftarrows V'''_{Al} + (Al-MX)_s^{\bullet\bullet\bullet}, \quad (37)$$

which describe the surface disordering in MX (36) and Al_2O_3 (37) at the MX–A interface. In addition to reaction (36), interstitial cations also can be transferred into the space charge layer [48, 74]

$$M_i^{\bullet} \rightleftarrows (M-A)_s^{\bullet}. \quad (38)$$

The formation of surface defects at the MX–A interface can also proceed by other mechanisms. If the energy of the interaction between aluminum cations and X anions is sufficiently high, the following reactions can proceed at the interface:[75]

$$0 \rightleftarrows V_X^{\bullet} + (X-A)'_s, \quad (39)$$

$$0 \rightleftarrows M_i^{\bullet} + (X-A)'_s. \quad (40)$$

Reaction (39) is analogous to reaction (36) except that the role of cations is played by the anions; this can occur in composites based on fluorides, *e.g*., PbF_2–A (A = CeO_2, ZrO_2, SiO_2, Al_2O_3).[75] Reaction (40) can be observed in $AgF-Al_2O_3$ composites. Since the binding energy of Al–X dramatically decreases on going from fluoride anions to other halide anions, the reactions (39) and (40) in $MX-Al_2O_3$ systems are unlikely. More probable is the reaction

$$0 \rightleftarrows X'_i + (M-A)_s^{\bullet}, \quad (41)$$

which can occur in the salt-based MF_2-SrCl_2 composites with the anti-Frenkel defects.

Shukla *et al*.[75] proposed to use the pE value of the isoelectric point of an oxide as an indicator of the surface activity of the oxide. Indeed, equations analogous to Eqns (36) and (39) can also be written for the surface interaction of an oxide with water

$$H_2O \rightleftarrows OH' + (H-A)_s^{\bullet}, \quad (42)$$

$$2H_2O \rightleftarrows H_3O^{\bullet} + (OH-A)'_s, \quad (43)$$

The former reaction dominates for oxides with p$E > 7$ (*e.g*., Al_2O_3, CeO_2) and the latter is predominant for oxides with p$E < 7$ (ZrO_2, SiO_2). By analogy with aqueous solutions one can expect that the surface reactions (36), (38) and (41) are typical of composites with basic oxides (p$E > 7$), while reactions (39) and (40) are typical of acid oxides (p$E < 7$). Currently, the lack of experimental data makes it impossible to assess the transferability of the model of acid-base equilibria in aqueous solutions to

composites. Nevertheless, the competition between the processes (36) and (42)

$$V'_M + (M-A)^{\bullet}_s + H_2O \rightleftarrows OH' + (H-A)^{\bullet}_s + M^*_M , \qquad (44)$$

where M^*_M is a cation with a zero effective charge, can be responsible for deterioration of the ionic conductivity of the composites $AgCl-Al_2O_3$ (see Ref. 64) and $AgI-Al_2O_3$ (see Ref. 65) and for the appearance of protonic conductivity in the composites $Li_2SO_4-Al_2O_3$ (see Ref. 76) and $M(NO_3)_n-Al_2O_3$ (see Refs 77 and 78) in a humid atmosphere.

3. Ionic conductivity of composites

In essence, reactions (36)–(41) represent the formation of an electrical double layer at the $MX-Al_2O_3$ interface. The formation of this layer affects the properties of the oxide; *e.g.*, a decrease in the Néel temperature of iron(III) oxide was observed in $AgI-Fe_2O_3$ composites.[79] The effect of the electrical double layer on the properties of the ionic salt is even more pronounced. A change in the energy upon the displacement of the ion from its normal (equilibrium) position characteristic of isolated MX crystal to the space charge layer (Δg_{i-A}) can be considered as the work of charging of the surface; therefore, Δg_{i-A} is related to the surface potential at the MX–A interface

$$\varphi_{As} \sim \frac{\Delta g_{i-A}}{q_i} , \qquad (45)$$

where q_i is the charge of the displaced ion. The exact φ_{As} value is determined not only by the Δg_{i-A} value, but also by the contribution of the spatial relaxation of the oxide ions; therefore, relationship (45) should be considered only as a correlation between Δg_{i-A} and φ_{As}. If adhesive binding is strong, the Δg_{i-A} value is always negative; hence

$$\varphi_{As} > 0 \text{ for } q_i < 0$$

and

$$\varphi_{As} < 0 \text{ for } q_i > 0.$$

For $T = 0$, there is a dense layer on the surface of the MX particle contacting the oxide. This layer is analogous to the Helmholtz layer. An increase in temperature leads to the formation of a diffusion space charge layer built of cationic vacancies, which is responsible for enhanced conductivity of the composite since the ion mobility in the dense layer is low. The mobilities of defects in the diffusion layer are taken to be equal to their mobilities in the bulk of the crystal[48,74] since the concentration of defects in this layer is low and the crystal structure remains unchanged (no deformations, surface phase transitions, *etc.*). In this case, the conductivity of the composite is given by expression (21) with φ_{As} introduced instead of φ_s and the migration energy E_m corresponding to those defects which form the diffusion layer; for the sake of simplicity, the entropy contribution to φ_{As} is taken as zero. For low potential φ_{As}, which corresponds to a relatively weak surface interaction, the conductivity is low and the activation energy of conductivity is

$$E_a = \frac{h_0}{4} - \frac{e\varphi_{As}}{2} + E_m .$$

Here, E_a ranges from $h_0/4 + E_m - e\varphi_{As}/2$ to $h_0/4 + E_m$ and depends on the state of the MX–A interface (on the presence of structural defects, adsorbed impurities, *etc.*). Therefore, the conductivity parameters measured in the experiments are poorly reproducible, which is sometimes observed in poorly sintered composites.

If the surface potential φ_{As} is high, the energy of adhesion is rather high, which favours the formation of a dense interphase contact and a substantial increase in the charge density in the diffusion layer. As φ_{As} increases, the concentration of surface defects increases and at a surface potential equal to

$$\varphi_{As} = \frac{h_0}{2e} , \qquad (46)$$

a full coverage of the surface with the similarly charged ions or defects is attained. If $e\varphi_{As} > h_0/2$, several layers of similarly charged ions should be on the surface, which is unlikely. Thus, the condition (46) determines the maximum value of the surface potential $e\varphi_{As}$ in a composite.[53] In composites with high surface potential, the concentration of surface defects is close to the limiting value. In this case, the conductivity and activation energy of conductivity are given by the relationships

$$\varkappa = \frac{A}{L} T^{-1/2} \exp\left(-\frac{E_m}{kT}\right),$$
$$E_a = E_m . \qquad (47)$$

The results obtained using these expressions are in good agreement with the experimental data for composite systems $AgCl-Al_2O_3$, $AgBr-Al_2O_3$, $TlCl-Al_2O_3$ and $LiI-Al_2O_3$.[48]

Certain new factors affecting the transport properties of ionic salts appear on going to nanoscale systems. The assumption of constant mobilities of defects within the diffusion layer and in the bulk of the crystal is acceptable if the thickness of the space charge region, $2\lambda_D$, does not exceed the size of the MX crystal. It is reasonable to assume that the mobilities of defects within the diffusion layer of the crystal depend on the position of the defect owing to the drag effect of the ion 'atmosphere'. Near the MX–A interface, the defect mobility is low; it gradually increases with distance from the surface and reaches a maximum deep in the interior of the crystal. Size reduction of the MX crystal (this can be achieved by increasing the concentration of A) leads to a decrease in the defect mobilities and to an increase in the activation energy of conductivity, which is equal to the migration energy of the defect. This effect is noticeable if the crystal size L is less than $2\lambda_D$. In fact, the activation energy of conductivity in $AgI-Al_2O_3$ nanocomposites monotonically increases as the oxide concentration increases.[65]

If $L < \lambda_D$, the total concentration of defects in the bulk of the crystal becomes high. The defect–defect interactions in crystals can lead to phase transitions into the superionic state.[80–82] It cannot be ruled out that the superionic phases can be formed in the near-surface region of the crystal. The formation of the superionic phase on the surface of the pure ionic crystal has been reported;[83] in composites, this seems to be even more probable.

If the concentration of defects, n, is temperature-independent, the expression for conductivity has the form

$$\varkappa = n\left(\frac{e^2 a^2 v_0}{6kT}\right)\exp\left(\frac{S_m}{k}\right)\exp\left(-\frac{E_m}{kT}\right), \qquad (48)$$

where a is the jump length of the defect, v_0 is the vibrational frequency of the mobile ion and S_m is the entropy of migration, which can be calculated using the formula for the compensation effect

$$S_m = \frac{E_m}{T^*} ,$$

observed in alkali halide crystals. In this case, $T^* = 2.1 \times 10^3$ K.[84] The formula given below[85] relates the conductivity of the composite at 25 °C to the activation energy of conductivity and to the concentration of defects in the MX particles; it includes the compensation effect and uses two empirical parameters, $a = 0.3$ nm and $v_0 = 3 \times 10^{-12}$ s^{-1}, typical of ionic crystals,

$$\log \varkappa_{25}\,(\text{S cm}^{-1}) = \log n\,(\text{cm}^{-3}) - 14.5\,E_a\,(\text{eV}) - 20.55. \qquad (49)$$

Figure 5 presents the experimental data for different composites. The straight lines were plotted using Eqn (49) with different defect concentrations. The experimental data for a number of superionic conductors are also shown in Fig. 5. As can be seen, the

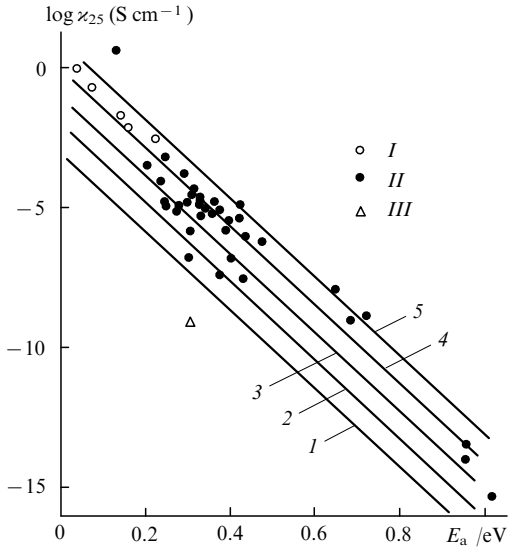

Figure 5. Theoretical (straight lines) and experimental (points) dependences of the conductivity of superionic conductors (*I*), composites (*II*) and AgCl single crystal (*III*) at 25 °C on the activation energy for conductivity at different concentrations of defects: 10^{17} (*1*), 10^{18} (*2*), 10^{19} (*3*), 10^{21} (*4*) and 10^{22} cm^{-3} (*5*).[85]

concentration of defects in the composites with the highest conductivity is also high and close to the corresponding values for superionic conductors. This indicates the possibility of stabilisation of disordered phases in composites.

4. Size effects in heterophasic systems

In studies of thin films it has been shown that the structures of solids in the near-interface regions depend strongly on peculiarities of the morphology and energetics of the contacting planes. As a rule, the epitaxial interphase contact is the most energetically favourable. In the case of strong adhesive binding, building up the layer of phase 2 on a support proceeds by the van der Merve mechanism. Owing to the crystal lattice misfit between the adjacent phases, elastic strain is accumulated in the bulk of the component 2 (the elastic strain energy increases as the thickness of the layer of phase 2 increases).[6, 86, 87] According to calculations,[88] the continuous layer is destroyed after reaching a certain critical thickness h_c and a network of misfit dislocations is formed at the interface. If the lattice misfit parameter lies between 0.1% and 1%, the calculated thickness of the epitaxial layer, h_c, is $\sim$5–25 nm (see Ref. 88), which is consistent with the experimental data. If the rate of film precipitation is high, thin films with an amorphous structure are deposited on the support instead of the epitaxial layer. As the temperature or the thickness of the layer increases, the amorphous phase undergoes transformation into a crystalline film.[7] The formation of thin epitaxial or amorphous films can be considered as manifestation of the phase size effect in heterogeneous systems, *viz*., the reduction of the characteristic size (film thickness) leads to the formation of new surface phases.

In composites, the role of the thickness of the epitaxial layer is played by the average distance between the grains of the inert component 2 (r_{22}). At low concentrations of the phase 2, the distance between the grains of this phase exceeds h_c and the properties of the phase 1 are similar to those of the island thick films oriented parallel to the faces that confine the intergrain space. On the contrary, at high concentrations of the component 2, the phase 1 is distributed in the micropores of the phase 2 after sintering. In this case, if the grain size of the phase 2 is sufficiently small (less than 10 nm), one gets $r_{22} < h_c$ and the phase 1 occurs in the form of a thin layer or a surface phase. Since the properties of substances in the surface phase differ substantially from the bulk properties of the same substance, two phases can coexist in composites, *viz*, the surface phase with anomalous properties and a conventional bulk polycrystalline phase with a high concentration of dislocations.

Thermodynamic properties of substances coated on solid supports in the form of adsorbed layers or thin films differ from their bulk properties.[2–7, 18, 19, 89] Noticeable distinctions between the thermodynamic properties appear at a characteristic crystal size of $\sim$10 nm.[2–7] Changes in the temperatures of phase transitions that occur in the bulk of the component 1 can be estimated using the formula

$$\frac{T_t}{T_t^0} = 1 - \left(\sigma_{\alpha 1}A_{\alpha 1} + \sigma_{\beta 1}A_{\beta 1} + \frac{\sigma_{\alpha 12}A_{\alpha 12} - \sigma_{\beta 12}A_{\beta 12}}{2} + \Delta G_e\right)H_t^{-1}, \quad (50)$$

where the subscripts α and β correspond to the α- and β-phases at temperature T_t, respectively, and ΔG_e is the excess elastic strain energy difference between these phases. If the changes in the volume and ΔG_e upon the phase transition are small ($A_{\alpha 1} \approx A_{\beta 1} \sim L^{-1}$; $A_{\alpha 12} \sim A_{\beta 12} \sim L^{-1}$; $\Delta G_e \approx 0$), the temperature of the phase transition into the α-phase decreases, which is usually observed in thin films. Some examples of the phase diagrams constructed in the coordinates T_t–(T, L^{-1}) for different supported metal films are available in the literature (see Refs 6–8, 18, 19). According to these phase diagrams, transition temperatures can decrease by hundreds of degrees upon reduction of L to 10 nm.[6, 7] Generally, the temperatures of phase transitions in composites can either decrease or increase depending on the particular form of the functions $G^\circ = f(T)$, $\sigma = f(T)$ and $\Delta G_e = f(T)$ for a given component in different phases.

The results of studies on the physicochemical properties of composites $AgI-Al_2O_3$ (see Refs 65, 90–94), $Li_2SO_4-Al_2O_3$ (see Ref. 66), $LiNO_3-Al_2O_3$, $NaNO_3-Al_2O_3$, $KNO_3-Al_2O_3$ (see Ref. 67), $RbNO_3-Al_2O_3$ (see Refs 68 and 95), $CsNO_3-Al_2O_3$ (see Ref. 68), $CsHSO_4-SiO_2$ (see Refs 96 and 97), $CsCl-Al_2O_3$ (see Ref. 98) with the specific surface area of Al_2O_3 particles, s, of 270 m^2 g^{-1} show that nanocomposites prepared by self-dispersion technique exhibit unusual structural, thermodynamic and transport properties. Thermodynamic calculations for all the above-mentioned systems showed that bulk chemical interaction at the temperatures of synthesis of nanocomposites is thermodynamically unfavourable. This is also confirmed by the results of special experiments on the sintering of the initial mixtures under 'severe' conditions (high temperatures and long-term heat treatment).

Thermodynamic properties of silver iodide in $(1-x)AgI-xAl_2O_3$ nanocomposites differ substantially from those of pure AgI. This can be illustrated by nearly complete absence of the thermal effect at 147 °C upon the phase transition into the α-phase of AgI in the nanocomposite with high Al_2O_3 concentrations ($x > 0.8$). Presumably, the superionic α-phase is stabilised in the composite; however, the absence of AgI reflections in the X-ray diffraction patterns (including those typical of the α-phase) suggests that silver iodide is in the amorphous state. This is also confirmed by the absence of a thermal effect at the melting transition in AgI (see Ref. 93) and by the unusual luminescence spectra observed upon UV irradiation of the nanocomposite.[94] More detailed studies have shown that an increase in the Al_2O_3 content in the composite leads to a gradual change in the properties of silver iodide. Namely, two phase transitions are observed instead of one $\alpha \rightarrow \beta$ transition, which gradually disappear as x increases. Both transitions are characterised by distinct hysteresis loops on the plots of the temperature dependences of conductivity and heat capacity, the temperature of the high-temperature phase transition depends slightly on x, while the temperature of the low-temperature phase transition decreases appreciably as the mole fraction of Al_2O_3 increases (see Refs 92 and 93).

This suggests that silver iodide can occur in two crystalline states during sintering of the composites under study. These are

the bulk state with the properties of pure AgI and the surface state localised at the $AgI-Al_2O_3$ interface. The properties of the latter are affected by the interfacial interaction. Like the bulk state, the surface crystalline state can be in the high-temperature and low-temperature disordered phases. As the Al_2O_3 content increases, the effective intercrystallite distance in the oxide (and the effective particle size of AgI) decreases and the conductivities of both phases approach each other, thus indicating a gradual levelling of distinctions between the phases.

In addition to this effect, the increase in the concentration of Al_2O_3 leads to a dramatic decrease in the enthalpies of melting and $\beta \rightarrow \alpha$ phase transition in AgI, which points to the appearance of the interface amorphous AgI phase in the composites (Fig. 6). At sufficiently high concentration of alumina, nearly all the silver iodide can be stabilised in the interface amorphous state.[91,93,94] It was shown that doping of AgI with Al_2O_3 leads to a decrease in the temperature and enthalpy of the phase transition in AgI.[99,100] This is in excellent agreement with the results of our investigations of composites with low Al_2O_3 content. However, the authors of the papers cited (*cf.* Refs 99 and 100) have observed only minor changes in the transition temperature and enthalpy, since the heterogeneous additive used in their experiments was a relatively coarse-grained (0.06 μm) Al_2O_3. The use of alumina with a grain size of 0.01 μm allowed us to observe much more pronounced effects.

Composites $MNO_3-Al_2O_3$ (M is an alkali metal) (see Refs 67, 68, 95) and the $CsHSO_4-SiO_2$ system[96,97] behave analogously. DTA studies of composites $(1-x)RbNO_3-xAl_2O_3$ have shown[95] that all the phase transition temperatures of $RbNO_3$ including the melting temperature remain virtually unchanged upon sintering, whereas the enthalpies of the phase transitions decrease dramatically. For $x \geqslant 0.7$, the DTA curves exhibit no peaks indicating the presence of crystalline $RbNO_3$ in the composite (Fig. 7). Instead, a weak broad peak appears near 250 °C with the maximum intensity for $0.4 < x < 0.6$.

These effects are not observed in the composites containing coarse-grained Al_2O_3 (with grain sizes of several micrometres),

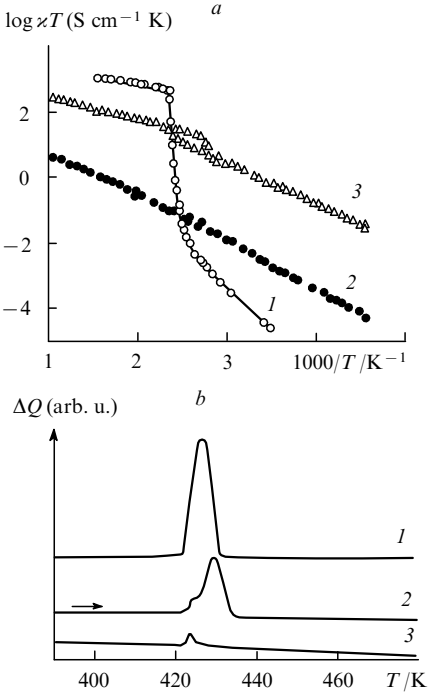

Figure 6. Temperature dependences of conductivity (*a*) and DTA curves (*b*) for pure AgI and the $(1-x)AgI-xAl_2O_3$ composites.[93]
AgI (*1*), $x = 0.6$ (*2*), $x = 0.8$ (*3*).

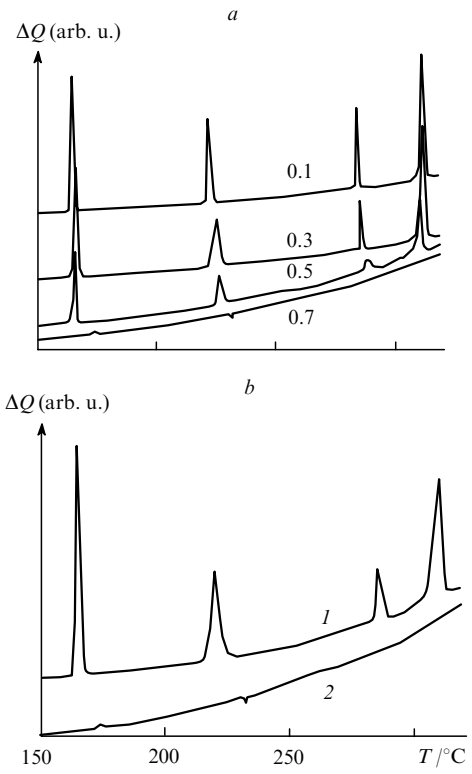

Figure 7. DTA curves for the $(1-x)RbNO_3-xAl_2O_3$ composites with a specific surface area of 270 $m^2\ g^{-1}$ (*a*) and for the $0.7\ RbNO_3-0.3\ Al_2O_3$ composites (*b*) with a specific surface area of 10 (*1*) and 270 $m^2\ g^{-1}$ (*2*). Figures near the curves shown in Fig. 7 *a* represent *x* values.[95]

which means that they are due to the influence of the oxide grain surface. Electron diffraction studies and conductivity measurements revealed the formation of an amorphous phase of $RbNO_3$ in the $RbNO_3-Al_2O_3$ composites. The thermal effect at 250 °C is due to the glass transition in the amorphous phase and the transition temperature is much higher than the calculated value (−55 °C).[101] However, it should be taken into account that in this case the amorphous $RbNO_3$ phase is formed at the $RbNO_3-Al_2O_3$ interface and its properties can be very different from those of pure amorphous rubidium nitrate. The results of thermodynamic studies of $RbNO_3-Al_2O_3$ composites are consistent with those obtained by the ionic conductivity measurements, Raman spectroscopy and X-ray diffraction analysis.[95]

The concentration and thickness of the interface phase in composites can be estimated using a simple brick-wall model for cubic particles.[85,93,95] The model is based on the assumption that the brick size is equal to the particle size of the dispersed additive (L_A) and uses the following formulae for the calculation of the volume fraction, f_s, or the mole fraction, x_s, of the interface phase

$$f_s = \beta \frac{2\lambda}{L_A} f(1-f), \tag{51}$$

$$x_s = \beta \frac{2\lambda}{L_A} \frac{\gamma x(1-x)}{1+x(\gamma-1)}, \tag{52}$$

where β is the geometric factor, λ is the thickness of the surface layer, f and x are the volume fraction and molar concentration of the dispersed phase 2 (the oxide A), respectively, and the coefficient γ depends on the densities (d) and molecular masses (μ) of the components and is defined as follows

$$\gamma = \frac{\mu_A d_1}{\mu_1 d_A}.$$

The fraction of the ionic salt (f_1 or x_1) that remained in the bulk phase can be calculated using the expressions

$$f_1 = 1 - f - f_s = \left(1 - f\beta\frac{2\lambda}{L_A}\right)(1-f), \quad (53)$$

$$x_1 = 1 - x - x_s = 1 - x - \beta\frac{2\lambda}{L_A}\frac{\gamma x(1-x)}{1+x(\gamma-1)}. \quad (54)$$

These formulae are convenient for estimating the thickness of the interface phase provided that the particle size of the dispersed component, L_A, is known. The ratio λ/L_A and the thickness of the interface phase, λ, can be estimated from the concentration dependence of any extensive characteristic of the phase 1 in the composite using expressions (53) or (54) (Fig. 8). According to calculations, the amorphous layer in $AgI-Al_2O_3$ and $RbNO_3-Al_2O_3$ composites is respectively 3 [93] and 4 nm [95] thick.

Studies of the conductivity of the nitrate-based composites revealed a substantial increase in the low-temperature conductivities and disappearance of the conductivity jumps observed upon phase transitions. Note that the Arrhenius plots of the temperature dependences of conductivity are nonlinear (Fig. 9). Among the composites based on alkali nitrates, the greatest increase in conductivity is observed for the $LiNO_3$-based ones. At 100 °C, the conductivity of the composite $0.5\,LiNO_3-0.5\,Al_2O_3$ is 7 orders of magnitude higher than that of pure lithium nitrate.[67] The smallest increase in conductivity is observed for the $CsNO_3-Al_2O_3$ system.[68] Similar effects were also found in $CsHSO_4-SiO_2$ composites.[96,97] Here, the physicochemical characteristics of cesium hydrosulfate depend on the pore size of silica gel used as a dispersed additive, that is, there is an optimum pore size ($\sim$2 nm) at which the thermodynamic, structural and transport properties of $CsHSO_4$ change to the greatest extent.[97]

Physicochemical properties of lithium sulfate change substantially on going from the bulk crystal to $(1-x)Li_2SO_4-xAl_2O_3$ nanocomposites.[66,85] The low-temperature ionic conductivity of the composite substantially increases while the well-defined (for pure Li_2SO_4) phase transition becomes diffuse in the composite (Fig. 10). The results of DTA studies of these composites showed that lithium sulfate occurs in two states at low oxide concentrations. One state exhibits the properties of the initial Li_2SO_4 while the other state possesses the properties of the phase localised near the $Li_2SO_4-\gamma$-Al_2O_3 interface. If the content of Al_2O_3 additive, x, exceeds 0.5, virtually the whole lithium sulfate is stabilised in the interface phase after sintering. In composites with the oxide particle size of the order of several nanometres the concentration of the interface phase is very low and no additional thermal effect is observed. Compared to the pure substance, the phase transition in the interface phase of Li_2SO_4 occurs at a much lower temperature (470 °C).

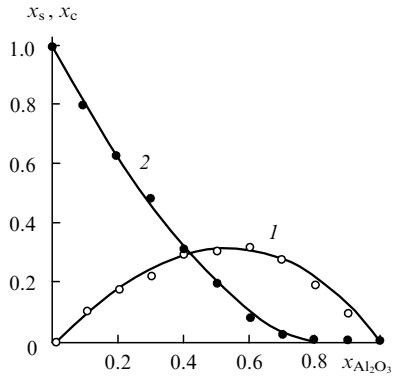

Figure 8. Dependences of the mole fraction of the interface amorphous phase (x_s) (curve *1*) and crystalline phase (x_c) (curve *2*) of AgI on the Al_2O_3 content in the $AgI-Al_2O_3$ composites according to DSC measurements of the enthalpy of the $\alpha-\beta$ phase transition in AgI. Solid lines represent the results of calculations with $\lambda \approx 4$ nm and $L_A \approx 10$ nm.[93]

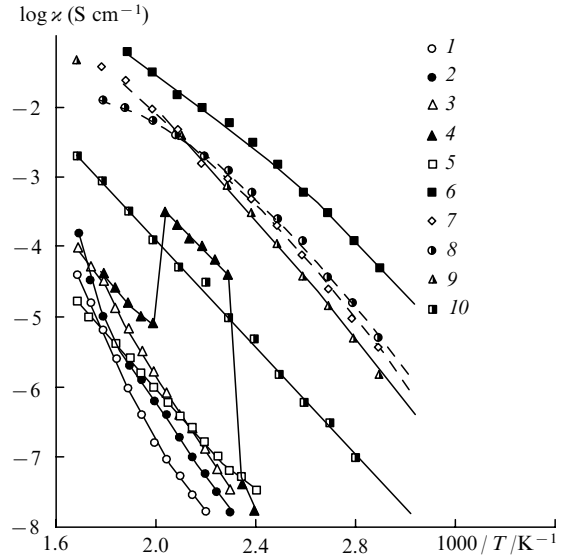

Figure 9. Temperature dependences of conductivities of nitrates MNO_3 (*1–5*) and composites $0.5MNO_3-0.5Al_2O_3$ (*6–10*); M = Li (*1*, *6*), Na (*2*, *7*), K (*3*, *8*), Rb (*4*, *9*) and Cs (*5*, *10*).[67,68]

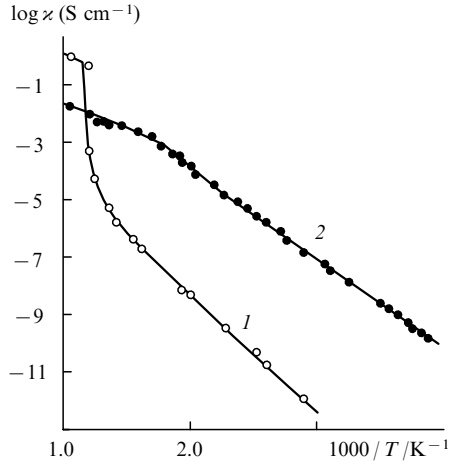

Figure 10. Temperature dependences of the ionic conductivities of pure Li_2SO_4 (*1*) and the $(1-x)Li_2SO_4-xAl_2O_3$ nanocomposite (*2*).[66]

In this case, the mechanism of adhesion involves a stage of surface chemical reaction between Li_2SO_4 and Al_2O_3 resulting in the formation of a thin interface lithium aluminate layer. The thickness of this layer was estimated at 1–2 monolayers on the surface of the Al_2O_3 grains. Analysis of the X-ray and electron diffraction patterns of the nanocomposite points to epitaxial character of the lithium sulfate layers, which is due to the close (111) interplanar spacing in Li_2SO_4 and Al_2O_3 and to strong adhesion of Li_2SO_4 to the alumina surface. Lithium aluminate forms an intermediate layer and represents a specific 'glue', which provides a denser epitaxial contact between the Li_2SO_4 and Al_2O_3 nanocrystals.

