These clinkers (the so-called diamond glasses) can easily be cut by ultrasound and laser, ground and polished. They can be used as abrasives in the working of materials of average hardness and in electronics.

Ultradispersed diamonds metallised by transition-metal clusters possess high microhardness [$h = (6–7) \times 10^3$ kg mm^{-2}] and represent excellent tool materials.

The use of UDD (0.5%–1.5%) for enhancing the strength properties of polymeric matrices of grinding and polishing tools results in a simultaneous increase in both strength (by a factor of 1.3–1.5) and elastic (by a factor of 1.8–2.0) properties of an abrasive tool.

5. Ultradispersed diamonds in microabrasive and polishing compositions.

Polishing systems (PS) that contain UDD are used in precision finishing of materials in radio engineering, electronics, optics, medicine and machinery.[79, 104–109]

The compositions allow one to obtain perfect mirror solid surfaces of required planeness, plane-parallelism, of any geometrical shape, containing no defects and dislocations, with the contour interval $R_z = 2–8$ nm (with an average deviation from a mean hypothetical surface $\sigma = 0.5–2.0$ nm).

The advantages of UDD-containing polishing systems are as follows.

1. The minute sizes of UDD ensure the minimum surface roughness and the colloidal stability of PS.

2. The chemical stability of UDD allows one to use chemically active additives to PS and to recover PS.

3. The amount of material removed from the surface being polished is small (the material losses decrease).

4. Owing to ion-exchange and sorption properties of UDD, the removed ionic and molecular products are immobilised on the UDD surface, which provides a clean surface.

5. The fractal structure of UDD aggregates ensures a controlled structurisation in PS suspensions and the absence of stressed and disrupted surface layers on a material being polished.

6. These systems are non-toxic.

7. Polishing systems with UDD allows one to enhance the quality and competitive characteristics of polished articles and to ensure the polishing of materials technologically difficult to work.

Nanodiamond consumption is 0.001–0.01 kg per 1 m^2 of the surface worked.

6. Ultradispersed diamonds in magnetic recording systems.

Nanodiamonds are used, first of all, as anti-friction additives and physical modifiers in ferromagnetic-varnish coatings of magnetic films and disks and, secondly, as the additives to electrochemical composition films destined to improve the magnetic recording device characteristics.[77, 79, 83]

1. The addition of UDD to a ferromagnetic layer sharply reduces its domain sizes (ferromagnetic grains), *i.e.*, the density of recording increases substantially.

When introduced into a varnish to form a special film destined for cleaning of recording heads, UDD provides polishing of the latter and enhances their resistance to wear.

Magnetically soft information carriers which contain UDD display the following advantages: abrasive wear of a magnetic-carrier layer decreases, optimum conditions are provided for operation of magnetic heads and reading devices, friction of the magnetic carrier decreases and stability of its motion is provided.

The consumption of nanodiamonds is 1% – 2% of the varnish mass.

2. As compared to individual CoP coatings, magnetically soft amorphous CoP – UDD films are shown to display the following advantages: a 1.3-fold increase in microhardness, a 4.5-fold increase in the resistance to wear, a 1.4-fold decrease in friction coefficient, a 2-fold increase in the service life of magnetic-head cores without any changes in their effectiveness.

For magnetically hard polycrystalline CoP – UDD coatings compared to individual CoP coatings both electrochemically and chemically deposited, the microhardness increases by a factor of 1.2, corrosion currents decrease by a factor of 1.6, the service life of the carriers of magnetic information increases.

Magnetic characteristics of both magnetically soft amorphous films and magnetically hard coatings remain unchanged with an addition of UDD.

Nanodiamond consumption is ~ 1 carat for a layer with 1×10^{-6} m thick.

7. Biological activity of ultra-dispersed diamonds

When UDD are used as potential medical drugs, their anomalously high adsorption capacities, high specific surface areas, abundance of free electrons on the surface (a multiple radical-donor), nanoscale sizes, a great amount of oxygen-containing functional groups on crystal surfaces, chemically inert grains and surface hydrophilicity are of great importance.[79, 110]

Nanodiamonds can be applied in oncology, gastroenterology, cardiology, dermatology, for curing vessel diseases, *etc*. They display no carcinogenic and mutagenic properties and are non-toxic.

Owing to their high adsorption capacities and other specific features, nanodiamonds exhibit extremely high activities with respect to pathogenic viruses, microbes and bacteria by absorbing them intensively. Nanodiamonds are selective sorbents and supports for biologically active substances, they can significantly enhance the action of drugs. The use of UDD normalises blood pressure. Moreover, UDD are effective drugs for different gastroenteric diseases, an excellent remedy for after-effects of burns, different skin diseases and intoxication.

The use of UDD in the form of aqueous and oil suspensions is beneficial for curing cancer patients; these tend to increase the effect of drugs, relieve pains, normalise peristalsis of the bowels, improve blood characteristics and activate the immune system, remove toxins from the organism and prolonge the patient's life.

The use of UDD in chemical and radio-therapy appears to be promising in the cure of malignant tumours for prevention of the mutagenic effect of drugs. At the same time, UDD do not reduce the therapeutic effect and are capable of preventing the appearance of mutations in normal cells or generation of secondary tumours under the action of anti-tumour drugs.

A therapeutic course requires $\sim 0.02 - 0.5$ g of UDD.

* * *

Thus, this survey demonstrates that UDD microcrystals with a narrow size distribution at about 430 nm manifest extremely varied and sometimes unusual properties. Undoubtedly, physico-chemical and chemical studies of UDD will be continued. It is possible that the main application fields of nanodiamonds are still to be found, although there are good grounds to believe that UDD can be applied virtually in any field, first of all, in high technologies.

Abstract. New spectroscopic techniques employing the scanning tunnelling microscope are considered. The new methods allow measurements of the vibrational spectra of single surface complexes, determination of the nonequilibrium distributions of such complexes over vibrational levels, studies on the kinetics of vibrational transitions, determination of vibrational relaxation parameters, detection of single surface electron spins and studies on the dynamics of fast surface migration of species. The physical grounds and possible applications of the methods in chemical research are also discussed. The bibliography includes 80 references.

I. Introduction

Determination of the structure and properties of surface complexes belongs to the key problems of modern chemical physics of surfaces including heterogeneous catalysis. The number of differently organised groups of adsorbed species can be rather large even in the simplest systems. For instance, the interaction of oxygen with metals can be accompanied by the formation of more than ten types of complexes, depending on the metal crystal face involved in the process, the metal oxidation state and temperature. These complexes differ not only in their adsorption sites, but also in atomic and electronic structure. Usually, such complexes coexist and interact with one another at sufficiently high coverages of the surface. In heterogeneous catalysis, the most reactive complexes play the role of active surface sites.[1, 2]

Different surface complexes can play the role of active surface sites in different stages of a catalytic reaction, *i.e.*, in the course of adsorption and surface migration and in various chemical transformations (dissociation, desorption, as well as substitution, recombination or exchange reactions). The internal structure and properties of the surface complexes have long been intensively studied by many experimental methods. However, the exact nature of the active surface sites remains a moot question as yet for the majority of systems including those studied in most detail. Determination of the exact nature faces great difficulties which are mainly associated with a large number of types of surface complexes and with low steady-state concentrations of the active sites due to their high reactivity.

Experiments with structurally and chemically homogeneous surfaces (the so-called 'ideal' surfaces) are free from these drawbacks. Carrying out high-vacuum experiments allows one to assemble macroscopic ensembles of regularly arranged surface complexes of a particular type by controlled low-temperature adsorption on microfacets of perfect single crystals.[3] The structure and properties of such systems can be studied in detail by various spectroscopic methods including optical and corpuscular ones, beam and field emission techniques, as well as steady-state and kinetic methods.[4] It should be noted that most of the widely used methods have initially been developed to study the dynamics of elementary processes in the gas phase.

Experiments with ideal surfaces have significantly extended the ideas of both the internal structure of surface structures and the dynamics of elementary acts in heterogeneous processes. In such experiments, many complexes have been found for the first time. Beam experiments provided direct evidence for the dependence of the reactivity of ideal surfaces on their atomic structure.[5] Femtosecond laser experiments allowed the characteristic times of electronic and vibrational relaxation of many surface complexes to be measured for the first time.[6] Currently, heterogeneous processes on ideal surfaces are studied with a time resolution of $\sim 10^{-13} - 10^{-14}$ s, which is sufficient for the real-time observation of the motion of individual species (molecules, ions, atoms) in elementary acts of chemical transformations.

Since 1960s, intensive studies of ideal surfaces as model systems have been carried out in many countries. The results of such studies serve as one of the main sources of information necessary for devising physical models of the interactions of atomic species with the surface and at the solid surfaces. However, the results of high-vacuum measurements bear no direct relation to the chemistry of real surfaces. Typically, the time taken to form a real surface is of the order of 10^{-7} s ($P \approx 1$ atm, $T \approx 300$ K). Such surfaces are characterised by disordered atomic structures. In real systems, the variety of types of ensembles of surface

complexes is much greater than in ideal systems. Often, real surfaces are covered by complexes that cannot be produced in desired amounts in high-vacuum experiments to be studied then by conventional spectroscopic methods such as IR, Auger and ESR spectroscopy, *etc*. Additionally, the dynamics of elementary acts of various heterogeneous processes in ordered and disordered ensembles of the same surface complexes can be essentially different. For chemisorbed species this is due to changes in the potential energy surfaces upon the formation of new chemical bonds, whereas in the case of physisorbed particles the distinctions can be due to multiple scattering of both products and reagents by the species surrounding the reacting complex.

Compared to modelling of gas-phase processes, the problem of devising physical models of heterogeneous surface reactions is much more complicated. The dynamics of all essential elementary gas-phase processes can be studied in detail using high-vacuum beam and optical experiments. However, the results of such experiments with ideal surfaces are insufficient to devise physical models of heterogeneous chemical reactions, especially catalytic ones, which are of prime interest in practice. Studies on the dynamics of elementary acts of gas-phase reactions can be successfully performed with femtosecond time resolution, which allows real-time monitoring of the motion of atomic species. In the case of heterogeneous chemical reactions, solving a similar problem requires not only real-time, but also real-space monitoring of the motion of atomic species and, hence, atomic-scale spatial resolution. The present state-of-the-art in chemical physics of surfaces is characterised by great demand for novel methods which would allow assembling of single complexes of adsorbed species at specified points of the surface, studies on their atomic and electronic structure, measurements of physical parameters, determination of chemical properties and studies on the dynamics of elementary acts of chemical transformations at the single-event level. Currently, the development of such methods requires the use of scanning tunnelling microscopy (STM). Hence, the new methods should be basically different from those used in studies of gas-phase processes.[7,8]

II. Single molecule chemical physics of surfaces

In experiments with STM, the atomic and electronic structure of conducting surfaces is probed with a thin metallic tip (the radius of curvature of well-fabricated tips is comparable with the characteristic atomic size) separated from the surface by a distance d of the order of 5–10 Å.[8] In this case, the overlap of the atomic orbitals of the tip and the surface is very weak and the surface–tip system represents a nanoscale tunnel junction whose conductance

$$\sigma = \frac{\partial J}{\partial V},$$

(J is the current and V is the voltage) at low voltages ($V \ll \varphi$, φ is the tip work function) is determined by the probability of electron tunnelling through the potential barrier (the barrier penetrability)

$$D(d) \propto \exp\left(-2d\sqrt{2\varphi}\right) \qquad (1)$$

and by the surface local density of electron states [$\rho(\varepsilon,\mathbf{r})$] at the position of the tip[9]

$$\sigma(V) \propto D(d)\rho[\varepsilon(V),\mathbf{R}], \qquad (2)$$
$$\varepsilon(V) = \varepsilon_F - V.$$

Here, ε and $\mathbf{r}$ are the energy and coordinate of an electron, respectively, $\mathbf{R}$ is the tip coordinate and ε_F is the Fermi level. (In the text below, we will use the system of atomic units, except otherwise specified; the tip polarity is assumed to be negative.)

According to relationship (2), displacements of the tip across the surface (at specified V and d) produce changes in the current flowing through the tunnel junction, which are proportional to the changes in the electron density $\rho[\varepsilon(V),\mathbf{R}]$, which are determined by the relief of the surface. For 'single-atom' tips, where the tunnelling current is determined by the overlap of the surface orbital with the orbital of the atom nearest to the surface, one gets $\delta J/\delta R \approx 0.1$ nA Å^{-1}. This is sufficient for 'current' imaging of a surface area with Ångström spatial resolution by simply scanning it. Spectroscopic measurements, *i.e*., measurements of the $\sigma - V$ dependences allow reconstruction of the energy distributions of electrons at specified points of the surface. [Note that relationships (1) and (2) include only the contribution of elastic tunnelling characterised by conservation of the energies of the tunnelling electrons. Usually, this is the most probable case.]

The invention of the STM[7] opened a new, amazing world of single-molecule phenomena. The STM is capable of imaging surfaces with Ångström spatial resolution and provides the possibility of seeing individual adsorbed atoms, molecules and adsorbate clusters in the real space, as well as of directly monitoring reconstruction† of ideal surfaces,[10,11] elementary acts of slow surface migration,[12] dissociation[13] and desorption.[14,15] Numerous examples of manipulating individual adsorbed species with the STM tip by their targeted desorption, adsorption, dissociation and transfer between the surface and the tip have been reported. In modern experiments with STM, the atomic and electronic structure of surfaces covered by adsorbed species are studied at the single complex level while the dynamics of heterogeneous processes is in increasing frequency studied at the single-event level. Chemical physics of surface becomes a 'single molecule' science.[16]

The opportunities of 'single molecule' chemical physics of surface seem to be almost boundless, especially taking into account continuous evolution of spectroscopic methods which make it possible to obtain information on the structure of single surface complexes and the dynamics of individual acts of elementary chemical transformations. Experiments with STM allow one not only to see individual adsorbed species and complexes and to reconstruct the corresponding electron energy distributions, but also to measure their vibrational spectra,[17,18] create and measure different types of nonequilibrium vibrational distributions[19] and reconstruct parameters of heterogeneous vibrational[20,21] and electronic[22,23] relaxation. It is also possible to study the kinetics of spontaneous and current-induced vibrational transitions in single surface complexes. (It is this kinetics that often determines the probabilities of elementary acts of chemical transformations of the complexes located under the tip of an STM.[21]) Recently, methods for detection of single surface paramagnetic centres have been proposed and evaluated.[24] Some new experimental schemes have been considered, which would initiate studies on the kinetics of spin transitions in single paramagnetic centres, measurements of spin–lattice relaxation times and relaxation times of individual electronically excited physisorbed molecules[22,23] and research in the field of detection of single molecule magnetic resonance effects.[25–27] New methods for STM studies on the dynamics of fast migration of those adsorbed atomic species whose stable images cannot be obtained have been proposed and theoretically substantiated.[28,29] The main goal of this review is to describe and analyse recent advances in single molecule heterogeneous chemistry.

III. Threshold and resonance features of currents flowing through nanoscale tunnel junctions containing adsorbed species

Most of new spectroscopic methods exploiting STMs also employ the effects of spin-dependent and inelastic electron tunnelling. The former effect is associated with the dependence of tunnelling probability on the electron spin orientation while the latter is due

† Before the invention of the STM, reconstruction of ideal surfaces was studied only by diffraction methods which allow one to obtain raw experimental information about the surface structure in the reciprocal lattice space rather than conventional coordinate space.

to processes in which energy exchange occurs between the tunnelling electrons and electronic and vibrational degrees of freedom of the adsorbed species. In experiments with STM, inelastic electron tunnelling including spin-dependent electron tunnelling can manifest themselves as two kinds of characteristic features on the $J-V$ curves, *viz*., threshold [17] and resonance features.[18]

Threshold features are observed at voltages corresponding to the opening of inelastic electron tunnelling channels. (Below the threshold voltage inelastic tunnelling of an electron is impossible since in this case the electron energy after excitation of a species located under the tip of an STM should be lower than that of the Fermi level corresponding to the highest occupied electron state.) An energy level diagram illustrating both elastic and inelastic electron tunnelling is presented in Fig. 1.

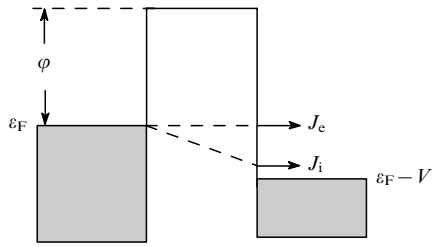

Figure 1. An energy level diagram illustrating electron tunnelling through a nanoscale tunnel junction at voltages $V \ll \varphi$; J_e and J_i are the elastic and inelastic electron tunnelling currents, respectively.

At threshold voltages $V_\omega = \omega$ (ω is the excitation energy of a species located under the STM tip) the conductance of a tunnel junction changes jumpwise

$$\sigma(V) \propto \eta(V - V_\omega), \tag{3}$$

where $\eta(x)$ is the Heaviside function

$$\eta(x) = \begin{cases} 0, & x \leqslant 0 \\ 1, & x > 0 \end{cases}$$

Experiments with STM are usually carried out at $\omega \gg kT$ (k is the Boltzmann constant and T is the temperature of the surface).

The conductance jump magnitude, $\delta\sigma(V_\omega)$, is proportional to the excitation probability of a surface complex, w_ω

$$\delta\sigma(V_\omega) \propto w_\omega \sigma^-(V_\omega), \tag{4}$$
$$\delta\sigma(V_\omega) = \sigma^+(V_\omega) - \sigma^-(V_\omega),$$
$$\sigma^\pm(x) = \sigma(x \pm 0).$$

Resonance features of the STM currents manifest themselves at voltages corresponding to 'bloomed' tunnel junctions (Fig. 2). The effect of resonance blooming of double potential barriers separated by a well with appropriate quasi-stationary electron energy level ε_0 is well known in quantum mechanics.[30] Resonance tunnelling of species involves three stages. A species tunnelling from the left half-space is captured by the well, spends some time in the quasi-stationary state and then tunnels through the second potential barrier to appear in the right half-space. Clearly, the tunnelling probability, $D(\varepsilon)$, is determined by three terms, *viz*., the resonance capture probability, Γ_1, the decay probability of the quasi-stationary state with retention of the initial tunnelling direction, Γ_2/Γ ($\Gamma = \Gamma_1 + \Gamma_2$, where Γ_2 is the probability of tunnelling through the second potential barrier) and the density of electronic states, $\rho_0(\varepsilon)$, near the quasi-stationary energy level ε_0.

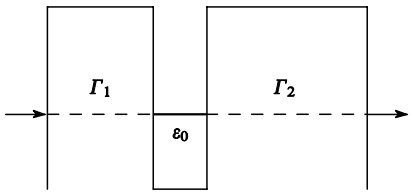

Figure 2. A scheme of tunnelling through the double potential barrier (resonance tunnelling mechanism).

$$D(\varepsilon) \approx \frac{\Gamma_1\Gamma_2}{\Gamma}\rho_0(\varepsilon), \tag{5}$$
$$\rho_0(\varepsilon) = \frac{1}{\pi}\frac{\Gamma}{(\varepsilon - \varepsilon_0)^2 + \Gamma^2}.$$

At $\varepsilon = \varepsilon_0$, the probability of tunnelling through the double potential barrier is equal to the ratio rather than product of the exponentially low probabilities of tunnelling through the single potential barriers

$$D(\varepsilon_0) \approx \frac{\Gamma_{\min}}{\Gamma_{\max}}, \tag{6}$$

where $\Gamma_{\min} = \min(\Gamma_1, \Gamma_2)$, $\Gamma_{\max} = \max(\Gamma_1, \Gamma_2)$. If $\Gamma_1 = \Gamma_2$, one gets $D(\varepsilon_0) = 1$, which means that the 'as-wide-and-high-as-it-wished' double potential barrier appears to be absolutely penetrable. This also holds for those potential barriers which contain electron traps with vibrational degrees of freedom. It has been shown that 'instantaneous' formation and decay of the quasi-stationary electron state can strongly 'shake' the slow vibrational subsystem ($\varepsilon_0 \gg \omega$, ω is the vibrational quantum), thus exciting not only single-quantum, but also multi-quantum vibrational transitions.[31]

The probability of inelastic resonance electron tunnelling, $D_{\upsilon\upsilon'}(\varepsilon)$ (υ and υ' are the vibrational quantum numbers before and after tunnelling), has the form

$$D_{\upsilon\upsilon'}(\varepsilon) = \frac{4\Gamma_1(\upsilon,\bar{\upsilon})\Gamma_2(\bar{\upsilon},\upsilon')}{[\varepsilon - \varepsilon_0(\bar{\upsilon}) + \omega\upsilon]^2 + \Gamma^2}, \tag{7}$$
$$\Gamma_{1(2)}(\upsilon,\bar{\upsilon}) = \Gamma_{1(2)}\langle\upsilon|\bar{\upsilon}\rangle^2,$$
$$\Gamma = \Gamma_1 + \Gamma_2. \tag{8}$$

Here, Γ_1 is the probability of resonance electron capture by the well in the quasi-stationary state (the probability of tunnelling through the first potential barrier), $\varepsilon_0(\bar{\upsilon}) = \varepsilon_0 + \bar{\omega}(\bar{\upsilon} + 1/2)$ is the energy of the vibronic level of the quasi-stationary state, $\bar{\upsilon}$ is the vibrational quantum number of the quasi-stationary state, $\langle\upsilon\bar{\upsilon}\rangle$ are the Franck–Condon factors and Γ_2 is the decay probability of the quasi-stationary state, followed by escape of the electron with retention of the initial tunnelling direction.

It is easily seen that if the potential barriers are characterised by equal Γ_1 and Γ_2 values and the electron energy ε takes its resonance value $\varepsilon = \varepsilon_0(\upsilon,\bar{\upsilon})$, the expression for inelastic tunnelling probability, $D_{\upsilon\upsilon'}(\varepsilon)$, does not contain exponentially small terms and, hence, double potential barriers can also be absolutely penetrable

$$D_{\upsilon\upsilon'}[\varepsilon = \varepsilon_0(\upsilon,\bar{\upsilon})] \propto \langle\upsilon|\bar{\upsilon}\rangle^2\langle\bar{\upsilon}|\upsilon'\rangle^2, \tag{9}$$
$$\varepsilon_0(\upsilon,\bar{\upsilon}) = \varepsilon_0 + \bar{\omega}\left(\bar{\upsilon} + \frac{1}{2}\right) - \omega\left(\upsilon + \frac{1}{2}\right),$$
$$\Gamma_1 = \Gamma_2.$$

It should be noted here that, strictly speaking, simple formula (7) for calculating the probabilities of elastic ($\upsilon = \upsilon'$) and inelastic ($\upsilon \neq \upsilon'$) resonance tunnelling is valid only for long-lived intermediate states ($\Gamma < \bar{\omega}$). On the other hand, the expression for the total tunnelling probability

$$D_\upsilon = \sum_{\upsilon'} D_{\upsilon\upsilon'}, \tag{10}$$

which determines the experimentally measured tunnelling current, is not subject to this limitation [see Ref. 31 which concerns the development of a general theory of inelastic resonance tunnelling and derivation of formulae that are valid at arbitrary ratios between the oscillation period, the lifetime of the quasi-stationary electron state and the times of electron tunnelling through single potential barriers $\tau_{1,2} = (\partial \ln \Gamma_{1,2}/\partial\varepsilon)^{-1}$].

Inelastic resonance tunnelling is a purely quantum-mechanical effect which can be observed in any nanoscale junctions including those formed by the tip of an STM and the surface. In this case, the role of electron traps can be played by adatoms having appropriate energy levels. However, this is a rare case which is of secondary importance. For the species which are of prime interest for practice, such as adsorbed O_2, H_2O, CO molecules, *etc*., the resonance electron energy levels lie below ε_F. The simplest (artificial) way of creating a near-surface electron trap consists of applying a voltage exceeding the tip work function for electrons to the junction.[32, 33] Figure 3 presents an energy level diagram illustrating the mechanism of electron tunnelling from the tip to a sample at such voltages, when the STM operates in the field emission mode.[34, 35] It is easily seen that in this case the tunnelling path has a segment of classically allowed motion of length l

$$l \approx \frac{V-\varphi}{V} d \approx 5-7\ \text{Å}.$$

At particular energies $\varepsilon_n(V,d)$, standing electron waves (field emission resonances, n is the resonance number) originate in this segment. In other words, a nanoscale resonator is formed near the surface, in which the tunnelling electrons are trapped to spend times

$$t_n \approx \Gamma_n^{-1} \approx \left(\frac{\partial \varepsilon_n}{\partial n}\right)^{-1} (1-\beta)^{-1}. \qquad (11)$$

Here, β is the surface reflection coefficient of an electron with energy ε_n. For pure metals, $\beta \approx 0.1-0.3$ [34, 35] and Γ_n values are sufficiently large ($\hbar\Gamma_n \approx 1$ eV, $t_n \approx 4\times10^{-15}$ s), so that the resonance maxima corresponding to different vibrational levels are overlapped. In this case, vibrational transitions of adsorbed species can manifest themselves as small-scale oscillations on the wings of broad field emission resonances.[33] For oxides and metal surfaces coated with thin oxide films, Γ_n values are much smaller [$\hbar\Gamma_n \approx 0.1$ eV, $t_n \approx 4\times10^{-14}$ s (see Refs 18, 19, 24)] and the resonance maxima corresponding to different vibrational transitions can be well resolved. Longer residence times of electrons near such surfaces can be due to the formation of space charge under the tip of the STM injecting electrons into the oxide (the current density $j \approx 10^6-10^8$ A cm^{-2}.)

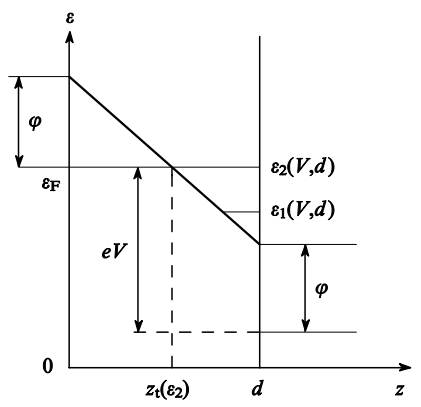

Figure 3. A scheme illustrating electron tunnelling in an STM operating in the field emission mode ($V > \varphi$);
$\varepsilon_{1(2)}(V,d)$ are the electron energy levels of field emission resonances, d is the surface – tip separation and z_t is the classical turning point.

Depending on the atomic and electronic structure of the tip, resonance features on the current – voltage characteristics of the STM can manifest themselves either as conductivity maxima [if $\rho_t(\varepsilon) \approx$ const, where $\rho_t(\varepsilon)$ is the local density of electron states at the position of the tip] or total current maxima [if $\rho_t(\varepsilon)$ exhibits a narrow peak, which is characteristic of 'single-atom' tips and tips containing adsorbed species [36, 37]]. In experimental studies of molecular adsorption on the metal and oxide surfaces by vibrational scanning tunnelling spectroscopy using resonance features of STM currents such maxima have been observed in the $J-V$ curves.[18–21, 24, 38–43]

IV. Inelastic electron tunnelling spectroscopy with STM

1. Single-quantum vibrational transitions of single adsorbed molecules

Threshold features of tunnelling currents in metal – dielectric – metal (M – D – M) junctions containing adsorbed species were predicted and experimentally found in 1966.[44] Threshold features of currents in tunnel $n-p$-junctions (tunnel diodes [45]) due to phonon excitation have been observed by Holonyak and Lesk.[46]

Since energy exchange between an electron and slow vibrational degrees of freedom of the surface is adiabatically forbidden, the probabilities of inelastic tunnelling are usually very low. According to recent estimates,[33] the probabilities of vibrational transitions can be described by a relationship

$$w_{\upsilon,\upsilon'} \propto \left(\frac{a_0}{R_0}\right)^{2|\upsilon-\upsilon'|}, \qquad (12)$$

where a_0 is the zero-point vibrational amplitude and R_0 is the equilibrium position of the oscillator simulating the vibrational subsystem. For single-quantum transitions ($|\upsilon-\upsilon'| = 1$), $w_\omega \approx 0.01-0.05$. Threshold features on the $J-V$ curves of M – D – M tunnel junctions are virtually unobservable. To distinguish them against the background noise, the dependences of $\partial\sigma/\partial V$ on V are usually measured. In this case, threshold features manifest themselves as peaks, the positions of which allow determination of the vibrational quantum energy ω.

Inelastic electron tunnelling spectroscopy of M – D – M tunnel junctions was widely used in 1970 – 1980s for measuring vibrational spectra of species adsorbed at the metal – dielectric interface (see publications on tunnelling vibrational spectroscopy, *e.g*., review [47]). These measurements were performed with macroscopic ensembles of adsorbed species. As a consequence, all the spectra measured by tunnelling vibrational spectroscopy were inhomogeneously broadened. Spectroscopy of threshold features of the STM currents is free from this drawback.

The possibility of observation of threshold features associated with single-quantum vibrational transitions in adsorbed species in experiments with STM seems to be apparent since the energy level diagrams used for illustration of elastic and inelastic tunnelling through M – D – M junctions and nanoscale tunnel junctions are the same (see Fig. 1). In essence, the problem of observation of small-scale threshold features in the experiments with STM is reduced to the problem of capabilities of the instrument the experimentalist has in hand.

As should be expected, single-quantum transition probabilities obtained in theoretical studies of the extent of threshold features of STM currents were estimated at $\sim 0.01-0.05$.[48, 49] Search for threshold features due to single-quantum vibrational transitions was carried out in many research laboratories over more than a decade. These studies were stimulated, in particular, by the necessity of solving one of the central problems of STM physics, *viz*., the problem of chemical identification of single adsorbed species, whose topographic images are strongly dependent on the scanning mode (*i.e*., on the specified V and d values).

The first example of a threshold feature associated with single-quantum excitations of stretching vibrations of the C – H bond has been reported only recently by Ho *et al*.[17] who studied

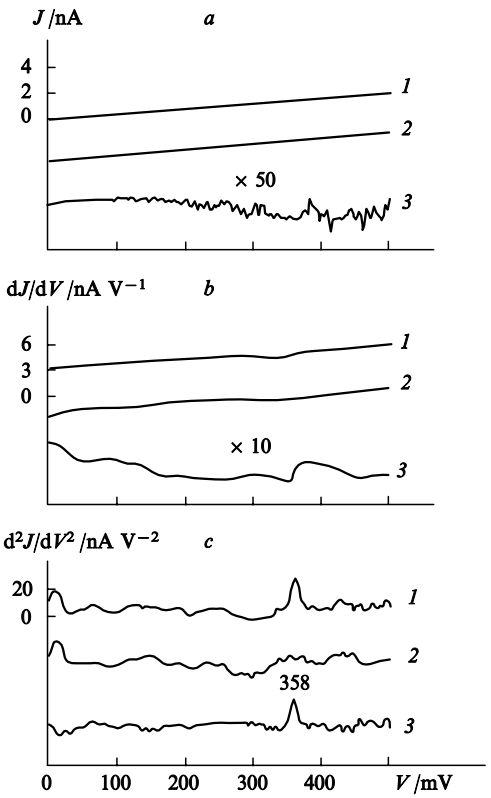

Figure 4. Threshold features of the STM current J (*a*), $\partial J/\partial V$ (*b*) and $\partial^2 I/\partial V^2$(*c*) recorded for a single acetylene molecule adsorbed on the Cu(100) surface.[17]
The curves were recorded with the STM tip positioned over the center of acetylene molecule (*1*) and over the clean surface area (*2*). Curves *3* represent the corresponding difference curves (*1*–*2*). Curves *2* and *3* are shifted along the ordinate axis.

adsorption of a single C_2H_2 molecule on the Cu(100) surface. The design of the new low-temperature STM specially developed to extend the capabilities of inelastic electron tunnelling spectroscopy to a single molecule level has been described elsewhere.[50] Some of the results obtained by Ho *et al.*[17] and presented in Fig. 4 can serve as an illustration of the difficulties associated with extraction of weak threshold signals from the intense background noise of the total current. (Recently,[51] it has been reported that Ho's continuous measurements of the spectra required signal accumulation during many hours.[17]) The isotope effect observed for deutero-substituted acetylene molecules has proven correctness of the assignment of the threshold feature shown in Fig. 4 to single-quantum vibrational transitions of the C–H bond. Later, inelastic electron tunnelling spectroscopy was used to observe elementary acts of dehydrogenation of single ethylene, benzene and pyridine molecules.[52] The topographic images obtained at different time instances allowed observation of displacements and rotations of single molecules, which would be induced by the STM current. Detection of a threshold feature due to the single-quantum vibrational excitations of CO molecules adsorbed on the Cu(001) and Cu(110) surfaces was reported.[53] However, multi-quantum (or combination) vibrational transitions, the probabilities of which do not exceed 0.001 [see expression (12)], have not been observed so far using inelastic electron tunnelling spectroscopy.

2. Electronic transitions in single adsorbed molecules

Conductance jumps of tunnelling gaps, due to vibrational transitions in adsorbed molecules represent an important but not the only example of manifestation of inelastic tunnelling in the experiments with STM. Other interesting examples are associated with electronic excitation of surface complexes. Since in this case there is no small characteristic parameter (energy exchange between two electrons having comparable energies occurs effectively), one should expect that the extent of the threshold features of STM currents associated with electronic transitions in the adsorbed species will be much greater than that observed in the case of vibrational transitions. This problem has been studied recently[22,23] taking a threshold feature associated with the $X^3\sum_g^- - a^1\Delta_g$-transition in physisorbed oxygen molecules as an example. In this case, the threshold feature should be observed at $V \approx 1$ V. Rather high probability of the excitation of oxygen molecules to the singlet state by the tunnelling electrons (the probabilities of such transitions in the gas phase can reach 10% to 15%, see Ref. 54) allows one to predict a new effect, namely, the dependence of the magnitude of the threshold jump on the tunnelling current. At currents $J \approx (w_{TS}\,\tau_{ST})^{-1}$, where w_{TS} is the excitation probability of oxygen molecules from the triplet to the singlet state by inelastically tunnelling electrons and τ_{ST} is the singlet–triplet relaxation time of oxygen, the time intervals between individual electronic transitions between the tip and the surface are insufficient for complete relaxation of the singlet oxygen molecule. Hence, the tunnelling current measured over a time interval $t \gg \tau_{ST}$ ($t \approx 10^{-3}$ s, $\tau_{ST} \approx 10^{-8}$ s) consists of two components,

$$J = J_T n_T + J_S n_S, \qquad (13)$$
$$J_{T(S)} = J_{eT(S)} + J_{iT(S)}.$$

The currents $J_{T(S)}$ are due to the tunnelling electrons which interact with the molecule that was initially in the triplet (singlet) state. In both cases, elastic and inelastic electron tunnelling is possible [the corresponding currents are $J_{eT(S)}$ and $J_{iT(S)}$]. The latter process, which is responsible for the formation of singlet oxygen, has a threshold

$$J_{iT} \propto \eta(eV - \hbar\omega_S),$$

where $\hbar\omega_S$ is the excitation energy of singlet oxygen ($\hbar\omega_S \approx 1$ eV).[1] The probabilities of different events (different types of tunnelling) are proportional to the time-average populations of the triplet and singlet states (n_T and n_S, respectively), which are determined by the kinetics of spontaneous (relaxation) and current-induced transitions. By varying the STM current (this can be done by simply changing the distance between the surface and the STM tip), *i.e.*, by changing the ratio of the excitation and relaxation rates one can achieve targeted variation of the parameters $J_{T(S)}\tau_{ST}$, which will affect the populations and, hence, the magnitude of the threshold feature of the STM current. The minimum tunnelling currents (J_{min}) at which the dependence of the conductance jump on J is observed will determine the singlet–triplet relaxation time of a single singlet oxygen molecule ($\tau_{ST} \approx J_{min}^{-1}$).

V. Vibrational scanning tunnelling spectroscopy using resonance features of STM currents

1. Multi-quantum and combination vibrational transitions in single molecules adsorbed on the oxide and metal surfaces

Measurements of vibrational spectra of surface complexes are widely used in studies of chemical processes on the surfaces of solids. Absorption IR spectroscopy,[55] electron energy loss spectroscopy,[56] tunnelling vibrational spectroscopy[47] and other versions of vibrational spectroscopy allow identification of main types of surface complexes and determination of their structure. However, these methods provide only averaged information about macroscopic ensembles of species (see above) and single-quantum vibrational transitions in them. Recently,[18–20,38,40] the method of vibrational scanning tunnelling spectroscopy (VSTS) has been developed. This technique, which uses an STM operating in the field emission mode, allowed the vibrational spectra of adsorbed species to be measured for the first time in experiments

with STM. As a rule, the bands observed in such spectra correspond to not only single-quantum, but also multi-quantum vibrational transitions including combination ones. These spectra allow virtually unambiguous chemical identification of the species located under the STM tip.

Vibrational series of field emission resonances, which allowed the first observation of the effects of inelastic resonance electron tunnelling in experiments with STM, were predicted and detected in 1997.[18] The first experiments with a commercial STM Omicron (Germany) were carried out on naturally oxidised titanium samples in air. The current–voltage characteristics obtained exhibited clearly defined groups of equidistant maxima. The current *vs.* voltage ($J-V$) dependences were measured at different points of the surface at constant separation d of the order of 5 Å, which was adjusted and maintained by choosing an appropriate current at $V_{max} = 10$ V. The currents J varied from 4 to 20 nA. The $J-V$ dependences were measured with variable V increments ranging from 0.01 to 0.05 V. To exclude small-scale fluctuations of the measured currents, the results obtained with the 0.01 V increment were averaged over two (four) close V values. It was found that at weak currents $J(V_{max})$ resonance lines appear on the $J-V$ curves only at $V > 8$ V. At $J(V_{max}) > 7$ nA, resonance features were clearly seen in the whole range of changes in V, that is, from 5 to 10 V ($\varphi \approx 5$ eV). An example of the vibrational spectra measured in the study cited [18] is shown in Fig. 5. Comparison of the measured vibrational quanta (0.1 eV) with those known for TiO_2 ($\hbar\omega \approx 0.09$ eV) allowed one to assign these lines to the vibrational transitions of the Ti–O bond. Simultaneously, spectra with $\hbar\omega \approx 0.27$ and 0.45 eV were also observed.[18] These quanta were associated with vibrational transitions in the adsorbed CO molecules and OH radicals. Further experiments were carried out in ultrahigh vacuum ($P < 10^{-9}$ Torr) with dosed adsorption of the gases under study.

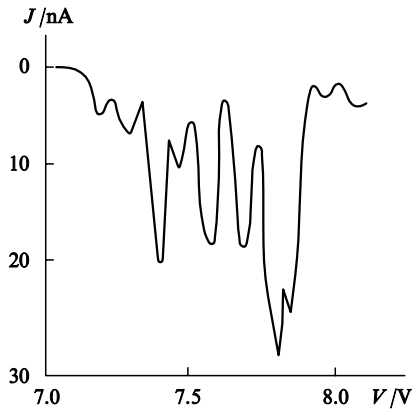

Figure 5. Vibrational spectrum of oxidised titanium ($\hbar\omega = 0.1$ eV).[18]

2. Adsorption of water on oxidised titanium. Isotope effect

Oxides are widely used as supports for many types of catalysts.[1,2] Adsorption of water on oxide surfaces has been repeatedly studied by different methods (see, *e.g.*, Ref. 57); nevertheless, one of the key issues, *viz.*, that of the forms of adsorption, remained open until the performance of the VSTS experiments.

The first measurements of the vibrational spectra of water adsorbed on the titanium surface oxidised in air using high-vacuum experiments with STM have been reported recently.[40] (This 'in-air' method was also used for measuring the vibrational spectra of water adsorbed in the nanoscale junction formed by the Ir–Pt tip and niobium.[58]) Measurements of the $J-V$ curves were preceded by a special procedure for the preparation of the surfaces under study, which included heating of samples to 550 K followed by long-term storage in high vacuum and exposure of the samples

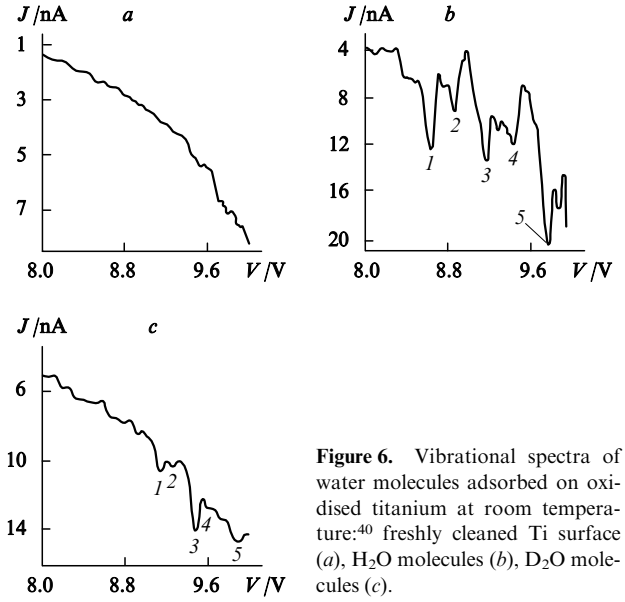

Figure 6. Vibrational spectra of water molecules adsorbed on oxidised titanium at room temperature:[40] freshly cleaned Ti surface (*a*), H_2O molecules (*b*), D_2O molecules (*c*).

to water vapour at a pressure of $\sim 10^{-6}$ Torr. After heating of the samples for ~ 2 h and subsequent storage in high vacuum the current–voltage characteristics measured at the majority of the surface points exhibited faintly visible series of field emission resonances corresponding to the vibrational frequencies of titanium oxide (see Fig. 6 *a*). Further exposure of the sample to water vapour (~ 300 K) was accompanied by significant changes in the spectral pattern; in particular, measurements at many surface points gave the spectra similar to that shown in Fig. 6 *b*. This spectrum exhibits clearly defined resonance lines corresponding to the single-quantum [$\hbar\omega_1 \approx e(V_3 - V_1) \approx 0.5$ eV, $\hbar\omega_2 \approx e(V_2 - V_1) \approx 0.2$ eV], two-quantum [$\hbar\omega_3 \approx e(V_5 - V_1) \approx 2\hbar\omega_1$] and combination [$\hbar\omega_4 \approx e(V_4 - V_1) \approx \hbar\omega_1 + \hbar\omega_2$] vibrational transitions in water molecule (the subscript at the quantities ω and V denotes the number of the resonance line in the spectrum). Small-scale maxima between the first and second (and between the third and fourth) resonances in Fig. 6 *b* correspond to the vibrations of the Ti–O bond ($\hbar\omega \approx 0.1$ eV). The magnitudes of the quanta $\hbar\omega_1$ and $\hbar\omega_2$ were found to be close to the known IR spectroscopy data on the stretching [$\hbar\omega_1(\mathrm{IR}) = 0.46$ eV] and bending [$\hbar\omega_2(\mathrm{IR}) = 0.20$ eV] vibrational quanta of H_2O molecules adsorbed on the oxidised titanium surface. It was found that the surface areas characterised by the spectra similar to that shown in Fig. 6 *b* have an island structure with the island size from 10 to 50 nm (this is typical of water adsorption on the surface of polycrystals). Blank runs with heavy water (D_2O) also gave similar spectra (see Fig. 6 *c*) with field emission resonances with the energies $\hbar\omega_1(D_2O) \approx 0.35$ eV and $\hbar\omega_2(D_2O) \approx 0.15$ eV. With an accuracy of $\sim 10\%$, this corresponded to the expected isotope effect

$$\frac{\hbar\omega(H_2O)}{\hbar\omega(D_2O)} \approx \sqrt{2}.$$

The shift of vibrational spectra towards smaller $\hbar\omega$ values represents the main, but not the only manifestation of the isotope effect. Replacement of hydrogen by deuterium leads to simultaneous change in frequency and the vibronic coupling parameter α

$$\frac{\alpha_D}{\alpha_H} \approx \sqrt{2}.$$

Correspondingly, the Franck–Condon factors determining the extent of the resonance maxima also change. For instance, for the transitions ($0 \rightarrow 1$) one gets

$$\frac{\langle 0|1\rangle_{\rm H}}{\langle 0|1\rangle_{\rm D}} = \frac{\alpha_{\rm H}}{\alpha_{\rm D}} \exp[-(\alpha_{\rm H} - \alpha_{\rm D})].$$

These relationships allow estimation of the parameter $\alpha_{\rm H}$. Using experimental data

$$\frac{J^{\rm r}_{\rm H}(\upsilon = 1)}{J^{\rm r}_{\rm D}(\upsilon = 1)} \approx 1.25,$$

where $J^{\rm r}_{\rm H,D}$ are the resonance components of the current (*i.e.*, the heights of the resonance maxima, calculated relative to the background curve), we get $\alpha_{\rm H} \approx 1.4$.

The observation of the isotope effect in the spectra of resonance features on the $J-V$ curves of the STM is unambiguous evidence for correspondence between the observed series of resonance maxima (see Fig. 6 *b*,*c*, peaks *1*–*5*) and vibrational transitions in the adsorbed water molecules. The absence of lines at $\hbar\omega \approx 0.2$ eV in particular spectra (see, *e.g.*, Fig. 7) suggests that the surface complex represents an OH radical (the value $\hbar\omega \approx 0.5$ eV corresponds to the stretching vibrational quantum of the OH radical). Hence, both types of adsorption (*viz.*, molecular and dissociative ones) on the TiO_2 surface are possible at room temperature, as was suggested recently.[57]

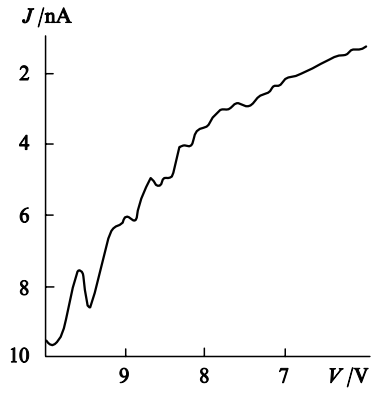

Figure 7. Vibrational spectrum of hydroxyl group adsorbed on oxidised titanium at room temperature.[41]

Vibrational scanning tunnelling spectroscopy (or spectroscopy of resonance features of STM currents) opens considerable opportunities for studies on the adsorption of various gases on the surface of oxides and metals coated with thin oxide films. The method allows one for the first time to obtain reliable chemical identification of the adsorbed species and to measure the spectra of not only single-quantum, but also multi-quantum vibrational transitions including combination ones in the adsorbed molecules and clusters. This has been exemplified by oxygen clusters adsorbed on the Al(100) surface at room temperature.[20, 39, 42]

3. Multi-quantum vibrational transitions in oxygen clusters adsorbed on aluminium

Initial stages of aluminium oxidation have been intensively studied by many experimental methods including scanning tunnelling microscopy,[59] high-resolution electron energy loss spectroscopy,[60, 61] IR spectroscopy, *etc*. Currently, it is known that at room temperature and low surface coverages the adsorbed oxygen forms small clusters with characteristic vibrational quanta $\hbar\omega_1 = 0.11-0.12$, $\hbar\omega_2 = 0.07-0.08$ and $\hbar\omega_3 = 0.036-0.040$ eV.[59–61] Low-energy electron diffraction studies[60, 61] showed that the intensities of the electron energy loss peaks depend on the oxygen dose to which the sample was exposed. At small doses [$< 10-20$ Langmuir (L), 1 L = 1 Torr s], the losses were found to be ~ 0.08 and 0.12 eV. Exposure to greater doses ($\gtrsim 100$ L) corresponding to the formation of nanoscale islands on

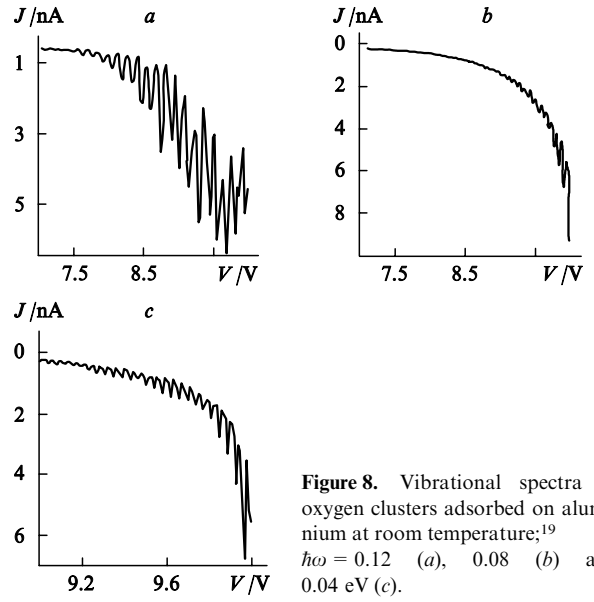

Figure 8. Vibrational spectra of oxygen clusters adsorbed on aluminium at room temperature;[19] $\hbar\omega = 0.12$ (*a*), 0.08 (*b*) and 0.04 eV (*c*).

the surface of the oxide phase resulted in the losses $\hbar\omega = 0.04$ eV. The same $\hbar\omega$ values were obtained [19] in the VSTS measurements of vibrational spectra of oxygen adsorbed on the Al(100) surface (Figs 8–10).

Experiments with the Al(100) and oxidised titanium surfaces were carried out using the same procedures for both the preparation of the surfaces and measurements of vibrational spectra with the STM. The $J-V$ curves measured for clean Al(100) surface with an increment $\Delta V = 0.01$ V exhibited no resonance features and were well described by the Fowler–Nordheim formula

$$J(V) = \exp\left(-\frac{C}{V}\right) \qquad (14)$$

($C = 10-100$ V), which corresponds to electron tunnelling from the tip of an STM operating in the field emission mode.

Measurements at different points of the surface carried out at $\sim 10-20$ L doses showed that nearly 10% of the $J-V$ curves exhibited vibrational series with $\hbar\omega_1 \approx 0.12$ eV. (The spectra with $\hbar\omega_2 \approx 0.08$ eV were observed more rarely.) This allows the determination of the sticking coefficient of oxygen to the clean Al(100) surface, $\theta \approx 0.005-0.01$. The same values were obtained in a STM study of the initial stages of Al(100) oxidation.[59]

Exposure to greater doses was accompanied by significant changes in the pattern of vibrational spectra. For instance, spectra with $\hbar\omega_3 = 0.04$ eV appeared at different points of the surface at

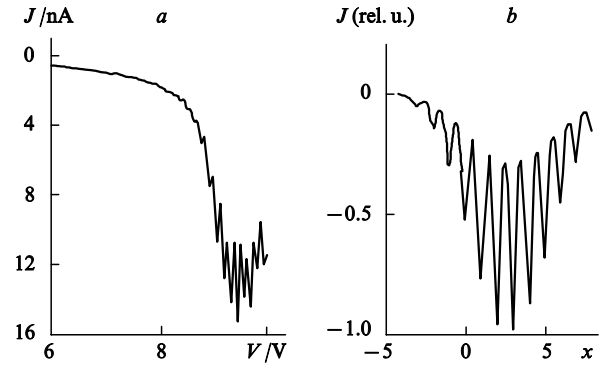

Figure 9. Vibrational spectrum of oxygen cluster adsorbed on aluminium ($\hbar\omega = 0.12$ eV, dose 20 L);[19] bell-shaped envelope (*a*) and theoretical curve calculated using formula (6) for the Boltzmann distribution over vibrational levels, $x = V/\omega$ (*b*).

oscillating envelope (*a*) and theoretical curve calculated using formula (6) for the inverse distribution over vibrational levels (*b*).

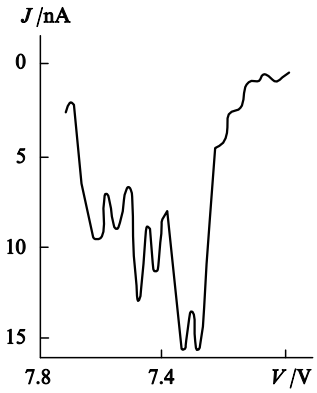

Figure 11. Doubled vibrational series of field emission resonances for paramagnetic radical ion O_2^- adsorbed on oxidised titanium (the effect of exchange splitting of resonance lines).[24]

50 L doses. Further increase in exposure doses led to a decrease in the number of spectra with the lines with larger $\hbar\omega$ (0.12 and 0.08 eV) and to rapid increase in the number of spectra with the vibrational quantum $\hbar\omega_3 = 0.04$ eV corresponding to the oxide phase. After exposure to $\sim$1000 L doses the $J-V$ curves measured at almost all points of the surface under study exhibited long series of resonance maxima corresponding to the oxide. Simultaneously, adsorption of CO molecules on the oxidised aluminium surface was observed. Such complexes can be readily identified using their spectra that exhibit lines corresponding to combination vibrational transitions

$$eV_{\upsilon_1\upsilon_2} = eV_0 + \hbar\omega_0\upsilon_1 + \hbar\omega_3\upsilon_2, \quad \upsilon_{1,2} = 0, 1, 2, \ldots, \tag{15}$$

where the largest vibrational quantum [$\hbar\omega_0 = 0.24$ eV (see Ref. 61)] equals the well-known value characteristic of the CO molecules.

4. Detection of single surface paramagnetic centres

The surfaces of oxides and oxidised metals are always covered by small amounts of paramagnetic centres [$< 1\%$ (see Ref. 2)] which are usually studied by ESR on polycrystals.[62] Attempts at detecting ESR signals from individual paramagnetic centres (PC) with the STM have been undertaken.[63, 64] Weak changes in the tunnelling currents were detected in experiments with oxidised silicon. Signals were observed at room temperature at distances $\sim$3 to 6 Å from the single point defects tentatively identified as PC. Such a dependence of the ESR signal on the tip position seems to be abnormal. The origination mechanism of 'single-atom' ESR in the case of equally populated Zeeman levels is currently unknown. The problem of integration of the ESR and STM methods needs further consideration.

Possible variants of such an integration have been considered.[25, 26] It was shown that using ferromagnetic tips (here, the tunnelling electrons are polarised) allows detection of ESR signals in the experiments with STM even at room temperature when $kT > \hbar\omega_L$ (ω_L is the Larmor frequency) and the Zeeman levels have equal equilibrium populations. This can be done with the operating currents $J > \tau_\sigma^{-1}$ (τ_σ is the characteristic spin–lattice relaxation time) at which the polarised tunnelling electrons create nonequilibrium distributions over the Zeeman levels. Practical implementation of this technique would make it possible to reveal the arrangement of paramagnetic centres on the surface using the capabilities of the STM; however, these experiments preclude measurements of *g*-factors since local magnetic fields under the ferromagnetic tip of the STM are currently unknown.

Another solution to the problem of detection with STM of a single PC has been suggested and evaluated.[24, 65] It was found that for metal oxides and metals coated with thin oxide films, the exchange splitting of the field emission resonances ($\delta_{j,n}$) can be larger than or comparable with the width of the energy level: $\delta_{j,n} \approx 0.1-0.2$ eV, $\Gamma_{j,n} \leqslant 0.1-0.04$ eV. Hence it follows that the vibrational spectra of the PC should have the form of two series of equidistant maxima on the $J-V$ curves, shifted with respect to each other by the exchange splitting $\delta V \approx 0.1-0.2$ V.

Such a spectrum has first been observed for oxidised titanium (Fig. 11). Based on the exchange splitting and the vibrational quantum magnitude ($\hbar\omega = 0.15$ eV), this PC can be unambiguously identified as a single surface paramagnetic radical ion O_2^-. [The vibrational frequency of dioxygen ion adsorbed on oxide surfaces is well known from the IR spectroscopy data:[2] $\hbar\omega(O_2^-) = 1180\ \text{cm}^{-1} = 0.15$ eV.] The characteristic spectral pattern corresponding to the adsorbed radical ion O_2^- represents a complete spin-vibrational 'portrait' of this species, which can also be used in studies of single O_2^- ions adsorbed on other surfaces. This can be exemplified by the spin-vibrational spectrum of a single O_2^- ion detected on the oxidised Al(100) surface (Fig. 12).

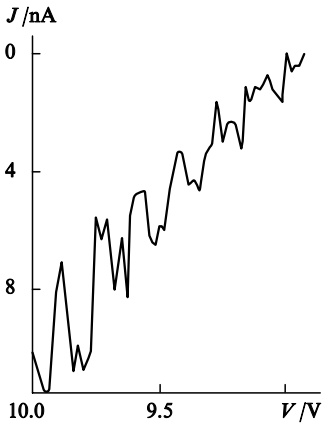

Figure 12. Spin-vibrational series for paramagnetic radical ion O_2^- adsorbed on oxidised aluminium surface.

VI. Kinetics of vibrational and spin transitions in single surface complexes

The development of new methods for detection with STM of single paramagnetic centres and measurements of multi-quantum vibrational spectra of single surface complexes creates prerequisites for the invention of 'kinetic' modifications of the scanning tunnelling spectroscopy of vibrational and spin transitions. This is of crucial importance.

According to the ergodic hypothesis, the kinetics of quantum transitions can be studied by two equivalent approaches. One of

them implies experiments with ensembles of identical subsystems while the other involves experiments with the same subsystem and multiple repetition of the transitions under study. Until recently, all kinetic modifications of spectroscopic methods were based on the first approach. However, spectroscopic measurements with ensembles can appear to be insufficiently informative in the case of inhomogeneous systems such as surfaces covered with adsorbed species. Scanning tunnelling spectroscopy of vibrational and spin transitions allows the second approach to be implemented for the first time. (In this case, the kinetics of quantum transitions in ensembles of elementary events occurring in the same surface complex rather than in ensembles of adsorbed species is studied.) These surface chemistry studies were impossible[‡] until recent publications.[18, 19, 22]

The idea of kinetic scanning tunnelling spectroscopy is very simple. In experiments with STM, the current densities can be as high as 10^{10} to 10^{11} A cm^{-2}. Thus, the time intervals between individual acts of tunnelling can be shorter (or at least comparable with the characteristic relaxation times of internal degrees of freedom of the surface complexes.) At such electron current densities, the distributions of the species located under the STM tip over vibrational states appear to be essentially nonequilibrium. If ferromagnetic tips are used, spin distributions of the species also appear to be nonequilibrium.[25, 26] Under these conditions, the average current J measured during the time of the order of 10^{-3} s includes contributions of a large number of transitions,

$$J(V) = \sum_{\upsilon,S,S_z} n(\upsilon, S, S_z) J_{\upsilon,S,S_z}(V). \tag{16}$$

Here, $n(\upsilon,S,S_z)$ is the current-dependent population of the state $|\upsilon,S,S_z\rangle$ of the surface complex 'sitting' under the STM tip, J_{υ,S,S_z} is the tunnelling current due to the electrons interacting with the species which initially was in the state $|\upsilon,S,S_z\rangle$ and S and S_z are the spin of the species and its projection, respectively.

Since individual acts of electron tunnelling are uncorrelated (the relaxation times of electronic subsystems for the surface and tip are much shorter than all other characteristic times), the kinetics of vibrational and spin transitions in the surface complex can be described by a system of balance equations

$$\frac{\partial n(v)}{\partial t} = \sum_{vv'} \left[n(v') w_{v'v} - n(v) w_{vv'} \right] = 0, \tag{17}$$

where v denotes the totality of vibrational and spin quantum numbers and $w_{v'v}$ are the probabilities of quantum transitions $v' \to v$, which, generally, can be both current induced and spontaneous (relaxation)

$$w_{v'v} = J_{v'v} + w_{\mathrm{r}\, v'v}\,. \tag{18}$$

Here, $J_{v'v}$ are the tunnelling currents corresponding to the electronic transitions for particular fixed initial (v') and final (v) values of the vibrational and spin quantum numbers of the complex and $w_{\mathrm{r}\, v'v}$ are the probabilities of spontaneous transitions.[§] Taken together, the system of equations (17) and expressions (16) and (18) make it possible to obtain a self-consistent description of the formation of resonance features on the $J-V$ curves of the STM. Resonance currents $J_{v'v}$ can be calculated using formula (7). According to expression (16), the series of field emission resonances on the $J-V$ curves depend on the distributions $n(v,S,S_z)$, which allows their reconstruction from experimental data.[19, 20, 25] From Eqns (17) and expression (18) it follows that the dependence of the distributions $n(v,S,S_z)$ on $w_{\mathrm{r}\, v'v}$ can be used for reconstructing the kinetics of spin and vibrational transitions.

Some examples of nonequilibrium spin effects, potentially observable in systems with ferromagnetic tips, have been considered recently.[25] Therefore, below we will restrict ourselves to the description of nonequilibrium effects which can be observed in the vibrational spectra of adsorbates.[19, 20]

1. Reconstruction of nonequilibrium distributions over vibrational states

The relation between the shape of the envelopes of vibrational spectra of adsorbed species and the distributions $n(\upsilon)$ can be easily understood by analysing a diagram of vertical vibrational transitions occurring in the case of capture of a tunnelling electron by a trap (resonator). Such a diagram illustrating the main model of multi-quantum vibrational transitions (the model of shifted harmonic oscillators[67]) is shown in Fig. 13. (Recent estimates[24] have shown that the vibrational frequencies of adatoms change by no more than 10% to 15% upon capture of an electron by the resonator.) It is easily seen that for the equilibrium vibrational distributions corresponding to rather weak tunnelling currents insufficient for strong heating of the vibrational subsystem

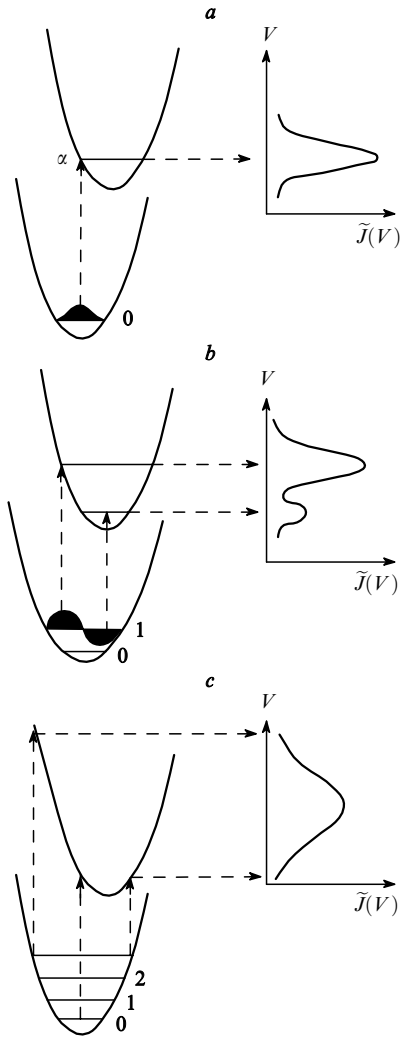

Figure 13. A scheme illustrating the formation of different types of envelopes for the vibrational spectra of adsorbates and the relation between the shape of the envelope and $\tilde{J}(V)$ and distributions over vibrational states.

[‡] It should be mentioned that single molecule spectroscopy by laser induced fluorescence also provides a means for studying the structure of and quantum transitions in single adsorbed species. However, spatially resolved experiments as well as studies on multi-quantum vibrational transitions and those involving highly excited states cannot be performed using this technique. The potentialities of this method have been considered in detail in a special issue of the *Chemical Physics* journal.[66]

[§] It will be recalled that we use the system of atomic units in which the electron charge $e = 1$.

$$n(\upsilon) = \begin{cases} 1, & \upsilon = 0 \\ 0, & \upsilon \neq 0 \end{cases}.$$

It will be recalled that usually the condition $kT \ll \omega$ is fulfilled. In this case, all the tunnelling electrons interact with the nonexcited surface complex and the envelopes of the resonance series are determined only by the Franck–Condon factors $\langle 0|\bar{\upsilon}\rangle^2$

$$\langle 0|\bar{\upsilon}\rangle^2 = \frac{\alpha^{\bar{\upsilon}} \exp(-\alpha)}{\bar{\upsilon}!}.$$

Here, α is the vibronic coupling parameter equal to the number of the energy level in which the species goes from the ground vibrational state (see Fig. 13 *a*). At $\alpha \approx 1$, the envelopes have a shape of sufficiently narrow bell-shaped curves.¶

For nonequilibrium distributions, the envelopes have a different shape. For Boltzmann-type distributions,

$$n(\upsilon) \approx \exp\left(-\frac{\upsilon}{\langle\upsilon\rangle}\right),$$

the envelopes are also bell-shaped, but have larger halfwidths which depend on $\langle\upsilon\rangle = \sum_{\upsilon} \upsilon n(\upsilon)$ (see Fig. 13 *c*). For inverse distributions, the envelopes exhibit oscillations, *i.e.*, the spectra are formed by groups of resonance maxima on the $J-V$ curves (see Fig. 13 *b*). The number of such groups, N, correlates with the number (υ_m) of the energy level with the highest population

$$N = \upsilon_m + 1.$$

Figures 8–10 present some examples of the vibrational spectra with bell-shaped and oscillating envelopes, obtained in our studies on the initial stages of the oxidation of aluminium at room temperature. The results of calculations of the $J-V$ curves using relationships (17) and (18) show the possibility of reconstructing the nonequilibrium distributions over vibrational states for the surface complexes located under the STM tip and 'heated' by the current of elastically and inelastically tunnelling electrons.

2. Kinetics of multi-quantum vibrational transitions

Combining the solution of equations (17) and calculations of vibrational series of the current–voltage characteristics of the STM using expression (16) allows the kinetics of vibrational transitions in single complexes located under the STM tip to be reconstructed from the experimental $J-V$ curves. Clearly, this also includes the reconstruction of the parameters determining the rate of vibrational relaxation of the surface complex to which the spectrum under study corresponds.

The dependences of the distributions $n(\upsilon)$ and corresponding $J-V$ curves on the excitation and de-excitation rates of vibrational degrees of freedom of surface complexes can be readily illustrated by the results of calculations presented in Figs 14–16. [Full information on the kinetics of vibrational transitions is contained in the shape of the envelopes, therefore the results of calculations of the $J(V)$ dependences are given in relative units.] The histograms of corresponding vibrational distributions calculated using formulae (7), (17) and (18) for both resonance and off-resonance V values are also shown in Figs 14–16.

In accordance with formula (7), the partial tunnelling currents ($J_{\upsilon\upsilon'}$) were approximated by resonance-type terms in which the probabilities of tunnelling from the tip to the trap, Γ_1, and from the trap to the sample, Γ_2, had the form

$$\Gamma_1 = C_1 \exp\left(-\frac{C}{V}\right), \quad \Gamma_2 = \text{const},$$

where C_1 and C are constants.

¶ Mention may be made of an analogy between inelastic resonance tunnelling and resonance absorption of light by molecules [67] and impurity centres in crystals.[68]

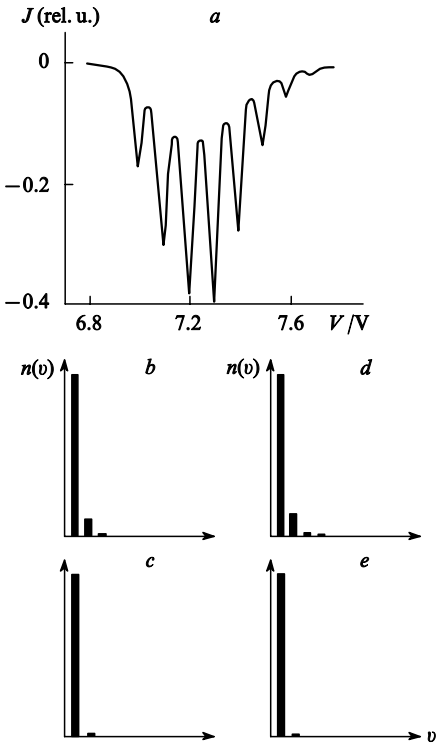

Figure 14. Vibrational spectrum with bell-shaped envelope (*a*) and distributions over vibrational levels (*b*–*e*).
Calculated using formulae (6), (16) and (17) for $w_{r\upsilon} > J_\upsilon$;
V/V: 7 (*b*), 7.05 (*c*), 7.4 (*d*) and 7.45 (*e*).

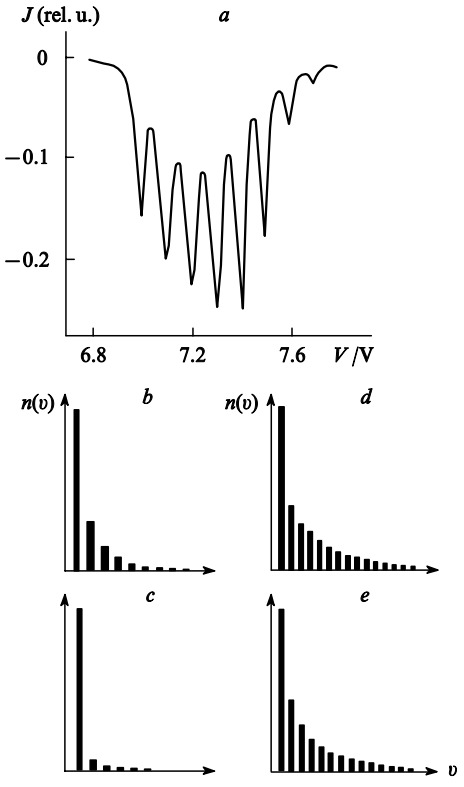

Figure 15. Vibrational spectrum with bell-shaped envelope (*a*) and distributions over vibrational levels (*b*–*e*). Calculated using formulae (6), (16) and (17) for $w_{r\upsilon} < J_\upsilon$; (*b*–*e*) see Fig. 14.

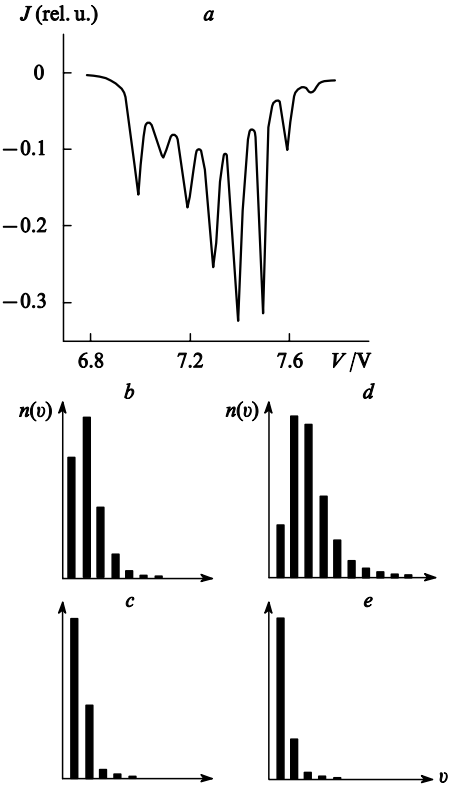

Figure 16. Vibrational spectrum with bell-shaped envelope (*a*) and distributions over vibrational levels (*b*–*e*). Calculated using formulae (6), (16) and (17) for $w_{r\upsilon} < J_\upsilon$, $w_{r\upsilon} \approx \upsilon^3$; (*b*–*e*) see Fig. 14.

Different conditions for the excitation of the vibrational subsystem by the currents $J_{\upsilon\upsilon'}$ and for current-induced and spontaneous (with the rate approximated by the dependence $w_{r\upsilon} = c_r\upsilon^n$) vibrational relaxation were simulated. This was achieved by varying the parameters Γ_1, C_1, C, Γ_2, c_r and n in such a manner that the distributions over vibrational levels corresponded to the histograms presented in Figs 14–16.

The calculated spectrum shown in Fig. 14 *a* corresponds to weak heating of the vibrational subsystem (*cf*. Fig. 13 *a*). Changes in the bell-shaped spectrum upon an increase in the temperature of the vibrational subsystem are presented in Fig. 15 *a* and the relation between the spectra with oscillating envelopes and inverse distributions $n(\upsilon)$ is illustrated by the plot shown in Fig. 16 *a*. (This type of distributions is formed if the currents are rather heavy while the vibrational relaxation is slow and its rate is a nonlinear function of the excitation level.)

VII. Scanning tunnelling spectroscopy using fluctuations of STM currents

Pioneering STM studies and direct observation of slow surface migration of species with a time resolution of the order of 0.1 s have been reported more than a decade ago.[69,70] Since then, surface diffusion was repeatedly studied by scanning tunnelling microscopy (see, *e.g.*, Refs 71 and 72). By and large, such experiments are similar to those carried out earlier with a field emission[73] and ion microscope.[74] The known procedure for reconstructing the surface migration parameters from the images taken at different time instants allows one to reconstruct the surface diffusion activation energies of species with a reasonable accuracy (~5%–15%). Unfortunately, the pre-exponential factors in the expressions for the diffusion coefficients are determined with much lower (from 1.5 to 2 orders of magnitude) accuracy. This precludes studies on the surface migration dynamics. In particular, the hop lengths distributions of the migrating species remain unknown so far. These distributions determine the rates of many heterogeneous chemical reactions, but often do not necessarily correspond to the nearest adsorption site.[1]

It is believed that the problem can be solved by studying the spectral characteristics of the noise of tunnelling currents in STM due to changes in the conductance of the tunnelling gap caused by the passage of the migrating species.[28,29,75] An optimum design of experiment using 'fluctuation scanning tunnelling spectroscopy' has been proposed and substantiated.[28,29] Suppose the STM tip scans the surface area containing the migrating species using a velocity close to the migration rate of the species. In this case, the spectral density of the low-frequency noise of the STM current strongly depends not only on the pre-exponential factor in the equation for the diffusion coefficient, but also on time taken for the migrating species to hop from one adsorption site to another one. Since even commercially sold STMs allow the surface scan velocity to be varied over a wide range (from 1 to 100 nm s^{-1}), scanning tunnelling spectroscopy using fluctuations of STM currents can be used for reconstructing the surface migration dynamics of not only slow particles, but also fast ones which cannot be imaged by surface topography measurements.

VIII. Time-resolved scanning tunnelling spectroscopy

Rapid progress in femtosecond laser spectroscopy and scanning tunnelling spectroscopy allows the surface structure to be studied with atomic-scale spatial or corresponding time resolution. This makes it possible to pose a more complicated problem of integrating the capabilities of these modern, powerful experimental methods for studying the surface.

Pioneering studies aimed at integrating the probe methods of studying solid surfaces including scanning tunnelling microscopy and femtosecond laser spectroscopy date back to early 1990s.[76–79] Currently, two main research avenues have been developed, the optical and tunnelling one, each with its specific problems and solution methods. To review them goes beyond the scope of this paper, so we will only briefly outline the state-of-the-art in the field.

In optical studies, the STM tip is replaced by a thin optical fibre brought to the surface under study to a distance shorter than the light wavelength. This type of probe instruments, *viz*., near-field scanning optical microscopes, provides atomic-scale time resolution in combination with rather high spatial resolution (~30–50 nm), which is one or two orders of magnitude higher than the resolution of conventional optical microscopes.

To achieve higher spatial resolution, one needs continue in use experimental methods employing STMs. Using the STM also allows time-resolved spectroscopic measurements to be performed by varying the conductance of the tunnel junction. As follows from expression (2), this can be done by varying the tunnelling gap or by changing the surface density of electron states (*e.g.*, by illuminating the contact) or the voltage. Each of these approaches has its own limitations that are due to inertia of the tip, finite switching rate of control circuits and small magnitudes of the tunnelling currents. Currently, time resolution achieved in experiments with STMs is no better than several picoseconds,[80] though integration of STM and femtosecond laser spectroscopy has been the subject of research activity in many research centres.

IX. Conclusion

The history of development of scanning tunnelling microscopy and spectroscopy demonstrates numerous examples of successful solutions to fundamental problems of surface chemistry and physics. One cannot but be surprised at increasing number of new possibilities provided by the STM, the perfect scientific instrument. Advanced research techniques in surface chemistry and physics owe their origin to the creators of the STM. On the other hand, mention should be made of rapid increase in applied

research in which the STM and related probe instruments (see a short review [80]) are used as instruments for assembling of various nanoclusters from individual atoms on the solid surfaces. Nanoclusters exhibit unique physical and chemical properties. For instance, they can be extremely hard and possess high adsorptive and emissive capacities and reactivity. The conductivity of nanoclusters can be controlled in a targeted manner by varying their atomic structure without changing the chemical composition, by doping them with individual impurity atoms or by applying mechanical strain or a magnetic field. Of course, this gives rise to lots of ideas associated with possible use of both single 'hand-assembled' nanoclusters and multicluster nanomaterials in different areas of chemistry, in electronics, technology, ecology, medicine, *etc*. The development of nanotechnologies also implies wide use of probe instruments. Crucial importance of nanotechnologies to high-tech processes of the 21st century has now gained general acceptance in all highly developed countries. It is a wide-spread, well-substantiated opinion that many economic, military, social, political and medicinal problems can be solved using the results of nanotechnological studies. There are strong grounds to believe that the mission of being a scientific basis for nanotechnologies falls to the single molecule chemical physics of surfaces, which has been rapidly developed in a manner much like that of the chemical physics of macroscopic ensembles of atomic species.

The authors express their gratitude to Academician A L Buchachenko for incessant support of their research, frequent discussions of the results obtained, valuable comments and criticism. We are also grateful to M V Sharova for help in preparing the manuscript.

Abstract. The published data on the use of 1,3-dipolar cycloaddition reactions of nitrile oxides in the synthesis of natural compounds and their analogues are systematised and reviewed. The bibliography includes 145 references.

I. Introduction

The cycloaddition of nitrile oxides to alkynes and alkenes is the most popular approach to the synthesis of isoxazoles and 4,5-dihydroisoxazoles.[1–7] Isoxazoles and 4,5-dihydroisoxazoles are used as intermediates in total syntheses of natural compounds. The fact that these compounds represent equivalents of definite functional groups can be exploited in different steps of the synthesis. On the other hand, isoxazoles and 4,5-dihydroisoxazoles are relatively stable compounds and remain intact in the course of multistep transformations.

The present review is devoted to the synthesis of natural compounds based on reactions of nitrile oxides with dipolarophiles with subsequent transformations of the adducts formed.

II. Methods for the generation of nitrile oxides

Nitrile oxides are usually unstable and prone to dimerisation resulting in the corresponding furoxans.[8] Therefore, they are usually generated *in situ* by dehydration of primary nitro compounds by phenyl isocyanate[9] or by dehydrohalogenation of hydroximoyl chlorides or bromides by triethylamine.[10] Hydroximoyl chlorides are generated from oximes by chlorination with chlorine, *N*-chlorosuccinimide (NCS),[11] nitrosyl chloride, sodium hypochlorite[12] or *tert*-butyl hypochlorite.[13] A procedure for the synthesis of functionalised and non-functionalised hydroximoyl chlorides, which involves treatment of nitroalkanes or conjugated nitroalkenes with titanium(IV) chloride, has been developed.[14]

Several modified procedures for the generation of nitrile oxides, *e.g.*, dehydration of nitroalkanes by toluene-*p*-sulfonic acid,[15] benzenesulfonyl chloride or ethyl chloroformate in the presence of triethylamine[16] were developed in the 1980's. All these reactions are carried out at elevated temperatures. The use of di-*tert*-butyl pyrocarbonate and catalytic amounts of *N*,*N*-dimethylaminopyridine (DMAP) allows the dehydration of nitroalkanes under much milder conditions.[17]

Chloramine T is effective for the generation of nitrile oxides from oximes.[18] This reaction is usually carried out by heating an aldoxime and an alkene in ethanol in the presence of chloramine T. Its role consists in the chlorination of aldoxime to hydroximoyl chloride. Subsequent elimination of HCl by treatment with a base results in nitrile oxide. Nitrosyl chloride or aqueous sodium hypochlorite can be used instead of chloramine T.[12]

Thermolysis of furoxans, which represent cyclic dimers of nitrile oxides, occurs under drastic conditions and is therefore seldom used;[19] thermal generation of nitrile oxides from hydroximoyl chlorides by boiling in toluene is used far more often.[20] This method was used, in particular, for the synthesis of fullereno-4,5-dihydroisoxazoles.[21]

A new method for the generation of nitrile oxides by microwave irradiation of hydroximoyl chlorides in the presence of dipolarophiles has recently been proposed. This procedure includes cycloaddition of nitrile oxides to weak dipolarophiles, such as nitriles[22] and polycyclic aromatic compounds (*e.g.*, phenanthrene, anthracene, pyrene, *etc.*) in the absence of solvents.[23] The yields of cycloaddition products exceed severalfold those obtained under standard conditions, whereas the reaction time is reduced to 3 – 10 minutes against ~ 24 h under standard conditions.

Nitrile oxides are generated from *O*-trimethylsilylhydroximoyl chlorides by treatment with potassium fluoride in acetonitrile at ~ 20 °C (see Ref. 24) or from hydroximoyl chlorides using molecular sieves (3 – 5 Å) in CH_2Cl_2.[25] In the latter case, the cycloadducts are formed in high yields, while no furoxans are formed at all.

III. Methods for the transformations of isoxazoles and 4,5-dihydroisoxazoles

Methods for the transformations of isoxazoles (**1**) and 4,5-dihydroisoxazoles are based on the lability of the N – O bond and are extremely diverse. In this section, we shall consider the main classes of compounds generated from the 1,3-dipolar cycloaddition adducts of nitrile oxides and the methods for their transformation with special emphasis on novel approaches.

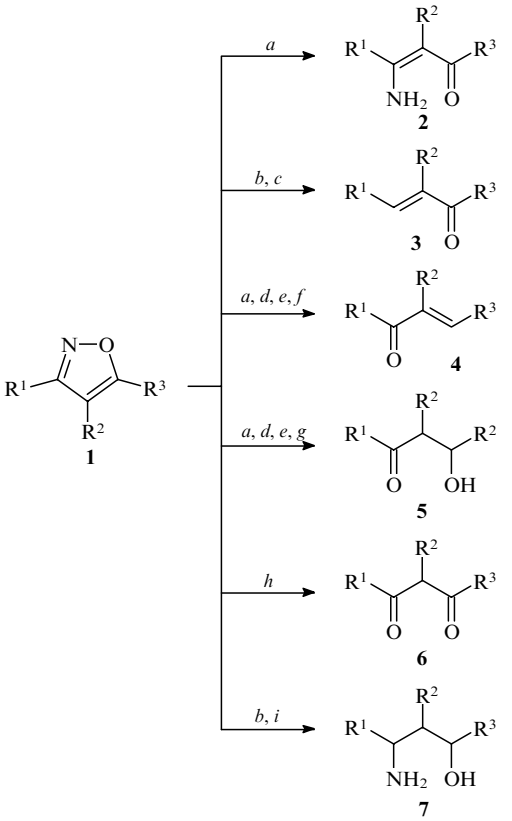
Uspekhi Khimii **70** (8) 730 – 743 (2001); translated by R L Birnova

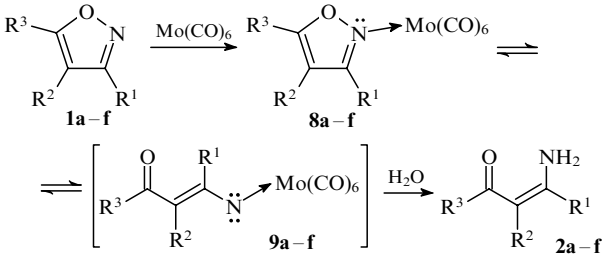
The most common procedure is the reductive scission of isoxazoles by hydrogenation over Raney nickel or platinum dioxide to afford enamino ketones **2**.[26–28]



(*a*) H_2, Ni/Ra (Pt_2O), EtOH; (*b*) Na/NH_3, 3 equiv. Bu^{t}OH, THF; (*c*) *p*-TsOH, PhMe, Δ; (*d*) PhCOCl, Py; (*e*) $NaBH_4$; (*f*) H^+; (*g*) 90% AcOH; (*h*) Ni/Ra, BCl_3, MeOH–H_2O; (*i*) Ni–Al, MeOH, KOH.

Enamino ketones **2** can also be prepared by reduction of isoxazoles with sodium in liquid ammonia in the presence of 1 equiv. of Bu^{t}OH.[29] With 3 equiv. of Bu^{t}OH, this reaction yields intermediate β-amino ketones; their acid hydrolysis results in enones **3**.[29] The regioisomeric enones of the type **4** are obtained by benzoylation of enamino ketones **2** followed by reduction of the amido ketones formed and hydrolysis of the intermediate hydroxy enamides.[30] Hydrolysis of hydroxy enamides by 90% AcOH yields β-hydroxy ketones **5**.[27,31] β-Diketones **6** are prepared by catalytic hydrogenation of isoxazoles in the presence of Lewis acids.[32] Isoxazoles are reduced to amino alcohols **7** using nickel–aluminium alloys in the presence of an alkali.[33]

However, reductive scission of isoxazoles cannot be used if the substrates contain double bonds or protective groups susceptible to hydrogenolysis. In this case, cleavage of the N–O bonds is achieved by using other methods. Thus molybdenum or iron carbonyls were recommended for use in the synthesis of enamino ketones **2a–f**.[34]

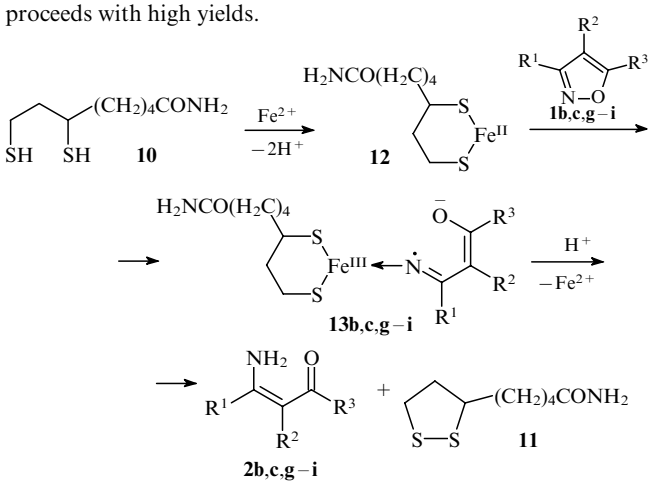


$R^1 = R^3$ = Ph, R^2 = H (**a**); R^1 = Me, R^2 = H, R^3 = Ph (**b**);
$R^1 = R^3$ = Me, R^2 = H (**c**); R^1 = Ph, $R^2 = R^3$ = H (**d**);
R^1 = Ph, $R^2 - R^3 = (CH_2)_4$ (**e**); R^1 = Ph, $R^2 - R^3 = (CH_2)_3$ (**f**).

The mechanism of this reaction includes the formation of the molybdenumhexacarbonyl complexes **8a–f** involving the nitrogen atom of the isoxazole with subsequent cleavage of the N–O bond and hydrolysis of the nitrene complexes **9a–f** to the enamino ketones **2a–f**.

The reductive opening of isoxazoles leading to enamino ketones is achieved with samarium iodide in tetrahydrofuran containing methanol as the proton source in 57% to 80% yields.[35]

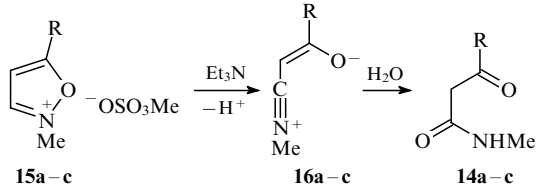
Dihydrolipoamide (**10**) was used for reductive cleavage of 4,5-dihydroisoxazoles[36] [lipoamide (**11**) is a coenzyme in redox reactions occurring in living organisms]. The reductive cleavage of N–O bonds in 3,5-disubstituted isoxazoles **1b**,**c**,**g–i** under the action of compound **10** in the presence of iron(II) salts also proceeds with high yields.



R^1 = Me, R^2 = H: R^3 = Ph (**b**), Me (**c**); $R^1 = R^2$ = H, R^3 = Me (**g**);
R^1 = Ph: R^2 = CO_2Me, R^3 = Me (**h**); R^2 = CO_2H, R^3 = Me (**i**).

It is suggested that isoxazoles **1b**,**c**,**g–i** react with the complex (**12**) to give the intermediates **13b**,**c**,**g–i** which are further hydrolysed to enamino ketones **2b**,**c**,**g–i**. Compound **10** is converted into lipoamide **11** under these conditions.

N-Methylated β-oxo amides **14a–c** are formed in high yields upon fragmentation of *N*-methylated isoxazoles **15a–c** catalysed by Et_3N.[37]

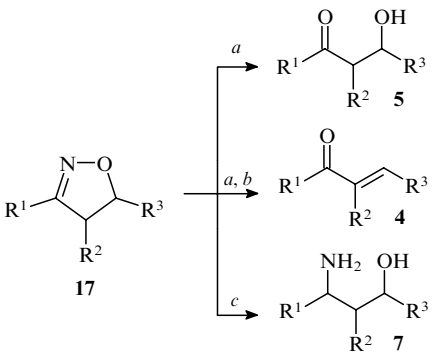


R = Me (**a**), CH=CHPh (**b**), $CH_2PO(OEt)_2$ (**c**).

The isoxazolium salts **15a–c** are deprotonated with subsequent cleavage of the N–O bond and generation of the nitrilium ions **16a–c** which are further converted into β-oxo amides **14a–c** in the presence of water.

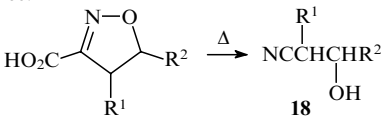
The reductive scission of 4,5-dihydroisoxazoles **17** has long been poorly understood. A method for their reduction over Raney nickel in the presence of trifluoroacetic or hydrochloric acid, which yielded a mixture of β-hydroxy ketones **5** and their dehydration products (α,β-unsaturated ketones **4**), was developed in 1979.[38] Later,[39] it was suggested to carry out this reaction in the presence of boric acid, which afforded β-hydroxy ketones **5** in high yields. The latter can further be dehydrated into enones **4**.[40] This method for the opening of 4,5-dihydroisoxazoles is widely used in the synthesis of natural compounds.[4]

The use of rhodium on Al_2O_3 and platinum dioxide as catalysts in the hydrogenation of dihydroisoxazoles **17** has been described.[41] Amino alcohols **7** are prepared by reduction of 4,5-dihydroisoxazoles by $LiAlH_4$,[42–44] the $BH_3 \cdot Me_2S$ complex (see Ref. 45) and zinc (or sodium) borohydride in the presence of nickel chloride in methanol.[46]

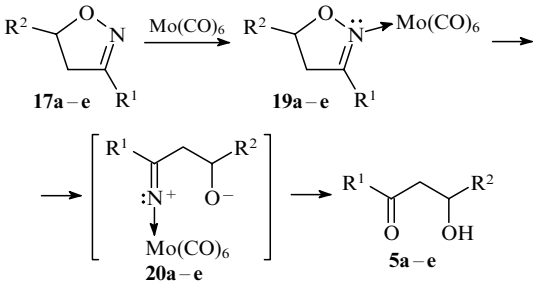


(*a*) H_2, Ni/Ra, H_3BO_3, EtOH; (*b*) p-TsOH; (*c*) $LiAlH_4$, Et_2O.

Hydroxy nitriles **18** are prepared from carboxydihydroisoxazoles.[47]

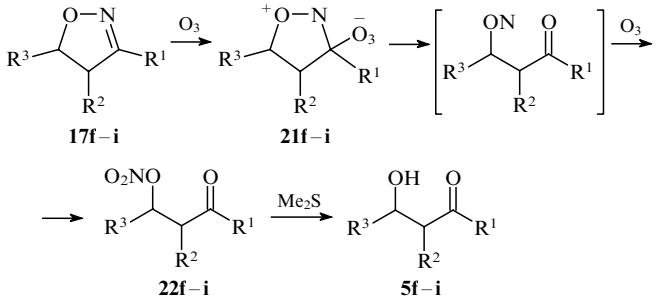


Similar to isoxazoles, 4,5-dihydroisoxazoles **17a–e** are opened under the action of molybdenum hexacarbonyl.[48] This reaction occurs *via* the complexes **19a–e** and **20a–e** which are further converted into β-hydroxy ketones **5a–e**. The complexes **19a–e** undergo retrodegradation in the absence of water.



$R^1 = Me_2C(OH)$: R^2 = n-C_8H_{17} (**a**), Bn (**b**); $R^1 = MeO_2C(CH_2)_2$, R^2 = n-$C_{10}H_{21}$ (**c**); $R^1 = HO_2C(CH_2)_2$, R^2 = n-$C_{10}H_{21}$ (**d**); $R^1 = CH_3(CH_2)_5$, R^2 = (*Z*)-MeCH=CH (**e**).

The possibility of opening of dihydroisoxazoles **17f–i** by ozonolysis resulting in β-hydroxy ketones **5f–i** has been studied.[49] It is suggested that similar to oxime ozonolysis [50] this involves the electrophilic attack of ozone at the C(3) atoms of dihydroisoxazoles resulting in the formation of the intermediates **21f–i** with subsequent cleavage of C–N bonds.



R^1 = Me, $R^2 = R^3$ = cyclo-C_5H_{11}, (**f**); R^1 = Ph, R^2 = H, R^3 = Bu^n (**g**); $R^1 = CH_2OH$, R^2 = H, R^3 = Bu^n (**h**); $R^1 = R^2 = R^3$ = Me (**i**).

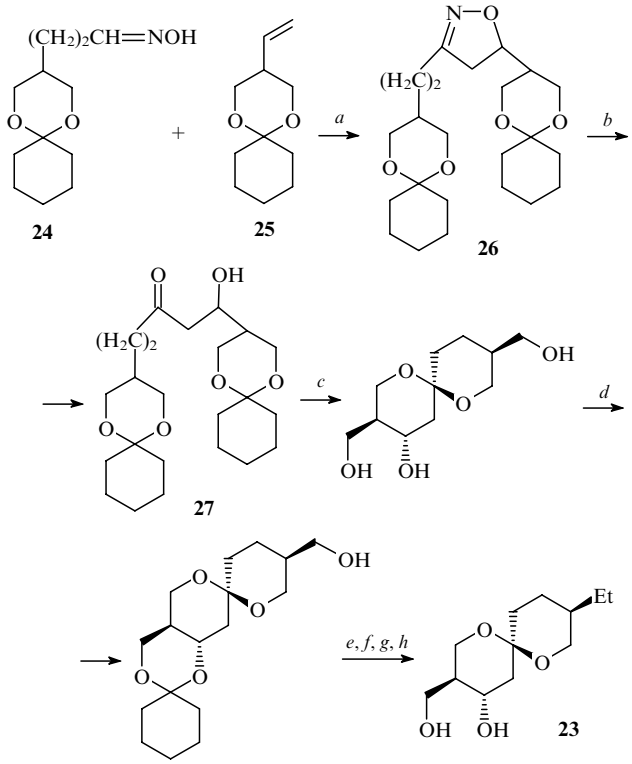
Further oxidation leads to hydroxy ketone nitrates **22f–i**; their reduction by dimethyl sulfide yield β-hydroxy ketones **5f–i**. Although the yields of the final products are lower (61%–74%) than those obtained by hydrogenolysis, the ozonolysis of 4,5-dihydroisoxazoles is effective if the substrates **17** contain functional groups susceptible to hydrogenolysis.

IV. Intermolecular 1,3-dipolar cycloaddition reactions of nitrile oxides

1,3-Dipolar cycloaddition of nitrile oxides used in the synthesis of natural compounds can be effected in two ways, *viz*., as intermolecular and as intramolecular reactions. The first approach entails convergent syntheses of complex molecules from two simpler blocks. The latter approach can be used for the generation of new C–C bonds in preformed molecules and/or for the introduction of additional functional groups.

1. Synthesis of talaromycin

The structures containing spiroketal groups were discovered in insects, microorganisms, plants and fungi in the mid-1970's.[51, 52] One of the representatives of this class, *viz*., talaromycin B (**23**), was isolated from the toxic fungus *Talaromyces stipitatus*.[53] The synthesis of talaromycin involved intermolecular 1,3-dipolar cycloaddition of a nitrile oxide to the alkene.[54]



(*a*) NaOCl, Et_3N, H_2O, CH_2Cl_2 (67%); (*b*) H_2, Ni/Ra (72%); (*c*) MeOH, Amberlyst-15 (93%); (*d*) Amberlyst-15, 1-methoxycyclohexene, THF (80%); (*e*) MsCl, Et_3N, Et_2O; (*f*) NaI, Me_2CO; (*g*) Me_2CuLi, THF; (*h*) HCl, MeOH, H_2O.

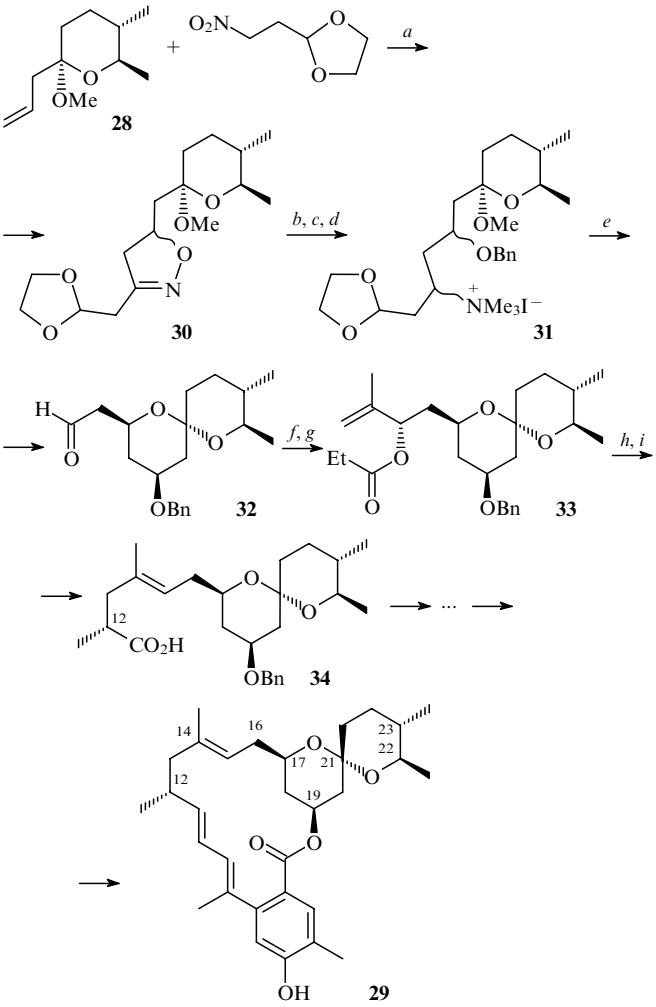
The nitrile oxide generated from the oxime **24** reacted with the alkene **25** to give 4,5-dihydroisoxazole **26**. Cleavage of the N–O bond was achieved by hydrogenation over Raney nickel. Spiroketalisation of the hydroxy ketone **27** proceeded in a weakly acidic medium in the presence of Amberlyst-15 in methanol. The resulting trihydroxy derivative **28** contained the main fragments of the talaromycin (**23**) backbone. After protection of *cis*-diol groups, racemic talaromycin (**23**) was formed in a total yield of 12%.

2. Synthesis of milbemycin β_3

Intermolecular 1,3-dipolar cycloaddition of a nitrile oxide to the alkene **28** was used in the first total synthesis of yet another compound containing a spiroketal system, *viz*., milbemycin β_3 (**29**).[55] Milbemycin β_3 was isolated in 1974 [56] and is one of more than twenty compounds of the milbemycin series. The interest in these compounds is due to their high antileukemic [57] and insecticidal [58, 59] activities and low toxicities for mammals. The synthesis

of milbemycin (**29**) faced several complicated problems including stereo-controlled formation of six asymmetric centres of the molecule, *viz*., C(12), C(17), C(19), C(21), C(22) and C(23).

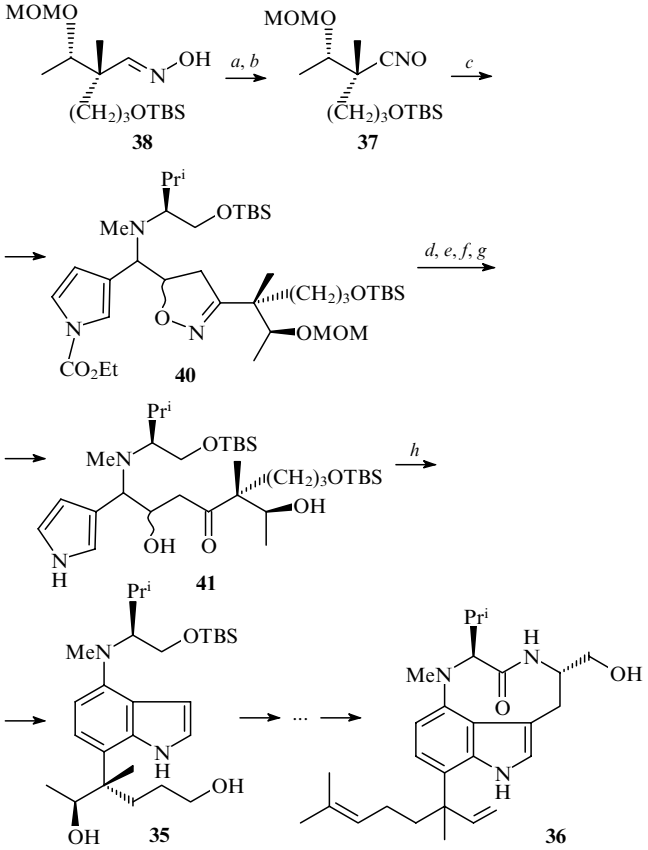
The first step of this synthesis included cycloaddition of the optically active 1,3-dipolarophile **28** and the nitrile oxide prepared by treatment of protected nitropropanal with methyl isocyanate. The resulting mixture of isomeric dihydroisoxazoles **30** was reduced by lithium aluminium hydride with subsequent protection of hydroxy and amino groups. The diastereomeric mixture of the ammonium salts **31** was treated with an aqueous solution of *p*-toluenesulfonic acid resulting in spiroketalisation and simultaneous deprotection of the aldehyde group. The addition of isopropenyllithium cuprate to aldehyde **32**, which was controlled by the chelate complex formed, yielded a mixture of allylic alcohols (7 : 1 in favour of the desired isomer). Compound **33** prepared by the reaction with propionyl chloride was selected for the Ireland–Claisen rearrangement. An attempt to use lithium diisopropylamide (LDA) in the synthesis of enolate was unsuccessful; the ester **33** could be deprotonated by potassium bis(trimethylsilyl)amide. Further treatment of the (*Z*)-enolate formed with trimethylchlorosilane and heating afforded the acid **34** with the required configuration of the C(12) centre. Total synthesis of the macrolide **29** required four additional steps.



(*a*) MeNCO, Et_3N, PhH (68%); (*b*) $LiAlH_4$, Et_2O; (*c*) KH, BnI; (*d*) MeI; (*e*) TsOH, H_2O (24%–30%); (*f*) $CH_2=CH(Me)CuLi$; (*g*) EtCOCl, CH_2Cl_2, Py (63%); (*h*) $(Me_3Si)_2NK$, THF, −78 °C; (*i*) Me_3SiCl (TMSCl), 55 °C (57%).

3. Synthesis of lingbiatoxin A

The synthesis of indole **35**, the intermediate product in the synthesis of the alkaloid lingbiatoxin A (**36**), has been described.[60] It is assumed that compound **36** is a potential carcinogen and plays a key role in cell responses to some hormones and drugs. Structurally, lingbiatoxin A (**36**) represents a tricyclic compound the indole fragment in which is fused to a nine-membered ring.



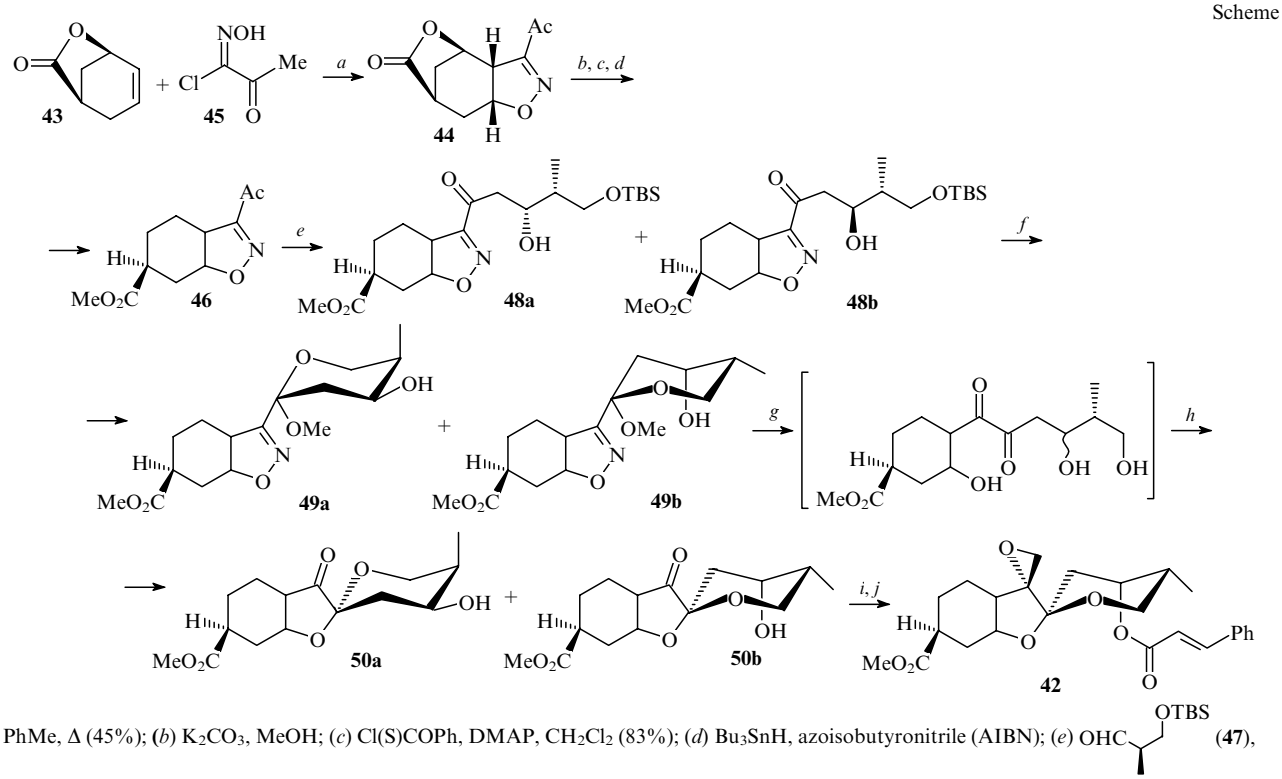
MOM — $MeOCH_2$, TBS — $SiMe_2Bu^t$; (*a*) Bu^tOCl, −78 °C; (*b*) Et_3N, 20 °C; (*c*) EtO_2CN (**39**), PhH, 80 °C, 20 h (78%); (*d*) HCl, MeOH (80 °C); (*e*) TBSCl, DMAP, THF; (*f*) 5% KOH, MeOH; (*g*) H_2, Ra/Ni, MeOH, H_2O, AcOH; (*h*) TBSOTf, CH_2Cl_2 (68%).

The strategy of this synthesis was based on the reaction of the nitrile oxide **37**, generated from the chiral oxime **38**, with the pyrrole derivative **39** as the dipolarophile. The attempts to synthesise hydroximoyl chloride (bromide) from the oxime **38** using conventional halogenating reagents (*e.g.*, *N*-chloro- or *N*-bromosuccinimide) were without success. Positive results were attained with *tert*-butyl hypochlorite in dichloromethane at −78 °C. Dehydrochlorination of hydroximoyl chloride by triethylamine at 20 °C afforded a highly stable nitrile oxide **37**, which was isolated in a pure state and characterised. The cycloaddition of the nitrile oxide **37** to the alkene **39** in benzene with heating gave 4,5-dihydroisoxazole **40**, which represented a mixture of diastereomers (2.5 : 1). The synthesis of hydroxy ketone **41** included manipulations with protective groups, elimination of the *N*-ethoxycarbonyl group and hydrogenolysis of 4,5-dihydroisoxazole under standard conditions. *tert*-Butyldimethylsilyl triflate proved to be the best catalyst in the formation of the annelated phenyl ring[61] of the indole **35**, a convenient intermediate for lingbiatoxin A (**36**).

4. Synthesis of (+)-phyllanthocin

Phyllanthocin (**42**) (Scheme 1) is an aglycone of the glycoside phyllanthoside isolated from the roots of the South American tree *Phyllanthus acuminatus* in 1977.[62] This glycoside manifests high activity against mouse leukemia P 388 and mouse melanoma B16; therefore, it was decided to carry out its clinical trials as an

Scheme 1



(*a*) PhMe, Δ (45%); (*b*) K_2CO_3, MeOH; (*c*) Cl(S)COPh, DMAP, CH_2Cl_2 (83%); (*d*) Bu_3SnH, azoisobutyronitrile (AIBN); (*e*) OHC–CH(OTBS)–CH(Me)–CH=CH$_2$ (**47**), LDA, THF (75%); (*f*) 5% HF, MeOH, 20 °C (70%); (*g*) H_2, Ni/Ra, H_3BO_3, MeOH–H_2O (89%); (*h*) CF_3SO_3H, CH_2Cl_2; (*i*) MeS(O)=CH_2, DMSO, THF, 1 h (89%); (*j*) *trans*-PhCH=CHCOCl, DMAP, CH_2Cl_2 (40%).

anticancer drug for humans.[63] Several structurally related compounds were isolated and given a common name 'phyllanthostatins'.[64] Total syntheses of (+)-phyllanthocin (**42**) have been described in a number of papers.[65–68] One of them involves 1,3-dipolar cycloaddition of a nitrile oxide to the cyclohexene derivative **43**. A detailed analysis of regio- and stereochemistry of the cycloadducts has been carried out (see Scheme 1).[69]

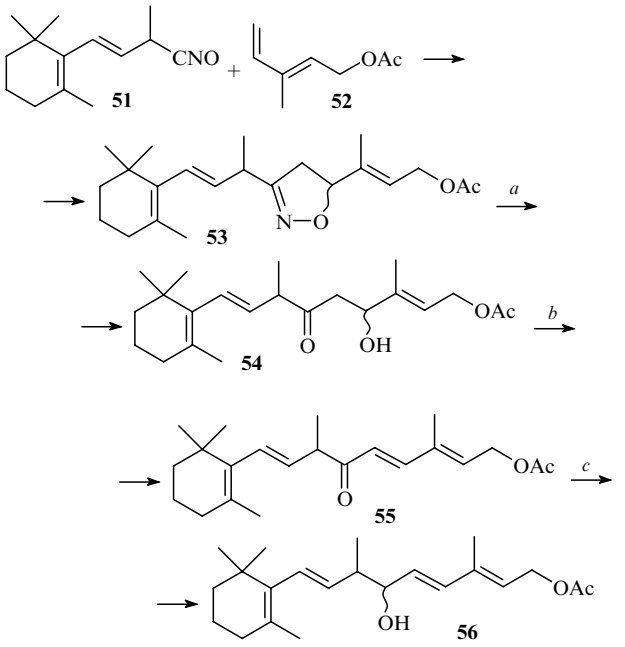
Lactone **43** was used as a starting compound for an increase in the stereo- and regioselectivity of the subsequent 1,3-dipolar cycloaddition reaction. The cycloadduct **44** of the required stereo- and regiochemistry was prepared by slow thermal generation of highly reactive nitrile oxide from the hydroximoyl chloride **45** in boiling toluene in the presence of the lactone **43** (yield 45%). 4,5-Dihydroisoxazole **46** was synthesised from compound **44** in three steps. Aldol condensation of the optically active aldehyde **47** with the ketone **46** gave a mixture of adducts **48a**,**b** in a 1 : 1.2 ratio.

It is of note that several attempts to open the heterocycle in compounds **48a**,**b** failed. Increased robustness of the 4,5-dihydroisoxazole ring is presumably due to its conjugation with the keto group. A mixture of isomers **48a**,**b** was converted into a mixture of methylglycosides **49a**,**b** followed by hydrogenolysis of the N–O bond in 4,5-dihydroisoxazole fragments and cyclisation of the intermediates which gave a mixture of spiroketals **50a**,**b** (1 : 18). The main isomer **50b** was converted to the target product, *viz*., (+)-phyllanthocin (**42**).

5. Synthesis of vitamin A

Vitamin A and its analogues remain in the focus of attention of synthetic chemists due to their prominent biological and pharmacological activities.[70,71] The Grignard reaction between compounds incorporating C_6- and C_{14}-fragments of vitamin A is one of the most general approaches to the synthesis of the vitamin A backbone.[72,73]

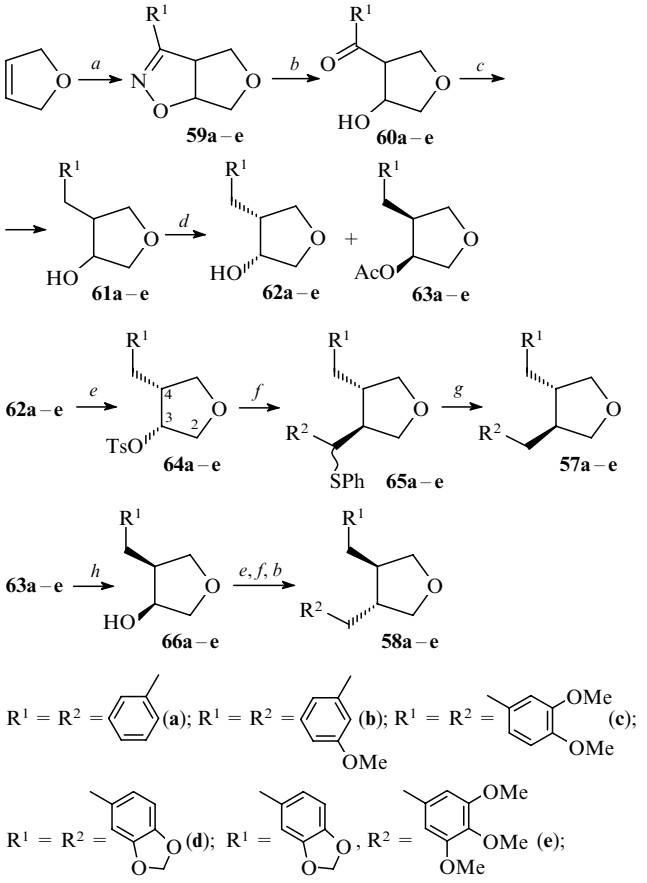
An alternative strategy for the construction of the basic backbone [74] consists in the simultaneous formation of the C–C bond and the introduction of functional groups in the interaction of the nitrile oxide **51** (the C_{14}-fragment) with the alkene **52** (the C_6-fragment) resulting in 3,5-disubstituted 4,5-dihydroisoxazole **53**. The cleavage of the N–O bond was achieved through the previously developed procedure using $Mo(CO)_6$.[48] The resulting β-hydroxy ketone **54** was dehydrated and enone **55** was reduced by $NaBH_4$ to the intermediate **56**, which is common in the synthesis of vitamin A. This scheme allows one to obtain large amounts of vitamin A and easy introduction of new functional groups in the synthesis of its analogues.



(*a*) $Mo(CO)_6$, MeCN (60%); (*b*) MsCl, Et_3N, 0 °C; (*c*) $NaBH_4$ (70%).

6. Synthesis of burseran and brassilignan

Preparations based on aloe have long been known in folk medicine.[75,76] Some aloe components are related to lignans, while certain representatives of this family possess antitumour activities and prevent metastasis.[77,78] Several approaches to the synthesis of natural lignans and their analogues manifesting biological activities have been developed.[79–82] In the majority of these syntheses, chiral compounds were used as starting materials. Achiral starting compounds were recommended for the synthesis of optically active natural lignans, *viz*., burserans **57e** and **58e** and brassilignans **57c** and **58c**, and some of their analogues.[83]



(*a*) $R^1CCl{=}NOH$, Et_3N, Et_2O, ~20 °C (58%–84%); (*b*) H_2, Ni/Ra, EtOH, H_3BO_3; (*c*) H_2, Pd/C, MeOH–H_2O; (*d*) $CH_2{=}CHOAc$, lipase PS; (*e*) MeLi, THF, −78 °C, TsCl; (*f*) R^2CH_2SPh, BuLi, THF, 0 °C; (*g*) Ni/Ra, EtOH, Δ, 20 h; (*h*) K_2CO_3, MeOH.

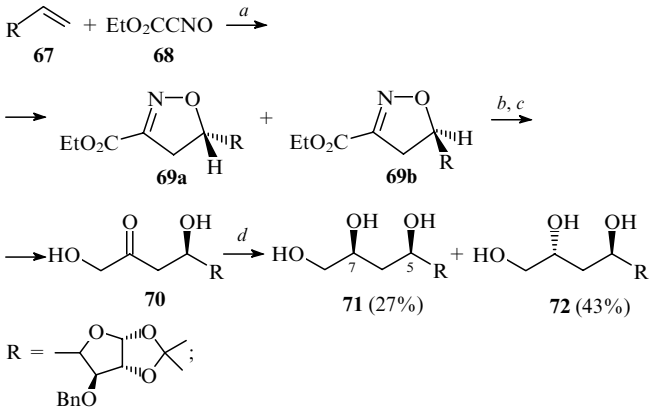
1,3-Dipolar cycloaddition of aromatic nitrile oxides to 2,5-dihydrofuran yielded furoisoxazoles **59a**–**e**. Hydrogenolysis of the cycloadducts **59a**–**e** over Raney nickel in the presence of a large excess of boric acid gave β-hydroxy ketones **60a**–**e** the keto group in which was reduced by hydrogen on palladium.

Lipase PS was used to separate the optical antipodes of the resulting alcohols **61a**–**e**. The absolute stereochemistry of alcohols **62a**–**e** and acetates **63a**–**e** was established later, following completion of the synthesis of the natural compounds **57e**, **58e**, **57c** and **58c**. Tosylation of compounds **62a**–**e** and **63a**–**e** (after preliminary hydrolysis) and subsequent nucleophilic substitution of the secondary tosyloxy group pursued two goals, *viz*., the introduction of the second aromatic substituent and the inversion of the C(3) centre so that the configurations of the substituents corresponded to those of the natural compounds. *p*-Toluenesulfonates **64a**–**e** gave a mixture of diastereomeric sulfides **65a**–**e**; their desulfurisation with Raney nickel in EtOH gave the target products **57a**–**e** in a total yield of 6%–16%. The same reaction sequence was applied to the isomers **66a**–**e** resulting in the preparation of optically active products **58a**–**e** (yield 6%–14%). Thus, a series of natural compounds, *viz*., burserans **57e** and **58e**, brassilignans **57c** and **58c** and artificial analogues *viz*., dehydroxycubebins **57d** and **58d**, 3,4-bis(3-methoxybenzyl)-tetrahydrofurans **57b** and **58b,** 3,4-dibenzyltetrahydrofurans **57a** and **58a**, were prepared. This method[83] gives an access to a vast variety of natural and non-natural lignans including their aza analogues owing to the high accessibility of 2,5-dihydrofuran, aromatic nitrile oxides and diverse phenyl sulfides.

7. Synthesis of higher monosaccharides

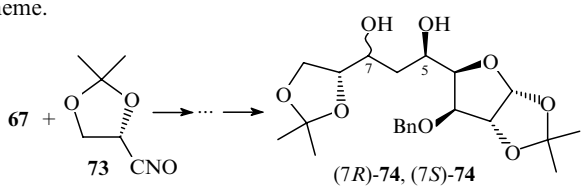
The role of monosaccharides in vital activities of animals, plants and human beings is generally acknowledged. The discovery of antibiotics[84,85] containing higher monosaccharides gave strong impetus to investigations into their synthesis.[86,87] An approach described by Poton and Young[88] is based on cycloaddition of accessible unsaturated monosaccharides to nitrile oxides with subsequent reduction of the dihydroisoxazoles formed.

Thus the reaction of the alkene **67** derived from D-glucose with the nitrile oxide **68** gave a mixture of diastereomeric 4,5-dihydroisoxazoles **69a**,**b** in a 14 : 86 ratio. Compound **69b** gave the dihydroxy ketone **70** in two steps; its reduction with sodium borohydride yielded a mixture of 6-deoxy-D- and 6-deoxy-L-*glycero*-D-*gluco*-octofuranoses **71** and **72**.

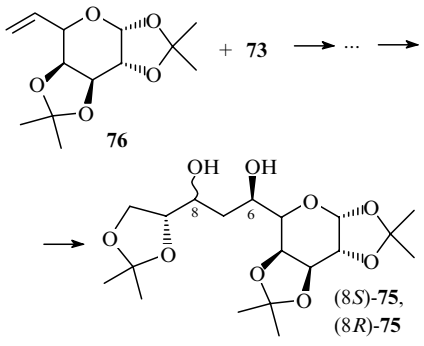


(*a*) Et_2O, Et_3N, 14 h (75%); (*b*) $NaBH_4$, THF, EtOH; (*c*) H_2, Pd/C, H_3BO_3, MeOH–H_2O, 18 h (78% **69b**); (*d*) $NaBH_4$, EtOH, H_2O.

The alkene **67** and D-glyceronitrile oxide **73** were used in the synthesis of (7*R*)- and (7*S*)-nonofuranoses **74** by the same reaction scheme.



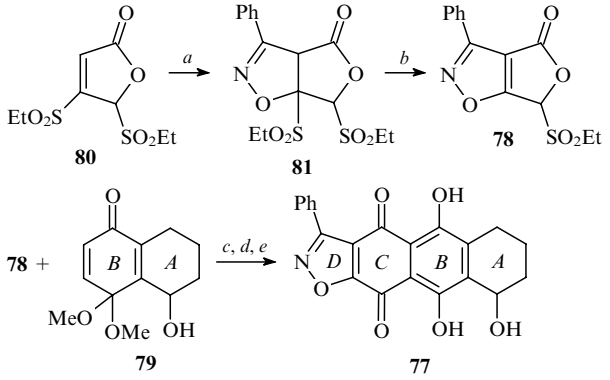
(8*S*)- And (8*R*)-7-deoxydecopyranoses **75** were prepared from the nitrile oxide **73** and the alkene **76** derived from D-galactose.



The configurations of the C(5) and C(7) centres in compounds **71**, **72** and **74** and of the C(6) and C(8) centres in compounds **75** were established on the basis of ^{1}H NMR spectroscopic data and stereochemistry of their precursors, *viz*., 4,5-dihydroisoxazoles, and confirmed by X-ray diffraction analysis. This approach enables the synthesis of diverse higher monosaccharides.

8. Synthesis of a heterocyclic analogue of daunomycin

Daunomycin is a typical representative of anthracycline antibiotics used in the chemotherapy of malignant tumours.[89,90] However, its application is restricted due to side effects including high cardiotoxicity. An attempt was made to synthesise modified anthracycline derivatives in which the benzene rings (*D*) is replaced by a heteroaromatic rings. The daunomycin analogues thus synthesised contained thiophene [91] or indole fragments [92] as rings *D* and manifested high activities comparable to that of daunomycin, but lower toxicities. The synthesis of compound **77**, an intermediate in the synthesis of the daunomycin analogue containing an isoxazole fragment as ring *D*, has been developed.[93]



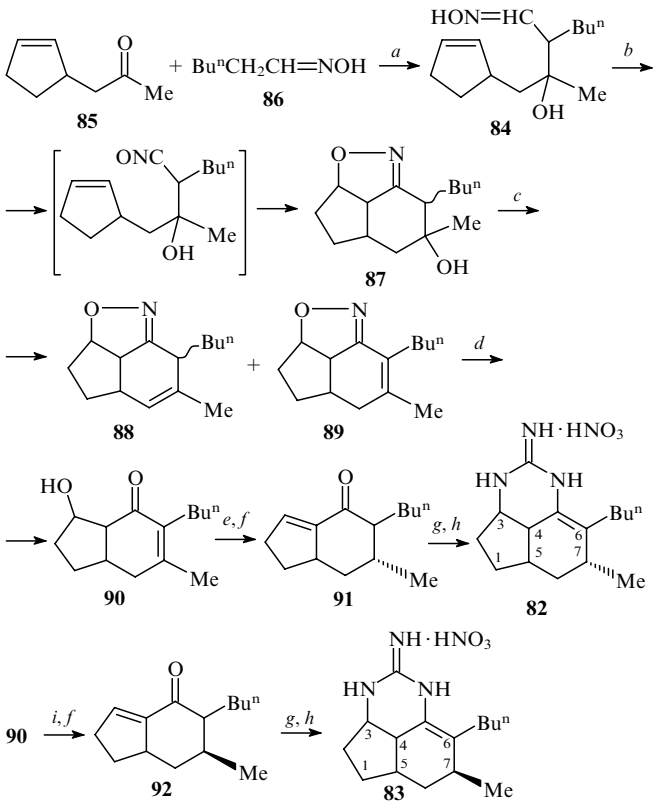
(*a*) PhCCl=NOH, molecular sieves, 20 °C, 10 h; (*b*) SiO_2 (85%); (*c*) LDA, THF, −78 °C; (*d*) −2 °C, 120 h (40%); (*e*) BCl_3, −78 °C, 45 min (50%).

The key stage in this synthesis is the annelation of furoisoxazole **78** and the bicyclic derivative **79** (the DC + BA strategy) under the action of lithium diisopropylamide. Compound **78** was synthesised by cycloaddition of benzonitrile oxide to 4,5-di(ethylsulfonyl)-2,5-dihydrofuran-2-one **80**. Numerous experiments showed [94] that this dipolarophile far exceeds other dipolarophiles as concerns reactivity. Moreover, the presence of the ethylsulfonyl group at the C(5) atom significantly affects the regio- and stereochemistry of the cycloaddition reaction, whereas the ethylsulfonyl group in position 4 enables subsequent aromatisation of compound **81** into isoxazole **78**.

V. Intramolecular 1,3-dipolar cycloaddition reactions of nitrile oxides

1. Stereoselective synthesis of ptilocaulin and its epimer

Ptilocaulin (**82**) and its epimer at the C(7) atom, *viz*., isoptilocaulin (**83**), isolated from the sea sponge *Ptilocaulis spiculfer* in 1982 [95] manifest antileukemic and antibacterial activities. These compounds have relatively simple but unusual structures in which guanidine is annelated with the hydrindan system. A seven-step stereoselective synthesis of compounds **82** and **83** has been developed,[96] which includes the formation of a six-membered carbocycle by intramolecular cycloaddition of a nitrile oxide to the double bond in the cyclopentene derivative **84**.

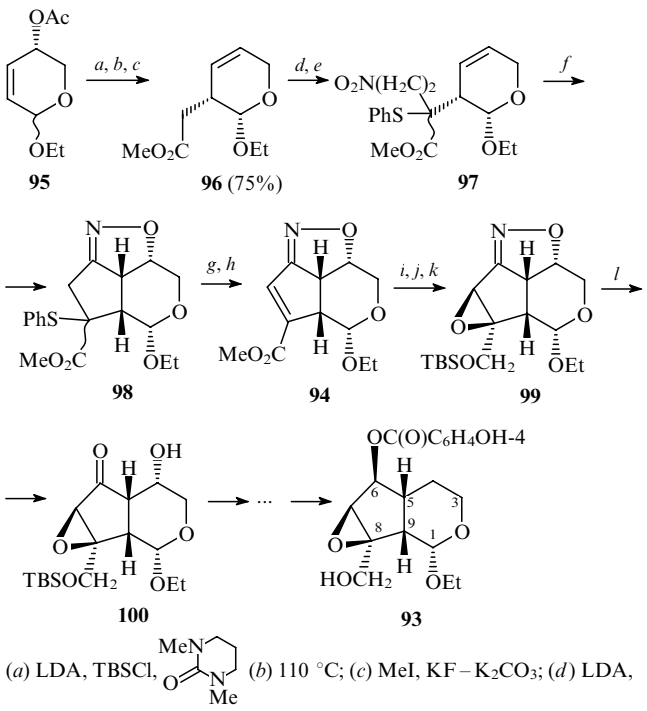


(*a*) 2 equiv. BuLi, THF, 0–20 °C, 6 h (90%); (*b*) NaOCl, CH_2Cl_2, −10 to −20 °C, 5 h (80%); (*c*) $SOCl_2$–Py, −10 °C, 40 min; (*d*) H_2, Ni/Ra, H_3BO_3, MeOH–H_2O (60%); (*e*) H_2, Pd/C (95%); (*f*) TsOH, PhH, 40 °C, 30 min; (*g*) $(H_2N)_2C$=NH, PhH, Δ, 36 h (35%); (*h*) HNO_3; (*i*) Li–$EtNH_2$, −70 °C, 30 min (85%).

Aldol condensation of the ketone **85** with the hexenal oxime (**86**) dianion yields the β-hydroxy oxime **84**. Its treatment with sodium hypochlorite gives tricyclic 4,5-dihydroisoxazole **87** as a mixture of four diastereomers. Compound **87** is dehydrated into a 1 : 1 mixture of unsaturated 4,5-dihydroisoxazoles **88** and **89** which are further subjected to reductive scission over Raney nickel. The unsaturated ketol **90** is the key intermediate in the synthesis of ptilocaulin (**83**) and its C(7) epimer (**82**).[97,98] The enone **91** prepared from the ketol **90** by hydrogenation of the double bond over palladium and subsequent dehydration reacted with guanidine to give isoptilocaulin **82**. The epimer of enone **91** with the β-configuration of the methyl group at C(7) (compound **92**) was prepared by reduction of the double bond in ketol **90** with lithium in diethylamine (in this case, the carbanion undergoes axial protonation) with subsequent dehydration. The use of lithium in liquid ammonia made it possible to achieve simultaneous reduction of the double bond and the keto group. Ptilocaulin (**83**) was prepared by heating of the enone **92** with guanidine. Compounds **82** and **83** were isolated as nitrates.

2. Synthesis of (−)-specionin

(−)-Specionin (**93**) was isolated from leaf extracts of the tree *Catalpa speciosa*.[99] This compound manifests insecticidal activity against various pests of coniferous plants which inflict severe damages to the wood-processing industry. The first synthesis of racemic specionin was carried out in 1985.[100] Synthesis of the optically active compound based on the nitrile oxide-based approach was developed by Curran *et al*.[41] The 4,5-dihydroisoxazole intermediate **94** was synthesised from the acetal **95** in eight steps.



(*a*) LDA, TBSCl, (*b*) 110 °C; (*c*) MeI, KF – K_2CO_3; (*d*) LDA, PhSSPh; (*e*) LDA, $CH_2=CHNO_2$ (85%); (*f*) *p*-ClC_6H_4NCO, Et_3N, 110 °C (89%); (*g*) *m*-chloroperbenzoic acid (*m*-CPBA); (*h*) PhH, 80 °C; (*i*) $Bu^i_2Bu^nAlHLi$ (42%); (*j*) TBSCl, DMAP, Et_3N (72%); (*k*) 3,5-dinitroperbenzoic acid, Na_2HPO_4, CH_2Cl_2 (77%); (*l*) H_2, Rh/Al_2O_3 (57%).

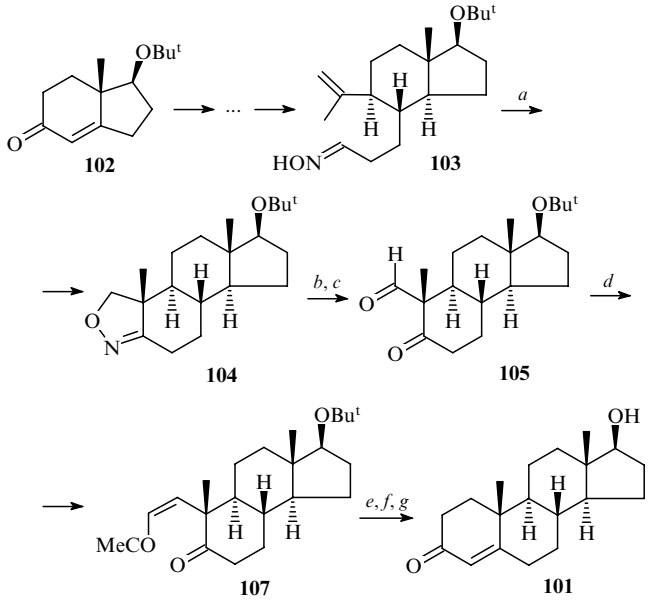
The Ireland – Claisen rearrangement yielded compound **96**; its sulfenylation and the addition of the α-sulfite formed to nitroethylene led to the derivative **97**, which was further involved in the intramolecular cycloaddition of the nitrile oxide fragment to the double bond. The sulfide group in the tricyclic 4,5-dihydroisoxazole **98** was oxidised and the sulfoxide formed was boiled in benzene, which resulted in elimination of $PhSO_2H$ and the formation of a double bond. Selective reduction of the ester group in the derivative **94** was carried out using a complex prepared from butyllithium and diisobutylaluminium hydride; the resulting alcohol was converted into the silyl ether. Its epoxidation by 3,5-dinitroperbenzoic acid could be performed due to the resistance of the dihydroisoxazole ring to oxidants; this reaction was stereoselective and yielded a single isomer (**99**). The dihydroisoxazole ring in compound **99** was opened smoothly by hydrogenolysis in the presence of 5% rhodium on Al_2O_3 in aqueous methanol resulting in β-hydroxy ketone **100**. The use of other catalysts (*e.g.,* Ni-Ra, Pd/C, Pt_2O) in this step resulted in the destruction of the molecule. (−)-Specionin (**93**) was obtained from its precursor **100** in eight steps; the total yield was 0.5% with respect to compound **95**.

3. Synthesis of testosterone

Total synthesis of steroids, which play an extremely important role in the human organism as well as in animal and plant organisms, has been the subject of numerous investigations.[101, 102]

The use of 4,5-dihydroisoxazoles in the formation of steroid backbones was described back in the 1960-70's. In some studies, 4,5-dihydroisoxazoles were used as parts of alkylating agents bearing a masked β-diketone function [103, 104] in the synthesis of D-homotestosterone, progesterone, testosterone and 13-ethyltestosterone.

The synthesis of testosterone (**101**) made use of a new approach based on intramolecular 1,3-dipolar cycloaddition.[105] This procedure enabled the construction of the ring *B* with the β-configuration of the C(19) methyl group and simultaneous introduction of functional groups for further synthesis of ring *A*. Starting from the optically active indanone **102**, the oxime **103** was prepared in eight steps (total yield 37%). The intramolecular 1,3-dipolar cycloaddition of the nitrile oxide prepared from this oxime occurred stereospecifically and resulted in the cycloadduct **104**. Although the stereochemistry of the angular methyl group of 4,5-dihydroisoxazole formed cannot be inferred from the spectroscopic data, the structure **104** was assigned to this compound [105] on the assumption [106, 107] that the chair-like conformation is more preferable in the transition state than the boat-like conformation leading to the C(10) isomer.



(*a*) NaClO, CH_2Cl_2 (87%); (*b*) H_2, Ni/Ra, $B(OMe)_3$, MeOH (97%); (*c*) SO_3 – Py, DMSO (97%); (*d*) $MeCOCH=PPh_3$ (**106**), $Me_2C_6H_3$ (89%); (*e*) H_2, 10% Pd/C; (*f*) KOH, MeOH; (*g*) CF_3CO_2H (76%).

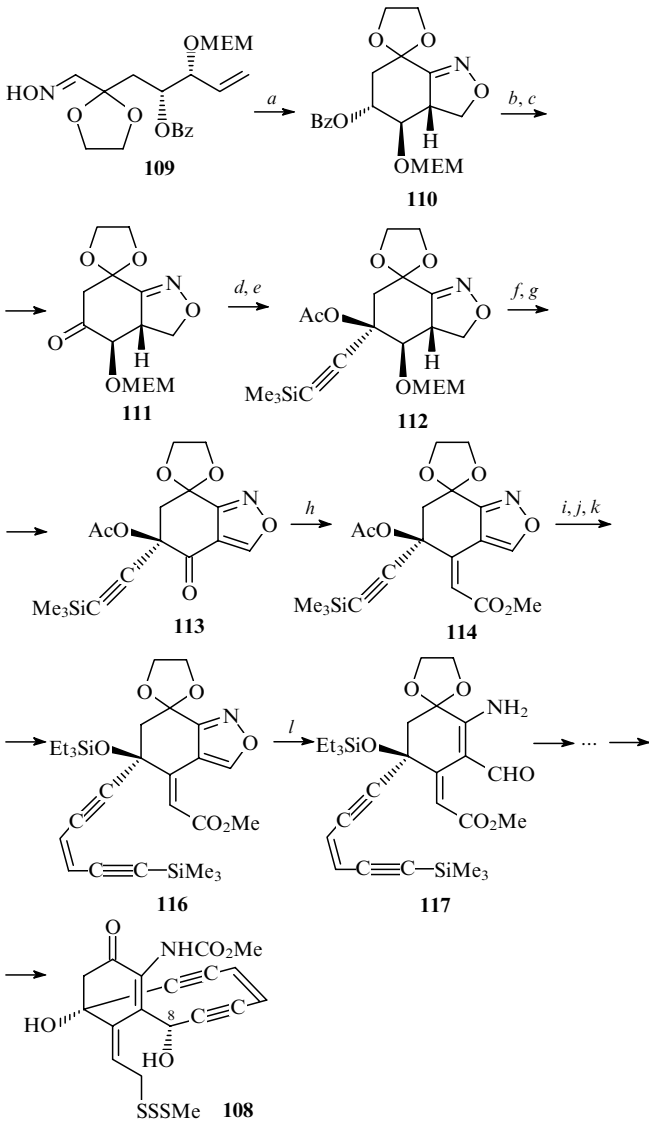
The reductive opening of 4,5-dihydroisoxazole **104** over Raney nickel in the presence of trimethyl borate in aqueous methanol gave a hydroxy ketone; its oxidation yielded the aldehyde **105**. A three-carbon fragment was introduced by the Wittig reaction with 1-triphenylphosphoranylidenepropan-2-one (**106**). The resulting enone **107** was converted into testosterone *tert*-butyl ether as a result of catalytic hydrogenation and treatment with potassium hydroxide in methanol, eventually resulting in the closure of the ring *A*. Removal of the protective group from the C(17) hydroxy group completed the synthesis of testosterone **101** in a total yield of 17%. Thus, the use of intramolecular 1,3-dipolar cycloaddition of nitrile oxide enabled effective construction of testosterone rings *A* and *B*.

4. Synthesis of calicheamicin γ_1^I

Compounds related to antitumour antibiotics of the enedyine series, *e.g.,* calicheamicin γ_1^I, esperamycin A_1, dinemycin A, were isolated from cultured bacterial cells of *Micromonospora echinospora*.[108, 109] These compounds produce strong therapeutic effects by cleaving double-stranded DNA at specific sequences.[110, 111] A number of papers published soon after their discovery [112 – 116] were devoted to the synthesis of their main backbones, *e.g.*, to the racemic calicheamicin aglycone, calicheamicinone (**108**). The syntheses of oligosaccharide fragments attached to the hydroxy group at C(8) of calicheamicinone (**108**) have also been described.[117, 118]

The first enantioselective synthesis of (−)-calicheamicinone (**108**) and a total synthesis of calicheamicin γ_1^I were carried out by Nicolaou and coworkers.[119, 120] This synthesis is based on the use of the intramolecular 1,3-cycloaddition reaction of alkenyl nitrile oxide prepared from the aldoxime **109**.

This aldoxime was treated with aqueous sodium hypochlorite under standard conditions, which resulted in intramolecular cyclisation and the formation of a 4 : 1 mixture of 4,5-dihydro-



MEM is $MeO(CH_2)_2$; (*a*) NaOCl, CH_2Cl_2, 25 °C, 2 h (65%); (*b*) NaOMe MeOH, 0 °C (100%); (*c*) CrO_3, H_2SO_4, Me_2O, 0 °C (95%); (*d*) 1.5 equiv. $Me_3SiC{\equiv}CLi$, THF, −78 °C (67%); (*e*) Ac_2O, 25 °C, 3 h; (*f*) 10 equiv. $ZnBr_2$, CH_2Cl_2, 25 °C, 2 h; (*g*) $COCl_2$, DMSO (54%); (*h*) $Ph_3P{=}CHCO_2Me$, PhMe, 90 °C, 16 h (84 %); (*i*) K_2CO_3, MeOH – CH_2Cl_2, 0 °C, 6 h (90%); (*j*) Et_3SiOTf, 2,6-lutidine, CH_2Cl_2, 0 °C, 30 min (96%); (*k*) (*Z*)-$Me_3SiC{\equiv}CCH{=}CHCl$ (**115**), $Pd(PPh_3)_4$, CuI, $BuNH_2$, PhH, 0 °C, 2 h (91%); (*l*) $Mo(CO)_6$, MeCN – H_2O, 80 °C, 1.5 h (82%).

isoxazole diastereomers; the main isomer **110** was isolated in 51% yield. After removal of benzoyl protection, the secondary alcohol formed was oxidised by the Jones reagent to the ketone **111**. The nucleophilic addition of lithium (trimethylsilyl)acetylenide to the ketone **111** was fully stereoselective; the hydroxy group in the resulting acetylenic alcohol was protected by acetylation.

Removal of the methoxyethoxymethyl group in compound **112** and subsequent Swern oxidation of the alcohol formed yielded unexpectedly isoxazole **113** instead of 4,5-dihydroisoxazole. The use of other oxidants gave the same results. Therefore, the strategy of the synthesis had to be changed in favour of the Wittig reaction of the ketone **113** with methyl triphenylphosphoranylideneacetate, which resulted in selective synthesis of compound **114** having the *E*-configuration of the double bond in the enediyne fragment.

After removal of the protective trimethylsilyl group, the enyne group was introduced by high-yielding palladium-catalysed addition of (*Z*)-chloroenyne (**115**), which gave the enediyne **116**. The opening of the isoxazole ring in this molecule under the action of molybdenum hexacarbonyl in aqueous acetonitrile resulted in the enamino aldehyde **117**.

The final product of this synthesis, *i.e.*, (−)-calicheamicinone (**108**), was prepared from the aldehyde **117** in 16 steps. The total yield of compound **108** was 2.6% with respect to the starting aldoxime **109**.

5. Synthesis of zoapatanol

The intramolecular cycloaddition reaction was used to prepare compound **118**, the optically active intermediate in the synthesis of zoapatanol (**119**), one of novel diterpenoids containing an oxepane ring.[121] This is endowed with contraceptive activity [122, 123] and was isolated from the leaves of the Mexican plant *Montanoa tomentosa*.[124] Syntheses of racemic zoapatanol [125, 126] and the optically active product (Scheme 2) have been described.[127]

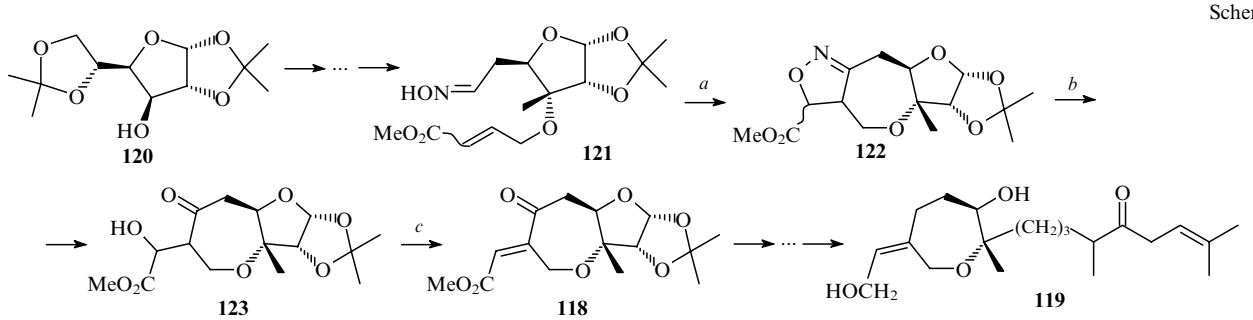
D-Glucose diacetonide (**120**) was used as the starting compound in the 13-step synthesis of the oxime **121**. The intramolecular nitrile oxide cycloaddition reaction was carried out under standard conditions. The resulting dihydroisoxazole **122** (a mixture of diastereomers) was reduced over Raney nickel to the hydroxy ketone **123**. Its dehydration gave α,β-unsaturated oxo ester **118** which is considered [121] to be a convenient intermediate in the synthesis of zoapatanol **119.**

VI. Syntheses based on enantiocontrolled 1,3-dipolar cycloaddition reactions of nitrile oxides

The optical purity of natural compounds is of crucial importance where they are used as medicinal drugs or plant protectors. In contrast to non-symmetrical Diels – Alder reactions, studies on enantiocontrolled cycloaddition reactions of nitrile oxides have a relatively short history.

The feasibility of stereocontrolled cycloaddition using optically active nitrile oxides or alkenes has been studied.[128, 129] Dipolarophiles containing bulky chiral auxiliaries have become especially popular. As a result, the nitrile oxide attack occurs in a strictly stereoselective manner; the chiral substituents are then removed. Chiral (−)-menthyl acrylates,[130] bornyl crotonates,[131] alkenes containing tricarboxylic Kemp's acid [132] or the Oppolzer

Scheme 2

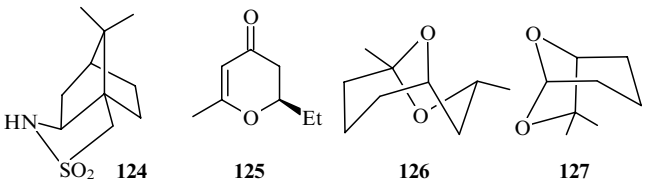


(*a*) NaOCl, CH_2Cl_2, Et_3N (61%); (*b*) Ra/Ni, H_2, MeOH – H_2O; (*c*) $MeSO_2Cl$, CH_2Cl_2, Et_3N.

sultam [133, 134] as substituents as well as alkenes coordinated to iron [135] or cobalt [136] complexes belong to such dipolarophiles.

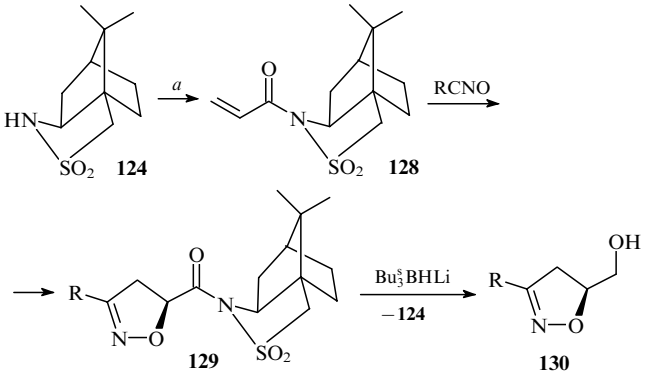
1. Syntheses using the chiral Oppolzer reagent

The chiral Oppolzer reagent, *viz*., L-camphor sultam (**124**), was used [137] in the synthesis of several natural compounds, *e.g*., the sex pheromone of the butterfly *Hepialis californicus* [(+)-hepialone **125**)[138]], (−)-(1*R*,3*R*,5*S*)-1,3-dimethyl-2,9-dioxabicyclo[3.3.1]nonane (**126**),[139] the constituent of the Norwegian spruce bark, and (−)-(1*S*)-7,7-dimethyl-6,8-dioxabicyclo[3.2.1]octane (**127**)[140] isolated from hop oil and confering characteristic odour to beer.



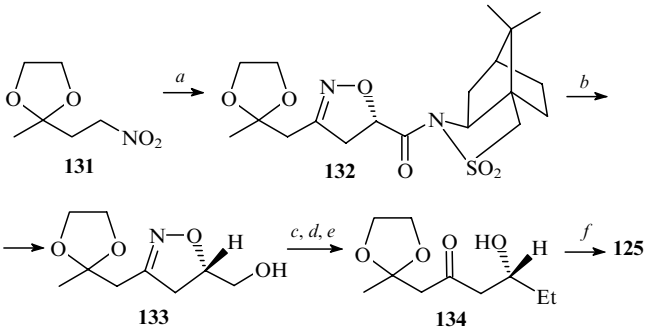
124 **125** **126** **127**

Syntheses of compounds **125**–**127** were performed according to non-sophisticated and efficient schemes the key step in which included the addition of readily accessible nitrile oxides to the amide **128** prepared by treatment of the chiral sultam **124** with acryloyl chloride in the presence of sodium hydride and CuCl. Subsequent reduction of the adducts **129** resulted in 4,5-dihydroisoxazoles **130** and regeneration of L-camphor sultam **124.**



(*a*) $CH_2{=}CHCOCl$, NaH, CuCl.

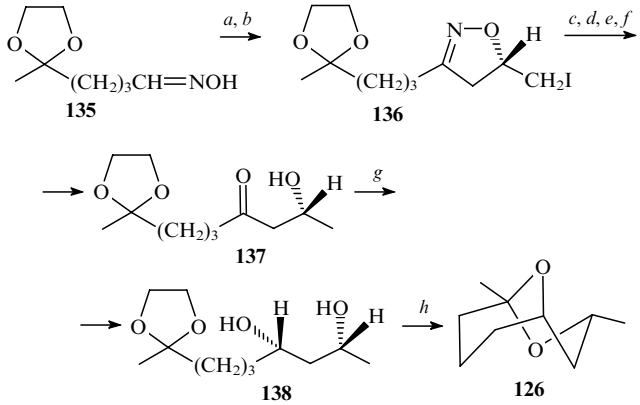
(+)-Hepialone (**125**) was synthesised from the nitro ketal **131**.[137] The cycloaddition performed under standard conditions [9] yielded a mixture of epimeric 4,5-dihydroisoxazoles (88 : 12); the main diastereomer **132** was isolated by chromatography. Its reduction by L-selectride (Bu^s_3BHLi) gave the alcohol **133** with recovery of the chiral reagent **124**. Tosylation of the alcohol **133** and subsequent treatment of the *p*-toluenesulfonate with lithium



(*a*) **128**, PhNCO, Et_3N; (*b*) Bu^s_3BHLi, THF, 25 °C, 30 min (85%); (*c*) TsCl, Et_3N, DMAP, 25 °C, 26 h (100%); (*d*) Me_2CuLi, Et_2O, −5 °C, 18 h (57%); (*e*) Ni/Ra, H_2O, MeOH, H_3BO_3 (75%); (*f*) 3 M HCl, Et_2O, 25 °C, 20 h (88%).

dimethylcuprate led to the replacement of the hydroxymethyl group by the ethyl group. Reduction of 4,5-dihydroisoxazole by hydrogen over Raney nickel occurred with the retention of the original configuration of the chiral centre and yielded the β-ketol **134** . Subsequent ring closure under conditions of acid catalysis afforded the pheromone **125**.

(−)-(1*R*,3*R*,5*S*)-1,3-Dimethyl-2,9-dioxabicyclo[3.3.1]nonane (**126**) was synthesised from the oxime **135** and the amide **128**.[137] Cycloaddition gave epimeric 4,5-dihydroisoxazoles (92 : 8); the main isomer was isolated in 89% yield by column chromatography. Deoxygenation of the hydroxy group had to be carried out following removal of the chiral reagent by L-selectride.

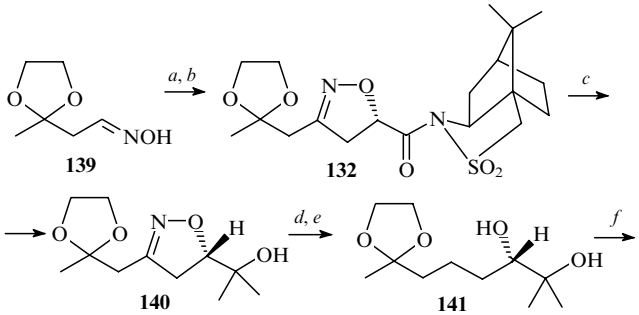


135 **136** **137** **138** **126**

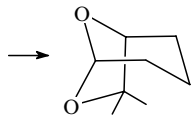
(*a*) **128**, NCS, DMF; (*b*) Et_3N, Et_2O; (*c*) Bu^s_3BHLi, THF, 25 °C, 45 min (86%); (*d*) TsCl, CH_2Cl_2, Et_3N, DMAP, 9 h (83%); (*e*) NaI, $NaHCO_3$, MeCOEt, Δ (98%); (*f*) Ni/Ra, H_2, H_3BO_3, MeOH – H_2O (15 : 1), 16 h (74%); (*g*) Et_2BOMe, −70 °C, $NaBH_4$, THF – MeOH (86%); (*h*) Et_2O, 3 M HCl, 20 °C, 16 h (57%).

Initially, this was attempted by radical reduction of the iodide **136** prepared from the corresponding *p*-toluenesulfonate, which however resulted in racemisation. Numerous experiments allowed finally elaboration of the optimum conditions for such reduction [*viz*., Bu_3SnH, diazabicycloundecene (DBU), AIBN, 50 °C]. Hydrogenation of the 4,5-dihydroisoxazole **136** over Raney nickel, which was accompanied by reductive deiodination, appeared to be the shortest way to the optically pure ketol **137**. The target product **126** was obtained by treatment of the optically active 1,3-diol **138** with HCl.

(−)-(1*S*)-7,7-Dimethyl-6,8-dioxabicyclo[3.2.1]octane (**127**) was synthesised from the oxime **139**.[137] The optically pure cycloadduct **132** was isolated in 70% yield from a mixture of epimers (85 : 15). The Grignard reaction of the 4,5-dihydroisoxazole **132** with MeMgBr gave compound **140**, the chiral reagent **124** was recovered simultaneously. Reduction of the dihydroisoxazole **140** with lithium aluminium hydride occurred stereoselectively to give the optically active amino alcohol in 97% yield. The latter was deaminated with sulfamic acid and the diol **141** obtained was treated with an acid, which resulted in the target bicyclic product **127**.



139 **132** **140** **141**

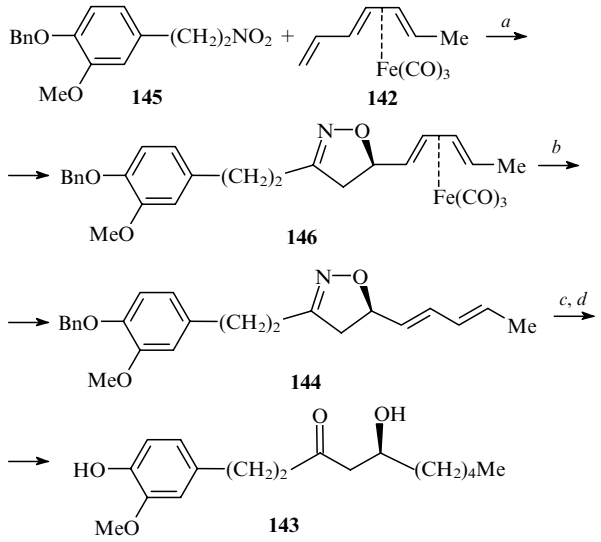


127

(*a*) **128**, NCS, CH_2Cl_2; (*b*) Et_3N, CH_2Cl_2 (70%); (*c*) MeMgBr, THF, −78 °C (72%); (*d*) $LiAlH_4$, Et_2O, −78 °C (97%); (*e*) NH_2OSO_3H, NaOH, CH_2Cl_2, 1 h, 60 °C (54%); (*f*) PhH, TsOH, 48 h, 60 °C (61%).

2. Synthesis of (+)-(*S*)-gingerol

A group of French chemists[141] studied the enantiocontrolled synthesis of dihydroisoxazoles using the chiral acyclic irontricarbonyl complex **142** as a dipolarophile. The complex **142** was prepared by olefination of optically active aldehydes coordinated to ironpentacarbonyl.[135] The method proved to be efficient in the synthesis of (+)-(*S*)-gingerol (**143**), a biologically active compound[144, 145] isolated from plants.[142–145]



(*a*) PhNCO, Et_3N, ~20 °C, 48 h (75%); (*b*) $(NH_4)_2Ce(NO_3)_6$, MeOH, −20 °C, 25 min (62%); (*c*) H_2, Ni/Ra, H_3BO_3, MeOH – H_2O, 3.5 h (80%); (*d*) H_2, 10% Pd/C, MeOH, 20 °C, 40 min (66%).

Synthesis of compound **143** has been the subject of numerous studies; two of those employ the 1,3-dipolar cycloaddition of nitrile oxides with subsequent reductive scission of the cycloadducts formed.[31, 46] The formation of the β-hydroxycarbonyl fragment in gingerol **143** was achieved by enantioselective reduction of chiral enamido ketones[31] and transformation of chiral 3-sulfenyldihydroisoxazoles.[46]

The 4,5-dihydroisoxazole **144** was synthesised by the 1,3-dipolar cycloaddition of a nitrile oxide to the chiral acyclic irontricarbonyl complex **142**.[141] The nitrile oxide precursor, *viz*., the nitrocompound **145**, was synthesised in five steps from the readily accessible 4-benzyloxy-3-methoxybenzaldehyde (total yield 33%). The cycloaddition of triene **142** to the nitrile oxide generated from the nitro compound **145** yielded a mixture of diastereomeric 4,5-dihydroisoxazoles in a 89 : 11 ratio; the main isomer **146** was isolated in 75% yield. The irontricarbonyl complex was decomposed by oxidation with cerium ammonium nitrate in methanol. The final product, *viz*., (+)-(*S*)-gingerol (**143**), was prepared from the 4,5-dihydroisoxazole **144** in two steps. First, 4,5-dihydroisoxazole was reduced into the corresponding β-hydroxy ketone over Raney nickel under standard conditions. In this step, the diene group was partly reduced. The reduction was completed by catalytic hydrogenation over palladium.