The nanocomposite $0.33\,Li_2SO_4-0.67\,Al_2O_3$ can be prepared in two ways, *viz.*, by sintering of the starting materials and by decomposition of the precursor, $Li_2SO_4 \cdot 4\,Al(OH)_3 \cdot mH_2O$.[85] The second method allows one to synthesise a nanocomposite with uniform distribution of the components and an average particle size of less than 10 nm for both Li_2SO_4 and Al_2O_3 (Fig. 11). If the alumina particles are uniform in size, both synthetic procedures

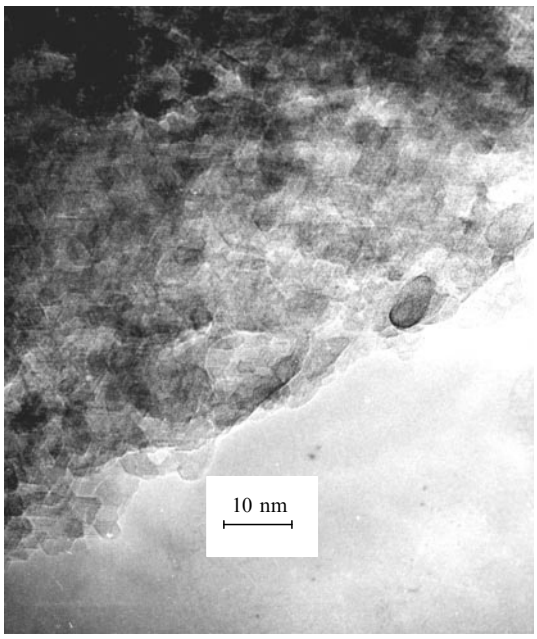

Figure 11. Morphology of the $Li_2SO_4-Al_2O_3$ nanocomposite obtained by thermal decomposition of its precursor, $Li_2SO_4 \cdot 2Al(OH)_3 \cdot mH_2O$.[66]

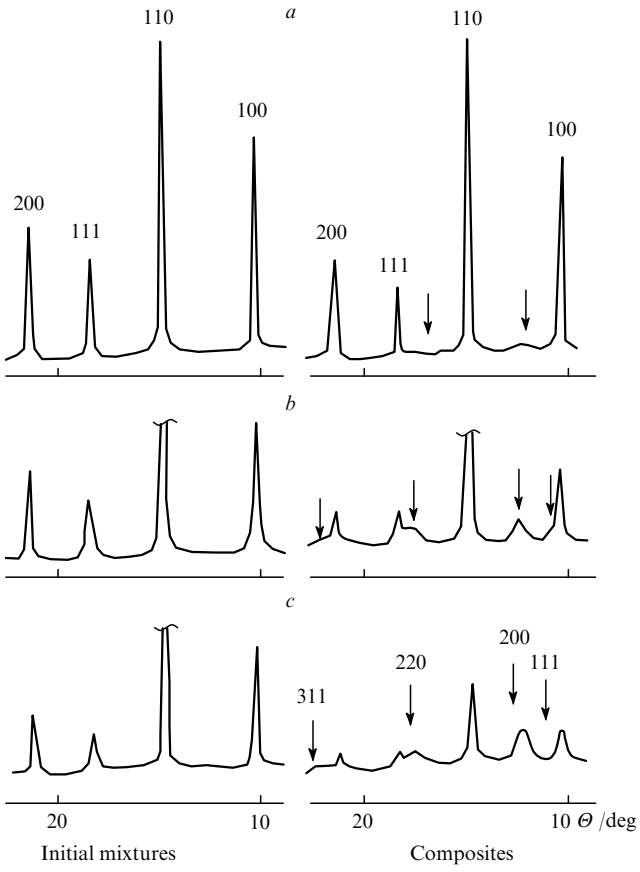

Figure 12. X-Ray diffraction patterns of the initial mixtures and $(1-x)CsCl-xAl_2O_3$ composites after long-term sintering at 600 °C. Arrows denote the reflections corresponding to the fcc phase of CsCl, figures denote the crystallographic plane indices.
$x = 0.3$ (*a*), 0.6 (*b*), 0.8 (*c*).

result in the formation of nanocomposites with identical structural, transport and thermodynamic characteristics after sufficiently long-term heat treatment of the mixtures. This indicates that the composites reached metastable thermodynamic equilibrium. Decomposition of precursors, $Li_nX \cdot 2nAl(OH)_3 \cdot mH_2O$, allows the preparation of nanocomposites with different lithium salts Li_nX (X = F, Cl, Br, I, SO_4, PO_4); these systems exhibit high ionic conductivities.[85]

X-Ray diffraction and DTA studies of $(1-x)CsCl-xAl_2O_3$ composites (with Al_2O_3 with a specific surface area, σ, of 270 $m^2\ g^{-1}$) showed that long-term sintering leads to stabilisation of a high-temperature CsCl phase localised at the interface (Fig. 12).[53,98] No changes are observed in the X-ray diffraction patterns as the particle size of Al_2O_3 increased up to ~ 1 μm; this is in agreement with the known results.[102] The size effect, *i.e.*, stabilisation of the high-temperature CsCl phase, seems to be due to the interface interaction, which is most pronounced in the composites with nanocrystalline additives.

In the ionic salt – Al_2O_3 systems, lithium salts form nanocomposites somewhat more easily than rubidium and cesium salts and iodides form nanocomposites more easily than chlorides or fluorides. This points to important role of the polarising power of the cation and the polarisability of the anion in the mechanism of surface interaction.

IV. Mechanochemical synthesis of nanocomposites and nanoparticles

Mechanochemical processes proceed at low temperatures where the formation of a perfect crystal structure is difficult. Therefore, the use of mechanochemistry for the synthesis of metastable products, in particular, nanoparticles and nanocomposites, is of considerable interest.[103–109] Mechanochemical methods for the preparation of nanocrystalline materials have been intensively developed recently [105–108] and investigations into the fundamental problems associated with the formation, relaxation and stabilisation of metastable states during mechanical activation seem to be of great importance.

1. Mechanical action on a solid and the formation of nanoscale systems

Mechanical action leads to the development of elastic stress in the crystal. For different reasons (crystal lattice anisotropy, specific features of electronic and ionic properties, different energies of chemical bonds), elastic stress relaxation can follow different mechanisms such as vibrational and electronic excitations, ionisation of chemical bonds, bond cleavage, rearrangements of atoms and migration of atoms and ions.[109] By varying the intensity and character of mechanical action one can control the properties of materials obtained by mechanical activation.[104]

One of the most often encountered effects accompanying mechanical activation is failure which leads to grinding of the particles of a substance. Failure is preceded by accumulation, interaction and concentration of defects as well as by crack formation and propagation into the interior of the crystal. However, direct mechanical grinding of a solid usually does not allow preparation of nanoparticles since mechanical activation leads to acceleration of mass transfer owing to the formation of metastable defects. In addition, the stored elastic strain energy is partly transformed into thermal energy and the temperature in the impact zone can be significantly increased, thus favouring both recrystallisation of the substance and 'healing' of defects that prevent grinding.[106]

Mechanical activation of heterogeneous mixtures seems to be more promising for the preparation of nanoparticles. Initially, the harder component acts as a crusher, thus favouring finer grinding of the softer component. Dispersion in deeper activation stages is due to the interfacial interaction between the components; here, the soft component plays the role of surfactant and facilitates the grinding of the harder component owing to the Rehbinder effect.

Mechanochemical reactions in heterogeneous mixtures represent the most efficient method for the preparation of nanocomposites.[106–108] In this case, nanoparticles of a new phase are

formed at the interface or as a result of decomposition of metastable states stabilised upon mechanical activation of the mixture. A unique feature of mechanochemical processes is the possibility of 'deformation mixing' (mechanical alloying) of the components of a mixture, *i.e.*, mixing of the starting components at the atomic level.[105–109] Mechanical alloying occurs at low temperatures whereupon diffusion is retarded. This allows stabilisation of various metastable intermediates including nanoparticles.

2. Methods for mechanochemical synthesis of nanocomposites and nanoparticles

Mechanochemical synthesis of nanocomposites in metal systems is fairly well studied. The main classes of mechanochemical reactions used for the preparation of metal nanocomposites are as follows.[110]

1. Conventional mechanical treatment of a composite resulting in transformation of one of the components into the nanocrystalline state.

This is the simplest and most widely used procedure for the preparation of nanocomposites by exposing mixtures of solids to high-power mechanical impulses. If one component of a mixture is hard while the other is soft, mechanical treatment will lead to comminution of the former and deformation of particles of the latter. This can result in the formation of a composite comprising plate-like particles of the soft component with a thickness of several nanometres separated by large nanoparticles of the hard component.

This type of nanocomposites has been obtained in, *e.g.*, bimetallic systems Cr–Fe,[111] Ni–Ti[112] and Ce–Yb[113] (for a detailed list of systems, see the review by Matteazzi *et al.*[114]). Mechanically alloyed $Cu_{30}Cr_{170}$ has been obtained by treatment of a Cu–Cr mixture[115] and studied by EXAFS, DSC and anomalous scattering of synchrotron radiation. It was shown that the alloy represents a nanocomposite rather than a solid solution of copper in chromium and that the Cu nanoparticles occur in the metastable phase. Mechanical treatment of a Cu–Co mixture, 80 : 20 (at.%), allowed the preparation of a nanocomposite containing nanoscale cobalt particles.[116] Thorough field-ion microscopy studies of the structure of the nanocomposite showed that the material contains both individual 15-nm Co nanoparticles and 1–3-nm cluster inclusions of Co atoms in the copper matrix.[117] The presence of small Co clusters is responsible for anomalous magnetoresistance of the nanocomposite. Layered Co–Cu structures obtained by vapour deposition or using pulse electrochemical deposition also possess analogous properties.[118]

2. Transformation of an amorphous phase into a nanocrystal owing to the elastic strain energy stored during mechanical treatment, *e.g.*, preparation of nanocomposites from amorphous alloys based on iron and aluminium:[119]

$$A_aB_b \text{ (amorphous solid)} \longrightarrow A_aB_b \text{ (nanocrystal)}.$$

Yet another example is the transformation of amorphous Fe–Si–B alloys into nanocrystals upon mechanical treatment. The process can be either accelerated by addition of cobalt or slowed down by addition of niobium (this can inhibit crystallisation and retain the amorphous alloy). The reasons for the transformation of the amorphous phase into a crystalline one upon mechanical treatment have been discussed.[120–122] If mechanical treatment is carried out in air, the formation of nanocomposite is often favoured by the formation of an oxide film on the metal surface.[119]

3. Decomposition of an amorphous phase (usually, an intermetallide) to give one of the components in the form of nanoparticles:

$$A_aB_b \text{ (amorphous solid)} \longrightarrow$$
$$\longrightarrow c\,A \text{ (nanocrystal)} + A_{a-c}B_b \text{ (amorphous solid)}.$$

4. More complex mechanochemical reactions:

$$a\,A + b\,B \longrightarrow A_aB_b \text{ (nanocrystals)},$$

$$A_aB_b + C \longrightarrow A_aB_bC \text{ (nanocrystals)},$$

$$A_aB_b + C_cD_d \longrightarrow A_aB_bC_cD_d \text{ (nanocrystals)}.$$

Mechanical alloying of the mixtures of different metals with graphite, silicon or tin is used for the preparation of carbide,[114,123] silicide and stannide nanoparticles.[124] Nanocomposites can also be obtained by mechanochemical solid-phase displacement and exchange reactions, *e.g.*, by the interaction of iron nitride with aluminium or silicon or by the reaction of iron carbide with chromium[125]:

$$Fe_{2.5}N + Al \longrightarrow AlN \text{ (nanocrystals)} + 2.5\,Fe,$$

$$4\,Fe_{2.5}N + 3\,Si \longrightarrow Si_3N_4 \text{ (nanocrystals)} + 10\,Fe,$$

$$Fe_3C + 3\,Cr \longrightarrow (Fe,Cr)_3C \text{ (nanocrystals)}.$$

Hydrogenation of an intermetallide $Pr(Co_{1-x}Cu_x)_5$ results in the formation of copper and cobalt nanoparticles with sizes 10–20 nm incorporated into the matrix of hydrogenation products $Pr(Co_{1-y}Cu_y)_5H_x$ and PrH_2 (see Ref. 126).

Specific methods are used if one needs to obtain nanoparticles of a single component of a nanocomposite rather than the nanocomposite itself. For instance, nickel–zinc ferrite nanoparticles with sizes 8–50 nm were obtained by long-term (200 h) heat treatment of a mixture of the ferrite and quartz.[127] To separate the metals from quartz and other components, the mixture was treated with 2 M $HClO_4$ for 1 h. This kind of treatment makes the particles on the ferrite surface charged, whereas other particles remain uncharged; this phenomenon is used for the separation of the mixture. Ferrite particles form a sol that can be destroyed by controlled change in the pH.

An efficient method for preparation and isolation of nanoparticles from mechanically alloyed composites has been proposed recently.[128–130] Nanoparticles were formed by solid-phase exchange reactions chosen in such a way that the by-products be readily soluble while the desired product, *i.e.*, nanoparticles, be insoluble in conventional solvents. For instance, ZnS nanoparticles were prepared by the solid-phase mechanochemical reaction

$$ZnCl_2 + CaS \longrightarrow ZnS + CaCl_2.$$

The newly formed zinc sulfide particles with an average size of 500 nm were found to represent aggregates comprised of smaller particles with characteristic sizes of 10–12 nm. The formation of aggregates can be prevented by adding calcium chloride to the initial mixture; in this case, the desired product is obtained as separated ZnS particles of size 7–9 nm. Calcium chloride is removed from the mixture of reaction products by selective dissolution in methanol followed by centrifugation. A similar procedure is used for the synthesis of CdS nanoparticles following the reaction

$$CdCl_2 + Na_2S \longrightarrow CdS + 2\,NaCl.$$

The starting mixture was additionally diluted with NaCl. After mechanical treatment for 1 h the mixture was washed with water to remove NaCl. The sizes of the CdS particles formed were from 4 to 8 nm (*i.e.*, less than the Bohr radius of an exciton), which allowed the mechanochemical synthesis of 'quantum dots'.

Mechanochemical reduction of oxides is also known. The use of a peroxide instead of oxide allows transformation of this reaction into self-propagating high-temperature synthesis.[131] By performing the reaction in the 'smouldering' (incomplete combustion) rather than conventional combustion regime (this can be achieved by changing the heat treatment regime of the mixture or by diluting it with an inert compound), one can obtain the reaction product in the form of nanoparticles with sizes 40–50 nm. Using this regime in the reactions of BaO_2 with metals, mixed titanium-molybdenum oxide, barium aluminate and barium stannate nanoparticles were obtained.[131]

Preparation of zinc ferrite nanoparticles by mechanical treatment of a mixture of zinc and iron oxides represents yet another example of mechanochemical synthesis of nanoparticles of complex oxides from simple ones. However, in this case heating leads to rapid growth of stable large ferrite crystals.[132] Mechanical treatment of the preliminarily prepared zinc ferrite, α-Fe_2O_3 and γ-Al_2O_3 nanoparticles also leads to their growth.[133] Therefore, optimisation of reaction conditions (in particular, mechanical treatment) should receive due attention when performing mechanochemical synthesis of nanoscale materials.

A specific case of mechanical activation of a topochemical reaction has been studied.[134] Intercalation of γ-$Al(OH)_3$ (gibbsite) with lithium salts from solution was shown to result in the development of wedging stress in the gibbsite lattice. This leads to an increase in the interlayer distances in the gibbsite structure, thus improving the intercalation conditions. Relaxation of mechanical stress can lead to the appearance of lattice defects. This will also favour an enhancement of the reactivity of gibbsite and can be used for carrying out various chemical reactions in the interlayer space of gibbsite.[135–138]

A salient feature of this type of reactions is the possibility of crystallographic control of mutual orientation of the reactants, intermolecular distances and their mobilities. Nanoparticles can be prepared by intercalating the reactants into the interlayer space. They can be formed either if both reactants are present within the interlayer space or if the second reactant (*e.g.*, oxygen) is supplied from the outside to oxidise the first reactant in the interlayer space. Nanoparticles thus formed can sometimes be retained within the interlayer space, as is the case of $[MnO_x(OH)_4]^{4-2x-y}$ nanoparticles formed by the reaction of the intercalated permanganate ions and unsaturated organic acids.[139] In other cases, the products can form a separate phase and break down the layered matrix structure, as in the thermal decomposition of complexes intercalated into the structure of hydrargillite (monoclinic gibbsite).[140]

V. Chemical properties of nanoscale systems

In studies of nanoparticles and heterogeneous nanoscale systems it is of great importance to take into account a 'feedback' between the reactivities of solid reactants and the character of the reaction between them.[1]

There are different forms of such a 'feedback'. Sometimes, it can arise owing to the development of mechanical stress due to the absence of structural correspondence between the starting substances and the reaction product (the so-called misfit).[141,142] In other cases, the reaction product can affect the electron–hole equilibrium or the concentration of ionic defects in the region adjacent to the starting point of the reaction. Finally, the 'feedback' can manifest itself in transformation of a kinetically controlled reaction into a diffusion-controlled one if the molecular volume of the product is larger than the molecular volumes of the starting materials. It should also be kept in mind that the 'feedback' can depend on the particle size of the solid reactants and products.

1. Properties of particles formed in the initial stages of heterogeneous chemical reactions

Let us consider the oxidation of lower iron and manganese oxides as an example. Here, the size effect can manifest itself in the dependence of the composition of the reaction products on the sizes of their particles. In some instances, the mechanism of a solid-phase reaction can change upon change in the particle sizes of the reactants. This is thought to be due to transformation of a homogeneous system into a heterogeneous one, as is the case of, *e.g.*, oxidation of Fe_3O_4 into Fe_2O_3.[143,144] Oxidation of fine Fe_3O_4 particles with a size less than 300 nm is a homogeneous process which involves the formation of a solid solution of oxygen in the magnetite lattice accompanied by gradual transformation of the Fe_3O_4 crystal lattice into the γ-Fe_2O_3 lattice. Oxidation of larger Fe_3O_4 particles is a heterogeneous process since the Fe ions have no time to diffuse through the whole bulk of the particle, so it is only the surface layer that is oxidised. The appearance of the oxide concentration gradients and the development of stress in the surface layer of the particles facilitate the nucleation of rhombohedral Fe_2O_3. Analogously, fine Mn_3O_4 particles are oxidised into Mn_5O_8, whereas oxidation of large particles gives α-Mn_2O_3.[145] Similar effects seem to be expected for other systems.

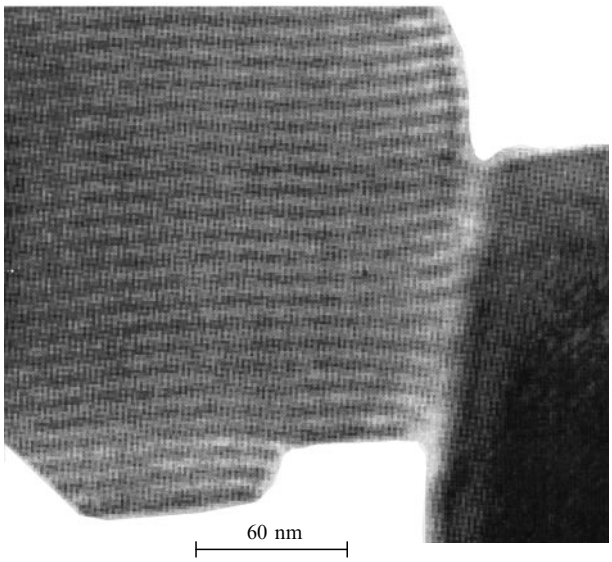

Figure 13. A HREM image of the AgBr–silver stearate interface.[153]

Size effect manifests itself in a somewhat different manner in the chemical and physical development of the latent photographic image, which begins as the Ag particle size exceeds a certain minimum value.[146–148] The usual chemical development involves treatment of silver bromide with a solution of a reducing agent and is due to the catalytic activity of Ag clusters formed upon aggregation of the surface silver atoms and comprising at least five atoms.[149,150] Physical development, or the appearance of an image owing to the deposition of the metal atoms from a solution on the potential crystallisation centres, occurs as the Ag crystallites become larger than the critical size of $\sim$4 nm.

Palladium-free metallisation of dielectrics is similar to physical development and proceeds analogously.[151,152] The process involves deposition of particles on a copper catalyst (obtained by thermal decomposition of copper hypophosphite) from a solution containing the copper salt and a reducing agent. The best results are obtained when the particle size of the copper catalyst is $\sim$25 nm. An increase in the particle size up to 80 nm leads to substantial reduction of the catalytic activity.

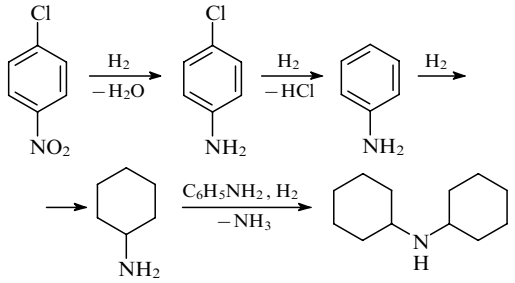
Treatment of silver stearate with bromides results in the formation of nanoscale AgBr particles which serve as sensitisers for silver carboxylates; the latter are candidates for modern photographic processes.[153] The case in point is as follows. Treatment of silver carboxylate with a KBr solution results in the formation of an AgBr particle and leads to the carboxylate lattice distortion at the AgBr–silver carboxylate interface owing to misfit. A HREM image of the AgBr–silver stearate interface is presented in Fig. 13. If the electron beam is oriented parallel to the basal plane of silver stearate, the layers of silver ions form rows of dark bands. As can be seen, these layers are disordered in the interface region and form an interfacial defect zone several nanometres wide. This zone seems to play a significant role in the sensitisation of silver stearate contacting the AgBr particles.

2. Catalytic properties

As mentioned above, the chemical properties of a substance including catalytic ones change on going from a bulk specimen

to a nanocrystal.[34, 154] For instance, the shifts of the energies of the conduction and valence bands in opposite directions cause changes in the photocatalytic properties of semiconductor particles. Khairutdinov[34] has reported numerous examples of the effect of particle sizes on the optical and redox properties as well as on the kinetics of photochemical processes in various oxide and sulfide systems. In particular, it has been shown that the specific photocatalytic activity of TiO_2 depends on its particle size. Unusual chemical properties of α-$Fe_2O_3-SnO_2$ nanocomposites have also been reported.[155] A salient feature of this system obtained by mechanical alloying of a mixture of oxides in high-energy mechanical activators is the high sensitivity and selectivity towards ethanol vapours and a moderate sensitivity to the accompanying gases, CO and CH_4. This is mainly due to the very large area of the contact surface between the two oxides and to the presence of tin ions on the surface of α-Fe_2O_3 particles. As a result, the oxide α-Fe_2O_3, initially assumed to be insensitive to ethanol vapours, acquires sensitivity and a gas sensor based on it allows detection of 1000 ppm of ethanol vapour in air.

A correlation was found between the particle size of a platinum catalyst and its catalytic activity in the reaction of hydrogenation of *p*-chloronitrobenzene, which is often used as a test for catalytic activity in hydrogenation reactions.[156] Using commercial catalysts, the process can proceed up to the stage of formation of chloroaniline. The use of nanoscale platinum particles with sizes 3–4 nm allows the hydrogenation to reach deeper stages with the formation of aniline and cylohexylamine. Nanocrystalline platinum catalyst also appeared to be suitable for further hydrogenation of cylohexylamine to give dicylohexylamine as the end product.



Finally, zinc ferrite nanoparticles were found to exhibit better sorption properties toward H_2S as compared to conventional pure ferrite.[125]

3. Hydrogenation of metal systems

Hydrogenation and dehydrogenation of magnesium have been studied.[157] The use of nanocomposites formed upon mechanical treatment of mixtures of magnesium with nickel and other metals leads to an increase in the rate of hydrogenation and in the yields of the end products. The rate of hydrogen absorption and the hydrogen capacity of the mechanically alloyed composite with stoichiometry Mg_2Ni also increased. Taking $LaNi_5$ as an example, it was shown that the addition of a hydrogenation catalyst (*e.g.*, palladium) to the system together with mechanically treated absorbent leads to even greater increase in the rate of hydrogen intake. Nanocomposites obtained by mechanical treatment of $Fe_{40}Ti_{60}$, $Fe_{50}Ti_{50}$ and $Fe_{67}Ti_{33}$ alloys and by direct mechanochemical alloying of elemental Fe and Ti were found to have a high hydrogen capacity. Compared to the starting alloys, these nanocomposites absorb hydrogen at lower pressures and are stable towards the phase transition of the materials into the γ-phase. Unusual properties of the alloys were explained by the presence of mechanical stress in the crystallites constituting the nanocomposites.

4. Electrochemical and anti-corrosion properties

Electrodes made of mechanically alloyed Ti_2Ni nanocomposite were found to be more efficient in the electrochemical production of hydrogen gas than those produced by conventional procedures.[158]

A distinguishing feature of mechanically alloyed nanomaterials is improved corrosion resistance.[159] Nanostructured material with stoichiometry $Fe_{32}Ni_{36}Cr_{14}P_{12}B_6$ obtained by crystallisation of an amorphous alloy exhibits a higher corrosion resistance than the initial alloy.[160] This was explained by the possibility of fast diffusion of Cr atoms towards the surface along numerous block boundaries in the composite followed by the formation of a protective layer. A similar effect has also been observed.[161] However, it does not always happen that the corrosion resistance increases. In studies of the behaviour of electrochemically deposited Ni–P alloys in 0.1 M H_2SO_4 (see Ref. 162) it was shown that nanocomposites exhibited a reduced corrosion resistance compared to bulk nickel owing to enhanced activities at block boundaries and the possibility of accelerated propagation of the reaction along these boundaries. Nanocomposites with stoichiometry $FeAl_8$ also exhibit a reduced corrosion resistance towards H_2SO_4 and Na_2SO_4 solutions.[163]

Overvoltage (up to 900 mV) on steel cathodes is one of the main sources of energy loss in the electrochemical production of chlorates. It was proposed to use nanocrystalline cathodes prepared by mechanochemical activation of a $RuO_2-Fe-Ti$ mixture.[164] The mechanically alloyed nanocomposite appeared to be an excellent material for cathode production. At a current density of 250 mA cm^{-2} and 70 °C, the overvoltage on the nanocomposite cathodes decreases by 300 mV, which allows a 15% reduction of the expenditure of electrical energy in the production of chlorates. A nanostructured material obtained by mechanical alloying of Ti and TiO in an Ar atmosphere exhibits similar properties.[165] The nanocomposite with oxygen content between 18.5 at.% and 33 at.% can be used as a cathode material in electrochemical production of sodium chlorate. At the operating current density of 250 mA cm^{-2} and solution temperature of 70 °C, the overvoltage on this cathode is 600 mV, which is nearly half as large as the overvoltage on the cathode made of metallic titanium (1107 mV).

5. Size effects in the chemistry of solid organic compounds

Back in the late 1930s, it was found that stearic acid, which usually crystallises in stable β-form, undergoes transformation into the α-form as the crystal size reduces.[166] As the size of molecular crystals decreases, the temperature of the $\alpha-\beta$-transition and the heat of melting also decrease. A change in the ratio between the surface area and volume of molecular crystals leads to changes in both dissolution rate and solubility. Reduction of the size of molecular crystals of chemical compounds used as medicinal drugs to submicron level enhances their biological assimilation and therapeutic efficiency.

Since microscopic and nanoscale molecular crystals are prone to aggregation, it is desirable to place nanoparticles obtained by certain procedures on a support or to prepare nanocomposites of the molecular crystal–support type. One of the well-known and popular methods for the preparation of this sort of nanocomposites involves treatment of the molecular crystal–support mixture in a mechanical activator. This procedure can be conveniently used to prevent transformations of highly active, metastable polymorphous crystalline modifications formed during mechanochemical activation into stable, low activity ones.[167, 168] Here, it is appropriate to refer to a number of studies on the preparation of highly active, readily soluble forms of aspirin, sulfathiazole and other medicinal drugs in order to eliminate their major drawback of low solubility.[169–173]

6. Specific chemical properties of nanocrystals of ionic compounds

Incomplete compensation of the anion and cation charges in ionic compounds leads to the appearance of charged nanoparticles; this is a reason for changes in their chemical properties on going from bulk crystals to nanocrystals.[174] This can be followed taking alkali

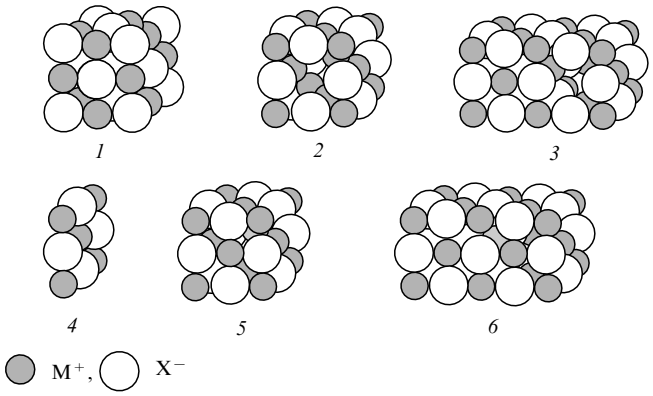


Figure 14. Structures of a (3, 3, 3) nanocrystal of an ionic salt MX (*1*) and clusters that are reactive (*2*, *3*) and passive (*4*–*6*) towards chemisorption of NH_3.
$[M_{14}X_{13}]^+$ (*1*), $[Na_{13}F_{12}]^+$ (*2*), $[Na_{22}F_{21}]^+$ (*3*), $[M_5X_4]^+$ (*4*), $[M_{14}F_{13}]^+$ (*5*) and $[M_{23}X_{22}]^+$ (*6*).[174]

halides as an example. It is known that alkali halide vapours contain charged clusters comprised of, in particular, a small odd number of ions.[175] In larger particles, electroneutrality can also be violated. Figure 14 presents the structure of a cubic nanocrystal of the (3, 3, 3) type (figures denote the number of ions along three edges). As compared to the ideal cubic lattice of ionic salt MX, the nanocrystal lattice is built in such a way that the X^- anions protrude out while the metal cations are recessed.

Charged nanocrystals possess some characteristic properties. For instance, adsorption of polar molecules such as NH_3 and H_2O occurs in different manner depending on the number of lattice sites on the crystal edges. Perfect crystals of the (3, 3, 3) or (3, 3, 5) types do not adsorb polar molecules at room temperature. The loss of two ions (M^+ and X^-, or a single MX unit) leads to the appearance of pits on the surface and to enhancement of the reactivity of crystals. In Fig. 14, the structures of clusters $[M_nX_{n-1}]^+$ (M = Na, X = F) with such pits are shown. These clusters are highly reactive towards NH_3. The structures of $[M_nX_{n-1}]^+$ clusters that are passive towards ammonia are also shown in Fig. 14. It should be mentioned that the cluster structure remains unchanged after the adsorption of a polar molecule.

The reaction of $[Na_{53}F_{52}]^+$ nanoparticles with the surface of silicon occurring in their collisions is yet another example of the reactions of ionic nanoscale clusters. Upon collision, a single fluorine atom is transferred to the silicon surface to form a F–Si bond. The reaction occurs only if the silicon surface is pure. If the silicon surface is preliminarily passivated with hydrogen, the collision event will only result in the cleavage of the nanoparticle.

Condensation of metal atoms on the surface of a nanoparticle leads to the formation of the structures similar to F-centres, where an electron is mainly localised at the anionic vacancy site. These centres are characterised by very low ionisation potentials, *e.g.*, 3 eV for $(Na^+)_n(F^-)_{n-1}e^-$ and 5 eV for $(Cs^+)_{13}(I^-)_{11}e^-$. As the temperature increases, the electron can wander onto the metal cation. A neutral metal atom thus formed leaves the surface. In the case of a perfect nanocrystal without anionic vacancies, an electron that is loosely bound to the surface forms a surface centre, which is a strong electron donor. Photolysis of nanocrystals leads to transfer of the electron from the anion to the cation followed by desorption of a halogen atom from the surface. The transfer energy lies between the energies of analogous transfer in diatomic molecules MX and in bulk $(MX)_\infty$ crystals.

By and large, studies of alkali halide nanocrystals showed that they are more passive towards many reagents as compared to bulk crystals. On the other hand, nanocrystals are prone to self-aggregation; therefore, the search for protective coatings for stabilisation of nanocrystals is topical.

VI. Conclusion

Size effects play an important role in chemical processes including mechanochemical reactions. One should distinguish two groups of size effects. Some of them, inherent in microcrystalline systems, are due to the purely surface phenomena. Stronger phase size effects manifest themselves if the particle size is less than 10 nm. In the former case, the properties of a substance can be interpreted in terms of the classical thermodynamic approach, which includes standard models for taking into account the contribution of surface effects. A basically new situation appears on going to nanoparticles since virtually the whole bulk of the sample under study falls within the action range of surface forces and classification of the atoms into the surface atoms and bulk ones becomes unjustified. In this case, a nanoparticle should be considered to be a cluster or a macromolecule, the structural, thermodynamic and transport properties of which are strongly different from those of the macrocrystal.

Various size effects are observed in heterogeneous systems represented by microcrystalline and nanoscale composites, the properties of which are affected by the interface interaction. Particularly strong are the interface effects typical of heterogeneous systems with the ionic type of bonding. Here, the interface interaction involves the stage of formation of surface defects, which leads to abrupt increase in the ionic conductivity. Similarly to isolated nanoparticles, the material nanocomposites are made of occurs in unusual states and its properties (like those of the adsorption layers) are to a great extent determined by the characteristics of the interface, *i.e.*, by the interatomic interactions within the adjacent phases in the near-surface region.

Practically, nanocomposites represent a promising class of advanced materials with unique electronic properties and high molecular, atomic and ionic mobilities. Mechanochemical processes in heterogeneous mixtures are strongly influenced by size effects, which is of great importance for solving practical tasks associated with controlling the process intensity and obtaining the desired reaction products. Problems which have arisen in this case are directly related to studies of the effect of particle size on the catalytic, electrochemical and specific chemical properties of materials. Therefore, further investigations of size effects in heterogeneous systems are of great theoretical and practical importance.

This review has been written with the financial support of the Programme 'Fundamental Problems of Modern Chemistry. Chemical Transformations Involving Nanoscale and Supramolecular Systems' of the Russian Federation Ministry of Industry, Science and Technology (Grant No. 3) and the US Civilian Research and Development Foundation (Grant REC-008).

Abstract. General characteristics of size-dependent phenomena in electrochemical systems are given. Primary attention is paid to methodical achievements of nanoelectrochemistry, which is a line of research created over the last 15 years. The development of the main concepts of electrochemistry initiated by the stream of nanoscopic information is considered. The prospects for local studies of processes on charged interfaces, elementary steps of these processes and application of nanoelectrodes and related systems in interdisciplinary fields are discussed. The bibliography includes 198 references.

I. Introduction

Electrochemistry studies homogeneous condensed ionic systems (solutions, melts, solid electrolytes) and heterogeneous systems which include electrified interfaces. The spatial scales of heterogeneous electrochemical systems vary over a wide range (Table 1). Correspondingly, the size effects observed in them are numerous and diversified, and quite a number of them are analogous to those in homogeneous electrochemical systems. However, the latter are beyond the scope of this review.

Characteristic dimensions of conventional components of electrochemical systems (electrodes, electrolytes and membranes) cover 5 – 10 orders of magnitude. The lower boundaries of the corresponding intervals approach typical sizes of specific space regions (layers) that arise only at the electrode – electrolyte, electrode – membrane and electrolyte – membrane junctions. In electrochemical systems, the concentration distribution of components near the electrode differs from that in the bulk. As the distance from the interface increases, this distribution changes, *i.e.*, the system contains nonuniform regions. The structure of such a region is considered in detail in Refs 1 – 3. Below, we only briefly comment on the concepts employed in this article.

Table 1. Characteristic scales of elements of electrochemical systems and devices.

Elements	Size intervals /m	Components
Electrodes for practical applications	0.1 – 10	metals, semiconductors, composition materials
for research	10^{-3} – 10^{-2}	
microelectrodes	10^{-5} – 10^{-4}	
ultramicroelectrodes	10^{-8} – 10^{-6}	
thin-film electrodes	$< 10^{-8}$	
Electrolyte layers		solutions, melts, solid electrolytes
electrolysers	0.1 – 10	
research cells	10^{-3} – 0.1	
thin-layer cells	10^{-6} – 10^{-5}	
microcells	10^{-7} – 10^{-6}	
Membranes	10^{-7} – 10^{-2}	polymers, porous inorganic materials
Diffusion layers	10^{-6} – 10^{-4}	all electrolyte components
Chemisorption layers	10^{-10} – 10^{-9}	the same
'Electronic tails' and near-surface layers in semiconductors	$< 10^{-11}$	electrons and other charge carriers

When an electrode process occurs on an interface, the boundary layer is depleted of the corresponding reactant and(or) enriched with the products formed. Insofar as diffusion rates are finite, a region always exists in which the concentration of one or several components depends on the distance. We call this region the diffusion layer and usually consider it as an electrolyte component.

A uniform distribution of components can also be disturbed under equilibrium conditions. Boundary regions that arise in the process are called the 'electrical double layer' (EDL).† Charged species are distributed in the EDL under the effect of different electrostatic interactions, the concentration of ions either decreasing or increasing with an increase in the distance from the

† This name is associated with the concept of metallic and ionic plates of a hypothetical capacitor commonly used as the interface model.

boundary. If the interaction of an ion with a charged electrode is much stronger than its interaction with induced charges, then the concentration distribution much resembles the diffuse distribution of charges in an ionic atmosphere and is described by a parameter having the meaning of the Debye screening length and equivalent to the effective thickness of the diffuse part of EDL, namely, the ionic diffuse layer.

If certain components of a system specifically interact with the electrode material, then a chemisorption layer (the dense part of EDL) is formed between the surface and the diffuse layer. For the vast majority of electrode–solution systems, dense layers are formed involving solution molecules and often exclusively by such molecules.

According to modern notions of the interface structure, the adsorbate layers and the 'edges' of surface atoms on metal electrodes are spatially separated with a gap in between attributed to the emerging electronic gas ('electronic tail'). In electrochemical systems, the properties of this gap depend on the electrode potential (charge). For semiconducting electrodes, the spatial dispersion of charge carriers is also characteristic of near-to-surface solid-phase layers.

We can assess the properties of electrochemical systems from electrochemical responses, *viz*., different dependences of electrical signals (current, potential, voltage) on time and also on polarisation conditions (for instance, modulation frequency and amplitude during ac polarisation). Size effects arise when the system's parameters are commensurate with the characteristic quantities that determine a particular response.

We can distinguish several basic groups of size effects caused either by the scale commensurability of two and more subsystems, or 'intrinsic' size-dependent properties of individual subsystems. Each of these groups merits special consideration (*e.g*., see Refs 4–30). In this review, we consider the general features of size effects in electrochemical systems and give them a sort of classification. The prospects of using size effects for intensifying electrode processes and also for technological (including nanotechnological) applications are discussed. The presented list of references does not exhaust all the literature (otherwise, it would be extremely large) and contains, apart from reviews, only representative papers of recent years.

Size-dependent thermodynamic properties of electrochemical systems related to equilibria involving two-dimensional adsorption layers and nanocrystals are the subject of an interdisciplinary research field that shares its frontiers with colloid chemistry, surface science and solid-state physical chemistry. Studies of other electrochemical size effects also show a trend for integration and are combined by a recently formed separate research field, *viz*., nanoelectrochemistry. Along with inherent electrochemical techniques, this actively developing new scientific discipline extensively uses probe techniques for local surface studies,[14,16,17,20,21,31–34] diffraction[35] techniques, and also optical[36,37] and small-angle X-ray methods[38] (including those *in situ*[39]).

Originally, nanoelectrochemistry was developed on the basis of studying classical size effects (for instance, the dependences of surface conductivity on film thickness[8]). However, during the past decade, it has begun to encroach more actively on the province of quantum size-dependent phenomena. The development of nanoelectrochemistry is also stimulated by the progress in electronics; the latter branch, in turn, diversifies its elemental basis due, in particular, to the introduction of micro- and nanoelectrochemical technologies. The reason for such a 'feedback' resides in the fact that by extending the scope of electrochemical systems to the nanoscale, one substantially strengthens the material basis of electrochemistry and sharply enhances its experimental potentialities.

The possibilities of experimental studies of micro- and nanoelectrochemical systems are largely determined by the facilities for measuring small currents and charges. The characteristic settling times usually lie within hundreds of milliseconds, and, even if we pass to the femtoampere range, the lower limit of measured charge will fall within 10^{-16} and 10^{-15} C. These values exceed the charges consumed in electrochemical reactions of single ions and molecules approximately by three orders of magnitude. At present, the unique measurements with nanosecond resolution have severe restrictions on the lower limit of the measured current. The crucial obstacle that prevents lowering of the limit mentioned results from the fact that characteristic polarisation capacities of micro- and nanoelectrochemical systems are commensurable with the inherent capacities of the measuring devices.

II. Size effects in diffusion kinetics. Microelectrodes and microcells.

The uppermost limit on the scale of size-dependent properties of electrochemical systems is occupied by those manifesting themselves in electrochemical processes with diffusion-controlled rates. Such properties are studied in detail for the systems in which the dimensions of either electrodes or layers of electrolyte solutions are commensurable with the diffusion layer thickness (micrometer range that may be upscaled, for instance, due to gravitation effects). That is why, when separating microelectrodes and microcells into a special class of electrochemical systems, the upper limits of sizes (volumes) cannot always be determined unambiguously, being dependent on the configuration and convection conditions.

For the majority of microelectrodes, such a limit is ~ 10 μm. For disk, spherical, semispherical, conical and microdrop liquid electrodes exact relationships for the dependences of the limiting diffusion current I_d on the characteristic size r were obtained.[40–42] Similar size limits for microcells are determined by a condition of the overlapping of diffusion layers for two electrodes between which the current flows.[43] The corresponding quantitative expressions are very complicated; hence, the applications of microcells are largely related to *in situ* surface spectroscopy (the so-called thin-layer cells for minimising absorption in the solution bulk) and microtechnologies. In those cases, the cell volume contains actually no regions with constant concentrations of reactants, and different non-steady-state size-dependent distributions of solution components can arise.

The most important basic application of microelectrodes deals with the determination of kinetic parameters of electrode processes and is limited by the ratio between the corresponding rate constants and the limiting currents of reactant delivery.

As an example, we consider the limiting diffusion current density i_d, which corresponds to the rate of an electrode process at a slow delivery of a reactant. For an electrode of a common (macroscopic) size r exceeding substantially the diffusion layer thickness, i_d is independent of the electrode configuration and determined only by the diffusion coefficient of the reactant D and its concentration c. Correspondingly, for an electrode of a geometric surface area S, the diffusion current

$$I_d = i_d S = \text{const}\ cD^m r^2, \tag{1}$$

where the power index $m < 1$.

The values of the constant and m are determined by the parameters that characterise the convection conditions (rotation velocity of a solid electrode, streaming velocity of a liquid metal from a capillary, *etc*.) and by the electrode shape and described by the rigorous relationships deduced within the framework of the planar diffusion model. Inasmuch as i_d and the rate of electron transfer stage are proportional to c, it is difficult to overcome the diffusion limitations and determine the rate constant for the electron transfer on common-size electrodes for quick processes.

When the diffusion layer thickness is commensurable with electrode dimensions, the planar diffusion model does not operate due to a significant role of edge effects. For example, for a disk microelectrode,

$$i_d = \text{const}'\ c\sqrt{D}r^{-1}. \tag{2}$$

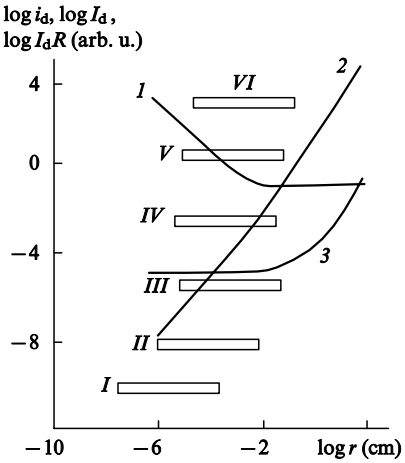

Figure 1. Size dependences of electrochemical responses (*1–3*) and typical scales of various nanotechnological processes (*I–VI*); (*1*) i_d, (*2*) I_d, (*3*) I_dR; (*I*) nanostructurisation in STM configuration, (*II*) electron-beam technologies, (*III*) ion-beam technologies, (*IV*) holographic lithography, (*V*) X-ray lithography, (*VI*) photolithography. Plotted on the basis of the results taken from Refs 19, 24.

Correspondingly, I_d turns out to be proportional to r rather than to r^2, which affects the dependence of the ohmic potential drop I_dR on r (where R is the resistance of the solution layer between the working electrode and a point in which the potential is measured by a reference electrode). Figure 1 illustrates how the most important characteristics of electrochemical systems tend to vary.

In the case of fast delivery of a reactant, regardless of the electrode size, the rate of an electrode process is proportional to the surface area (in the absence of other types of size effects, see Sections IV and V). Hence, with a decrease in r, it becomes possible to overcome the diffusion limitations for still faster reactions. Microelectrodes allow quantitative measurement of the rate constants of an order of magnitude of centimetres per second, whereas the limits of conventional rotating and dropping electrodes do not exceed 10^{-2} cm s^{-1}.

To determine the rate constants of fast reactions, the arrays of microelectrodes which include flow-through channel systems with ensembles of microband electrodes are also widely used.[44] A rotating ring-disk electrode can be considered as the first array electrode which allowed measurement of the kinetics of separate steps of electrode processes, owing to its optimum hydrodynamics.[45] The electrochemical responses of electrode arrays are characterised by special types of size dependences determined by the relative positions of their fragments (for instance, by the spaces between them).

Microelectrodes are widely used in electroanalysis,[46,47] especially for solving environmental and biological problems (for example, in electrochemical measurements *in vivo* in the monitoring of the composition of biological media, diffusion of drugs and poisons, accumulation of glucose, *etc.*). These applications stimulated further miniaturisation of electrodes. As a result, a large class of the so-called ultramicroelectrodes with surface areas of less than 1 μm^2 was developed.[48,49]

Modern methods of insulation of the surfaces of metal wires and other items provide electrodes of characteristic sizes of $\sim$ 10 nm (sometimes named nanodes). Standardisation of the geometry (shape) of nanodes presents a particular problem which can be solved by using nanosize materials of known structures, for example, carbon nanotubes as the electrodes.[50]

The term 'nanoelectrodes' is sometimes used in a different context when considering the phenomena in solutions of monodispersed colloidal metals. Thus when stabilising colloidal gold particles in dichloroethane by ferrocene-containing organic molecules, the responses of redox transformations of the latter could be detected in the single contacts of particles (nanoelectrodes) with the polarising macroelectrodes.[51] In this case, an analogy can be traced with well known suspension electrodes in which macroelectrodes play the role of current collectors.[52]

A new impact for the development of microelectrode technology was made in the end of the 1980s when Bard *et al.*[15] proposed a basically new method for carrying out local studies of surface processes and phenomena, namely, the technique of scanning electrochemical microscopy (SECM). This technique is based on the possibility of measuring the current on a probe microelectrode as a function of the distance h between the probe and the surface of an electrode under study of arbitrary dimensions dipped into a solution containing a redox system with a high electron-transfer rate constant and known diffusion coefficients of redox forms. When the diffusion layers of the probe and the electrode under study overlap (which occurs if h is commensurable or less than r), the processes on both electrodes can either be accelerated or decelerated, depending on the potentials of the probe and the electrode. The corresponding relationships for steady-state and non-steady-state currents in SECM configuration were derived as two-dimensional integral equations (for example, see Ref. 26) for systems with different geometry of probes and surfaces under study as applied to both heterogeneous and homogeneous processes.

Inasmuch as the diffusion layer boundary repeats to a certain extent the surface relief, the SECM technique allows one to visualise the latter with submicron resolution. Scanning tunnelling microscopy (STM) in air may be considered as a version of SECM, because the surface under study always bears an ultrathin film of condensed moisture playing the role of a liquid electrolyte.[53] The resolution that can be achieved depends largely on the curvature radius of the probe tip (even for tips of uncertain general geometry). Moreover, the size of the tip exerts the most critical effect on distortions of the images of surface fragments with small curvature radii. The corresponding size effects can be simulated numerically,[54] and there is a prospect of using advanced models for different convolution procedures (*e.g.*, for recovery of real images of the surface studied and for the determination of the tip geometry from the distortions of standard surface images). The development of the STM method provided special procedures for the pretreatment of well characterised tips, which are common for all probe techniques including SECM.[55,56]

The resolution in the SECM technique is enhanced if a non-uniform surface contains areas of different nature where the rates of local processes differ. Various specialised versions of SECM are developed, for instance, those for the studies of enzymic processes,[57] combined technique (SECM – probe microscopy[43]) and related techniques for investigations on the boundaries of two immiscible liquids.

A unique result achieved in SECM configuration is the measurement of responses of an electrochemical transformation of a single molecule.[58–60] This became possible owing to the accumulation of the signals from multiple successive reversible transformations of a reactant and its product in a limited solution volume between a deepened probe ultramicroelectrode ($r \approx 10$ nm) and a planar surface (Fig. 2). It is the localisation of small solution portions in micro- and nanocells the volumes of which can be reduced down to 10 nl and realisation of systems with two ultramicroelectrodes arranged along a common axis at a small distance from one another that will determine further progress in this field.[61]

Certain basic problems of microelectrochemistry formulated only recently[24,26,48] still remain unsolved. They pertain to the analysis of the potential distribution for overlapped diffusion and diffuse layers (including the case of diffuse layers of two closely spaced electrodes). This is observed, for example, in the configuration of electrochemical tunnelling microscopes (*in situ* STM). Under these conditions, certain anomalies are observed which have not yet found unambiguous explanations.[62] Thus the cathodic deposition of a metal phase can occur at electrode potentials

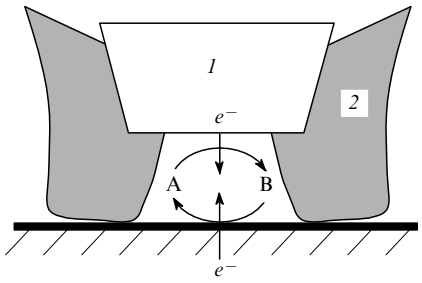

Figure 2. A scheme of a microcell for measuring electrochemical transformations of single molecules.[15]
(*1*) Ultramicroelectrode, (*2*) insulation; A and B are oxidised and reduced reactant forms, respectively.

banned by formal thermodynamics. Hence, one cannot rule out the possibility that distortions in the surface equipotentiality can occur in the vicinity of the tunnelling gap. It is still more probable that the configurations used do not provide correct measurement of the potential drop between the working and reference electrodes.

III. Electrical double layer as a nanostructure

As noted above, an electrochemical interface demonstrates a sufficiently complicated space distribution of components, due to chemisorption and electrostatic factors.[23, 63, 64]

Being the most important EDL characteristic, the zero-charge potential is directly related to the physical properties of electrodes (for example, the electronic work function).[63] Its value depends on both the electrode material nature and the crystallographic orientation of the surface. For a thin-film (especially, semiconducting) electrode, such a thickness can be reached that permits the work function to manifest size-dependent effects;[65] correspondingly, variations of film thickness can cause changes in the electrode charge *vs*. potential dependence.[7]

The models of EDL structure deal with space distributions of the potential in the dense and diffuse parts. For electrodes with pronounced heterogeneous structures and compositions, the potential can vary not only along a normal to the surface but also in parallel to it, both in the dense and diffuse parts. Comprehensive phenomenological models are developed for size-dependent parameters of EDL on polycrystalline surfaces constructed from different lattice faces with different values of zero-charge potential.[66] For small heterogeneities, EDL structure is well approximated by a model with a uniform diffuse layer. With an increase in the heterogeneity size, transition layers appear between neighbouring regions of diffuse layers of different structures. Probe techniques make it possible to study the heterogeneities of the potential distribution near the surface and describe quantitatively the interaction between the diffuse layers of the electrode and the probe.[62] This may be considered as further development of the approaches dealing with interaction of crossed filament electrodes.[63]

In the general case, the EDL is a multicomponent system in which not only concentrations but also the states of species may differ from those in the bulk. For example, the lateral Coulomb repulsion of ions adsorbed with charge transfer [67] weakens so that their surface coverage can reach a complete layer. The phenomenon of the formation of adatomic submonolayers stabilised by the interaction with the support is called *underpotential deposition* (UPD), because it provides deposition before the redox system involved reaches its equilibrium potential (for example, the deposition of adatoms M at potentials more positive than the equilibrium potential of an M/M^{n+} system). The different rates of formation and dissolution of adatomic monolayers compared with metal phases also point to the differences between these systems. Apparently, the properties of a layer start to approach those of a phase only after the deposition of the third or fourth monolayer.

Like adatoms, the molecules of organic adsorbates form structurally non-uniform adsorption layers. In the case of strong lateral interactions, different domains appear on a supporting surface, their structures being dependent on the surface geometry and charge as well as on the presence of other adsorbates. Two-dimensional condensation [68] typical of adamantane and camphor derivatives and of certain amino acids is a spectacular manifestation of lateral interactions. For adsorption with partial charge transfer (or without it at all), the co-adsorption of anions and cations can be responsible for the formation of closely packed monolayers. For example, the adsorption of multicharged polyoxometalate anions is accompanied by the formation of the so-called salt-like layers.[69–71]

Many adsorbates were reliably shown to preferentially adsorb on defective surface sites and behave specifically with respect to surface areas of different coordination.[72, 73] Figure 3 shows, as an example, the results on CO adsorption on high-index faces of a platinum single crystal. A size effect manifests itself in an increase in the surface coverage by CO molecules on areas with a high density of steps (*i.e*., with a decrease in the terrace length). For well characterised systems, the general thermodynamic approach was applied for the analysis of the contributions made by terraces and steps into reversible adsorption processes and, in particular, for the elucidation of the effects of surface crystallography on the observed zero total charge potential value.[72] Moreover, we can assume that the electronic work function is different in different surface points and, apparently, it makes sense to invoke the concept of the local work function (and, correspondingly, the local zero free charge potential [74]). An argument for such an assumption may be the difference in adsorbabilities of the surfaces of terraces and steps.