* * *

The data presented in the rewiew illustrate the efficiency of the nitrile oxide-based approach as both an alternative to classical reactions employed in organic chemistry (*e.g.*, the aldol condensation) and an independent method aimed at the solution of complicated problems in the synthesis of pheromones, alkaloids, vitamins, monosaccharides, antibiotics, steroids and other natural compounds.

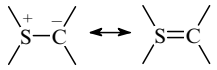
Abstract. Data on the use of sulfonium ylides in the synthesis of carbocyclic and heterocyclic compounds published over the last 15 years are analysed, systematised and generalised. The bibliography includes 139 references.

I. Introduction

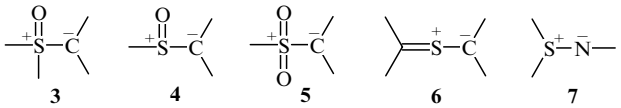
The chemistry of ylides attracted considerable interest in the early 1950s after Wittig has discovered the reaction of phosphonium ylides with carbonyl compounds giving rise to alkenes.[1] Investigations carried out by Corey[2] and Franzen[3,4] extended the Wittig reaction to sulfur ylides and initiated extensive studies of sulfonium ylides. The further development of the chemistry of these compounds demonstrated that they could be widely used in organic synthesis.

Sulfur ylides contain a negatively charged carbon atom directly bound to a positively charged sulfur atom. In the general form, these compounds can be represented by two resonance structures, *viz*., ylide **1** and ylene **2**.[5]



1 **2**

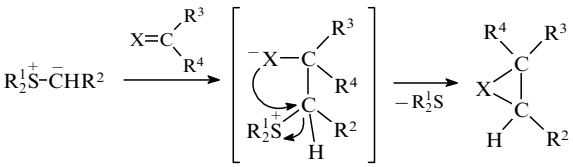
Sulfonium (**1**) and sulfoxonium (**3**) ylides containing two organic substituents at the sulfur atoms are most often used in organic synthesis.[6–9] Sulfinyl ylides (**4**), sulfonyl ylides (**5**), thiocarbonyl ylides (**6**) and iminosulfuranes (**7**) are also known.[8]



3 **4** **5** **6** **7**

Sulfur ylides act as nucleophilic reagents, their reactivities being inversely proportional to their stability. Ylides are stabilised through the electron density delocalisation under the action of electron-withdrawing substituents at the carbanionic centre. The properties of stabilised sulfur ylides are summarised and compared with the properties of non-stabilised ylides in reviews.[6,10,11]

The reactions of sulfur ylides with compounds containing C=X bonds (X = O, C or N) gained wide acceptance in organic synthesis. These reactions proceed as the nucleophilic addition followed by 1,3-elimination of a sulfur-containing group to form epoxide, cyclopropane or aziridine, respectively.[6]



X = O, C, N.

The data on these reactions were surveyed in detail in the monograph[6] and in a series of studies.[7,12–16] Due to their zwitterionic character, sulfonium ylides are also widely used in rearrangements generating new C–C bonds (often with high stereo- and regioselectivity).[16–20] In the last decade, interest in sulfur ylides was quickened owing to their successful use in asymmetric synthesis.[16] A one-stage procedure, which has been developed recently for the synthesis of optically active epoxides and aziridines,[21,22] represents a considerable achievement in this field. Optically pure sulfur ylides, which are generated *in situ* in reactions of catalytic amounts of chiral sulfides with diazo compounds in the presence of dirhodium tetraacetate or copper acetylacetonate, react with aldehydes or imines to give epoxides or aziridines, respectively, and the sulfide is recovered and recycled to the catalytic cycle. This procedure was used for the syntheses of various substituted epoxides and aziridines in good yields and with high enantioselectivity.[16,23–25]

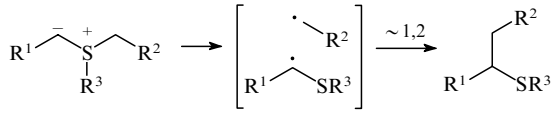
Sulfur ylides also find wide application in the synthesis of other cyclic compounds as well as of hetero-, macro- and polycyclic structures, including natural compounds and their analogues. Special-purpose reviews devoted to this aspect are lacking. The only study dealing with this problem [13] has covered the results published up to 1986 inclusive. The present review surveys the data on the use of sulfur ylides in syntheses of complex cyclic, heterocyclic and natural compounds published over the last 15 years. Systematisation and analysis of the available data will help in evaluating the possibilities of the use of sulfur ylides in the synthesis of complex structures and give a deeper insight into prospects of the further development of this line of investigation. Reactions of ylides giving rise to three-membered carbo- and heterocycles are beyond the scope of the present review.

II. Rearrangements of cyclic sulfur ylides

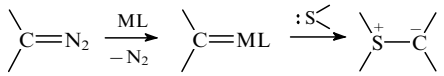
Sigmatropic rearrangements of cyclic sulfur ylides were investigated in most detail. In these studies, sulfur ylides were used in the synthesis of various carbo- and heterocyclic compounds. The reactions are carried out with the use of either ylides generated *in situ* or individual compounds prepared in advance. The 1,2-Stevens rearrangements [18, 20] and 2,3-sigmatropic rearrangements of sulfur ylides find most extensive synthetic applications.[16–20, 26]

1. 1,2-Stevens rearrangements

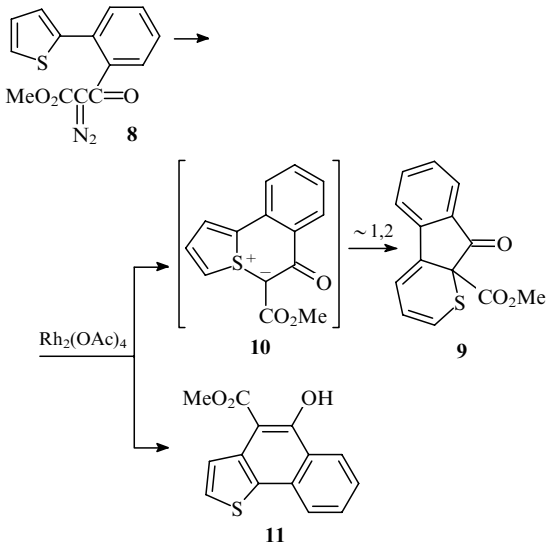
The 1,2-Stevens rearrangements of sulfur and nitrogen ylides were discovered in 1928.[27] According to orbital symmetry rules, the concerted mechanism of this thermal rearrangement is forbidden.[28] Hence, the most probable mechanism involves the dissociation–recombination process. It was demonstrated [29, 30] that the rearrangements proceed through the formation of a radical pair, the rate of radical recombination being higher than the rate of their diffusion into a solvent.



The employment of rearrangements of sulfur ylides in the synthesis of cyclic compounds appeared to be particularly promising in connection with the development of the carbene method for the generation of cyclic sulfur ylides.[20, 31–34] Ylides are formed through the electrophilic addition of a carbenoid species, which is generated from the diazo group under the action of transition metal (predominantly, Rh or Cu) compounds, to the sulfur atom.[34] These reactions are most often performed with stable diazoesters or diazoketones. Recently,[35, 36] it was demonstrated that trimethylsilyldiazomethane can also be successfully used for the generation of sulfur ylides.

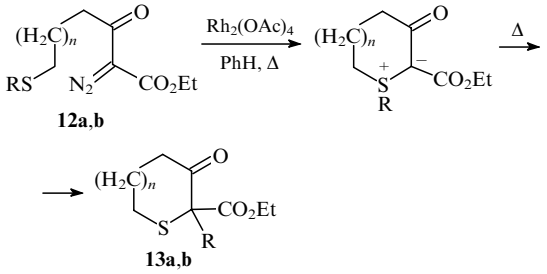


Sometimes the process is complicated by a side reaction of insertion of the carbene formed into the C–H bond. Thus intramolecular cyclisation of diazosulfide **8** afforded not only the major reaction product **9**, generated through the 1,2-rearrangement of intermediate unstable tricyclic thiophenium ylide **10**, but also a product of insertion into the C–H bond (**11**).[37]

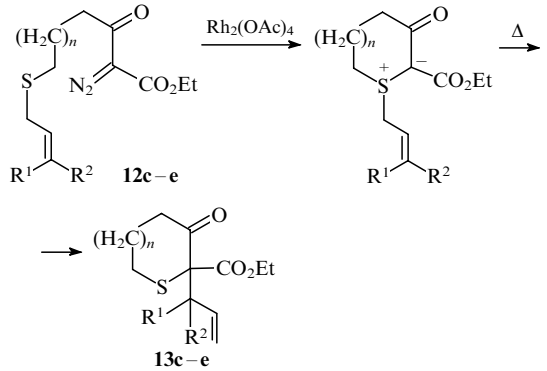


New stable four-to-seven-membered cyclic ylides were synthesised by intramolecular cyclisation of diazosulfides and their thermal rearrangements giving rise to heterocyclic compounds were carried out virtually simultaneously by two independent research groups.[38–40] It was demonstrated [38, 39] that six- and seven-membered cyclic ylides **12a**,**b** underwent the 1,2-Stevens rearrangement on heating to give the corresponding substituted cyclic thioesters **13a**,**b** in 40%–60% yields.

Decomposition of the diazoallyl sulfide **12b** catalysed by $Rh_2(OAc)_4$ afforded directly the rearranged thiepane **13b** (the yield was 59%); intermediate cyclic sulfonium ylide was not detected. The fact that the thiepane **13b** was formed through the 2,3-rearrangement rather than through the [1,2]-shift was exemplified by the reactions of diazosulfides **12c–e** containing the prenyl, cinnamyl or crotyl substituent at the sulfur atom, which were accompanied by the allylic inversion.



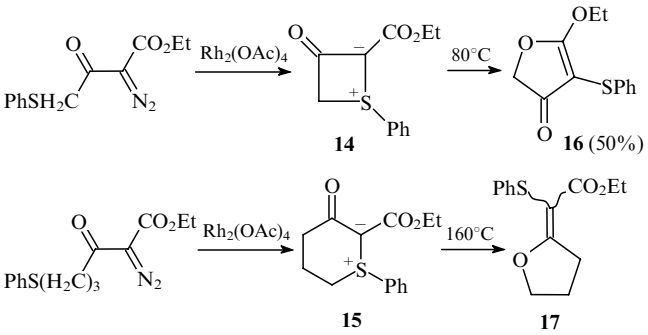
R = Bn, n = 1 (**a**); R = $H_2C{=}CHCH_2$, n = 2 (**b**).



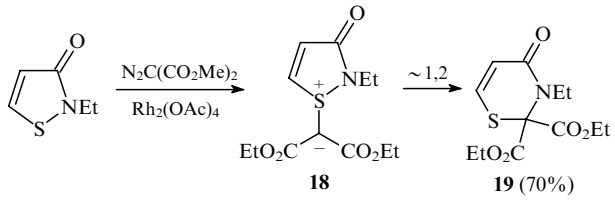
$R^1 = R^2$ = Me, n = 1 (**c**); R^1 = Ph, R^2 = H, n = 2 (**d**); R^1 = Me, R^2 = H, n = 2 (**e**).

On heating, four- (**14**) and six-membered *S*-phenyl-substituted (**15**) sulfur ylides underwent the 1,4-rearrangement to form derivatives of dihydro- (**16**) and tetrahydrofuran (**17**), respec-

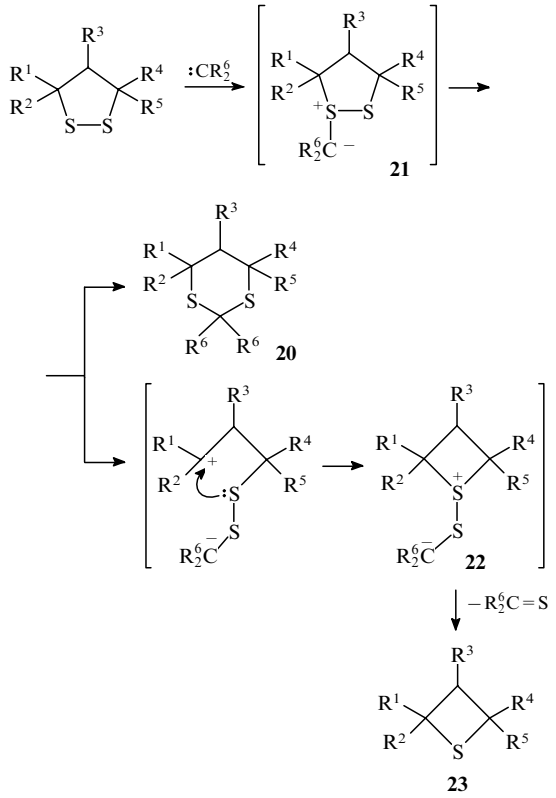
tively.[40] Seven-membered and some six-membered cyclic ylides decompose giving rise to unsaturated sulfur-free compounds.[40]



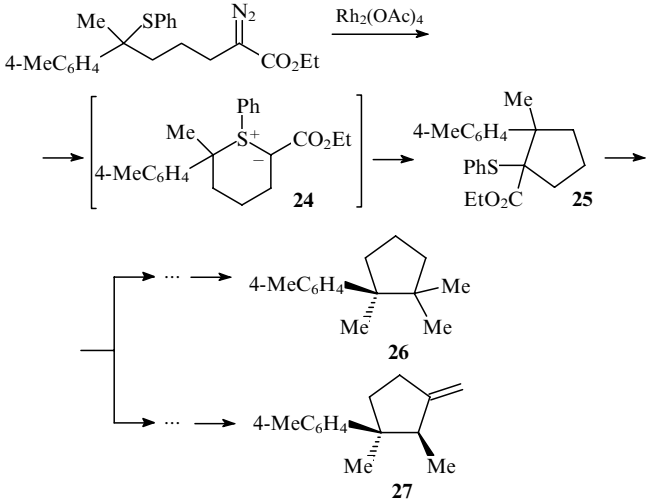
The 1,2-rearrangement of cyclic ylide **18** stabilised by two ethoxycarbonyl groups, which was formed in the reaction of 2,3-dihydroisothiazol-3-one with diazomalonic ester, was accompanied by insertion of carbene into the S–N bond to form 3,4-dihydro-1,3-thiazin-4(2*H*)-one **19**.[41]



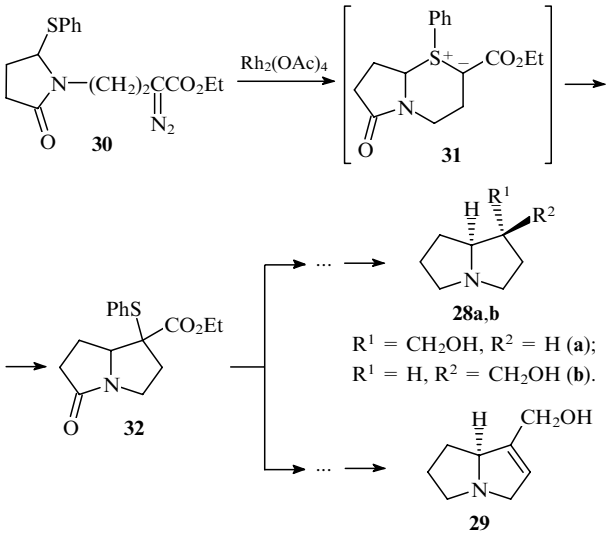
Substituted 1,3-dithianes **20** were synthesised by the 1,2-rearrangement proceeding with the cleavage of the S–S bond of intermediate 1,2-dithiolane ylides **21**.[42] The ylides **21** were generated by the reactions of cyclic disulfides with carbenes, which were prepared from diazo compounds under conditions of catalytic or photochemical reactions. If cyclic disulfides contain more than four substituents, the C–S bond in the ylides **21** can be cleaved. Subsequent desulfation of intermediates **22** afforded thietanes **23**.



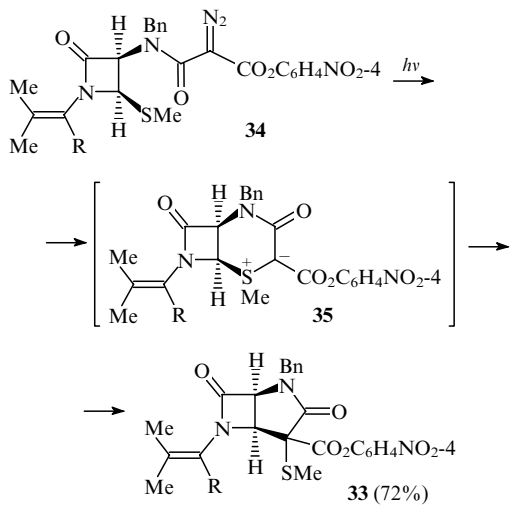
The generation of cyclic ylides by intramolecular reactions of sulfur-containing compounds with carbenes followed by their thermal rearrangements was successfully used in the synthesis of carbocyclic natural compounds. Thus the 1,2-rearrangement of ylide **24** proceeded with ring contraction to give substituted cyclopentane **25**. The latter served as the key compound in the synthesis of sesquiterpenes (±)-cuparene (**26**) and (±)-laurene (**27**).[43,44]



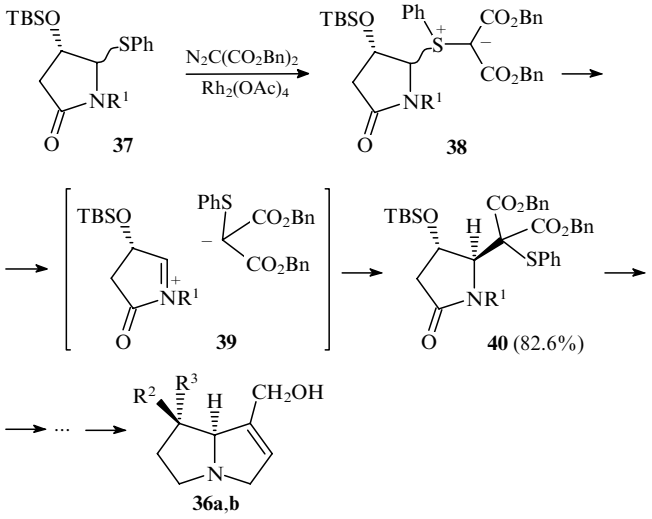
An analogous strategy was applied to the synthesis of pyrrolizidine alkaloids, *viz*., (±)-trachelanthamidine (**28a**), (±)-isoretronecanol (**28b**) and (±)-supinidine (**29**).[45,46] Diazoketone **30** was converted under the action of a rhodium catalyst into bicyclic sulfonium ylide **31** whose subsequent rearrangement afforded a compound of the pyrrolizidine series (**32**). The latter was used for the synthesis of the alkaloids **28a**,**b** and **29**.



1,2-Rearrangements proceed with high stereoselectivity, particularly, at low temperature and in viscous solvents. These reactions involving chiral sulfides can be employed in asymmetric synthesis.[18] In particular, the Stevens rearrangement allows one to solve the key problem in the synthesis of natural nitrogen-containing compounds consisting in the stereoselective formation of new C–C bonds at the α position with respect to the nitrogen atom. Thus a new approach to 6-amidocarbopenicillan antibiotics was exemplified by the synthesis of bicyclic β-lactam **33**.[47] Photolysis of diazoketone **34** afforded ylide **35**, which was rearranged to give the compound **33**, the new C–C bond being formed stereoselectively.



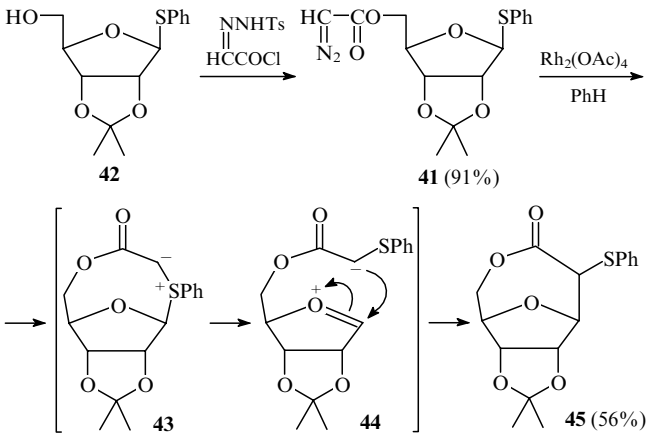
This synthetic approach was further developed in the stereoselective synthesis of alkaloids (+)-heliotridine (**36a**) and (+)-retronecine (**36b**).[48]



TBS is Bu^tMe_2Si;
36a: $R^1 = (CH_2)_2OC(O)Bu^t$, $R^2 = H$, $R^3 = OH$;
36b: $R^1 = (CH_2)_2OC(O)Bu^t$, $R^2 = OH$, $R^3 = H$.

The catalytic reaction of optically active sulfide **37**, which can be readily derived from (*S*)-malic acid, with dibenzyl diazomalonate afforded ylide **38** whose 1,2-rearrangement proceeded with high stereoselectivity. It is believed that the first stage of this reaction involved the cleavage of the C–S bond to produce salt **39**. The attack of the carbanion on the C=N bond proceeded predominantly from the less shielded side to form 2,3-*trans*-pyrrolidone derivative **40**, which was used as the starting compound in the synthesis of the alkaloids **36a**,**b**.

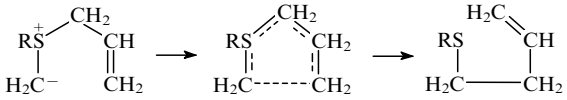
The application of the intramolecular rearrangement of cyclic sulfonium ylides allowed the development of a new method for the preparation of lactones,[49] which were used in the synthesis of C-nucleosides. Diazoacetyl thioglycoside **41** was prepared from precursor **42** according to the modified Corey method.[50] When refluxed in benzene with a catalytic amount of rhodium acetate, the compound **41** was converted into lactone **45** through sulfur ylide **43** and oxonium intermediate **44**. The lactone **45** served as the key compound in the synthesis of nucleoside antibiotic (+)-showdomycin.



2. 2,3-Sigmatropic rearrangements

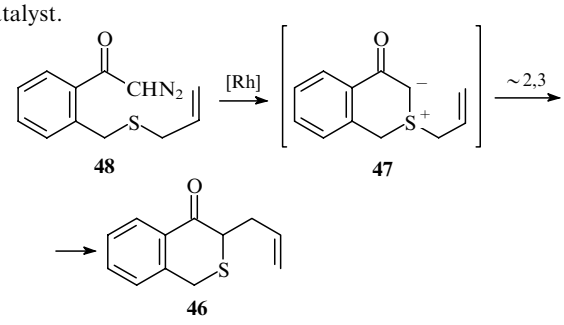
In the last two decades, the synthesis of cyclic compounds made wide use of 2,3-sigmatropic rearrangements of allylic and benzyl sulfur ylides. Baldwin was the first to carry out these studies [51–53] as early as 1968. Since then the 2,3-sigmatropic rearrangements of ylides have found many applications.

The rearrangement of allylic ylides into homoallylic sulfides can be represented in general form as follows:



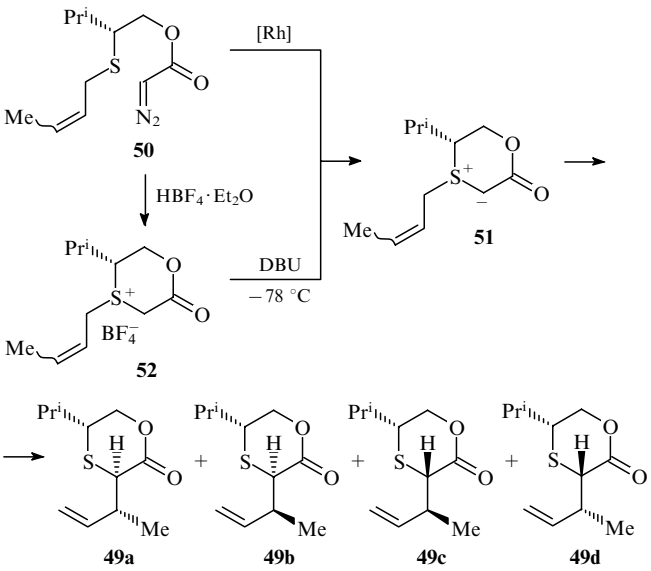
According to the orbital symmetry rules, 2,3-sigmatropic rearrangements are allowed [28] and they proceed either on heating or photolysis of ylides with complete inversion of the allylic substituent.[54,55] Since these reactions proceed by a concerted mechanism, high regio-, diastereo- and enantioselectivity are achieved, which is of particular interest from the standpoint of their application in asymmetric synthesis.

A gentle and efficient procedure for the synthesis of 3-allylisothiochroman-4-one (**46**)[56] involves the 2,3-sigmatropic rearrangement of cyclic sulfur ylide **47** formed by intramolecular cyclisation of diazosulfide **48** under the action of a rhodium catalyst.



The use of chiral allylic sulfides in 2,3-sigmatropic rearrangements offers considerable possibilities for enantioselective syntheses of cyclic compounds, including analogues of natural compounds.

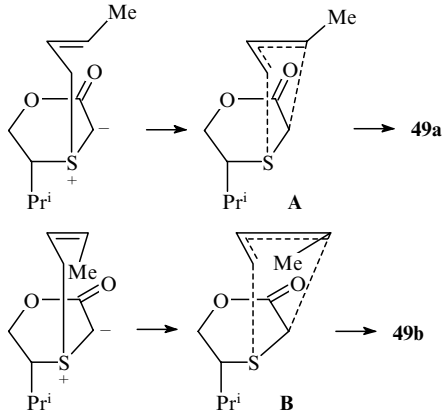
Thus the synthesis of optically active thioxanones **49a**–**d** was based on the 2,3-sigmatropic rearrangement of optically pure cyclic sulfur ylide **51**, which proceeded with high asymmetric induction.[57,58] Crotyl thiodiazoester **50** derived from L-valine was converted into the corresponding cyclic allylic sulfur ylide by either rhodium-catalysed intramolecular cyclisation or deprotonation of sulfonium salt **52** derived from the compound **50**. The rearrangement of the ylide **51** afforded four isomeric thioxanones **49a**–**d**. The best yield and diastereoselectivity were achieved on deprotonation of the sulfonium salt **52**.



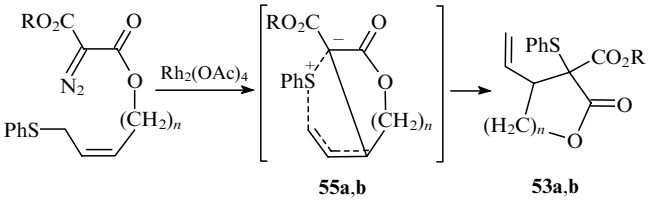
DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.

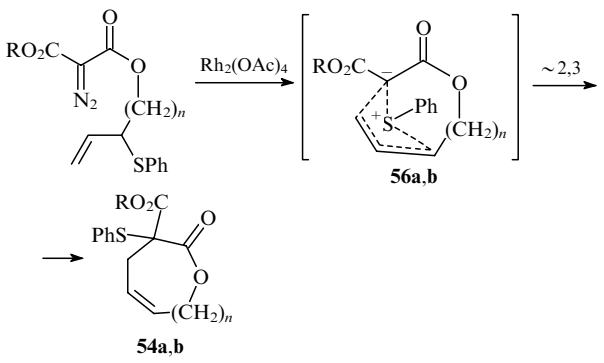
Starting compound	Reagent	Total yield (%)	Isomer ratio			
			49a	**49b**	**49c**	**49d**
(*Z*)-**50**	[Rh]	35	84	8	7	1
(*E*)-**50**	[Rh]	28	10	83	2	5
(*Z*)-**52**	DBU	66	94	4	2	traces
(*E*)-**52**	DBU	64	4	93	1	2

The reactions involving the *Z*-isomers of the compounds **50** and **52** yielded the thioxanone **49a** as the major product, whereas the reactions with the participation of the *E*-isomers gave rise to the thioxanone **49b**. This stereoselectivity was attributed [59] to the *endo* conformation of the allyl-containing five-membered ring in the prevailing transition states **A** or **B**.



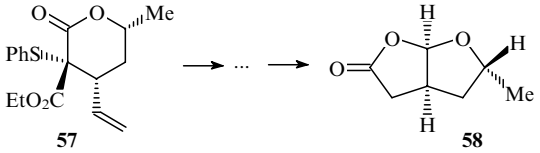
Substituted five-to-eight-membered lactones **53a**,**b** and **54a**,**b** were prepared by the 2,3-sigmatropic rearrangements of allylic sulfonium ylides **55a**,**b** and **56a**,**b** generated from the corresponding diazoesters under the action of dirhodium tetraacetate.[60–63]



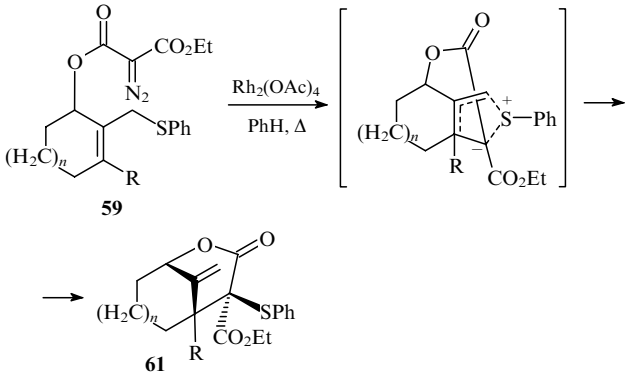


R = Me, Et; *n* = 1, 2.

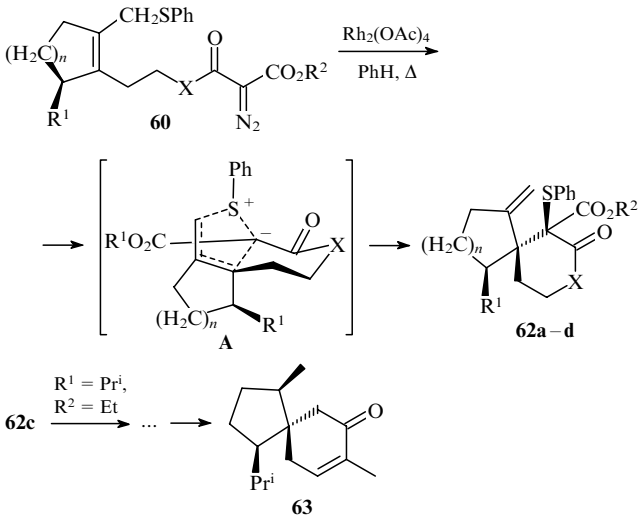
Lactone **57** was prepared according to an analogous procedure and was used in the stereoselective synthesis of perhydro[2,3-*b*]furanone derivative **58**.[62]



The rearrangement of sulfur ylides, which were prepared by treatment of sulfur-containing diazoketones **59** and **60** with dirhodium tetraacetate in boiling benzene, was used in a new approach to the synthesis of bridging δ-lactones **61** [64] as well as of spiro-fused five- and six-membered lactones **62a**,**b** [65] and spirocarbocyclic compounds **62c**,**d**.[66]



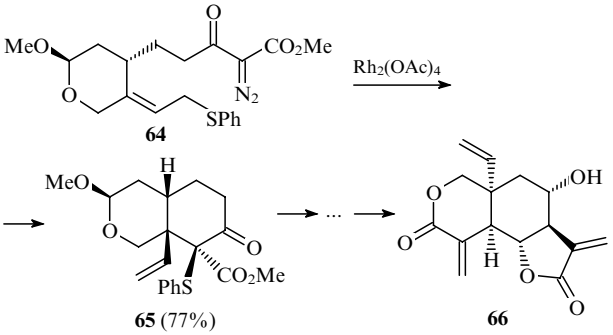
R = H, Me; *n* = 1, 2.



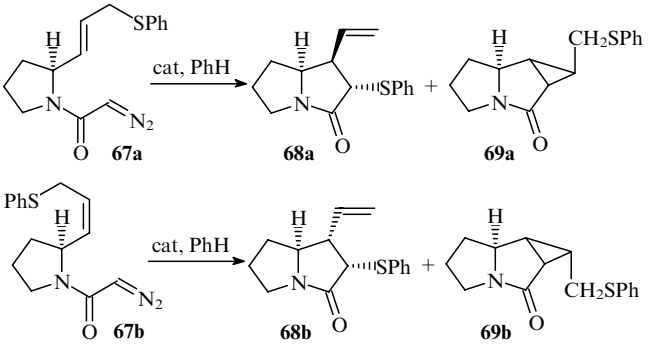
R^1, R^2 = Alk; X = O, *n* = 1 (**a**), 2 (**b**); X = CH_2, *n* = 1 (**c**), 2 (**d**).

Spiroannelation using the [2,3]-sigmatropic rearrangement *via* cyclic allylic sulfonium ylide was applied in the enantioselective synthesis of sesquiterpene (+)-acorenone B (**63**).[66] High stereoselectivity of the sigmatropic rearrangement is attributed to the fact that the less sterically hindered side opposite to the isopropyl group is favourable for the attack of the carbanion on the sulfonium reaction centre (transition state **A**).

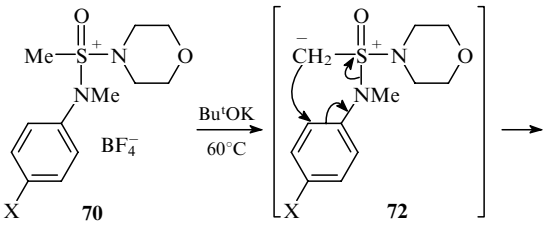
Rhodium-catalysed stereoselective cyclisation of diazosulfide **64** followed by the 2,3-rearrangement of the resulting ylide afforded *cis*-2-oxa-9-vinyldecalin derivative **65**, which served as the starting compound in the synthesis of vernolepin (**66**).[67]

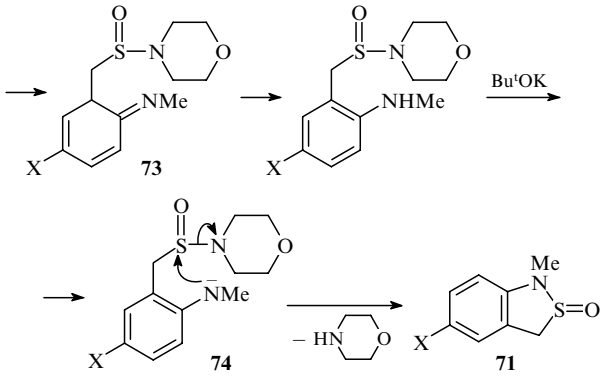


The rhodium-, copper- and palladium-catalysed stereoselective reactions of diazosulfides **67a** and **67b** were studied.[68] Depending on conditions, these reactions can afford either sulfonium ylides, which undergo the 2,3-sigmatropic rearrangement to form bicyclic compounds **68a** and **68b**, or tricyclic cyclopropane derivatives **69a** and **69b**. The latter are products of intramolecular cyclopropanation. Decomposition of the diazoamides **67a**,**b** in the presence of the rhodium complex with caprolactam gave rise predominantly to the azabicyclooctanes **68a**,**b**, whereas cyclopropane derivatives were selectively formed as the major products in the presence of catalysts containing electron-withdrawing ligands [$Rh_2(OAc)_4$, $Cu(acac)_2$, $Cu(OTf)_2$ or $Pd(OAc)_2$].



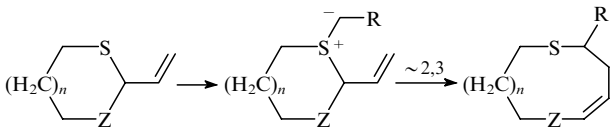
The rearrangements of diaminosulfoxonium salts of type **70** to form dihydro-2,1-benzoisothiazole derivatives **71** were described.[69] Treatment of the salts **70**, which were prepared by alkylation of sulfonimidoamides, with Bu^{t}OK resulted in the 2,3-sigmatropic rearrangement of intermediate ylides **72** to produce cyclohexadieneimine derivatives **73** in the first stage. The transfer of the hydrogen atom in the latter compounds was accompanied by rearomatisation. Cyclisation of intermediates **74** afforded the final products **71**.





X = Me, Cl.

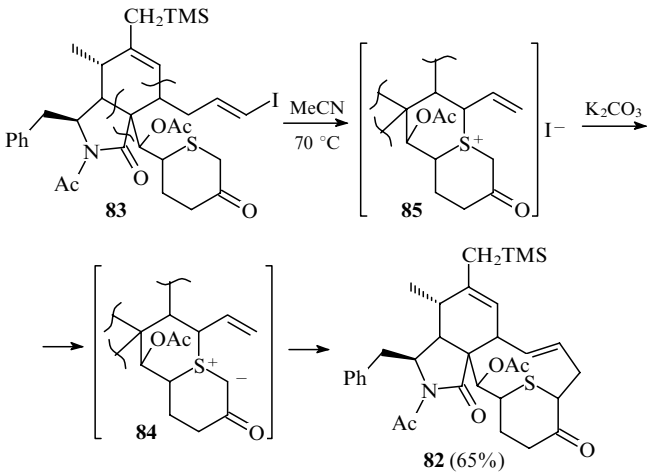
Yet another promising synthetic application of sulfur ylides is based on the 2,3-sigmatropic rearrangements of cyclic allylic sulfonium ylides proceeding with ring expansion.[17,70]



Z is the carbon atom or a heteroatom.

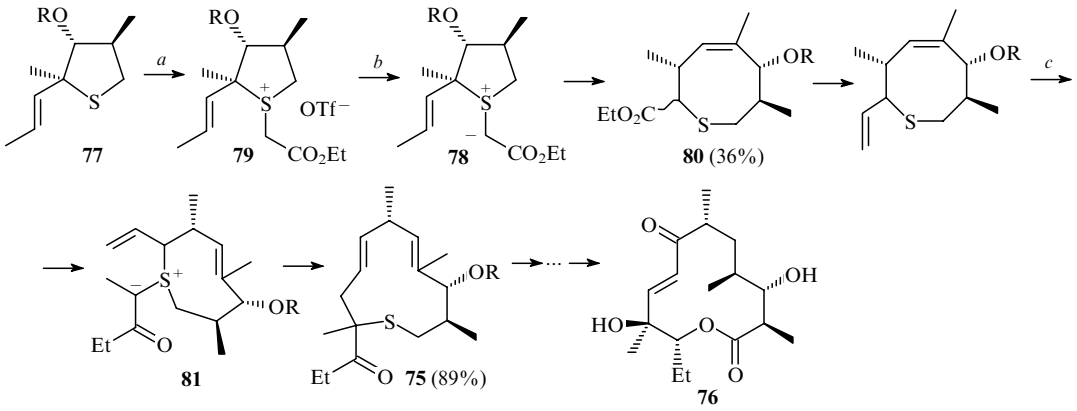
Ylides can be generated by reactions of cyclic α-vinyl sulfides with diazo compounds in the presence of copper [17,70] or rhodium catalysts [71] or by reactions of bases [17,70] with sulfonium salts. These procedures were used for the preparation of various macrocyclic compounds. For example, the synthesis of thiacycloundeca-4,7-diene derivative **75**, which is a precursor of aglycon of macrolide antibiotic methymycin, *viz*., methyneolide **76**, was carried out starting from tetrasubstituted thiolane **77**.[72–74] The rearrangement of ylide **78** derived from salt **79** afforded thiacyclooctene **80** from which ylide **81** was synthesised in several steps. The subsequent stereoselective 2,3-sigmatropic rearrangement of the ylide **81** gave rise to thiacycloundecadiene **75** (Scheme 1).

The 2,3-sigmatropic rearrangements of bicyclic allylic sulfonium ylides, which gave rise to compound **82** containing the thiabicyclo[6.3.1]undec-3-ene fragment, was used in the total synthesis of cytochalasines.[75,76] In this synthesis, vinyl iodide **83** served as the starting compound. The key stage of this synthesis involved the rearrangement of ylide **84** generated from sulfonium salt **85** under the action of potassium carbonate.



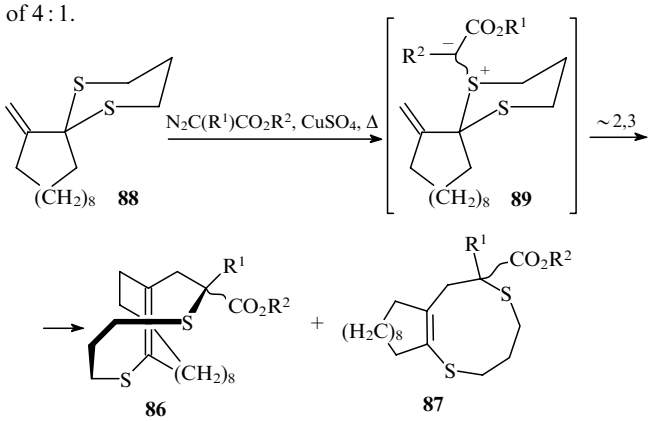
Difficultly accessible bicyclic unsaturated disulfides **86** (the so-called betweenanene structures) and **87** were synthesised.[77,78] Heating of dithioketal **88** with diazoacetate in the presence of $CuSO_4$ afforded ylide **89**, which underwent the 2,3-sigmatropic

Scheme 1

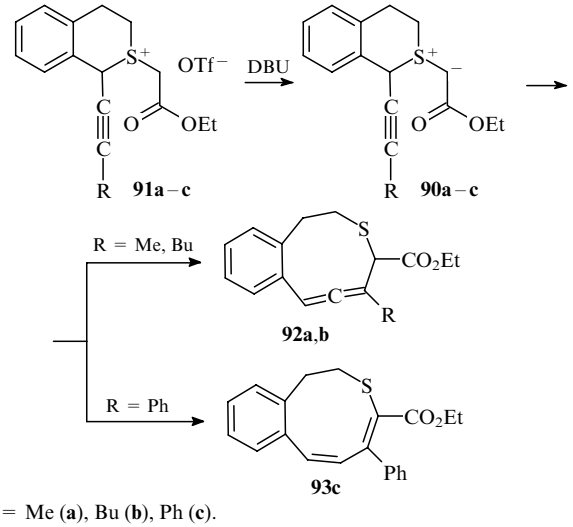


Tf = F_3CSO_2; (*a*) $TfOCH_2CO_2Et$; (*b*) K_2CO_3; (*c*) $TfOCHMeCOEt$, K_2CO_3.

rearrangement to give two geometric isomers **86** and **87** in a ratio of 4 : 1.

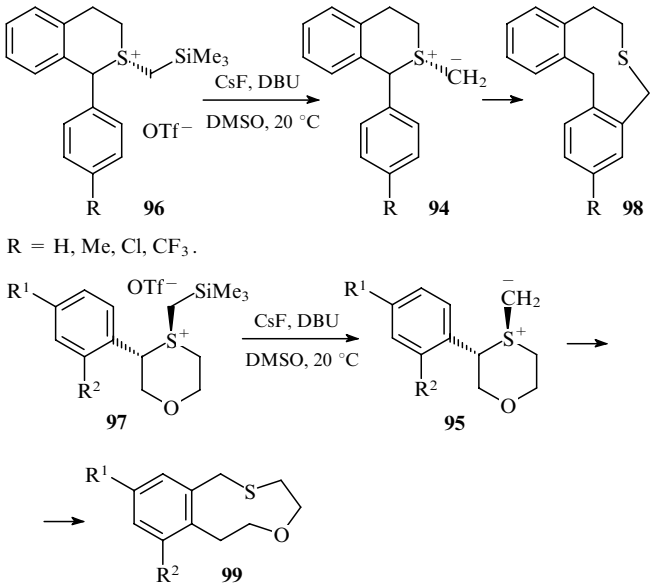


The structures of the 2,3-sigmatropic rearrangement products of acetylenic ylides **90a**–**c** derived from the corresponding sulfonium salts **91a**–**c** depend on the nature of the substituent at the triple bond. Thus the ylides containing alkyl substituents were converted into allenic sulfides **92a**,**b**, whereas the phenyl substituent promoted isomerisation into 1,3-diene **93c**.[79]



R = Me (**a**), Bu (**b**), Ph (**c**).

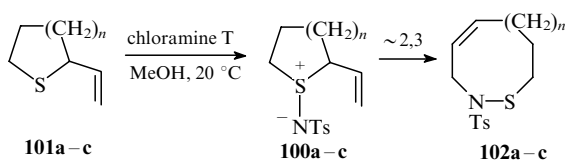
Aryl-substituted ylides **94** and **95**, which were formed on desilylation of salts **96** and **97**, underwent the Sommelet–Hauser rearrangement giving rise predominantly to substituted 2,5,8,9-tetrahydrodibenzo[*c*,*f*]thionines **98**[80] and 3,4,6,7-tetrahdydro-1*H*-5,2-benzooxathionines **99**, respectively.[81]



R = H, Me, Cl, CF_3.

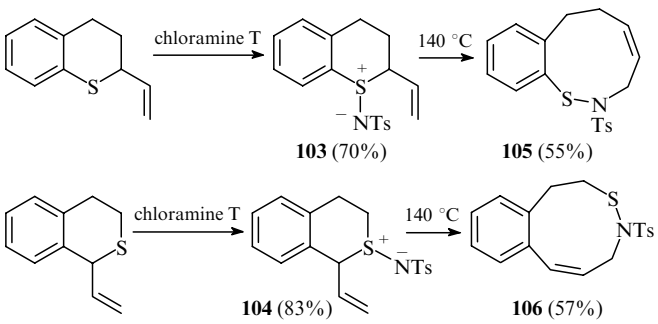
R^1, R^2 = H, Me, OMe, CF_3.

Analogous thermal 2,3-sigmatropic rearrangements accompanied by ring expansion proceeded in the case of α-vinyl iminosulfurane ylides **100a**–**c**, which were prepared by treatment of sulfides **101a**–**c** with chloramine T in methanol at ~20 °C.[82] The rearrangements of the ylides **100a**–**c** afforded azathiacyclenes **102a**–**c**. It should be noted that treatment of 2-vinylthiepane **101c** with chloramine T gave rise to the final product **102c** even at room temperature. Attempts to isolate the intermediate ylide **100c** failed.

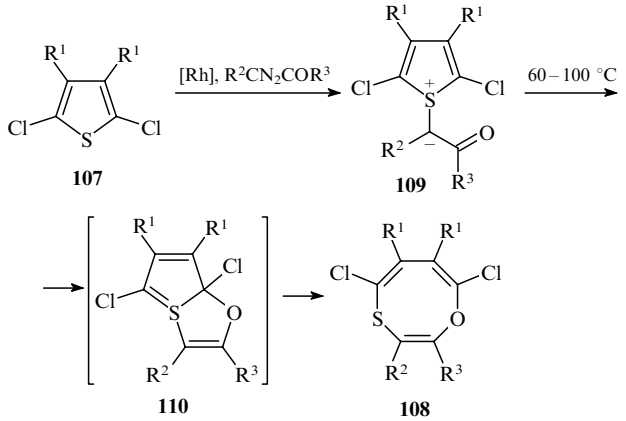


Compound **101**	*n*	Yield of **100** (%)	Temperature of the rearrangement /°C	Yield of **102** (%)
a	1	70	140	55
b	2	61	140	54
c	3	–	~20	61

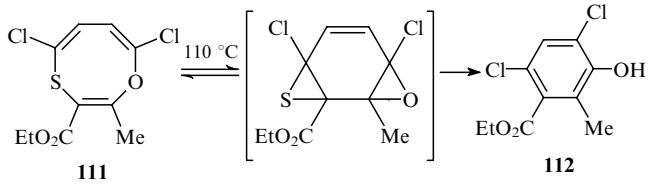
Under the same conditions, benzoiminosulfuranes **103** and **104** produced 1,2- (**105**) and 3,4-benzothiazonines (**106**), respectively.[82]



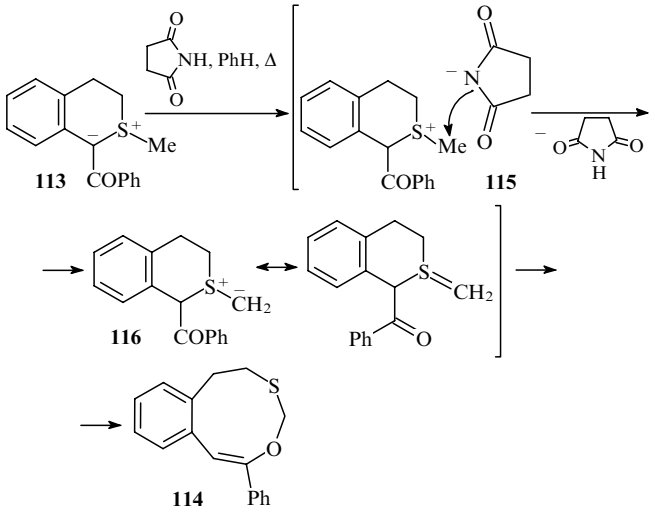
The reactions of 3,4-disubstituted 2,5-dichlorothiophenes **107** with diazoketones in the presence of rhodium catalysts afforded derivatives of a new heterocyclic system, *viz*., of 1,4-oxathiocine **108**.[83,84] The reaction scheme involves the formation of sulfur ylides **109** and their subsequent thermal 2,3-sigmatropic rearrangement proceeding through intermediates **110**. Heating of oxathiocine **111** at 110 °C gave rise to benzene derivative **112** due to elimination of the sulfur atom and 1,2-shift of the chlorine atom. It should be noted that the reactions of diazoketones with thiophenes, which do not contain chlorine atoms at positions 3 and 5, do not yield oxathiocine derivatives.



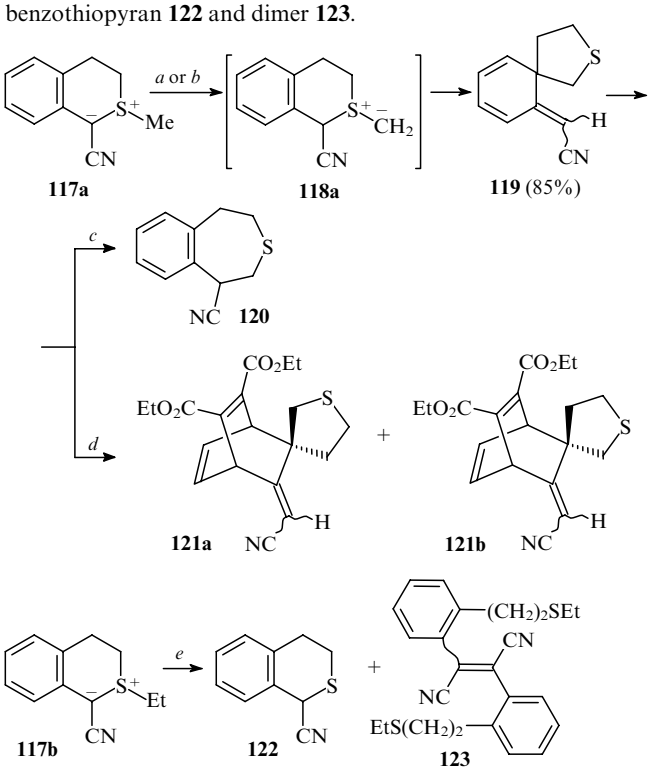
R^1 = H, Cl; R^2 = CO_2Et, CO_2Bu^t, Ts; R^3 = Me;
R^2–R^3 = $COCH_2CMe_2CH_2$.



The 2,3-sigmatropic rearrangements of bi- and tricyclic sulfur ylides derived from substituted thiaphenanthrenes and isothiochromans, respectively, afforded both ring expansion products and spirane compounds.[85–88] The direction of the reaction and the structures of the final products depend essentially on the nature of the substituents at the sulfur atom and at position 1 of the initial ylide. For example, the reaction of stabilised ylide **113** with succinimide gave rise to the ring expansion product, *viz*., 2-phenyl-4,5-dihydro-3,5-benzooxathionine **114**, in high yield. The reaction mechanism involves deprotonation of intermediate **115** with the imide anion to form exocyclic methylide **116** whose 2,3-sigmatropic rearrangement yielded the target product **114**.[85] The reaction of the ylide **113** with phthalimide proceeded analogously.

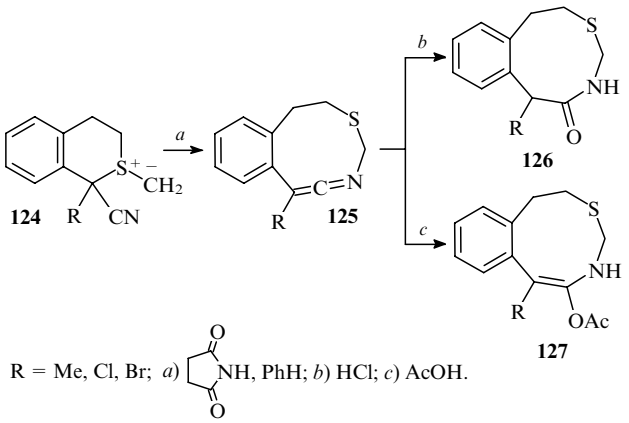


The reaction of 1-cyanoisothiochroman ylide **117a** proceeded by the same mechanism; however, due to the presence of the cyano group, the 2,3-sigmatropic rearrangement of intermediate exomethylide **118a** proceeded differently to form spirocyclic compound **119**.[86] On thermolysis, the compound **119** was isomerised to tetrahydrothiepin **120**, whereas its reactions with acetylenedicarboxylic esters afforded cycloadducts **121a**,**b**. The course of the reaction is substantially affected by the substituent at the sulfur atom. Thus the bulkier ethyl substituent in the ylide **117b** hinders the 2,3-rearrangement and the reaction gave rise to a mixture of benzothiopyran **122** and dimer **123**.



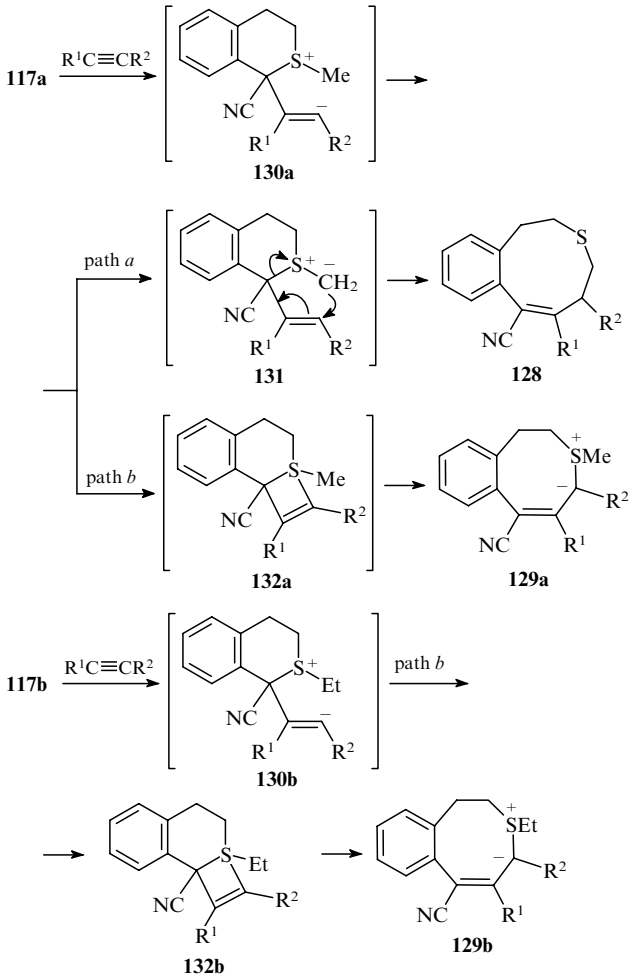
(*a*) EtOH or MeOH, Δ; (*b*)  ; (*c*) 205 °C;
(*d*) $EtO_2CC{\equiv}CCO_2Et$; (*e*) EtOH, Δ.

Due to the presence of one more substituent (Cl, Br or Me) at position 1 in ylides **124**, their reactions proceeded through the 2,3-sigmatropic rearrangement involving the S–N bond. The reactions of the ylides **124** with succinimide afforded ketenimines **125**, which gave amides **126** or enol acetates **127** upon acid hydrolysis.[86]



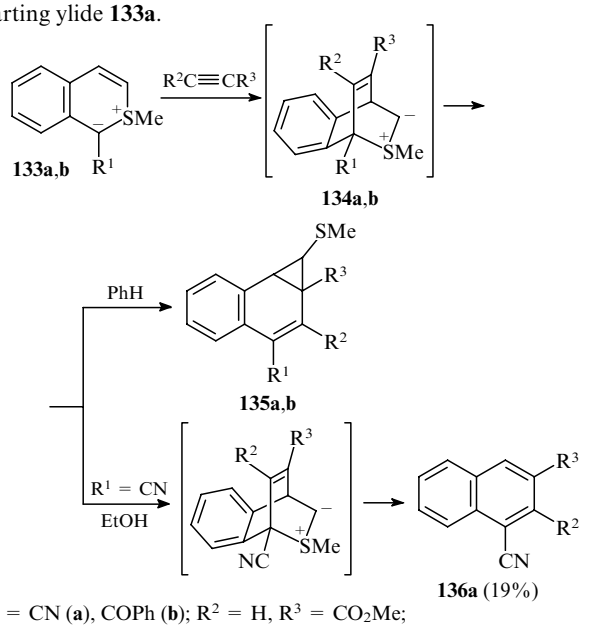
R = Me, Cl, Br; *a*) NH, PhH; *b*) HCl; *c*) AcOH.

The reactions of the 1-cyano ylides **117a**,**b** with activated acetylenes (dimethyl acetylenedicarboxylate or methyl propiolate) afforded fused compounds **128** and **129a**,**b**.[86] The methyl derivative **117a** gave a mixture of the compounds **128** and **129a** ($\sim$1 : 1) in 75% total yield. The reaction mechanism involves the intermediate formation of zwitterions **130a**,**b** whose isomerisation can take two different pathways (path *a* and path *b*). Intramolecular deprotonation of the *S*-methyl group (path *a*) gave rise to ylide **131** whose 2,3-sigmatropic rearrangement afforded the compound **128**. The nucleophilic attack of the vinyl anion on the positively charged sulfur atom produced unstable σ-sulfurane intermediate **132a**, which was converted into the ylide **129a**. The ethyl derivative **117b** gave only the doubly stabilised ylide **129b** in 31% yield.

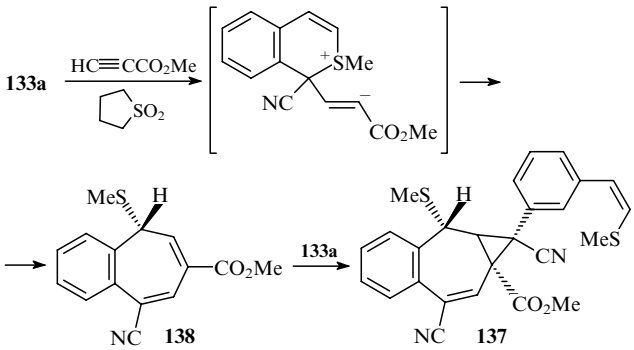


R^1 = H, R^2 = CO_2Me (**129a**); R^1 = R^2 = CO_2Me (**129b**).

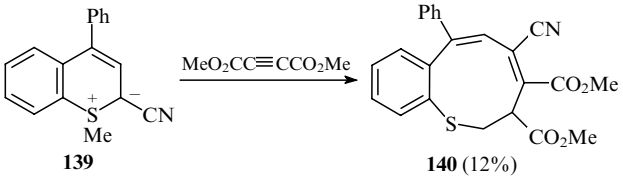
The reactions of stabilised isothiochromene sulfonium ylides **133a**,**b** with acetylenic dienophiles proceeded differently.[87] These compounds reacted as heterodiene systems and the reactions proceeded as [4 + 2]-cycloaddition to yield intermediates **134a**,**b**. Depending on the solvent, subsequent conversions of these intermediates afforded either dihydrocyclopropa[*a*]naphthalene derivatives **135a**,**b** (in aprotic solvents) or naphthalene derivative **136a** (in protic solvents). It should be noted that only [2 + 1]-adduct **137** was formed in high yield in the reaction of the compound **133a** with methyl propiolate in sulfolane. This adduct was generated by the interaction of intermediate **138** with the starting ylide **133a**.



R^1 = CN (**a**), COPh (**b**); R^2 = H, R^3 = CO_2Me;
R^2 = R^3 = CO_2Me, CO_2Et.

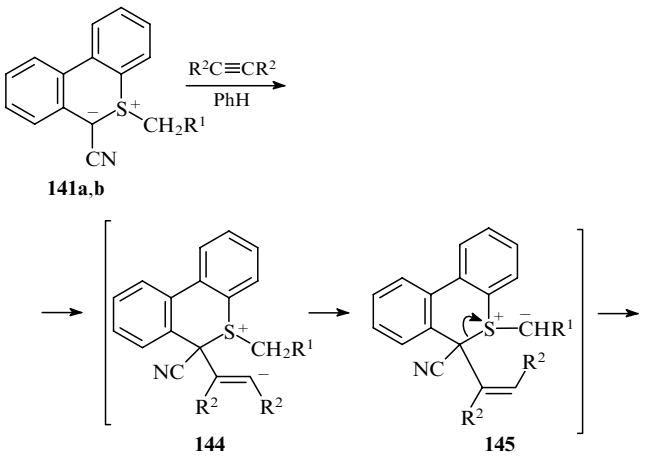


The reaction of 2-cyano-α-thiochromene ylide **139** with dimethyl acethylenedicarboxylate afforded the ring expansion product **140** in low yield.



The reactions of tricyclic sulfur ylide **141a** stabilised by the adjacent cyano group (the thiaphenathrene derivative) with activated acetylenes produced spirocyclic compounds **142** (the yields were up to 31%), which underwent the 1,5-rearrangement upon heating to give dibenzothionine derivatives **143** in yields of up to 95%.[88] It is assumed that the reaction mechanism involves the formation of zwitterionic intermediates **144**, which are rearranged to exocyclic sulfonium ylides **145**. The ylides **145** can undergo the

Sommelet–Hauser rearrangement to produce the compounds **142**. In the case of the ethyl-substituted ylide **141b**, spirocyclic compounds were not formed; instead, the reaction afforded dibenzothiepin derivatives **146** as the major products (the yields were up to 38%). Since the ethyl substituent at the sulfur atom in the compound **141b** causes steric hindrances to the Sommelet–Hauser, this compound underwent the 1,2-Stevens rearrangement to form the ring expansion product **146**. The rearrangements of the zwitterions **144** afforded dibenzothiocine derivatives (in the yields of up to 22%) along with the compounds **146** (see the scheme for the formation of the compound **129a**).[86]

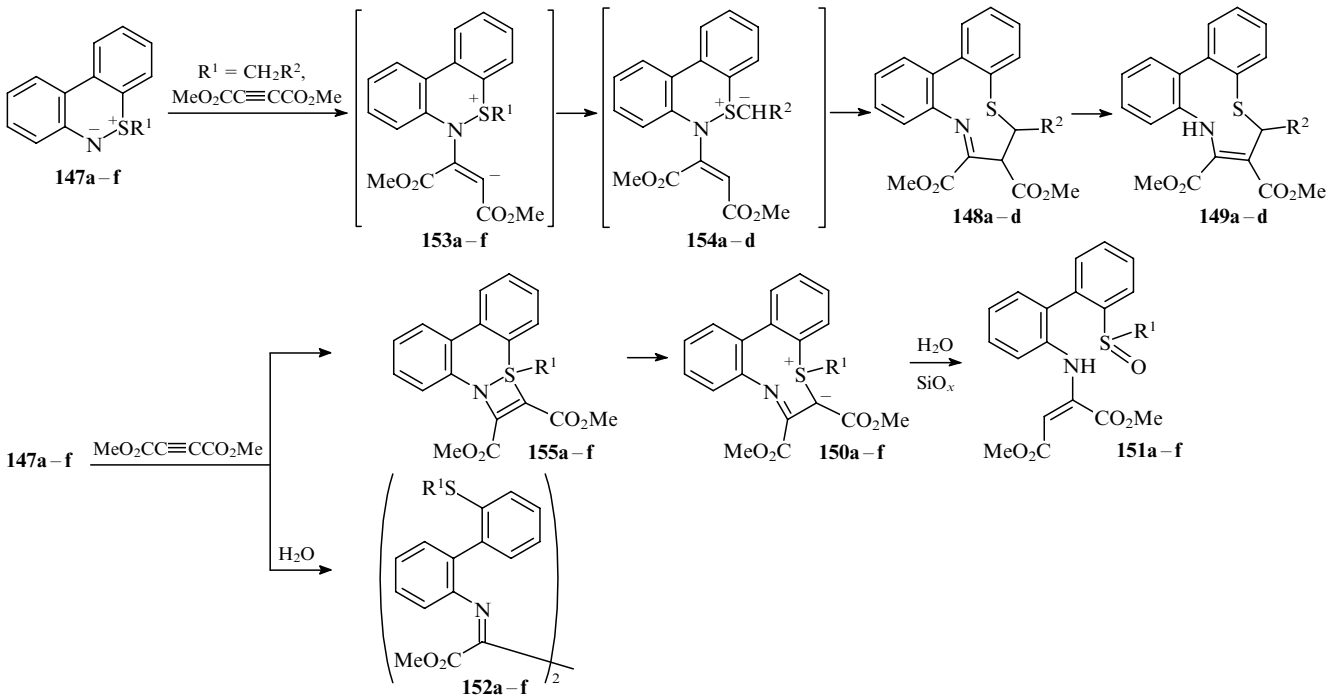


R^1 = H (**a**), Me (**b**); R^2 = CO_2Me, CO_2Et.

The reactions of sulfur ylides **147a–f**, *viz*., 9-alkyl-9-thia-10-azaphenanthrenes, with dimethyl acetylenedicarboxylate gave rise to dibenzothiazonium derivatives (compounds **148** and **149**), dibenzothiazocine derivatives (compounds **150**), 2-alkylsulfinyl-2′-vinylamionbiphenyls **151** and bis(biphenylylimino)ethane derivatives **152** (Scheme 2).[89]

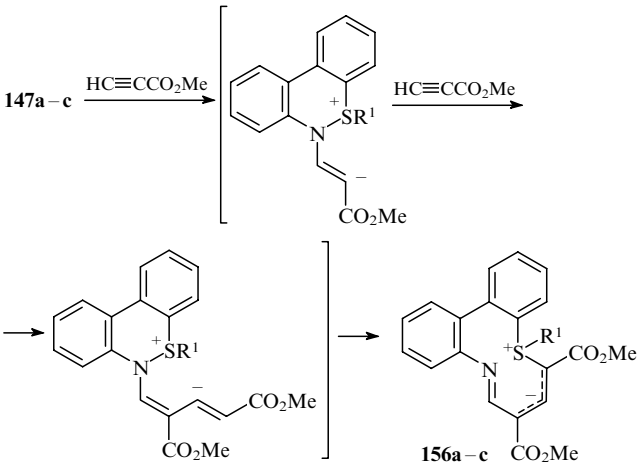
The composition of the reaction products depends substantially on the substituent at the sulfur atom. Thus the compound **147a** produced predominantly dibenzothiazonine derivatives **149a** and **148a**, whereas the ylides **147b**,**c**,**d** gave predominantly dibenzothiazocine derivatives **150** and biphenyls **151**. The ylides **147e**,**f**

Scheme 2

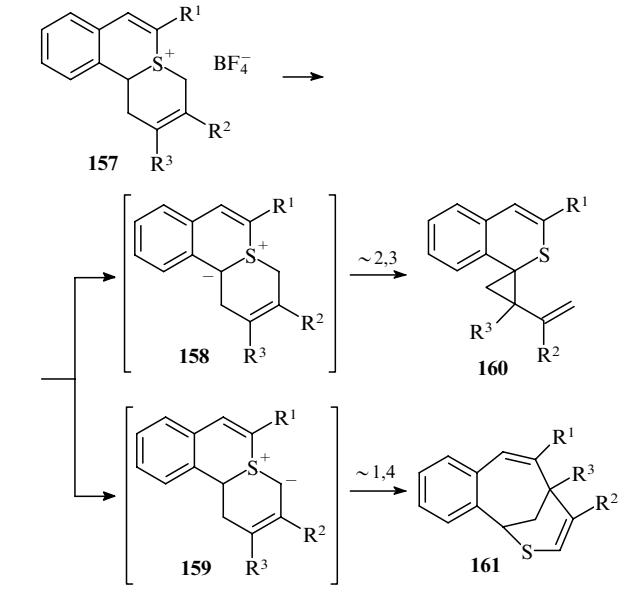


R^1 = CH_2R^2 (R^2 = H (**a**), Me (**b**), Et (**c**), C_5H_{11} (**d**)); R^1 = Ph (**e**), CH=CPh_2 (**f**).

containing the phenyl or vinyl substituent at the sulfur atom produced only dibenzothiazocine derivatives **150e**,**f**. The reaction mechanism involves the formation of zwitterions **153** and **154**. The exocyclic ylide **154** was isomerised to form the compounds **148** and **149**. The zwitterion **153** can produce intermediate **155** from which the derivatives **150** and **151** are generated or can react with water giving rise to the dimers **152**. The reactions of 9-alkylthiaazaphenanthrenes **147a – c** with methyl propiolate afforded 1 : 2 adducts, which are dibenzothiazocine derivatives **156a – c**.[89]

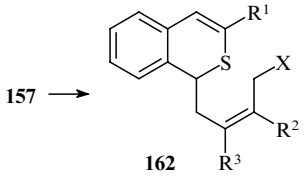


The rearrangements of tricyclic sulfonium salts **157** under the action of various bases have been studied thoroughly.[90] Thus treatment with strong bases [lithium diisopropylamide(LDA), NaH or K_2CO_3] afforded ylides **158** and **159**, which underwent the 2,3- and 1,4-sigmatropic rearrangements to form spirovinylcyclopropane derivatives **160** or tricyclic compounds **161**. The ratio of the reaction products depends on both the base used and the nature of the substituents.



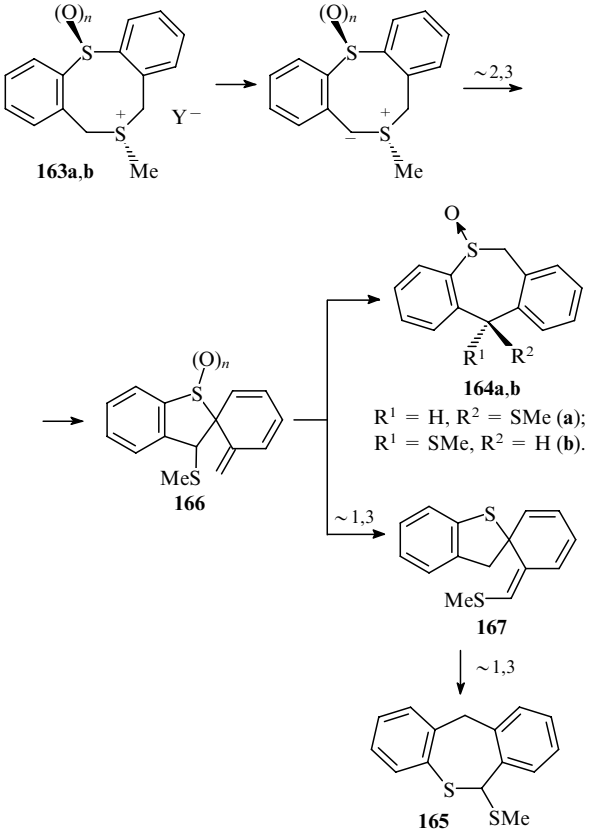
R^1	R^2	R^3	Base	Yield (%)	
				160	**161**
H	Me	Me	LDA	35	52
Bz	Me	Me	LDA	57	7
H	Me	Me	NaH	28	70
Bz	Me	Me	NaH	75	0
H	H	Me	NaH	44	45
Me	Me	Me	NaH	46	46
H	Me	Me	K_2CO_3	21	22
Bz	Me	Me	K_2CO_3	64	0

In the reactions with the salts **157**, weak bases, such as Et_3N, Et_2NH, $BuNH_2$ or AcOK, act as nucleophilic reagents and attack the CH_2 group adjacent to an electron-deficient centre to yield ring expansion products **162** in high yields.



X = NEt_3BF_4, NEt_2, OAc, NHBu.

Interesting results were obtained in studies of the rearrangements of dibenzothiocine salts **163a**,**b**, which took place under the action of a KOH solution in methanol.[91] Thus the sulfoxide **163a** was converted into a mixture of enantiomers of dibenzothiepin derivative **164a**,**b** (in a ratio of ~2 : 1). Under the same conditions, the sulfide **163b** unexpectedly gave compound **165**. The assumed reaction mechanism involves the tandem of the 2,3- and 1,3-sigmatropic rearrangements with the intermediate formation of spirocyclic intermediates **166** and **167**.



n = 1, Y = $SbCl_6$ (**a**); *n* = 0, Y = BF_4 (**b**).

III. Intramolecular cyclisation of sulfur ylides

A promising approach to the synthesis of nitrogen-containing heterocycles, including analogues of alkaloids, is based on intramolecular cyclisation of phthalimido-substituted sulfur ylides stabilised by the carbonyl group.[92–98] Under the conditions of the Arndt – Eistert reaction,[99] *N*-phthaloyl-α- (**168**) and -β-amino acids (**169**) generated bromo ketones, which were converted into the corresponding sulfonium salts. Deprotonation of these salts afforded stabilised ylides **170** and **171**, respectively, which underwent intramolecular cyclisation on heating in toluene with an equimolar amount of benzoic acid[96] to give methylthio-substituted pyrrolizidine- (**172**) and indolizidinediones **173** and **174**. It is significant that racemisation does not take place in the reactions

involving optically active ylides. Longer-chain sulfur ylides derived from γ- and δ-amino acids did not undergo cyclisation; instead, alkyl thioketones and oxobenzoates were formed as the major products.[96] The effect of the substituents in the phthalimide fragment on the regioselectivity of the reaction and the yields of the products was also studied.[97]

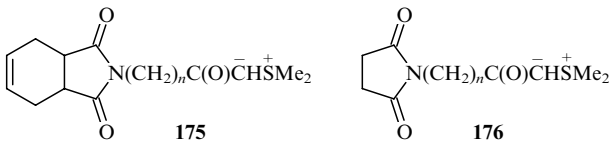
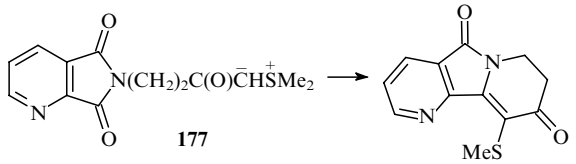
Ylides **175** and **176** containing the tetrahydrophthalimide or succinimide fragment, respectively, instead of the phthalimide fragment did not undergo cyclisation.[97]



175 **176**

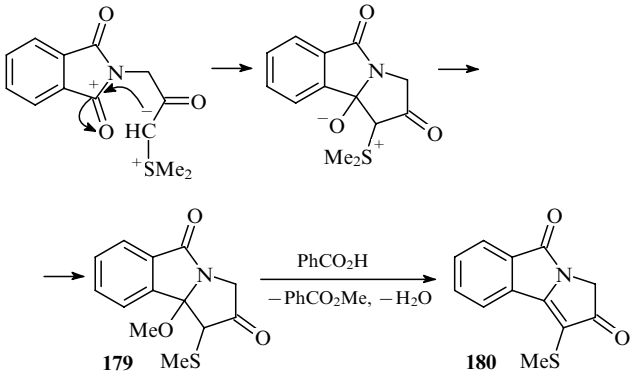
n = 1, 2.

Under the conditions of cyclisation, ylide **177**, which was synthesised from β-alanine and pyridine-2,3-dicarboxylic anhydride, selectively formed a tricyclic compound, *viz*., 5-methylthio-7,8-dihydro-4,8*a*-diazafluorene-6,9-dione (**178**).[98]



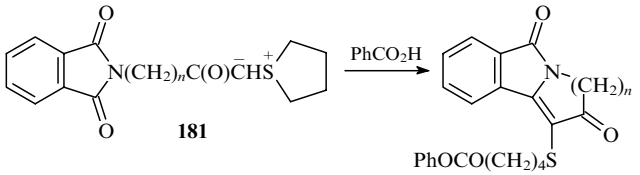
177 **178** (58%)

The assumed mechanism of a new type of intramolecular cyclisation, which is not quite typical of sulfonium ylides, involves, apparently, the attack of the anionic centre on one of the carbonyl groups of the phthalimide fragment followed by migration of the methyl group.[100, 101] The reaction ends in elimination of the methanol fragments from intermediate **179** under the action of benzoic acid to form rearrangement product **180**, methyl benzoate and water.



179 **180**

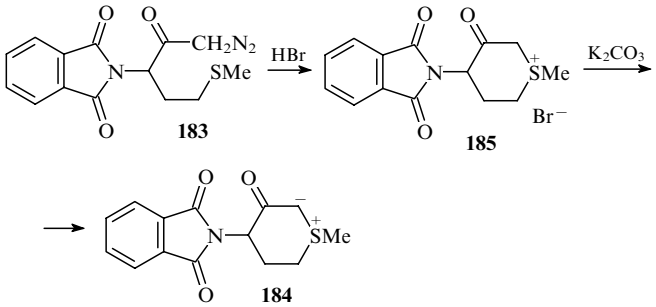
Intramolecular cyclisation of ylides **181** containing the sulfur atom in the ring gave rise to benzoates **182**.



181 **182**

n = 1, 2.

Diazosulfides (*R*)- or (*S*)-**183** generated from D- or L-methionine, respectively, underwent cyclisation under the action of HBr to form optically active sulfonium salts (*R*)- or (*S*)-**185** (the yields were 54 and 62%, respectively). Subsequent treatment of these salts with potassium carbonate afforded cyclic ylides (*R*)- or (*S*)-**184** stabilised by the carbonyl group (the yields were 75% and 90%, respectively).[102]



183 **185** **184**

A new approach to the stereoselective synthesis of amino acids from chiral lactams through intermediate formation of β-ketosulfoxonium ylides was developed.[103, 104] Previously,[105, 106] it was found that these ylides were converted into intermediates of the carbene type on photolysis or under the action of transition metals. The reactions of activated chiral lactams **186a**,**b** with dimethylsulfoxonium methylide were demonstrated to produce ylides **187a**,**b** in high yields.[103, 104] Under the action of rhodium

catalysts, the reactions of the ylides **187a**,**b** proceeded stereoselectively giving rise to derivatives of 4-oxopyrrolidine **188a** or 5-oxopiperidine **188b** formed as a result of cyclisation of intermediate carbenes **189a**,**b**. The compounds **188a**,**b** were used in the synthesis of optically active α-amino acids.[107]

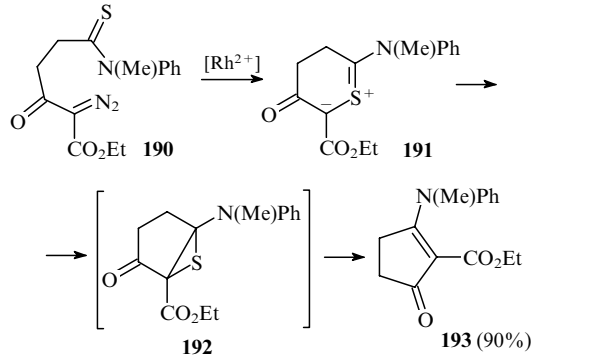
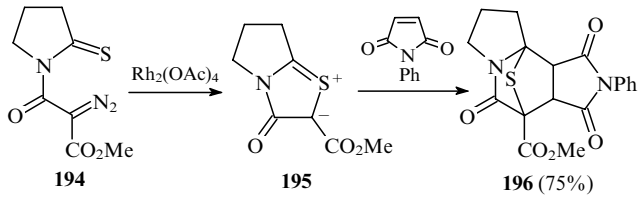
IV. Reactions of thiocarbonyl ylides

Considerable recent attention has been given to thiocarbonyl ylides, which are readily accessible and highly reactive intermediates. Several procedures were developed for the preparation of thiocarbonyl ylides among which are the 1,3-dipolar cycloaddition of diazo compounds to thioketones to form 1,3,4-thiadiazolines followed by nitrogen elimination,[108] the addition of thioketones to oxiranes[109] or photoisomerisation of aryl vinyl sulfides.[110] Thiocarbonyl ylides readily undergo rearrangements. These compounds are involved in cycloaddition with dipolarophiles and in 1,3- and 1,5-electrocyclisations, which often proceed with high regio- and stereoselectivity. The reactions of thiocarbonyl ylides with compounds of the RXH type (X = N, O or S) giving rise to 1 : 1 adducts were also studied.[111–113] Recently, cyclisation of carbenes generated by catalytic decomposition of diazothioamides has gained wide acceptance for the preparation of thiocarbonyl ylides.[114] Thus diazothioamide **190** gave cyclic thiocarbonyl ylide **191** under the action of a rhodium catalyst. The ylide **191** was converted into enaminoketone **193** due to elimination of sulfur from intermediate episulfide **192**.[115]

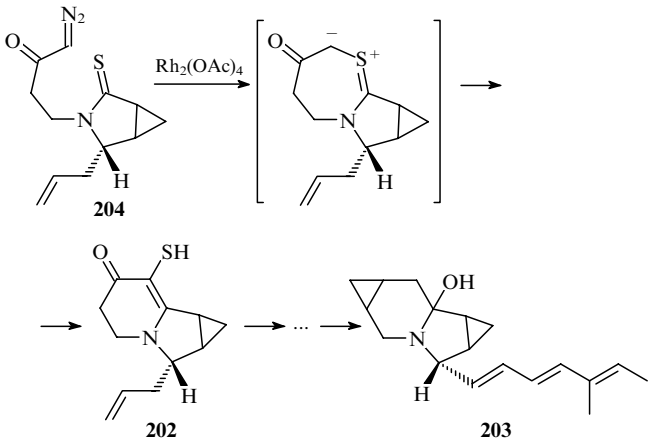


Intramolecular cyclisation of diazothioamide **194** catalysed by dirhodium tetraacetate afforded thiocarbonyl ylide **195** stabilised through the aromatic mesoionic structure. The ylide **195** reacted with *N*-phenylmaleimide according to the scheme of the diene synthesis to give adduct **196**.[115]



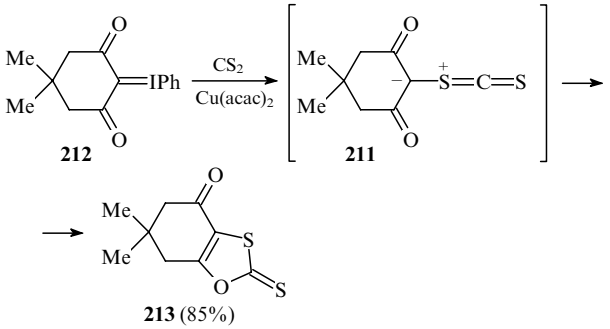
Thiocarbonyl ylides were successfully used in the synthesis of natural alkaloids.[116–120] Thus non-stabilised ylide **198** was generated from diazothioamide **197** under the action of rhodium acetate followed by the rearrangement of the latter into episulfide **199**. Isomerisation of the compound **199** afforded thioketone **200**, which underwent desulfurisation under the action of Raney nickel to yield dihydropyridone **201**.[116]

This procedure was used for the synthesis of dihydropyridone **202**, which was the key intermediate in the total synthesis of antibiotic indolisomycin **203**.[117, 118] Diazothioamide **204** was used as the starting compound.

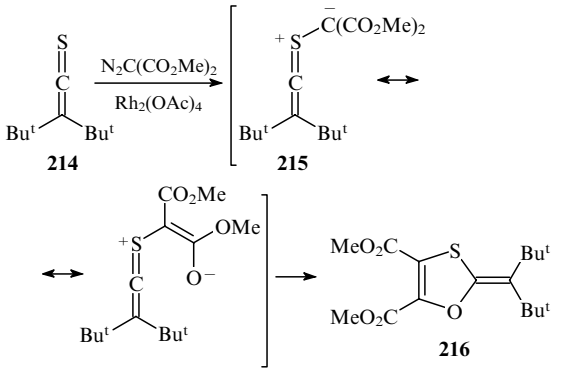


Alkaloids helenine (**205**)[119] and cephalotaxine (**206**)[120] were synthesised using compounds **207** and **208**, respectively. The latter were prepared by cyclisation of hydrazones **209** and **210**, which were synthesised from substituted benzaldehydes and *N*-amino-1,2-diphenylaziridine, in the presence of dirhodium tetraacetate. The reactions proceeded through the corresponding carbenoids and cyclic thiocarbonyl ylides (Scheme 3).

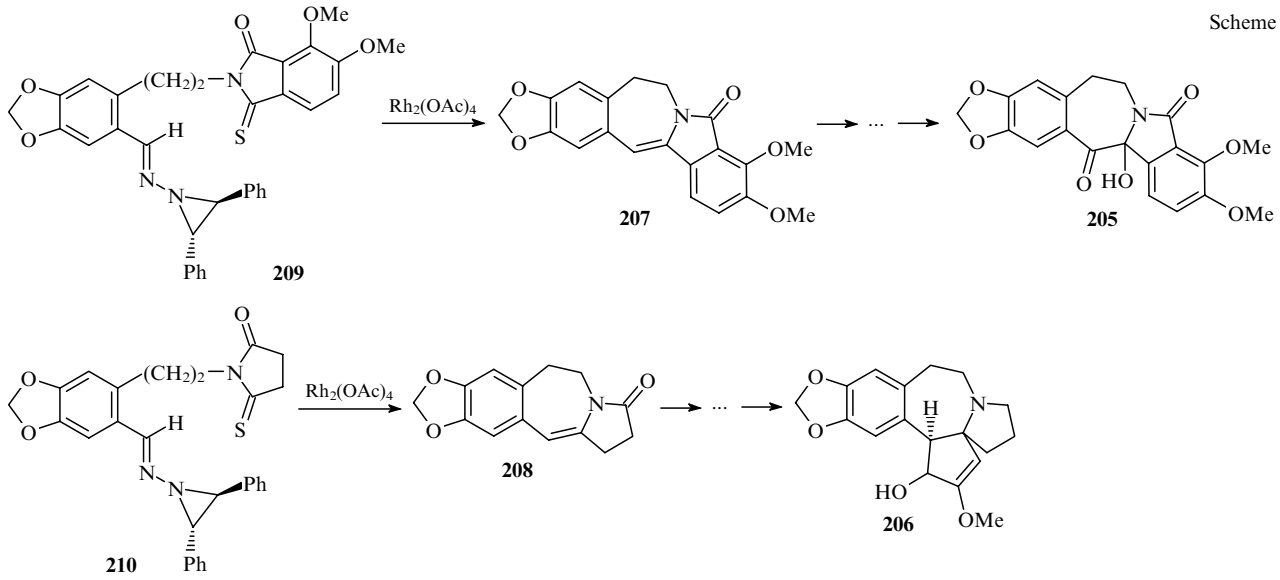
Thiocarbonyl ylide **211**, which was generated *in situ* on heating of a suspension of iodonium compound **212** in carbon disulfide in the presence of copper acetylacetonate, underwent cyclisation to yield oxathiol heterocycle **213**.[121]



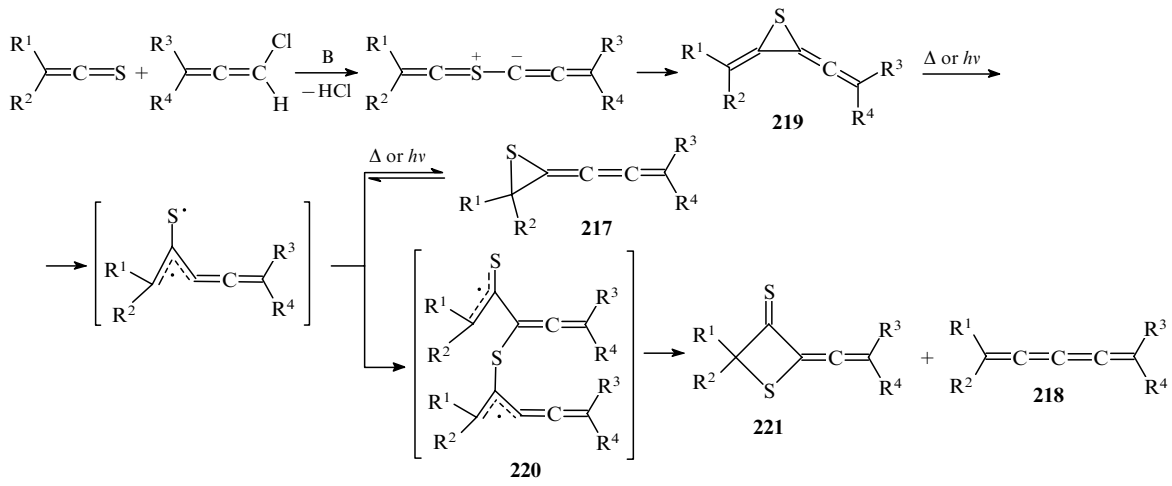
The reaction of di-*tert*-butylthioketene (**214**) with diazomalonate afforded thioketene ylide **215**, which underwent cyclisation to give 2-alkylidene-1,3-oxathiol **216**.[122]



Scheme 3



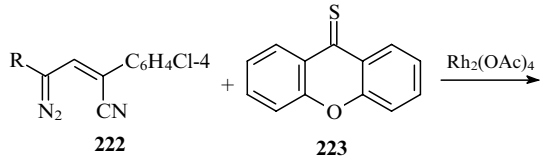
Scheme 4

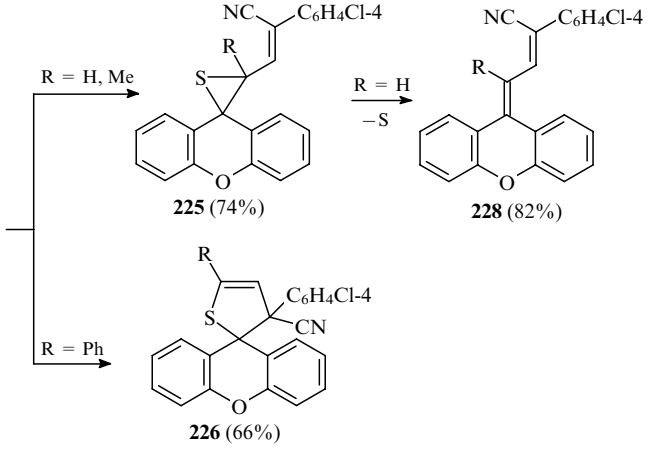


$R^1 = R^2 = R^3 = R^4 = Bu^t$; $R^1 - R^2 = CMe_2(CH_2)_3CMe_2$, $R^3 = R^4 = Bu^t$; B is a base.

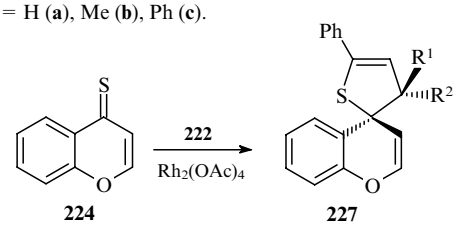
Various cumulenes and cumulene episulfides were prepared by the addition of alkenylidene dicarbenes to thioketenes.[123] Episulfides **217** were isolated as stable crystal compounds, which underwent predominantly desulfurisation on heating or photolysis to give tetraenes **218** in yields from 50% to 69% and were also partially isomerised to episulfides **219**. Substituted thietanethiones **221** were obtained as by-products (9% – 20%) due to the intermolecular transfer of the sulfur atom through biradical intermediate **220** (Scheme 4).

Vinylthiocarbonyl ylides generated from vinyldiazoalkanes **222** and thiochromones **223** or **224** gave 1,3- (**225**) or 1,5-electrocyclisation (**226** or **227**) products depending on the nature of substituents in the ylide.[124] Unstable thiirane **225** (R = H) was immediately converted into diene derivative **228** with elimination of sulfur. The reactions of diazo compounds **222a**,**b** with thiochromone **224** proceeded through the formation of analogous dienes. Diazo compound **222c** containing the bulkier phenyl substituent was involved in 1,5-electrocyclisation with the thiochromones **223** and **224** to give dihydrothiophene derivatives **226** and **227**, respectively.



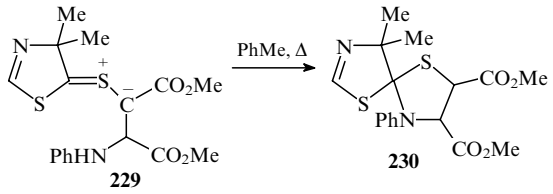


R = H (**a**), Me (**b**), Ph (**c**).

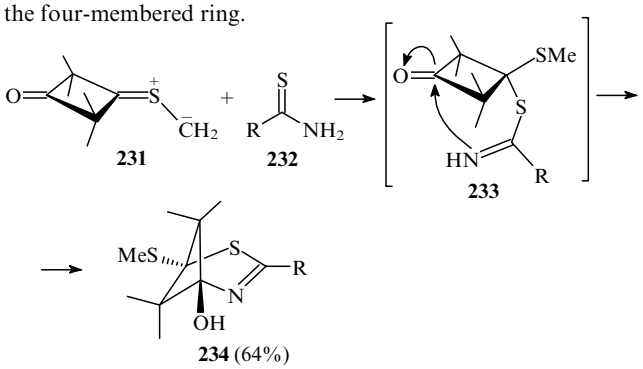


R^1 = CN, R^2 = C_6H_4Cl-4 (55%); R^1 = C_6H_4Cl-4, R^2 = CN (28%).

Amino-substituted thiocarbonyl ylide **229** underwent intramolecular condensation of a new type providing an approach to 1,6-dithia-3,9-diazaspiro[4.4]non-2-enes **230**.[125]



The reactions of thiocarbonyl ylide **231** with thioamides **232** were accompanied by unusual intramolecular cyclisation.[108] Adduct **233** generated initially underwent cyclisation to give 2-thia-4-azabicyclo[3.1.1]hept-2-ene derivative **234**. This is the first example of the nucleophilic addition of a cyclobutanone derivative to the carbonyl group proceeding without opening of the four-membered ring.

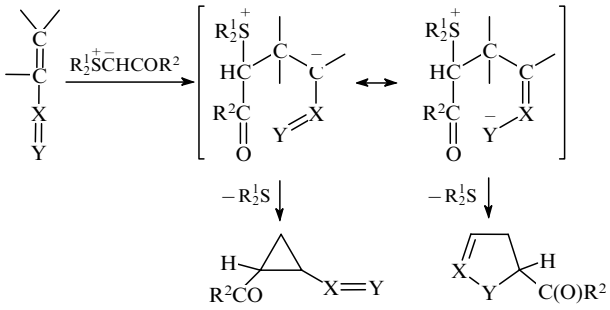


234 (64%)

R = Me, Ph.

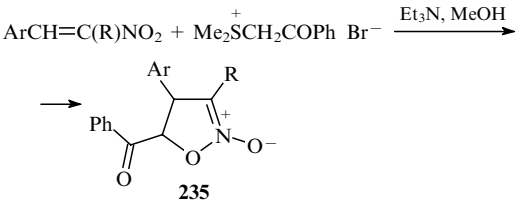
V. Cycloaddition of ylides to alkenes

The reactions of stabilised sulfonium ylides with electron-deficient alkenes of the C=C–X=Y type generally afford cyclopropanes (the $Ad_N-E_{1,3}$ mechanism);[6] however, five-membered heterocycles can also be formed due to the involvement of the activating X=Y group, where X=Y = NO_2, N=O or N=NAr (the $Ad_N-E_{1,5}$ mechanism).[10, 13]



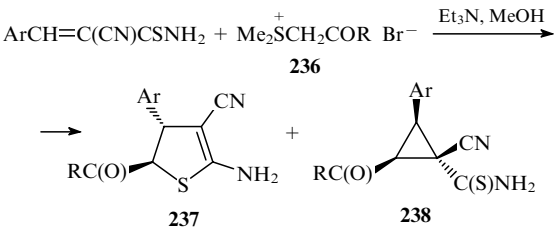
These reactions were considered in sufficient detail in the review,[13] which surveyed the data available up to 1986. Hence, we dwell only on the recent most interesting results published in the literature.

The reactions of nitroalkenes with stabilised sulfonium ylides were demonstrated [126, 127] to proceed stereoselectively to give both *trans*-4,5-dihydroisoxazole *N*-oxides **235** and substituted cyclopropanes, the ratio of the reaction products being essentially dependent on the α-alkyl substituent in nitroalkenes. In the case of bulkier substituents R, heterocyclic adducts are formed in substantially higher yields.



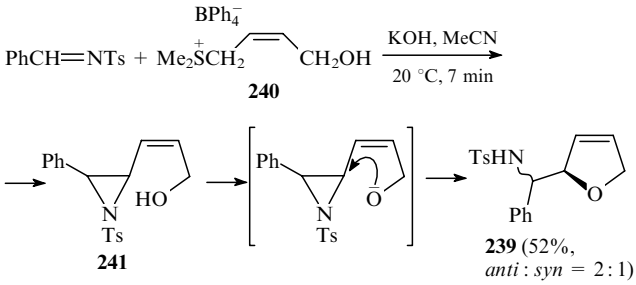
Ar = 3-$NO_2C_6H_4$, R = CO_2Et (85%); Ar = Ph, R = Me (41%).

The reactions of arylmethylenecyanothioacetamides with stabilised sulfur ylides **236** proceeded stereoselectively to give mixtures of 2-amino-4,5-dihydrothiophenes **237** and cyclopropanethiocarboxamides **238**.[128] In most cases, the dihydrothiophenes **237** were obtained as the major reaction products. For R = cyclo-C_3H_5, cyclopropane derivatives did not form at all.



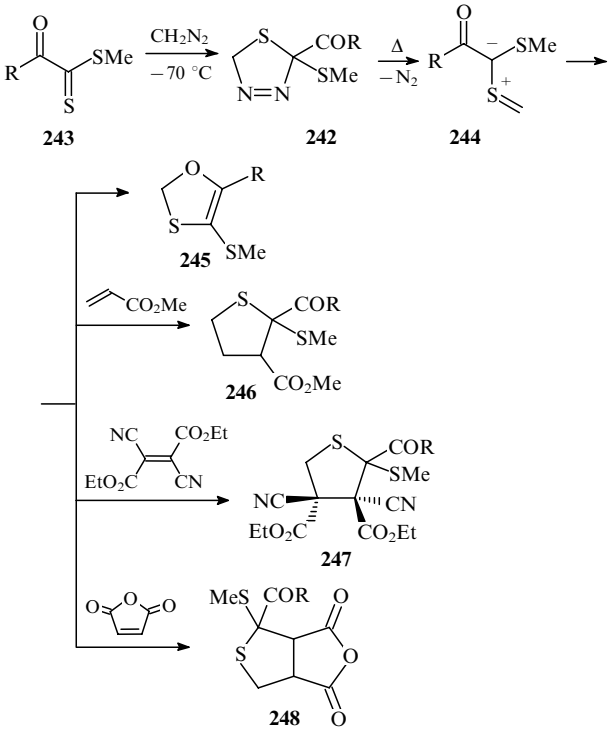
Ar = 2-MeC_6H_4, 2-$NO_2C_6H_4$, 4-$MeOC_6H_4$, 3-pyridyl, 2-thienyl;
R = Ph, 2-thienyl, cyclo-C_3H_5.

A simple and efficient procedure for the preparation of 2,5-dihydrofurans **239** containing the *N*-tosylamino substituent is based on the reaction of *N*-sulfonylimines with sulfur ylides generated from *cis*-4-hydroxybut-2-enyldimethylsulfonium salts **240**.[129] The assumed mechanism involves the formation of aziridine derivative **241**, ring opening through the attack of the internal nucleophile and subsequent cyclisation to form 2,5-dihydrofuran. The reaction involving the *trans*-isomer of the sulfonium salt **240** afforded only the aziridine derivative.

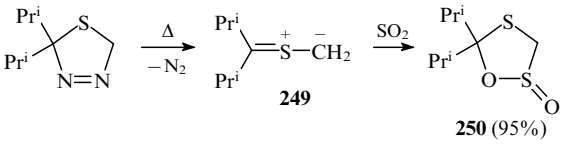


239 (52%, *anti* : *syn* = 2 : 1)

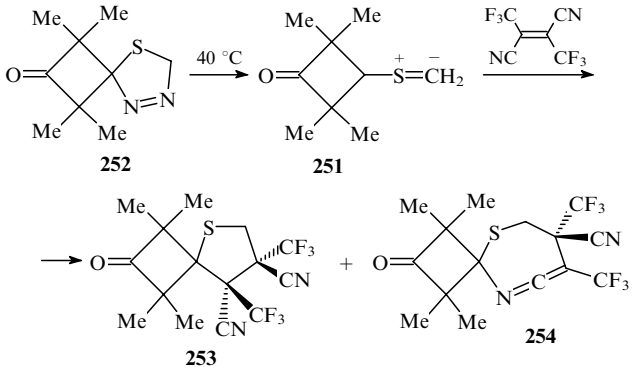
As mentioned above, thiocarbonyl ylides are readily involved in 1,3-dipolar cycloaddition to give the corresponding cycloadducts in high yields and with high regioselectively. Thus when heated, dihydrothiadiazoles **242**, which were formed in the reactions of diazomethane with derivatives of oxodithiocarboxylic acids **243**, gave intermediate **244**, which reacted with dienophiles to yield substituted thiolanes **246**–**248**.[130] In the absence of dienophile, the ylide **244** produced intramolecular cyclisation product **245**.



1,3-Dipolar cycloaddition of thiocarbonyl ylide **249** to sulfur dioxide gave rise to 1,2,4-oxadithiolane 2-oxide **250**.[131]

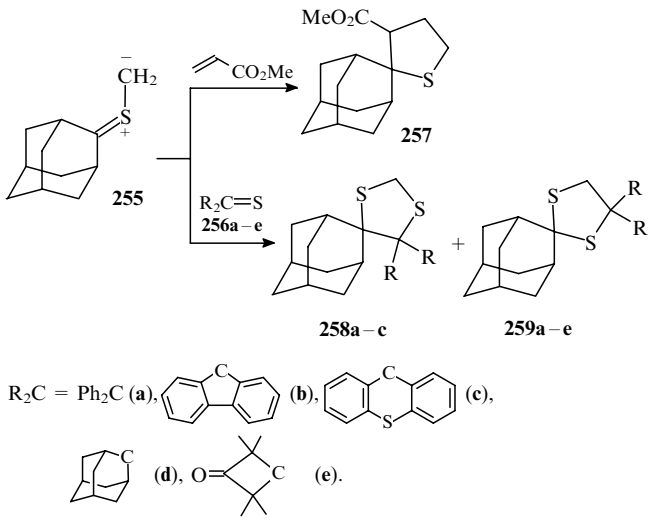


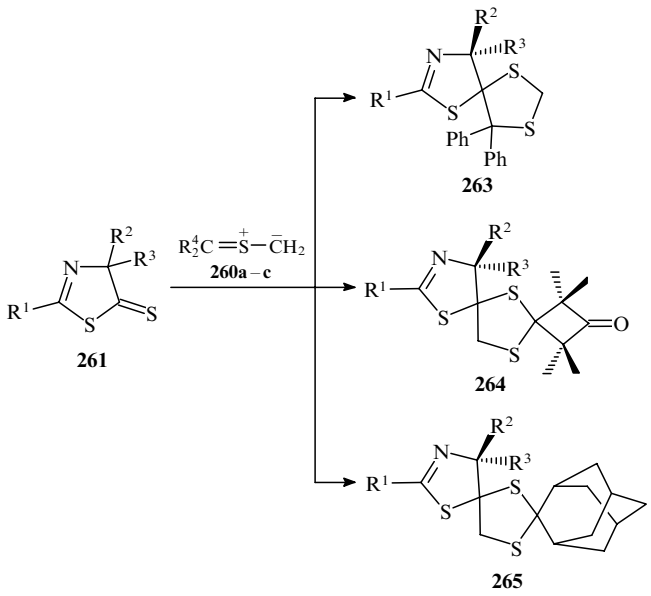
The reaction of thiocarbonyl ylide **251**, which was generated *in situ* from oxospiro[cyclobutanedihydrothiadiazole] **252**, with *trans*-1,2-bis(trifluoromethyl)-1,2-dicyanoethylene afforded thiolane **253** and stable strained cyclic ketenimine **254** in a ratio of ~1 : 4.[132]

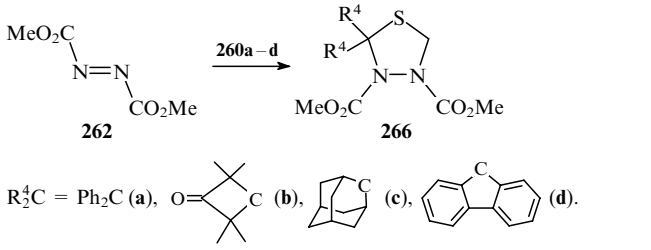


Adamantanethione-*S*-methylide (**255**) reacted with methyl acrylate to form substituted thiolane **257**, whereas its reactions with thioketones **256** gave rise to 1,3-dithiolanes **258a–c** and **259a–e**. The reactions involving thiobenzophenone (**256a**), thiofluorenone (**256b**) or thioxanthione (**256c**) produced two regioisomers.[133]

1,3-Dipolar cycloaddition of thiocarbonyl ylides **260** to thiazole-5(4*H*)-thiones **261**[134] or azodimethyl carboxylate **262**[135] proceeded with high regioselectivity to give the corresponding spirocyclic adducts **263–266** in high yields.







Cycloaddition of the thiocarbonyl ylides **251** and **260a** to *N*-sulfinylaniline and *N*-sulfinyltosylamide gave rise to both substituted 1,3,4-dithiazolidine 3-oxides (adducts at the N=S bond) and 1,2,4-oxadithiolane-2-tosylimides (adducts at the S=O bond).[136] The reactions of thioketones with diazoacetates performed on heating in THF[137,138] afforded acyl-substituted thiocarbonyl ylides as the initial reaction products, which either underwent 1,3- or 1,5-dipolar electrocyclisation or reacted with the second thioketone molecule to give a 1,3-dipolar cycloaddition product. The first example of 1,3-dipolar cycloaddition of thiocarbonyl ylide $CH_2=S-CH_2$ to fullerene C_{60} giving rise to a tetrahydrothiophene derivative was reported.[139] This product is a convenient starting compound for subsequent functionalisation.

* * *

As evident form the published data, the recent investigations dealt with more and more complex conversions involving sulfur ylides. We believe that the synthesis of heterocyclic compounds with unique structures and the total synthesis of natural products and biologically active synthetic analogues will be the major field of application of ylides in the coming years. The reactions of ylides producing alkaloids and alkaloid-like compounds are worthy of particular attention because they have an increasingly important place among drugs used in oncology and cardiology. There is no doubt that new biologically active compounds will be discovered among organosulfur heterocyclic compounds prepared by ylide procedures.

Abstract. Structures, taxonomic distribution and biological activities of polar steroids isolated from various marine organisms over the last 8 – 10 years are considered. The peculiarities of steroid biogenesis in the marine biota and their possible biological functions are discussed. Syntheses of some highly active marine polar steroids are described. The bibliography includes 254 references.

I. Introduction

The marine biota differs essentially from the terrestrial one in taxonomic composition and extreme diversity. This includes representatives of much more numerous large animal and plant taxa (*i.e.*, animal phyla and plant divisions) in comparison with those dwelling on land. Many of these taxa contain exclusively marine organisms (*e.g.*, echinoderms, bryozoans, ascidians, nearly all divisions of algae) or comprise very small groups of terrestrial species. For example, only one sponge family inhabits freshwater reservoirs, whereas all other sponges are exclusively sea and ocean dwellers. Taxonomic peculiarities of various producers and their unusual dwelling habitat provide the rationale for the non-coincidence of structures of the absolute majority of marine secondary metabolites and natural products found in terrestrial organisms.

The uniqueness and structural diversity of natural compounds isolated from marine organisms draw the attention of chemists to this particular field. Published material devoted to this problem can now be found in virtually every issue of the majority of international chemical journals. Chemical investigations of marine organisms are making rapid strides. Of $\sim$12 000 newly discovered compounds, 1400 are marine steroids.

It is well known that steroids play an important biological role. They represent constituents of biomembranes and hormones, fulfil protective functions, stimulate plant growth, *etc.* Many representatives of this group are widely used in medicine as essentials of antiinflammatory, anabolic and contraceptive drugs. Steroids isolated from various marine organisms (marine steroids) manifest diverse biological activities. Some of them are extremely toxic against tumour cells and show antimicrobial and other effects. It is therefore not surprising that marine steroids arouse considerable interest in not only chemists, but also in pharmacologists and physicians. Besides, these compounds fall under the scope of biology and biochemistry. Studies on taxonomic distribution of marine steroids make it possible to detect compounds which can be used as chemotaxonomic markers able to resolve many moot points in systematics of marine organisms and phylogenetic relationships in the marine biota. Since marine organisms comprise a large number of the so-called living fossils, comparison of their metabolisms with those of representatives of younger taxa sheds additional light on the evolution of secondary metabolic processes.

Polar (often, water-soluble) steroids constitute an abundant group of marine steroids;† many highly active and structurally unique compounds belong to this group. Studies of marine (including polar) steroids carried out before 1987 are reviewed in a monograph.[1] Some problems related to marine polar steroids are also discussed in the reviews [2, 3] published in the early 1990's. This review is an attempt to generalise the experimental data on marine polar steroids published over the last 8 – 10 years.

II. Polyhydroxysteroids and related compounds

Marine organisms contain a great number of oxygenated sterol derivatives; the majority of these secondary metabolites are related to polyhydroxylated derivatives. These compounds were found in algae and marine invertebrates, particularly in sponges, echinoderms and octocorals (one of the orders of the Anthozoa class which in turn belongs to the phylum Coelenterata). In this section, we shall consider those oxygenated marine steroids and related compounds which have been discovered very recently, namely, after 1993 when Minale *et al.*[2] published a review devoted to polyhydroxylated marine steroids.

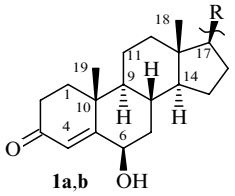
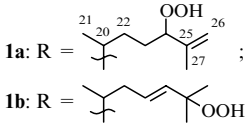
† Steroid compounds which contain three or more oxygen atoms as well as steroid alkaloids, sulfates, phosphates and glycosides of steroid aglycons are usually referred to as polar steroids.

1. Polyhydroxysteroids from algae

A series of steroid hydroperoxides **1a**,**b** and **2a**,**b** were isolated from the red alga *Galaxaura marginata* collected near the coasts of Taiwan.[4] These compounds manifest high cytotoxic activities against tumour cells P-388, KB, A-549, HT-29 (their semi-inhibiting concentrations, IC_{50}, lie within the range 0.2–1.0 μg ml^{-1}).

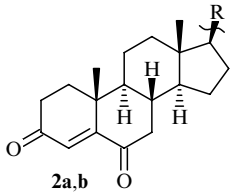


1a,**b**

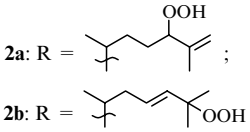


1a: R = ;

1b: R = .



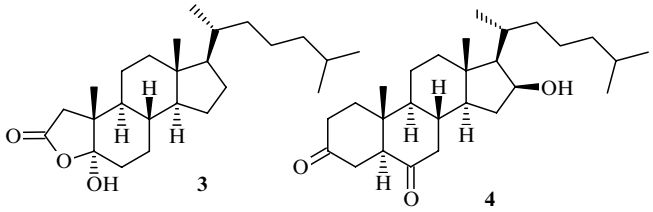
2a,**b**



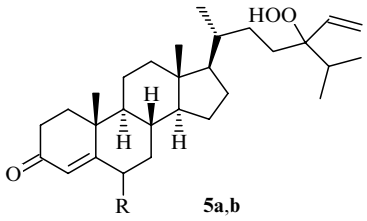
2a: R = ;

2b: R = .

The oxygenated 3,4-dinorcholestane derivative **3** was isolated from extracts of the red alga *Laurencia obtusa*.[5] The steroidal 3,6-diketone **4** oxygenated at C(16) was isolated from the alga *Jania rubens*, it exhibited high toxicity against some tumour cells ($IC_{50} \approx 0.5$ μg ml^{-1}) (see Ref. 6). The hydroperoxides **5a**,**b** isolated from the brown alga *Turbinaria conoides* also possessed cytotoxic properties.[7]



3 **4**



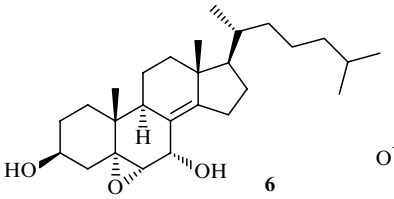
5a,**b**

5a: R = O;
5b: R = β-OH.

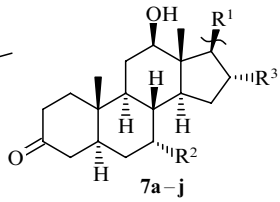
However, highly oxygenated sterols are not very common in algae. These metabolites are much more widely distributed in marine invertebrates.

2. Polyhydroxysteroids from sponges

The 5,6-epoxide **6** isolated from the sponge *Ircinia fasciculata* collected near the coasts of India [8] and a series of steroids isolated from the Taiwanese sponge *Xestospongia* sp., *viz*., aragusterols A–D (**7c**–**f**),[9–11] xestokerols A, B (**7a**,**b**) and aragusterols E–H (**7g**–**j**), relate to sponge polyhydroxysteroids.[12] Aragusterols and related compounds have unusual side chains, which contain cyclopropane fragments, while aragusterol C (**7e**) contains a chlorine atom in the side chain, which is a unique structural feature of natural steroids.



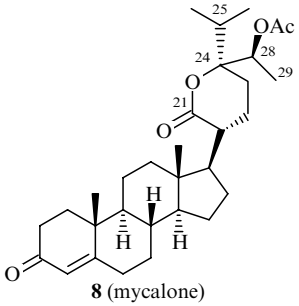
6



7a–**j**

Compound **7**	Name	R^1	R^2	R^3
a	xestokerol A		H	H
b	xestokerol B		OH	H
c	aragusterol A		H	H
d	aragusterol B		H	H
e	aragusterol C		H	H
f	aragusterol D		H	H
g	aragusterol E		H	H
h	aragusterol F		H	OH
i	aragusterol G (3α-OH)		H	H
j	aragusterol H (3β-OH)		H	H

It should be noted that the presence of unusual side chains in sponge polar steroids is due to the presence in the sponges of their precursors (sterols) having identical side chains. In contrast to higher plants where sterols represent minor components, some representatives of sponges and cnidarians (coelenterates) contain unusual sterols as predominant, and sometimes single components of steroid fractions. The side chain of the steroid ketone mycalone **8** from the Australian sponge *Mycale* sp. contains a lactone fragment formed upon oxidation of the ketone precursor at C(21) and C(24).[13]



8 (mycalone)

Among the compounds mentioned above, aragusterols manifesting strong cytotoxic and antitumour activities present special interest. The IC_{50} values of aragusterols **7c** and **7d** against tumour cells (KB) are 0.042 and 0.041 μg ml^{-1}, respectively. These steroids (1.6 mg kg^{-1}) increase the lifespan of mice with leukemia L-1210 *in vivo* by 220% and 257%, respectively.

5-Epiaragusterol A synthesised from deoxycholic acid possessed cytotoxic properties comparable to those of aragusterol A (**7c**).[14] The synthesis of aragusterols from (+)-hekogenin[15] included stereoselective formation of side chains, the addition of the corresponding fragment **9** to the 20-ketosteroid **10** prepared from hekogenin and preparation of aragusterol B (**7d**) *via* the intermediate **17** with subsequent transformation of **7d** into **7c**, **7e** and **8f** (Scheme 1). The triethylsilyl (TES) derivative **10** was synthesised in six steps from the readily available hekogenin. The fragment **9**, which is structurally similar to the side chain of

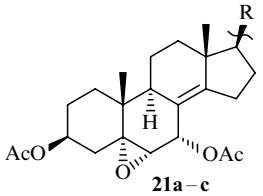
(*a*) Bu^t_3SiCl (TBSCl), imidazole, DMF (92%); (*b*) Me_2CuLi, Et_2O, −78 °C (90%); (*c*) $LiAlH_4$, THF; 80% AcOH (89%); (*d*) $Pb(OAc)_4$, K_2CO_3, benzene; $Ph_3P{=}CHCO_2Me$, benzene (67%); Bu^tPh_2SiCl (TBDPSCl), imidazole, DMF; Bu^i_2AlH (DIBAH), CH_2Cl_2, −78 °C (91%); (*e*) CH_2I_2, Et_2Zn + $BuBO_2(CH)_2(CONMe_2)_2$, CH_2Cl_2 (99%); (*f*) Ph_3P, CBr_4, CH_2Cl_2; $LiAlH_4$, THF–Et_2O; Bu^n_4NF, THF (88%); (*g*) Ph_3P, *N*-bromosuccinimide (NBS), CH_2Cl_2 (75%); (*h*) lithium naphthalenide, THF, 0 °C; Bu_4NF, THF (93%); (*i*) $Al(OBu^t)_3$, cyclohexanone, toluene (66%); (*j*) ethylene glycol, TsOH, boiling benzene (79%); (*k*) Bu^tO_2H, $VO(acac)_2$, CH_2Cl_2 (78%); (*l*) Pr^i_2NMgBr, THF (93%); 80% AcOH (98%); (*m*) *m*-CPBA, Na_2HPO_4, CH_2Cl_2, 0 °C (54%); (*n*) Li_2CuCl_4, THF (90%); (*o*) pyridinium dichromate (PDC), molecular sieves (4 Å), CH_2Cl_2 (100%).

aragusterols, was synthesised from (5*R*)-hydroxymethyl-2(5*H*)-furanone (**11**) which in its turn was prepared from L-ascorbic acid. Protection of the hydroxy group (as the tris-*tert*-butylsilyl ether) and subsequent reaction of the derivative **12** with lithium dimethylcuprate yielded the lactone **13** with high stereoselectivity. The latter was reduced, and the protective group was removed by treatment with acetic acid. The intermediate triol was converted into the allylic alcohol **14** in four steps, which included oxidation with lead tetraacetate, the Wittig reaction, protection of the hydroxy group as a silyl ether and subsequent reduction of the ester with diisobutylaluminium hydride. The key step in the synthesis of compound **9** was the conversion of the alcohol **14** into the cyclopropane derivative **15** by treatment with diiodomethane in the presence of diethylzinc and *N*,*N*,*N*′,*N*′-tetramethyl-(*S*,*S*)-tartarodiamide n-butylboronate. This reaction proceeded with high stereospecificity (yield 99%). Compound **15** was first converted into the alcohol **16** and then into the bromide **9**.

The stereoselective reaction of the 20-ketosteroid **10** with the alkyllithium derivative prepared from the bromide **9** and subsequent removal of the protective group at C(3) with tetrabutylammonium fluoride resulted in the alcohol **17** with high stereoselectivity. Its Oppenhauer oxidation gave aragusterol B (**7d**) which was further used for the synthesis of the other three aragusterols **7c**,**e**,**f** by chemical modification of the side chain *via* the intermediates **18**–**20**. The oxidation of the steroid alkene **18** to the epoxide **19** was carried out stereoselectively with *tert*-butyl hydroperoxide in the presence of vanadyl bisacetylacetonate.

The sponge *Spongia officinalis* represents the source of a series of novel 5,6-epoxysteroids **21a**–**c** and **22a**–**c** which were isolated as acetates and differed in the structures of side chains and the positions of double bonds in the steroid nuclei.[16] Compound **21a** was also isolated from *Ircinia fasciculata*.[8]



21a–**c**

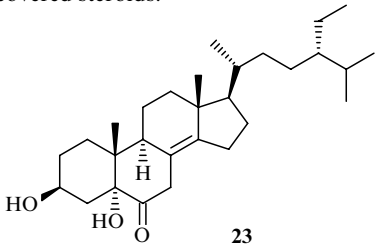
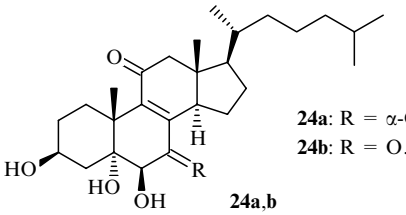
Steroids oxidised in positions 5 and 6 were repeatedly found in sponges where they were apparently formed from Δ^5-sterols.[17] The ketone **23** from *Spirostrella inconstans* is one of such newly discovered steroids.[18]



23

Incrustasterols A and B (**24a**,**b**) from the Mediterranean sponge *Dysidea incrustans* differ from other polar sponge steroids in the presence of $\Delta^{8(9)}$-7-hydroxy-9-keto- and $\Delta^{8(9)}$-7,9-diketo-fragments, which are uncommon for marine steroids.

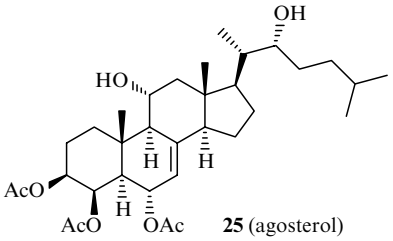


24a: R = α-OH, H;
24b: R = O.

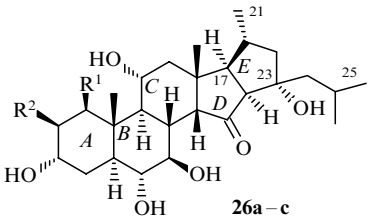
24a,**b**

Compounds **24a**,**b** are toxic for tumour cells (lung and kidney carcinomata, melanoma).[19] These compounds were synthesised from the readily available cholest-7-enol.[20]

The so-called agosterol **25** from *Spongia* sp. abrogates drug resistance of carcinoma cells, conditioned by enhanced expression of membrane glycoproteins.[21] Xestobergsterols A–C (**26a**–**c**), which contain five carbocycles with the *cis*-fused rings *C* and *D*, were found in *Xestospongia bergquistia* and *Ircinia* sp.[22,23] Presumably, the presence of an additional ring in these steroids is due to intramolecular aldol condensation of the yet non-isolated 23-keto derivative. Compounds **26a** and **26b** manifest cytotoxic activities and inhibit the anti-IgE-induced release of histamine from mast cells when used in small doses. Thus these compounds present considerable interest as potential active substances of novel antihistamine drugs. Their activities are closely related to strong inhibition of phosphatidylinositol phospholipase C.



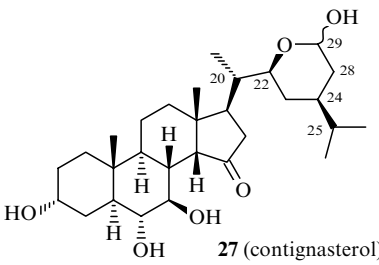
25 (agosterol)



26a: $R^1 = R^2 = H$;
26b: $R^1 = H$, $R^2 = OH$;
26c: $R^1 = R^2 = OH$.

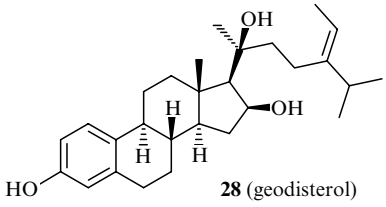
26a–**c**

Yet another polar sponge steroid with the *cis*-fused rings *C* and *D*, *viz*., contignasterol (**27**) from *Petrosia contignata*, discovered simultaneously with xestobergsterols[24] produces strong antihistamine effect. Although contignasterol is inferior to compounds **26a** and **26b** in the activity, it is far more active than antihistamine drugs routinely used in clinical practice and is the subject of intense pharmacological studies as a promising candidate for antiallergic and antiasthmatic drugs.



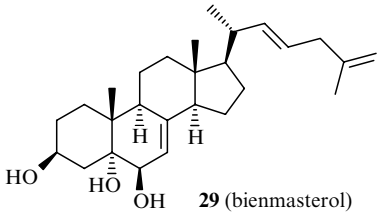
27 (contignasterol)

Geodisterol (**28**), the first marine steroid containing an aromatic ring *A*, was isolated from extracts of *Geodia* sp.[25]



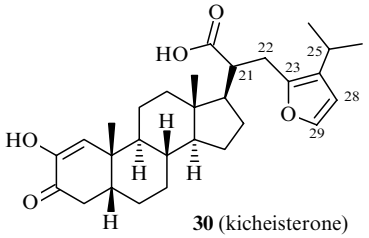
28 (geodisterol)

Previously, such compounds were referred to as hormones; however, in contrast to the latter, geodisterol (**28**) has a ten-carbon side chain characteristic of sterols. Bienmasterol (**29**) from *Bienma* sp.,[26] which is toxic against tumour cells (L-1210 and KB), contains a 22,25-diene fragment in the side chain, which is uncommon for natural steroids. An analogous fragment has been detected by us previously in baicalosterol isolated from the sponge *Baicalospongia bacilifera*.[27]

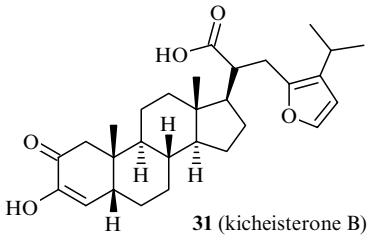


29 (bienmasterol)

Cytotoxic kicheisterones A and B (compounds **30** and **31**) with the *cis*-fused rings *A* and *B*, which contain carboxy groups in position 21 and furan fragments in the side chains, were isolated from an unidentified Hawaiian sponge of the Poecilosclerida order. These compounds are rather stable in acidic media but are easily interconverted in alkaline media to form 1 : 1 mixtures.[28]

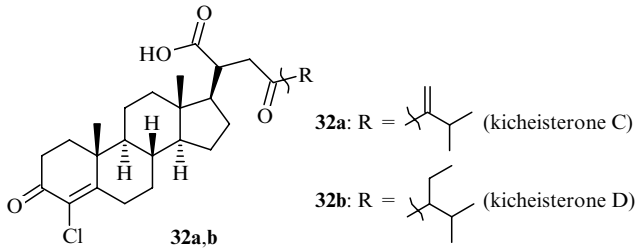


30 (kicheisterone)



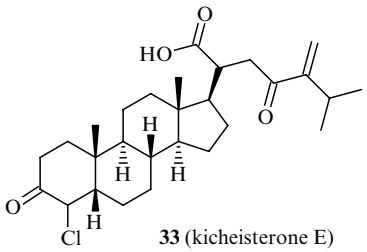
31 (kicheisterone B)

Steroids **30** and **31** were found in the sponge *Strongylacidon* sp. together with kicheisterones C–E (compounds **32a**,**b**, **33**). The latter contain chlorine atoms and belong to the group of extremely rare halogenated steroids.[29]



32a: R = (kicheisterone C)
32b: R = (kicheisterone D)

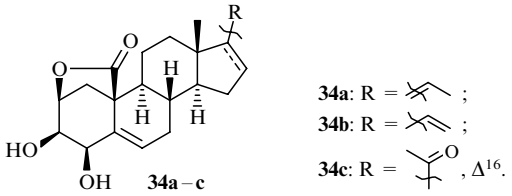
32a,**b**



33 (kicheisterone E)

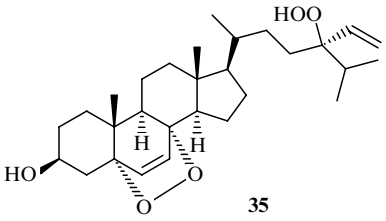
It is of note that no bromine-containing steroids have been isolated so far despite the wide occurrence of brominated metabolites in marine organisms.

Three pregnane derivatives **34a–c** from *Strongylophora* sp. were found to contain unusual (19 → 2)-lactone rings; their structures were established by X-ray diffraction analysis.[30] Hydroperoxides and related peroxides are more common for algal steroids; however, the novel biofouling inhibitor steroid **35** containing a peroxy group has recently been isolated from the sponge *Lendenfeldia chondrodes*.[31] Peroxides similar to compound **35** are readily formed by oxidation of $\Delta^{5,7}$-sterols, which are abundant in fungi, but scarce in sponges.



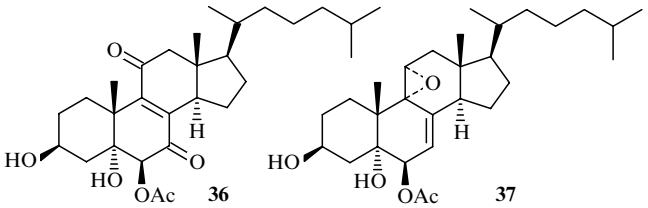
34a–c

34a: R = ;
34b: R = ;
34c: R = , Δ^{16}.

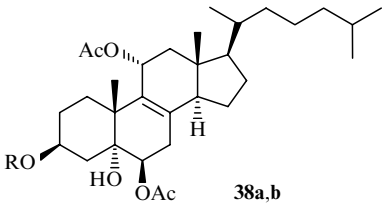


35

The novel acetylated polyhydroxysteroids **36**, **37**, **38a**,**b**[32] and related steroids[33] were detected in some sponges of the *Dysidea* genus. The steroid **37** and, to a lesser degree, steroids **38a**,**b** inhibit the binding of interleukin-8 to its specific receptor of the type A.



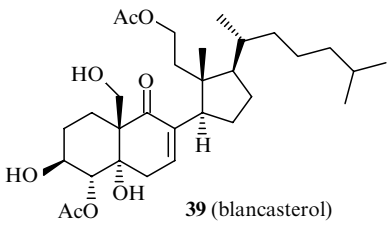
36 **37**



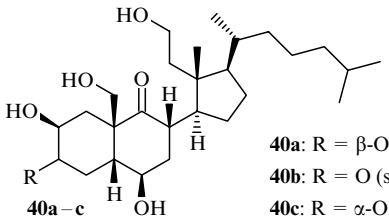
38a,**b**

38a: R = H;
38b: R = Ac.

Secosteroids occur widely in sponges. The most common of them are 9,11-secosteroids, such as blancasterol (**39**), a cytotoxic diacetate from the Northern Pacific sponge *Pleraplysilla* sp., which inhibits the growth of various tumour cells including drug-resistant cell cultures of human mammary carcinoma MCF-7.[34] Stelletasterol (**40a**), the antifungal secosteroid from *Stelletta* sp. isolated simultaneously with stelletasterone (**40b**),[35] differs from the previously known herbasterol (**40c**) from *Dysidea herbacea* only in the stereochemistry of the hydroxy group at the C(3) atom.



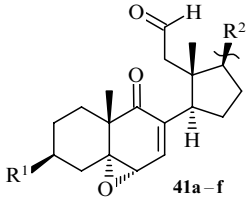
39 (blancasterol)



40a–c

40a: R = β-OH, H (stelletasterol);
40b: R = O (stelletasterone);
40c: R = α-OH, H (herbasterol).

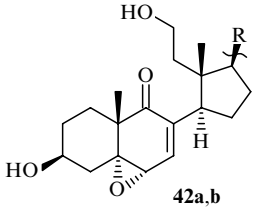
Like many other marine secosteroids, luffasterols A–C (**41a–c**) from *Luffariella* sp.[36] and the related secosteroid **41d** from *Spongia matamata*[37] contain 5,6-epoxy rings. 3-Deacetylluffasterol B (**41e**) and the related compound **41f** were isolated from *Spongia agaricina*. Both compounds manifest highly toxic activities against tumour cells.[38]



41a–f

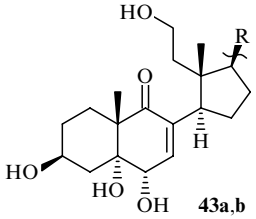
41a: R^1 = OAc, R^2 = (luffasterol A);
41b: R^1 = OAc, R^2 = (luffasterol B);
41c: R^1 = OAc, R^2 = (luffasterol C);
41d: R^1 = OH, R^2 = ; **41e**: R^1 = OH, R^2 = ;
41f: R^1 = OH, R^2 = .

Secosteroids **42a**,**b** and **43a**,**b** along with biogenetically related oxygenated sterols **44** and **45** were found in the Mediterranean sponge *Dysidea fragilis*.[39]



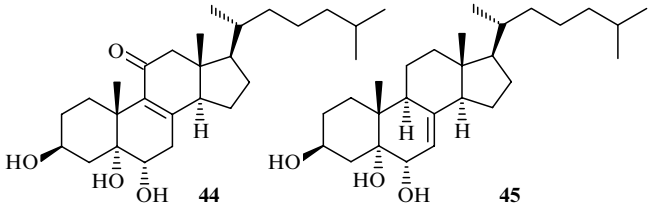
42a,**b**

42a: R = ;
42b: R = .



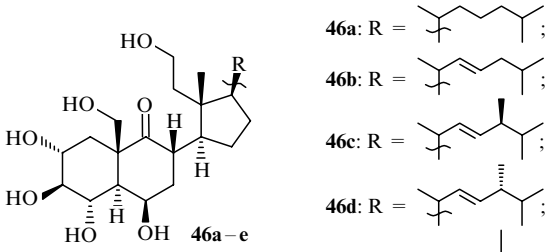
43a,**b**

43a: R = ;
43b: R = .

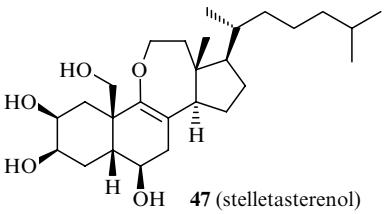


44 **45**

A series of euryspongiols **46a**–**e** and the epimeric 3α-hydroxy analogues possessing antihistamine properties were isolated from the sponge *Euryspongia* sp.[40] These compounds are the most strongly oxygenated sponge secosteroids known so far. The strong inhibiting effect of these and some other secosteroids on histamine release from mast cells during stimulation of the latter with anti-IgE suggests that marine secosteroids are promising candidates for antiallergic and antiasthmatic drugs.



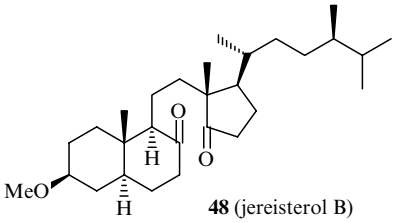
46a–**e**



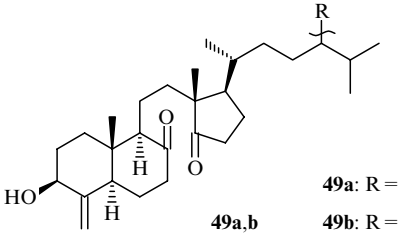
47 (stelletasterenol)

The unusual cyclic 9(11)-secosterenol, *viz*., stelletasterenol (**47**) from *Euryspongia arenaria,* contains an oxygen atom between the C(9) and C(11) atoms and manifests the properties of a PAF (platelet activation factor) agonist.[41]

In addition to 9,11-secosteroids common for marine invertebrates, sponges contain less abundant groups of compounds, which comprise 8,14- and 8,9-secosteroids. The former include jereisterol B (**48**) from *Jereicopsis graphidiophora*[42] and swinhosterols A and B (**49a**,**b**) from *Theonella swinhoe*.[43] Sponge 8,9-secosteroids are represented by unique 8α,9α-epoxy compounds, *e.g*., jereisterol A (**50a**) from *J. graphidiophora*[42] and its homologue **50b** isolated from the Senegalese sponge *Microscleroderma spirophora* together with the isomeric $\Delta^{8(14),9(11)}$ steroid **51**.[44] These compounds contain *O*-methyl groups, which occur rarely in natural steroids. Their structural analogues, *viz*., tilopiols A (**52**) and B (**53**), have recently been found in the microscopic fungus *Tilopilus plumbeoviolaceus*.[45] This finding suggests that microorganisms can be involved in the biosynthesis of sponge steroids **50a**,**b** and **51**.

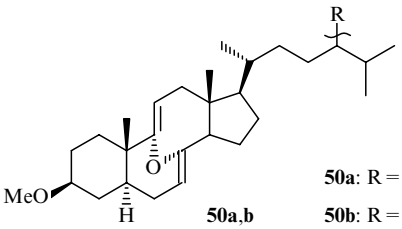


48 (jereisterol B)



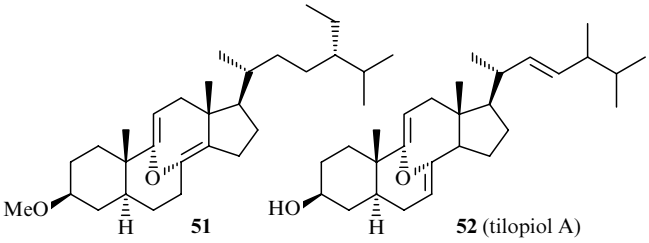
49a,**b**

49a: R = (swinhosterol A);
49b: R = (swinhosterol B).

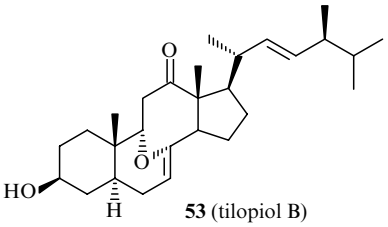


50a,**b**

50a: R = (jereisterol A);
50b: R = .



51 **52** (tilopiol A)



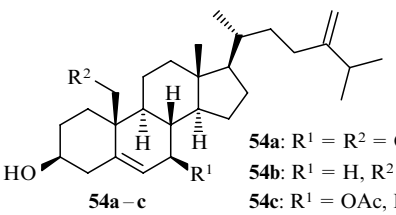
53 (tilopiol B)

It is not excluded that the great diversity of polar sponge steroids and the unique structures of many of them are due to biochemical conversions of the original sterols of both the sponge cells and microbial endosymbionts which are present in some sponges in amounts comparable to the populations of host cells. However, this hypothesis needs further verification and experiment in each particular case.

Although not a single sterol-oxidising enzyme has been isolated from sponges, symbiont bacteria, fungi or microalgae so far, such enzymes obviously differ from analogous enzymes of higher animals and terrestrial microorganisms in those sites in their sterol systems which oxidise the respective substrates. Thus some sponges were found to contain various secosteroids which are absent in terrestrial animals.

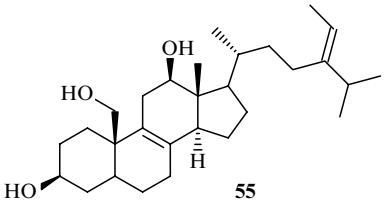
3. Polyhydroxysteroids from cnidarians

Polyhydroxysteroids are even more abundant in cnidarians (Coelenterata), particularly octocorals (soft corals) and gorgonian corals than in sponges. A great number of polyhydroxysteroids and secosteroids were detected in these marine invertebrates as long ago as 1970–1980. In the recent years, the list of these compounds was supplemented with many new names. Thus nephalsterol B (**54a**) found in *Nephthea erecta*,[46] *N. chabroli*[47] and *Litophyton arboreum*[48] [the latter contains additionally the $\Delta^{8(9)}$-triol **55** and related compounds, *e.g*., litosterol (**54b**) and nephalsterol C (**54c**)] are characteristic components of soft corals of the *Nephthea* genus. Compounds **54b**,**c** manifest strong antimicrobial activities, *viz*., they inhibit *Mycobacterium tuberculosis* by 90% and 96% when used in the doses of 3.13 and 12.5 μg ml^{-1}, respectively. The antituberculotic activity of nephalsterol B (**54a**) is less pronounced.[49]



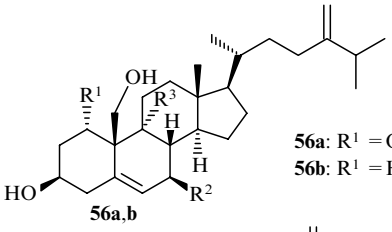
54a–**c**

54a: $R^1 = R^2 =$ OH (nephalsterol B);
54b: $R^1 =$ H, $R^2 =$ OH (litosterol);
54c: $R^1 =$ OAc, $R^2 =$ OH (nephalsterol C).



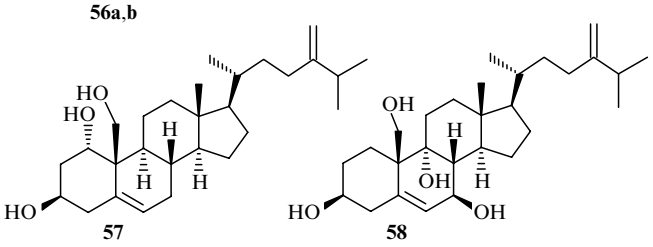
55

Some novel steroids of this series, *viz*., polyols **56a**,**b**, the triol **57** and the tetrol **58** from *Nephthea chabroli*, have recently been described.[47] Their structurally related analogues, *viz*., the triol **59** and the dihydroxy ketone **60**, were isolated from *Nephthea erecta* collected near the coasts of Taiwan.[46]

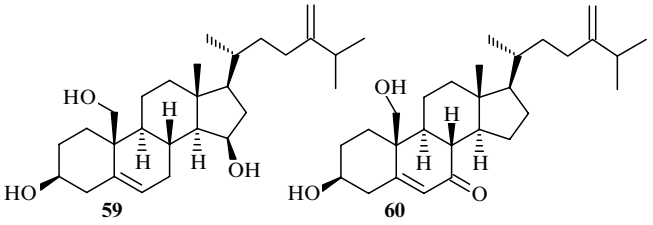


56a,**b**

56a: R^1 = OH, R^2 = R^3 = H;
56b: R^1 = H, R^2 = R^3 = OH.

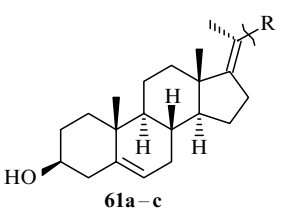


57 **58**



59 **60**

Triols **61a**,**c** and the tetrol **61b** from *Sinularia mayi* contain several hydroxy groups in their side chains.[50] The novel steroidal polyol **62** oxygenated at C(3), C(6), C(9) and C(11) was found in *S. hirta*.[51] The triol **63** and the corresponding glycosides were isolated from extracts of *S. gibbrosa*,[52] whereas the novel steroid pentol **64a** and its acetate **64b** were isolated from *S. dissecta*.[53] The pentol **65a** and the ketone **65b** from *Sinularia* sp.[54] and *S. microclavulata*,[55] respectively, contain oxygen atoms in the same positions, *viz*., at C(1), C(3), C(5), C(6) and C(16). The steroidal peroxide **66** from *Sinularia* sp.[56] proved to be highly toxic for tumour cells (IC_{50} = 0.4–2.7 μg ml^{-1}). This compound was isolated together with pregnenolone earlier detected in the sponge *Haliclona rubens*.[57] The stereochemistry of the C(22), C(23) and C(24) asymmetric centres of the peroxide **66** was established by comparison of its spectra with those of some synthetic model compounds.



61a–**c**

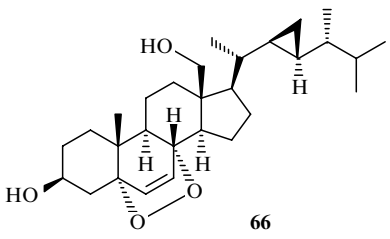
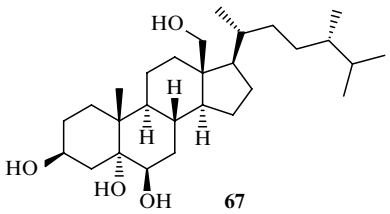
65a,**b**

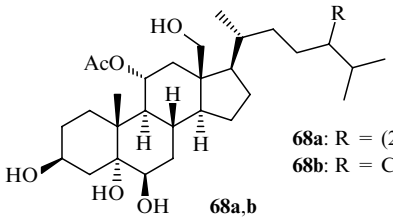


66

Several novel polar steroids were discovered in soft corals of the *Lobophyton* genus. For example, the tetrol **67** was isolated from *L. crassum*,[58] whereas two monoacetates **68a**,**b** were isolated from *L. cf. pauciflorum*.[59] These steroids contain 5α,6β-diol fragments similar to those present in oxygenated steroids isolated from soft corals of the *Sarcophyton* genus. For example, sarcoaldesterol B (**69a**) represents a deacetylated derivative of the steroid **68a**. It was isolated from the Okinawian soft coral *Sarcophyton* sp.



67



68a: R = (24*S*)-CH_3;
68b: R = CH_2=.

68a,**b**

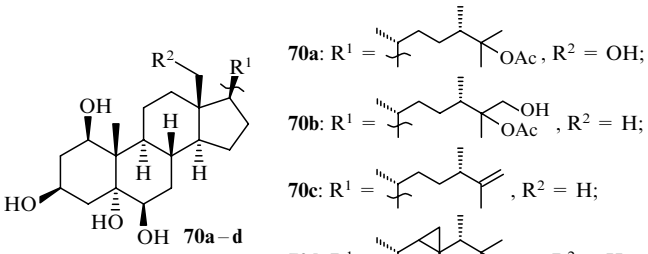
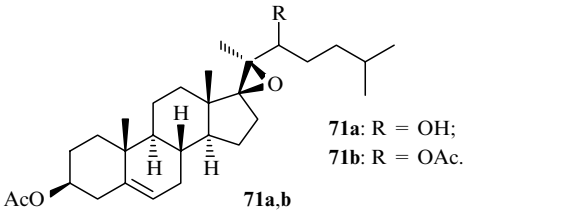
69b: R =  .

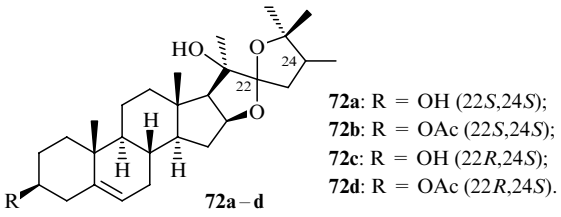
69a,**b**

together with sarcoaldesterol A (**69b**), which contains a side chain similar to that of gorgosterol, the well-known sterol of cnidarians.[60]

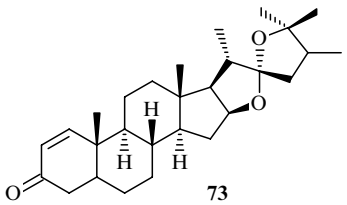
Steroids **70a**–**d** from the soft coral *S. subviride* collected near the coasts of the Andaman Islands are oxygenated to a greater degree. Some of them contain an acetate group at C(25) characteristic of polar steroids of Coelenterata.[61] Two novel polar steroids **71a**,**b** containing unique 17,20-epoxy fragments, two hippurin derivatives **72a**,**c** differing in stereochemistry at C(22) (hippurin is a well-known polar steroid of Coelenterata) and their acetates **72b**,**d**, were isolated from extracts of *S. crassocaule*.[62]

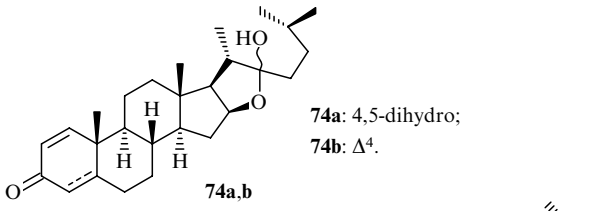


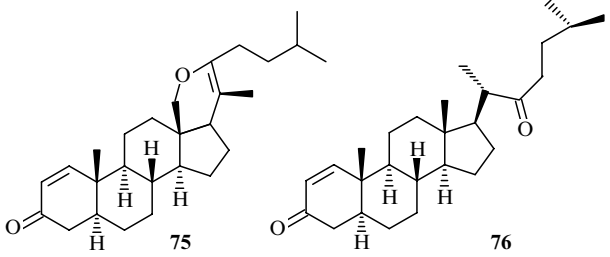




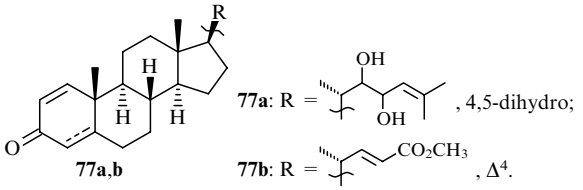
A series of polar steroids including the hippurin analogue, *viz*., compound **73**, as well as derivatives **74a**,**b**, **75** and **76** were detected in the soft coral *Alcyonium gracilum* by Shin *et al*.[63] Presumably, compound **76** is a biosynthetic precursor of all this group of secondary metabolites.



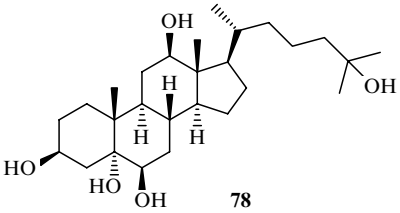


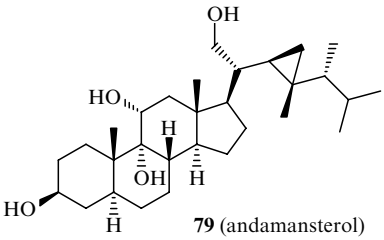


Yet another species of this genus, *viz*., *Alcyonium gracilum* (its mixture with *Dendronephthea* sp. has been studied), contains related steroids **77a**,**b**,[64] which are toxic for barnacle (*Balanus amphitrite*) larvae (LD_{100} = 100 μg ml^{-1}).

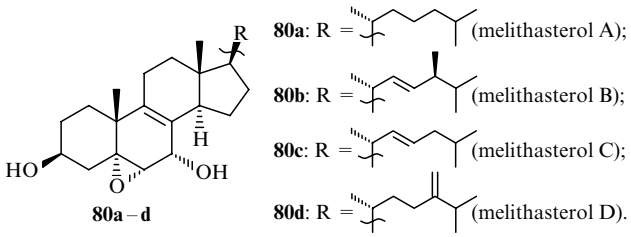


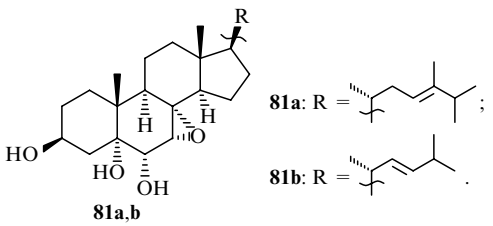
The steroidal pentol **78** was found in the soft coral *Sclerophytum* sp. together with several previously known steroids.[65] Andamansterol (**79**) [66] containing hydroxy groups in positions 9 and 11, which takes its name after the place where it was first collected (Andaman Islands), was detected in another unidentified species of the same genus. Such oxidation can precede the formation of 9,11-secosteroids widely distributed in marine invertebrates. An interesting feature of andamansterol (**79**) is the presence of a hydroxy group at C(21), which is uncommon for polar steroids of Coelenterata, but is common for steroids of some echinoderms, particularly, for ophiuroid metabolites.

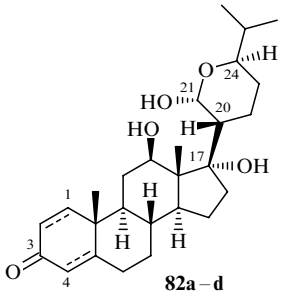




Gorgonian corals are distinguished for a great diversity of oxygenated steroids containing from 2–3 to 5–6 oxygen atoms. Thus melithasterols A–D (**80a**–**d**), each containing an 5,6-epoxy ring and an additional OH-group in position 7, were found in *Melithaea ocracea*.[67] Melithasterol A (**80a**) has recently been synthesised.[68] Steroids **81a**,**b** from *Acabaria undulata* also contain epoxide rings, however, in positions 7 and 8.[69] Anastomosacetals A–D (**82a**–**d**) from *Euplexaura anastomosans* collected near the coasts of Korea contain oxygen atoms in positions 17, 21 and 24.[70]



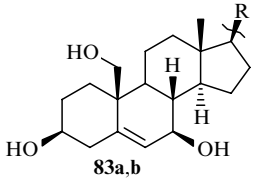




82a–**d**

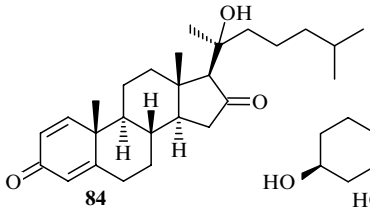
82a: $\Delta^{1,4}$ (anastomosacetal A);
82b: Δ^{4} (anastomosacetal B);
82c: Δ^{1} (anastomosacetal C);
82d: 1,2,4,5-tetrahydro (anastomosacetal D).

The so-called black coral *Anthiphates subpina* related to the Antipatharia order contains steroid triols **83a**,**b** and diketone **84**, which are toxic for crustaceans.[71] The tetrol monoacetate **85a** and the corresponding tetrol **85b** were isolated from *Telesto viisei*.[72]

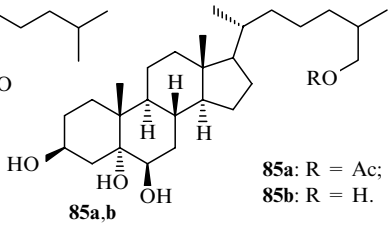


83a,**b**

83a: R =  ;
83b: R =  .



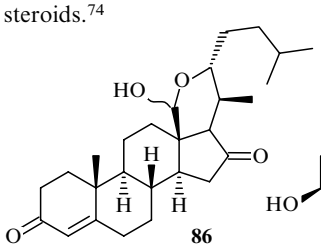
84



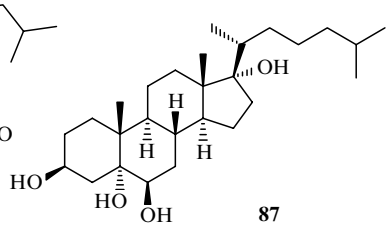
85a,**b**

85a: R = Ac;
85b: R = H.

The steroidal hemiacetal **86** possessing antimicrobial, antiviral and antitumour properties was isolated from the gorgonian coral *Ctenocella* sp.[73] Punacine (**87**) from the gorgonian coral *Lophogorgia punicea* dwelling near the coasts of Brazil contains a hydroxy group at C(17), which is uncommon for cnidarian steroids.[74]

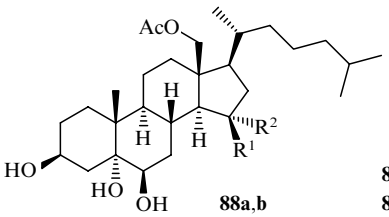


86



87

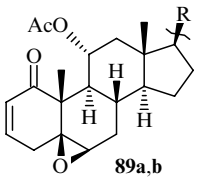
Polyhydroxylated steroids **88a**,**b** from the octocoral *Dendronephthea gigantea*[75] manifested moderate cytotoxic activities against tumour cells (L-1210).



88a,**b**

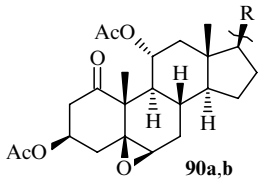
88a: $R^1 = R^2 = H$;
88b: $R^1 = OH$, $R^2 = H$.

A series of steroids oxygenated in positions 1, 5, 6 and 11 (compounds **89a**,**b**, **90a**,**b**, **91a**–**d** and **92**) were isolated from the Okinawian coral *Clavularia viridis*.[76] Compounds **89a**,**b** manifest cytotoxic properties and are similar to vitanolides, the higher terrestrial plant metabolites, in the structures of their polycyclic fragments.



89a,**b**

89a: R =  ;
89b: R =  .



90a,**b**

90a: R =  ;

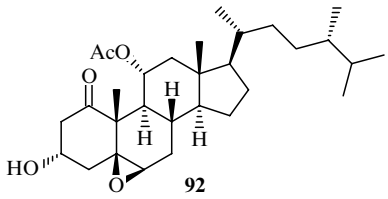
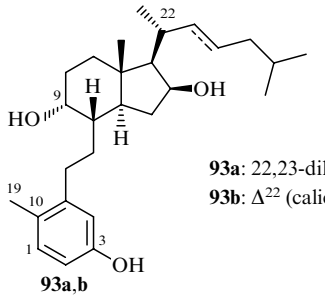
91a: R =  ;
91b: R =  ;
91c: R =  ;
91d: R =  .



92

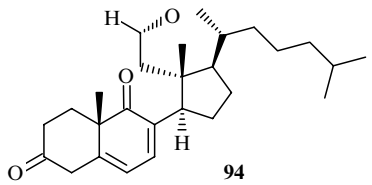
Secosteroids are common metabolic products of octocorals. The 9,10-secosteroids, *viz*., calicopherols A and B (**93a**,**b**), which are toxic for shrimps, were isolated from the gorgonian coral *Caligorgia* sp. collected near the coasts of Japan.[77] A series of novel calicopherols differing structurally from compounds **93a,b** have recently been isolated from the gorgonian coral *Muricella* sp. These compounds manifest high cytotoxic activities against tumour cells and inhibit phospholipase A_2.[78]



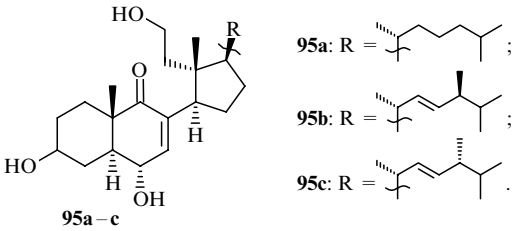
93a,**b**

93a: 22,23-dihydro (calicopherol A);
93b: Δ^{22} (calicopherol B).