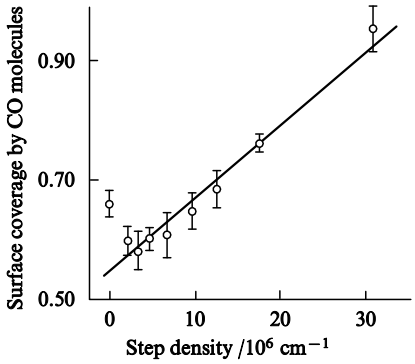

Figure 3. Surface coverage by adsorbed CO species determined from the coulometric data in 100 mM $HClO_4$ as a function of atomic step density on Pt[n(111) × (111)] single-crystal faces.[72]

It should be noted that, along with equilibrium properties of adlayers, the characteristic sizes of areas of given configurations also strongly affect the dynamic characteristics of adsorption processes. For instance, STM data at high time resolution showed that during the formation of the second layer of silver adatoms on a gold electrode surface diffusion on terraces proceeds more quickly than that on sites near the steps.[75] As a result, the adatoms are stabilised near the steps, which is beneficial for the smoothing of the relief in the early deposition stages (Fig. 4). The dynamics of adatomic-layer fragments can be followed in STM experiments with high time resolution.[24]

Unusual nanosize structures with barrier properties are formed by alkanethiol molecules adsorbed on metal atoms

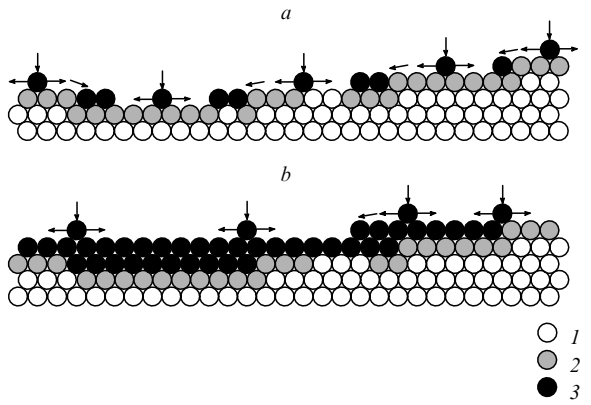

Figure 4. Schematic representation of a mechanism of silver deposition on an Au(100) surface.[75]
(*a*) Initial stages, (*b*) formation of multilayer deposit; (*1*) gold atoms, (*2*) silver atoms in equilibrium states, (*3*) mobile adatoms (marked by arrows) and silver adatoms incorporated into the lattice.

owing to chemical (virtually irreversible) interaction of terminal thiol groups with metals.[76–78] For example,

$$RSH + Hg - e^- \longrightarrow Hg(SR) + H^+.$$

By changing the alkyl chain length, one can obtain, with high precision, a sufficiently closely packed interlayer of molecules arranged in parallel (the area occupied by a thiol centre is ~ 20 Å^2) with a thickness invariant over the surface. The capacitances of alkanethiol-modified electrodes do not exceed several microfarads per square centimetre and decrease for longer alkyl chains.[79] This suggests that the solvent is practically completely forced out from the EDL dense part, and a uniform dielectric interlayer is formed on the interface. Alkyl chains are shown not to be arranged along a normal to the surface but to be bent at a substantial angle (up to 40°). Peculiarities of the formation and properties of alkanethiol layers are sensitive to surface defects,[77] which offers a unique possibility of diagnosing the latter, for example, by following different manifestations of the barrier properties of alkanethiol layers during charge-transfer processes. These systems can also be applied for studying the discrete charging of double layers formed on small particles that operate as nanoelectrodes.[80]

Considerable progress in studies of nanosize structures became evident with the possibility of visualisation of adsorbates *in situ* by probe techniques.[17, 76, 81, 82] Special attention should be drawn to the potentialities of these techniques for studying adsorption-induced phenomena, such as the appearance of surface stresses and the surface reconstruction.[83, 84] Thus the latter can be simulated on the atomic level according to the results for faces of single crystals of gold and platinum (Fig 5).

However, the problem of interpretation of STM data still remains sufficiently complicated, because the electrical double layers of a probe electrode and a scanned surface tend to overlap and interact with one another.[62]

Studies of the EDL structure on an atomic level is important for quantitative description of the interaction of reactants with electrified interfaces, *i.e.*, for the solution of problems of electrochemical kinetics. These studies can also shed light on the microscopic origin of discreteness-of-charge effects arising in the specific adsorption of ions, the effects exerted by metal hydrophilicity on the dense-layer capacitance, *etc.*, which were considered so far within the framework of phenomenological approaches. Modern approaches to building physical models of charged interfaces are surveyed in Ref. 23.

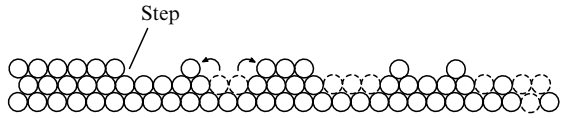

Figure 5. A scheme of island formation on a Pt(111) surface induced by potential cycling in a region that includes oxygen adsorption.[84]

IV. Size effects in electrocatalysis

Size-dependent electrochemical phenomena occur in chemisorptive and electrocatalytic processes that take place on highly dispersed, small (for instance, ultrathin) and surface-heterogeneous electrodes. In such processes, the heterogeneities of characteristic sizes commensurable with either the thicknesses or lateral periods of adsorption layers (nanosize range) play a significant role.

Many active electrocatalysts represent the so-called nanostructurised materials that exhibit periodic inhomogeinities not only on the surface but also in the bulk.[22, 85] Nanostructures are at equilibrium only in rare cases, most commonly they are metastable, but long-lived.

Nanosize materials were introduced into the practice of electrochemical studies long before the methods of their structural, morphological and electronic characterisation became available. First of all, these were the electrodes with well developed surfaces (the ratio of the real surface area S_{real} to the geometric area S being equal to 1000 and higher) of platinum-group metals consisting of nanocrystals.[4, 6, 7] For them, the experimentally determined rates of electrocatalytic processes, the surface coverages by adsorbates and the polarisation capacitances were referred not to the individual characteristics of small particles but to the values of S_{real}.[86, 87] It is the dependence of the specific (calculated per S_{real}) activity on the fabrication method that was the subject of numerous studies aimed at intensification of practically important processes applied mainly in fuel cells.

The concepts of the related structural (size) effects in heterogeneous catalysis[88] as applied to dispersed electrodes have also generated certain simplified notions based on the analysis of 'electronic' and 'structural' factors. For example, the latter factor was considered in the mitohedral approach,[89] which was developed further in the 1980s–1990s. During this period, well characterised electrode materials of similar compositions but substantially differing in surface coordination became available, *viz.*, faces of single crystals and polycrystalline materials with pronounced preferential crystallographic orientations.[10] Numerous attempts were undertaken (for example, see Refs 4, 12) to describe the activities of small metal particles in terms of an additive approach to the contributions of low-index faces. Usually, the ratio of faces on the surface was calculated for ideal equilibrium crystals (in the nanosize range, it strongly depends on the grain size).

Although a number of activity–surface coordination relationships have been revealed, the attempts to substantiate the decisive role of crystallographic orientation in electrocatalysis by dispersed materials have failed for virtually all actively studied processes of oxidation of organic compounds and hydrogen, as well as of oxygen reduction. Undeniably, the main reason for the deviations between experimental and model dependences lies in the non-equilibrium nature of small particles of real catalysts. It is also significant that the particle sizes used in the calculations were not necessarily determined by direct methods.

The technique of high-resolution electron microscopy[90–92] made it possible to refine the data on the real geometry of nanosize particles for a number of materials. However, the potentialities of this technique for the analysis of multilayer deposits and dispersed electrodes are limited. Reliable results are obtained mainly for smooth carbon supports with low surface coverages by catalysts. It should be noted that the interactions of small particles with the support substantially complicate the behaviour of these systems;[6, 7] no adequate models exist for the description of these

interactions. The activity – particle size relationships for different electrocatalytic processes are analysed in several papers (*cf.* Refs 92–98). However, these relationships pertain to relatively narrow intervals of particle sizes. Moreover, the technological methods of fabricating catalysts with different particle sizes do not provide permanence of several important structural characteristics. In different studies, the specific activity was shown either to increase or to decrease with an increase in the particle size not only in the nanometre range but also in submicron range for which one can hardy expect any manifestations of equilibrium 'structural' (and, all the more, 'electronic') size effects.

To date, different dispersed materials based on platinum and palladium have been examined by means of the STM technique with a nanometre resolution.[99–101] A comparative analysis of the data on the real surface area, porosity [102] and characteristic sizes of surface fragments (independently determined by different techniques) allows highly reliable conclusions to be drawn on the real structures of nanosize electrocatalysts: the latter include globules constituted by quasispherical particles. Sufficiently wide size distributions of particles and globules are revealed for electrodeposited dispersed catalysts. This result requires that a great number of property – size relationships be reconsidered for those cases where the sizes were estimated from S_{real}: the particle size thus determined certainly exceeds that corresponding to the distribution maximum. At a high degree of screening (or coalescence) of particles in the globules, the aforementioned differences can reach an order of magnitude, as in the case of certain materials based on electrodeposited palladium.[101]

At present, the controversial views on the structure of different boundary regions in nanosize electrocatalysts, first of all, of intergrain boundaries in globules of metal crystals pose a problem which is extremely difficult to solve experimentally. Probably, as in the case of other nanostructurised materials,[22,85] it is these highly defective regions that play a significant role in adsorption and electrocatalytic phenomena. For a number of cases, a phenomenological analysis [103,104] based on an assumption of high surface defectiveness of these electrocatalysts makes it possible to find a self-consistent set of experimental results. However, it fails to rationalise the nature of defective surface regions.

Yet another aspect of size-dependent electrocatalytic effects that manifest themselves on the scale of molecular sizes is associated with the structure of chemisorption layers. The mechanisms of the vast majority of electrocatalytic processes involve strongly bound adsorbates for which co-adsorption and competitive adsorption play important roles.[9]

A rather universal type of size effect occurs within the framework of the mechanism known as bifunctional catalysis.[9] This mechanism is realised on bi- and milticomponent surfaces where the process is controlled by the chemical reaction of two different adsorbates. Electrocatalytic hydrogenation of organic substances involving hydrogen atoms and their oxidation involving adsorbed hydroxyl radicals may serve as examples of these processes. The activity of a catalyst proves to be highest where its surface contains simultaneously two components which selectively chemisorb the species involved in the slow stage of the reaction. In this case, both the mutual arrangement of components and the ratio of their surface concentrations are of importance. Particularly, there exists an optimum (depending on the reactant structures) size of surface areas with one or another composition which provides the greatest number of reaction sites. Such an area is always commensurable with the size of the adsorbate species. Homogeneous alloys which exhibit no pronounced segregation and adatomic submonolayers are typical bifunctional catalysts. Figure 6 shows the rate of electrocatalytic oxidation of ethylene glycol on platinum covered by different amounts of tin adatoms as a function of the electrode potential.[105] Tin adatoms are the adsorption centres for active oxygen species and exhibit the maximum activity at medium surface coverages.

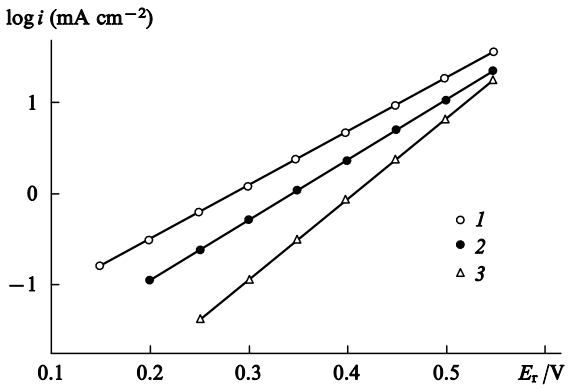

Figure 6. Steady-state polarisation curves of ethylene glycol oxidation (0.5 M, in the presence of 1 M NaOH) on platinised platinum modified by tin adatoms.[105]
Surface coverage by adatoms: (*1*) 0, (*2*) 0.76, (*3*) 0.48; E_r is the potential referred to the reversible hydrogen electrode.

If a process is controlled by the recombination of atoms, then, conversely, optimisation of the electrocatalyst requires an increase in the number of neighbouring active adsorption centres of the same nature. For this mechanism, the dependence of the process rate on the geometry and sizes of reaction sites can be well simulated by hydrogen evolution on platinum-group metals modified by different adatoms. Depending on their sizes, adatoms can occupy one, two or three neighbouring positions otherwise available for adsorbed hydrogen. In real systems, we cannot always provide a uniform distribution of a modifying additive over the surface; therefore, the observed effects of recombination inhibition appear to be smaller than is expected. This situation can be used for solving the inverse problem, *viz.*, studying the geometry of island structures.

Yet another typical mechanism of electrocatalysis (first of all, for processes involving organic substances on platinum-group metals, Fig. 7) occurs for two and more parallel processes of

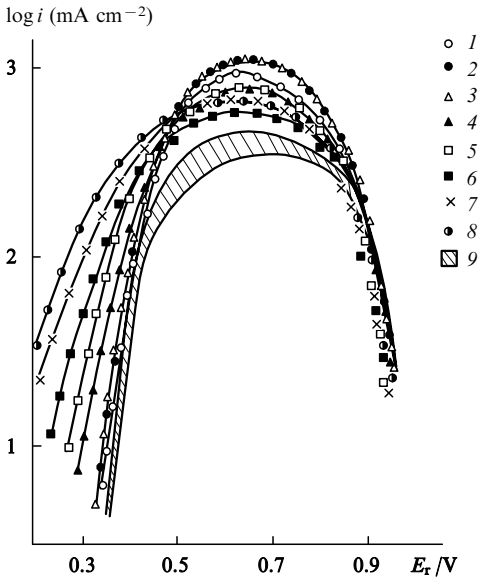

Figure 7. Steady-state polarisation curves of formic acid oxidation (1 M, in the presence of 0.5 M H_2SO_4) on platinised platinum modified by thallium adatoms.[106]
Concentration of added Tl^+ /mM: (*1*) 0.01 (*2*) 0.033, (*3*) 0.1, (*4*) 0.33, (*5*) 0.48, (*6*) 0.96, (*7*) 1.9, (*8*) 4.8, (*9*) 0. In the vicinity of the maximum, current fluctuations occur with the amplitude shown by the dashed area.

reactant chemisorption, one of which produces non-reactive strongly bound adsorbates that partly block the surface. For such self-inhibited catalytic processes, the selective suppression of the inhibitor adsorption is an important size-dependent factor. In systems with organic reactants, the blocking adsorbate occupies usually several neighbouring surface sites; hence, its formation is hindered by foreign adatoms that modify the surface (the so-called 'third-body effect'[9]). This is exemplified in Fig. 7 by the data on the acceleration of formic acid oxidation on platinum modified by thallium adatoms each blocking three neighbouring adsorption centres, according to estimates. The 'third-body' effect is manifested only in the ascending branch of the curve in the potential region where the process is inhibited by strongly adsorbed CO-like species.

Blocking adsorbates of this and nearby components are formed in both the destructive adsorption of various organic molecules and immediately in the adsorption of CO molecules. Thus the problem of designing systems with a pronounced 'third-body effect' is of prime significance for the solution of an urgent applied problem, *viz.,* preparation of CO-tolerant catalysts.

In principle, macrokinetic effects in systems with porous catalysts can be also assigned to size effects. These are discussed in detail by Chizmadzhev *et al.*[107]

V. Size effects in the elementary act of charge transfer

At present, subnanometre-scale size effects are actively studied on the molecular level within the framework of theoretical descriptions of electrochemical interfaces and attendant processes of the transfer of charged species (for example, see Refs 108–112). In such a consideration, both the sizes of molecular subsystems (reactant and product species involved in the charge transfer, solvent molecules adsorbed on electrodes) and the characteristic scales of electron density distribution are of substantial importance. Charge transfer processes cannot be studied without invoking quantum-mechanical approaches, which in turn requires a changeover from spatial scales to spatial–temporal scales.

The probability of electron transfer in an electrode–reactant system is determined by a number of factors that depend on the characteristic sizes of reaction layers.[108] The most 'large-scale' and complex factor is the distance of the closest approach of a reactant to the surface $z_{\lim}$, which is determined by steric restrictions and by chemisorptive and electrostatic interactions.

For ionic and molecular reactants, such distances do not usually exceed fractions of several tenths a nanometre. If $z_{\lim} > 1$ nm, we speak of the 'long-range' electron transfer. The limiting value $z_{\lim}$ is arbitrary and is determined by a substantial attenuation of the electron overlap, which exponentially depends on the electrode–reactant distance. By introducing the transmission coefficient K, one may represent this dependence as follows:[108]

$$K = \text{const}'' \exp\left(-\frac{z}{b}\right), \tag{3}$$

where the parameter b depends on the degree of electron delocalisation and is of an order of magnitude of a hundredth part of a nanometre. Usually, the delocalisation of reactant electrons plays the decisive role, in particular, the greatest b values (< 0.1 nm) are known for transition-metal complexes in which the charge transfer proceeds to orbitals of a mixed nature.

In principle, all reactant species located at any distance from the surface contribute to the observed rate; however, the contributions of species located in a thin near-surface layer not exceeding $z_{\lim}$ prevail. In place of the parameter $z_{\lim}$, another parameter of the same order of magnitude δz known as the reaction layer volume is used, for example, in the expression for the current density (rate of the process)

$$i = \text{const}''' (z_{\lim})\, \delta z \exp\left(-\frac{E_a}{RT}\right), \tag{4}$$

where E_a is the activation energy, R is the universal gas constant, T is the temperature. In modelling the electron transfer, δz is determined by integrating the expression (3) within the limits from $z_{\lim}$ to the infinity.

The 'long-range' transfer can be observed in systems with barrier layers on the electrode surfaces[79, 113, 114] and is studied most comprehensively for thiol systems. In particular, unambiguous dependences of the transfer rate on the barrier layer thickness are established. Thiol layers with redox-active terminal substituents that provide rigid localisation of the reactant are widely used.[115] The introduction of two redox centres, with a variable distance between them, into a thiol molecule is an interesting extension of this approach (Fig. 8).

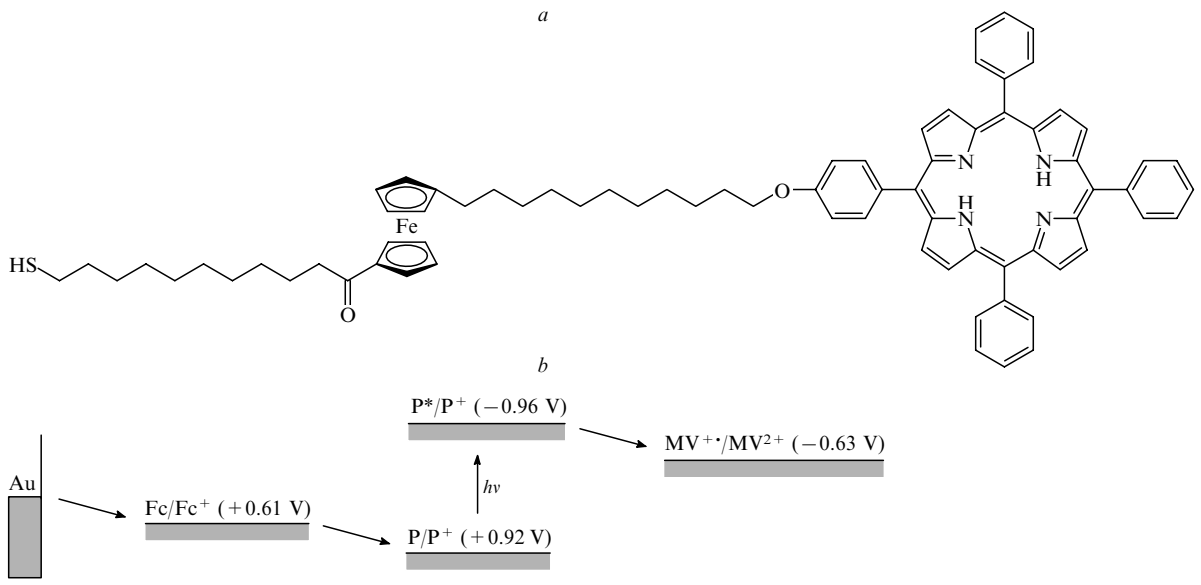

Figure 8. A scheme of a model system with two fixed redox centres, *viz*., those based on ferrocene (Fc/Fc^+) and porphyrin (P/P^+) (*a*) and the sequence of charge transfer steps to different redox centres (*b*).[116] A self-assembled layer of substituted thiols is immobilised on the surface of an illuminated gold electrode in a solution of methyl viologen (redox pair $MV^{+\bullet}/MV^{2+}$); the equilibrium potentials of the corresponding systems are shown in parentheses.

'Long-range' charge transfer is also observed for reactant species of considerable intrinsic sizes and with a pronounced degree of localisation of the transfer site (metalloproteins,[112] polynuclear complexes [71]). It should be noted that the characteristic length of the 'electronic tail' (and, correspondingly, electron overlap) depends on the electrode charge; however, the theoretical analysis of these dependences is possible so far only in terms of simplified models.[109]

The quantity z_{lim} affects not only the ovelap, which determines the prexponential factor in the equation for the rate constant of electrode reactions, but also different components of E_a: the work terms of reactants and products (if we deal with charged species, the Coulomb interactions weaken with the distance from the interface as the potential changes) and the solvent reorganisation energy. A detailed theoretical consideration of this problem is given in Refs 117, 118.

Pronounced size effects can be observed in photoelectrochemical processes involving semiconducting particles separated from the metal surface by barrier layers. The size effects are caused by a shift of absorption edge when the diameter of particles ranges from 10 to 20 nm.[119, 120] Substantial acceleration of photoelectrochemical processes occurs on passing from massive to nanosize semiconductors. This phenomenon has already found a practical application, *viz*., in photoelectrolysis of water.[121] Similar 'intrinsic' size effects of metal particles should be weaker and manifest themselves for particles with sizes below 5–7 nm. However, in principle, there exist no methodical obstacles from discovering them in the nearest future.

Prediction of the kinetics of electron transfer by taking into account all size-dependent factors becomes possible only when adequate ion–molecular models of reaction layers are built. For a number of systems, this problem can successfully be solved by invoking quantum-chemical methods [122] based on the quantum-mechanical theory of the charge-transfer elementary act.[123] Along with the classical effects of the cation size which manifest themselves in the reduction of anions on a negatively charged surface,[124] we must especially mention the inhibition of electron transfer with increase in the ligand size for a number of transition-metal complexes.[125] For non-symmetrical reactants, this dependence gives rise to various orientation effects in reaction layers.[126]

The independent (additional) possibilities of experimental simulation of the size effects of a quantum origin are provided by carrying out electron transfer processes in the STM configuration at fixed tunnelling voltages, which govern the location of energy levels of transferred electrons in the metal.[110, 127] Interesting similarities between STM and electrochemical responses can be traced for polyatomic reactants with dense outer barrier layers and for gold clusters, particularly those stabilised by alkanethiols.[128] In both cases, the current responses reveal the appearance of Coulomb blocking (up to six steps separated by potential intervals of ~ 0.3 V). The latter system, which allows one to trace the dependence of electrochemical responses on the cluster size, is considered in the literature as 'transition': for a small number of atoms in a cluster, the differences between the electrochemical charging of the gold cluster ('nanoelectrode') and an electrode process involving this cluster as a reactant in solution actually vanish.[129]

VI. Size effects in processes of new phase formation in electrochemical systems

A complex combination of size effects of different origins is realised in electrochemical processes with the formation of new phases, for instance, in electrocrystallisation processes.[25]

In the nucleation on electrode surfaces (as in the formation of a new phase in a homogeneous medium), the key role is played by supersaturation determined by the electrode potential deviation from the equilibrium value for a given redox system (overpotential η). A redox-system component formed as a result of a transfer of n electrons takes part in the nucleation process. A thermodynamic description of this phenomenon relies on the analysis of the probabilities of formation and dissolution of new-phase nuclei [5] and gives the following expression for the critical nucleus radius r_c (the minimum size, for which the probability of dissolution of a nucleus formed does not exceed the probability of its further growth):

$$r_c = \frac{\gamma A}{nF\eta} \quad \text{or} \quad r_c = \frac{2\sigma\upsilon}{nF\eta},$$

where γ is the surface tension of a two-dimensional nucleus, A is the area occupied by a mole of the substance in a monoatomic layer, F is the Faraday number, σ is the surface tension of a three-dimensional nucleus, and υ is the molar volume. When estimating the size of an extremely small critical nucleus, one cannot use the value σ characteristic of macroscopic fragments of the same solid, because, in principle, this parameter is size-dependent.

For the analysis to be correct, the EDL structure and involvement of chemisorbed solvent molecules and other solution components, as well as adatoms should also be taken into account. All these factors affect the surface energy of a nucleus and, hence, its critical size. Along with thermodynamic models, non-thermodynamic models of nucleation on the electrode surface have also been developed.[25] The latter are based on either a statistical dynamic approach or on quantum-chemical studies of different-size clusters.

The mentioned factors also play an important role in the description of steady-state and non-steady-state kinetics of nucleation and growth of new-phase particles on electrodes: in many cases, these factors can change the rate and the limiting stage of a process. Largely pertaining to potentiostatic models, the expressions for the non-steady-state current of nucleation–growth of a unit nucleus and nuclei ensembles are described in detail in numerous reviews (for example, see Refs 5, 14, 130). The time-dependent nucleus size plays a key role in deriving such expressions. The other important parameters include the number of active nucleation centres, the nucleation rate constant and a parameter characterising the kinetics of the limiting stage (the diffusion coefficient or the rate constant for electron transfer). Moreover, even the simplest approximations (for example, for the formation of spherical or semispherical nuclei on a uniform plane) allow the criteria for diagnosing the nucleation type: two-dimensional or three-dimensional growth, diffusion or kinetic control, the ratios of nucleation and growth rates, to be found. The nucleation type is elucidated from experimental current transients (for instance, power dependences at small times) by analysing the maximum current corresponding to the hindrance of growth due to the coalescence of neighbouring nuclei.

From electrochemical data, by using the corresponding algorithms, one can indirectly characterise the morphology of a system at any moment of deposition (even for a crystal size commensurable with the atomic size). However, the differences between the properties of real and model systems cause substantial deviations of the calculated values from the experimental results. For example, the calculated concentrations of active centres are often several orders of magnitude lower than those found from electron microscopy data (direct visualisation of grown crystals).

Model systems for which the active centres represent certain surface areas (for example, dislocations) and the growth rate of a new phase is limited by a process localised immediately on the surface, *viz*., the surface diffusion, are of special interest [25, 130] In this case, the key size-dependent factor is the distance between the growth steps which incorporate the adatoms slowly diffusing over the surface. However, it is difficult to fabricate such systems, especially when using real polycrystalline materials the active centres (and point defects) of which may be represented by any surface areas with small radii of curvature. The exchange of adatoms on the growth steps can be observed by means of STM.[24]

The methods of independent determination of the number and sizes of nuclei at different moments are of prime interest, especially

those that do not require the electrode to be withdrawn from solution. These requirements are fulfilled by the STM technique realised with an atomic resolution *in situ* in electrolyte solutions.[16, 17, 20, 73, 131–133] However, at present, local changes in the deposition conditions that occur near the probe, especially, for nucleation under diffusion control cannot be reliably eliminated. It was also reported that nanosize crystals are unstable in the electric field around the probe if adhesion is low (for example, this concerns the important group of model processes of metal deposition on highly oriented pyrographite). An efficient approach to the determination of the number and sizes of nuclei consists in substitution of the background solution for the deposition solution without opening the circuit.[73] The probe is brought to the surface after all the deposition stages studied are completed. This, however, dramatically reduces the time resolution.

The techniques of atomic-force microscopy in a noncontact mode progressively gain importance.[32, 134] The advantage of such methods is the possibility of studying objects of low conductivities, for example, in electroplating on wide-band semiconductors,[31, 32] in structural transformations of polymer deposits during dedoping [135] and in the course of formation of nanosize barrier oxide layers.[136] Combined photo-assisted probe techniques are being actively developed.[21, 33] It should be noted that quantitative probe-microscopic data on nanosize particles of electrodeposits (*i.e.*, where the radius of curvature of a probe is commensurable with that of the particles) can be obtained only when special convolution procedures are used, the algorithms of which are being extensively developed.[54, 137, 138]

A quantitative description of electrochemical responses in the formation of a new phase is complicated by the appearance of the so-called screening zones caused by the overlap of either the neighbouring nuclei or the corresponding diffusion layers. Certain effects of this sort can be simulated, which however always increases the number of fitting parameters, thus reducing the diagnostic possibilities of the model. Experimentally, the overlap can be avoided if the distances between the active centres are of an order of a micrometre: in this case a single nucleus can be grown on an ultramicroelectrode.[139, 140] In fact, such experiments allow one to observe the elementary events that constitute the nucleation process and then to use the obtained information for the analysis of the growth of ensembles.

Screening under diffusion control can also be used for obtaining the so-called fractal deposits (for example, see Ref. 141). Such deposits are formed in thin-layer cells, which includes the boundaries of two immiscible liquids and the solution–air interfaces. The main contribution to the growth of a new phase is made by the secondary nucleation processes which can be intensified by pulsed deposition modes (Fig. 9). Simulation of secondary nucleation which plays a significant role in many systems is a very complicated task, which defies analytical solution unless being considerably simplified. In this case, numerical techniques should be invoked.[143]

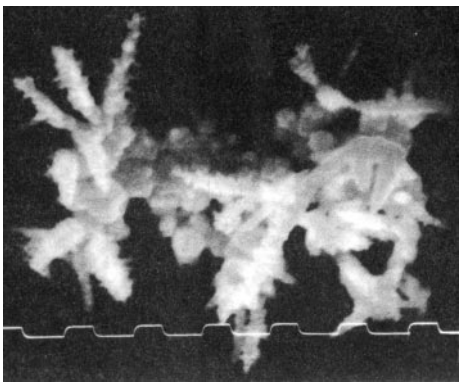

Figure 9. SEM image of platinum deposit on a carbon surface electroplated from a solution of 40 mM H_2PtCl_6 by square-wave pulses.[142] The horizontal measuring interval is 1 μm.