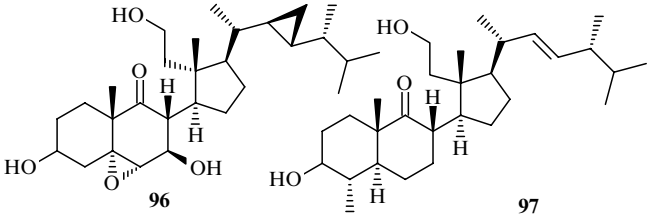
9,11-Secosteroids are much more abundant in soft and gorgonian corals. Among the most recent findings, we should make reference to dioxoaldehyde **94** from *Subergorgia suberosa* collected near the coasts of India;[79] steroids **95a**–**c** from the same species collected near the coasts of the Comores Islands;[80] the epoxide **96** from the Indonesian coral *Lobophytum* sp.[81] and 4α-methylsecosteroids **97** and **98** from *Pseudopterogorgia* sp.[82] manifest moderate inhibitory activities with respect to protein kinase C and possess antiinflammatory and cytotoxic properties.



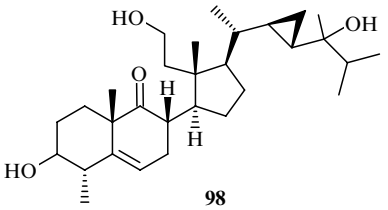
94



95a–c

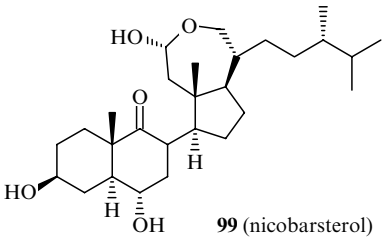


96 **97**



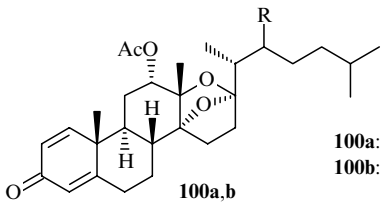
98

The unusual hemiacetal **99** (nicobarsterol) from *Sclerophytum* sp. was named after the place where it was first collected (the Nicobar Islands in the Indian Ocean).[66]



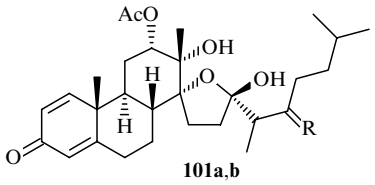
99 (nicobarsterol)

A search for novel compounds able to prevent biofouling of ship bottoms and submerged structures undertaken by the Fusetani group[93] resulted in the isolation of four novel unprecedented 13,17-secosteroids **100a**,**b** and **101a**,**b** (isogosterols A–D) from *Dendronephthea* sp. They manifested much higher antifouling activities in comparison with steroids **77a**,**b** and inhibited the settlement of barnacle (*Balanus amphitrite*) larvae when used in concentrations of ~ 2 μg ml^{-1} (see Ref. 83).



100a,**b**

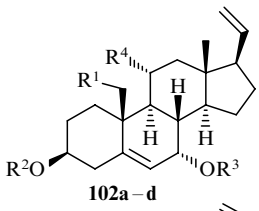
100a: R = H (isogosterol A);
100b: R = OAc (isogosterol D).



101a,**b**

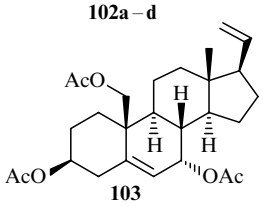
101a: R = O (isogosterol B);
101b: R = OAc, H (isogosterol C).

Oxygenated steroids with the pregnane skeleton were often found in various representatives of Coelenterata; in particular, acetylated pregnanes **102a–d** and **103** have recently been found in the South African population of *Pieterfaura inilobata*.[84]



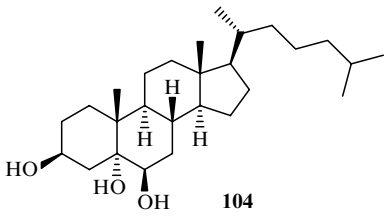
102a–d

102a: $R^1 = R^3 = H$, $R^2 = Ac$, $R^4 = OH$;
102b: $R^1 = H$, $R^2 = R^3 = Ac$, $R^4 = OH$;
102c: $R^1 = OAc$, $R^2 = Ac$, $R^3 = R^4 = H$;
102d: $R^1 = OAc$, $R^2 = R^3 = Ac$, $R^4 = OH$.



103

The detection of polar steroids in the sea pens of the Pennatulaceae order is the most uncommon case. Thus the triol **104**, the simplest oxygenated steroid formed upon oxidation of cholesterol at the 5(6)-double bond, was isolated from *Pteroides esperi*.[85]



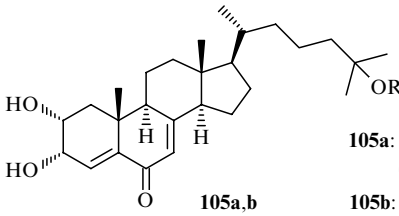
104

It should be said in conclusion that hydroxylation in Coelenterata predominantly occurs in positions 3, 5, 6, 22 and 25 and less frequently in positions 1, 2, 11, 16, *etc*. Steroids containing angular hydroxymethyl groups are widespread in these invertebrates; the oxygenation of the 19-methyl group occurs most often. In these animals, sterols can be oxidised to pregnane derivatives. 9,11-Seco compounds are as widely occurring in cnidarians as in sponges. It is noteworthy that polar steroids are seldom found in other taxa of Coelenterata, with the exception of octocorals.

4. Polyhydroxylated steroids from molluscs

Polar steroids are seldom found in molluscs, usually these are of exogenous origin, *viz*., they are consumed with food and accumulated in either an unchanged or a modified form. In most cases, the steroids accumulated in molluscs play the protective role.

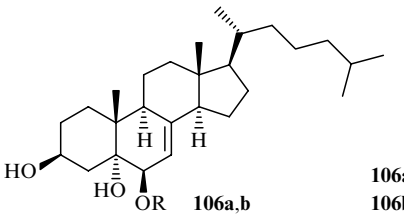
For example, unusual 2α,3α-dihydroxy cross-conjugated ketones, such as diaulusterols A and B (**105a**,**b**), one of which containing a hydroxybutyrate substituent in the side chain, were detected in the nudibranch mollusc *Diaula sandiegensis*.[86] Recent *in vitro* studies of 1,2-^{13}C-acetate as a biosynthetic precursor showed that the steroid **105a** is not biosynthesised by these molluscs but is modified by addition of a substituent to the hydroxy group at C(25); this substituent is biosynthesised from acetate.[87] It is of note that nudibranch molluscs are devoid of shells and other mechanical protective means, they readily absorb toxic and deterrent metabolites from the sponges they feed on.



105a,**b**

105a: R = $COCH_2CH(OH)CH_3$ (diaulusterol A);
105b: R = H (diaulusterol B).

The triol **106a** and its 6-*O*-methyl derivative **106b** widely occurring in sponges were isolated from fertilised eggs of the mollusc *Aplysia juliana*.[88]



106a,**b**

106a: R = H;
106b: R = CH_3.

5. Polyhydroxysteroids of echinoderms

Echinoderms, particularly starfishes, are the source of the most oxygenated steroids. A great number of polyhydroxy derivatives have been discovered in these organisms since 1974. More than 20 novel compounds, (compounds **107**–**128**)[89–95] have been isolated recently (Table 1). The hydroxy groups in positions 3β, 6α or 6β, 8β, 15α or 15β, 16β and 26 are especially abundant in starfish steroids, while polyhydroxysteroids containing hydroxy groups in positions 4α or 4β, 7α, 14α, 24, 28 and 29 are isolated less often. Some starfish polar steroids contain eight or nine hydroxy groups,

Table 1. The structures of polyhydroxysteroids isolated from starfishes.

Compound	Unsaturation type	R^1	R^2	R^3	R^4	R^5	R^6	The side chain (R^7)	The biological source	Ref.

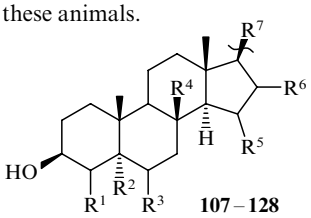
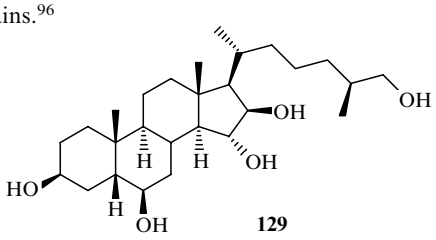
although the corresponding pentols and hexols are more common for these animals.

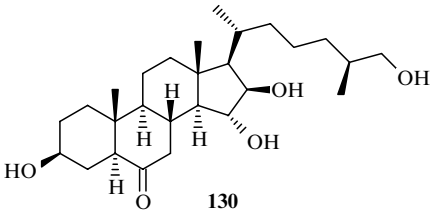


107 – 128

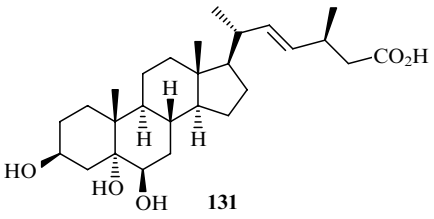
Sometimes starfish metabolites contain other functional groups or manifest other structural features. For example, the pentol **129** from *Luidia clathrata*[92] is a 5β-cholestane derivative in contrast to other polar steroids of this series. One of the hydroxy groups in compound **130** from Echinasteridae gen sp. is oxidised to the keto group,[91] whereas steroids **131** and **132** from *Myxoderma platyacanthus* contain carboxy groups in their side chains.[96]



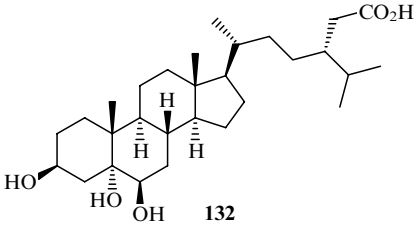
129



130



131



132

Recent studies on the distribution of polyhydroxy compounds in various body components and organs and structures of starfishes[97] prompted several conclusions concerning their biological roles. Since polyhydroxysteroids and related mono- and biosides were found only in digestive organs and solubilise lipid suspensions like bile acids, their role in starfishes can be similar to that of bile acids and bile alcohols in vertebrates.

Some starfish polyhydroxysteroids manifested antimicrobial activities against the gram-positive bacterium *Staphylococcus aureus* but did not inhibit the gram-negative bacterium *Escherichia coli*. A series of octols and nonols containing hydroxy groups in positions 4, 7, and 8 manifested high cytotoxic activities against human lymphoma cells JURCAT.[98]

It is interesting to note that polyhydroxysteroids are not common in other classes of echinoderms. Related sulfated polyols were found only in ophiuroids, whereas in holothurians and sea urchins polar steroids have not been identified yet. Recently, steroidal 3β,5α,6β-triols of the Δ^7-series were found in one representative of sea lilies (Crinoidea).[99]

Not all groups of marine invertebrates are rich in polyhydroxysteroids. The latter are not common for bryazoans and ascidians, but occur predominantly as ecdysteroids in crustaceans; however this group of polar steroids fall beyond the scope of the present review. In sponges, cnidarians and echinoderms, they are represented by only very few orders or classes. Notwithstanding, the immense diversity of marine polyhydroxysteroids is amazing and seems to reflect the intense evolutional search characteristic of taxa located in the basements of phylogenetic trees. Obviously, cnidarians and sponges are the most ancient animal organisms that have come down to us.

The biological roles of oxygenated sterol derivatives and related pregnane and other steroids are different in vertebrates and marine invertebrates. Whereas in the former they predominantly act as hormones and take part in digestion as bile acids, in sponges and cnidarians they usually perform protective functions, *e.g.*, they frighten away predators, inhibit the growth of pathogenic microorganisms, protect producers from fouling with algae, barnacles, molluscs, *etc.*

It is interesting to note that there are such biochemical transformations of sterols in some primitive marine invertebrates, which as happy findings of the Nature are repeated many time in other types of organisms and become to be of considerable importance in more advanced animal taxa and in higher plants. For example, as it was mentioned above, sponges and cnidarians contain pregnenolone, a biosynthetic precursor of steroid hormones of higher animals. Compounds of the spirostane series, which are analogous to aglycons of steroid saponins of higher plants, were repeatedly found in cnidarians and some other marine invertebrates. C_{28}-Steroid lactones, which are structurally similar to some witanolides (metabolites of terrestrial higher plants of the *Solanaceae* family), were found in the soft coral *Minabea* sp.[100] These biochemical parallelisms presumably testify to some degree of determinism in evolution of secondary metabolic processes occurring in living organisms.

III. Steroid sulfates

Sulfated compounds are extensively distributed in marine organisms. They were found in micro- and macroalgae, marine invertebrates (*e.g.*, sponges, echinoderms, molluscs), hemichordates and fishes. Sulfation is an essential mechanism of biosynthetic conversions occurring in the marine biota. This is not surprising, since sulfur (in the form of a sulfate ion) is the fourth most abundant

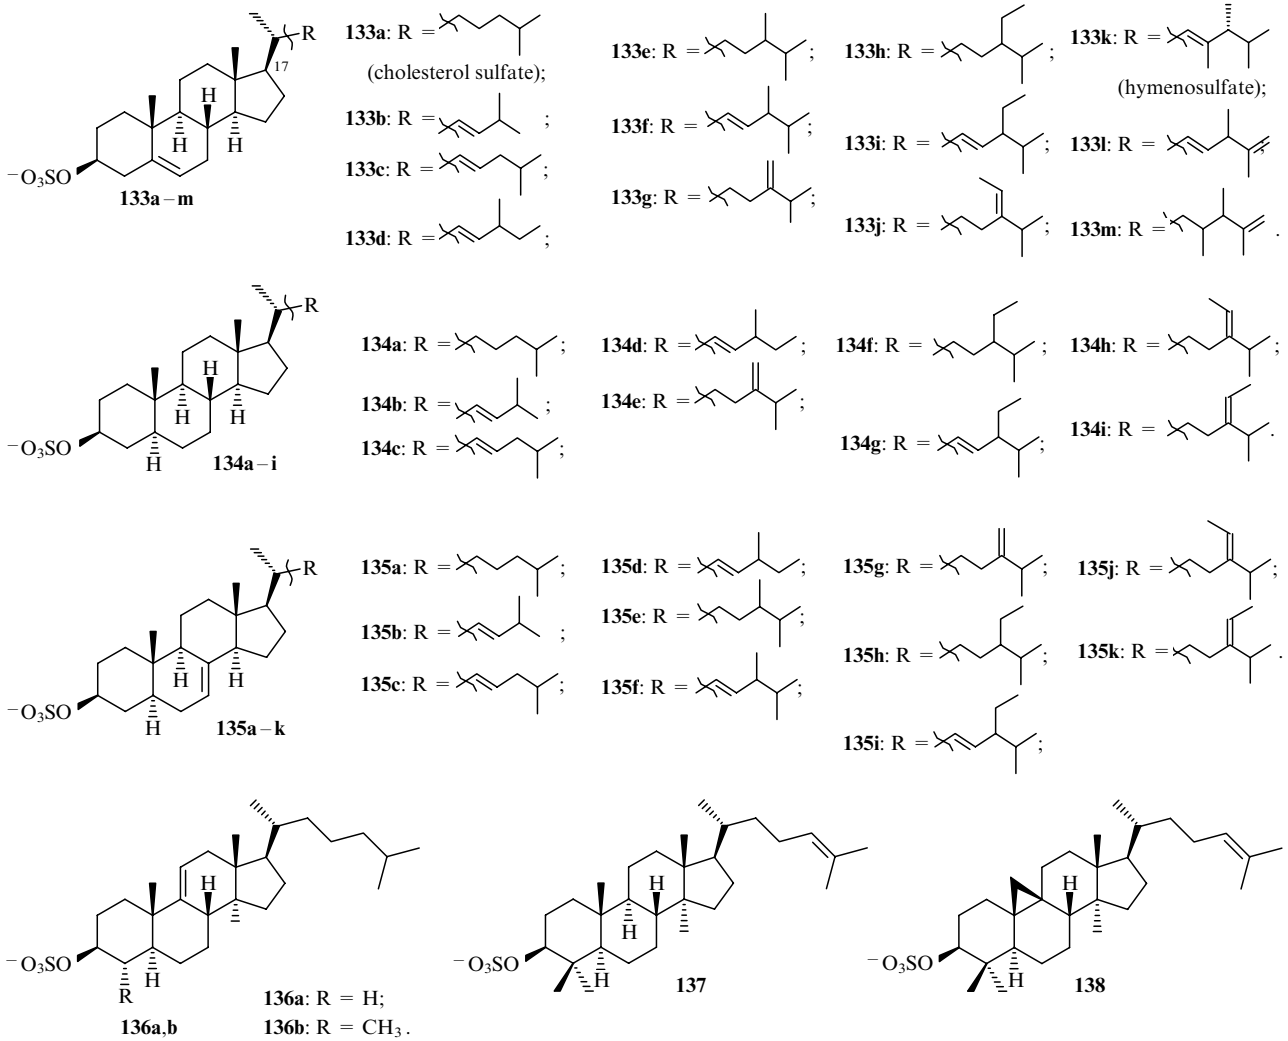
element in sea water after chlorine, sodium and magnesium. The introduction of a sulfate group increases the solubility of marine natural products and makes them biphilic, which is especially important for manifestation of their detergent and toxic activities and signal functions in various inter- and intraspecies interactions. The presence of sulfate groups ensures efficient transport of the corresponding compounds in water, while the presence of hydrophobic fragments in their molecules facilitates their binding to hydrophobic receptors of recipient organisms.

In macroalgae and some microalgae, sulfated compounds are largely represented by polysaccharides, while those in marine animals are represented by low-molecular-weight bioregulators. Over 500 sulfated secondary metabolites of different chemical groups (*e.g.*, terpenoids, carotenoids, steroids, alkaloids, aromatic metabolites, *etc.*) have been identified.[101]

Sulfated steroids constitute one of the most numerous groups of these compounds. They were mostly isolated from animals related to two large phyla of marine invertebrates, *viz.*, echinoderms (Echinodermata) and sponges (Porifera), although sulfated steroids were also found in other marine organisms. The biological functions of compounds related to this group are still poorly understood, although the facts that the least polar of them are essential components of biomembranes, while other representatives of this group are used for chemical protection against predators and pathogenic or fouling microorganisms leave no doubts.

1. Sterol sulfates

Structurally, sterol sulfates are the simplest sulfated steroids. In echinoderms, they occur as common metabolites; their concentrations in starfishes (Asteroidea), holothurians (Holothurioidea), ophiuroids (Ophiuroidea) and sea lilies (Crinoidea) amount to 4–5 mg per gram of dry tissue, those in sea urchins (Echinoidea) are somewhat lower.[1] The predominant component in the respective fractions is cholesterol sulfate **133a**. In addition, these fractions always contain sulfates of other Δ^5-sterols. Toxic representatives of holothurians and starfishes contain small amounts of sulfated stanols and sulfates of Δ^7-sterols along with sulfates of the Δ^5 series. For example, the Far Eastern holothurian *Eupentacta* (= *Cucumaria*) *fraudatrix* was found to contain polar steroids **133a**–**i**, **134a**–**k** and **135a**–**l**. Moreover, the same holothurian species contain trace amounts of sulfates of 14α-methyl-$\Delta^{9(11)}$-sterols **136a**,**b** and of triterpenoids **137** and **138**.[102] Practically all free sterols from *E. fraudatrix* are subject to sulfation, however, in different degrees. Δ^5-Sterols (in the first place, cholesterol), which are consumed with food, are sulfated in the greatest degree. In contrast with sulfates, free sterols of the Δ^5 series are present in toxic holothurians in small amounts; they can be transformed into sulfates, stanols and Δ^7-sterols. Stanols and Δ^7-sterols, contrariwise, predominate in fractions of free sterols, but are sulfated in a very low degree. These peculiarities of steroid metabolism in holothurians and starfishes are explained by the presence of toxic glycosides, which react with the membrane cholesterol and other Δ^5-sterols resulting in the formation of membrane pores. This is why cholesterol and its homologues are highly toxic for holothurian cells; their substitution by $\Delta^{9(11)}$- and Δ^7-sterols, stanols and sulfates of the type **133**, which are less capable to form membrane complexes with holothurian toxins, protects these animal cells from deleterious effects of their intrinsic glycosides.[103]



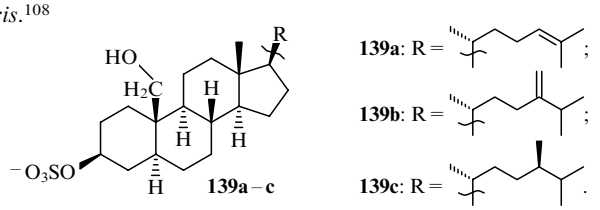
These data suggest that sulfation of free cholesterol in echinoderms is a result of their adaptation to the effects of intrinsic membranolytic toxins and that sterol sulfates fulfil a membrane-protective function by preventing the effects of these toxins on cell membranes.

Recently, Indian and Italian scientists have isolated two novel sulfated sterols **133l**,**m** from the tropical sea cucumber *Holothuria* sp.[104]

Sterol sulfates were detected not only in echinoderms but also in some other marine organisms. For example, 24-methylidene-cholesterol sulfate **133g** was detected in the diatomic microalga *Nitzchia alba* as long as 35 years ago,[105] whereas the so-called hymenosulfate **133k**, which contains an unusual side chain similar to those of some free microalgal (dynoflagellate) sterols, was found in the haptophytic microalga *Hymenomonas* sp.[106]

2. Polyhydroxysteroid monosulfates

Polyhydroxysteroid monosulfates from sponges and echinoderms contain sulfate groups in 3β- or other positions. Thus compounds **139a**–**c** containing additional hydroxy groups at C(19) were isolated from the sponge *Toxadocia zumi*.[107] A new β-1,3-glucanase inhibitor, *viz*., annasterol sulfate **140**, was isolated in our laboratory from the Pacific deep-water sponge *Poecilastra laminaris*.[108]

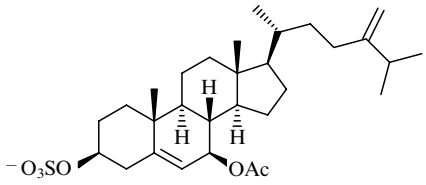


139a–**c**

139a: R = ;

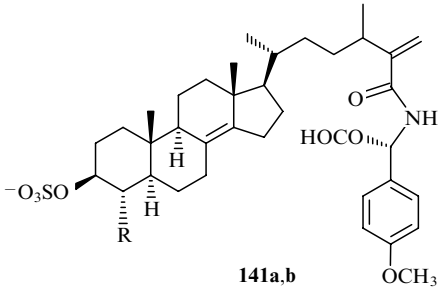
139b: R = ;

139c: R =  .



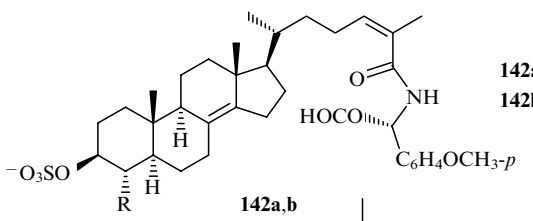
140 (annasterol sulfate)

The unusual steroid polymastiamide A (**141a**) was isolated from the sponge *Polymastia boletiformis* collected near the coasts of Norway.[109] This is the amide of a rarely occurring amino acid, *viz*., *p*-methoxyphenylglycine, and its steroidal fragment is a $\Delta^{8(14)}$-derivative methylated in position 4. Earlier, 4α-methyl-$\Delta^{8(14)}$-sterols were detected in some archaebacteria of the *Methylococcus* genus. This points to participation of symbiont bacteria in biosynthesis of compound **141a**, since archaebacteria have recently been identified as symbionts in some sponges. Polymastiamides B–F (**141b**, **142a**,**b**, **143a**,**b**) isolated from the same sponge are structurally close to polymastiamide A (**141a**). Their treatment with CH_3OH/HCl is accompanied by both migration of the double bond and aromatisation of the ring C resulting in the artificial products **144** and **145**.[110]



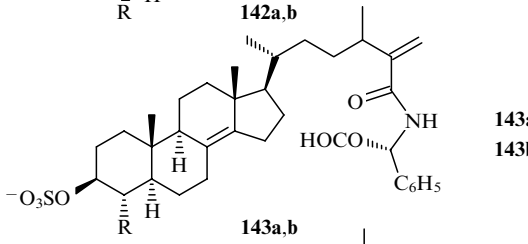
141a,**b**

141a: R = CH_3;
141b: R = H.



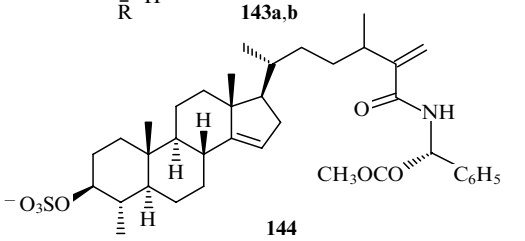
142a,**b**

142a: R = CH_3;
142b: R = H.

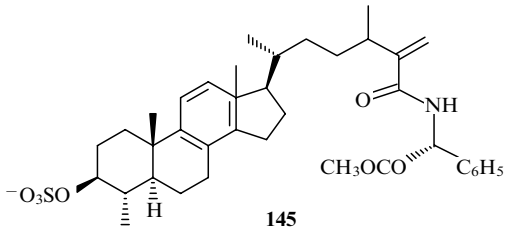


143a,**b**

143a: R = CH_3;
143b: R = H.

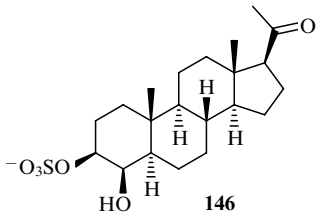


144



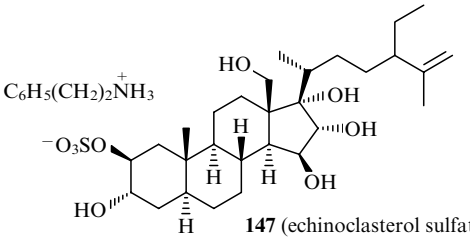
145

The steroid **146** from the sponge *Stilopus australis*[111] is unrelated to sterol derivatives, this rather resembles steroid hormones because of the presence of the pregnane skeleton.



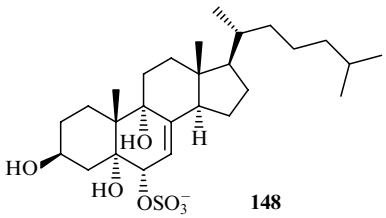
146

One of a few steroid monosulfates **147** with the sulfate group in position 2β was isolated from *Echinoclathria suhispida* collected near the coasts of Japan. Echinoclasterol sulfate **147** is a salt in which protonated tyramine is the counter-ion.[112]

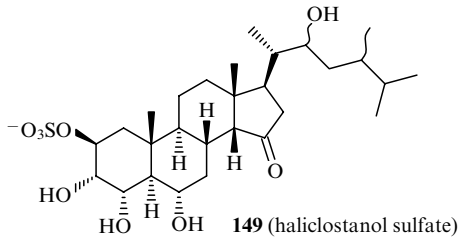


147 (echinoclasterol sulfate)

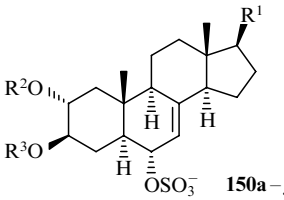
The unique cytotoxic steroid **148** containing a sulfate group in position 6α was found in the sponge *Dysidea fragilis* collected from the lagoon of Venice.[39] Haliclostanone sulfate (**149**) from the Malaysian sponge *Haliclona* still remains the only sulfated sponge steroid with an uncommon *cis*-fusion of rings *C* and *D*.[113] Sulfates of acanthosterols A–J (**150a**–**j**) from the sponge *Acanthodendrilla* sp. contain sulfate groups in position 6.[114] Thus, sponges contain various steroid metabolites, mostly those sulfated in positions 3, 2 or 6.



148



149 (haliclostanol sulfate)



150a–**j**

Compound **150**	R^1	R^2	R^3

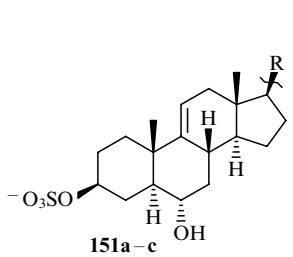
i		H	H
j		Ac	H

Non-glycosylated polyhydroxysteroid sulfates are abundant in starfishes and usually contain sulfate groups in the side chains. If sulfation takes place in the steroid nucleus, the sulfate group is bound to C(3), C(6), C(15) or C(16). Thus different starfish species contained steroids of the general formula **151**. Steroids **151a**,**c** are genuine algycons of many asterosaponins.[3, 115] Presumably, these compounds are biosynthetic precursors of asterosaponins, which are converted into them after the attachment of the carbohydrate chain. The related compound apheloketotriol (**151b**) was isolated from *Aphelasterias japonica*.[116]

The novel steroid **152** sulfated at C(6) was detected in the starfish *Oreaster reticulatus* together with 16 steroid glycosides and several polyhydroxysteroids.[117]

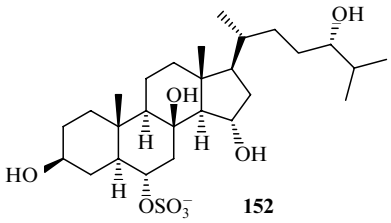


151a–**c**

151a: R =  (tornasterol A sulfate);

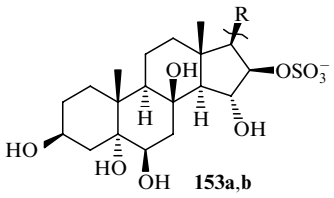
151b: R =  (apheloketotriol);

151c: R = (asterone sulfate).



152

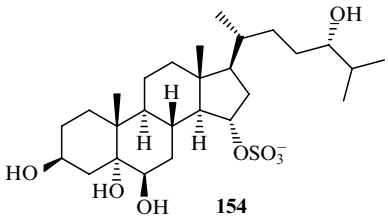
The monosulfates **153a**,**b** and **154** containing sulfate groups in position 15 or 16 were isolated from *Luidia clathrata*,[92] whereas the 3-monosulfate **155** was isolated from *L. quinaria*.[118]



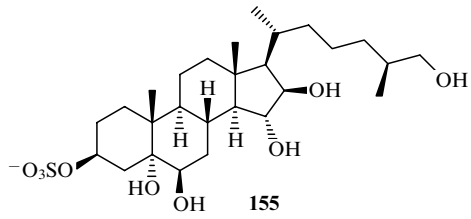
153a,**b**

153a: R =  ;

153b: R =  OH.



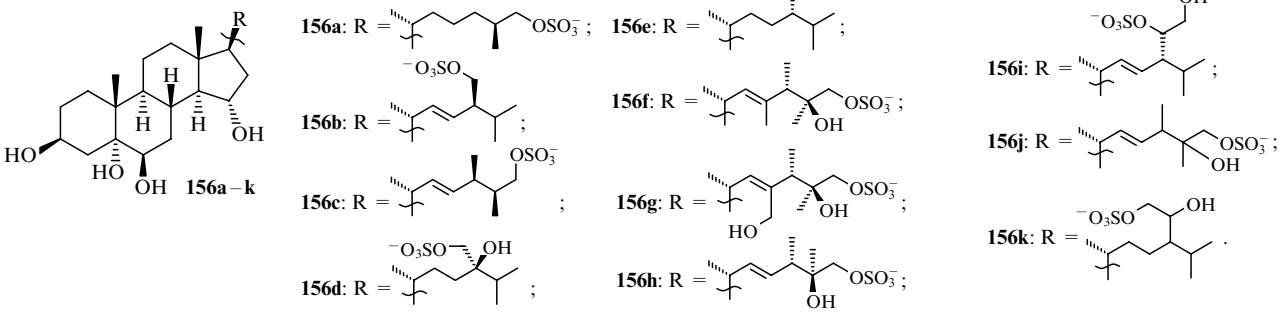
154

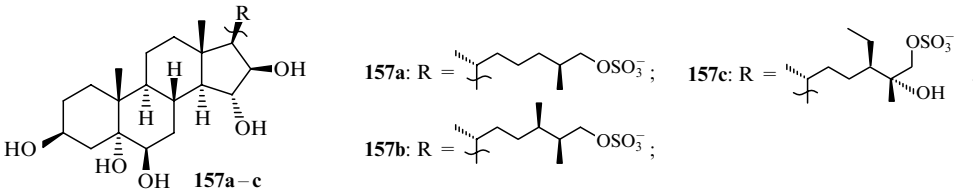


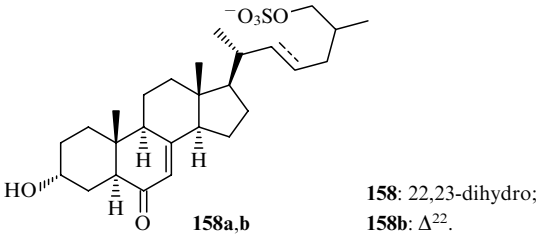
155

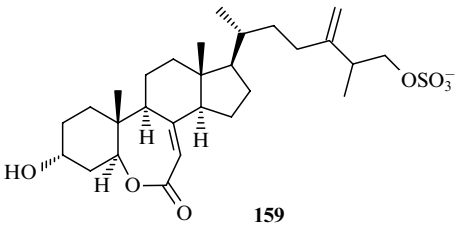
A large series of compounds **156b**–**e** containing sulfate groups in different positions of their side chains were found in *L. clathrata*.[92] The structurally related monosulfate **156a** was isolated from extracts of *Luidia ludwigi*.[119] The related sulfates **156f**–**i** from the starfish *Styracaster caroli*[120] collected at 2-km depth near the coasts of New Caledonia have highly oxygenated side chains. Sulfates **156j** and **156k** were isolated from the starfish *Ctenodiscus crispatus*.[94] Steroids **157a**–**c** sulfated in side chains and hydroxylated at C(16) of the side chains were found in *L. clathrata* [92] and *Styracaster caroli* (**157c**).[120]

The unusual steroidal ketones, *viz*., asterosterols B and C (**158a**,**b**) containing saturated ketone fragments in rings *B* characteristic of ecdysteroids, were isolated from antarctic starfishes belonging to the Asteriidae family.[121] These animals also contained a unique sulfate **159** with a seven-membered unsaturated lactone ring. Regioisomeric lactone rings are present in brassinosteroids, the higher-plant growth stimulants.

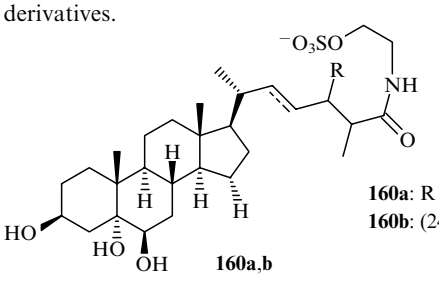


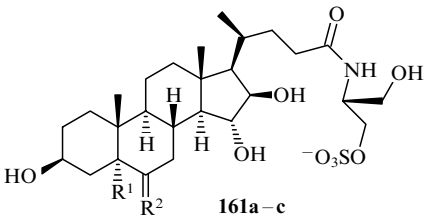




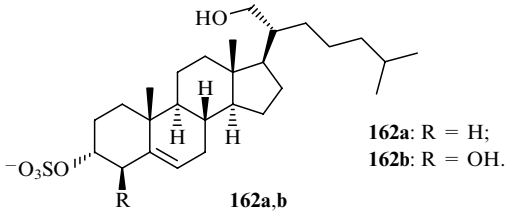


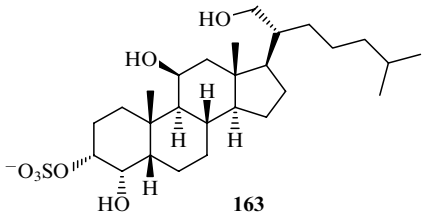
Finally, a group of steroid sulfates containing sulfate groups in the taurine fragments or in other sulfated amino alcohol fragments, which represent the corresponding amides, have been isolated recently from *Myxoderma platyacanthum* (compounds **160a**,**b**)[96] and *Styracaster caroli* (compounds **161a**–**c**).[122] In contrast to other starfish steroids, the latter are cholanic acid derivatives.



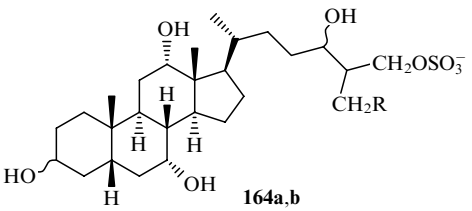


In ophiuroids (brittle stars) belonging to yet another class of echinoderms, polyhydroxysteroid sulfates are represented predominantly by 3α-derivatives. Monosulfates are less widely distributed in these animals in comparison with di- and trisulfates, although several compounds of this type have been isolated from different representatives of the class Ophiuroidea. Thus compounds **162a**,**b** were found in Far Eastern brittle stars *Ophiura leptoctenia* and *O. sarsi*.[123, 124] The monosulfated steroid **163** was isolated from *Ophiarachna incrassata* collected near the coasts of New Caledonia.[125] Later, it was found that this compound inhibits protein kinase pp $60^{v\text{-}src}$ responsible for regulation of cell growth and intercellular signalling.[126]

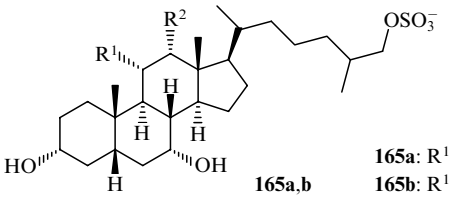




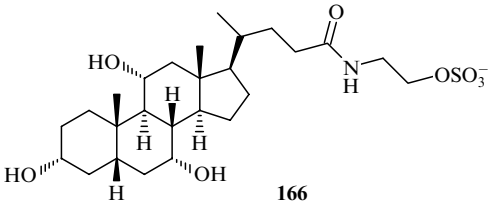
Sulfated bile alcohols from fishes (for an early review, see Ref. 1) are also related to polyhydroxysteroid monosulfates. Among those, scymnol sulfate **164a** isolated from the shark *Scymnus borealis* as long ago as in 1898 is the most widely known one. Recently, both C(24) epimers of this compound have been isolated from the shark *Lamna ditropis*.[127] The related bile alcohol, chymaerol sulfate **164b**, was found in the bile of two shark species, *viz*., *Lamna ditropis* and *Rhizoprionodon acutis*.[128] Three novel steroid sulfates **165a**,**b** and **166** were found in the bile of the sunfish *Mola mola*.[129] Compounds **165a**,**b** represent 25*R*- and 25*S*-isomers, whereas compound **166** represents a taurine conjugate of an acid, which differs from cholic acid in that one of its hydroxy groups occupies position 11 rather than 12. The novel sulfated pregnane derivative **167** was isolated from the urine of



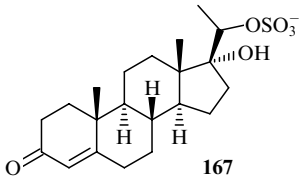
164a: R = OH, 3β-OH, 24*S* and 24*R* (scymnol sulfate);
164b: R = H, 3α-OH, 24*R* and 25*S* (chymaerol sulfate).



165a,**b** **165a**: R^1 = OH, R^2 = H; **165b**: R^1 = H, R^2 = OH.



166

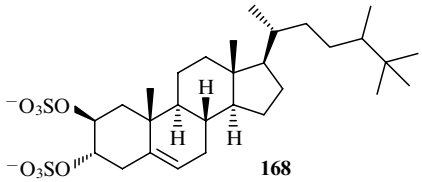


167

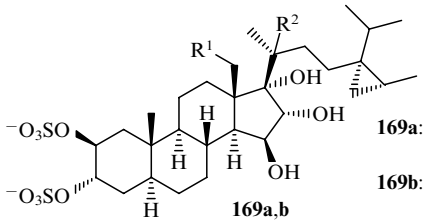
female salmon *Salmo solar*.[130] The most recent findings and the data obtained previously testify to the fact that sulfated steroids are extensively distributed in fishes.

3. Steroid disulfates

Some sponge steroids contain sulfate groups in positions 3α and 2β. This series of compounds includes compound **168**, a possible biogenetic precursor of halistanol sulfate,[131] which is the most widely occurring trisulfate of sponges, and weinbersterols A and B (**169a**,**b**) from the sponge *Petrosia weinbergi*. The latter have unique side chains containing cyclopropane fragments, which makes them different from other polysulfated sponge steroids. Steroids **169a**,**b** manifest antiviral activities against cat leukemia and mouse influenza viruses.[132] The absolute configurations (24*S*,28*S*) of weinbersterols A and B were established by comparing them with those of the free sterols, which represent biogenetic precursors of steroids **169a**,**b** isolated from the same sponge.[133]



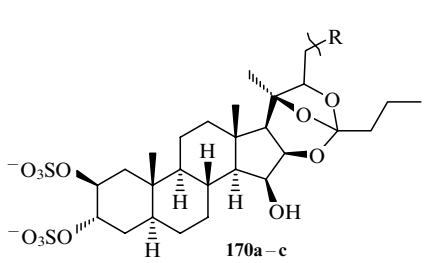
168



169a,**b** **169a**: R^1 = H, R^2 = OH (weinbersterol A); **169b**: R^1 = OH, R^2 = H (weinbersterol B).

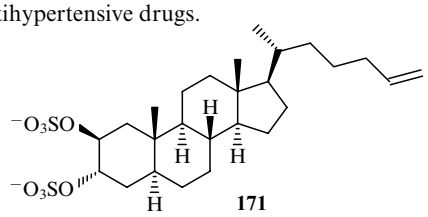
Yet another group of antiviral disulfates, the so-called orthoestrols A–C from the Caribbean sponge *P. weinbergi*,[134] comprises derivatives of orthobutyric acids. The stereochemistry of orthoestrol B (**170b**) appears as 24*R*,28*S*; that of orthoestrol C (**170c**) is 24*R*.

Halistanol B disulfate (**171**) from the South African sponge *Pachastrella* sp.[135] presents interest with regard to both its structure (its side chain contains no methyl group in position 27, which makes this compound different from cholesterol) and biological activity. It inhibits the activity of the enzyme catalysing the conversion of the protein precursor of endothelin into endothelin-1 (IC_{50} = 1.3 μg ml^{-1}). Endothelin induces vascular



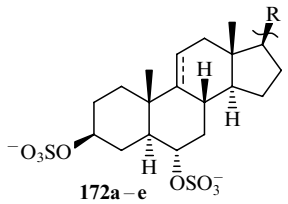
170a–**c** **170a**: R = (orthoestrol A); **170b**: R = (orthoestrol B); **170c**: R = (orthoestrol C).

spasms and is abundant in patients with hypertension and renal insufficiency. Compound **171** as an inhibitor of endothelin synthesis is a promising model substance for development of new antihypertensive drugs.



171

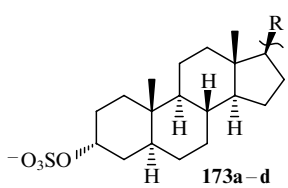
A series of steroid disulfates were found in starfishes and ophiuroids. Thus compounds **172a**–**d** were isolated from the starfish *Tremaster novaecaledonia*[136] and compound **172e**, from *Aphelasterias japonica*.[137]



172a–**e**

172a: R = , Δ^0; **172b**: R = , Δ^0; **172c**: R = , $\Delta^{9(11)}$; **172d**: R = , $\Delta^{9(11)}$; **172e**: R = , $\Delta^{9(11)}$.

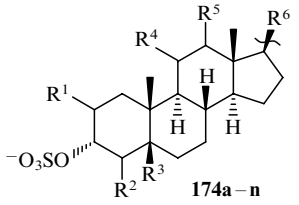
In contrast to their starfish counterparts, steroid disulfates isolated from ophiuroids have a number of specific structural features. In nearly all of them, one sulfate group is in position 3α and the second one is in the side chain at C(21). These steroids comprise stanol derivatives as well as 5(6)-unsaturated derivatives. For example, sulfated stanols of the general formulas **173** and **174** are widely distributed in various representatives of this class, *e.g.*, in more than 30 species of Ophiuroidea.[3,99] Disulfate **173a**, which was first discovered together with compound **173b**,**c** in *Ophioderma longicaudum*[138] and later in different species of Ophiuridae, Gorgonocephalidae and Asteronychnidae families,[99] is the most widespread disulfate of the general formula **173**. The steroid **173d** was isolated from the antarctic brittle star *Astrotoma agassizii*.[139]



173a–**d**

173a: R = ; **173b**: R = ; **173c**: R = ; **173d**: R = , 2β-OH.

Steroid disulfates of many ophiuroids are characterised by *cis*-fusion of rings *A* and *B*. For example, compound **174a** first described by Italian scientists in 1985[140] was later discovered in various representatives of the *Ophiocoma*, *Ophioarthrum*, *Ophiolepis*, *Ophionereis* and *Ophiozona* genera.[3,99] The steroid **174b** was found in *Ophiocoma dentata*, *Ophioarthrum elegans*, *Ophiorachna incrassata*, *Ophiolepis superba* and *Ophiomastix annulosa*.[3] The steroid **174c**, which differs from the latter in the structure of its side chain, was first discovered in *Ophiocoma dentata*,[3] whereas compounds **174d**–**f** were found in *Ophiolepis superba*, which also contains additionally oxygenated derivatives **174g**,**h**,**i**.[141] The steroid **174j** containing an additional hydroxy group at C(12) was isolated from *Ophioderma longicaudum*,[138] whereas steroids **174k**,**l** were isolated from *Ophiomastix annulosa*[142] and *Ophiopholis superba*.[141] The steroid **174m** containing an unusual 5,9-epoxy fragment was found in *Ophiomastix annulosa*[142] and compound **174n** was detected in the antarctic ophiura *Astrotoma agassizi*.[139]



174a–**n**

Compound **174**	R^1	R^2	R^3	R^4	R^5	R^6
a	H	α-OH	H	β-OH	H	b	H	α-OH	H	H	H	c	H	α-OH	H	H	H	d	H	α-OH	H	H	H	e	H	α-OH	H	H	H	f	H	α-OH	H	H	H	g	H	α-OH	β-OH	H	H	h	β-OH	α-OH	H	H	H	i	β-OH	α-OH	H	H	H	j	H	α-OH	H	β-OH	β-OH	k [$\Delta^{9(11)}$]	H	α-OH	H	H	H	l	H	α-OH	α-OH	H	H	m	H	4α,9α-epoxy	H	H	H	n	β-OH	H	H	H	H	
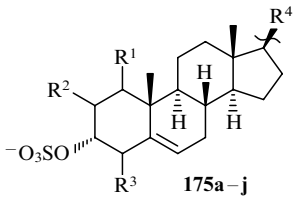
5(6)-Unsaturated steroids of the general formula **175** are often present in ophiuroids. Thus compounds **175a** and **175b** were isolated from the Far Eastern brittle star *Ophiura sarsi*[124] and steroids **175c-f** were isolated from *Ophiopholis aculeata*.[143] The steroid **175a** was also isolated from *Ophiura texturata*,[144] *Gorgonocephalus caryi*,[145] *Ophiotrix fragilis*[2] and some other species. The steroid **175g** was found in *O. texturata*,[144] the steroid **175h** was detected in *Ophiarachna incrassata*.[140] The disulfate **175i** containing three functional groups in the ring *A* was isolated from the antarctic brittle star *Ophiosparte gigas*[146] as well as from *Astroclades exiguus* and *Amphiophiura ponderosa*.[147]



175a–**j**

Compound **175**	R^1	R^2	R^3	R^4
a	H	H	β-OH	b	H	β-OH	H	c	H	H	β-OH	d	H	H	β-OH	e	H	β-OH	H	f (24*S* and 24*R*)	H	β-OH	H	g	H	H	β-OH	h	β-OH	H	H	i	H	β-OH	β-OH	j	H	β-OH	H	
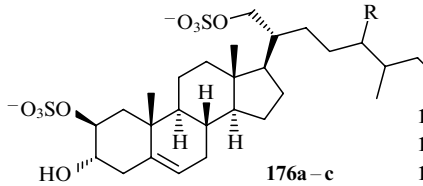
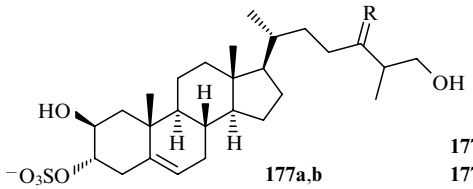
The unusual steroid disulfate **176a** was detected in the brittle star *Ophiosparte gigas*.[146] It contains a sulfate group in position 2β but not in position 3α, like other sulfates of this series. Later, this disulfate was isolated from several other representatives of this class.[99] Its 24(25)-unsaturated derivative **176b** and related ophiuroid disulfates **175j** and **174n** from *Astrotoma agassizii*[139] and their acetates manifested strong antiviral activities against the pathogenic virus HSV-2, which evokes meningitis and other severe infections in humans.[147]



176a–**c**

176a: R = H, X = H;
176b: R = H, X = H, Δ^{24};
176c: R = H, X = OH.

The typical ophiuroid steroids **175a**,**b** and **176a** were unexpectedly found in the starfishes of the *Pteraster* genus.[148] These compounds differ from steroids of the majority of other starfish species in the stereochemistry of substituents at C(3) (3α instead of more common 3β) and oxygenation at C(21). A detailed analysis of steroids isolated from this group of starfishes led to the discovery of a compound earlier identified in ophiuroids (compound **175g**) and novel compounds **176c** and **177a**,**b** which combine structural features of steroids from brittle stars (*e.g.*, oxygenation in positions 3α and 21) and starfish (*e.g.*, oxygenation in position 26).[149] The presence of the same or structurally related secondary metabolites in brittle stars and starfishes corroborates the viewpoint of some taxonomists that these two classes of echinoderms are phylogenetically more closely related in comparison with other classes of Echinodermata.

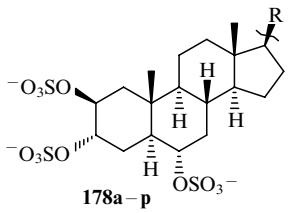


177a,**b** **177a**: R = CH_2; **177b**: R = H_2.

Disulfates from ophiuroids manifest the properties of activators of some enzymes, particularly glucanases.[150] Steroids of the Δ^5-series isolated from *Ophiopholis aculeata* activate the transport of calcium ions into different cells without disturbing the integrity of biomembranes.[151]

4. Steroid trisulfates

Trisulfated polyhydroxysteroids are typical representatives of marine metabolites. They were found in sponges and echinoderms.[1, 17, 99, 152] Halistanol sulfate (**178a**), the most widespread sponge steroid sulfate, was isolated from the sponge *Halichondria moori* in 1981 by Fusetani *et al.*[153] It contains three sulfate groups in rings *A* and *B* of the steroid tetracyclic nucleus. The structure of socotrasterol sulfate (**178b**) isolated repeatedly from different sponges was established in our laboratory.[154] Both compounds have unusual side chains, which are additionally alkylated (compared with those of terrestrial sterols). The side chain of socotrasterol sulfate is unique in that it contains two 'extra' methyl groups at C(26) and a 23(24) double bond uncommon for natural steroids. A large series of analogous natural compounds have been isolated from different sponges. These include halistanol sulfates A–D (**178c**–**f**) from *Epipolasis* sp.,[155] norsocotrasterol sulfate (**178g**) from sponges of the *Halichondridae* family,[156] dihydrosocotrasterol sulfate (ophirapstanol sulfate) **178h** from *Topsentia ophiraphidites*,[157] halistanol sulfates F–H (**178i**–**k**) from *Pseudaxinyssa digitata*,[158] compound **178l** from *Trachiopsis halichondroides*[159] and steroids **178m**–**p** from *T. halichondroides* and *Cymbastella coralliophila*.[160]



178a–**p**

Compound **178**	Name	R
a	halistanol sulfate	b	socotrasterol sulfate	
c	halistanol sulfate A	d	halistanol sulfate B	e	halistanol sulfate C	f	halistanol sulfate D	g	26-norsocotrasterol sulfate	h	ophirapstanol sulfate	i	halistanol sulfate F	j	halistanol sulfate G	k	halistanol sulfate H	l	–	m	–	n	–	o	–	
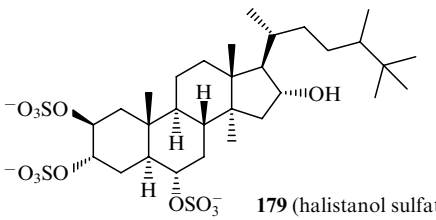
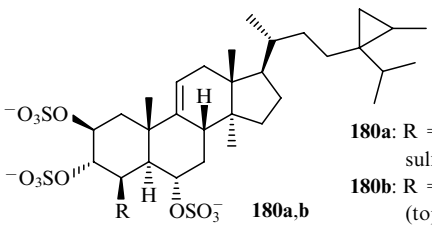
p	–	

The sulfated steroids of this series manifest a broad range of biological activities (*e.g.*, antimicrobial, hemolytic, ichthyotoxic, *etc.*), inhibit HIV-1-induced infection,[161] suppress the activities of some enzymes including that of β-1,3-glucanase[162] and interact with the thrombin receptor.[155]

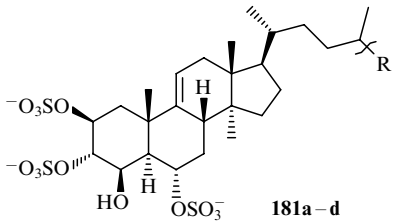
Several related trisulfates have recently been identified in sponges. These include halistanol sulfate E (**179**) from *Epipolasis* sp.,[155] which contains an additional hydroxy group at C(16), ibisterol sulfate **180a** from the sponge *Topsentia* sp., which inhibits HIV-1 and, in contrast to related steroids, possesses a 9(11)-double bond and an unusual side chain with a cyclopropane fragment.[163] Topsentiasterols **180b** and **181a**–**d** from an unidentified sponge of the *Topsentia* genus carry hydroxy groups at C(4) and in the majority of cases contain oxygenated side chains. These compounds possess antimicrobial properties.[164]



179 (halistanol sulfate E)



180a,**b** **180a**: R = H (ibisterol sulfate); **180b**: R = OH (topsentiasterol E).



181a–d

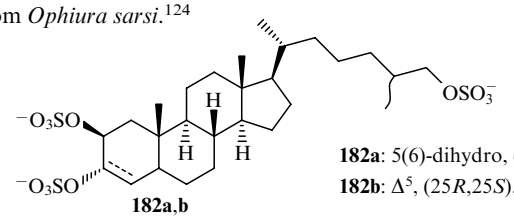
181b: R =  (topsentiasterol B);

181c: R =  (topsentiasterol C);

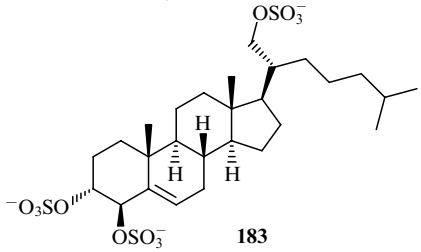
181d: R = (topsentiasterol D).

Several trisulfated steroids were found in echinoderms, particularly in ophiuroids. Thus steroids **182a**,**b** were isolated from *Ophiorachna incrassata* extracts[3] and the steroid **183** was isolated from *Ophiura sarsi*.[124]



182a,**b**

182a: 5(6)-dihydro, (25*R*,25*S*);
182b: Δ^5, (25*R*,25*S*).



183

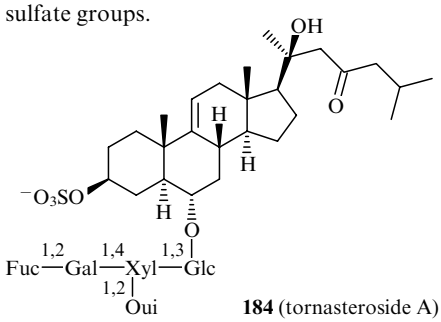
On the whole, sulfated steroids present substantial interest owing to their unusual chemical structures and biological activities. Some of them are attractive objects for synthetic modelling aimed at the design of novel antimicrobial, antiviral and other drugs. It is of note that sulfated steroids seem to be absent in Coelenterata. In any case, none has been isolated from these invertebrates so far.

IV. Steroid glycosides

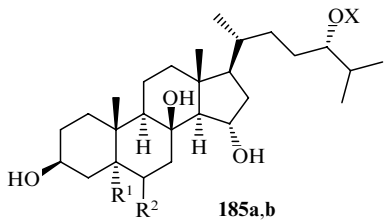
Over a long time, steroid glycosides were considered to be typical metabolites of higher plants; however, in the last 25–30 years they were isolated from starfishes along with the corresponding polyols and sulfates.[1,3] Later, they were found in sponges, cnidarians and fishes of the *Pardachiras* genus. A small review devoted to marine steroid glycosides was published in 1996.[165] Therefore, in this section we shall consider the results of the most recent studies published 4–6 years ago and those data which have not been discussed in this review.

Marine steroid glycosides, like any other marine polar steroids, have original structures, no one of them coincides with the structures of glycosides isolated from taxonomically remote biological sources, such as terrestrial plants.

Starfish glycosides are conventionally divided into several large groups,[3] *viz*., (i) steroid glycosides, which are sulfated at C(3) [their carbohydrate chains are attached at O(6) (classical asterosaponins)]; (ii) mono- and biosides of polyhydroxylated steroid, containing as a rule carbohydrate residues in their side chains and (iii) glycosides containing carbohydrate fragments attached to C(3) and C(6) of the aglycons to form macrocycles. The structures of individual representatives of these groups are given below. Glycosides related to the first structural type, *e.g*., tornasteroside A (**184**)[166] from *Acanthaster planci* (a starfish commonly referred to as the 'crown of thorns'), differ from each other in both the structures of their carbohydrate chains which usually contain from four to six monosaccharide residues and in the structures of the aglycon side chains. Glycosides related to yet another structural type, *e.g*., nodososide (**185a**) from *Protoreaster nodosus*[167] and asterosaponin P_1 (**185b**) from *Asterina* (= *Patiria*) *pectinifera*[168]), are structurally very diverse and may contain sulfate groups.



184 (tornasteroside A)

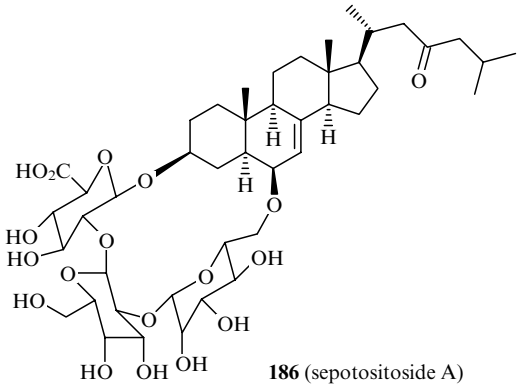


185a,**b**

185a: R^1 = OH, R^2 = β-OH, X =  (nodososide);

185b: R^1 = H, R^2 = α-OH, X =  (asterosaponin P_1).

Glycosides containing carbohydrate chains involved in a macrocycle exemplified in sepositoside A (**186**)[169] were detected only in a few species of starfishes of the *Echinaster* genus.



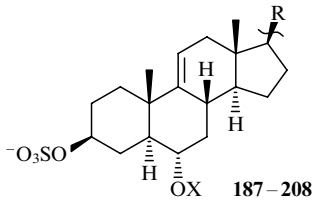
186 (sepotositoside A)

Classical asterosaponins are usually present in starfishes as complex mixtures; they are toxic to fishes, manifest cytotoxic and hemolytic activities, are predominantly accumulated in animal body walls and probably fulfil protective functions. All these compounds contain aglycons of the same structural type with a 9(11) double bond and a sulfate group at C(3), the aglycon of tornasteroside A being the most common fragment.

Tetraosides usually possess linear carbohydrate chains, whereas the carbohydrate chains of penta- and hexaosides have one or (more seldom) two branch points, predominantly at the second monosaccharide of the chain. Monosaccharides are represented mostly by pyranose forms of D-fucose, D-quinovose, D-glucose, D-galactose, D-xylose and 6-deoxy-D-*xylo*-hexos-4-

ulose (the latter contains the hydrated keto group in position 4). The glycosidic bonds have usually β-configurations.

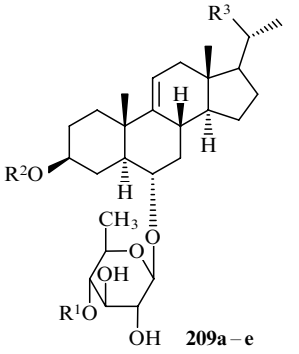
Quite a lot of novel asterosaponin oligoglycosides have recently been isolated from starfishes (Table 2). For example, the so-called nipoglycosides A – D (**187** – **190**) were isolated from the starfish *Distolasterias nipon*[170] and brasiliensoside (**191**) was isolated from *Echinaster brasiliensis*.[171] In contrast with the glycosides from the other two species of this genus, these glycosides are devoid of carbohydrate chains incorporated in a macrocycle. Cosmasterosides A – D (**192** – **195**) containing two xylose residues each in their carbohydrate chains were isolated from the starfish *Cosmasterias lurida*.[172]



187 – **208**

In contrast to most asterosaponins containing five to six sugar residues, compounds **194** and **195** have only four monosaccharide residues. Reticulatosides A and B (**196**, **197**) and asterosaponin (**198**) containing a pregnane aglycon were found in *Oreaster reticulatus*.[117] About 20 steroid glycosides including the novel asterosaponins **199** – **203** were isolated from a non-identified starfish species belonging to the Echinasteriidae family collected near Antarctic coasts by Italian scientists,[173] whereas asteriidosides A – E (**204** – **208**) were isolated from a non-identified Antarctic species belonging to the Asteriidae family.[174]

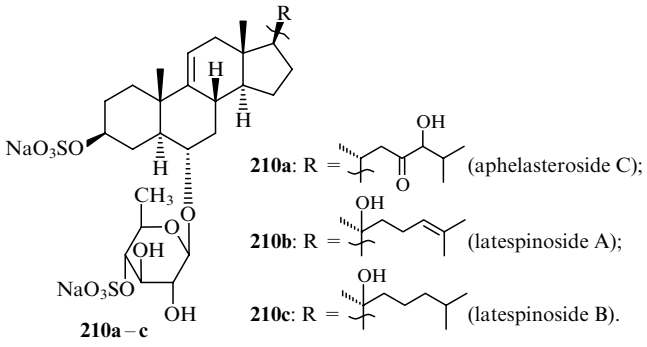
Asterosaponin-like glycosides with 'shortened' carbohydrate chains were first isolated from *Asterias forbesi*[175, 176] and *Lethasterias nanimensis chelifera*.[115] Forbesides E, E_1, E_2 and E_3 (**209a** – **d**) and cheliferoside L_1 (**209e**) represent pregnane monoquinovosides; most of them contain additional sulfate groups in their monosaccharide residues.



209a – **e**

Compound **209**	Name	R^1	R^2	R^3
a	forbeside E	SO_3Na	SO_3Na	OH
b	forbeside E_1	H	SO_3Na	OH
c	forbeside E_2	SO_3Na	H	OH
d	forbeside E_3	H	SO_3Na	O
e	cheliferoside L_1	SO_3Na	SO_3Na	O

Aphelasteroside C (**210a**) from *Aphelasterias japonica* differs from cheliferoside L_1 (**209e**) in its relatedness to cholestane, rather than to pregnane derivatives; its side chain contains a 23-keto-24-hydroxy fragment uncommon for asterosaponins.[116] Latespinosides A – D (**210b**,**c**, **211**, **212**) from *Asteropecten latespinus* differ from aphelasteroside C (**210a**) exclusively in the structures of their side chains, compound **212** being the first androstane steroid isolated from starfishes.[177]

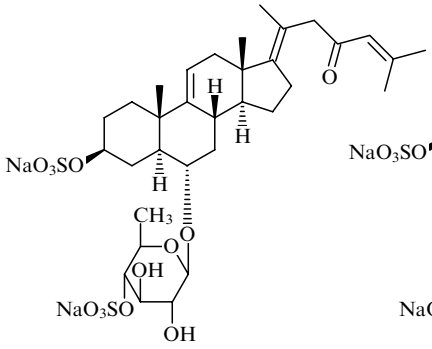


210a – **c**

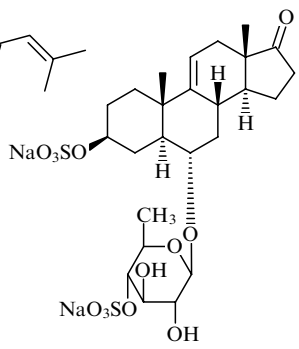
210a: R = (aphelasteroside C);

210b: R = (latespinoside A);

210c: R = (latespinoside B).

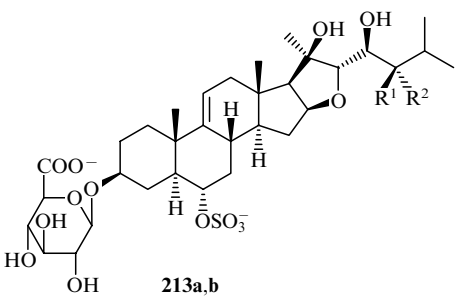


211 (latespinoside C)



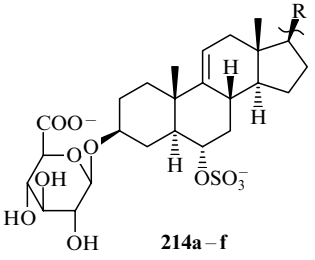
212 (latespinoside D)

Yet another recently discovered group of asterosaponins with shortened carbohydrate chains includes downeosides (**213** – **216**) from *Henricia downeyae*.[178, 179] These compounds contain one or two monosaccharide residues in their carbohydrate fragments; their high polarities are due to the presence of glucuronic acid residues, which are not common in 'classical' asterosaponins, but are present in cyclic asterosaponins. In contrast to other asterosaponins, the carbohydrate fragments in these glycosides are bound to C(3) atoms, whereas their sulfate groups are bound to C(6). Downeyosides A and B (**213a**,**b**) possess additional tetrahydrofuran rings and side chains containing three contiguous hydroxy groups at C(20), C(22) and C(23), which is uncommon for natural steroids. Downeyosides C – G and J (**214a** – **f**) resemble 'classical' asterosaponins in the structures of their side chains, whereas downeyosides K and L (**215a**,**b**) contain additional hydroxy groups at C(16). And, finally, downeyosides H and I



213a,**b**

213a: $R^1 = CH_3$, $R^2 = H$ (downeyoside A);
213b: $R^1 = H$, $R^2 = CH_3$ (downeyoside B).



214a – **f**

214a: R =  (downeyoside C);

214b: R =  (downeyoside D);

214c: R =  (downeyoside E);

214d: R =  (downeyoside F);

214e: R =  (downeyoside G);

214f: R =  9(11)-dihydro, (downeyoside J) .

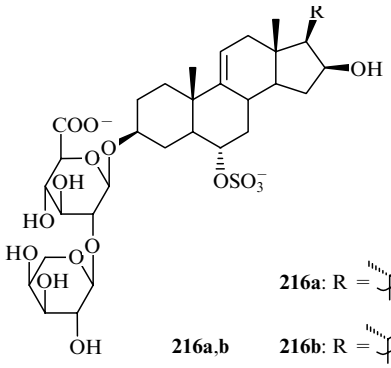
215a: R =  (downeyoside K);

215b: R =  ,

9(11)-dihydro (downeyoside L).



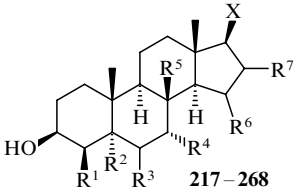
216a,**b**

216a: R =  (downeyoside H);

216b: R =  (downeyoside I).

(**216a**,**b**) are biosides, each containing an additional L-arabinose residue bound to glucuronic acid by α-glycosidic bond.

In recent years, the list of newly discovered mono- and biosides of polyhydroxysteroids has been supplemented with more than 50 new names (Table 3).

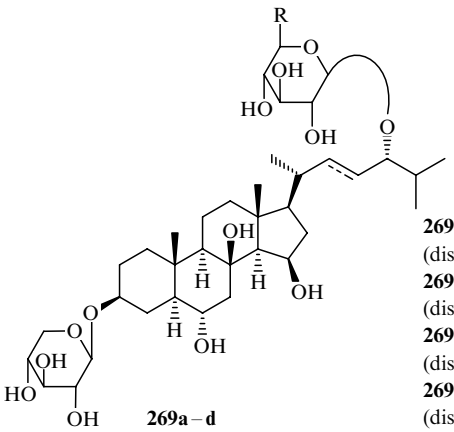


217–**268**

As a rule, the carbohydrate fragments of these compounds are bound to C(24) or C(26) (cholestane series), to C(28) or C(26) (ergostane series) and to C(29) or C(26) (stigmastane series). Xylose, its various methylated derivatives (in a pyranose form), arabinose and 3-*O*-methylarabinose (in a furanose form) are the monosaccharide components. Glucopyranose, arabinopyranose, xylofuranose, galactofuranose and fucofuranose are found less often. The glycosides of this series contain sometimes one or several sulfate groups in the carbohydrate part and the aglycons. In biosides, the monosaccharides are linked by 1,2-bonds or, less frequently, by 1,5- and 1,6-bonds (the author's data), *e.g.*, as in compounds **262**, **264**–**267**.[184–186]

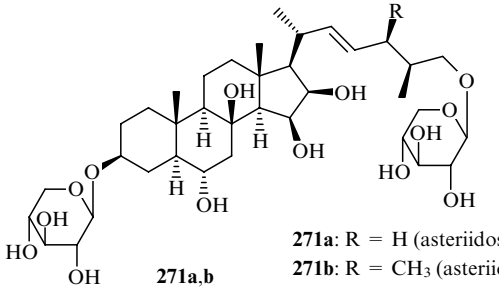
Novel structural series of glycosides recently discovered in starfishes include compounds containing two monosaccharide fragments, *viz*., one at C(3) and the other in the side chain. Some representatives of this class, *viz*., distolasterosides D_1–D_3 (**269a**–**c**) were found in *Distolasterias nipon*.[187] Reinvestigations of polar steroids from the same species collected near the coasts of Japan led to the isolation of yet another steroid bisglycoside, *viz*., distolasteroside D_4 (**269d**) and distolasteroside D_5 (**270**), which contains a sulfate group instead of a monosaccharide residue at C(3).[170]

In the most recent times, this group of compounds was further expanded owing to asteriidosides F–I (**271a**,**b** and **272a**,**b**)



269a–**d**

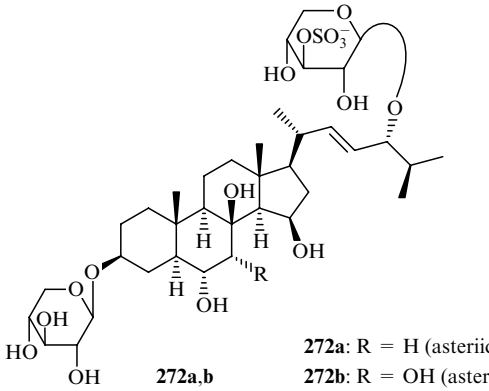
269a: R = H (distolasteroside D_1);
269b: R = H, Δ^{22} (distolasteroside D_2);
269c: R = CH_2OH (distolasteroside D_3);
269d: R = $CH_2OSO_3^-$ (distolasteroside D_4).



270 (distolasteroside D_5) isolated from the Antarctic starfish belonging to Asteriidae gen. sp.[174] and echinasterosides B_1 (**273**) and F (**274**) from *Echinaster sepositus*[188] and *E. brasiliensis*,[171] respectively.

271a,**b**

271a: R = H (asteriidoside F);
271b: R = CH_3 (asteriidoside G).



272a,**b**

272a: R = H (asteriidoside H);
272b: R = OH (asteriidoside I).

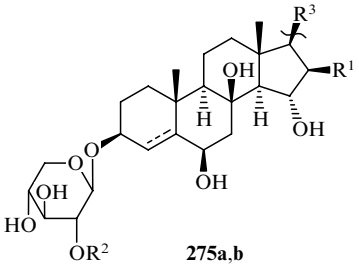
274

Yet another group of recently discovered glycosides contains only one carbohydrate fragment linked to the C(3) atom. These compounds include desulfated 26-norechinasteroside A (**275a**)



275a,**b**

Compound **275**	Name	R^1	R^2	R^3
a (Δ^4)		OH	CH_3	b	asteriidoside L	H	H	
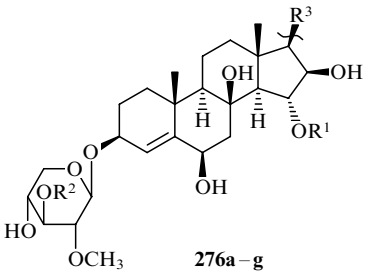
from *Henricia downeyae*,[179] compounds **276a**–**e** from *Echinaster brasiliensis*,[171] henriciosides H_2 and H_3 (**276f**,**g**) from *H. derjugini*[93] and asteriidoside L (**275b**) from Asteriidae gen sp.[174]



276a–**g**

Compound **276**	Name	R^1	R^2	R^3
a		SO_3^-	H	b		H	H	c	echinasteroside C	SO_3^-	H	d	echinasteroside D	SO_3^-	H	e	echinasteroside E	H	H	f	henricioside H_2	H	CH_3	g	henricioside H_3	H	CH_3	
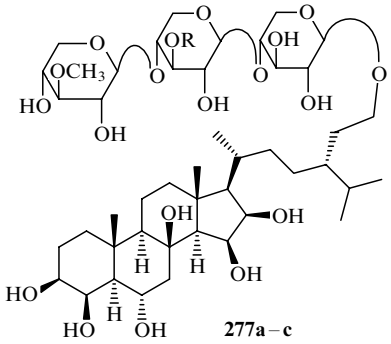
In contrast to all other polyhydroxysteroid glycosides containing one or two monosaccharide residues, cytotoxic compounds **277a**–**c** from *Fromia monilis*[189] contain three monosaccharides.



277a: R = CH_3;
277b: R = CH_3, Δ^{22};
277c: R = H.

277a–**c**

The impressive diversity of glycosides of polyhydroxysteroids and other polar steroids found in starfishes reflects the immense variety of oxidising and glycosylating enzymes present in these animals, which is comparable only to the wide occurrence of steroid-oxidising enzymes in microorganisms and glycosyl transferases in terrestrial higher plants. Several newly discovered groups of glycosides not mentioned in previous reviews[2,3] include monoquinovosides related to classical asterosaponins as well as mono- and biosides sulfated at C(6) and containing carbohydrate chains in position 3.

It should be stressed that starfish enzymes differ from known enzymes of terrestrial origin in the specificities of hydroxylation and ability to transfer mono- or oligoside residues into definite positions of sterol substrates. Sulfation of metabolites in different positions is a distinguishing feature of biogenesis of steroid glycosides in starfishes.

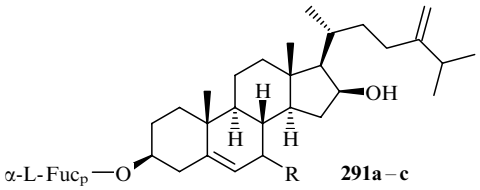
In other phyla of marine invertebrates, such as sponges, glycosides have been discovered much later than in starfishes. Sponge glycosides usually contain mono-, di- or trimethylsterol aglycons and carbohydrate chains linked to C(3). These metabolites were first isolated from *Asteropus sarasinosum* by Kitagawa *et al.*[190,191] Sarasinosides represent oligoglycosides of hitherto unknown dimethylsterol aglycons. They manifest high ichthyotoxic activities and moderate cytostatic activities in tests with fertilised eggs of the starfish *Asterina pectinifera*. Compounds **278a**–**c**, **279a**–**c** and **280a**–**c** were found in the starfish *A. sarasinosum* collected near the Palau Island in the Pacific Ocean,[191] whereas compounds **281**, **282a**–**b** and **283** were isolated from the same sponge species dwelling in the region of the Solomon Islands.[192] The aglycons of sarasinoside D (**281**) contain a rarely occurring 4,4,8-trimethylsterane skeleton system similar to that of scalarane sesterterpenoids, but differing from that of dammarane triterpenoids in a 1,2-shift of the methyl group from C(14) to C(13).

The so-called pachastrelloside A (**284**), which inhibits cell division in fertilised sea urchin eggs without affecting cell nuclei resulting in the formation of multinuclear unicellular embryos, was isolated from *Pachastrella* sp. Unlike other steroid glycosides, pachastrelloside A (**284**) contains monosaccharide residues in unusual positions. Thus, one of them, *viz*., galactose, is linked to C(4), whereas the other one, *viz*., xylose, is bound to C(7) of the aglycon.[193] Comparison of the aglycon structures of eryloside A (**285**) from *Erylus lendenfeldi*,[194] erylosides C and D (**286a**,**b**) from

Erylus sp.,[195] eryloside E (**287**) from *E. goffrileri*[196] and ulososides (**288**, **289**) isolated by us from *Ulosa* sp.[197,198] showed that stepwise demethylation of the lanostane or the related terpene precursor in sponges resembles the conversion of lanosterol into cholesterol in higher animals. This process consists in oxidative removal of the methyl group from position 14 and subsequent elimination of the methyl groups linked to C(4) (Table 4).

The hopaioside **290** isolated from the Micronesian sponge *Cribrochalina olemda* differs significantly from other sponge steroid glycosides.[199] This compound is related to 19-norpregnane rather than to sterol or norlanostane derivatives.

Interesting steroid glycosides were also detected in some octocorals. Most of them are monosides of the pregnane series and contain one or several acetate or propionate groups. Several novel glycosylated sterol derivatives and novel pregnane glycosides have recently been isolated from these animals. Thus α-L-fucosides containing aglycons of the 24-methylcholesterol series **291a**–**c** were found in some soft corals (*e.g.*, *Alcyonium* sp.) and some representatives of the *Sinularia* and *Lobophytum* genera.[200] The related glycosides **292a**,**b** and **293** were isolated from *Sinularia gibberosa*[52,201] and *S. grandilobata*.[202]



291a–**c**

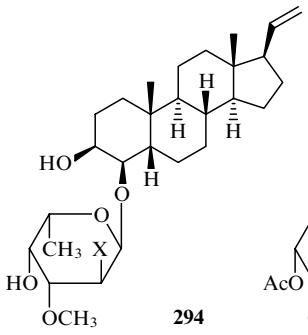
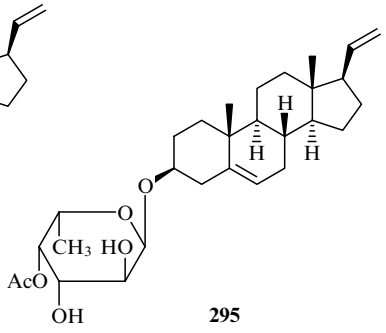
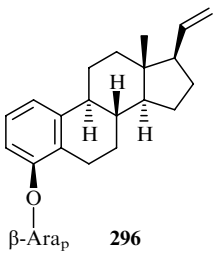
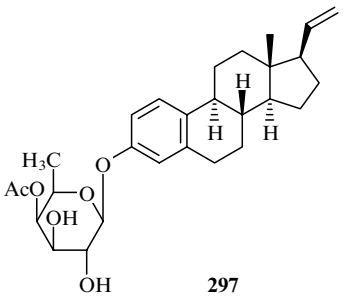
The cytotoxic pregnane glycoside verrucoside (**294**) from *Eunicella verrucosa*[203] contains L-digitalose as a carbohydrate component, enantiomeric with the corresponding 6-deoxyhexose occurring in terrestrial plants. This compound inhibits tumour cells P-388, A-549 and HT-29 (IC_{50} = 5.9, 7.2 and 6.3 μg ml^{-1}, respectively). The glycoside **295** from the gorgonian coral *Eunicea* sp. is its structural analogue.[204] Glycosides **296** and **297** from the soft corals *Scleronephthya palida*[205] and *Alcyonium* sp.[64] collected near the coasts of Thailand represent 19-norpregnane derivatives.

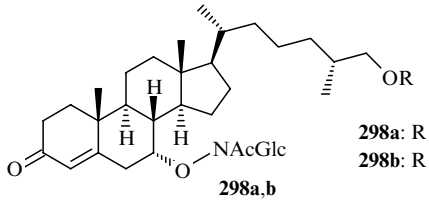


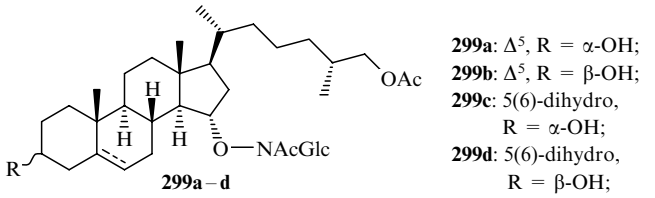


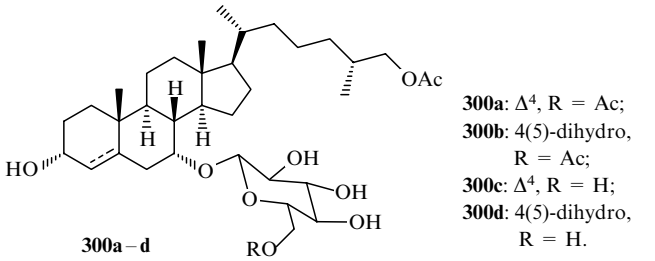


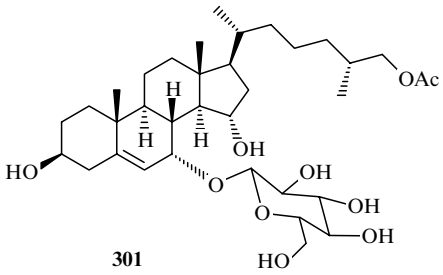


Some fish species also contain steroid glycosides. This fact is surprising in that glycosides are not common for terrestrial vertebrates. Among other known secondary marine glycoside metabolites, special mention should be made of shark reppelant compounds isolated from the corresponding glands of the sole *Pardachirus marmoratus* and the peacock fish *Pardachirus pavoninus*. Although these fishes swim extremely slowly, they successfully withstand the attacks of predatory fishes in their vehement struggle for existence under conditions of coral reefs. Both fish species belong to the same genus and secrete toxic substances at the moment of danger. These substances contain the peptides pardaxins causing paralysis of shark's gnathic muscles and two groups of toxic glycosides endowed with hemolytic activities, *viz*., pavonins **298a**,**b** and **299a**–**d** from *P. pavoninus*[206,207] and mosesines **300a**–**d** and **301** from *P. marmoratus*.[208]









These data suggest that steroid glycosides can be synthesised by taxonomically very distant and diverse groups of marine animals (from invertebrates to fishes). As regards the diversity of their constituent biologically active steroid glycosides, starfishes resemble other well-known sources of these compounds, *viz*., higher terrestrial plants.

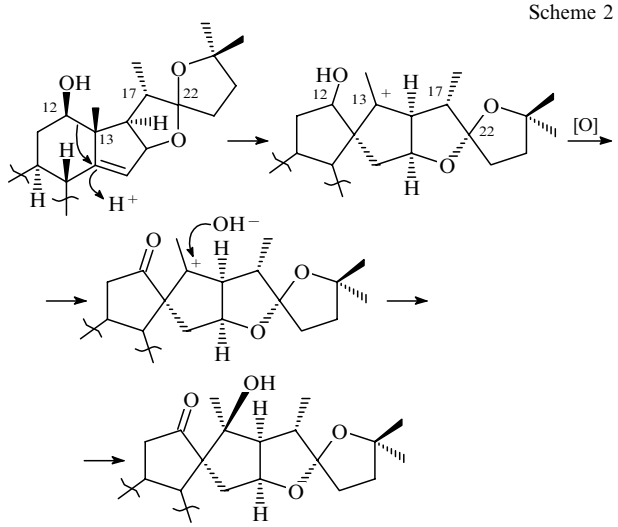
V. Steroidal alkaloids

Bissteroidal pyrazines constitute a special group among other natural compounds, which are supertoxic for tumour cells. The structure of cephalostatin 1 (**302a**), the first compound of this series isolated from the marine tubular worm *Cephalodiscus gilchristi* by Pettit *et al*. (USA),[209] was established by X-ray diffraction analysis. This compound in extremely low concentration was toxic for tumour cells P-388 (IC_{50} = 10^{-7}–10^{-9} μg ml^{-1}). Later, about 20 cephalostatins of this series, *e.g*., compounds **302b**–**g**, **303**, **304a**,**b**, **305**, **306a**,**b** and **307**, were isolated from this animal.[210–215]

Structurally close dimeric steroid alkaloids were unexpectedly found in the sea squirt *Ritterella tokioka* by Fusetani *et al*.[216–219] Ritterasine A (**308a**), the first compound in this series, is highly toxic for P-388 cells (IC_{50} = 3.5×10^{-3} μg ml^{-1}) (see Ref. 216). The origin of the unusual fragment containing four five-membered rings in ritterazine A and related compounds was explained by the rearrangement of the 12-hydroxy-Δ^{14}-steroid system of their precursor (Scheme 2).

Later, this group of Japanese chemists isolated more than twenty ritterazines, *e.g*., compounds **308b**, **309a**,**b**, **310**, **311**, **312a**,**b** and **313**, differing in the structures of rings *C*, *D*, *E* and *F* in one or both steroid fragments.[217–219] The majority of ritterazines appeared to be highly toxic for tumour cells; some of them manifested superhigh activities (Table 5).[218]

Scheme 2



The isolation of two closely related groups of compounds from phylogenetically distant taxa, such as sea worms and ascidians, prompted a suggestion that their biosynthesis is carried out by symbiont microorganisms rather than by the host organism. Cephalostatin 7 (**305**) is the most active compound of this series. Studies carried out at the National Cancer Institute (USA) showed that its average IC_{50} for 60 strains of tumour cells was equal to 10^{-9} mol litre^{-1}. Later, this and some other dimeric steroidal alkaloids were synthesised. According to Pettit,[209] these compounds are formed by dimerisation and subsequent oxidation of steroidal α-amino ketones. Fuchs *et al.*[220] described the biomimetic synthesis of cephalostatins 7 (**305**), 12 (**307**) and ritterazin K (**311**). The starting compound in this synthesis was steroid pentacyclic aldehyde **314** prepared from readily available hekogenin acetate. This was converted *via* the intermediate ketones **315**, **316** and bromo ketones **317** and **318** into azido ketones **319** and **320** (Scheme 3). Treatment of the azido ketone mixture (1 : 1) with 6 equiv. of NaHTe in ethanol for 1 h and subsequent addition of silica gel as a mild catalyst yielded a mixture of **321** (14%), **322** (35%) and **323** (23%). 321–**323** were purified by chromatography; their subsequent deprotection gave products identical with natural cephalostatins 7 (**305**) and 12 (**307**) and ritterazine K (**311**), respectively.

Pyrazine steroidal dimeric alkaloids belong to the most toxic natural products for tumour cells presently known. The synthesis of some of them has opened new opportunities for their further pharmacological and clinical investigations.

Squalamine (**324a**), an unusual sulfated derivative of spermidine, was isolated from the shark *Squalus acanthis*.[221, 222] Its structure was determined by spectroscopic methods; the stereo-

chemistry of the asymmetric centre C(24), (24*R*), was established based on the synthesis of desulfosqualamine and its (24*S*) isomer starting from stigmasterol.[223] In contrast to bile alcohols of fishes, squalamine (**324a**) is present not only in the liver and the gallbladder but also in other shark organs, *e.g.*, in the spleen and ovaries. Squalamine (**324a**) manifests interesting properties, *viz.*, its antibacterial activity is comparable to that of the broad-spectrum antibiotic ampicillin (see Table 6), but its antifungal and antiprotozoan effects are stronger.

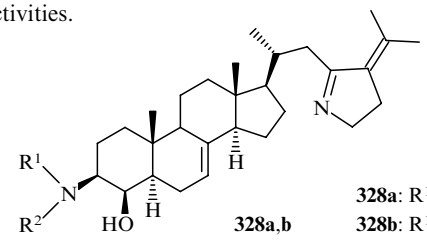
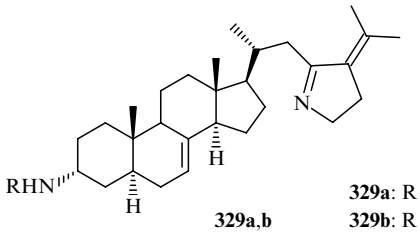
Two novel alkaloids **328a**,**b**[225] related to the previously known antimicrobial metabolites, plakinamides A and B (**329a**,**b**) from the sponge *Plakina* sp.,[226] were isolated from extracts of the sponge *Corticum* sp. collected near the coasts of Indonesia. Compounds **328a**,**b** are highly toxic for tumour cells and manifest moderate immunomodulating and antimicrobial activities.

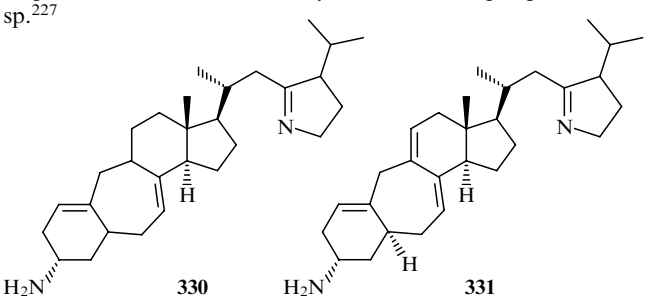


328a,**b** **328a**: $R^1 = R^2 = CH_3$; **328b**: $R^1 = COCH_3$, R^2 = H.



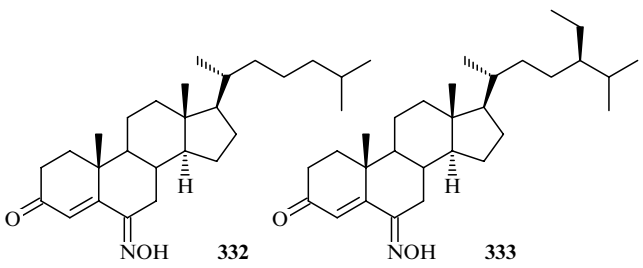
329a,**b** **329a**: R = H; **329b**: R = $COCH_3$.

The unusual steroidal alkaloids **330** and **331** with expanded ring *B* have been found recently in the Pacific sponge *Corticum* sp.[227]



330 **331**

The steroidal oximes **332** and **333** from the sponge *Cinachyrella* sp. inhibit competitively human placental aromatase and are



332 **333**

potential inhibitors of hormone-dependent tumours.[228] The syntheses of these compounds have been described.[229]

Although marine steroid alkaloids known thus far are not numerous, they present substantial interest with regard to their chemical structures and physiological activities.

VI. Miscellaneous marine steroids

In this section, we shall consider those marine steroids which can hardly be related to any of the above-mentioned structural groups.

Steroid phosphates were found in the starfish *Tremaster novaecaledoniae*. Tremasterols A–C (**334a–c**) related to glycosides were the first to be described.[230] The monosaccharide residues in these compounds are bound to aglycons by phosphodiester rather than glycosidic bonds. The signals for the protons at C(6) in the ^{1}H NMR spectra of tremasterols represented doublets of doublets of doublets of doublets (J = 9.5, 9.5, 7.5 and 4.5 Hz), *i.e.*, they contained an additional spin coupling constant compared with the corresponding spectra of 6α-hydroxy cholestane derivatives due to the HC–O–P coupling. Their ^{31}P NMR spectra contained triplet signals at δ 3.54, which coalesced into doublets upon irradiation of C<u>H</u>(6) or C<u>H</u>(1′), which suggests the presence of a phosphate group between C(6) and the monosaccharide residue. Chemical shifts of phosphorus atoms for phosphate and other functional groups in the ^{31}P NMR spectra are well established (see, *e.g.*, Ref. 231). Later, the steroid **335** containing sulfate and phosphate groups in positions 3 and 6, respectively, was isolated from the same starfish species.[136]

Some sponges were found to contain dimeric steroids. Thus bistheonellasterone (**336**) and bisconicasterone (**337**) were isolated from the Okinawian sponge *Theonella swinhoei* by Japanese scientists.[232,233] Compound **338** was prepared in nearly quantitative yield from theonellasterone **338** upon heating and evaporation of the latter in chloroform (50 °C, 2 h). The coupling occurred with excellent regio- and stereospecificity. It is assumed that the dimeric steroids **336** and **337** are formed as a result of the Diels–Alder cycloaddition of theonellasterone **338** to its Δ^4-isomer or, correspondingly, by cycloaddition of two molecules of conicasterone **339** to each other. Ketones **338** and **339**, the possible precursors of compounds **336** and **337**, and related compounds have been isolated from the same sponges where they occur as crystalline inclusion compounds.

Crellastatin A (**340**) was the first sulfated steroid dimer isolated from the sponge *Crella* sp.[234] The related compounds **341, 342**, *etc.*, were isolated later.[235]

Hymnosterone A (**343**), the unusual cytotoxic steroid derivative of mixed biogenesis, was isolated from the microscopic fungus *Gymnascella dankaliensis* associated with the sponge *Halichondria japonica*.[236] Hymnostatins containing a non-steroid fragment of compound **343**, *e.g.*, hymnostatin A (**344**), were detected in the same microorganism. They manifest high toxicities against tumour cells P-388.[237]

Polar steroids are seldom found in scleroactinian corals. However, steroidal acids **345a** and **346**, the carbon skeletons of which are identical with those of cholic acids, were discovered in deep-water *Deltocyanthus magnificus* by Pietra *et al.*[238]. Some of

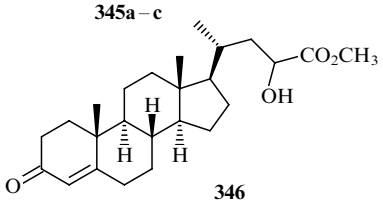
345c: R = CO_2CH_3.

345a – c

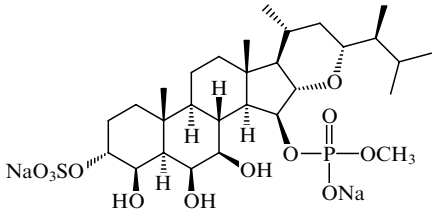


346

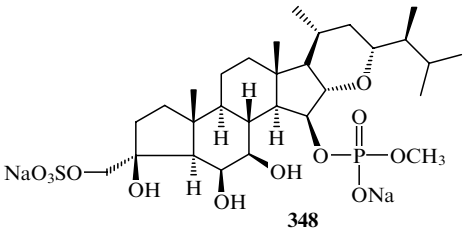
these compounds were isolated as methyl esters by treatment of the corresponding fractions with diazomethane.

* * *

Several interesting papers devoted to marine polar steroids were published after this review had been written. Thus Fujita *et al.*[239] reported on the isolation of two novel unusual polar steroids, *viz.*, haplosamate A (**347**) and the minor steroid **348** from the sponge *Cribrochalina* sp. dwelling near the Western coast of Japan.



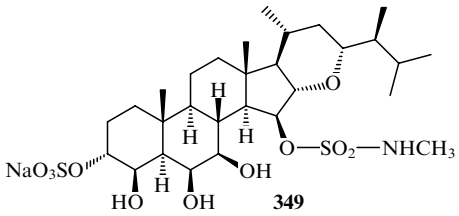
347 (haplosamate A)



348

These compounds were discovered during the search for inhibitors of matrix metalloproteinases of the membrane type (MT-MMPs), the key enzymes in tumour metastasis. These enzymes activate progelatinase A, which causes the degradation of type IV collagen. The latter inhibits invasion of tumour cells in different body organs and tissues. It is suggested that MT-MMPs inhibitors hold considerable promise as antitumour agents. Compounds **347** and **348** inhibited MT-MMPs (IC_{50} = 150 and 160 μg ml^{-1}, respectively).

Haplosamate A was found to be identical with the inhibitor of integrase, a specific enzyme of the human immunodeficiency virus, with a tentative formula **349**, which has earlier been isolated from two Philippine sponges.[240]

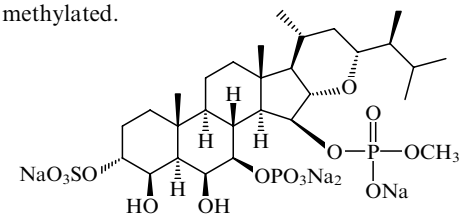


349

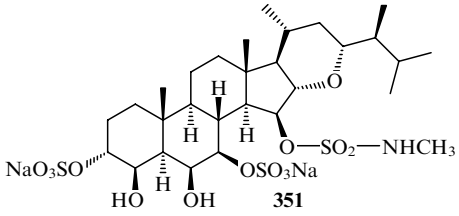
It was suggested that this polyhydroxylated steroid contains one sulfate group and one *N*-methylsulfamate group. However, the NMR spectra of haplosamate A displayed additional splitting of signals for certain protons, which could not be inferred from the formula **349**. Thus the proton signal corresponding to the methoxy group occurred as a doublet, which points to the presence of a phosphorus atom in this steroid. Further structural analysis corroborated the correctness of the structure **347** for haplosamate A and the compound isolated from Philippine sponges.

Haplosamate A (**347**) and the related steroid **348** are the first sponge steroids containing both sulfate and methyl phosphate groups. The absolute stereochemistry of compounds **347** and **348** was established on the basis of their chemical conversions and using a modified Mosher's method.

The structure of haplosamate B (**350**),[239] which was erroneously identified as compound **351**,[240] is even more surprising. Haplosamate B is the first polar steroid containing two phosphate and one sulfate groups; one of the phosphate groups in steroid **350** is methylated.

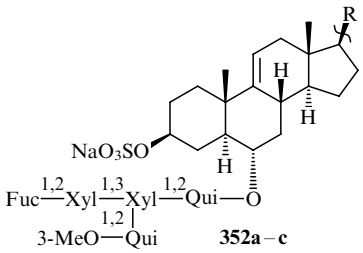


350 (haplosamate B)



351

The number of marine steroid glycosides is rapidly increasing. A recent report is devoted to the isolation of three novel antibacterial asterosaponins, *viz.*, goniopectenosides A – C (**352a – c**), from the starfish *Goniopecten demonstrans*.[241]

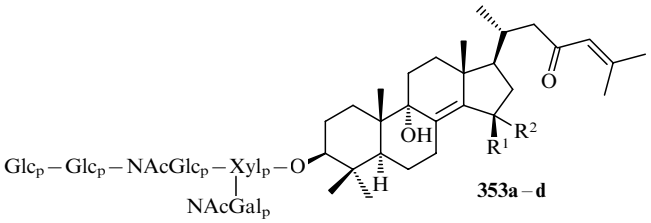


352a: R =  ;
352b: R =  ;
352c: R =  .

352a – c

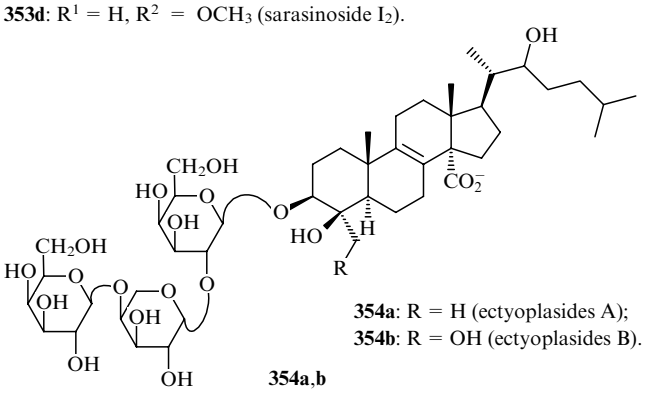
The carbohydrate chains of these compounds contain a rarely occurring monosaccharide, *viz.*, 3-*O*-methylquinovose, whereas their aglycons contain a keto group in position 22 rather than in 23. The use of a new instrumental approach, *viz.*, liquid chromatography combined with NMR and mass-spectroscopic detection (LC-NMR-MS), in the analysis of the well-studied asterosaponin fraction isolated from the starfish *Asterias rubens* revealed five novel steroid glycosides named ruberosides A – D.[242]

Four novel glycosides of this series, *viz*., sarasinosides H_1, H_2, I_1 and I_2 (compounds **353a**–**d**), were isolated from the sponge *Melophlus isis* together with the previously identified sarasinosides A_1 and A_3.[243] In contrast to sarasinosides, the cytotoxic glycosides ectyoplasides A and B (**354a**,**b**) from the Caribbean sponge *Ectyoplasia ferox*,[244] represent oxygenated derivatives of 4,14-dimethylsterols and contain two galactose and one arabinose residues in their carbohydrate chains.



353a–**d**

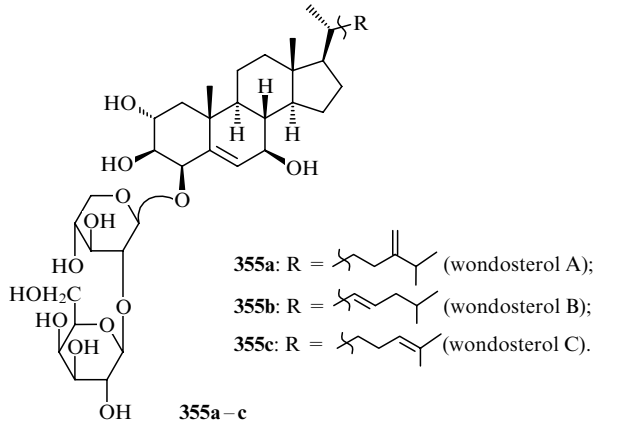
353a: R^1 = OH, R^2 = H (sarasinoside H_1);
353b: R^1 = OCH_3, R^2 = H (sarasinoside H_2);
353c: R^1 = H, R^2 = OH (sarasinoside I_1);
353d: R^1 = H, R^2 = OCH_3 (sarasinoside I_2).



354a: R = H (ectyoplasides A);
354b: R = OH (ectyoplasides B).

354a,**b**

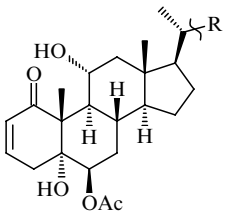
Yet another series of steroid glycosides, *viz*., wondosterols A–C (**355a**–**c**), were detected in a mixture of two different sponge species dwelling near the coasts of Korea.[245] These compounds contain carbohydrate chains linked to C(4) of the aglycons. Wondosterols (**355a**–**c**) belong to the same structural series as the known bioside pachastrelloside A (**284**), but differ from the majority of other sponge glycosides in that they derive from polyhydroxysterols rather than from methylsterols.



355a: R = (wondosterol A);
355b: R = (wondosterol B);
355c: R = (wondosterol C).

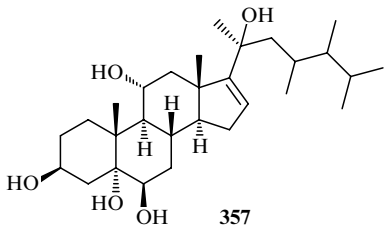
355a–**c**

Among novel steroids isolated from Coelenterata, special mention should be made of a series of compounds similar to witanolides isolated recently from the Okinawian soft coral *Clavularia viridis*, *viz*., the so-called jonarasterols A–C (**356a**–**c**)[246] and the steroidal pentol **357** from the soft coral *Sarcophyton trocheliophorum*,[247] which was weakly toxic against normal human leucocytes, but inhibited leukemia cells HL-60, melanoma cells M-14 and mammary carcinoma cells MCF-7 (IC_{50} = 3–5 μg ml^{-1}).



356a–**c**

356a: R = (jonarasterol A);
356b: R = (jonarasterol B);
356c: R = (jonarasterol C).



357

VII. Problems of isolation and structural analysis of marine polar steroids

Polar steroids are usually present in marine organisms as very complex mixtures of structurally related compounds, which significantly complicates their isolation and separation. These steroids may contain several functional groups or fragments. Thus trisulfated sterol derivatives are widespread in sponges, whereas steroids containing sulfate or phosphate groups in addition to monosaccharide fragments are more common for starfishes. Moreover, many highly active marine steroids are minor components of extracts where their concentrations do not exceed 0.001% of the dry weight of the corresponding organisms. Their isolation and purification present a difficult and not always solvable problem, although these procedures are usually carried out with the use of the most advanced separation techniques.

In our laboratory, we use reversed-phase column chromatography on a PTFE powder (Polychrome-1) in the first step of isolation of polar steroids. This consists in application of aqueous extracts on columns with this sorbent, elution of salts by washing the columns with water and elution of polar steroids with aqueous alcohol.[99,160]

Italian chemists perform this procedure on a column with Amberlite XAD-2.[3,165] Further separation usually requires the use of several separation techniques including gel-permeation chromatography on Sephadexes LH-20 and LH-60, adsorption chromatography on silica gel, reversed-phase HPLC as well as drop counter-current distribution. The isolation of 22 novel polar steroids from the starfish *Oreaster raticulatus*,[117] about 20 cephalostatins from *Cephalodiscus gilchristi*[211–217] and 20 ritterazines from *Ritterella tokioka*[216–219] provide illustrative examples of progress achieved.

NMR spectroscopy including the most updated techniques, *e.g*., HMBC and NOESY experiments, is the most popular structural physicochemical method. The absolute configurations of asymmetric carbon atoms of polyhydroxysteroids are often established by the Mosher's method,[248] which consists in the conversion of the corresponding hydroxy groups into ester groups by treatment with chiral *R*-(+)- and *S*-(−)-α-methoxy-α-trifluoromethylphenylacetyl chlorides (MTPA) with subsequent determination of the chemical shifts of protons at the adjacent carbon atoms of the diastereomeric esters formed. In the case of the 24*R*-configuration of the corresponding asymmetric centres in (+)- and (−)-MTPA esters, the signals corresponding to the $C(26)H_3$ and $C(27)H_3$ groups are observed at δ 0.89–0.91, whereas those for the 24*S*-isomers are found in the higher field, *viz*., at δ 0.83–0.86.

FAB-mass spectrometry is the most popular modern mass spectrometric technique for the determination of molecular masses of polar steroids and establishment of the sequences of

monosaccharide units in carbohydrate chains of steroid glycosides.

Although the chemical properties of many marine polar steroids are still poorly investigated, the use of chemical procedures for the establishment of their chemical structures sometimes demonstrates their unusual or unpredicted chemical behaviour especially in acidic media, *e.g.*, migration of the double bond in the steroid nucleus from position 8(9) to positions 8(14) and 14(15),[110, 191, 197] aromatisation of a ring in the steroid skeleton,[110] *etc*.

VIII. Conclusion

In marine organisms, steroid substrates can be oxygenated at any carbon atom without exceptions (Table 7). Even the products of steroid metabolism formed by oxidative cleavage of the bonds between the quaternary carbon atoms, *e.g.*, C(10) or C(13), and the neighbouring carbon atoms, were found in these organisms. Compounds containing hydroxy groups in methine and methylene groups instead of hydrogen atoms are even more numerous. Some representatives of starfishes, sponges and cnidarians contain steroids with three, four and even more (up to nine) hydroxy groups. Further modifications of polar steroids in marine organisms include sulfation (sponges, starfishes, ophiuroids and fishes), acylation (octocorals and some other cnidarian species and sponges), methylation (sponges), oxidation of hydroxy groups to keto and carboxy groups (sponges, cnidarians and echinoderms), phosphorylation (starfishes and sponges) and glycosylation (starfishes, sponges, fishes, cnidarians, less frequently, ophiuroids). Sometimes, biochemical conversions of polar steroids lead to the formation of nitrogen-containing derivatives, *viz*., alkaloids. All this provides evidence for the wide structural diversity of marine polar steroids.

The analysis of published data suggests that in-depth studies in this area are still in progress. In the last few years, the number of newly discovered marine steroids increases annually by 50 – 100 compounds. Many novel unexpected findings still remain to be made.

Although the biological activities and functions of marine polar steroids have not been adequately investigated yet, many of them have attracted the attention of pharmacologists and physicians. This concerns supercytotoxic antitumour compounds, efficient antimicrobial agents, inflammation inhibitors, *etc*. In-depth studies of antiinflammatory activities of contignasterol, antitumour activities of cephalostatins and specific physiological activities of other marine polar steroids are currently under way. However, the array of activities tested employed in the isolation of novel polar steroids is still rather narrow. Thus the majority of investigators have concentrated on the search for novel antitumour compounds, whereas all other types of activities of marine steroids are neglected.

The experimental data and the unusual structural peculiarities of some polar steroids attract keen attention of synthetic chemists. Recent developments in this field culminated in complete and partial syntheses of these natural compounds, their analogues and derivatives. Thus the syntheses of two novel sponge 9,10-secosteroids,[250] *viz*., calicopherol E and astrogorgiadiol (by the method of Barton [249]); of cytotoxic stolonipherones earlier isolated from the soft coral *Clavularia viridis;*[251] of incrustasterols possessing antitumour activities;[252] of xestobergsterol A obtained in 24 steps from stigmasterol [253] and of 3-epi-6,7-dideoxysestobergsterol A [254] have recently been carried out. Apparently, the synthetic trend in the study of marine polar steroids will be developed in the future.

It is obvious that the vast pool of fundamental knowledge concerning the structure, taxonomic distribution and properties of marine polar steroids created owing to joint efforts of many research groups all over the world will serve as a basis for the development of novel biotechnological approaches to their preparation in sufficiently large amounts. Close cooperation of bioorganic chemistrs and specialists in aquatic, cell and tissue cultures and gene engineering will be a valuable contribution.

In the next few years, significant progress can be anticipated in the study of biogenesis of marine steroids, particularly in isolation and investigation of enzymes responsible for their biosynthesis

Table 7. Examples of marine organisms containing oxygenation polar steroids with oxiden-containing functional groups at different positions.

Carbon atom	Marine organisms	Carbon atom	Marine organisms	Carbon atom	Marine organisms
1	sponges (*Xestospongia*), corals (*Sinularia*), *etc*.	10	gorgonian corals (*Caligorgia*), sponges (*Corticum*)	19	corals (*Nephthea*, *Antiphates*, *Litophyton*), sponges (*Toxadocia*, *Strongylophora*, *Crella*)

III.	Magnesium diboride, a medium-T_c superconductor	720
IV.	Conclusion	730

Abstract. The discovery of superconductivity in magnesium diboride ($T_c \approx 40$ K), announced in January 2001, stimulated intensive research into the nature of superconductivity and electrophysical, magnetic and thermodynamic properties and spectroscopic characteristics of MgB_2 and related compounds. The review concerns methods for the synthesis of new MgB_2-based superconductors with more complex chemical composition. Particular emphasis is placed on the results of investigations on the electronic structure and peculiarities of chemical bonding in these compounds. Materials science aspects of practical utilisation of materials based on the new superconductor are analysed. Main results of theoretical and experimental studies in the above-mentioned fields are generalised. The bibliography includes 228 references.

I. Introduction

In his lecture at the International Symposium on Transition Metal Oxides (Sendai, South Korea, 2001) J Akimitsu announced [1] the discovery of superconductivity in MgB_2 (for more detailed information, see Ref. 2). Magnesium diboride is a relatively poorly studied representative of a broad class of metal borides.[3–14] The discovery of superconductivity in MgB_2 has immediately attracted considerable interest in this system. The transition temperature for MgB_2 ($T_c \approx 40$ K) is almost twice as high as the values of T_c for all other binary superconductors, *e.g.*, compounds and alloys with B1- (NbN, $T_c \approx 17.3$ K) or A15-type (Nb_3Ge, $T_c \approx 23$K) structures.[15,16] From the viewpoint of its properties, magnesium diboride stands apart from all known borides. For instance, the values of T_c for binary *d*-metal borides,[9,17] as well as for ternary ($LnRuB_2$, $LnRh_4B_4$) and pseudoternary $[(Ln_{1-x}Ln'_y)Rh_4B_4]$ borides [18] lie between $\leqslant 0.5$ and 8 K. The highest transition temperatures ($T_c \approx 16-23$ K) were found for intermetallic borocarbides (IBC), namely, layered quaternary compounds of the $LuNi_2B_2C$ type [19–21] belonging to 'conventional' superconductors.[22]

A distinctive feature of magnesium diboride is that the value of T_c for this compound is 'intermediate' between those of classical low-temperature (LTSC) and high-temperature superconductors (HTSC). To emphasise this feature, MgB_2 is sometimes called a medium-T_c superconductor. It is of great importance that, unlike high-temperature superconducting complex oxides, MgB_2 is a non-oxygen compound with very simple chemical composition and structure.[3–8]

The discovery of superconductivity in MgB_2 has raised a number of questions.

1. What is the nature of the superconductivity in MgB_2?
2. Is magnesium diboride a unique compound of this kind or is it the first representative of a new class of superconductors?
3. What physical and chemical properties should related superconductors possess?

Answers to these questions can predetermine a breakthrough in understanding the nature of the superconductivity in crystals and physical chemistry of inorganic compounds and in outlining possible application areas of new superconductors.

In spite of short time that has elapsed since the discovery of superconductivity in MgB_2, experimentalists and theoreticians have accumulated a great body of information about its properties.

New superconductors have been found and superconducting materials based on MgB_2 were obtained in the form of powders, single crystals, films, wires and composites. It was found that the superconductivity parameters of MgB_2 remain stable in magnetic fields and upon neutron irradiation. Magnesium diboride is characterised by high critical transport currents and, at the same time, by their low sensitivity to grain boundary contacts. These and some other properties of this novel superconductor seem to be rather attractive for its practical utilisation.

The main goal of this review is to generalise a considerable body of information about magnesium diboride, its functional properties and possible application areas accumulated to date. Taking into account a great deal of interest in MgB_2, we have briefly outlined the history of investigations of the system Mg – B and reported the available data on the properties of magnesium borides. Particular emphasis is placed on the results of recent studies on the nature of the superconductivity in and physicochemical properties of MgB_2 (including the year 2001). The review concerns the results of both theoretical modelling and experimental research into the electronic structure and the nature of chemical bonding in magnesium diboride and related compounds. Problems associated with search for new superconductors based on MgB_2 and some materials science aspects are also outlined.

II. Magnesium borides: a brief history of investigations (1895–2000)

Magnesium borides were first obtained by Moissan in 1895.[23] Analysis of products of the interaction between metallic magnesium and boric anhydride revealed two magnesium borides with strongly different chemical stabilities. One of the borides was found to decompose in acids to give boranes, mostly B_4H_{10}. More recently, this boride, with the chemical composition Mg_3B_2,[24–28] was studied[24] for use as starting material in the synthesis of boranes. The assumption of the existence of the second boride, Mg_2B_4 (MgB_2), was proposed[29] based on the results of analysis of boride hydrolysis products.

Studies carried out by researchers from the USSR[3,8] and other countries[4–7] over a period of two decades, from 1950s to 1970s, serve as a basis for present-day knowledge of the system Mg–B. Magnesium borides can be obtained by (i) reduction of B_2O_3 with metallic magnesium,[23] (ii) direct interaction of elemental Mg and B, (iii) reduction of MgO with boron, (iv) reduction of Na_2BF_6 with magnesium and (v) by reactions between Mg and BCl_3 and between MgO and boron carbide.[3,8] Pioneering studies on the phase equilibria in the system Mg–B and physicochemical properties of particular magnesium borides also date back to the above-mentioned two decades.

1. Phase relations in Mg–B system

No detailed phase diagram of the system Mg–B is available. Information about stable magnesium borides is contradictory (see, *e.g.*, Refs 3–13, 30). On the one hand, the occurrence of four phases (MgB_2, MgB_4, MgB_6 and MgB_{12}) is assumed.[30] On the other hand, the assumption of the occurrence of the lowest magnesium boride, Mg_3B_2, was rejected.[31] Six magnesium boride phases (MgB_2, MgB_4, MgB_6, a variable composition phase MgB_6–MgB_{17} and two phases of unknown composition) have also been reported.[32] The following phases were found in the phase diagram of the system Mg–B reported in monograph[33]: MgB_2, MgB_4 and MgB_7 (Fig. 1). Below we will consider only those magnesium borides for which reliable structural information is available.

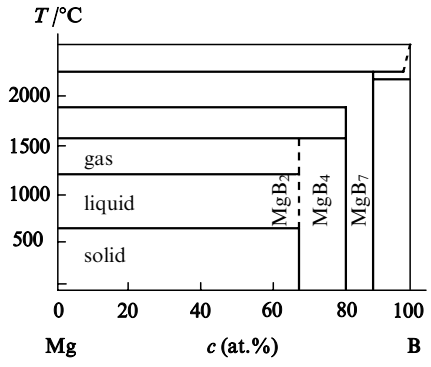

Figure 1. Phase diagram for the Mg–B system.[33]

2. Crystal chemistry of magnesium borides

Pioneering studies on the crystal structure of MgB_2 date back to the early 1950s.[34–40] Magnesium diboride has a hexagonal AlB_2-type structure. The space group is $P6/mmm$ (D^1_{6h}), the number of formula units in the unit cell $Z = 1$. Boron atoms occupy positions at the centres of trigonal prisms while magnesium atoms occupy positions at their vertices. Such prisms share all faces, thus forming a three-dimensional packing. The structure of MgB_2 can be represented as alternating planar hexagonal Mg layers and graphite-like (honeycomb) boron sheets (Fig. 2). The alternation pattern is Mg–B_2–Mg–B_2... The coordination number (CN)

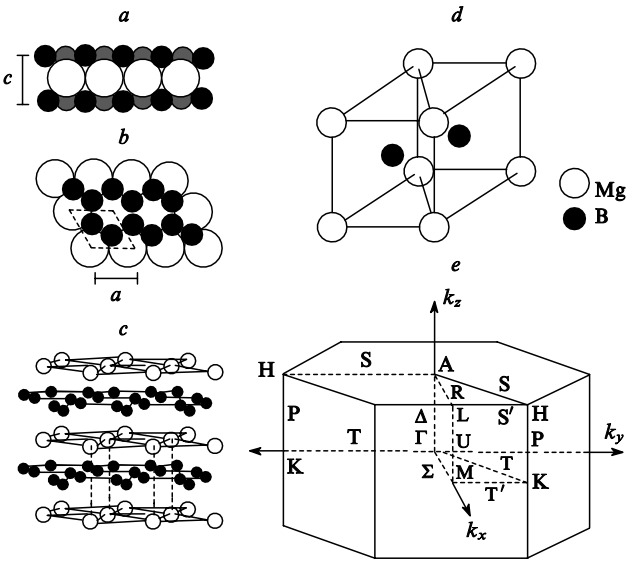

Figure 2. Structure of MgB_2.
Types of atomic packing: interlayer packing, side view (*a*); in-plane packing, top view (*b*); packing of atomic layers, side view (*c*); primitive unit cell (*d*) and the Brillouin zone (*e*).

of magnesium atoms is 20 and their coordination polyhedron (CP) is [$MgB_{12}Mg_8$]. For boron atoms, CN = 9 and the CP is [BMg_6B_3]. The atomic positions in the unit cell are as follows: Mg, 1*a* (0,0,0) and B, 2*d* (1/3, 2/3, 1/2) and (2/3, 1/3, 1/2). The lattice constants are $a = 3.0834$ and $c = 3.5213$ Å; $c/a = 1.142$. The interatomic distances are B–B ($a/\sqrt{3}$) = 1.780, B–Mg ($\sqrt{a^2/3 + c^2/4}$) = 2.503, Mg–Mg (in-plane) = 3.083 and Mg–Mg (interlayer) = 3.520 Å.[10,38–40]

Currently, more than a hundred of binary compounds with the AlB_2-type structure are known, including diborides of *p*- and *d*-elements.[3–13,38–40] Nevertheless, the problem of the existence of general physical or chemical criteria determining the conditions for the formation of structural types of various borides remains a moot question as yet. From the standpoint of crystal chemistry,[10] structural types of borides can be explained taking into account the ratio of atomic radii (r) of the components M/B (M is metal). According to the theory of symmetry of close crystal packings of spheres, an 'ideal' value of r_M/r_B for trigonal prismatic coordination is 1.89. For stable hexagonal MB_2 phases, the ratio r_M/r_B varies from 1.14 to 2.06[38] (*e.g.*, $r_M/r_B = 1.571$ for aluminium diboride and 1.758 for magnesium diboride).

Pearson[40] proposed an empirical criterion for the existence of AlB_2-type structures, namely, a correlation between structural parameters (c/a) of stable phases and the ratio r_M/r_X (here, X is an element whose atoms can form graphite-like sheets; in addition to boron, the set X can include Be, Si, Ga, Hg, Zn, Cd, Al, Cu, Ag and Au, see Refs 38–40). The ratio c/a varies from 0.59 to 1.2 (Fig. 3). As can be seen, the point corresponding to MgB_2 ($c/a = 1.142$) is located near the upper critical bound of structural stability. According to Pearson,[40] the occurrence of hexagonal CaB_2, which is the closest analogue of superconducting MgB_2 (see below), is impossible.

Magnesium tetraboride was first synthesised in 1953.[35] The crystal structure and properties of this compound have been studied in detail.[31,41–43] Crystals of MgB_4 belong to orthorhombic system (the space group $Pnam$, $Z = 4$) and are characterised by the unit call parameters $a = 5.464$, $b = 7.472$ and $c = 4.428$ Å.[42,43] The structural motif can be represented as pentagonal pyramids built of boron atoms, which form extended chains. Magnesium atoms occupy positions between boron polyhedra. The shortest distances are Mg–B = 2.392 and Mg–Mg = 3.075 Å. The atomic positions in the unit cell are as follows: Mg, 4*c*: x, y, 1/4 ($x = 0.051$, $y = 0.136$); $B_{1,2}$, 4*c*:

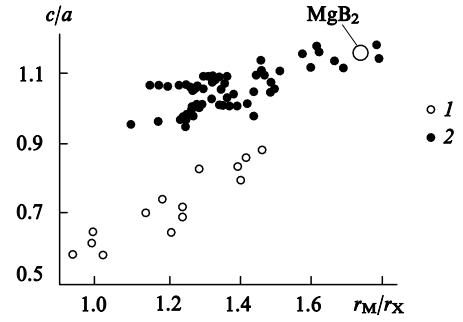

Figure 3. Dependence of the ratio of lattice parameters (c/a) on the ratio of atomic radii (r_M/r_X) for AlB_2-type binary phases MX_2;[40] c/a: <0.9 (*1*) and >0.95 (*2*).

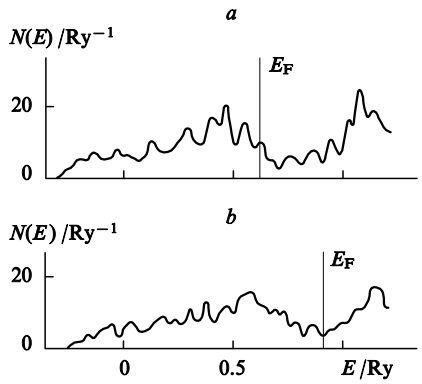

Figure 4. Total densities of states for MgB_2 (*a*) and AlB_2 (*b*) obtained from FLMTO calculations.[49]

($x_1 = 0.725$, $y_1 = 0.657$; $x_2 = 0.559$, $y_2 = 0.854$) and B_3, 8*d*: x, y, z ($x = 0.130$, $y = 0.434$, $z = 0.442$).[10] This structural type is unique in its kind since most of binary metal tetraborides [5–9, 12, 13] belong to the CrB_4 and ThB_4 structural types.

The existence of magnesium hexaboride, MgB_6, also remains a moot question as yet. It is thought that such a hexaboride represents a mixture of magnesium heptaboride MgB_7 and magnesium tetraboride MgB_4 while MgB_9 represents a mixture of MgB_7 and elemental boron.[44] The structure of magnesium heptaboride MgB_7 (Mg_2B_{14}) is characterised by a CN of 28 for the magnesium atom.[45] Similar structural elements are also inherent in $MgAlB_{14}$ ($Mg_{1-x}Al_{1+y}B_{14}$), $LiAlB_{14}$ and NaB_{15}.[10] On the other hand, MgB_7 and Mg_2B_{14} were described as individual phases with different lattice constants.[13]

3. Magnesium borides: properties, electronic structure and chemical bonding

Information about physicochemical properties of magnesium borides is scarce.[3, 8, 9, 11, 13] Only hydrolytic stability of magnesium borides and their reactions with acids have been studied in detail. It was found that boranes are formed only in the reactions with MgB_2. From the viewpoint of its reactivity and solubility in acids, this compound differs strongly from both higher magnesium borides and most of *d*-metal diborides which possess high chemical stability. Some thermochemical and thermal properties of MgB_2 (heat capacity, enthalpy, entropy and dissociation pressure, heats of formation) have been reported.[8, 9, 13]

To our knowledge, no studies on the electronic structure and the nature of chemical bonding in magnesium borides, except for MgB_2 and 'MgB_6', have been carried out so far. By analogy with other metal–boron systems, it can only be assumed that covalent B—B bonds (within boron polyhedra) should have increased importance in the overall system of interatomic interactions responsible for improvement of thermomechanical properties and chemical stability of magnesium borides on going from lower borides to higher (from MgB_2 to 'MgB_{12}').

The energy band structure of MgB_2 was studied [46–48] by the semiempirical LCAO,[47] tight binding [48] and non-self-consistent orthogonalised plane wave (OPW) methods.[46] The structures of the valence bands of MgB_2 and graphite were found to be similar.[46] The major contribution to the valence band of magnesium diboride comes from the combination of boron $p_{\sigma,\pi}$-orbitals.[47] Charge transfer occurs from Mg to B. The position of the bottom of the conduction band is determined by B boron p_π-orbitals. Comparison of the energy band structure for MgB_2 and the hypothetical crystal $\square B_2$ with 'empty' cation sublattice allowed one to draw a qualitative conclusion about the dominating role of B—B interactions in the overall system of chemical bonds.

The energy band structure as well as the chemical bonding and energy parameters of MgB_2 obtained from the first nonempirical calculations carried out by the self-consistent full-potential linear muffin-tin orbital (FLMTO) method [49] were analysed and compared with the corresponding characteristics of isostructural borides (AlB_2 and TiB_2). Among the known diborides MB_2, titanium diboride exhibits exceptionally high thermomechanical and strength properties.[7–9] The total densities of states (DOS) for MgB_2 and AlB_2 are shown in Fig. 4. The energy band structure consists of two broad bands separated by a DOS minimum (a pseudogap). A qualitative explanation for differences between the properties of MgB_2 and AlB_2 was obtained [49] in the framework of the rigid band model (RBM) [50–52] based on the structure of the valence band. According to this model, both chemical stability and thermomechanical properties of MB_2 are related to the parameter

$$V = \frac{V_b}{V_v},$$

where V_b is the width of the filled band of electron states and V_v is the total width of the valence band (up to the DOS minimum). An optimum stability corresponds to $V = 1$ (*i.e.*, all bonding bands are filled while all antibonding bands are empty). This condition holds for such *d*-metal diborides as TiB_2, ZrB_2 and HfB_2 [the valence electron concentration, VEC, is 3.33 e per atom per formula unit (see Refs 50–57)]. For MgB_2 (VEC = 2.67),[49] the calculated values are $V_v = 1.011$, $V_b = 0.912$ Ry, $V = 0.902$. For AlB_2 (VEC = 3.0 e per atom), $V_b = V_v = 1.146$ Ry, $V = 1.0$, which means that this diboride should exhibit the highest stability.

Analysis of chemical bonding in MgB_2, AlB_2 and TiB_2 using charge density maps (Fig. 5) shows that the overlap of the B—B wave functions in the plane of graphite-like sheets decreases from MgB_2 to TiB_2.[49] For TiB_2, the most pronounced is the effect of interlayer Ti—B covalent bonds, while MgB_2 is characterised by retention of spherical symmetry of the cation charge density contours. The cohesive energies (E_{coh}),† and the energies of particular (B—B, M—B and M—M) bonds were calculated (Table 1). As can be seen, the major contribution to the cohesive

† As is known, E_{coh} describes the overall effect of chemical bonding in crystals.

Table 1. Cohesive energies (E_{coh}) and energies of particular bonds (E_b) for magnesium, aluminium and titanium diboride /Ry per unit cell.[49]

Parameter	MgB_2	AlB_2	TiB_2
E_{coh}	1.26	1.42	1.58
E_b (see[a])			
M—M	0.11	0.28	0.36
B—B	0.86	0.83	0.86
M—B	0.29	0.24	0.36

[a] For calculation procedure, see Refs 53–57.

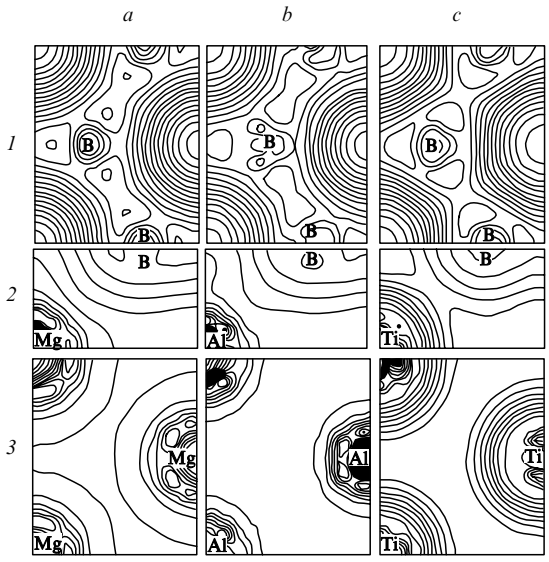

Figure 5. Charge density distributions for magnesium (*a*), aluminium (*b*) and titanium diboride (*c*): in-plane for boron sheets (*1*), in-plane for metal atom layers (*3*) and between boron sheets and metal layers (*2*).[49]

energies of MgB_2 comes from the B – B-interaction (68%). The contributions of other types of chemical bonds are much smaller (23% for B – Mg and 9% for Mg – Mg bonds). An increase in the cohesive energy on going from MgB_2 to AlB_2 is due to strengthening of the M – M bonds while the B – B and M – B binding energies vary only slightly. This is the main distinction between these compounds and *d*-metal diborides for which the value of E_{coh} depends first of all on the 'interlayer' M – B interactions.[53–57]

4. Application areas of magnesium borides

Information about application areas of magnesium borides concerns mainly MgB_2. The most attractive properties of this compound are its mechanical characteristics and high reactivity.

Magnesium diboride is used as an abrasive; polycrystalline composites based on MgB_2 and boron nitride were proposed to be used as materials for cutting devices.[13] As mentioned above, magnesium boride was used as starting material to obtain boranes following the hydrolytic decomposition reaction of the boride. Currently, the role of MgB_2 (i) as precursor in reactions of fast chemical exchange in the synthesis of refractory *d*-metal borides and ceramics based on them and (ii) in the preparation of close-packed boron nitride polymorphs has been studied intensively.

The known methods for the preparation of cubic boron nitride (c-BN), a material with record hardness, are based on heat treatment of hexagonal BN (h-BN) under pressure or precipitation from melts. Crystallisation and nucleation of c-BN are strongly affected by various catalysts, *e.g.*, C, B, Fe, Co, Ni, Cu, Al, their alloys and mixtures, as well as metal nitrides, oxides and borides.[58,59] Magnesium diboride is an efficient catalyst of spontaneous crystallisation of c-BN.[13,60–68] Studies of c-BN nucleation from melts in the system MgB_2 – BN at pressures up to 6.8 GPa and temperature up to 2000 K allowed one to determine the threshold pressure ($P \approx 4.5$ GPa) for the lower temperature bound of the c-BN phase formation ($T \approx 1630$ K).[67] The role of small additives of the third component (P, Si) on the crystallisation kinetics of c-BN in pseudoternary systems MgB_2 – BN – P (see Ref. 65) and MgB_2 – BN – Si[63,64] has been studied.

Magnesium diboride and higher magnesium borides occur among reaction products if refractory *d*-metal borides are obtained by reduction of corresponding oxides by magnesium-reduced boron

$$MO_y + B \longrightarrow MB_z + B_2O_3$$

or by magnesium reduction of such oxides

$$MO + Mg + B_2O_3 \longrightarrow MgO + MB_z.$$

At the formation temperatures of refractory borides MB_z, magnesium borides thermally decompose into boron and magnesium, the latter being removed nearly completely.[13] The procedure for preparation of dispersed ZrB_2 powders[69] is based on competitive reduction processes of ZrO_2 and boric anhydride in the system ZrO_2 – Mg – B_2O_3 (at 1100 °C) and boronation of α-Zr and Mg in the system ZrO_2 – Mg – amorphous boron (at 700 °C) followed by removal of MgO and MgB_2. A thermal reaction in the system TiO_2 – Mg – B_2O_3 in Ar atmosphere results in titanium diboride as the major product and magnesium oxide and magnesium borate ($Mg_3B_2O_6$) as side products.[70] Metal borides, solid solutions based on them and boride ceramics can also be synthesised by solid-state reactions of fast chemical exchange with participation of MgB_2.[71–73] A mechanochemical reaction in a Ti – 4% MgB_2 mixture, resulting in a nanocrystalline Ti matrix with inclusion of MgB_2 grains of size 20 to 300 nm has been studied.[74] Subsequent sintering of the reaction product at 600 °C resulted in a new compound with NiAs-type structure and unknown composition.

Along with TiB_2, B_4C, CrB_2, BN and amorphous boron, MgB_2 was announced to be an antioxidant, *i.e.*, an additive to carbon-containing refractory materials used in metallurgy to prevent them from breakdown upon oxidation of carbon in the surface layer.[75] Oxidation and phase formation in the mixture of MgB_2 synthesised in the reaction $MgB_{12} + Mg \rightarrow MgB_2$ with periclase – carbon composite have been studied as functions of temperature.[75] The process is characterised by exothermic effects, begins at ~470 °C and results in MgO, $Mg_2B_2O_5$ and boric anhydride. Similar magnesium polyborides (mixtures of amorphous boron and MgB_{12} obtained by magnesium reduction of B_2O_3) were found to behave similarly. According to DTA, the mass increased by 43%. Amorphous boron of purity 95% to 98% exhibited the best antioxidant properties; in this case, a mass increase of 124% to 147%.

The results of applied research on the use of MgB_2 as a catalyst in the synthesis of c-BN,[76] as antioxidant additive to refractory materials[77–79] and for production of dispersed alloys[80] and SiC powders (see Ref. 81) were patented.

Prospects for practical utilisation of superconducting MgB_2 will be considered below.

III. Magnesium diboride, a medium-T_c superconductor

The discovery[1,2] of superconductivity in MgB_2 and publication of pioneering studies,[82–87] in which the nature of the effect was rationalised in the framework of electron – phonon mechanism of superconductivity, has stimulated discussion about possible analogues of superconducting magnesium diboride. Both chemical composition and crystal structure aspects of the problem were considered and some other factors responsible for superconductivity were analysed. Chemical analogues of MgB_2, that is, binary and multicomponent borides, have been considered in the preceding Section of this review.

Considerable attention has been given to the role of quasi-two-dimensional (quasi-2D) structure of magnesium diboride. It has been generally thought that high lattice symmetry (preferably, cubic) is favourable for superconductivity. This can be exemplified by elemental superconductors (Nb, La under pressure and fullerite C_{60} with the transition temperatures of 9, 13 and 33 K, respectively), binary compounds (ZrN, NbN and Nb_3Ge with T_c of 10.7, 18 and 23 K, respectively) and a number of ternary compounds.[88–90]

Recently, a group of 2D-HTSC has been found. Oxides with CuO_2 layers in their structures can serve as the best known

example of these compounds. Quasi-2D β-nitrides ZrNCl (T_c = 15 K) and HfNCl (T_c = 25 K) also represent layered structures with alternating (Zr, Hf)–N and chlorine layers. Interlayer interactions in these compounds are weak and superconductivity is observed upon intercalation with alkali metal atoms.[91–93] A possible mechanism of superconductivity in anisotropic media taking into account the quasi-2D character of the energy bands has been discussed.[94]

Special attention has been given[87] to similarity in the atomic structure and electronic properties of MgB_2 and graphite. Both compounds are isoelectronic [the ionic formula of magnesium boride is $Mg^{2+}(B_2)^-$], have layered structures and exhibit a similar type of chemical bonding with strong in-plane σ-bonds and weak interlayer π-bonds. Moreover, electron-doped intercalated graphites (*e.g.*, LiC_8 and KC_8) are superconductors (up to T_c = 5 K).[95,96] There is also evidence[97] for substantial enhancement of superconductivity in specially treated fullerite C_{60} to $T_c \sim 52$ K (*cf.* $T_c \leqslant 33$ K for the known medium-T_c superconductors based on M_3C_{60}, where M is an alkali metal), which points to potentially significant role of intercalation.

The nature of these analogies can be understood by analysing the band structure and phonon spectrum of magnesium diboride. Before considering them, let us discuss methods for the synthesis of MgB_2.

1. Synthesis and properties of superconducting MgB_2

a. Synthesis of MgB_2

Currently, superconducting MgB_2 is mainly obtained as polycrystals by solid-phase synthesis from elemental B and Mg.[1,2,82–84,98–120] Synthetic procedures differ from one another in composition of starting materials, atmosphere, and heat treatment regimes. For instance, MgB_2 samples were synthesised[84] from magnesium flakes and sub-micron powder of amorphous boron which were pressed in pellets, placed on Ta foil and subsequently fired in a tube furnace under inert atmosphere (95% Ar + 5% H_2) at 600 (1 h), 800 (1 h) and 900 °C (1 h) and then lightly ground. The resulting powders were hot pressed (10 kbar, 650–800 °C) for periods between 1 and 5.5 h. The samples thus obtained were characterised by multiphase composition; however, they exhibited high critical currents.

Other sintering conditions are listed in Table 2. For instance, $Mg(^{11}B)_2$ was prepared[101] from a boron powder enriched with ^{11}B and Mg lumps placed in a BN crucible and heat-treated for 1.5 h in Ar atmosphere (P = 50 bar). No chemical composition of the sample obtained was reported. The superconductivity parameters were T_c = 39 K and the width of the transition ΔT_c = 0.4 K. Magnesium diboride samples were also synthesised[82] from a Mg : B = 2 : 1 mixture in a Ta tube placed in a quartz ampoule in Ar atmosphere. The mixture was heated to 950 °C and kept 2 h at this temperature. The procedure proposed by Gerashenko *et al.*[99] involved pressing of magnesium and amorphous boron into pellets which were placed in a Ta crucible and then subjected to two-step annealing in purified helium flow. At first, the pellets were annealed at 800 °C for 1 h. The resulting phase contained MgB_2 (78.6%), Mg (16.6%), MgO (4.7%) and BN (traces). Subsequent annealing at 875 °C (1 h) led to evaporation of the unreacted metallic magnesium. The final phase was composed of MgB_2 (89.9%), MgO (5.2%) and BN (1.7%) and characterised by T_c = 39.5 K and ΔT_c = 2.5 K. Thus, superconducting magnesium diboride powders can be obtained using rather simple synthetic procedures which do not require costly starting materials and equipment.

b. Physicochemical properties of superconducting MgB_2

The mechanism of superconductivity in MgB_2 was elucidated by measuring the isotope effect on $Mg(^{10}B)_2$ and $Mg(^{11}B)_2$ powders.[82] Replacement of ^{10}B by the heavier isotope, ^{11}B, led to a decrease in T_c from 40.2 to 39.2 K and to narrowing of the transition region by 0.1 K (Fig. 6). The isotope coefficient,

$$\alpha_B = -\frac{\Delta \ln T_c}{\Delta \ln M_B},$$

where M_B is the magnetisation of the boron sublattice, was found to be ~ 0.26. This is close to the α_B values for IBC,[105,106] the superconductivity of which is due to electron–phonon interaction (with high-frequency optical B A_{1g} modes) and is described in the framework of the Bardeen–Cooper–Schrieffer (BCS) model.[22]

Experiments with different samples[102,107,108] revealed rather high critical current densities (j_c) ($2 \times 10^4 - 10^5$ A cm^{-2}). It was found that the temperature dependences of the critical fields H_{c2} and H_{c1} near T_c have a slope of 0.012 T K^{-1} and that the magnetisation curves are reversible.[107,108] The H_{c2} anisotropy (1.73) was first measured[108] on aligned crystallite samples. The temperature dependence $H_{c1}(T)$ was reported to be linear for the whole temperature region in which superconductivity is observed.[109] At $T > T_c$, the temperature dependence of the resistivity has the form[110]

Table 2. Conditions for the synthesis of superconducting MgB_2 powders.

Atmosphere (sheath)	Sintering conditions		Phase composition	Lattice parameters /Å		T_c /K	Ref.
	T /°C	time /h		a	c		
92% Ar + 8% H_2 (Ta foil)	600 + 800 + 950, after compaction	2 + 2 + 1,	MgB_2 + MgO (impurity)	3.0815(6)	3.5191(7)	37	100

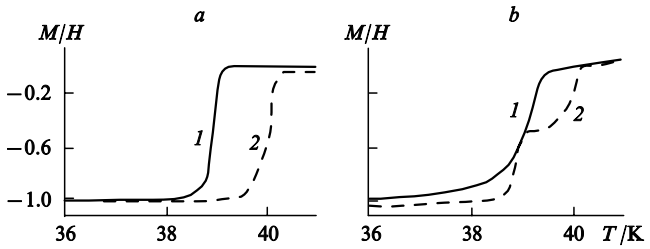

Figure 6. Isotope effect in magnesium diboride.[82]
(*a*) Magnetisation divided by magnetic field strength (M/H) as function of temperature for $Mg(^{11}B)_2$ (*1*) and $Mg(^{10}B)_2$ (*2*); (*b*) the same for $Mg(^{10}B)(^{11}B)$ (*1*) and sum of $Mg(^{11}B)_2$ and $Mg(^{10}B)_2$ data (*2*).

$$\rho(T) \approx T^2.$$

It was found that magnetic field has no effect on ρ. The Hall coefficient[111] R_H of magnesium diboride is positive (4.1×10^{-11} m^3 deg^{-1} at 100 K and a hole concentration, n, of 1.5×10^{23} cm^{-3}) and increases in the temperature range from 40 to 300 K.

An important distinction of superconducting MgB_2 from cuprate HTSC has been pointed out.[84] Due to high anisotropy, cuprate HTSC rapidly lose their performance in external fields, while the supercurrents flowing throughout even untextured, multiphase MgB_2 samples are little sensitive to weak magnetic fields. The spin–lattice relaxation rate[99,112] and the Knight shift[99] were measured by NMR spectroscopy; the behaviour of the former parameter was interpreted within the framework of *s*-wave model in the strong electron–phonon coupling limit.[112]

Magnesium diboride was also studied by the scanning tunnelling microscopy.[113–115] Particular attention was paid to the current-*vs*.-voltage characteristics used for the determination of the width of the superconducting energy gap (Δ). Large scatter of the gap widths Δ (from 5 to 7 meV, see Refs 113–115) was first of all explained by different compositions of the samples studied. The gap widths Δ were also evaluated from the tunnelling spectra of Au/MgB_2 point-contact tunnel junctions[116] (Δ = 4.3 meV) and IR reflectance spectra[117] (Δ = 4.5 meV).

The specific heat of magnesium diboride and its dependences on the magnetic field and temperature were measured,[118,119] as well as some other thermodynamic and mechanical characteristics [*e.g.*, the elasticity modulus $B_0 = 151 \pm 5$ GPa (see Ref. 120)].

The possibility of self-consistent interpretation of the results of the above-mentioned experiments in the framework of the model of electron–phonon mechanism of superconductivity in magnesium diboride[82,85–87] should be emphasised. On the other hand, Hirsch[121] proposed a 'universal' model of 'hole superconductivity' in MgB_2,[122] which implies pairing of spin carriers driven by the Coulomb interaction. However, the results obtained upon treatment of MgB_2 according to Hirsch[121] in order to increase T_c (*e.g.*, by doping with aluminium or by hydrostatic lattice compression) contradict the conclusions reported in theoretical studies based on the electron–phonon mechanism of superconductivity.

2. Electronic structure and superconductivity of MgB_2

According to McMillan,[123] the critical temperature in crystals with electron–phonon mechanism of superconductivity can be determined using the formula

$$T_c \approx \langle\omega\rangle \exp[f(\lambda)],$$

where $\langle\omega\rangle$ is the averaged phonon frequency (which is inversely proportional to the masses of the atoms), λ is the electron–phonon coupling constant [$\lambda \approx N(E_F)\langle I^2\rangle$], $N(E_F)$ is the density of states (DOS) at the Fermi level and $\langle I^2\rangle$ is the electron–ion matrix element determined by the bond ionicity. Information about the electronic structure and vibrational states of MgB_2 is of crucial importance for correct interpretation of superconductivity in and other properties of MgB_2 as well as for targeted search for new superconductors.

a. Electronic structure

The discovery of superconductivity in MgB_2 stimulated intensive theoretical[85–87,124–130] and experimental[131–133] studies of the electronic structure of magnesium diboride[85–87,124–133] and a large number of stable and metastable isostructural diborides of Li, Na,[87,125,126] Be, Ca,[124] Al,[124,126] Sc, Y, Ti, V,[124,134] Ag and Au,[127] as well as some related phases [MgB_6, CaB_6,[128] $CaSi_2$, CaSiBe,[125] $ZrBe_2$, $HfBe_2$, $CaGa_2$,[127] Mg_3BN_3 (see Ref. 129)]. Calculations were carried out using rigorous, self-consistent density functional approach.

The valence band structure of MgB_2 is determined[85–87,124–126] by the B $2p$ states which form four $\sigma(2p_{x,y})$-bands and two $\pi(2p_z)$-bands (Fig. 7). They exhibit strongly different dispersion $E(k)$. For the B $2p_{x,y}$-bands, the dispersion $E(k)$ is maximum along the $k_{x,y}$ direction (Γ–K). These bands reflect the distribution of the B states within graphite-like sheets, which have a quasi-2D type and form flat zones along the k_z direction (Γ–A). Two B $2p_{x,y}$-bands cross the Fermi level and contribute largely to the total density of states at the Fermi level [$\sim$30% (see Ref. 85)]. These bands are responsible for the metal-like properties of magnesium diboride. The Fermi level is located in the region of bonding states. Magnesium diboride exhibits hole-type conductivity, which is consistent with the results of Hall coefficient measurements.[111] Charge transfer occurs from magnesium to boron.

One of the most distinctive features[85–87,124–130] of the electronic structure of MgB_2 is the position of the B $2p_{x,y}$ energy bands. Namely, they are above the E_F at the Γ point of the

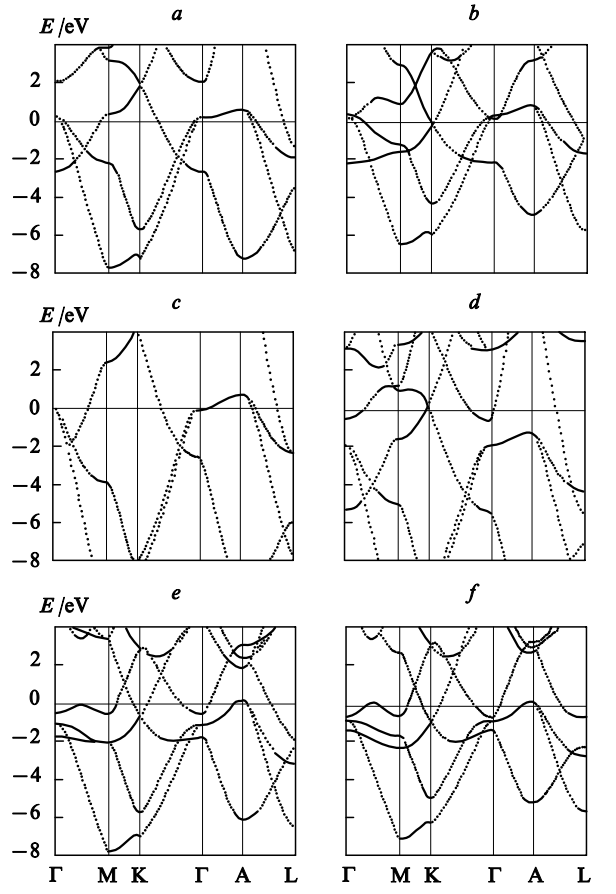

Figure 7. Energy band structures for MgB_2 (*a*), CaB_2 (*b*), BeB_2 (*c*), AlB_2 (*d*), ScB_2 (*e*) and YB_2 (*f*).[124]

Brillouin zone and form two hole-type cylinders on the Fermi surface.[85–87] The B $2p_z$-like states have a 3D-type, are oriented perpendicular to the boron sheets and are responsible for weak interlayer π bonds.[85–87, 124–126] Both π-bands cross the Fermi level and are characterised by the maximum dispersion along the k_z direction (Γ – A). The Mg *s*, *p*-states and B *s*-states are mixed with the system of B 2*p*-like bands near the valence band edge and in the conduction band. The determining role of boron in the formation of the electronic structure of MgB_2 has been particularly emphasised by Kortus *et al.*[85] who titled their communication 'Superconductivity of metallic boron in MgB_2'.

The electronic structure of magnesium diboride was studied by X-ray emission spectroscopy (XES),[131, 132] X-ray absorption spectroscopy (XAS)[131, 132] and photoemission spectroscopy (XPS).[131, 133] Comparison of the C K_α XES lines ($1s \rightarrow 2p$-transitions) for graphite and corresponding B K_α lines for MgB_2 and AlB_2 (Fig. 8) clearly demonstrates differences in positions of their emission maxima determined by the p_{xy}-states.[135] This supports the idea[85–87, 124–130] of correlation of the superconductivity in MgB_2 with the relative positions of the σ- and π-bands (the presence of hole-type σ-states). The results of XES and XAS studies[132] of the structure of B bands near the Fermi level are in excellent agreement with the results of calculations (Fig. 9). The spectra exhibit a number of resonance lines indicating the presence of a protective oxide film formed on the sample surface upon exposure to air.

High-resolution XPS studies of magnesium diboride allowed direct observation[133] of the superconducting energy gap (~4.5 meV at 15 K). This gap (~3 meV at $T = 0$ K) is of the *s*-wave character and its temperature dependence is consistent with the BCS theory.

Band structure calculations were carried out for magnesium diboride and isostructural diborides of Li, Na,[87, 126] Be, Ca,[124] Al,[124, 126] Sc, Y, Ti, V,[124, 134] Ag and Au (see Ref. 127). The band structures are compared in Figs 7 and 10. The absence of superconductivity in BeB_2 (see Ref. 136) was assumed[124] to be due to the low-energy shift of σ-bands and the absence of hole states at the Γ point, which changes the Fermi surface topology in such a manner that cylinders (along the Γ – A directions) are transformed into cones. The absence of superconductivity in AlB_2 is due to filling of σ-bands caused by the VEC increase.[83] Variations of superconducting properties for a number of *d*-metal diborides can be rationalised based on the results of calculations.[53–55, 124, 134] For ScB_2 and YB_2, the 2D-p_{xy}-bands at the A point are above the E_F (see Fig. 7), but the concentration of hole carriers is low. It is important that metal *d*-states contribute largely to $N(E_F)$. As a result, these diborides are characterised by low T_c (1.5 – 2.0 K).[9, 17] Among hexagonal transition metal diborides, the lowest T_c values should be exhibited by TiB_2, ZrB_2 and HfB_2, for which the Fermi level is located in the pseudogap.[50–55] As electron concentration increases, the *d*-band is filled and $N(E_F)$ increases[50, 52–55] (*e.g.*, for Group V and VI *d*-metal diborides). This can lead to an increase in T_c; *e.g.*, a rather high $T_c \sim 9$ K was reported for TaB_2.[137]

Analysis of the energy band structures of metastable diborides of Li, Na,[87, 126] Ca,[124] Al,[124, 126] Ag and Au (see Ref. 127) showed that the σ- and π-band configurations and band filling types

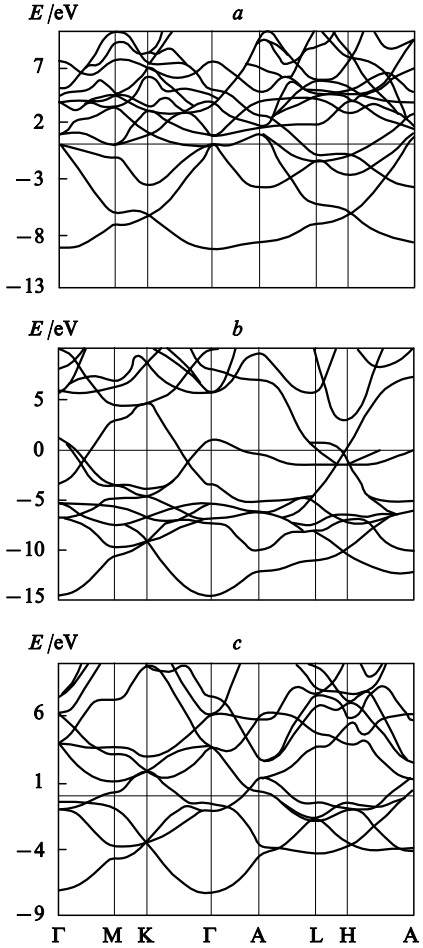

Figure 10. Energy band structures for $CaGa_2$ (*a*), AgB_2 (*b*) and $ZrBe_2$ (*c*).[127]

calculated for CaB_2 are the same as the 'optimum' parameters of superconducting MgB_2. Calcium diboride was suggested [124] to be the most probable new superconductor. Estimates [124] of the enthalpy of formation of CaB_2 (-0.12 eV per formula unit) showed the possibility of real synthesis of this compound. It is thought that calcium diboride can be stabilised by, *e.g.*, doping with isoelectronic or hole dopants (Mg, Li, Na) or by forming layered superstructures, *e.g.*, $Ca-B_2-Mg-B_2-Ca$. The electronic properties of ternary systems based on MgB_2 will be considered in the next Section of this review. Here, we will only mention that an increase in the unit cell volume will assist the formation of the electronic structure of diborides in a manner favourable for superconductivity. This can be done by, *e.g.*, isoelectronic replacement of magnesium by cations with larger atomic radii (Ca, Sr, Ba).[124]

Structural similarity between MgB_2 and hexagonal BN has been pointed out.[129] Like MgB_2, boron nitride also contains planar boron sheets while its structural stability is due to strong in-plane covalent bonds.[14, 138] The energy band structures of MgB_2 and solid solutions of composition $MgB_{2-y}N_y$, where boron was partially replaced by nitrogen, were compared.[129] Solid solutions with $y = 0.25$ and 1.00 were studied. The solution $MgB_{1.0}N_{1.0}$ (in which the composition of the non-metal sublattice formally matches the composition BN) can be considered as a model of magnesium boronitride prepared by intercalating atomic h-BN sheets with hexagonal magnesium layers. The energy band structure of the individual ternary phase Mg_3BN_3 with separated layers of different-type metalloids (B and N) was calculated.[139]

An increase in the N/B ratio in the composition of solid solutions leads to a shift of the Fermi level towards higher values, filling of antibonding states and a decrease in $N(E_F)$. The bonding B $p_{x,y}$-like bands become completely filled while the hole states are absent. According to calculations,[129] Mg_3BN_3 is a semiconductor [transition at the Γ point of the Brillouin zone, the forbidden gap (FG) width is 0.88 eV (0.065 Ry)]. The valence band structures of MgB_2 and Mg_3BN_3 are fundamentally different, *viz.*, the determining role in the mechanism of superconductivity in MgB_2 is played by the B 2*p*-bands while for Mg_3BN_3 these bands lie much below E_F and contribute negligibly to the region of the spectrum near the Fermi level.

The energy band structure of metastable cubic magnesium hexaboride (the space group *Pm*3*m*) has been studied.[140] The optimised lattice parameter corresponded to $a = 4.115$ Å. The main building blocks of the MgB_6 structure are B_6 octahedra. The energy band structure contains 10 valence bands of hybrid B 2*s*,*p*-states, which are responsible for B—B bonds both within and between B_6 octahedra. The upper filled band forms a flat zone along the $X-\Gamma$ direction and is composed of B $p_{x,y}$-orbitals involved in B—B interactions between B_6 octahedra. The first unfilled band is characterised by strong *k*-dispersion and is composed of contributions of cation states. Unlike CaB_6 (FG $\approx$ 0.0163 Ry, direct transition at the Γ point), magnesium hexaboride is a narrow-gap semiconductor with indirect transition (FG $\approx$ 0.0150 Ry, $X \rightarrow R$ transition).[10, 141–144] Despite the determining role of B—B bonds in MgB_2 and MgB_6 crystals, they possess basically different electronic properties that is, metallic for MgB_2 and semiconducting for MgB_6.

'Non-boride' AlB_2-type phases with silicon, beryllium or gallium graphite-like sheets have been reported [$CaSi_2$, CaSiBe,[125] $ZrBe_2$, $HfBe_2$, $CaGa_2$ (see Ref. 127)].