The technological possibilities of electrocrystallisation are extremely high and today are only partly used. The systems in which the crystals are formed on the surface of preliminarily developed adatomic submonolayers allow variation of the geometry of deposits on a nanolevel. In these layers, various two-dimensional phase transitions occur, and three-dimensional growth of nuclei is initiated by different mechanisms on domains of different structures.[144]

Tuning the fine structures by using the accompanying adsorption phenomena is also possible in the dissolution of metals: the processes of this group can be generally considered as electrocrystallisation with the formation and growth of cavity-type nuclei.

For the studies on the nanoscale level, a more precise control over the processes of new phase growth in the presence of organic additives traditionally used in industrial electroplating as the brighteners is possible by varying the ratio of the rates of nanocrystal growth in different directions.[145] Deposition of unusually long-lived metastable highly defective solids deserves mention as a promising approach.[146–148] The deposition becomes possible due to the formation of crystals on electrodes under substantially non-equilibrium conditions. A related direction is associated with the controlled variation of the stoichiometry of multicomponent phases that are deposited.[149–151]

In connection with the development of nanotechnology (see the next Section), it seems reasonable to outline the range of materials which can be deposited or formed by electrochemical mechanisms. On inert supports, one can carry out cathodic deposition of metals, alloys and certain semiconducting materials based on sulfur, selenium and tellurium and of solid complex compounds (for example, Prussian Blue and its analogues). The latter are of interest for electrochromic and sensor devices. Using anodic deposition on inert supports, one can obtain oxides and hydroxides,[152] different polymers [153, 154] and salt phases with variable electrophysical properties.[155] Anodising of metals in specially chosen media results in the formation of nanosize layers of passivating oxides many of which exhibit high photochemical activities.[156]

The formation of intercalates is an extremely important group of electrocrystallisation processes. Crystallisation of a new phase proceeds in the electrode bulk and, as a rule, is controlled by solid-state diffusion. Strains caused by intercalation can be observed by probe techniques.[157] Rapid intercalation processes are typical of a number of oxohydroxide phases and are accompanied by changes in the oxygen stoichiometry, which often proceed simultaneously with the proton transfer. High intercalation rates can be reached, for example, in materials based on oxides of ruthenium [158] and tin [159] for lattices of certain oxygen deficiencies. In such materials, as in metal hydrides, intercalation seems to be accompanied by the formation of nanosize regions with different compositions. The structure of intergrain boundaries is of principal significance for the reversibility and rate of intercalation, in particular for prevention of cracking by changing the local composition of grains.[22]

VII. Electrochemical nanotechnologies

Electrochemical fabrication of small-size articles occupies an important place in the system of chemical materials science and design of new materials having special properties. The mechanisms of formation or removal of individual small portions of solids play a decisive role in the field of electrochemical nanotechnology. These mechanisms are not quite clear which prevents the use of the most important advantage of electrochemical methods of fabricating nanoobjects, *viz.*, their controllability and the possibility of on-line quantitative monitoring. The controllability is provided by carrying out a process at a fixed potential (similar modes of deviation from equilibrium are practi-

cally unrealisable in beam and in CVD and PVD technologies). In the general case, monitoring is provided by measuring current and charge. The sensitivity to the rate of product accumulation is determined by the aforementioned limits of measuring these parameters. Additional possibilities of monitoring will arise with the use of a quartz-crystal microbalance technique, which can easily be realised in electrochemical systems, but have not yet found any practical application.

The existing nanotechnologies can be classified as local [31] and non-local.[19, 160] Most often, the latter represent different versions of lithographic techniques, *i.e.*, multistage combined technologies using photoinduced processes.

Non-local nanotechnologies based on different self-organisation processes in electrochemical systems represent an alternative to lithography. A typical example is the anodic electrosynthesis of alumina in which the ordered cylindrical pores with diameters of several tens nanometres are characterised by an extremely narrow size distribution.[145, 161] Being of interest for catalysis, this nanotube material [162] is widely used in combined technologies as a nanosize matrix. Metals [163, 164] and carbon materials [165] can be deposited into the pores of such an alumina matrix, and then alumina is removed at room temperature by dissolving it in alkali or HF. Similar processes can be realised for certain polymeric matrices (Fig. 10).

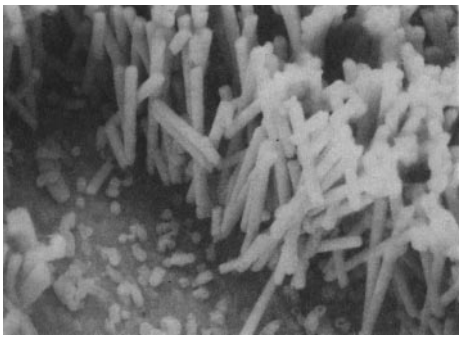

Figure 10. SEM image of an array of gold nanowires fabricated by electroplating into a polycarbonate matrix (after removal of the matrix).[166]

Electrodeposition of a metal into a porous matrix (templating) and co-deposition of a metal and a matrix (quasitemplating) form the basis of technologies for production of metallised conducting polymers.[167, 168]

Under certain conditions, the phenomenon of the formation of ordered new-phase nuclei in the absence of a matrix can also be used in nanotechnologies, for instance, in the preparation of catalytically active materials with particles of fixed sizes and also in combined low-temperature technologies for the preparation of semiconducting particles.[169–172]

Electrodeposition of lamellar bimetallic structures which is carried out either by different step-wise modes from a complex electrolyte or by consecutive deposition from different solutions constitute a separate group of processes. Continuous alternating 2-nm layers can be reproducibly obtained in systems characterised by two-dimensional growth. Layer-by-layer deposition finds wide application in the technologies of preparation of magnetic bimetallic materials.[173–176] Layer-by-layer deposition of single layers of semiconducting oxide phases [177] and of special polymeric compositions [178] is promising for the preparation of semiconducting superlattices.

Cathodic deposition of Cu/Cu_2O structures in the presence of organic complexones in a weakly alkaline medium, which is carried out in a simplest galvanostatic mode, is an example of a nanoelectrochemical technology for fabricating lamellar compositions.[179–181] Deposition of alternating layers of nanosize thicknesses is accomplished owing to a spontaneous initiation of potential oscillations caused by periodic changes in the pH and copper ion concentration in the near-electrode layer. In future, this method can be extended to other oscillating electrode processes.

The methods of dispersing metals by anodic dissolution are also worth being mentioned. Bach and coworkers [182–185] appear to be the first to apply this approach for the preparation of platinum colloids in aqueous media in the electric arc. In less severe conditions, a similar method is possible for palladium in non-aqueous solvents.[186] However, the problem of stabilisation of colloids is demanding, which requires introduction of organic additives in most cases.

We also assign the methods of immobilisation of molecular ensembles, clusters and metal particles on electrode surfaces to electrochemical nanotechnologies. The particles are bound with the surface by adsorption induced by the potential (charge) of an electrode. In a number of cases, this process occurs under electrophoretic supply and often involves surfaces preliminarily functionalised, for example, by alkanethiols. The best developed methods are those of colloid immobilisation [54, 187–189] which provide virtually monodispersed coatings. When using weak stabilisers, for example, citrates, it is possible to simultaneously provide a narrow size distribution of particles and their high adsorbabilities (Fig. 11).

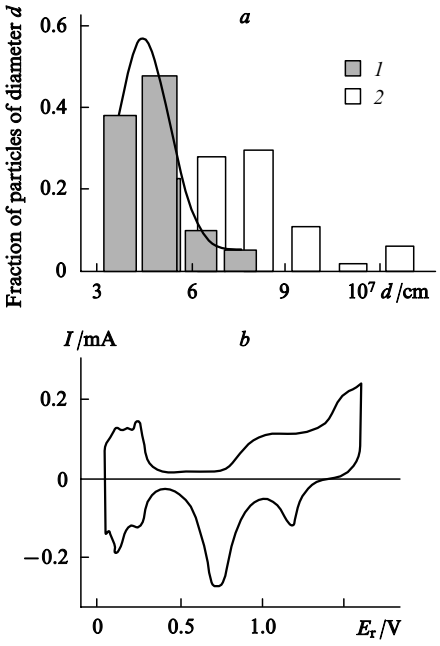

Figure 11. Size distribution of particles of immobilised platinum citrate colloid on polycrystalline gold (*a*) and potentiodynamic curve of the immobilised colloid (*b*). The distribution is plotted from STM data (*1*); for comparison, a wider distribution (*2*) corresponding to platinum electrodeposition is shown.[54]

Various local nanotechnologies can be realised in the configuration of probe microscopes [18] based on diverse processes. Thus one can locally deposit polymers and metals either by supplying reagents from the solution bulk [190] or by generating them on the probe tip.[191] It is also possible to modify a surface by transferring metal to it from the probe during short mechanical contact.[192] In this process, no electrochemical reaction occurs, and adsorption phenomena on the charged surface appear to play a significant role in the stabilisation of clusters formed. Figure 12 shows a scheme of this procedure. The methods of local etching near the tip, which are realised in STM configuration (both *in situ* [193] and *ex situ* [194]) where the role of an electrolyte is played by the moisture concentrated from air, are also gaining acceptance.

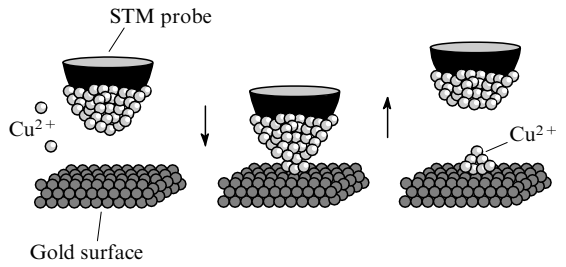

Figure 12. A procedure for local modification of a gold surface by copper clusters in an STM configuration.[20]

The adsorption and related combined nanotechnologies based on self-organisation in two-dimensional layers and spontaneous chemical deposition employ efficiently electrochemical methods to govern the process.[195]

Local modification of a surface in a scanning mode with the formation of sufficiently stable cluster ensembles is sometimes called electrochemical nanolithography.[192–193] The response time of probe microscopes leaves only few chances for nanolithography in fabricating items on the nanosize scale. However, with the progress in nanoelectronics, the scale of these electrochemical technologies will clearly increase. We can offer quite a number of examples where island, lamellar and other nanostructures formed by applying electrochemical methods are successfully used as quantum wells, superlattices, tunnelling diodes, *etc*.

Apparently, one of the main directions is associated with the achievement of quantum-size and resonance effects on the tips of STM probes modified electrochemically or by adsorption.[196, 197] In particular, this involves the quest for systems with a negative differential resistance. Figure 13 shows an example of such a response for a local quasi-one-dimensional nanostructure.

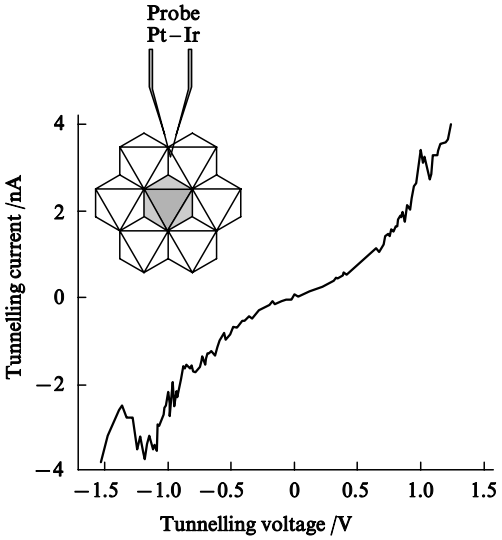

Figure 13. Tunnelling current *vs*. voltage characteristic demonstrating the negative differential resistance effect using a probe modified by heteropoly molybdate.[197]

VIII. Conclusion

The material reported in this review does not exhaust all the approaches to the research and application of size effects in electrochemistry. At present, prospects for the development of nanoelectrochemistry appear to be somewhat remarkable. This is associated with the fact that, in principle, possibilities of governing the operations on an atomic level have already been demonstrated. However, such achievements are realisable only at the lower limits of the possibilities of the available equipment.

An on-line observation of elementary steps of electrochemical charge transfer, even if for relatively slow reactions, seems to be most impressive.[24] However, this will require a substantial decrease in the operation time of probe techniques (to date, scanning of 50 images per second with an atomic resolution is apparently a record, however, not as yet for liquid phases). Conceptually, electrochemistry arrives at quite a novel stage of development when we must reconsider many common concepts and relationships. This reconsideration concerns now, particularly, the modification of the traditional Nernst equation of the equilibrium potential when applied to nanosize materials and the relationships of the classical theory of electrocrystallisation. Which of the predicted issues will remain in the status of science fiction and which will enter common research and technological practice and when this will occur, depends on many factors. However, the fast progress of nanochemistry in the recent years lends optimism.

Great expectations are associated with the integrating trends of different branches of physics and chemistry. Carrying out their experiments, modern scientists actually deal not only with elementary events that accompany transformations of single atoms and molecules, but also with transition states.[198] In the near future it may become possible to transform the experimental basis of these studies so as to adapt it to electrochemical systems.

This work was supported by the Ministry of Industry, Science and Technologies of the Russian Federation and the Foundation 'Integration' (United Educational and Research Centre A0114). We are grateful to the Corresponding member of the RAS Professor Yu M Polukarov for discussing the topical problems of nanochemistry.

Abstract. Studies on the development of procedures for the synthesis of five isomeric pyridopyridines, *viz*., 1,5-, 1,6-, 1,7-, 2,6- and 2,7-naphthyridines, their chemical properties and biological activities performed over the last 15 years are surveyed and systematised. The bibliography includes 223 references.

I. Introduction

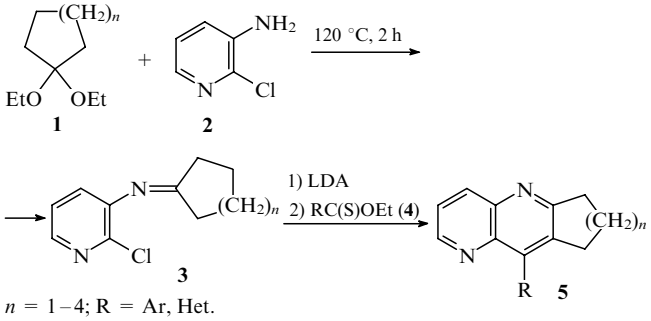
Pyridopyridines (diazanaphthalenes, napthyridines) are fused heterocyclic systems containing two nitrogen atoms in the adjacent rings. Naphthyridine derivatives attract interest because of the broad spectrum of their biological activities. These compounds are used in diagnostics and treatment of different human diseases (including HIV infection), agriculture, animal husbandry for external- and internal-parasite control, in industry as preservatives and components of lubricating coolants for metal processing, in analytical chemistry as ligands, *etc*.

Previously, we have considered general methods for the synthesis of naphthyridines, their structures and properties.[1] In the present review, we survey procedures for the synthesis of five isomeric pyridopyridines, *viz*., 1,5-, 1,6-, 1,7-, 2,6- and 2,7-naphthyridines, their chemical properties and biological activities. For convenience, the data are systematised according to the types of isomeric naphthyridines.

II. 1,5-Naphthyridines

The major synthetic approach to the construction of the 1,5-naphthyridine system involves condensation of 3-aminopyridine derivatives with dicarbonyl compounds followed by the intramolecular reaction of the pyridine ring with the terminal carbonyl group under the action of acid catalysts to form a C–C bond. This approach serves as the basis for well-known syntheses according to Skraup, Friedländer, Knorr, *etc*.[1] Amino derivatives of pyridine,[2] indole,[3–6] and quinuclidine,[7] oximes of the isoquinoline series[8–10] and substituted anilines[11] were successfully used as substrates in these reactions.

Unlike the above-listed reactions, condensation of cycloalkanone diethyl acetals **1** with 3-amino-2-chloropyridine (**2**) afforded azomethines **3** whose successive treatment with lithium diisopropylamide (LDA) and thioesters **4** gave rise to aryl(hetaryl)cyclo(penta – octa)[*b*][1,5]naphthyridines **5**.[2]



n = 1–4; R = Ar, Het.

Tryptamine, tryptophan and their derivatives are widely used in the synthesis of indolo[3,2,1-*de*][1,5]naphthyridine derivatives. Thus refluxing of tryptamine (**6**) with 2-formylbenzoic acid (**7**) in alcohol followed by the addition of concentrated hydrochloric acid afforded hexahydrobenzo[*h*]indolo[3,2,1-*de*][1,5]naphthyridine hydrochloride (**8**) used as the starting compound in the synthesis of compounds **9** and **10**. The latter have an application in the treatment of oxygen deficiency.[3]

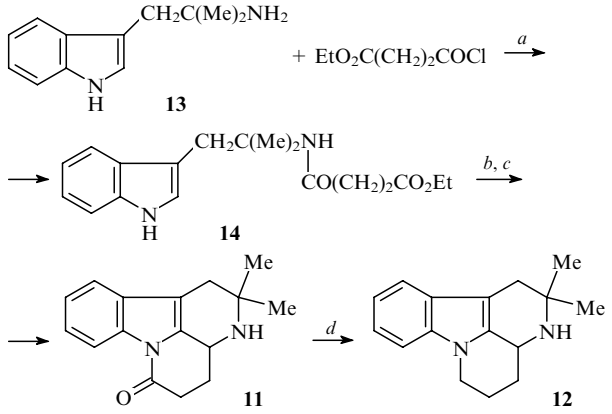
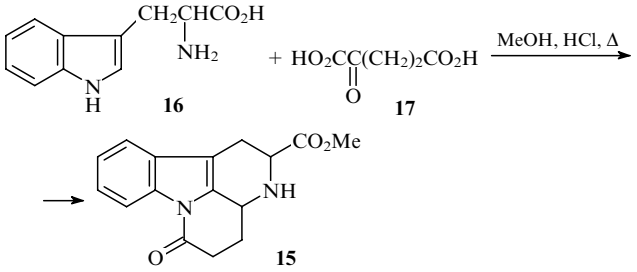
Received 27 July 2000
Uspekhi Khimii **70** (4) 343 – 367 (2001); translated by T N Safonova

1,5-Naphthyridine derivatives **11** and **12** prepared from α,α-dimethyltryptamine (**13**) and ethyl 3-chlorocarbonylpropionate are also used in the case of cerebral-vascular insufficiency and oxygen deficiency. Cyclisation of the intermediate **14** was carried out under the action of $POCl_3$ and KBH_4.[4]

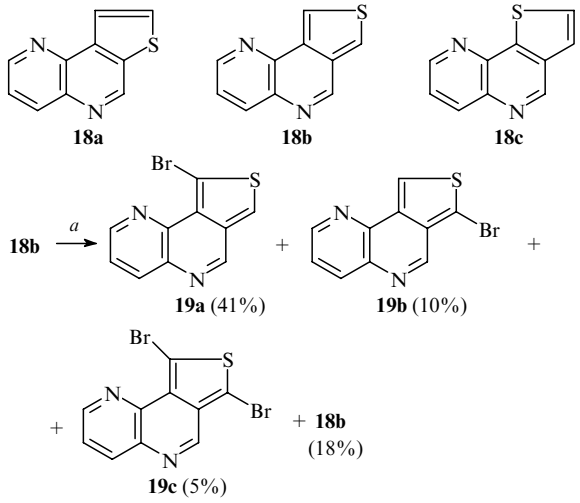


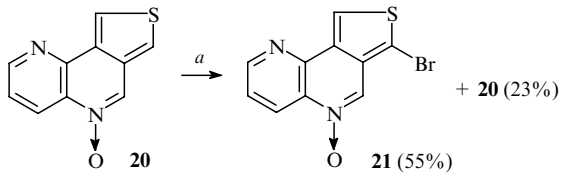
(*a*) Py, 20 °C, 1 h; (*b*) $POCl_3$; (*c*) KBH_4, EtOH – AcOH (5 : 1); (*d*) $LiAlH_4$, $AlCl_3$.

Indolonaphthyridine **15** was prepared by cyclocondensation of tryptophan (**16**) with 2-oxoglutaric acid (**17**) upon refluxing in methanol in the presence of HCl.[10]



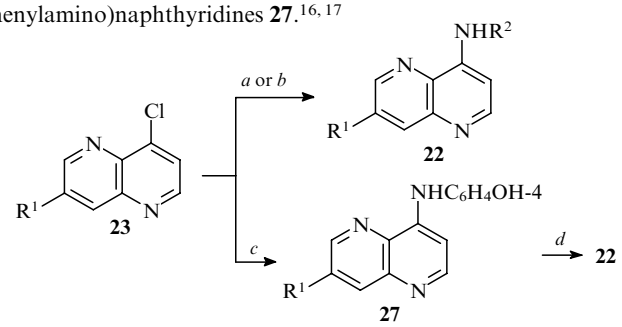
The chemical properties of 1,5-naphthyridines and the possibilities of their use for the preparation of biologically active compounds have been studied extensively. In particular, bromination of three isomeric thieno[*c*][1,5]naphthyridines **18a**–**c** and their *N*-oxides with tetrabutylammonium perbromide or bromine in the presence of $SOCl_2$ was investigated.[12] The reactions involving *N*-oxides proceed with higher regioselectivity. Thus bromination of thienonaphthyridine **18b** with tetrabutylammonium perbromide afforded a mixture of halogeno derivatives **19a**–**c**, whereas bromination of its *N*-oxide **20** under the same conditions gave rise to bromide **21** in 55% yield (23% of the initial compound remained unconsumed).[12]



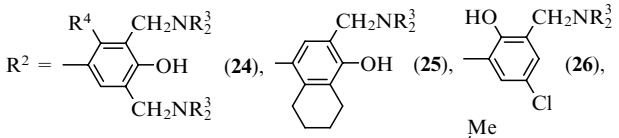


(*a*) 1.2 equiv. $Bu_4N^+Br_3^-$, $NaHCO_3$, CH_2Cl_2, 20 °C.

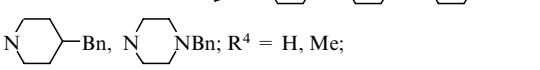
One of the recent major procedures used in the synthesis of biologically active 1,5-naphthyridines is based on the replacement of the halogen atom at position 4 of the naphthyridine ring.[13–23] Thus substituted 1,5-naphthyridin-4-ylamines **22** were prepared by the reactions of 4-chloro-1,5-naphthyridines **23** with aminophenols **24**–**26**[13–15] or by the Mannich reaction of 8-(4-hydroxyphenylamino)naphthyridines **27**.[16,17]



R^1 = H, Me, Cl, Br, CF_3;



NR_2^3 = NEt_2, NPr_2, $NHBu^t$, 

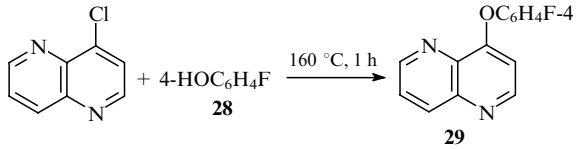


(*a*) H_2NR^2, MeOH (EtOH), HCl, Δ; (*b*) $AcNHR^2$, MeOH (EtOH), HCl, Δ; (*c*) 4-$HOC_6H_4NH_2 \cdot HCl$, MeOH, Δ; (*d*) CH_2O, HNR_2^3, EtOH, Δ.

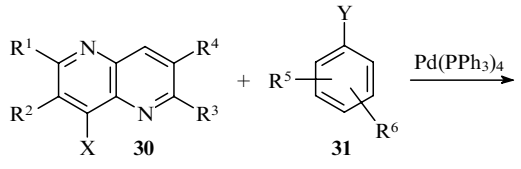
The compounds **22** exhibit antimalarial activity both *in vitro* and *in vivo*. This activity is less pronounced in the case of R^1 = Br or CF_3 and R^2 = Me or Et.[14,15]

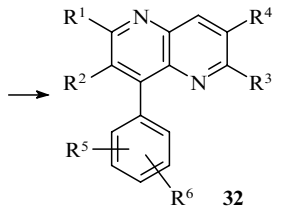
(7-Bromo-1,5-naphthyridin-4-yl)(piperidin-2′-yl)methanol, which is a potential antimalarial drug of a new type, was synthesised in four steps starting from 4,7-dibromo-1,5-naphthyridine.[22]

The reaction of 4-chloro-1,5-naphthyridine with 4-fluorophenol (**28**) afforded 4-(4-fluorophenoxy)-1,5-naphthyridine (**29**) exhibiting fungicidal and insecticidal activities.[23]



Cross-coupling of 1,5-naphthyridines **30** containing the bromine or iodine atom at position 4 with organotin, -silicon or -boron compounds **31** in the presence of $Pd(PPh_3)_4$ gave rise to aryl-substituted 1,5-naphthyridines **32** covered by a patent as herbicides.[24]

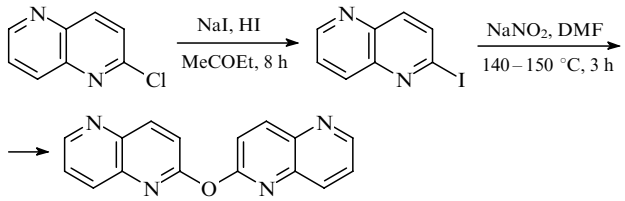




32

R^1 = Alk(C_1–C_4), OAlk, SAlk; R^2 = H, Me, F, Cl;
R^3–R^6 = H, Alk(C_1–C_4), OAlk, CN, Hal; X = Br, I;
Y = $SnMe_3$, $SiMe_3$, $B(OH)_2$.

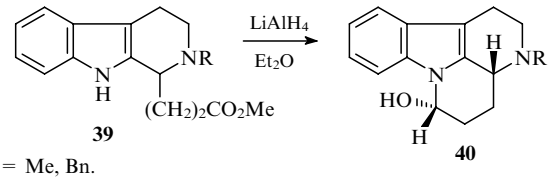
The chlorine atom in 2- or 4-chloronaphthyridines was replaced by the iodine atom under the action of NaI in the presence of hydroiodic acid yielding 2- or 4-iodo-1,5-naphthyridines, respectively.[25] It was noted[25] that treatment of 2-iodo-1,5-naphthyridine with $NaNO_2$ in DMF gave rise to 2,2′-bis(1,5-naphthyridyl) ether (**33**) in 44% yield, whereas an analogous reaction with 4-iodo-1,5-naphthyridine did not proceed.



33

In 6-chloronaphtho[1′,2′:4,5]thieno[2,3-c][1,5]naphthyridine (**34**), the chlorine atom is readily replaced by the amino or hydrazinoamino group and also is reduced to yield the corresponding 1,5-naphthyridine derivatives **35**–**37**. Under the action of ethyl orthoformate, the hydrazine **37** underwent cyclisation to give triazole **38**[26] (Scheme 1).

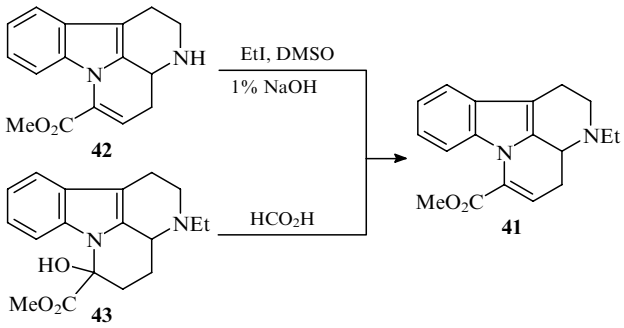
Reductive cyclisation of esters **39** afforded 1,5-naphthyridine derivatives **40**, which were dimerised under the action of acids.[27]



39 **40**

R = Me, Bn.

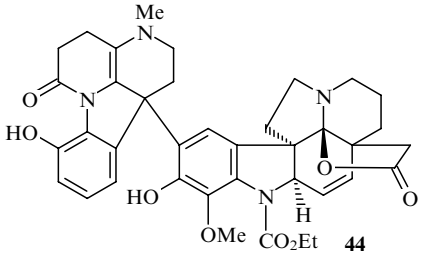
Methyl (±)-3-ethyl-2,3,3*a*,4-tetrahydro-1*H*-indolo[3,2,1-*de*]-[1,5]naphthyridine-6-carboxylate (**41**) possessing psychostimulating activity was prepared by alkylation of ester **42** with iodoethane in DMSO or by dehydration of hydroxy derivative **43**.[28]



42 **43** **41**

1,5-Naphthyridine derivatives, like other isomeric pyridopyridines, were found in many natural substances and were used for the construction of a series of efficient medicines.