Rhombohedral $CaSi_2$ (the space group *R*3*m*) obtained under equilibrium conditions is known to be a nonsuperconducting semimetal.[145] Heat treatment of $CaSi_2$ under pressure can cause a polymorphous transformation into an AlB_2-type structure.[146] Similarity between the energy band structure of this disilicide and those of *sp*-element diborides and $CaGa_2$ (see Fig. 10)[127,146] was found.[125] The main distinctions are due to Ca *d*-orbitals which are mixed with the Si states near the bottom of the conduction band due to hybridisation. The antibonding π^*-bands are partly filled, which can be the reason for structural instability of the high-pressure phase under normal conditions. Stabilisation of hexagonal $CaSi_2$ by replacement of Si by Be was studied taking calculations of a model phase CaSiBe as an example. It was assumed [125] that (i) replacement of Si by an atom of smaller radius (*cf.* $r_{Si} = 1.34$ and $r_{Be} = 1.13$ Å) will produce 'chemical pressure', which is favourable for stabilisation of the AlB_2-type structure, and (ii) partial depletion of the π^*-band with a decrease in the electron concentration in the system will an additional stabilising factor. As was found, stabilisation of the AlB_2-type structure requires the reduction of the VEC in the system by $\sim$0.7 e.[125] The electronic properties of $HfBe_2$ and $ZrBe_2$ are fundamentally different from those of superconducting MgB_2 (see Fig. 10).

b. Electronic structure and properties of superconducting MgB_2

Some properties of MgB_2 were explained using information about its electronic structure obtained from calculations. Kortus *et al.*[85] estimated the constant λ ($\sim$1) and phonon frequencies (300–700 cm^{-1}) and calculated the T_c value within the rigid atom sphere model. Their results were found to be consistent with the experiment.[2] The *ab initio* approach was also successfully used in phonon spectrum calculations, simulation of the effect of heat treatment on superconductivity in magnesium diboride and calculations of its elasitc characteristics (see below). Calculations [134] of the electric field gradients (EFG) reflect asphericity of the electron density distribution in the vicinity of atomic nuclei and are closely related to the symmetry of their nearest environment, electronic structure and the nature of chemical bonding.

Experimental EFG values are obtained in studies of quadrupole effects in the NMR spectra of MgB_2 (see Refs 99, 112) and some other diborides.[147] Analysis of the nature and regularities of variations of the EFG depending on the energy band structure of several diborides MB_2 (M = Be, Mg, Al, Sc, Ti, V, Cr) has been reported.[134] The results are listed in Table 3. Among *sp*-metal borides, BeB_2 is characterised by the largest V_{zz} component of the EFG. For 3*d*-metal diborides, the V_{zz} component changes nonmonotonically, with a minimum for TiB_2. These changes were explained [134] based on results of band structure calculations for these phases (see Fig. 7). For boron nuclei, the EFG characterises the anisotropy of partial charge density distributions

$$V_{zz} \approx \frac{p_z - (p_x + p_y)}{2},$$

where p_z, p_x and p_y are the corresponding band populations.

Table 3. EFG components on boron nuclei in borides.

Diboride	10^{-21} V_{zz} /V m^{-2}		
	FLMTO [134]	FLAPW [148] (see [a])	experiment [147]
MgB_2	1.88	—	1.69
BeB_2	2.10	—	—
AlB_2	0.99	—	1.08
ScB_2	0.60	—	—
TiB_2	0.35	0.38	0.37
VB_2	0.38	0.39	0.43
CrB_2	0.59	0.60	0.63

[a] Full-potential linearised augmented plane wave method.

According to calculations, diborides with partially unfilled p_{xy}-bands (BeB_2, MgB_2) are characterised by the largest EFG. Additional increase in EFG for BeB_2 depends on the mutual position of the p_{xy}- and p_z-bands and is determined by an increase in the population of the latter. The increase in V_{zz} in order $TiB_2 \rightarrow VB_2 \rightarrow CrB_2$ is due to fundamentally different reasons, namely, weakening of the interlayer hybrid $p-d$ metal—boron

bonds affecting the relative position and populations of the B p_{xy}- and p_z-bands.[124] Estimation of changes in the EFG on magnesium and boron nuclei in MgB_2 with pressure (up to $P = 10$ GPa) showed that an increase in pressure has little effect on the EFG at boron nuclei, whereas the EFG at magnesium nuclei rapidly increases.[134]

c. Phonon spectrum and electron – phonon interaction

Preliminary estimation of phonon frequencies obtained from band structure calculations showed [85, 87, 149] that they were consistent with the observed T_c. The authors of pioneering studies [85, 87] reported only particular modes responsible for electron – phonon coupling. The results of phonon spectrum calculations [149–151] point to the dominating role of optical phonons in the electron – phonon interaction. Similarly to electron states of the σ-bands, these optical phonons are of quasi-2D type (along the Γ – A direction of the Brillouin zone) and correspond to the in-plane vibrational modes. An important distinction between the phonon characteristics of MgB_2 and AlB_2 (Fig. 11) consists in 'softening' of the high-frequency vibrational modes in magnesium diboride and their strong coupling ($\lambda \approx 0.75$) with electrons near the Fermi level.[150] Nonsuperconducting AlB_2 is characterised by a much smaller constant λ (0.4).[150] Inelastic neutron scattering studies [101] revealed four peaks of the generalised density of phonon states, the maximum energy of atomic oscillations was found to be higher than 90 meV. The maximum energy of acoustic phonons (36 meV) was determined from analogous experiments [98] and it was shown that optical modes are characterised by strong dispersion and form peaks at 54, 78, 89 and 97 meV. The estimate [98] of the constant λ ($\lambda \approx 0.9$) obtained using the Born – von Karman model [98] is consistent with the results of calculations by Andersen *et al.*[149]

3. Search for new superconductors based on MgB_2 and related phases: theory and experiment

The discovery of superconductivity in MgB_2 stimulated intensive theoretical and experimental search for new related superconductors. A general trend has been to extend the variety of possible MgB_2-based superconductors by varying their chemical compositions.

a. Theoretical studies

The possibility of chemical modification of the electronic structure of 'ideal' MgB_2 by varying its chemical composition was systematically studied by the FLMTO method in the framework of supercell approach.[124, 152] The effects analysed were those produced on the band structure of MgB_2 by doping the boron sublattice with Be, C, N and O, by doping the magnesium sublattice with Be, Ca, Li, Na, Zn and Cu and by changing the diboride composition due to addition of lattice vacancies in Mg- and B-sublattices (nonstoichiometry effects). The compositions of compounds studied are listed in Table 4.

Table 4. Results of FLMTO calculations of the DOS at the Fermi level [state per (eV per formula unit)] for magnesium diboride and related binary and ternary systems.[124]

Diboride	$N(E_F)$	Diboride	$N(E_F)$
MgB_2	0.73	$Mg_{0.75}Li_{0.75}B_2$	0.73
CaB_2	0.92	$Mg_{0.50}Li_{0.50}B_2$	0.75
BeB_2	0.47	$Mg_{0.75}Na_{0.75}B_2$	0.73
$MgB_{1.75}C_{0.25}$	0.56	$Mg_{0.50}Na_{0.50}B_2$	0.76
$MgB_{1.75}$	0.61	$Mg_{0.75}Cu_{0.25}B_2$	0.89
$Mg_{0.75}B_2$	0.74	$Mg_{0.75}Be_{0.25}B_2$	0.62
		$Mg_{0.75}Zn_{0.25}B_2$	0.51

Qualitative changes in the energy band structures of solid solutions have been discussed in the framework of the RBM model.[152] It was found that dopants can act as hetero- or isoelectronic impurities which change or have no effect on the VEC in the system, respectively. According to calculations, Be impurity in the boron sublattice, Li, Na and Cu impurities in the magnesium sublattice as well as both types of lattice vacancies ('hole dopants') will, first, decrease the VEC in the system, thus leading to an increase in the concentration of hole states in the σ-band and, second, assist a shift of the E_F towards high energies with an increase in $N(E_F)$. Both these factors are favourable for superconductivity (see above). On the contrary, Al impurity in the magnesium sublattice, C, N and O impurity in the boron sublattice ('electron dopants'), will deteriorate the superconducting properties of the system due to filling of the σ-band and reduction of $N(E_F)$. In the framework of the RBM model, the role of isoelectronic replacement of Mg by Be or Ca remains unclear as yet. One can only assume that the main effects will be associated with structural factors, that is, magnesium diboride lattice distortion depending on the ratio of radii of 'host' and 'guest' elements.

Numerical calculations [124, 152] give a more complex picture (see Table 4 and Figs 12, 13). The addition of vacancies to boron sublattice ($MgB_{1.75}$) leads to a decrease in $N(E_F)$. In the series of solid solutions $MgB_{1.75}C_{0.25} < MgB_{1.75}N_{0.25} < MgB_{1.75}O_{0.25}$ the $N(E_F)$ increases nonmonotonically. This is due to the filling of antibonding states. The σ-band becomes fully occupied. It was concluded that there is no prospect for obtaining superconductivity in the system by doping the boron sublattice.[124] Based on consideration of particular binding energies (see Table 1), it was suggested that insertion of impurity into the boron sublattice is much less probable than substitution in the cation sublattice. In the latter case, the energy band structures of solid solutions $Mg_{1-x}M_xB_2$ (M = Be, Ca, Li, Na, Cu, Zn) remain essentially

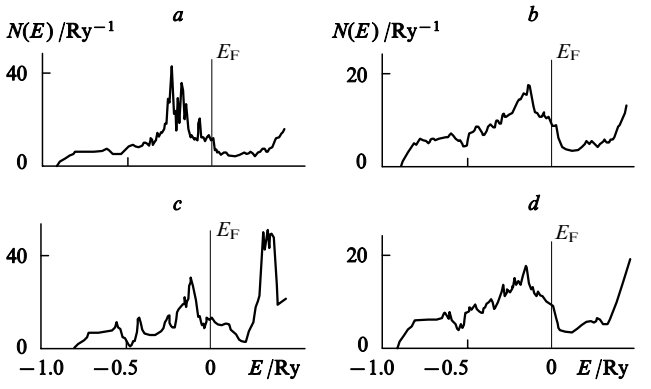

Figure 12. Total densities of states for $Mg_{0.75}Cu_{0.25}B_2$ (*a*), $Mg_{0.72}Na_{0.75}B_2$ (*b*), CaB_2 (*c*) and MgB_2 (*d*).[124]

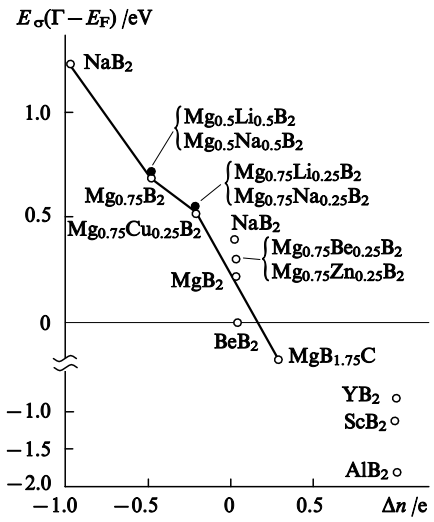

Figure 13. Dependence of the σ-band position at the Γ point of the Brillouin zone relative to the Fermi level in crystals $[E_\sigma(\Gamma - E_F)]$ on the electron concentration (relative to MgB_2, Δn) for binary diborides and ternary solid solutions based on MgB_2.[124]

similar to that of superconducting MgB_2 (see Fig. 12 and Table 4). The $N(E_F)$ value depends first of all on the impurity concentration. Hence, the main procedure for modifying the properties of magnesium diboride is to dope its cation sublattice. In addition to the VEC, electron distributions and superconductivity were also found to be dependent on the impurity concentration that affects structure peculiarities of MgB_2-based multicomponent solid solutions (first of all, the ratio between the in-plane distance and interlayer spacing).

Calculations of solid solution $Mg_{0.5}Al_{0.5}B$ [125] revealed the presence of hole states near the Z point of the Brillouin zone. It was also found that cation substitution and corresponding electron distributions cannot be completely described using the rigid band model.

Changes in the energy band structure with concentration and, in particular, the dependence of the σ-band energies on the composition of solid solutions $Mg_{1-x}Al_xB_2$ and $Mg_{1-x}Na_xB_2$ (x = 0, 1/3, 2/3, 1.0) were studied[126] using the density functional theory in the framework of supercell approach ($\sqrt{3} \times \sqrt{3}$) (Fig. 14). For $Mg_{1-x}Na_xB_2$ with any x, the top of the B p_{xy}-band at the Γ point is above E_F; in other words, the major electronic criterion for the existence of superconductivity holds. For $Mg_{1-x}Al_xB_2$, this condition is valid at $x < 0.6$. At $x > 0.6$, the hole states at the centre of the Brillouin zone disappear. The concentrations of the σ-holes (n_h /cm^{-3}) depend on the compositions of solid solutions as follows:[126]

for $Mg_{1-x}Al_xB_2$, $n_h = (0.8 + 0.8x) \times 10^{23}$,

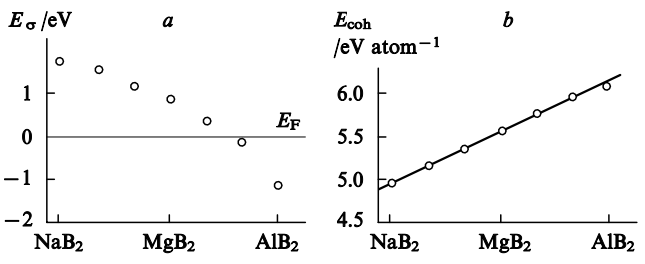

Figure 14. Changes in the σ-band position at the Γ point of the Brillouin zone (E_σ) relative to the Fermi level (*a*) and cohesive energies (*b*) in the order $NaB_2 \rightarrow Mg_{1-x}Na_xB_2 \rightarrow MgB_2 \rightarrow Mg_{1-x}Na_xB_2 \rightarrow AlB_2$.[126]

for $Mg_{1-x}Na_xB_2$, $n_h = (0.8 - 1.4x) \times 10^{23}$.

The hole concentration is a maximum ($\sim 1.6 \times 10^{22}$ cm^{-3}) for NaB_2. The cohesive energy (see Fig. 14) monotonically increases in the order $NaB_2 < Mg_{1-x}Na_xB_2 < MgB_2 < Mg_{1-x}Al_xB_2 < AlB_2$ as the corresponding bonding states in the valence band are filled.

b. Experimental studies

Theoretical studies of systems mentioned above are accompanied by experimental search [83, 136, 153–159] for new superconductors based on MgB_2 (variation of its elemental composition was mostly considered). Substitution solid solutions were synthesised using cation ($Mg_{1-x}M_xB_2$; M = Li, Be, Al, Zn, Cu) [83, 136, 153–155] and anion ($MgB_{2-y}C_y$) [156–158] sublattice substitution. Earlier,[159] only the formation of solid solutions in the MgB_2–AlB_2 system was reported.

Solid solutions were synthesised from elements in inert atmosphere, the samples obtained were analysed by elemental and structural analyses and their superconductivity parameters (T_c, ΔT_c) were measured (Table 5).

System Mg–B–Be.[155] A mixture of MgB_2 + BeB_2 phases was obtained. Beryllium diboride has a hexagonal structure (the space group $P6/mmm$, $c/a = 0.977$) and is paramagnetic at $T < 5$ K. It was found that beryllium does not replace the Mg atoms.

System Mg–B–Li.[155] The homogeneity region of solid solutions $Mg_{1-x}Li_xB_2$ was determined ($x < 0.3$). As lithium content increases, the interlayer distance remains unchanged while the in-plane B–B distance (parameter *a*) is shortened by ~0.014 Å (at $x = 0.3$). A decrease in T_c is observed beginning with $x = 0.1$ and becomes pronounced near the single-phase composition bound of the solid solution ($x = 0.3$). Loss of superconductivity occurs for the sample with $x = 0.5$.

System Mg–B–Al.[83] Two homogeneity regions of solid solutions $Mg_{1-x}Al_xB_2$ were found (see Table 5). As the Al/Mg ratio increases, anisotropic lattice compression occurs: the interlayer spacings decrease appreciably while the B–B distances do not exhibit considerable changes. This leads to structural instability of the crystal and phase transition at $x = 0.1$. A decrease in T_c in the homogeneity region of the solid solutions was explained [83] by an increase in the electron concentration and a decrease in $N(E_F)$. Analysis of the phase diagram shows that the superconducting phase is very close to the structural instability point of the system.

System Mg–B–Cu.[153, 154] Information about this system is contradictory. Abnormally high T_c = 49 K announced [153] for a sample with stoichiometric composition $Mg_{0.8}Cu_{0.2}B_2$ has not been confirmed; attempts at preparing copper-containing single-phase solid solutions failed.[154]

System Mg–B–Zn.[154] The homogeneity region for $Mg_{1-x}Zn_xB_2$ samples is up to $x = 0.1$. Analysis of the lattice parameters for a sample with $x = 0.1$ revealed their increase compared to those of MgB_2, namely, 0.17% for *a* and 0.2% for *c*. It was suggested [154] that nonmonotonic change in T_c is due to positive for the parameter *a* (in-plane B–B distances) and negative for the parameter *c* (interlayer spacings) expansion effects.

System Mg–B–C.[156–158] AlB_2-Type borocarbides $MgB_{2-x}C_x$ were synthesised from elements. Transition temperature T_c decreases in the homogeneity region ($x \leqslant 0.20$) by ~2 K (at $x = 0.20$, see Ref. 157) while the width of the transition, ΔT_c, substantially increases (by ~3–7 K as compared to 'pure' MgB_2, see Refs 156, 157). Introduction of carbon impurity leads to compression of graphite-like boron sheets: $a(MgB_2) - a(MgB_{1.8}C_{0.2}) = 0.013$ Å. The interlayer distances (the lattice parameter *c*) remain unchanged.[156] Magnesium borocarbides with much narrower homogeneity region ($x < 0.1$) were also synthesised;[158] transition temperature of these compounds decreases as the C/B ratio increases.

Table 5. Conditions for synthesis and characteristics of particular ternary systems based on MgB_2.

Starting materials [a]	Reaction conditions	Products (phase composition)	T_c /K	Lattice parameters /Å		Ref.
				a	*c*	
Mg + B + Al	95% Ar + 5% H_2, 600–900 °C	$Mg_{1-x}Al_xB_2$: solid solutions at $0 < x < 0.1$ and $0.25 < x < 0.40$ mixture of phases at $0.1 < x < 0.25$	38 ($x = 0$) 36 ($x \approx 0.1$) 0 ($x > 0.1$)	decreases as x increases		83
Mg + B + Cu	95% Ar + 5% H_2, 600–900 °C	$Mg_{0.8}Cu_{0.2}B_2$ (?) [mixture of phases $MgB_2 + Cu_2Mg + MgO$ (traces)]	49 (?)	3.068	3.505	153

Mg + B + Zn	100% Ar 600–900 °C	solid solutions $Mg_{1-x}Zn_xB_2 + MgO$ (traces) + MgB_4 at $x \approx 0.1$, mixture of phases at $x > 0.1$	changes nonmonotonically	3.0841 ($x \leqslant 0.1$)	3.5250 ($x = 0.1$)	154
Mg + B + Li	100% Ar, 950 °C	$Mg_{1-x}Li_xB_2$: solid solutions at $x < 0.3$ mixture of phases at $x > 0.3$	decreases as x increases	3.070 ($x = 0.3$)	3.524 ($x = 0.3$)	155
Mg + B + Be	Ar	mixture of phases	–	–	–	136
Mg + B + C	100% Ar, 850 °C, 20 atm	$MgB_{1.8}C_{0.2}$ + MgO (traces)	$T_{c1} \approx 41$ $T_{c2} \approx 37$	3.070	3.520	156
	950 K	the same	~34	3.070	3.523	157

[a] Amorphous boron powder was used in most cases.

The synthesis of 'superstoichiometric' compositions $Mg_{1+x}B_2$ with 10 at.%, 20 at.% and 30 at.% of excess Mg added to the reaction mixture has also been reported.[157] It was found that 'superstoichiometry' has no effect on the superconductivity in magnesium diboride.

4. Materials science and some aspects of practical utilisation of MgB_2

a. Pressure dependence

Studies on the effect of pressure (as well as joint effect of pressure and temperature) on the properties of MgB_2 attract considerable attention both in solving fundamental problems of the nature of superconductivity in anisotropic media and in developing new procedures for improving the properties of superconducting MgB_2.[120, 160–166]

The structure of MgB_2 polycrystals as function of hydrostatic pressure up to 0.62 GPa was studied by neutron diffraction in the temperature range from 11 to 297 K.[163] It was found that the lattice parameters a and c change linearly with pressure, *viz*., $a = a_0 - 0.00187P$, $c = c_0 - 0.00307P$, where a_0 and c_0 are the lattice parameters under normal conditions and P is the pressure (in GPa). Essentially nonuniform lattice compression was emphasised: compression along the c axis is 64% larger than along the a axis (in the B–B plane). Similar results were obtained in synchrotron X-ray diffraction studies of isothermal compression (Fig. 15). Thermal expansion of the crystal lattice is also anisotropic and is mainly due to changes in the interlayer distances (the parameter c).[163] It was found that the effect is due to anisotropy of chemical bonding in MgB_2.[120–163]

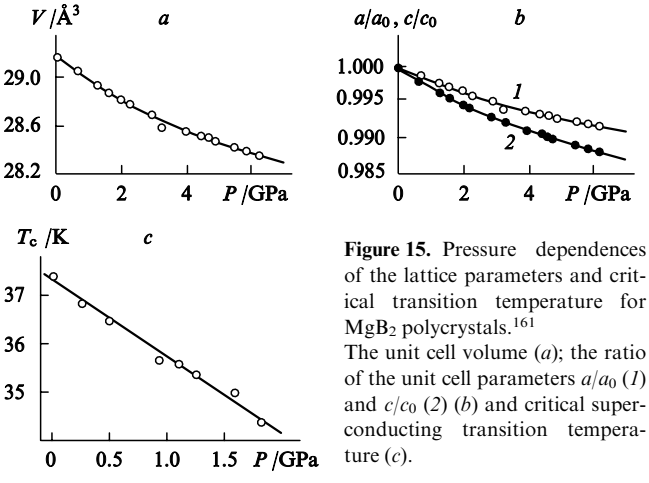

Figure 15. Pressure dependences of the lattice parameters and critical transition temperature for MgB_2 polycrystals.[161]
The unit cell volume (*a*); the ratio of the unit cell parameters a/a_0 (*1*) and c/c_0 (*2*) (*b*) and critical superconducting transition temperature (*c*).

Superconductivity parameters of MgB_2 are pressure dependent. For instance, it was found that the superconducting transition temperature decreases with a rate of -2.0 [162] and -1.6 K $(GPa)^{-1}$,[164] respectively (see Fig. 15). This is consistent with the results of calculations [165] [-1.4 K $(GPa)^{-1}$] and can be explained based on the BCS theory of the mechanism of superconductivity in magnesium diboride.[120, 165]

b. Neutron irradiation

Experiments [167] on thermal ($\Phi = 1 \times 10^{19}$ cm^{-2}) and fast ($\Phi = 1 \times 10^{18}$ cm^{-2}) neutron irradiation of MgB_2 (the total dose was greater than 10 doses per atom) were carried out with a IVV-2M nuclear reactor at $T = 350$ K. The transition temperature of irradiated samples decreased from 40 to 5 K, the residual resistance ρ_0 increased (from 0.35 to 2.0 mΩ cm) and the upper critical field exhibited minor changes ($-dH_{c2}/dT \approx 0.5$ T K^{-1}). By analogy with A15-type superconductors (Nb_3Sn, V_3Si), the results obtained were explained [167] by a decrease in $N(E_F)$. It was concluded that high radiation resistance of MgB_2 under conditions of neutron irradiation (other superconductors undergo amorphisation under such conditions) is of prime importance for practical utilisation of this compound. Irradiation of MgB_2 samples leads to anisotropic lattice expansion (mostly, to an increase in the parameter c from 3.5216 to 3.5533 Å), which is accompanied by an increase in the unit cell volume by ~1.4%.[157] The occupation number of Mg sites decreases from 0.94 to 0.89, while the occupation number of B sites remains unchanged. No antisite defects were found.

c. Grain boundary effects

Heat treatment of MgB_2 under high pressure to improve superconducting properties of highly porous (under the synthesis conditions) magnesium diboride polycrystals has been proposed.[160] At $T = 950$ °C and $P = 3$ GPa, the surface morphology of MgB_2 samples changed, their porosity decreased and the grain boundary contact area increased. High-resolution transmission electron microscopy studies of the morphology of the MgB_2 samples obtained by high-pressure sintering ($P = 3$ GPa) revealed the absence of porosity and strong connections between grains. The impurity phase (magnesium tetraboride) occurred in the form of small inclusions.[113] Specific features of some properties of

MgB_2 polycrystals, determined by the grain structure of the surface, have been discussed.[168, 169]

d. Surface and films

The development of methods for reproducible synthesis of epitaxial superconducting MgB_2 thin films for various electronic devices is one of the key problems of practical utilisation of this material. Here, the use of many conventional film growth procedures is complicated by the large differences in vapour pressure, adsorption coefficients and mobilities between boron and magnesium as well as due to a tendency of magnesium to undergo oxidation.

Currently, such films are synthesised using two, *ex situ* and *in situ*, approaches.[170–178] The former[174, 175] implies preliminary preparation of boron films which are then saturated with magnesium while the latter includes fabrication of MgB_2 films during the same run.

Currently, films with the highest current density and T_c (37–39 K) have been obtained by *ex situ* processes.[174, 175] The procedure included pulsed laser deposition (PLD) of thin boron films onto a substrate ($SrTiO_3$) followed by their reaction with magnesium vapours at 900 °C. The film surfaces were characterised[175] by well-developed grain structure. This approach has a drawback, that is, the high-temperature stage (here, temperatures are higher than the decomposition temperature of magnesium diboride). Therefore, this method is inapplicable to the growth of multilayers and heterojunctions. In addition, in the case of *ex situ* synthesis the film growth is driven by diffusion of magnesium through an already formed magnesium diboride surface layer, which makes it difficult to obtain an epitaxial relationship between the film and the substrate.[174, 175]

The *in situ* film growth involves two stages.[170–173] Initially, magnesium diboride films are prepared by PLD of various targets on different substrates, *e.g.*, Al_2O_3, $LaAlO_3$, $SrTiO_3$.[173] The targets (Fig. 16) were dispersed (< 45 μm) powders of MgB_2 synthesised from elemental boron and magnesium, commercial MgB_2 powders (AA), *etc*. Typically, the films were 100–500 nm thick. Superconductivity was observed only for films annealed in the rather narrow temperature interval (550–600 °C). Atomic force microscopy images revealed a reasonably smooth surface of these films, which is in stark contrast to the surface of the *ex situ* prepared films with well-defined grains. Films were deposited on the (100) and (111) surfaces of $SrTiO_3$ by (i) PLD of MgB_2, (ii) PLD of multilayers of MgB_2 and Mg followed by *in situ* annealing at high temperature and (iii) PLD of multilayers of Mg and B followed by *in situ* annealing at high temperature.[174] The highest superconducting transition temperature (T_c = 22 K) was observed for the films grown from magnesium diboride target. An increase in the annealing temperature deteriorates the superconductivity characteristics (for instance, T_c was no higher than 8 K after annealing at temperatures > 800 °C). This is thought to be due to layer-by-layer deviation from perfect nonstoichiometry.[174] It was emphasised that the necessary condition for growth of superconducting films consists in retaining the necessary Mg content.

Films grown *in situ* from room-temperature deposited Mg + MgB_2 powder targets and post-annealed at 600 °C were also characterised by relatively low T_c (12–22 K). It is believed that one of the key factors consists in the choice of reaction conditions to prevent oxidation of magnesium in plasma and in the film deposited. In this case, of great importance is the choice of the pressure of the inert gas in the vacuum chamber. Yet another reason for the low T_c is associated with the possibility[172] of formation of nonsuperconducting higher magnesium borides (MgB_4, MgB_7) and elemental boron, which deteriorates the superconductivity parameters of the film. The formation of magnesium borides is associated with the nature of plasma generated by the laser. In different ionisation zones, the temperature of plasma can be as high as several thousands of degrees. In this connection, of great importance are the results of thermodynamic modelling[179] of the system Mg–B using the CALPHAD technique.[180] Calculations[179] of composition–temperature, composition–pressure and pressure–temperature phase diagrams were carried out using experimental values of thermodynamic parameters of the components (MgB_2, MgB_4, MgB_7 as well as the gas, liquid and solid magnesium phases and β-boron). Magnesium diboride can be formed only at vapour pressures of magnesium falling into specific range and in particular temperature range (Fig. 17). Clearly, operation under these conditions will favour optimisation of the composition and, as a consequence, superconductivity characteristics of *in situ* grown films.

A 'mixed' film fabrication procedure has been proposed.[177] Films deposited *in situ* from MgB_2 targets in high vacuum exhibited the properties of pure metals or semiconductors; super-

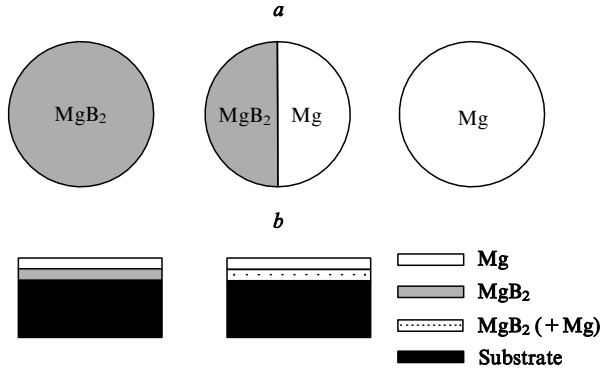

Figure 16. Schematical drawings of the targets (*a*) and chemical compositions of *in situ* prepared films (*b*).[173]

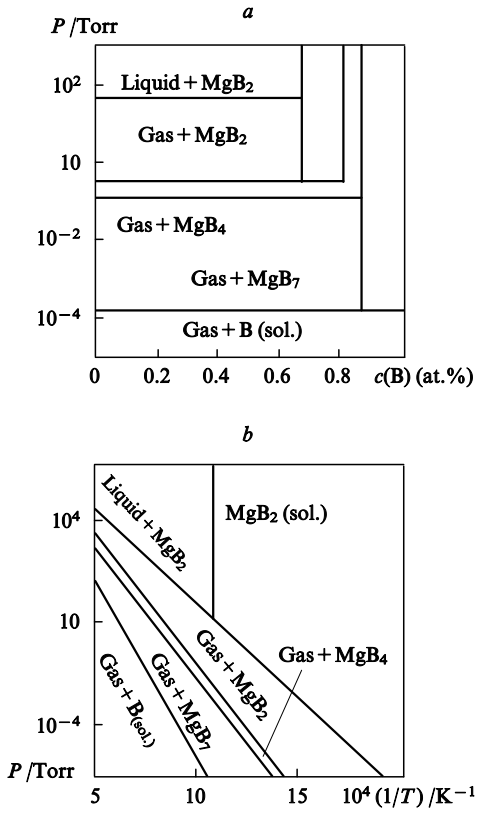

Figure 17. Calculated diagrams of the Mg–B system.
The pressure–composition diagram at T = 850 °C (*a*) and P–T-diagram for the ratio Mg : B > 1 : 2 (*b*). The 'gas + MgB_2' region corresponds to thermodynamic conditions for the preparation of MgB_2 thin films. Obtained from CALPHAD calculations.[179]

conductivity ($T_c \approx 25$ K) was observed only after additional exposure to magnesium vapours. Films with $T_c = 24$ K were obtained from stoichiometric MgB_2 targets by PLD on silicon substrates followed by heating in Ar atmosphere.[178] Uniform surface morphology and thickness of films were pointed out. Oxygen contamination of the outermost layers was assumed to be the main reason for the low T_c.

Vasquez *et al.*[181] reported a special XPS study of the elemental composition of the surface of MgB_2 polycrystals. The XPS spectrum of the surface of initial sample exhibited strong impurity signals from C and O, two signals from Mg 2*p*-state with binding energies (E_b) of 49.5 and 50.8 eV and signals from B 1*s*-states. Among the last-named group of signals, a weak peak with $E_b = 193$ eV is due to the presence of boric anhydride. The main signal of the B 1*s*-state was a doublet with the energies $E_b = 186.7$ and 187.9 eV comparable with the corresponding energies for isostructural *d*-metal diborides (187.2 – 188.5 eV, see Ref. 182).

According to Vasquez *et al.*[181] there are three main concentration zones near the MgB_2 surface. The first zone, *i.e.*, the surface of initial sample, is covered with oxide film and is substantially enriched with magnesium (the Mg : B ratio is 1 : 1.25). The oxide layer can be efficiently removed in the course of chemical purification (by, *e.g.*, 1% and 0.5% solutions of HCl and Br_2 in ethanol). The second, 'subsurface', zone under the oxide film is, on the contrary, depleted of magnesium (Mg : B = 1 : 3). In this zone, nonstoichiometry with respect to magnesium leads to a decrease in the electron density in boron sheets. The corresponding signal of B 1*s*-state is observed at higher binding energy ($E_b = 187.9$ eV). The second B 1*s*-peak ($E_b = 186.7$ eV) corresponds to the states of boron atoms in the third zone (magnesium diboride bulk with stoichiometric ratio Mg : B = 1 : 2). The energies of Mg 2*p*-level and Auger-signal are lower than that of metallic magnesium due to cationic state of Mg^{2+} in magnesium diboride.

e. New MgB_2-based superconducting materials: wires, ribbons, composites

A simple procedure for fabricating high density MgB_2 wires has been developed.[183] As mentioned above, MgB_2 polycrystals are obtained by solid-phase synthesis (a mixture of boron and magnesium powders is heat treated); mechanistically, magnesium diboride is formed *via* diffusion of Mg vapour into the boron grains. Bud'ko *et al.*[183] proposed to use this technique with boron fibres instead of powder. Boron fibres ($d \approx 100$ μm, Textron Systems, USA) and metallic magnesium taken in a stoichiometric ratio were placed in a Ta tube and heated at 950 °C for 1 h. Compared to the unreacted boron fibres, the MgB_2 wires thus obtained were brittle and somewhat deformed (see Fig. 18), but they did not break down. A tungsten core ($d \approx 15$ μm) of the starting boron fibres did not appear to be affected during the reaction, it also has no effect [183] on the superconducting characteristics of the MgB_2 wires. The diameter of the MgB_2 wires increased from 100 to 160 μm (synthesis of magnesium diboride powder is also accompanied by an increase in the particle size compared to the initial boron grains [82]). The density of wire segments was determined to be ~ 2.4 g cm^{-3} [$\sim 80\%$ of the theoretical density of MgB_2 crystal, 2.55 g cm^{-3} (see Ref. 82)]. The superconductivity parameters of the wires were $T_c = 39.4$ and $\Delta T_c = 0.9$ K. At room temperature, the wires exhibited the properties of highly conducting material (the resistivity, ρ, had a value of 9.6 μΩ cm), whereas near the critical transition temperature ($T = 40$ K) ρ decreased to 0.38 μΩ cm. Temperature dependence of the resistivity ($\rho = \rho_0 + \rho_1 T^{\alpha}$, where $\alpha \approx 2.6$) is close to that found for MgB_2 polycrystals [$\alpha \approx 2.8$, measured for $Mg(^{10}B)_2$ pellets].[82]

To choose optimum conditions for the preparation of superconducting MgB_2 wires, the mechanism of Mg diffusion into boron was systematically studied using commercialy sold boron fibres ($d = 100$ and 141 μm).[184] Boron fibres were exposed to magnesium vapours at 950 °C, the course of the reaction was monitored by the scanning electron microscopy (SEM) using the

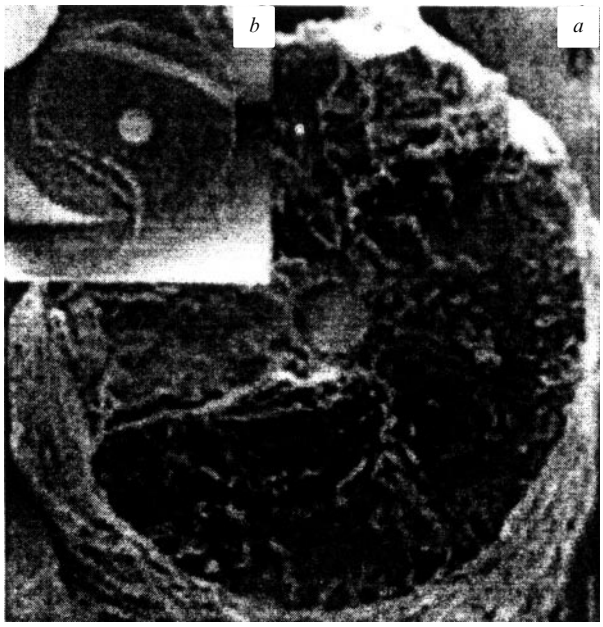

Figure 18. Electron microscope images of cross-section of a MgB_2 wire of diameter 160 μm (*a*) and unreacted boron filament with a tungsten core (*b*).[183]

SEM images of the cross-sections of the MgB_2 wires taken after time intervals. It was found that magnesium diboride begins to form after 15 min and is 50% complete after 1 h. The wire segments thus produced were of little porosity. In Fig. 19, the resistivities of MgB_2 pellets and wires are shown as functions of temperature. Different behaviour of the curves is thought to be due to larger density of wires.[184] Studies [185] on magnetotransport characteristics of dense wires revealed a very narrow resistive transition, a linear temperature dependence of H_{c2} in the range 7 K < T < 32 K and a positive curvature of this dependence near T_c. This is similar to the behaviour of layered IBC.[186–188]

Another technique for fabrication of superconducting MgB_2 wires involves placing powdered MgB_2 inside a sheath (a niobium,[189] gold, copper of nickel tube [190]). For instance, a niobium tube of diameter 6 mm was filled with MgB_2 powder and then a ribbon was prepared by cold drawing followed by rolling.[189] The ribbon with a superconducting core (a cross-section of 0.232 mm^2) had a cross-section of 2.56×0.32 mm^2.[189] At 4.2 K, the measured current density in the ribbons heated at 900 °C for 1, 2 and 3 h in an Ar atmosphere was 4.7, 7.5 and 1.1×10^4 A cm^{-2}, respectively. Experiments [190] with ribbons

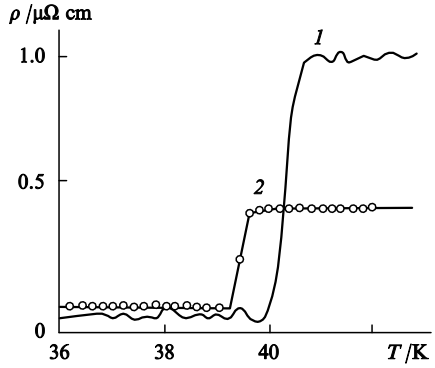

Figure 19. Resistivity of a dense MgB_2 wire (*1*) and polycrystalline MgB_2 pellet (*2*) as function of temperature.[184]

sheathed with different metals (Au, Ni, Cu) revealed the highest current density ($\sim 10^5$ A cm^{-2}) at 4.2 K for the ribbon with Ni sheath.

Magnesium diboride is highly brittle, which is typical of ceramics. Therefore, the problem of improving mechanical properties of MgB_2, *i.e.*, making the material more malleable without significant deterioration of its superconducting properties is of great importance. The most obvious way is to fabricate composites with ductile metals (or alloys) which should have low melting temperatures comparable with that of MgB_2 (1073 K) and be conductors and highly plastic substances. The formation of such composites should also not be accompanied by reactions between the ductile additive and magnesium diboride resulting in solid solutions. Recently, aluminium (T_m = 933 K) was found to be appropriate for this purpose.[191] Pellets of MgB_2–Al composite (11 vol.% Al) were prepared from MgB_2 (AA) and Al powders (the particle size of both components was 1 to 3 μm) by pressing at 500–700 K, *i.e.*, below the formation temperature of nonsuperconducting $Mg_{1-x}Al_xB_2$ solid solutions.[83] The samples were studied by scanning tunnelling microscopy and the transport and magnetic characteristics of the composites were measured. Particular attention was given to the proximity effect (the formation of a typical 'mini-gap' structure was observed, which is due to contact between magnesium diboride and aluminium, T_c^{Al} = 1.2 K) and to the effect of structural disordering on the superconducting transition temperature of the MgB_2–Al composite. The T_c value for the composite (38 K) was found to be comparable with that of pure MgB_2 (39 K).

IV. Conclusion

Information collected and systematised in this review describes the infancy of research into the properties of recently found new superconductor, MgB_2. In spite of short time that elapsed after the discovery of superconductivity in MgB_2, experimentalists and theoreticians have accumulated a great body of information about its physicochemical properties. The results obtained are of crucial importance for an understanding of the nature of superconductivity in anisotropic media. They gave a strong impetus to search for new superconductors among metal borides and related compounds and opened attractive prospects for their technological utilisation.

The state-of-the-art in this field can be outlined as follows. To date, a number of methods for the synthesis of MgB_2 have been developed. Peculiarities of the electronic structure and chemical bonding in MgB_2 as well as its electrophysical, magnetic, thermodynamic properties and spectroscopic characteristics have been studied. Based on the results of theoretical modelling and synthetic experiments, some new MgB_2-based solid solutions have been found and ways to further search for new superconductors have been directed. Materials science studies allowed the obtaining of MgB_2 powders, films, wires and composites.

On the other hand, magnesium diboride, as a medium-T_c superconductor, remains a unique compound in its kind except for a few solid solutions based on this substance. All attempts at increasing the critical transition temperature of MgB_2 or finding new superconductors with close T_c have failed so far. Many problems of the synthesis and detailed investigations of multicomponent systems with participation of magnesium diboride are still to be solved. These are, *e.g.*, studies of the phase diagrams, determination of homogeneity regions of solid solutions and criteria for optimum doping of MgB_2 as well as establishment of reasons for changes in T_c. Further search for new candidates for superconductors with graphite-like boron sheets in their structure is undoubtedly required. We believe that these problems will be the focus of research interest in the near future.

* * *

Studies on superconducting MgB_2 and related compounds have been continued in the course of preparation of the manuscript. The most interesting recent results are as follows.

Single crystals of MgB_2 have been first obtained.[192–195] A magnesium-enriched precursor sealed in a niobium ampoule was placed in a quartz tube,[192] heated to 1050 °C (1 h) and then very slowly cooled down to 700 °C (the cooling duration was 120 to 360 h). The MgB_2 single crystals were found to have various shapes (spherical, rod-like, or hexagonal-plate) depending on the cooling regime. The samples studied were characterised by excellent superconductivity parameters (T_c = 38 K and ΔT_c = 0.3 K). Experiments with MgB_2 single crystals revealed strong anisotropy of superconductivity.[192–195]

An original method for the synthesis of high density, single-phase MgB_2 ceramics with T_c = 38 K by crystallisation of magnesium diboride melt under pressure has been proposed.[196] The slope and the onset of transition to the superconducting state were found to be dependent on the grain size of the material.

Epitaxially grown, oriented MgB_2 films were prepared and their properties have been studied:[197–210] superconductivity,[197, 199–210] the Hall effect [207] and surface resistance.[206] Anisotropy of some characteristics of the oriented films (in particular, conductivity and upper critical field [198, 200]) was revealed. Degradation of superconductivity in MgB_2 films in the presence of water has been studied.[205] Preparation of nanostructured superconducting MgB_2 films has also been reported.[203] Pioneering calculations of the electronic structure of the boron- and magnesium-terminated MgB_2 (0001) surfaces have been carried out.[211, 212]

Summing up, mention may be made that there are three main lines of inverstigations in the field of search for MgB_2-related superconductors. The first research avenue is associated with extension of the class of possible MgB_2-based superconductors by varying their chemical compositions to obtain different types of solid solutions or by forming superstructures (see Section III.3). The second investigation line includes studies of a much broader spectrum of substances. Here, the search for possible superconductors has been performed among binary or multicomponent compounds which are to some extent structurally or chemically similar to MgB_2. The discovery of critical transitions in ZrB_2 (5.5 K, see Ref. 213), TaB_2 (9.5 K, see Ref. 137), Re_3B (4.7 K, see Ref. 214) and in the new phase of beryllium boride with the chemical composition $BeB_{2.75}$ and the unit cell containing 110.5 atoms (0.72 K, see Ref. 215) represent recent advances in this field.

The third line of research activity was initiated by the discovery of superconductivity at $T_c \approx 8$ K in a perovskite-like intermetallide $MgCNi_3$.[216] From the standpoint of 'renewed chemical paradigm' it was proposed [216] that the whole class of intermetallides should be considered as potential superconductors. The results obtained by Cava *et al.*[216] are of particular interest for the following reasons.

Highly symmetric structure of $MgCNi_3$ (the space group $Pm3m$) favours superconductivity. However, superconductivity in all the known isostructural compounds — oxide perovskites [*e.g.*, (Ba, K)BiO_3, see Ref. 217] — is due to electron–hole states of the oxygen atoms occupying 3*c*-type positions (0, 1/2, 1/2). Since in the $MgCNi_3$ structure these positions are occupied by Ni atoms, the mechanism of superconductivity should be of fundamentally different nature.

Most of the known 'non-oxide,' perovskite-like compounds MXM'_3 (M′ = Zn, Al, Ga, In, Sn; M = Mn, Fe; X = C, N) are ferromagnetic (and antiferromagnetic) or are characterised by more complex (mixed) types of spin ordering.[218] Hence, among structurally similar compounds, $MgCNi_3$ can be considered as an 'intermediate' between the classes of perovskite-like superconductors (oxides) and magnetics (non-oxide perovskites).

Among superconductors, nickel-containing IBC $LuNi_2B_2C$ ($T_c \approx 16$ K) and YNi_2B_2C ($T_c \approx 15.6$ K) are the closest 'chemical analogues' of $MgCNi_3$. However, unlike the last-named compound, these IBC belong to magnetic superconductors and exhibit

a distinct quasi-2D structure.[22] In addition, the Ni content in IBC is much less than in $MgCNi_3$. Taking into account clearly defined magnetic properties of nickel, the fact that superconductivity occurs in the nickel-rich compound $MgCNi_3$ is quite surprising.

Based on the results of pioneering studies on the properties of $MgCNi_3$ (the critical field, H_{c2}, the Hall coefficient, *etc*.,[219–221]) and critical transition temperatures of $MgCNi_{3-x}M_x$ (M = Mn, Co, Cu) samples doped at Ni sites, the parent compound, $MgCNi_3$, was placed into the class of 'conventional' superconductors with electron–phonon interactions.[222,223] Band structure calculations for $MgCNi_3$ (see Refs 224–227) revealed a distinctive feature, *viz*., the presence of an intense DOS peak near the Fermi level. It was found that the major contribution to $N(E_F)$ comes from the Ni 3*d*-states (~88.2%). Band structure calculations for new $MgCNi_3$-like superconductors have been carried out. The possibility of superconductivity in a nonstoichiometric (with respect to C sublattice) perovskite, in perovskite-like $ScBNi_3$ and $InBNi_3$ as well as in $MgCCo_3$ and $MgCCu_3$ (all of them are isoelectronic and isostructural to $MgCNi_3$) has been discussed.[228]

The discovery of superconductivity in intermetallic compounds MgB_2 and $MgCNi_3$ with simple and highly symmetric structures has given a creative urge to search for application areas of these promising superconductors.

The author expresses his gratitude to N I Medvedeva, V G Zubkov, V N Diev and V G Bamburov for valuable discussions.

Abstract. The scope of this review encompasses methods and synthetic protocols leading to conjugated dienes bearing no heteroatoms in the C=C–C=C moiety. Attention is concentrated on methodologies developed during the last decade, particularly, to the metal complex-mediated synthesis. The bibliography includes 494 references.

I. Introduction

Until about 1960, the synthetic chemistry of conjugated dienes was focused mainly on their simplest representatives. Usually, these dienes were prepared either by dehydrating diols and allylic or homoallylic alcohols or by eliminating the elements of HX (X = OAlk, OCOR, OSO_2R, Hal, *etc*.) from properly selected unsaturated substrates. However, such techniques were unsuitable for the synthesis of higher homologues, because the use of these reactions resulted in mixtures of isomers.

Then, in the mid-sixties a new period in the synthesis of conjugated dienes began, as this class of compounds became increasingly in demand. This popularity was due to the fact that dienes with fixed position of configurationally defined double bonds and with various sensitive functional groups (and their combinations) had been identified by that time as fragments of many natural products. Moreover, inter- and intramolecular Diels – Alder reactions employing conjugated dienes had become widely used tools in the synthesis of cyclic molecules.

Advances in organometallic chemistry and metal complex catalysis highlighted dienes as useful four-electron π-ligands capable of forming interesting metal complexes. These aspects of diene chemistry are considered, with due attention to details, in two recently published review collections.[1,2] Finally, stereospecific 1,4-*cis* hydrogenation of conjugated dienes using chromium carbonyl complexes proved to be an efficient, preparatively viable method for stereocontrolled synthesis of alkenes.[3,4]

Abundant literature on the synthesis of conjugated dienes has been accumulated, and systematic surveys have been periodically attempted during the last thirty years. Among early sources (up to the late 1980's), the serial edition of Houben – Weyl[5] and a few monographs and collective volumes[6–9] should be mentioned, because some chapters there are dedicated to conjugated dienes. Another good source of references (not commented on) is a compendium of reactions leading to dienes.[10] Also useful is a monograph,[11] where numerous methods for constructing conjugated dienes are cited in the context of pheromone synthesis. A review on the synthesis of conjugated polyenes, where the dienes were considered as parental polyene systems,[12] was published in 1997 in a book[1] that is nearly inaccessible in Russia. This makes the appearance of an updated review quite opportune, let alone the fact that in the last four years the chemistry of conjugated dienes has been enriched with some new and interesting synthetic methods.

This review aims at a systematic survey of selective methods for obtaining conjugated carbo-substituted dienes that were elaborated between the end of 1960 and March, 2001. Methods leading to the molecules with heteroatomic substituents on the C=C–C=C unit will be mentioned just in a few exclusive cases. The description of reactions used will be focused on their preparative aspects; the mechanisms will be mentioned only when it is necessary, since most of them have been considered in detail in original publications.

II. Elimination reactions

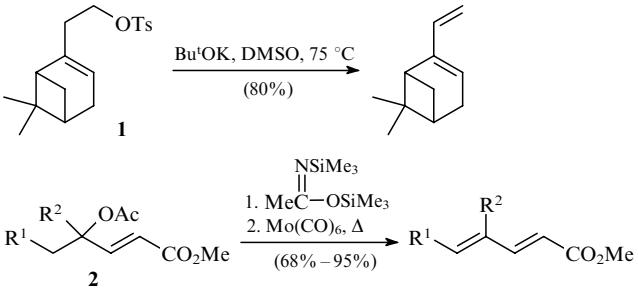
Elimination reactions leading to alkenes basically can be divided into two groups. The first group involves the ejection of a nucleofugal group and a vicinal hydrogen or metal atom. The second one involves reductive elimination of two vicinal groups. When the substrate already has a double bond adjacent to one of the groups undergoing elimination, the product of the reaction is a conjugated diene.

1. Elimination of HX

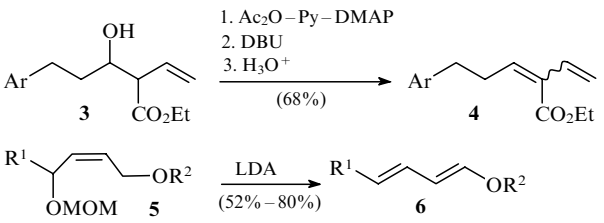
Elimination of one molecule of water from 2-methylbut-3-en-2-ol (Favorskii's method) or of two molecules of water from butane-1,3-diol (the last step in Lebedev's process) as well as catalytic

thermolysis of 4,4-dimethyl-1,3-dioxane (Farberov's method) are classical ways of obtaining dienic monomers applicable to other lower conjugated dienes. However, the conditions under which the processes are performed are too drastic to be useful for obtaining more labile, functionally substituted higher dienes.

Elimination of HX from substrates of allylic or homoallylic type proceeds regiospecifically only for molecules with specific patterns of substitution, *e.g.*, for compounds **1**[13] or **2**.[14] If the substrate contains a functional group strongly stabilising only one of the possible isomeric products, this also can favour an unambiguous course of the process (*e.g.*, in the case of reactions **3** → **4**[15] and **5** → **6**[16]).

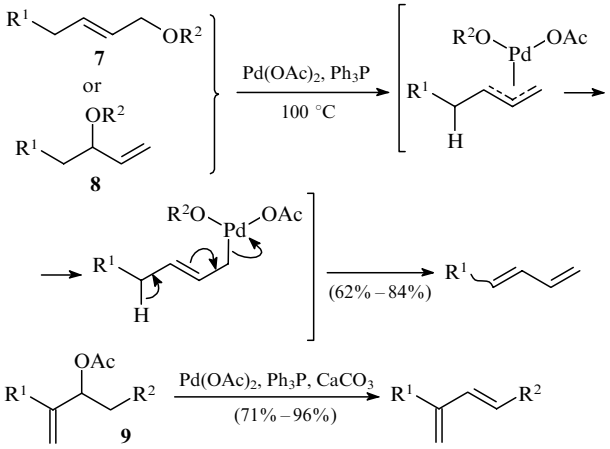


R^2 = H, CH_2R^1.



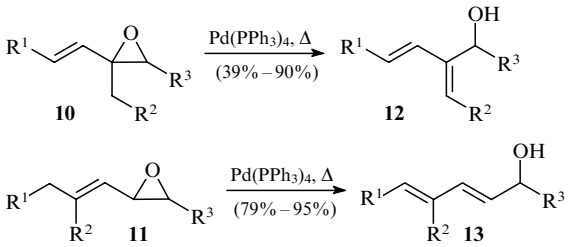
DMAP is 4-dimethyaminopyridine; DBU is 1,8-diazabicyclo-[5.4.0]undec-7-ene; MOM is methoxymethyl; LDA is lithium diisopropylamide.

Generally, elimination of HX or MX from allylic-type substrates affords isomer mixtures. However, in the presence of palladium catalysts the reaction proceeds regioselectively. In these cases substituents R^1 in starting compounds **7**–**9** can contain functional groups.[17, 18]

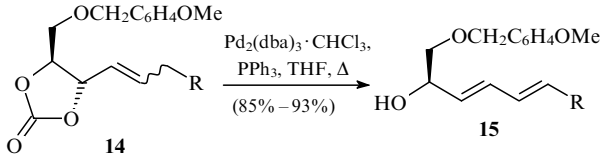


In this way neryl acetate was converted to myrcene, while geranyl acetate afforded a mixture of *cis* and *trans* isomers of β-ocymene.[19]

In the presence of palladium catalysts, the ring opening in acyclic vinylic oxiranes **10** and **11** proceeds smoothly to give α-dienols **12** and **13**.[20] The regioselectivity of these reactions depends on the position of substituents at the epoxide ring.

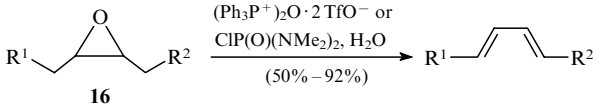


Elimination of CO_2 from alkenyl-substituted cyclic carbonates **14** takes place in the same manner, but the resulting diene **15** is obtained predominantly as the *E*,*E*-isomer whatever the configuration of the starting compound.[21]

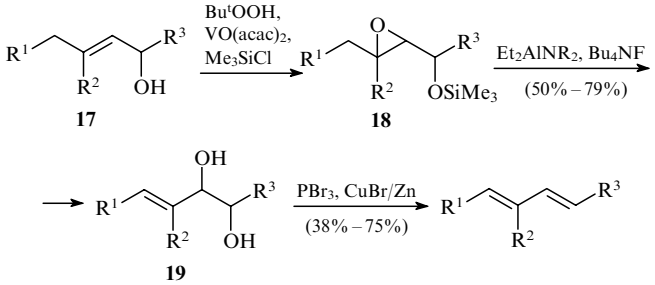


dba is dibenzylideneacetone.

Epoxides **16** (substituents R^1 and R^2 can contain ester groupings) undergo regiospecific formal dehydration mediated by organophosphorus reagents.[22, 23]



A three-step protocol of formal α,α′-elimination of water from allylic alcohols **17** is based on their chemoselective epoxidation in the presence of a silylating agent and vanadium catalysts.[24, 25] Subsequent opening of the epoxide ring in compounds **18** by mild Lewis acids proceeds regiospecifically (the ejection of proton occurs exclusively from the substituent lying in the *trans*-position relative to the silyloxy group), and affords unsaturated diols **19**. Finally, circumventional elimination of vicinal hydroxy groups from **19** gives an additional double bond. In this way nerol is readily transformed to myrcene, and geraniol to *trans*-β-ocymene.



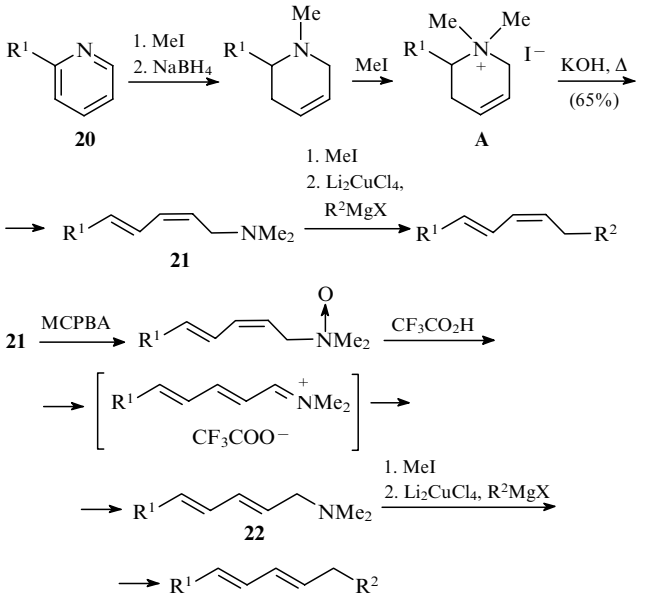
2. Deamination

An interesting method for the conversion of pyridines **20** into allylic (*Z*,*E*)-dienylamines **21** begins with quaternisation of their nitrogen atom followed by reduction, another methylation and subsequent Hofmann degradation of the resulting intermediate **A** (Scheme 1).[26, 27] Then, after yet another quaternisation, the amino group of compound **21** can be replaced by a carbonaceous substituent. The intermediate *Z*,*E*-dienes **21** can be isomerised to give the corresponding *E*,*E*-dienes **22** by treating the corresponding *N*-oxides with trifluoroacetic acid, and subsequently by reductive substitution. This protocol was employed in the synthesis of insect pheromones.[27]

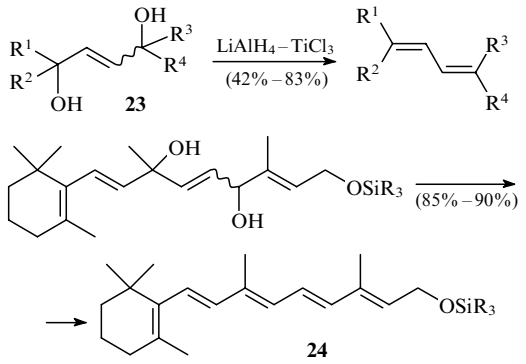
3. Reductive elimination

The reduction of alk-2-ene-1,4-diols[28] **23** or of the respective ethers[29, 30] in the system $LiAlH_4 – TiCl_3$ was used in the synthesis of retinoids **24**[31, 32] and other natural products.[30, 33]

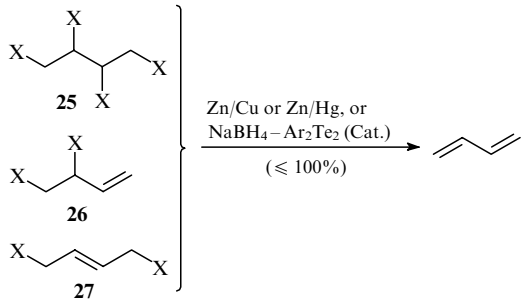
Scheme 1



MCPBA is *m*-chloroperbenzoic acid.

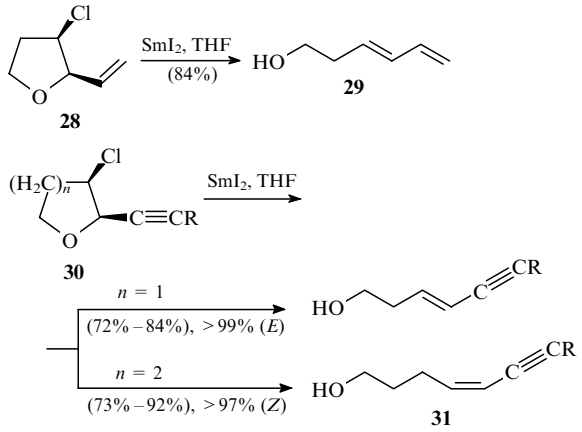


Reductive elimination of halogen atoms from 1,2,3,4-tetrahaloalkanes **25**, 1,2-dihaloalk-3-enes **26** and 1,4-dihaloalk-2-enes **27** gives 1,3-dienes in good yields. In addition to the traditional zinc,[34,35] the salts of arenetellurols were recommended.[36] In the latter case, the process can be performed readily using catalytic amount of Ar_2Te_2 that is periodically reduced by titrating the reaction mass with sodium borohydride. This method was applied to a number of linear and cyclic substrates, including those bearing additional functional groups.†

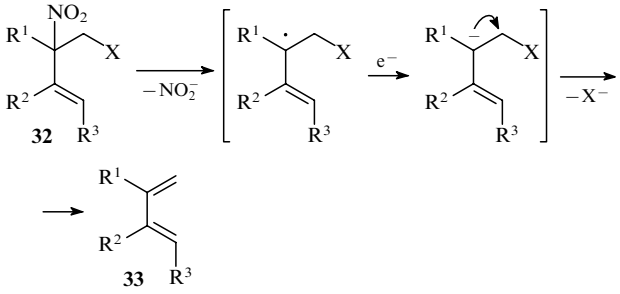


† 1,4-Dibromoalk-2-enes **27** can be prepared by treating internal[35] and, what is particularly interesting, terminal alkenes with 2 equiv. *N*-bromosuccinimide.[36] In the latter case, the bromination occurs in a stepwise mode involving allylic rearrangement. 1,2-Dibromoalk-3-enes **26** can be prepared from the corresponding diols which, in their turn, are obtainable from allylic alcohols.[25]

Reductive scission of *cis*-3-chloro-2-vinyltetrahydrofuran (**28**) with samarium iodide results in (*E*,*E*)-hexa-3,5-dien-1-ol (**29**) of > 97% geometric purity.[37] The same stereochemical result is observed in the case of 2-alkynyl-3-chlorotetrahydrofurans (**30**, $n = 1$). By contrast, their tetrahydropyran homologues (**30**, $n = 2$) in the same reaction afford the *Z*-configured enynols **31**, supposedly due to different conformational behaviour of five-membered and six-membered heterocycles.[37]



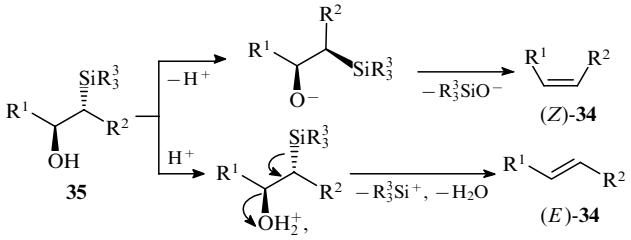
When allylic nitro compounds of the type **32** are treated with chromium(II) diacetate [$Cr(OAc)_2$ – Dipy system in dimethylformamide], their vicinal nitro- and mesyloxy (or acetoxy) groups undergo reductive elimination, which results in the formation of an additional double bond. These transformations were used to obtain conjugated dienes **33**, albeit in moderate yields.[38]



X = OMs, OAc.

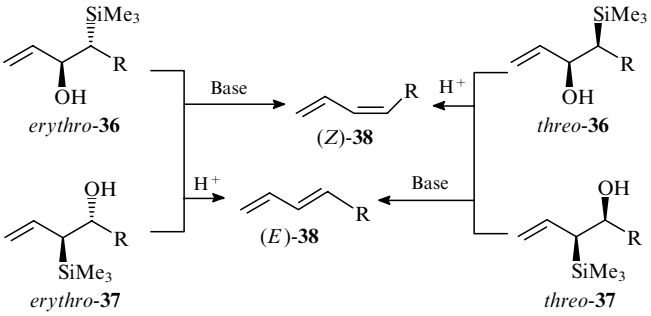
4. Stereocontrolled 1,2-elimination of R_3SiX and R_3SnX

The Peterson reaction (see a review[39]) consists in simultaneous elimination of vicinal hydroxy and silyl groups and results in the formation of a double bond. This transformation can occur both in the presence of bases (*e.g.*, Bu^{t}OK, KH) and acids (AcOH, H_2SO_4). The double bond configuration in product(s) **34** depends on the reaction conditions. When the starting compound **35** is treated with a base, the primarily formed alkoxide undergoes *syn*-elimination upon which a molecule of metal silanolate is ejected. When the process is initiated with an acid, it starts with protonation of the hydroxy group, followed by *anti*-elimination of a molecule of water, together with a silyl cation.

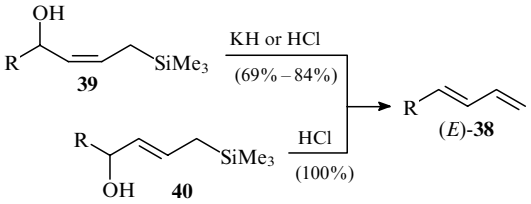


This approach can be used for the synthesis of dienes, when a double bond is already present in the starting compound. Depending on the mutual arrangement of substituents in substrates **36** and

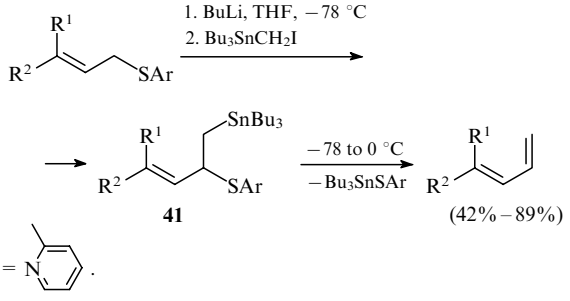
37 and on the process conditions, one obtains diene(s) **38** in the required configuration.‡



In a vinylogous version of the Peterson reaction, compounds **39** and **40** in which the allylic hydroxyl and the silyl group are located at the opposite ends of the double bond are employed as the starting substrates.[50,51] If the silyl group is attached to the terminal carbon atom (as in compounds **39** and **40**), the resulting diene **38** has always the *E*-configuration. When both the hydroxyl and the silyl group are attached to secondary carbon atoms in *erythro* relationship, the reaction affords the *E*,*E*-dienes.[52]. However, in the case of their *threo*-relationship, the resulting dienes are in the *E*,*Z*-configuration, the *Z*-bond being formed at the hydroxyl-bearing carbon atom.

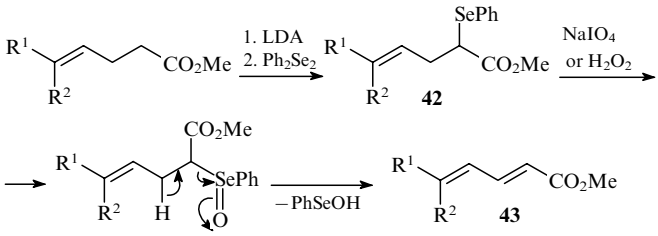


Compounds **41** containing Group IV and VI higher elements (*e.g.*, S and Sn, instead of O and Si) react similarly and spontaneously under very mild conditions; no catalyst is needed.[53]

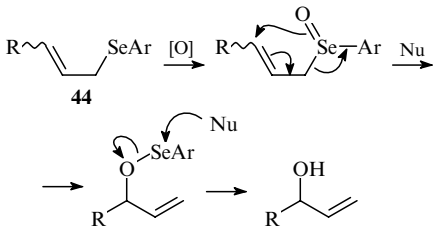


5. Oxidative 1,2-*syn*-elimination of RSeOH and RSOH

Oxidative elimination of an organoselenium fragment from aliphatic selenides is a relatively new method of alkene synthesis (see reviews [54–57]). This process involves the oxidation of a selenide to the corresponding selenoxide, which then undergoes spontaneous *syn*-elimination to give an alkene and a selenenic acid. This method has been widely used in syntheses of natural products of rather complicated structure, because there are many versatile methods for obtaining necessary organoselenium precursors (see, *inter alia*, the publications on the synthesis of α-arylseleno-γ-alkenoic acids [58–60]). Elimination of RSeOH from homoallylic selenides **42** leads to conjugated alkyl dienoates **43**.[60–65]



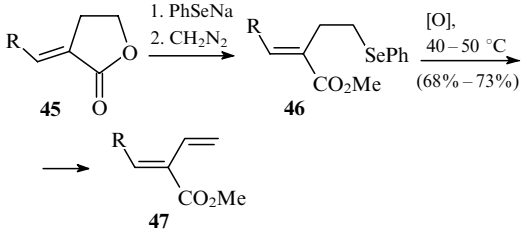
By contrast, instead of giving conjugated dienes *via* oxidative elimination, the oxidation of allylic selenides **44** mostly triggers a [2,3]-sigmatropic rearrangement that finally results in 're-arranged' allylic alcohols.[66,67]



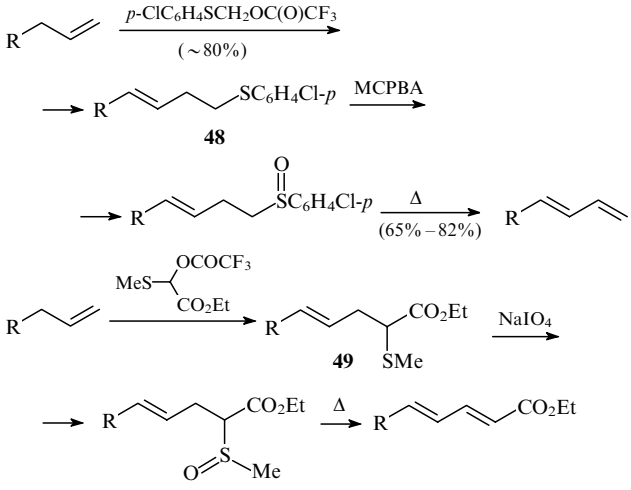
R = Alk, Ar′; Ar = *p*-$NO_2C_6H_4$.

Allylic 2,4-dinitrophenyl selenides appear to be an exclusion,[68] but even in this case, the resulting conjugated dienes are accompanied by noticeable amounts of allylic alcohols.

Due to high nucleophilicity of areneselenolates, they can open the five-membered lactone ring in compounds **45** to give selenides **46**, and subsequently conjugated dienes **47** with a functional group in the side chain.[69]



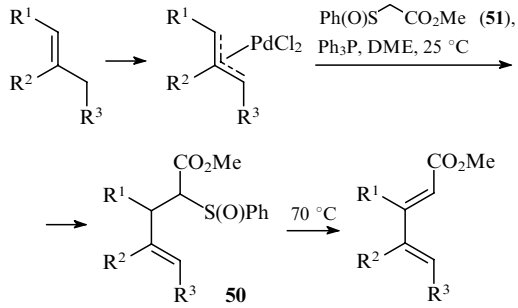
By analogy with selenoxides, aliphatic sulfoxides can undergo oxidative elimination to give alkenes, but at higher temperatures. This can be illustrated by the fragmentation of sulfoxides that were prepared by oxidising sulfides **48** and **49**.[70,71] The latter were obtained upon the addition of sulfur-containing cationoid reagents to terminal alkenes.



Elimination of a sulfoxide unit was used as the final stage in the synthesis of 2-hydroxymethylbuta-1,3-diene from 2-bromoethyl phenyl sulfide.[72]

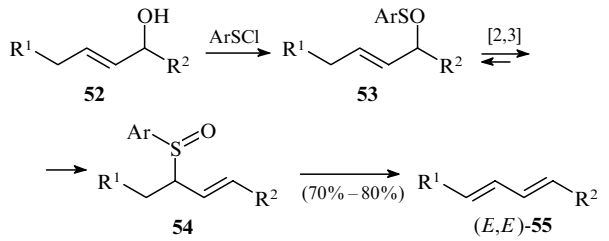
‡ Various protocols for the preparation of starting β-hydroxysilanes have been elaborated.[40–49] Particularly interesting are the reagents of the type R_3SiCH_2X (X = CO_2Alk, CN, *etc.*), which are widely used in the olefination of carbonyl compounds.[46–49]

α-Sulfinyl esters **50**, immediate precursors of alkyl alka-2,4-dienoates, are stable at room temperature. They can be readily prepared from synthon **51**, which already contains a sulfoxide grouping.[73]

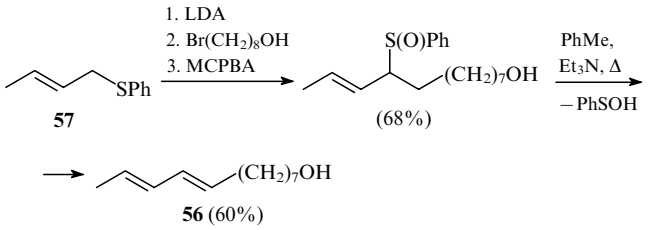


DME is 1,2-dimethoxyethane.

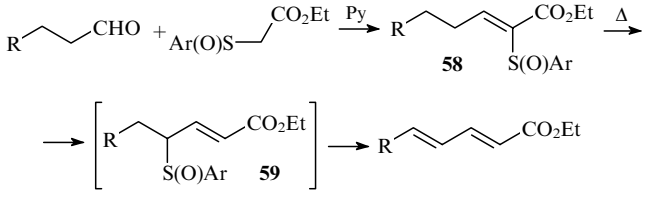
Unlike allylic selenoxides, allylic sulfoxides can be used for obtaining conjugated dienes.[66, 74] A convenient way of performing this process involves the esterification of allylic alcohols **52** with arenesulfenyl chlorides (the best results are obtained when Ar = 2,4-dinitrophenyl) followed by the rearrangement of intermediate sulfenates **53** into sulfoxides **54**; the latter then undergoing elimination to give dienes **55**.



Conjugated dienes with extended carbon chains (*e.g.*, dienic alcohol **56**) can be synthesised from suitable allylic sulfides.[75]

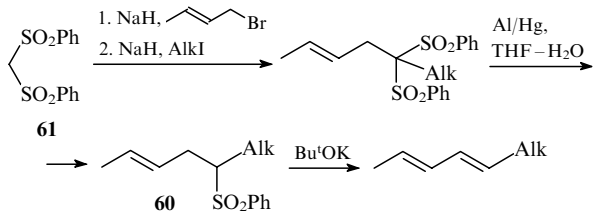


Vinyl sulfoxides of the type **58** rearrange on heating to allylic sulfoxides **59** that afford conjugated dienes upon eliminating ArSOH.[76]



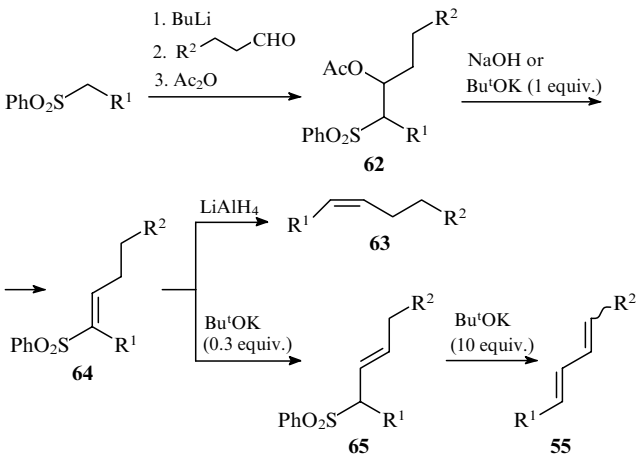
6. 1,2-Elimination of $ArSO_2H$

On treatment with bases, alkyl phenyl sulfones eject the phenylsulfinate anion to give alkenes. If the molecule of sulfone has already a double bond, this reaction leads to dienes. A synthesis of conjugated dienes from homoallylic sulfones **60** is known,[77] where the latter were obtained by sequential alkylation of bis(phenylsulfonyl)methane (**61**) first with allyl- and then with alkyl halides.

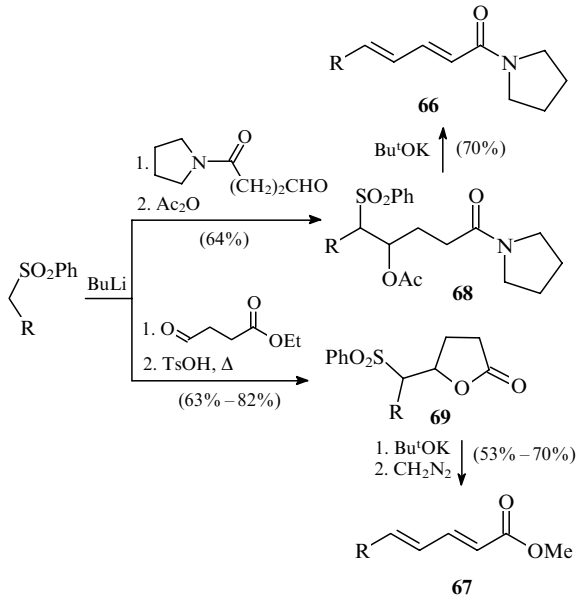


β-Acetoxysulfones **62** can be used as the precursors of alkenes **63** in the Julia method of olefination (aldol-like alkylation of an alkyl phenyl sulfone followed by acylation to give **62**, then elimination of AcOM, and reduction of the resulting vinyl sulfones **64** to give alkene **63**)[78, 79] However, when a large excess of a stronger base is used (~10 equiv.), both substituents in the acetoxy sulfone **62** undergo elimination, which gives rise to the conjugated dienes **55**.[80, 81] The dienes **55** can be obtained from the sulfones **64** either directly, or *via* intermediate allylic sulfones **65** (Scheme 2).

Scheme 2



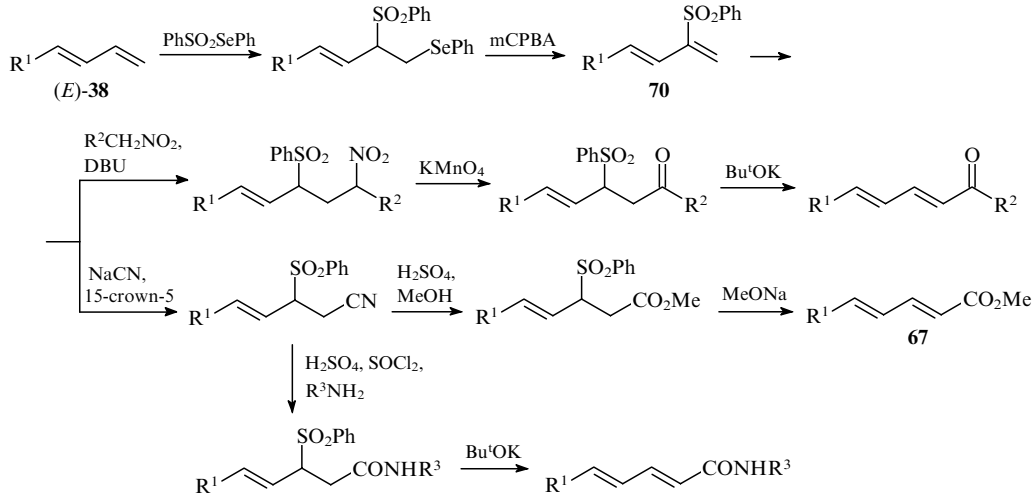
This approach is also applicable to the synthesis of amides (**66**)[82, 83] or esters (**67**)[83] of conjugated dienoic acids.



It should be noted that in the former case, there is no need to isolate the intermediate amides **68**, while in the latter case, the isolation of (1-sulfonylalkyl)butyrolactones **69** is necessary.

The terminal 1,3-dienes (*E*)-**38** are readily converted into the corresponding 2-phenylsulfonyl-1,3-dienes **70** upon treatment with $PhSO_2SePh$ (see a review[84]). The latter are strongly electrophilic, and thus are capable of adding C-nucleophiles. This is a

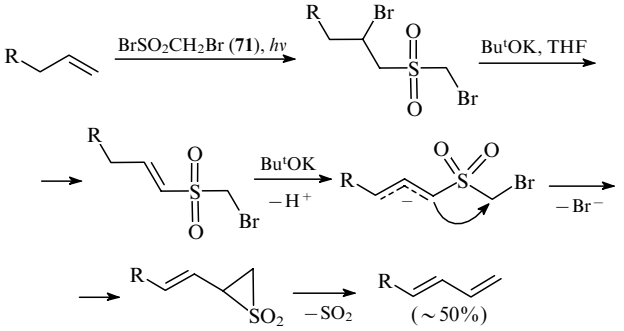
Scheme 3



convenient method for the introduction of a functionalised alkyl substituent to the 1-position of conjugated dienes (Scheme 3).[85,86]

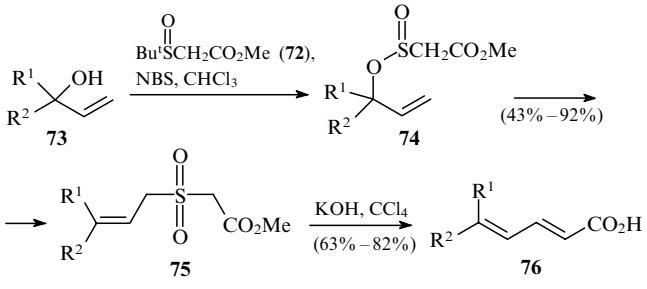
7. Fragmentation of α-halogen-substituted sulfones

The 'vinylogous' Ramberg–Bäcklund reaction (see a review [87]) is yet another example of obtaining 1,3-dienes from sulfones. From preparative standpoint, it is a C_1-homologation of alkenes with a view of introducing an additional double bond; bromomethylsulfonyl bromide (**71**), readily accessible upon bromination of 1,3,5-trithiane, is used here as a C_1 synthon.[88,89]



High regiospecificity of diene formation is observed when cyclic alkenes are used as the starting compounds. Thus the only products obtained from cycloalkenes are 3-methylenecycloalkenes, 1-methylcycloalkenes react to give 1,2-dimethylenecycloalkanes, and methylenecycloalkanes afford 1-vinylcycloalkenes.[90] In all cases, the yields of dienes are moderate. Functionally substituted alkenes have been rarely used in these reactions.

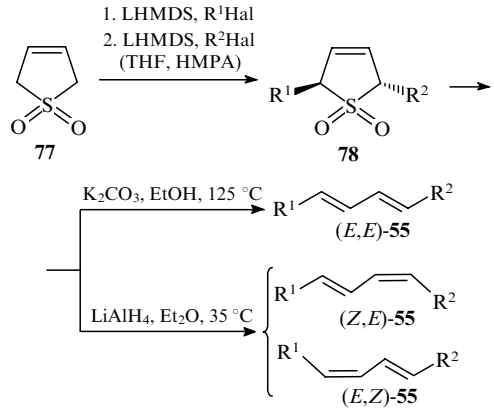
tert-Butyl methoxycarbonylmethyl sulfoxide (**72**) proved to be a convenient synthon for elongating the skeleton of allylic alcohols **73** by a C_2 moiety. The transformation takes place *via* intermediates **74** and **75** to afford alka-2,4-dienoic acids **76**.[91] Its final step is the Ramberg–Bäcklund reaction, the key intermediate of which is generated by deprotonating sulfone **76** and submitting the carbanion to α-chlorination with CCl_4 (not shown).



NBS is *N*-bromosuccinimide.

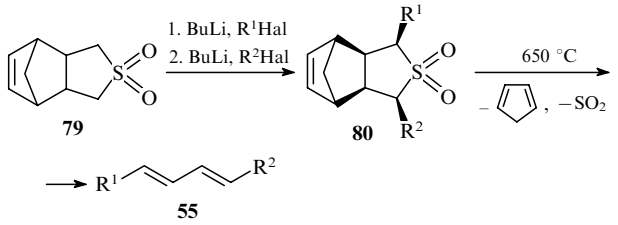
8. Cheletropic elimination

The ability of β-sulfolenes to undergo reversible fragmentation into 1,3-dienes and SO_2 (see a monograph [92]) underlies a versatile synthesis of dienes with somewhat sophisticated structure starting with successive α,α′-bis-alkylation of parental sulfolene **77**.[93,94] Depending on the procedure used to decompose the alkylated sulfolene **78**, one obtains either *E*,*E*- or *E*,*Z*-dienes. The parental sulfolene **77** acts in this method as a synthetic equivalent of 1,4-dianion of buta-1,3-diene. This strategy was employed in the synthesis of some pheromones of *Lepidoptera* that contain terminal or internal *E*,*E*-configured diene substructures.



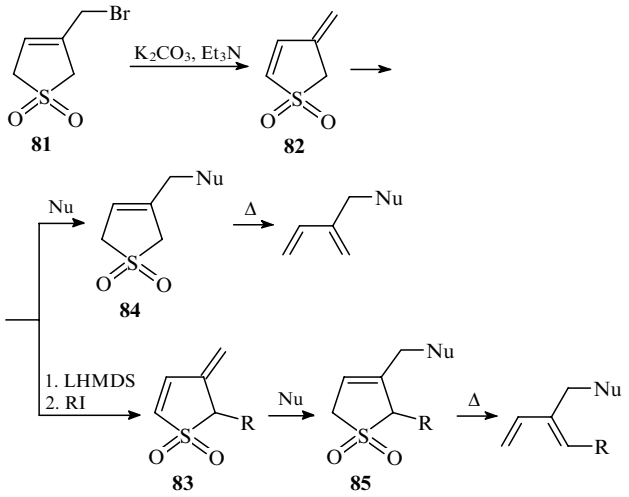
LHMDS is the lithium derivative of hexamethyldisilazane, HMPA is hexamethylphosphoramide.

For the alkylation of sulfolene-derived carbanions, it was recommended to use manganese as the counter-ion. The use of manganese counter-ion enhances the thermal stability of carbanions, so that even allylic halides with additional electrophilic groups (*e.g.*, methyl 4-bromocrotonate) [95] can be used as alkylating reagents. Another way to overcome the lability of sulfolene-derived anions is the use of its synthetic equivalent, tricyclic compound **79** (this sulfolane is prepared by cycloaddition of cyclopentadiene to 3-sulfolene). Upon vapour-phase thermolysis (650 °C), the alkylated derivatives thus formed (**80**) undergo two-step retro-fragmentation to give the *E*,*E*-configured internal dienes **55** of 91%–95% purity.[96]

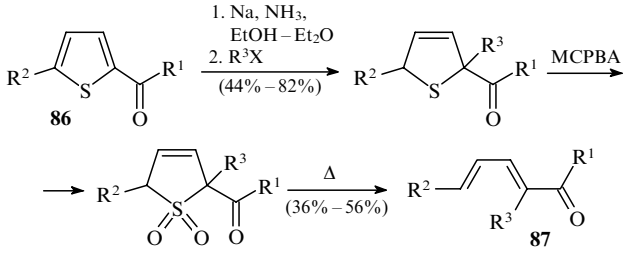


The latter approach proved useful also in the synthesis of insect pheromones.[97,98]

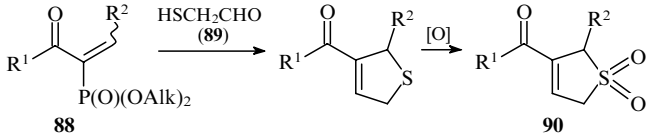
On treatment with NEt_3, 3-bromomethyl-3-sulfolene **81** is converted into 4-methylene-2-sulfolene **82**.[99] The latter, as well as its alkylated derivatives **83**, can readily enter into the Michael reaction with such nucleophiles as amines, thiols and nitroalkane-derived anions, which leads to modified β-sulfolenes **84** and **85** in up to 90% yields. Subsequent thermolysis of **84** or **85** gives rise to the branched 1,3-dienes with functionalised substituents.

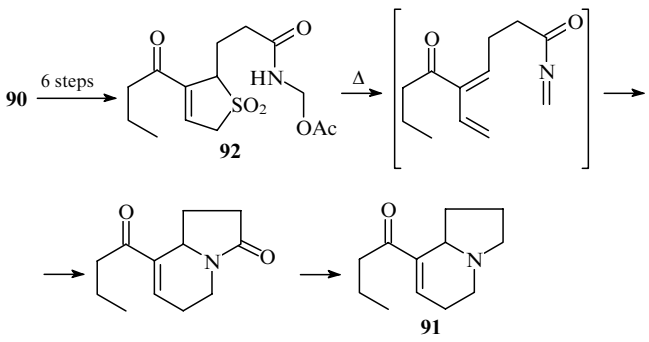


Other approaches to conjugated dienes from variously substituted and functionalised β-sulfolenes have been also reported. In one of them, readily accessible α-acylthiophenes **86** were used as the starting compounds for obtaining α-branched conjugated dienones **87** in three or four synthetic operations.[100]



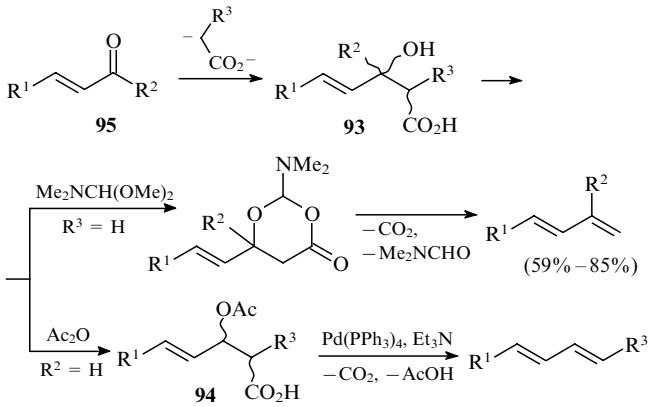
Another group of sulfolenes suitable for the synthesis of conjugated dienes can be obtained from vinylic phosphonates **88** and mercaptoacetaldehyde **89**; the synthetic protocol comprises two sequential Michael reactions followed by intramolecular Horner – Wadsworth – Emmons (HWE) reaction and oxidation.[101] It is recommendable to perform the thermolysis of sulfolenes **90** directly in the presence of electron-deficient dienophiles. This technique was employed in an elegant synthesis of compound **91**, an alkaloid of eleocanine group, from sulfolene **92**.[102]



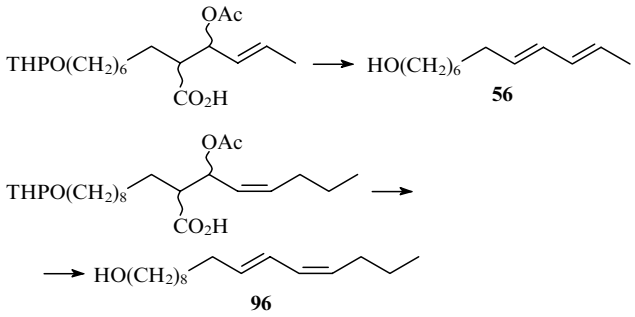


90: $R^1 = Pr^n$, $R^2 = (CH_2)_2CH=CH_2$.

β-Hydroxy acids are prone to decompose with the formation of alkenes and concomitant ejection of carboxy and hydroxy groups. If such substrates (*e.g.*, β-hydroxy acid **93**) have already a double bond, their fragmentation will give dienes. This process can be carried out by treating acids **93** either with *N*,*N*-dimethylformamide acetals [103] or with acetic anhydride.[104] Decomposition of β-acetoxy acids **94** is catalysed by palladium complexes.

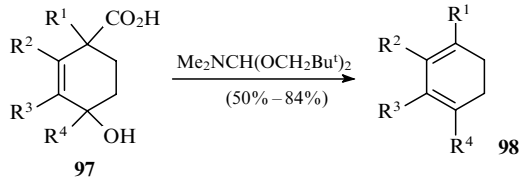


Although intermediate acetoxy acids **94** are obtained as mixtures of stereoisomers, the newly formed double bond acquires the *E*-configuration, while the double bond of the starting enal **95** ($R^2 = H$) retains its configuration in the resulting diene. These transformations were employed in stereocontrolled synthesis of the pheromones **56** and **96**.[104]



THP is tetrahydropyranyl.

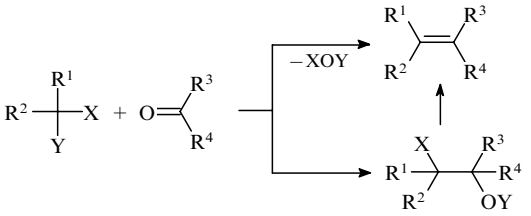
Elimination of carboxy and hydroxy groups from 4-hydroxycyclohex-2-enecarboxylic acids **97** was used in the synthesis of cyclohexadienes **98**.[105]



III. Olefination of carbonyl compounds

Olefination of a carbonyl compound means the replacement of its oxo group by the alkylidene grouping (Scheme 4).

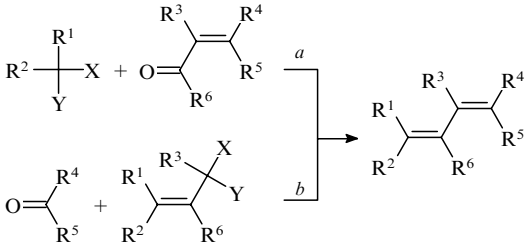
Scheme 4



The process takes place in stepwise manner and includes the addition of olefinating agent to the C=O group followed by the elimination of an X–O–Y species from the primary adduct. In some cases elimination occurs spontaneously, in others the adduct has to be isolated first, after which the second step is carried out separately. The most widely used olefination reactions are shown in Table 1.

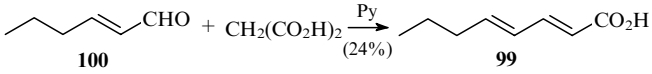
For the synthesis of conjugated dienes, it is necessary that one of the reactants should already possess a double bond. In general, two cases are possible: the double bond is present in the carbonyl compound (*a*), or the double bond belongs to the olefinating agent (*b*) (Scheme 5). Each of the cases displays its particular features depending on the chosen variant of olefination (see the corresponding subsections below). A detailed enough compendium on olefination of carbonyl compounds can be found in Larock's monograph,[10] but some of the methods cited there were used only to obtain monounsaturated compounds.

Scheme 5

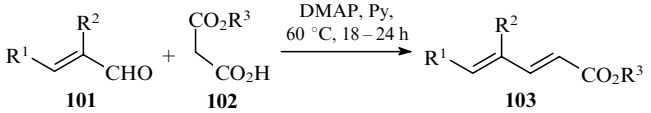


1. Condensation of CH acids with carbonyl compounds

Different variants of direct condensation of α,β-enals with active methylene compounds to give conjugated dienes are described now in all high-school textbooks. Several examples of preparation of dienoic acids are given in a review dedicated to the Knoevenagel reaction.[106] In its classical version, the highest yields (25% – 40%) are attained by heating an enal with malonic acid in pyridine [107–110] (see, *inter alia*, the preparation of octa-2,4-dienoic acid **99** from hex-2-enal **100** [109]). Instead of enal, one can use the corresponding acetal, and perform the reaction in the presence of piperidine in pyridine at 100 – 140 °C.[111] However, the yield of the dienoic acid remains about 20%.



The DMAP-catalysed condensation of enals **101** with alkyl hydrogen malonates affords dienoates **103** in good yields.[112] However, noticeable amounts of deconjugated β,γ,δ,ε-dienoates are formed when β-substituted acroleins ($R^1 \neq H$) are used in the reaction.



When the process is carried out at 140 °C in xylene in the presence of piperidine or its acetate, deconjugated *E* isomers of alk-3-enoic acids are formed as the main products.[113] The extension of this procedure to α,β-enals affords partly deconjugated alkyl dienoates **104**.[114] In total, the yield of isomeric dienes amounts to 60% if DMSO is used as the solvent (100 °C); however, a higher content of the 3*Z*,5*E*-isomer in total products is

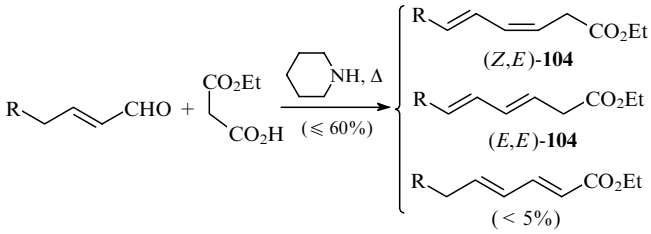


Table 1. Main types of carbonyl olefination reactions.

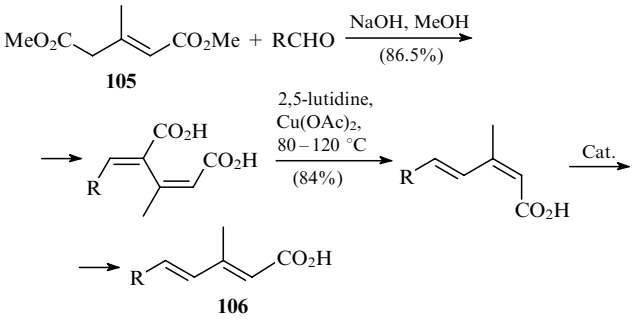
Olefination variant	The reagent $R^1R^2C(X)(Y)$			Comments
	X	Y	R^1 and R^2	
Aldol condensation	H	H [a]	$R^1 = CO_2R^3$, COR^3, CN	the reaction is sensitive to the nature of the carbonyl substrate
The Knoevenagel reaction	H	H [a]	$R^1 = R^2 = CO_2R^3$, CN	the reaction is characteristic of aldehydes
The Wittig reaction	$=PPh_3$		R^1 and R^2 can contain various functional groups	the reaction is sensitive to the nature of the carbonyl substrate
The Horner – Wadsworth – Emmons reaction	$P(O)(OR)_2$	H [a]	$R^1 = CO_2R^3$, COR^3, CN	the reaction is characteristic of aldehydes and less predictable with ketones
The Peterson reaction	SiR_3	H [a]	$R^1 = CO_2R^3$, CN	the reaction is applicable to nearly all types of aldehydes and ketones if they have no other reactive functional groups
The Julia – Baudin approach	SO_2Ar	H [a]	R^1 and R^2 contain no reactive functional groups	the primary adduct undergoes elimination in a separate step
The Krief reaction	SeR [b]	SeR [b]	the same	the reaction is applicable to nearly all types of aldehydes and ketones if they have no other reactive functional groups

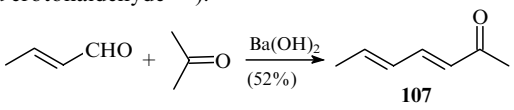
[a] Upon activation, this hydrogen atom is replaced by a positively charged counter-ion. [b] One of these RSe groups is exchanged for lithium.

attained when xylene (140 °C) is used. The unwanted 3*E*,5*E*- and 2*E*,4*E*-isomers (the content of the latter does not exceed 5%) can be removed upon converting them into inclusion complexes with urea.

Since the esters of pentenedioic (glutaconic) acid are the vinylogues of dialkyl malonates, they readily react with unsaturated aldehydes to give substituted conjugated dienes (see a review [115]). Thus the esters of 3-methylglutaconic acid (*e.g.*, **105**) were successfully employed in the synthesis of methoprene (**106**) [R = (MeO)$Me_2C(CH_2)_3CH(Me)CH_2$] as the equivalents of isoprenoid C_5 block.[116] The primarily isolated products of condensation of aldehydes with the glutaconate **105** are configurationally pure 4-carboxy-3-methylalka-(2*Z*,4*E*)-dienoic acids, which are subsequently converted into (*E*,*E*)-3-methylalka-2,4-dienoic acids **106** in several steps.

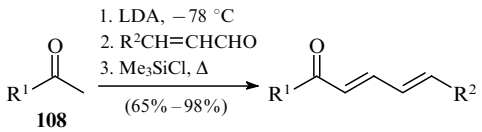


The 'classical' aldol condensation of α,β-enals with aldehydes or ketones (see a review [117]) is also used for obtaining conjugated dienes (*e.g.*, for preparing hepta-3,5-dien-2-one **107** from acetone and crotonaldehyde [118]).

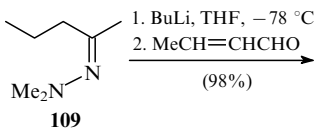


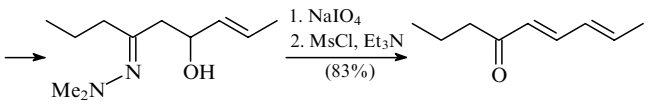
In traditional variants, hydroxides [119] or sodium sulfite [120, 121] are usually used as the bases. The yields of the products, particularly of dienals are moderate, and (quite often) even low. The yields of dienones vary over wide limits and strongly depend on the reaction conditions and on the particular nature of the reaction partners. The industrial large-scale syntheses of pseudoionone and its analogues from citral and acetone (or butan-2-one) were the objects of special research and development studies, and their conditions were duly optimised.[122]

Lately, a number of advanced procedures for directed aldol condensation have been developed. Thus high regioselectivity can be attained by using alkyl acetates or methyl ketones as the active methylene component (**108**), and lithium diisopropylamide as the base [123]. Upon treatment with LDA, ketones of the type **108** with two activated positions undergo deprotonation almost entirely at the methyl group due to the kinetic control.[124]

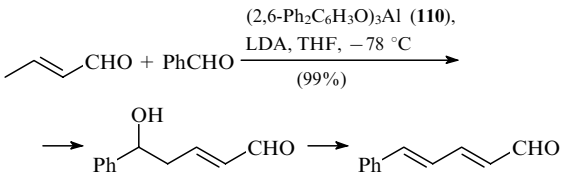


Another regioselective method of deprotonation consists in using dimethylhydrazones of asymmetric aliphatic ketones like **109**.[125]





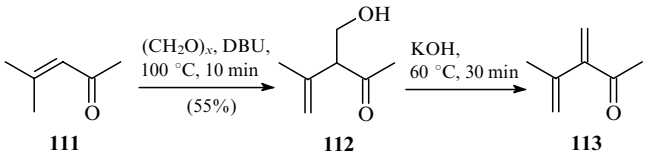
Recently [126] a conceptually new mode of aldol condensation has been developed. It consists in treating a mixture of two aldehydes, one of which is an α,β-enal, with LDA at −78 °C in the presence of aluminium tris(2,6-diphenylphenoxide) **110**. Under these conditions, α,β-enals behave exclusively as the vinylogues of the active methylene components.



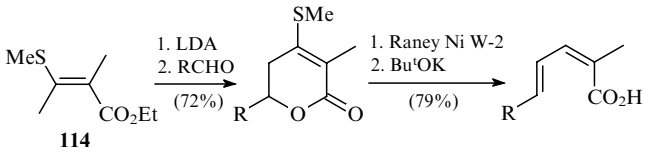
The choice of enals in this method is not confined to crotonaldehyde-like structures; higher polyenals $Me(CH=CH)_nCHO$ and conjugated enones (that react by their vinylogous anionic termini) also are suitable. Thus in 4-methylacetophenone it is the remote methyl, not the COMe group, that is activated under above conditions!

It was speculated that on mixing, the reactants form a specifically shaped conglomerate the deprotonation of which at vinylogous positions is the most favoured one. The addition of the resulting carbanion to the aldehyde component is believed to take place inside the conglomerate.

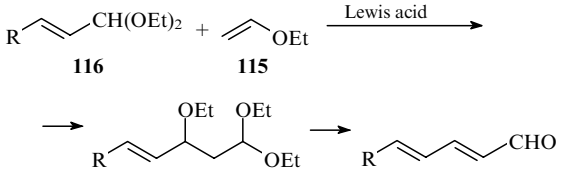
Under other conditions, the α,β-unsaturated carbonyl compounds like mesityl oxide **111** after deprotonation, add to the carbonyl substrates (electrophiles) with formation of deconjugated products, *e.g.*, **112** [127] Subsequent dehydration of the latter leads to the branched conjugated diene **113**.



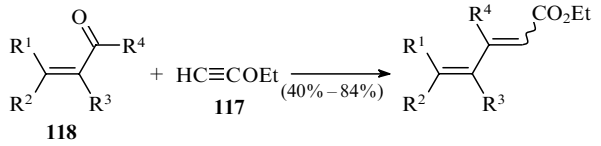
An original regio- and stereocontrolled approach to α-branched (2*Z*,4*E*)-dienoic acid relies on the use of a vinylogous synthon **114** with a methylthio group.[128]



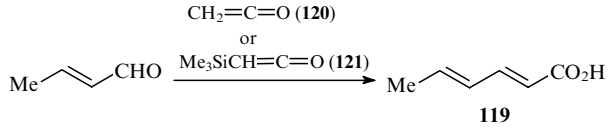
Yet another way of securing high regioselectivity in the condensation of two different carbonyl compounds is to replace conventional active methylene component by its synthetic equivalent, vinyl ether (*e.g.*, **115**). Moreover, not only aldehydes but acetals **116** can be used as carbonyl components, which operationally is more convenient. Characteristic features of this process have been thoroughly studied and discussed in a review [129] and a monograph.[130] The main shortcomings of this method are its tedious procedures and moderate yields.



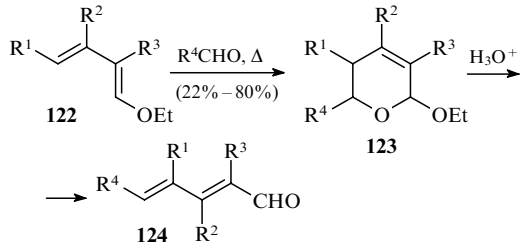
Similar results were obtained by employing ethoxyacetylene **117** instead of the active methylene component.[131–135] Using this agent, the reaction can be performed not only with aldehydes but also with ketones (**118**, $R^4 \neq H$). In this case, the overall reaction product is a mixture of stereoisomers. The process can be implemented either in the presence of $BF_3 \cdot OEt_2$, or by adding the organometallic derivative of **117** to the carbonyl component, and then by subjecting the adduct to acid hydrolysis.



Sorbic acid (**119**, fungistatic agent for food) is manufactured industrially on a multitonne scale by a process where ketene (**120**) is used as the C_2 component.[136, 137] In the laboratory practice, it can be conveniently replaced by trimetylsilyl ketene **121**.[138]



The Diels–Alder reaction of 1-alkoxybuta-1,3-dienes **122** with strongly electrophilic aldehydes leads to dihydropyran derivatives **123**, which can be subsequently transformed into dienals **124**.[139, 140] In this protocol, the compound **122** acts as a synthetic equivalent of crotonaldehyde.



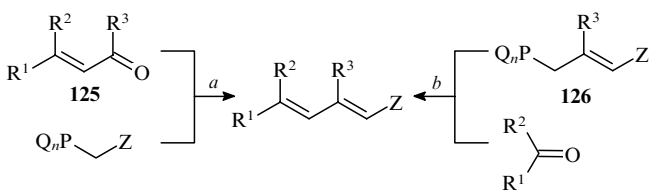
R^1, R^2, R^3 = H, Me; R^4 = H, CCl_3, CO_2Et.

2. The Wittig reaction and related processes

The Wittig reaction (in its classical or newer variants) is one of the most popular methods of olefin synthesis. Recently, its mechanistic and preparative aspects have been studied in much detail, and discussed in reviews.[141–143] In general (Scheme 6), for the construction of a conjugated diene system. it is necessary that one of the reactants, either the carbonyl compound **125** (pathway *a*) or the phosphorus-bearing compound **126** (pathway *b*) should already have a double bond in its structure.

From the standpoint of operational convenience, pathway *a* is technically simpler and thus preferable, provided that the olefinic carbonyl compound is readily accessible.

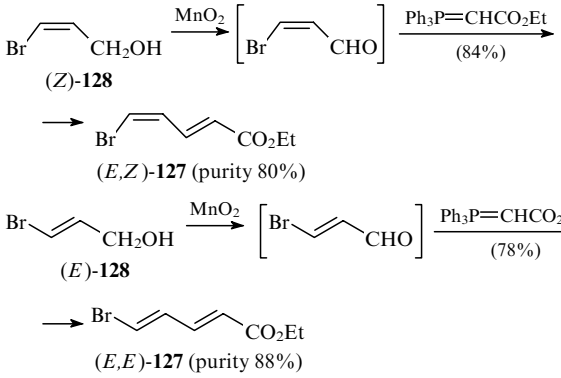
Scheme 6



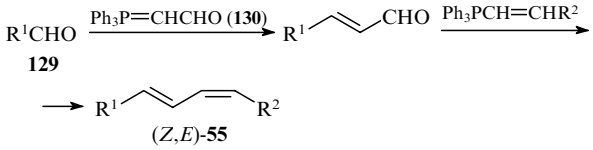
Q_nP = Ph_3P^+, $Ph_2P(O)$, $(AlkO)_2P(O)$ *etc.*; Z = Alk, Alkenyl, Ar, Het, CO_2R^4, CN, $CONR^4_2$, $C(O)R^4$ *etc.*

a. Phosphoranes

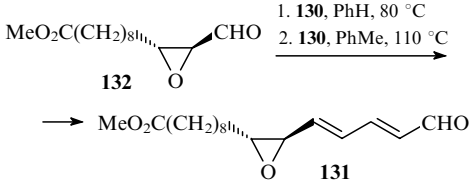
As a rule, the use of phosphoranes like $Ph_3P=CHCO_2Et$ or $Ph_3P=CHCN$ in reactions with α,β-unsaturated aldehydes is unproblematic; this is confirmed by abundant literature records. Thus a recent work describes a stereoselective *in situ* synthesis of (2*E*,4*Z*)- and (*E*,*E*)-5-bromopenta-1,3-dienoates (**127**), where the oxidation of (*Z*)- and (*E*)-3-bromoallyl alcohols was carried out in the presence of $Ph_3P=CHCO_2Et$.[144]



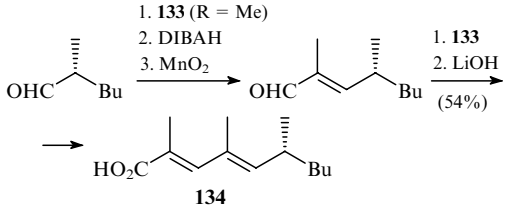
The starting α,β-enals can be obtained by elongating saturated aldehydes **129** by a C_2 fragment using 2-oxoethylidene phosphorane **130**. A stepwise process for preparing the *Z*,*E*-configured dienes **55** from alkanals **129** consisting of two sequential Wittig olefinations has been developed.[145]



The *E*,*E*-configured 5,6-*trans*-epoxyalka-2,4-dienals **131** are obtained in moderate yields by two-step elongation of *trans*-2,3-epoxyalkanals **132** with phosporane **130** first under mild, and afterwards under somewhat more drastic conditions.[146–148] Alternatively, dienal **131** can be prepared in one step using the vinylogous phosphorane $Ph_3P=CH-CH=CHCHO$.[149]



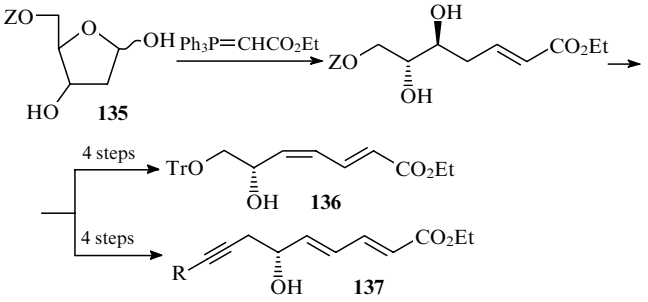
For the first stage of elongation, the phosphorane **130** can be replaced by more accessible alkoxycarbonyl-substituted phosphoranes $Ph_3P=C(CO_2Et)R$ (**133**, R = H, Alk); after that, the CO_2Et group introduced is transformed into CHO.[150] The (*E*,*E*)-dienoic acid **134** was synthesised in this way with high stereoselectivity.



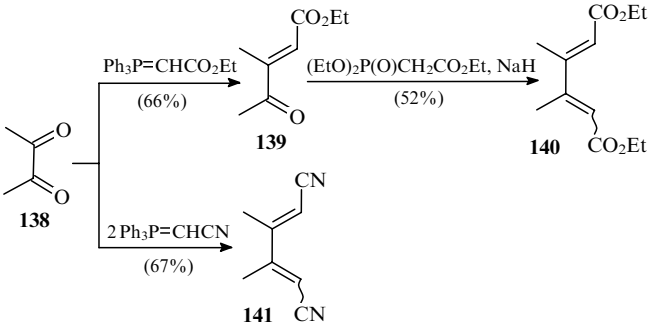
DIBAH is diisobutylaluminium hydride.

Aldol hemiacetals can be successfully used in the Wittig olefination instead of aldehydes. Thus starting from 2-deoxy-D-ribose (a naturally occuring aldol hemiacetal) or its derivatives

135, dienes **136** and **137** have been synthesised.[151, 152] Depending on the procedure employed for eliminating the 5-OH group from the intermediate dihydroxy alkenoate, the configuration of the second double bond in the target dienes can be *Z* or *E*.

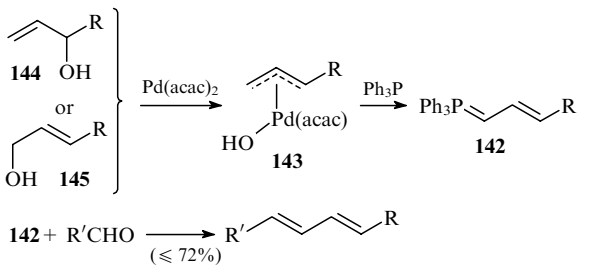


Unlike aldehydes, conjugated ketones enter reluctantly into the Wittig reactions. The α,β-enones that are not branched at the β-position sometimes enter into the Michael reaction with phosphonates of the type $(RO)_2P(O)CH_2CO_2Alk$ to give the products of 1,4-addition.[153] It is noteworthy that α-diketones **138** can react with two molecules of the above phosphonates and give conjugated dienes *via* the intermediate α,β-enone **139**.[154, 155] For the synthesis of diesters **140**, it is necessary to adopt a two-step procedure,[154] while the preparation of dinitriles **141** can be performed in one step due to the higher reactivity of the corresponding intermediate.[155]

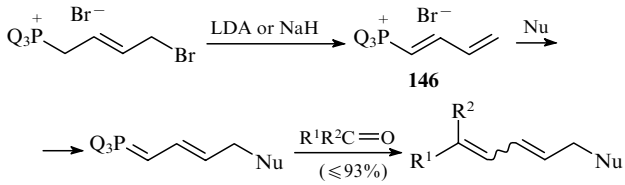


Cyclic α-diketones such as cyclobutane-1,2-dione and cyclohexane-1,2-dione also react in this way to give semicyclic dienes.

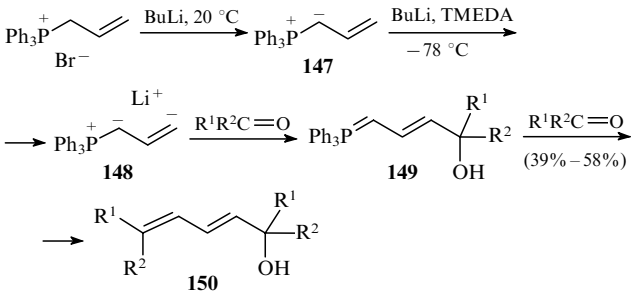
Pathway *b* of Scheme 6 looks equally attractive. The use of allylic phosphoranes **126** (Z = Alk, Ar) is justified, particularly when the precursor of the phosphonium salt, the corresponding allylic halide, is readily accessible.[156] Allylic halides of higher molecular complexity are rather difficult both to prepare and, particularly, to purify. As a consequence, roundabout approaches to allylic phosphoranes have been developed. Thus allylic phosphoranes **142** are formed *in situ* from the η^3-allylic palladium complexes **143** (prepared by heating allylic alcohols **144** or **145** in dioxane in the presence of $Pd(acac)_2$ and triphenylphosphine.[157, 158] The subsequent reaction of phosphoranes **142** with aldehydes affords conjugated dienes. This way of preparing conjugated dienes is lengthy enough and complicated by side reactions.



Another synthesis of conjugated dienes that involves indirect approach to allylic phosphoranes relies on the ability of (buta-1,3-dienyl)phosphonium compounds **146** to react with C-nucleophiles such as the dianions of β-dicarbonyl compounds or organocuprates.[159, 160]



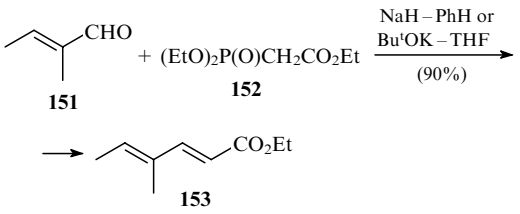
On treatment with strong bases, allyltriphenylphosphorane **147** gives metallated derivative **148**, which reacts with one molecule of a carbonyl compound as a C-nucleophile to afford the modified allylic phosphorane **149**. Then the Wittig reaction of **149** with the second molecule of aldehyde or ketone brings forth dienic alcohols **150** in moderate yields.[161]



TMEDA is *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

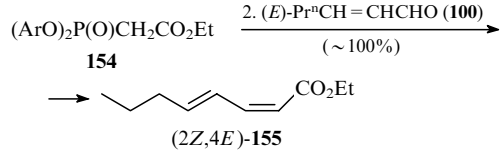
b. Phosphonates

It is profitable to replace phosphoranes by the corresponding phosphonates of the type $(EtO)_2P(O)CH_2Z$. This variant of olefination is known as the Horner – Wadsworth – Emmons reaction. Thus the olefination of tiglic aldehyde **151** with triethyl phosphonoacetate **152** affords ethyl dienoate **153** in 90% yield.[162, 163] The newly formed double bond has almost pure *E* configuration.

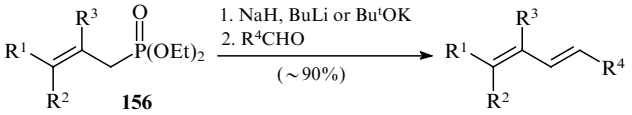


A simple procedure for implementing such a process has been proposed. It consists in mixing together and stirring an aldehyde, phosphonate **153** and concentrated aqueous K_2CO_3. The method is applicable to the synthesis of alkyl dienoates or alkadienones and provides satisfactory yields (60% – 70%).[164] Time and again, it was used in the synthesis of natural products.[4, 165, 166]

In the case of phosphonates with phenoxy groups (**154**), the stereoselectivity of olefination is reversed (with respect to the case of **152**) *i.e*, the *Z*-isomers of alk-2-enoates are produced.[167] For the reactions involving phosphonates **154**, it was recommended to use NaH, Triton B or the DBU – NaI system as the base. The reaction of hex-2-enal (**100**) with **154** afforded ethyl (2*Z*,4*E*)-octa-2,4-dienoate **155** with 97% isomeric purity.[168]



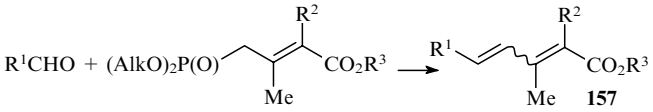
The reaction of allylic phosphonates of the type **156** with saturated aldehydes can be successfully applied to the synthesis of dienes.[169]



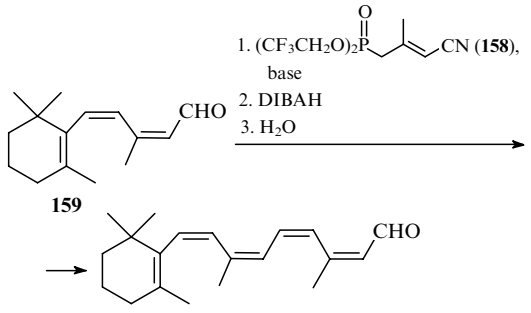
R^1, R^2, R^3 = H, Alk.

For allylic phosphonates **156** with additional functional groups (R^1 or R^2 = CO_2Alk, $CONR_2$, RCO, or CN) the HWE reaction is one of the most studied because it is widely used in the synthesis of polyenes. Such phosphonates are usually prepared by employing the Arbuzov or Michaelis–Becker reactions (see a review[142]). Recently, an interesting method for the synthesis of γ-phosphono-α,β-enones from allylic phosponates was reported.[170] Its protocol involves silylation, alkylation (if necessary) and finally acylation.

The experience accumulated since the mid-sixties suggests that the HWE reactions are sensitive to the nature of the reactants and bases used and to conditions under which they are implemented. Thus for the preparation of alkyl dienoates of the type **157**, it was recommended to use such bases as MeONa in DMF,[171] $NaNH_2$ in THF,[171] NaH in DMF,[172] and, what is particularly convenient, the systems of phase transfer catalysis: solid KOH–benzene–18-crown-6 (Cat.)[173–176] or solid KOH–benzene–$Alk_4N^+Br^-$ (Cat.).[177,178] In the latter case, 3-methylalka-2,4-dienoates **157** are formed with 90%–96% *E*,*E*-selectivity[143,178] By contrast, when the phosphonate grouping contains the 1,3,2-phospholane fragment, the reaction results in 2*Z*,4*E*-isomers (~70%–85% selectivity).[179,180]

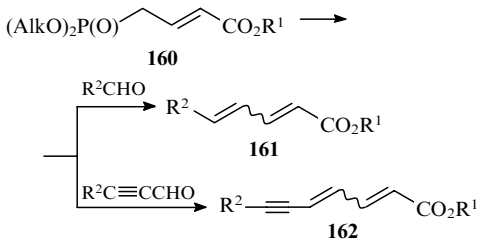


Bis(β,β,β-trifluoroethyl) esters of aliphatic phosphonic acids (Still–Gennari phosphonates) react with aldehydes to give *Z*-alkenes. The reactions of α,β-enals with bis(β,β,β-trifluoroethyl) 3-cyano-2-methylprop-2-enylphosphonate (**158**) afford the 2*Z*,4*E*-isomers of 2-methylalka-2,4-dienonitriles with high selectivity.[181] The possibility of using the phosphonate **158** for the synthesis of 1,3-dienes with *Z*-configured newly formed double bond is indicated by the reaction of (2*Z*,4*Z*)-β-ionylideneacetaldehyde (**159**) with this phosphonate.[182]



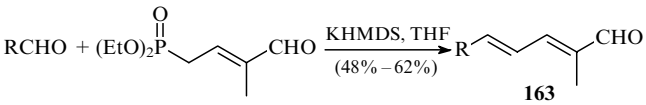
In the mixture of four stereoisomers of retinal formed in this reaction, the proportion of products with *Z*-configuration of the newly formed double bond amounts to 72%.

When non-branched phosphonocrotonates **160** are used, the yields of dienes **161** decrease (to 59% with the use of $NaNH_2$ in THF[4,166]); under conditions of phase transfer catalysis, the dienes **161** are not formed at all. However, with the use of lithium derivative of hexamethyldisalazane,[183] the dienes **161** are produced in 84% yield, whereas the use of LDA having close properties[184] provides only 27% yield. Recently, a method for the synthesis of conjugated dienes has been proposed according to which a mixture of the initial phosphonocrotonate and aldehyde is refluxed in THF in the presence of LiOH and 4 Å molecular sieves. The yield of dienes is 86%.[185] Cyclohexanones can be used successfully in place of aldehydes in this reaction.

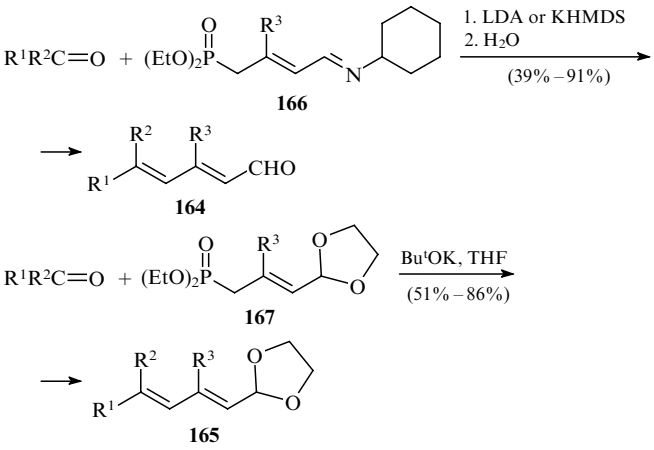


Olefination of acetylenic aldehydes by the phosphonate **160** in the presence of $NaNH_2$ in THF gives rise to the corresponding dienynoates **162** in a yield not higher than 36%.[4,186]

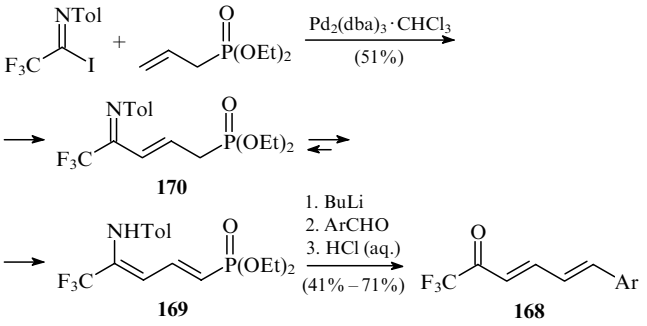
Apart from esters, dienals **163** have also been synthesised using this route.[187]



Dienic aldehydes **164** and their acetals **165** can be prepared using synthons **166** and **167** with the protected aldehyde group.[188,189]

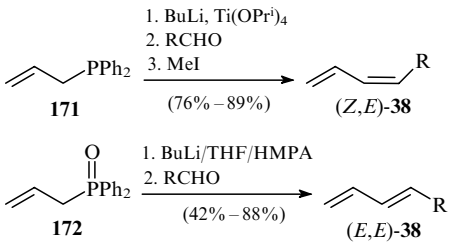


Dienyl trifluoromethyl ketones **168** are formed from dienamines **169**, tautomers of Schiff's bases **170**.[190]

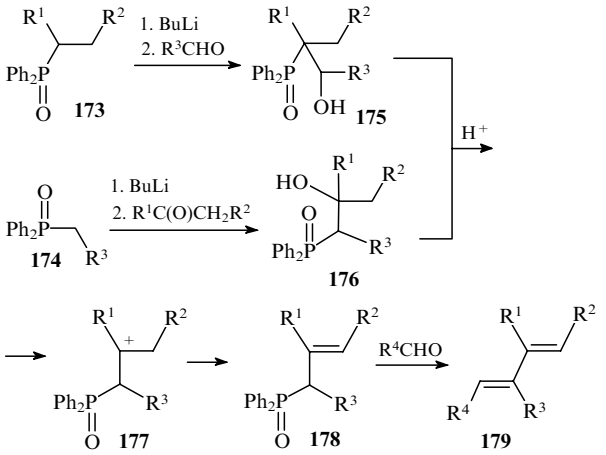


c. Allylic phosphines and phosphine oxides

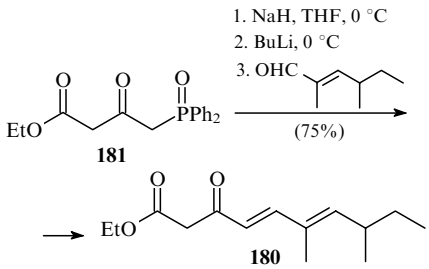
Olefination of carbonyl compounds can also be performed by means of allylic phosphines **171** and allyl phosphine oxides **172**;[191] the products **38** thus formed differ in the stereochemistry of the newly formed double bond.



Allylic phosphine oxides with more complex structures used for the synthesis of functionally substituted conjugated dienes can be prepared from simpler phosphine oxides **173** or **174**.[192] To this end, compounds **173** and **174** are made to react with aldehydes and ketones, and the reaction products **175** and **176** are subjected to dehydration. Acidic dehydration of secondary β-hydroxyphosphine oxides **175** is accompanied by the migration of the phosphorus-containing group, while dehydration of tertiary β-hydroxyphosphine oxides **176** follows the standard pathway. In both cases, tertiary carbocation **177** is formed, which is transformed, under thermodynamic control, into thermodynamically more favourable alkene **178**. Thus the same product **179** can be prepared in different ways, which makes the phosphine-oxide route more versatile.

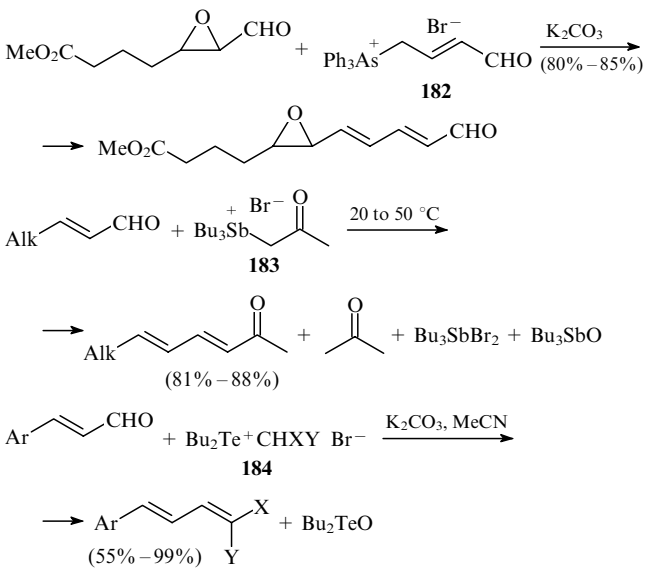


The synthesis of conjugated diene **180** containing an ethyl acetoacetate fragment as a substituent has been reported.[193] This compound was prepared using phosphine oxide **181**.



d. Related methods

In conclusion, we shall consider methods of olefination of carbonyl compounds making use of 'non-phosphorus' equivalents of the Wittig reagents based on arsenic **182**,[194,195] antimony **183**[196] and tellurium **184**.[197,198] It should be noted that in the case of complex syntheses, the use of arsonium derivatives has substantial advantages. The advantages and shortcomings involved in the use of antimony and tellurium derivatives have not been adequately elucidated.

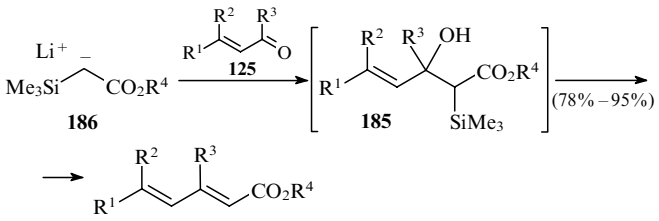


X = CN, CO_2Et; Y = H, Ph.

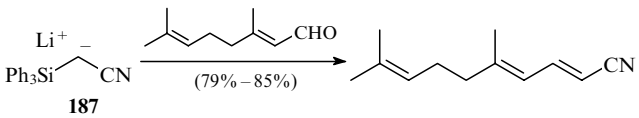
3. Miscellaneous methods of olefination of carbonyl compounds

a. The Peterson reaction

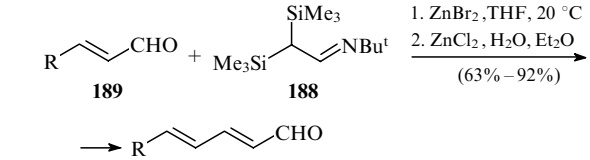
The Peterson reaction consists in elimination of vicinal silyl and hydroxy groups, resulting in the formation of a double bond (see Section II). Here, we consider the version used to olefinate α,β-unsaturated carbonyl compounds. In this technique, the starting β-hydroxy silanes **185** are formed *in situ* upon the addition of silicon-containing carbanion reagents **186** to the carbonyl compounds **125**.[46,47]



An advantage of this approach is the possibility of using not only α,β-unsaturated aldehydes but also ketones including relatively non-reactive chalcone.[48] An organosilicon reagent should contain a group exhibiting a $-M$-effect. Apart from esters **186**, the acetylene derivative $Me_3SiCH_2C{\equiv}CSiMe_3$ and the nitrile **187**[49] have also been involved in this reaction. Deprotonation is carried out by amides such as LDA; the yields are high in all cases.

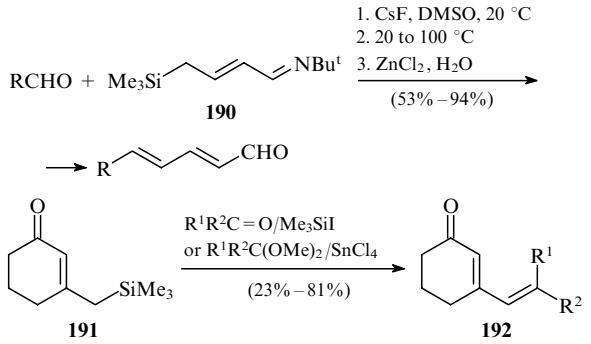


In recent years, a convenient C_2 olefinating synthon **188** has been devised; it contains two geminal silyl groups and is able to react with aldehydes **189** in the presence of Lewis acids under very mild conditions.[199]



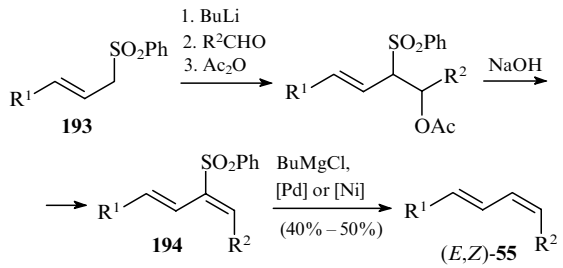
A similar vinylogous C_4 synthon with two silyl groups has not been prepared; however, C_4 olefination can be accomplished under other conditions using monosilyl reagent **190**.[200,201] The

reactions of carbonyl compounds and acetals with cyclic γ-silyl-α,β-enones **191** giving rise to dienones **192** have been described.[202]

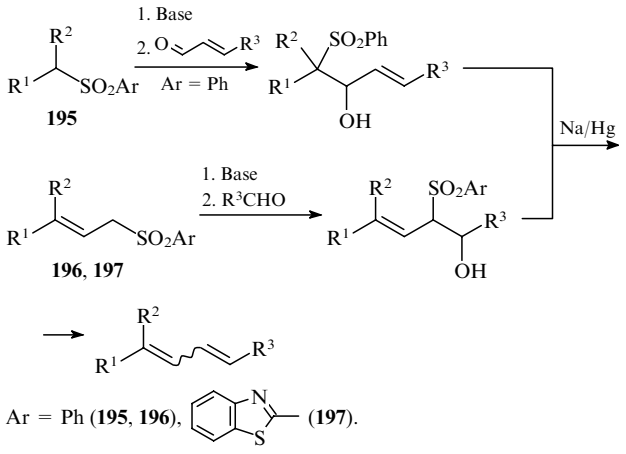


b. The Baudin – Julia method

The Julia method consists in condensation of aryl sulfones with aldehydes followed by reductive elimination of the sulfone group from unsaturated sulfone of the type **64** (see Scheme 2),[78,79] for example, on treatment with $LiAlH_4$. The involvement of unsaturated sulfones **193** in this process should furnish dienes. It has been proposed [203] to use BuMgCl for the reduction of the intermediate *Z*-olefinic sulfones **194** in the reaction catalysed by $Pd(acac)_2$ or $Ni(acac)_2$. The isomeric purity of the products **55** was 93% – 97%; however, the yields were moderate.



In another study,[204] olefination of α,β-enals with saturated sulfone of the type **195** and olefination of saturated aldehydes with allylic sulfones **196** (Ar = Ph) have been studied in substantial detail with verification of numerous factors. Elimination of vicinal sulfonyl and hydroxy groups was induced by sodium amalgam. The yields of dienes were moderate, despite the efforts made by the authors.

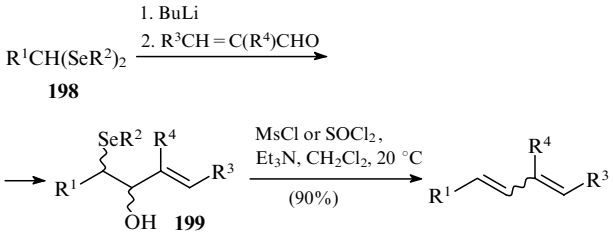


In a perfected method, the phenyl group in the sulfone **196** was replaced by various heterocyclic groups, which resulted in higher product yields, the best results being attained for the 2-benzothiazole substituent (compound **197**).[205–207] This is due to the fact that heteroatoms in the aryl group change the final steps of the olefination mechanism; this influences the product yield, which can reach 86%.

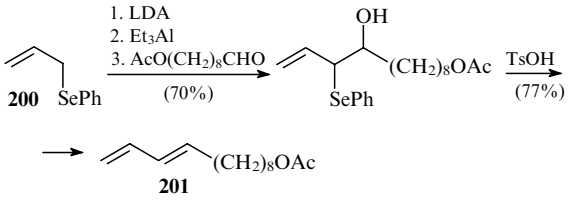
Both reactions — unsaturated sulfone + saturated aldehyde and *vice versa* — are used for the synthesis of dienes. Usually, this gives a mixture of *E,E*- and *E,Z*-isomers, their ratio being dictated by the pattern of substitution at the double bond in the reactants.

c. The Krief reaction and other olefination methods

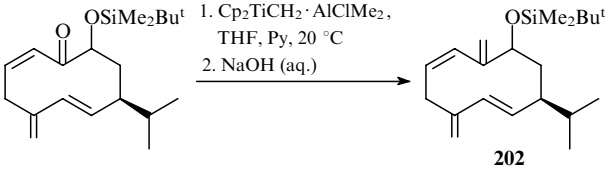
The ability of selenoacetals **198** to exchange one selenium-containing group for lithium has underlain the new Krief olefination method.[208–210] The reaction of the carbanion formed (stabilised by the remaining selenium atom) with aldehydes or ketones yields β-hydroxy alkyl selenides **199**, which readily form olefins on the subsequent treatment with acidic reagents. In the case of unsaturated aldehydes, the method results in conjugated dienes.[211,212]



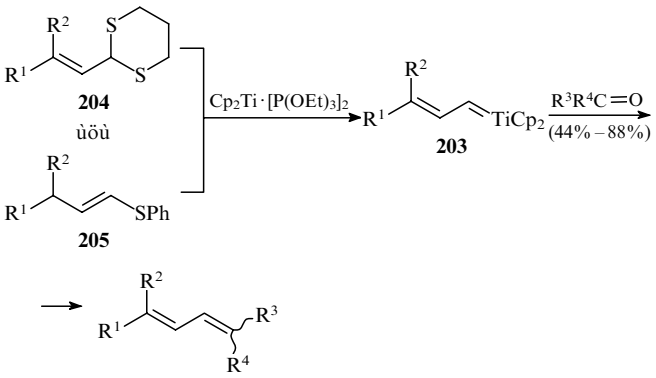
Another variant of organoselenium synthesis of dienes, namely, the reaction of a saturated aldehyde and an unsaturated selenium component, is also possible. Allyl selenides **200**, the CH acidity of which is high enough for hydrogen to be eliminated on treatment with LDA, are possible precursors of this type of selenium component. The resulting carbanion, however, exhibits ambident properties and furnishes mixtures of isomeric products in reactions with electrophiles.[213] To ensure the required regiodirectivity, the reagent is treated with Lewis acids; the ate-complex thus formed reacts with an aldehyde to give the 'normal' product **201**.



The titanium carbene complex $Cp_2Ti{=}CH_2$ (the Tebbe reagent) is an efficient methylenating agent.[214] It reacts with unsaturated carbonyl compounds giving rise to conjugated dienes including those difficult to prepare by other methods, such as **202**.[215]

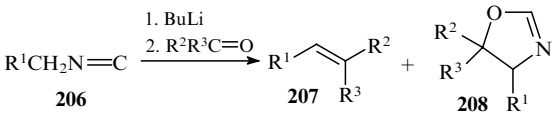


Recently, it has been shown that unsaturated analogues of the Tebbe reagent (**203**) can be prepared from α,β-enal cyclic thioacetals **204** on treatment with a titanocene(II) complex with triethyl phosphite.[216] The reactions of the carbenes **203** with aldehydes, ketones, and even esters (!) result in the formation of a new double bond. Instead of the thioacetals **204**, 1,3-diphenylthioalk-1-enes **205** (R^1 = SPh) [217] can be used in the reaction (they are produced from α,β-enals under conditions of acetalisation with monothiols). In the case of non-branched dienes ($R^2 = R^4 = H$), the proportion of *E,E*-isomer exceeds 87%.



R^3 = Alk; R^4 = H, Alk, Ar, OAlk.

Isocyanides **206** can also serve as olefinating agents;[218] however, in this case, in addition to alkenes **207**, the reaction gives substantial amounts of oxazolines **208**. This route was use to convert cinnamaldehyde into 1-phenylbuta-1,3-diene (R^1 = R^2 = H, R^3 = PhCH=CH) in 28% yield.



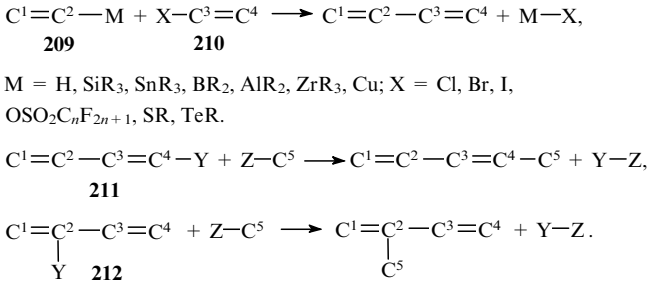
The reaction of aldehydes with diazo esters leading to α,β-unsaturated esters can also be classified as olefination. In the only known example, namely, in the reaction of cinnamaldehyde with diazo ester, the yield of the corresponding conjugated diene is 92%.[219]

IV. Organometallic reactions

1. Cross-coupling of vinylic and/or acetylenic components

Cross-coupling reactions belong to the most advanced methods for the creation of a C−C bond. The thermodynamic factor, which accounts for the occurrence of these reactions, is the formation of a favourable bond between the electropositive element M of reactant **209** and the electronegative element X of reactant **210** (Scheme 7). The reactions of the general form **209** + **210** are usually classified according to the sort of the electropositive element in the reactant **209**, the nature of which governs the mechanism of the process, although the outcome is formally the same.

Scheme 7

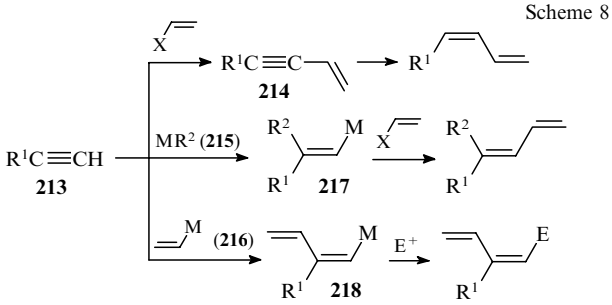


M = H, SiR_3, SnR_3, BR_2, AlR_2, ZrR_3, Cu; X = Cl, Br, I, $OSO_2C_nF_{2n+1}$, SR, TeR.

In the synthesis of carbo-substituted conjugated dienes, cross-coupling of two vinylic components giving rise to the central single bond is used most often. The replacement of the heteroatom in a preformed diene system **211** or **212** by a carbon-centred fragment is used more rarely. A fundamental feature of cross-coupling reactions is retention of the configuration of the reacting centres, which permits one to prepare, as desired, any of the possible isomers of conjugated dienes (*E*,*E*-, *E*,*Z*-, *Z*,*E*- and *Z*,*Z*-isomers).

Cross-coupling can also involve components with triple bonds such as **213**. First, they react with alkenyl reagents to give conjugated enynes **214**. Second, some organometallic reagents of the type **215** or **216** are capable of adding to triple bonds to give

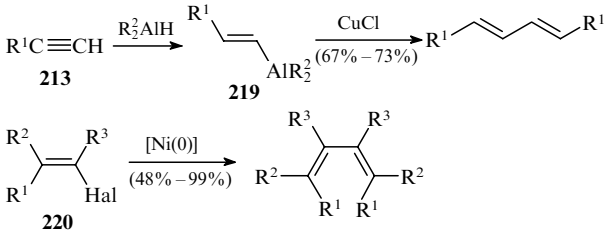
Scheme 8



new metal alkenyls, **217** or **218**, respectively. All the compounds obtained can be further converted into dienes (Scheme 8).

The reactions listed above have been thoroughly studied and discussed in numerous publications;[220–227] therefore, in this review, we present only a brief characterisation. There is a fairly detailed list of published data on each type of reaction.[10]

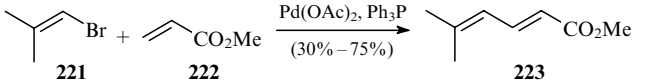
In early examples, cross-coupling has been carried out with stoichiometric amounts of organometallic reagents. The scope of these reactions is limited as they mainly permit the preparation of symmetrical compounds. This is indicated by homodimerisation of alkenylalanes **219** induced by CuCl[228] or of various alkenyl halides **220** in the presence of stoichiometric amounts of nickel complexes such as $Ni(cod)_2$ (cod is cycloocta-1,5-diene)[229] or $Ni(bipy)_n$ prepared *in situ*.[230]



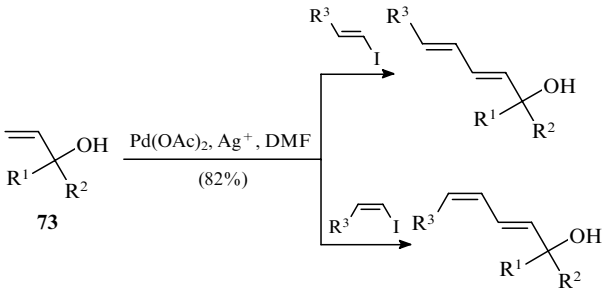
Catalytic cross-coupling protocols are much more efficient. Palladium or nickel complexes are the most popular catalysts of these processes.

a. The Heck reaction and its modifications

The coupling of α-alkenes (**209** with M = H, see reviews[220,221]) with alkenyl or aryl halides catalysed by palladium complexes is called the Heck reaction. Coupling of the vinylic components **221** and **222** affords conjugated dienes **223**.[231]

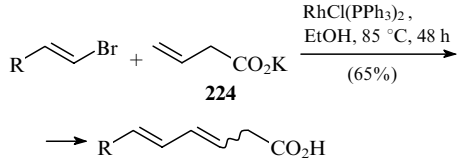


It is advantageous to perform this process in the presence of Ag salts as HHal acceptors;[232,233] in this case, the allylic alcohols **73** can also be introduced in the reaction.



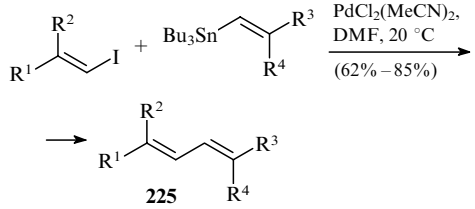
Apart from alkenyl halides, the Heck reaction can be carried out for alkenyl perfluoroalkyl sulfonates,[234,235] alkenylsilanols,[236] alkenylpentafluorosilicates[237] and alkenyl(aryl)iodonium salts.[238] Coupling of alkenyl bromides with potassium but-3-enoate (**224**), similar to the Heck reaction in the outcome but

catalysed by the rhodium complex $RhCl(PPh_3)_2$, has been described.[239]

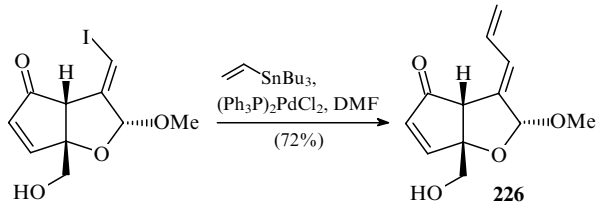


b. The Stille reaction

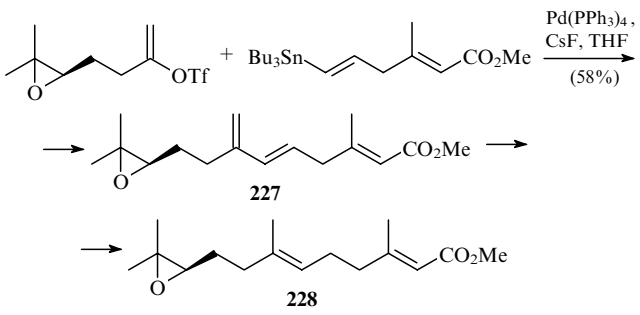
Coupling of organotin compounds with halides catalysed by palladium complexes has been called the Stille cross-coupling (**209** with M = SnR_3, see reviews [222, 223]). In addition to the synthesis of biaryls, styrenes and enynes, this reaction is also good for the synthesis of various conjugated dienes **225**.[240, 241] The reaction proceeds with full retention of the configurations of the reacting centres; the initial compounds may contain diverse substituents and the product yields are usually high.



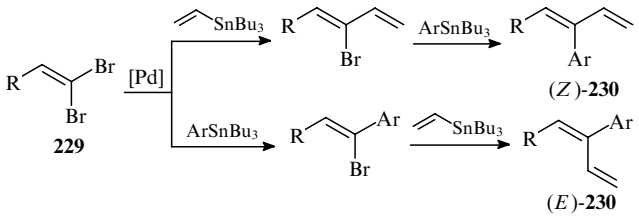
The Stille reaction has been used in the total synthesis of complex natural products, for example, didemnenones **226**, biologically active compounds generated by marine *Tunicata*.[242]



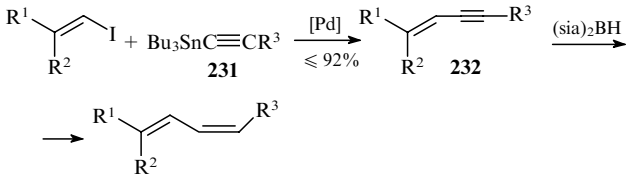
Triflates can be involved in this reaction instead of halides;[243] this has been used in the synthesis of triene **227**, the closest precursor of the C_{16} juvenile hormone (**228**).[244]



1,1-Dibromoalkenes **229** react with organotin compounds, first of all, at the bromine atom located in the *trans*-position.[245] By varying the order of addition of the alkenyltin and aryltin reagents, either *E*- or *Z*-isomers of 3-aryl-1,3-dienes **230** can be obtained as desired.



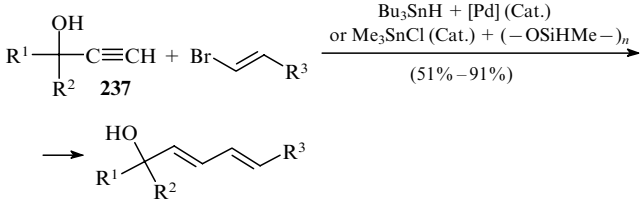
Alkynyltin derivatives **231** can also enter into the Stille cross-coupling. Conjugated enynes **232** thus formed can be reduced selectively yielding *E*,*Z*-dienes.[246]



sia is 3-methylbutan-2-yl.

Using this strategy, two pheromones **235** and **236** with similar structures but opposite configurations of the conjugated double bonds have been synthesised from the same initial alkyne **233** and alkynol **234** (Scheme 9).[246]

Direct coupling of tertiary acetylenic alcohols **237** with alkenyl bromides in the presence of stoichiometric amounts of tin hydrides seems to involve the hydrostannylation step, the overall reaction looking like the Stille cross-coupling.[247]

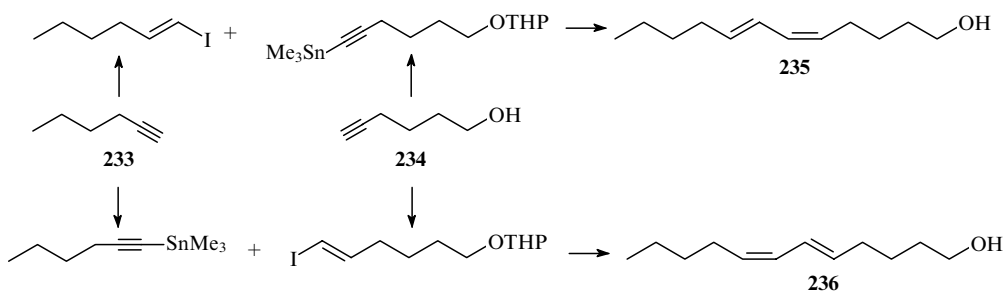


The reaction in question can also involve alkynylamines $R^1R^2C(NH_2)C{\equiv}CH$ and other sterically hindered terminal acetylenes. The same result is attained when catalytic amounts of $(Bu_3Sn)_2O$ [247] or Me_3SnCl,[248] and stoichiometric amounts of polymethylhydrosiloxanes are used instead of tin hydrides as hydride-ion donors. This modification of the Stille reaction opens up prospects for extending the scope of its application because this version implies markedly smaller proportions of tin-containing wastes.

c. The Suzuki reaction and its modifications

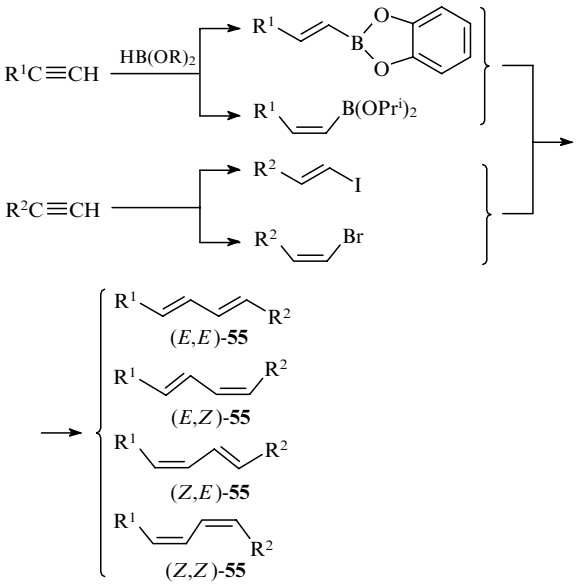
Coupling of organoboron compounds with halides or their equivalents (*e.g.*, triflates) catalysed by palladium complexes has been called the Suzuki coupling (**209** with M = BR_n, see reviews [224, 225]). Like the Stille cross-coupling, this reaction can be applied to the synthesis of various types of compound including conjugated dienes. An important feature of the process is that it

Scheme 9

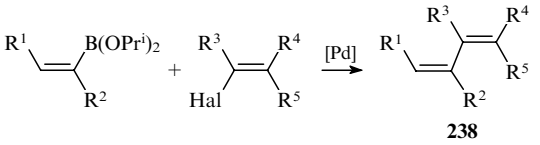


should be carried out in the presence of bases (NaOEt, NaOH, KOH, K_3PO_4, Na_2CO_3, *etc.*): coordination of the anion to the boron atom results in a higher electron density on the reaction centre, which facilitates the replacement of boron by palladium. In the case of sterically hindered alkenyl bromide, methyllithium proved to be a more suitable base.[249] The catalyst used most often is $Pd(PPh_3)_4$.

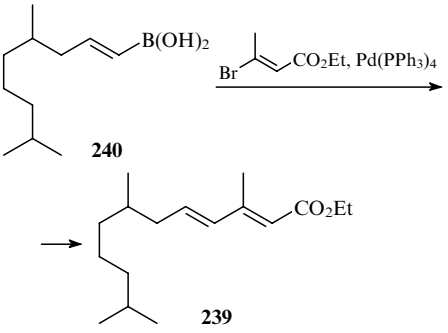
The organoboron approach is distinguished by versatility — by using specific protocols, both *E*- and *Z*-isomers of both the boron and halogen components can be prepared from terminal alkynes. The subsequent coupling in a required combination provides, at one's discretion, any isomer of the conjugated diene **55**.[222] The initial compounds can contain additional substituents and functional groups.



The Suzuki cross-coupling has been used successfully for the stereocontrolled preparation of dienes **238** with a more complex pattern of substitution including cyclic and polyfunctional compounds.[250–254]

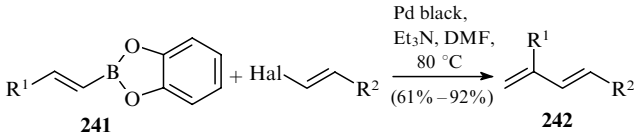


Thus this reaction has been used to prepare hydroprene (**239**) from alkenylboronic acid **240**.[255, 256]



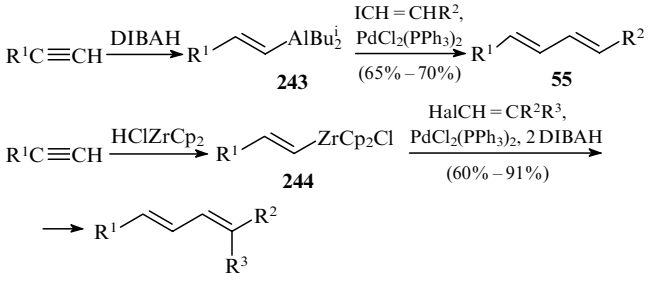
An interesting methodological expedient is to carry out this process in the aqueous acetonitrile medium.[257] The reaction was catalysed by a system comprising $Pd(OAc)_2$ and water-soluble sulfonated triphenylphosphine, $P(C_6H_4SO_3H)_3$. Both compounds subjected to coupling contained functional groups.