Recently, the previously unknown dimeric indole alkaloid cimiciduphytine (**44**) containing the 1,5-naphthyridine fragment[29] and derivatives of eburnane alkaloids **45** exhibiting hypotensive and pain-relieving activities have been isolated from naturally occurring sources. These compounds are suitable for the treatment of cerebral circulation disturbance.[30–35]



44

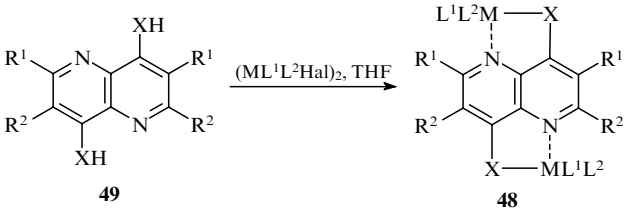
R = OEt, OPr, 
Derivatives of annelated benzoindolo-1,5-naphthyridines suitable for improvement of memory attenuated by drugs were described.[3,5] These are benzo[*b*][1,5]naphthyridines, which are analogues of inhibitors of neurokinin NK_1-receptors. Various 1,5-naphthyridine derivatives, in particular, 2-naphthyridinecarboxamide, possessing antiviral activity were also reported.[38].

Complexes **48** of Group IB or VIII metals with 1,5-naphthyridine derivatives **49** were synthesised.[39] The compounds **48** are used for the preparation of singlet oxygen. These compounds serve as sensitisers in photoinitiation of polymerases and electrophotography and as redox catalysts in organic reactions.[39]



49 **48**

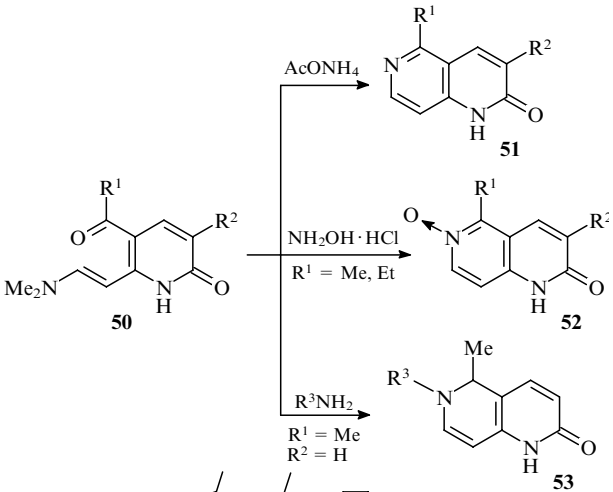
R^1, R^2 = H, Me, Et, cyclo-Alk(C_3–C_7); R^1–R^2 = $(CH_2)_n$, n = 3–6; X = O or S, M is Group IB or VIII metal; L^1, L^2 = Hal, NO, PPh_3, CN, CO.

The electronic structures and the UV spectral parameters of six isomeric formyl-substituted 4,6-benzo-1,5- and -1,6-naphthyridines were calculated.[40]

III. 1,6-Naphthyridines

Chemistry and biological activities of 1,6-naphthyridine derivatives were studied in much more detail than those of 1,5-, 1,7- and 2,7-naphthyridine derivatives. A wide variety of approaches to their syntheses are available.

One of the promising procedures for the synthesis of 1,6-naphthyridine derivatives involves functionally substituted pyridones as the starting compounds. Thus enamines **50** prepared from 6-formylpyrid-2-ones underwent cyclisation upon refluxing with ammonium acetate in DMF to give 1,6-naphthyridin-2-ones **51** in good yields.[41–47] *N*-Oxides **52** were prepared by cyclisation of the enamines **50** under the action of hydroxylamine hydrochloride.[42,45] The reactions of the compounds **50** with amines in methanol or DMF afforded 6-substituted 1,2,5,6-tetrahydro-1,6-naphthyridin-2-ones **53**.[48]

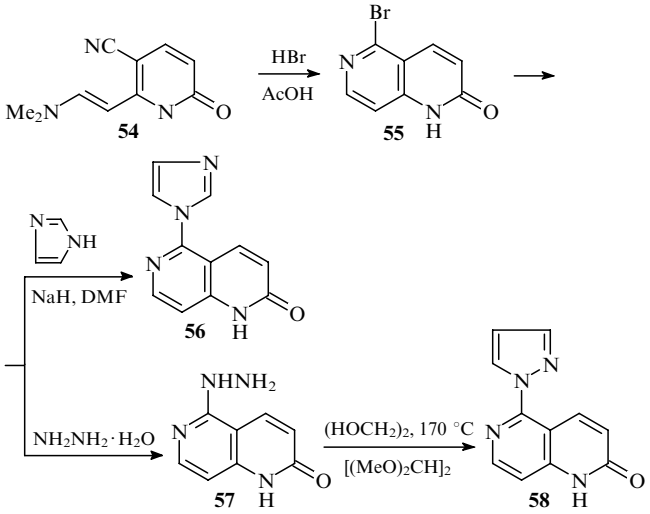


50 **51** **52** **53**

R^1 = Me, Et, Pr, Bu, Ph,  ;

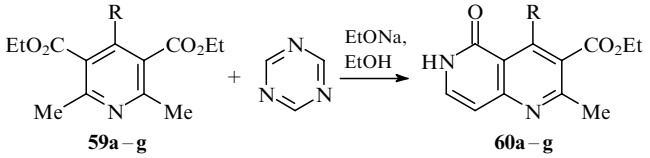
R^2 = H, Br, CN; R^3 = 4-$MeOC_6H_4$, NH_2, NMe_2.

Treatment of enamine **54** derived from 5-cyano-6-formyl-2-pyridone with gaseous HBr in AcOH gave rise to 5-bromo-1,6-naphthyridin-2-one (**55**). The bromine atom in the compound **55** is readily replaced by nitrogen nucleophiles. This fact was used in the synthesis of 1,6-naphthyridine derivatives **56**–**58**.[49–52] The compounds **51**, **52** and **55**–**58** exhibit cardiotonic activity.[41–52]



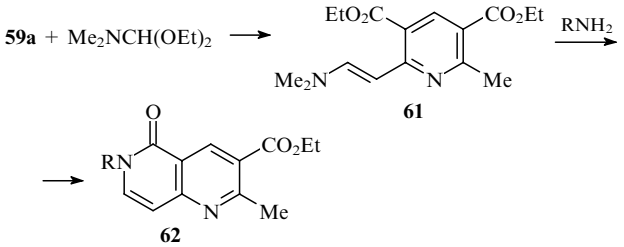
54 **55** **56** **57** **58**

1,6-Naphthyridin-5(6*H*)-ones **59a**–**g** were prepared by the reactions of pyridines **60a**–**g** with 1,3,5-triazine upon refluxing in ethanol in the presence of sodium ethoxide. The reaction of the compound **60a** with dimethylformamide diethyl acetal gave rise to enamine **61**. The reactions of the latter with amines upon refluxing in ethanol, DMF, *m*-xylene or pyridine afforded 6-substituted naphthyridinone derivatives **62**.[53,54] Refluxing of vicinal diamines **63** with enamine **61** yielded naphthyridinones **64**, which were converted into tetracyclic derivatives **65** under the action of $POCl_3$.[55]



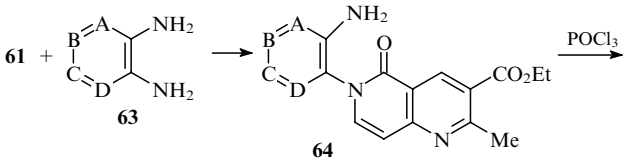
59a–**g** **60a**–**g**

R = H (**a**), Ph (**b**), 4-ClC_6H_4 (**c**), 3,4-$(MeO)_2C_6H_3$ (**d**), 2-$NO_2C_6H_4$ (**e**), 4-$NO_2C_6H_4$ (**f**), 3-pyridyl (**g**).

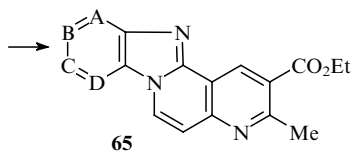


61 **62**

R = H, Ph, 2-FC_6H_4, 4-FC_6H_4, 3-$F_3CC_6H_4$, 2-$NH_2C_6H_4$.



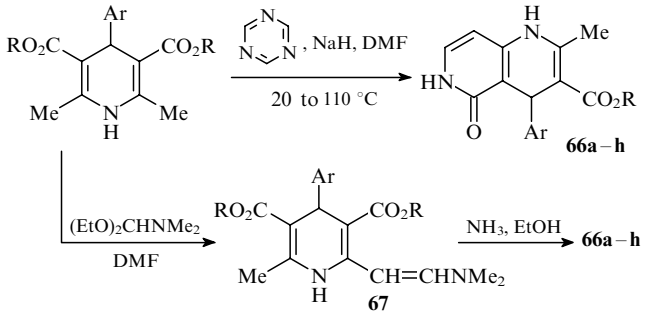
63 **64**



65

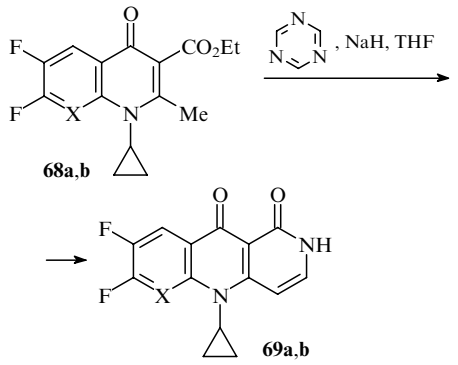
A = B = C = D = CH; A = B = C = CH, D = N; A = N, B = C = D = CH; A = C = D = CH, B = N; A = C = N, B = D = CH; A = C = CH, B = D = N.

The reactions of 1,4-dihydropyridines with 1,3,5-triazine in the presence of a base afforded 1,4-dihydro-1,6-naphthyridines **66a**–**h**. These compounds can also be prepared in two stages by the reactions of 1,4-dihydropyridines with dimethylformamide diethyl acetal followed by treatment of aminovinyl intermediates **67** with ammonia.[56] The compounds **66a**–**h** were covered by patents as agents promising in the treatment of cardiovascular diseases.[57–61]

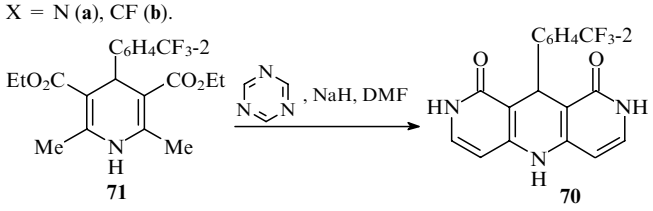


Ar = Ph (**a**), 4-ClC_6H_4 (**b**), 2-$NO_2C_6H_4$ (**c**), 2-pyridyl (**d**), 2-thienyl (**e**), 2-FC_6H_4 (**f**), 2-$CF_3C_6H_4$ (**g**), 2-F-3-ClC_6H_3 (**h**);
R = Me, Et, Bu^t.

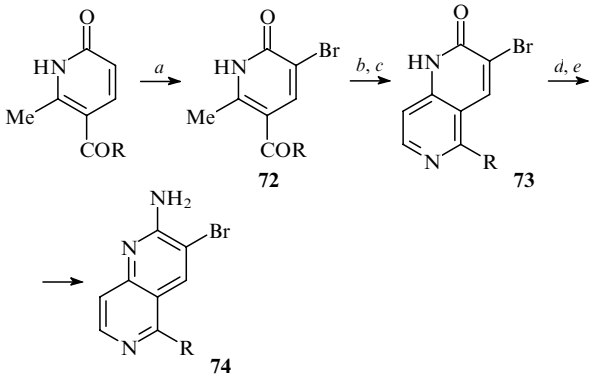
Substituted pyridones are widely used as the starting compounds in the synthesis of substituted 1,6-naphthyridines. Thus the reactions of 1,3,5-triazine with pyridones **68a**,**b** yielded annelated 1,6-naphthyridines **69a**,**b**. The tricyclic compounds **69** containing the cyclopropyl substituent were covered by patents as efficient antibiotics.[62] Pyrido[2,3-*b*][1,6]naphthyridine **70** prepared from 1,4-dihydropyridine **71** possesses spasmolytic activity and is used in the treatment of cerebral, cardiac and peripheral artery diseases.[63]



X = N (**a**), CF (**b**).



The reactions of 5-alkanoyl(aroyl)-6-methylpyridin-2(1*H*)-ones with *N*-bromosuccinimide in CCl_4 afforded bromides **72**. Successive treatment of the latter with $(Me_2N)_2CHOBu^t$ (Bredereck's reagent) and ammonium acetate gave rise to 5-alkyl(aryl)-3-bromo-1,6-naphthyridin-2(1*H*)-ones **73** in high yields.[64] The compounds **73** were converted under the successive action of $POCl_3$ and ammonia into 5-alkyl(aryl)-2-amino-3-bromo-1,6-naphthyridines **74**, which are promising starting compounds for the preparation of new biologically active compounds.



R = Me, Et, Pr^n, Bu^i, Ph, 4-$NO_2C_6H_4$;

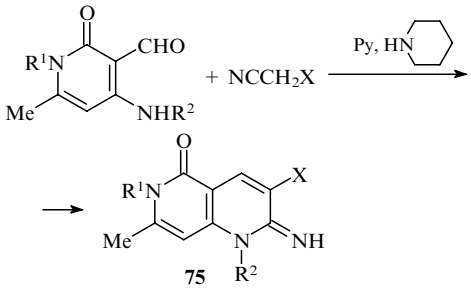
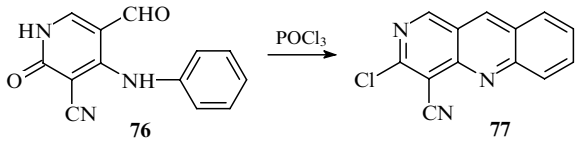
The Knoevenagel reaction of substituted 4-amino-3-formylpyridin-2-ones with CH-acids in the presence of piperidine was used in the synthesis of 2-imino-1,6-naphthyridin-5(6*H*)-ones (**75**) possessing antitubercular activity.[65]

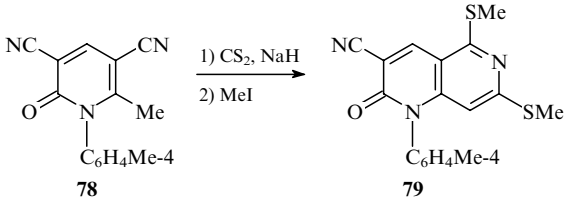


R^1, R^2 = $PhCH_2$, $Ph(CH_2)_2$; X = CN, CO_2H, CO_2Me, CO_2Et, 4-$NO_2C_6H_4$.

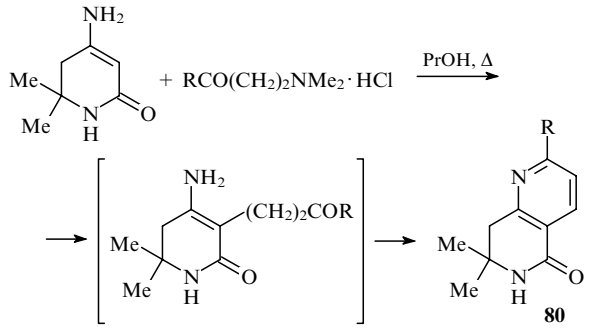
When heated with $POCl_3$, substituted pyridone **76** underwent cyclisation with simultaneous replacement of the 2-oxo group by the chlorine atom to give 3-chloro-4-cyanobenzo[*b*][1,6]naphthyridine **77**.[66,67]



The reaction of pyridone **78** with carbon disulfide and sodium hydride in benzene followed by methylation with iodomethane produced the 5,7-bis(methylthio)-1,6-naphthyridinone derivative **79**.[68]



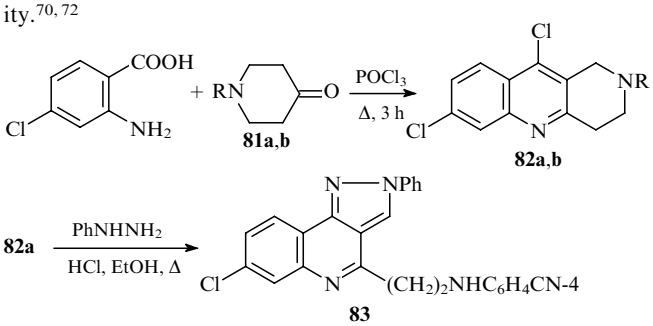
5,6,7,8-Tetrahydro-1,6-naphthyridin-5-ones **80** were synthesised by the reactions of 4-amino-5,6-dihydropyridin-2(1*H*)-one with amino ketone hydrochlorides.[69]



R = Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4.

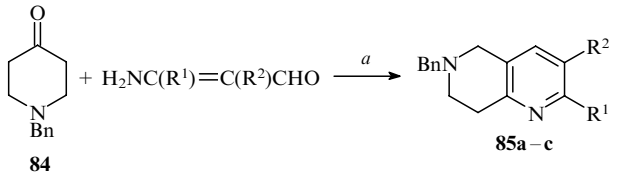
Piperidones are used as starting compounds in the synthesis of 1,6-naphthyridines. Thus the reactions of *N*-substituted piperidones **81a**,**b** with 2-amino-4-chlorobenzoic acid afforded 2-aryl(heteryl)tetrahydrobenzo[*b*][1,6]naphthyridines **82a**,**b**, which serve as inhibitors of interleukin 1 and were covered by patents as antiinflammatory agents.[70–72]

The reaction of the compound **82a** with phenylhydrazine in the presence of concentrated hydrochloric acid gave rise to pyrazolo[4,3-*c*]quinoline (**83**) exhibiting antiinflammatory activity.[70,72]



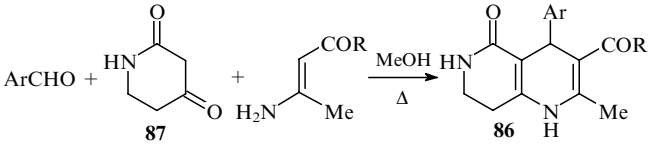
R = 4-NCC_6H_4 (**a**), pyrimidin-2-yl (**b**).

The reactions of *N*-benzylpiperidin-4-one (**84**) with 3-aminoacrolein and its homologues were used for the preparation of 5,6,7,8-tetrahydro-1,6-naphthyridines **85a**–**c**.[73]



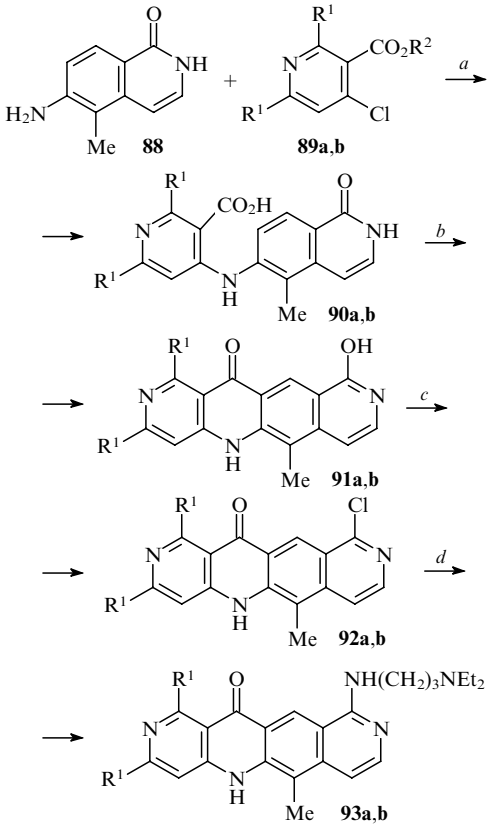
$R^1 = R^2 = H$ (**a**); R^1 = Me, R^2 = H (**b**); R^1 = H, R^2 = Me (**c**);
(*a*) NH_2 AcO^-, Et_3N, 120 °C, 24 h.

Partially hydrogenated 1,6-naphthyridines **86** were synthesised by the Hunch condensation of aromatic aldehydes with 2,4-dioxopiperidine (**87**) and derivatives of 3-aminocrotonic acid.[74] The compounds **86** were covered by a patent as drugs for the treatment of cardiovascular diseases.[75]



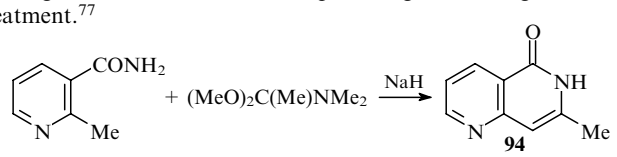
R = MeO, EtO, MeNH, Et_2N, $NH(CH_2)_2OH$.

The reactions of 6-amino-5-methylisoquinolin-1(2*H*)-one (**88**) with 4-chloronicotinic acid (**89a**) or ethyl 4-chloro-2,6-dimethylnicotinate (**89b**) afforded amino-substituted 6-aminoisoquinolines **90a**,**b**, which underwent cyclisation to form 5*H*-isoquinolino[6,7-*b*][1,6]naphthyridin-12-ones **91a**,**b**, respectively.[76] The latter were used in the synthesis of 10-substituted 1,6-naphthyridine derivatives **92a**,**b** and **93a**,**b**, which are analogues of 9-azaellipticine possessing antitumour activity. However, it appeared that the replacement of the pyrrole fragment in 9-azaellipticine by the 4-pyridone fragment led to a loss of biological activity.[76]

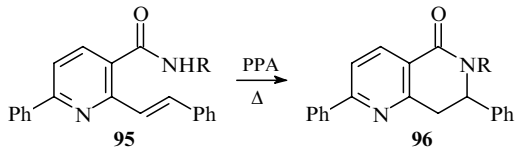


$R^1 = R^2 = H$ (**a**), R^1 = Me, R^2 = Et (**b**); (*a*) H_2SO_4, CF_3CO_2H; (*b*) H_2SO_4 or CF_3SO_3H; (*c*) $POCl_3$, PCl_5; (*d*) $NH_2(CH_2)_3NEt_2$.

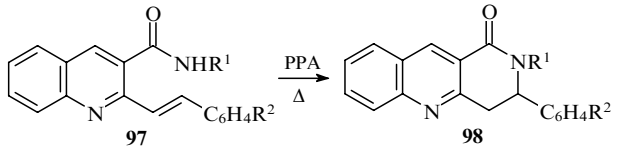
Pyridinecarboxylamides are widely used in the synthesis of 1,6-naphthyridines. Thus heating of a mixture of 2-methylnicotinamide with *N*,*N*-dimethylacetamide dimethyl acetal in the presence of NaH gave rise to 7-methyl-1,6-naphthyridin-5(6*H*)-one (**94**), which is used for eliminating harmful effects caused by ionising radiation or chemotherapeutic agents during tumour treatment.[77]



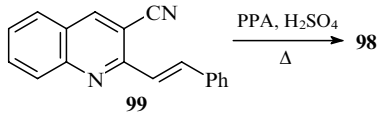
When heated in polyphosphoric acid (PPA), 6-phenyl-2-styrylnicotinamides (**95**) underwent cyclisation to form substituted 5-oxo-5,6,7,8-tetrahydro-1,6-naphthyridines **96**.[78] Analogously, benzo[*b*][1,6]naphthyridines **98** were prepared from amides of the quinoline series **97**.[78–80] Naphthyridine **98** ($R^1 = R^2 = H$) was also synthesised by cyclisation of 3-cyano-2-styrylquinoline **99** under the action of a mixture of polyphosphoric and sulfuric acids.[80]



R = $CH_2=CHCH_2$, iso-C_5H_{11}, Ph, 3-MeC_6H_4.



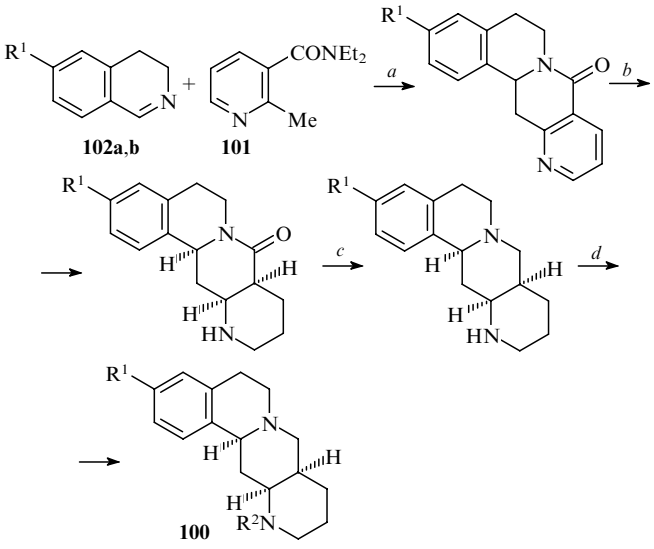
R^1 = H, Ph, Bn; R^2 = H, 4-MeO, 3-Br.



The reactions of *N*-substituted 2-chloro- or 4-chloronicotinamides with nitriles containing the active methylene group in the presence of bases were used for the preparation of amino derivatives of 1,6-naphthyridin-5(6*H*)-one or 2,7-naphthyridin-1(2*H*)-one, respectively.[81,82]

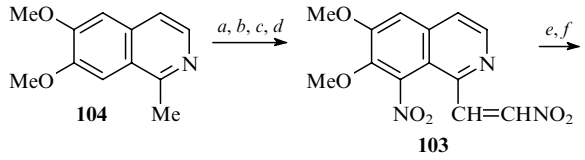
A procedure was developed for the synthesis of dodecahydroisoquinolino[2,1-*g*][1,6]naphthyridines **100** based on diethyl-2-methylnicotinamide (**101**) and 3,4-dihydroisoquinolines **102a**,**b**. The compounds **100** are highly efficient α_2-adrenoreceptor antagonists[83,84] and were covered by patents as drugs for the treatment of hypertonia, depression and diabetes, for inhibition of thrombocyte aggregation and for weight reduction.[85–90]

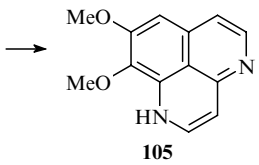
It should be noted that the structural analogue of α-yohimbine, *viz*., 6-methoxy-*N*-methylsulfonyl-6*H*-isoquinolino[2,1-*g*][1,6]naphthyridine (**100**, R^1 = MeO, R^2 = $MeSO_2$, the preparation RS-15385),[91] proved to be a very efficient drug in the treatment of impotence. A laboratory procedure for its preparation on a kilogram scale was developed.[92,93]



R^1 = H (**102a**), MeO (**102b**); R^2 = $MeSO_2$, $MeO(CH_2)_2SO_2$, $HO(CH_2)_2SO_2$, Bu^tNHSO_2, H_2NSO_2, Me_2NCO, $Cl(CH_2)_3SO_2$;
(*a*) Pr^i_2NLi, THF, −40 °C; (*b*) H_2, Rh/Al_2O_3, AcOH; (*c*) $LiAlH_4$, THF, Δ; (*d*) R^2X (X = Cl, Br), CH_2Cl_2, Et_3N.

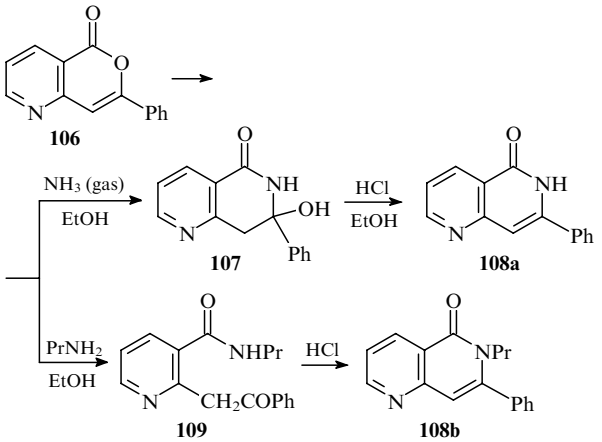
Reductive cyclisation of substituted isoquinoline **103**, which was prepared from 6,7-dimethoxy-1-methylisoquinoline (**104**) in four steps, was successfully used in the synthesis of 8,9-dimethoxy-1*H*-benzo[*d*,*e*][1,6]naphthyridine (aaptamine) (**105**). The latter compound was isolated from sea sponge *Aaptos aaptos* and exhibits sympatholytic and hypotensive activities.[94,95]



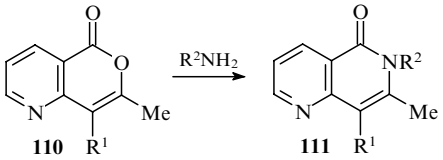


(*a*) HNO_3, −40 °C; (*b*) SeO_2, dioxane; (*c*) $MeNO_2$, Al_2O_3; (*d*) Al_2O_3, PhH, Δ; (*e*) Fe, AcOH, 20 °C, 2 h; (*f*) 90 °C, 45 min.

Pyranopyridines are convenient starting compounds in the synthesis of 1,6-naphthyridine derivatives. Thus, the reaction of 7-phenylpyrano[4,3-*b*]pyridin-5-one (**106**) with gaseous ammonia in ethanol was accompanied by the replacement of the oxygen atom of the pyran ring by the nitrogen atom to form hydroxynaphthyridine **107**. The latter was dehydrated with an alcoholic solution of HCl to give 7-phenyl-1,6-naphthyridin-5(6*H*)-one (**108a**). Treatment of pyranopyridine with propylamine led to the pyran ring opening to form 2-phenacyl-*N*-propylpyridine-3-carboxamide (**109**), which underwent cyclisation under the action of a 5% HCl solution giving rise to *N*-propyl-substituted naphthyridinone **108b**.[96]

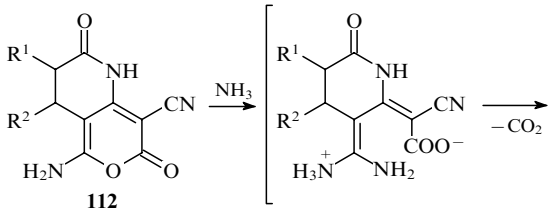


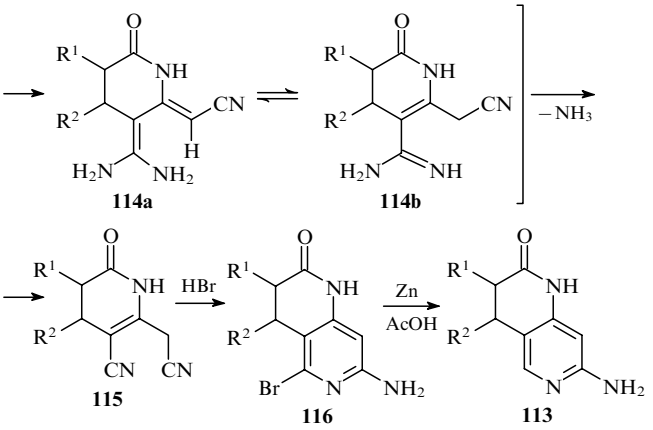
Analogous reactions of 7-methylpyrano[4,3-*b*]pyridines **110** with ammonia or aliphatic primary amines afforded 1,6-naphthyridinones **111**.[97]



R^1 = Ac, CO_2Et; R^2 = H, Me, Bu, $(CH_2)_2NH_2$, $(CH_2)_2OH$, CH_2=$CHCH_2$.

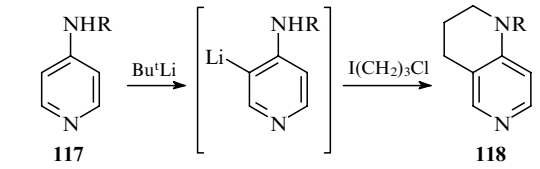
1,6-Naphthyridin-2(1*H*)-ones **113** were prepared from pyrano[4,3-*b*]pyridine-2,7-diones **112** by successive treatment with NH_3, HBr and Zn in acetic acid.[98] It was believed that the attack of the ammonia molecule on the C(5) atom led to the pyran ring opening. Subsequent decarboxylation afforded a tautomeric mixture of substituted tetrahydropyridines **114a**,**b**. Dinitrile **115** generated by elimination of the ammonia molecule underwent cyclisation under the action of HBr to form 1,6-naphthyridine derivative **116**. Dehydrobromination with Zn in acetic acid gave rise to the final products **113**.





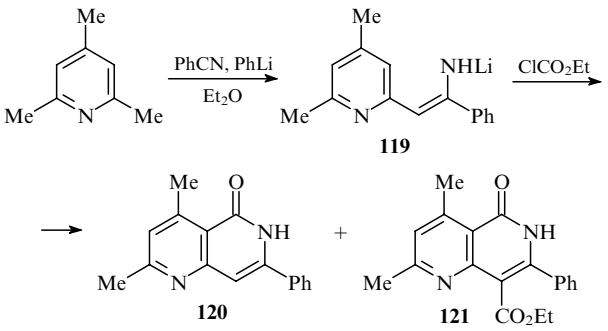
R^1, R^2 = H, Me, Ph.

Successive treatment of *N*-substituted 4-aminopyridines **117** with *tert*-butyllithium and 1,3-chloroiodopropane yielded tetrahydro-1,6-naphthyridines **118**.[99]

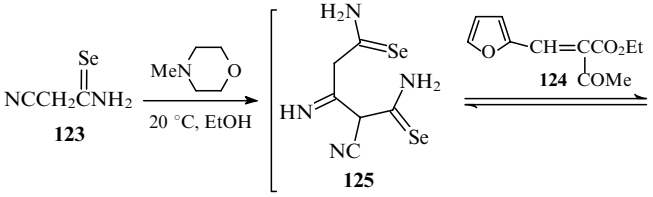


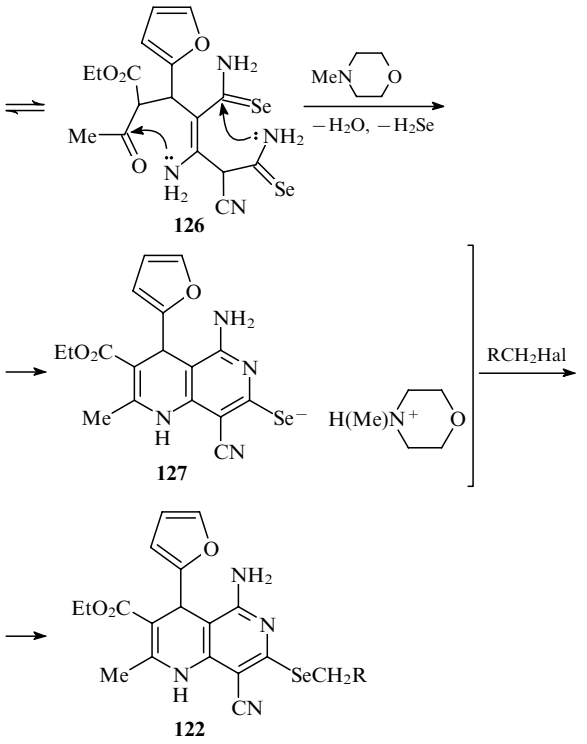
R = $COBu^t$, CO_2Bu^t.

The reaction of chlorocarbonic ester with the lithium derivative of enamine **119**, which was prepared by the reaction of 2,4,6-trimethylpyridine with benzonitrile and phenyllithium, afforded a mixture of 1,6-naphthyridin-5(6*H*)-ones **120** and **121**.[100]



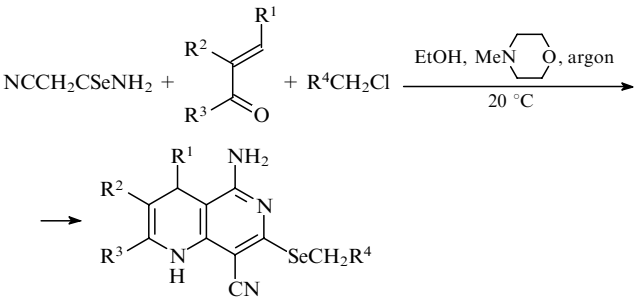
A convenient procedure was developed [101, 102] for the synthesis of 1,6-naphthyridine derivatives **122** containing the alkylselanyl substituent at position 7. Thus multicomponent condensation of cyanoselenoacetamide (**123**), 2-furfurylideneacetoacetic ester (**124**) and alkyl halides was carried out under the action of a twofold excess of *N*-methylmorpholine. The reaction involves the Thorpe dimerisation of the amide **123** yielding compound **125**, its reaction with a molecule of furfurylideneacetoacetic ester (**124**) to form adduct **126**, regioselective cyclocondensation of the adduct **126** producing substituted 1,4-dihydro-1,6-naphthyridine-7-selenolate (**127**) and alkylation of the selenolate **127** with alkyl halides giving rise to naphthyridines **122**.





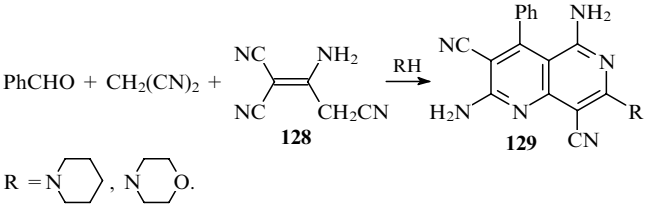
R = H, Me, Et, Pr, C_5H_{11}, CH_2Br, $(CH_2)_3Br$, $C(Me)=CH_2$, $HC=CH_2$, CO_2Et; Hal = I, Br, Cl.

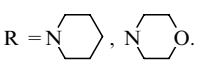
This procedure also allows one to construct the naphthyridine system from other α,β-unsaturated carbonyl compounds under mild conditions.[103]



R^1–R^3 = H, Alk, Ar, Het, CN, COOH, COOAlk, COAr, COHet, $CONH_2$, CONHAr; R^4 = Alk.

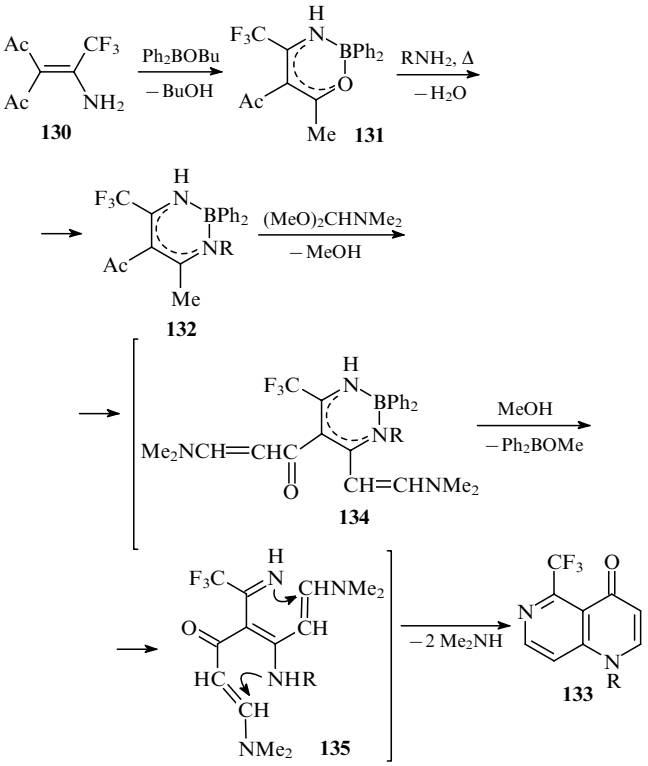
Multicomponent heterocyclisation of benzaldehyde with malononitrile and its dimer **128** in the presence of piperidine or morpholine was used for the construction of the 1,6-naphthyridine system **129**. Heterocyclisation was accompanied by the insertion of the cyclic-amine fragment into the molecule to form the compounds **129**.[104]





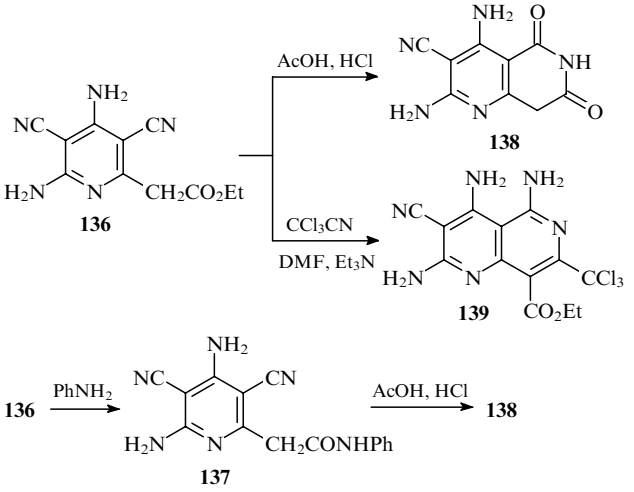
An ingenious method for the construction of the 1,6-naphthyridine system with the use of the 'chelate' methodology was developed.[105] Thus the reaction of 3-acetyl-4-amino-5,5,5-trifluoro-3-penten-2-one (**130**) with Ph_2BOBu afforded chelate complex **131** in which the oxygen atom was replaced by the nitrogen atom upon heating with primary amines. The resulting complexes

132 reacted with two equivalents of dimethylformamide dimethyl acetal to give 5-trifluoromethyl-1,6-naphthyridin-4(1*H*)-ones **133** in 77%–87% yields. It was believed [105] that the complexes **132** reacted with dimethylformamide dimethyl acetal to give condensation products at the methyl groups (**134**), which underwent deborylation with simultaneous cyclisation of intermediates **135** under the action of the methanol eliminated.

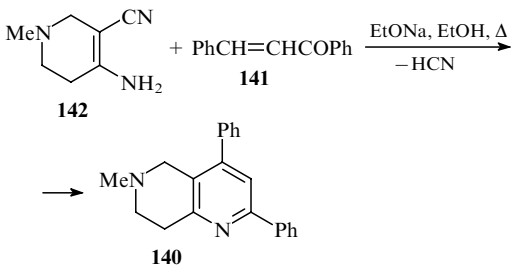


R = Bu, Bn.

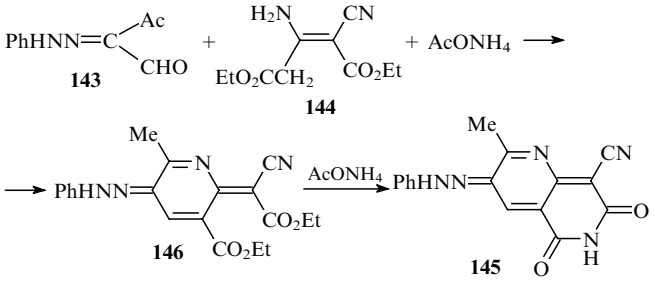
Ethyl (4,6-diamino-3,5-dicyano-2-pyridyl)acetate **136** or (4,6-diamino-3,5-dicyano-2-pyridyl)acetanilide **137** were converted into 1,6-naphthyridine-5,7(6*H*,8*H*)-dione **138** upon refluxing in acetic acid in the presence of HCl. Treatment of the ester **136** with trichloroacetonitrile in the presence of triethylamine afforded naphthyridine **139**.[106]



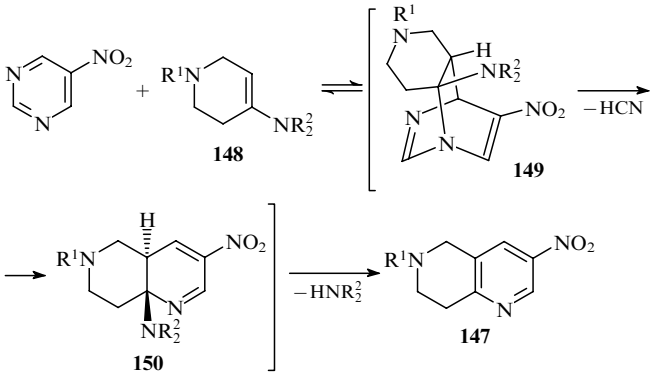
6-Methyl-2,4-diphenyl-5,6,7,8-tetrahydro-1,6-naphthyridine (**140**) was synthesised by cyclocondensation of benzylideneacetophenone (**141**) with enamino nitrile **142** in the presence of sodium ethoxide.[107]



Of other procedures for the synthesis of 1,6-naphthyridines, noteworthy is three-component cyclisation of 2,3-dioxobutanal phenylhydrazone (**143**) with diethyl 3-amino-2-cyanopent-2-enedioate (**144**) and ammonium acetate to form substituted 1,6-naphthyridine-5,7(3*H*,6*H*)-dione **145**. Polyfunctionalised pyridine derivative **146** was obtained as the intermediate in this reaction.[108]

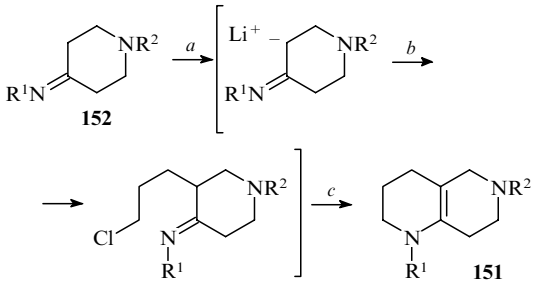


The synthesis of partially hydrogenated *N*-substituted tetrahydro-3-nitro-1,6-naphthyridines **147** involved diene condensation with the inversion of electrophilicity. 5-Nitropyrimidine reacted as the diene component with enamines **148**. Elimination of HCN from adducts **149** followed by elimination of pyrrolidine from intermediates **150** afforded the products **147**.[109]



R^1 = Me, Ac; NR_2^2 = .

A handy procedure for the one-pot synthesis of the previously unknown 1-substituted 1,2,3,4,5,6,7,8-octahydro-1,6-naphthyridines **151**, which are convenient building blocks and precursors of

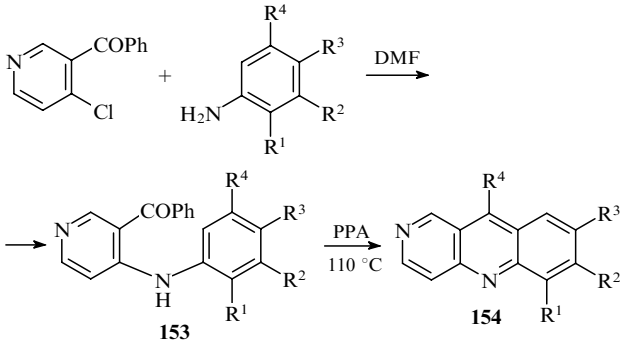


R^1 = Ph, CH_2Ph, (dl)-CH(Me)Ph, (*S*)-CH(Me)Ph; R^2 = Me, Bn, COPh; (*a*) LDA or Et_2NLi, THF, −30 °C, 30 min; (*b*) $Cl(CH_2)_3Br$, −78 °C; (*c*) Δ, 4 h.

biologically active compounds, was developed. The procedure involves metallation of imines **152** with lithium diisopropylamide or diethylamide followed by alkylation of the lithium derivatives with 1,3-bromochloropropane and intramolecular cyclisation of the resulting chloroalkylamines.[110]

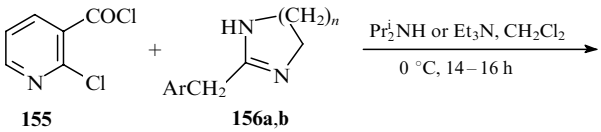
2-Benzyl-1,6-dimethyl-3,10-di(methoxycarbonyl)-8-phenyldecahydro-1,6-naphthyridin-4-one was synthesised and its structure was confirmed by X-ray diffraction analysis.[111]

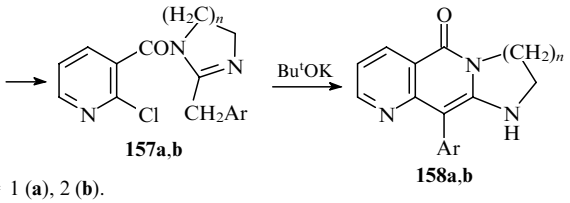
At the end of the section dealing with the synthesis of 1,6-naphthyridines, let us consider special procedures for the preparation of their annelated analogues. Thus a general procedure involves cyclisation of carbonyl derivatives of 4-chloropyridine with aromatic and heterocyclic amines under the action of acids. The reactions of 3-benzoyl-4-chloropyridine with substituted anilines afforded amine **153**, which underwent cyclisation under the action of polyphosphoric acid to form 1,6-naphthyridine derivatives **154** [112] (see also the synthesis of the compounds **91a**,**b** [76]).



R^1, R^2 = H, OH, OMe, Cl; R^1–R^2 = CH=CH–CH=CH;
R^3 = H, OMe, NO_2; R^4 = H, OMe.

2-Chloronicotinoyl chloride (**155**) was used as the starting compound in the synthesis of heteryl-annelated 1,6-naphthyridines. Its reactions with 4,5-dihydro-1*H*-imidazolines (**156a**) or tetrahydropyrimidines (**156b**) gave rise to the corresponding *N*-acyl derivatives **157a**,**b**, which underwent cyclisation under the action of potassium *tert*-butoxide to yield imidazo- (**158a**) or pyrimido[1,2-*g*][1,6]naphthyridinones (**158b**), respectively. The compounds **158a**,**b** exhibit antiallergic and antiinflammatory activities.[113, 114]

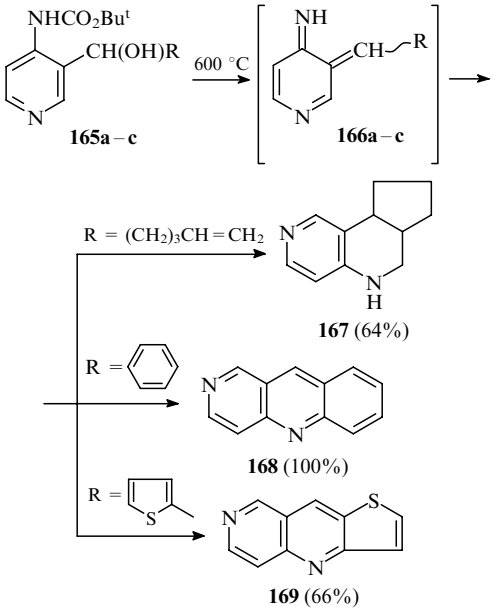




n = 1 (**a**), 2 (**b**).

The reactions of 3-aminocoumarins **159** with 2-chloronicotinoyl chloride (**155**) or 2-chloro-3-formylquinoline (**160**) afforded *N*-acyl derivatives **161** or Schiff bases **162**, which were dehydrochlorinated under the action of bases with simultaneous cyclisation to give benzopyrano[3,4-*h*][1,6]naphthyridines **163** or **164**, respectively (Scheme 2).[115, 116]

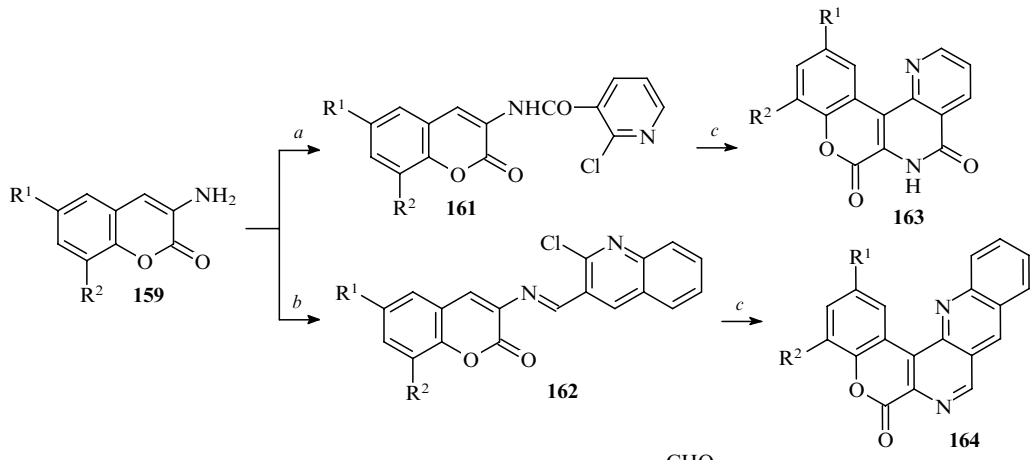
Flash pyrolysis of aminopyridine derivatives **165a**–**c** gave rise to intermediates **166a**–**c** containing the heterodiene system. Intramolecular cyclisation of the latter involving the substituent R produced annelated naphthyridines **167**–**169**.[117]



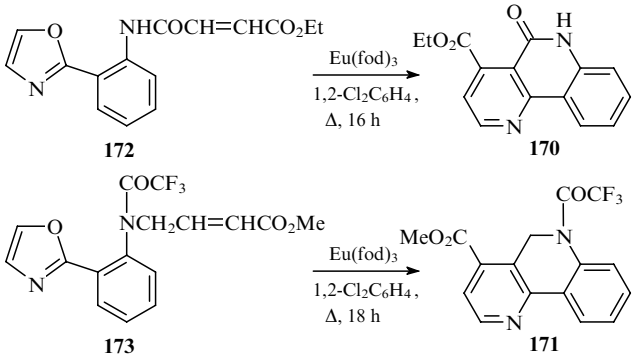
R = $(CH_2)_3CH=CH_2$ (**a**), Ph (**b**), 2-thienyl (**c**).

Dihydrobenzo[*h*][1,6]naphthyridines **170** and **171** were synthesised by Eu(fod)$_3$-catalysed intramolecular Diels–Alder cyclisation of the diene system of oxazoles **172** and **173**, respectively, with the double bond of the side-chain substituent.[118]

Scheme 2

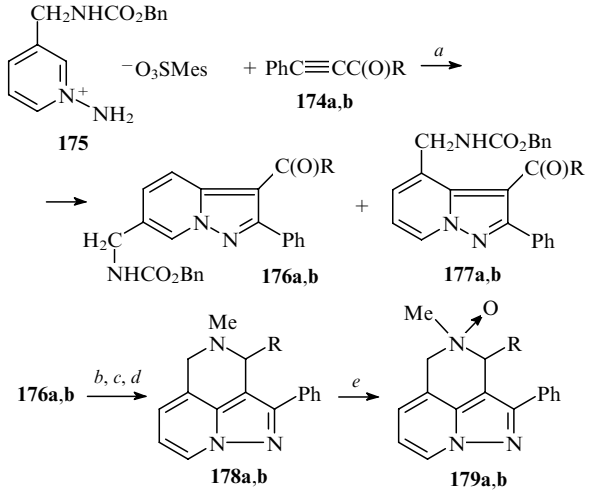


R^1 = H, Br, Cl; R^2 = H, OMe, Br; (*a*) **155**, Et_3N, PhH, Δ, 8 h; (*b*)  (**160**), AcOH; (*c*) Py or Et_3N–$PdCl_2$.



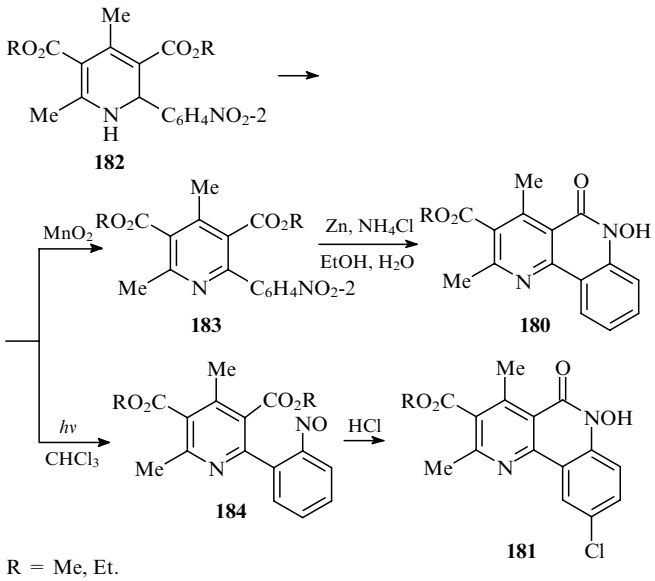
Eu(fod)$_3$ = Eu[Bu^{t}C(O)CH$_2$C(O)(CF$_2$)$_2$CF$_3$]$_3$.

1,3-Dipolar cycloaddition of 3-phenylpropynal (**174a**) or phenyl phenylethynyl ketone (**174b**) to the *N*-aminopyridinium salt **175** afforded a mixture of isomeric pyrazolo[1,5-*a*]pyridines **176a**,**b** and **177a**,**b**. Debenzylation of the compounds **176a**,**b** followed by successive treatment with formaldehyde and sodium cyanoborohydride gave rise to naphthyridines **178a**,**b**. Oxidation of the latter with *m*-chloroperbenzoic acid yielded *N*-oxides **179a**,**b**.[119]



R = H (**a**), Ph (**b**); Mes = 2,4,6-Me$_3$C$_6$H$_2$; (*a*) K$_2$CO$_3$, MeCN; (*b*) 30% HBr, AcOH; (*c*) HCHO; (*d*) NaBH$_3$CN; (*e*) 3-ClC$_6$H$_4$CO$_2$H.