The nature of the base in the Suzuki cross-coupling can influence the process regioselectivity. Thus in the presence of triethylamine, catecholboranes **241** are coupled with alkenyl halides (or aryl halides) according to the 'head-to-tail' pattern giving rise to branched dienes **242**, the process regioselectivity being higher than 94%.[258]



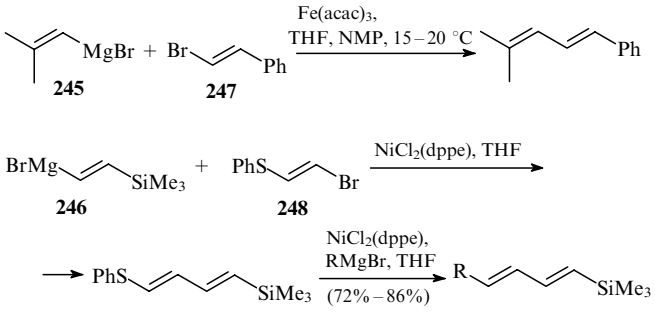
d. Other variants of cross-coupling of vinyl components

Vinyl derivatives of other elements are used somewhat less extensively in the cross-coupling reactions. The use of zinc, magnesium, aluminium and zirconium compounds for this purpose has been surveyed in a review.[224] For example, hydrometallation of terminal alkynes with R_2AlH [259, 260] or Cp_2ZrClH [261] to give the corresponding organometallic intermediates **243** and **244** followed by proper coupling resembles conceptually the Suzuki coupling discussed above.



The cross-coupling of vinylcopper reagents with alkenyl halides is also catalysed by palladium or nickel complexes. This reaction had been discovered earlier than the more convenient Stille and Suzuki reactions. Characteristic features of this process have been studied in detail by Normant and Alexakis.[9] The main work rule that ensures high yields and involvement of both alkenyl fragments of the reactants $(RCH=CH)_2CuLi$ is preliminary transmetallation of these compounds carried out by adding equivalent amounts of magnesium and zinc halides to the reaction mixture. Thus it is actually an organozinc compound that enters into the coupling reaction. Cross-coupling of neat organocopper compounds catalysed by nickel or palladium complexes gives products in a yield not exceeding 50%.

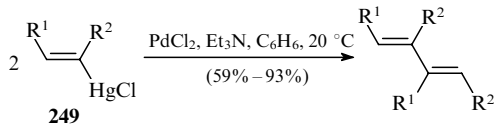
The coupling of alkenylmagnesium bromides **245** and **246** with alkenyl bromides **247** and **248** can be induced not only by palladium complexes but also by iron [262] or nickel [263, 264] complexes; in the latter case, thiolate ion can act as the leaving group.



NMP is *N*-methylpyrrolidone.

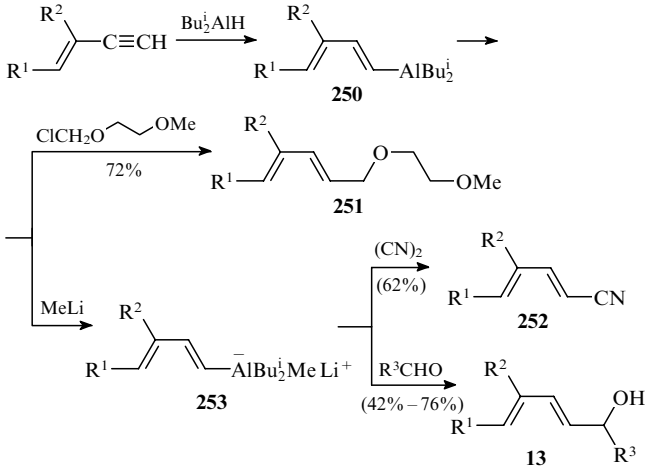
Vinyl silicon derivatives, unlike similar tin compounds, normally do not enter into the cross-coupling reaction (see reviews [265, 266]). Nevertheless, a particular type of active vinylsilanes containing fluorine atoms at silicon has been identified among them.[267–269] Vinyl iodides and triflates were used as electrophiles; $(\eta^3\text{-}C_3H_5)PdCl_2$ was found to be the best catalyst. The process was carried out in THF at 60 °C in the presence of Bu_4NF.

Dimerisation of alkenylmercury reagents **249** follows the 'head-to-tail' pattern.[270]

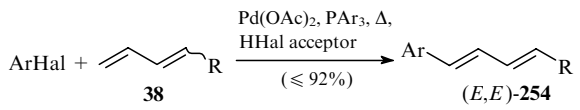


e. Cross-coupling of diene and saturated components

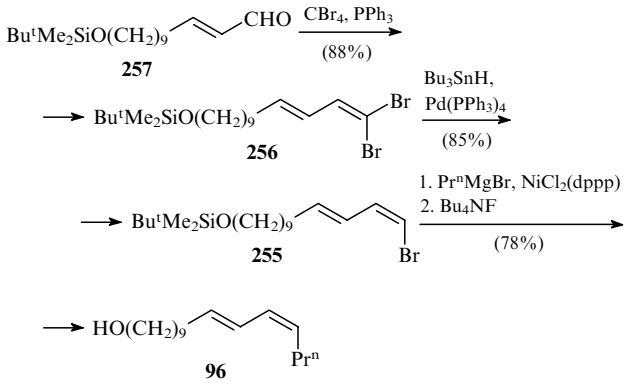
This reaction is used more rarely. Two general cases are known, one with the diene component acting as the nucleophile and the saturated one being the electrophile and *vice versa*. Dienylalane **250** reacts with methoxyethoxymethyl chloride (MEMCl) to give the expected ether **251**.[271] The compound **250** does not react properly with aldehydes and cyanogen; however, the target dienonitriles **252** and dienic alcohols **13** can be prepared from the corresponding ate-complex **253**.[271, 272]



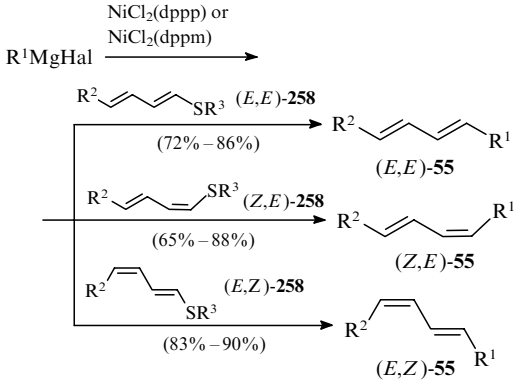
Yet another example of using a 'nucleophilic' diene component is the Heck arylation of the terminal conjugated dienes **38**.[273, 274] The process is carried out in the presence of HHal acceptors such as amines [273] and silver or thallium acetates,[274] the *E*,*E*-isomer of diene **254** being formed predominantly irrespective of the configuration of the initial compound **38**.



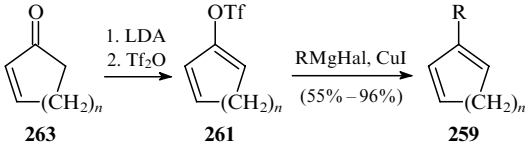
An original synthesis of bombykol **96** can serve as an example of cross-coupling with 'electrophilic' diene component **255** (easily prepared from dibromide **256** formed upon bromination of unsaturated aldehyde **257**) and a 'nucleophilic' saturated component.[275] In this case, the bond configuration at the reaction centre is not violated. This strategy was verified using numerous examples, the yields of *Z*,*E*-dienes ranging from 58% to 85%.[275]

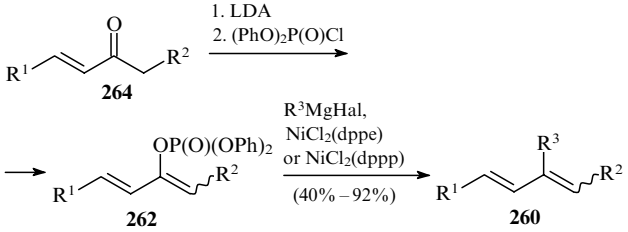


Some examples of using dienyl sulfides **258** (R^3 = Ph, Bu^t) in these reactions are documented;[45, 263, 276] in this case, the thiolate ion is the leaving group (the *tert*-butyl substituent is preferred [45]). The configuration of the products **55** remains the same as in the initial sulfides **258**.

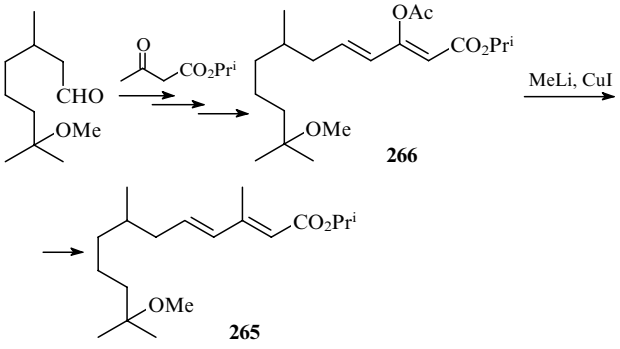


The cross-coupling strategy makes it possible to substitute a nucleofugal group at the 2-position of the diene system; this results in branched derivatives **259** and **260**. Dienol triflates **261** or phosphates **262**, which are easily prepared from the corresponding α,β-enones **263** or **264**, can serve as convenient substrates for this purpose. The cyclic dienol triflates **261** react with the Grignard reagents in the presence of catalytic amounts of CuI,[277] while the acyclic phosphates **262** react in the presence of complex nickel catalysts.[278] The dienes **260** are formed as mixture of geometric isomers. The phosphate strategy is suitable also for the synthesis of cyclic dienes **259**.



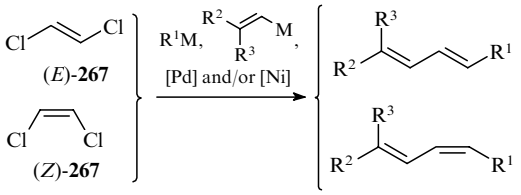


This technique has been used to introduce a methyl group during the synthesis of methoprene (**265**) according to the $C_{10} + C_4 + C_1$ pattern; the substitution of the methyl group for the OAc group in compound **266** occurred with complete retention of the initial configuration.[279]



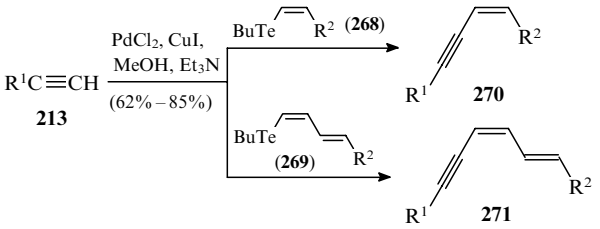
f. Cross-coupling involving 1,2-dihaloethenes

The (*E*)- and (*Z*)-isomers of 1,2-dichloroethene (**267**) can serve as convenient and inexpensive synthons for the preparation of conjugated dienes (as well as styrenes, enynes and so forth) (see a review [280]). By varying the conditions and catalysts, it is possible to perform consecutive coupling of these compounds, first, with a saturated and then, a vinylic component (or *vice versa*),[281] resulting in the formation of the target dienes in high yields and with high isomeric purity. It is of interest that 1,2-dibromoethene is much less effective in this type of process.[280]

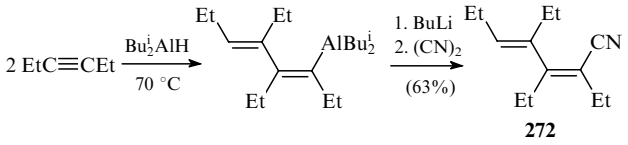


g. Synthesis of 1,3-dienes from alkynes and allenes

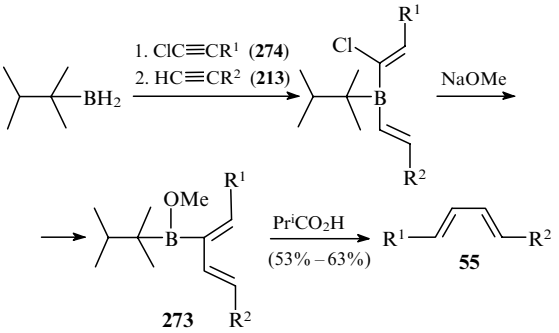
As noted above, alkynes can be used in the cross-coupling instead of alkenes. The reactions of terminal alkynes or their metallated derivatives with alkenyl halides (the Sonogashira reaction, see a review,[282] and transformation of **213** into **214** in general Scheme 8) yield conjugated enynes, which can be reduced to dienes (the reduction techniques are described in Section VII). In addition to alkenyl halides, these reactions can be carried out for alkenyl- (**268**) and dienyl tellurides **269**; these afford conjugated enynes **270** and dienynes **271**, respectively.[283]



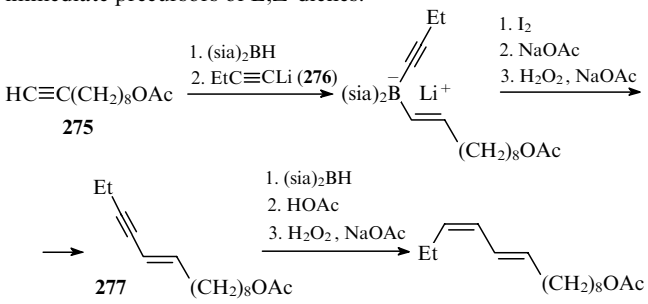
The addition of metal hydrides or organometallic reagents to the triple bond is stereospecific (*cis*-1,2-addition), which permits the preparation of pure isomers. Of relatively early studies, one should note the synthesis of dienonitrile **272** on the basis of hydroalumination of hex-3-yne.[272]



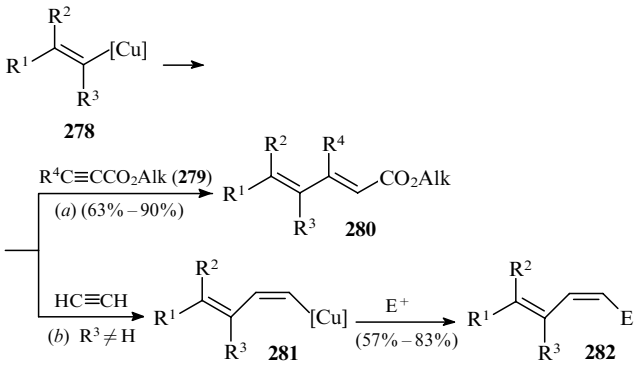
Hydroboration of alkynes resulting in alkenylboranes is the obligatory first stage of the Suzuki cross-coupling (see above). However, other methods of transformation of alkenylboranes **273** into the conjugated dienes **55** are also known, for example, successive hydroborations of chloroalkyne **274** and the alkyne **213** followed by the borotropic rearrangement.[284]



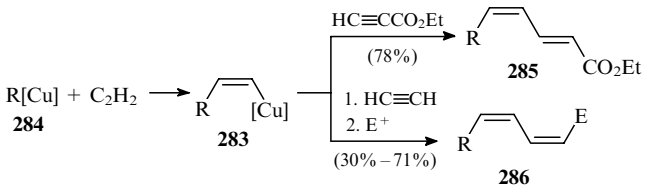
Yet another organoboron method consists in sequential chemoselective coupling of two alkynes (**275** and **276**, the latter as the lithium derivative), which gives conjugated enynes **277**, the immediate precursors of *E*,*Z*-dienes.[285, 286]



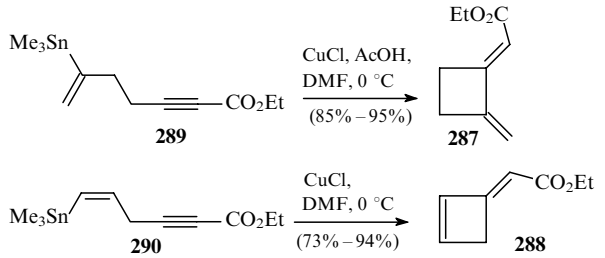
The addition of the cuprate reagents at the triple bond has been studied most comprehensively (see reviews [9, 287]). In early studies,[288, 289] cuprate reagents **278** have been prepared from the corresponding vinyllithium derivatives; their subsequent *syn*-addition to the triple bond in alk-2-ynoates **279** furnished dienoates **280** (pathway *a*). The stereochemical outcome of the reaction is important: the new double bond always has the *E*-configuration and the initial configuration of the vinylcuprate reagent does not change.



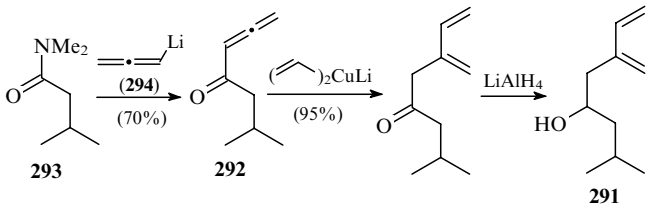
The development of methods for the addition of cuprate reagents to a non-activated triple bond has markedly extended the scope of the synthesis of dienes.[287, 290] Starting from different vinylcuprates **278** ($R^3 \neq H$) and acetylene (pathway *b*), one can obtain diene intermediates **281**, which then react with C-electrophiles (AlkI, CO_2, $PhSCH_2NEt_2$). This affords dienes **282** in which the double bond is *Z*-configured. Simple vinylcuprates **283** are formed from alkylcuprates **284** and acetylene; according to the stereochemistry of this process, this vinylcuprate has a *cis*-configuration.[291 – 293] By varying the natures of the second, acetylenic component and the final electrophile, one can obtain products **285** and **286** with a desired configuration of the second double bond.



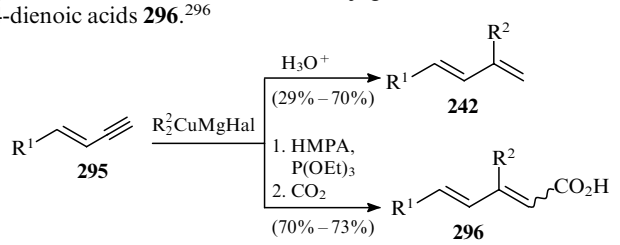
Recently, the organocuprate method has been successfully used for the preparation of dienes of the cyclobutane series of type **287** and **288** using an intramolecular reaction.[294] Fairly stable organotin substrates **289** and **290**, which underwent transmetallation under the reaction conditions, served as the precursors of active species.



The ability of cuprate reagents to add to the double bond of α,β-enones has been used for the formation of the conjugated diene system in the synthesis of ipsenol **291**. The α-allenyl ketone **292** needed for this purpose was prepared from amide **293** and allene **294**.[295]



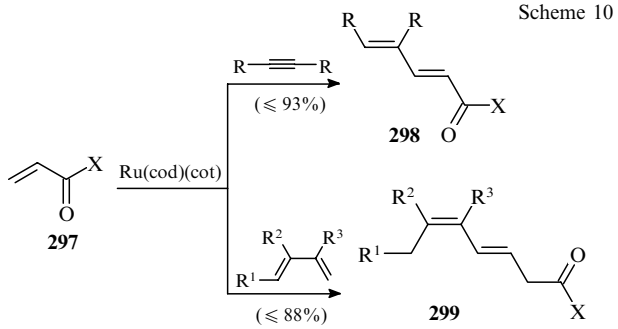
The addition of alkylcuprate reagents at the triple bond of enynes **295** results in the branched conjugated dienes **242** or alka-2,4-dienoic acids **296**.[296]



h. Coupling of alkene and alkyne components using ruthenium catalysts

The last decade was marked by enhanced interest in the catalysts based on ruthenium complexes (see a review [297]) which catalyse other types of transformation than palladium, which has become a routine material. These processes include coupling of activated alkenes **297** with alkynes (Scheme 10). This reaction catalysed by the Ru(cod)(cot) complex (cot is cycloocta-1,3,5,7-tetraene) and resulting in conjugated dienes **298** is a stereospecific addition of a terminal alkene to the triple bond.[298] The product yield depends dramatically on the nature of the substituents: in the case of acrylates (X = OAlk), good results were obtained only with diphenylacetylene (R = Ph); on passing to acrylamides (X = NMe_2), the range of possible acetylenic components is broader.

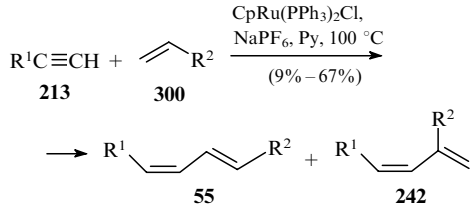
Scheme 10



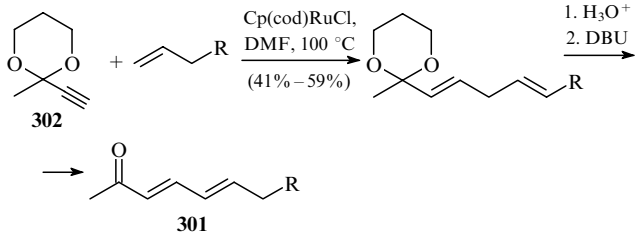
X = OAlk, Alk, $NAlk_2$.

Instead of alkynes, diene hydrocarbons can also been used in this reaction;[299] in this case, incompletely conjugated dienyl carbonyl compounds **299** are formed as the reaction products. This reaction is also sensitive to the type of substitution at the double bonds of the reactants and can result in isomer mixtures.

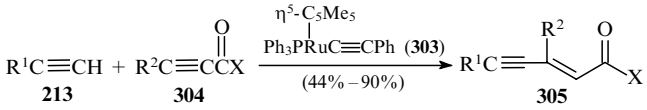
Coupling of terminal non-activated alkynes **213** with non-activated alkenes **300** takes place on prolonged refluxing in pyridine in the presence of $CpRu(PPh_3)_2Cl$ and $NaPF_6$.[300] The newly formed double bond in the diene **55** always has the *Z*-configuration, the process being accompanied by the formation of noticeable amounts (up to 13%) of non-linear isomers of **242**.



The reactions of alkynes with alkenes catalysed by another ruthenium catalyst, Cp(cod)RuCl, result in 1,4-dienes.[301] This method is suitable for the preparation of conjugated dienones **301** only in the case where the initial acetylene derivative **302** contains a latent carbonyl group. This facilitates isomerisation of the 1,4-diene system to a conjugated one.

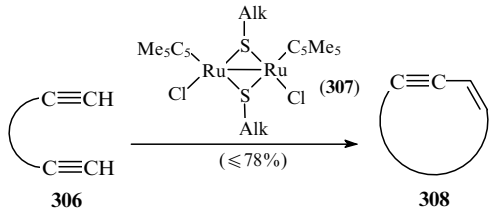


Coupling of two different acetylene derivatives **213** and **304** catalysed by the complex **303**, which gives enynes **305** (potential precursors of dienes), proceeds strictly stereospecifically.[302, 303]



C_5Me_5 is pentamethylcyclopentadienyl.

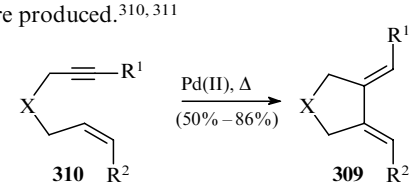
Intramolecular cyclisation of diterminal diacetylenes of the general type **306** with a relatively long linking chain (which can contain functional groups and even a ferrocene residue) induced by ruthenium complex **307** is accompanied by the formation of enynes of the macrocyclic series **308** (see Ref. 304).



i. Syntheses of exocyclic dienes

In conclusion, mention should be made of several intramolecular cross-coupling reactions of the same type, resulting in five-membered vicinally substituted carbo- or heterocyclic compounds **309**. Of these, cyclisation of 1,6-enynes of the general type **310** has been studied most comprehensively. When catalysed by palladium complexes,[305 – 308] this reaction proceeds smoothly in most cases if the vinyl group of the initial enyne **310** does not contain a substituent (R^2 = H). A single example has been reported [309] where this reaction occurred smoothly in the presence of a substituent in this group, namely, $R^2 = CH_2OR^3$. However, in most cases, mixtures of isomers having the same carbon skeleton

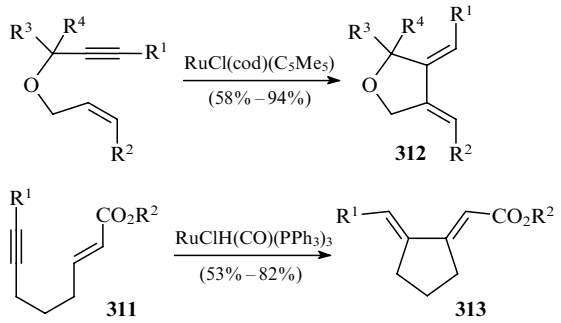
of the type **309** and differing in the position of the double bonds are produced.[310, 311]



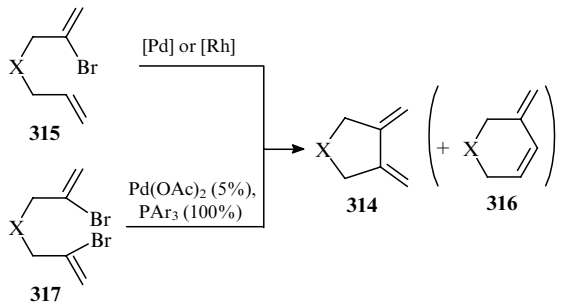
X = CMe_2, $C(CO_2Me)SO_2Ph$, $C(CO_2Me)_2$, NR.

In some cases, this approach can be used to prepare six-membered rings but with some limitations regarding the type of substitution in the initial compounds.[312, 313] Similar regularities have been found for the same transformation catalysed by nickel complexes immobilised on phosphinylated polystyrene.[313]

Ruthenium complexes, for example, $RuCl(cod)(C_5Me_5)$ and $RuClH(CO)(PPh_3)$, are capable of inducing cyclisation of allyl propargyl ethers[314] and derivatives of alk-2-en-7-ynoic acids **311**[315] the products of which are dienes **312** and **313**, respectively. Reactions catalysed by ruthenium complexes are much less sensitive to the nature of substituents than the same reactions catalysed by palladium complexes.

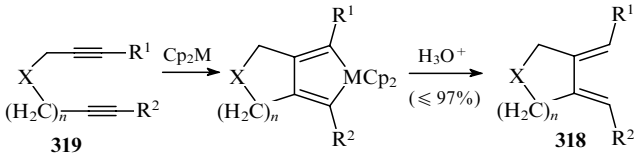


The preparation of vicinal di-*exo*-methylene compounds **314** by intramolecular cyclisation of bromides **315** (process of the Heck reaction type) has been described.[308, 316] The reaction takes place smoothly in the presence of the $Pd(OAc)_2 - PPh_3$ catalytic system[308] or the $RhCl(PPh_3)_4$ catalyst,[316] whereas with the $Pd(PPh_3)_4$ catalyst, the six-membered isomer **316** is the major product.[316] Intramolecular coupling of dibromides **317** affords the dimethylene isomer **314** as the only product; according to the balance, a stoichiometric amount of a reducing agent [Ph_3P or $(p\text{-}MeOC_6H_4)_3P$] is required.[317]



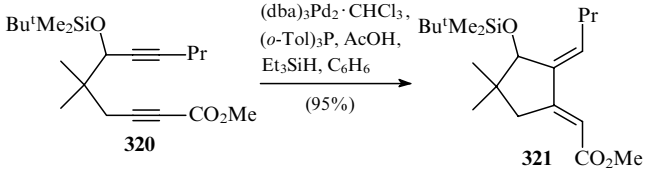
X = $PhCH_2N$, $C(CO_2Et)_2$, $C(COMe)_2$.

1,2-Dialkylidene-substituted cyclic compounds **318** can also be prepared from diacetylene derivatives **319**; this requires participation of a reducing reagent. In one of the procedures, cyclisation is induced by titanocene (Cp_2Ti)[318] or zirconocene (Cp_2Zr) generated *in situ*.[319] In most cases, the use of zirconium is more advantageous than titanium:[320] in the synthesis of four-, five-, six- and seven-membered rings, good yields are obtained even in the case of bulky R^1 and R^2 substituents. However, when $R^1 = R^2 = OEt$, it is necessary to use the titanium reagent.



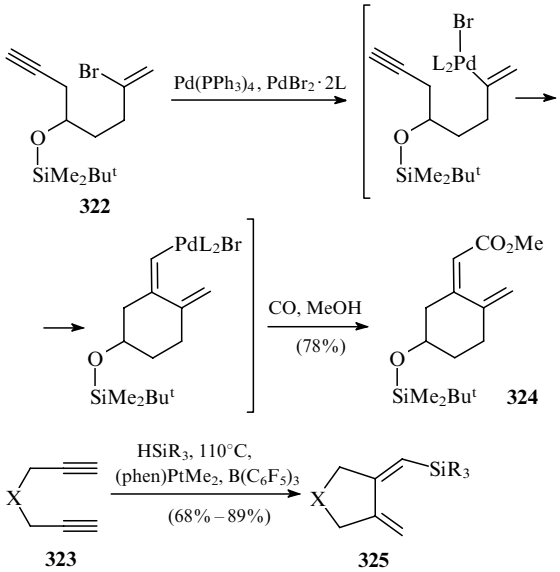
X = CH_2, O; $n = 0-3$; M = Ti, Zr.

The transformation of 1,6-diynes, for example, **320**, into the corresponding exocyclic diene **321** can be carried out with participation of the $(dba)_3Pd_2 \cdot CHCl_3$ palladium catalyst and the Et_3SiH reducing agent (stoichiometric amounts).[321]



In the case of other substrates of this chemical type, the yields vary in the range of 34% – 95%.

Two cases of cyclisation of compounds **322** and **323** followed by functionalisation are known.[322, 323] The functional groups being introduced occupy the *Z*-position in products **324** and **325**, which is related to the mechanism of intramolecular *syn*-carbometallation at the cyclisation stage.



X = $C(CO_2Me)_2$, $C(CH_2OR^1)_2$, $[C(CO_2Et)_2]_2$.

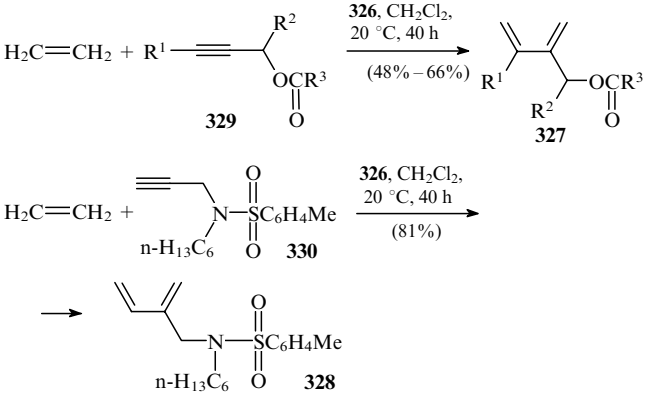
2. Miscellaneous reactions catalysed by organometallic compounds

The reactions considered in this Section are difficult to classify on the basis of a particular feature. Most of them have been discovered in the current decade and it is obvious that these investigations are at the stage of accumulation of facts. Nevertheless, it can be noted that the interest of researchers tends towards reactions catalysed by ruthenium complexes. These complexes are active in transformations differing from those catalysed by Pd and Ni complexes. Some of them (cross-coupling of alkenes and alkynes) were described in the preceding Section.

a. Alkene – alkyne metathesis

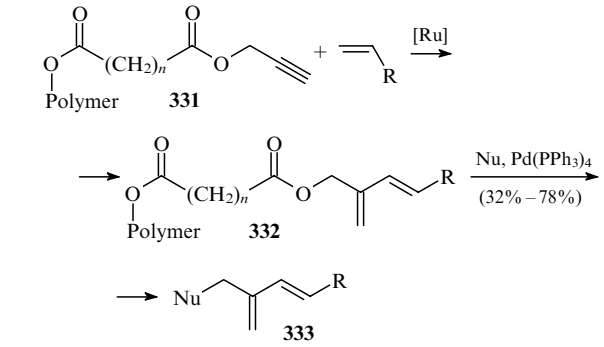
Ruthenium carbenoid complexes catalyse an interesting coupling reaction of alkenes with alkynes during which the reactants undergo metathesis to give branched conjugated dienes.[324, 325] One of these complexes, $Cl_2(Cy_3P)_2Ru{=}CHPh$ (**326**, Cy is cyclohexyl), the so-called Grubbs catalyst II, has now become com-

mercially available and has been tested in reactions of ethylene with numerous acetylene derivatives of various structures. Unfortunately, only for dienes of the type **327** and **328**, have preparative yields been attained; esters of propargyl alcohols **329** and *N*-tosylpropargylamines **330** served as the precursors of these products. However, even in these cases, reactions did not proceed to completion, which is in line with the concept of reversibility of metathesis.

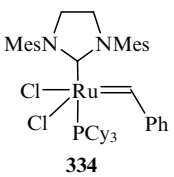


By conducting reactions under a pressure of ethylene (~4 atm), one can shift the equilibrium towards the products (for esters of type **329** with the terminal triple bond, $R^1 = H$, the yields increased to 92%);[326] however, upon further increase in the ethylene pressure, the reactions were retarded due to the degenerate ethylene–ethylene metathesis.[326, 327]

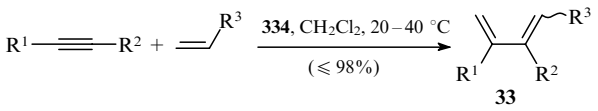
The problem of separation of the initial and final compounds, the polarities of which are close, should also be mentioned. An ingenious solution of this problem has been proposed.[328] The researchers suggested that the initial propargyl alcohol be immobilised on a polymeric support through a linker of an ester structure **331**.[328] In this case, after metathesis, the immobilised product has already the allyl carboxylate structure **332**. The subsequent reaction of the compound **332** with nucleophiles catalysed by palladium complexes results in diene product **333**, which passes to the solution, while the unreacted propargyl derivative **331** remains on the support.



Stable imidazolidinylruthenium complex **334**, obtained recently

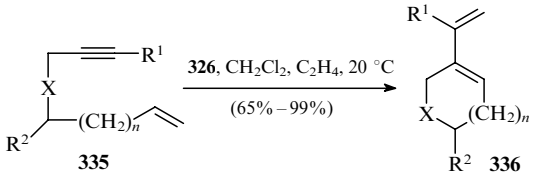


exhibits in many cases a much higher efficiency than the Grubbs catalyst II.[329] In particular, with the assistance of this complex, metathesis can be carried out for alkenes and alkynes characterised by a substantially broader spectrum of functionalisation and substitution [330] (*cf.* data of Refs 325 and 327).



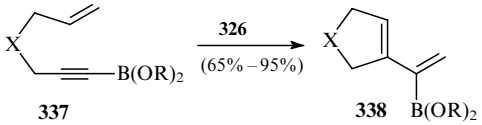
R^1 = $Ph_3CO(CH_2)_2$, Me_3Si, Cy, CO_2Bu^t, CH_2OAc, $CH_2OSiR^4_3$;
R^2 = H, Alk, CH_2OAc; R^3 = CH_2SiMe_3, $CH_2OSiR^4_3$, CH_2CO_2Bn.

The intramolecular alkene–alkyne metathesis of enynes **335**, discovered previously, is much less sensitive to the chemical type of the initial compounds than the intermolecular process because it is accompanied by the formation of favourable cyclic systems **336**.[331, 332] The product yields are very high, except for the case of terminal alkynes (R^1 = H). Later, the problem of low yields from terminal alkynes has been unexpectedly solved: it was found that this process should be carried out under an atmosphere of ethylene.[333] Ethylene does not formally participate in the reaction but it favours catalyst transfer in the form of the carbene $Ru=CH_2$.



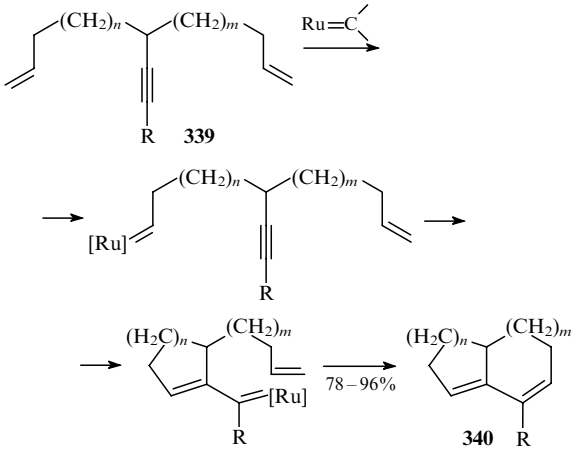
X = O, NR^3, $C(CO_2Et)_2$; R^1 = Me, CH_2OAc, $CH_2OSiMe_2Bu^t$, CO_2Me, H; R^2 = H, Ph; n = 0–2.

A study [334] demonstrating the possibility of involvement of alkynylboronic acids **337** in intramolecular metathesis deserves attention. Under the action of Ru catalyst **326**, they are smoothly converted into boryl-substituted dienes **338**, potential substrates for the Suzuki cross-coupling.[334]

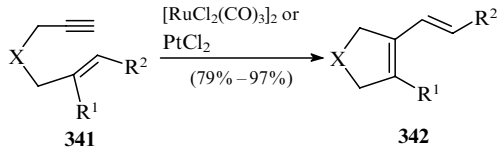


X = CH_2, $(CH_2)_2$, O, TsN, OCH_2O, $C(CO_2Et)_2$.

It is of interest that compounds **339** with an appropriate mutual arrangement of the two double bonds and one triple bond undergo double metathesis catalysed by $Cl_2(Cy_3P)_2Ru=CHCH=CPh_2$ (Grubbs catalyst I) to give bicyclic 1,3-diene structures of the general type **340** (n = 1, 2; m = 0–2).[335] The nature of the substituent R at the triple bond plays a crucial role: high product yields were obtained for R = H, Alk, Ph, CO_2Me, whereas for R = Br, I, Me_3Si or Bu_3Sn, cyclisation did not proceed. When tungsten-based catalysts of metathesis are used, cyclisation of the same substrates involves two double bonds and is accompanied by the ejection of a lower alkene without participation of the acetylene fragment.

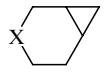


1,6-Enynes **341** are converted in the presence of $[RuCl_2(CO)_3]_2$ to give diene product **342**. The process fits formally the concept of the intramolecular alkene–alkyne metathesis considered above. Nevertheless, the researchers [336] suggest a different reaction mechanism.



341 **342**

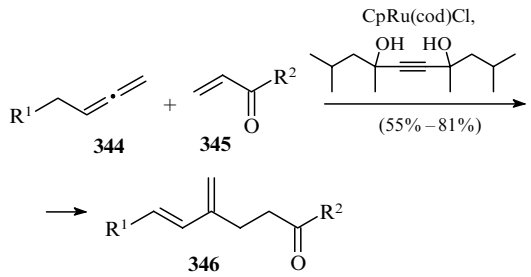
With $PtCl_2$ catalysis, enynes of the type **341** containing electron-withdrawing groups or a cyclic enyne fragment (with a medium or large ring) are also converted into formal metathesis products **342**).[337] Otherwise, they tend to form cyclopropane derivatives **343**.



343

b. Synthesis of 1,3-dienes from allene derivatives

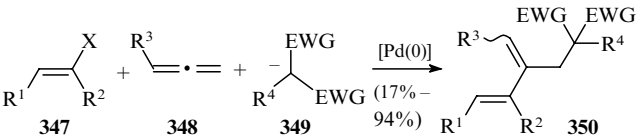
Ruthenium complexes catalyse an unusual addition of allenes **344** to activated alkenes **345** giving rise to 1,3-disubstituted conjugated dienes **346**.[338] To activate the catalyst, alkynols are used, the best results being attained with 2,4,7,9-tetramethyldec-5-yne-4,7-diol.



344 **345** **346**

The presence of a nitrile, ester or amide substituent in the side chain of the allene does not influence the course of the reaction. Regarding allene alcohols, a limitation has been found in the study of the mechanism — the number of carbon atoms between the allene system and the hydroxy group should not equal three or four; otherwise, oxygen-containing heterocyclic compounds are formed.[339]

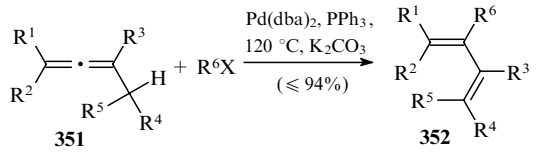
Palladium complexes can catalyse not only cross-coupling of vinylic components but also other types of reaction resulting in conjugated dienes. A series of studies dealing with coupling of vinylic (**347**), allene (**348**) and CH-acidic (**349**) components,[340–344] resulting in branched functionalised dienes of the type **350**, has been reported. Various combinations of three components differing in the nature of the substituents and functional groups have been tested. Thus the vinylic component can be either linear or incorporated in a carbo- or heterocyclic system; the leaving group can be represented by either bromide or triflate. Among C-nucleophiles, Schiff's base $Ph_2C{=}NCH_2{-}\ CO_2Me$ has been studied, apart from the standard β-dicarbonyl compounds. The yields vary over broad limits and can reach 94%.



347 **348** **349** **350**

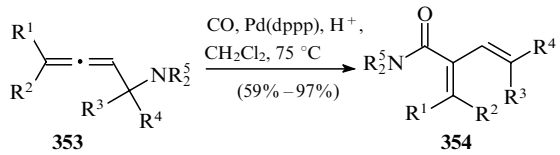
EWG is electron-withdrawing group.

Allene hydrocarbons **351** containing an allylic α-hydrogen atom undergo a $Pd(dba)_2$-catalysed reaction with aryl and alkenyl halides and triflates [345] to give conjugated diene compounds **352**. The highest yields (60% – 94%) were obtained in the case of aryl bromides and iodides.



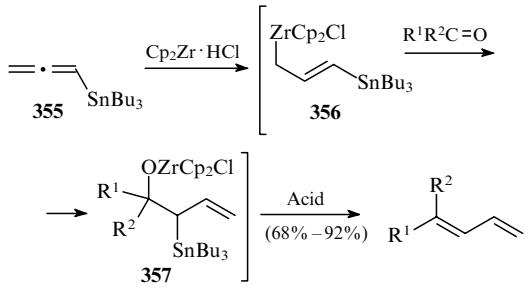
351 **352**

Carbonylation of allenylmethylamines **353** is directed at the allylic position, to the central atom of the allene system. The allylic rearrangement affords conjugated dienes **354** with the amino-carbonyl function at the 2-position.[346]



353 **354**

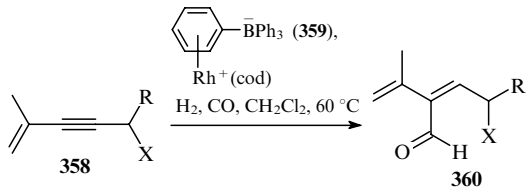
Hydrozirconation of allenylstannane (**355**) yields intermediate **356**, the reaction of which with aldehydes or ketones is accompanied by the allylic rearrangement [347] (the same outcome is provided by the reaction of aldehydes with pinacol 1-trimethylsilylprop-1-ene-3-boronate [43,44]). Decomposition of adduct **357** is accompanied by the formation of conjugated dienes, the proportion of *E*,*E*-isomer being more than 93% in the case of aldehydes (R^2 = H).[347]



355 **356** **357**

c. Synthesis of 1,3-dienes on the basis of alkynes

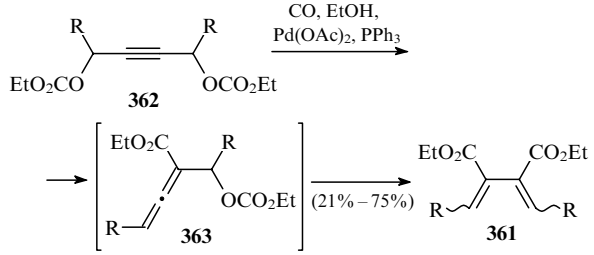
Hydroformylation of conjugated enynes **358** in the presence of rhodium complex **359** gives branched dienic aldehydes **360**.[348] A minor admixture of monounsaturated aldehyde is also formed.



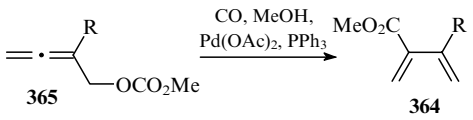
358 **360**

X = H, OAc, OMe.

Diethyl dienedioates **361** are produced upon carbonylation of alkyne-α,α′-diol dicarbonates **362**.[349] The reaction occurs through the intermediate formation of allene derivative **363**. The possibility of preparing dienoates **364** from the corresponding α-allenyl carbonates **365** was also demonstrated.

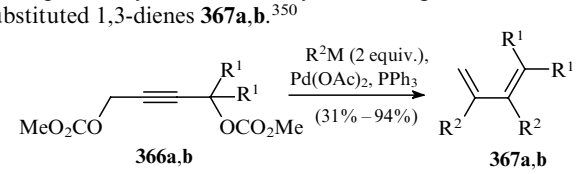


362 **363** **361**



365 **364**

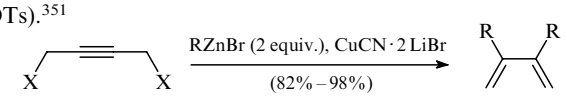
The reaction of propargyl dicarbonates **366a**,**b** with organoboron or -tin compounds catalysed by palladium complexes is accompanied by the double allylic rearrangement, resulting in substituted 1,3-dienes **367a**,**b**.[350]



366a,**b** **367a**,**b**

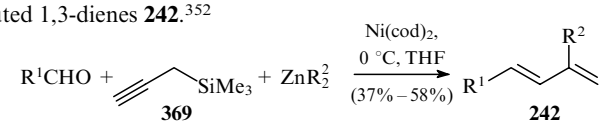
R^1 = H (**a**), Me (**b**); R^2M = $NaBPh_4$, $ArB(OH)_2$, $HetB(OH)_2$, $HetSnBu_3$, $PhC{\equiv}CSnBu_3$.

A reaction with a similar outcome giving rise to similar dienes consists in the interaction of organotin compounds of various structures with α,α′-disubstituted acetylenes **368** (X = Cl, OTs).[351]



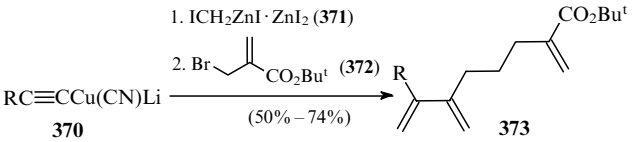
368

In the presence of $Ni(cod)_2$, propargylsilane **369** reacts with aldehydes and organozinc compounds to give the 2,4-disubstituted 1,3-dienes **242**.[352]

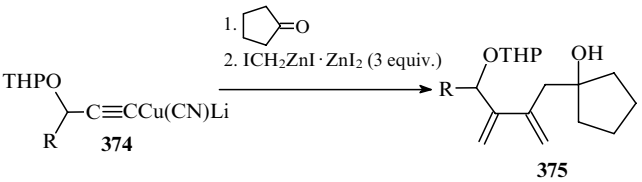


369 **242**

Complex cyanocuprates **370** derived from terminal alkynes add 4 moles of iodomethylzinc iodide (**371**). The subsequent treatment of the addition product with electrophilic reagent **372** furnishes conjugated 2,3-disubstituted diene **373**.[353] The reaction includes the stages of insertion of a carbenoid and two allylic rearrangements. In the case where the cyanocuprate complex **374** contains a fragment of sterically hindered ether and the process is initially carried out in the presence of an electrophile (cyclopentanone), three moles of the reagent **371** are added. This route was used to prepare diene **375**.

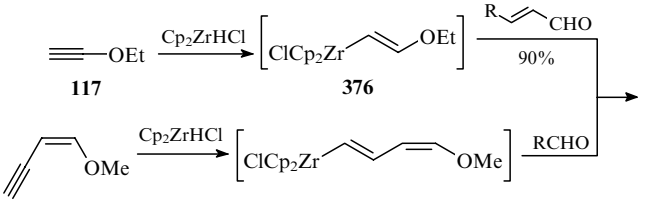


370 **373**



374 **375**

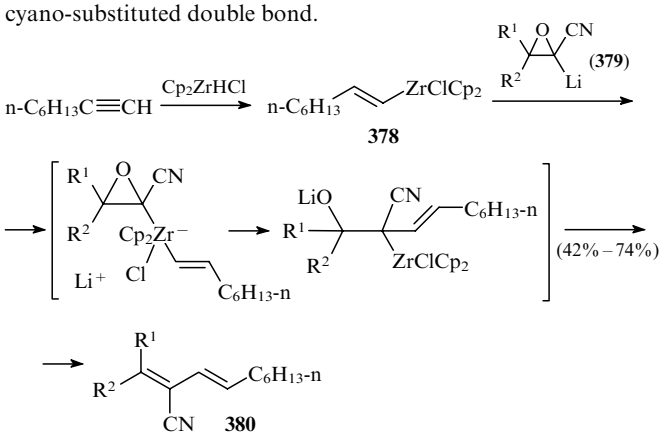
Hydrozirconation of ethoxyacetylene (**117**) and treatment of the resulting zirconium intermediate **376** with α,β-enals affords dienals **377** in a preparative yield.[354] The same products can be obtained using the same reactions but starting from 1-methoxybut-1-en-3-yne and a saturated aldehyde.



117 **376**

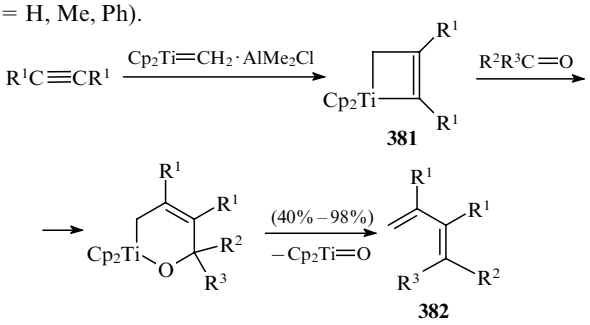
377

Alkenylzirconium compound **378** reacts with lithiated epoxy nitriles **379** to yield nitriles **380**.[355] If pure epoxy nitrile isomers are used, the reaction still gives a mixture of geometric isomers at the cyano-substituted double bond.



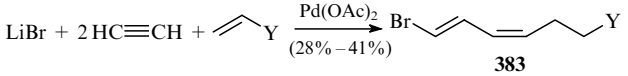
378 **380**

The reaction of disubstituted acetylenes with the carbene derivative of titanocene (the Tebbe reagent) results in a [2 + 2]-addition product, substituted titanacyclobutene **381**.[356] The subsequent regioselective reaction of **381** with carbonyl compounds gives conjugated dienes **382**. In the case of dimethyl- or diethylacetylene (R^1 = Me, Et), various aldehydes and ketones can be used, whereas in the case of tolan (R^1 = Ph), the range of carbonyl compounds is limited to reactive aldehydes (R^2 = H; R^3 = H, Me, Ph).



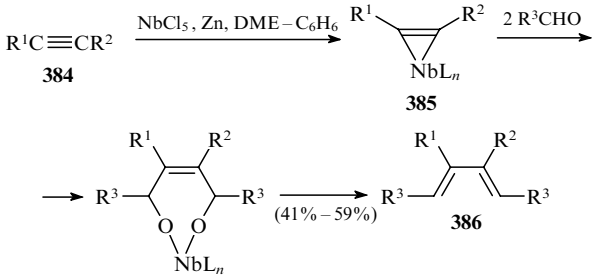
381 **382**

A curious process of acetylene dimerisation in the presence of electron-deficient alkenes makes it possible to prepare bifunctional *Z*,*E*-dienes **383**.[357] Acrolein (Y = CHO), vinyl ketones (Y = COR), nitroethylene (Y = NO_2) and β-substituted crotonaldehyde were tested in this reaction. In the latter case, the product yield was not more than 3%.



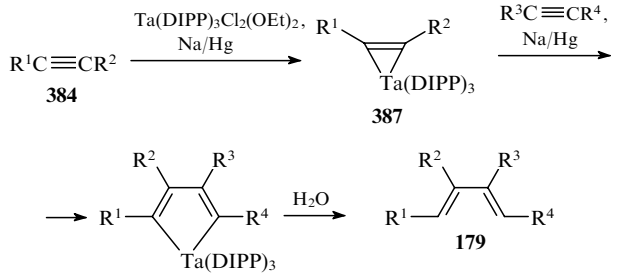
383

The reactions of disubstituted alkynes **384** with niobium pentachloride under reductive conditions gives intermediate **385**, containing the niobiacyclopropene fragment, able to add two equivalents of aldehydes.[358] Finally, conjugated dienes **386** with identical substituents at the ends of the system are produced.



384 **385** **386**

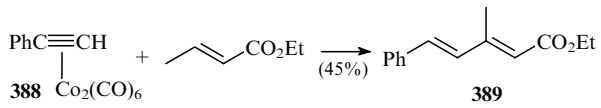
Similar tantalum compounds **387** add a second acetylene molecule; after hydrolysis, the conjugated diene **179** is liberated.[359] The scope and limitations of this method have not been adequately studied.



384 **387** **179**

DIPP is 2,6-diisopropylphenoxide.

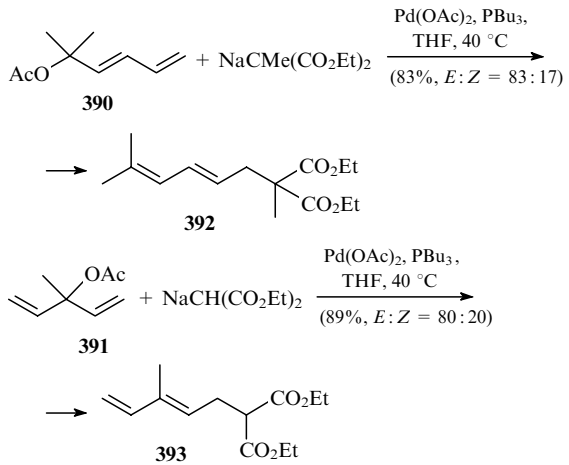
The reactions of hexacarbonyldicobalt complexes of alkynes **388** with activated alkenes afford conjugated dienes **389** in moderate yields.[360]



388 **389**

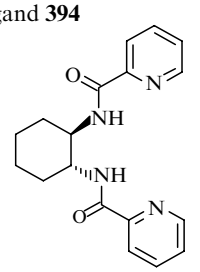
d. Syntheses of conjugated dienes from other dienes

Allylic acetates **390** and **391** react with malonate anions in the presence of palladium catalysts to give products **392** and **393** with a diene system.[361, 362] To ensure the maximum regio- and stereoselectivity, the process should be carried out in the presence of tributylphosphine. When triphenylphosphine is used, the regioselectivity substantially decreases. For example, the transformation of the acetate **391** gives, in addition to the product **393**, 40% of the product of nucleophile addition at the central carbon atom.



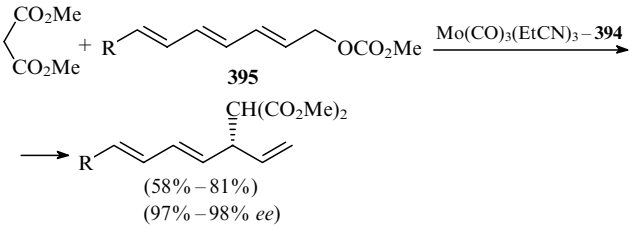
390 **392** **391** **393**

The reaction of allylic carbonates with the dimethyl malonate carbanion catalysed by the $Mo(CO)_3(EtCN)_3$ system with chiral ligand **394**



394

is accompanied by allylic rearrangement producing optically active homoconjugated compounds.[363] When triene carbonates **395** are used, the conjugated diene system is retained in the product and is connected to the chiral carbon atom.

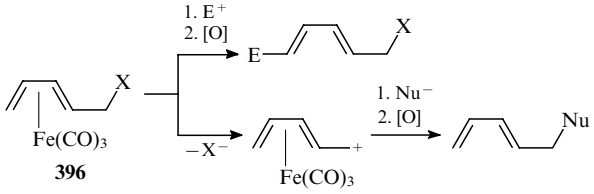


395

The reaction of dienes with electron-deficient alkenes (see Scheme 10)[299] catalysed by ruthenium complexes should also be attributed to this type of reaction.

e. Reactions of iron diene complexes

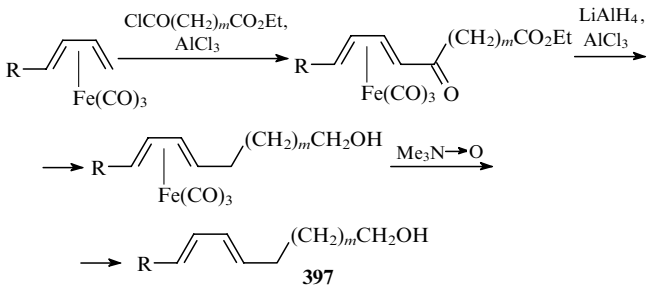
Conjugated dienes form stable complexes **396** with tricarbonyliron (see a review[364]). The electron-donating properties of $Fe(CO)_3$ facilitate the addition of electrophilic reagents at the termini of the diene system and contribute to the stabilisation of the allylic carbocation; this enables introduction of nucleophilic reagents into this position.



396

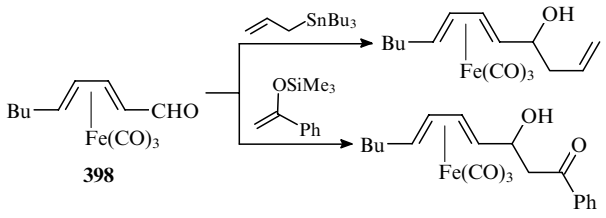
It has been proposed to use this type of complexation as a temporary protection of a diene system. The diene regeneration from the complex takes place on treatment with mild oxidants, for example, $(NH_4)_2Ce(NO_3)_6$ or *N*-oxides.

The following examples demonstrate the successfulness of using this strategy in fine organic synthesis. Complexes of terminal dienes can easily be converted into functional derivatives **397** some of which are insect pheromones.[365]



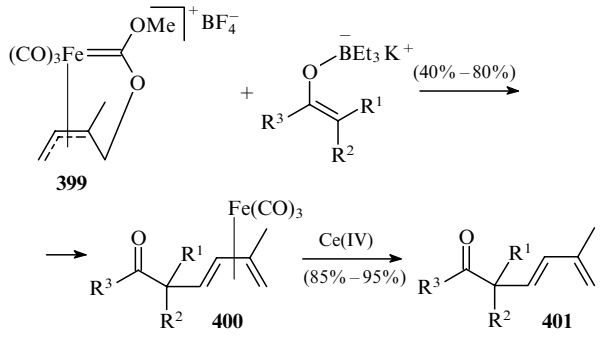
397

The complex of conjugated dienal **398** can react with some C-nucleophiles at the aldehyde group without a catalyst.[366]

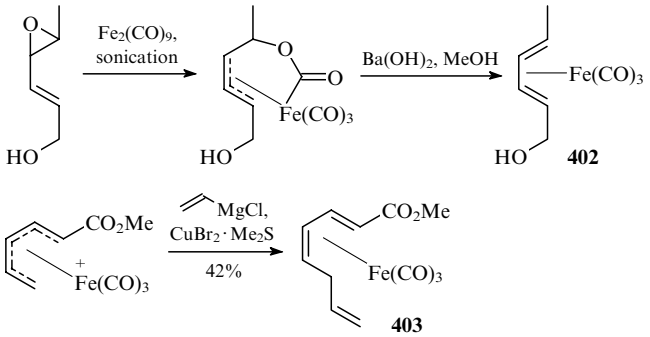


398

The reaction of π-allylcarbene cationic complex of tricarbonyliron **399** with boron ate-complexes of enolates yields η^4-complex derived from conjugated diene **400**.[367] Decomposition of the complex **400** on treatment with Ce(IV) gives rise to diene **401** containing an oxo group in the β-position.

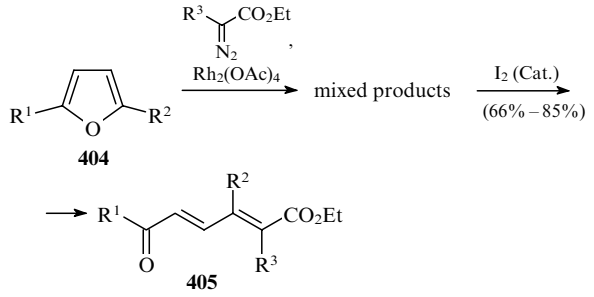


Mention should be made of recent publications [368, 369] describing the synthesis of functional derivatives of diene tricarbonyliron complexes **402** [368] and **403**.[369]

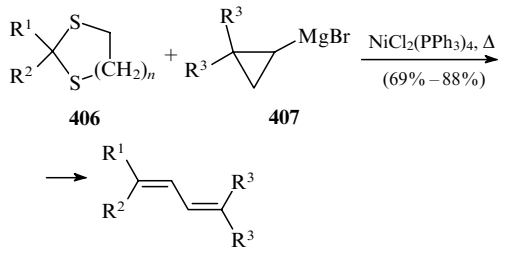


f. Miscellaneous organometallic reactions

The reaction of furans **404** with diazo esters in the presence of $Rh_2(OAc)_4$ affords a product mixture containing, among other compounds, oxodienoate **405**.[370] On treatment with catalytic amounts of iodine, this mixture can be converted into the pure diene (*E*,*E*)-**405** (or a mixture of *E*,*E*- and *E*,*Z*-isomers if $R^2 \neq H$).



Cyclic thioacetals **406** react with cyclopropyl Grignard reagents **407** in the presence of catalytic amounts of $NiCl_2(PPh_3)_2$ on refluxing in benzene or toluene to give dienes.[371] If the type of substitution in the three-membered ring differs from that in **407**, the reaction gives a mixture of isomers.

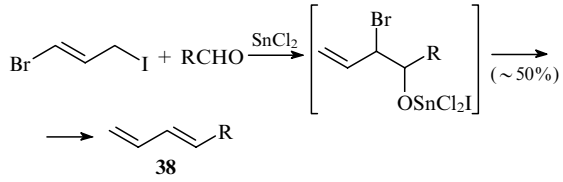


V. The synthon approach to conjugated dienes

Many reactions considered above could have been placed in this Section because versatile reagents can simultaneously be regarded as synthons if they contain fragments incorporated in the product molecule. Below we consider 'synthon syntheses' not included in the preceding Sections. They are arranged according to the type of fragment introduced in the final conjugated diene.

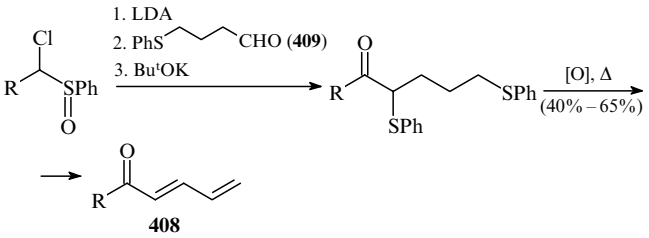
1. The $=CH-CH=CH_2$ (C_3) synthons

The widely known allylic Wittig reagents and their analogues are equivalent to the $=CH-CH=CH_2$ synthon. This type of reagents also includes 1-bromo-3-iodopropene.[372] The reaction of this compound with aldehydes on treatment with tin(II) chloride is accompanied by allylic rearrangement and gives terminal 1,3-dienes **38** in moderate yields.

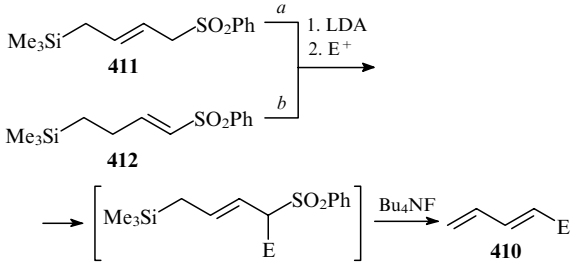


2. The $-CH=CH-CH=CH_2$ (C_4) synthons

In a known four-step procedure for the preparation of butadienyl ketones **408**, 4-phenylthiobutanal (**409**) is used as the source of the diene fragment for 'dienylation' of α-chlorosulfoxides.[373]



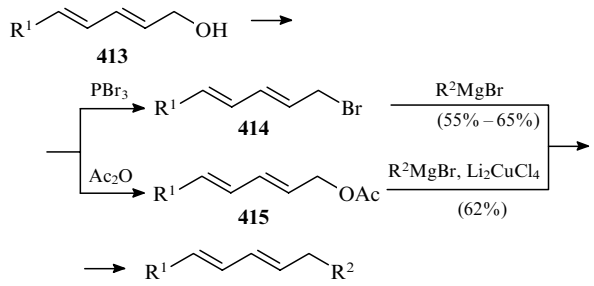
A broader range of compounds of type **410** can be prepared on the basis of 1-phenylsulfo-4-trimethylsilylbut-2-ene (**411**) (pathway *a*).[374] The same products are formed when a more readily available isomer, 1-phenylsulfo-4-trimethylsilylbut-1-ene (**412**) is used instead (pathway *b*).[375]



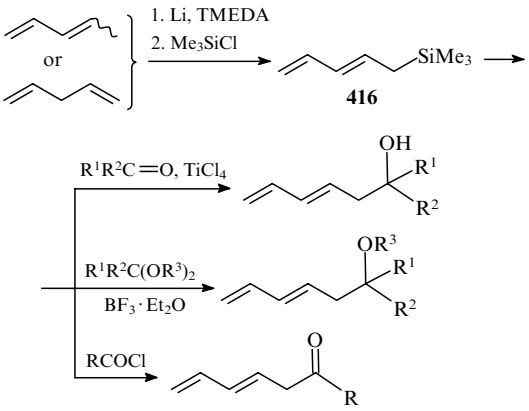
E = Alk, RC(O), , R_3Si, R_3Ge.

3. The $-CH_2-CH=CH-CH=CH_2$ (C_5) synthons and their homologues

The readily available 2,4-dienes of the general formula **413** containing a functional group (for example, a hydroxy group) at the 1-position can serve as the sources of these synthons. The corresponding allyl bromide **414** or acetate **415** acts as an electrophile when treated with Grignard reagents.[376, 377]

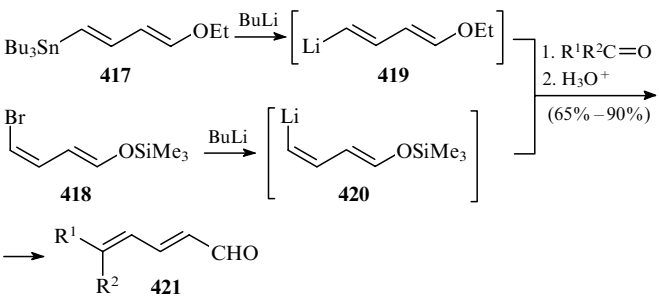


The reaction of pentadiene isomers with lithium followed by treatment with trimethylchlorosilane yields only one product, 1-trimethylsilylpenta-2,4-diene (**416**).[378, 379] This compound reacts with C-electrophiles of various types.

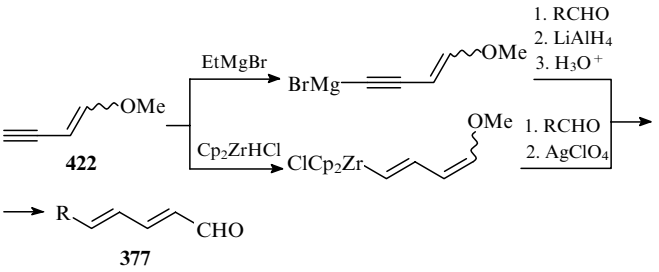


4. The =CH–CH=CH–CHO (C_4) synthons

Many compounds considered in Section III can be considered among the reagents capable of serving as sources of these synthons. Nevertheless, other versatile reagents for such 'dienylation' also do exist. For example, 1,4-heterodisubstituted butadienes **417** or **418** can be easily converted into organolithium derivatives **419** or **420**, which are much more reactive towards aldehydes and ketones than the Wittig–Horner reagents. Final hydrolysis gives rise to dienals **421**, formed predominantly as the *E*,*E*-isomers [380–382] (almost 100% for R^2 = H).

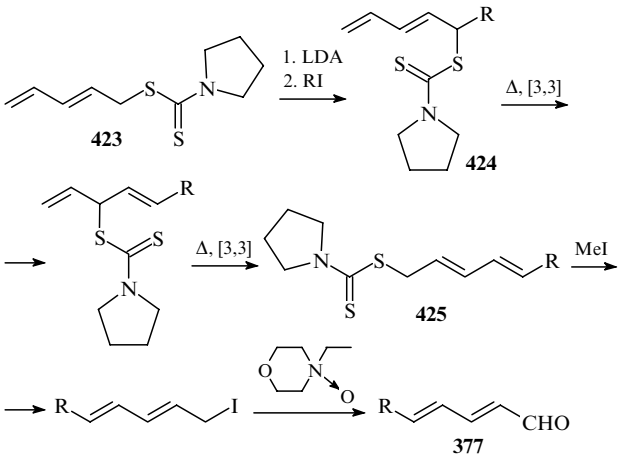


The dienals **377** can also be prepared using 1-methoxybut-1-en-3-yne (**422**) or its homologues.[354, 383, 384]

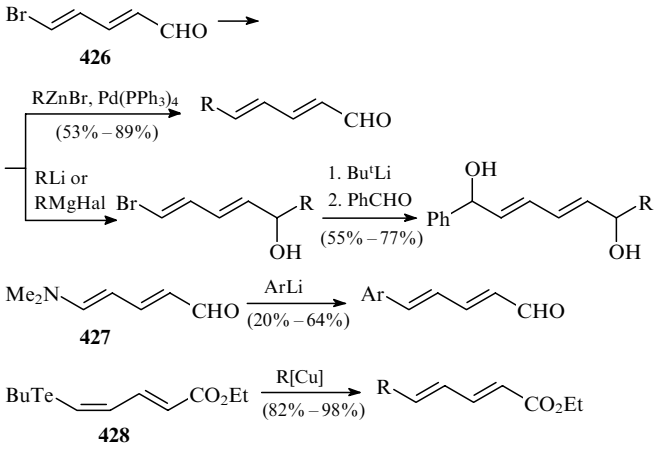


5. The –CH=CH–CH=CHCHO and –CH=CH–CH=CHCO$_2$R (C_5) synthons

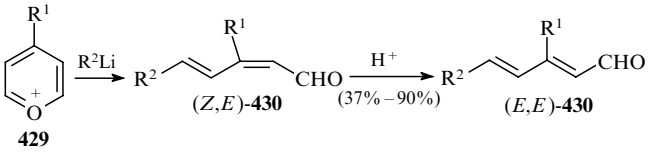
Reagent **423**, equivalent to a nucleophilic synthon of the given type, belongs to the class of thiol thiocarbamates. The products of its α-alkylation (**424**) undergo two [3,3]-heterosigmatropic rearrangements giving ultimately linear dienes **425**,[385] which are precursors of the dienals **377**.



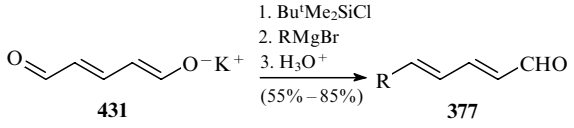
However, the most widely used synthons of this type are electrophilic reagents such as 5-bromopenta-2,4-dienal (**426**),[386, 387] 5-dimethylaminopenta-2,4-dienal (**427**)[388] and ethyl 5-(butyltelluro)penta-2,4-dienoate (**428**).[389] Substitution of alkyl groups for the electronegative elements (Br, NMe_2 and BuTe) in these compounds is accomplished by means of organometallic reagents.



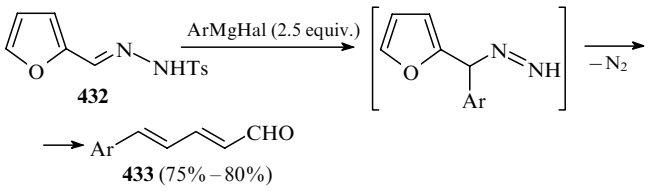
Yet another source of the synthons in question is represented by pyrylium salts **429**.[390, 391] The (*Z*,*E*)-alkadienals **430** formed initially in their alkylation are easily transformed into the *E*,*E*-isomers.



A similar role is played by the potassium derivative of glutacondialdehyde (**431**), which can be easily converted into the dienal **377** upon protection of one of the functional groups, treatment with a Grignard reagent and acid hydrolysis.[392]

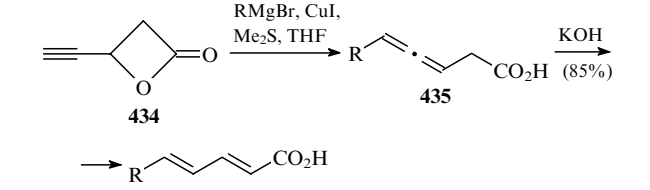


Furfural tosylhydrazone (**432**) can serve as a convenient synthon for the preparation of various 5-arylpenta-2,4-dienals **433**.[393]

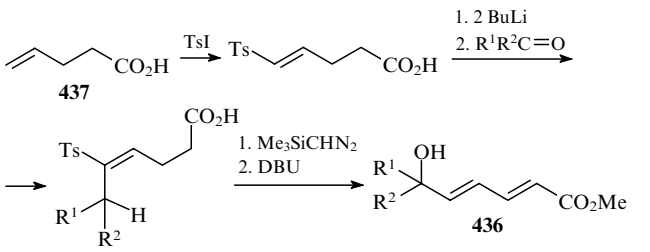


When made to react with alkylmagnesium halides, the same furfural **432** furnishes other products, namely, furan derivatives.

3-Ethynyl-β-propiolactone (**434**) reacts with organomagnesium compounds in the presence of copper(I) salts to give allenic acids **435**, which can be isomerised to dienoic acids.[394]

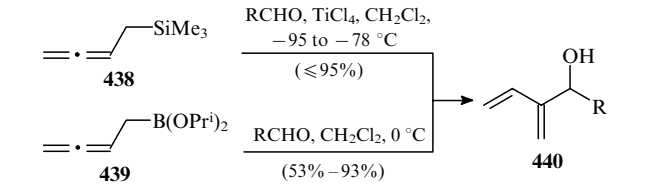


Finally, a three-step procedure for the synthesis of methyl 6-hydroxyalka-2,4-dienoates **436** has been developed; in this method, pent-4-enoic acid (**437**) serves as the source of the diene fragment.[395]

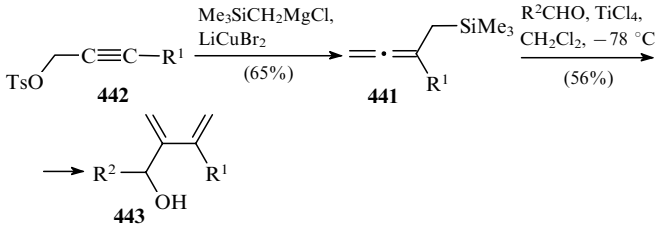


6. The $-C(=CH_2)-CH=CH_2$ (C_4) synthons

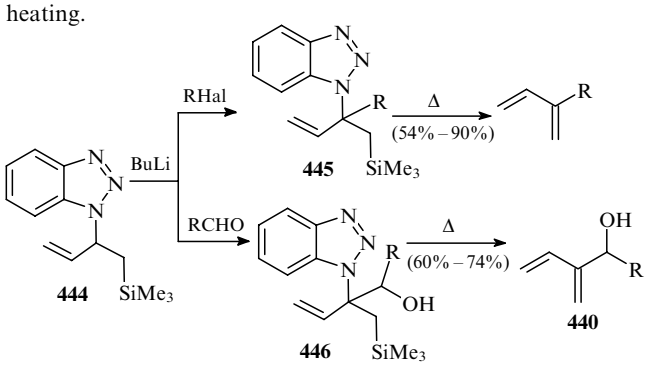
The synthon approach has been implemented successfully for the preparation of branched 1,3-dienes with functional substituents at the 2-position. One approach is based on the allylic rearrangement of allylsilanes and allylboranes in the reactions with carbonyl compounds. α-Allene derivatives **438** and **439**, similar to the allylic derivatives of silanes and boranes, react with carbonyl compounds at the *sp*-hybridised carbon atom yielding branched compounds **440**, which contain a conjugated diene fragment.[396, 397] In the case of the silyl derivative **438**, not only aldehydes but also acetals can be used, resulting in the corresponding ethers. The effect of a chiral group present in the electrophilic reagent was studied; after removal of this group, the resulting secondary dienic alcohols had *ee* values of up to 96%.



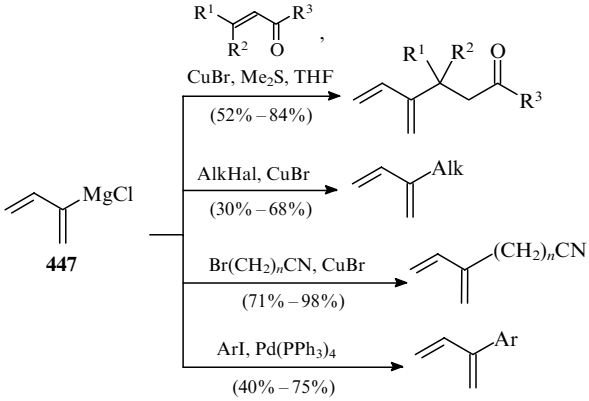
Branched allene silanes **441**, which can be easily prepared from acetylene derivatives **442**, behave in a similar way. They can be used to prepare 2,3-disubstituted butadienes **443**.[398]



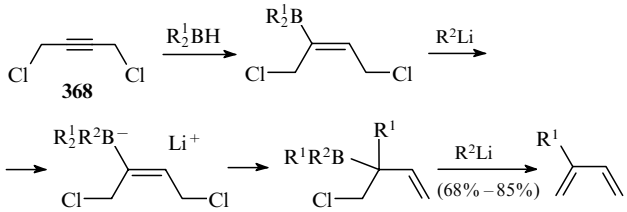
Great synthetic capabilities are provided by the butene derivative **444**, containing benzotriazole and trimethylsilyl vicinal groups.[399] After introduction of a desired fragment, the vicinal groups from the structures **445** and **446** can be eliminated by heating.



The Grignard reagent **447**, prepared from 2-chlorobuta-1,3-diene (chloroprene), can react with a number of electrophilic reagents, namely, α,β-unsaturated carbonyl compounds,[400] alkyl halides[400, 401] (including various bromoalkanonitriles[401]) and aryl iodides.[402] This is a very simple and versatile approach to the synthesis of 2-substituted 1,3-dienes. In the absence of copper salts, the Grignard reagent **447** can add to ketones; however, this gives about 25% of the rearranged allene-type product.[403]



2-Substituted butadienes with a bulky substituent R^1 can be prepared from 1,4-dichlorobut-2-yne (**368**) using hydroboration.[404] The mechanism of this reaction has been studied in detail.[405]

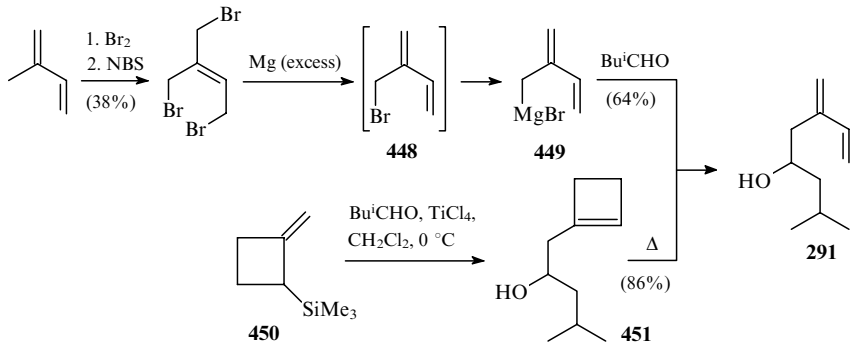


7. The $-CH_2-C(=CH_2)-CH=CH_2$ (C_5) synthons

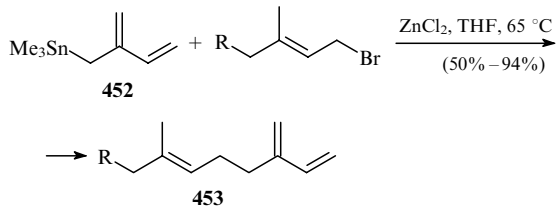
α-Bromoisoprene (**448**) and organometallic derivatives prepared from it are typical examples of the title synthons. A convenient method has been proposed for the preparation of the corresponding Grignard reagent **449** in two simple steps without isolation of the bromoisoprene **448**.[34] The reaction of the Grignard reagent **449** with isovaleraldehyde results in ipsenol (**291**) (Scheme 11). 1-Methylene-2-(trimethylsilyl)cyclobutane (**450**) can be used instead of the Grignard reagent **449**; the compound **450** reacts with aldehydes with the allylic rearrangement to give a cyclobutene derivative **451**.[406] Pyrolysis of this product furnishes the same diene derivative **291**.

Organotin compound **452** with an isoprene fragment reacts with allylic bromides in the presence of Lewis acids giving rise to

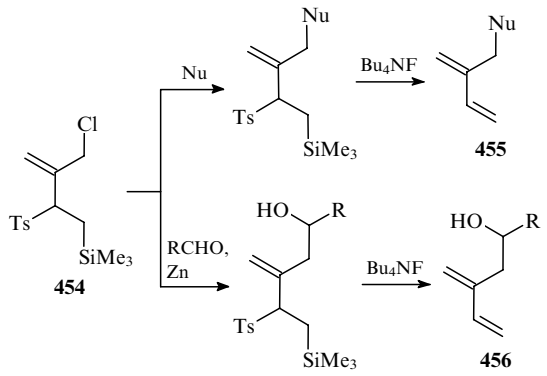
Scheme 11



branched 1,3-dienes.[407] This method was tested in the synthesis of the corresponding terpenes **453** — myrcene (R = H) and β-farnesene (R = $Me_2C=CHCH_2$).



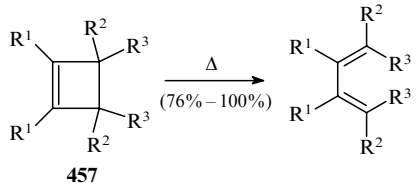
In compound **454**, the allylic chloromethyl group can serve as both an electrophilic and a nucleophilic centre, depending on the reaction conditions.[408] The tosyl and trimethylsilyl vicinal substituents act as a latent double bond, resulting in the vinyl fragment in the final products **455** and **456**.



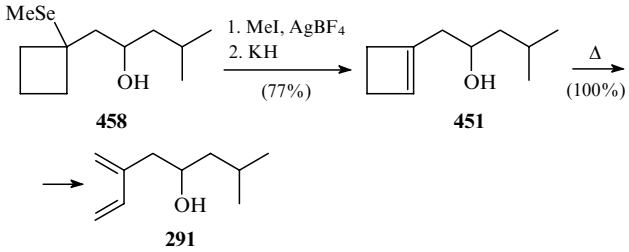
VI. Electrocyclic reactions

1. Thermolysis of cyclobutenes

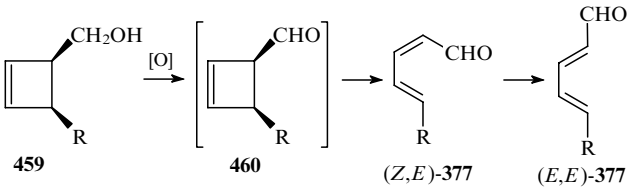
Two electrocyclic reactions resulting directly in conjugated dienes are known, namely, thermal disrotatory closure of conjugated hexatrienes accompanied by the formation of cyclohexadienes and conrotatory opening of cyclobutenes to give conjugated dienes, occurring at high temperatures. The use of the former reaction for preparative purposes is limited; some publications dealing with this topic are cited in a monograph.[10] The latter reaction has found a more extensive synthetic application. Depending on the nature of substituents in the initial compound, the process can be performed either by heating cyclobutene derivatives having the general formula **457**[409,410] or by passing them through a heated Vigreux column at a reduced pressure.[411]



This method has been used in elegant syntheses of ipsenol **291**;[406,412] in one of them, the initial cyclobutene derivative **451** was prepared from the corresponding selenide **458**.



Unlike primary alcohols **459**, 3-formylcyclobutenes **460** undergo ring opening even at low temperatures.[413] The low-temperature Swern oxidation of the alcohol **459** affords the expected *Z*,*E*-isomer **377** (conrotatory ring opening), which is readily transformed into the *E*,*E*-isomer when allowed to stand. Oxidation of the cyclobutenol **459** with pyridinium chlorochromate at room temperature directly affords (*E*,*E*)-**377**.

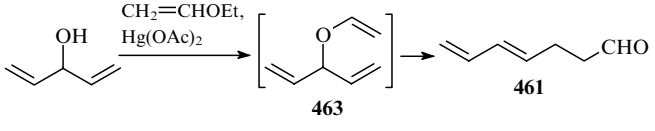


Other electrocyclic reactions are suitable for the synthesis of conjugated dienes only in those cases where the compounds under study contain additional double bonds or functional groups capable of being readily detached to give a double bond.

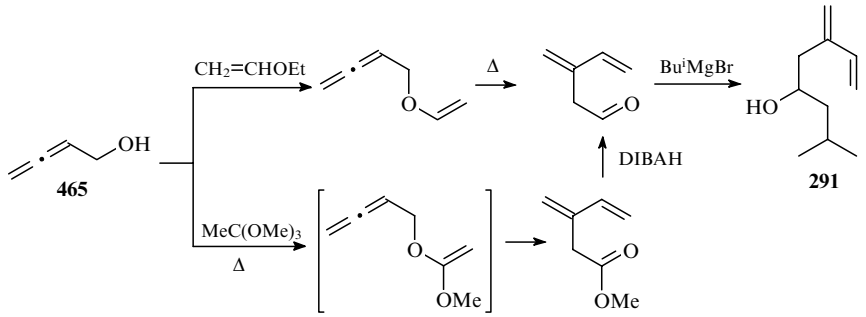
2. Sigmatropic [3,3]-rearrangements

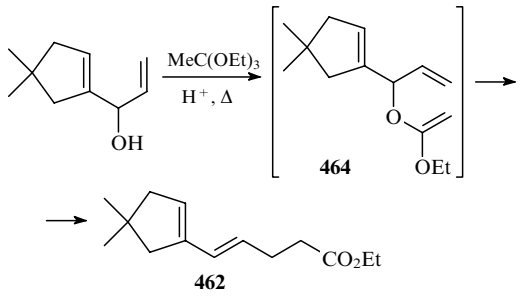
Sigmatropic [3,3]-rearrangements have been often used for the preparation of conjugated dienes; the variant used most often is the Claisen rearrangement consisting in the thermal transformation of vinyl allyl ethers into Δ^4-unsaturated functional derivatives (see a review[414]).

An example is provided by the syntheses of diene derivatives **461** and **462** by the Claisen rearrangement of vinyl ethers of divinylmethanols **463** and **464**, respectively.[415–417] In the latter case, triethyl orthoacetate serves as an equivalent of the vinyl ether.



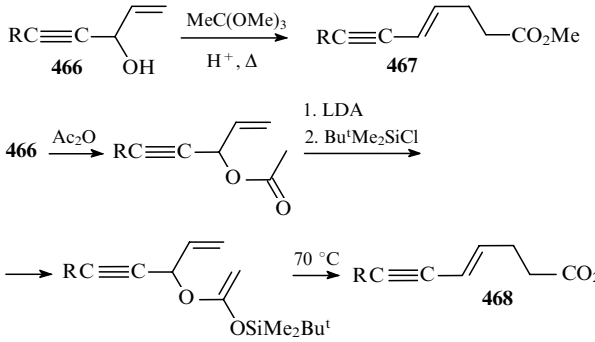
Scheme 12



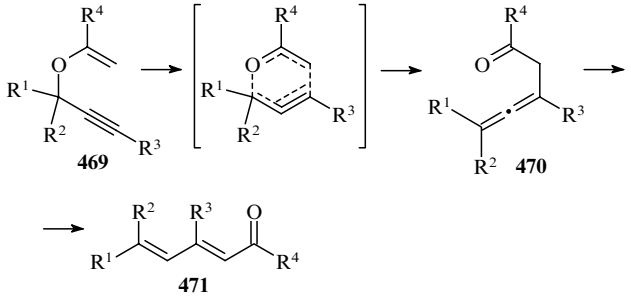


A similar reaction involving buta-2,3-dien-1-ol **465** results in branched conjugated dienes; this was employed in two equivalent syntheses of ipsenol **291** (Scheme 12).[418, 419]

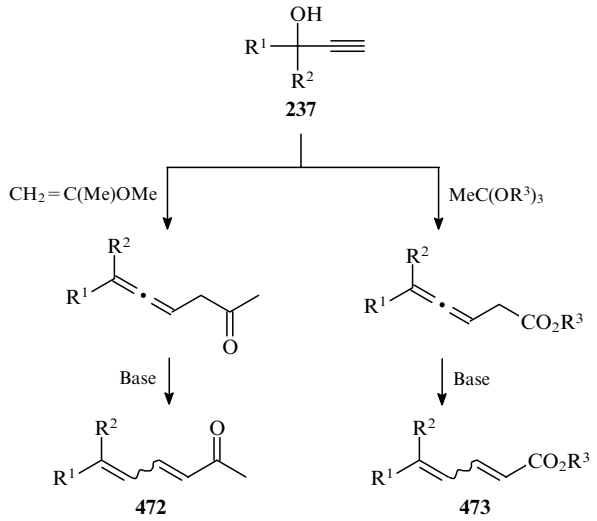
Vinylalkynylmethanols **466** can be used to prepare conjugated enynoates **467** and enynoic acids **468**, which are the closest precursors of dienes.[420, 421]



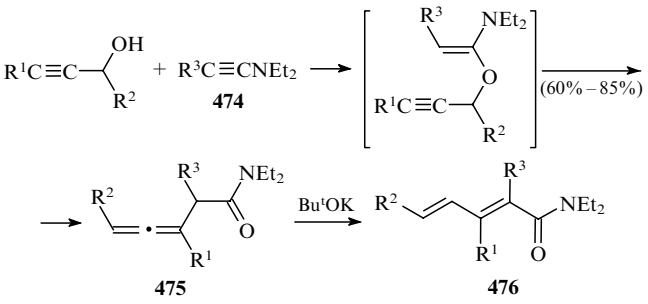
The Claisen rearrangement of propargyl vinyl ethers with the general formula **469** gives rise to β-oxoallene derivatives **470**, which readily isomerise into conjugated diene derivatives **471**. This process became exceptionally important after it had proved to be useful for the synthesis of vitamins A and E and some valuable terpenoids.



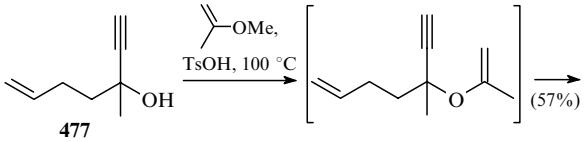
In many cases, there is no need to synthesise these propargyl vinyl ethers because they are formed *in situ* under the reaction conditions from the corresponding propargyl alcohols **237**. Initially, this was attained by either pyrolysis of their acetoacetates or heating with ethyl acetoacetate or diethyl malonate (the product yields were moderate in this case).[422–424] Later, these reactions were substantially updated; more precisely, isopropenyl methyl ether was taken instead of ethyl acetoacetate [425] and orthoesters of carboxylic acids were used in place of diethyl malonate.[426–428] The yields of products **472** and **473** depend markedly on the pattern of substitution in the initial compounds, being very high under favourable circumstances.

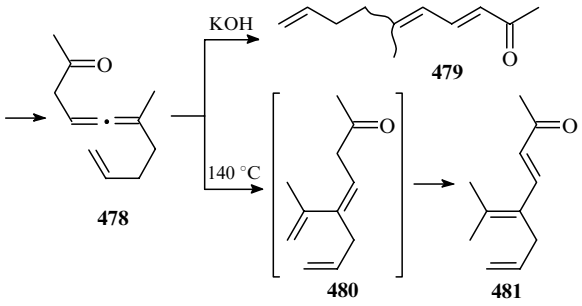


The reaction of propargyl alcohol with ynamine **474** occurs in a similar way, giving rise to *N*,*N*-diethylamides of allenic **475** and dienoic **476** acids.[429]

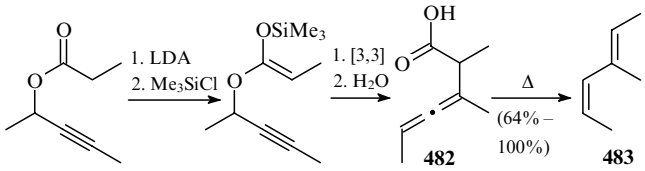


Acetylenic alcohol **477** containing a butenyl fragment reacts with isopropenyl methyl ether to give allene ketone **478**. On treatment with an alkali, this product isomerises in a conventional way to give ketone **479** with a diene fragment.[430] However, on prolonged heating, the ketone **478** can undergo one more [3,3]-sigmatropic rearrangement accompanied by the formation of intermediate **480** and, further, the conjugated dienone **481**.

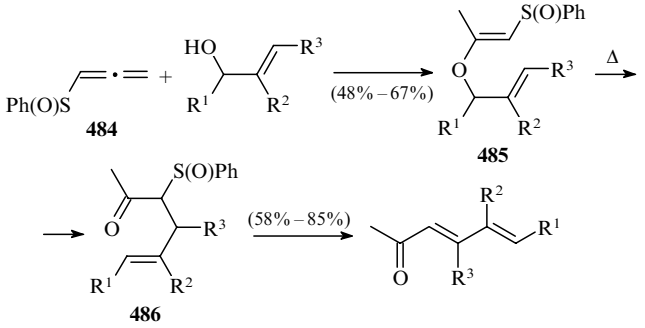




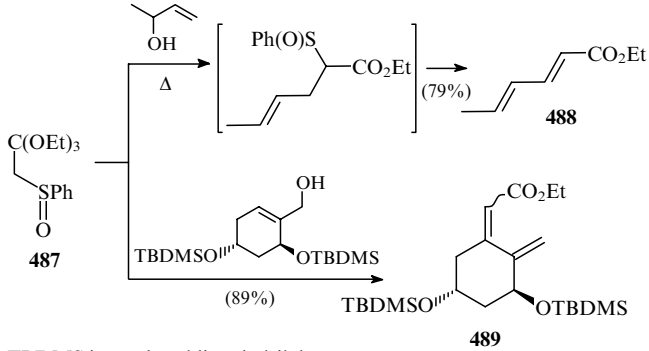
β-Allene acids obtained from ethers of propargyl alcohols upon [3,3]-sigmatropic rearrangement can also be used in another synthesis of dienes; decarboxylation of allene acid **482** is accompanied by the migration of the β,γ-double bond, resulting in the formation of conjugated 3-methylhexa-2,4-diene (**483**).[431]



The Claisen rearrangement can also involve allyl vinyl ethers of a more complicated structure. Thus allenyl phenyl sulfoxide **484** reacts with allyl alcohol derivatives to give adduct **485** with a suitable mutual arrangement of the double bonds.[432] The driving force of the rearrangement is transformation of the β-alkoxyvinyl sulfoxide fragment into the α-sulfinyl ketone fragment. Conjugated diene is formed in the subsequent thermal elimination of the sulfoxide group from compound **486**.

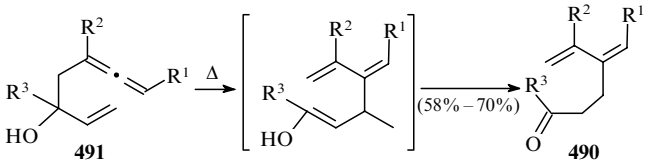


α-Phenylsulfinyl-Δ^4-unsaturated derivatives can be synthesised from allylic alcohols using yet another reagent, *viz*., triethyl phenylsulfinylacetate (**487**). Elimination of the sulfoxide group occurs simultaneously with the sigmatropic rearrangement.[433] This method allows one-step synthesis of not only linear (**488**) but also exocyclic (**489**) conjugated dienes.

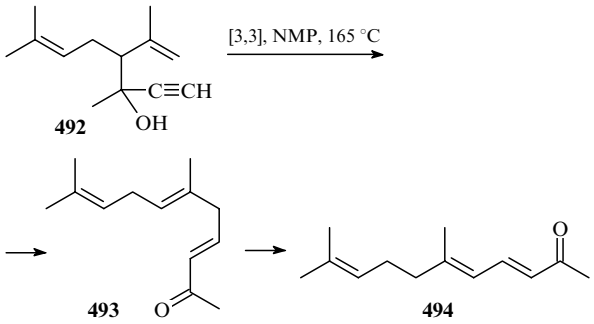


TBDMS is *tert*-butyldimethylsilyl.

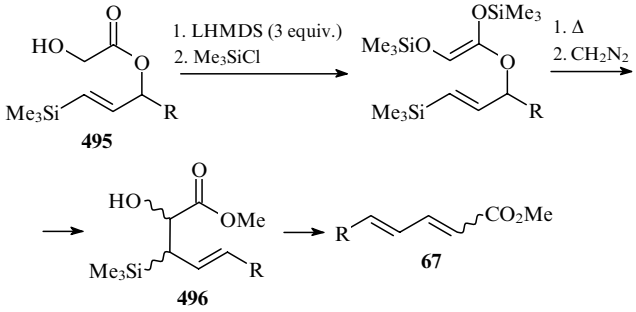
Branched dienes of the type **490** are produced in the allene version of the oxy-Cope rearrangement of alcohols **491**.[434, 435]



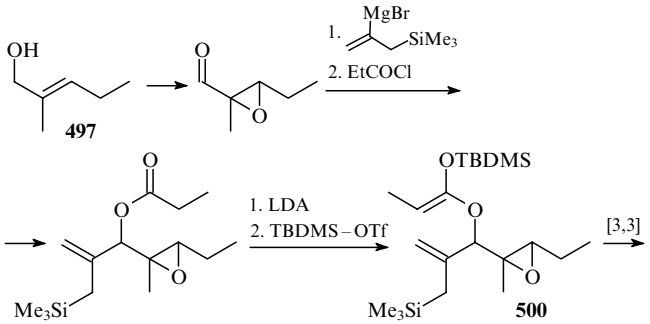
The oxy-Cope [3,3]-rearrangement of 1,5-enyn-4-ols **492** results initially in a compound with incompletely conjugated α,β,δ,ε-dienone fragment (**493**), which can be subsequently isomerised to give compound **494** with a conjugated α,β,γ,δ-dienone fragment.[436] It is convenient to combine isomerisation with the rearrangement by adding inorganic halogen compounds (HCl, HBr, I_2, NH_4Br) to the reaction mixture.[437] The method is applicable for the synthesis of pseudoionone.

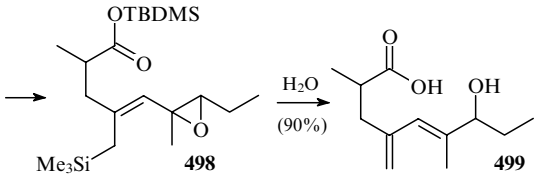


The hydroxy and trimethylsilyl vicinal groups can serve as a source of the double bond (the Peterson reaction). If the molecule of the initial compound **495** is constructed in such a way that, after rearrangement, these substituents in the product **496** occur in the required positions, this may provide a route to the conjugated dienes **67**.[438] The initial compounds **496** were resolved into individual *erythro*- and *threo*-diastereomers, which were convrted into individual *E*,*E*- and *Z*,*E*-isomers of the dienoates **67** by varying the elimination method.



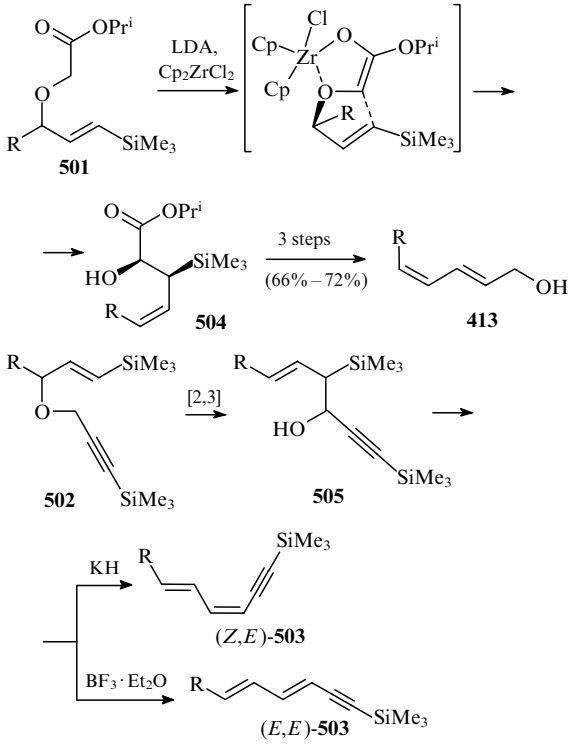
Compound **498**, which contains a trimethylsilyl group and an epoxide ring on different sides of the double bond, is unstable and is easily converted into hydroxy acid **499** with a diene fragment. The compound **498** is formed in the [3,3]-sigmatropic rearrangement of the precursor **500**,[439] which is, in turn, prepared from 2-methylpent-2-enol (**497**).





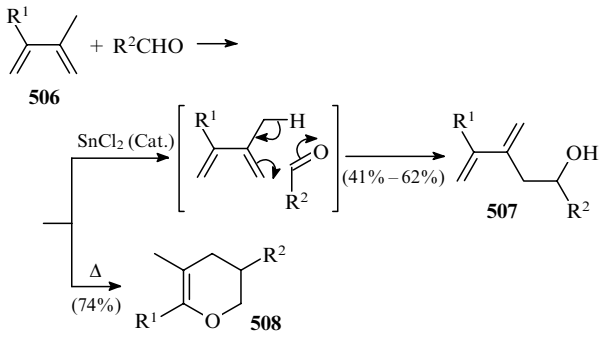
3. The Wittig sigmatropic [2,3]-rearrangement

The Wittig rearrangement of carbanions derived from compounds **501** and **502** has also been used to synthesise conjugated dienes of the type **413** and **503**.[440,441] In both cases, the second double bond was formed upon elimination of the silyl and hydroxy groups from the corresponding alcohols **504** and **505** (the Peterson reaction); in the former case, zirconium served as the counter-cation to ensure the required configuration of alcohol **504** (*cf.* data of Ref. 442).



4. Ene reaction

Ene reactions take place between the dienes **506** and reactive aldehydes and afford dienic alcohols **507**.[443] The formation of the compounds **507**, however, can be explained in terms of the Prins reaction mechanism, which is known to be accelerated by acids. On heating without a catalyst, the above-mentioned reactants enter into a [4 + 2]-cycloaddition reaction giving rise to dihydropyrans **508**.



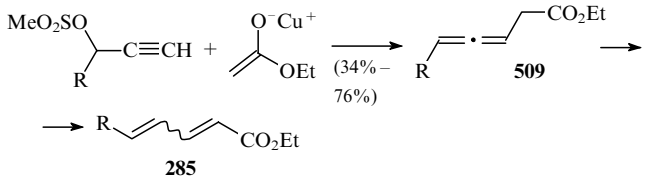
R^1 = H, Me; R^2 = CCl_3, CO_2Bu.

VII. Methods based on migration or reduction of multiple bonds

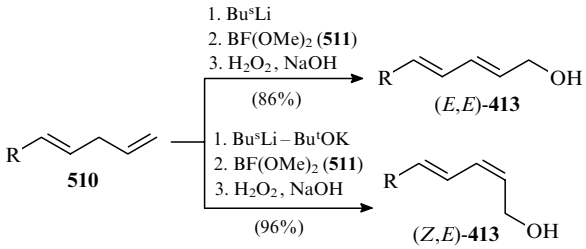
The strategy for the synthesis of dienes making use of migration and reduction is attractive because a conjugated diene system is formed at the final stage of the synthesis in a molecule which already has the required carbon skeleton and functional groups in the required positions.

1. The migration of multiple bonds

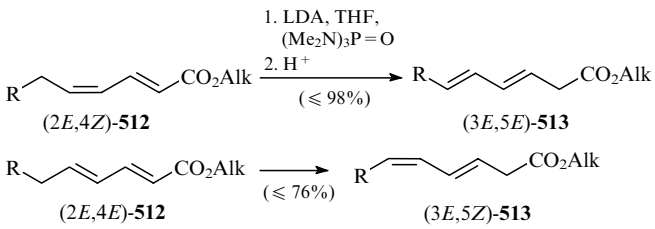
On treatment with bases or some transition metal complexes, non-conjugated dienes are converted into thermodnamically more favourable conjugated isomers. Generally, this reaction is not regioselective, therefore, it has a preparative value for hydrocarbon substrates only in a few cases, for example, in the synthesis of cycloocta-1,3-diene by heating cycloocta-1,5-diene in DMSO in the presence of potassium *tert*-butoxide.[444] However, the situation changes dramatically if the molecule contains a carbonyl group; in this case, the migration of multiple bonds results in an individual product. Examples of isomerisation of 2,5-dien-1-ones and β-allene ketones and esters into 2,4-diene derivatives are considered in Section VI. An organocopper route to the dienes **285** from β-allene esters **509** is also known. Unfortunately, this route is suitable only in the case where sulfonates of secondary acetylenic alcohols and ethyl acetate enolate are used as the initial compounds.[445]



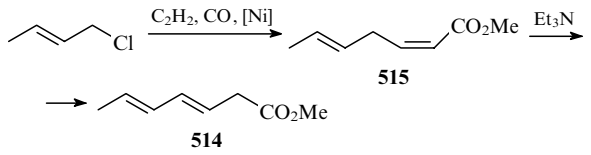
On treatment with strong bases, homoconjugated 1,4-dienes **510** form a delocalised carbanion, which is attacked regioselectively by specific reagents, for example, $BF(OMe)_2$ (**511**).[446] The subsequent treatment of these products with hydrogen peroxide yields primary conjugated dienic alcohols (*E*,*E*)-**413** or (*Z*,*E*)-**413**. Depending on the configuration of the Δ^4-double bond in the initial 1,4-diene **510** and the type of base, definite stereoisomers **413** are produced.



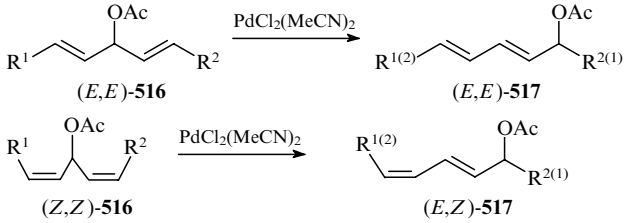
The diene system of alka-2,4-dienoates **512** can be deconjugated from the carbonyl group by treatment with LDA in THF in the presence of HMPTA[162,447] or *N*,*N*′-dimethyl-*N*,*N*′-(1,3-propylene)urea (DMPU).[163] It is of interest that the dienes (2*E*,4*Z*)-**512** are converted into (3*E*,5*E*)-**513**, while (2*E*,4*E*)-**512** are converted into (3*E*,5*Z*)-**513**.[447]



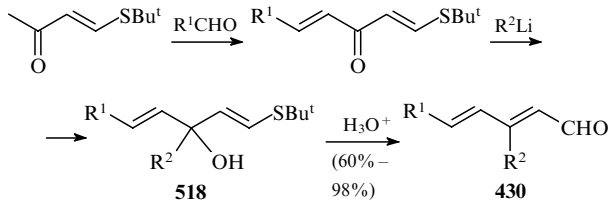
Thus methyl hepta-3,5-dienoate (**514**) can be prepared from incompletely conjugated dienoate **515** on prolonged keeping (12 h) in the presence of Et_3N.[448]



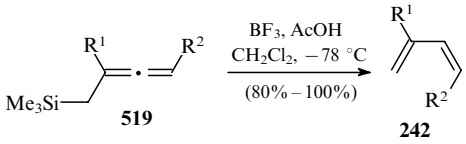
Divinylmethanols and their derivatives are readily isomerised on treatment with acidic reagents to give conjugated diene derivatives. For example, the allylic rearrangement of dialkenylmethyl acetates **516** catalysed by palladium complexes takes place with retention of the configuration of one double bond.[449] It is evident that in the case of non-symmetrical substrates ($R^1 \neq R^2$), the reaction gives rise to a mixture of regioisomers **517**.



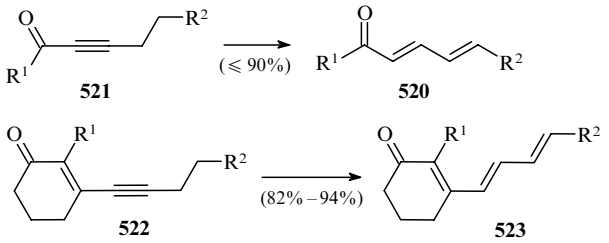
The regiodirectivity of this type of rearrangement can be controlled by introducing a heteroatom into the β-position of one of the vicinal groups. For example, readily available thio derivatives **518** can be smoothly converted into dienals **430**.[450]



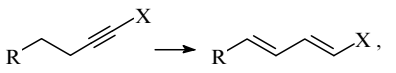
The rearrangement of α-silylallenes **519** into dienes **242** is also regioselective and, in some cases, stereoselective.[451]



In the last decade, an absolutely new method for the synthesis of conjugated diene derivatives **520** was discovered; this is isomerisation of alkynes **521**, in which the triple bond is located close to an electron-withdrawing group. In the first publication, it was noted that this isomerisation is induced by various palladium catalysts.[452] Similar results have been obtained with ruthenium or iridium complexes,[453, 454] which have also proved suitable for isomerisation of cyclohexene derivatives **522** into the corresponding trienes **523**.



Later, it has been found that the crucial role in the isomerisation is played by the phosphine ligands contained in the catalysts. Indeed, prolonged refluxing of various activated alkynes in toluene in the presence of triphenylphosphine alone also furnishes the diene isomers of type **520** in very good yields.[455] Later, factors influencing the reaction route have been studied in detail

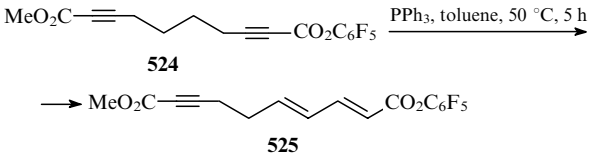


and recommendations for methods have been given. The data are summarised in Table 2. For isomerisation of less reactive amides of alk-2-ynoic acids (X = $C(O)NR_2$) to take place, the process should be carried out at higher temperatures (refluxing in xylene) in the presence of acetic acid. Conversely, more reactive acetylenic ketones [X = C(O)Alk and C(O)Ar] are isomerised even at room temperature on treatment with Ph_3P. For a similar transformation of esters (X = CO_2R) and *N*,*N*-dialkylamides [X = $C(O)NR_2$], tributylphosphine was found to be the reagent of choice.[456]

Table 2. Isomerisation of acetylene derivatives into conjugated dienes.

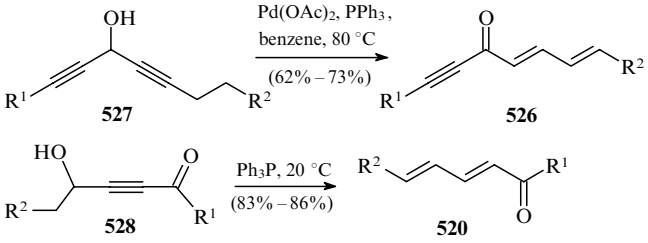
X	R	Catalyst	Reaction conditions		Yields (%)	Ref.
			T /°C	*t* /h		
$C(O)Bu^t$	Me	$Pd(OAc)_2$, Ph_3P	100	22	73	452
C(O)Cy	H	$Pd(OAc)_2$, dppb	100	21	73	452
C(O)Ph	Et	$Pd(OAc)_2$, dppb	100	0.75	82	452
CO_2Bn	Me	Ph_3P	110	6	75	455
C(O)Ph	Et	Ph_3P	80	4	83	455
C(O)NHPh	Me	Ph_3P, AcOH	140	14	84	455
C(O)Me	C_5H_{11}	Ph_3P	25	34	84	456
CO_2Me	Et	Ph_3P	25	35	0	456
CO_2Me	Et	Bu_3P	110	24	82	456
CO_2All	Me	Bu_3P	25	48	80	456
C(O)N(All)Bn	Me	Bu_3P	110	24	60	456
$CO_2C_6F_5$	Bu	Ph_3P	50	5	96	457, 458
$CO_2C_6F_5$	$HC \equiv C(CH_2)_2$	Ph_3P	50	5	76	457, 458
$(CF_2)_8Cl$	Me	Ph_3P	110	24	0	459
$(CF_2)_8Cl$	Me	$Pd(dba)_2$, Ph_3P, AcOH	110	12	82	459
$(CF_2)_4Cl$	Me	$Pd(dba)_2$, Ph_3P, AcOH	110	12	75	459
CF_3	$(CH_2)_5OH$	$Pd(dba)_2$, Ph_3P, AcOH	110	12	85	459

However, pentafluorophenyl esters (X = $CO_2C_6F_5$), which exhibit strong electron-withdrawing properties, can be isomerised under milder conditions, namely, at 50 °C and in the presence of Ph_3P; if the molecule contains other acetylenic groups, they remain intact.[457, 458] In this connection, an interesting example is the selective transformation of diacetylene **524** into dienyne **525**.

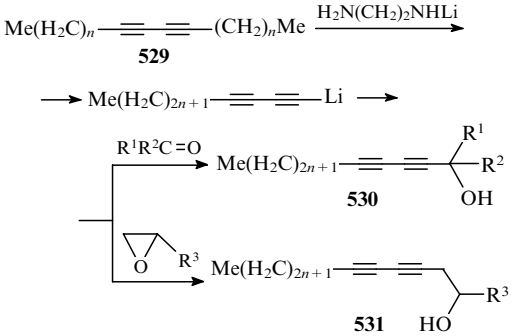


Among acetylene derivatives able to undergo isomerisation, 'non-carbonyl' polyfluoroalkyl compounds proved to be an interesting type of substrates [459] (see Table 2). The transformation of these compounds into dienes requires the presence of palladium catalysts and acetic acid, apart from phosphines.

Two processes, similar at the first glance, are known to form a diene system (for example, in compounds **526** and **520**) from dialkynylmethanols **527**[460] and α-oxo-α′-hydroxyacetylenes **528**.[461] Nevertheless, for balance, the former reaction requires involvement of an oxidising agent, while the latter, of a reducing agent.

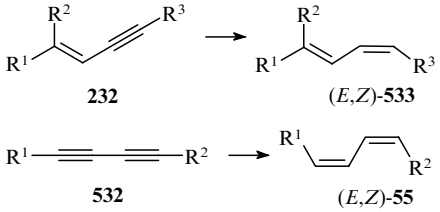


On treatment with superbases, for example, lithium aminoethylamide, internal alkynes are transformed into terminal isomers. It has been shown recently that this process can also be applied successfully to diacetylenes **529**. Since terminal diynes are unstable, it has been suggested that the lithium derivatives formed initially should be quenched immediately with electrophilic reagents; this provides a pathway to diacetylenic alcohols **530** and **531**, which are potential precursors of the corresponding conjugated dienes.[462–464]



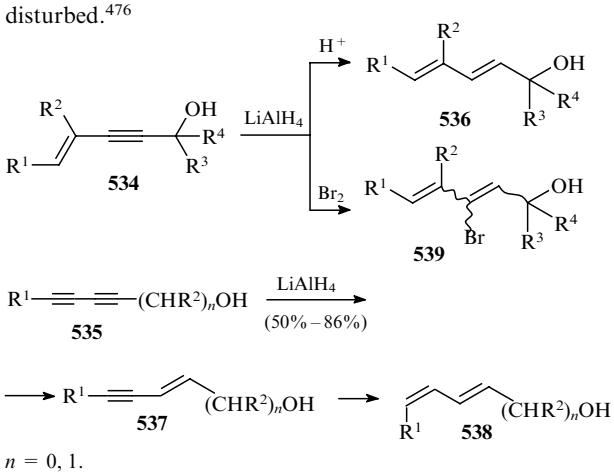
2. Partial reduction of a triple bond in enynes and 1,3-diynes

Incomplete reduction of the conjugated enynes **232** and diynes **532** to the dienes **533** and **55** has been considered comprehensively in the literature;[8, 10, 12] therefore, only the basic principles are discussed here. The transformation of a triple bond into a *Z*-double bond in these systems is accomplished using the same techniques as employed for monoacetylenes. Hydrogenation in the presence of Lindlar-type catalysts ensures, in principle, the required transformation (see, for example, Ref. 465); however, the presence of the second, conjugated bond activates the substrate molecule, resulting in a lower selectivity. Better results are obtained when hydrogen carriers are used; for this purpose, the substrate is refluxed in ethanol-containing solvents with activated zinc.[466–468]



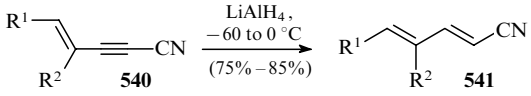
However, hydroboration of the triple bond followed by protolysis of the resulting vinylborane has won the greatest recognition. The hydroborating reagent of choice is di(*sec*-isoamyl)borane $(sia)_2BH$, which is reactive, under the reaction conditions, only towards triple bonds but does not affect double bonds. This method was used to transform enynes and diacetylenes into insect pheromones containing a conjugated diene system in which either one or both double bonds have *Z*-configuration.[246, 420, 469]

Unfortunately, known methods of reduction of alkynes into *E*-alkenes (sodium in liquid ammonia, $LiAlH_4$ with heating) are inapplicable to the reduction of enynes and diynes, because in this case reactions give complex mixtures of products. Exceptions are enynic alcohol **534**[26, 470–472] and diynic alcohol **535** (*n* = 0, 1),[473–475] which are hydrogenated to dienic **536** and enynic **537** alcohols, respectively. In the compound **535**, the triple bond closest to the hydroxy group is reduced fairly smoothly to the *E*-double bond on treatment with $LiAlH_4$ in ether or THF. Hydrogenation products, namely, conjugated *E*-enynic alcohols **537**, can further be converted into *E*,*Z*-dienic alcohols **538**.[475] In the case of propargyl compounds, the desired effect is also attained by transforming the alcohol into alcoholate with the subsequent addition of DIBAH, the reduction taking place within the ate-complex formed.[473] It is noteworthy that careful bromination of the reaction mixture carried out instead of the final hydrolysis in the reduction of the enynic alcohols **534** results in bromo-containing dienic alcohols **539** being formed as the major products; in this case, the configuration of double bonds is disturbed.[476]



n = 0, 1.

Enynonitriles **540** can undergo similar reduction, the cyano group in products **541** being stable against lithium aluminium hydride under the reaction conditions.[477]

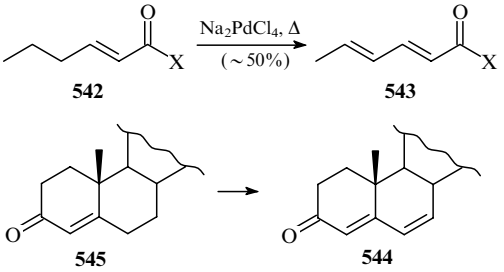


VIII. Miscellaneous methods

The methods discussed in this Section could be assigned, if desired, to one or another type of reactions considered in the preceding Sections. However, these examples are usually single

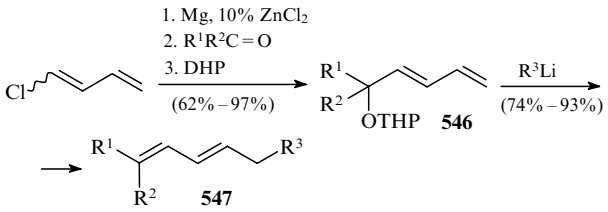
and have substantial differences from the typical processes; therefore, we consider them separately.

The introduction of double bonds by elimination of vicinal hydrogen atoms finds only limited use. The high-temperature catalytic dehydrogenation occurs selectively only in the preparation of simple dienes, for example, butadiene from butane and butenes or isoprene from isopentane. Of more complex examples, one should note the transformation of α,β-unsaturated oxo compounds **542** (X = Ph, OEt) into the corresponding dienes **543** on treatment with stoichiometric amounts of Na_2PdCl_4 as an oxidant.[478] The yields are moderate in all cases. This method has been used to prepare steroidal dienones with fragment **544** from the corresponding enones **545**.



542 **543** **545** **544**

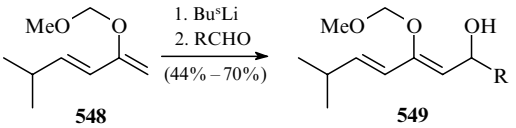
The tetrahydropyranyl derivatives of α-dienic alcohols **546** can react with a number of C-, N-, Si- or Sn-nucleophiles giving rise to dienes **547** with a different arrangement of double bonds.[479] The methoxymethyl derivatives react in a similar way; however, the reaction stereoselectivity is lower.



546 **547**

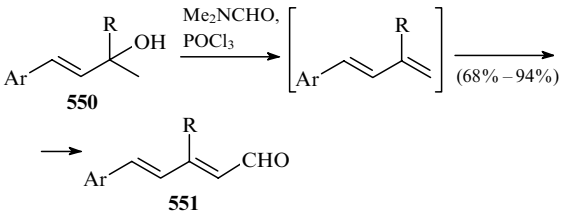
DHP is dihydropyran; R^3 = Alk, NEt_2, $SiMe_2Ph$, $SnMe_3$.

The methoxymethyl ether of the enol **548** can be introduced, after lithiation, into reactions with aldehydes.[480] The resulting dienes **549** contain an oxygen function at the diene system. The presence of this function is necessary for this reaction to take place (chelate control).



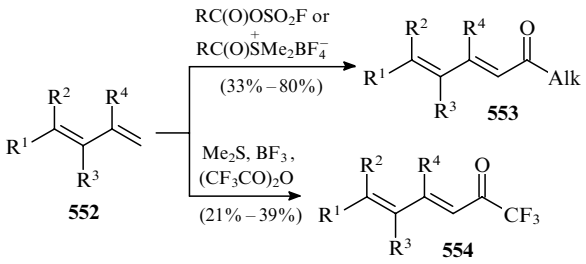
548 **549**

The tertiary analogues of cinnamic alcohols **550** are dehydrated under reaction conditions and the resulting diene is formylated giving rise to dienals **551**.[481]



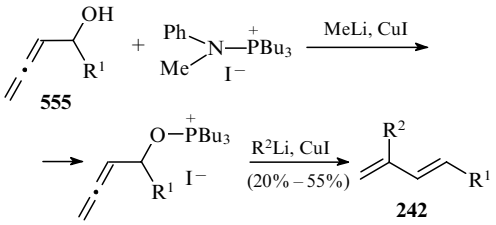
550 **551**

Direct acylation of conjugated dienes **552** has remained problematic until recently. However, development of reactive cationoid reagents has enabled the synthesis of dienones **553** and **554** in reasonable yields.[482–484]



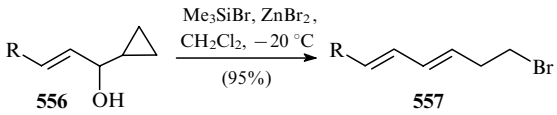
552 **553** **554**

The use of α-allenyl alcohols **555** in the synthesis of alkenes according to the Murahashi method affords the conjugated dienes **242**.[485]



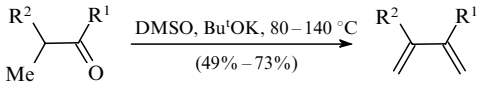
555 **242**

The carbocationic rearrangement of cyclopropylalcohols can proceed smoothly under appropriate conditions to yield homoallyl derivatives. In the case of cyclopropyl(alkenyl)methanols **556**, conjugated diene system **557** is produced.[486–488]



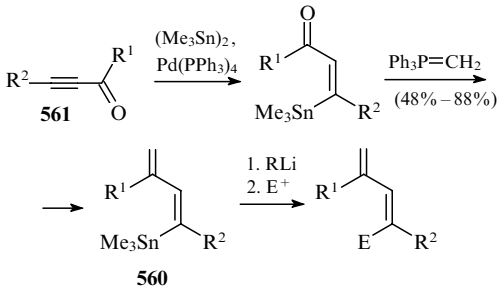
556 **557**

A very simple method for the synthesis of dienes consists in heating of aliphatic α-branched ketones **558** in DMSO with potassium *tert*-butoxide,[489] DMSO serving as the source of a new carbon atom in the molecule of product **559**. Unfortunately, in many instances, these reactions give mixtures of isomers.



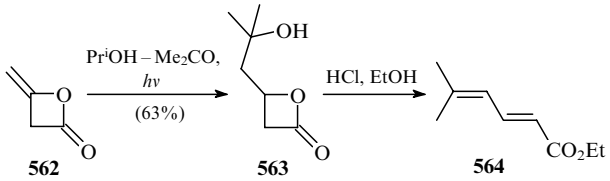
558 **559**

A two-step method for the preparation of dienylstannanes **560** from acetylenic carbonyl compounds **561** is documented.[490] Transmetallation provides a nucleophilic diene equivalent.



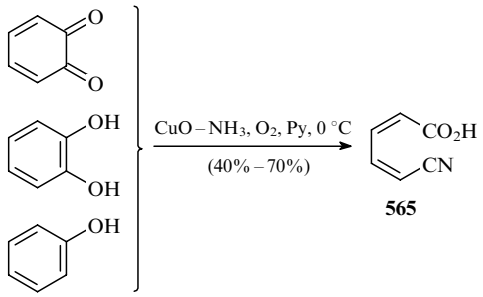
561 **560**

Diketene **562** exposed to UV radiation in a mixture of propan-2-ol and acetone gives adduct **563**, which is a convenient precursor of conjugated dienoate **564**.[491]



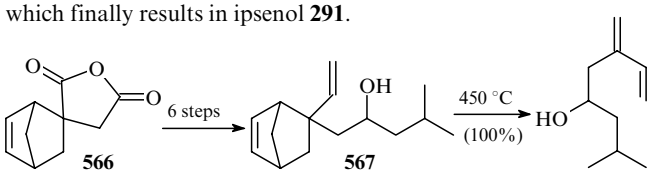
562 **563** **564**

Oxidation of *o*-quinone, pyrocatechol or phenol with ammoniacal copper oxide in pyridine results in *cis,cis*-muconic acid mononitrile (**565**).[492] In the case of substituted compounds, for example, 4-*tert*-butyl-*o*-quinone, a mixture of regioisomers is formed.



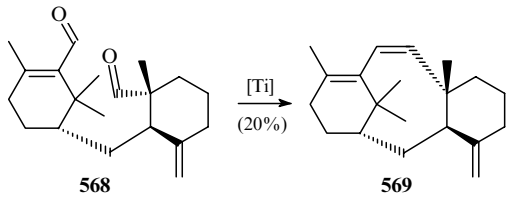
565

The adduct **566** of itaconic anhydride with cyclopentadiene was converted into compound **567**. Pyrolysis of this compound liberates the methylene group, which had initially been protected; this group is found to be conjugated with a new vinyl group,[493] which finally results in ipsenol **291**.



566 **567** **291**

The coupling of two carbonyl compounds by means of the McMurry titanium reagent results in alkenes; if one compound is unsaturated, the expected product is a diene. Thus intramolecular cyclisation of dialdehyde **568** results in diterpene hydrocarbon **569** difficult to prepare by other methods.[494]



568 **569**

IX. Conclusion

One cannot but note the great diversity of the methods for synthesis of conjugated dienes considered in this review. Nevertheless, despite the wide range of choice, when selecting the method of synthesis of a target object, a researcher would be guided, first of all, by its reliability and simplicity as well as the availability and cost of initial compounds and, strange though it may seem, by the reputation and popularity of the method. Table 3 presents a comparative analysis of the methods considered. It is fairly difficult to evaluate the true 'rating' of each of them because this requires analysis of a different type of literature, namely, the use of these methods in target-directed syntheses of intricate structures in which they are often used only as an episode in a multistep protocol. The more reliable the method, the less the attention researchers draw to it! The popularity of a method can be judged to some extent by the presence of reviews devoted to it, or (less reliably) by mentions of this method in textbooks.

When methods' reputations are equivalent, when planning the synthesis, one should analyse first of all the possibility of performing the task on the basis of standard reactions, *viz*., elimination (the formation of double bonds with a preformed carbon skeleton), olefination of carbonyl compounds (the $C_1 + C_3$ pattern of diene formation with formation of a double bond) and, more rarely, cross-coupling (the $C_2 + C_2$ pattern of diene formation with the formation of the central single bond, or the C_4 + substituent pattern). Each of these general approaches has its own limitations. In particular, alkenyl halides and alkenyl derivatives of elements used in cross-coupling are rather expensive and their synthesis requires high skills. This and other reasons stimulate the search for new, different reactions which would provide an absolutely untrivial approach to the synthesis of conjugated dienes. The progress achieved in the alkene – alkyne metathesis over the last three years can serve as an example. This method, as well as new organometallic reactions, undoubtedly hold great promise because it requires rather simple initial compounds and commercially available metal complex catalysts.

Table 3. Brief characterisation of the most important methods for the preparation of conjugated dienes (from the bibliography of this review).

Reactions	Stereohemical outcome	Features	The range of yields (%)	The number of references (of these, reviews)
Elimination	depends on the method and the substrate	effective methods are expensive	36 – 97	92 (8)
Reduction of enynes and diynes	good for the synthesis of *Z*-isomers, poorer for *E*-isomers	inexpensive method	50 – 86	15
Olefination of carbonyl compounds				118 (9)
condensation	high for linear *E*-dienes	used for the synthesis of α-functionalised dienes	24 – 98	35 (6)
Wittig reactions	depends on the method and the substrate but is controllable	adjustment of details for a particular synthesis is often required	27 – 98	58 (3)
other reactions	depends on the method and the substrate	more reliable than the Wittig olefination	23 – 94	25
Cross-coupling	very high; determined by the reactant structure	high cost of the reactants	30 – 93	104 (16)
Miscellaneous organometallic reactions	depends on the method and the substrate	some procedures are very effective	21 – 99	48 (1)
Electrocyclic reactions	high	industrially feasible	25 – 90	35 (3)
Miscellaneous methods	depends on the method and the substrate	–	20 – 95	75

Abstract. The crystal structures and magnetic properties of complex oxides of the $LiMO_2$ series (M = Sc – Ni) and of solid solutions they form are described. Although the structures of the oxides are all derived from the NaCl structure, their magnetic properties are fairly diverse and depend on the type of cationic ordering. Primary attention is given to the oxides with layered structures in which the degree of ordering is a variable. The bibliography includes 225 references.

I. Introduction

During the past 15 years, compounds with the general formula of $LiMO_2$, where M is a transition 3*d* metal, have actively been explored, and the interest in them is not lost up to date. First of all, this is related to the prospects of considering many $LiMO_2$ complex oxides as promising cathodic materials for chemical power sources.[1–3] These prospects are usually determined by such properties as a high positive potential, small molecular mass and structural stability during electrochemical intercalation and deintercalation

$$LiMO_2 \rightleftharpoons Li_{1-x}MO_2 + x\,Li^+ + x\,e^-.$$

Besides this applied aspect, interesting magnetic properties of $LiMO_2$ complex oxides draw the attention of many theoreticians and researchers.[4] These oxides include antiferromagnetic, ferromagnetic, paramagnetic, diamagnetic, weak ferromagnetic materials, *etc*. The magnetic properties of $LiMO_2$ oxides are largely determined by the type of superstructures they form. The whole spectrum of structures found in $LiMO_2$ is based on the rock-salt structure, the deviations being determined by the way the cations are distributed over the positions of this basal structure. This distribution can either be random or ordered, the latter giving rise to the formation of a superstructure. In solid solutions of complex oxides, the type and the degree of ordering can change depending on the component concentrations. This is why compounds for which the degree of structural ordering (η) varies as a function of synthetic conditions, which entails profound changes in magnetic structures, are of particular interest. In this review, the studies in which the magnetic properties of $LiMO_2$ compounds and solid solutions based on them are correlated with the peculiarities of their crystal structures are analysed. Most of numerous electrochemical studies are beyond the scope of this review, these being surveyed elsewhere.[3–5]

II. Structures of $LiMO_2$ oxides

The crystal structures of $LiMO_2$ complex oxides derive from the NaCl structure and differ from one another only in the way the cations of alkali and transition metals are distributed over the planes of the basal cubic lattice. When lithium and transition-metal ions occupy severally the alternating (111) planes of the sodium chloride cubic lattice, layered structures characterised by a high diffusion mobility of alkali-metal atoms are formed. Hence, in such compounds as, *e.g.*, $LiCoO_2$ and $LiNiO_2$, deep and reversible electrochemical intercalation of lithium can occur which attracts the attention of scientists. The quest for a wide array of new compounds with the layered structures favourable for electrochemical processes stimulates the development of the methods for the preparation of metastable $LiMO_2$ modifications. For this purpose, low-temperature methods which involve precursor synthesis and ion-exchange processes, chemical and electrochemical intercalation, etc. are used. Usually, these phases lose their stabilities with an increase in temperature and transform into stable modifications.

The $LiMO_2$ compounds preferentially form three structural types. The first structure represents a disordered cubic lattice of α-$LiFeO_2$ (NaCl), the second structure of the α-$NaFeO_2$ type represents a trigonal superlattice on the basis of the NaCl structure and the third compound represents a spinel in which transition-metal and lithium atoms occupy, correspondingly, the 16*a* and 16*b* positions. The effects of the size and the charge of a transition-metal ion on the formation of a particular lattice type have been discussed.[6] As was shown by calculation, if the ionic radii of alkali and transition metals are close, the random distribution of ions over the positions corresponds to the state with the minimum energy, *viz*., the cubic lattice of α-$LiFeO_2$. With an increase in the differences in the ionic sizes, the probability of formation of the α-$NaFeO_2$-type layered structure also increases, which is favoured by lower charges of transition-metal ions. The low stability of spinel phases (*e.g.*, the low-temperature $LiCoO_2$ phase), which exist only in very narrow temperature and pressure intervals is explained by the fact that their origination is governed by kinetic factors rather than by thermodynamic ones.

$LiScO_2$ represents a nonconducting white powder under ordinary conditions. A review of the structural data one can see in Ref. 4. $LiScO_2$ was first described in 1959 (Ref. 7). X-Ray diffraction studies carried out for both single crystals[8] and powders[9] and Mössbauer studies of Fe^{3+} impurity centres in $LiScO_2$ (see Refs 10, 11) have shown that the perfect ordering of Sc^{3+} and Li^+ cations in the basal NaCl structure produces a superlattice with $I4_1/amd$ symmetry ($a = 4.18$, $c = 9.30$ Å), which is similar to the superlattice of totally ordered γ-$LiFeO_2$ phase. This structure is characterised by the atoms of transition and alkali metals regularly occupying the alternate positions along the tetragonal c axis.

Yet another approach to the description of the $LiScO_2$ structure is known.[12] According to experimental results,[12] the oxygen octahedra which enclose lithium ions are shown to be distorted in a such way as if lithium represented a Jahn–Teller ion (four short and two long Li–O distances). The concept of distorted anatase seems to describe the $LiScO_2$ structure more precisely than the model of a tetragonally ordered NaCl modification.

$LiTiO_2$ has a completely disordered cubic structure of the NaCl type ($a = 4.140$ Å).[13, 14] Extensive information on $LiTiO_2$ is cited in Ref. 4. Low-temperature chemical lithiation of $LiTi_2O_4$ spinel gave rise to a modification of $LiTiO_2$.[15] X-Ray diffraction patterns of this phase virtually did not differ from those of the parent spinel. Using the neutron diffraction technique, it was shown[16] that the formation of $LiTiO_2$ ($Li_2Ti_2O_4$) ($a = 8.3756$ Å) is accompanied by transposition of lithium from tetrahedral sites to octahedral ones unoccupied in the parent spinel. Thus, the titanium and lithium ions in the metastable phase are distributed over the positions 16c and 16d, respectively, of the $Fd3m$ space group, and a superstructure of the atacamite type is formed.[17] Heating above 920 K results in irreversible transition of the $Li_2Ti_2O_4$ spinel into a stable disordered cubic phase of $LiTiO_2$.[15] This transition appears to occur in several steps, because DSC (differential scanning calorimetry) revealed three endothermic effects (in total, 950 cal mol^{-1} were liberated).[18]

$LiVO_2$ represents a black powder. It was described for the first time in 1954 (Ref. 19). This compound is isostructural to the hexagonal α-$NaFeO_2$. Generally, such a structure is typical of this class of compounds (Fig. 1). It is formed by the ions of alkali and transition metals ordered in parallel (111) planes of the NaCl cubic lattice. In the ordered structure, all vanadium ions have six-fold oxygen coordination, the V–O distances are equal to 1.987 Å. At 450 K, a phase transition occurs in $LiVO_2$,[13, 20–22] which is accompanied by pronounced changes in the unit cell volume and interatomic distances [$a = 2.837$, $c = 14.775$, V–O = 1.98, V–V = 2.84 Å at 300 K; $a = 2.913$, $c = 14.640$, V–O = 2.02, V–V = 2.91 Å at 550 K for $Li_{0.7}VO_2$ (see Ref. 23)], although the main structural motif remains unchanged. A substantial temperature hysteresis was observed. During the transition, the enthalpy changed by 50–1000 cal mol^{-1} (see Ref. 22). It was assumed[24] that at room temperature vanadium ions are combined in V_3 trimers which disintegrate during the phase transition. The formation of trimers was confirmed experimentally. Thus, the structure of $Li_{0.8}VO_2$ single crystals prepared by the flux method (see Ref. 26) was analysed in detail using X-ray diffraction and EXAFS techniques.[25] It was shown that vanadium ions are shifted by 0.160 Å from the positions they should occupy in the perfect hexagonal structure. Probably, the symmetry of the low-temperature phase differs from the $R\bar{3}m$ symmetry as followed from the presence of very weak additional reflexes in the X-ray patterns of this phase ($a' = a\sqrt{3}$, $c' = c$).[23]

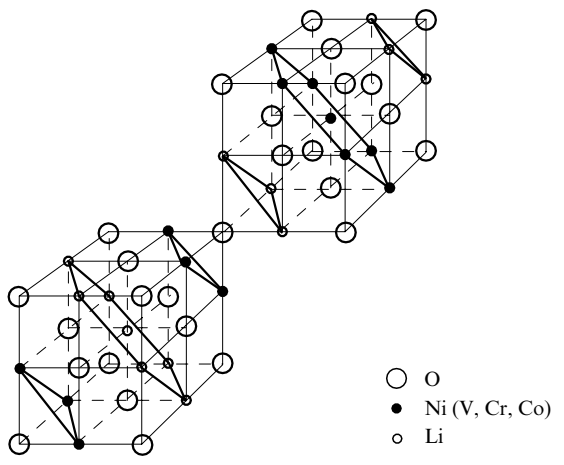

Figure 1. Schematic representation of the formation of layered structures for $LiVO_2$, $LiCrO_2$, $LiCoO_2$ and $LiNiO_2$ as a result of cationic ordering in the NaCl-type cubic lattice.

It was shown that stoichiometric $LiVO_2$ can be transformed into $Li_{1-x}VO_2$ phases by both chemical and electrochemical deintercalation.[27, 28] Studies on the structure of deintercalated vanadates showed that the removal of lithium from the layered structure for $x \geqslant 0.3$ results in redistribution of vanadium ions. For example, in $Li_{0.22}VO_2$, approximately one third of vanadium ions occupy the octahedral positions in Li layers, which favours stabilisation of the cubic structure. With increasing temperature, the $Li_{1-x}VO_2$ phase becomes unstable, and its disproportionation can proceed by two routes[29]

$$Li_{1-x}VO_2 \longrightarrow (1-2x)\,LiVO_2 + x\,LiV_2O_4,$$

$$Li_{1-x}VO_2 \longrightarrow (1-8x)\,LiVO_2 + 8x\,Li_{0.875}VO_2.$$

The coexistence of hexagonal and cubic phases was established.[30]

At high pressures, another polymorphous modification of $LiVO_2$ with a superlattice of the atacamite type was obtained.[31] Heating above 700 K resulted in irreversible transition of this phase into a stable hexagonal form.

$LiCrO_2$ prepared by ceramic technology represents a green powder with a layered trigonal structure of α-$NaFeO_2$ ($a = 2.88$, $c = 14.6$ Å). Like $LiVO_2$, the $LiCrO_2$ oxide was first prepared and described in 1954 (Ref. 19). Single crystals of $LiCrO_2$ were grown by the flux method.[32] In contrast to most $LiMO_2$ compounds, deintercalation of lithium from $LiCrO_2$ is hindered; however, under hydrothermal conditions, the ion-exchange reaction is possible, which results in the formation of an isostructural phase of $HCrO_2$.[33]

$LiMnO_2$ in the form of a brown powder (orthorhombic unit cell) was first synthesised with the aim of studying the $Li_xMn_{1-x}O$ system.[34] The crystal structure of $LiMnO_2$ was studied in more detail for polycrystalline material[35] and single crystals[36], the latter being obtained by the hydrothermal method.[37] A number of structural peculiarities of orthorhombic $LiMnO_2$ compared with other $LiMO_2$ complex oxides[38] are apparently caused by the Jahn–Teller effect.

The orthorhombic lattice of $LiMnO_2$ ($a = 2.805$, $b = 5.757$, $c = 4.527$ Å), $Pmmn$ (see Ref. 36) also represents one of the versions of the NaCl basal structure ordering (Fig. 2). The MnO_6 octahedra are substantially distorted due to the Jahn–Teller effect. Two long distances along the b axis (2.291 Å) and two pairs of almost identical equatorial distances, *viz.*, 1.920 and 1.937 Å, were observed. In each (001) plane, cations of one type are arranged in chains along either ⟨100⟩ (orthorhombic) or ⟨110⟩ (cubic) directions. In alternate (001) planes, the chains retain their orientation with respect to the upper and lower planes, but are shifted forming the ABA packing along the c axis. Compared to the hypothetical cubic lattice with a parameter a', the parameters of the real lattice are as follows: $a = (1/2)\sqrt{2}a'$, $b = \sqrt{2}a'$ and $c = a'$.

Considerable anisotropy of the thermal expansion coefficient was observed[39] at temperatures < 300 K. The thermal expansion coefficient did not exceed 10^{-7} K^{-1} in the directions a and b and was 3.7×10^{-6} K^{-1} in the direction c.

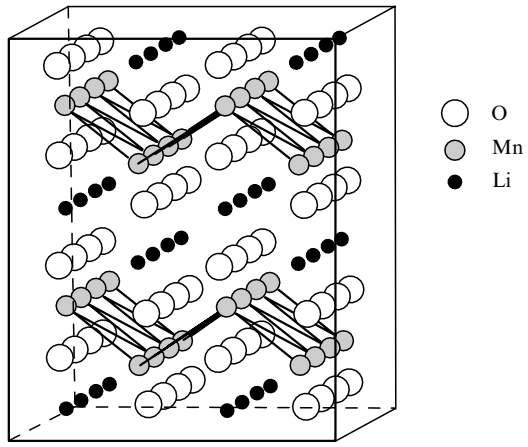

Figure 2. Crystal structure of $LiMnO_2$.

Studies on the morphological peculiarities of orthorhombic $LiMnO_2$ synthesised by a conventional ceramic procedure (sintering of an Mn_2O_3 + LiOH mixture at 1073 K in an inert atmosphere) revealed the presence of certain cationic disordering, namely, the existence of defects of the Li_{Mn} and Mn_{Li} types.[40] The degree of disordering (3% – 12%) was attributed to the preset excess or deficiency of LiOH. Scanning electron microscopy showed that the sizes and shapes of grains also depended on the LiOH content in the reaction mixture. The deficiency of lithium favoured the formation of fine and size-uniform grains, whereas excess of lithium resulted in a wide scatter of the grains both in sizes and shapes. It was the former modification that demonstrated good characteristics in the electrochemical process.[41] The stacking faults in orthorhombic $LiMnO_2$ with a small ($d \approx 0.3$ μm) grain size were studied in detail.[42] It was concluded that these represent monoclinic interstitial layers between the orthorhombic blocks. The portion of such defects was 1% – 6%, which correlated well with the degree of cationic disordering.

The existence of a low-temperature modification of $LiMnO_2$ with a tetragonal structure, which was obtained by chemical lithiation of $LiMn_2O_4$ spinel: $a = 5.662$, $c = 9.274$ Å, $I4_1/amd$, $Z = 8$, was reported.[43,44] Above 500 °C, the tetragonal phase transformed into the stable orthorhombic phase.

Recently, yet another metastable low-temperature modification of $LiMnO_2$ has attracted great interest. This phase was first synthesised in 1996 (Ref. 45). The phase has a monoclinic lattice ($C2/m$, $a = 5.4387$, $b = 2.8086$, $c = 5.3878$ Å, β = 116 °). For its synthesis, the ion-exchange method was applied in which layered α-$NaMnO_2$ was used as the precursor. The product also exhibited a layered structure. In addition, it was noted[46,47] that the ion-exchange reaction can also proceed in a mixture of γ-MnOOH and $LiOH \cdot H_2O$. The lower symmetry of the layered $LiMnO_2$ modification compared, for instance, with layered $LiCoO_2$ was associated with the strong Jahn–Teller effect for Mn^{3+} ions (see Ref. 45). As was shown by the results of X-ray diffraction analysis and neutron diffraction,[45,48,49] the Li-layers of the layered $LiMnO_2$ modification contain 3% – 9% of manganese ions. An electron-diffraction study in a convergent beam[50] have shown that a typical specimen synthesised by the ion-exchange method contains, in addition to layered $LiMnO_2$, an admixture of a tetragonal spinel phase of $Li_2[Mn_2]O_4$ and traces of orthorhombic $LiMnO_2$. The following atomic planes and directions were also shown[50] to be equivalent for the spinel and layered phases:

$$(200)_{lay} \equiv (222)_{sp}$$

$$(020)_{lay} \equiv (4\text{-}40)_{sp}$$

$$[001]_{lay} \equiv [11\text{-}2]_{sp}$$

A comparative analysis of the stability of orthorhombic and monoclinic layered structures of $LiMnO_2$ was carried out.[51] The calculations have shown that the antiferromagnetic exchange coupling of Mn^{3+} ions plays a substantial role in stabilisation of the orthorhombic structure; and, therefore, stabilisation of the layered structure requires that manganese was partly replaced by elements that weaken this interaction. The elements Al, Co, Cr, V, Ti, Mo, Mg, Nb, Zn and Pd can serve as the dopants.

In the Li–Mn–O system, yet another monoclinic phase designated as m-Li_xMnO_2 ($x = 0.2 – 0.3$) was detected and identified.[52] It can be obtained by durable sintering of intimately mixed β-MnO_2 and LiOH at 420 K. According to the results of X-ray diffraction analysis, the new phase has a primitive monoclinic unit cell ($a = 9.38$, $b = 5.65$, $c = 4.906$ Å, β = 102.2 °) and is stable up to 820 K.

In a thermobaric treatment ($P = 6.5$ GPa, $T = 100$ K) of orthorhombic $LiMnO_2$, a totally disordered phase with the rock-salt structure ($a = 4.1658$ Å) was obtained. According to crystallographic data, no structural distortions caused by the Jahn–Teller effect were observed.[4]

$LiFeO_2$ exists in several polymorphous modifications (Fig. 3). A disordered structure of cubic α-$LiFeO_2$ is identical to that of NaCl ($a = 4.158$ Å).[53] The structure of $LiFeO_2$ represents a rare example of structures in which two different cations occupy the same positions.[54,55] The results of electron-microscopic studies have shown[56,57] that the α-$LiFeO_2$ cubic structure involves the elements of the short-range order. For γ-$LiFeO_2$, an ordered tetragonal structure similar to that of $LiScO_2$ is typical ($a = 4.057$, $c = 8.759$ Å).[58] Apparently, the metastable β-$LiFeO_2$ modification is intermediate between α- and γ-phases. Discrepant opinions were advanced on the β-$LiFeO_2$ structure: some authors (see, *e.g.*, Ref. 53) claim the existence of a body-centred tetragonal unit cell, while others believe it to be monoclinic.[59,60] The monoclinic structure of the β-phase was confirmed by electron microscopy[56] ($C2/c$, $a = 8.571$, $b = 11.59$, $c = 5.147$ Å, β = 145.70 °, $Z = 8$). The tetragonal structure exhibits no ordering in the distribution of cations over the positions. In contrast, the monoclinic phase is ordered.

Detailed studies[53,61] have detected the transition of α-$LiFeO_2$ first to β-$LiFeO_2$ at $T > 570$ K and further to the ordered γ-$LiFeO_2$ phase at $T > 870$ K. The latter phase transforms back into the disordered α-modification with further increase in temperature (> 920 K). The transitions proceeded slowly and depended on the sample's prehistory.

Currently, many efforts are concentrated on the synthesis of metastable modifications of $LiFeO_2$ with layered structures. For

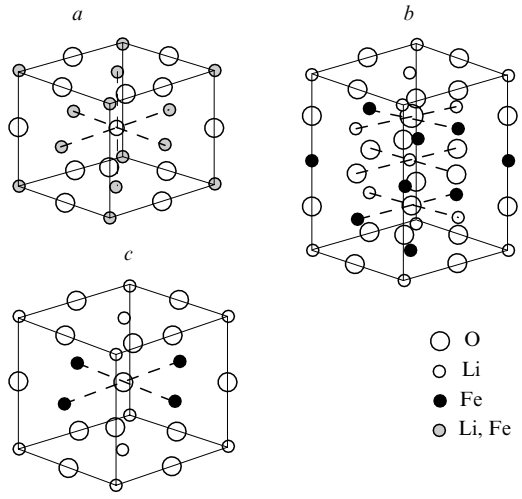

Figure 3. Structural modifications of $LiFeO_2$; (*a*) is the cubic α-phase, (*b*) is the tetragonal β-phase and (*c*) is the tetragonal γ-phase (1/2 of the unit cell is shown).

example, the preparation of $LiFeO_2$, the corrugated layered structure of which is similar to that of a stable orthorhombic modification of $LiMnO_2$, was described.[62] The synthesis involved the ion exchange reaction between γ-FeOOH and $LiOH \cdot H_2O$. The reaction was carried out under hydrothermal conditions at 370 – 520 K. The structure of the phase obtained was noted to resemble very closely that of the original γ-FeOOH. The transition from γ-FeOOH to $LiFeO_2$ presumes a shift of corrugated layers by 1/2 along the *b* direction. According to the X-ray diffraction studies, the lattice parameters of $LiFeO_2$ are $a = 4.0610(5)$, $b = 2.9621(5)$ and $c = 6.0319(11)$ Å. Yet another orthorhombic structure of the goethite type with the parameters $a = 9.677(5)$, $b = 2.934$ and $c = 5.005$ Å, *Pmna* was also synthesised by using an ion-exchange reaction (carried out in an ethanolic solution, in contrast to the previous reaction).[63] It is interesting that at certain Li to Fe ratios, a totally disordered cubic modification of α-$LiFeO_2$ ($a = 4.161$ Å, *Fm3m*) can be obtained by this method,[64] its conventional synthesis requires high temperatures.

The ion-exchange reaction of $NaFeO_2$ in a lithium chloride melt resulted in $LiFeO_2$ with a layered trigonal structure of α-$NaFeO_2$, which is typical of this class of compounds.[65] The degree of cationic ordering was found to depend on the ordering of the precursor phase.

In addition to metastable forms of $LiFeO_2$ discussed above, yet another low-temperature modification, *viz*., a phase with a tunnel structure was documented.[66] However, this has not been described in detail in further publications.

$LiCoO_2$ is usually obtained at 1200 – 1300 K as a black powder from cobalt oxide and lithium carbonate. This phase is referred to as a high-temperature (HT) one. It is thermally stable up to 1120 K.[67] According to results of neutron diffraction studies,[68] HT-$LiCoO_2$ has a perfectly ordered structure of the α-$NaFeO_2$ type ($R\bar{3}m$) with the cell parameters $a = 2.8166$ and $c = 14.052$ Å.[69] The $LiCoO_2$ structure was studied for single crystals obtained by the flux method.[70] The layered structure of HT-$LiCoO_2$ is very stable and, as was shown by calculations,[71] the order – disorder transition can occur only at ~5100 K. This is substantially higher than the melting point, which makes such a transition practically unfeasible. On the other hand, according to calculations,[72] the use of high pressures can stimulate the transition with the formation of a cubic phase.

Synthesis at temperatures below 700 K produces a low-temperature (LT) phase with a structure somewhat different from that of HT-$LiCoO_2$.[73 – 81] According to the results of neutron diffraction analysis,[75] nearly 6% of lithium sites in LT-$LiCoO_2$ are occupied by cobalt. The phase formed upon deintercalation of lithium from LT-$LiCoO_2$ (Li_xCoO_2; $1 \geqslant x \geqslant 0.5$) can be described[77] either as a spinel modification ($Fd\bar{3}m$) in which up to 80% of lithium atoms occupy tetrahedral positions[74] or a phase with the trigonal layered structure ($R\bar{3}m$). NMR studies[82] are in favour of the second version, because the substantial structural disordering observed by this method corresponds to the second co-ordination sphere of lithium. Hence, the nearest neighbouring of lithium remains octahedral so that LT-$LiCoO_2$ may be considered as a partly disordered trigonal structure based on NaCl. A different opinion on this problem has been advanced.[83] Based on the combined use of transmission electron microscopy and X-ray diffraction analysis, it was concluded that the structure of LT-$LiCoO_2$ may be considered as an intermediate between the structures of perfect spinel and the layered modification.

A number of studies dealt with the phase transitions that occur both in HT-[84 – 86] and LT-$LiCoO_2$ [75 – 77] during electrochemical deintercalation of these compounds. The stabilities of the phases obtained were calculated,[87, 88] and the phase diagram of Li_xCoO_2 was constructed.

The completely deintercalated layered phase of CoO_2 ($a = 2.822$, $c = 14.29$ Å) was first isolated and described in 1997 (Ref. 89). Unexpectedly, it was found that despite the structural disordering processes that occur during electrochemical deintercalation the product exhibited a very high degree of structural ordering. Several metastable polymorphous modifications were formed upon electrochemical deintercalation of Li_xCoO_2 [90] synthesised from $Na_{0.7}CoO_2$ by ion-exchange.[91] Depending on the depth of the deintercalation process, the mode of CoO_6 octahedra packing changed.

In studies of phase transitions that occur during the chemical extraction of lithium from $LiCoO_2$ with the formation of $Li_{0.5}CoO_2$ it was found [92] that a common hexagonal structure is retained only up to the $Li_{0.92}CoO_2$ composition. For deeper extraction of lithium, a second, also hexagonal phase appears, which becomes the only phase present starting from the $Li_{0.79}CoO_2$ composition. The hexagonal structures differ in the *c*/*a* ratio, which is substantially higher for the second phase.

$LiNiO_2$ with a structure similar to that of α-$NaFeO_2$ ($a = 2.878$, $c = 14.19$ Å) was described for the first time in 1953 (Ref. 93). This oxide is isostructural to $LiCoO_2$ and $LiVO_2$. The distribution of atoms over the positions is as follows: Ni(3*a*) (0, 0, 0); Li(3*b*) (0, 0, 1/2); O(6*c*) (0, 0, 1/4) (0, 0, −1/4). The ratio $c/a = 4.93$ indicates the presence of an almost perfect face-centred cubic sublattice of oxygen, for which $c/a = 2\sqrt{6} = 4.90$. An EXAFS study of the Jahn – Teller co-operative effect has shown that two long (2.09 Å) and four short (1.91 Å N – O distances are present as a result of local distortion in NiO_6 octahedra.[94 – 95]

The layered $LiNiO_2$ oxide is traditionally considered as an end member of the series of $Li_xNi_{1-x}O$ solid solutions. The cationic ordering that takes place with increasing concentration of lithium in Li_xNiO_2 is well known and was discussed in a number of publications.[96] The disordered phase ($x < 0.56$) is isostructural to NiO (NaCl type), and the formation of a layered structure involves the ordering of ions of transition and alkali metals in alternate (111) planes of the NaCl-type cubic lattice, which is accompanied by lowering of the symmetry to trigonal. Due to the close radii of Ni^{3+} and Li^+ ions, the degree of ordering of cations over the positions in the alternate planes (η) can vary widely even for an invariant transition-to-alkali metal ratio. For example, the synthesis and properties of virtually stoichiometric $LiNiO_2$ with $0 \leqslant \eta \leqslant 1$ were described.[97, 98] The structural order $\eta = 0$ corresponds to cubic $LiNiO_2$ prepared by quenching of $LiNiO_2$ with $\eta = 1$ from a temperature of 1200 K.[97] The quenched phase is metastable; hence, the ordering process can occur at temperatures above 600 K.

The temperature of the order → disorder transition (layered → cubic structure) is 1020 K.[99] The transition proceeds slowly and is not completely reversible.

The difficulties of synthesising the stoichiometric $LiNiO_2$ were associated with the loss of lithium during sintering.[100 – 102] In this case, the parameter of cubic or trigonal cell depended linearly on the value of *x* in $Li_xNi_{1-x}O$.[96] Different versions of the synthesis, which allow one to minimise lithium losses, were described.[103]

It is of note that even upon annealing for a long time at sufficiently high temperatures (1100 K) $Li_xNi_{1-x}O$ is characterised by a heterogeneous bulk composition.[104] The procedure of refining of structural data turned out to be more efficient being carried out within the framework of a multiphase system rather than a 'single-phase' one.

The cationic distribution in nonstoichiometric $Li_{1-x}Ni_{1+x}O_2$ solutions was studied by X-ray diffraction analysis.[105] It was confirmed that, with an increase in *x*, the degrees of occupation of 3*a* and 3*b* positions by lithium (nickel) ions approach one another, which results in their random distribution for $x \geqslant 0.4$.

Two models of cationic distribution in $Li_{1-x}Ni_{1+x}O_2$ exist. According to the first model, superstoichiometric nickel occupies free sites in lithium layers, and the oxide can be described by the formula $[Li_{1-x}Ni_x][Ni]O_2$.[106] The second model assumes partial mixing of cations in both sites; in this case, the oxide has the following formula: $[Li_{1-x-\delta}Ni_{x+\delta}][Ni_{1-\delta}Li_\delta]O_2$.[105, 106] If the oxide composition approaches stoichiometric, then the first model is assumed[107] to be more probable.

It should be noted that the nickel that occupies 3*a* positions in the nickel sublattice of $Li_{1-x}Ni_{1+x}O_2$ corresponds predominantly to the Ni^{3+} state, whereas the lithium sublattice (2*a* positions) mainly involves bivalent nickel ions.[108]

It was shown[106] that the concentration-induced order–disorder transition in $Li_{1-x}Ni_{1+x}O_2$ is well simulated by using the 'lattice gas' concept. The dependences of the ordering parameter on the lithium content were obtained, and $\eta_{max} = 0.96$ was found even for the stoichiometric composition. Moreover, it was shown that even the region of the existence of cubic structures ($x \geqslant 0.4$) is characterised by the effects of the short-range structural order, which were studied in detail by synchrotron X-ray emission.[109] Based on the results obtained, the sizes of short-range order domains were assessed.

A small magnitude of the X-ray scattering factor for lithium makes it impossible to determine the degree of cationic disordering in $Li_{1-x}Ni_{1+x}O_2$ near the stoichiometric composition. For this purpose, other methods, such as ESR[110] or X-ray absorption spectroscopy[111] were used. Thus it was found[111] that two different Ni–O distances (2.07 and 1.94 Å) whose ratio varies with *x* are present.

Three successive first-order transitions which occur during electrochemical extraction of lithium[112,113] (at high potentials, completely deintercalated 'NiO_2' phases can also be obtained[114]) cause the following changes in the $LiNiO_2$ structure: hexagonal → monoclinic → hexagonal′ → hexagonal″. The relationships between the unit cell parameters of monoclinic (*C*2*m*, similar to that observed for $NaNiO_2$) and hexagonal phases are as follows:

$$a_m = \sqrt{3}a_h,$$

$$b_m = a_h,$$

$$c_m = \frac{c_h}{3\sin\beta},$$

$$\beta = 180 - \operatorname{arctg}\frac{c_h}{\sqrt{3}a_h}.$$

It is also important that the monoclinic phase is only formed upon deintercalation of virtually stoichiometric $Li_{1-x}NiO_2$, whereas intercalation of $Li_{1-x}NiO_2$ with $x \geqslant 0.05$ does not affect the symmetry.[115] Stoichiometry of the initial compound also affects the process of chemical deintercalation: with a decrease in the lithium content, extraction of lithium and admixed nickel from lithium layers is supplemented by ion exchange which involves protons.[116]

The presence of nickel in the lithium layers plays a significant role in the stabilisation of the monoclinic phase.[117] Using EXAFS methods, it was shown[118] that the local distortion of NiO_6 octahedra in the monoclinic deintercalated phase of Li_xNiO_2 ($0.5 < x < 0.75$) is substantially weaker compared with the stoichiometric trigonal phase. This was attributed to the electron exchange between Ni^{3+} and Ni^{4+} sites. Also, the results of electron-microscopic studies have shown the monoclinic phase to involve a superstructure formed by partially ordered lithium ions (vacancies in the lithium layers).[119] The deintercalated Li_xNiO_2 phase is thermally unstable, and the layered hexagonal structure gives way to the cubic spinel structure at 453 K, which is accompanied by oxygen loss.[120]

Efforts were undertaken to obtain the $Li_{1+x}NiO_2$ oxide superstoichiometric with respect to lithium.[121,122] For instance, a phase with $x \geqslant 0.3$ having a monoclinic structure was described.[122,123] The latter was formed by closely packed oxygen layers (slightly distorted) which separated purely lithium layers from those filled by 1/3 with lithium ions and by 2/3 with nickel ions.

III. Magnetic properties of $LiMO_2$ oxides

Structural differences in the series of $LiMO_2$ oxides, where M is a transition 3*d* metal, are not significant: the crystal structures differ only in the mode in which the cations of alkali and transition metals are ordered in the planes of the parent cubic lattice. Nonetheless, these compounds exhibit fairly diverse magnetic properties.

$LiVO_2$. Magnetic effects which suggest phase transitions in $LiVO_2$ were first described by Bongers.[13] Heating above 450 K results in a fourfold increase in the magnetic susceptibility (Fig. 4); at higher temperatures, the latter is practically independent of the temperature. To explain the magnetic properties of $LiMO_2$ in the region below the transition temperature, a mechanism of formation of molecular orbitals in the basal plane of the hexagonal $LiVO_2$ structure was proposed.[125] The trigonal V_3 clusters thus obtained are nonmagnetic due to Heisenberg antiferromagnetic exchange coupling, and the phase transition is associated with their decomposition.

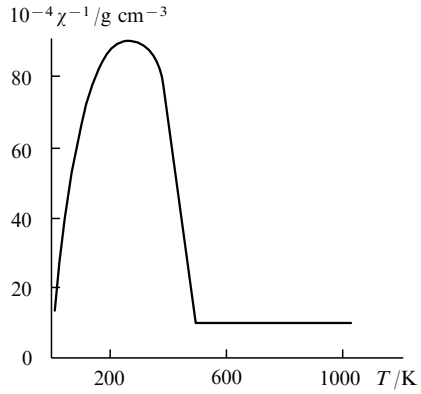

Figure 4. Temperature dependence of the reciprocal magnetic susceptibility of $LiVO_2$.[124]

Another model proposed[4,126] does not imply any changes in the symmetry. This interprets the low-temperature magnetic data in terms of the existence of a two-dimensional 'metal' cluster built by vanadium ions bound by metal–metal bonds. In the high-temperature region, *d* electrons are delocalisated, and $LiVO_2$ becomes a narrow-zone metal. This fact was evidenced by IR spectra, results on electrical conductivity[4] and the data from X-ray absorption spectroscopy.[127] Phase transitions which, as in the above model, were attributed to the changes in the critical M–M distance are typical of many transition-metal simple oxides: V_2O_3, VO_2, V_4O_7, Ti_3O_5, Ti_4O_7.[128–131] The role the structural changes in $LiVO_2$ play in the first-order phase transition from nonmagnetic to magnetic phase was discussed in detail.[132] It has been found that due to the changes in the magnetic energy the high-temperature phase is more stable.

$LiCrO_2$. The studies on the magnetic properties of $LiCrO_2$ as well as of many other oxides were pioneered by Bongers.[13] Magnetic susceptibility data indicated antiferromagnetic ordering to exist below 300 K and the Curie–Weiss paramagnetism with $\Theta = -577$ K and $\mu_{ef} = 3.71\ \mu_B$ to be present above 300 K. These characteristics were refined later: the Néel temperature (T_N) was found to be 56 K[133]; the value of μ_{ef} obtained by ESR technique[134] was 3.8258 μ_B (the deviation from an intrinsic spin value by 0.0529 μ_B was attributed to spin-orbit coupling).

Many studies have been made of the magnetic structure of $LiCrO_2$.[135–137] The structure was assumed[135] to be two-dimensional with an exchange-coupling constant inside the layer of $J = -39 \pm 1$ K. Based on the results of neutron scattering on $LiCrO_2$ single crystals, a magnetic structure with a single propagation vector $\mathbf{k} = [1/3, -2/3, 3/3]$ has been proposed.[137]

The relative orientation of the spins of neighbouring Cr^{3+} ions in the magnetic planes of $LiCrO_2$ was explained by the competition of direct antiferromagnetic interactions and indirect ferromagnetic double exchange coupling.

In many studies (see, *e.g.*, Refs 138, 139), the structure of $LiCrO_2$ was considered as a Heisenberg trigonal lattice. Such compounds attract attention due to the fact that ferromagnetic compounds can involve different magnetic orders compared with the classical Néel order. A joint analysis of the data on susceptibility, neutron scattering and magnetisation have led to the following conclusions:[140] first, during the magnetic phase transition, a 120-degree magnetic structure which involves Cr^{3+} ions is formed in each layer; in the process, the magnetic ordering both in the layers and along the *c* axis occurs at the same Néel temperature; second, the magnetic structure is characterised by two wave vectors $\mathbf{k} = [1/3, 1/3, 0]$ and $[-2/3, 1/3, 1/2]$.

Figure 5 shows the temperature dependence of the magnetic susceptibility of $LiCrO_2$.

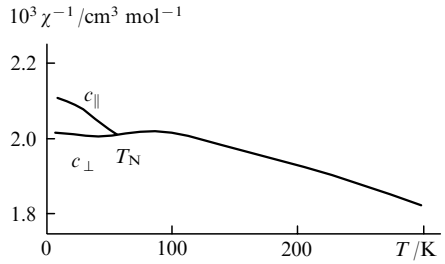

Figure 5. Temperature dependence of the magnetic susceptibility of $LiCrO_2$.[140]

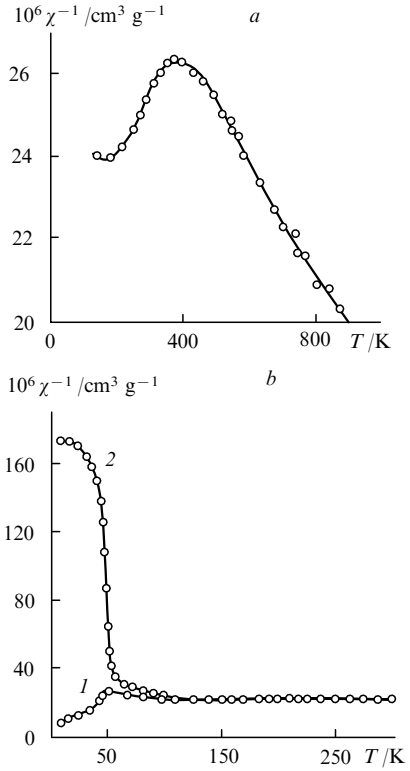

Figure 6. Temperature dependence of the magnetic susceptibility of $LiMnO_2$ in the regions (*a*) 100 – 1000 K and (*b*) 4 – 300 K.[141, 142] (*1*) Cooling in a zero field; (*2*) cooling in a 100-Œ field.

$LiMnO_2$. The first information on the magnetic properties of orthorhombic $LiMnO_2$ can be found in Ref. 13, in which the antiferromagnetic transition at 300 K was deduced. This fact was confirmed by more detailed studies.[39, 141] The magnetic susceptibility variation is characterized by the following features: the paramagnetic behaviour follows the Curie – Weiss law at temperatures above 600 K ($\Theta = -1056$ K, $\mu_{ef} = 4.82\ \mu_B$ per Mn^{3+} ion); the magnetic susceptibility passes a broad maximum at 400 K and its polytherms diverge below 100 K, being measured upon cooling both in the zero field and in the 100-Œ applied field (Fig. 6). Based on the results on neutron scattering, the magnetic structure of $LiMnO_2$ was supposed to have a propagation vector $\mathbf{k} = [1/2, 1/2, 1/2]$ and a magnetic moment equal to 3.69 μ_B per Mn^{3+} ion and preferentially oriented along the *b* axis. The Néel temperature, which characterises a phase with three-dimensional magnetic order, is 261.5 K;[141] above this value, the effects of short-range 2D order are observed.

Yet another magnetic effect observed in $LiMnO_2$ at 50 K was probably the result of weak ferromagnetism.[139, 141] Its magnitude and the temperature of its manifestation depended on the stoichiometry. It was shown [142] that even a small number of structural defects can radically change the magnetic characteristics of $LiMnO_2$ in this region. The magnetic susceptibilities of $Li_{0.99}MnO_2$, $Li_{1.01}MnO_2$ and $LiMnO_{1.99}$ compositions were measured. Presumably, the manganese ions present in lithium sites which serve as the bridges between the double layers of manganese are the most probable reason for the formation of the three-dimensional magnetic structure.[142] This is why $Li_{0.99}MnO_2$ was assumed to be more prone to three-dimensional ordering than $LiMnO_2$. At the same time, the presence of excess lithium in $Li_{1.01}MnO_2$ should apparently hinder the formation of defects of the Mn_{Li} type and, hence, the formation of the three-demensional magnetic structure. The results obtained for defective samples confirmed this assumption: indeed, the appearance of Mn_{Li} defects favoured the formation of the three-dimensional magnetic structure. An analysis of magnetisation curves have shown the spontaneous magnetisation to increase in the sequence $Li_{1.01}MnO_2$, $Li_{0.99}MnO_2$, $LiMnO_{1.99}$ and to be equal to 0.282, 0.333 and 0.421 G cm^3 g^{-1}, respectively. The coercive force increases in the same sequence: 1100, 2651 and 5974 Œ. The fact that the temperature of magnetic ordering is higher for lithium-deficient and oxygen-deficient compositions compared with stoichiometric $LiMnO_2$ also confirms the hypothesis put forward.

A cubic modification of $LiMnO_2$ obtained at high pressure exhibits antiferromagnetic properties with $T_N = 40$ K, $\Theta = -200$ K and $\mu = 4.90\ \mu_B$.[4]

$LiFeO_2$. At low temperatures, all three modifications of $LiFeO_2$ (α, β and γ) are antiferromagnetically ordered (Fig. 7); the Néel temperature is 42 K for α- and β-$LiFeO_2$ and 295 K for γ-$LiFeO_2$. For all three modifications, the temperature dependences of the magnetic susceptibility were shown to deviate in the paramagnetic region from the Curie – Weiss law, which was

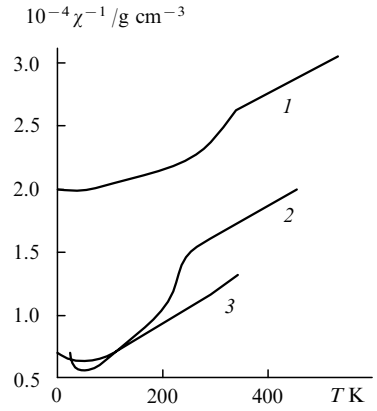

Figure 7. Temperature dependence of the reciprocal magnetic susceptibility of $LiFeO_2$.[57] (*1*) γ- $LiFeO_2$; (*2*) α-$LiFeO_2$: (*3*) β-$LiFeO_2$.

associated with the fact that distributions of iron and lithium ions involve elements of the short-range order. The magnetic structures of α- and γ-$LiFeO_2$ were found [143] in studies on the Mössbauer effect and from the results of neutron scattering. The latter structure is characterised by tetragonal magnetic symmetry with strong antiferromagnetic superexchange coupling of Fe^{3+} ions in (001) planes and much stronger interplane interaction. Magnetic moments of ions are directed along the [001] axis. The magnetic structure of the α-$LiFeO_2$ cubic phase is characterised by ferromagnetically ordered spins inside parallel (111) planes, the latter being antiferromagnetically bound with one another. For this structure to appear, it is necessary that lithium and iron ions are substantially separated in alternate (111) planes. Such a trend was demonstrated by the studies on the Mössbauer effect.

Magnetic properties of a metastable layered modification of $LiFeO_2$ prepared by the hydrothermal method were described.[144, 145] The antiferromagnetic ordering was shown to exist below 20 K. No effects associated with the transition into the spin-glass state typical of the isostructural $LiNiO_2$ phase were observed. It was shown that variations in the degree of cationic ordering affect the Néel temperature.

$LiCoO_2$. Trivalent cobalt in $LiCoO_2$ is in the low-spin state [146] $(t_{2g}^{\alpha})^3 (t_{2g}^{\beta})^3 (e_g)^0$, hence, its magnetic moment is equal to zero. This is why the magnetic susceptibility of $LiCoO_2$ should not depend on the temperature. However, this statement is only true for stoichiometric specimens.[147] The defects present in $LiCoO_{2-x}$ and the attendant paramagnetic centres which are apparently represented by Co^{2+} ions increase the magnetic susceptibility and make it temperature-dependent. This was confirmed by the results of thermogravimetry. The paramagnetic component was also described for $LiCoO_2$ superstoichiometric with respect to lithium.[82]

Above 750 K, the polytherms of magnetic susceptibility of both stoichiometric and defective $LiCoO_2$ were found to ascend reversibly [13, 147] (Fig. 8). Such an increase with the temperature indicated the appearance of paramagnetic centres. The following assumptions on the nature of these centres were drawn.

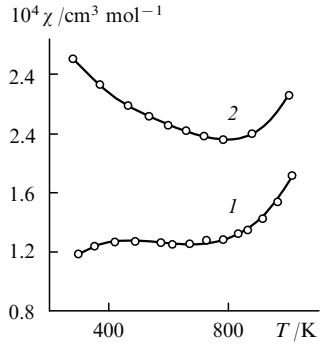

Figure 8. Temperature dependences of the magnetic susceptibility of $LiCoO_2$.[147] (*1*) Synthesis and measurements in an oxygen atmosphere; (*2*) synthesis and measurements under reduced pressure.

1. At temperatures above 750 K, thermally activated centres appear in $LiCoO_2$ as a result of oxygen exchange with the gas phase. The following process of defect formation is possible, which results in the formation of paramagnetic centres Co^{2+} (Co'_{Co}):

$$2Co_{Co} + O_O \longrightarrow (1/2)\,O_2(g) + V_O^{\cdot\cdot} + 2Co'_{Co}\,.$$

The appearance of each oxygen vacancy leads to the formation of two paramagnetic centres.[147]

2. The reason for the increase in the magnetic susceptibility is the transition of Co^{3+} ions to the high-spin state $(t_{2g}^{\alpha})^3 (t_{2g}^{\beta})^1 (e_g)^2$ ($\mu_{ef}^2 = 24\ \mu_B^2$).[13]

The magnetic susceptibility of chemically delithiated $LiCoO_2$ was studied.[92] This was shown to obey the Curie–Weiss law in the temperature interval from 83 to 300 K for all compositions irrespective of the degree of lithium extraction. The values of the effective moment were as follows:

Oxide	$LiCoO_2$	$Li_{0.92}CoO_2$	$Li_{0.76}CoO_2$	$Li_{0.61}CoO_2$
μ_{ef}/μ_B	1.157	1.164	1.731	1.733

The effective magnetic moments of the latter two compositions almost coincided. This was associated with changes in the degree of electron localisation.

$LiNiO_2$. The magnetic properties of layered $LiNiO_2$ depend on both the stoichiometry and the degree of structural order. The results of numerous experiments were often conflicting. This also concerns the manifold interpretations of the data obtained.

Thus it was concluded [96] that magnetic properties of $LiNiO_2$ can adequately be described on an assumption that trivalent nickel ions are in the low-spin state $[(t_{2g}^{\alpha})^3 (t_{2g}^{\beta})^3 (e_g)^1]$. Later, this fact has found an experimental confirmation [148] and was substantiated theoretically.[149] However, in a number of studies (*e.g.*, in Ref. 150), trivalent nickel is assumed to be in the high-spin state $[(t_{2g}^{\alpha})^3 (t_{2g}^{\beta})^2 (e_g)^2]$, which forms a Kramers doublet with $S = 1/2$.

A different viewpoint exists: the magnetic properties of $LiNiO_2$ are determined by the exchange-coupled ($Ni^{2+} - O^{1-}$) pairs.[151] Charge-compensation processes in $LiNiO_2$, which are responsible for the appearance of holes in the oxygen zone, resemble those observed in high-temperature superconductors and were revealed for the first time in the studies of X-ray absorption spectra for the $Li_xNi_{1-x}O$ system.[151] Similar results were obtained in other studies.[152, 153] Calculations [154] confirmed that an electron hole appears in the 2*p* oxygen band rather than in the 3*d* nickel band. However, the fact that such techniques as ^{7}Li NMR and ESR [155] have not confirmed this observation deserves mention.

In a number of studies, the magnetic properties of $LiNiO_2$ were considered in relation to the problem of the ground state of a two-dimensional (2D) triangular lattice antiferromagnet with $S = 1/2$. Thus within the framework of the model of a quantum liquid (resonance valence zone), it was assumed for the first time [156] that the ground state of such systems in the absence of long-range magnetic order has a low energy compared with the classical Néel state. This problem was the subject of wide speculation in the context of the assumption that it is the resonance valence zone that is responsible for high-temperature superconduction in copper complex oxides.[157] The $LiNiO_2$ oxide characterised by $S = 1/2$ and a structure based on face-centred cubic packing of oxygen atoms where nickel and lithium atoms occupy the interstices and form alternate layers (as a result, the interlayer distances substantially exceed those between magnetic atoms inside a layer) can well be described by the aforementioned model.[150, 155, 158, 159]

The magnetic properties of a number of $Li_xNi_{1-x}O$ solid solutions and $LiNiO_2$ as the end member of this series were studied in detail.[96] The main attention was focused on the magnetic transition in the temperature range of 200–300 K (this temperature is usually denoted as T_{N1}), which was claimed to be of the ferromagnetic nature. The dependences of the Curie temperature and magnetisation of $Li_xNi_{1-x}O$ on concentration had maxima at $x = 0.43$ (Fig. 9), and the degree of structural order η [the degree of cationic ordering in (111) alternate planes of the basal NaCl lattice] increased monotonically with an increase in the lithium content and reached a maximum for $LiNiO_2$, which, however, was below 100%. It is the latter observation that explained the fact that magnetic measurements carried out later [97, 98, 160–162] for $LiNiO_2$ samples with a higher degree of structural ordering revealed no magnetic transition described in Ref. 96. Thus, the magnetic ordering is an indicator of $\eta < 1$. The fact that the magnetic properties of $LiNiO_2$ can indicate the structural ordering of a sample stems from the structural peculiarity of perfectly ordered $LiNiO_2$ [namely, the fact that each plane occupied by

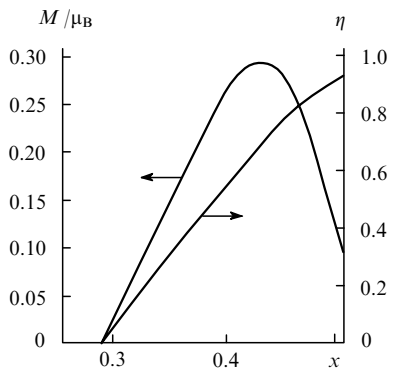

Figure 9. Concentration dependences of magnetisation M and degree of ordering η in $Li_xNi_{1-x}O$.[96]

magnetic ions (Ni^{3+}) is separated from another plane by three nonmagnetic planes (O–Li–O)] and the partial disordering caused by the presence of nickel ions in lithium sites (and *vice versa*).

A complete cationic disordering ($\eta = 0$) is typical of cubic $LiNiO_2$ the magnetic properties of which have been described.[98] The polytherm of its magnetic susceptibility demonstrated an anomalous feature, which allowed the paramagnetic—antiferromagnetic transition at 280 K to be deduced (Fig. 10).

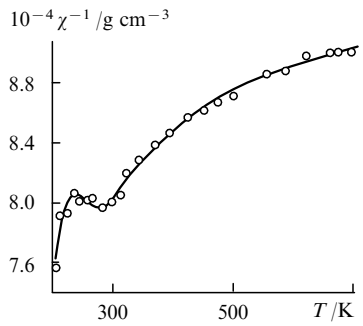

Figure 10. Temperature dependence of the reciprocal magnetic susceptibility of $LiNiO_2$ with the degree of ordering $\eta = 0$.[98]

The magnetic transition occurring in this oxide at 210 K was studied in detail [150, 158, 159]. The magnetic structure of $LiNiO_2$ was simulated on an assumption of a perfect ordering. However, from the synthetic conditions mentioned ($LiOH + Ni_2O_3$; $T = 1100$ K) suggest that the degree of ordering in the samples studied did not exceed $\eta = 0.8$. Below the transition temperature, $LiNiO_2$ was found to exhibit the ferrimagnetic behaviour. However, in contrast to classical ferrimagnetic materials, the field dependence of the magnetisation [$M(H)$] in $LiNiO_2$ was nonlinear below T_{N1}, did not reach saturation and infinitely increased with the field strength according to $M \propto H^{1/\delta}$.

It should be noted that the possibility of assigning the magnetic transition which occurs in $LiNiO_2$ with $\eta < 1$ in the temperature interval of 150–300 K to the ferrimagnetic type [96] was not confirmed later. In neutron diffraction studies,[150, 163] magnetic reflexes were not observed below the transition point even on long-term exposures. The ordering at 240 K was found [161] to be of a ferromagnetic nature. The same conclusion was made in Ref. 98.

In addition to the magnetic transition observed in the region of 150–300 K, the temperature and even the possibility of which depend on the degree of the structural order of $LiNiO_2$, other anomalous magnetic features were observed at lower temperatures. A broad spectrum of mechanisms were invoked for their

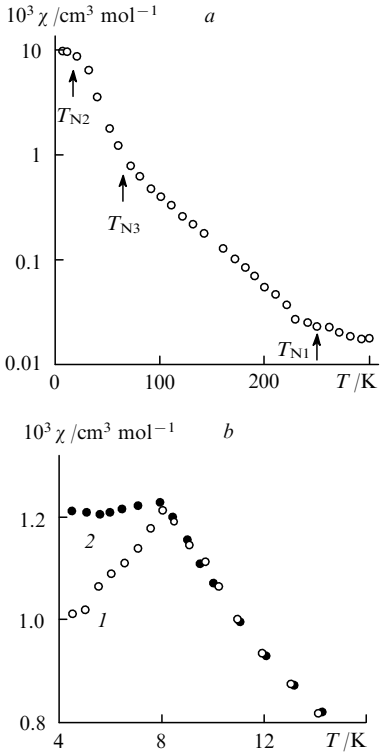

Figure 11. Temperature dependences of the magnetic susceptibility of $LiNiO_2$ measured in an applied field of (*a*) 1000 [165] and (*b*) 10 Œ.[162] (*1*) Cooling in a zero field; (*2*) cooling in a 10-Œ field.

explanation. For example, virtually stoichiometric and perfectly ordered $LiNiO_2$ with Ni–Ni interactions of the 2D type was shown [160, 162, 164] to behave as a typical spin glass. The temperature dependence of the magnetisation measured upon zero-field cooling demonstrated a sharp peak at 9 K (this temperature was denoted as T_{N2}; according to the results of other authors, T_{N2} is 35–50 K, see, *e.g.*, Ref. 165). At the same time, upon cooling in a nonzero field, the magnetic susceptibility increased monotonically (Fig. 11). The frequency dependence of the height and position of the peak, which was obtained by measuring the AC susceptibility, also indicated the attainment of a spin glass state. In certain studies,[159, 166] the state below T_{N2} was considered as the quantum liquid state in which the spins form mobile pairs. The temperature $T_{N2} = 6$ K was claimed [161] to be the Curie temperature for a two-dimensional Ising system. Such a conclusion was drawn by taking into account the fact that the slope of the linear dependence $\ln(M/H)$ *vs.* $\ln(T - T_c)$ was found to be equal to -1.7, which agrees with the critical factor of $-7/4$ for the 2D model of Ising.[167]

The temperature dependence of the magnetic susceptibility of $LiNiO_2$ demonstrated yet another special point in the temperature range from 70 to 80 K, *viz.*, T_{N3}.[165] The values of both T_{N2} and T_{N3} depended on the sample quality.[165] The magnetic behaviour of $LiNiO_2$ at low temperatures can be described as follows.[164]

1. The $T_{N3} < T < T_{N1}$ interval corresponds to nonlinear magnetisation in the external field. The magnetic entropy decreases by 20%. A model of the spin-system inhibition for the antiferromagnetic triangular lattice with the planar short-range order is realised.

2. In the $T_{N2} < T < T_{N3}$ region, magnetisation sharply increases. The magnetic entropy decreases twofold in the absence of any noticeable anomalies which would have indicated the appearance of a long-range magnetic order. The interactions between the layers are assumed to generate the effects of the three-dimensional short-range order.

3. In the $T < T_{N2}$ region, the temperature dependence of the magnetisation tends to saturation. A noticeable residual magnetic

entropy is preserved up to T_{N2}. No anomalies associated with the long-range order are observed. The existence of a frozen spin state somewhat different from that of common spin glasses is assumed. The difference lies in the fact that the temperature dependence of the specific heat is quadratic in the former case and linear in the latter case.

Due to a strong 180-degree aniferromagnetic $Ni_{Li}-O-Ni_{Ni}$ interaction, a ferromagnetic coupling of nickel ions located above and below the Li layer arises, and a small ferromagnetic cluster forms around the Ni_{Li} defect.[168] The existence of such a cluster was proved experimentally by ESR in an applied field of up to 245 GHz.[169] Two types of clusters were observed: those of the first type are formed below 235 K, the other are formed below 120 K. Such a system was proposed to be considered as a superparamagnetic one, *i.e.*, built of separate ferromagnetic domains.[155] The formation of the latter is consistent with the fact that spontaneous magnetisation is suppressed in layered oxides.[170]

Above the temperature of magnetic ordering, the magnetic susceptibility of $LiNiO_2$ is adequately described by the Curie–Weiss law the parameters of which found by different authors differ substantially [μ_{ef} = 1.84 μ_B, Θ = 79.3 K (see Ref. 164); μ_{ef} = 2.2 μ_B, Θ = 2 K (see Ref. 171)]. These parameters also depended on the stoichiometry and the degree of structural order. The temperature dependence of $1/\chi$ in the magnetically disordered region was not smooth and consisted of linear segments.[98] Taking this into account, it was assumed that yet another phase transition takes place in $LiNiO_2$, *viz.*, a paramagnetic–paramagnetic transition. A possible reason for the break observed in $1/\chi$ *vs.* T dependences is the transition of nickel from the low-spin to high-spin state. Table 1 lists the parameters of the Curie–Weiss equation determined for the low-temperature and high-temperature segments of the $1/\chi$ *vs.* T dependences for $LiNiO_2$ samples with different η values. It is noteworthy that the magnetic moments and the Weiss constants of two paramagnetic phases approach one another with an increase in the degree of structural ordering. It appears that these parameters can serve as indicators of the completeness of the cationic ordering in $LiNiO_2$.

Table 1. Magnetic moments and Weiss constants of $LiNiO_2$ with different degrees of structural ordering.[98]

η	T = 200–400 K		T = 600–900 K	
	μ_{ef}/μ_B	Θ /K	μ_{ef}/μ_B	Θ /K
0.67	1.489	185	2.547	−287
0.85	1.751	131	2.201	−87
0.94	1.869	31	2.061	−36
0.98	1.987	33	2.237	−20

It is interesting that $LiNiO_2$, which was shown to be antiferromagnetically ordered in its metastable structurally disordered state and ferromagnetically ordered at sufficiently high degrees of structural ordering [η = 0.6–0.8 (see Ref. 98)], retained its paramagnetic properties up to the liquid helium temperature for the case of perfect ordering. The latter observation can be explained by the fact that, as was shown by de Jongh and Miedema,[172] two-dimensional Heisenberg systems which apparently involve the perfectly ordered $LiNiO_2$ oxide [98] have no long-range magnetic order. The experimentally observed phase transitions in these systems were caused by deviations from the ideal behaviour, which resulted in an interaction arising between the layers. For example, $(C_nH_{2n+1}NH_3)Cu_4Cl_2$ (see Ref. 173) with a small number of nonmagnetic layers separating the magnetic layers has ferromagnetic properties, while the same substance with a greater number of nonmagnetic layers exhibits no ferromagnetism. For $LiNiO_2$, it is those nickel ions which occur in the lithium layers due to partial disordering that are responsible for the interlayer interaction.

In view of the fact that the degree of structural order in $LiNiO_2$ is closely related to stoichiometry, the magnetic properties depend even on small changes in x in $Li_{1-x}Ni_{1+x}O_2$. This was confirmed in a study [160] in which it was shown that samples with $x \leqslant 0.01$ demonstrate a thermomagnetic hysteresis typical of a spin glass at 8 K, whereas samples with $x \approx 0.08$ exhibit spontaneous magnetisation at 5 K, which corresponds to a magnetic moment of ~ 0.3 μ_B/Ni. Similar results were obtained in another study [174]: it was observed that $LiNiO_2$ is a spin glass, in contrast to $Li_{0.93}Ni_{1.07}O_2$.

IV. Structure and magnetic properties of $LiM_{1-x}M'_xO_2$ solid solutions

The $LiMO_2$ oxides under consideration can form solid solutions. The attention paid to solid solutions, first of all, is associated with the prospects of stabilising the structural types which can be used as cathodic materials in electrochemical devices. Moreover, solid solutions formed by compounds with different types of cationic ordering are interesting from the viewpoint of studying the short-range order effect, the three-dimensional–two-dimensional structural transitions and the formation of new superstructures.

$LiNi_{1-x}Co_xO_2$ ($0 \leqslant x \leqslant 1$). Oxides $LiNiO_2$ and $LiCoO_2$ form a continuous series of solid solutions, which, like the original phases, have a trigonal structure with the $R\bar{3}m$ symmetry. With a decrease in the content of cobalt (the ionic radius of which is smaller than that of nickel), the cell parameters a and c decrease monotonically. However, the concentration dependence of the c/a ratio is not monotonic, and for x = 0.3 its slope changes, *i.e.*, the increase in the c/a ratio slows down.[175] This result was reproduced in another study;[176] however, the authors of the latter study have attributed the singular point to the composition with x = 0.5. In their opinion, an increase in c/a from 4.96 (x = 0.5) to 4.99 (x = 1) does not bring about mixing of lithium and nickel ions in the octahedral positions of the hexagonal face-centred lattice. The value c/a = 4.99 corresponds to a perfect hexagonal unit cell. For smaller c/a values and hence for higher nickel concentrations, partial cationic disordering takes place, which results in a deviation of the $LiNi_{1-x}Co_xO_2$ symmetry from the ideal hexagonal towards the parent cubic one. For a perfect close-packed structure of the $Fm\bar{3}m$ symmetry, c/a = 4.90. Based on the results of X-ray diffraction analysis (the Rietveld method), it was found [177] that, at low cobalt contents ($x \leqslant 0.2$), the excessive bivalent nickel ions are always present in solid solutions studied: $Li_{1-z}Ni_{1+z-t}Co_tO_2$ [$t = x(1 + z)$]. An increase in the cobalt content reduces the nonstoichiometry and stabilises the 2D structure.

The stabilising effect cobalt has on the 2D structure of the solid solution also manifests itself in electrochemical intercalation. Phase transitions that take place during electrochemical intercalation of $LiNiO_2$ do not occur in solid solutions.[178] This is explained by the fact that cobalt suppresses the ordering of lithium vacancies. At the same time, it is noteworthy that deep chemical extraction of lithium from solid solutions enriched with nickel results in a monoclinic distortion of the lattice.[179]

To avoid the distortion of the regular layered structure (2D) of $LiNi_{1-x}Co_xO_2$ solid solutions, the low-temperature synthetic methods were applied, using, *e.g.*, β-$Ni_{1-y}Co_yOOH$ [180] or $Ni_{1-y}Co_y(OH)_2$[181] as the starting materials. Solid solutions with minimum cationic disordering were obtained by the sol–gel method [182, 183] (this also refers to pure $LiNiO_2$), pyrolysis [184] and co-precipitation from solutions.[185]

^{6}Li and ^{7}Li NMR studies on $LiNi_{1-x}Co_xO_2$ solid solutions ($0 \leqslant x \leqslant 1$) carried out in both static and dynamic modes [186, 187] have revealed structural microheterogeneities unrelated to the cationic ordering. These microheterogeneities did not cause any phase formation and could not be revealed by the diffraction techniques. They represented clusters of several cobalt atoms.

A magnetic phase diagram (Fig. 12) was constructed based on the results of detailed studies of magnetic properties of $LiNi_{1-x}Co_xO_2$ solid solutions ($0 \leqslant x \leqslant 1$).[188] A model was pro-

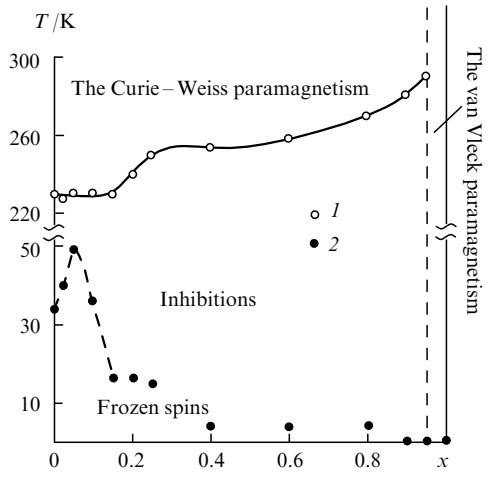

Figure 12. Magnetic phase diagram of $LiNiO_2-LiCoO_2$ system.[188] (*1*) T_{N1}; (*2*) T_{N2}.

posed that described the magnetic properties of both $LiNiO_2$ and $LiNi_{1-x}Co_xO_2$. This model is based on an assumption of an antiferromagnetic interaction within a layer and a weak ferromagnetic bonding between the layers. A conclusion that a system of three sublattices is unstable which was drawn from this model is of prime importance. It is with this conclusion that the absence of magnetic reflexes (1/3 1/3 *n*) is related.

The data on $LiNi_{1-x}Co_xO_2$ solid solutions additionally doped with manganese,[189] magnesium [190] and strontium [191] can be found in the literature.

$LiNi_{1-x}Ti_xO_2$ ($0 \leqslant x \leqslant 0.5$). According to the results of X-ray analysis,[192] the solid solutions with $0 \leqslant x \leqslant 0.3$ are isostructural to the layered $LiNiO_2$. At a higher titanium content, the structure becomes cubic, due to complete cationic disordering. The structural data refined using the Rietveld technique indicated that $LiNi_{0.7}Ti_{0.3}O_2$ also involves a certain number of transition metal ions in the lithium layers; hence, the regular two-dimensional structure is distorted. It is of note that these layers involve bivalent nickel and trivalent titanium. This result was obtained by means of the XPS technique. The authors of this study [192] did not mention the mechanism of the charge compensation in $LiNi_{0.7}Ti_{0.3}O_2$ solid solutions which involve Ni^{2+} ions: whether a certain number of titanium ions appears or the oxygen content changes. It should be noted that the degee of oxidation of Ti (Ti^{3+}) is not typical of titanium compounds synthesised in air at sufficiently high temperatures, *i.e.*, under conditions in which the solid solutions under discussion have been prepared.

$LiNi_{1-x}Mn_xO_2$. Solid solutions isostructural to $LiNiO_2$ were studied.[193–199] Certain cationic disordering was described [197] within the frameworks of the hexagonal structure and later confirmed.[193] To stabilise the trivalent state of nickel ions and thereby stabilise the layered structure, a special procedure of coprecipitation in an oxidative medium was developed.[193] As a result, solid solutions with the composition $LiNi_{1-x}Mn_xO_{2+\delta}$ ($0 \leqslant x \leqslant 0.5$) were obtained. The oxidation states of the transition metals in these solid solutions were determined by measuring the magnetic susceptibilities. It was shown that both transition metals in the sample bulk are in the trivalent state, whereas traces of Mn^{4+} were detected on the surface. All solid solutions studied exhibited a ferromagnetic transition at a temperature (T_C) which increased with the manganese content. The exception was pure $LiNiO_2$, which is characterised by a strong interlayer ferromagnetic interaction of the Ni(3*b*)–O–Ni(3*a*)–O–Ni(3*b*) type responsible for the high T_C. The existence of the ferromagnetic transition both in pure $LiNiO_2$ and $LiNi_{1-x}Mn_xO_{2+\delta}$ solid solutions points to the incomplete cationic ordering and to the presence of transition metal ions in the lithium layers. Table 2 shows the magnetic characteristics of $LiNi_{1-x}Mn_xO_{2+\delta}$ ($0 \leqslant x \leqslant 0.5$).

Table 2. Magnetic characteristics of $LiNi_{1-x}Mn_xO_{2+\delta}$ ($0 \leqslant x \leqslant 0.5$).[193]

0.4	−96	3.0	3.00	72
0.5	−107	3.3	3.32	88

$LiNi_{1-x}Fe_xO_2$. The $LiNi_{1-x}Fe_xO_2$ system demonstrates two types of solid solution. Compositions with $0 < x < 0.22$ are isostructural to $LiNiO_2$. Their degree of ordering gradually decreases, which manifests itself in weaker X-ray reflections superstructural to those of the sodium chloride cubic lattice. Moreover, cubic solid solutions are formed in the concentration interval of $0.42 < x < 1$. In the intermediate region, two phases are present.[200–202] By studying this systems, one can follow the changes in the magnetic properties that occur with a decrease in the dimensionality from 3D ($LiFeO_2$) to 2D ($LiNiO_2$).

At $T > 300$ K, the magnetic susceptibilities of all $LiNi_{1-x}Fe_xO_2$ compositions obey the Curie–Weiss law. The first group of solid solutions is characterised by a transition to a magnetically ordered phase. The transition temperature and spontaneous magnetisation both increase with the iron content. The presence of magnetic ordering in the interval from 150 to 200 K points to partial cationic disordering, *i.e.*, the presence of a certain amount of transition metal ions in the Li layers. These results were confirmed by crystallographic data.[203] For a composition with 20% iron, the distribution of cations over positions is: $[Li_{0.965}M_{0.035}]_{3b}[M_{0.965}Li_{0.035}]_{3a}O_2$, M = 0.2Fe + 0.8Ni.

The fact that X-ray patterns of the second group of solid solutions involve no lines superstructural with respect to the NaCl lattice unambiguously indicates that the ions of alkali and transition metals are not ordered in the planes, in contrast to $LiNiO_2$. Nonetheless, at $T < 200$ K, the magnetic susceptibility of this solid-solution group depends on the field strength. This dependence becomes more pronounced with an increase in the nickel content, which points to a magnetic ordering.[201] The magnetisation polytherms statistically processed using the technique of thermodynamic coefficients have revealed no spontaneous magnetisation. Hence, the nonlinear variation of magnetisation for structurally disordered samples is a result of the short-range order associated with the trend of nickel ions for aggregation within the framework of this structure. In other words, the exchange couplings, which are the reason for the magnetic ordering, are limited in solid solutions by certain atomic ensembles. In this case, the condition for percolation do not arise. Such a system is considered [201] as a superparamagnetic one. Based on the concepts mentioned, the cluster size was estimated. The volume of magnetic clusters increased with the nickel content in the cubic solid solution phase, and, at a nickel concentration above 43%, the system first became two-phase and then a hexagonal one.

The number of atoms in clusters (*n*) and the mean size (*d*) of the latter for the superparamagnetic region of $LiFe_{1-x}Ni_xO_2$ are as follows:[201]

x	0.1	0.2	0.3	0.4
n	17	28	38	116
d /Å	7	8	9	13

$LiMn_{1-x}Co_xO_2$ ($0 \leqslant x \leqslant 1$). This group of solid solutions was studied by two groups of researchers.[204, 205] The lattice type was found to be determined by the ratio of transition metal

ions;[205] for $x < 0.2$, oxides with trigonal structures are formed, for $0.2 \leqslant x \leqslant 0.7$, cubic structures are realised and, for higher manganese contents, the symmetry of solutions is tetragonal ($I4_1/amd$). It should be noted that, to obtain solid solutions in the $0.2 \leqslant x \leqslant 1$ concentration interval, the synthesis was carried out in a nitrogen atmosphere.

A different way [205] was chosen for synthesising solid solutions of two layered compounds, *viz*., $LiCoO_2$ and Li_2MnO_3. It was shown that in order to prepare a solid solution (rather than a mechanical mixture of the extreme members), the synthesis should be carried out with an excess of lithium. All solid solutions thus obtained had monoclinic structures. The transformation of a trigonal (hexagonal) unit cell of $LiCoO_2$ into a monoclinic one is expressed as follows (for parameter a as an example):

$$a_h = \frac{1}{\sqrt{3}} a_m .$$

The magnetic properties of $LiMn_{1-x}Co_xO_2$ solid solutions ($0 \leqslant x \leqslant 1$) formed by diamagnetic $LiCoO_2$ and antiferromagnetic $LiMnO_2$ [$T_N = 50$ K, $\Theta = -33$ K, $\mu_{ef} = 3.83\ \mu_B$ (see Ref. 206)] change nonmonotonically: the compounds are paramagnetic for $x \leqslant 0.5$ and the antiferromagnetic transition is observed for higher manganese content. The analysis of the concentration dependence of the effective magnetic moment showed that the oxidation state of manganese is Mn^{4+} for the manganese content > 75%, whereas for its content < 75% the presence of trivalent manganese ions may be assumed.

Methods for the synthesis of $LiMn_{1-x}Co_xO_2$ solid solutions and of $LiMn_{1-x}Ni_xO_2$ and $LiMn_{1-x}Fe_xO_2$ solid solutions with layered structures have been discussed.[207]

$LiCr_{1-x}Fe_xO_2$. This system was studied for both polycrystalline specimens and single crystals.[208] Like $LiNi_{1-x}Fe_xO_2$, this system is formed by two phases, one of which has an ordered layered structure and another has a cubic lattice characterised by a random distribution of metal ions over the lattice positions. It was found that the transition from the cubic structure to trigonal one corresponds to the solution with 73% $LiFeO_2$. A somewhat different value ($\sim 85\%$) was found in another study.[209] The magnetic susceptibility of structurally ordered compositions was shown to have anomalies in the vicinity of 50 K. These anomalies seem to indicate the three-dimensional order. Above the mentioned temperature, the magnetic interactions corresponded to two-dimensional interactions. An analysis of the Mössbauer spectra has shown [210] that 2D interactions also play the key role at low temperatures. At temperatures above 400–600 K, the variation of the magnetic susceptibility obeys the Curie–Weiss law. Table 3 shows the magnetic characteristics of the system. Divergence between experimental and calculated values of the magnetic moment was attributed to anisotropy of magnetic interactions.

In order to explain the parabolic shape of the dependence of the Weiss constant (Θ) on the concentration, the exchange-coupling parameters were separated and the intra- (J_1) and interlayer (J_2) exchange-coupling constants were estimated based on the data from the magnetic susceptibility). In addition, the partial values of the Weiss constants related to different types of coupling were obtained. Thus for interlayer interactions, $\Theta_2^{Cr-Cr} = -185$ K, $\Theta_2^{Cr-Fe} = 59$ K and $\Theta_2^{Fe-Fe} = -30$ K.

$LiV_{1-x}Mg_xO_2$ and **$LiV_{1-x}Al_xO_2$**. These systems were synthesised and studied [211] with the aim of following how the partial substitution of vanadium for an ion with a spin $S \neq 1$ in $LiVO_2$ affects the structural and magnetic parameters of the phase transition. It was assumed that the first system involves V^{2+} ions with $S = 3/2$ and the second system involves Al^{3+} with $S = 0$; the solid solutions have sufficiently narrow homogeneity regions, *viz*., $0 \leqslant x \leqslant 0.06$ and $0 \leqslant x \leqslant 0.1$, respectively. In both systems, the phase transition temperatures were lower than those of pure $LiVO_2$. Moreover, a weak but systematic decrease in the Curie constant was observed in the low-temperature region, which indicated that 'triangular' clusters $V^{3+}-V^{2+}-V^{3+}$ with $S = 1/2$ separated by singlet trimers contributed to the overall susceptibility. Based on these studies, it was concluded that the exchange-coupling constant of V^{3+} ions and the transition temperature both depend on the V–V distance and on the shift of vanadium ions from their positions.

Other solid solutions. Information on $LiAl_xNi_{1-x}O_2$ solid solutions ($x \leqslant 0.25$) with the $LiNiO_2$ structure is availiable.[212, 213] With an increase in the aluminium content, the c/a ratio somewhat increases. It is noteworthy that introduction of aluminium in $LiMO_2$ compounds is considered as one of the factors that stabilise the α-$NaFeO_2$-type layered structure, the latter being the most suitable from the electrochemical viewpoint. Calculations of miscibility carried out for eight compositions of the $LiAl_{1-x}M_xO_2$ system have shown [214] that for M = Ti, V, Cr and Mn layered solid solutions are formed at the temperatures of the conventional synthesis. For M = Fe, Co, Ni and Cu, a low temperature region of immiscibility exists. Special attention was given to $LiAl_{1-x}Co_xO_2$ and $LiAl_{1-x}Cr_xO_2$ systems, which, according to calculations, were completely miscible up to 600 °C. Limitations that arose at higher temperatures were associated with the transition of $LiAlO_2$ into a tetragonal γ-modification.[215] It was experimentally shown [216] that the synthesis carried out at 650 K results in an amorphous modification, whereas at 700–900 K a layered hexagonal structure is formed. It is essential that in $LiAl_{1-x}Co_xO_2$ as well as in $LiAl_{1-x}Ni_xO_2$ aluminium can be shifted from octahedral positions.[217] Synthesis of $LiAl_{1-x}Cr_xO_2$ solid solutions ($0 \leqslant x \leqslant 1$) was described.[218]

Solubility of aluminium in $LiMnO_2$ reached a maximum (5%–7%) at 1220 K.[219] As in the previous case, the existence of the maximum was explained by the formation of γ-$LiAlO_2$. Introduction of even minor amounts of aluminium to $LiMnO_2$ gives rise to a layered structure of the $NaFeO_2$ type. The use of chromium as the dopant led to a similar result.[220]

In addition, the possibility of formation of $LiCr_{1-x}Co_xO_2$, $LiCr_{1-x}Ni_xO_2$,[221] $LiFe_{1-x}Co_xO_2$ [222] and $LiNi_{1-x}B_xO_2$ [223] solutions was demonstrated.

Table 3. Magnetic characteristics of $LiCr_{1-x}Fe_xO_2$.[210]

V. Conclusion

Complex oxides with the general formula $LiMO_2$ where M is a trivalent transition 3*d* metal are considered as inorganic functional materials of a new generation.[224,225] First of all, this is associated with their good electrochemical characteristics. This factor has stimulated numerous studies not only in applied but also in fundamental directions. Of prime importance are structural and magnetic studies, because the layered structure characteristic of many $LiMO_2$ compounds not only provides adequate diffusion of the alkali metal atoms, which is essential for electrochemical processes, but also is of special interest from the viewpoint of studying low-dimensional magnetic interactions.

At present, the crystal structure of $LiMO_2$ is sufficiently thoroughly described for all stable modifications, and efforts are mainly concentrated on the synthesis and structural description of metastable phases preferentially with layered structures of the α-$NaFeO_2$ type.

The results of investigations of the magnetic properties of $LiMO_2$ show that structural defects may often play the key role in the formation of magnetic structures. First of all, this refers to compounds with variable degrees of structural order.

V. Conclusion 799

Abstract. Data on the heterophase polymerisation of styrene under conditions of surfactant formation at the monomer – water interface are generalised. A new, in principle, approach is proposed the essence of which is to obtain a monomer emulsion simultaneously with the synthesis of an emulsifier at the monomer – water interface and with initiation of the polymerisation in the interfacial layer. The preparation of surfactants at the interface allows one to control efficiently the degree of dispersion and the stability of the emulsions formed. By varying the nature of the acid and the metal counter-ion used in the surfactant synthesis at the interface, it is possible to change the interfacial tension, to influence the microemulsification, disintegration of the monomer, and the formation of structure of interfacial adsorption layers. The mechanism of formation of polymer-monomeric particles as well as their diameter and size distribution depend substantially on the solubility of the resulting surfactants in water. The bibliography includes 47 references.

I. Introduction

For several decades, researchers' assumptions concerning the compositions of monomer emulsions and the patterns of emulsion polymerisation have been based on the Harkins – Yurzhenko views; these also underlie the only existing quantitative theory (the Smith – Ewart theory).[1–4] However, numerous deviations of experimental data from theoretical predictions have stipulated the search for new approaches to the description of this process. These deviations have been detected even in a study of styrene polymerisation initiated by potassium persulfate carried out in the presence of an ionic emulsifier, which is exactly the reaction that served initially as the basis for the Smith – Ewart theory. The problem of description of emulsion polymerisation became especially topical after the appearance of results which could not be predicted by existing theories. Thus the occurrence of a quasi-spontaneous microemulsification of the monomer at phase interface has been observed;[5,6] polystyrene microbeads with a narrow size distribution have been prepared in the absence of surfactants;[7,8] the governing role of the composition of monomer emulsions in the mechanism of formation of polymer-monomeric particles (PMP) and its influence on the particle size distribution have been established.[9–14]

Detailed study of emulsions of monomers with various natures — styrene, methyl methacrylate, chloroprene, isoprene, mixtures of polar and non-polar monomers (for example, styrene and methacrylic acid) —has shown[15–19] that the emulsion composition and the degree of dispersion can be controllable. For example, the addition of water-insoluble surfactants to the monomer phase of the emulsion or to the other phase gives rise to emulsions consisting mainly of monomer microdroplets. Meanwhile, emulsions prepared in the presence of sodium alkylsulfonate insoluble in the monomer consist of emulsifier micelles and monomer macrodroplets. Thus, the procedure used to prepare the initial emulsion of the monomer (or monomers) can pre-determine the particle diameter in the polymer suspension and the size distribution of particles.

It has been proposed to perform heterophase polymerisation of monomers with simultaneous synthesis of a surfactant at the phase interface in order to control the emulsion composition. This polymerisation method differs essentially from the commonly accepted one,[20–26] as becomes obvious already when the initial monomer emulsion is prepared.

Traditionally, a monomer and an aqueous solution of an emulsifier are stirred at a rotational velocity of 600 – 800 rpm until a uniform emulsion is produced. The size of monomer droplets in this emulsion depends on the rotational velocity, interfacial tension ($\sigma_{1,2}$) and temperature. The size of monomer droplets and the nature of the surfactant influence the emulsion stability. Various stability factors act in the interfacial adsorption layer (IAL). The surfactant concentration in the IAL is determined by the surfactant capability of being adsorbed at the surface of droplets. Since the surfactant concentration is usually higher than the critical micelle concentration (CMC), it is generally accepted that the initial emulsion consists of surfactant micelles, which solubilise the monomer, and of monomer macrodroplets.

The method used to prepare the initial emulsion for polymerisation under conditions of surfactant synthesis at the interface differs in principle from the above-described one. In this case, a long-chain carboxylic acid is dissolved preliminarily in the mono-

mer phase, while an alkali is dissolved in the aqueous phase. This procedure gives a fine emulsion of the monomer, owing to the significant decrease in the interfacial tension caused by the fact that the emulsifier formed in the neutralisation reaction is accumulated in the interfacial layer. In this case, the interfacial tension decreases much more significantly than in the case when the same emulsifier is adsorbed on the surface of droplets from the aqueous phase in the conventional preparation of the emulsion (< 1 and ~ 10 mN m^{-1}, respectively).

The degree of dispersion of the resulting emulsion must also depend on the nature of the emulsifier synthesised at the interface. For example, if the emulsifier is soluble both in the monomer and in water, its mass transfer through the interface takes place in conformity with the partition coefficient, the stability of the interfacial boundary is degraded, and the monomer undergoes disintegration and microemulsification. In this case, apart from monomer droplets, the resulting emulsion contains monomer microdroplets and emulsifier micelles if the emulsifier content in the aqueous phase is greater than that required for stabilisation of monomer droplets and microdroplets.

The composition of the monomer emulsion determines the mechanism of formation and the diameter distribution of the PMP. When the PMP are formed from emulsifier micelles and monomer microdroplets, the polymer suspension contains particles of different sizes (with diameters from 0.06 to 0.4 μm) and is characterised by a broad size distribution.

Polymerisation of an emulsion consisting of monomer microdroplets affords a polymer suspension with an average particle diameter of 0.08 to 0.7 μm, depending on the structure and the surface-active properties of the emulsifier synthesised at the interface.

The particle size distribution (PSD) depends on the stability of the PMP during the synthesis. If some factors providing stabilisation of the interfacial adsorption layer arise at initial stages of monomer conversion, the PSD is narrow.

This review describes new approaches to the control of the composition of monomer emulsions. These methods allow the preparation of polymer suspensions with particles of different diameters and with a narrow PSD.

II. Surface properties of the potassium salts of carboxylic acids with alkyl substituents of different lengths and the composition of styrene emulsions prepared during their formation at the interface

In several studies,[20–26] salts of oleic acid, salts of saturated fatty acids with the $C_{11}-C_{25}$ hydrocarbon chains, and the potassium soap from disproportionated rosin have been used as the objects of investigation.

The interfacial tension $\sigma_{1,2}$ at the styrene–water interface decreases from 42.2 to 30.8 mN m^{-1} over the homologous series from lauric to cerotic acid. For none of the acids does the interfacial tension depend on the time the surface has existed, *i.e.*, adsorption of the acid is not the limiting stage of the surfactant formation. However, the interfacial tension sharply decreases with an increase in the alkali concentration to reach ~ 1 mN m^{-1} for an alkali content in water of 10^{-2} mass %.

Figure 1 presents the data on the neutralisation kinetics of oleic acid with potassium hydroxide at the styrene–water interface at a temperature of 20 °C. The data were gained by gravimetry (curve *1*) and refractometry (curve *2*). It can be seen that neutralisation is almost completed over a period of several minutes. After 5–10 min, the concentration of potassium oleate in water becomes ~ 4 mass %.

The substantial difference between the interfacial tension at the interface between styrene solutions of lauric acid of various concentrations and aqueous solutions of alkali in the synthesis of potassium laurate and the interfacial tension for the adsorption of the same emulsifier from the aqueous phase is illustrated in Fig. 2.

When potassium laurate is synthesised at the interface, the interfacial tension is less than 1 mN m^{-1}, whereas this value for the interface between an aqueous solution of potassium laurate, on the one hand, and styrene, on the other hand, is $\sigma_{1,2} = 8$ mN m^{-1}.

The isotherms of interfacial tension were used to calculate the limiting adsorption value (Γ_{max}), the area occupied by one surfactant molecule in a saturated adsorption layer (S_{min}) and the surface activity of the surfactant (G) (Table 1). It can be seen that for the formation of emulsifiers at the interface, the G value markedly increases, Γ_{max} also increases, and S_{min} decreases.

The procedure of formation of emulsions should have a pronounced influence on the formation and properties of the interfacial adsorption layers on the surface of monomer droplets.[27–30] Indeed, when the monomer is emulsified by an aqueous solution of an emulsifier, the interfacial layer is formed by the molecules of a highly ionised carboxylic acid salt adsorbed from the aqueous phase, and when the emulsifier is synthesised at the interface, this layer is formed initially by the adsorbed molecules of the carboxylic acid and after neutralisation, it is formed by salt molecules.

The instability of the phase interface caused by the chemical synthesis of the emulsifier taking place in the boundary layer and the emulsifier mass transfer to the aqueous phase, which are accompanied by the transformation of the chemical reaction energy directly into the surface energy,[31–33] result in effective fragmentation of monomer droplets and monomer microemulsification. This influences, first of all, the average diameter of the droplets of the monomer emulsion. If the emulsion is prepared

Table 1. Surface properties of emulsifiers at the interface.

Emulsifier	The way of introducing the emulsifier [a]	$10^6\Gamma_{max}$ /mol m^{-2}	S_{min} /nm^2	G /mN m^2 mol^{-1}
Potassium laurate	A	4.0	0.41	18
	B	6.4	0.26	84

Potassium cerotate	A	2.9	0.58	12
	B	9.6	0.18	33

[a] A — the emulsifier is introduced in the aqueous phase, B — the emulsifier is formed at the interface.

under conditions of synthesis of potassium laurate and the potassium soap from disproportionated rosin at the interface, the average diameter of monomer droplets is $\sim$2 times smaller than that for the case of monomer emulsification by an aqueous solution of the surfactant (10 and 20 μm, respectively).

Study of monomer microemulsification under static conditions has shown [20] that the intensity of this process depends on the method for the preparation of emulsions. In a styrene emulsion prepared with the formation of the emulsifier at the interface, the volume of the microemulsion layer is several times as great as that at the interface between styrene and an aqueous solution of the emulsifier. This can be clearly seen when considering the preparation of styrene emulsions by these methods in the presence of rosin soap (Fig. 3). A large volume of the microemulsion increases the emulsion stability. For example, styrene emulsions prepared with the formation of ionogenic surfactants at the interface are 5–10 times as stable as the emulsions formed upon emulsification of the monomer by an aqueous solution of the emulsifier.

Procedures making use of small-angle X-ray diffraction and electron microscopy of liquid–liquid systems have been developed to study the composition of styrene emulsions. Using these procedures, the degrees of dispersion of liquid–liquid systems can be studied without hardening the monomer phase.[34, 35]

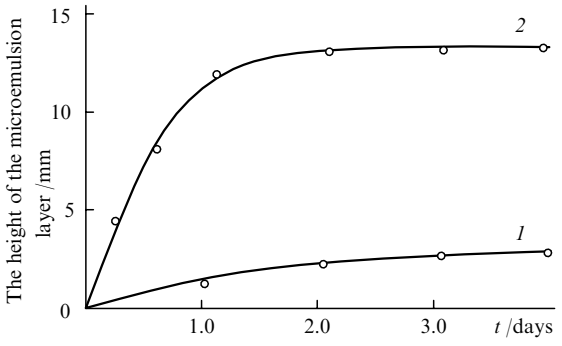

Figure 3. Variation of the height of a microemulsion layer under static conditions at the interfaces 'styrene–aqueous solutions of the rosin soap' (*1*) and 'styrene solution of rosin–an equimolar aqueous solution of KOH' (*2*). Emulsifier concentration is 1.1×10^{-2} mol litre^{-1}, 25 °C.

X-Ray diffraction and electron-microscopic investigations [22, 23] of styrene emulsions prepared with the synthesis of potassium carboxylates at the interface showed that they contain particles of various sizes, namely, monomer macrodroplets with a size of not more than 10 μm, monomer microdroplets 0.03–0.04 μm in diameter, and emulsifier micelles with a size of 0.003–0.005 μm. The surfactant concentration calculated for the aqueous phase equals 2 mass %–5 mass %, which is 50–100 times as high as the CMC.

If the concentration of the emulsifier formed at the interface is decreased to the level sufficient only for stabilisation of monomer microdroplets, the surfactant content in the aqueous phase would be lower than the CMC and the formation of emulsifier micelles would become impossible. In this case, the emulsion would mainly consist of monomer microdroplets. This situation has been realised in the preparation of styrene emulsions under conditions of synthesis of potassium carboxylates at the interface. It can be seen from the data presented in Table 2 that the emulsifier concentration corresponding to the minimum $\sigma_{1,2}$ values in the aqueous phase is several times lower than that corresponding to complete neutralisation of the acid. This means that some of the surfactant is consumed for the formation of the adsorption layer on the surface of monomer droplets and microdroplets.

Table 2. Variation of the emulsifier concentration during neutralisation of the acid under static conditions (25 °C, overall time of reaction 24 h).

Emulsifier	Total emulsifier concentration /mass %	Emulsifier concentration in the aqueous phase at $\sigma_{1,2\,min}$ /mass %
Potassium laurate	0.15	0.08
(CMC 0.22%)	0.25	0.10
	0.50	0.21
	4.00	1.00
Potassium oleate	0.15	0.02
(CMC 0.04%)	0.25	0.04
	0.50	0.12
	4.00	1.50

The critical micelle concentration of the emulsifier in the aqueous phase is attained only in the case where the acid concentration in the monomer phase exceeds 0.5 mass % with respect to styrene.[36] As was to be expected, the lithium salts of acids have lower concentrations in the aqueous phase than the potassium salts.

Since all the salts synthesised at the interface are soluble in water, effective mass transfer of these salts to the aqueous phase takes place as well as quasi-spontaneous emulsification of the monomer and the formation of microemulsions as a quite visible white belt.

Under dynamic conditions, the CMC of the emulsifier in the aqueous phase is attained when the acid concentration in the monomer phase is >1 mass %. This is twice that in the synthesis of surfactants under static conditions; this is explained by the increase in the interfacial area owing to stirring and to the consumption of the emulsifier for the stabilisation of monomer droplets and microdroplets.

Thus, if the concentration of the emulsifiers (potassium carboxylates) formed at the interface is 0.5 mass % relative to the monomer, the initial emulsion of styrene contains only monomer microdroplets because the rest of the emulsifier is spent for their stabilisation. This means that, upon initiation of polymerisation in these emulsions, the polymer-monomeric particles would be formed from monomer droplets and the polymer suspensions would have a narrow particle size distribution.

III. Bulk properties of the salts of carboxylic acids sparingly soluble or virtually insoluble in water and the composition of styrene emulsions formed in parallel with their synthesis at the interface

The solubility of lithium salts of carboxylic acids in water exceeds only slightly the CMC. Thus the solubilities of lithium laurate, stearate and oleate at 50 °C are 0.28 mass %, 0.10 mass % and 0.13 mass %, while the CMC values are 0.25 mass % – 0.30 mass %, 0.07 mass % and 0.12 mass %, respectively.[37] The solubilities of the barium, calcium and zinc salts of the same acids in water do not exceed 0.004 – 0.008 g per 100 g of water. The Li, Ba, Ca and Zn salts are also virtually insoluble in the organic phase, in particular, in styrene.[37]

Analysis of the interfacial tension isotherms shows that the surface tension for the formation of lithium, barium, calcium and zinc myristates at the styrene – water interface is of the order of 21 – 31 mN m^{-1}, whilst potassium myristates decrease the interfacial tension almost to zero (Fig. 4).

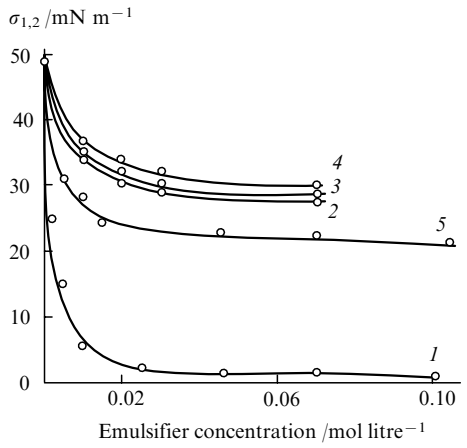

Figure 4. Interfacial tension at the interfaces 'styrene solution of myristic acid – aqueous solution of potassium (*1*), barium (*2*), calcium (*3*), zinc (*4*), or lithium (*5*) hydroxide' *vs*. emulsifier concentration. The time of droplet formation is 20 s, 20 °C.

The surfactants insoluble in both phases exhibit a much lower (by a factor of 10 – 20) surface activities than water-soluble potassium myristate (Table 3). Lithium myristate occupies an intermediate position; its surface activity at the styrene – water interface is 3 – 6 times higher than those of the barium, calcium, and zinc salts but is ~3 times lower than the activity of the potassium salt.

Emulsions prepared under the conditions of formation of potassium myristate at the interface are 2 – 3 times as stable as emulsions prepared in parallel with the synthesis of lithium, barium, calcium and zinc salts (all other conditions being the same), which is due to the formation of microemulsions at the surface of monomer droplets.

Table 3. Surface properties of emulsifiers at the styrene – water interface.

Emulsifier	G /mN m^2 mol^{-1}	$\sigma_{1,2\,min}$ /mN m^{-1}
Potassium myristate	67.0	< 0.5
Lithium myristate	22.5	20.6
Barium myristate	7.3	27.1
Calcium myristate	5.4	28.7
Zinc myristate	3.5	30.2

Table 4. Size of particles in an emulsion of styrene prepared with simultaneous synthesis of surfactants of various natures at the interface (styrene : water volume ratio of the phases 1 : 2, surfactant concentration in the aqueous phase 0.084 mol litre^{-1}).

Surfactant	Method used to determine the particle size [a]	Particle size [b] /nm

	SAXD	34
	EM	36
Lithium stearate	LCS	120
	EM	115
Lithium laurate	LCS	210
	EM	200
Barium stearate	LCS	500
Zinc stearate	LCS	490

[a] SAXD is small-angle X-ray diffraction, EM is electron microscopy, LCS is laser correlation spectroscopy; [b] The first line in the column implies the size of surfactant micelles, while the other numbers are the sizes of monomer microdroplets.

It has been shown by electron microscopy and laser correlation spectroscopy that, when poorly water-soluble or virtually water-insoluble surfactants, namely, lithium and barium stearates, are employed, the emulsions formed during their synthesis at the interface consist of macro- and microdroplets of the monomer, the size of the latter ranging from 120 to 500 nm, and no emulsifier micelles are present.

The data on the degree of dispersion of the styrene emulsions prepared simultaneously with the synthesis of various surfactants at the interface are summarised in Table 4. These data indicate that the composition of a styrene emulsion depends substantially on the method of its preparation and that it is much more intricate than it has been considered in the classical works by Smith – Ewart, Yurzenko, and their pupils.[3, 4]

The investigations have shown that the reaction of surfactant formation at an interface affects substantially the surface phenomena in the interfacial adsorption layers and can serve as a powerful factor for controlling the dispersivity of emulsions, and, hence, the mechanism of formation of particles.

IV. Synthesis of polystyrene suspensions with a narrow particle size distribution under the conditions of formation of surfactants at the interface

Research into the synthesis of polymer dispersions with a specified diameter of particles and a narrow particle size distribution has shown that these properties are mainly dictated by the granulometric composition of the initial emulsion of the monomer, the time of formation of the PMP, and the creation of conditions which ensure stability of emulsions in the interfacial layer.[38, 39] These factors depend on many parameters, most of all, on the conditions chosen for the preparation of emulsions and for polymerisation.

The granulometric composition of the initial emulsion of the monomer and, hence, the mechanism of PMP formation can be readily controlled by selecting appropriate surfactants and an appropriate way of introducing them into the system (either as separate solutions in water or in the monomer or as solutions both in water and in the monomer the concentration of which is determined by the surfactant solubility in these phases) and by the synthesis of surfactants at the interface.[14, 18, 26] Any of these methods gives monomer emulsions characterised by different degrees of dispersity due to different concentrations of the surfactant at the interface. Correspondingly, the interfacial tensions also differ significantly.

The time of formation of the PMP is a very important factor which largely determines the diameter and the size distribution of particles; this factor depends considerably on the efficiency of initiation of polymerisation and on the process temperature.

Finally, the stability of the PMP during polymerisation is ensured by the existence of factors of PMP stability acting in the interfacial adsorption layers (electrostatic or structure-mechanical factor or both). These factors also influence the diameter of particles and their size distribution.

The duration of the stage of PMP formation can vary from several minutes to several hours. It depends appreciably on the granulometric composition of the emulsion and the efficiency of initiation. At this stage, particles can coalesce due to instability giving rise to a coagulum. Such a phenomenon has been observed, for example, in suspension polymerisation of styrene in the presence of poly(vinyl alcohol), starch, or gelatin as stabilisers. It is at the stage of PMP formation that the diameter of particles of a polymer suspension can be controlled by affecting their coalescence in one or another way. This process is extremely complex. In order to eliminate the coagulum formation, surfactants are added to the system. They, in turn, can induce the formation of new PMP and extend markedly the size distribution of particles.

When styrene polymerisation is carried out in the presence of organosilicon surfactants, insoluble in water and incompatible with the resulting polymer, this stage occurs in a different way.[40,41] In this case, a strong interfacial layer consisting of the surfactant displaced by the polymer and of the polymer itself is formed on the PMP surface at relatively low degrees of monomer conversion. The diameter of particles in a polymer suspension can be controlled by varying the nature of the surfactant and the temperature.

Performing styrene polymerisation with simultaneous synthesis of a surfactant at the interface ensures, on the one hand, the possibility of realisation of either emulsion or suspension polymerisation mechanism giving rise to polymer suspensions in which the diameter of particles can differ by an order of magnitude and, on the other hand, it ensures stability of these suspensions because the surfactant concentration in the interface is higher than that in the case where the surfactant is adsorbed onto the PMP surface from the aqueous phase. Thus polymerisation can be carried out at lower concentrations of the surfactant and gives polymer suspensions more stable during storage or modification (*e.g.*, by proteins).

The morphology of particles prepared under conditions of surfactant synthesis at the interface should differ essentially from that resulting from conventional synthesis.

When emulsions are prepared under ordinary conditions, the interfacial adsorption layer is formed upon adsorption of the emulsifier from the aqueous phase first on monomer droplets and then on the PMP. When polymerisation is carried out with synthesis of an emulsifier at the interface, the initial monomer emulsion as such does not actually exist. In this case, simultaneously with vigorous disintegration (microemulsification) of monomer droplets, initiation of polymerisation takes place; the resulting microdroplets capture radicals being thus converted into the PMP. In parallel, the interfacial adsorption layers are formed from the acid molecules dissolved in the monomer, the salt molecules resulting from neutralisation of the acid, and polymer molecules (polymerisation occurs in the area of the PMP adsorption layers). The preliminary dissolution of the acid in the monomer ensures the optimal orientation of the acid and salt molecules in the interfacial layer, which gives rise to the electrostatic factor of stabilisation. Due to the high polymer concentration in the interfacial layer, the viscosity of the IAL substantially increases and the structure-mechanical factor of stabilisation also starts to be effective.

The synthesis of water-insoluble surfactants at the interface should yield particles with the 'core–shell' type structure. The formation of these particles is responsible for the specific features of polymerisation kinetics. Even at early stages of the process, the PMP become a sort of microreactors in which polymerisation progresses involving the monomer and the radicals present therein. In this case, the rate of polymerisation and the PMP diameter should not depend on the concentration of the initiator, and an increase in the surfactant concentration would entail an increase in the polymer molecular mass due to the decrease (caused by diffusion restrictions) in the concentration of radicals which enter the PMP at an initial stage of the process.

Thus, by conducting polymerisation of monomers with simultaneous synthesis of surfactants at the interface, one can obtain polymer suspensions which differ not only in the particle diameter and size distribution but also in the morphology of particles. For example, in the case of synthesis of water-soluble sodium or potassium carboxylates, polymeric suspensions with a broad size distribution of particles should be produced because the initial emulsion contains monomer microdroplets and emulsifier micelles from which the PMP are formed.

Preparation of polymer suspensions with a narrow particle size distribution by polymerisation under conditions of the synthesis of water-soluble surfactants at the interface proved possible only when the concentrations of the monomer (volume ratio of the phases) and the surfactant were such that the surfactant being formed was consumed only for stabilisation of the monomer microdroplets and of the PMP formed from them, *i.e.*, when virtually no surfactant micelles were present in the aqueous phase.

The foregoing is illustrated by experimental data. Figure 5 shows the kinetic curves for the emulsion polymerisation of styrene under conditions of formation of potassium salts of carboxylic acids at the interface. In these experiments, aliphatic acids with alkyl substituents from C_{11} (lauric acid) to C_{25} (behenic acid) were used; the conditions of polymerisation were identical. It can be seen that polymerisation occurs without any induction period, which could have corresponded to the stage of formation of polymer-monomeric particles, and the high rate of the process is retained almost to the complete monomer conversion. The reaction system is stable, and the final polymer suspension contains no coagulum. The stability of particles in the suspension is largely ensured by the action of the electrostatic factor of stabilisation, as indicated by the high ξ-potential of particles (Table 5).

It follows from the data given in Table 5 that the polymerisation rate w_p somewhat increases as the alkyl radical of the

Note. Here and in other tables: MM is the viscosity-average molecular mass, d is the average particle diameter, n is the polydispersity coefficient.

surfactant becomes longer; this is due to a slight change in the number of PMP formed.

The molecular mass (MM), equal to $(2.5-4.2)\times10^6$, and the molecular-mass distribution (MMD) of the polymers correspond to known published data on the emulsion polymerisation of styrene initiated by an oil-soluble initiator, namely, azobis(isobutyronitrile)[39] (Fig. 6). For low degrees of monomer conversion (1% and 5%), the MMD curves exhibit two peaks, one at lower and one at higher molecular masses (MM ≈ 100 000 and MM > 1 000 000, respectively). When the degree of monomer conversion increases to 90%, the lower-molecular-mass peak substantially decreases or even disappears. The presence of the lower-molecular-mass peak is due to the fact that polymerisation occurs both in the bulk PMP and in the emulsifier micelles.[13, 39]

As noted above, an increase in the length of the alkyl radical is accompanied by a decrease in the solubility of its salts in the aqueous phase. Whereas potassium laurate, myristate, palmitate, and stearate are soluble in water fairly readily (30 mass % – 70 mass %), potassium cerotate and behenoate are much less soluble (3 mass % – 5 mass %).[24] This should influence the mechanism of PMP formation. In the former case, the particles are formed by a mixed mechanism — both from micelles of the surfactant which solubilises the monomer and from the monomer microdroplets. In the latter case, the particles are mainly formed from monomer microdroplets. Indeed, polymer suspensions formed under conditions of synthesis of potassium laurate at the interface have very broad particle size distributions, whereas suspensions prepared with the synthesis of potassium behenoate are virtually monodisperse (Fig. 7).

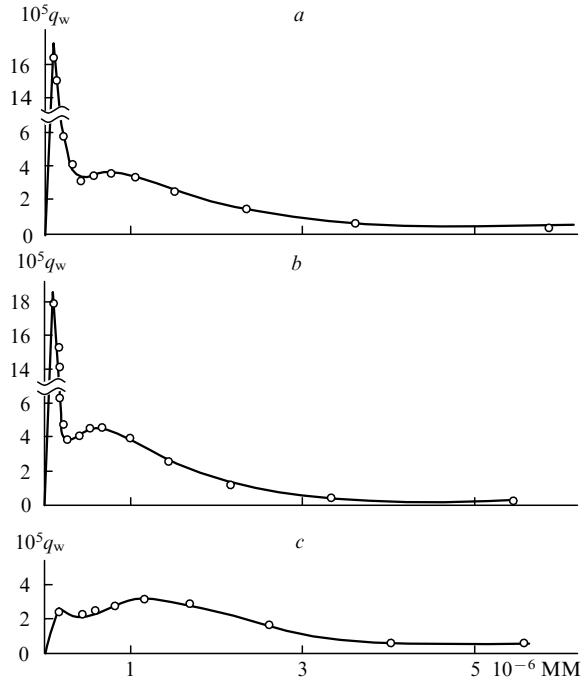

Figure 6. Molecular-mass distribution (q_w) of polystyrene prepared by polymerisation of the monomer under conditions of formation of potassium laurate at the interface for degrees of conversion of (%): (*a*) 1; (*b*) 5, (*c*) 90.

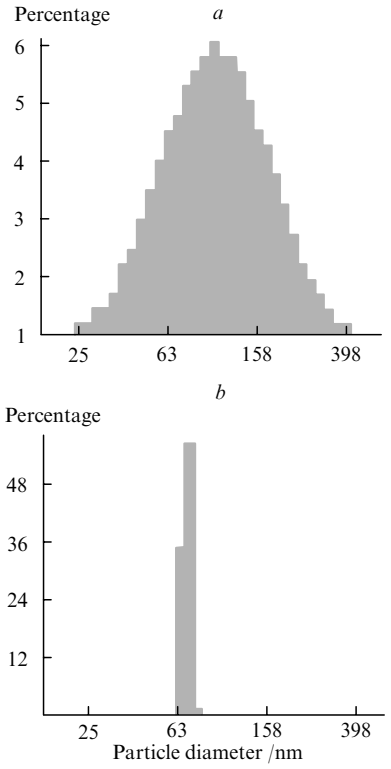

Figure 7. Particle size distribution for a polystyrene suspension prepared with simultaneous formation of potassium laurate (*a*) and potassium behenoate (*b*) at the interface.

If the emulsifier formed at the interface is poorly soluble in water (for example, lithium salts of carboxylic acids), the initial emulsion of styrene, as shown above, contains only microdroplets of the monomer, the emulsifier being spent entirely for their stabilisation.

Polymerisation of styrene under conditions of the synthesis of lithium carboxylates has some distinctive features (Fig. 8), which are due, first of all, to the fact that these salts are less soluble than the potassium salts. Thus the solubility of lithium myristate in water does not exceed 0.28 mass % and the surface activity of this compound is lower. Therefore, when styrene polymerisation is conjugated with the synthesis of lithium salts of fatty acids, the mean diameter of particles of polymer suspensions is 1.5 – 3 times greater than that attained with potassium salts, all other factors being the same (Table 6). The particle size distribution in the 'lithium' suspensions is fairly narrow because all the emulsifier is consumed for the formation of the interfacial adsorption layer of droplets, microdroplets and the polymer-monomeric particles formed from them.

The rate of polymerisation and the molecular mass of the polymer prepared in the presence of lithium myristate are lower than those with lithium laurate because the number of PMP produced in this case is smaller.

[a] Emulsifier concentration in the aqueous phase; [b] size variation coefficient.

Attempts to synthesise polymer suspensions consisting of larger particles with a narrow size distribution failed: either the reaction system was unstable, resulting in a substantial amount of the coagulum, or the particle size distribution was too broad.

Polymerisation of styrene accompanied by the formation of barium, calcium and zinc salts of carboxylic acids taken in the same concentration occurs in a different way. This was demonstrated in relation to myristates. In this case, the diameter of particles scarcely depends on the metal nature and equals ~800 nm (Table 7). The average diameter of particles also remained nearly constant as the degree of monomer conversion changed, and the polymer suspensions had a narrow distribution

of particles over diameters. This implies that, from the very moment of formation of the polymer-monomeric particles, a strong interfacial layer appears on their surface and protects the particles from coalescence.[42, 43]

The kinetic curves for styrene polymerisation under the conditions of synthesis of barium, calcium and zinc myristate at the interface are presented in Fig. 9. The curves are all S-shaped, which is typical of heterophase polymerisation; the formation of polymer-monomeric particles occurs over a period of 120–240 min, and the time it takes to achieve the complete conversion of styrene is 10–12 h.

It is of interest to compare these data with the results obtained for styrene polymerisation under conditions in which the monomer emulsions were formed *via* emulsification of the monomer with aqueous suspensions of insoluble salts of myristic acid. The resulting polymer suspension had low stability, and the average particle diameter or the size distribution could not be determined due to the high content of coagulum (more than 30%). Thus, polymerisation with the synthesis of surfactant at the interface has certain advantages pointing to good prospects of this method.

As was to be expected, the change in the concentration of the insoluble salt synthesised at the interface (Table 8) barely influences the rate of polymerisation, the particle diameter and the particle size distribution, which remains narrow over the whole range studied. The increase in the polymer molecular mass with an increase in the concentrations of the insoluble salts synthesised at the interface is, apparently, due to the decrease in the concentration of radicals entering the PMP from the aqueous phase, caused by the increase in the thickness and viscosity of the

Table 8. Effect of the emulsifier concentration (barium myristate) on the rate of styrene polymerisation, the size of particles in the polymer suspensions and on the molecular mass of the resulting polymer.

interfacial adsorption layer, resulting in the appearance of diffusion restrictions.

The stability of PMP during polymerisation is ensured by the structure-mechanical and electrostatic factors of stabilisation acing in the interfacial layer. The ξ-potential of the particles in a polymer suspension is -27 mV, which is much lower than that for styrene polymerisation under the same conditions but without an emulsifier (-70 mV).[44] The low ξ-potential can be accounted for by diffusion restrictions arising due to a definite orientation of the functional groups of polymer chains at the interface.

Thus, styrene polymerisation accompanied by the synthesis of salts of myristic acid insoluble in both phases makes it possible to prepare polymer suspensions with a narrow particle size distribution (the particle diameter is 600–900 nm). The conditions of synthesis of these polymer suspensions are technologically simple and the reaction system remains stable during polymerisation.

Due to the low ξ-potentials, the particles of a polystyrene suspension stabilised by barium, calcium and zinc myristates prove unstable during immobilisation of bioligands in an isotonic solution. An increase in the stability of polymer suspensions without substantial change in the particle diameter and without deterioration of the narrow size distribution of particles can be attained by using the synthesis of mixtures of potassium and barium myristates at the interface during polymerisation.[45] When the content of the water-soluble potassium salt in the salt mixture is 6.25 mass % to 12.5 mass %, polymerisation gives rise to stable polymer suspensions with a mean particle diameter of 580–680 nm and a narrow particle size distribution (Table 9). An increase in the stability is explained by an increase in the ξ-potential of the particles to -40 mV.

Table 9. Dependence of the rate of styrene polymerisation, the molecular mass of the polymers and the average diameter of particles in a polymer suspension on the ratio of emulsifiers, barium and potassium myristates (the total concentration of emulsifiers in the aqueous phase was 0.4 mass %).

Emulsifier percentages		$10^2 w_p$ /mol litre^{-1} s^{-1}	10^{-5} MM	d /nm (see [a])
barium myristate	potassium myristate			
50	50	14.4	25	100
62.5	37.5	12.7	19	130
75	25	8.5	14	280
87.5	12.5	5.8	8.5	580
93.75	6.25	5.5	7.8	680

[a] For particles with sizes of 100 and 130 nm, the stability to electrolytes was 0.15 mol litre^{-1}; for other particles, it was 0.20 mol itre^{-1}.

It of interest to compare the properties of the polymer suspensions prepared under conditions of surfactant formation at the interface with the properties of those prepared by conventional polymerisation (*i.e.*, with emulsification of the monomer with an aqueous solution of an emulsifier) as well as the kinetic features of both processes. As an example, we shall consider polymerisation of styrene accompanied by the synthesis of myristic acid salts at the interface.

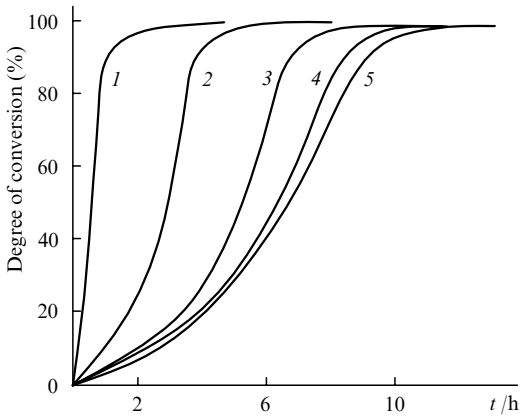

Figure 10. Yield of polymer *vs.* time of styrene polymerisation in the presence of emulsifiers. Emulsifier: (*1*) potassium myristate; (*2*) lithium myristate, (*3*) barium myristate, (*4*) calcium myristate; (*5*) zinc myristate.

The kinetic curves for styrene polymerisation with the synthesis of the myristates under discussion are presented in Fig. 10.

They all have an S-like shape, typical of heterophase polymerisation, and differ from one another in the duration of the non-steady-state stage of the formation of polymer-monomeric particles, the rate of polymerisation, the range of degrees of conversion in which the rate of the process is constant, and in the time required for the full monomer conversion. For example, polymerisation of styrene accompanied by the synthesis of potassium myristate starts almost immediately, while in the case of synthesis of barium, calcium, and zinc salts insoluble both in water and in the monomer, the formation of polymer-monomeric particles requires 120–240 min. The time periods required to attain complete conversion of styrene are also different: in the former case, polymerisation occurs over a period of 2.5–3 h and in the latter case, this takes 10–12 h.

For clarity, we shall compare the processes taking place in the PMP formed in the styrene polymerisation performed simultaneously with the synthesis of soluble and insoluble salts of carboxylic acids (Table 10). The concentration of free radicals during bulk polymerisation is known[46] to be usually about 10^{-7}–10^{-8} mol litre^{-1}, or 10^{12}–10^{13} radical ml^{-1}, *i.e.*, the volume per radical is, on average, 5×10^{-1}–5×10^{-2} μm^3. The microdroplets formed under conditions of synthesis of soluble surfactants at the interface have a volume of 10^{-3}–10^{-4} μm^3, which is much less than the volume per radical for bulk polymerisation. Therefore, each particle does not contain more than one radical; only when the termination rates are very low (for example, when radicals are fixed in the polymeric matrix of the interfacial layers), can a microdroplet contain several radicals. If the concentration of microdroplets in the system is 10^{14} ml^{-1}, the rate of initiation is close to that for bulk polymerisation

Table 10. Characteristics of styrene bulk polymerisation (I) and polymerisation in microdroplets of various sizes (II, III).

Characteristics	I	II [a]	III [b]
The number of particles	–	10^{14}–10^{15}	10^{12}–10^{13}
The number of radicals per particle	–	0.5	5–10
The total number of radicals in 1 ml of the system	10^{12}–10^{13}	0.5×10^{14}–0.5×10^{15}	0.5×10^{13}–0.5×10^{14}
Volume of the monomer per radical /μm^3	10^{-1}–10^{-2}	10^{-3}–10^{-4}	10^{-1}–10^{-3}
Rate of initiation /radical ml^{-1} s^{-1}	10^{12}–10^{13}	10^{12}–10^{13}	10^{12}–10^{13}
Average lifetime of radicals /s	1	10–100	5–10

[a] The size of microdroplets is 0.05–0.1 μm (water-soluble surfactants); [b] the size of microdroplets is 0.4–0.8 μm (water-insoluble surfactants).

($10^{-7}-10^{-8}$ mol litre^{-1} s^{-1}, or $10^{12}-10^{13}$ radical ml^{-1} s^{-1}), and the initiation efficiency is equal to unity, the lifetime of radicals in these particles should be fairly long (10–100 s). With this lifetime, the molecular mass of the polymer is determined by the rate of chain transfer *via* the monomer. In the case of styrene, MM = $1\times10^6-2\times10^6$.

A different situation arises when styrene polymerisation proceeds in the monomer microdroplets formed in the synthesis of water-insoluble surfactants at the interface. Their volume is now $10^{-1}-10^{-3}$ μm^3; therefore, they can accommodate several radicals (5 to 10), the lifetime of which is several seconds, and the polymer molecular mass is up to 10^5.

These differences are consistent with the data on the diameter of the polymer-monomeric particles in which polymerisation proceeds (Table 11). Indeed, in the styrene polymerisation accompanied by synthesis of potassium myristate at the interface, the average diameter of the PMP is 63 nm, while for the synthesis of barium myristate under the same conditions, the diameter is an order of magnitude greater and equals 700 nm.

Table 11. Polymerisation of styrene in the presence of myristates.

Surfactant	$10^2 w_p$ /mol litre s^{-1}	10^{-5} MM	d /nm (see [a])	ξ-Potential /mV
Potassium myristate	15.1	50	65	−52
Lithium myristate	11.3	15	270	−35
Barium myristate	5.5	6.7	700	−29
Calcium myristate	5.4	6.6	800	−26
Zinc myristate	4.9	6.2	850	−23

[a] For particles with sizes of 65 and 270 nm, the stability to electrolytes is 0.15 mol litre^{-1}; for other particles, 0.20 mol litre^{-1}.

In the former case, when small particles contain not more than one radical, emulsion polymerisation of styrene takes place, which is characterised by a high rate and gives polymers with high molecular masses. In this case, the PMP are formed, apparently, both from the monomer microdroplets and from micelles of the emulsifier which solubilises the monomer.

In large particles with an average diameter of about 700 nm, polymerisation follows a suspension mechanism and has a rate close to the rate of suspension polymerisation of styrene in the presence of conventional stabilisers of suspension particles, namely, poly(vinyl alcohol), gelatin, *etc*. However, the molecular masses of the polymers formed in the PMP stabilised by water-insoluble salts of myristic acid are higher than those attained in styrene polymerisation in the presence of standard stabilisers. Presumably, the high viscosity of the interfacial layer creates diffusion restrictions which prevent the penetration of radicals and the monomer into the layer bulk; therefore, only radicals that have entered the PMP during initiation of the polymerisation and the monomer present in the PMP bulk participate in the polymerisation.

V. Conclusion

On the basis of the published data cited and the results of authors' research, a new, in principle, approach to the conduct of heterophase polymerisation has been proposed.[47] The essence of the approach is that monomer emulsions are prepared simultaneously with the synthesis of the emulsifier at the monomer–water interface and with initiation of the polymerisation in the interfacial layer.

For the preparation of emulsions of monomers sparingly soluble in water, the formation of the emulsifier at the monomer–water interface is an efficient way of controlling the stability and the granulometric composition of the emulsions.

The synthesis of emulsifiers at the interface makes it possible to control the interfacial tension, disintegration and microemulsification of the monomer, to form the structure of interfacial adsorption layers of surfactants by an appropriate selection of the carboxylic acid and the counter-ion.

The mechanism of formation of the polymer-monomeric particles and their diameter and size distribution are dictated by the solubility in water of the surfactant formed at the interface. When polymerisation is carried out under conditions of synthesis of a soluble surfactant at the interface, the polymer-monomeric particles are produced from the emulsifier micelles and monomer microdroplets. This ensures the formation of polymer suspensions with a broad particle size distribution. Owing to the low concentration of the resulting surfactant, which is, however, sufficient for providing the stability of polymer-monomeric particles, micelles are excluded from the formation of the PMP, and polymer suspensions with narrow size distributions of particles are formed.

When surfactants poorly soluble or insoluble in water are synthesised at the interface, the PMP are mainly produced from monomer microdroplets, and a narrow size distribution of particles in the resulting suspensions is achieved.

Abstract. Main mechanisms of the anion (fluoride ion) transport in fluoride and oxyfluoride glasses are analysed. The variation in the transport number of F^- ions depending on the glass composition is followed. Methods for optimisation of the conductivity characteristics of the glasses in question are considered. The prospects of using fluoride-conducting glasses in electrochemical devices are discussed. The bibliography includes 90 references.

I. Introduction

The discovery [1] of the anionic (fluoride) conductivity of fluoroberyllate glasses of the $BeF_2 + MF$ (M = Na or Cs) type and fluorophosphate glasses of the $Ba(PO_3)_2 + MF_2$ (M = Ca, Sr, Ba or Mg) type and, particularly, the preparation of fluorozirconate glasses in systems involving ZrF_4 and BaF_2 and investigations [2] of their transport properties gave impetus to extensive studies of fluoride transport in glassy materials. Glasses possessing high F^- ionic conductivity constitute a special class of anion-conducting solid electrolytes. Since the glassy state is characterised by a distinctive structural solid-state disordering, one would expect that high anionic conductivity can be achieved in amorphous materials. In addition, fluoride glasses are of practical interest in a search for new solid electrolytes because of their technological effectiveness and cheapness as compared to crystalline materials. A search for glassy solid electrolytes follows two main directions: first, new glass-forming systems are investigated and, second, the electrophysical properties of the known fluoride glasses are modified by doping (by increasing the number of components).

Difficulties encountered in preparing fluoride glasses are associated with their high tendency to crystallisation. With the aim of suppressing this effect, various metal fluorides are introduced as stabilisers, which complicates the glass composition. By varying the composition, one can enhance the chemical stability of glasses, prepare specimens up to ~ 1 cm in thickness,[3] extend the temperature range of their application, reveal the contributions of various components to the dynamics of the ionic conductivities and obtain information on the mobility and concentration of charge carriers.

Problems of the formation and atomic structures of glasses in fluoride systems were surveyed in reviews.[4–9] Structural models are generally constructed based on comparison of the structural data for glassy and crystalline phases with the same chemical composition. Presently, a disordered network is used as the basic model for the glass structure.[10] According to this model, the glass structure represents a disordered (the long-range order is absent) three-dimensional glass-forming network consisting of coordination polyhedra of glass-forming cations, which are linked to each other through shared vertices occupied by bridging F_b^- anions. The cavities of the network are occupied by modifying cations bound to non-bridging F_{nb}^- anions. To gain insight into the glass structure, the reasons for the formation of disordered networks need to be revealed.

The model for a disordered network (the short-range order in the glass structure) is refined taking into account up-to-date experimental data. Among various structural models for fluoride glasses, the cluster (the short-range order and 'medium-range' order in the glass structure) model (see, for example, Ref. 11), which is closely related to the model for the disordered network, is most universally employed.[8] Structures of fluoride crystalline phases, which are chemically close to glasses, contain infinite chains of coordination polyhedra of glass-forming cations linked through F_b^- anions. The chains of the polyhedra, in turn, are linked in a three-dimensional disordered glass-forming network. Large low-charge modifying cations are not involved in this network and give rise to ionic cation – fluoride bonds. The introduction of modifying fluoride ions exhibiting high bond ionicity leads to strengthening of covalent bonds in the glass-forming network through the charge transfer.

The keys to an understanding of the anion transport in fluoride glasses are, apparently, the formation of the F_{nb}^- anions and the variation in the coordination number of glass-forming cations. It is the ability of glass-forming cations to adapt themselves to the change in the coordination number that promotes jumps of mobile anions between the adjacent polyhedra. The results of ^{19}F NMR studies [12–14] and computer simulation [15] demonstrated that it is precisely the F_{nb}^- anions located in the vicinity of the modifying cations that serve as mobile charge carriers. Local motions of F_{nb}^- anions initiate the diffusive motion of fluoride anions (anionic conductivity) through the glass-forming network.

Glasses possessing ionic conductivity are characterised by dielectric relaxation associated with the jump migration of charge carriers resulting in the frequency dependence of the ionic conductivity.[16] Ion-conducting glasses follow the universal relationship: the direct-current conductivity σ is directly proportional to the dielectric relaxation frequency ω_m. This universal regularity was explained [17] within the framework of a model for the potential barrier distribution according to which the frequency of the dielectric loss peak is the minimum jump frequency of conducting ions. Hence, the directly proportional dependence of σ on ω_m is physically justified. Within the framework of this approach, the characteristic features of the jump mechanism for electric current carriers in ZrF_4-based fluoride glasses were examined.[18–20] The anionic conductivity in fluoride glasses depends primarily on the activation energy of the ion transport.

Particular mechanisms of the anion transport in glasses remain poorly studied because the available structural data are scarce. A necessary condition for the manifestation of essential anionic conductivity is the existence of glass-forming cations, which adopt high coordination numbers and differ in the form and size of their coordination polyhedra. Low coordination numbers of glass-forming cations (in fluoroberyllate and fluoroaluminate glasses) are responsible for low anionic conductivities.

For cation-conducting glasses, the polycationic (polyalkali) effect is well known. This effect lies in the fact that the replacement of one alkali metal cation by another gives rise to a minimum in the composition dependence of the ionic conductivity. The polycationic effect in fluoride and oxyfluoride glasses is manifested if the cationic conductivity exceeds the fluoride-ionic conductivity.[21–24] In the $Ba(PO_3)_2 + NaX$ (X = F, Cl or I) and $Ba(PO_3)_2 + BaF_2 + BaX_2$ (X = Cl or Br) glasses, the polyanionic effect (which was called by analogy with the polycationic effect) was experimentally observed upon the replacement of one halogen by another.[25,26] The polyanionic effect was confirmed for the $ZrF_4 + BaX_2$ (X = F or Cl) [27] and $30\,SiO_2 \cdot 55\,PbO \cdot 15\,Pb(F_{1-x}Cl_x)_2$ ($0 \leqslant x \leqslant 1$) glasses.[28] The $ZrF_4 + BaF_2 + MX$ (M = Li or Na; X = F or Cl) [29] and $ZrF_4 + BaF_2 + MF_n + LiF$ glasses ($M^{n+} = La^{3+}$ or Th^{4+}, the Li^+ and F^- mobile ions) exhibit the combined effect associated with lowering of the conductivity due to the simultaneous presence of mobile cations and anions.[30]

In the present review, the results of studies of the fluoride-ion transport in glassy solid electrolytes are analysed. Mechanisms of the cation transport in fluoride and oxyfluoride glasses call for a special discussion and are beyond the scope of the present review. The abundant experimental data on fluoride glasses are classified, wherever possible, into groups according to the type of the basis glass-forming fluoride. It should be noted that this classification becomes more difficult as the composition of multicomponent glasses is complicated (the most stable fluoride glasses contain three or more components). Various families of glasses based on MF_2, MF_3 or MF_4 are considered. Recently, glasses based on MF_5, where M = Nb, Ta, V or Mo, have been discovered (the glass transition temperature T_g varies from -45 to -60 °C; the crystallisation temperature T_{cr} ranges from 0 to -10 °C),[31] but their electrophysical properties remain to be explored. The characteristics of the anionic conductivities of some two- and three-component fluoride and oxyfluoride glasses are given in Table 1.

Fluoride glasses attract considerable interest because they are transparent in the IR region and possess low glass transition temperatures as well as because they are promising materials for fibre optics. According to the results of calculations, theoretical losses in the optical transmission of information in these glasses are an order of magnitude smaller than those in traditional oxide (silicate) glasses.

Table 1. Characteristics of the fluoride-ionic conductivity in two- and three-component fluoride and oxyfluoride glasses.

Note. E_a is the activation energy of the conductivity. Different researchers calculated the E_a values according to the formula: $\sigma T = A\exp(-E_a/kT)$ or $\sigma = A\exp(-E_a/kT)$. The results differ by less than 0.05 eV.

[a] The original studies were cited in Ref. 32.

II. Fluoride glasses based on MF_2

Of simple fluorides MF_n ($n = 1-4$), BeF_2 is the only fluoride compound capable of undergoing a glass transition. The coordination polyhedron of the glass-forming Be^{2+} cation is the $[BeF_4]^{2-}$ tetrahedron (the coordination number is 4). The structural motif of crystalline BeF_2 (isostructural to SiO_2) is based on an ordered three-dimensional framework formed by the $[BeF_4]^{2-}$ tetrahedra, which are linked to each other *via* shared vertices. The transformation of BeF_2 into the glassy state occurs through rotations of the tetrahedra about the bridging $Be-F_b-Be$ bonds accompanied by distortions of the angles in the tetrahedra. As a result, a disordered three-dimensional framework consisting of the distorted $[BeF_4]^{2-}$ tetrahedra is formed. This framework is characterised by the absence of the long-range order. Tetrahedral fluoroberyllate glasses are structural analogues of silicate glasses. The introduction of alkali metal fluorides acting as modifiers leads to the cleavage of the bridging $Be-F_{nb}-M$ bonds and the occurrence of non-bridging fluorine atoms. It was found that the ratio between the cationic and anionic components of the conductivities in alkaline fluoroberyllate glasses is a function of the alkali metal–fluorine bond. Measurements of the transport numbers demonstrated that the $BeF_2 + MF$ and $BeF_2 + MF + M'F$ glasses (M and M′ = Na or Cs) exhibit virtually unipolar anionic conductivities.[1] The mechanism of the anionic conductivity in these glasses is associated with the increase in the amount of mobile non-bridging F^-_{nb} ions as the content of the MF modifying component increases. However, the fluoride-ionic conductivities are low and reach $\sim 10^{-6}$ S m^{-1} at 300 °C.

The electrical properties of multicomponent glasses based on manganese and zinc fluorides in the MnF_2-BaF_2, ZnF_2-MF_2 (M = Ba or Pb), ZnF_2-BaF_2-LiF, $ZnF_2-BaF_2-YF_3$, $ZnF_2-PbF_2-AlF_3-LiF$ and $ZnF_2-BaF_2-InF_3-SrF_2-NdF_3-MF$ systems (M = Li, Na, K or Rb) were studied.[33,34,43,44]. Apparently, crystalline phases formed in the ZnF_2-BaF_2 system, for example $BaZnF_4$, are most similar in structural units to fluorozincate glasses.[45,46] The crystal structure of $BaZnF_4$ consists of the $[ZnF_6]^{4-}$ octahedra linked in chains through shared vertices, whereas the barium atoms are located in the cavities. An analogous motif composed of the $[ZnF_6]^{4-}$ octahedra is observed in the structure of Ba_2ZnF_6. It can be assumed that fluorozincate glasses retain the short-range order of the arrangement of the $[ZnF_6]^{4-}$ octahedra, whereas the Ba^{2+} positions are partially occupied by the modifying Sr^{2+}, Nd^{3+}, Y^{3+}, Li^+, Na^+, K^+ or Rb^+ cations, their arrangement meeting the condition for charge compensation. The indium atoms, which adopt the coordination numbers of 6 and 7 in fluoride structures,[9] are, apparently, incorporated into the glass-forming network. In the octahedral $50\,ZnF_2 \cdot 19.5\,BaF_2 \cdot 10\,InF_3 \cdot 10\,SrF_2 \cdot 0.5\,NdF_3 \cdot 10\,MF$ glasses, the conductivity at 127 °C changes from 5×10^{-6} to 3×10^{-4} S m^{-1} and the activation energy E_a changes from 0.82 to 0.68 eV as the ionic radius of M^+ increases from 0.9 (Li^+) to 1.66 Å (Rb^+)†. In the $30\,ZnF_2 \cdot 25\,AlF_3 \cdot (45-x)\,PbF_2 \cdot x\,LiF$ ($0 \leqslant x \leqslant 20$, T_g = 230–275 °C) glasses, the ZnF_2-AlF_3 group acts as a glass-forming agent, whereas PbF_2 and LiF serve as modifiers. The anionic conductivity (at 200 °C) decreases from 1×10^{-4} to 1×10^{-5} S m^{-1}, whereas the activation energy E_a increases from 0.86 to 1.24 eV as the LiF content increases due to capture of mobile F^- ions by Li^+ cations.

III. Fluoride glasses based on MF_3

Trifluoride-based glasses are formed in systems containing MF_3 (M = Al, Fe, Ga or In) or AF_2 (A = Ba or Pb).[48,49] As for the glass-forming $MF_3 + M'F_2 + M''F_2$ (M = Fe, Ga or In; M′ = Pb or Ba; M″ = Mn, Zn, Cd, Sn or Ba) systems, the most stable glasses appear in the $InF_3-BaF_2-PbF_2$ system (T_g = 250–280 °C, $\Delta T = T_g - T_{cr} \approx 70$ °C). The structures of MF_3-based glasses consist of the $[MF_6]^{3-}$ octahedra linked in zigzag chains through fluorine atoms. The $[AlF_4]^-$ and $[GaF_4]^-$ tetrahedra can be present, but they are not involved in formation of glass networks. The data on the $46.7\,InF_3 \cdot 19\,PbF_2 \cdot 23.8\,BaF_2 \cdot 1.9\,AlF_3 \cdot 4.9\,SrF_2 \cdot 2.8\,YF_3$ glass obtained by Raman spectroscopy, the optical transmission method and magneto-chemistry[50,51] are indicative of octahedral coordination about the small indium ($r_{In^{3+}} = 1.06$ Å) and aluminium ($r_{Al^{3+}} = 0.675$ Å) atoms; whereas the large lead ($r_{Pb^{2+}} = 1.43$ Å) and barium ($r_{Ba^{2+}} = 1.56$ Å) atoms act as modifiers and occupy cavities in the three-dimensional octahedral glass-forming network. Consideration of the structure of this glass from the standpoint of the close packing of fluorine atoms leads to the same conclusion, *viz*., small In^{3+} and Al^{3+} cations occupy octahedral positions in the anionic packing, whereas large Pb^{2+} and Ba^{2+} cations introduce strong disturbance in the packing of fluoride anions.[52] It was assumed that the $[InF_7]^{4-}$ polyhedra are present in the glass-forming networks of indium-containing glasses.[9]

The properties of the $40\,MF_3 \cdot 40\,BaF_2 \cdot 20\,YbF_3$ glasses (M = Al, Ga, Sc or In) whose compositions are determined by the position of a low-melting eutectic in the phase diagrams of the $MF_3-BaF_2-YbF_3$ systems were examined.[35] In the course of formation of these glasses, the MF_3 trifluorides serve as glass-forming agents. The structures of the $40\,ScF_3 \cdot 40\,BaF_2 \cdot 20\,YbF_3$ and $40\,InF_3 \cdot 40\,BaF_2 \cdot 20\,YbF_3$ glasses contain fragments both of two-dimensional networks formed by the seven- and eight-vertex $[MF_n]^{-n+3}$ polyhedra (n = 7 or 8) and chains formed by the $[MF_6]^{3-}$ octahedra. Since the Al^{3+} and Ga^{3+} ions cannot be incorporated in seven-vertex polyhedra, the structure of the glass-forming network changes.[53] These glasses are characterised by a sharp increase (by three orders of magnitude) in the isothermal conductivity as the ionic radius of M^{3+} increases (as the $M^{3+}-F^-$ chemical bond is weakened) due to a linear decrease in the activation energy of the conductivity (see Table 1). The introduction of GaF_3 into the fluoroindate glasses $(40-x)\,InF_3 \cdot x\,GaF_3 \cdot 20\,ZnF_2 \cdot 16\,BaF_2 \cdot 20\,SrF_2 \cdot 2\,GdF_3 \cdot 2\,NaF$ ($0 \leqslant x \leqslant 30$) also leads to a sharp decrease in their conductivities.[54]

The mobility of the fluoride ions and the conductivities of glasses in the $InF_3-BaF_2-PbF_2$, $InF_3-BaF_2-BiF_3$ and $InF_3-BaF_2-PbF_2-AlF_3-LiF$ systems were examined.[36–38,55] The addition of AlF_3 and LiF to the former system promotes the preparation of $InF_3 + BaF_2 + PbF_2$ glasses and allows one to vary their composition over a wider range. Two phases were identified among the crystallisation products obtained in the $InF_3-BaF_2-PbF_2-AlF_3$ system,[56] *viz*., a fluorite-like solid solution based on PbF_2 and BaF_2 and a solid solution based on the high-temperature tetragonal modification of $Ba_3In_2F_{12}$. The conductivities of glasses of the $InF_3-BaF_2-PbF_2-AlF_3-LiF$ system are improved as the PbF_2 content increases, whereas the conductivities are impaired as the AlF_3 content increases. At room temperature, the anionic conductivity of the $20\,InF_3 \cdot 50\,PbF_2 \cdot 10\,BaF_2 \cdot 10\,AlF_3 \cdot 10\,LiF$ glass is 30 times as large as that of the superionic conductor β-PbF_2, which is widely used in scientific and applied studies. This fact underlines the important role of indium and lead fluorides in the preparation of new amorphous superionic conductors.

IV. Fluoride glasses based on MF_4

In the middle 1970s, ZrF_4 and BaF_2-based fluoride glasses were prepared. This result was unexpected because the glass-forming Zr^{4+} cation is characterised by high ($\geqslant 6$) coordination numbers, which is contradictory to the conventional criteria for glass formation. The data of analysis of the shielding tensors and the chemical shifts of the signals in the ^{19}F NMR spectra[14,57] and the results of calculations by the Monte-Carlo method and molecular dynamics[58] demonstrated that the short-range structures in the barium fluorozirconate glasses $50\,ZrF_4 \cdot 50\,BaF_2(BaZrF_6)$ and $60\,ZrF_4 \cdot 40\,BaF_2$ are similar to the structure of crystalline

† The crystal-chemical ionic radii were taken from Ref. 47.

α-$BaZrF_6$ and that the medium-range ordering of the cluster type occurs along with the short-range order. Fluorozirconate glasses can contain Zr polyhedra with the coordination numbers of 6, 7 or 8. The structural networks of the glasses consist predominantly of the $[ZrF_7]^{3-}$ and $[ZrF_8]^{4-}$ polyhedra linked through bridging bonds; BaF_2 acts as a modifier.[59] The glass-forming ability of the ZrF_4-BaF_2 system is insufficient for the preparation of glasses several millimetres in thickness. These glasses can be prepared by introducing additional MF_n components ($n = 1-4$); the number of the components can be 10 or even larger.

The pioneering study on the anionic conductivities of fluorozirconate glasses[2] was concerned with the glasses $ZrF_4 + BaF_2 + ThF_4$ (55 mol.% – 62.5 mol.% ZrF_4, 28 mol.% – 36.3 mol.% BaF_2 and 7.5 mol.% – 13.8 mol.% ThF_4, $T_g \approx 320$ °C), $62\,ZrF_4 \cdot 30\,BaF_2 \cdot 8\,MF_3$ (M = La, Pr or Nd; $T_g = 310$ °C), $60\,ZrF_4 \cdot 33\,ThF_4 \cdot 7\,LaF_3$ ($T_g = 455$ °C) and $60\,ZrF_4 \cdot 25\,BaF_2 \cdot 8\,ThF_4 \cdot 7\,LaF_3$ ($T_g = 320$ °C). Measurements of the transport numbers demonstrated that the glasses possess unipolar fluoride-ionic conductivities (the transport numbers of the electron transport are $< 10^{-3}$). In the $ZrF_4 + BaF_2 + ThF_4$ glasses, the conductivity increases moderately as the content of the BaF_2 modifier increases. On the average, the fluoride-ionic conductivity in these glasses is $\sim 10^{-4}$ S m^{-1} at 200 °C and $E_a \approx 0.8$ eV.

Later on, the electrophysical properties of the multicomponent glasses $ZrF_4 + BaF_2 + AlF_3$,[39] $ZrF_4 + BaF_2 + MF_n$ (M = Li, Na, Rb, Cs, Ca, Sr, Ba, Sb^{3+}, Bi, La, Nd or Hf),[60] $60\,ZrF_4 \cdot 30\,BaF_2 \cdot 10\,LnF_3$ (Ln = La – Lu or Y),[61] $ZrF_4 + M'F_2 + M''F_3$ (M' = Ba or Sn^{2+}; M'' = Ga, La or Nd),[62,63] $ZrF_4 + BaF_2 + AlF_3 + LnF_3$ (Ln = La or Y),[64] $ZrF_4 + BaF_2 + LaF_3 + M'F$ (M' = Na or Li),[19,20] $ZrF_4 + BaF_2 + ThF_4 + LiF$,[20] $ZrF_4 + MF_n + AlF_3 + YF_3 + NaF$ (M = Ba or La),[18,19,65] $ZrF_4 + BaF_2 + LaF_3 + LiF + NaF$[66] and $ZrF_4 + BaF_2 + AlF_3 + YF_3 + ZnF_2 + CdF_2 + LiF$[67] were examined with the aim of improving the anion-transport characteristics. It was found that the anionic conductivity of fluorozirconate glasses depends primarily on the activation energy of the conductivity. The polarisability and the ionic radius of M^{n+} are the major factors influencing the E_a value. The activation energy of the fluoride-ion transport decreases as the ionic radius and the polarisability of the M^{n+} cations increases, which is, apparently, due to weakening of the $M^{n+} - F^-$ bond. The ZrF_4-BaF_2-CsF system exhibits the most promise for preparing glasses possessing high fluoride-ionic conductivity.

According to the ^{19}F NMR data,[12–14,64] the mechanism of the anionic conductivity in fluorozirconate glasses is associated with the non-bridging F^-_{nb} anions localised at the modifying cations. These anions execute local motions ($E_a \approx 0.2$ eV) in the vicinity of the modifying cations and diffusion motions ($E_a \approx 0.6$ eV) between the modifying cations. The fluorine diffusion is limited by the potential barriers between the modifying cations. In the $55\,ZrF_4 \cdot (38.5-x)\,BaF_2 \cdot 4AlF_3 \cdot (2.5+x)\,LaF_3$ ($0 \leqslant x \leqslant 7$) and $55\,ZrF_4 \cdot (37-x)\,BaF_2 \cdot 4\,AlF_3 \cdot (4+x)\,YF_3$ ($0 \leqslant x \leqslant 5$) glasses, the conductivity is enhanced as the BaF_2 content increases.[64]

In lithium fluorozirconate glasses containing less than 20 mol.% of LiF, the conductivities are determined by the Li^+ and F^- ions, whereas the conductivities in the glasses containing more than 20 mol.% of LiF are conditioned only by the Li^+ cations. In the sodium fluorozirconate glasses, the conductivities are governed exclusively by the F^- ions. For the $50\,ZrF_4 \cdot (45-x)\,BaF_2 \cdot 3\,AlF_3 \cdot 2\,YF_3 \cdot x\,NaF$ ($10 \leqslant x \leqslant 40$) and $45\,ZrF_4 \cdot 3\,LaF_3 \cdot 3\,AlF_3 \cdot 4\,YF_3 \cdot 45\,NaF$ glasses, the concentrations of the charge carriers were estimated within the framework of the jump mechanism of the conductivity.[18,19] A small portion of fluoride ions (3% – 5% of their total amount) is responsible for the transport properties of these glasses. The conductivity decreases as the NaF content increases due to a decrease in the mobility of the charge carriers and partial capture of mobile F^- anions by Na^+ cations.

Since zirconium and hafnium tetrafluorides (the ionic radii $r_{Zr^{4+}} = 0.98$ and $r_{Hf^{4+}} = 0.97$ Å) have similar physicochemical and structural characteristics, fluorohafnate glasses are isovalent analogues of fluorozirconate glasses. The electrolytic properties of glasses in the HfF_4-BaF_2 and $HfF_4-BaF_2-MF_3$ systems (M = Nd, Yb or Y) were investigated.[35,68] The parameters of the anion transport in HfF_4-containing glasses are virtually independent of the type and concentration of trifluorides of rare-earth elements, *viz.*, $\sigma \approx 3 \times 10^{-4}$ S m^{-1} at 223 °C and $E_a \approx 0.9$ eV. Trivalent rare-earth cations replace zirconium (hafnium) in glass-forming networks. Apparently, the addition of trifluorides of rare-earth elements with substantially different ionic radii (for example, $r_{Nd^{3+}} = 1.249$ and $r_{Yb^{3+}} = 1.125$ Å) to the glass-forming HfF_4-BaF_2 system has no effect on the surface contour of the potential energy (~ 0.9 eV), where the fluoride ions move. These results of conductometric studies are, apparently, indicative of microheterogeneity of glasses including large (from the viewpoint of the atomic scale) spatial regions free of trifluorides of rare-earth elements.

According to the NMR data,[69] high mobility of the F^- ions is observed in glasses based on tin tetrafluoride, *viz.*, in $SnF_4-BaF_2-MF_3$ (M = Al, Sc or Ga); however, the data on their ionic conductivities are lacking.

V. Oxyfluoride glasses

To prepare glasses, fluorides are added to mixtures of oxides. Thus, no glass was obtained from a mixture of pure oxides SiO_2, Al_2O_3 and BeO, whereas a transparent glass was prepared in the presence of even a small amount (several mass percent) of CaF_2. This is associated with a decrease in viscosity and an increase in mobility of structural units in melts in the presence of fluoride. The properties of these glasses are determined by the influence of fluorides on the structure of the oxide matrix. Glasses possessing unipolar fluoride-ionic conductivities were prepared by introducing fluorides MF_n ($n = 1-3$) into glass-forming oxyphosphate compounds of the $NaPO_3$, $M(PO_3)_2$ (M = Ba, Pb, Sr or Zn) and $Al(PO_3)_3$ types.[1,32,70] In the $Ba(PO_3)_2-MgF_2$ system whose glass-forming region extends to 70 mol.% of MgF_2, as an example, the fluoride-ion transport number reaches 0.98. For the most extensively studied fluorophosphate glasses, the following regularities were revealed:

(1) the fraction of fluoride anions involved in the conductivity increases sharply as the fluoride content in the glass increases;

(2) the F^- transport number is determined by the strength of the metal – fluorine bond;

(3) glasses with a fluoride content higher than 30 mol.% – 50 mol.% (depending on the system) are characterised predominantly by anionic conductivity.

The electrophysical properties of fluorine-containing oxyfluoride glasses were studied in the $Ba(PO_3)_2-AlF_3-MF_2$ (M = Mg, Ca, Sr or Ba; $T_g = 450-550$ °C), $ZnB_2O_4-CdB_2O_4-AlF_3-PbF_2$ ($T_g = 250-500$ °C) and $BaGeO_3-BaAl_2GeO_8(Ca_2Al_2GeO_7, Pb_2GeO_4)-CaF_2-MgF_2$ ($T_g = 550-700$ °C) systems.[71] Fluorine plays a binding role in the construction of the structural networks of glasses. The meta-, pyro- and monofluorophosphate groups and the fluoride fragments coexist in networks of fluorophosphate glasses. In borofluoride glasses, the function of fluorine consists primarily in changing the coordination of the boron atoms. The germanate and fluoride structural fragments coexist in fluorogermanate glasses. At 20 °C, the conductivity of fluorophosphate glasses varies from 10^{-11} to 10^{-6} S m^{-1} and the conductivity of borofluoride glasses ranges from 10^{-11} to 10^{-4} S m^{-1}.

In glassy oxyfluoride systems, fluorine can serve different functions depending on the type of the modifying cation. The structural positions and the dynamics of fluoride ions in glasses of the $Al(PO_3)_3-BaF_2$, $Ba(PO_3)_2-CdF_2$ and $Al(PO_3)_3-BaF_2-AlF_3-MF_n$ systems (M = Li, Na, K, Rb, Cs, Mg, Zn or Cd) were studied by ^{19}F NMR spectroscopy.[72,73] Several structurally

nonequivalent positions of the fluorine atoms involved in the coordination polyhedra about Ba, Al and Cd were found. In glasses of the $Al(PO_3)_3-BaF_2$ system, the F^- anions exhibit high mobility, the most mobile anions being bound to the barium atoms. In glasses of the $Ba(PO_3)_2-CdF_2$ system, no mobility of fluoride ions was observed.

Particular attention was given to PbF_2-containing glasses formed in the $M_nO_m-PbF_2$ ($M_nO_m = B_2O_3$, Bi_2O_3, V_2O_3, SnO_2, GeO_2),[34] $Al(PO_3)_3-PbF_2-MnF_2$,[74] $Pb(PO_3)_2-PbF_2-MnF_2$,[75] $SiO_2-PbO-PbF_2$,[32,42,76,77] $B_2O_3-PbO-PbF_2$ and $B_2O_3-PbO-PbF_2-AlF_3$ systems.[40] For glasses of the $M_nO_m-PbF_2$ systems, the activation energy of the conductivity varies from 0.8 to 1.0 eV and the conductivity at 127 °C ranges from 1×10^{-8} to 1×10^{-5} S m^{-1}. In the $SiO_2-PbO-PbF_2$ system, the F^- transport number increases as the concentration of PbF_2 rises from 0.4 for the $95(2\,PbO:SiO_2)\cdot5\,PbF_2$ glass to 1 for the $80(2\,PbO:SiO_2)\cdot20\,PbF_2$ glass. The change of the proton conductivity exhibited by the above-mentioned oxide glasses to the fluoride-ionic conductivity is attributed to a decrease in the content of structurally bound water as PbF_2 is added. The fluoride-ionic conductivity of the $80(2\,PbO:SiO_2)\cdot20\,PbF_2$ glass is $\sim10^{-4}$ S m^{-1} at 200 °C. The electron transport occurs primarily with the participation of the F^- ions bound to the Pb^{2+} ions. The structures of the $30\,B_2O_3\cdot(70-x)\,PbO\cdot x\,PbF_2$ ($0\leqslant x\leqslant25$) and $10\,B_2O_3\cdot20\,AlF_3\cdot(70-x)\,PbO\cdot x\,PbF_2$ ($0\leqslant x\leqslant60$) glasses are formed by borate groups and aluminium atoms each coordinated by six fluorine atoms. The charge transport involves F^- anions. The conductivity of glasses increases (or decreases) by several orders of magnitude as the concentration of PbF_2 increases (or upon addition of AlF_3).

Therefore, the best characteristics of the fluoride-ionic conductivity were achieved for oxyfluoride glasses with a high PbF_2 content in the $Al(PO_3)_3-PbF_2-MnF_2$ and $Pb(PO_3)_2-PbF_2-MnF_2$ systems. The conductivity of the $Al(PO_3)_3+PbF_2+MnF_2$ glasses containing 70 mol.%–80 mol.% of PbF_2 reaches $\sim10^{-2}$ S m^{-1} at 200 °C, which is comparable with that of the oxide glass $67\,B_2O_3\cdot33\,Na_2O$. A model was proposed for the superionic glass $10\,Al(PO_3)_3\cdot80\,PbF_2\cdot10\,MnF_2$ In the latter case, the glass structure is described by alternating layers of a conductor and an insulator.[78]

VI. Optimisation of characteristics of fluoride-conducting glasses and prospects of their practical applications

In the study,[8] the crystal-chemical concept of isomorphism was extended to the glassy state. Isovalent (in some cases, heterovalent) substitutions can be realised in series of glass-forming cations and/or in series of modifying cations. Cations, which can isomorphically replace each other, must have close sizes, similar bond ionicities and coordination polyhedra of the same type and occupy approximately equal volumes. For fluoride glasses, the following isomorphous series are most important: Li–Na–K–Rb–Cs, Ca–Cd–Sr–Pb–Ba, $Mg-Ni^{2+}-Co^{2+}-Fe^{2+}-Zn-Mn^{2+}$, Ln–Bi–Y–In–Sc, $Al-Ga-V^{3+}-Fe^{3+}-Cr^{3+}-In-Sc$ and Zr–Hf–U–Th.

The possibility of the application of the crystal-chemical concept of isomorphism to the glassy state was experimentally exemplified by the execution of the control over the electrophysical properties of glasses by changing their chemical compositions in the isoconcentration series $55\,ZrF_4\cdot20\,BaF_2\cdot25\,MF$ (the conductivity increases in the series Li < Na < Cs), $59\,ZrF_4\cdot26\,BaF_2\cdot15\,MF$ (Na < Rb < Cs),[60] $50\,ZnF_2\cdot19.5\,BaF_2\cdot10\,InF_3\cdot10\,SrF_2\cdot10\,MF\cdot0.5\,NdF_3$ (Li < Na < K < Rb),[34] $65\,ZrF_4\cdot25\,BaF_2\cdot10\,MF_2$ (Ca < Sr < Ba),[60] $59\,ZrF_4\cdot26\,BaF_2\cdot15\,MF_3$ (Sb < Nb < Bi),[60] $60\,ZrF_4\cdot30\,BaF_2\cdot10\,LnF_3$ (Lu < Gd < La)[61] and $40\,MF_3\cdot40\,BaF_2\cdot20\,YbF_3$ (Al < Ga < Sc < In).[35]

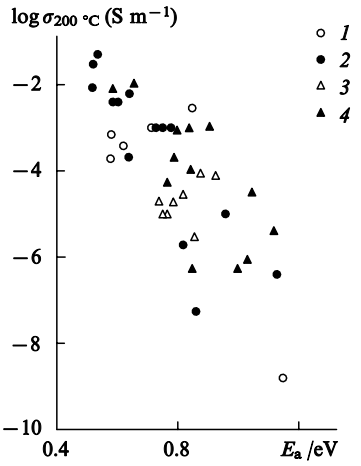

Figure 1. Dependence of $\log\sigma_{200\,^\circ C}$ on the activation energy of the conductivity for various families of fluoride glasses.
(*1*) MF_2-based glasses; (*2*) MF_3-based glasses; (*3*) MF_4-based glasses; (*4*) oxyfluoride glasses. The conductivity was calculated for 200 °C, the activation energy was calculated by the equation $\sigma T = A\exp(-E_a/kT)$.

The dependence of the conductivity on its activation energy for various families of anion-conducting glasses is shown in Fig. 1. It can be seen that the fluoride-ionic conductivity is determined primarily by the activation energy. To perform the directed search for glassy fluoride-conducting solid electrolytes and optimisation of their transport characteristics, it is necessary to reveal the factors responsible for the mechanism of the conductivity. The following facts are evidence for the high fluoride-ionic conductivity in glasses:

(1) the presence of highly coordinated glass-forming cations located in polyhedra of different types and sizes;[12]

(2) high polarisability of the cations;[60]

(3) weak energy of the cation–fluorine bond;[12]

(4) an increase in the molar volume of the glass.[34,35]

From the aforesaid it follows that the Ba^{2+} and Pb^{2+} ions acting as modifiers have the most substantial and yet different effect on the fluoride-ion transport. Taking into account the essential role of the electron shells of the ions in interionic interactions, it can be assumed that this distinction is due to the difference in the configuration of the outer electron shells of the Pb^{2+} ion (Group IV element) and the M^{2+} ions (M = Ca, Sr, Ba and Cd, which are Group II elements). Studies of the mixed $Pb_{1-x}Cd_xF_2$ crystals demonstrated[79,80] that the anionic conductivity in these isovalent solid solutions occurs predominantly with the participation of the fluoride ions whose nearest environment is formed by lead cations. This is confirmed by the fact that the energies of formation of Frenkel defects in the β-PbF_2 and BaF_2 crystals are substantially different (1 and 1.8 eV, respectively[81]). The temperature dependences of the anionic conductivity for fluoride glasses and crystalline conductors based on PbF_2 are shown in Fig. 2. It can be seen that the conductivities of glasses are higher than that of the superionic conductor PbF_2 but lower than those of the fluorite solid solutions $Pb_{0.85}Yb_{0.15}F_{2.15}$ and $Pb_{0.9}In_{0.1}F_{2.1}$.

Presently, problems associated with the environmental protection from various fluorine-containing pollutants gain momentum. The use of fluoride solid electrolytes as functional elements in detectors and chemical current sources is a topical line of investigations in this field.[70,85,86] Let us consider the prospects of the practical use of fluoride-conducting glassy solid electrolytes in electrochemical devices. Since glasses are isotropic and have no grain boundaries (as opposed to ceramics), their conductivities do not decrease as the temperature is lowered due to the blocking effect of grain boundaries. The chemical composition and the structure of glasses can be varied over wide ranges (the composi-

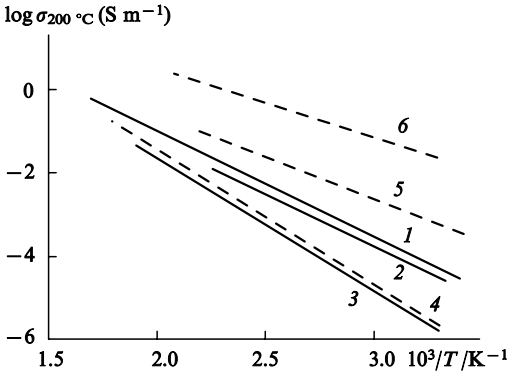

Figure 2. Temperature dependences of the anionic conductivities for glassy and crystalline fluoride solid electrolytes; (*1*) the $40\,InF_3 \cdot 45\,PbF_2 \cdot 15\,BaF_3$ glass,[37] (*2*) the $30\,InF_3 \cdot 35\,BaF_2 \cdot 35\,BiF_3$ glass,[38] (*3*) the $10\,Al(PO_3)_3 \cdot 85\,PbF_2 \cdot 5\,MnF_2$ glass,[32] (*4*) β-PbF_2 single crystal,[82] (*5*) $Pb_{0.85}Yb_{0.15}F_{2.15}$ single crystal,[83] (*6*) $Pb_{0.9}In_{0.1}F_{2.1}$ polycrystal.[84]

tional and structural flexibility), which allows one to optimise the requirements imposed on materials used in devices and ensure a good interface contact between solid electrolytes and electrodes taken in the glassy state, thus eliminating the problems inherent in crystalline systems.

The use of solid electrolytes as active elements of detectors is based on the Nernst equation:

$$E = \frac{RT}{nF} \ln\left(\frac{a'_F}{a''_F}\right),$$

where E is the electromotive force of the electrochemical cell , n is the number of electrons involved in the electrode reaction, F is the Faraday constant, a'_F and a''_F are the activities (in particular cases, the concentrations) of fluorine at two solid electrolyte–electrode interfaces.

The ionic conductivity is responsible for the rate of the establishment of thermodynamic equilibrium between the electrode and the solid electrolyte with respect to the F^- ions (the response speed of the detector). It is generally essential that the anionic conductivity of a solid electrolyte should be higher than 10^{-4} S m^{-1} for it to be used in detectors. This anionic conductivity of a fluoride glass can be achieved by various means.

The construction of chemical current sources based on fluoride solid electrolytes is appealing due to high free energies of the formation of fluorides. Taking into account these values, high calculated electromotive forces (several Volts) were obtained. The fluoride-ionic conductivities of fluoride glasses used presently in chemical current sources are in the range of 10^{-5}–10^{-4} S m^{-1} at room temperature. The internal resistances of these sources are higher than those of traditional cells based on liquid electrolytes. To reduce the internal resistance of a current source, it is necessary to use either high temperature (heating to 150 °C) or a thin-film technology. It should be noted that amorphous solid electrolytes readily form thin films, which do not require high annealing temperatures and are compatible with the silicon technology.

VII. Conclusion

By applying the principles of the isomorphism of atoms to the glassy state, multicomponent glasses possessing the required electrophysical properties can be prepared in the basic glass-transition region of the fluoride system. Isovalent substitutions in the series $Li^+ < Na^+ < K^+ < Rb^+ < Cs^+$, $Ba^{2+} < Pb^{2+}$, $Al^{3+} < Ga^{3+} < Sc^{3+} < In^{3+}$ and $Hf^{4+} < Zr^{4+}$ lead to the enhancement of the ion transport in fluoride glasses. However, it should be noted that the introduction of hygroscopic KF, RbF and CsF or readily hydrolysable PbF_2, InF_3 and BiF_3 leads to a decrease of the chemical stability of glasses.[8]

Compositions of fluoride glasses, which possess high anionic conductivities and can serve as a basis for ion-selective membranes and detectors, have been formulated. An increase in the fluoride-ionic conductivity is associated primarily with a decrease in the activation energy of migration of charge carriers. High conductivities are characteristic of fluoroindate glasses of the $40\,InF_3 \cdot 45\,PbF_2 \cdot 15\,BaF_3$ ($\sigma_{200\,°C} = 5 \times 10^{-2}$ S m^{-1}) and $30\,InF_3 \cdot 35\,BaF_2 \cdot 35\,BiF_3$ ($\sigma_{200\,°C} = 3 \times 10^{-2}$ S m^{-1}) types and also of fluorophosphate glasses of the $10\,Al(PO_3)_3 \cdot 85\,PbF_2 \cdot 5\,MnF_2$ type ($\sigma_{200\,°C} = 1 \times 10^{-2}$ S m^{-1}).

Investigations of the cation (particularly, lithium) transport in fluoride glasses call for special consideration. For example, high lithium-ionic conductivities are manifested by the fluoride and oxyfluoride glasses $50\,LiF \cdot 30\,Li_2O \cdot 20\,Al(PO_3)_3$ ($\sigma_{300\,°C} = 1$ S m^{-1}),[87,88] $80\,LiF \cdot 20\,UF_4$ ($\sigma_{150\,°C} = 1 \times 10^{-1}$ S·m^{-1}), $60\,LiF \cdot 30\,ThF_4 \cdot 10\,BaF_2$ ($\sigma_{170\,°C} = 2 \times 10^{-2}$ S m^{-1}, $E_a = 0.58$ eV), $80\,LiF \cdot 20\,Al(PO_3)_3$ ($\sigma_{200\,°C} = 3 \times 10^{-3}$ S m^{-1}, $E_a = 0.61$ eV),[32] $60\,LiF \cdot 20\,ZrF_4 \cdot 10\,ThF_4 \cdot 10\,BaF_2$ ($\sigma_{175\,°C} = 2 \times 10^{-2}$ S m^{-1});[89] high sodium-ionic conductivities are exhibited by the glasses $80\,NaF \cdot 20\,Al(PO_3)_3$ ($\sigma_{200\,°C} = 2 \times 10^{-3}$ S m^{-1}, $E_a = 0.80$ eV)[23] and $50\,NaF \cdot 50\,B_2O_3$ ($\sigma_{200\,°C} = 2 \times 10^{-5}$ S m^{-1}, $E_a = 0.93$ eV);[90] potassium-ionic conductivity is manifested by the $80\,KF \cdot 20\,Al(PO_3)_3$ glass ($\sigma_{200\,°C} = 4 \times 10^{-6}$ S m^{-1}, $E_a = 0.76$ eV).[23]

Studies of crystallisation of glasses are of interest in connection with the possibility of the construction of nanocrystalline superionic conductors. One of the problems is the design of a microcrystalline structure in an amorphous glass by crystallisation (the preparation of superionic composites); in fluoride systems, the conductivities of partially disordered crystalline phases (solid solutions) are higher than those of glassy phases (see Fig. 2). To produce a microcrystalline structure in a glass, annealing should be carried out in such a way that a large number of crystallisation centres appear and the rate of crystal growth is low. The first stage of crystallisation may involve isolation of small crystals of intermediate metastable phases. It is assumed that the growth of large crystals is retarded by the amorphous phase.

Abstract. The results of studies on the nanochemistry of metals published in recent years are generalised. Primary attention is centred on the methods for the synthesis of nanoparticles and their chemical reactions. The means of stabilisation of nanoparticles which involve individual metals and incorporate atoms of several metals are considered as well as their physicochemical properties. Self-assembling processes of nanoparticles are described. The prospects of using metal nanoparticles in semiconductor devices, catalysis, biology and medicine are discussed. The bibliography includes 165 references.

I. Introduction

The last decade of the XXth century was marked by the increased attention of scientists in the fields of physics, chemistry, materials science, *etc*. devoted to nanoparticles, *viz*., to their synthesis, properties and different reactions. The reason for this lies in the fact that particles of nanometer sizes exhibit peculiar mechanical, optical, electrical and magnetic properties different from those of the corresponding macroparticles. Since 1990, the annual growth in publications devoted to both nanoparticles themselves and the prospects of their application in nanotechnologies has been observed. The methods of synthesis and stabilisation of nanoparticles as well as their optical, magnetic and other properties have already been summarised. In particular, quite a number of books, collections of papers and surveys devoted to metal and semiconductor nanoparticles and materials fabricated on their basis have already been published.[1–15]

At the same time, studies on the chemical reactions that involve nanoparticles are still in their infancy, and even the keyword 'nanochemistry' has appeared in reference journals relatively recently. This review is intended to make up for this gap. It mainly deals with chemical reactions that involve metal nanoparticles; however, a special section is devoted to the synthesis, stabilisation and physicochemical properties of nanoparticles based on individual metals, several metals and metal compounds.

In this review, an attempt is undertaken to follow the main trends in the development of this new scientific field by considering studies published mostly in 2000. Primary attention is given to the use of low temperatures in studies on the activities of metal nanoparticles and size effects. (The question of how the particle size affects its reactivity still remains one of most challenging and stubborn questions of modern chemistry.[16]) Self-assembling of nanoparticles and their application in catalysis and photocatalysis are discussed. Major problems of the chemistry of nanoparticles and nanomaterials are considered and approaches to their solution are suggested.

II. Synthesis and chemical reactions of metal nanoparticles

Until recently, particles with sizes in the range from 1 to 100 nm were assigned to nanoparticles (in certain studies, this interval was even extended to 1000 nm), although, in accordance with the International System of Units (SI) (the prefix nano- is used for fraction units, *viz.,* 10^{-9}), nanoparticles should involve only particles with sizes in the range from 1 to 10 nm, and it is more correct to consider 100-nm particles as ultradispersed ones and the materials based on them as macroscopic materials.

Nanochemistry studies synthetic methods and chemical properties of particles with sizes of 1 – 10 nm. The most interesting problems of nanochemistry are concerned with the reactivity of nanoparticles. For example, chemical properties of 1-nm particles that contain $\sim$10 metal atoms can be changed by introduction of only one atom. This is why, it is important to know and correctly understand the chemical and physical regularities that govern the activities of particles with the sizes of an order of magnitude of 1 nm.

Investigation of the dependence of chemical and physical properties of nanoparticles on the number of constituent metal atoms and the nature of ligands bound to nanoparticles represents a new direction in nanochemistry. At present, this field accumulates the knowledge which will allow one to understand the effects of the geometry, electronic properties and sizes of such systems on their reactivities. Properties of nanoparticles synthesised in the gas

phase have been studied in more detail. The joint use of a supersonic jet, pulse lasers and mass spectrometry made it possible to obtain, identify and characterise 'free' nanoparticles containing different numbers of metal atoms. The dependence of the chemical activity of nanoparticles in the gas phase on the number of the constituent atoms was studied in detail for niobium [17] and iron [18] particles.

At present, attention is focused on the development of methods for the synthesis and stabilisation of nanoparticles in the liquid phase. Special attention is paid to the preparation of monodispersed particles.

1. Reduction in solution

Methods of chemical reduction play an important role in the solution of the problem of synthesis of monodispersed particles. These methods were mainly used for the synthesis of gold and silver nanoparticles and less often for platinum, cobalt, nickel and copper nanoparticles.

Spherical silver nanoparticles with sizes of 3.3–4.8 nm were synthesised by reduction of silver nitrate by sodium borohydride in the presence of bis[(trimethylammoniodecanoylamino)ethyl] disulfide dibromide as a stabiliser.[19] The particles obtained were characterised by active light absorption in the wavelength range near 400 nm, which corresponded to the silver plasmon peak and indicated the metallic nature of the particles. The environment effect on the stability of silver particles formed showed that the latter form aggregates in the presence of sulfuric and hydrochloric acids. The stability of silver particles was also shown to depend on the pH of the medium; at pH 5–9 in aqueous media, the particles remained stable for a week. Both an increase and a decrease in the pH resulted in fast aggregation and precipitation of silver particles. The effect of the pH on the stability of gold particles was less pronounced compared with silver particles.

Metal nanoparticles of controllable sizes (1–2 nm) were prepared using amphifillic poly(octadecylsiloxane) as a matrix.[20]

Hybrid matrices based on polyelectrolyte gels with oppositely charged surfactants were used as nanostructurised media for the reduction of various platinum salts by sodium borohydride and hydrazine. It was shown that with $NaBH_4$ as the reductant small platinum particles with radii of $\sim$2–3 nm were mainly formed, whereas the use of hydrazine resulted in particles of $\sim$40 nm.[21]

For cobalt nanoparticles in aqueous solutions, the formation mechanism, electronic spectra and reactions were studied.[22] Radiation-induced chemical reduction of cobalt ions from aqueous solutions of $Co(ClO_4)_2$ and HCOONa produced spherical cobalt particles with diameters of 2–4 nm. Sodium polyacrylate with a molecular mass of 2100 was used as a stabiliser. Radiolysis produced solvated electrons e^-_{aq}, hydroxyl radicals, hydrogen atoms and $CO_2^{-\bullet}$ radical ions

$$H_2O \longrightarrow e^-_{aq}, H^\bullet, OH^\bullet,$$

$$OH^\bullet(H^\bullet) + HCO_2^- \longrightarrow H_2O(H_2) + CO_2^{-\bullet}.$$

Hydrated electrons and $CO_2^{-\bullet}$ radical ions reduced Co^{2+} ions producing cobalt nanoparticles which demonstrated an absorption maximum in the 200 nm wavelength range. The use of pulse radiolysis has shown that the reduction of Co^{2+} with the formation of cobalt nanoparticles occurred by an autocatalytic mechanism.

Radiation-induced chemical reduction of Ni^{2+} ions in aqueous solutions of $Ni(ClO_4)_2$ containing propan-2-ol in the presence of polyethylene, polyacrylate and poly(vinyl sulfate) produced metal sols comprising spherical particles with diameters of 2–4 nm. Nickel nanoparticles easily oxidisable by O_2 and H_2O_2 form sufficiently stable Ni–Ag nanosystems in the interaction with silver ions.[23]

Spherical copper particles measuring 20–100 nm were obtained by γ-radiolysis of $KCu(CN)_2$ aqueous solutions in the presence of methanol and propan-2-ol as the acceptors of hydroxyl radicals.[24]

Silver particles were obtained upon γ-radiolysis of solutions of silver nitrate in water, ethanol and 0.01 M $C_{12}H_{25}OSO_3Na$.[25] The fractal dimensions of aggregates were 1.81, 1.73 and 1.70 in water, ethanol and $C_{12}H_{25}OSO_3Na$, respectively.[25] Stable nanoparticles (the average size of 1–2 nm) of platinum, rhodium and ruthenium were prepared in organic media by heating the corresponding colloidal solutions of the metal hydroxides in ethanol.[26]

Silver particles measuring 2–7 nm were obtained by electrochemical dissolution of a metal anode (silver plate) in an aprotic solution of tetrabutylammonium bromide in acetonitrile.[27] This process was shown to depend on such characteristics as the current density and the nature of the cathode material. Thus at high current densities under nonequilibrium conditions, particles of irregular shapes can be formed. In the interval from -1.35 to -6.90 nA cm^{-2}, the particle diameter changed from 6 ± 0.7 to 1.7 ± 0.4 nm. In the reduction of silver ions stabilised by tetrabutylammonium bromide, silver nanoparticles were formed and deposited on cathodes made of either platinum or aluminium (Fig. 1). The use of platinum cathodes resulted mainly in the formation of spherical silver nanoparticles, whereas only films were deposited on aluminium cathodes. An analysis of the optical spectra of nanoparticles measured during their syntheses led to the conclusion that this process includes an autocatalytic stage. It was also shown that the half-width of the surface plasmon peak of a particle linearly depends on $1/R$ (R is the particle radius) and the plasmon band shifts to lower frequencies with a decrease in the particle size.

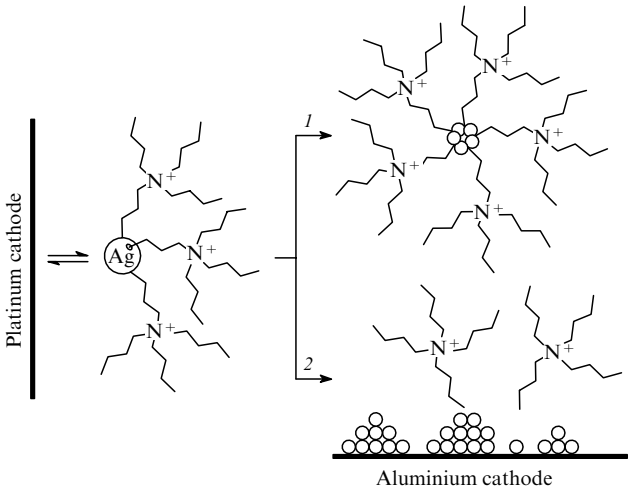

Figure 1. Schematic illustration of the competition between two processes. (*1*) Formation of silver particles and (*2*) deposition of particles and formation of a film.[27]

2. Reactions in micelles, emulsions and dendrimers

Micelles, emulsions and dendrimers,† which can be considered as a sort of nanoreactors, which make it possible to synthesise particles of definite sizes, are used for preparing metal nanoparticles. Crystalline bismuth nanoparticles measuring less than 10 nm were obtained by reduction of aqueous solutions of bismuth salts inside reverse micelles based on sodium diisooctyl sulfosuccinate (usually designated as AOT).[28] Mixing of AOT dissolved in isooctane with a certain volume of an aqueous solution of $BiOClO_4$ resulted in the formation of reverse micelles. The

† A dendrimer represents a highly branched macromolecule which includes a central core, internal repeating units and terminal functional groups. Dendrimers with small numbers of internal units exist in an 'open' form, whereas those involving large number of units form spherical three-dimensional structures. Terminal groups of dendrimers can be modified by hydroxy, carboxy and alkyl groups.

micellar solution of $NaBH_4$ was prepared in the same fashion with the same ratio $w = [H_2O]:[AOT]$. Both solutions were mixed under argon. Bismuth particles precipitated after the mixture was kept for several hours at room temperature. The liquid phase was removed *in vacuo*, and the dry residue was dispersed in toluene. According to X-ray powder diffraction and electron spectroscopy data, a dark solution thus obtained contained bismuth particles measuring 3.2 ± 0.35 nm for $w = 2$ and 6.9 ± 2.2 nm for $w = 3$. When polymers were used for the protection of crystalline bismuth particles, the particle size increased to 20 nm and further.[29]

Reduction of rhodium salts in water in the presence of an amphiphilic block copolymer of styrene with ethylene oxide and an anionic surfactant (sodium dodecyl sulfate) produced rhodium particles with diameters of 2–3 nm stabilised by the block copolymer.[30] Luminescent nanomaterials based on yttrium oxide doped with europium were synthesised using non-ionic reverse microemulsions based on poly(ethylene oxide) and other ethers.[31]

At present, an active search is directed to macromolecules that can be used as matrices in syntheses of nanoparticles. In such methods, the stabiliser molecules interact with the surfaces of metal particles and affect their growth. For example, the reduction of bivalent copper in the presence of poly(*N*-vinylpyrrolidone) produced particles with the diameters of 7 ± 1.5 nm at 11 °C and 10 ± 2 nm at 30 °C.[32] Studies on the temperature effect on the stability of preformed nanoparticles have shown that if copper particles formed at 11 °C were heated to 30 °C, their polymeric shell lost its protective properties, which enhanced aggregation and accelerated oxidation of metal particles. The opposite result was achieved by cooling to 11 °C the system formed at 30 °C. In this case, the particles do not aggregate, their sizes remain unchanged and the resistance to oxidation increases. The competition of different temperature-dependent processes is reflected not only in the stabilities of particles formed but also in their size distribution.

Photochemical reduction of Ag^+ ions in the presence of dendrimers with terminal amino and carboxy groups produced silver particles with an average diameter of ~7 nm.[33] Below, a possible mechanism of particle formation is shown.

$$Ag^+ + [\text{dendrimer}]-CO_2^- \xrightarrow{h\nu} Ag^0 + [\text{dendrimer}]-CO_2^{\bullet} \longrightarrow$$
$$\longrightarrow [\text{dendrimer}]^{\bullet} + CO_2,$$
$$Ag^+ + [\text{dendrimer}]-NH_2 \xrightarrow{h\nu} Ag^0 + [\text{dendrimer}]-NH_2^{+\bullet}.$$

The particle size can be controlled by varying the nature of the dendrimers. Currently, stabilisation of metal nanoparticles is performed in the presence of dendrimers based on polyamidoamines and their derivatives. The use of dendrimers as microreactors for the synthesis of metal nanoparticles was documented in Ref. 34. Monodispersed spherical polyamidoamine dendrimers are permeable to low-molecular reactants. Thus an addition of $HAuCl_4$ to an aqueous solution of a dendrimer with primary and tertiary amino groups results in the appearance of a protonated dendrimer with $AuCl_4^-$ as the counter-ion. Reduction of $AuCl_4^-$ anions by sodium borohydride have produced 1–5-nm gold particles. By varying either the concentration ratio (D) of $AuCl_4^-$ counter-ions to terminal amino groups or the diameter (generation) of the dendrimer, one can control the particle size. Reduction of gold ions in a dendrimer of the ninth generation (G.9) resulted in the formation of spherical gold particles with the sizes of 2.5, 3.3 and 4 nm for $D = 1:4$, $1:2$ and $1:1$, respectively. For $D = 1:1$, gold particles measuring 2, 2.5, 3.2 and 4 nm were formed in dendrimers of the G.6, G.7, G8 and G.9 generations, respectively.

Reduction of gold and silver salts in the presence of modified dendrimers produced particles with an average diameter of 2–6 nm. The autocatalytic mechanism of the reaction has been revealed using spectral methods.[35]

The prospects of using mesopores for the preparation of different nanosize materials were discussed.[36] Nanoparticles of silver and silver sulfide were obtained in nanosize cavities of perfluorinated ionomer membranes.[37] Reduction of metal ions in the presence of aminodextran and styrene resulted in the formation of spherical polystyrene particles with diameters of ~2.0 μm covered with gold and silver islets measuring from 5 to 200 nm.[38]

3. Particles of different shapes and films

The sizes and shapes of particles often depend on the synthetic methods; however, the ratio of nucleation to growth rates of particles is also of great importance. Each of these processes depends in turn on variations in the reaction conditions such as temperature, the nature and concentrations of metal and ligand and the nature of stabiliser and reductant. The problems of nucleation and particle growth are surveyed in detail elsewhere.[15]

The shapes of metal nanoparticles formed in the reduction of metal salts can be controlled using tetra-n-octylammonium carboxylates $(n\text{-}C_8H_{17})_4N^+(RCO_2)^-$ as the reductants and stabilisers (see Ref. 39). Palladium particles measuring 1.9 and 6.2 nm were formed in the reaction

$$Pd(NO_3)_2 + (n\text{-}C_8H_{17})_4N^+(RCO_2)^- \xrightarrow{\text{THF, 66 °C}} \text{Pd particles.}$$

Their sizes and shapes were determined by electron microscopy. It was found that if acetate, dichloroacetate, pivalate or pyruvate anions were used, the particles formed had largely spherical shape. However, if palladium nitrate was treated with an excess of $(n\text{-}C_8H_{17})_4N^+(HOCH_2CO_2)^-$, triangular particles with an average size of 3.6 nm were formed in addition to spherical ones. The shape changes observed were attributed [39] to the presence of the hydroxy group in the anion.

A nickel compound $Ni(COD)_2$ (COD is cycloocta-1,5-diene) was used for elucidating the role (reductant or stabiliser) the glycolic acid residue plays in the reduction.[39] The reaction was as follows:

$$Ni(COD)_2 + (n\text{-}C_8H_{17})_4N^+(HOCH_2CO_2)^- \xrightarrow{H_2,\ 60\ °C} \text{Ni particles.}$$

Inasmuch as nickel in $Ni(COD)_2$ is in its zerovalent state, the glycolate can act only as a stabiliser, whereas it is hydrogen that reduces COD to cyclooctane. By means of electron microscopy it was found that the reaction produces crystalline nickel particles with an average size of 4.5 nm preferentially shaped as triangles. In control experiments using $(n\text{-}C_8H_{17})_4N^+Br^-$ or $(n\text{-}C_8H_{17})_4N^+NO_3^-$ as stabilisers, spherical particles were formed. The triangular shape of particles was additionally confirmed by the results of scanning tunnelling microscopy. The glycolate effect on the morphology of particles formed seems to be associated with the selective adsorption of anions on growing nanocrystals, which can be traced by changes in the absorption spectra. During synthesis of nanoparticles, the band at 1621 cm^{-1} which belongs to dissolved glycolate disappears, and a new band appears at 1604 cm^{-1}, which corresponds to adsorbed glycolate. It is believed [39] that the changes observed in the IR spectra recorded *in situ* agree with the proposed mechanism.

The formation of spherical and cylindrical silver nanoparticles was observed upon photochemical reduction of silver salts in the presence of polyacrylic acid.[40,41] Polyacrylic acid and Ag^+ ions form a complex which, being illuminated, produces silver nanoparticles. According to electron microscopy and sedimentation analysis data, photoreduction of the complex produced spherical silver nanoparticles measuring 1–2 nm. In the presence of a modified (partially decarboxylated) acid, apart from spherical particles, elongated particles (nanorods) with lengths of up to 80 nm characterised by light absorption in the 500–800-nm range were also formed. Apparently, decarboxylation disturbs the cooperative mechanism of the bonding between polyacrylic acid and

silver cations, making the stabilisation of spherical particles less effective and favouring the growth of nanorods.

The sizes of metal particles formed in the presence of macromolecular stabilisers depend on the conditions of formation of the polymeric protective shell. If the polymer involved is an insufficiently effective stabiliser, a particle already bound to the macromolecule may continue to grow. Changing the monomer and the corresponding polymer and varying the polymer concentration in solution, enables one to control the sizes and shapes of particles formed.

An original method of changing the stabilising ability of a polymer was proposed.[42] The authors studied how the conformation of poly(*N*-isopropylacrylamide) affected the shape of platinum nanopartilcles formed upon the reduction of K_2PtCl_4 by hydrogen. This polymer can change its conformation with temperature. Below 306 K, polymer molecules are hydrophilic and represent swelled globules; in this case, up to 60% of platinum nanoparticles formed have irregular shapes. At temperatures above 306 K, polymer molecules are hydrophobic and begin to collapse. The stabilising ability of such molecules decreases. At 313 K, the reduction of platinum ions proceeded on the most active (111) face of the growing nanocrystal, and cubic nanoparticles were preferentially formed (in up to 68% yield). The morphology of the particles also depended on the concentration ratio of platinum salt and polymer in solution (however, to the lesser extent than on the temperature).

The shapes and sizes of silver nanoparticles can be controlled when the methods of pulse sonoelectrochemistry (the use of ultrasound in electrochemistry) were applied.[43,44] Ultrasound allows one to clean and degasify the electrode surface, accelerate mass transfer and increase the reaction rate. Silver particles shaped as spheres, rods and dendrites were obtained by the electrolysis of aqueous solutions of $AgNO_3$ in the presence of $N(CH_2COOH)_3$. These were characterised by electron microscopy, X-ray diffraction and electron spectroscopy. The shapes of particles were found to depend on the reagent concentration. Spherical particles had diameters of $\sim$20 nm. The diameters of rods were 10–20 nm. In certain cases, their surfaces exhibited protrusions which could be developed into dendrites.

An interesting method of successive layer-by-layer deposition of thin (100–300 nm) films incorporating magnetic nanoparticles was considered.[45] Alternating layers of magnetic nanoparticles, *e.g.*, Fe_3O_4, and poly(diallyldimethylammonium bromide) were first deposited on a glass plate covered with paraffin and acetyl cellulose. Upon reaching the desirable film thickness, the cellulose layer was removed, and the whole specimen was dissolved in acetone. The suspension thus obtained could be applied on any porous surfaces and dense supports. It was noted that the films which incorporate uniform magnetic nanoparticles measuring $\sim$10 nm, can be used in memory devices.[46]

At present, the control over the shapes and sizes of nanoparticles seems to be the most important problem of nanochemistry.[47] Synthesis of uniform spherical and rod-like particles of metallic iron have been described.[48] Nanoparticles were prepared by thermal decomposition of iron pentacarbonyl in the presence of stabilisers. Spherical particles measuring 2 nm were uniformly dispersible in solution and formed rods of 2-nm diameters and 11-nm lengths. These particles were amorphous, whereas the rods had the face-centred cubic structure of α-iron.