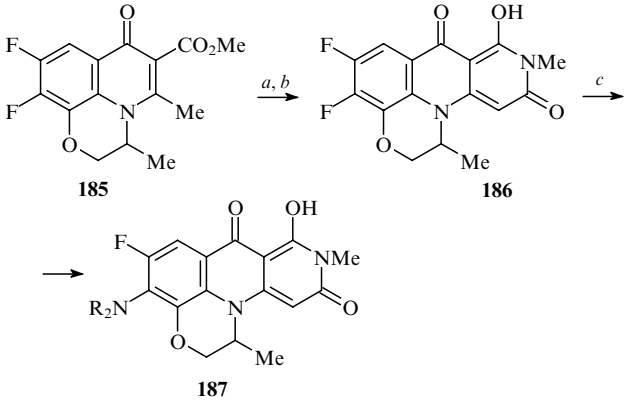
Dihydrobenzo[*h*][1,6]naphthyridines **180** and **181** can be prepared from 4,6-dimethyl-2-(2-nitrophenyl)-1,2-dihydropyridine-3,5-dicarboxylic esters (**182**) according to two procedures,



R = Me, Et.

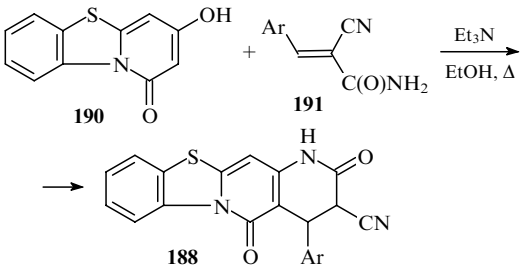
viz., by oxidation of the dihydro derivative **182** to form pyridinedicarboxylic ester **183** followed by reduction of the nitro group with simultaneous cyclisation or by storage of a solution of the compound **182** in chloroform in sunlight to give nitroso compound **184**, which undergoes cyclisation under the action of concentrated HCl.[120]

Treatment of a solution of pyrido[1,2,3-*de*][1,4]benzooxazine **185** with a 60% NaOH solution in DMF followed by the addition of methyl isocyanate afforded the tetracyclic 1,6-naphthyridine derivative **186**. The reactions of the latter with substituted pyrrolidines or piperazines gave rise to amino derivatives **187**. The compounds **186** and **187** and their salts possess bactericidal properties.[121]

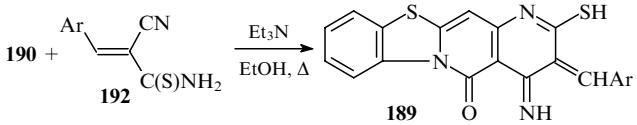


NR$_2$ are substituted pyrrolidinyls or piperazinyls;
(*a*) 60% NaOH, DMF; (*b*) MeNCO; (*c*) R$_2$NH, DMSO.

Amido and thioamido derivatives of α,β-unsaturated nitriles were used in the synthesis of annelated 1,6-naphthyridines. Thus substituted benzothiazolo[3,2-*g*][1,6]naphthyridin-5-ones (**188** and **189**) were prepared by refluxing 3-hydroxy-1*H*-pyrido-[2,1-*b*]benzothiazol-1-one (**190**) with arylmethylidenecyano(thio)-acetamides **191** and **192**, respectively, in ethanol in the presence of triethylamine.[122]

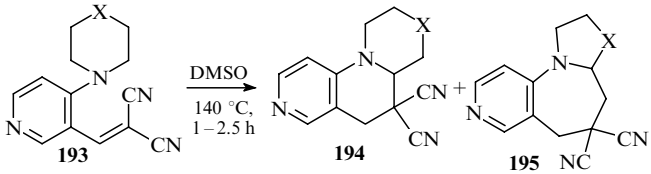


Ar = 4-MeOC$_6$H$_4$, 4-ClC$_6$H$_4$.



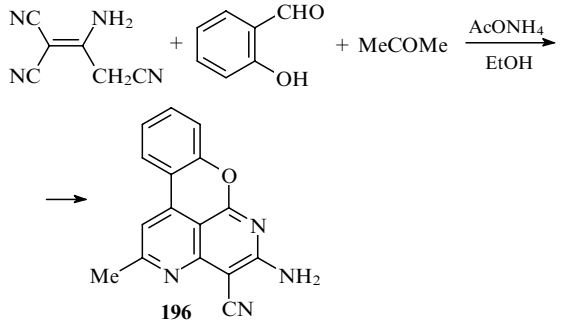
Ar = Ph, 4-MeOC$_6$H$_4$.

Thermal isomerisation of 3-(2,2-dicyanovinyl)-4-aminopyridines **193** in DMSO afforded a mixture of annelated 1,6-naphthyridines **194** and azepines **195**.[123]

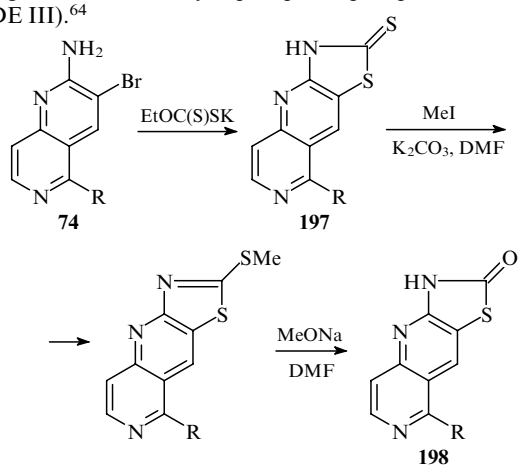


X = CH$_2$, NPh, O, S.

Of other procedures for the synthesis of annelated 1,6-naphthyridines, noteworthy is three-component condensation of the malononitrile dimer, salicylaldehyde and acetone giving rise to 1,6-naphthyridines **196**.[124]



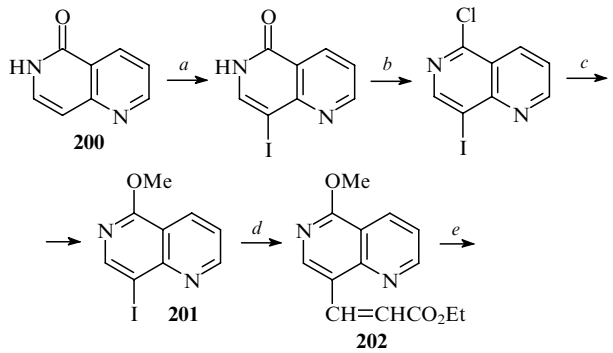
Considerable recent attention has been focused on procedures for modifications of 1,6-naphthyridine derivatives with the aim of searching for new biologically active compounds. Thus condensation of 2-amino-3-bromo-1,6-naphthyridines **74** with potassium *O*-ethyl xanthate in *N*-methylpyrrolidone afforded thiazolo[4,5-*b*][1,6]naphthyridine-2(3*H*)-thiones **197** whose subsequent methylation and hydrolysis of the methyl group in the presence of sodium methoxide afforded thiazolonaphthyridones **198** inhibiting adenosine-3′,5′-cyclophosphate phosphodiesterase (cAMP PDE III).[64]

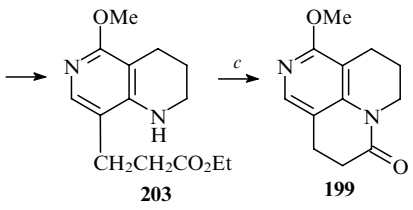


R = Me, Et, Pr^n, Bu^i, Ph, 4-$NO_2C_6H_4$.

The structural fragment of hydrogenated pyrido[3,2-*ij*]-1,6-naphthyridin-6-one **199** is present in the alkaloid matrine (sophocarpidine) found in dried roots of several plants belonging to the genus *Sophora*.

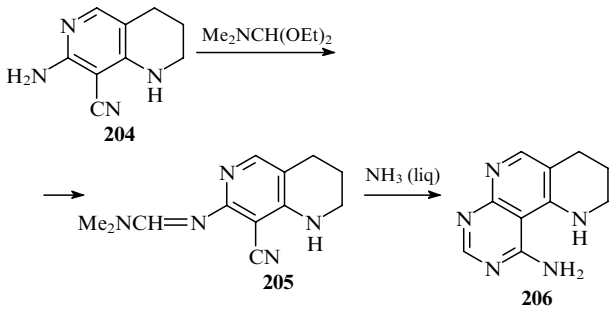
The compound **199** was synthesised from 1,6-naphthyridin-5(6*H*)-one (**200**) in six steps.[125] The key stage of the scheme consists in the Heck reaction of 8-iodo-5-methoxy-1,6-naphthyridine (**201**) with ethyl acrylate. Reduction of the double bond in the resulting derivative **202** and cyclisation of compound **203** under the action of sodium methoxide complete the synthesis.



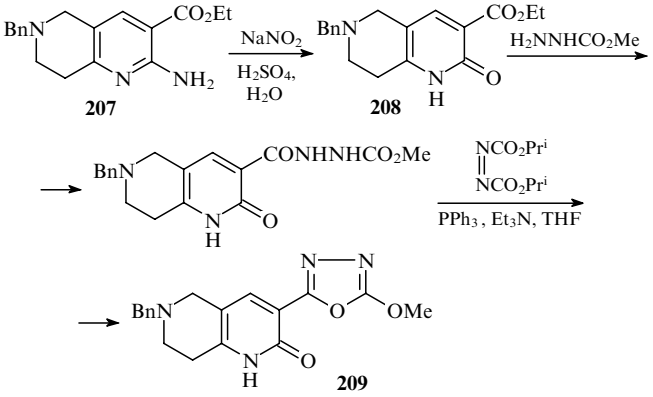


(*a*) I_2, 4M NaOH, 80 °C, 4 h; (*b*) $POCl_3$; (*c*) MeONa, MeOH; (*d*) $CH_2=CHCO_2Et$, $Pd(OAc)_2$, Et_3N, MeCN; (*e*) H_2, PtO_2, MeOH.

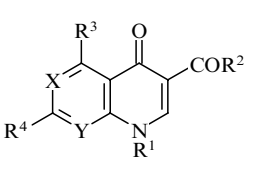
Condensation of 7-amino-8-cyano-1,2,3,4-tetrahydro-1,6-naphthyridine (**204**) with dimethylformamide diethyl acetal afforded azomethine **205**. Its treatment with ammonia gave rise to 1-amino-7,8,9,10-tetrahydropyrimido[4,5-*h*][1,6]naphthyridine (**206**).[126]



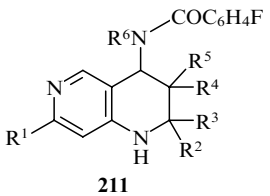
Diazotisation of the amine of the naphthyridine series **207** with a solution of sodium nitrite in 10% H_2SO_4 afforded naphthyridinone **208**, which was used as the starting compound in the synthesis of the antagonist of benzodiazepine receptors **209**.[127–129]



The compounds **210**, including 1,6-naphthyridine derivatives, as well as octahydronaphthyridines **211** are of interest from the pharmacological standpoint.[130–134] Thus the compounds **210** possess low toxicity and are used as components of drugs for prophylaxis and treatment of infectious diseases caused by various pathogenic bacteria.[130–133] Octahydronaphthyridines **211** are used in the treatment of depression or in cases of abstinence.[134]

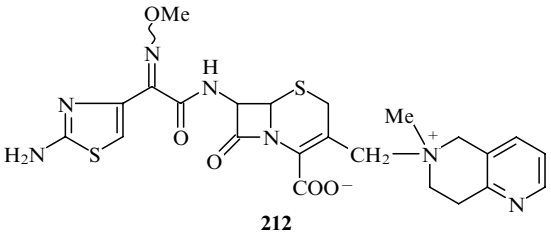


R^1 = H, Et, $(CH_2)_2OH$, $(CH_2)_2Cl$, $CH_2=CH$, cyclo-Alk; R^2 = OH, OAlk; R^3 = H, Hal, NH_2; R^4 = H, Alk, Hal; X, Y = N, CH



R^1 = H, Alk(C_1–C_6), CF_3, CN, NO_2; R^2, R^3 = H, Alk(C_1–C_4); R^2–R^3 = $(CH_2)_n$, n = 2–4; R^4 = H, Me, Et; R^5 = OPh, OBn, NO_2; R^6 = H, Alk(C_1–C_6)

The 1,6-naphthyridine fragment is present in the cephem molecule (**212**), which is active with respect to both gram-positive and gram-negative bacteria.[135]

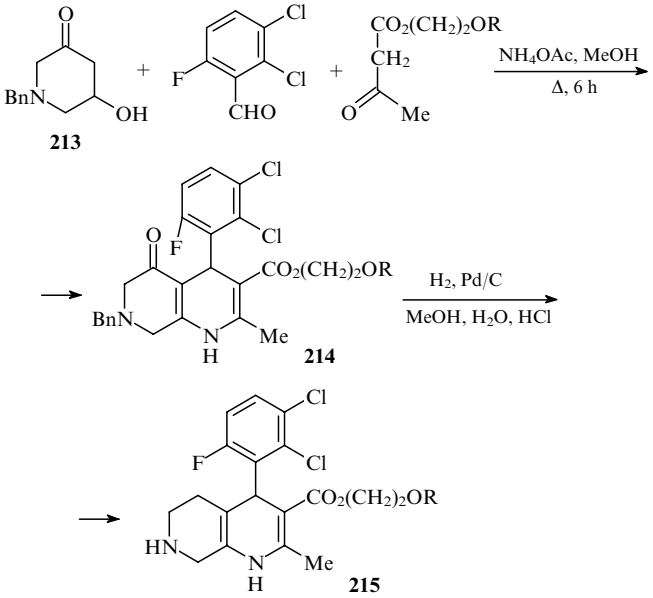


212

Recently, 1,4-dihydro-4-oxo-1,6-naphthyridine derivatives have also been covered by patents as antibacterial agents.[136] 1,4-Dihydro-5-isopropoxy-2-methyl-4-(2-trifluoromethylphenyl)-1,6-naphthyridine-3-carboxylic esters are efficient components of cytokinin inhibitors.[137] 1,6-Naphthyridine-2-carboxylamides were covered by patents as drugs used in the therapy and prophylaxis of cytomegalovirus infection.[138] 1,2,3,4,5,6,7,8-Octahydro-1,6-naphthyridine derivatives were covered by patents as anticonvulsive agents[139] and tachykinin NR_3-receptor antagonists.[140] Oxadiazolyl-substituted 1,6-naphthyridin-2-ones were covered by patents as benzodiazepine receptor antagonists.[141]

IV. 1,7-Naphthyridines

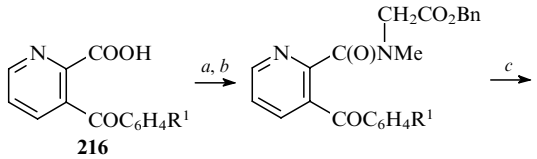
Among procedures for the synthesis of 1,7-naphthyridines, four-component condensation of 1-benzyl-3-hydroxy-5-piperidone (**213**) with 2,3-dichloro-6-fluorobenzaldehyde, acetoacetic esters and ammonium acetate giving rise to 1,4,5,6,7,8-hexahydro-1,7-naphthyridin-5-one-3-carboxylic esters **214** attracts attention due to its simplicity. The compounds **214** and their *N*-debenzylation products **215** exhibit hypotensive activity.[142, 143]



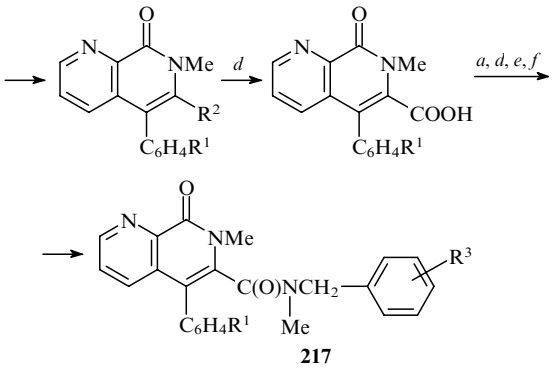
213 **214** **215**

R = Ph, 2,3-$Cl_2C_6H_3$.

3-Aroylpyridine-2-carboxylic acids **216** were used as the starting compounds for the preparation of 7-methyl-1,7-naphthyridin-8(7*H*)-one derivatives **217**, which are new strong neurokinin NK_1-receptor antagonists.[144]



216



217

R^1 = H, 4-Me, 4-F; R^2 = CO_2CH_2Ph, CN, CHO, $CONH_2$;

R^3 = 3,5-$(CF_3)_2$, 2-MeO, 2-Cl, 2,5-Cl_2;

(*a*) $SOCl_2$, DMF, THF; (*b*) $BnCO_2CH_2NHMe \cdot HCl$, Et_3N, CH_2Cl_2;

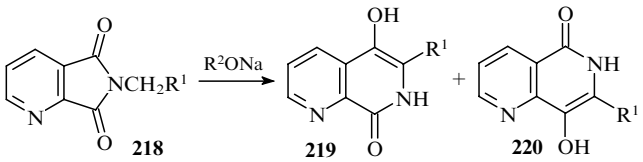
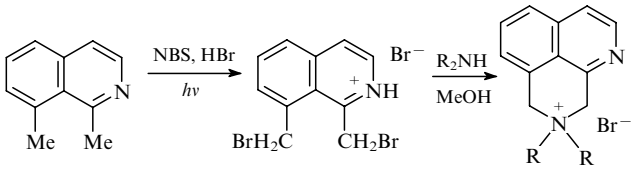
The reactions of *N*-substituted pyridine-2,3-dicarboxylimides **218** with sodium alkoxides afforded a mixture of 5-hydroxy-1,7-naphthyridin-8(7*H*)-ones **219** and 8-hydroxy-1,6-naphthyridin-5(6*H*)-ones **220**.[145]



218 **219** **220**

R^1 = CO_2Me, CO_2Et, CO_2Pr^i, COPh; R^2 = Me, Et.

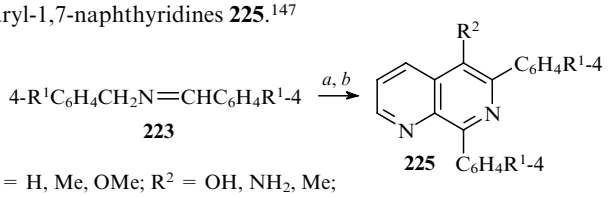
Treatment of 1,8-bis(bromomethyl)isoquinolinium bromide (**221**) prepared from 1,8-dimethylisoquinoline with secondary amines yielded *N*,*N*-dialkylbenzo[*de*][1,7]naphthyridinium bromides **222**.[146]



221 **222**

R = Me, Et, Pr^n, Pr^i.

Condensation of the lithium salt, which was prepared by metallation of Schiff bases **223** with lithium diisopropylamide, with ethyl 3-acetyl-2-halogenonicotinates, 3-cyano-2-halogenopyridines or 3-acetyl-2-halogenopyridines **224** gave rise to 6,8-diaryl-1,7-naphthyridines **225**.[147]

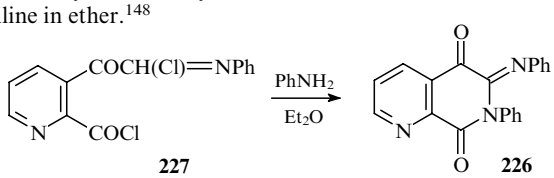


223 **225**

R^1 = H, Me, OMe; R^2 = OH, NH_2, Me;

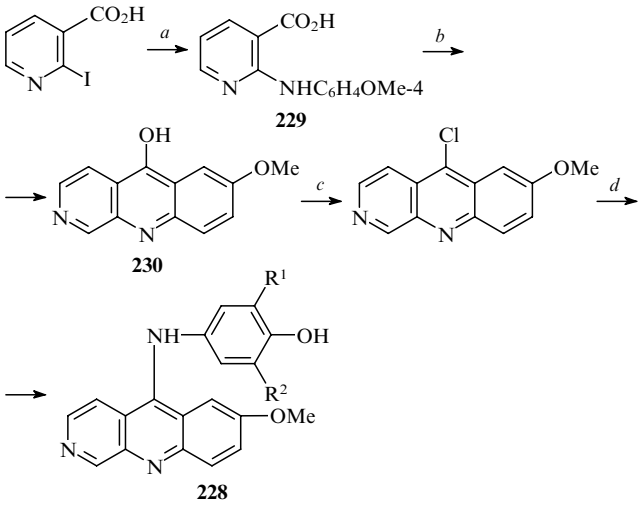
(*a*) Pr^i_2NLi; (*b*)  (**224**), R^3 = CO_2Et, CN, COMe; R^4 = Cl, Br.

The imino derivative of tetrahydro-1,7-naphthyridinedione **226** was synthesised by the reaction of acid chloride **227** with aniline in ether.[148]



227 **226**

With the aim of searching for new antimalarial drugs among annelated 1,7-naphthyridines, compounds **228** were synthesised. Cyclisation of amino acid **229**, which was prepared from 2-iodonicotinic acid, under the action of $POCl_3$ in polyphosphoric acid afforded 10-hydroxy-2-methoxybenzo[*b*][1,7]naphthyridine **230**. The subsequent reactions with $POCl_3$ and then with aminophenols complete the synthesis. The preliminary assay of the biological activities of the compounds **228** demonstrated that these compounds are inferior to the well-known antimalarial agent pyronaridine.[149]



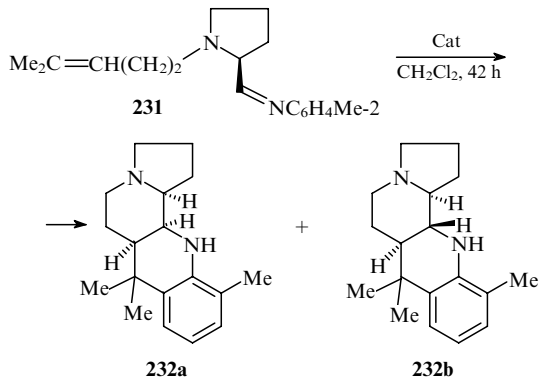
229 **230** **228**

R^1, R^2 = H, CH_2NEt_2;

(*a*) H_2N–C$_6$H$_4$–OMe; (*b*) $POCl_3$, PPA; (*c*) $POCl_3$;

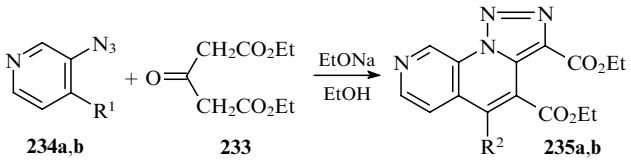
(*d*) H_2N–C$_6$H$_3$(R^1)(R^2)–OH.

Treatment of (*S*)-*N*-[*N*-(4-methylpent-3-enyl)pyrrolin-2-ylmethylidene]-*o*-toluidine (**231**) with Lewis acids ($FeCl_3$, $SnCl_4$, $AlCl_3$, $MeAlCl_2$, Me_2AlCl, $EtAlCl_2$, Et_2AlCl or $BF_3 \cdot OEt_2$) or Brønsted acids (CF_3COOH or TsOH) led to formal Diels–Alder heterocyclisation giving rise to 1,7-naphthyridines **232a**,**b** in yields of > 80%. The isomer ratio depends substantially on the nature of the catalyst used. In the case of monodentate Lewis acids of the $MeAlCl_2$ or $EtAlCl_2$ type, the *cis*-isomer **232a** was obtained as the major product (99%), whereas the reactions involving bidentate Lewis acids of the $SnCl_4$ type or Brønsted acids afforded predominantly the *trans*-isomer **232b** (87%–99%).[150]



231 **232a** **232b**

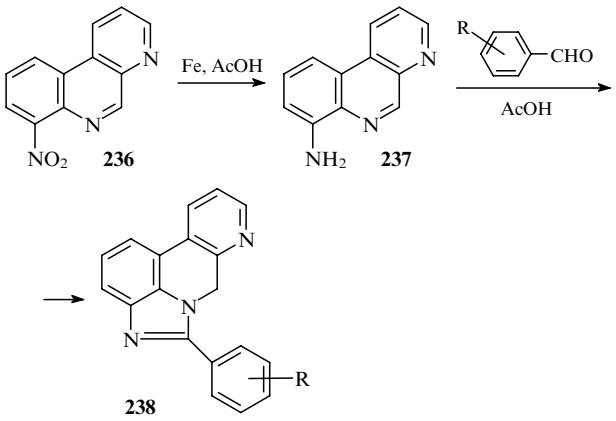
1,2,3-Triazolo[1,5-*a*][1,7]naphthyridines **235a**,**b** were synthesised by the reactions of diethyl acetone-1,3-dicarboxylate (**233**) with *ortho*-substituted azides of the pyridine series **234a**,**b**.[151]



234a,**b** **233** **235a**,**b**

R^1 = CN (**234a**), CO_2Et (**234b**); R^2 = NH_2 (**235a**), OH (**235b**).

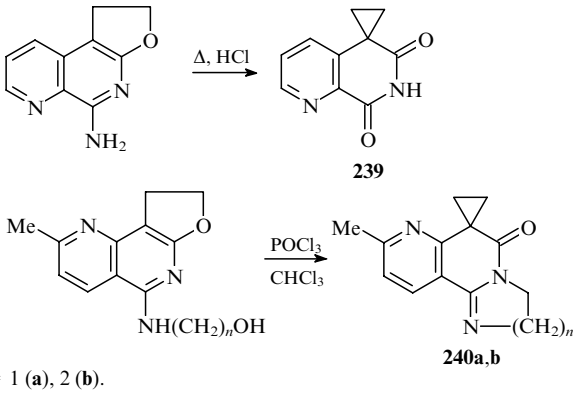
Reduction of 7-nitrobenzo[*f*][1,7]naphthyridine **236** with iron in 80% acetic acid gave rise to amine **237**, whose condensation with aromatic aldehydes afforded benzoimidazo[4,3-*fg*][1,7]-naphthyridines (**238**) exhibiting antibacterial and antifungal activities.[152, 153]



236 **237** **238**

R = H, Me, NO_2, Cl.

The rearrangement of amine of the 1,2-dihydrofuro[3,2-*f*]-[1,7]naphthyridine series produced naphthyridine derivative **239** containing the spirocyclopropane fragment.[154] The reactions of analogous 1,2-dihydrofuro[2,3-*h*][1,7]naphthyridine derivatives containing the hydroxyalkylamino group with $POCl_3$ afforded imidazo[2,1-*f*]- (**240a**) or pyrimidino[2,1-*f*][1,7]naphthyridinones (**240b**) bearing the spirocyclopropane fragment.[155]

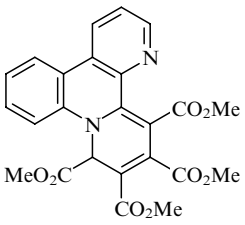


239 **240a**,**b**

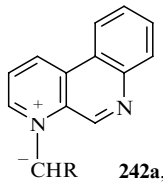
n = 1 (**a**), 2 (**b**).

The reactions of 5,8-dihalogeno-1,7-naphthyridines with potassium amide in liquid ammonia were demonstrated to give mixtures of aminohalogeno, monohalogeno and monoamino derivatives of 1,7-naphthyridines.[156]

The reactivity of 4,6-benzo[*h*][1,7]naphthyridine in the Diels–Alder reactions with maleic acid and dimethyl acetylenedicarboxylate was examined. In the former case, the corresponding quaternary salt was obtained, whereas the latter reaction afforded adduct **241**.[157] 6-Ethoxycarbonyl- (**242a**) and phenacylmethylides (**242b**) were used as 1,3-dipolar reagents in the reactions with methacrylic acid, methyl methacrylate, butyl vinyl ether, methyl vinyl ketone, maleic anhydride and dimethyl acetylenedicarboxylate.[157, 158]

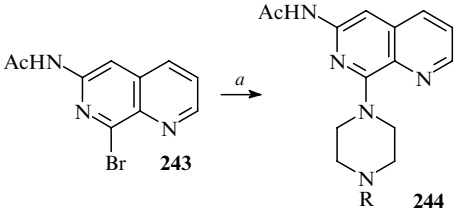


241



R = CO_2Et (**a**), PhCO (**b**). **242a,b**

The reactions of 6-acetamido-8-bromo-1,7-naphthyridine (**243**) with substituted piperazines in the presence of NaH afforded 6-acetamido-8-(4-R-piperazin-1-yl)-1,7-naphthyridines **244** possessing antiinflammatory, antiarrhythmic, cardiotonic, vasodilator, broncholytic, diuretic and antichlolinergic activities.[159–162]



243 **244**

R = H, $(CH_2)_2OH$, CHO, Ar; (*a*) NR, $EtO(CH_2)_2OH$, NaH.

Hydrochloride of the derivative of 1,7-naphthyridine-3-carboxylic acid **245**, which lowers high blood pressure, was prepared from compound **246** and oxirane **247** upon refluxing in MeOH followed by saturation of the reaction mixture with HCl.[163]