Different supports with films of 4-mercaptobenzoic acid applied in high vacuum were used for the preparation of thin heterogeneous films with incorporated nanoparticles of gold, silver, and cadmium sulfate. The heterogeneous films were synthesised by successive immersion of supports in the corresponding solutions.[49]

High-resolution electron microscopy has shown that, being encapsulated into micelles, rod-like gold nanoparticles prepared by an electrochemical method grow along the [001] axis. Here, (100) faces of the particles remain stable, whereas (110) faces are unstable.[50]

The possibility of structural changes in platinum nanoparticles supported on silicon and the microcrystalline structure of individual nanoparticles were studied by electron microscopy before and after the system was heated *in vacuo* and in hydrogen and oxygen atmospheres.[51] In all the cases, the mass of particles remained unchanged, but the sizes of constituent crystals increased with temperature. This was attributed to surface fusion and self-diffusion of platinum particles. Studies of adhesion of platinum particles to silica which were carried out using atomic force microscopy have shown that heating changes the crystalline nature of particles and strengthens their adhesion to silica. Moreover, platinum nanoparticles were shown to be stable both under oxidative and reductive conditions.

4. Reactions of oxides

Like metals, oxides also find extensive application in practice. The reactivity of metal oxides is low compared with the corresponding metals; therefore, oxide formation is used for stabilising metal nanoparticles. Recently, metal oxide nanoparticles have been employed in reactions which are of interest for nanochemistry.

An original application of nanocrystalline zinc oxide has been described,[52] where zinc oxide was synthesised by a modified sol–gel method by the reactions

$$ZnEt_2 + 2\,Bu^tOH \longrightarrow Zn(OBu^t)_2 + 2\,C_2H_6,$$

$$Zn(OBu^t)_2 + 2\,H_2O \longrightarrow Zn(OH)_2 + 2\,Bu^tOH,$$

$$Zn(OH)_2 \longrightarrow ZnO + H_2O.$$

The process of ZnO preparation involved three stages: synthesis, isolation and activation. The latter process, in turn, consisted of several successive stages of thermal treatment. First, the powder was slowly heated to 90 °C and kept at this temperature for 15 min. Then, the temperature was gradually increased to 250 °C, held at this level for 15 min and slowly decreased to room temperature. Zinc oxide thus obtained represented crystalline nanoparticles measuring 3–5 nm with a surface area of $\sim$120 $m^2\ g^{-1}$. Nanosize zinc oxide was used in the reaction

$$2\,ZnO + CCl_4 \longrightarrow CO_2 + 2\,ZnCl_2.$$

The process was carried out at 250 °C, and CCl_4 was introduced into the reaction vessel portionwise at 7-min intervals. Carbon dioxide and nonconsumed CCl_4 were quantitated by gas chromatography. Nanocrystalline zinc oxide was shown to be more reactive than common commercial specimens. It was also shown that the adsorption of sulfur dioxide and the destructive adsorption of diethyl 4-nitrophenyl phosphate (a noxious organophosphorus compound) proceed with a higher efficiency on nanocrystalline zinc oxide.[52] In these processes, nanocrystalline ZnO exhibited higher reactivity compared with commercial specimens.

Nanocrystalline oxides of alkali-earth metals were successfully used for deactivation of yperite (mustard gas) and other war gases. Autocatalytic dehydrohalogenation of 2,2′-dichlorodiethyl sulfide on nanocrystalline calcium oxide was studied using NMR technique.[53] The decomposition products of 2,2′-dichlorodiethyl sulfide were found to involve divinyl sulfide ($\sim$80%) and thioglycol and/or a sulfonium ion ($\sim$20%) with a hydroxyalkyl group, which seem to provide its binding to the surface of the alkali-earth metal oxide. In addition to the reaction of CaO with yperite, its reactions with organophosphorus compounds were studied. The kinetics of the reactions of all studied substances with calcium oxide was shown to be characterised by a rapid initial stage followed by a slow diffusion-controlled stage.

An interesting application of transition metal oxides has been discussed.[54] Particles of cobalt, nickel, copper and iron oxides measuring 1–5 nm were used as the electrode materials in lithium power sources (electrochemical capacity of 700 $\mu A\ h\ g^{-1}$). Here, the formation and decomposition of Li_2O and the accompanying reduction and oxidation of nanoparticles occur on electrodes

made of CoO nanoparticles. The scheme of reversible reactions is as follows:

$$2\,Li - 2e^- \rightleftharpoons 2\,Li^+$$
$$CoO + 2\,Li^+ + 2e^- \rightleftharpoons Li_2O + Co$$
$$CoO + 2\,Li \underset{2}{\overset{1}{\rightleftharpoons}} Li_2O + Co$$

The direct reaction (*1*) is possible and thermodynamically permissible. The reverse reaction (*2*) is unusual for electrochemistry, because Li_2O is traditionally considered to be electrochemically inactive. Electrochemical decomposition of Li_2O using mechanically ground Li_2O and CoO powders could not be effected.[54] Thus, the possibility of the reverse reaction is associated with the use of nanoparticles and the increase in their electrochemical activity with a decrease in size.

Currently, great attention has been drawn to the preparation and analysis of physicochemical properties of hybrid nanomaterials of the core–shell type and the particles which involve two and even three different metals.

New nanocrystalline hybrid core–shell materials such as TiO_2-MoO_3 were prepared and studied in detail.[55] The $TiO_2-(MoO_3)_x$ particles were synthesised by co-nucleation of metal oxides on the surfaces of micelles.

In such materials, the photoabsorption energy correlates with the particle size. With a decrease in the sizes of TiO_2-MoO_3 particles from 8 to 4 nm, the absorption energy decreased from 2.9 to 2.6 eV. For comparison, it may be noted that the forbidden gap energies of bulk TiO_2 and α-MoO_3 are 3.2 and 2.9 eV, respectively. Unfortunately, the materials obtained turned out to be less efficient in photocatalysed oxidation of acetaldehyde compared with common titanium dioxide produced by Degussa (France).

To facilitate the electron transport in metal nanoparticles, it was proposed to use the pH-induced changes in the charges of stabilising shells which are bound to the particle surface. Molecules of rigid mercaptophenylacetylenes were shown to bind strongly gold and silver particles.[56] It was found that electron transport in charged gold particles is better described in terms of classical rather than quantum-mechanical concepts.[57]

The use of nanoparticles of metals and their oxides in optical and electronic devices requires that new approaches be found to the solution of such problems as: establishment of reliable electrical contacts between individual nanoparticles; determination of characteristics of electromagnetic interactions between particles in symmetrical well-organised aggregates of nanoparticles; elucidation of how the chemical properties of the surface of nanoparticles depend upon their size and its effect on their optical and electronic properties.[58]

5. Bi- and trimetallic particles

Nanoparticles that involve two or more different metals are of particular interest for the development of materials with novel properties, because at the nanolevel it is possible to synthesise such intermetallic compounds and alloys that can never be formed for bulk specimens.

Nanoparticles involving two[59] and even three[60] different metals were obtained by radiation-induced reduction of salt solutions. A two-step synthesis was used for the preparation of Au–Hg particles. First, radiation-induced reduction produced 46-nm gold particles. Then, $Hg(ClO_4)_2$ and propan-2-ol were added to the gold sol, which resulted in deposition of mercury ions on the gold particles. Finally, mercury ions were reduced by free radicals formed upon radiolysis.

Palladium particles measuring 4 nm with a narrow size distribution were prepared by the reduction of Na_2PdCl_4 by hydrogen in the presence of sodium citrate. The addition of $K_2Au(CN)_2$ to the sol of palladium particles in methanol followed by γ-irradiation resulted in the reduction of gold ions. No individual gold particles were formed: all gold was deposited on palladium particles and formed an outer layer. A silver layer could also be deposited on the Pd–Au particles obtained. These multilayer clusters seem to be of interest for studying rapid (femtosecond) electronic processes.[61,62]

The use of silicates modified by organic compounds as matrices and stabilisers made it possible to synthesise bimetallic nanoparticles, their sols and gels by a single-step method.[63] Scanning tunnelling microscopy studies of Pd–Pt particles have shown the latter to consist of palladium cores covered with platinum shells. Thin silicate films with bimetallic nanoparticles were used in electrocatalytic oxidation of ascorbic acid.

A sonochemical method was applied to produce bimetallic gold–palladium nanoparticles.[64] The particles were synthesised in aqueous solutions of $NaAuCl_4 \cdot 2H_2O$ and $PdCl_2 \cdot 2NaCl \cdot 3H_2O$ with sodium dodecyl sulfate added. The latter functioned as both the stabiliser and the reductant. The bimetallic particles synthesised represented cores of gold atoms surrounded by shells of palladium atoms. The sizes of cores and shells were measured for different gold to palladium ratios using high-resolution electron microscopy. The use of X-ray spectroscopy allowed the gold and palladium contents in the particles to be determined. With the known density, mass and initial ratio, one can estimate the sizes of cores and shells (Table 1). Using the sonochemical synthesis of bimetallic particles, one can control the sizes of cores and shells by varying Au^{3+} and Pd^{2+} concentrations. Bimetallic Au–Pd particles exhibited high catalytic activity in hydrogenation of pent-4-enoic acid.

Table 1. Core diameter (gold) and shell thickness (palladium) in Au–Pd bimetallic nanoparticles.

Au : Pd ratio	Experiment		Estimate	
	core diameter	shell thickness	core diameter	shell thickness
1 : 1	6.0	1.0	6.4	0.8
1 : 4	5.0	1.5	4.8	1.6

A comparative study of gold, nickel and bimetallic Au–Ni nanoparticles on amorphous carbon supports, which were obtained by laser ablation of the corresponding pure metals and the alloy, was carried out.[65] Studies accomplished by different methods have shown the bimetallic particles to have, on average, diameters of 2.5 nm and a narrow size distribution, while their composition was found to correspond to that of the evaporated alloy.

Nanoparticles of FeTiH were prepared by mechanical synthesis from a mixture of iron and titanium hydride.[66] Nanosize iron–tungsten composite particles with a tungsten concentration varying from 2 at.% to 85 at.% were synthesised by coreduction of a mechanical mixture of iron hydroxide ($FeOOH \cdot nH_2O$) and tungstic acid (H_2WO_4) in a flow of hydrogen at 740 °C for 1 h. The particles obtained were studied by X-ray diffraction and Mössbauer spectroscopy.[67]

III. Cryonanochemistry of metals

The presence of stabilisers, the size distribution of nanoparticles, their different shapes and the interactions between nanosize particles and the medium complicate the studies of the reactions involving metal nanoparticles. In addition, high chemical activities of metal atoms and nanoparticles they form require special approaches to their studies to be developed. One of such approaches is isolation of nanoparticles at superlow temperatures (4–10 K) in inert-gas matrices. Co-condensation of a large amount of an inert gas, *e.g.*, argon, and a small number of nanoparticles (more than 1000 inert gas species per metal particle) allows active particles to be effectively isolated from one another,

while low temperatures hinder diffusion of these particles and provide their stabilisation in an inert matrix.

Here, we will not analyse all the studies devoted to reactions of metal atoms and the corresponding nanoparticles at low and superlow temperatures and only consider the results of recent publications.[68–70] The specimens under discussion were prepared by co-condensation of vapours of metals and ligands on surfaces cooled either to 10 or 77 K. In certain experiments, the vapours were diluted by argon. The amount of metal deposited was determined using quartz-crystal microbalances. The co-condensates obtained were studied by spectroscopy in UV, visible and IR ranges. ESR spectroscopy was also used. Table 2 lists the products formed upon reactions of magnesium and samarium particles with different ligands in argon matrices at 10–40 K.[68,69]

Table 2. Reaction products of samarium and magnesium particles with different ligands in an argon matrix at 10–40 K.

Metal	Ligand		
	CO_2	C_2H_4	CH_3X (X = Cl, Br)
Mg	$Mg^+CO_2^-$, upon annealing of the matrix	cyclic $Mg(C_2H_4)_2$ (see Fig. 2 *a*), upon annealing of the matrix	CH_3MgX, upon irradiation ($\lambda > 280$ nm for Mg and $\lambda > 300$ nm for Mg_{2-4} and Mg_x)
Mg_{2-4}	$Mg^+CO_2^-$, upon co-condensation		
Mg_x	$Mg^+CO_2^-$, upon annealing of the matrix		
Sm	$Sm^+CO_2^-$, CO, $SmCO_3$, upon annealing of the matrix	$Sm(C_2H_4)$ and $Sm(C_2H_4)_2$ complexes	methane, upon co-condensation
Sm_2, Sm_x	$Sm^+CO_2^-$, CO, $SmCO_3$, upon co-condensation		

Studies of properties of metal nanoparticles, in particular at low temperatures, face various difficulties. Therefore, theoretical simulation of the structures of metal nanoparticles, their electronic, optical and other properties and the processes of their aggregation is gaining in importance.

In theoretical studies of nanoparticles, valuable results can be obtained by *ab initio* quantum-chemical calculations which use the concepts developed by solid-state physics, and by calculations based on the molecular dynamics approach. At present, the Hartree–Fock method is applied for the determination of properties of atoms and small clusters. Particularly, this method was successfully employed for the calculation of the properties of nickel particles which involved $n = 4$, 6, 8 and 13 atoms.[71] The density functional method is also widely used for the simulation of the behaviour of metal nanoparticles.[13] For example, the latter method was used for studying the structure and properties of Pt_{13} and Pt_{55} species.[72] The results obtained were also compared with those of different *ab initio* and semi-empirical quantum-mechanical methods which are used in calculations of properties of metal nanoparticles. The density functional method was applied[73] for studying the products of carbon monoxide adsorption on palladium particles deposited on magnesium oxide. An extended Hückel method was used for studying bimetallic nanoparticles of Pt–Fe alloys with a number of atoms ranging from 13 to 309.[74]

The *ab initio* quantum-mechanical calculations have shown that the magnesium–carbon dioxide system represents a metastable $Mg^+{}^{\bullet}CO_2^{-\bullet}$ radical-ion pair. According to calculations, this pair is stabilised by the argon matrix. The IR spectrum of the argon–ethylene co-condensate have revealed absorption bands of ethylene dimers. As was shown by calculations, the potential

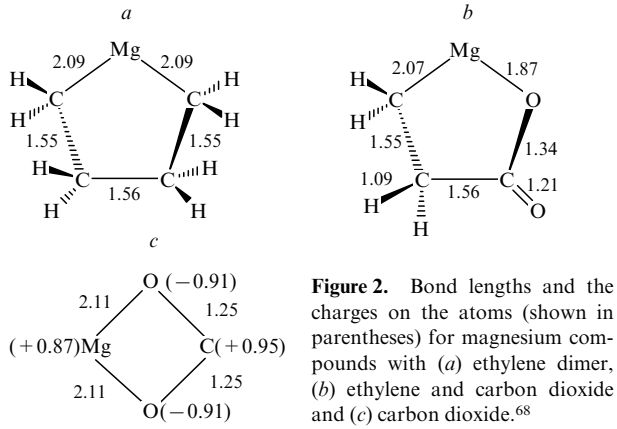

Figure 2. Bond lengths and the charges on the atoms (shown in parentheses) for magnesium compounds with (*a*) ethylene dimer, (*b*) ethylene and carbon dioxide and (*c*) carbon dioxide.[68]

surface of the $Mg \cdot 2C_2H_4$ complex demonstrates no global minimum corresponding to the C_{2v} symmetry. The global minimum can be obtained if only all the restrictions on the system's symmetry are removed. In the Møller–Plessett (MP2) approximation, the minimum corresponded to a cyclic structure which involves an ethylene dimer and a magnesium atom. The interatomic distances in the structures of magnesium complexes with ethylene and carbon dioxide were calculated. Figure 2 shows the structures of these complexes.

Studies of a samarium–carbon dioxide co-condensate have shown that samarium and CO_2 form a complex with an angular structure. In the reaction products, CO and CO_3^{2-} were detected. Radical anions $CO_2^{-\bullet}$ and a samarium carbonyl compound of an uncertain composition were also formed. Figure 3 shows the data on the reaction products identified and on their interconversions. Figure 4 shows the temperature dependence of the relative activity of samarium nanoparticles in the reaction with CO_2. The results

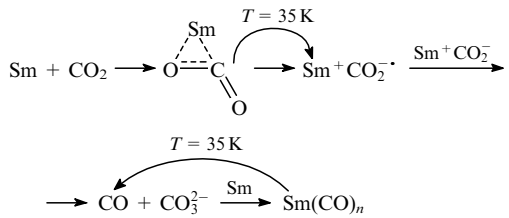

Figure 3. Schematic illustration of the reactions of samarium atoms with carbon dioxide molecules in an argon matrix. Straight arrows are the reactions occurring during co-condensation; curved arrows are the reactions occurring during heating of the co-condensate.[68]

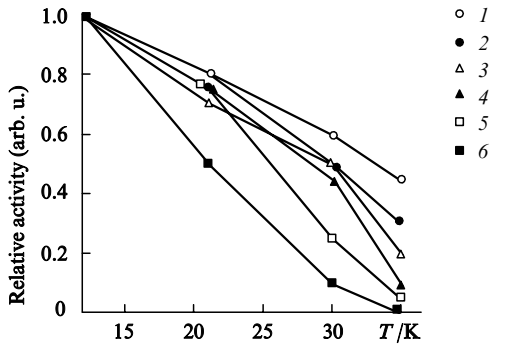

Figure 4. A temperature dependence of the relative activity (in arbitrary units) of samarium atoms and nanoclusters in the reaction with carbon dioxide.[9] (*1*) Sm, $\lambda = 501$ nm; (*2*) Sm, $\lambda = 557$ nm; (*3*) Sm, $\lambda = 520$ nm; (*4*) Sm_x, $\lambda = 641$ nm; (*5*) Sm_x, $\lambda = 600$ nm; (*6*) Sm_2, $\lambda = 541$ nm (λ is the wavelength in the electronic spectrum).

shown suggest a higher activity of samarium nanoparticles compared with samarium atoms. A similar trend was observed for magnesium nanoparticles. According to IR spectroscopic data, in samarium – ethylene co-condensates, 'sandwich' π-complexes of samarium and ethylene SmC_2H_4 and $Sm(C_2H_4)_2$ are formed rather than cyclic compounds typical of magnesium co-condensates.

At ordinary temperatures, the reactions of bulk magnesium and samarium with alkyl halides occur in a similar way to give organometallic compounds. At low temperatures, atoms and small clusters of these metals react with haloalkanes (*e.g.*, with halomethanes) by different routes. Magnesuim inserts into the C – Br and C – Cl bonds with the formation of Grignard reagents, whereas samarium, being more reactive, reduces CH_3Cl and CH_3Br to methane. Thus, on the nanoparticle level, magnesium and samarium behave differently.

Another peculiarity in the behaviour of magnesium and samarium nanoparticles was observed in their reactions with mixtures of two ligands, *viz*., CO_2 and C_2H_4. It was found that under comparable conditions magnesium and samarium react only with CO_2 and do not react with ethylene. The results obtained demonstrate that no unambiguous relationship exists between the activity and selectivity of metal nanoparticles.

The formation of complexes and organometallic nanostructures was studied by an example of film co-condensates of the vapours of metallic silver and mesogenic cyanobiphenyls $C_nH_{2n+1}C_6H_4C_6H_4CN$ ($n = 5$ and 8) and $C_nH_{2n+1}OC_6H_4.C_6H_4CN$ ($n = 8$) in the temperature interval of 80 – 350 K.

Low-temperature co-condensation of silver particles with $C_5H_{11}C_6H_4C_6H_4CN$ and $C_8H_{17}C_6H_4C_6H_4CN$ produced π-complexes stable at low temperature.[68] IR and UV spectroscopic studies have confirmed their formation and revealed their sandwich structures and 1 : 2 composition; 1 : 1 complexes were also detected. The structure of π-complexes determined from IR spectroscopic data was confirmed by model quantum-chemical calculations.[75] Vibrational frequencies of CN groups were also calculated and compared with the experimental ones. Spectral properties of the reaction products of mesogenic cyanobiphenyls with silver particles were discussed in detail elsewhere.[76]

Thermal degradation the complexes undergo on being heated to the room temperature results in the formation of nanosize (15 – 30 nm) silver clusters and their subsequent aggregation with formation of anisotropic particles (more than 200 nm long) stabilised in a liquid-crystal line matrix.[76] An analysis of the ESR spectrum of a co-condensate of silver particles with 4-pentyl-4′-cyanobiphenyl at 90 K has revealed two spectral doublets. The values of the *g*-factor and the hyperfine coupling constant (*a*) for ^{107}Ag and ^{109}Ag are as follows: $g(^{107}Ag) = 2.001$, $a(^{107}Ag) = 48.5$ mT and $g(^{109}Ag) = 2.003$, $a(^{109}Ag) = 72.75$ mT. The occupation degree (ρ_m) of valence *s* orbitals of the metal in the complex was estimated ($\rho_m = 0.77$). The value obtained suggests that electron density is shifted from a silver atom to the π-orbitals of the ligand. The ESR spectrum also revealed a broad anisotropic singlet which was tentatively attributed to zero-valent silver nanoparticles.

Optical spectroscopy in the UV and visible ranges in combination with the dynamic light scattering technique were used for studying the properties of polymer-stabilised silver nanoparticles.[77] Co-condensation of vapours of silver and 2-dimethylaminoethyl metacrylate *in vacuo* occurred on the walls of a glass vessel cooled by liquid nitrogen. According to the electron microscopic data, heating of the co-condensate to room temperature resulted in the formation of polymer-stabilised silver nanoparticles measuring 5 – 12 nm. Dynamic light scattering studies have shown that the size distribution of these particles is bimodal. Such a distribution seems to suggest that both isolated silver particles and their aggregates are simultaneously present in the system. The dependence of the radius of a solvated particle on the nature of the solvent was studied. Among the solvents such as water, toluene and acetone, the latter gave solutions containing silver particles with the smallest radii.[78]

Co-condensation of lead and a monomer polymerisable at low temperatures, *viz*., *p*-xylylene, vapours at 80 K, afforded films with incorporated lead nanoparticles. Conductivity of the films was studied in the course of co-condensation and subsequent heating.[79] The metal – polymer films obtained exhibited satisfactory sensor activity with respect to ammonia in air and ammonia in the presence of water vapour.

Complexes of zero-valent samarium with 1,3,5-tri(*tert*-butyl)-benzene were obtained by co-condensation of metal and ligand vapours at 80 K. Kinetics of thermal decomposition of these complexes was studied.[80,81] Transformations that occur in samarium complexes with mesogenic cyanobiphenyls were also studied at low temperatures.[82] It was shown that the complex with the composition $Sm : C_5H_{11}C_6H_4C_6H_4CN = 1 : 2$ transforms in the temperature range 170 – 210 K into the complex $Sm : C_5H_{11}C_6H_4C_6H_4CN = 1 : 1$; this reaction is characterised by an effective activation energy of 8 kJ mol^{-1}. The reaction of magnesium particles with chloro-, bromo- and iodobutanes at low temperatures was studied.[83] It was shown that the yield of octane (the Würtz reaction product) depends on the amount of magnesium and the carbon – halogen binding energy. The mechanism of the reaction of magnesium with alkyl halides and the earlier data on the cryonanochemistry of metal particles have been discussed elsewhere.[2,3]

IV. Ensembles involving nanoparticles

When metal nanoparticles are synthesised by the condensation method, the process begins with the formation of nanoparticles of individual metal atoms; this may be considered as 'self-assembly' or 'self-organisation'‡ of atoms with the formation of atomic ensembles.

As applied to metal nanoparticles, it is common practice to consider both the ensembles of particles themselves and the ensembles of stabilising protective layers. Prime attention is given to the effect of the chemical nature of stabilisers on self-assembly processes. An analysis of studies devoted to self-assembly and performed before 2000 is given elsewhere.[13] The synthesis of thiol-covered metal particles and their self-assembly into one-, two- and three-dimensional superlattices were surveyed in Ref. 85.

The processes of assembly and self-assembly of nanoparticles were discussed most extensively by the example of silver and gold nanoparticles. Monodispersed silver nanocrystals were stabilised by chemisorption of dodecanethiol on the receptor sites of the crystal surface.[86] The kinetics of aggregation and the structure of the formed ensembles of stabilised particles depend on the number of receptors on the nanocrystal surface.

The formation of alternating positively charged gold particles and negatively charged silver particles and their self-assembly in the presence of 4-mercaptoaniline and 4-mercaptobenzoic acid on a glass surface were described.[87] One-dimensional layers of gold particles on silicon supports were also formed.[88] The latter process was realised using atomic force microscopy (AFM) for surface treatment and chemical deposition of gold particles.

Self-assembly of gold particles measuring 4.6 nm results in aggregates with diameter of ~30 nm.[89] The initial gold particles were prepared by the reduction of $HAuCl_4$ by $NaBH_4$ in the presence of $HSCH_2COONa$. Removal of the excess metal ions from the solution by dialysis resulted in the formation of coarser aggregates. Before the dialysis, the electronic spectra of particles revealed no plasmon peak typical of gold particles.

A method of synthesising materials from 'bricks and mortar' was first described in Ref. 90. Binding between a polymer and

‡ General description of such self-organisation is given in a monograph by Lehn.[84]

thymine-protected gold particles was provided by hydrogen bonds formed. The process of self-association of particles into aggregates, the sizes of the aggregates and their morphology were temperature-controlled. At 23 °C, the initial 2-nm gold nanoparticles formed spherical aggregates with diameter of 97 ± 17 nm. At -20 °C, spherical aggregates with diameter of 0.5 – 1 μm, which in turn comprised finer aggregates as individual subunits, were formed. At 10 °C, ~50-nm-long chains built of spherical nanoparticles were formed. These self-association processes were studied using X-ray small-angle scattering and transmission electron microscopy (TEM). It was assumed that the formation of aggregates at 10 °C is an intermediate stage of the formation of coarser ensembles at -20 °C, and the former aggregates can be used as the precursors of nanoensembles of different shapes and sizes.

Self-assembly of rod-like gold particles with diameter of 12 nm and lengths of 50 – 60 nm was studied using high-resolution electron microscopy.[91] By choosing concentrations of these particles, their size distribution, the conditions of solvent evaporation, its ionic strength and the surfactant concentration, one-, two- and three-dimensional structures can be obtained by electrolysis. A mixture of hexadecyltrimethylammonium bromide and tetraoctylammonium bromide was used as the water-soluble electrolyte. Tetraoctylammonium bromide provided the formation of cylindrical particles, where the ratio of two surfactants determined the diameter to length ratio of the gold nanorods formed. The electrolysis was carried out for 4.5 min. Gold nanorods were formed on a copper wire net partially immersed in solution (on net – solution contacts). Presumably, the following two factors are most important for further self-assembly of the rods, *viz*., the induced convective transfer of particles from the solution to the thin film by evaporation of water and the interaction of particles within the film, which results in the formation of different structures.[91] A possible reason for the parallel arrangement of rod-like particles is associated with capillary forces that act between parallel rods, although more accurate theoretical analysis is required to explain the anisotropy of the rod ensembles observed.

Self-assembly of nanoparticles entails not only the translational ordering but also the orientational one. The orientational ordering is typical of particles with well determined shapes.[92] Structural changes in gold nanorods upon the action of femtosecond and nanosecond laser pulses were studied by high-resolution electron microscopy.[93] The energy of a pulse did not exceed the value necessary for melting the rods but was sufficient for inducing deformational processes which caused changes in the shapes of nanoparticles: a transition of nanorods into nanospheres was observed. The size and shape distributions of nanorods before and after their exposure to a laser beam were statistically analysed.[94]

In connection with the problem of the development of electronic nanodevices, the problem of synthesising nanoparticles protected by monolayers has attracted attention. The methods of preparation of such layers on gold particles by using solutions of hexanethiols and hexanedithiols in organic[95] and aqueous[96] media were developed.

Stable gold films which involved particles measuring ~4 nm were prepared[97] by the reaction of low-molecular-weight ($M \leqslant 4000$) polymers (such as polyethylenimine and poly-L-lysine) with gold particles covered with carboxylic acids. The film morphology was shown to depend on the nature of the acid which covers the particles. The use of mercaptododecanoic and mercaptosuccinic acids has provided films with higher degrees of ordering.

Glass-supported thin porous gold films were prepared using colloidal gold crystals as the templates. These films were studied by scanning tunnelling microscopy.[98, 99]

Microstructures, wettabilities and thermal stabilities of self-assembly manolayers of partially fluorinated alkanethiols of the $F(CF_2)_{10}(CH_2)_nSH$ (n = 2, 6, 11, 17, 33) type on gold particles were studied.[100] Introduction of fluorocarbon chains as the terminal groups into alkanethiols enhanced the stability of self-assembly manolayers (a gold-supported monolayer of non-fluorinated alkanethiols loses its ordering at ~100 °C). Fluorinated compounds with the numbers of methylene groups in a chain n = 11, 17, 33 formed well ordered monolayers. For smaller numbers of methylene units, the degree of ordering decreased. Wettabilities of the layers were also shown to depend on the number of methylene units. Thermal stabilities of self-assembled gold monolayers increased with an increase in n, and for n = 33 the monolayer films formed remained stable in air at 150 °C for 1 h.

The effect of the nature of the support on the morphology of two- and three-dimensional superlattices formed by dodecanethiol-covered silver sulfide nanocrystals of sizes of 5.8 nm were studied.[101] Oriented pyrolylic graphite and molybdenum disulfide were used as the supports. The self-assembly process was monitored by scanning electron microscopy and AFM. It was found that self-assembly into superlattices depends on the nature of the support and is governed, in addition to capillary forces, by van der Waals interactions of the particle – particle and particle – support types.

Self-assembled monolayers of 4′-hydroxy-4-mercaptobiphenyl, 4-(4-mercaptophenyl)pyridine and their mixtures with 4′-methyl-4-mercaptobiphenyl were deposited on the (111) faces of gold crystals and used as the templates for growing glycine crystals.[102] The morphology of glycine crystals obtained depended on the properties of supporting surfaces and was determined by hydrogen bonds formed between glycine molecules in the growing layer and functional groups on the self-assembled monolayer. Hydrogen bonds formed between the CO_2^- and NH_3^+ groups of glycine and a hydroxy group on the surface of a monolayer comprised of $HOC_6H_4C_6H_4SH$ molecules was assumed to be stronger than the interaction between the NH_3^+ group of glycine and the nitrogen atom of pyridine on the surface of a monolayer built of $NC_5H_4C_6H_4SH$ molecules.

As a rule, self-assembly of monolayers of different substances on metal nanoparticles and films was studied using X-ray photoelectron spectroscopy, ellipsometry and diffraction techniques. Electronic spectroscopy was successfully used [103] in studying self-assembly of monolayers of metalloporphyrins and metallophthalocyanines on ultrathin gold films. Gold films 1.3 – 10-nm thick were prepared using high-vacuum evaporation on mica at low temperatures. The deposition rate was varied in the range 0.2 – 0.4 A s^{-1}. The films were annealed at 250 °C for 2.5 – 4 h. The resulting films were studied using scanning atomic force microscopy, electronic spectroscopy and X-ray diffraction techniques. It was shown that isolated structurised islets were formed on the mica surface the sizes and optical properties of which were governed by the conditions of evaporation and subsequent annealing. The electronic spectra of such films demonstrated a peak due to a gold surface plasmon with a wavelength shifting from 606 to 530 nm as the thickness of the film decreased from 10 to 1.3 nm. The kinetic data on the light absorption were used for making semiquantitative estimates of the nature of bonding and chemical and structural properties of the monolayers. It was shown that the absorption in the region of the gold surface plasmon band, which is caused by association of molecules of organometallic compounds on gold films, may be used for monitoring molecules devoid of chromophore groups.

In addition to the sodium salt of AOT, its derivatives with other metals were used as the templates for self-assembly. To correctly interpret the template effect on the self-assembly of metal particles, phase diagrams of such systems are necessary.[104] By the example of the $Cu(AOT)_2 - iso\text{-}C_8H_{18} - H_2O$ system used as a template, it was shown that the shapes of nanocrystalline particles can be dramatically changed under the effect of various salts in small concentrations.[105]

The development of methods for synthesising metal nanoparticles of controllable sizes is of great interest. Apparently, the

majority of studies in this direction employed thiolates and were devoted to the preparation of gold nanoparticles. The use of alkanethiol monolayeres made it possible to synthesise gold particles stable both in solution and in the 'dry' state. Introduction of functional groups in alkanethiols [57] extended the possibilities of such a synthesis.

In the presence of alkanethiols, the formation of gold nanoparticles and the appearance of a protective layer proceed in two steps [106]

$$AuCl_4^- \text{ (in toluene)} + RSH \longrightarrow (Au^ISR)_n \text{ (polymer)},$$

$$(Au^ISR)_n + BH_4^- \longrightarrow Au_x(SR)_y .$$

This reaction combines the processes of nucleation and passivation. An increase in the RSH : Au molar ratio and the addition of the reductant at the earlier stage result, on average, in the formation of particles with smaller metal cores. A short interruption of the reaction favours the formation of thicker coatings with very small cores (< 2 nm).

The dynamics of growth of gold cores in the presence of protective monolayer coatings was studied.[106] The use of transmission electron microscopy made it possible to monitor slow changes in the sizes of gold particle cores which followed the active initial stage of the reaction. Thus it was found that with hexanethiol as the stabilising coating, the core size of a particle based on gold atoms increased to 3 nm during the first 60 h of the reaction and then remained unchanged. The knowledge of the mechanisms of growth and annealing of nanoparticles will allow one to refine the methods for synthesising finer particles with narrower size distributions.

V. Photochemistry and nanophotonics

Recently, studies which deal with kinetics and dynamics of reactions that involve metal nanoparticles have appeared. A photochemical reaction which involves n-dodecanethiol-covered silver nanoparticles dispersed in cyclohexane was studied in a picosecond time interval.[107] Figure 5 schematically shows the photoreaction mechanism.

According to electron microscopic data, the average size of polyhedral $Ag_xSC_{12}H_{25}$ nanoparticles was ~6.2 nm. Under short-term irradiation, the nanoparticles first decomposed to smaller particles (< 2 nm). However, an increase in the irradiation time to 9 min resulted in the appearance of larger (20-nm) particles. Photochemical transformations were detected from the time variations of the intensity and broadness of silver plasmon absorption lines (marked by heavy lines in Fig. 5). It was found that this absorption depends nonlinearly on the light intensity. The kinetics of photolysis of the particles was studied in the nanosecond range, and the corresponding kinetic constants were determined. Changes in the dielectric properties of the environment occurred within 0.5 ns. In response to optical excitation, a part of alkanethiol molecules were split off over the time (3.6 ns) determined by the energy liberated as heat (E_{th}). The proportion of particles with split off thiol groups depended on the excitation-pulse energy. Within 40 ns (recombination time), the thiol-covered particles could also undergo fragmentation. Subsequent exposure to light partially prevented fragmentation of nanoparticles.

In contrast to silver-based nanoparticles, which undergo light-induced chemical transformations, the behaviour of gold-based nanoparticles under similar conditions is characterised by changes in their shapes. Fragmentation of these nanoparticles is dramatically weakened both in polar solvents and with the changes in the length of the alkanethiol chain.[108]

Silver nanoparticles were used for carrying out photochemical transformations of phenazine and acridine.[109] Being adsorbed on the surfaces of silver particles, both molecules were found to decompose under the action of light in a single-photon process with N–C bond cleavage. The reaction rate and the degree of photodecomposition depended on the light wavelength. Being exposed to short-wave laser light, phenazine decomposed with the formation of graphite. The decomposition rate of phenazine was higher compared to acridine, which apparently is due to different orientation of these molecules on the surfaces of silver particles. The reason for the decomposition these molecules undergo on the surfaces of silver nanoparticles remains unclear.[109] The spectra of acridine adsorbed on nanoparticle surfaces revealed two new

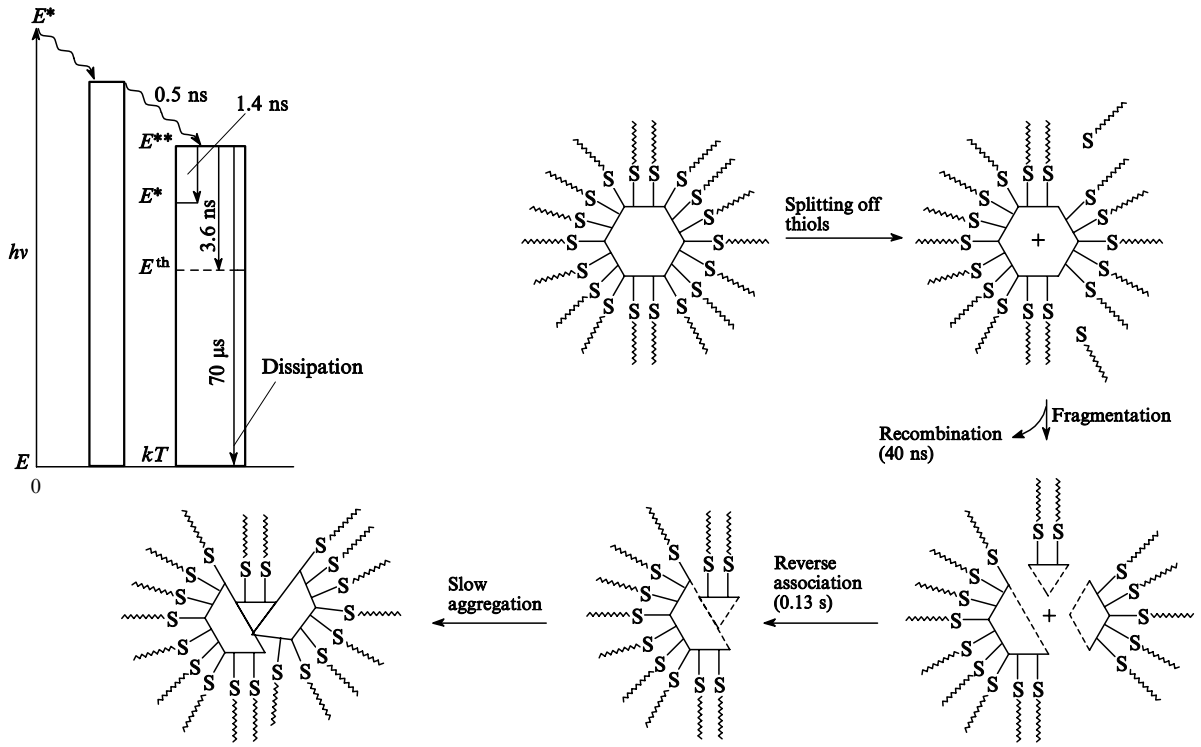

Figure 5. Schematic illustration of the photoreaction involving $Ag_xSC_{12}H_{25}$ dispersed in cyclohexane.[107]

bands at 543 and 619 cm^{-1}, which are close to those observed for quinazoline adsorbed on a silver surface.[110] It was noted that the rate and the extent of photoreactions described are not interrelated. It was assumed that to be decomposed the molecules of phenazine and acridine should either be adsorbed on certain surface sites or form definite geometrical configurations; hence, only a small proportion of molecules can be involved in the reaction.

Optical properties of gold nanoparticles with radii of 2.5, 9 and 15 nm prepared by γ-radiolysis of an aqueous solution of $KAuCl_4$ and stabilised in polyvinyl alcohol were studied.[111] It was found that solutions containing 2.5-nm particles do not attenuate transmitting light, whereas those with larger particles severely decrease the intensity of a laser pulse with a wavelength of 530 nm. The effects observed were attributed to the appearance of a great number of light-diffusion centres formed as a result of evaporation of gold nanoparticles under the laser pulse. Light-diffusion centres were formed in several nanoseconds and largely relaxed to the initial state; upon the next pulse, they partially degraded to small particles.

By means of time-resolved laser measurements, the electron–phonon interactions in metal particles based on Au particles with sizes ranging from 2 to 120 nm and in bimetallic particles based on Au, Ag and Pb were studied. Particles with Au cores and Ag shells and those with Au cores and Pb shells were studied in most details. All the particles were synthesised by radiolysis.[61] It was shown that for Au, in contrast, *e.g.*, to Ag, the time scale of the electron–phonon interaction is independent of the particle size.[112]

Finally, the studies dealing with the prospects of obtaining nanosize quantum dots, quantum wells and quantum wires in inorganic semiconductors [113] should be mentioned, as well as the works on nanophotonics. The latter studies optical properties of objects with much smaller sizes compared with the irradiation wavelength. The efforts were largely focused on investigation of linear optical effects, while the field of non-linear nanoscale optical phenomena is still under way.[114] The problems and prospects of nanophotonics were analysed in Ref. 115.

VI. Semiconductors and sensors

Semiconducting nanoparticles are widely used in heterogeneous catalysis, they are also promising materials for laser engineering, in manufacturing flat displays, light-emitting diodes and sensors. The use of AOT-based reverse micelles for the preparation of ZnSe nanoparticles was first reported in Ref. 116. ZnSe particles measuring 5.7 nm were studied using X-ray diffraction, electronic spectroscopy, light scattering, electron microscopy and luminescence techniques.

A method of stabilisation of nanoparticles of a semiconductor (exemplified by CdS, co-deposition of CdS–ZnS) and a metal (exemplified by gold) was put forward by Japanese scientists.[117] Reverse micelles were prepared and nanoparticles were stabilised by *in situ* polymerisation of (cetyl)dimethyl(*p*-vinylbenzyl)ammonium chloride which was initiated either by light or the addition of azobisisobutyronitrile. The polymer obtained was soluble in polar solvents and formed transparent films with incorporated nanoparticles of cadmium sulfide measuring from 4.7 to 6.3 nm. The proposed method seems to be versatile.

Internal cores of vesicles based on α-phosphatidylcholine can be used as 'nanoreactors' for growing monodispersed (with ~8% deviation) nanocrystals of CaS, ZnS, HgS with definite sizes.[118]

A simple and inexpensive method of synthesising gram quantities of stable water-soluble nanocrystalline powders of zinc sulfide (particles measuring ~6 nm) was put forward.[119] Cysteine-covered ZnS particles were obtained by introduction of sulfide to predissolved zinc salt and cysteine. Following deposition, redissolution and drying, crystalline ZnS powders were obtained, which remained stable for 30 months at 4 °C. Their stability was checked by carrying out catalytic decomposition of *p*-nitrophenol on freshly prepared and aged powders. Upon long-term storage, the optical properties of powders remained unchanged. Highly concentrated aqueous solutions (up to ~100 mmol $litre^{-1}$) of semiconducting particles were used as fluorescent biological labels.

Multilayer films incorporating CdSe nanoparticles were synthesised.[120] The particles measuring 1.7–2.0 nm were obtained from a dimethylformamide solution of cadmium salts and selenium. The films incorporating CdSe particles were prepared by successive formation of layers on quartz or CaF_2 plates. Layers of benzoic acid derivatives and polyvinylpyridine were first applied to the plate surface. The plate thus treated was placed in a dimethylformamide solution of CdSe in order to form a layer containing particles of cadmium selenide. Multilayer (up to five layers) films were obtained by severally adding polyvinylpyridine and cadmium selenide to the solution. Such films are interesting for the development of new types of light-emitting diodes and non-linear optical devices and can serve as conducting films.

Preparation of semiconducting nanowires of definite diameters by using colloidal nanoparticles of metal-catalysts was described.[121–124] As an example, we consider the results of controlled synthesis of GaP nanowires with diameters of 10, 20 and 30 nm and lengths exceeding 10 μm.[124] The wires were obtained by laser ablation of a solid target made of GaP and gold (catalyst). For this purpose, a solution that contained gold particles was applied on a target. The latter was placed in a quartz tube with a solid ZnS target. The tube was located in a blown end of an oven, which was heated to 700 °C and the target was ablated for 10 min by means of an excimer laser. Simultaneous generation of nanoclusters of gold and of GaP semiconductor occurred; the latter particles formed semiconducting nanowires.

Control experiments have shown that in the absence of gold particles no semiconducting wires form. A relationship between the sizes of gold nanoparticles and the diameters of semiconducting GaP wires allowed the authors to conclude that the diameters of the wires obtained can be controlled. A similar method of governing the diameters of silicon nanowires was proposed.[123]

The effect of the size of a semiconducting nanoparticle on its forbidden gap width was studied using CdSe particles measuring from 0.7 to 2 nm as an example.[125,126] All the particles were obtained by using the methods of organometallic chemistry so that their surfaces bore phosphorus atoms and phenyl and propyl groups. For example, the composition of one of the particles studied was $Cd_{10}Se_4(SePh)_{12}(PPr_3)_4$. The atomic structure of the particles was determined using the X-ray diffraction technique. Figure 6 shows the dependence of the forbidden gap width of cadmium selenide nanoparticles on their sizes. It is seen that as the

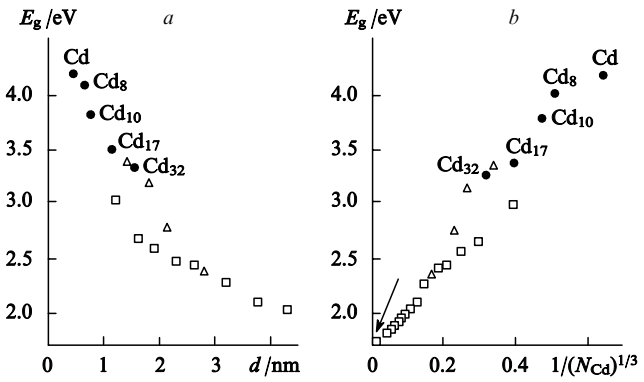

Figure 6. Forbidden gap thickness of CdSe nanoparticles as a function of their (*a*) diameter and (*b*) reciprocal radius.[125] *N* is the number of atoms in a particle. Black points are experimental data, open points are literature data for larger particles (results by different authors). The arrow marks a bulk particle.

nanoparticle size increases the forbidden gap width (E_g) of a particle approaches the E_g value of CdSe bulk samples.

Dynamic properties of charge carriers on the liquid–semiconductor interface are important for photocatalysis, solar energy conversion and photoelectrochemistry. The properties of charge carriers, *viz*., electrons and holes, were studied in a number of semiconducting nanosystems using laser techniques.[127]

Suspensions of cadmium sulfide nanoparticles were used for the initiation of acrylonitrile polymerisation. The polyacrylonitrile (PAN) obtained and the products of its partial hydrolysis were used as the templates which governed the shapes of CdS nanoparticles and CdS/PAN composite nanowires with diameters of 6 nm and lengths varying from 200 nm to 1 μm.[128]

A nanosize electronic switch was built of gold nanoclusters and compounds containing redox groups.[129] Synthesis of *N,N′*-di(10-mercaptodecyl)-4,4′-bipyridinium dibromide containing a bipyridinium fragment as the redox group was described.[130] When gold nanoparticles are bound to the film of bipyridinium dibromide molecules, the reduction of the bipyridinium group on a gold electrode proceeds readily and reversibly.

$$bipy^{2+} + e^- \rightleftharpoons bipy^{+\bullet}.$$

Figure 7 schematically shows an electronic switch measuring less than 10 nm which is controlled by the voltage applied to the STM probe.§ When a molecule involves bipyridinium in a reduced ($bipy^{+\bullet}$) state, a noticeable tunnelling current flows in the nanocluster–molecule–electrode circuit. If a certain threshold voltage is applied to the gold electrode, the tunnelling current decreases. The threshold voltage corresponds to the oxidation of $bipy^{+\bullet}$ to $bipy^{2+}$. At present, such devices operate slowly and require an amplifier. However, they can be used in those fields where amplification is of less importance, *e.g*., as the chemical sensors for detection of single molecules or individual chemical reactions. Moreover, based on these systems, memory devices for computers can be developed.[131]

§ The scheme is taken from Ref. 131, in which the results of another study (Ref. 130) are commented upon. The system shown was assumed [130] to correspond to approximately 60 organic molecules and required no less than 30 electrons to operate.

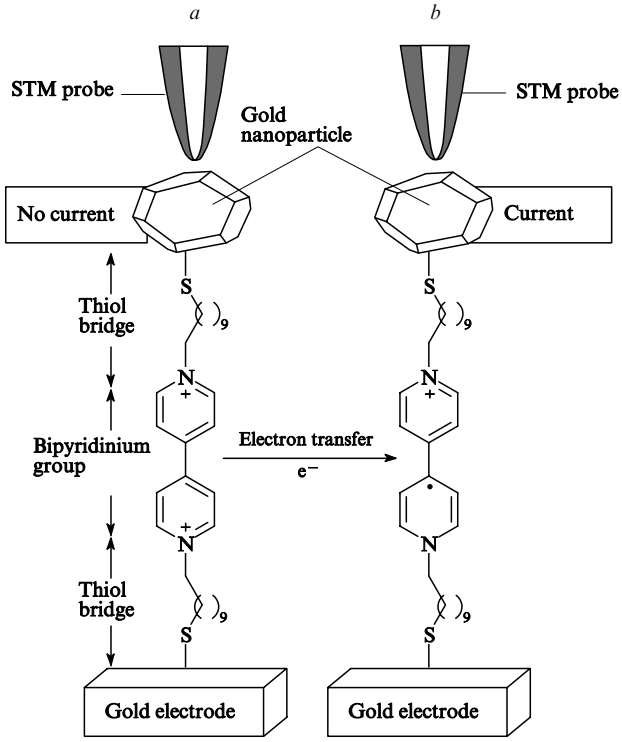

Figure 7. Schematic illustration of the performance of an electronic switch.[131] (*a*) Bipyridinium group is in the oxidised state and no current flows, (*b*) accepting an electron, the bipyridinium group is reduced and a current arises.

New possibilities in designing sensors and optoelectronic devices including those with nanoparticles have been pioneered.[132] It was shown that pore-free crystals of organoplatinum compounds can reversibly absorb and evolve sulfur dioxide without any losses in their crystallinity. Figuratively speaking, the crystals 'breath'. Figure 8 schematically shows the corresponding transitions.

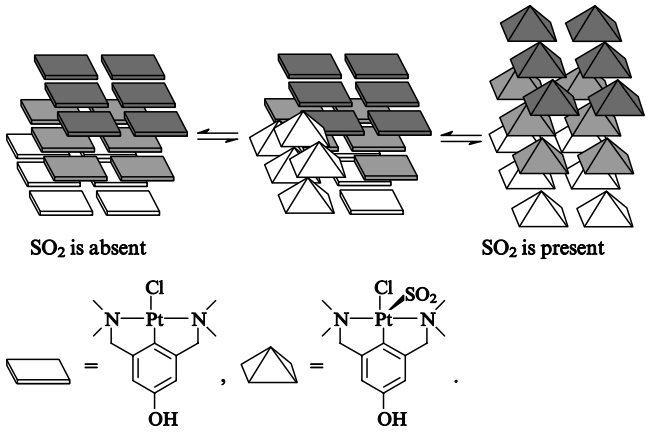

Figure 8. Crystals that reversibly absorb SO_2.[133]

On being exposed to SO_2 for one minute, the crystal acquires an orange colouring. The colour change is accompanied by a transition of planar square platinum complexes into square-pyramidal complexes which involve SO_2 as the fifth ligand. In the process, the crystal increases its volume by 25% but retains the ordered crystal structure. Then, if the crystal is exposed to air, it breathes out SO_2 and relaxes to its initial colourless SO_2-free state. The process can be repeated many times without loss of the crystallinity. It was suggested to use such crystals as optical switches and SO_2-sensors. It is possible that some other similar compounds can reversibly interact with chlorine, CO_2 and other gases. There are strong grounds to believe that substances that bind gases in solution can also bind them in the solid state.

Nanocrystalline films of semiconducting oxides can also be used as the sensitive units of gas sensors. The effects of ethanol and nitrogen dioxide vapours on the properties of SnO_2 nanocrystals applied on single-crystal silicon and of SnO_2 nanocrystals doped by nickel, palladium and copper were studied.[134] Doped SnO_2 nanocrystals were synthesised by pyrolysis of aerosols. According to X-ray diffraction data, their average size was 6–8 nm. It was shown that diffusion of gases affects the voltammetric characteristics of heretostructures, which manifests itself in variations of the potential-barrier height on the heterogeneous boundary and in the changes in the tunnelling processes at the interface.

A new generation of chemical sensors can be synthesised by using non-uniform nanosystems and unusual electronic and physicochemical properties of nanoparticles involved in such systems. In these systems, compact crystalline cores of nanoparticles are surrounded by outer amorphous shells, and the electron transfer induced by adsorbed gas molecules proceeds through the nanoparticles arranged in ensembles and interacting with one another. The sensor properties of non-uniform nanocomposite films were studied[135] for the oxide–oxide (SnO_2–TiO_2), metal–oxide (Cu–SiO_2) and metal–polymer [Cu–poly(*p*-xylylene)] systems. The sensor activities of the specimens with respect to hydrogen, wet air and ammonia were

determined from conductivity variations. All specimens were synthesised under non-equilibrium conditions, which seems to be necessary for the preparation of effective sensor materials.

VII. Catalysis on nanoparticles

The studies devoted to using nanoparticles in the development of novel catalysts which were published before 2000 are surveyed in detail by Bukhtiyarov and Slin'ko.[14] In this section, we consider only the studies published in 2000.

Methane combustion in air proceeds steadily at temperatures above 1300 °C. However, at these temperatures, noxious nitrogen oxides evolve resulting in smog. In this connection, the search for new catalysts of methane combustion is urgent. A new catalyst was synthesised[136] which provided methane combustion at 400 °C. This was prepared using reverse microemulsions based on isooctane, water and surfactants such as the polyethylene oxide–alcohol adducts. Alkoxides $Ba(OC_3H_7)_2$ and $Al(OC_3H_7)_3$ were dissolved in isooctane and mixed with the microemulsion at room temperature: the resulting solid crystalline nanosize barium hexaaluminate exhibited high catalytic activity in CH_4 combustion. The advantage of barium hexaaluminate lies in the fact that the sizes and surfaces of its particles remain unchanged at high temperatures. Moreover, this can be modified by cerium, cobalt, manganese and lanthanum. Modification with cerium oxide produced a composite which enabled methane combustion at temperatures below 400 °C. The history of the search for new methane-combustion catalysts and their characteristics are described elsewhere.[137]

In aqueous AOT–n-heptane buffer microemulsions, a number of reactions were catalysed by palladium nanoparticles. The reaction of *N,N*-dimethyl-*p*-phenylenediamine with $Co(NH_3)_5Cl^{2+}$ catalysed by palladium nanoparticles was described.[138] The catalytic oxidation of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine by $Co(NH_3)Cl^{2+}$ was also studied in similar microemulsions at pH 5.6.[139] The limiting stage of the reaction was the adsorption of *p*-phenylenediamine on palladium particles of 2.5-nm radii within the microemulsion. This conclusion relies on an observation that the activation energy of the reaction changes from 97 at 15 °C to 39 kJ mol^{-1} at 40 °C and on the results of electrochemical measurements. The specific features of the reaction were discussed in terms of the microreactor model.

Synthesis of platinum, palladium, rhodium and iridium nanoparticles and their use in catalytic hydrogenation of cyclooctene, dodec-1-ene and *o*-chloronitrobenzene were described.[140] Nanoparticles were synthesised by reduction of metal salts by alcohols and stabilised by an amphiphilic copolymer of 1-vinylpyrrolidone with acrylic acid (PVP–AA). The diameters of particles were 0.74 (Ir), 1.93 (Rh), 2.2 (Pd) and 1.2–2.2 nm (Pt), which were determined by electron microscopy.

The introduction of nickel ions into the PVP–AA–Pt catalytic system enhances the effeciency of the latter. Hydrogenation of chloronitrobenzene to chloroaniline at 330 K was carried out with a selectivity of 97.1% and 100% conversion. Introduction of Co^{2+} and Fe^{3+} ions reduced the hydrogenation selectivity to 78.1% and 72.1%, respectively. The analysis of IR spectra have shown that, on being exposed to hydrogen, the ions of nickel, iron and cobalt were not reduced to zero-valent metals. This was explained by the fact that the metal ions interact with two C=O groups in the PVP–AA copolymer and only with a single C=O group in poly(1-vinylpyrrolidone).[141]

The problems of measuring sizes of metal particles applied on supports and size and surface-area distributions for particles with diameters smaller than 2.5 nm were discussed in Ref. 142.

When chemisorption is used for the determination of a catalyst's properties, it is necessary to know how to follow catalyst operation with contaminated surfaces and make an allowance for strong interaction of the metal with the support. A systematic study (in the temperature interval of 573–973 K) of palladium particles of average size ~2 nm applied on activated carbon has been accomplished.[143] The use of two methods, *viz*., X-ray small-angle scattering and transmission electron microscopy allowed the effective sizes of palladium particles to be estimated and the results to be compared with the data obtained in studying CO chemisorption on supported palladium. The agreement between the results of two aforementioned methods was observed for the stoichiometric ratio Pd : CO = 2.

A high catalytic activity of nanoparticles composed of metal cores and outer shells was demonstrated in several studies.[144–147] Gold nanoparticles measuring 2 and 5 nm surrounded by decanethiol molecules were used for electrochemical oxidation of carbon monoxide.[145] Figure 9 schematically shows the electrode reaction. It is noteworthy that the use of thiol-covered gold nanoparticles suggests a co-operative increase in the catalytic activity.

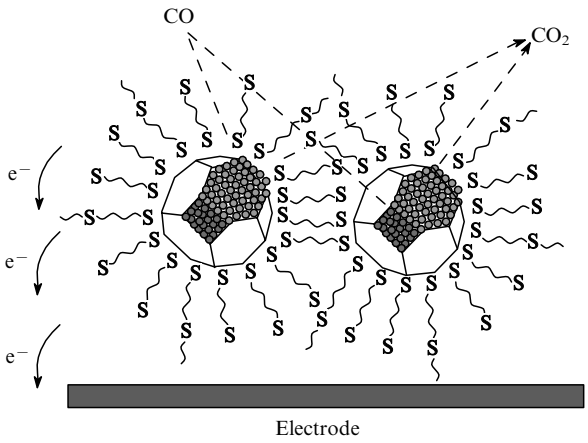

Figure 9. Catalytic oxidation of carbon monoxide on an ensemble of thiol-covered gold nanoparticles on the electrode surface.

The methods of preparation of optimal catalysts may involve varying the shapes of cores, the structures and properties of molecular shells and the types of core–shell bonding. The latter factor affects active sites, defect packing and co-operative electronic properties of nanoparticles.

Platinum nanoparticles were obtained by reducing chloroplatinic acid ($H_2PtCl_6 \cdot 6H_2O$) by ethanol in the presence of poly(*N*-vinylformamide), poly(*N*-vinylacetamide), poly(*N*-isopropylacrylamide) or poly(*N*-vinylpyrrolidone). The particles synthesised had an average diameter of ~2.0–2.5 nm.[148] The effects of additon of KCl and Na_2SO_4 and of temperature variations on the stability of nanoparticles were studied. The particles obtained were used in hydrogenation of allyl alcohol in water and in a salt solution (0.8 M Na_2SO_4). It was shown that catalytic platinum particles are stable in the salt solution and their activity is equal to that in water.

Bimetallic Au–Pt/C(graphite) catalysts were prepared by selective deposition of gold on a platinum film on graphite as a support.[149] The latter monometallic catalyst was obtained by the reduction of H_2PtCl_6 in anhydrous ethanol. The monometallic catalyst was modified by two methods. The first method used platinum as the reagent which reduced $AuCl_4^-$. In the other method, the monodispersed catalyst was first treated with hydrogen and then $HAuCl_4$ was added. At pH 1, bimetallic particles were formed according to the reaction

$$3\,PtH + AuCl_4^- \longrightarrow Pt_3Au + 4\,Cl^- + 3\,H^+.$$

The average size of particles was ~10 nm. The properties of particles and their reactions were studied by several techniques.

Being chemically inactive, gold did not attract much attention as a catalyst until recently. However, gold ions Au^{n+} ($1 \leqslant n \leqslant 3$) in zeolites turned out to be active in the reaction

$$H_2O + CO \longrightarrow H_2 + CO_2$$

at 323 K.[150]

Lithographic systems comprising SiO_2-supported platinum nanoparticles and Al_2O_3-supported silver nanoparticles, which were prepared using electronic beams, were used as model metallic catalysts.[151] The particles with the average sizes of 20–50 nm were spaced at 100–200 nm. The thermal stability of the systems obtained was studied by means of electron microscopy and AFM. The system with platinum particles was stable up to 973 K, whereas the system with silver particles was stable up to 773 K in both vacuum and hydrogen and up to 623 K in oxygen. The catalytic effect of a model catalyst with SiO_2-supported platinum nanoparticles was compared to that of a platinum foil in hydrogenation and dehydrogenation of cyclohexene at 100 °C.[152] The reactivity of a system with platinum particles of 28 nm diameter was shown to be twice as high compared with that of the foil, and its selectivity was higher by a factor of 3.

Isomerisation of dichlorobutanes catalysed by iron-containing nanoparticles stabilised in polymeric matrices was studied.[153] The catalytic activity was shown to depend on the nature of the matrix and the metal content.

Photocatalytic reduction of bis(2-bipyridyl) disulfide (RSSR) to pyridine-2-thiol (RSH) by water selectively proceeded on the surface of titanium dioxide. The reaction rate substantially increased when silver nanoparticles (0.24 mass %) with sizes < 1 nm were applied on TiO_2.[154]

The following mechanism was assumed [154] for this reaction:

$$(1)\ RSSR + 2\,AgTiO_2 \overset{K_a}{\rightleftharpoons} 2\,RSAgTiO_2,$$

$$(2)\ 2\,RSAgTiO_2 \xrightarrow{I\varphi} 2\,RSAgTiO_2(e^- \ldots h^+),$$

$$(3)\ 2\,RSAgTiO_2\,(e^- \ldots h^+) \xrightarrow{k_{d1}} 2\,RSAgTiO_2,$$

$$(4)\ 2\,RSAgTiO_2\,(e^- \ldots h^+) \xrightarrow{k_{cs}} 2\,RSAg(e^-)TiO_2(h^+),$$

$$(5)\ 2\,RSAg(e^-)TiO_2(h^+) \xrightarrow{k_{d2}} 2\,RSAgTiO_2,$$

$$(6)\ 2\,RSAg(e^-)TiO_2(h^+) + H_2O \xrightarrow{k_0} 2\,RSAg(e^-)TiO_2 + 2\,H^+ + \frac{1}{2}O_2,$$

$$(7)\ 2\,RSAg(e^-)TiO_2 + 2H^+ \xrightarrow{k_r} 2\,RSH + AgTiO_2,$$

where K_a is the equilibrium adsorption constant, I is the light intensity, φ is the intensity of light absorption.

In the first stage, the selective adsorption of RSSR on the surfaces of silver nanoparticles is accompanied by the cleavage of the S–S bond. In the second stage, upon the excitation of nanoparticles in the forbidden gap range of TiO_2, an electron (e^-)–hole(h^+) pair is generated. Most of electron–hole pairs recombine (stages *3* and *5*). In stage *4*, charge separation occurs: silver nanoparticles accept electrons, and holes are transferred to the TiO_2 support. The positive potential of a hole is sufficient for water to be oxidised with the formation of H^+ ion and O_2 molecule (stage *6*). In stage *7*, the catalytic system is reduced producing RSH. As a result, the deposited silver nanoparticles seem [154] to cause the following effects:

— acceleration of RSSR adsorption;

— space separation of sites responsible for reduction (silver particles) and oxidation (TiO_2 support), *i.e.*, the effect of charge separation;

— selective adsorption of the substance to be oxidised (RSSR) and the reducing agent (H_2O) in the reduction and oxidation sites, which makes the process highly selective.

Comparison of TiO_2 and $AgTiO_2$ catalytic systems has shown that both systems provide equal activation energies in the photocatalytic reduction (30 ± 1.5 kJ mol^{-1}), which suggests that the multistage process is limited by stage *6* rather than by photocatalysis. Below, the reduction on TiO_2 is shown.

$$2\,RS...TiO_2(e^-) + 2\,H^+ \xrightarrow{k_r} 2\,RSH + TiO_2.$$

In recent years, semiconducting nanoparticles have been actively used in photocatalysis. In this connection, the catalytic activities of nanoparticles of different oxides and sulfides in aqueous and polar (acetonitrile) organic solvents were compared [155] using photooxidation of pentachlorophenol (a toxic compound used as a fungicide and a bactericide and for wood conservation) as an example. Figure 10 shows the relative concentration of pentachlorophenol as a function of the time of its exposure to light in the presence of nanoparticles of different metal sulfides.

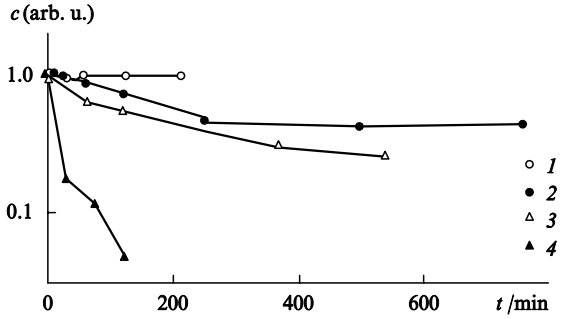

Figure 10. Changes in the relative concentration of pentachlorophenol (c) in water with the time of its exposure to light of the wavelength $400 < \lambda < 700$ nm (*1*) in the absence and (*2–4*) in the presence of catalysts.[155] (*1*) Without catalyst (or TiO_2); (*2*) CdS powder (0.1 mg ml^{-1}), (*3*) MoS_2 particles with diameters of 4.5 nm (0.036 mg ml^{-1}), (*4*) MoS_2 particles with diameters of 3 nm (0.09 mg ml^{-1}).

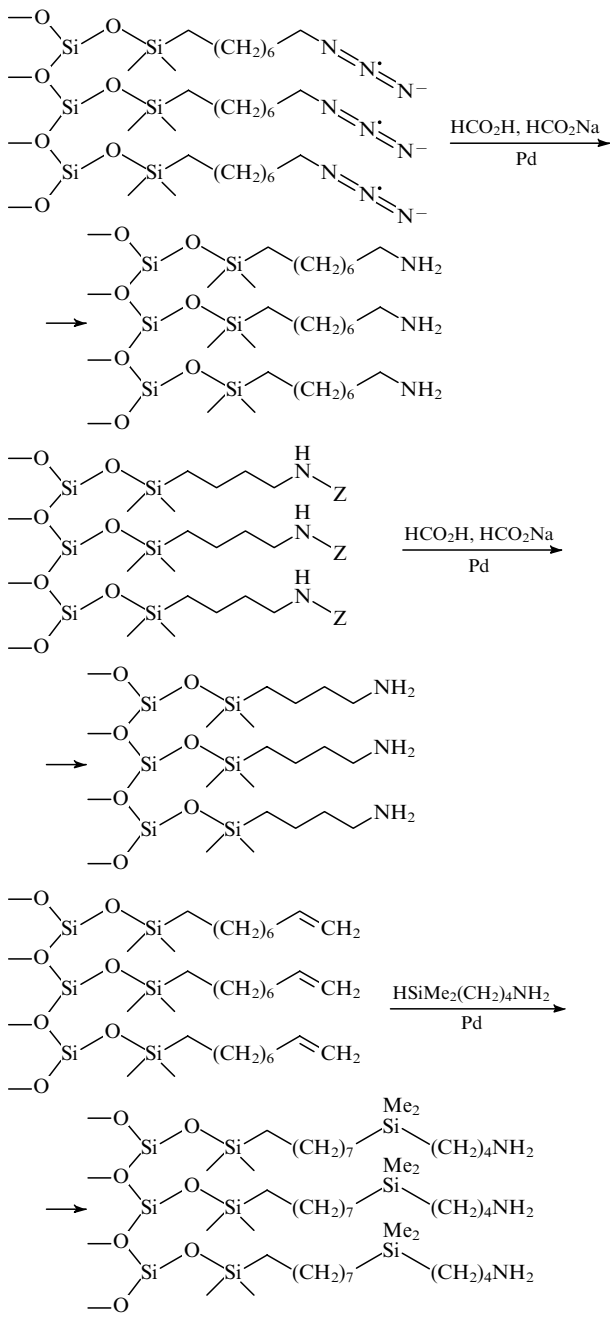
It is of note that the effect of the nanoparticle size on the reaction rate is extremely strong for MoS_2 particles. This reflects the effect of the forbidden gap width of particles on the reaction and is associated with the corresponding change in the reduction potential. In contrast to a common photocatalyst, *viz.*, titanium oxide, which is active in the UV region, molybdenum disulfide particles measuring 3 nm catalyse the reaction in the visible range. When SnO_2 nanoparticles measuring 26 and 58 nm were used, the nanoparticle size did not significantly affect the photooxidation of pentachlorophenol.

One can predict the development of a new direction of nanochemistry which is associated with realisation of chemical reactions by means of AFM and STM probes. Interesting examples of chemical modification of terminal functional groups in aggregates of organosilicon molecules were carried out by the catalytic action of an AFM probe covered (at open circuit conditions) with palladium.[156]

A minimum effort required for such chemical reactions to occur is ~2.5 μN at a scanning rate below 5 μm s^{-1}. It should be noted that the typical activation energy of the bimolecular reactions shown is ~50 kJ mol^{-1}. At the same time, according to estimates, the energy of surface deformation of an associate formed by organosilicon molecules is ~340 kJ mol^{-1}, which far exceeds the activation energy.

An approach to 'chemical lithography', which consists in chemical modification of functional groups in the molecules arranged along definite preset lines in a sample, was first documented in Ref. 157.



Z is a benzyloxycarbonyl group.

VIII. Nanoparticles in biology and medicine

At present, a new direction of nanochemistry is being developed vigorously. The goal of these studies is the synthesis and application of systems comprising metal nanoparticles (mainly, gold and silver) and various biomolecules: DNA, peptides and oligonucleotides. The optical properties of aggregates of gold nanoparticles bound by DNA fragments containing from 27 to 72 nucleotide pairs were discussed.[158] Alkanethiol-modified gold particles of diameter $\sim$15 nm were used. The effect of the length of an oligonucleotide chain on the optical properties of aggregates obtained was studied, and the position of the metal plasmon peak was found to depend on the chain length. The sizes of nanoparticle aggregates were determined by the kinetic method, because their growth rate depended on the lengths of oligonucleotide chains and on the distances between nanoparticles. Among the factors that affect the growth rate of aggregates, the rate of binding of DNA linkers ¶ with complementary DNA molecules on the surfaces of gold nanoparticles (k_1) and the rate of aggregate growth (k_2) are the most important. Optical changes were also observed upon annealing of structures formed by two longest nucleotides-linkers at temperatures below their melting point. Thus, DNA linkers can be used for kinetic control over aggregate growth.

A new method of introduction of biomaterials into living cells was proposed [159] based on electrospraying of metal particles with large electrical charges and high velocities. If one disperses gene-covered metal particles using the equipment developed, these particles disintegrate in liquid drops under the external non-uniform field. Gene fragments thus obtained have charges of the same sign as the metal particles and are present in high concentrations. Monkey fibroblasts were used as the living cells and either suspensions of plasmids † labelled with fluorescent peptides or plasmids with gold nanoparticles measuring 5–10 nm were used as the biomaterials. UV fluorescent microscopic studies have shown plasmid suspensions with gold particles to penetrate into cells. The fact that gold-free plasmid suspensions also penetrated into the cells and got incorporated into its DNA is of prime importance. This result seems to be most significant, because this allows one to dispense with gold traditionally used for these purposes. It was noted that electrostatic spraying opens up new possibilities for transfection of genes and gene therapy.

Nanoparticles doped with gadolinium ions were proposed for use as new contrast materials for NMR studies in medicine. Such nanoparticles with diameters of 120 nm are sufficiently small to penetrate easily into blood vessels. These have been used for obtaining the images of hearts and gastric channels in rats.[160]

Approaches to using biomolecules for identification of common inorganic materials are being developed. These can be realised by applying the principles of selective binding known from molecular biology. Selective binding of peptides to different semiconductors was proposed as a method of preparation of nanocrystalline ensembles.[161] It was shown that nanocrystalline semiconductors can be used for the isolation of certain peptides which bind specifically to the semiconductor surface. Five different faces of semiconducting single crystals were used, as the substrates, *viz*., GaAs(100), GaAs(111)Ga (with Ga atoms on the surface), GaAs(111)As (with As atoms on the surface), InP(100) and Si(100). Each substrate was found to select and bind certain amino acid sequences from a large number of random peptides. The nanocrystalline ensembles obtained were studied using antibodies labelled with 20-nm gold nanoparticles and the methods of transmission and fluorescent microscopy, photoelectron spectroscopy and atomic-force and scanning tunnelling microscopy.

Figure 11 illustrates two different approaches to the development of biomolecular ensembles on surfaces of inorganic materials.[162] Development of these approaches is a challenge to materials science of the XXIst century.

In this context, attention should be drawn to a study [163] in which the prospects of synthesising two- and three-dimensional nanostructures based on biological principles were considered. It is believed that the strategy of synthesising complex ensembles from simpler ones will be developed in the new century. Biological structures may be used as surface detectors which organise binding of large organic and inorganic building blocks. Indeed, in this approach, the principles developed in the course of evolution for building new functional structures may be used for synthesising new materials.

¶ Linkers are nonhelical segments of a double-stranded DNA which interlink compact DNA segments stabilised by peptides and polyamines.
† Plasmids are extrachromosome formations representing closed circles of double-stranded DNA.

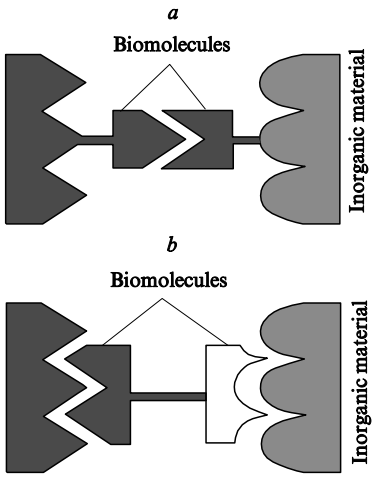


Figure 11. Two approaches to assembly of inorganic materials into complex structures with the use of biological molecules.
(*a*) The use of complementarity of two biomolecules, (*b*) the use of biomolecule interaction with an inorganic material.[162]

IX. Conclusion

The analysis of studies published in recent years shows that many aspects of nanochemistry of metals and semiconductors are gaining importance, and considerable progress has been made towards their solution.

The factors that affect the sizes and shapes of nanoparticles during their synthesis, the processes of self-assembly of both nanoparticles themselves and ligands that stabilise them are being actively studied. The list of polymers, surfactants, reversed micelles and thiols, which are traditionally used for the stabilisation of nanoparticles, was successfully replenished with dendrimers. The use of nanoparticles in catalysis has been extended, as well as the use of semiconducting particles in photocatalysis. The studies in which metal nanoparticles are used in carrying out unusual reactions are conducted more intensively. The problem of synthesising and studying the reactions of non-protected metal nanoparticles becomes increasingly pressing. Interest is shifting to reactions of metal nanoparticles measuring less than 1 nm. In this aspect, the use of inert gas at low and superlow temperatures as the matrices for the synthesis of nanoparticles seems to be very promising.

Yet another challenging direction of nanochemistry may be developed at the boundary of such sciences as biology, organic and inorganic chemistry and materials science. Mutual 'recognition' and joint self-assembly of inorganic and biological molecules are the key problems which being solved, will provide new advanced materials.[164]

At the beginning of 2000, a new programme aimed at the development of fundamental and applied studies in nanotechnology was formulated in the USA.[165] In 2001, this issue is additionally financed by 500 million dollars. The following directions were chosen as the most challenging:

— the use of modern experimental equipment for studying the processes which involve nanoparticles or proceed on the surfaces of nanostructures;

— elucidation of the roles nanoparticles play in such important processes as deposition of proteins, desorption of contaminants, stabilisation of colloidal dispersions, aggregation of micelles and control over microorganism mobility;

— development of experimental techniques and their computerisation for studying the role of nanoparticles in the processes that occur in the atmosphere and water sources;

— the use of mesoporous structures integrated with appropriate microcomponents to provide highly sensitive and highly selective contamination detectors.

In conclusion, it should be stated that at present the studies of nanoparticle properties form an interdisciplinary scientific field which largely determines the development of the other neighbouring fields.

The author is grateful to his co-workers, post-graduate students and students of the Laboratory of Low-Temperature Chemistry for their assistance in the preparation of this review. This review was partially financially supported by the Russian Foundation of Basic Research (Project No. 99-03-32206).

VIII.	Potential fields of application of carbon nanotubes	840
IX.	Conclusion	854

Abstract. The review concerns the main chemical and physicochemical properties and the methods of modification of carbon nanotubes, a novel promising material. The feasible and potential fields of applications of carbon nanotubes are outlined. The bibliography includes 573 references.

I. Introduction

Nanotubes (nanotubulenes, hereafter NTs) were discovered by Iijima in 1991.[1] A decade has passed since then; however, solid state chemists and physicists as well as materials scientists persist in giving increasing attention to NTs.[2] Moreover, it is NTs that are believed to be a tool for passage from macromolecules to nanotechnology and for transformation of the latter from a scientific concept into reality.

Currently, we cannot say whether these dreams will come true or not. Intensive research into NTs continues to expand, the number of publications increases rapidly;[3] some monographs, books of collected works and a textbook on NTs have been published.[4–10] Unfortunately, only a few out of the dozens of journal reviews concerning NTs were reported in the journals published in the Russian Federation.[11–16] In addition, at present these reviews fail to cover not only some recent advances, but also entire avenues of research into NTs. The author of this review strove to bridge this gap.

The background of the NT problem was briefly outlined recently.[15,16] The structure, some physical properties and methods for the preparation of NTs have also been reviewed.[14,16] To get acquainted with carbon NTs, we can also recommend a visit to the Website of the Michigan State University (USA) at URL http://www.pa.msu.edu/cmp/csc/nanotube.html. Here, it will only be remembered that perfect, defect-free NTs are formed by rolling planar atomic graphite sheets (graphenes) into seamless cylinders. Nanotubes can be multi-walled (MWNTs), comprising several coaxial cylinders, or single-walled (SWNTs). As a rule, the proportion of defects in SWNTs is less than in MWNTs. Moreover, SWNTs can become defect-free after high-temperature annealing in inert media. The structure of NTs affects their electronic, mechanical and chemical properties; because of this, SWNTs and MWNTs behave in fundamentally different manners.

The inner diameters of NTs vary between 0.4 nm and several nanometres. The volume of the inner cavity of NTs is sufficient for the molecules of other substances to occupy the cavity.

Graphene sheets in SWNTs and in each shell of MWNTs can have different orientations of the primitive graphene lattice vectors. This affects the properties of NTs.

The as-prepared NTs are usually closed by hemispherical or conical 'caps' at their ends.

A salient feature of NTs is their aggregation into rather stable bundles (bunches or ropes), which can be either bent or even closed (ring-like structures). The axes of individual NTs in the bundles are parallel to one another. The shortest distance between individual NTs is $\sim$0.32 nm. Nanotube bundles arise due to van der Waals forces. The intertubular space can be filled with 'guest' molecules.

Initially, most of NTs were synthesised by the arc method which involves graphite vaporisation in a dc arc struck between graphite electrodes in an inert gas flow. This technique was replaced by laser-induced thermal synthesis. This technique involves vaporisation of a graphite target under the action of a scanning laser beam in a furnace heated to a particular temperature and has a higher performance. In recent years, increasing attention has been given to pyrolytic synthesis from gaseous hydrocarbons (CH_4, C_2H_2, *etc.*) and CO. Preference is given to the catalytic processes which allow the preparation of not only MWNTs, but also SWNTs in relatively high yields.[16] It is thought that the processes proceeding in the presence of a 'volatile catalyst' introduced into the reaction zone in the form of vapours along with the substances to be decomposed can provide the highest performance.

Nanotubes can be prepared in different forms. Synthesis of NTs can give a tough precipitate of different density, *e.g.*, a rubber-like material consisting of entangled NTs (compact 'nanopaper', 'buckypaper', 'mats'), a web-like material and a textured material comprised of arrays of aligned NTs separated by some distance from one another (nanotube 'forest', nanotube 'towers').

Received 13 February 2001
Uspekhi Khimii **70** (10) 934 – 973 (2001); translated by A M Raevsky

In addition to hollow cylindrical NTs, conical, helical, horn-like ('nanohorns'), bamboo-like (consisting of individual closed extended sections), different types of alternating conical NTs ('nanobells' and 'fishbone') as well as L-, T- and Y-shaped NTs (both bent and branched) can also be formed.

The synthesis of NTs is often accompanied by the formation of other forms of carbon (*e.g.*, fullerenes, polyhedral particles and amorphous carbon). Therefore, in many instances purification of NTs (removal of side products) is a necessary stage.

Before going to the main body of the text, mention should be made of the term 'carbon nanotube chemistry', which is currently used in a rather broad sense.† Carbon nanotube chemistry covers, first of all, the synthesis and purification of carbon nanotubes and their opening in reactions with various oxidants. In addition, the subject matters of carbon nanotube chemistry are modification of NTs (filling the inner cavity with different reactants, attachment of functional groups to the NT ends and side walls and decoration of these surfaces with particular molecules, replacement of some of the carbon atoms on the NT side walls by atoms of other elements, insertion of 'guest' atoms and molecules into the intertubular space of NT bundles); the use of carbon NTs for template synthesis of nanowires, nanorods and nanotubes made of other substances; adsorption of gases on NTs and NT bundles and physicochemical properties of NTs. Research in the field of carbon nanotube chemistry also includes studies on the effect of the chemical modification on the electronic, magnetic, mechanical and other properties of NTs.

With rare exceptions, in this review we will not dwell on the methods for the preparation and purification of NTs and filling their inner cavities. These problems have been considered in detail recently.[16]

Chemical transformations of fullerenes, graphite and NTs exhibit some common features. Nevertheless, it should be emphasised that nanotube chemistry differs essentially from both fullerene and graphite chemistry. This is due to the unique shape, structural peculiarities and small diameter of NTs. Nanotubes differ from fullerenes in the relatively large volume of the inner cavity (stable fullerene molecules are too small to contain more than three or four atoms of other elements within the inner cavity). Perfect (defect-free) NTs differ from graphite in very low percentage or even the absence of chemically active dangling bonds. A feature of NTs is a variety of specific distances that are due to van der Waals forces (*e.g.*, the separations between individual shells of MWNTs, between individual tubules in NT bundles, *etc.*).

Each fullerene can be considered as a molecule which can form or be a constituent of molecular crystals. Graphite represents a typical layered polymeric crystal. In contrast to them, individual NTs cannot be thought of as individual molecules (SWNTs resemble molecules, while MWNTs are similar to carbon fibres) and NT bundles cannot be classified as conventional three-dimensional crystals (topologically, individual NTs and NT bundles represent one-dimensional and two-dimensional crystals, respectively.[18]).

Graphite, NTs and fullerenes can form intercalation compounds with fundamentally different structures. Graphite forms two-dimensional structures, NTs usually form one-dimensional structures (formation of two-dimensional structures is possible for the rolled-up NTs), whereas fullerenes form [topologically] zero-dimensional structures. In addition, only NTs can form several types of intercalation compounds with different geometries.

Sometimes, NTs exhibit quite unexpected chemical behaviour. For instance, bent NTs contain topological defects (*e.g.*, pairs of carbon pentagons and heptagons) and their reactivity differs from that of straight NTs. Carbon NTs also allow one to study the effect of the radius of curvature of the surface on the strength of the bonding between the substances reacting on the NT surface and the carbon atoms.

Modification of NTs can lead to essential changes in their electronic structure and functional properties and to creation of novel materials including those with unbelievable properties. The possibility of modification of fullerenes and NTs was first predicted theoretically (see, *e.g.*, Refs 19 and 20) and then confirmed experimentally.

This review concerns the chemical properties of NTs and their role in the processes of fabrication of the NT-derived end products. In the largest part of the review (Section VIII), we consider the potential fields of application of NTs. This seems to be of great importance since NTs are no longer 'exotic fruits'.

II. Filling of the inner cavities of carbon nanotubes

The inner cavities of NTs can be filled in the course of synthetic procedures or in a targeted manner after the preparation and purification of NTs. The latter strategy was found to be more versatile and rational.

Targeted filling can be performed with melts, solutions or reactive gases that are either involved in the chemical vapour deposition reactions or form covalent chemical bonds with carbon atoms within the NTs. Filling the NT cavities with gases due to adsorption represents a special case.

1. Nanotube filling in the course of synthetic procedures

Many substances can fill the inner cavities of NTs in the course of synthetic procedures.[16] In this review, we will dwell on the results reported in some of the most recent reviews and original studies.

According to Seraphin,[21] in the case of arc synthesis of NTs the additives (B, Mg, Mn, Fe, Co, Ni, Cu, Y, Nb, Mo and Ta) can be encapsulated into the NTs in the form of carbides. The filling of NTs with Nb, Ta and Mo carbides has been studied in more detail.[22] Nanotubes can also be filled with rare-earth element carbides and, in an H_2 atmosphere, with metallic Cu and Ge which do not tend to form carbides.

Two types of NT filling, a complete and incomplete one, have been described.[23] For instance, Se, Sb, S and Ge fill NTs completely (up to several micrometres long), whereas Bi, B, Al and Te form short particles. No rationalisation was provided to this phenomenon.

Sulfur is thought to play the key role in the formation of filled NTs in arc synthesis.[24] Thorough removal of sulfur from the anodic material reduces the probability of the growth of filled NTs.

The effect of sulfur on the NT growth mechanism in the case of arc synthesis was confirmed by Demoncy *et al.*[25] who found that sulfur added to the anode material favours the filling of NTs with such metals as Co, Ni, Cr and Dy if the content of S is less than 1% of the metal mass.

Boron, a well-known graphitisation catalyst, also has a strong effect on the NT growth mechanism.[26] A theoretical study of the effect of boron on the growth rate and morphology of NTs showed that boron stabilises the zigzag-shaped end of a NT, thus preventing it from 'capping' and favouring the NT filling.[27]

Other substances also can act as promoters. The addition of both a catalyst (2% Co) and promoter (5% Bi) to the anode material (graphite) resulted in an increase in the diameter of the grown SWNTs, namely, nearly 50% of them were found to be 1.5 nm and more in diameter and a large proportion of the SWNTs had a diameter of 2 nm.[28]

It seems to be more interesting to consider the growth of NTs with encapsulated fullerene molecules. In this case, the encapsulated fullerene molecules must affect the properties of composites filled with such NTs, the electronic properties of the NTs and their filling with other substances. Smith *et al.*[29] showed that the molecules of C_{60} and C_{70} and elongated capsules with diameters close to that of C_{60} can exist within NTs. It was also found that the

† This term was first used by the researchers from the Oxford University in 1996.[17] Their communication concerned the synthesis, opening (removal of 'caps'), filling and potential uses of NTs.

encapsulated fullerene molecules can move jumpwise and form pairs.

The assumption of the possibility of filling the NT cavity with C_{60} molecules was first proposed in the study of the products of laser-induced thermal synthesis.[30] After a short time, an experimental confirmation of this hypothesis was obtained, *viz*., nanoscale 'peapod' structures were found among acid treated and *in vacuo* annealed (1100 °C) reaction products.[31] Most of such structures have a NT diameter of 1.4 nm, which is twice as large as that of the C_{60} molecule (0.7 nm). They are characterised by yet another, third, type of specific separation that is due to the van der Waals forces (the above-mentioned two types are characteristic of MWNTs and NT bundles,[32] see also Section I). This separation differs from the interlayer spacing in graphite but is close to this value (the shortest distance between the C_{60} molecule and the NT wall is ~0.35 nm). The fact that the C_{60} molecules form pairs indicates that some other interactions occur in these systems in addition to the van der Waals forces.

Two-walled NTs with the inner diameter equal to that of the C_{60} molecule were found to be less abundant than SWNTs.[29]

It was assumed that C_{60} molecules are formed in the gas phase independently of NTs and enter the NT cavities most likely through defects due to diffusion that occurs in the gas phase (or, which is less probably, due to the diffusion over the NT surface) in the course of *in vacuo* annealing.[33] Then, the defects are 'healed' and the C_{60} molecules self-assemble into chains up to 30 units long and coalesce into interior tubes at temperatures above 1100 °C. There is an optimum temperature for the C_{60} molecules adsorbed on the outer surface to pass inside the NTs. At low temperatures, the saturated vapour pressure of C_{60} is too low and filling the NT cavity takes a long time. At high temperatures, the saturated vapour pressure is, on the contrary, too high and the desorbed fullerene molecules move away from the NTs.

The formation of interior elongated (several nanometres long) capsules was also explained by coalescence of the C_{60} encapsulated within NTs due to electron irradiation. The electron beam also damages the outer NT shell; however, this occurs at a lower rate than the inner coalescence.[34]

To prove that NTs are filed with C_{60} molecules, the NT walls were acid etched and the 'peads' were suspended in toluene.[35] The results of spectral studies of the suspension showed that the sample under study was characterised by a C_{60}-filled tube length fraction of 4.5%. The 'peapod' structures were found to be stable to at least 1200 °C (*cf.* 1000 °C for the transformation of pure cubic solid C_{60} into amorphous carbon).

Initially, it was assumed that nanoscale 'peapods' are solely comprised of NTs 1.3 to 1.4 nm in diameter and C_{60} molecules. More recently, this opinion was rejected. The C_{60} fullerene molecules can also be encapsulated within SWNTs obtained by arc method.[36] In this case, molecular fullerenes were found to be present inside 5% to 10% of all of the observed NTs and to have different chemical compositions spanning the range from C_{36} to C_{120} (C_{60} was the most abundant). A clear correlation was also found between the NT diameter and the encapsulated fullerene size.

Blockage of the filling of fullerene-containing NTs with other substances was observed.[36]

The inner cavities of NTs can be filled with carbides using not only the arc method, but also laser-induced thermal synthesis. The addition of boron to the material of graphite target resulted in the appearance of carbide particles inside the grown NTs near their ends.[37] Filling of NTs also seems not to be improbable in the case of catalytic pyrolysis of hydrocarbons (see, *e.g.*, Ref. 38).

2. 'Targeted' filling of carbon nanotubes

Filling pre-fabricated NTs requires that they be opened (in other words, 'caps' at the NT ends should be removed). Most often, this can be done by selective oxidation, which, therefore, is a necessary stage of the process of 'targeted' filling of NTs.

a. Oxidation of carbon nanotubes

'Caps' at the ends of closed NTs are built of carbon pentagons and hexagons. The former type of polygon is more reactive, which determines the possibility of its selective oxidation. This can be achieved by using gaseous reactants, aqueous solutions or melts. Processes in solutions and melts can be initiated or activated electrochemically. Reactions in gaseous media are sometimes initiated using electric discharge or laser irradiation.

It should be kept in mind that NTs prepared *via* different synthetic routes can exhibit different behaviours in oxidation and other chemical reactions. For instance, the densities of materials produced by electric arc method and by laser-induced thermal synthesis can differ by an order of magnitude. Multi-walled NTs and SWNTs also behave in different manner, the latter being oxidised more readily.

Air, oxygen, CO_2 and oxygen plasma represent conventionally used gaseous oxidants. According to *ab initio* calculations,[39] the oxygen atoms bound to the carbon atoms at the end of an open NT cause its stabilisation. However, the authors of this study [39] believe that the heat of desorption of the CO_2 molecules changes its sign as the NT radius increases, so that an endothermic process is transformed into an exothermic one. Therefore, NTs with relatively large diameters are more prone to 'capping'. An increase in temperature also favours the formation of closed NTs. According to calculations, the oxidation energies of 'caps' and lateral surfaces of NTs differ appreciably.

The oxidation of a SWNT material containing carbonaceous impurities, Ni and Co begins at ~370 °C (Fig. 1), a large fraction of NTs being oxidised along with other forms of carbon at relatively low temperatures [40] {see also information posted at the website of the Rice University (USA) at URL [http://www.ruf.rice.edu/~johnz/researchorig.html]**D**}.‡ Exothermic oxidation of metals and amorphous carbon causes a local increase in temperature, which results in the oxidation of NTs at these 'hot spots'. Noteworthy is the coincidence of the curves shown in Fig. 1 *b* at temperatures above 450 °C. Probably, the conditions for preliminary oxidation in HNO_3 do not affect the amount of NTs consumed. (For unknown reasons, the curve *3* in Fig. 1 *a* and curve *2* in Fig. 1 *b* in the original study differ.)

Intercalation with $CuCl_2$ or Br_2 changes the character of the oxidation of MWNTs and allows their purification with O_2.[41–44] The interaction of Br_2 with unpurified NTs leads to intercalation of bromine molecules into graphite nanoparticles that are 'swelled' due to an increase in the interlayer spacings, which

‡ In most cases, the original research results posted at the Webpages cited in this review are represented in the form of abstracts or in other popular forms. Detailed information can be obtained by visiting the Websites labelled as **D**.

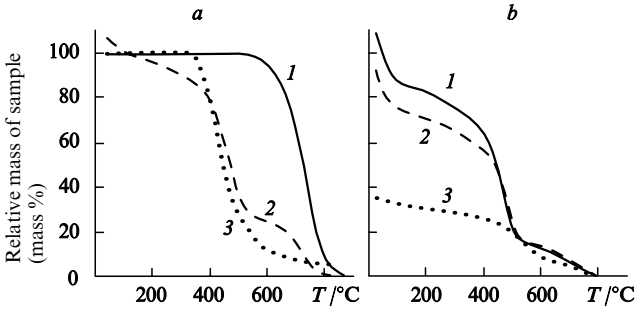

Figure 1. TGA curves for the oxidation of 1–2 mg NT samples in air.[40] The air flow rate was 100 cm^3 min^{-1} and the temperature was raised at a rate of 5 K min^{-1}. The data for the refluxed material was normalised to 100% at 100 °C to compare dry weights; (*a*): purified NTs (*1*), unpurified NTs (*2*) and NTs after a 16 h reflux in 3 M HNO_3 (*3*); (*b*): NTs after a reflux in 3 M HNO_3 for 4 (*1*), 16 (*2*) and 48 h (*3*).

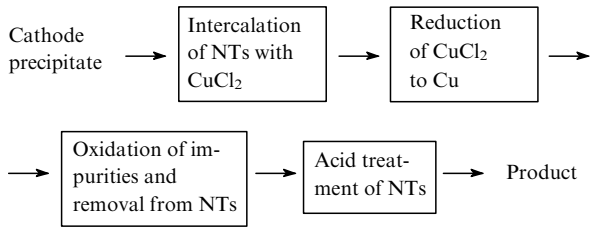
favours a more ready oxidation of the nanoparticles. The reaction with Br_2 is completed after 96 to 240 h while the oxidation (4% O_2 in He, 530 °C) takes a period of 48 to 72 h.[42] The yield of purified NTs is determined by the O_2 flow rate, the sample mass and the conditions for arc synthesis and can reach a value between 10% and 20%. Some of the Br_2 molecules form complexes with the carbon atoms of the NT walls.

Purification of NTs using $CuCl_2$ is carried out as follows:



This procedure is inapplicable to SWNTs since the yield of the pure product obtained using the Br_2-O_2 system is very low (only ~3%). This is thought to be related to different curvatures of the MWNT and SWNT surfaces.[45]

Functionalisation of SWNTs reduces the rate of their oxidation. Zimmerman *et al.*[45] studied purification of NTs with moist chlorine and proposed a mechanism which involves the formation of hydroxy- and chloride-functionalised NT 'caps' with the $\rangle C-Cl$ and $\rangle C-OH$ groups that withstand further oxidation. The description of the experimental setup and material of a discussion concerning the purification mechanism can be obtained *via* the Internet [URL http://www.ruf.rice.edu/~johnz/researchorig.html]**D**.

Smith and Luzzi[46] reported the 'closure' of NT ends in inert atmosphere at a very low temperature (~550 °C). This is consistent with the idea of the 'closure' of dangling bonds at the open NT ends in O_2, Cl_2 or H_2 atmospheres.

The selectivity of impurity oxidation in the course of purification of SWNT bundles in a 1% O_2–Ar mixture can be enhanced by using catalysts, *e.g.*, ultrafine gold particles with a diameter of ~20 nm, and benzalkonium chloride as surfactant.[47] (The article contains no information on whether or not the NT opening occurs in the low-temperature oxidation at 350 °C.) After a short time the oxidation conditions were refined and the optimum concentrations were found to be 0.6 at.% for gold particles and 7 g litre^{-1} for benzalkonium chloride.[48] It was also shown that amorphous carbon burns out in the temperature range from 300 to 550 °C, the NT oxidation temperatures span the range from 550 to 750 °C and the residual graphite flakes are oxidised at temperatures above 730 °C. It was suggested that benzalkonium chloride facilitates breakdown of NT bundles.

The list of reactants that can be used in the form of melts is also short. Opening of 'capped' NTs was carried out in air using molten lead at 400 °C (the lead oxide that is formed in the course of the reaction acts as a catalyst).[49,50] The reaction in the presence of molten bismuth in air at 850 °C follows the same pattern (in this case, Bi is oxidised into Bi_2O_3). Experiments on NT opening can also be performed with V_2O_5 (see Ref. 51) and low-melting metal nitrates (see below).

Aqueous solutions were found to be the most appropriate and efficient reagents for NT opening. High yields of open NTs can be achieved by prolonged refluxing of NTs in HNO_3. The efficiency of aqueous solutions of other reagents (*e.g.*, $K_2Cr_2O_7$, $KMnO_4$, H_2O_2, OsO_4, RuO_4, $HClO_4$, H_3IO_5) and various mixtures was also studied. It was shown that treatment with concentrated hydrochloric acid can lead to the opening of NTs.[52] Relatively high yield of the open purified NTs obtained by pyrolytic technique was achieved using a $KMnO_4$ solution in H_2SO_4.[53,54] Experiments with $H_2SO_4-HNO_3$ mixtures were also reported.[55]

The mechanism of the interaction between various oxidants and NTs remains unclear as yet. It is known that NT shells with different chiralities are oxidised at different rates.[56]

Studies on the NT oxidation in the course of their purification were reviewed by Duesberg *et al.*[57]. They pointed out that the results obtained by different authors who used nitric acid treatment of NTs are close despite considerable differences in duration of the acid treatment, the concentration of nitric acid and the operating temperatures. After oxidation, acid-treated NTs are covered by small fragments of carbon particles which should be washed off with alkali solutions. Duesberg *et al.*[57] also described mechanical and physicochemical methods for purification of NTs.

b. Filling of carbon nanotubes from liquid media

General methods of filling carbon NTs from liquid media can be conventionally divided into three groups. These are one-step, two-step and three-step methods. The one-step method uses the interaction of NTs with metal nitrates in the course of nitric acid assisted opening of NTs. Subsequent removal of HNO_3 and thermal decomposition of the nitrates upon calcination of NTs leads to the formation of metal oxide crystallites inside the NTs.[17,58]

The two-step method involves the interaction of pre-opened NTs with concentrated salt solutions. Preference should be given to this method in those cases where fillers are unstable or poorly soluble in acid.[58]

The three-step method involves an intermediate stage between the opening and filling of NTs, namely, *in vacuo* annealing at 2000–2100 °C.[59,60]

Surface tension is an important characteristic of liquids that fill NTs. Only those substances can be soaked in the NT cavities that have a surface tension of at most 150 mN m^{-1} (see Ref. 61). On the other hand, this numerical value is a function of the NT diameter. For instance, the action of capillary forces allows the filling of NTs with a diameter of at least 4 nm for $AgNO_3$ [61] and ~1 nm for PbO and V_2O_5.

In air, NTs can also be filled with PbO_2; *e.g.*, a nanorod with a diameter of 4 nm and a length of more than 400 nm was obtained at 450 °C.[59] Molten V_2O_5, Bi_2O_3, B_2O_3 and MoO_3 also fill the inner cavities of NTs with ease to form continuous crystals along the entire nanotube length.[51,62] If the NT diameter is less than 3 nm, a disordered glassy phase is formed instead of the crystalline phase for unknown reasons.

Filling of SWNTs with a diameter of at most 3.5 nm with bismuth occurs upon heating of mixtures of capped NTs with the metal nanoparticles to 400 °C in air.[28,63] The stability of the filled NTs under conditions of electron irradiation in vacuum was studied.[64]

Kiang *et al.*[63] reported a study on the NT filling with bismuth (i) in the course of the arc synthesis of NTs (equal amounts of Bi and Co were introduced into the graphite anode material), (ii) from melt or vapours (a mixture of NTs and Bi was heated in air) and (iii) from aqueous solutions [boiling in 1 M solution of $Bi(NO_3)_3$ in HNO_3 followed by reduction with H_2]. The abundance of filled NTs was found to be less than 1% for method (i), ~10% for method (ii) and more than 30% for method (iii) provided that the experiments were performed with the same type of NTs.

Since only a few low-melting metal oxides are known, recent studies were carried out using metal halides and nitrates. In particular, NTs were 'doped' with $ZrCl_4$, UCl_4, AgCl, $CdCl_2$, CsCl, AgBr, with AgCl–AgBr mixture and with eutectic mixtures KCl–UCl_4 and KCl–$ThCl_4$.[36,65,66] Filling with uranium tetrachloride was found to occur only in the presence of KCl, since the surface tension of UCl_4 exceeds 370 mN m^{-1} at 900 K. At temperatures above the liquidus temperature, the mixtures with the molar ratios KCl : UCl_4 = 1 : 1 and 2 : 1 are characterised by a surface tension of 120 (750 K) and 68 mN m^{-1} (950 K), respectively. The surface tension of silver chloride is 173 mN m^{-1} (833 K) while that of silver bromide is 151 mN m^{-1} (800 K).

The structure of the metal halide 'dopant' affects the crystal chemistry features of the product (for detailed information, we recommend visiting the Website at URL http://www.cpes/sussex.

ac.uk/nanotec99/present/mlhg.htm). For instance, depending on the NT structure, layered $CdCl_2$ and CdI_2 encapsulated in NTs were found in different polymorphous modifications. Substances that form chain structures can either retain native polyhedral chain patterns ($ZrCl_4$, NbI_4) or change them inside NTs. Bulky chain halides ($ThCl_4$, UCl_4) form one-dimensional structures inside NTs.

A 0.1 nm space resolution study of the structure of an ultra-small single crystal, a KI inclusion into a SWNT, obtained by heating open NTs with molten salt revealed considerable lattice distortion as compared to bulk crystals.[67–69] The cross-section of the KI crystal encapsulated within a 1.6-nm-diameter NT represented a 3×3 atomic array. A longitudinal contraction of the KI crystal by 0.695–0.705 nm along the $\langle 001 \rangle$ axis as compared to the 'bulk' substance was determined. The coordination numbers (CN) of the face and edge atoms were found to be 5 and 4, respectively. Since the proportion of such atoms is rather large, one can expect that differences in the geometry and CN will affect the electronic properties of substances. For instance, typical metals can turn into dielectrics or *vice versa*. This opens up possibilities for the design of new materials.

Even smaller KI single crystal was obtained in an 1.4 nm-diameter NT. The cross-section of this crystal represented a 2×2 atomic array. Each atom was found to have a CN of 4.[68] Compared to the bulk phase, a strong tetrahedral distortion of the cubic crystal lattice was observed and the lattice parameter was found to be more than halved. As in the preceding case, the $\langle 001 \rangle$ direction was parallel to the NT axis.

Lattice distortions and changes in the crystal lattice parameters of the substances encapsulated within NTs were also observed by other authors (see, *e.g.*, Ref. 63); however, detailed study and discussion concerning the prospects for practical implementation of this phenomenon were first undertaken.[67]

Silver, cobalt and copper nitrates have low melting temperatures and their melts are characterised by low surface tension. They are oxidants and can therefore be encapsulated into capped NTs. These compounds were used for the preparation of NTs with encapsulated continuous silver rods 4 nm in diameter and up to 47 nm in length and CoO rods 1.7 nm in diameter and 17 nm long.[59]

Govindaraj *et al.*[70] used metal halide hydrates (in particular $HAuCl_4 \cdot x\,H_2O$) as the reactants for filling open SWNTs and reported the conditions for filling NTs with molten $PdCl_2$.

β-Tin nanowires were obtained by electrolysis of a $LiCl-SnCl_2$ melt using graphite electrodes.[22]

Electrochemical preparation of Sn–Pb nanowires 40 to 90 nm long inside NTs was reported.[71]

Usually, nanowires are 1.0 to 1.4 nm in diameter and up to 90 nm long. In some cases, it has been possible to prepare single-crystalline metal nanowires; however, most often they represent polycrystalline structures.[70] Sometimes, filling of NTs was accompanied by their decoration due to insertion of the metal atoms into the intertubular space of NT bundles.[70] The thickness of the intercalated metal layers was 0.4 to 0.5 nm, which is somewhat larger than the van der Waals separation between individual NTs ($\sim$0.3 nm).

Most often, carbon NTs are filled using aqueous solutions[17] since this method is easy to operate.

The substances encapsulated into NTs can participate in chemical reactions. These are, *e.g.*, thermal decomposition of nitrates resulting in the formation of oxides or metals; reduction of metal chlorides and oxides with hydrogen to obtain NTs filled with Cu,[41] Ni, Fe, Ag, Au, Pd and Rh (see Ref. 58); reactions between chlorides and dioxygen to prepare NTs with encapsulated uranium oxychlorides[65]) and alkali hydrolysis of $SnCl_2$. Kyotani *et al.*[72] studied the filling of carbon NTs with the acid $H_2PtCl_6 \cdot 6\,H_2O$ in solution and reduction of the acid by $NaBH_4$ at room temperature. Sulfidising reactions of NTs with encapsulated CdO or $AuCl_3$ in an H_2S atmosphere to give CdS and AuS_x were investigated.[58] It was found that many substances encapsulated into NTs can be dissolved in HNO_3. Decomposition of silver chloride and silver bromide encapsulated within NTs and then exposed to light or electron beam has been reported.

To prepare NTs with encapsulated SnO, they were opened, washed with HNO_3, placed in a concentrated $SnCl_2$ solution and then the pH value of the suspension was slowly increased to 10.2 using a solution of Na_2CO_3.[73] Encapsulated crystallites were found to have a spherical or ellipsoidal shape and a diameter from 2 to 6 nm.

Successful synthesis[74] of MWNTs with extremely small inner diameter (0.4 nm) opens up the prospects for the preparation of nanowires with uniquely small diameter by encapsulation into such NTs.

c. Filling of carbon nanotubes from gaseous media

Filling the inner cavity of NTs using chemical vapour deposition technique can be performed using, *e.g.*, volatile metal compounds which can decompose on heating to give non-volatile substances. Using this method and $Fe(C_5H_5)_2$, the inner cavities of the NTs grown in the pores of anodised aluminum (Fig. 2) were filled with Fe or Fe_3O_4 nanoparticles.[75] The formation of the oxide inside NTs in the decomposition of ferrocene was explained by partial oxidation of the iron.

A similar process was performed using $Ni(C_5H_5)_2$ at 275 °C.[76] Carbon NTs with the outer diameter of 30 nm were found to be filled with Ni wires 4 nm in diameter and up to 500 nm long. It is noteworthy that no nanowires were formed near the open ends of the NTs; this can hardly be rationalised. It is also unclear why the diameter of the nickel nanowires appeared to be much smaller than the inner diameter of the carbon NTs. Usually, the diameters of the nanowires prepared using other methods were only slightly different from the inner NT diameter (see, *e.g.*, Refs 23 and 50).

Filling of NTs with various compounds was studied by the molecular dynamics method. Simulation was performed assuming that filling occurs due to the capillary forces and that the model NT 2.74 Å in diameter comprised 56 carbon atoms. According to calculations, lead clusters can fill NTs along their entire length, whereas carbon and sulfur clusters are retained near the open ends of the NTs.[77] Carbon NTs can also be filled with molten selenium which forms atomic chains.[78]

Targeted filling without pre-opening the NTs occurs in the course of catalytic pyrolysis of hydrocarbons in porous $AlPO_4$.[79] The porous material is preliminarily filled with cobalt which is then encapsulated into NTs. Experiments with NaY zeolite template also revealed the formation of NTs; however, no filling of the NTs with the catalyst particles was observed due to different character of the interaction between the catalyst and template.

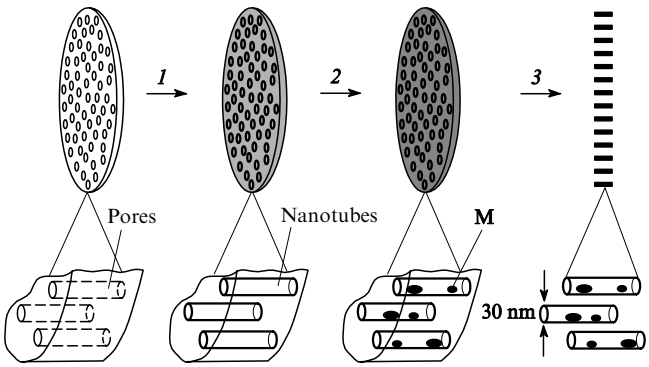


Figure 2. A scheme illustrating the filling of NTs from the gas phase using a porous Al_2O_3 film.[75]
Propylene pyrolysis (*1*), chemical vapour deposition of the metal (*2*) and dissolution of the template in NaOH (*3*). The metal particles are labelled as M.

A short review of recent advances in the field of the preparation of filled NTs and metallic nanowires was reported by Terrones *et al.*[80]

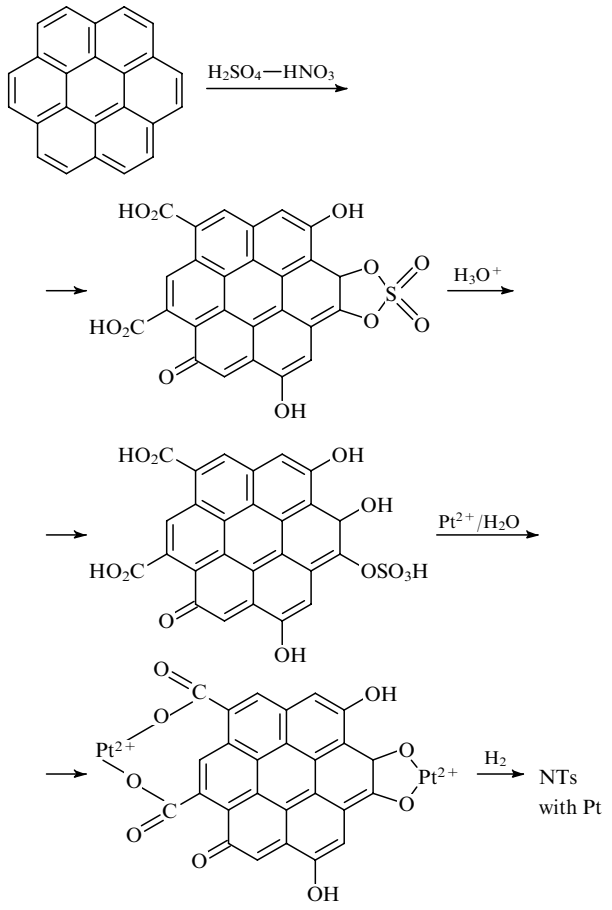
III. Functionalisation of carbon nanotubes

Chemical modification of activated carbons and carbon fibres has been studied in detail. Several methods for attachment of oxygen-containing groups to the NT surfaces have been developed.[81,82]

Cahill and Rohling[83] showed that functional groups can bound to the NT side walls. The oxidised surfaces of NTs were found to be covered by the carboxylic, carbonyl and hydroxyl groups in the approximate ratio 4 : 2 : 1.[53]

The behaviour of acid groups on the surfaces of nitric acid treated NTs was studied by temperature-programmed decomposition and acid-base titration.[84] The concentration of these groups on the NT surfaces was found to be $\sim 1 \times 10^{20}$ g^{-1}, whereas graphite treated under the same conditions showed a lower concentration (5.3×10^{19} g^{-1}). Sonication of NTs prior to the functionalisation in acids increases the concentration of acid groups.

Oxidation of NTs with a $H_2SO_4-HNO_3$ mixture leads to a higher concentration of functional groups on the surface than in the case of treatment with HNO_3.[85] The formation of functional groups and their subsequent bonding to the metal ions can be described by the following mechanism:



Prolonged acid treatment followed by heating in air is used for purification of SWNTs {see Ref. 40 and material posted at URL [http://www.ruf.rice.edu/~johnz/researchorig.html]**D**}. After a 16 h reflux in 3 M HNO_3 (120°C), washing and drying the mass loss was 18%, of which ~6% were identified as metal impurities. The surfaces of acid treated NTs were found to be uniformly coated with polyaromatic hydrocarbons, which can be removed by oxidation in air at 550 °C for 30 min. The residue (~20% of the initial mass) represented high-purity pristine SWNTs. The impurity content was at most 2%. Oxidation of these NTs begins at 735 °C. This temperature is ~125 °C higher than that reported earlier,[55] which indicates that the NTs are defect-free and contain no dangling bonds.

Long-term acid treatment of NTs leads to changes in the chemical composition of the material. Indeed, the uniform hydrophilic carbonaceous precipitate disappears and NTs randomly coated with both the precipitate 'spots' and particle aggregates appear in addition to the pristine NTs after 48 h with 3 M HNO_3. A large fraction of NTs was found to be damaged and shortened ('cut'). Being oxidised in air, this material behaves in a different manner compared to the material obtained after acid treatment for shorter times (see Fig. 1) and the yield of purified NTs becomes nearly halved.

It should be noted that SWNTs obtained by different methods exhibit different behaviour in the course of acid treatment and subsequent oxidation. Oxidation of nitric acid treated SWNTs with gases results in selective removal of thin NTs.[86]

Functional groups can be removed from the surface of NTs by heating. The process begins at temperatures above 623 K;[87] however, complete removal is observed at 1073 K (higher stability of functional groups up to a temperature of 1173 K was also reported[83]).

The density of oxidised (defect) carbon sites in closed (10,10)-NTs after acid treatment and removal of CO_2 and CO at 1273 K can be determined using ozone titration.[88] The fraction of defect carbon sites was estimated to be 5.5%.

To enhance the possibilities of atomic force microscopes (AFM) with nanotube probe tips, the tip ends are functionalised.[89–91] This can be done with both solutions[89–91] and gases.[92–94] The latter approach is thought to be preferred since it involves a single-step treatment.[92] A schematic representation of the AFM cantilever functionalisation process is shown in Fig. 3. The treatment procedure uses electric discharge in O_2, H_2, N_2 and H_2-N_2 mixtures. Modified probes can be used for studying the surfaces of non-ionisable self-assembled layers terminated in OH

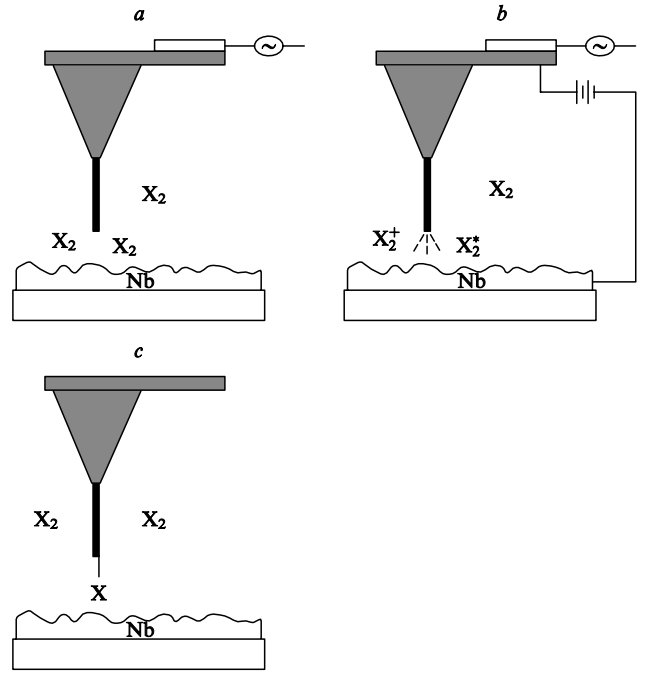


Figure 3. Schematic representation of the AFM cantilever functionalisation process.
Carbon nanotube attached to a cantilever is oscillated above a sputtered niobium surface in the presence of gas, X_2 (*a*); applying a potential produces electric discharge between the oscillating NT and the surface (*b*) and the nanotube probe tip functionalised with X (*c*).

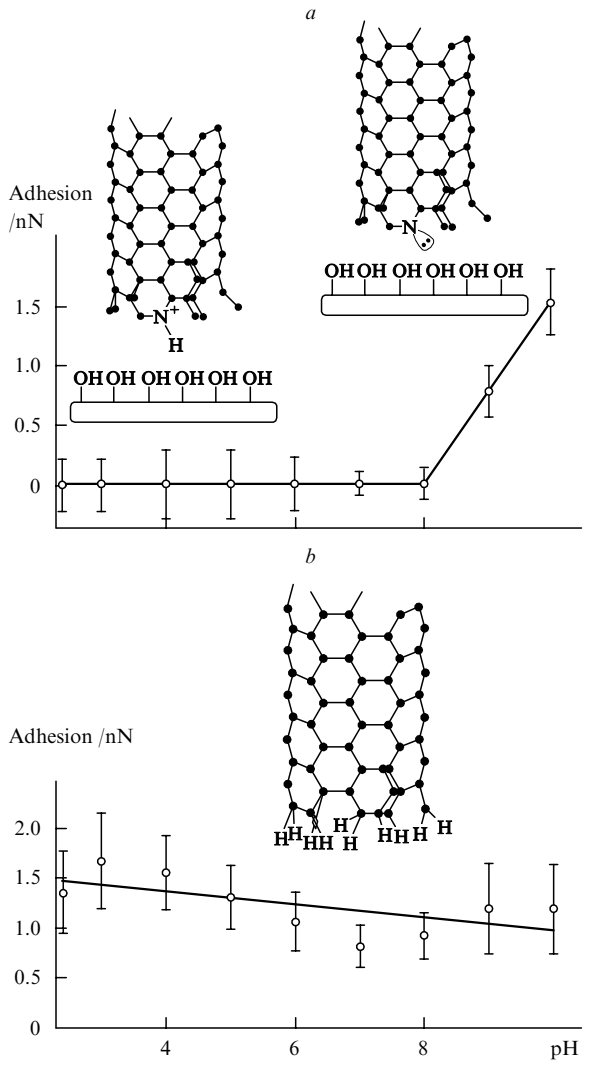

Figure 4. Adhesion of nanotubes to the surface of self-assembling monolayers as a function of pH (measured using an AFM).
A probe with a nanotube tip modified by nitrogen (*a*) and hydrogen (*b*) atoms.[92]

groups. Modification of nanotube tips using a discharge in N_2 atmosphere results in the formation of nitrogen-containing heterocycles at the tip ends. Chemically modified nanotube tips can be used for measuring the pH values of different surfaces (Fig. 4).

High degree of saturation of nanotube tips with functional groups (up to the atomic ratio O : C = 0.2) is achieved by treatment with a low-pressure ammonia plasma followed by oxidation with a $NaClO_3$ solution.[93]

According to calculations, bombardment of SWNT bundles with $CH_3^{\bullet}$ radicals with energies between 10 and 80 eV must result in bonding the radicals or their fragments to the surface.[94]

A theoretical study on the hypothetical structure of NTs 1 nm in diameter and 5 nm long with acid functionalities attached to the outer surface and on the structure of NTs linked through such functional groups has been reported.[95]

a. Fluorination of carbon nanotubes

Fluorination plays a distinctive role in the modification of NTs and functionalisation of NTs.

A review by Touhara and Okino [96] covers the latest studies of researchers from Japan in the field of fluorination of carbon materials. The authors of this review believe that fluorination belongs to the most efficient chemical methods of modification and control of the physicochemical properties of these materials. They constructed a binding energy scale for the C – F bonds and inferred that these bonds can be of different nature and can vary from covalent to semi-ionic and thus be responsible for the variety of properties of fluorinated materials.

Graphite fluorides and intercalation compounds based on them are known to be of paramount importance as compared to other graphite compounds (oxides and salts). They are readily available, exhibit relatively high chemical and thermal stability and are characterised by high energy content, which makes them the subject of great practical interest as promising materials for chemical current sources and components for solid lubricants. Studies on fluorination of NTs have led to some remarkable findings.

Pioneering experiments on the fluorination of MWNTs were carried out by researchers from Japan in 1996.[96,97] It was shown that fluorine is first of all intercalated into the outer layers of NTs. Fluorinated graphene sheets were found to retain their tubular structure on heating up to 300 – 400 °C, the spacing between them being increased to 0.53 and even to 0.65 nm at higher temperatures. As in the case of graphite, nanotube fluorination is accompanied by buckling of graphene sheets and the formation of a polymeric structure 2 to 3 nm thick with covalently bonded fluorine atoms on the surfaces of NTs. By analogy with fluorination of graphite, nanotube fluorination was assumed [97] to proceed as stepwise process. However, this hypothesis was not confirmed more recently.

Experiments on fluorination of MWNTs 20 to 40 μm in diameter and up to 10 μm long obtained by catalytic pyrolysis [98] showed that these NTs are more reactive than graphite but less reactive than C_{60} and C_{70}.[96] The reaction of the NTs with a $F_2 - HF - IF_5$ mixture at room temperature resulted in the formation of a black compound of composition $CF_{0.4}$ (fluorination of graphite under the same conditions resulted in graphite monofluoride). The reaction product was found to represent an intercalate, though no intercalation of IF_5 into the NTs was observed. The product retained the tubular morphology and sp^2-hybridisation of the carbon atoms.

Fluorination of NTs at 500 °C for 4 h resulted in distortion of a regular structure of NT bundles and in the formation of a white compound with a chemical composition close to that of graphite monofluoride (at 600 °C).

Studies of the electrochemical properties of fluorinated NTs [96,99] revealed that the capacity of a nanotube-derived electrode material fluorinated at 480 °C and then used in batteries can be as high as 620 A h kg^{-1}.[96]

The results of earlier studies [98,99] were to some extent confirmed by the results of experiments on the fluorination of 'buckypaper' fabricated from purified SWNTs with dilute F_2 (9% F_2 in He).[100] It was shown that fluorine atoms can be attached to the side walls of NTs.[100] The atomic ratio F : C was found to be merely ~0.1 at 150 °C, ranged between 0.46 and 0.52 at 250 °C and within nearly the same limits at 325 °C and corresponded to the formation of a compound with approximate composition C_2F, which retained its tubular structure. At temperatures above 500 °C most of the NTs were destroyed and the formation of structures similar to MWNTs was observed at 500 °C. Fluorination was found to have a strong effect on the electronic properties of NTs, namely, the untreated NTs were conductors while the fluorinated NTs were insulators.

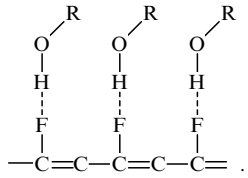
Surprisingly, fluorination of NTs at $T \leqslant 325$ °C appeared to be reversible. The interaction between fluorinated NTs with a composition close to C_2F and anhydrous hydrazine resulted in removal of the fluorine atoms and in recovery of the initial structure of the NTs. This was accompanied by recovery of many (but not all) initial properties of the NTs. This was associated [100] with the reaction

$$CF_{n\,(NTs)} + \frac{n}{4}\,N_2H_4 \longrightarrow C_{(NTs)} + n\,HF + \frac{n}{4}\,N_2\,.$$

However, no structure recovery was observed if NTs were fluorinated at 400 °C.

'Fluorocarbon' NTs were shown to react with such a strong nucleophile as sodium methoxide to give a relatively stable compound with an approximate composition $C_{4.4}F(OCH_3)_{0.25}$. Sonication of fluorinated NTs in various alcohols leads to solvation of the NTs, the degree of solvation being much higher than that reported by Chen *et al.*[102] Solvated NTs can form solutions, which is of great importance for the development of nanotube chemistry and some technological procedures, *e.g.*, for nanotube sizing and purification.

Mickelson *et al.*[101] studied the fluorination of thoroughly purified NTs primarily with the (10,10) structure. The reaction product consisted of ~70 at.% C and 30 at.% F and corresponded to the empirical formula $C_{2.33}F$. The C–F bond ionicity was found to be much higher than in, *e.g.*, alkyl fluorides. This allowed the preparation of metastable solutions of the NTs in methanol, ethanol, 2,2,2-trifluoroethanol, propan-2-ol, butan-2-ol, n-pentanol, n-hexanol, cyclohexanol and n-heptanol by sonication. These solutions were stable for 24–168 h. Of the solvents used, propan-2-ol and butan-2-ol were found to be the best. The solubility of NTs in butan-2-ol was at least 1 mg ml^{-1}. It was assumed that solvation is accompanied by the formation of hydrogen bonds following the scheme



Prolonged sonication of the fluorinated NTs (~10 min and longer) results in removal of some of the fluorine atoms from the surface of NTs.

The solutions of the NTs in chloroform appeared to be much less stable. Attempts at solvating the NTs in perfluorinated liquids, acetic acid and aqueous acetone solutions also failed.

Reactions in solutions also proved the role of hydrazine as defluorinating agent. The structures of the NTs precipitated out of the solution after adding anhydrous hydrazine and characterised by low fluorine content were only slightly different from those of the untreated NTs.

Smalley *et al.*[103] succeeded in replacing the fluorine atoms attached to the side walls of NTs by alkyl groups. Fluorinated NTs of stoichiometry $C_{2.33}F$ were treated with either a solution of alkyllithium in alkane or with Grignard reagents RMgBr (R = Me, Et, Bu, C_6H_{13}, C_8H_{17} or $C_{12}H_{25}$) in THF. The reactions were activated by sonication.

It was found that the NTs alkylated with hexyl groups can be dissolved in chloroform (up to a concentration of ~0.6 g $litre^{-1}$), THF (~0.4 g $litre^{-1}$) and methylene chloride (~0.3 g $litre^{-1}$). No flocculation was observed over a period of several weeks.

Heating of the alkylated NTs in air can lead to recovery of the initial composition the NTs had before fluorination. The hexylated NTs decompose or are oxidised at 250 °C. Judging from the mass loss over a period of 1 h, there are 10 carbon atoms of the outer surface of the NT per hexyl group.

Smalley *et al.*[103] also reported convincing proofs of the chemical nature of the bonding between alkyl groups and the surface of NTs. They also found that alkylated NTs can form true solutions and various complex functional nanostructures linked through the atoms attached to their side walls.

To establish the fluorination and functionalisation mechanisms, Kelly *et al.*[104] studied fluorinated and butylated NTs by scanning tunnelling microscopy (STM) and carried out quantum-chemical calculations of the energies of different isomers. The observed STM images were consistent with the formation of the 1,4-isomer (Fig. 5), though the calculations predict that this isomer is only slightly more stable than the 1,2-isomer. The

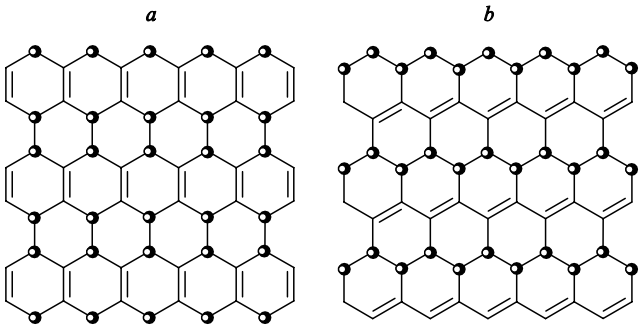


Figure 5. Structure of fluorinated nanotubes. 1,4-isomer (*a*) and 1,2-isomer (*b*).

mechanism of fluorination involves the addition of fluorine atoms to the side walls of NTs around the circumference of the NTs in the intermediate stages.

Fluorination of the external side walls of NTs affects their electronic properties. For instance the conductivity type of NTs can vary from semiconducting to metallic (and *vice versa*).[105]

The binding energies of one, two, three and four fluorine atoms to the side-wall carbon atoms of a (10,0)-NT have been calculated.[106] The sum of the binding energies of two fluorine atoms to the carbon atoms of the NT is much higher than the binding energy in the F_2 molecule.

A group of researchers from Japan studied the process of fluorination of the inner cavity of NTs and the effect of changes in the chemical composition of the NTs on their properties.[107] The starting material, open-end SWNTs, was produced in a porous Al_2O_3 template with a pore diameter of ~30 nm and a pore length of 75 μm. After treatment with F_2 under isothermal conditions at 50 to 200 °C and atmospheric pressure the template was dissolved to separate the fluorinated NTs (Fig. 6). The product was shown to retain the tubular structure.

Fluorinated carbon nanotube membranes are thought to be a perfect material for electrochemical batteries or capacitors.[96]

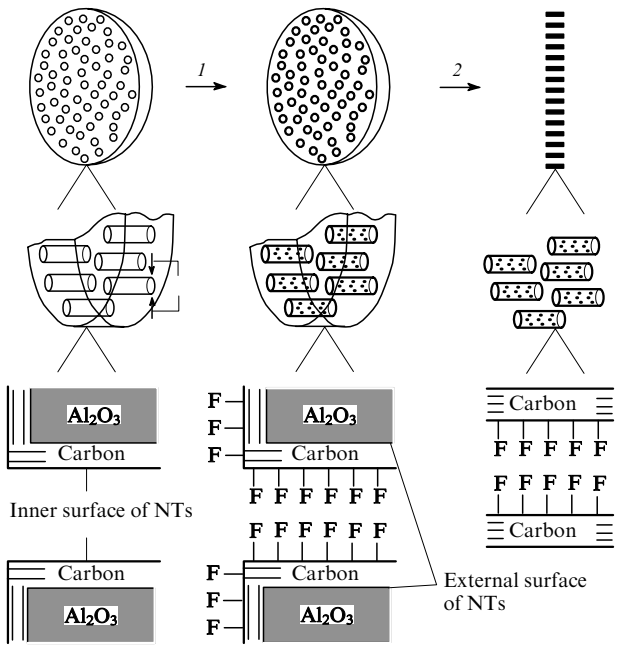

Figure 6. The preparation of nanotubes with fluorinated inner cavity using a porous Al_2O_3 film (deposition of the carbon layer is not shown).[107] Fluorination (*1*) and dissolution in HF (*2*).

Long-term (168 h) fluorination of MWNTs with 'roll' structure and nanoparticles obtained by arc method with BrF_3 vapours at room temperature results in tubular or quasi-spherical C_2F.[108] This is accompanied by corrugation of the external shells of the NTs while the inner shells of the NTs retain the shape of coaxial cylinders. As the depth of fluorination increases, the interlayer spacings and the NT diameter also increase. At a critical fluorination depth (or, in other words, at some critical strain), a number of the outer shells are simultaneously unrolled, thus leading to the formation of multilayered plate-like particles.

This phenomenon was first observed. The interlayer spacing for the untreated NTs was 0.342 nm (by 0.007 nm larger than for graphite), whereas that for the fluorinated NTs was 0.614 nm, which is indicative of a very weak interlayer coupling. However, the role of Br_2 used in the form of (i) vapours to pre-saturate the NTs and (ii) solution to evaporate BrF_3 is still to be clarified.

b. Soluble carbon nanotubes

The ability of NTs to dissolve in various solutions opens new possibilities for their purification, classification (selection of fractions with uniform structure and equal length) and modification.

Pioneering studies on the attachment of organic functional groups to NT bundles by radiation-induced photolabilisation using biradicals and nitrene sources followed by treatment with dichlorocarbene were carried out by Smalley *et al.*[109] They found that the interaction with dichlorocarbene leads to the appearance of chlorine within the NT bundles but failed to determine whether the reactant is attached to the NT walls or to amorphous carbon due to insufficient purity of the starting material. Dichlorocarbene was attached to the double bond of a NT using another reaction, namely, the interaction of NTs with $PhHgCCl_2Br$.[109] The reaction product was found to contain $\sim$2 at.% of chlorine.

Solvation of SWNTs due to the attachment of octadecyl groups has been reported.[102] Single-walled NTs with an average diameter of 1.38 nm were obtained by arc discharge technique, purified, cut to 100 to 300 nm, opened, acid-functionalised (in HCl in the final stage) and treated with $SOCl_2$ containing a small amount of DMF for 24 h at 70 °C. The solid phase was separated from the solution, washed with anhydrous THF, dried and heated with octadecylamine at 90–100 °C for 96 h. The solid residue obtained after removal of excess amine and four-fold washing with ethanol contained up to 60% of NTs that were extracted using a dichloromethane solution. It was found that the functionalised NTs can be dissolved in chloroform, benzene, toluene, chlorobenzene, dichlorobenzene and CS_2. The solubility limit in dichlorobenzene and CS_2 was greater than 1 g litre^{-1}. Dilute solutions were brown while nearly saturated solutions were black.

Functionalisation was accompanied by noticeable swelling of NTs, which was tentatively related to the breakdown of the NT bundles. It should be noted that a $\sim$300-nm (10,10)-NT contains $\sim$50 000 carbon atoms and has a molecular mass of $\sim$600 000 Da.

Solutions of solubilised SWNTs with attached $CONH(CH_2)_{17}CH_3$ groups were studied by IR, Raman and UV spectroscopy[102] and by the ^{1}H NMR (see Ref. 102) and ESR spectroscopy.[110] The ESR signal with the parameters $g = 2.003$ and $\Delta H = 2.1$ G observed by Chen *et al.*[110] is characteristic of the cut NTs. Reactions of NTs with Br_2 and I_2, which can also proceed in solutions, were shown to cause changes in the electronic structure of the NTs.

Dissolution of SWNTs *via* their functionalisation has been studied in detail.[111] The SWNTs were first treated with $SOCl_2$ and then the chloride groups were replaced by amino groups using the reaction with 4-$CH_3(CH_2)_{13}C_6H_4NH_2$. Solution-phase doping of the solubilised NTs with iodine and bromine resulted in pronounced changes in the vibrational spectra of the NTs and served as evidence that the reactions in the solutions do proceed. Compared to the cut NTs, the uncut functionalised NTs were found to be much less soluble. Distinctions between the absorption bands of semiconducting and metallic NTs and better solubility of the NTs of larger diameter (their fraction is small) in pyridine than in THF, CH_2Cl_2 and CS_2 were also pointed out. Dissolution of the amine-functionalised NTs can be achieved using the amines with long alkyl radicals since the interaction with aniline was found to have almost no effect on the solubility of the NTs.

Soluble NTs were also obtained by treating with poly(phenylacetylene).[112] Short NTs helically wrapped by the polymer molecules (the NT content in the composite was 1.9 mass % to 6.0 mass %) were dissolved in THF, toluene, chloroform and 1,4-dioxane.

The addition of poly(*m*-phenylene vinylene-*co*-2,5-dioctyloxy-*p*-phenylene vinylene) to powdered NTs allows their dissolution in standard organic solvents (*e.g.*, toluene) and purification from insoluble particles of turbostratic graphite.[113, 114] The polymer is prone to form helices with a diameter of $\sim$20 nm and a pitch of $\sim$6 nm. The NTs under study were 15 to 20 nm in diameter and 0.5 to 1.5 μm long. Because of the correspondence between the NT diameter and the diameter of the polymer helix, the polymer molecules can wrap the NTs, though in some instances they were found inside the NTs. Noteworthy is that the interaction of bright yellow polymer with black NTs resulted in a dark green composite. The nanotube/polymer suspensions were stable for a period of at least 6 months.

c. Colloidal solutions and dispersions of carbon nanotubes

Solubilisation of NTs can also be achieved by colloid chemistry tools. Functionalised soluble NTs differ from surfactant-coated NTs in strength of the bonds they form (only in the former case these bonds are covalent). Suspensions of NTs are stabilised using common surfactants.[91] Surfactant-stabilised dispersions of MWNTs and SWNTs are convenient for chromatographic purification.[115–117]

The most often used surfactants are DMF and *N*-methylpyrrolidone. Dispersions of NTs in DMF are stable.[103, 118] However, the authors of a more recent study[119] showed that these dispersions tend to aggregate after a period of several days. One can assume that NTs tested by different authors exhibited different properties.

The most stable are dispersions of NTs in strong Lewis bases which do not form hydrogen bonds.[119] These are (in the descending order of the optical density of NT dispersions) *N*-methylpyrrolidone, DMF, hexamethylphosphoric triamide, cyclopentanone, tetramethylenesulfoxide and ε-caprolactam. The optical spectra of NT dispersions in these solvents follow the same pattern. Dispersions of NTs in DMSO, acrylonitrile, 4-chloroanisole and ethylisothiocyanate follow another spectral pattern, while NT dispersions in 1,2-dichlorobenzene, 1,2-dimethylbenzene, bromobenzene, iodobenzene and toluene follow yet another, third, spectral pattern.

The third group of solvents is thought to be the best for C_{60} and C_{70} (see Ref. 120).

Complexation with polyacrylic acid and surfactants allows solubilisation of MWNTs up to several micrometres long.[121]

Exact reproduction of the geometry of NT-derived nanoscale devices required studies on the behaviour of micellar dispersions of NTs on patterned surfaces[122] and preparation of the Langmuir–Blodgett films based on amphiphilic molecules and NTs.[123] Such films were fabricated by dispersion of NTs in aqueous solution of lithium dodecyl sulfate, isolation of the residue by centrifugation and introduction of the residue into the subphase of the aqueous solution of poly(allylamine hydrochloride).

Burghard *et al.*[124] coated electrodes with NTs using surfactant-stabilised NT suspensions or Langmuir–Blodgett films. At low temperatures, SWNT bundles in the Langmuir–Blodgett films exhibit nonlinear current-*vs*.-voltage characteristics.[125]

IV. Decoration of carbon nanotubes and their use as templates

Coating of the side walls of NTs can be achieved *via* their pre-treatment (functionalisation) or without it. The first route implies the chemical interaction as a necessary stage and is often called nanotube decoration. The second route implies that NTs are used only as templates for the deposition of other substances, though in this case the chemical interaction between the NTs and the substance to be deposited cannot often be ruled out.

A clear correlation was established between the amount of adsorbed Pd^{2+} ions and the concentration of acid groups on the surfaces of both closed and open NTs and graphite.[84] Adsorption of Cu^{2+}, Co^{2+}, Fe^{2+}, Ni^{2+}, Pr^{3+} and UO_2^{2+} ions on the surface of functionalised open NTs was also studied. The adsorption capacity was found to range between 0.005 (UO_2^{2+}) and 0.029 (Pd^{2+}) mmol per gramme of carbon. To obtain metallic palladium using NTs, they were first reduced with H_2 at 250 °C.

Coating of acid-treated NTs with platinum clusters has been described.[85]

To show that NTs can be used as a template, they were oxidised in two steps,[124] namely, by long-term (3 h) reflux in HNO_3 followed by short-term treatment with a strongly acidic $KMnO_4$ solution (the oxidant was decomposed after less than 1 min by adding acetic acid). The oxidised NTs acquired the ability to be readily dispersed in water and to attach copolymers with hydrophobic (butyl methacrylate) and hydrophilic (4-vinylpyridine) groups. The external surfaces of the functionalised NTs were then decorated with gold nanoparticles that form a conducting layer.

Copper nanoparticles with narrow particle size distribution can hardly be obtained by conventional techniques; because of this, they were synthesised using NTs as a template.[126] The NTs used in this study were prepared by catalytic pyrolysis of CH_4. Changing the catalyst composition enabled production of NTs with different diameters and narrow diameter distributions (from 5–10 to 25–35 nm). In addition to variation of (i) the copper salt concentration in the aqueous solution and (ii) the initial ratio Cu : NTs, the procedure involved the reduction in H_2 and washing from the template by sonication and resulted in either Cu nanoparticles or nanofibres. The smaller the NT diameter and the lower the salt concentration in the solution, the smaller the diameter of the copper particles (with the smallest particle size between 5 and 10 nm). An increase in the salt concentration in the solution and the Cu : NTs ratio resulted in the formation of copper nanofibres from 100 nm to 5 μm in diameter and up to hundreds of micrometres long.

Decoration of activated NTs with copper and nickel particles in the presence of Pd complexes using one-step and two-step activation-sensitisation has been reported.[127] Both methods imply coverage of the NT surface with Pd or Pd–Sn nuclei followed by the formation of a continuous coating of the NTs with copper and nickel. The coating density was determined by the activation conditions.

The structure of the coating formed on the external surfaces of NTs interacting with molten V_2O_5 was studied and discussed by Ajayan *et al.*[51,62] This coating can be formed due to surface tension and be very thin. Vanadium oxide has a pseudolayered structure with pyramidal VO_5 units held together by bridging oxygen atoms. These layers can uniformly cover the entire surface of NTs and form thin films. Oxidation of such films in air at 650–675 °C resulted in removal of carbon and preparation of V_2O_5 flakes less than 1 nm thick and rod-like V_2O_5.

A topotactic correspondence between the oxide layer and NTs should be pointed out, *viz.*, the *c* axis of the oxide is perpendicular to the NTs axis. Mention was also made of preferred orientation of the crystallites found inside and outside the NTs (see, *e.g.*, Ref. 52).

The possibility of coordinating $Cr(CO)_6$ to NTs has been reported.[128] Molecular dynamics simulations showed that the chromium center of the $Cr(CO)_3$ group is coordinated to the three double bonds of a benzene ring of the NT side wall.

Nickel and cobalt with small additives of P and B can be chemically deposited onto the MWNT 'forest' to form a continuous polycrystalline coating.[129,130] Similar experiments on the deposition of Ni on the NTs that were dispersed in $SnCl_2$ and $PdCl_2$ solutions by sonication and transferred then into the bulk solution were also carried by Li *et al.*[131] who, however, failed to obtain continuous coating. Strong effect of the pH value of the bulk solution on the character of the coating and, in particular, on the degree of aggregation of the nickel particles was pointed out.

Decoration of NTs with complex molecules including DNA is also possible. For instance, long-term storage of the solutions of such compounds with the NTs pre-treated to be covered with acidic centres resulted in immobilisation of 'small proteins' metallothioneine, cytochrome C_3 and β-lactamase I. The fact that most parts of the immobilised proteins remain catalytically active indicates the absence of pronounced conformational changes. The adhesion force between the proteins and the surface is rather strong and the proteins cannot be washed off with water.[132]

Multi-walled NTs coated with a rhodium phosphine complex were prepared.[133]

The use of gel techniques and, in particular, sol-gel process opens considerable opportunities for NT decoration. For instance, coating of NTs with zirconium propoxide followed by calcination and burning out of carbon resulted in zirconia nanotubes.[134] After functionalisation and interaction with $Zr(OPr^n)_4$ the NTs was washed with methanol and dried at 373 K. The gel was then calcinated at 723 K and carbon was burnt out in air at 973 K. The zirconia nanotubes thus obtained were 40 nm in diameter, had the side walls 6 nm thick and represented a mixture of equal amounts of monoclinic and tetragonal zirconia phases.

Fabrication of Y_2O_3-stabilised zirconia NTs *via* gelation of colloidal solutions of $ZrOCl_2$ and $Y(NO_3)_3$ by addition of NH_4OH followed by heat treatment is a considerable step forward. A similar procedure was used for the synthesis of hollow NTs or nanorods from SiO_2, Al_2O_3, V_2O_5, Sb_2O_5, MoO_2, MoO_3, WO_3 and RuO_2.[135,136] Gels were prepared using (i) the vanadium, molybdenum or tungsten acids synthesised from corresponding salts by ion exchange technique and (ii) metal chlorides. TiO_2-Coated NTs were also prepared (this report can be accessed *via* the Internet at URL http://www.fys.kuleuven.ao.be/vsm/spm/Ti_oxidation_fig11.html).

It was established that physically deposited Ti, Ni and Pd coatings cover the surfaces of NTs by continuous or quasi-continuous layers, whereas Al, Au and Fe coatings only form isolated discrete particles on the NTs.[137,138]

Calculations[139] of the adsorption of potassium atoms on the external and internal NT surfaces showed that the process is energetically favourable for small-diameter NTs.

A theoretical study of the interaction of Ni and Ni_2 with graphite and NT side walls[140] revealed considerable differences in bonding sites, magnetic moments and the direction of charge transfer. The effect of the NT surface curvature[§] on the reactivity of graphene sheets has been studied.[141] Some conclusions drawn based on the results of quantum-chemical calculations were confirmed experimentally.

V. Substitution of the carbon atoms of nanotubes by atoms of other elements

The interest in carbon NTs in which some of the carbon atoms are partially or completely replaced by atoms of other elements, as well as the interest in the NTs made of other substances stems from the fact that these NTs can exhibit improved electronic properties as compared to the carbon NTs. For instance, the electronic

§ The study[141] concerns bending of NTs and has a new term in the title, 'Kinky Chemistry'.

characteristics of boron nitride NTs (hereafter, BN-NTs) are known to be independent of their structure.[142] Young's modulus of BN-NTs is ~1.2 TPa, which is a record value for fibrous dielectrics.[143] Therefore, BN-NTs are thought to be the best material for encapsulation of conductors in their inner cavities. This type of NTs is promising for fabrication of low-voltage field emission devices and preparation of composites from coaxial sandwiches of carbon NTs and BN-NTs.[144]

The structure and electronic properties of nitrogen-containing NTs have been studied at different N : C ratios and different structure of isomers.[145] It was found that, depending on the mutual arrangement of nitrogen and carbon atoms, NTs can exhibit either metallic or semiconducting properties with a narrow energy gap.

However, BN-NTs as well as B_xC-NTs or B_xCN_y-NTs are difficult to prepare using the procedures developed for production of carbon NTs. An original method of attacking the problem of preparation of B_xC-NTs involves replacement of the C atoms in carbon NTs by B atoms.[146, 147] Indeed, the oxidation of NTs by B_2O_3 vapours in Ar stream at 1373 K resulted in B_xC-MWNTs ($x \leqslant 0.1$) with the same diameter and length as those of the untreated NTs.

$$x\,B_2O_3 + (2 + 3x)\,C_{(NTs)} \longrightarrow 2\,B_xC_{(NTs)} + 3x\,CO.$$

It was suggested that the low degree of substitution is related to the multi-walled nature of the starting material (the untreated NTs) and that mostly the outer shells were involved in the reaction. In addition to B_xC-NTs, crystalline rod-like nanomaterials of stoichiometry B_4C and $B_{13}C_2$ were found among the reaction products.

Preparation of $(BN)_xC$-NTs from carbon NTs with an average diameter of 10 nm and B_2O_3 powder in N_2 stream at 1573 K has been reported.[148] In this case, the graphite crucible used for the synthesis of B_xC-NTs should be replaced by a BN crucible. Noteworthy, C → B substitution was found to lead to a more ordered NT structure.

The same procedure was also used for the synthesis of BN-SWNTs and carbon NTs doped with boron and nitrogen.[149]

The reaction

$$B_2O_3 + 3\,C_{(NTs)} + N_2 \longrightarrow 2\,BN_{(NTs)} + 3\,CO$$

was conducted in an induction furnace at temperatures between 1523 and 1803 K and resulted in B_xC-NTs, $B_xC_{1-x-y}N$-NTs and BN-NTs. The yield of the BN-NTs increased as the temperature increased. However, not all NTs were involved in the reaction. It is interesting that some of the BN-NTs were filled with octahedral BN particles, which resembles the formation of nanoscale 'pea-pod' structures of carbon NTs.

A more complicated procedure for increasing the yield of substituted NTs consists of MoO_3-promoted synthesis using B_2O_3.[150] The reaction was carried out at the mass ratio $B_2O_3 : MoO_3 : NTs = 5 : 2 : 1$ at 1773 K. The reaction was nearly complete after 30 min due to the stronger oxidative effect of the MoO_3 additive compared to that of B_2O_3 and resulted in the formation of BN-NT bundles up to 1 μm long. The authors of this study [150] suggest that the process begins with the oxidation of NTs following the reaction

$$MoO_3 + 3C_{(NTs)} \longrightarrow Mo + 3\,CO.$$

As a result, the NTs are opened, thus enhancing their reactivity towards B_2O_3 and N_2. The Mo atoms chemisorbed at the NT ends act as catalysts to preclude the formation of 'caps'. This is accompanied by filling the NTs with Mo-containing clusters.

Boron- and nitrogen-doped SWNTs containing up to 10 at.% B and up to 2 at.% N were produced in high yield using substitution reactions.[151] The highest yield was achieved at 1553 K after 30 min synthesis. All the SWNTs synthesised were found to form bundles with an inter-tube spacing of ~0.3 nm.

A multistage substitution reaction was used for the template synthesis of GeO_2 nanorods (NR).[152] A mixture of powdered Ge, Si and SiO_2 with carbon MWNTs 15 nm in diameter was heated in Ar atmosphere at 850 °C for 3–4 h. The overall process is assumed to involve a number of reactions of Ge vapours, *viz.*, partial exchange with SiO_2, a reaction with the carbon atoms on the NT surfaces and oxidation into GeO_2 in the presence of O_2.

$$Ge_{(gas)} + 2\,O_2 + 2\,C_{(NTs)} \longrightarrow GeO_{2(NR)} + 2\,CO.$$

Nanotubes were used for the template synthesis of SiC,[153, 154] TiC, NbC, Fe_3C and BC_x (see Ref. 153); GaN,[155] Si_3N_4 (see Ref. 156) and TaC [157] *via* reactions with volatile oxides (SiO, Ga_2O, B_2O_3), chlorides ($FeCl_3$) and iodides (TiI_x, NbI_x).

Nanotubes can be coated with titanium.[137, 138, 158]

Reactions of the type

$$xC_{(solid)} + M_{(solid,gas)} \longrightarrow MC_{x(solid)}$$

do not belong to but are much the same as substitution reactions. The interaction of SWNTs and SWNT bundles with silicon begins at temperatures above 800 °C and is accompanied by the formation of β-SiC nanorods that retain the morphology of the carbon NT bundles (this holds even for long rods!).[159] The reactions of individual NTs or NT bundles at 970 °C in ultrahigh vacuum resulted in structures with the $Si-SiC_{(NR)}-C_{(NTs)}$ heterojunctions. Similar structures with well-defined carbide–metal interfaces were obtained in reactions of NTs with titanium. A schematic illustration of the method is shown in Fig. 7.

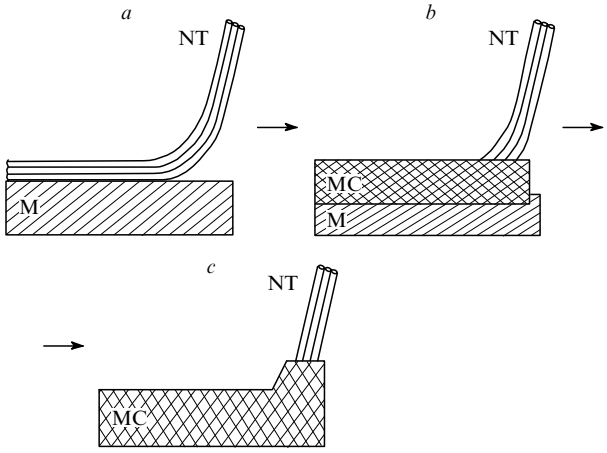

Figure 7. A schematical illustration of the method for fabricating $MC-C_{(NTs)}$ heterojunctions.
Before reaction (*a*), formation of carbide in the reaction of the nanotube with the metal (*b*) and after reaction (*c*).

Preparation of structures with $NbC-C_{(NT)}$ heterojunctions appeared to be a more difficult task due to peeling of NTs from the carbide on cooling. However, the reaction with niobium is convenient for cutting long NTs and making a uniform morphology of NT ends, which is of great importance for fabrication of field emitting devices.[160] To this end, a perforated Nb wafer was coated with a suspension of NTs, the solvent was removed and the NT-coated wafer was kept in $\sim 10^{-8}$ mm Hg vacuum at 950 °C.

VI. Insertion of 'guest' atoms and molecules into the intertubular space of multi-walled nanotubes and nanotube bundles

Intercalation compounds of carbon materials are of considerable interest in many respects. Lithium-intercalated graphite and related substances are commercially used in lithium batteries; the theoretical limit for the specific energy capacity of these materials equals 372 mA h g^{-1} and corresponds to the composition LiC_6 (see Ref. 161). Sometimes, the second electrode in lithium chem-

ical current sources is fabricated from fluorinated graphite (see, *e.g.*, Ref. 162). Fullerenes and NTs can also be used for these purposes.[163] Theoretically, NTs must possess a higher degree of intercalation than fullerenes.

Intercalation of MWNTs and SWNTs are two basically different processes. In the case of MWNTs, the intercalated particles penetrate into the space between the nested shells through topological defects and stay there.[164, 165] Single-walled NTs cannot be intercalated in this manner, but the 'guest' atoms or molecules can penetrate into the intertubular space of the SWNT bundles.

Intercalated NTs are also fundamentally different from fullerene intercalation compounds. For instance, fullerene C_{60} can form charge-transfer complexes only with electron donors.[166, 167] On the other hand, the results obtained by Raman [168] and optical [169] spectroscopy and from conductivity measurements [170] show that SWNT bundles exhibit the double behaviour typical of graphite and can be doped with either electron donors or acceptors. Charge transfer in SWNTs was also observed in many other experimental studies. This is characteristic of both metallic and semiconducting SWNTs.[169] Charge transfer in MWNTs also does occur.

The conductivity temperature coefficient of crystalline bundles of single-walled (10,10)-NTs is positive, thus indicating their metallic properties. Intercalation with Br_2 or K reduces the electrical resistance of the NTs at 300 K by a factor of 30 and extends the temperature range in which the conductivity temperature coefficient is positive. This points to the fact that Br_2- or K-doped NTs ($C_{52}Br_2$ and $C_{116}Br_2$) belong to the synthetic metals.[170]

Intercalates are ionic compounds and intercalation leads to an increase in the charge carrier density. Optical spectrometry studies [171] proved the possibility of controlled shift of the Fermi level of individual SWNTs by doping them with various substances. The results of electrochemical measurements also point to reversible doping of SWNTs ('nanopaper') with Li^+ ions in organic radical anions (naphthalene, benzophenone, fluorenone, anthraquinone and benzoquinone) and to shift of the Fermi level.[20] No intercalation stages typical of graphite intercalation reactions were observed. It was found that the chemical composition of the doped NT samples can be varied smoothly.

Absorption spectra of intercalated SWNTs in the visible region exhibit complex patterns which depend on the dopant concentration.[172]

Conclusions drawn by Iijima *et al.*[173] contradict the known idea that NT intercalation is accompanied by a rather high degree of charge transfer. The results obtained in this study should be more thoroughly analysed because of the high scientific authority of the authors.

1. Intercalation of electron donors

Multi-walled NTs [164, 165] and SWNT bundles [170, 174] are characterised by a different structure of the van der Waals spacings between individual NTs. However, both types of NTs can be intercalated with alkali metal vapours up to the composition MC_8 (M = K, Rb, Cs). The capacity of these materials is comparable to that of graphite which also forms compositions of stoichiometry MC_8 upon intercalation.

Multi-walled NT bundles increase their mass by 33% upon intercalation with potassium and by 260% upon intercalation with $FeCl_3$. The intercalation is accompanied by changes in the NT shape, volume and morphology and by swelling and formation of necks. Intercalation products can be readily hydrolysed; however, subsequent washing leads to recovery of their initial state. Different types of MWNTs (*i.e.*, with the 'Russian doll' and 'roll' structure) are believed to exhibit different intercalation behaviours.[175, 176]

In vacuo intercalation of SWNT bundles with Cs and K vapours at room temperature is reversible and leads to structural disordering of NT bundles.[177] The chemical composition of the intercalation products corresponds to the empirical formulae KC_{24} and CsC_x ($x = 8-24$). Disordered structure of SWNT bundles prevents locating the metal sites.[177] Disordering is due to presence of the metal atoms in the intertubular space rather than filling of individual NTs (the samples used in the experiments were 'capped').

Electrochemical intercalation of SWNTs with alkali metals involves three stages characterised by different rates. These are charge transfer through the macroscopic electrolyte–electrode interface, diffusion through the mesopores of the electrode and diffusion in the NT bundles.[178]

A number of studies [168, 170, 179] were carried out using 'mat'-like SWNT structures. However, NT 'mats' consist of a mixture of metallic and semiconducting NTs and the results obtained appeared to be hardly interpretable.

Chemically doped semiconducting NT bundles change their hole-type conductivity to electron conductivity.[180] A correlation between the concentration of the intercalated potassium and the charge carrier density was found. Typically, the electron density varies between 100 and 1000 μm^{-1}. The effective mobility of electrons was found to be 20 to 60 $cm^2\ V^{-1}\ s^{-1}$, which is in agreement with the corresponding numerical estimate obtained for holes.[181]

Intercalation of SWNTs and SWNT bundles with potassium also changes their transport properties.[182–184] Pichler *et al.*[184] found that at 425 K the C : K ratio in potassium-intercalated NT bundles approaches 7, which corresponds to the formation of a stage-1 intercalation compound, KC_8. According to Pichler *et al.*,[184] intercalation leads to a relatively small increase in the intertubular spacing and the total conductivity of the intercalated bundles is somewhat lower than that of the untreated NT bundles.

Molecular dynamics simulation [185] predicted the most stable structures of K-doped single-walled (10,10)-NTs. These were found to be KC_{16} (filling of the intertubular space) and KC_{10} (filling of both the inner NT cavities and intertubular space). The optimum structure corresponds to the compositions $K_5^{exo}C_{80}$ for the former type of NT filling and $K_5^{exo}K_3^{endo}C_{80}$ for the latter.

2. Intercalation of electron acceptors

As mentioned above, charge transfer occurs between the NTs and intercalated Br_2. Photoelectron spectra [42] point to the formation of surface complexes $C-Br_2$. The nature of the interaction between Br_2 and the NTs was studied by high-resolution transmission electron microscopy.[186] A preferential orientation of the bromine atoms was found, which is consistent with the results obtained in other studies. It appeared quite surprising that the region of Br_2 accumulation in MWNTs extends perpendicular to the NTs axis, which means that the liquid Br_2 behaves to some extent like a solid. The complexes formed were found to be not too stable and Br_2 can be washed off with CCl_4. Br_2-Intercalated NTs retain tubular structure, though the arrangement of the nested carbon shells becomes somewhat disordered (the NTs are 'amorphised'). After removal of Br_2, the NTs were more readily oxidised with oxygen than the unintercalated NTs.¶

The interaction of molten iodine with NT bundles in a sealed ampoule at 140 °C results in disordering within the NT bundles.[187] The two-dimensional crystal lattice of the NT bundles expands (the cross-section area increases).

In the intertubular space the iodine atoms are grouped and form $(I_5)^-$ chains separated by ~2.1 nm at moderate intercalation degrees. Intercalation reduces the electrical resistance and thermal electromotive force (emf) of the NTs. The iodine-doped

¶ A somewhat arbitrary use of the term 'intercalation' for the description of the above-mentioned processes should be pointed out. Strictly speaking, no increase in the interlayer spacing occurs in this case and the crystal lattice parameter increases insignificantly. Liquid Br_2 is adsorbed on the outer surfaces of NTs and is soaked into the inner cavity after opening the NTs due to wetting.

NTs are stable in air. More recently,[188] the poly(iodide) chains formed inside SWNTs were found to have a helical shape.

Bower *et al.*[189] studied the interaction of 70% HNO_3 with SWNT bundles and found that (i) intercalation occurs reversibly and (ii) the intertubular spacing increases upon the insertion of the acid molecules. The starting material was a 'mat'-like substance, or 'nanopaper', with the NT content of about 70%. The intercalation occurred at room temperature and, in contrast to the interaction with graphite, took a rather short time due to the capillary effect of the NT bundles and was accompanied by an increase in the intertubular spacing within the bundles. The crystallinity of the NT bundles remained after intercalation; however, an increase in the lattice parameter from $\sim$1.7 to 2.0 nm was observed. No proton abstraction from the HNO_3 molecule was suggested. The structure of the HNO_3/SWNTs intercalate is shown in Fig. 8. *In vacuo* heating of the samples to 500 K caused the onset of the reverse process. Extention of intercalation time to 12 h and longer times resulted in the loss of order within the NT bundles and in partial or complete breakdown of the NT bundles into individual NTs upon removal of HNO_3.

A study of electrochemical oxidation of SWNT bundles by H_2SO_4 revealed some remarkable features.[190] A spontaneous charge-transfer reaction was observed in the NT bundles. In contrast to the graphite–H_2SO_4 system, this reaction proceeds even before applying the potential difference. On the other hand, both systems share some common features. Under the action of electric current the NT bundles behave similarly to graphite, namely, the reaction

$$H_2SO_4 + \bar{e} \longrightarrow HSO_4^- + \frac{1}{2}H_2$$

proceeds by the 'charge exchange' mechanism and there is an 'overoxidation' regime (irreversible formation of covalent bonds C–O).

$FeCl_3$-Intercalated MWNT bundles exhibit metallic conductivity.[175, 176, 191] The temperature dependence of this parameter was studied by Baxendale and Amaratunga.[192]

Intercalation of NTs with $CuCl_2$ followed by reduction of the chloride to metallic Cu can be used for purification of the NTs.[41]

An interesting reaction was studied by Hsu *et al.*[193] The main goal of the study[193] was to obtain diamond from NTs *via* treatment of potassium-intercalated NTs with CCl_4 to give KCl and excess carbon. This reaction seems to be of no interest for large-scale implementation; however, it opens new prospects for synthetic chemistry. The authors hoped that the reaction

$$4K + CCl_4 \longrightarrow 4KCl + C$$

would result in cross-linking of adjacent graphite basal planes and in replacement of the sp^2-bonds by sp^3-bonds within the intertubular space of the MWNTs. The reaction was carried out in an autoclave at 200 °C; however, no diamond was produced. Analysis of the reaction products revealed the loss of ordering ('amorphisation') of the tubular structure and the formation of KCl crystallites within the space between graphite shells with presumably distorted structure. No KCl crystallites were found (i) within the NTs with the outer diameter of less than 10 nm and (ii) far from the outer surface of the MWNTs.

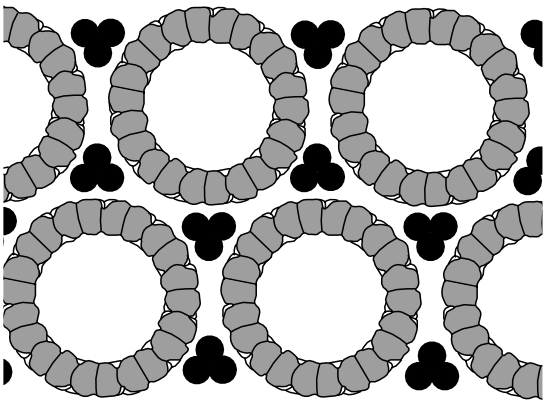

Figure 8. A model of the structure of the HNO_3/SWNTs intercalate. The C–O distance was assumed to be the same as in the case of HNO_3 intercalated graphite, the distance between the centres of the nanotube cross-sections was set to $\sim$2.0 nm.

VII. Adsorption and storage of gases in carbon nanotubes

Nanotubes can adsorb gases at high pressures or under conditions of electrochemical saturation. Adsorption can occur on the internal surfaces of NTs (within the innner cavities), on the external surfaces of free-standing NTs and in the intertubular space of NT bundles.

Pioneering calculations of the adsorption of gases on NTs were carried out by Maddox *et al.*[194]

Model calculations of the sorption of hydrogen, oxygen and chlorine atoms by SWNTs and graphite revealed three types of surface sites and provided an explanation for high efficiency of hydrogen storage in NTs.[195]

Compared to fluorine atoms, attachment of hydrogen atoms to the side walls of NTs is less probable; the attachment of two or four hydrogen atoms to a (10,0)-NT is an endothermic process.[108]

Adsorption of a Lennard-Jones gas mixture on single-walled arm-chair NTs with inner diameters of 6.125, 7.482 and 8.16 Å was theoretically studied by Ayappa.[196, 197] He showed that at $T \geqslant 388.9$ K adsorption of large particles occurs for the most part. These particles interact relatively strongly with the NTs walls. As the temperature decreases, the equilibrium is shifted towards smaller particles which completely replace the large particles at $T \leqslant 303$ K. Condensation of the small particles occurs in pores.

A series of theoretical studies on the adsorption of gases in NTs was carried out by Stan *et al.*[198–204] In the case of adsorption of inert gases on NTs the bonding between the adsorbate and the surface is stronger than in the case of graphite.[198] At low surface coverages, the adsorption strongly depends on the NT structure and size. A salient feature of the process is its one-dimensional character.

Helium and neon readily fill the intertubular space of NT bundles. They are strongly bound to the NT side walls even under those conditions where almost no adsorption occurs on the basal planes of graphite.[200] The condensed phase is strongly anisotropic. Since adsorption leads to the formation of a quasi-one-dimensional system, the properties of this system differ from those of standard systems.[201]

According to calculations, adsorption of small atoms occurs both inside NTs and in the intertubular space of NT bundles, whereas the adsorption of relatively large atoms and molecules with rare exceptions occurs only inside the NTs.[203] Helium atoms are strongly bound to the side walls within the intertubular space of NT bundles. The system can behave like a lattice gas or condensed phase; despite the fact that the content of the adsorbate atoms is at most 2% they contribute much more to the specific heat capacity than the 'host' molecules at low temperatures.[202] In the case of adsorption of a $^3He-^4He$ mixture the partial pressure of each component is determined by the ratio of their concentrations within NT bundles; the situation looks like adsorption is controlled by some rule similar to Raoult's law.[204]

A study on the desorption of ^4He at 14–23 K showed[205, 206] that the process can be described by the equation for one-dimensional adsorption of neutral particles with very high binding energy estimated as 330 K (at 14–16 K), which is very close to the calculated value (340 K).[200] Channels in the intertubular space of NT bundles can be represented by cylinders 0.21 nm in

diameter and their cross-sections can be filled by at most one helium atom. At temperatures above 16 K, the experimental adsorption capacity was higher than the theoretical value for unknown reasons.

The binding energies of other noble gases (neon and xenon) and CH_4 to the external surfaces of closed SWNT bundles are nearly 75% higher than to the flat graphite surface.[207, 208] However, neither of the gases can be adsorbed in the intertubular space of the NT bundles.

Enhanced adsorption of xenon inside SWNTs at 95 K in the presence of defects, especially after removal of carboxylic groups from the NT surface was observed.[87] The experimentally determined activation energy of xenon desorption (26.8 kJ mol^{-1}) was found to be close to the calculated value (22.6 kJ mol^{-1}).[198]

Experimental study of N_2 adsorption on MWNTs that were open at one end, with mesopores of width 4.0 ± 0.8 nm, at 77 K showed [209] that nitrogen molecules are adsorbed on both the external and inner NT surfaces. It was found that adsorption on the external surface is five times greater than that on the inner surface and that the corresponding adsorption isotherms are considerably different. Adsorption in mesopores was described in terms of the classical theory of capillary condensation and the calculated pore diameter was found to be 4.5 nm. The adsorption isotherms exhibited no hysteresis, in stark contrast to the curves reported by Kyotani *et al.*[210] who studied adsorption in mesoporous NTs open at both ends. These differences were rationalised by accessibility of only one NT end.

Single-walled NT bundles also readily adsorb N_2. Unpurified NTs prepared by the arc method were characterised by an inner specific surface of 233 $m^2\ g^{-1}$ and an external specific surface of 143 $m^2\ g^{-1}$ (see Ref. 211). Acid treatment of the NTs resulted in an increase in the total specific surface from 376 $m^2\ g^{-1}$ to 483 (HCl) and 429 $m^2\ g^{-1}$ (HNO_3) and enhanced the adsorption capacity towards benzene and methanol.

Adsorption of gases affects the electronic [212] and emission [213] properties of NTs. The effect of O_2 adsorption on the electronic and magnetic properties of NTs has been studied.[214]

VIII. Potential fields of application of carbon nanotubes

Increasing interest in NTs is due to great potentialities of their efficient use in industry.[2, 18, 215–219] Small size and unique structure of NTs determine their unusual mechanical and electronic properties (these can be controllably varied over a wide range). In contrast to graphite, NTs are free from dangling bonds and are therefore chemically inert. Nanotubes represent a highly rigid and, at the same time, elastic material that exhibits the ability to undergo reversible swelling (buckling up) and folding (compression, flattening).

The fields of application of NTs can be arbitrarily divided into two groups. The first group of applications utilises NTs in the form of relatively large devices or parts (many NTs 'function') such as light, strong, conducting (if necessary) and impact energy absorbing fillers for various composites, materials for chemical current sources and accumulators of gases. The second group of applications uses NTs in mini- and microcomponents and devices (individual NTs 'operate'). These are electronic components and devices including ultrasmall and ultrafast computers, cathodes for electron field emitters, indestructible nanoscale scanning microscope probes, high-frequency resonators, 'nanostraw' and nanopipettes for introduction into living cells to study their chemical nature.

1. Composites

a. Chemical composition and properties

Nanotubes can serve as ideal reinforcing fillers for composite materials with matrices of any chemical nature, *i.e.*, polymeric and inorganic (metals, ceramics). Many characteristics of NT-filled composite materials can reach record values. Of great importance is also the fact that NTs have low density. This allows one to obtain light composite materials. However, it should be kept in mind that the properties of NTs depend on their origin. For instance, the flexural rigidity of graphitised arc-grown NTs is ~ 1 TPa, which is two orders of magnitude higher than that of the NTs synthesised by chemical deposition of hydrocarbons.[220]

Development of methods for obtaining uniformly distributed and oriented fillers is a vital issue in the fabrication of filled composite materials. Nanotubes are characterised by large aspect ratios (1000 and more), which makes possible reinforcement of composite materials. At the same time, NTs are very short and therefore standard equipment for the production of polymers can be utilised. Using conventional long fibres imposes restrictions on the shape of finished products (carbon fibres are brittle). In the case of NTs these restrictions are removed since products of any shape can be produced by moulding.

Nanotubes are known to be highly rigid. They exhibit high axial strength [221] and a record value of Young's modulus, which approaches 1.25 TPa.[144] This value remains unchanged on going from SWNTs to MWNTs, since it is determined by the strength of the C–C bonds in individual shells.[222, 223] Not without reason theoretical estimates of possible mechanical properties of some composite materials were obtained assuming that the Young moduli of SWNTs (along the NTs axis) and diamond are comparable in magnitude.[224]

The tensile strength of MWNTs can be as high as 63 GPa, which is 50 to 60 times greater than that of high-quality steels (this material can be accessed *via* the Internet at URL http://wupa.wustl.edu/record/archive/2000/02-03-00/articles/nanotube.html).

The limiting pressure for NTs approaches 100 GPa. This is two orders of magnitude higher than for other fibres and allows the use of NTs for production of bullet-proof jackets, car and truck bumpers and for construction of earthquake-proof buildings.[225]

According to *ab initio* calculations, NTs can undergo plastic deformation.[226] Experimental studies of NTs confirmed the possibility of creating NT-derived accumulators of mechanical energy.[227] Compression of purified, oriented, highly crystalline SWNTs is accompanied by exceptionally large and reversible volume reduction. The properties of the NTs resemble those of an ideal flat spring. Under load the NT density increases smoothly to reach that of graphite, which was related to compression and flattening of entangled NT bundles. This phenomenon was also observed in studies of MWNTs.

A theoretical study on the strain and bending behaviour of NTs and the influence of defects on their transport properties was reported.[228]

The lack of the filler materials precluded extensive research into reinforcement of polymers by filling them with NTs. Nevertheless, pioneering experiments [229, 230] showed that design of various types of composite materials is possible. Single-walled NTs appeared to be the best fillers, since the inner shells of MWNTs are not involved in reinforcement.[231] Potential advantages and disadvantages of this type of composite materials have been discussed by Ajayan *et al.*[232]

Tensile test of an epoxy resin/MWNTs (5 mass %) composite showed that only the outer MWNT shells were loaded.[233] On the other hand, the results of compression test of the same composite indicated loading of all the MWNT shells.

Mechanical tests of composite materials [234–236] revealed that mechanical strength of the composites filled with MWNTs is an order of magnitude higher than that of materials filled with conventionally used fibres. The ultimate compression strength of NT-filled composite materials was found to be ~ 60 GPa, which is nearly two orders of magnitude higher than that of standard composites.[235]

The bonding between the matrix and filler in composite materials is known to be neither too weak nor too strong. In this respect the situation with NTs was unclear. The effect of the origin and concentration of SWNTs on their interaction with the

polymer matrix was studied taking PMMA-based composites filled with NTs as examples.[237] Mixtures with the NT content ranging from 1 to 20% were also studied.[238] It was found that at low NT concentrations (2.5% and 5%) the NT bundles remain unchanged, though one can assume that they do interact with the matrix since the Raman spectra indicate an increase in the intertubular spacings within the bundles.[238]

One of the nondestructive methods for increasing the surface energy of NTs consists in attachment of functional groups to the NT surfaces.[231] Chen *et al.*[102] studied solubilisation of NTs and showed that they can be dispersed in polymeric matrices without cutting. The bonding between NTs and matrix can also be increased by using defect NTs, though this can lead to some decrease in the strength of the composite material.

Of particular interest are conjugated polymer/NT composites. A salient feature of this class of polymers is the presence of an extended π-electron system that is due to the formation of a specific electronic structure with energy gaps 1.5 to 2.5 eV wide. Usually, these polymers exhibit low hopping conductivity. Introduction of NTs into composites must increase their conductivity, mechanical strength, thermal conductivity and resistance to optical damage. Indeed, a composite material with interesting optoelectronic properties was obtained from electroluminophor poly(*m*-phenylene vinylene-*co*-2,5-dioctyloxy-*p*-phenylene vinylene) and MWNTs.[113,114] The electrical conductivity of this material was measured to be eight orders of magnitude higher than that of the starting polymer. Polymer chains were found to wrap themselves around the NTs, thus making the composite material extremely strong and allowing the NTs to be suspended in the excess polymer solution. Introduction of low concentrations of NTs had little effect on the luminescent properties of the polymer. Moreover, it was found that NTs act as a nanoscale heat sink, thus preventing the composite material from overheating and destruction (under the action of, *e.g.*, laser beams).

Coleman *et al.*[239] studied the properties of poly(*m*-phenylene vinylene-*co*-2,5-dioctyloxy-*p*-phenylene vinylene)/NT composites with the NT content ranging from 0.5% to 36%. It is noteworthy that at low NT concentrations an increase in the NTs content is accompanied by insignificant increase in the conductivity of the composite material. At the NT concentrations in the range between 7% and 10% the conductivity of the material increases jumpwise by ten orders of magnitude and then again increases insignificantly at higher NT content. This behaviour is also typical of composites filled with other carbonaceous materials, *e.g.*, soot. It was found that charge transfer occurs between the polymer and NTs; however, the effective mobility of the charge carriers decreases. A study on the percolation character of the conductivity of composite materials was reported.[240] At low NT concentrations, no aggregation of MWNTs in the polymeric system occurs despite the weak interaction between the polymer and NTs.[241]

Single-walled NTs in conjugated polymers with hole-type conductivity can trap charge carriers.[242] Methods for preparation and fields of application of composite materials comprised of conjugated polymers and C_{60} or NTs were reviewed by Dai.[243]

Wrapping of polymer molecules around NTs was also observed by Seifert *et al.*[105] who polymerised phenylacetylene in the presence of NTs to prepare NTs that could be dissolved in organic solvents. The use of polymers for dissolution of NTs was studied by M in het Panhius *et al.*[244] Nanotube solutions can be used as optical filters while composite materials as converters of light into electricity.[245] Ago *et al.*[246] reported fabrication of photovoltaic devices based on NT-filled composites.

Raman spectroscopy provides the largest body of information in studies of the structure of novel carbon nanomaterials.[247] This method has also been successfully applied to composites. Raman spectroscopy allowed the researchers to follow tension due to load of an epoxy resin/NT composite material and to show that reinforcement with fibrous fillers is usually more pronounced than reinforcement with particles.[248] Wood *et al.*[249] identified the components responsible for the appearance of particular lines in the Raman spectrum of an SWNT-filled polymer, studied the effect of temperature on the spectral patterns, revealed the lines caused by thermal stress and established a stress–strain correlation.

Fragmentation of MWNTs in an urethane–diacrylate polymeric matrix under load has been studied[250] (the content of NTs was not reported).

Composites with NTs can be used for production of aligned NT arrays. By cutting thin slices (50–200 nm) of a composite material based on epoxy resin with random orientation of NTs one can obtain partial alignment of the NTs on the surface of the slice.[229] A more simple and efficient procedure involves the use of composite materials based on thermoplastic polymers. Aligned NT arrays can also be produced by mechanical tension on heated composite material followed by cooling under load.[251] The desired effect was observed only in the experiments with MWNTs.

Nanotube alignment by applying mechanical shear to a composite material sandwiched between two pieces of glass slides was reported by Tang and Xu.[112]

Composite materials based on NTs and polyvinyl alcohol[252] and polypyrrole[253] were prepared. An increase in the NT content to 10 mass % is accompanied by a sharp increase in the electrical conductivity. At higher NT concentrations, the increase in the conductivity is less pronounced.[252] Introduction of 1% MWNTs leads to an increase in the tensile strength and elasticity modulus of the polystyrene films by 36%–42% and ~25%, respectively.[254]

Nanotube fillers can be used for production of high-strength composite fibres, ribbons and coatings with enhanced wear resistance, which can find application in military, aerospace and automotive industries and pharmacy.

For instance, Andrews *et al.*[255] introduced SWNTs (Carbolex, USA) into fibres based on petroleum pitch. The filler was added to a hot pitch solution in quinoline, the solvent was removed and fibres containing 1 mass % or 5 mass % NTs (extrusion at higher NT concentrations becomes difficult) were extruded and carbonised at 1100 °C. Tests showed that the ~18-μm-diameter composite fibres with 5% NTs exhibited improved tensile strength, elasticity modulus and conductivity as compared to those of the unfilled fibres (by 90%, 150% and 340%, respectively).

An original method for fabrication of macroscopic composite fibres and ribbons incorporating flow-aligned SWNTs by forming a net from solution of NTs in a polymer followed by directed alignment was proposed.[256] Such fibres with regularly aligned NTs exhibit an elasticity modulus of 15 GPa, which is lower than that of free-standing NTs but much higher than that of, *e.g.*, 'nanopaper' (1 GPa). The fibres can be bent, crumpled and even knotted.

Reinforced PMMA fibres filled with oriented NTs were prepared.[257]

Two methods for production of composite materials based on commercially sold polymers and NTs have been developed.[258] To synthesise polymer-coated NTs, poly(ethylene glycol), poly(2-vinylpyridine), poly(4-vinylpyridine), poly(4-vinylphenol) or poly(ethylene oxide) were dissolved in DMF and NTs were added. To obtain polymer-grafted NTs, the NTs were mixed with a solution of $SOCl_2$ in C_6H_6, kept in N_2 atmosphere for 120 h, dried *in vacuo* and then triethylamine and poly(ethylene oxide) were added (140 °C, N_2, 48 h). Poly(ethylene oxide) was washed off with DMF. Thin films of the composite materials and NT solutions exhibited remarkable nonlinear optical properties.

Conducting NT-containing composite materials can be used in car body panels to replace metallic car bodies, since they allow spray painting by giving the spray electrostatic charge.[231] In this respect the properties of a composite material based on polyphenylene ether/polyamide mixture containing 10% NTs were found to be quite interesting and useful.[245] The conductivity of the epoxy resin increases by several orders of magnitude upon introduction

of minute amounts of NTs (merely 0.1 vol.%) and becomes higher than that measured after addition of the same amount of soot.[259]

It is assumed that lightweight composite materials will find use in the preparation for human Martian mission.[245]

Nanotubes can be used as additives to polymeric electroluminophors. Colouration of these luminophors occurs by giving them electrostatic charge, which makes possible painting of metallic rather than dielectric surfaces. It is believed that these limitations can be removed by introducing NTs as conductivity-enhancing additives into thermoplastic polymers.[240]

Research efforts aimed at creating chemoresistive sensors based on NT/polymer composites for a multichannel 'electronic nose' are being undertaken.

Sun and Crooks[260] reported the preparation of NT-filled polymeric membranes for sensing large neutral molecules.

Composite materials comprised of a dielectric matrix and conducting filler in the form of small extended particles can be used for electromagnetic shielding, in aerials, waveguides, *etc*. Nanotubes can serve as ideal fillers (http://www.sbirsttr.com/SbirMisc/alld991.htm). The introduction of SWNTs 10 nm in diameter (23 mass %) into ethyl methacrylate matrix leads to a nearly 35-fold increase in the dielectric constant of thick films at 500 MHz.[261]

At low NT concentrations (4% to 7%), composite materials based on NT-filled thermoplastic polymers can exhibit relatively high and uniform electrical conductivity (a short communication was posted in the Internet at URL http://www/rtpcompany.com/news/press/nanotube.htm).

Nanotubes coated with conducting polypyrrole represent a special class of materials.[262] They were prepared by polymerisation of pyrrole immediately on the NT surfaces. No chemical interaction between the polymer and NTs was observed; nevertheless, the modification led to pronounced changes in the properties of the NTs.

Methods for purification of NTs can employ stability of NT solutions in polymers[113,114,263] or the difference in precipitation rates between NTs and impurities in polymer solutions.[264,265] The proportion of short and thin NTs increases upon purification.[263]

A NT/crystalline C_{60} composite was prepared (see Ref. 266).

Research into metal/NT composites has been less intensive compared to studies on polymeric composite materials. Xu *et al*.[267] studied the morphology, mechanical and electric properties of NT/aluminium composites obtained by hot pressing of powder-like mixtures. Introduction of NTs leads to a slight increase in the electrical resistance of aluminium at room temperature and to a sharp drop of the resistance at 80 K. Related composites were prepared and investigated by researchers from Japan (this material can be accessed *via* the Internet at URL http://www.mrs.org/publications/jmr/jmra/1998/sep/013.html). It was found that hot pressing or hot extrusion do not damage NTs and that the NTs do not form products of chemical interaction with aluminium. In contrast to aluminium produced by powder metallurgy, mechanical properties of the aluminium/NT composites remained virtually unchanged upon annealing (873 K).

Introduction of NTs into a titanium matrix substantially increases its hardness.[268]

A composite NTs(3%)/metallic glass $Fe_{82}P_{18}$ was prepared by pressing a mixture of powdered starting components with NTs, melting and quenching of the melt on a copper wheel rotating at a linear speed of 30 m s^{-1}. Composite ribbons 40 μm thick were characterised by uniform distribution of the NTs that retained their initial structure.[269] Some of the NTs 'capped' at both ends were filled with iron alloy.

The number of studies on the composites with ceramic matrices is a little more than those concerning the composites with metallic matrices. Introduction of NTs into composites with $Bi_2Sr_2CaCu_2O_{8-\delta}$ (a Bi-2212 superconductor) has the same effect as irradiation of the Bi-2212 by heavy ions and favours an increase in the current density.[270] Nanotube composites with superconductors of other chemical composition were also studied.[271–273]

To prepare NT/Fe/Al_2O_3 composites, Laurent *et al*.[274–276] calcined amorphous solid solution $Al_{1.8}Fe_{0.2}O_3$ at 1025–1100 °C and then reduced it with a 88% H_2–12% CH_4 mixture at 1050°C. Calcination at 1100 °C resulted in the formation of a solid solution α-$Al_{2-2x}Fe_{2x}O_3$ ($x < 0.1$) and trace amounts of the Fe-enriched phase α-$Al_{2-2y}Fe_{2y}O_3$. Iron particles isolated upon reduction of this phase catalysed the growth of flattened (ribbon-like) arrays of NT bundles. It was found that homogenenous solid solution α-$Al_{1.8}Fe_{0.2}O_3$ with large specific surface area (this favours an increase in the NT yield and improves NT quality) can be obtained only at temperatures between 1025 and 1050 °C. This method results in two-walled NTs with an average inner diameter of ~2 nm as the main product. The proportion of SWNTs was nearly 20%.

The same authors reported the synthesis of powder-like NT/Co/MgO mixtures.[277]

b. Space cable

In 1910 F A Tsander put forward an idea of connecting the Earth and the Moon by a cable. More recently this idea was transformed into the concept of a transport cable connecting the Earth and a geostationary artificial satellite {for references, please visit the Internet Website at URL [http://www.isd.net/anowicki/SPBI120.HTM]**D**}. Conventional space rocket mass transportation systems would travel a predetermined length to transfer cargo and then mass transportation would be performed along the cable due to the action of centrifugal force.

However, no materials suitable for such a cable have been developed as yet. Polymers are vulnerable to space radiation while steel has too high density so a steel cable must have enormous weight. The best commercially available fibrous material based on specially prepared polyethylene fibres, 'Spectra 1000', has a characteristic length of 315 km. (Characteristic length is the maximum length of a cable that can carry its own weight). Recently, NASA's specialists returned to the idea of implementation of a space elevator using a NT-based fibre. The calculated characteristics of this fibre and other materials are listed in Table 1.

Table 1. Properties of particular fibrous materials (http://www.isd.net/anowicki/SPBI1MA.NTsM).

Material	Tensile strength /Pa	Young's modulus /GPa	Density /kg m^{-3}	Longitudinal speed of sound /m s^{-1}
Steel	1–5	200	7900	5000
Beryllium fibre	3.3	310	1870	12870
Boron fibre	3.5	400	2450	12778
Fused silica	–	73	2200	5760
Pyrex glass	–	62	2320	5170
E-Glass fibre	2.4	72.4	2540	5339
S-Glass fibre	4.5	85.5	2490	5860
Kevlar-49 (aramid fibre)	3.6	130	1440	9502
'Spectra 1000'	3.0	170	970	13239
PBO[a]	5.8	365	1580	15199
Carbon fibre	2–5	250–830	1850	11600–21200
Buckytube cable (theoretical data)	150	630	1300	22014

[a] PBO is poly(*p*-phenylene benzobisthiazole), a plastic fibre.

As can be seen, none of the other materials is comparable to the NT cable in tensile strength. The NT cable also must have the greatest characteristic length.

c. Artificial muscles †

As long ago as 1940s it was found that fibres made of polymeric gel-like materials compress in acidic solutions and extend in alkali solutions. The phenomenon can be used in practice by changing the direction of direct electric current. This idea provides the basis for the development of actuators and artificial muscles. For some time, conducting polymers were thought to be the most promising material for electrochemical actuators.[278] However, recent studies [279, 280] revealed that NTs are even more promising.

To function, most of the previously studied materials required application of a voltage of at least 30 V, whereas the operating voltage for 'nanopaper' varies from 1 and 4 V.[279, 280] The new material is characterised by a deformation (changes in linear dimensions) of $\sim 1\%$ and is capable of developing a maximum force of $\sim 3 \times 10^7$ J m^{-3} per cycle, which is about 30 times greater than the characteristics of the best ferroelectric, electrostriction and magnetostriction materials and is even greater than the force developed by human muscles. Schematic representation of the 'nanopaper' test device is shown in Fig. 9 and the relative elongation-*vs*.-voltage curve of this actuator is presented in Fig. 10.

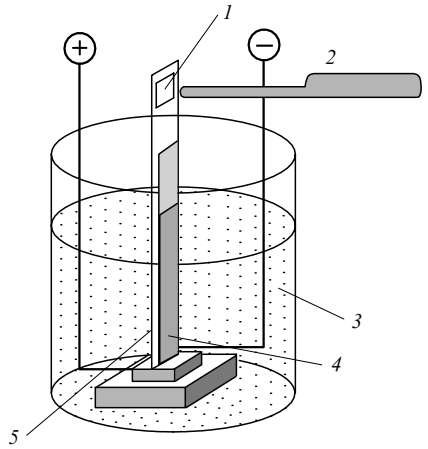

Figure 9. A scheme for a 'nanopaper' test device.
Mirror (*1*), optical sensor (*2*), electrolyte (*3*), 'nanopaper' ribbons (*4*) and insulator, a poly(vinyl chloride) film (*5*).

'Nanopaper' was studied electrochemically.[281] Samples with apparent densities of 0.30 to 0.40 g cm^{-3} containing NT bundles 1.2 to 1.4 nm in diameter were tested in various electrolytes, in the presence of both light and heavy ions, over a wide range of pH values and at different voltage scan rates. It was found that, in contrast to other forms of porous carbon, the capacity of 'nanopaper' depends only slightly on most of the parameters studied (except for the regions characterised by very low and very high pH values). Typically, the 'nanopaper' capacity varies between 18.0 and 40.7 F g^{-1} in 1.0 M NaCl solution at 0.4 V and a scan rate of 50 mV s^{-1}. These results show that pores inside the NT bundles are readily accessible to ions of different size and charge and that, at least for small samples, penetration of the electrolyte into the pores is not controlled by diffusion. The charging mechanism is described by the equation

$$\rangle C{=}O + H^+ + \bar{e} \longrightarrow \rangle COH.$$

The results obtained in these studies are of great importance for further development of not only electromechanical actuators, but also supercapacitors, sensors, *etc*.

† Information presented in this Section does not take into account the results obtained for many new chemical systems that are thought to be potentially used for the creation of artificial muscles.

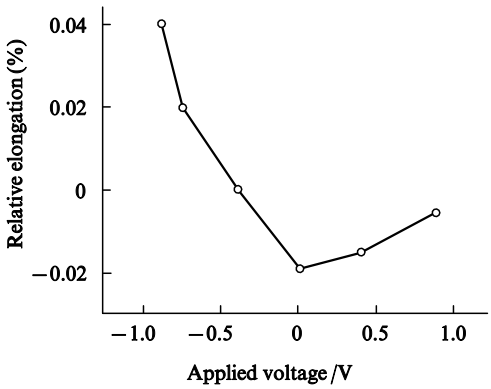

Figure 10. A relative elongation-*vs*.-voltage curve for a 'nanopaper' actuator.[279]

Che *et al*.[282] experimented with an actuator made of a 'nanostructured carbon material' (most likely, NTs).

Potential fields of application of artificial muscles cover a rather wide range from mechanical actuators that operate under severe conditions (as, *e.g*., 'windshield wipers' for space vehicles, in jet engines at 1000 °C, *etc*.) to prostheses, though the last-named task requires considerable research and development efforts and is quite time-consuming. The reverse process, *i.e*., conversion of mechanical energy into electric energy, can draw attention in the context of development of electric generators that use the energy of sea waves.

2. Fields of application of nanotubes in electronics ‡

Miniaturisation (the characteristic size of electronic chips is halved every 3 years) and improvement of performance of silicon-based electronic devices should sooner or later stop (see, *e.g*., Ref. 283). On going from micrometre (0.3 – 1.0 μm) to nanometre scale ($\sim$10 nm) electronics comes into the world of quantum effects and materials change their behaviour. Industry will make this step in the coming decade, this makes research aimed at developing new electronics vitally important.

The use of single molecules or quantum dots as functional devices can be considered the ultimate point of miniaturisation process. However, electrical contacts can hardly be attached to molecules. Therefore, the most promising candidates for practical implementation in molecular electronic devices are NTs, which can serve as the basis for creation of a new generation of integrated circuits (ICs). Search for suitable chemical substances for future electronics has been carried out since the mid-1990s. Recently, research plans were corrected and focussed on NTs.[284 – 287]

Depending on their structure, NTs possess metallic or semiconducting properties (see, *e.g*., Refs 288 and 289). For this reason alone they can be used for fabrication of heterostructures with metal – metal, metal – semiconductor and semiconductor – semiconductor junctions. In this respect particular emphasis is placed on SWNTs.

Nanotube conductivity is of quantum character.[290 – 293] Defect-free metallic NTs appeared to be ballistic conductors of electric current that flows without heat release. The current density can reach a colossal value of 10^7 A cm^{-2} and, were NTs classical conductors, they would be immediately vaporised. Ohm's law is not valid for ideal ballistic conductors, namely, their resistance is independent of length and approaches a theoretical (quantum) limit of 6500 Ω. The conductivity in NTs differs from that in two- and three-dimensional systems and can be described in the framework of the Luttinger liquid theory.[294, 295]

‡ In this Section, we present the results of selected research studies in physics and technology that are of prime interest for chemists.

Nanotube conductivity also differs from conductivity in conducting polymers where free electrons are supplied by dopants. Graphite is characterised by delocalisation of one of the four valence electrons. Graphene is an electronic hybrid; it is neither a dielectric nor a conductor, and also not a metal as well. Rather, it is a zero-gap 'semimetal' or semiconductor. Therefore, the properties of graphene depend on some extra conditions, in particular, the manner of rolling into NTs.

Of course, there is no need to discard silicon-based electronics with billion-dollars investments and start new, NTs-based electronics at the very beginning, the more so as many problems (in particular, high surface resistance of contacts, *etc*.) are still to be solved. On the other hand, production of various devices exploiting unique electronic properties of NTs that will function along with 'old' electronic is thought to be a short distance in the future. This can be a new generation of electronic and logical microchips and mechanical and electromechanical devices. Theoretically, the switching rate of NT-derived electronic devices can be as high as 10 THz. It is believed that the first step of new electronics will be fabrication of hybrid circuits. Therefore, Si-supported NTs have been the subject of intensive studies.

a. Diodes and transistors

Semiconductor diodes (two-electrode elements with one junction) and transistors (three-electrode elements with two of more junctions) are main building blocks of ICs. It is these components that first of all appeared to be the focus of research activity.

Junctions can be formed in several ways, namely, by matching two NTs (in particular, NTs of different diameters) with different electronic properties; by bending NTs; by partial filling of the inner NT cavities with those substances that give the filled parts of the NTs distinct electronic properties; by branching NTs or by making them three-terminal (Y- or T-shaped NTs). Matching two NTs with different structures requires insertion of pair defects (pentagon–heptagon) into their hexagonal atomic sheets. If the pair defects form a 'belt' along the circumference of the junction, the NTs keep their coaxial structure. If the defects are arranged opposite each other, the NTs become bent (Fig. 11). Bent NTs do exist and can be found among products of catalytic pyrolysis of hydrocarbons, as was reported by Han *et al*.[296] who observed NTs bent at angles from 18 to 34 °.

Service *et al*.[297] reported the first, theoretical, study on the subject. Insertion of pair defects into the NT structure was studied [298–302] and their energy characteristics were discussed.[303, 304]

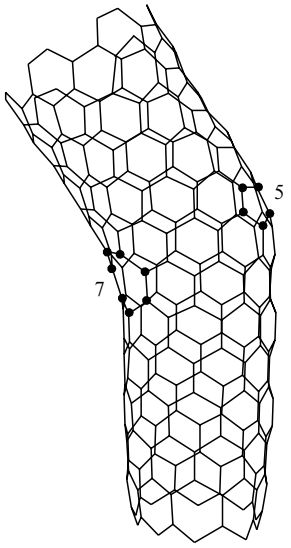

Figure 11. Schematical representation of a bent nanotube with topological defects.

Rectification of alternating electric current by a molecular diode comprised of semiconducting SWNTs and impurity molecules has been studied by Antonov and Johnson.[305] A number of theoretical studies is devoted to the properties of different junctions. [306–309] Nanotube junctions can function as Schottky barriers.

A prototype of single-electron transistor was first fabricated from SWNT bundles.[290] This type of transistor can also be assembled from free-standing NTs.[291, 310] Yao *et al*.[311] found that a bent NT with metal–semiconductor junction functions as diode rectifier. Among a total of nearly 500 NTs they found four nanotubes with one junction and one NT with two junctions and studied their current-*vs*.-voltage characteristics and the temperature dependence of conductivity.

A prototype of single-electron MWNT transistor was fabricated [312] {for references, please visit the Website at URL [http://haithabu.fy.chalmers.se/abstracts/031-html]**D**}. Researchers from Japan reported high operational characteristics of diodes based on NTs with homo- and heterojunctions.[313]

Nanotube-based field effect transistors were called TUBUFETs by analogy with the abbreviation MOSFET (Metal Oxide–Semiconductor Field-Effect Transistor).[314] Characteristics of the TUBUFET transistors fabricated from aligned SWNT arrays approach those of silicon-based MOSFET transistors. IBM Corp. (USA) also reported successful development of SWNT- and MWNT-based field effect transistors (for references, visit IBM 's Website at URL http://www.research.ibm.com/nanoscience/nanotubes.html). Researchers at IBM believe that NT-based transistors will soon be quite competitive with silicon transistors.

Junctions consisting of two crossed SWNTs (a metallic NT and a semiconducting one) were studied experimentally.[315] This type of junction can be readily fabricated and they can serve as the basis for large-scale production of useful devices.

Fabrication of integrated circuits of NTs requires enabling controlled growth and arrangement of NTs in the space between electrodes. A feature article by Dai *et al*.[316] concerns methods for the synthesis of NTs and integrated NT-based devices; particular emphasis was placed on SWNTs. The authors of this study pointed to the fact that, in contrast to traditional architectures of microelectronic devices and ICs based on the 'top–down' fabrication techniques, the methods being developed for NTs are based on the 'bottom–up' approach.

Lefebvre *et al*.[317] briefly outlined different techniques for fabrication of ICs incorporating SWNTs. Using electron beam lithography and nanomanipulation with an AFM, they showed the possibility of fabricating diodes, devices with junctions between matched individual SWNTs, single-electron transistors and field effect transistors. This study seems to be the first communication that concerns the effect of chemical environment, *i.e*., the adsorbate molecules, on the characteristics of electronic devices, since adsorption can change the electronic properties of substances when fabricating nanometre size NT-based devices. Mention was also made of the effect of mechanical deformation on the functional properties of NTs.

Very recently, strong limitations on the use of NTs in electronic devices were found.[318] They are due to specific noise that appears as electric current flows through NTs. Impurities adsorbed on the external surface of NTs are thought to be the source of the noise (or one of the noise sources). If so, NTs will enable production of very sensitive sensors.[319] Noise reduction can be achieved by simply cleaning the NT surfaces.

In a continuation of their research [318] Collins *et al*.[320] studied the effect of O_2 impurity on the electrical conductivity and thermal emf of NT bundles and films. It was found that adsorption of O_2 (i) changes the *n*-type conductivity of the NTs to *p*-type conductivity, (ii) increases the NT conductivity by 10% to 15% as compared to the value in vacuum and (iii) changes the thermal emf from -10 to $+20\,\mathrm{mV\ K^{-1}}$.

Model calculations predict that bonding of O_2 molecules to SWNTs will affect their electronic and magnetic properties.[214]

Electronic devices can be fabricated by controlled deposition of individual SWNTs with attached CO_2H groups through a mask on the surface that was chemically pre-functionalised with NH_2 groups.[118] Another closely related technique [321] involves plasma etching prior to the adsorption of functionalised NTs. Both procedures allow a space resolution of several micrometres.

Schematic representation of a chemical process of fabrication of integrated circuits incorporating nanotubes by pyrolysis of CH_4 on a Fe–Mo catalyst patterned by electron beam lithography is shown in Fig. 12.[322] Recent developments in this field allow fabrication of metal–horizontally aligned NT arrays–metal structures [323] or three-dimensional Si–vertically aligned NT arrays–metal aggregates [324] on silicon substrates using lithography and chemical vapour deposition.

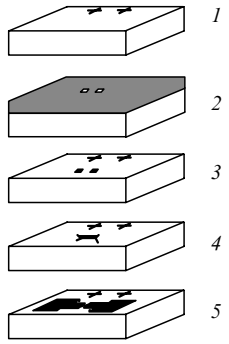

Figure 12. A scheme illustrating the order of operations in the production of integrated circuits with embedded nanotubes.[322]
Patterning with Ti–Al alloy (*1*), coating with PMMA with Petri dishes (*2*), catalyst deposition on the Petri dishes and dissolution of PMMA (*3*), chemical vapour deposition of nanotubes by catalytic pyrolysis of CH_4 (*4*) and coating with metallic electrodes (*5*).

Tests for the best ohmic contact between NTs and metallic electrodes were carried out with Ag, Al, Au, Ca, Cr, Mg, Nb, Ni and Ti.[316] The lowest contact resistance was found for titanium. One can also use Sc and V in addition to Ti, whereas Fe, Co, Ni and Cu exhibit high contact resistance.[325] A procedure for improving the stability of contacts with Ti–Al electrodes involves short-term (30 s) heating at 600–800 °C.[326] Special research into MWNT-based electrical contacts carried out to develop a fabrication procedure resulted in a rather simple method consisting in placing a tungsten wire 4.3 μm in diameter (a shadow mask) crosswise on the MWNTs, deposition of a conducting layer and removal of the wire.[327]

Since chemical methods for fabrication of NT-based devices are currently in a primitive state of development, the problem of manipulating NTs is usually solved by using scanning probe microscopes.[312, 313, 328]

Some rather exotic types of NTs have been studied. Molecular dynamics simulation revealed the possibility of fabricating metal–semiconductor–metal junctions in three-terminal NTs taking T-shaped [329] and Y-shaped [330] NTs as examples. Electronic properties of these systems were also studied theoretically.[331–333]

Branched NTs (a mixture of Y-, T- and L-shaped NTs) were first obtained in low yield by the arc method.[334] Formation of Y-shaped NTs in the course of hot wire activated CVD synthesis of diamond was reported.[335]

Higher yields of this type of NTs can be obtained by other methods, *e.g.*, CVD in the course of pyrolysis of hydrocarbons [336–338] and transition metal catalysed decomposition of C_{60}.[339] Branched NTs were also obtained by pyrolysis of acetylene followed by deposition on an Al_2O_3 template with electrochemically etched, Y-shaped channels, which was dissolved after completion of the process.[336] Microwave plasma enhanced pyrolysis of CH_4 diluted with H_2 was catalysed by nanocrystalline Pd on the surface of porous silicon.[337]

Yet another procedure for the synthesis of Y-shaped NTs involves pyrolysis of a gaseous nickelocene–thiophene mixture at 1000°C.[338] The yield of ~40 nm-diameter, Y-shaped NTs with an angle of nearly 90° between the junctions was as high as 70%. Asymmetry of the current-*vs*.-voltage curves of these NTs with respect to the bias current points to the fact that the NTs function as rectifiers. These synthetic results were found outstanding.[340]

A chlorophyll-containing protein in spinach is capable of not only receiving photons of light, but also transmitting electric signals in one direction at a rate 100 times faster than in silicon photodiodes. A nanodiode 10 nm long was fabricated from the molecules of this protein. Using 2-mercaptoethanol, the protein molecules were oriented perpendicular to the surface of a gold support and then connected by NTs to give a biomolecular device. This biochip was first demonstrated in spring 1999. Illumination by a pulse of light caused the device to conduct an electric current {this material can be accessed *via* the Internet at URL [http://www.ornl.gov/ORNLReview/rev32_3/brave.htm]**D**}.

b. Field emission devices

Cathode-ray tubes (CRT) with hot-cathode electron sources appeared more than 50 years ago. Now it is timely to replace CRT by compact flat panel displays with field (or tunnel) emitters.[341, 342] Field emission, *i.e.*, the emission of electrons from highly curved surfaces (tips, blades, *etc*.) under influence of an applied voltage, is usually observed only in ultrahigh vacuum at high voltages and the emission current is limited to several μA. Fabrication of field emitters is complicated and expensive since tips are made of single-crystalline silicon or diamond pyramids. However, these devices offer some clearly seen advantages over the hot-cathode sources, such as operation in the cold emission regime, small size, small energy expenditure in the operating mode and high density of the emission current. Because of this, field emitters have been the subject of intensive current research. For instance, it was found that ~7 μm-diameter carbon fibres used as field emitters operate under somewhat lower vacuum than other materials do (see, *e.g.*, Ref. 343).

Graphite is characterised by a relatively high work function of electrons (4.4 eV) and many graphite-based materials (in particular, micro-coarse, powder-like, ion-irradiated graphite) can be used for fabrication of field emitter cathodes. However, all of them have a great drawback consisting in rapid degradation under operating conditions. Nanotubes were proposed to be used as field emitters based on similarity of the field emission mechanisms from graphite materials and NTs.[344] Large aspect ratio, small radius of curvature of the NT end, high electrical and thermal conductivity and chemical stability of NTs make them promising for field emission applications. Not only individual NTs, but also NT bundles can serve as field emitters and function in moderate vacuum.

Schematic representation of an NT-based field emitter is shown in Fig. 13.[345]

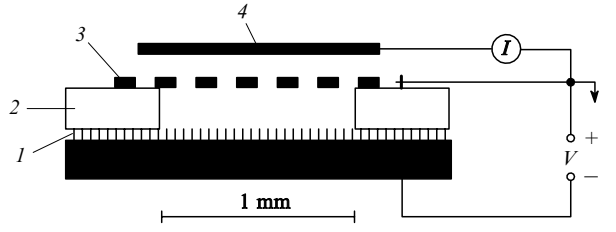

Figure 13. A scheme of a nanotube-based field emitter.
A film comprised of nanotube arrays grown perpendicular to the support surface (*1*), insulator (mica) (*2*), grid (*3*) and anode (*4*).

Let us consider the properties of NTs as field emitters. For purified MWNTs, the work function for electrons is 4.3 eV and increases up to 4.8 eV on oxidation of the NT surface.[346] The work function for NT-containing films is much lower than for graphite, though it depends on the film surface relief.[347]

Pioneering experimental studies of the emission properties of NTs were carried out by Chernozatonskii *et al*.[348] in the Russian Federation and by Ugarte *et al*.[349, 350] (in Western countries) who fabricated NT-based field emitters. An NT-based cathode can have a surface area of up to several hundreds of square centimetres, it is cheap and stable in air. However, the procedure for fabrication of aligned NT arrays (suspension, filtering and fixation of precipitate) proposed by Ugarte *et al*.[349, 350] was found to be too complicated to be used in large-scale production.

Nanotubes are characterised by emission current densities of up to 10 mA cm^{-2} at a rather low gate electric field (0.8 V μm^{-1}).[351, 352] The gate fields for SWNTs are lower than for MWNTs; however, the latter have longer lifetimes.[353]

Both open and closed NTs can emit electrons. The effect of opening of the NT ends on the emission properties has been studied.[354] Free-standing MWNTs 10 to 15 nm in diameter were produced by arc method and opened by oxidation in air at 650 °C or by laser ablation. It was found that (i) opening of NTs enhances field emission and (ii) opening by oxidation in air is more efficient than laser ablation. In their short review Schonenberger and Forro [222] pointed out that closed NTs are more efficient emitters. Theoretically, open NTs must produce higher emission currents than closed NTs; however, impurities (*e.g*., oxygen atoms) attach themselves to the free dangling bonds at the end of the NT and the emission current reduces. Nevertheless, in both cases the emission current reaches colossal values for such small-size emitters. Emitters based on aligned arrays of 'capped' MWNT were found to exhibit the most reproducible properties and the longest lifetimes.

Nanotubes operating in the field electron emission mode emit light.[355, 356] In a dark room, the glow can be seen by the naked eye. This phenomenon is of great importance for understanding the emission mechanism.

Nanotubes produced by different methods and having different structures possess markedly different emission properties (Table 2).[357]

Table 2. Average field amplification coefficients (β), trigger and threshold electric field strengths (E_t and E_{thr} /V μm^{-1}) and average NT lifecycles (τ /h) at a current density of 0.2 mA cm^{-2} for different NT samples.

NT	β	E_t	E_{thr}	τ
Multi-walled nanotubes				
open	1100	4.5	30	20
closed	1600	1.1	2.2	120
catalytic	830	5.6	14	10
Single-walled nanotubes	3400	1.5	3.9	12.9

Kim *et al*.[359] fabricated field emitters with improved characteristics (β = 17 000 – 33 000, $E_t \leqslant 1.0$ V μm^{-1}, the brightness of the green phosphor was 1800 cd m^{-2}) using highly dense (5 – 10 μm^{-1}), well-aligned NT arrays. Diamond-'capped' silicon whiskers are characterised by record values of the turn-on (E_t) and threshold (E_{thr}) fields; however, parameters of the best samples of NT-based field emitters approach them.[358]

Characteristics of field emitters are closely related to the methods and conditions for the synthesis and purification of NTs.[44, 360] Experiments with NTs grown by plasma-assisted CVD showed that the emission current can change by an order of magnitude upon variation of the procedure for coating the catalyst (at different substrate – solution contact times).[361]

Information reported in studies on the field emission from NTs is often contradictory and the mechanism of the process is still to be clarified. The limiting field emission currents differ by orders of magnitude. Some contradictions were eliminated by Dean and Chalamala [213] who showed that saturation of the emission current is due to the presence of adsorbed impurities (the effect of saturation is observed at voltages between 1600 and 1800 V and leads to deviation of the emission currents by 2 to 4 orders of magnitude from that expected from the Fowler – Nordheim theory) . On the one hand, the presence of impurities favours an increase in the emission current. On the other hand, the impurities are removed as the emission current increases and after some time the dependence follows another pattern. Predesorption of impurities by heating samples *in vacuo* eliminates the saturation effect and reduces the emission current.

Electron energy distribution for emitting *n*-Si-supported SWNTs has been studied.[362] The observed current densities were as high as 25 mA cm^{-2}. The emitter appeared to be stable with time and exhibited well-reproducible properties. A similar study on SWNT bundles was carried out.[363]

Emission from NT bundles gives a bright structureless spot on a phosphor screen. Unexpectedly, emission from a free-standing NT with an open end gave a conical spot. The cone angles were estimated at $\sim$0.2 rad for the external and 0.05 rad for the internal parts of the cone.[364, 365]

Field emitters can also be fabricated from entangled NT arrays. The emission current density achieved in experiments with a material incorporating randomly oriented NTs (according to Collins and Zettl,[353] this favours elimination of defects) was as high as 400 mA cm^{-2} at 200 V. Cathodes for field emitters can be fabricated from NTs sintered under mild conditions (2273 K, 25 MPa).[366]

Dai and Mau [367] discussed some of the known methods for fabrication of aligned NTs. These methods can be arbitrarily divided into two groups. The first group comprises two-step procedures that involve individual stages of NT synthesis and alignment , namely, the above-mentioned cutting of thin composite slices,[229, 368] passage of a NT dispersion through a microporous filter [350] and rubbing a NT-coated plastic surface with a thin Teflon plate or Al foil.[349]

The second group comprises one-step methods that involve synthesis-induced alignment of NTs and are of much greater importance. These are template synthesis using microporous substrates and synthesis with patterned catalyst coated on the substrate surface (possible patterns are strips, squares, *etc*). Usually, experiments are carried out using Al_2O_3 membranes with parallel pores obtained by anodisation of Al, mesoporous SiO_2 and porous silicon as microporous substrates. The catalyst is either deposited on the bottom of micropores by CVD or sputtered onto the substrate surfaces that were pre-treated by lithography or programmed etching. Precipitation of catalyst from solutions is also used.

Fabrication of ordered structures from NTs by thermal decomposition of silicon carbide represents a special case.[369, 370]

Nanotube synthesis using porous Al_2O_3 has been described [129, 350, 371 – 375] (some of these studies do not concern fabrication of field emitters). The diameter, length and degree of ordering of NT arrays are completely determined by the properties of the template and can be varied over a rather wide range. Synthesis of NTs using mesoporous SiO_2 has also been reported.[376 – 378]

Fan *et al*.[379] succeeded in growing a 'forest' of NTs with uniform length distribution on the surface of porous n^+-Si substrate with an area of $\sim$4 cm^2 by catalytic pyrolysis of C_2H_4. Catalytic iron particles were deposited on the silicon surface through a shadow mask. It is thought that this method can be applied to larger surface areas (Fig. 14). The MWNT 'forest' was grown perpendicular to the substrate and presented regularly arranged, square (2 × 2 μm) NT arrays, or towers, of the same height varied in the range from 10 to 240 μm. Each of the 15 samples fabricated by the authors of this study [379] exhibited stable low-voltage electron emission. Considerable advantages of

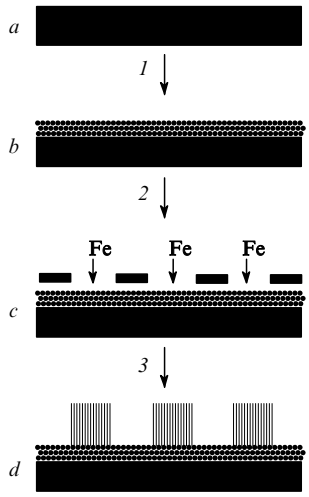

Figure 14. A scheme illustrating the process of fabrication of aligned NT layers on the surface of porous silicon.
Anodisation (*1*), sputtering of iron (*2*) and growth of NTs (*3*); n^+-silicon (*a*), porous silicon (*b*), mask (*c*) and product (*d*).

porous silicon in the synthesis of oriented NTs were pointed out. (A special issue of the journal '*Physica Status Solidi A*'[380] was dedicated to the preparation, properties and applications of porous silicon). The substrate surface can be patterned with the catalyst either lithographically or by vaporising a fraction of pre-coated catalyst.

Fabrication of field emitters from SWNTs is a more complicated problem. Nevertheless, the use of pyrolytic method and substrates patterned with 1 to 5 μm wide catalytic islands resulted in the synthesis of NTs that were 0.7 to 4.0 nm in diameter and bridged adjacent islands.[322, 381, 382] A special procedure was developed for the deposition of NTs on top of Si 'towers' pre-coated with catalyst using a contact printing technique.[383] The NT structures obtained resembled power lines with suspended SWNT bridges.

Related NT structures of some larger size were fabricated by researchers from the Russian Federation. Nanotubes for field emitters were grown by catalytic pyrolysis of acetone or by disproportionation of CO on silicon whiskers.[384]

Enhanced performance of acetylene pyrolysis and an increase in the surface area for NT deposition can be achieved by patterning the substrate with the catalyst using microcontact printing technique.[385] Experiments were carried out using hydrophilised polydimethylsiloxane as 'stamp' and solutions of iron, cobalt and nickel nitrates or their mixtures in ethanol as 'ink'. The method allows one to obtain NT strips $\sim$10 μm wide, grow NTs 5 to 15 μm high and control the NT density on the surfaces.

Fabrication of NT structures by pyrolysis of hydrocarbons in the presence of volatile catalyst or by pyrolysis of the chemical NT precursors containing both the carbon source and metal catalyst [386–390] represents a special case. [To some extent, decomposition of a $Fe(CO)_5-C_2H_2$ mixture [391] also falls in this category].

There are two ways for fabricating NT structures on thermally unstable substrates, in particular, polymeric materials. These are transfer of the precipitate obtained on thermally stable materials to polymer and reduction of the pyrolysis temperature by introducing particular additives into the chemical composition of the starting gas mixture followed by physical activation of the process. For instance, pyrolysis of C_2H_2 in excess NH_3 allowed NT deposition immediately on the low-melting glass.[392, 393]

Polymeric substrates are coated with NT 'forests' using NT deposition on quartz glass followed by dissolution of the substrate and oriented transfer of the precipitate.[321, 388]

Hot filament activated pyrolytic synthesis of NTs on different substrates was developed by researchers from France.[394] By varying the reaction conditions they grew carbon nanostructures with different morphologies and emission characteristics. It was shown that a coral-like material containing NTs and nanoparticles with reasonable emission properties can be deposited immediately on the glass surface.

Catalytic pyrolysis was used for NT deposition from gaseous hydrocarbons and fabrication of field emitters from entangled randomly oriented NTs on large surface areas.[395]

Emission characteristics of oriented NTs grown by glow discharge method from a CH_4-H_2 mixture were studied by researchers from Moscow and Novosibirsk, Russian Federation {this material can be accessed *via* the Internet at URL http://carbon.phys.msu.su/MRS/Mrs.htm]**D**}.

Emission properties of an NT 'forests' grown pyrolytically from C_2H_2 on oxidised Si surfaces coated with nickel, cobalt or a nickel–cobalt alloy were reported.[396–400]

Swiss researchers grew NTs on a silicon substrate and showed that field emission is observed without preliminary treatment of the deposited film and even in the presence of catalyst.[401] The work function for electrons was estimated to be 5.3 eV.

Field emitters are produced in the USA, Japan, Russian Federation, Australia, in EC and South-East Asia. It was shown that NT-based field emitters can exhibit improved technological characteristics (density of emission current, gate voltage, brightness and lifetime) compared to analogous devices made of other materials and hot-cathode emitters. For instance, experiments at the Oak Ridge National Laboratory (USA) showed that NT-based field emitters are 10 times more efficient than diamond ones {this material can be accessed *via* the Internet at URL [http://www.ornl.gov/ORNLReview/rev32_3/brave.htm]**D**}.

MWNT-Based cathode tubes for elements of large-area outdoor displays were produced in Japan.[402–404] The tube diameter and length were 20 and 74 mm, respectively. The devices exhibited stable electron emission and long lifetimes (continuous glow over a period of 3 months). Their brightness was twice as high as that of conventional hot-cathode devices.

The results of research into NT-based field emitters for CRT displays and light sources carried out in Japan were reviewed by Saito and Uemura.[405]

A flat plane display with a brightness of up to 800 cd cm^{-2} at 5 V μm^{-1} was fabricated in Taiwan.[406] A method for fabrication of field emitters from SWNT bundles was developed by researchers from the PR China.[407]

Nanotubes represent a new kind of goods on the world market. The emission properties of commercially sold SWNTs and MWNTs were studied by Monteiro *et al.*[408]

An SWNT-based display 11.4 cm in diagonal with a brightness of 1800 cd cm^{-2} was fabricated (see Ref. 409). In 1998 and 1999, Ulvac Japan Ltd. and ISE Electronics Corp. (both from Japan) and Samsung Corp. (South Korea) demonstrated elements of CRT and prototypes of MWNT-based displays (these materials can be accessed *via* the Internet at URLs http://www.jnmr.com/intro/nanotubes.html and http://www.itron-ise.co.jp/english/nano/). In the late 1999, ISE Electronics Corp. had test-produced these display devices (this material can be accessed *via* the Internet at URL http://www.jnmr.com/intro/nanotubes.html). Research at Samsung Advanced Institute of Technology led to development of an NT-based 9 inch colour flat panel display with a resolution of 576 × 242 lines (this material was presented by J M Kim at the American Physical Society Conference in March 2000 and can also be accessed *via* the Internet at URLs http://www.eps.org/aps/meet/MAR00/baps/abs/S2090003.html and http://fuji.stanford.edu/seminars/spring00/slides/kimSlides.html). Samsung Corp. plans to start commercial production of NT-based colour displays in 2001–2002.

Large-scale industrial production of NT-based displays requires solving two major problems, *viz*., to make NTs cheaper

and to develop methods for fabrication of large-area NT-based emitting surfaces with uniform nanotube characteristics.

Nanotube-based field emitters can find applications not only in flat panel displays, but also in production of light sources, in such devices as vacuum pressure probes, microtriodes, klystrons, *etc*.

c. Memory devices

No NT-based memory devices have been fabricated so far. Nevertheless, some proposals that NTs can be used for this purpose have been made. Such memory elements can consist of, *e.g*., $K@C_{60}^{+}$ complex encapsulated into short, closed 1.4 nm-diameter (10,10)-NTs (any other alkali metal can be used instead of K). The $K@C_{60}^{+}$ 'molecule' can change the equilibrium position from the 'bit 0' to the 'bit 1' ends of the capsule under the action of an electric current. The time taken to reach the opposite end of the NT is only 4 ps, which is ten times shorter than the switching time of conventionally used memory elements.[410] The system resembles a kind of nanoscale 'abacus' or a nanoscale 'shuttle'. The authors of this study[410] have discussed some approaches to large-scale fabrication of these structures; however, solving this problem faces great difficulties at present.

Nanotube structures with encapsulated neutral C_{60} molecules (nanoscale 'peapods')[31] are formed by cyclic raising and lowering the temperature. The yield of these structures can be increased by varying the reaction conditions.[33] It was stated that this method allows mass production of the nanoscale 'peapods'.[34]

Prospects for fabrication of NT-based memory devices for molecular computers have been outlined.[411] Memory arrays built of NTs are expected to store 10 000 to 30 000 times larger amounts of information and operate 1000 to 10 000 times faster than modern memory chips.

d. Nanolithography

Currently, intensive research has been carried out into fabrication of semiconductor devices with a characteristic size of 100 nm and less. Optical lithography using sources of short-wave UV radiation (λ = 193 nm) is limited by the lack of optically transparent materials at wavelengths shorter than 190 nm. This requires development of alternative methods for nanoscopic etching that use, *e.g*., a new type of microscope probes.

The invent of scanning tunnelling microscope (STM) dates back to the early 1980s. The AFM, which is based on measurement of the adhesive force, is known since 1986. Usually, the STMs provide better resolution than the AFMs which are capable of operating without conducting substrate. The invention of the STM and AFM offered the possibility of manipulating individual atoms and molecules and moving them nanometre-scale distances.[412–420] The greatest drawback of both types of instrument consists in frequent metallic probe tip 'crashes' with the surface. The probe lifetime can be extended by using a carbon NT attached to the end of a silicon cantilever as the probe tip.[421]

Molecular dynamics simulations demonstrated that diamond surface can be selectively etched using an NT tip with attached C_2 groups.[422] It was concluded that NTs with the unmodified ends with strong covalent C–C bonds can be used for atomic-scale etching of semiconductor surfaces with relatively weak bonds (*e.g*., Si and Ge). Another simulations performed by the same method revealed the possibility of nanoscale etching and indentation of the Si(001) surface using NT ends (this material can be accessed *via* the Internet at URL http://www.foresight.org/Conferences/MNTs6/Papers/Dzegilenko/).

Local anodisation of hydrogenated Si(100) surface and lithographic transfer of silicon dioxide in the form of lines 10 nm wide at a speed of $\sim$0.5 mm s^{-1} in the experiments with an AFM equipped with a MWNT probe tip were reported.[423] The lithographic writing speed achieved using the MWNT probe tip was 5 times higher than with other probes. It was shown that the NT tips present a solution to the tip-wear problem and are impervious to breakdown in high electric field. Theoretical foundations of the method were considered.

Nanoscale lithography experiments with polysilane films using an STM equipped with an NT probe tip showed that the NT tip provides higher resolution, larger groove depth-to-width ratio at higher scanning speeds and extended tip lifetime than the probe tips made of other materials.[424]

Impressive experiments were carried out on the manipulation and deposition of individual atoms on a surface using the STM probe tip[425,426] and the possibility of atomic-level modification of nanostructures was shown.[415] This gave an impetus to the study by Král and Tománek[427] who tried to eliminate the major drawback of modern STM, that is, manipulation of a single atom. They theoretically substantiated the possibility of design of a 'molecular pump'. Open NTs serve as ideal material for such a 'pump'. The atoms filling the inner cavities of NTs can be pumped through the NTs by irradiating with two pulsed lasers.

New lithographic methods are expected to provide fabrication of ICs with the circuit density 8 times higher and performance 16 times higher than those of the ICs produced using optical lithography technique by 2004.

e. Amplifiers and generators for cell phone communication

Using the ability of NTs to emit electrons upon application of relatively low voltages (this requires small energy expenditures but the current density remains high), researchers from the North Carolina University (USA) developed an NT-based microwave generator.[428] This property of NTs can find applications in wireless communication devices. Usually, cell phones generate weak signals that are amplified at a central office. Unique properties of NTs allow production of the central offices characterised by smaller size and longer service life. A prototype of such central office has been developed.

The property of NTs to change their electric characteristics under the action of mechanical stress was proposed for use in a new generation of phones.[428]

f. Other applications

Tsukagoshi *et al*.[429] obtained rather encouraging results concerning the use of NTs for design of electron spin devices. Injection of spin-polarised electrons into MWNTs resulted in coherent electron spin transport.

Nanotubes have unusually high thermal conductivity which approaches or even reaches some record values.[430–433] This suggests the possibility of using NTs as heat sink for ICs and electric motors (this material can be accessed *via* the Internet at URL http://composite.about.com/industry/composite/library/PR/2000/blupenn1.htm). According to model calculations,[430] individual nanotubes in NT bundles interact with one another rather weakly and thermal vibrations occur solely along the NT axis.

Prospects for design of an NT-based molecular-scale digital computer and a new chemical approach to production of ICs have been discussed (this material can be accessed *via* the Internet at URL http://marble.he.net/~foresite/Conferences/MNT7/Abstracts/Ellenbogen2/index.html).

To reduce the size of electrical contacts in future ultraminiature ICs and electromechanical nanosystems, researchers at ORNL proposed to replace the wires and pins by NTs placed both on and off the chip. It is assumed that carbon NTs outside the chip will communicate with the on-chip NTs through field-emitted electron beams (this material can be accessed *via* the Internet at URL http://www.ornl.gov/ORNLReview/rev32_3/brave.htm).

Nanotube-based electrodes can find efficient application in gas-discharge tube protector units which are used in telecom network interface device boxes and central office switching gears to provide protection from lightning and AC power cross faults. Tests showed that characteristics of experimental NT-based gas-discharge tubes (mean DC breakdown voltage and breakdown

reliability) were better than those of commercial products (this material can be accessed *via* the Internet at URL http://www.eps.org/aps/meet/MAR00/baps/abs/S4890/html; communication M10.003).

3. Fields of application of nanotubes in power engineering

a. Lithium batteries

Research on current sources with high specific (per unit mass and unit volume) energy capacity is an important avenue of development of 'small' power engineering. Here, the most widely used are lithium current sources in which lithium is intercalated into graphite or other carbon materials (see, *e.g.*, Ref. 434). Nearly immediately after their discovery, fullerenes appeared to be the subject of intensive studies in this field. This also holds for NTs. If the capacity of graphite is limited to one lithium atom per six carbon atoms, the capacity of NT bundles must be higher, since lithium atoms can fill both the intertubular space of the NT bundles and the inner cavities of individual NTs. According to *ab initio* calculations, the content of lithium in SWNT bundles can be much higher than in graphite and correspond to the composition LiC_2.[435]

Intercalation of lithium and other alkali metals follows the same pattern and is accompanied by charge transfer without structural distortions. Single-walled NTs recovering their initial structure after de-intercalation similarly to NT bundles seem to be of greatest interest for the use in rechargeable batteries.[174]

Single-walled NT bundles were intercalated with Li not only by vapour transport, but also electrochemically.[178,436] The limiting intercalation degree corresponded to the composition $Li_{1.7}C_6$, which is much higher than the ideal value for graphite and that determined for MWNTs (LiC_6).[437–439] The irreversible specific capacity was as high as 952 mA h g^{-1}. The reversible specific capacity was measured to be 447 mA h g^{-1}; however, it reduced to 237 mA h g^{-1} and lower after fifth charge–discharge cycle. For comparison, the reversible capacity of lithium cells with graphite electrodes lies between 280 and 330 mA h g^{-1} (see Ref. 434).

As a rule, electrochemical intercalation of lithium into SWNT bundles is performed using a pressed NT mat placed on a platinum plate as the working electrode and a 1 M $LiAsF_6$ solution in ethylene carbonate and diethyl carbonate (1 : 1) as electrolyte.

Heat treatment of NTs improves their texture and reduces the oxidation–reduction overvoltage difference but has a drawback consisting in reduction of capacity.

High intercalation degrees (up to $Li_{2.7}C_6$) were achieved using impact grinding pre-treatment of purified SWNTs followed by electrochemical intercalation in 1 M $LiClO_4$ solution in a mixture of ethylene carbonate and dimethyl carbonate taken in equal volumes.[161] Mechanical treatment for some time resulted in the loss of ordering of the NT bundles and in an increase in the average intertubular spacing. However, the mechanism of such a strong enhancement of the NT capacity to lithium remains unclear. Most likely, the metal atoms fill not only the intertubular space, but also the inner cavities of NTs.[161]

The metal content in the product can be increased by increasing pressure.[440] Intercalation of lithium into NTs at high pressures resulted in a material with the atomic ratio Li : C = 2. The NTs retained their structure and the lattice parameter along the *c* axis increased to 0.411 nm.[441]

Another method involves coating of NTs with copper, their oxidation in air for 12 h at 160 °C and subsequent electrochemical intercalation with lithium.[442] Carbon NTs obtained in this manner can reversibly store the amount of lithium (per gramme of carbon) corresponding to a capacity of 700 mA h (*cf.* 268 mA h per gramme of CuO for composites). Intercalation of lithium into and deintercalation from CuO require applying a voltage ranging from 1.7 to 1.0 V and from 2.3 to 2.5 V, respectively (*vs.* lithium electrode). The reactions proceed by the following mechanism

$$CuO + x\bar{e} + x\,Li \longrightarrow CuOLi_x.$$

Yet another, relatively recently proposed route to enhancement of the capacity of lithium current sources consists in the use of membranes with vertically aligned NT arrays as anodes. (The NTs were prepared by template synthesis followed by removal of the template, as shown in Fig. 2). Che *et al.*[374] used a 60 μm thick Al_2O_3 template with 200 nm pores. Nanotubes were deposited within the pores. The NTs were held together by the thin layer of carbon precipitate formed on the external surface of the template. Multistage treatment of the product followed by dissolution of the Al_2O_3 template resulted in a pure carbon NT membrane consisting of the NTs of relatively large diameter which replicated the structure of the template. The inner cavities of this membrane were filled with iron catalyst (from solution), the CVD procedure was repeated to obtain thin helical NTs inside the large-diameter NTs and then the system was electrochemically intercalated with lithium. It was found that the well-developed membrane surface allowed the capacity to lithium to be nearly doubled as compared to that of a membrane without 'internal' NTs.

The use of NTs in lithium current sources is thought to be promising. Recently fabricated SWNT- and MWNT-based Li anodes are characterised by a discharge capacity of 640 and 385 mA h g^{-1}, respectively, which is much higher than the parameters of industrially produced samples.

b. Hydrogen accumulators

The development of lightweight and safe systems for H_2 storage is necessary for wide use of highly efficient H_2–air fuel elements in, *e.g.*, transportation vehicles. According to calculations, for a car with rechargeable hydrogen 'reservoir' to travel 500 km, 3.1 kg of H_2 is required. To this end, the 'reservoir' must have a capacity of 62 kg m^{-3} and the concentration of H_2 in the hydrogen-saturated material must be at least 6.5% (these values represent the U.S. Department of Energy targets for hydrogen storage for fuel cell vehicles). Hydrogen fuel is more environmentally safe than hydrocarbon fuel, since the only combustion products are water vapour. For long, industry looked to hydride-forming metals and alloys as the basis for high-capacity and safe H_2 storage systems.[443] On the other hand, a number of studies on the use of fibrous and tubular forms of carbon and SWNTs has been published recently.[444–449]

The first experimental data on the hydrogen sorption on NTs were reported by Dillon *et al.*[444] in 1997. In studies of temperature-programmed desorption of H_2 from a material containing only 0.1% of SWNTs 1.2 nm in diameter and obtained by arc method in the presence of Co catalyst using the Siverts apparatus, they inferred that the adsorption capacity of nanotubes to hydrogen varies between 5 mass % and 10 mass % or 20 kg m^{-3} at −140 °C and 40 kPa. Since the measurements were performed for unpurified material, the authors had to make a far-reaching extrapolation to NTs of purity 99%, so the results obtained can hardly be considered precise. It was found that the adsorption capacity of NTs 2.0 nm in diameter (up to 50 kg m^{-3}) approaches the desired characteristics (Fig. 15).

Ye *et al.*[450] studied pristine SWNTs and found that hydrogen adsorption on the NTs was 8.25 mass % at 80 K and a pressure of 12 MPa. Single-walled NTs were prepared by laser-induced thermal synthesis in the presence of catalysts. Individual NTs were 1.3 nm while NT bundles were 6 to 12 nm in diameter. The specific surface area of the material was 285 m^2 g^{-1}. At pressures above 4 MPa, the SWNT material undergoes a transition to a new state of hydrogen coverage. Here, adsorption occurs not only on the external surfaces of the NT bundles, but also on the surface of individual NTs (according to calculations, the specific surface area of the NTs was 1600 m^2 g^{-1}). The cohesive energy of the SWNT bundles was estimated at 4.5 meV per carbon atom. The behaviour of sonicated material differs from that of the untreated material.

Bacsa *et al.*[451] prepared NTs with a specific surface area of 790 m^2 g^{-1} and suggested even higher adsorption capacity of their material.

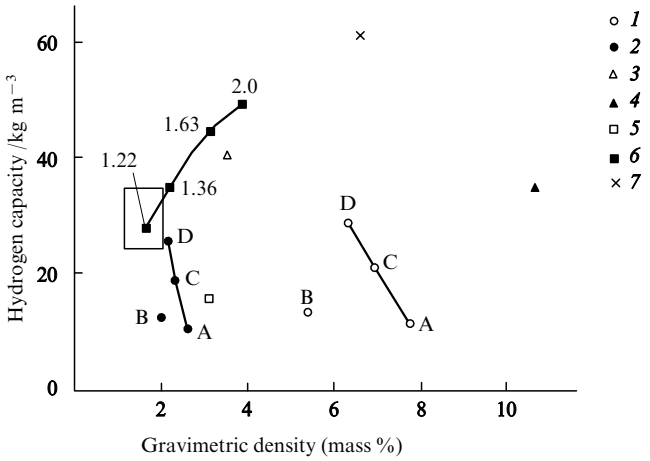

Figure 15. Characteristics of different materials as hydrogen accumulators.[444]
H_2 in the C/polymer composite cylinders at different pressures (*1*), H_2 in the glass fibre/Al composite cylinders at different pressures (*2*), H_2 produced in the reaction of Fe with H_2O (*3*), liquefied H_2 (*4*), H_2 on activated carbon (*5*), H_2 in SWNTs (figures denote the nanotube diameters given in nm) (*6*) and the region of desired parameters (*7*). The region of metal hydrides is shown within a rectangle. Pressure /MPa: 20 (A), 24.8 (B), 40 (C) and 60 (D).

Table 3. H_2 Storage properties of various systems.

Material	Max. mass % H_2	T/K	P /MPa	Ref.
Single-walled NTs (low purity)	5–10	133	0.040	444
Single-walled NTs (high purity)	8.25	80	7.18	450
Single-walled NTs (50% mass pure)	4.2	300	10–12	449
Nanofibres (tubular)	11.25	298	11.35	446
Nanofibres (herringbone)	67.55	298	11.35	446
Nanofibres (platelet)	53.68	298	11.35	446
No structure given	0.4	298–773	0.101	447
Graphite	4.52	298	11.35	446
Li–NTs	20.0	473–673	0.101	447
Li–graphite	14.0	473–673	0.101	447
K–NTs	14.0	<313	0.101	447
K–graphite	5.0	<313	0.101	447
FeTi–H	<2.0	>263	2.5	455
NiMg–H	<4.0	>523	2.5	456
Sorbent saturated at low temperature	~5	~77	2.0	456
Octane gasoline [a]	17.3	>233	0.1	456

[a] Given for comparison.

Single-walled NTs of relatively large diameter (1.85 nm) were synthesised by the arc technique. The reaction was performed in an apparatus with a rotating 400 mm-diameter cylindrical anode with drilled radial openings filled with graphite powder and a catalyst.[448] To obtain cheaper NTs, the synthesis was carried out in a H_2–Ar rather than H_2–He mixture using S-containing additives. Nanotubes were produced at a rate of several grammes per hour.

Specially treated NTs 1.85 nm in diameter can store up to 4.2% of H_2 with respect to their own mass (the atomic ratio H : C = 0.52) at room temperature and a pressure of 10 MPa. It was found that ~80% H_2 can be desorbed and room temperature at atmospheric pressure. Complete desorption of H_2 requires some heating of the material.[449] The samples under study were pre-annealed at 773 K for 2 h, which favoured enhancement of the adsorption capacity. The capacity was nearly unchanged after four charge–discharge cycles. The NT content in the material was varied between 50% and 60%, so its purification was suggested to result in considerable enhancement of the adsorption capacity.

Chen *et al.*[447] reported sensational results, according to which lithium-doped MWNTs can adsorb up to 20% of H_2 with respect to their own mass over a period of 2 h at 380 °C while the adsorption capacity of potassium-doped MWNTs can be as high as 14% at room temperature. According to calculations, a 20% adsorption corresponds to 3 hydrogen atoms per carbon atom while the fuel necessary for a car to travel 500 km can be stored in a 18 litres 'reservoir' of carbon NTs (this material can be accessed *via* the Internet at URL http://www.nus.edu.sg/INTsRO/newsletters/issue_20/CurrRes.htm). The results obtained by Chen *et al.*[447] were considered doubtful.[452] Indeed, attempts at reproducing these results using NTs produced by the same methods inferred that such a large increase in mass was due to the presence of water vapour in H_2.[453] Alkali metals do enhance the adsorption capacity of NTs, but to a much lesser extent than was reported by Chen *et al.*[447]

Great interest was attracted to the study by Rodriguez *et al.*[446] who synthesised graphite fibres capable of storing up to 67% of their own mass of H_2, which corresponds to a H : C ratio of 24. These results met initially with wide spread scepticism, since no experimental details were reported. Park *et al.*[454] to some extent clarified the situation. Unusual behaviour of the fibres was related to their structure with a specific surface area of 1000 $m^2\ g^{-1}$ and specific volumes of microscopic and macroscopic pores of 0.36 and 0.41 $m^2\ g^{-1}$, respectively. However, this issue requires further investigations.

The data listed in Table 3 characterise the hydrogen storage properties of NTs and other hydrogen accumulators and the state-of-the-art in this field.

Hydrogen storage in NTs was reviewed by Fischer[457] and Tarasov *et al.*[458]

Electrochemical storage of hydrogen in unpurified MWNTs 2 to 15 nm in diameter and SWNTs 0.7 to 1.2 nm in diameter was studied.[459] Relatively reliable results were obtained only in the experiments with SWNTs whose specific energy capacity was found to be rather high (110 mA h g^{-1}, or 0.39%). The reaction proceeded reversibly.

Electrodes with open SWNTs provided reversible electrochemical charging of up to 2.9 mass % of hydrogen, which corresponds to a specific energy capacity of up to 800 mA h g^{-1} (see Ref. 460). As the charge current changed from 10 to 100 mA, the capacity changed only by 50 mA h g^{-1}. This differs NTs from metal hydrides whose specific capacities are strongly dependent on the charge current. The maximum specific capacity was achieved after 20 charge–discharge cycles and was kept constant for the next nearly 50 cycles.

A large number of theoretical studies on H_2 adsorption has been published. Most of them were cited by Park *et al.*[454] Pederson and Broughton[461] were the first to propose that NTs can be filled with gas molecules due to the action of capillary forces.

The results of model calculations of H_2 adsorption[199] differ appreciably from experimental data. Insignificance of quantum effects at temperatures above 50 K and low hydrogen coverages of the NT surfaces was pointed out. The calculated storage capacities were found to be lower than those obtained from gravimetric measurements.[462–464]

Hydrogen adsorption in SWNT bundles was calculated.[465] The bundles consisted of square arrays of SWNTs 0.7 to 1.96 nm in diameter with an intertubular spacing of 0.334 nm. The effect of variation of the intertubular spacing on the NT storage capacity was studied taking 1.174-nm-diameter NTs as an example. It was shown that the highest H_2 storage capacity at room temperature

(10.7 kg m^{-3}) is achieved at an intertubular spacing of 0.7 nm. However, the manner in which the intertubular spacing in the NT bundles can be changed remains unclear.

The possibility of electrochemical storage of H_2 in SWNTs was confirmed by Lee *et al.*[466,467] who also performed a theoretical study of the process. Several adsorption sites in and on the SWNTs were found. According to Raman spectroscopy data, the inner NT cavities are filled with H_2 molecules. Molecular dynamics simulations showed that the highest hydrogen storage capacity of (10,10)-NTs is 14.3 mass % (160 kg H_2 m^{-3}) and increases linearly with the NT diameter. Multi-walled NTs exhibit a lower hydrogen storage capacity. In this case, hydrogen is adsorbed on the external MWNT surfaces and their capacity is independent of diameter.

Based on the above-mentioned experimental results, yet another group of theoretical studies was carried out. For instance, it was found that the desired 62 kg m^{-3} capacity (3.1 kg of H_2) of the NT 'reservoir' at 77 K can be achieved using SWNTs 0.6 nm in diameter at an intertubular spacing greater than 1.0 nm. Nanotubes carrying an electric charge were predicted to exhibit an enhanced hydrogen storage capacity (by 10% to 20% at 298 K and by 15% to 30% at 77 K).[468]

Williams and Eklund[469] attempted to bridge the gap between the results of theoretical and experimental studies. They pointed to the fact that all calculations performed so far used a model of infinite three-dimensional SWNT crystal lattice, whereas electron microscopy data show that SWNT bundles form a close-packed triangular 'honeycomb' lattice and have finite diameters and length. Mention was also made of inadequacy of the approach relating enhanced adsorption to arbitrarily changed symmetry or increased intertubular space.

c. Electrolytic capacitors

Thin NT films coated on metallic surfaces are of considerable practical interest for production of supercapacitors characterised by high capacity and the ability to survive a large number of charge–discharge cycles. The capacity of capacitors with an electrical double layer is known to increase linearly with the specific surface area that is rather large in the case of NTs (more than 300 m^2 g^{-1}).[470] In addition, it is important to use low-resistance electrode materials and to know the resistance of the electrolyte in the porous electrode structure. Carbon or graphite provide no possibility for fabrication of highly porous, 'mat'-like electrodes, which is necessary for obtaining an optimum pore structure; however, this can be readily done using NTs. The specific capacitance of catalytically grown NTs of size $\sim$8.0 nm in 38% H_2SO_4 reaches 102 and 49 F g^{-1} at 1 and 100 Hz, respectively. A single cell device had a power density exceeding 8000 W kg^{-1} (see Ref. 471).

Cyclic voltammetry measurements[472] revealed an effective capacitance of 283 F g^{-1} at 0.5 V (*vs.* silver reference electrode), which is twice as large as the maximum value for carbon electrodes in non-aqueous media (120 F g^{-1}). The material was stable on potential cycling and no differences were observed after continuous cycles over 30 min at 50 mV s^{-1}.

Capacitors with NT block electrodes and specific capacitance of 90 F g^{-1} were produced.[473]

Nanotube-derived capacitors can be used for laser power supplies, wrist watches, flash lamps, starters for electric motors, *etc.* They can also find military applications in, *e.g.*, bird- or insect-size reconnaissance airborne vehicles.[470]

4. Fields of application of nanotubes in analytical instruments

a. Sensors

Single-walled NTs are rather sensitive to gas atmosphere and can change their electrical resistance and thermal emf upon adsorption of N_2 or He.[212] This was the starting point for work on an 'electronic nose', or a chemical gas sensor.

SWNT-Based chemical NO_2 and NH_3 sensors are characterised by extremely short response time, thus being different from conventionally used sensors.[474] The sensitivity of the new sensors is three orders of magnitude higher than that of standard solid-state devices. A 0.02% concentration of NO_2 increases the electrical conductivity by 3 orders of magnitude after 10 s exposure, while exposure to 1% NH_3 decreases it by two orders of magnitude after 2 min. To reset the new sensors, they must be heated because of the low relaxation rate at room temperature. These sensors are very small (their size does not exceed several micrometres), simple in design (an NT connecting two conductors), cheap and operate at room temperature. A CO_2 sensor has been developed (this material can be accessed *via* the Internet at URL http://www.newscientist.com/ns/19991225/newsstory13.html). It should be mentioned that providing the possibility of sensing particular gases in complex mixtures selectively remains a moot question.

Nanotubes are thought to be of use for development of miniature sensors that each soldier might carry to detect poison gas or biological weapons (this material can be accessed *via* the Internet at URL http://www.post-gazette.com/healthscience/1999101nanotubes1.asp).

Frequency shift in the Raman spectra upon immersion of SWNTs in various liquids can find practical application in the development of sensors to test liquids. The frequency shift magnitude depends on the surface tension of a particular liquid, which can be used for the determination of its chemical composition.[249,475]

Construction and characteristics of items fabricated from individual MWNTs were reported.[476] Nanotubes 80 to 120 nm in diameter and 15 to 50 μm long were attached to a platinum tip using conducting epoxy resin. The NT side walls were insulated with polyphenol. Cyclic voltammograms measured at different electrode immersion depths in electrolyte solutions were obtained.

Nanotubes can be used as electrode material.[477] Redox-proteins immobilised on the surface and inside NTs exhibited well reproducible cyclic voltammograms. Immobilisation of DNA treated with I_2 and $[Pt(NH_3)_2]^{2+}$ and other proteins on NTs was also carried out.[478]

The possibility of attachment of metal porphyrins (including enzymes) to NTs allows fabrication of biosensors for studying different biomolecules and other biological objects. In particular, a proposal was made that NTs can be used as microelectrodes for the determination of glucose and cholesterol concentrations. The use of NTs can lead to basic change in the blood count procedure, so a drop will be enough to perform complete blood count over a very short time. The results reported by Balavoine *et al.*[479] who obtained ordered helical shells of protein molecules on the NT surfaces can be considered as the first step towards the development of new biosensors.

b. Microscope probes

Usually, STM probes are made of tungsten or platinum while AFM cantilevers are made of silicon or Si_3N_4. Typically, the radius of curvature of the AFM cantilever tips varies between tens and hundreds of Ångström. The use of NTs as probe tips was first reported by Dai *et al.*[421] who attached SWNTs to a pyramidal silicon cantilever, tested the device and obtained encouraging results. The use of chemically inert, conducting, hydrophobic, thin and flexible NTs makes the research process more simple; allows penetration into narrow grooves; improves resolution and provides the possibility of performing non-destructive studies of delicate biological objects.

A detailed instruction for attachment of NTs to commercial STM probes was posted on the Internet at URL {[http://cnst.rice.edu/mount.html]**D**}.

Nanotube growth immediately on commercial STM probes by pyrolysis of hydrocarbons was reported.[480–483] This method is considered to be much more simple than attachment of arc-grown NTs. Yet another technique consists in attachment of NTs in an electric field.[484–486] However, the simplest and most closely related to large-scale production conditions method[487] involves

a combination of (i) CVD of NTs on a special cartridge by catalytic pyrolysis [384] and (ii) transfer of the grown NT from the cartridge to the microscope probe tip in an electric field.

The properties of 'capped' NTs as materials for tunnelling microscope probes have been described by Harrison *et al.*[488] The radius of curvature of an SWNT probe tip is 3 to 6 nm (sometimes, even 0.2 to 0.5 nm), which is several times smaller than for conventional probe tips.[489]

Using an AFM with an NT probe tip, Choi *et al.*[490] obtained images of individual NTs on mica surface, while Zha *et al.*[491] studied chromium-filled NTs with an STM.[491]

Wong *et al.*[89, 90, 92, 492] oxidised NTs in air at 700 °C (98% of the carbon material was burnt out), functionalised their tips with carboxylic groups and obtained world's first chemically sensitive probe microscope capable of analysing different substances at the molecular and atomic levels. Then they performed amino, hydrocarbon and bioactive functionalisation of the carboxy-modified probe tips by the formation of chemical bonds between CO_2^- groups and one of the amino groups of ethylenediamine molecule, amide bonds with benzylamine molecule and amide bonds with biotin derivatives, respectively. The first (carboxy-functionalised), second and third probe tips possessed acidic, basic and hydrophobic properties, respectively. The fourth probe tip was sensitive to streptavidine. In principle, CO_2^- groups can form bonds with a broad spectrum of functional groups, which allows fabrication of probe tips for various applications.

Wong's 'constructions' exhibit some advantages over the previously used probes. The point is that earlier functionalisation of the Si_3N_4 or SiO_2 cantilevers resulted in attachment of functional groups not only to the tip, but also to the side walls, which damaged the objects under study. In contrast to this, no damages were observed in the experiments with NT tips since the functional groups were attached only to the 'cap'. In addition, NT probes are characterised by small effective radius and provide higher resolution. Finally, 1.4-nm-diameter (10,10)-NTs contain only 20 atoms at the open end, so it is an easy matter to choose the conditions for fabrication of a probe tip functionalised with a single group with known structure and orientation even at random distribution of the NTs with different number of carboxylic groups at the end.

Specifically functionalised NT probe tips can be used for selective removal of atoms from the surface.

Probe microscopes were used to obtain the first images of DNA molecules.[489] Microscopes with NT probe tips allow shortening the time taken to analyse large DNA molecules.[493]

Atomic force microscopes with NT probe tips were used for the determination of the structure of protein complexes [494] and for manipulating DNA molecules. At particular voltages, the DNA molecules were adsorbed on NTs and arranged on their surfaces in a predetermined manner (this material can be accessed *via* the Internet at URL http://www.eps.org/aps/meet/MAR00/baps/abs/S4890/html; communication M10.010). A well-resolved image of right-hand helical DNA molecule has been reported.[495]

Nanotube-modified cantilevers allow improving the resolution of electrostatic force microscopes.[496]

Improved AFMs with NT probe tips can be used in studies of both rigid and soft surfaces in aqueous solutions. According to recent predictions, these microscopes will serve as the basis for a breakthrough in biological studies.[497]

Nanotube probe tips can also be used as the 'reading' probes in memory storage devices of supercomputers. A possible candidate would be a system consisting of layering H and F atoms on a diamond surface and a pyridine molecule attached to the probe tip end. Theoretically, the system can store 10^{15} bytes cm^{-3} (this material can be accessed *via* the Internet at URL http://www.msu.edu/~hungerf9/nanotube.html).

5. Nanotubes as catalyst and sorbent supports

The idea of using NTs as catalyst supports was proposed nearly immediately after the discovery of this form of carbon.[498, 499] This application of NTs is based on their chemical stability and well-developed surface. Catalysts can be obtained by the filling of the inner cavities of NTs or in the course of their decoration or, in particular, in the course of the NT synthesis.

Only one study concerning SWNTs was cited in a short review on the application of fullerenes and NTs as catalyst supports.[500] After long-term storage in hydrogen at 673 K a material grown by arc method in the presence of cobalt and platinum exhibited high selectivity in the liquid-phase hydrogenation of cinnamaldehyde.[501]

Multi-walled NTs were also studied as catalyst supports. A Ru catalyst coated on arc-grown MWNTs with a specific surface area of 27 $m^2\ g^{-1}$ allowed an increase in the yield of hydrocinnamic alcohol obtained by hydrogenation of cinnamaldehyde to 80%. It was found that reduction selectivity increased from 30% – 40% to 92%.[502] A nanotube-supported rhodium catalyst was found to be efficient in the thermal decomposition reaction.[503] Complete decomposition of NO occurs at 600 °C on NTs without catalyst, at 450 °C on NTs containing 1 mass % Rh and at 300 °C on the catalyst pre-treated with H_2 at 300 °C or higher temperatures. After 2 h exposure to NO at 500 °C the Al_2O_3 – Rh (1%) catalyst contained rhodium only in the form of Rh_2O_3, while the NTs – Rh catalyst contained metallic Rh (8 nm particles).

The efficiency of different supports was compared taking the reaction of catalytic hydroformylation of propene as an example.[133] It was found that MWNT-supported ruthenium phosphine complex is not only much more active than other supports, but also exhibits high regioselectivity towards butyraldehyde (the reaction product) despite relatively small specific surface areas (155 and 237 $m^2\ g^{-1}$) and pore volume (0.46 and 1.33 $cm^3\ g^{-1}$) and relatively small pore diameter (3.2 – 3.6 and 2.4 – 3.2 nm) of the MWNTs used. Nanotubes were compared with supports characterised by much larger specific surface area (up to 1210 $m^2\ g^{-1}$, a carbon molecular sieve TDX-601), larger pore volume (up to 1.66 $cm^3\ g^{-1}$, a polymeric support GDX-102), and a larger (20 – 100 nm, GDX-102) or smaller pore diameter (1.4 – 2.0 nm, activated carbon).

Efficient catalysts were obtained by filling the inner cavities of the above-mentioned carbon membranes (see Section VIII.3.a) [374] with catalytically active metals. For instance, solution-coated platinum enhanced the rate of electrocatalytic reduction of O_2, while a Pt – Ru mixture enhanced the reduction of CH_3OH, which means that these catalysts are promising to be used for fuel elements. A study of the electrocatalytic reduction of dissolved O_2 using NTs showed that the exchange current density in the H_2SO_4 solution (pH 2) was five times higher than in the reaction carried out on graphite. This suggests possible use of NTs in fuel batteries.[504]

The rates of electrochemical processes occurring at platinum- and ruthenium-coated NT electrodes are higher than at platinated glass electrodes.

'Nanohorns', a recently found kind of NTs, appeared to be an excellent adsorbent of liquid ethanol. (The properties of 'nanohorns' were studied by Murata *et al.*[505]). The oxygen adsorption capacity of 'nanohorns' is 3.5 times higher than that of other forms of carbon with the largest specific surface area.[506] Moreover, 'nanohorns' catalyse oxidation of ethanol into acetaldehyde.

6. Application of nanotubes in optical devices

Molecules with high third-order optical nonlinearity and second-order hyperpolarisability are considered promising for use in photonic devices, *e.g.*, optical switches, data processing systems, optical filters and sensors. However, most of the third-order nonlinear optical materials have low second-order hyperpolarisability. Exotic electronic structure of NTs allowed researchers to hope for their application in nonlinear optical devices.

A theoretical model for SWNTs was proposed by Xie.[507 – 511] who also reported a third-order optical nonlinearity in chiral carbon NTs.[512] Chiral NTs as nonlinear optical materials are

quite competitive with conducting polymers. Large nonlinear optical effects are typical of zigzag and B-(N-)doped NTs.[513]

Second-order hyperpolarisability of NTs was predicted.[514, 515] The optical properties of NTs are strongly affected by the NT symmetry, the presence or absence of the 'cap' and the number of constituent carbon atoms.[516]

A theoretical expression for the third-order nonlinear optical susceptibility of NTs, related to the third harmonic generation, was derived by Margulis *et al.*[517] who pointed out that the resonant optical susceptibility of NTs is several orders of magnitude higher than that of C_{60} or C_{70}.

The properties of SWNTs 1.3 nm in diameter and ~ 160 nm long in a DMF solution were studied.[518] The ultrafast second-order hyperpolarisability was estimated at 2.1×10^{-28} esu.

Absorbing cells filled with a suspension of SWNTs in water were used as protection from laser radiation.[519] The effect of optical limitation was observed at 1064 and 532 nm. It was found that an increase in the radiation intensity by three orders of magnitude can reduce the optical transparency by two orders of magnitude.

Due to their unique properties, SWNTs rank first as nonlinear optical switches among all the materials used in this field, though the mechanism of the phenomenon is still to be clarified. Studies on the optical limitation of SWNT suspensions in water, ethanol and ethylene glycol showed that the magnitude of the effect can differ substantially in different liquids.[520]

Multi-walled NTs also exhibit remarkable nonlinear optical properties[258, 521, 522] that are comparable with those of soot and C_{60} suspensions. This type of NTs combines the advantages of both soot and C_{60}. Similarly to soot particles, NTs are relatively large. Similarly to fullerenes, NTs can be readily modified by, *e.g.*, filling to acquire desired optical properties.

Third-order optical nonlinearity of MWNTs was measured experimentally.[523] However, more recently it was found that incorrect experimental design led to observation of unusually high and unstable nonlinear optical response.

Nanotubes are poorly soluble; however, their composites with polymeric matrices can be used for protection from laser radiation. Laser irradiated solutions of NT solubilised in poly(phenylacetylene) exhibited unusual behaviour, *viz.*, they turned opaque with an increase in the radiation intensity.[112] Nanotube additives preclude optical damage to the polymer even at such high fluences as 10 J cm^{-2}.

Soluble complexes of MWNTs with polyacrylic acid and surfactants exhibit nonlinear optical properties.[121]

Dispersions of NTs in ethanol can be used for alignment of NTs under the action of electric current; they possess anisotropic properties and can change the direction of polarisation of the incident laser beam.[524] Conclusions drawn by the authors of this study deserve further confirmations, since all the measurements were carried out using insufficiently purified material.

Nanotube-containing composites can find application in photoelectric (photovoltaic) devices and light emitting diodes (LEDs).[113, 114, 246] Filling conjugated polymers with fullerenes was shown to be promising in the early 1990s. More recently, NTs became the subject of research. For instance, attempts at fabricating LEDs with microfiltration-aligned NT layer have been undertaken. However, the method involving preparation of an NT film by centrifugation and subsequent coating of the NT film with a poly(*p*-phenylene vinylene) film led to the best results.[246] Multi-walled NTs on the surface of polymer films somewhat reduce photoluminescence. The efficiency of NTs as hole-collecting electrodes of photovoltaic devices appeared to be twice as large as that of standard indium–tin oxide electrodes (the quantum yield at 2.9 to 3.2 eV was 1.8%).

Thin films of this composite can be used as emitting layer of LEDs and glow at lower current densities compared to the untreated polymer.[113]

7. Molecular nanotechnology

Nanotechnology is a field in which unique properties of NTs can best be used. Molecular nanotechnology concerns fabrication of functional structures and devices by atom-by-atom or molecule-by-molecule assembling using programmed robots (assemblers) capable of self-replication. According to calculations, the mass of an assembler equipped with a molecular computer and actuator can be at most 10^9 amu (this material can be accessed *via* the Internet at URL http://www.public.iastate.edu/~bhein/FAQ.html). The assembly will occur consistent with the chemical laws; however, under conditions of 'position' synthesis, where an atom or a molecule is supplied exactly to the place, these laws act in another manner compared to conventional chemical reactions conditions; if necessary, the overcoming of activation barriers can be achieved by consuming mechanical energy supplied from outside.

After the invention of STM and AFM, molecular nanotechnology is no longer only a scientific concept. There remains only some disagreement about how long its development will take {[this material can be accessed *via* the Internet at URLs http://www.nanomedicine.Com/2.1.html]**D**, .../2.2.html]**D**, .../2.3.html]**D** and .../2.4.html]**D**}.

In 1998, Zivex LLC (USA) demonstrated the possibility of three-dimensional manipulating NTs inside a scanning electron microscope with a resolution approaching that of the scanning probe microscopes and near real-time video control. The development of this manipulator and especially its improvement to provide the possibility of simultaneous operation of several independent manipulators inside one microscope is a great stride in the development of nanotechnology.

Probe microscopes allow one to manipulate NTs and move ('push around') molecules over the surface. Using a 'nanoplotter', one can draw lines up to 30 nm wide. However, these devices have a strongly confined action range.

New possibilities for manipulating nanoscale objects and studying their properties are opened after the development of the scanning probe microscope with 'nanotweezers', that is, two tiny plates of gold separated by a thin glass layer and attached to the tips of 100-nm-diameter NTs.[525] By applying an electric field it is possible to close and open the NTs and to grab and move submicrometre-size clusters and nanowires. Nanotubes of smaller diameter should make it possible to manipulate objects only 2 nm in size, *i.e.*, single molecules and structures inside biological cells, thus modifying them.

Initially, the greatest interest of experts in nanotechnology was attracted to various organic substances, especially a number of products of biosynthesis. It is assumed that molecular computers will be the first commercial fruit of the development of nanotechnology {this material can be accessed *via* the Internet at URL [http://www.resonance-pub.com/e-print%201.htm]**D**}. Currently, more definite hopes are associated with fullerenes and especially NTs. In particular, severe requirements imposed on the chemical and thermal stability of structural elements of molecular machines for aerospace industry make the use of NTs for fabrication of these elements justified.

Experts at NASA's Research Center (Ames, USA) also point out that NT-based nanotechnology can provide a way to reduce the cost of space missions.[526–529]

Bearings, springs and gears are important components of future nanomechanical systems. Their development is one of the main research avenues.

In 1992, benzene was found to react with C_{60} by the 2,4-cycloaddition mechanism. According to calculations (1997), such reactions on the external side walls of NTs are possible. That is why one of the pioneering studies on the development of NT-based nanomechanical devices was concerned with molecular dynamics simulation of a NT-based gear with benzene gear teeth {see Ref. 530 and material posted on the Internet at URLs [http://www.nas.nasa.gov/Groups/Nanotechnology/publications/MGMS_EC1/simulation/]**D** and [...MGM_EC1/quantum/index.

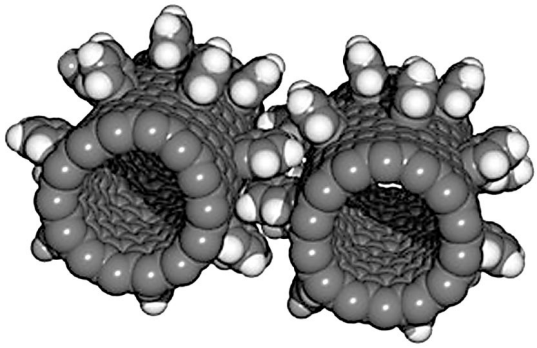

Figure 16. A nanotube gear with attached C_6H_6 molecules.

html]**D**}. Calculations were carried out for systems containing up to 2000 atoms. The angular momentum was transferred *via* two (14,0)-NTs 1.1 nm in diameter (Fig. 16). According to calculations, the gear could operate at frequencies up to 100 GHz *in vacuo* at room temperature. More recently, systems comprised of hundreds of thousands of atoms were calculated.

Other types of molecular gears were also calculated (this material can be accessed *via* the Internet at URLs http://www.nas.nasa.gov/Groups/Nanotechnology/publications/MGMS_EC1/simulation/paper.html and ...MGMS_EC1/index.html) and the behaviour of molecular devices in helium and neon atmosphere was studied. A phenomenological model of a laser-driven molecular motor was studied. The motor supplied power to a nanotube gear.[531]

Several video clips and animations illustrating the operation of various nano-gear devices can be accessed *via* the Internet at URL http://science.nas.nasa.gov/Groups/Nanotechnology/publications/MGMS_EC1/simulation/data/index.html.

Calculations of gears consisting of internal and external NTs were carried out. A concept of fullerene motor consisting of two concentric graphite cylinders (a shaft and a clutch) was proposed.

Possible conditions for coaxial arrangement of two NTs of different diameter (10 carbon atoms around the circumference of the shaft and 30 or 34 atoms around the circumference of the clutch) were calculated.[532]

Pioneering experimental studies attracted considerable attention. A team from the California University at Berkeley (USA) and Lawrence National laboratory (Berkeley, USA) managed to elongate MWNTs by pulling out the inner shells and then to shorten them by reducing the force exerted.[533] No indications of the 'nanospring' fatigue or wear were observed after 10 to 20 in/out cycles. The author of a popular essay on the subject predicts a passage from microelectromechanical systems that are on the scale of a human hair to nanoelectromechanical systems (NEMS) that are so small that 10 000 bearings for such systems can be stretched across the diameter of a human hair (this material can be accessed *via* the Internet at URL http://www.berkeley.edu/news/media/releases/2000/07/27_nano.html). According to expert evaluations, these systems will be developed in the nearest two years. At first, these will be hand-made devices and then some methods for their mass production are expected to be developed.

Based on the results of their studies on the behaviour of MWNTs under load, Yu *et al.*[534–536] pulled out inner shells of MWNT using an AFM and estimated the magnitudes of forces that act in this system. The proposed model of the process included the shear interaction, a specific type of 'capillary' effect (an interaction between two solids) and boundary effect (the influence of dangling bonds at the end of the inner NT 'immersed' in the outer shell).

The development of NT-based nanotechnology is associated with the breakthrough studies on nanolithography,[423] development of 'nano-fountain pen',[427] fabrication of functionalised probe tips and theoretical investigation of selective removal of hydrogen atoms from diamond surface.[422]

A rather large number of communications on NTs were reported at the 8th Conference on molecular nanotechnology held in the USA in November 2000 and called 'foresight'. In particular, new results were obtained on the character of conductivity in the 'arm-chair' NTs (http://www.foresight.org/Conferences/MNTs8/Abstracts/White/index.html); on the possibility of fabricating all-carbon electronic devices (.../Fuhrer/index.html); on the application of SWNTs of different chemical compositions (including metal-doped NTs) for fabrication of ICs (.../Darsey/index.html); on the stability of composite (cluster-type) structural elements made of NTs and diamond; on the possibility of fabricating heterojunctions for nanoscale logical and memory devices and NT-based field emitters 'capped' with diamond (.../Shenderova2/index.html); on theoretically studied gas separation processes using NTs and on the effect of NT filling with gases and C_{60} molecules on the mechanical properties of the NTs (.../Sinnott/index.html); on the thermodynamic properties of polyatomic liquids inside NTs and on the stability of NTs in aqueous solutions (.../Walther/index.html); on the quantum-mechanically studied effect of the surface curvature on the reactivity of NTs and fullerenes (.../Srivastava/index.html).

A recently published short review 'Carbon nanotubes. From macromolecules towards nanotechnology' [537] contains almost no information on applications of NTs in nanotechnology.

IX. Conclusion

Nanotube chemistry becomes a rather large division of general chemistry. Currently, it includes inorganic, colloid, polymer, physical and analytical chemistry of nanotubes (analytical chemistry of NTs also includes sensorics, the subject of which is development of chemical and biochemical sensors). Nanotube chemistry is closely related to nanotube physics, materials science and quantum chemistry. Some problems of NT chemistry are common to electronics and photonics.

Nanotube chemistry is also related to biochemistry. Some of the potential fields of application of NTs in biology were pointed out by Guo *et al.*[478] These are vessels for pharmaceuticals, biomimetic systems, which simulate biological objects and processes, catalysts prepared from immobilised enzymes, sensors, selective electrodes, biomolecule sensors, *etc*.

Studies on NT filling with various compounds can lead to applications of NTs as specific type of chemical reactors. One can expect that chemical reactions in the NT cavities will proceed in a significantly different manner compared to processes that are on different scale, since even such phenomena as melting of crystals and crystallisation of liquids or glasses inside NTs are characterised by some salient features.[538–540]

Nanotube chemistry is expected to become an integral part of nanotechnology which undergoes rapid development. Close relation between methods for fabrication of devices incorporating NT-derived elements and nanotube chemistry is also evident. Many applied research avenues have demands for NTs with uniform structure and size, and require chemical modification of NTs, *etc*.

Nanotubes continue to surprise researchers by their unusual properties. Among new discoveries are, *e.g.*, the superconductor proximity effect (a change in the electronic properties of a conventional conductor in the immediate vicinity of a superconductor);[541] superconductivity in $\sim$1-nm-diameter NTs at 4 K; magnetic flux trapping by a MWNT 'forest';[542] and oriented growth of SWNTs prepared by catalytic pyrolysis of CH_4 on the surface of single-crystalline Si.[543] For instance, NTs grown on the Si surface are oriented parallel to the surface in two perpendicular directions for Si(100) and in three directions at angles of 60° for Si(111). Probably, in the future this discovery will allow simplification of the fabrication process of hybrid NT structures and devices based on them.

However, the period when the results of almost all studies on NTs were considered fundamentally important (or at least of great importance) and when the search for new methods for the NT synthesis and the studies of their properties were the focus of research activity is now over. The focus of current research has been applied studies.

On the other hand, the synthesis of NTs with reproducible properties is still a challenge. For instance, a semi-continuous setup with a rotating anode for the arc synthesis of NTs has been reported;[448] an installation with rotating cathode for preparation of NTs under microgravitation conditions has been developed,[544] a method for continuous preparation of NTs using an arc immersed in liquid nitrogen was proposed,[545] a technique for the preparation of mostly two-walled NTs was developed;[546] and the performance of the setups for production of NTs by laser-induced thermal synthesis was improved and is now as high as 20 g per 24 h.

New synthetic approaches were developed. These are synthesis of NTs under hydrothermal conditions,[547] by exposure of a mixture of graphite and iron nanoparticles to atomic hydrogen,[548] by irradiation of amorphous carbon (fly ash) with Ar ions (this material can be accessed *via* the Internet at URL http://www.jnmr.com/intro/nanotubes.html) and thermal decomposition of aminoazines (in the presence of catalysts)[549] and saccharose.[550] A plasma jet method for the preparation of NTs was tested.[551] A joint team from Osaka Gas Co. (Japan) and Laboratory for New Technology developed a new technique for the synthesis of NTs, based on electron irradiation of a solid residue obtained by decomposition of fluorocarbons. This method allows the obtaining of a product containing $\sim$50% of SWNTs. The process requires the use of powerful electron accelerators and is expected to be readily scaled up (this material can be accessed *via* the Internet at URLs http://www.jnmr.com/intro/nanotubes.html and http://www.kippo.or.jp/news/1998-e/0617.htm).

Researchers from the Russian Federation were involved in the R&D of a method for the preparation of NTs by vaporisation of carbon at gas mixture pressures up to 1300 atm,[552] while researchers from Belorussia undertook considerable efforts aimed at developing the synthesis of NTs at temperatures below room temperature.[553]

However, the greatest advances were made in the preparation of NTs by the pyrolytic method, in particular, by decomposition of CO. The most remarkable is the development of a setup 'Marc II'[554] for production of highly pure SWNTs (up to 99%) by catalytic decomposition of CO. A jet of a mixture of CO and a metal carbonyl flows out of a high-pressure (tens of atmospheres) chamber and is heated to 900–1000 °C using a laser. The performance of the setup is expected to be $\sim$100 g of NTs per 24 h.[554]

A process of catalytic decomposition of CO under pressure (trade mark HiPCO^{TM}) was proposed to be of use for commercial production of SWNTs. It is expected that NTs will be produced at a rate of up to 10 kg per day in 2002 and at rates of hundreds or thousands of kilogrammes per day in 2003–2004 (this material can be accessed *via* the Internet at URL http://www.cnanotech.com; htth://carbonnanotech.com/CNI_ home.html).

A mixture of CO with 25% H_2 and iron carbonyl can be used for the synthesis of SWNTs at atmospheric pressure at 1100 °C (this material can be accessed *via* the Internet at URL http://fy.chalmers.se/f3a/Fullerenes/Nanotubes/projects/Ntproduction.html).

Catalytic pyrolysis of hydrocarbons at temperatures above 1000 °C was proposed to be a method for NT production at a rate of several hundreds of kilogrammes per day. The National Institute of Materials and Chemical Research (JNMR, Japan) and the Showa Denko Co. (Japan) work on a pilot plant since 1999 (this material can be accessed *via* the Internet at URL http://www.jnmr.com/intro/nanotubes.html).

Currently, various MWNT-based products are produced. These are NT powders, 'spaghetti', suspensions in various solvents and substrates covered with NT 'forest' arrays. An industrial process for the preparation of MWNTs of purity 95% is based on pyrolysis of hydrocarbons performed according to the method proposed by Ren *et al.*[392] The assortment of NTs and price lists are available in the Internet at URL http://www.nano-lab.com/SubPages/prices.html. In 1999, the market price was 100 USD per gramme for unpurified NTs and 1400 USD per gramme for purified SWNTs.[245] In March 2001, the price of purified SWNTs was reduced down to 60 to 100 USD per gramme (this material can be accessed *via* the Internet at URL http://www.carbolex.com/).

The pyrolytic method is expected to allow realisation of the idea of NT synthesis (build-up) on a 'seed' (a short NT with particular structure), thus presenting a solution to a complex problem of sorting the synthesised products by structure or shape (this material can be accessed *via* the Internet at URL http://cnst.rice.edu/VARENNA.html).

The idea of existence of a critical size for a catalytic particle is well known. It is believed that the use of catalytic particles of larger size makes preparation of NTs impossible.[555] This gave an impetus to search for novel approaches to development of catalysts. A JNMR's technology for mass production of MWNTs to be used in cathodes of television displays is based on the reversed micelle method. (this material can be accessed *via* the Internet at URL http://www.jnmr.com/dez/online/nlpage1013.html).

Flame preparation of NTs represents a kind of pyrolytic synthesis of NTs.[556–558] This process has much in common to an industrial processes of soot production and can be adapted to large-scale synthesis of NTs. Pyrolysis of sputtered solution of $Fe(C_5H_5)_2$ in C_6H_6 is yet another pyrolytic technique.[557]

In Russian Federation research into NTs are well-based (see, *e.g.*, recently published reviews[559, 560] covering studies in a close field of catalytic pyrolysis of hydrocarbons to prepare carbon filaments). A setup for catalytic decomposition of CO operating at a rate of kilogramme quantities of products per day was tested.

* * *

A number of studies on the subject of this review were published in the course of preparation of the manuscript. The most important and interesting results are outlined below.

A special issue of the journal 'Physics World'[561] dedicated to research into NTs was published.

Hirahara *et al.*[562] reported the synthesis of unique compound, $(Gd@C_{82})_n@$NTs. Structurally, it represents a nanoscale 'peapod' consisting of a SWNT with encapsulated electrically charged C_{82} 'peas' with a Gd atom inside each 'pea'. This 'doubly endohedral' substance was synthesised by the interaction of $Gd@C_{82}$ vapours with pre-open NTs. Electrical resistance measurements revealed electron transfer from the metal atom not only to the C_{82} molecule, but (tentatively) to the NTs. This opens new possibilities for modification of NTs and brings the advent of unique memory devices closer.

Two studies[563, 564] carried out independently concern chemical modification of particular sections of NTs, which can lead to the formation of intramolecular heterojunctions and creation of molecular electronic devices. Researchers from the Stanford University (USA) studied the adsorption of potassium atoms on semiconducting and *p*-type conducting NTs.[564] Theoreticians from the N S Kurnakov Institute of General and Inorganic Chemistry (Moscow, Russian Federation) calculated the properties of fluorinated NTs.[563] Their results are in agreement with those reported by Kelly *et al.*[104] who showed that fluorinated isomers capable of forming ring-like fluorinated sections should be the most stable.

Ouyang *et al.*[565] experimentally and theoretically studied the atomic structure and electronic properties of metal–semiconductor and metal–metal heterojunctions in SWNTs. This appeared

to be a step towards fabrication of intramolecular heterojunctions.

The first biological study of the structure of malaria-infected erythrocytes using an AFM with an NT probe tip was reported by Nagao *et al*.[566] The space resolution obtained using an NT probe tip was four times better than with the Si probe.

Mattson *et al*.[567] proposed the use of functionalised NTs as substrates for neural growth.

Nanotubes appeared to be excellent sorbents for purification of waste gases from low concentrations of highly stable carcinogenic dioxins.[568] In this respect, NTs are more efficient than activated carbon and sorbents based on porous graphite.

New procedures for preparation of NTs at moderate temperatures have been developed. One of them consists in reduction of hexachlorobenzene with potassium in the presence of bimetallic Co – Ni catalyst at 350 °C,[569] while the second involves hydrolysis of $Al(OBu^s)_3$ in the presence of acetylacetone or acetic acid and $Co(NO_3)_2 \cdot 6H_2O$, followed by gelation, drying of the gel and heating to 300 – 400 °C.[570]

A method for quantitative determination of the NT content in the reaction products using conjugated polymer filtration was first developed.[571] The method involves preparation of a NTs – polymer composite dispersion of the composite in toluene and storage until complete precipitation of impurities for at least 48 h.

A method for obtaining stable colloidal solutions of carboxylated SWNTs in water, ethanol, acetone and DMF was proposed[572] and some of their nonlinear optical properties were measured. These solutions were shown to be promising for the use in optical information processing systems.

The synthesis of NTs decorated with hydrated RuO_2 was reported.[573] Using these NTs, the specific capacity of electrochemical capacitors was enhanced up to 560 F g^{-1}.

This review has been written with partial financial support of the Russian Foundation for Basic Research (Project No. 01-03-33225) and the Ministry of Education of the Russian Federation (Grant No. 00-5.0-24).

The author expresses his gratitude to Prof. E V Zharikov for submitting the preprints of the NASA Conference (June 6 – 8, 2000, Hantsville, Alabama, USA) on the materials prepared under microgravitation conditions, to Prof. E I Givargizov, Prof. N A Kiselev, Prof. A V Okotrub and all colleagues who sent him reprints.

Abstract. Modern procedures for the synthesis of coordination and organometallic compounds of actinides and technetium and the properties of these compounds are surveyed. Experimental techniques, including methods for the synthesis of actinide and technetium complexes from elemental metals (oxidative dissolution and direct electrosynthesis), salts and halide, carbonyl and other complexes are generalised. The bibliography includes 283 references.

I. Introduction

Among compounds of natural and artificial radioactive elements (Tc, Pm, Po, Fr, Ra, Ac and actinides), only organometallic compounds and complexes of technetium and actinides (An) have been well studied. Complexes of these metals attract interest because technetium, which is available in multikilogram quantities, is widely used for medical and technical purposes and actinides find application in nuclear industry and power engineering. Over a period of the last two decades, a large number of experimental studies, reviews and monographs were devoted to Tc and An complexes.[1–16] The aim of the present review is to give a comprehensive survey of modern synthetic procedures for the preparation of coordination and organometallic compounds of radioactive elements. The data are systematised according to the nature of the ligands in these complexes.

II. General notion of technetium and actinide complexes

Actinium (atomic number 89) and all elements with atomic numbers from 90 to 103 (actinides) are radioactive.[17] Only four actinides (Th – Np) and actinium by itself were found in nature, whereas the remaining elements were prepared artificially by irradiation of U and other elements with neutrons or by bombardment with heavy atoms. Actinides are analogues of lanthanides. They belong to the same IIIB Group but reside in the next row.

Technetium (atomic number 43) has several isotopes two of which are characterised by large half-lifes (2.12×10^5 and 1.5×10^6 years for ^{99m}Tc and ^{98}Tc, respectively) and is a rhenium analogue.[18]

The electronic states of the actinide atoms and ions differ substantially from those of the lanthanide atoms and ions. In both series, the *f* level is successively filled up to the f^{14} configuration; however, this filling in actinides begins with Th only formally because Th does not bear *f* electrons and is an electronic analogue of hafnium.[16] In contrast to lanthanides, actinides can exist in various oxidation states. Actinides in the oxidation state +3 are analogues of lanthanides, whereas actinides in the oxidation state +4 are analogues of Hf(IV) and Ce(IV).

Actinides produce the An^{m+} ($m = 2-4$) and AnO_2^{m+} ($m = 1$ or 2) ions whose highest occupied level is filled only with *f* electrons. In the series of the An^{3+} anions, the actinide contraction is observed, this contraction changing in parallel with the lanthanide contraction. The 5*f* and 6*d* energy levels of the An^{m+} ions as well as the 4*f* and 5*d* energy levels of the Ln^{m+} ions correlate with each other. The difference in the correlations for the An^{3+} and Ln^{3+} ions leads to the noticeable difference in the magnetic properties and electronic spectra of their compounds.[17] Technetium (the $4s^24p^64d^55s^2$ or $4s^24p^64d^65s^1$ electronic configuration) exists in the oxidation states from +1 to +7, the oxidation states from +4 to +7 being most stable.[18]

Spin – orbit coupling (*J*) in the An^{3+} ions is very strong (2000 – 4000 cm^{-1}) and it is ~1000 cm^{-1} stronger than *J* in the Ln^{3+} ions. In contrast to lanthanides, the splitting due to spin – orbit coupling in actinides is comparable with the crystal field splitting and, hence, the *J* value is no longer a good quantum number. Since the 5*f* and 6*d* orbitals have close energies and the

thermally accessible excited states of actinides are filled, the equation for the effective magnetic moment

$$\mu_e = g[J(J+1)]^{1/2}$$

is less appropriate than in the case of lanthanides.[17, 19]

Actinide organometallic complexes contain actinide–carbon π bonds, actinide–carbon σ bonds or bonds of both types. Organometallic complexes of all early actinide elements from thorium to californium are known.[20] However, most data have been obtained for the chemistry of organometallic compounds of Th and U due to the extremely large half-lifes of natural ^{232}Th and ^{238}U (1.41×10^{10} and 4.468×10^9 years, respectively). The first actinide organometallic compound, *viz*., Cp_3UCl, was isolated by Reynolds and Wilkinson in 1956.[21]

The actinide atoms possess rather large atomic and ionic radii and large (up to 14) coordination numbers.[22] Examples of actinide compounds characterised by various coordination numbers and oxidation states are listed in Table 1.

The maximum coordination numbers were found for polymeric uranium hydroborates, whereas the presence of bulkier ligands, for example, of NPh_2, leads to a decrease of the maximum coordination number to 5 or even to 4.[17] Like lanthanides, the spherical An^{3+} and An^{4+} ions have the highest coordination numbers (generally, 8 or 9) and often form isomorphous complexes in which the polyhedron type is determined by repulsions between the ligands (steric factors) or packing factors rather than by the electronic effects.[23] For example, the square antiprism in the rhodanide complexes $Cs_4An(NCS)_8$ and $U(NCS)_4(Ph_3PO)_4$ is transformed into the dodecahedron in the case of $Th(NCS)_4[(Me_2N)_2CO]_4$ or into the cube in the case of $(NEt_4)_4An(NCS)_8$.[17]

The nature of the bond between the π-donor ligand and the actinide centre has been discussed.[24, 25] The authors emphasised that there is no simple answer to the question as to the nature of the bond in organoactinide complexes. Examples of almost completely ionic binding of the Cp^- anions or cyclooctatetraene (COT) with U^{4+} (see Ref. 26) as well as of covalent binding of the metal atom with the aromatic ring of the ligand in uranocene accompanied by essential ligand-to-metal electron transfer are available in the literature.[24, 27, 28] It was concluded [24, 29] that the

Table 1. Coordination numbers (CN) and coordination polyhedra in actinide compounds.[17]

Oxidation state	CN	Coordination polyhedron	Examples of compounds

	9	tricapped trigonal prism	$NaPuF_4$, $AnCl_3$ (An = U, Np, Pu, Am, Cm), $Am(sal)_3\cdot H_2O$
+2	6	framework structure	Th_6Br_{12}
0	8	cube	$U(bipy)_4$

Note: acac is acetylacetonate, Hacac is acetylacetone, HMPA is hexamethylphosphoramide, dmed is *N*,*N*′-dimethylethylenediamine, TMPO is trimethylphosphine oxide, tta is thenoyltrifluoroacetonate, TOPO is tri-n-octylphosphine oxide, tfa is trifluoroacetylacetonate, sal is salicylate, bipy is bipyridyl.

covalent binding of the metal atom with the ligand in $U(COT)_2$ involves primarily the 6*d* orbitals of uranium, while the 5*f* orbitals are of secondary importance.

As mentioned above, actinides show various oxidation states in aqueous solutions. Stable oxidation states vary from +3 for Ac to +6 for U and Np and then gradually decrease to +3 for Am and the following elements, except for No (+2). For Ac, Th, Pa, U, Md and Lr, the maximum oxidation states are stable; Np and Pu can occur in the oxidation state +7; Am can exist in the oxidation state +6; Cm, Bk, Cf, Es and Fm can occur in the oxidation state +4; the oxidation state +3 is possible for No. In aqueous solutions, virtually all actinides can exist in the unstable oxidation state +2.[17] The hydrated An^{2+}, An^{3+}, An^{4+}, AnO^{2+} and AnO_2^{2+} ions behave as Brönsted acids.[30]

$$An^{n+} + H_2O \longrightarrow An(OH)^{(n-1)+} + H^+.$$

The An^{4+} ions are typical of actinides from thorium to californium (however, U^{4+} is readily oxidised). As for Th, only Th^{4+} ions exist in solutions. The acidity decreases in the series $Pa^{4+} \gg U^{4+} > Pu^{4+} > Np^{4+} > Th^{4+}$.[17] Individual ions occur only in very dilute solutions. These ions tend to form polynuclear species as the concentration increases

$$m An^{4+} + n H_2O \rightleftharpoons An_m(OH)_n^{(4m-n)+} + n H^+ .$$

The acidity of the An^{n+} ions depends on their charge and radius. The An^{4+} and AnO_2^{2+} ions are much stronger acids than the An^{3+} and AnO_2^{+} ions, respectively.[17] The redox behaviour of actinides is complicated by their high radioactivity, which, in particular, results in the formation of hydrogen peroxide in aqueous solutions.

The data on the complex formation of the actinide ions An^{3+}, An^{4+}, AnO_2^{+} and AnO_2^{2+} (An = U, Np or Pu) with chlorides were surveyed in several comprehensive reviews.[30–32] The results of recent studies of hydrated and chloride complexes of UO_2^{2+}, NpO^{2+}, Np^{4+}, Pu^{3+}, *etc.* by XAFS (X-ray absorption fine structure) spectroscopy were covered in Refs 33 and 34. In particular, using hydrated ions and fluoride complexes of U(IV) and Th(IV) as examples, it was demonstrated that the coordination number of these hydrated ions is 10 and the M–O distances for U(IV) and Th(IV) are in the ranges of 2.42 ± 0.01 and 2.45 ± 0.01 Å, respectively.[34] The results of physical and chemical studies of hydrated complexes of uranium were published in the literature.[35,36]

Mössbauer spectroscopy is very convenient to use for studying the oxidation states and the symmetry of the ligand environment. The Mössbauer effect is observed for ^{232}Th, ^{231}Pa, ^{238}U, ^{240}Pu, ^{243}Am and, particularly, ^{237}Np generated upon the ^{237}U β^--decay. The maximum isomer shifts (up to -70 mm s^{-1}) are observed for Np(VII) compounds; for Np(III) compounds, these shifts decrease to +30 mm s^{-1} (see Ref. 37).

III. Actinide alkoxides and other oxygen-containing complexes and salts

Uranium alkoxides are similar to alkoxides of transuranium elements. Their chemistry has been surveyed in the recent review.[37] Homoleptic alkoxides $An(OR)_n$ are known for $n = 3$ (U and Pu), 4 (Th, U, Np and Pu), 5 (Pa and U) and 6 (U). A great quantity of such U and Th compounds are available, whereas only a few Pa and Pu complexes were prepared. Alkoxides of uranium in the the oxidation states +3, +4, +5 and +6 are known. Complexes characterised by mixed oxidation states, such as $[U(OPh)_3(THF)]_2[UO_2(THF)_2]_2(\mu\text{-}OPh)_4(\mu_3\text{-}O)_2$, were also prepared.[38] Compounds of U(IV) are analogous to Th(IV) compounds.

Most actinide alkoxides are oligomeric {like $[U_3O(OBu^t)_{10}]$}. However, derivatives of bulky alcohols and 2,6-disubstituted phenols are monomeric,[17] for example, $U(OCHBu^t_2)_4$,[39] $U(OEt)_5$,[37] $U(OMe)_6$, $U_2(OEt)_{10}$, $U(OAr)_4$ and $U(OAr)_3$ (Ar = 2,6-$Bu^tC_6H_3$).[37,40,41] The influence of electronic factors on the structure and stability of complexes of uranium tri-*tert*-butylmethoxide was examined.[42]

Monomeric alkoxides can react with each other[43]

$$U(OEt)_4 + U(OEt)_6 \xrightarrow{C_6H_{14}} U_2(OEt)_{10}.$$

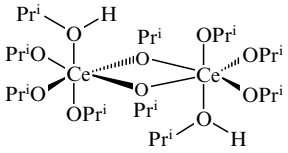
Anionic alkoxide complexes, such as $(Bu^t_4N)[U_2(OBu^t)_9]$ and $[Li(THF)_4][U(OAr)_5]$, were also obtained.[44] Treatment of $[U(COT)(BH_4)_2]$ with alcohols ROH (R = Et, Pr^i or Bu^t) afforded the alkoxide derivatives $[U(COT)(BH_4)(OR)]$.[45]

In a toluene solution of the $Th(OCHPr^i_2)_4$ complex, a monomer–dimer equilibrium occurs; however, only the dimeric form crystallises (with trigonal-bipyramidal geometry).[46]

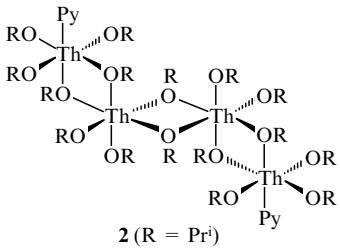
Actinide alkoxides are very readily hydrolysed[17]

$$3\,U_2(OBu^t)_8(HOBu^t) + 2\,H_2O \xrightarrow{PhMe} 2\,U_3O(OBu^t)_{10} + 7\,HOBu^t.$$

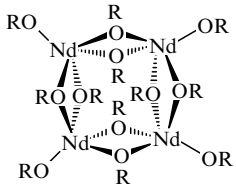
The actinide ions have large radii and, consequently, high coordination numbers, which are often responsible for oligomerisation of homoleptic alkoxide complexes of *f* metals[37,47–49] giving rise to dinuclear (**1**), tetranuclear (**2**, **3**) or higher oligomers.[47]



1

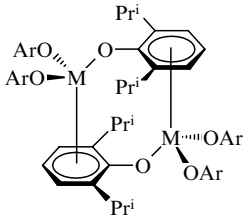


2 (R = Pr^i)



3 (R = CH_2Bu^t)

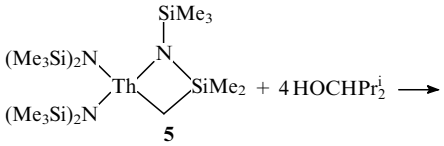
Dimeric actinide complexes are exemplified by the $\{U[O(2,6\text{-}Pr^i_2C_6H_3)]_3\}_2$ complex (**4**), which contains the unusual π-arene bridge and is sterically hindered due to the presence of the isopropyl groups.[47,49] This complex is stabilised through π-arene interactions both in the solid state and in solution.



4

Ar = 2,6-$Pr^i_2C_6H_3$; M = La, Nd, Sm, Er, U.

Some actinide complexes can occur both in the monomeric and dimeric forms. Thus treatment of metallacycle **5** with isopropyl alcohol afforded the homoleptic $Th_2(OCHPr^i_2)_8$ complex.



5

$$\longrightarrow 1/2\,Th_2(OCHPr^i_2)_8 + 3\,HN(SiMe_3)_2$$

6

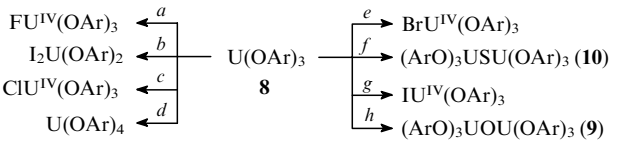
In the solid state, the latter exists as dimer **6** (the coordination number of thorium is 5) consisting of two ThO_5 fragments (with trigonal-bipyramidal geometry), which are linked *via* a shared

axial-equatorial edge.[44] At room temperature, this complex in non-coordinating solvents exists as monomer **7**.[46,47]

$$\underset{\mathbf{6}}{Th_2(OCHPr^i_2)_8} \rightleftharpoons 2\,\underset{\mathbf{7}}{Th(OCHPr^i_2)_4}$$

The dimeric halide-alkoxide complex $Th_2I_4(OPr^i)_4(HOPr^i)_2$ was prepared by the reaction of metallic thorium with 2 equivalents of iodine in isopropyl alcohol.[50] This reaction provides an example of the direct synthesis from elemental metals. The $Th_2I_4(OPr^i)_4(HOPr^i)_2$ complex (the triclinic system, space group $P\bar{1}$) has a bioctahedral structure (the octahedra are linked *via* a shared edge), the isopropyloxy anions occupying the bridging positions. This complex is isostructural to its uranium analogue $U_2I_4(OPr^i)_4(HOPr^i)_2$ (see Ref. 51) and is structurally similar [50] to a number of alkoxide and halide-alkoxide compounds of lanthanides and early transition metals, such as $M_2(OPr^i)_8(HOPr^i)_2$ (M = Zr or Ce) [52] and $Ti_2Cl_4(OR)_4(HOR)_2$ (R = CH_2CH_2Cl).[53] It was assumed that the $[AnI(OPr^i)_2(HOPr^i)_4]I$ intermediates (An = U or Th) were initially formed, which then underwent dimerisation.[50] Other alkoxide complexes of actinides, for example $Th_2(OBu^t)_8(HOBu^t)$,[54] $(TBA)U_2(OBu^t)_9$ (TBA is tetrabutylammonium) and $KU_2(OBu^t)_9$,[55] were also characterised. It was demonstrated that the K^+ cations in the latter complex in solutions remain associated with the dimeric anions, the structures of the molecular unit in the crystalline state and solution being, apparently, identical.

Oxidation of the uranium(III) aryloxide complex $U(OAr)_3$ (**8**) (OAr is 2,6-di-*tert*-butylphenoxide) afforded various oxide and halide-oxide complexes of U(IV).[50]



(*a*) $AgBF_4$ or $AgPF_6$; (*b*) CI_4; (*c*) PCl_5; (*d*) O_2; (*e*) AgBr, CBr_4 or PBr_5; (*f*) COS or $Ph_3P=S$; (*h*) N_2O, NO, Me_3NO or pyridine *N*-oxide.

In the presence of an appropriate source of chalcogenide, oxidation gave rise to bridged binuclear uranium(IV) complexes **9** or **10**.[50]

Alkoxide complexes of cyclooctatetraenyluranium(IV) were synthesised by the reactions of cyclooctatetraenyluranium precursors with alcohols.[56]

The unusual monomeric complex $U(OTeF_5)_6$ can be considered as an analogue of metal alkoxides.[57] In spite of the large molecular weight, this complex sublimes at 333 K (1.3 Pa).[57]

Actinide alkoxides are generally prepared from dialkylamides and alcohols.[44] The homoleptic $UX_4(MeCN)_n$ complex can serve as a precursor in the synthesis of mixed halide-alkoxide compounds of uranium. The coordination environment in the reaction product depends on the nature of the halogen. Thus the reaction of $UBr_4(MeCN)_4$ with 2 equivalents of KOAr in THF afforded the $Br_2U(OAr)_2(THF)\cdot 4THF$ complex, whereas UCl_4 produced the anionic $[K(THF)_4][UCl_3(OAr)_2]$ complex. In solution, mixed halide-aryloxide complexes do not undergo ligand exchange. Light halides of uranium(IV) are reagents of choice in the metathesis because $UI_4(MeCN)_4$ is thermally unstable.[58] A series of aryloxides and alkoxides of (triamidoamine)uranium(IV) were described.[59]

One of the approaches to the synthesis of methoxide derivatives of actinides of type **11** involves the reactions of $Cp^*_2MH_2$ (Cp^* is pentamethylcyclopentadienyl; M = U or Th) with trimethyl phosphite in pentane.[60]

$$Cp^*_2ThH_2 \xrightarrow[-H_2]{P(OMe)_3} Cp^*_2Th(OMe)_2 + \underset{\mathbf{11}}{[Cp^*_2Th(OMe)_2](\mu\text{-}PH)}$$

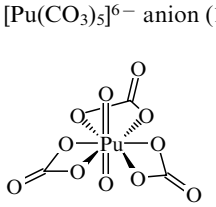
The corresponding thorium derivatives can also be prepared by alcoholysis of alkyl complexes, for example, of $Cp^*_2ThMe_2$, the reactions of $Cp^*_2ThCl_2$ with alkali metal hydroxides, the insertion of ketones at the Th–Alk bond (see the review [37] and references cited therein)

$$Cp^*_2ThCl(Me) + Me_2CO \xrightarrow{PhMe} Cp^*_2ThCl(OCMe_3)\,,$$

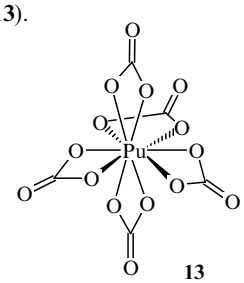
and hydrogenation of η^2-acyl complexes [37]

$$Cp^*_2ThCl(\eta^2\text{-}OCCH_2Bu^t) \xrightarrow{H_2} Cp^*_2ThCl(\eta^2\text{-}OCH_2CH_2Bu^t).$$

Crystallisation of a Pu(IV) salt (0.15 mol litre^{-1}) from a solution of Na_2CO_3 (2.6 mol litre^{-1}) afforded single crystals of $[Na_6Pu(CO_3)_5]_2\cdot Na_2CO_3\cdot 33\,H_2O$ (the space group is $P2_1/c$).[61] In the solid state, the asymmetric unit contains a complex framework consisting of $[Pu(CO_3)_5]^{6-}$ anions and Na^+ cations linked through interactions between the CO_3^{2-} ligands and the H_2O molecules. The $[Pu(CO_3)_5]^{6-}$ anion can be considered as a pseudohexagonal bipyramid with three carbonate ligands in the equatorial plane and two carbonate ligands in the axial positions. Its structural unit is very similar to that of the related $[Th(CO_3)_5]^{6-}$ anion involved in the crystal structures of $Na_6[Th(CO_3)_5]\cdot 12\,H_2O$ and $[C(NH_2)_3]_6[Th(CO_3)_5]\cdot 4\,H_2O$ (see Ref. 61 and references cited therein). Clark *et al.*[61] believed that the well-known coordination polyhedron (hexagonal bipyramid) in the $[PuO_2(CO_3)_3]^{4-}$ complex (**12**) [62–64] is analogous to that of the $[Pu(CO_3)_5]^{6-}$ anion (**13**).



12



13

The structure of yet another carbonate complex, *viz.*, $(Me_4N)_4[NpO_2(CO_3)_3]\cdot 8\,H_2O$, consists of alternating anionic and cationic layers.[65] The water molecules of crystallisation are involved in the formation of the $\{[NpO_2(CO_3)_3]\cdot 8\,H_2O\}_n^{4n-}$ anionic layers. Analogous uranium and uranyl complex ions in carbonate,[66,67] sulfate,[68] nitrate,[69] phosphate,[70] silicate [70] and citrate complexes [71] as well as in other oxygen-containing compounds were also studied. In particular, the behaviour of carbonate complexes of uranium in $CO_2-HCO_3^-$ solutions of various ionic strengths (I = 0.5, 1.0, 2.0 or 3.0 mol litre^{-1} of $NaClO_4$) at 25 °C was examined by UV/Vis spectrophotometry.[65] The authors believed that tetracarbonate complexes exist in an equilibrium with pentacarbonate complexes

$$[U(CO_3)_4]^{4-} + CO_3^{2-} \rightleftharpoons [U(CO_3)_5]^{6-}\,.$$

Citric acid forms mixed Fe and U complexes analogous to the citrate complex of uranium. The mixed Fe–U citrate complex is stable to biodegradation.[71]

Among other oxygen-containing actinide compounds, uranium peroxo complexes with various ligands, *viz.*, with tri- and tetradentate Schiff's bases,[72] amines or aminocarboxylic acids,[73] were described. The einsteinium(II) complexes with crown ethers $[Es(18\text{-}C\text{-}6)]L_2$ (L = ClO_4^- and BF_4^-, BPh_4^-) were prepared.[74] The behaviour of einsteinium(II) in THF was examined by co-crystallisation. It was found that the coefficients of co-crystallisation of Es(II) with solid $[Sr(18\text{-}C\text{-}6)]I_2$ in THF depend on the ClO_4^- and BF_4^- ions as additives and are independent of the presence of the BPh_4^- ions.

Very stable actinide complexes with β-diketones [for example, with $An(acac)_4$ or $AnO_2(acac)_2$] are used for isolation and separation of actinides by extraction. These complexes are prepared by the reactions of metal or actinyl halides with the

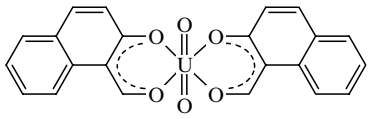
[a] Direct electrochemical synthesis; [b] alkylation of the product afforded $Th(OAr)_2(CH_2SiMe_3)_2$; [c] recrystallisation from hot isopropyl alcohol gave rise to $Pu(OPr^i)_4(HOPr^i)$; [d] the product lost acac[7] to form $Th(acac)_3$; the known Th(III) complexes are few in number.

corresponding diketone in the presence of a base. In the case of An(IV) actinides, only fluorine-containing diketonates form complexes with Lewis bases; diketonates of actinyls AnO_2 (An = Np or Pu) generally exhibit the Lewis acid properties and are stabilised through the formation of adducts. The fluorinated complex $UO_2(hfa)_2$ (hfa is hexafluoroacetylacetonate) exhibits pronounced acidic properties and its adducts with water and alcohols can be sublimed without decomposition.[17]

Uranyl acetylacetonate,[75,76] other actinide β-diketonates[77] and uranyl complexes with 2-hydroxy-1-naphthaldehyde (**14**)[78] and 2-hydroxybenzaldehyde[79] were studied in detail by spectroscopic methods. These investigations made it possible to establish the structure of the complex **14** synthesised previously.[80]

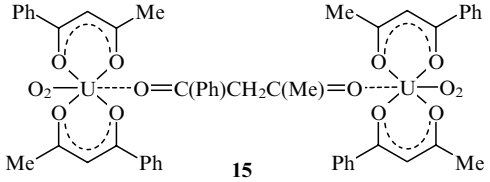


14

Based on the data on the electronegativities obtained earlier (see references cited in the study [78]), the U–O bond orders in the complexes **14**, $UO_2(acac)_2$, $UO_2(Hdbm)_2$ and $UO_2(HBTF)_2$ (Hdbm is dibenzoylmethane, HBTF is 1,1,1-trifluoropentane-2,4-dione) were calculated. The results of the calculations indicated that the equatorially coordinated 2-hydroxy-1-naphthaldehyde ligand exerts a pronounced effect on the oxygen atoms of the UO_2^{2+} anion.[78]

Based on the spectra of neptunium β-diketonates,[77] the Np(IV) complexes with acetylacetonate, dibenzoylmethane, benzoylacetone (Hbac), benzoyltrifluoroacetone (Hbtfa) and thenoyltrifluoroacetone (Htta) can be divided into two groups according to the type of coordination polyhedron about the central atom. In $Np(acac)_4$, $Np(dbm)_4$ and $Np(tta)_4$, the coordination polyhedron is a tetragonal antiprism, whereas $Np(bac)_4$ and $Np(btfa)_4$ (dbm is dibenzoylmethanate, bac is benzoylacetonate and btfa is benzoyltrifluoroacetonate) have bitetrahedral structures. Apparently, when Np(IV) β-diketonates are dissolved in benzene, the bidentate ligands are oriented about the central atom so that the oxygen atoms form the tetragonal-pyramidal coordination.[77]

It should be noted that uranium β-diketonates were also prepared by direct electrochemical synthesis using a dissolving anode. Thus electrochemical oxidation of uranium in the presence of β-diketones afforded chelate complexes of the UL_4 or UO_2L_2 type (L is diketonate).[81–83] The reaction with benzoylacetone gave rise to a compound with composition $UO_2(bac)_2(Hbac)_{0.5}$ along with the above-mentioned complexes.[82] In our opinion, the structure **15**, which was assigned to this compound on the basis of the IR spectroscopic data, needs further investigation.



15

Selected methods for the synthesis of actinide alkoxides are listed in Table 2.

IV. Halide complexes of actinides

Light actinides (U, Np and Pu) react with iodine or bromine in donor solvents[97,98] to give complexes of trivalent actinides AnX_3L_4 (X = Br or I).

$$U + 1.5\,I_2 + n\,L \xrightarrow{0\ ^\circ C} UI_3L_n$$

16a–c

$n = 2$, L = DME (**a**); $n = 4$, L = THF (**b**), Py (**c**).

This reaction is a convenient and highly efficient procedure for the preparation of halide complexes of actinides in quantitative yields, which does not require special equipment.

Complexes of uranium triiodide with Lewis bases are used as intermediates in the synthesis of other trivalent uranium compounds. For example, the $UI_3(THF)_4$ adduct (**16b**), which can be prepared in large amounts, is a soluble form of UI_3 convenient for subsequent use in synthesis.[98] Reactions involving solvate complexes of other uranium halides or alkoxides can be complicated, for example, by the formation of mixtures of products.

The mononuclear complex $UI_3(THF)_4$ (**16b**) crystallises in the space group $P2_1/c$. The coordination environment about the central U atom is a pentagonal prism. The complex **16b** is stable up to 75 °C. At a higher temperature, the THF molecules are successively eliminated; at 162 °C, UI_3 is finally formed.

Other adducts of uranium halides UX_3 were also described.[99–103]

Actinide tetrahalides readily react with Lewis bases to give complexes containing two or four donor atoms. The compositions of some resulting products differ from usual $AnCl_4 \cdot 2L$ or $AnCl_4 \cdot 4L$. For example, the $AnCl_4 \cdot nL$ complexes, where $n = 2.5$, 5 [L is *N*,*N*-dimethylacetamide (DMA)] or 6 (L = DMSO or TMPO), were prepared. Complexes with composition $AnCl_4 \cdot 2$ HMPA (An = Th or U) are extremely volatile.[17] The coordination polyhedron typical of the $AnCl_4 \cdot 2L$ complexes is a *trans*-octahedron.[17]

The cationic uranium(IV) complexes $UX_2L_4Y_2$ [X = Cl, Br or I; L is a bulky neutral O-donor ligand, such as tris(pyrrolidin-1-yl)phosphine oxide; Y = ClO_4 or BPh_4] were described.[102]

The reactions of UI_4 with a series of sulfoxide donor ligands in non-aqueous media were investigated. The behaviour of UI_4 was compared with that of UCl_4 and UBr_4 in the presence of the same ligands. It was demonstrated that UI_4 was readily oxidised with dimethyl or diisobutyl sulfoxide at ~20 °C. Only complexes with compositions $UI_4(DMSO)_8$ and $UI_4(DIBSO)_6$ (DIBSO is diisobutyl sulfoxide) appeared to be stable and were isolated.[104]

All actinide halides tend to accept Hal^- ions to form anionic complexes. The stability of the complexes decreases in the series F ≫ Cl > Br ≫ I. Adducts of actinide trihalides are ionised to a large extent. Thus uranium trichloride crystallises from dimethyl sulfoxide as the solvate $UCl_3 \cdot 3$ DMSO. Its structure consists of the dodecahedral $[U(OSMe_2)_8]^+$ cations and the octahedral $[UCl_6]^-$ anions. X-ray diffraction study demonstrated that americium chloride hexahydrate has an ionic structure built of the $[AmCl_2(H_2O)_6]^+$ cations and $[Cl(H_2O)_6]^-$ anions, which are linked *via* hydrogen bridges.[17]

Uranium and protactinium pentahalides generate complexes of the $AnX_5 \cdot L$ type (X = Cl or Br; L = R_3PO or HMPA). Dissolution of UO_3 in thionyl chloride afforded the $UCl_5 \cdot SOCl_2$ adduct, whereas dissolution of Pa(V) hydroxide gave rise to the ionic complex $(SO)(PaCl_6)_2$. Generally, actinide hexahalides do not react with Lewis bases (except for the $UCl_6 \cdot$ bipy complex), whereas actinyl halides readily form complexes with composition $AnO_2X_2 \cdot nL$ ($n = 1$, 1.5, 2, 3 or 4).[17]

Uranium fluorides UF_5 and UF_6 give complexes with 2-fluoropyridine (F-Py) or bipy.[105] Thus UF_6 in CH_2Cl_2 produced the $UF_4 \cdot$(F-Py) and $U_2F_{12} \cdot$ bipy complexes, respectively. However, in the case of the UF_6–bipy system, reduction of UF_6 was the predominating process and the formation of $U_2F_{12} \cdot$ bipy {the authors believed that this complex has the structure $[UF_4(bipy)_2]^{2+} \cdot [UF_7]_2^- \cdot UF_6$} can be considered as the first stage of this reduction.

In the case of UF_5, two products were obtained and structurally characterised. These are the extremely moisture-sensitive $UF_5 \cdot$ bipy and the ionic derivative $[(bipy)_2H]^+[UF_6]^-$.

The $AnX_3(THF)_4$ complexes serve as synthetic precursors of a number of inorganic and organometallic complexes due, in particular, to their high solubility in toluene and THF. The use of $UI_3(THF)_4$ can also provide a convenient approach to the synthesis of many other compounds of trivalent uranium.[97]

Salts of organic ligands with alkali metals react with $AnX_3(THF)_4$ to give the corresponding aryloxides, amides, *etc*. This reaction can serve as a highly efficient procedure for the preparation both of the known and new complexes of trivalent actinides. Thus reduction of uranium tetrachloride with NaH or Na/Hg in THF afforded poorly soluble $UCl_3(THF)_n$.[106] This compound is sometimes used for the synthesis of other uranium complexes. However, this procedure is of limited application due to the formation of by-products. For example, the synthesis of $U[N(SiMe_3)_2]_3$ from $UCl_3(THF)_n$ and $NaN(SiMe_3)_2$ often give rises[97] to a mixture of a U(III) complex and a uranium(IV) derivative, *viz*., the metallacycle $[(Me_3Si)_2N]_2U(CH_2SiMe_2NSiMe_3)$.[107]

Selected procedures for the synthesis of halide complexes of actinides are listed in Table 3.

Table 3. Synthesis of halide complexes of actinides.

Starting compound or metal	Reaction system	Products	Ref.
Synthesis from elemental metals			
U	X_2 (X = Cl, Br, I), THF	$UX_3(THF)_4$	97, 98
Th	X_2 (X = Br, I), THF	$ThX_4(THF)_4$	44
Th anode [a]	Br_2, MeCN	$ThBr_4(MeCN)_4$	108
U	$HgCl_2$, THF	$UCl_4(THF)_3$ (see [b])	109
An (U, Np, Pu)	Br_2 or I_2, THF	$AnX_3(THF)_4$ (see [c])	97
Synthesis from salts or halide complexes			
UI_4	DMSO	$UI_4(DMSO)_n$ ($n = 6, 8$)	104
	DIBSO	$UI_4(DIBSO)_n$ ($n = 6, 8$)	104
UCl_4	NaH	$UCl_3 \cdot n$ THF	44
$ThBr_4(THF)_4$	$KNPh_2$, THF KNMePh, THF	$Th(NPh_2)_4 \cdot$ THF $K[Th(NMePh)_5]$	110
$ThBr_4(THF)_4$	Cp*MgBr(THF)	$Cp^*ThBr_3(THF)_3$	111
$UI_3(THF)_4$	KCp*, THF	$Cp^*UI_2(THF)_3$	20, 98
$AnI_3(THF)_4$ (An = U, Np, Pu)	$NaN(SiMe_3)_2$, THF	$An[N(SiMe_3)_2]_3$	97, 112

[a] Direct electrochemical synthesis; [b] a large amount of a uranium amalgam was obtained as a by-product; [c] air-sensitive.

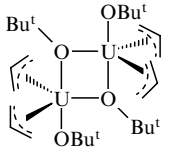
V. Actinide π-complexes with allyl, cyclopolyene, arene and related ligands

Considerable recent attention has been given to actinide complexes with allyl, cyclopolyene and arene ligands, particularly, with cyclopentadiene and its derivatives (see review [20]).

Allyl complexes can be synthesised from $AnCl_4$ and the Grignard reagent[44]

$$AnCl_4 + AllMgCl \xrightarrow[<0\ ^\circ C]{Et_2O} An(\eta^3\text{-All})_4 .$$

According to the data of low-temperature NMR spectroscopy,[20] the allyl groups in these complexes are η^3-coordinated and can be replaced under the action of HX or alcohols to produce, for example, $U(C_3H_5)_3X$ or $[U(C_3H_5)_3(OR)]_2$.[44] Thus the dimeric *tert*-butyloxyallyl complex $[U(C_3H_5)_3(OR)]_2$ (**17**) was synthesised.[20]



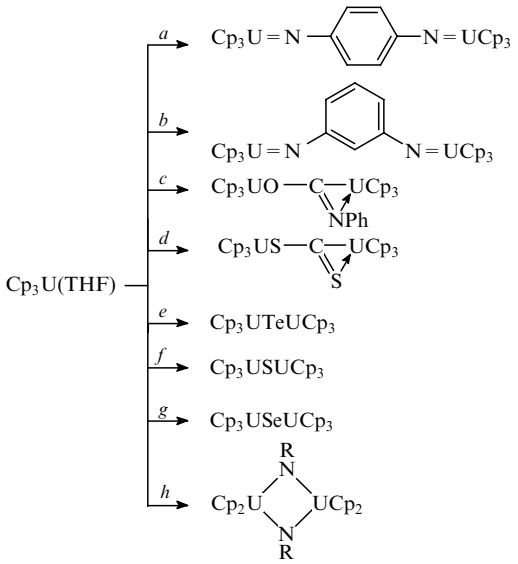
17

Of actinide π-complexes, the uranium(III, IV) and thorium(III, IV) complexes with cyclopentadiene and its derivatives were obtained in the widest range.

Uranium(V, VI) complexes [20] and neptunium(VI) and californium(III) sandwich complexes were also prepared.[44] These complexes can be compositionally divided into the following groups: Cp_nAn (n = 3 or 4), Cp_nAnX (n = 2 or 3), Cp_2AnX_n (n = 1 or 2) and $CpAnX_n$ (n = 2 or 3), X being generally Hal. The corresponding cyclopentadienyl alkyls, carbonyls, alkoxides, *etc*. are also known.[20] All Cp_4An complexes are poorly soluble in organic solvents. The U–C distances in the Cp_4U complex are 2.81(2) Å. The bonds between the An atom and the ligand are covalent in character.[20, 44]

The Cp_3An complexes are strong Lewis acids and form complexes with various Lewis bases (see Ref. 24 and references cited therein).

The Cp_3UCl complex, which was the first synthesised organoactinide compound,[21, 44] serves as a precursor of compounds containing the non-bridging metal–metal bond between, for example, uranium and iron or ruthenium [$Cp_3U-MCp(CO)_2$, M = Fe or Ru] or between uranium and germanium (Cp_3UGePh_3).[20, 113] The first organouranium(III) complexes,[24, 114, 115] *viz*., tris[(cyclopentadienyl)uranium] and some its derivatives of the Cp_3UL type, are also used for the synthesis of bimetallic compounds.[24]



(*a*) 1,4-$(N_3)_2C_6H_4$; (*b*) 1,3-$(N_3)_2C_6H_4$ (*c*) PhNCO; (*d*) CS_2; (*e*) $TePBu_3$; (*f*) COS or $Ph_3P=S$; (*g*) $Ph_3P=Se$; (*h*) $Cp_3U=NR$; R = Ph, $SiMe_3$.

Voltammetric studies [116] demonstrated that oxidation of $(RC_5H_4)_3UCl$ (R = H, Me, Bu^t or Me_3Si) was accompanied by disproportionation. NMR studies revealed electron transfer and ligand exchange in Cp_3UX (X = Hal, BH_4 or Alk).[24, 117]

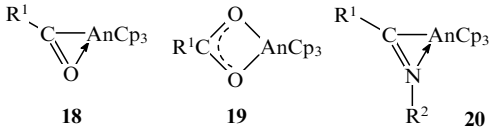
$$Cp_3UX \underset{-e^-}{\overset{e^-}{\rightleftharpoons}} Cp_3UX^-,$$

$$Cp_3UX + Cp_3U^*(THF) \rightleftharpoons Cp_3U^*(THF) + Cp_3U^*X,$$

$$Cp_3UX^- + Cp_3U^*(THF) \rightleftharpoons Cp_3U^*(THF) + Cp_3U^*X^-.$$

The equilibrium constants of the ligand exchange in complexes with substituted cyclopentadienyl ligands were determined.[24, 118] It was found that binding of ligands with $(MeCp)_3U$ is reduced in the series of the ligands PMe_3 > $P(OMe)_3$ > Py > tetrahydrothiophene > THF > quinuclidine > CO, whereas binding of $(Me_3SiC_5H_4)_3U$ with the EtNC ligand is stronger than with the EtCN ligand, which is indicative of substantial π-back bonding with uranium in the case of π-acceptor ligands.[24] The results of calculations of the electronic structure of the model $Cp_3U(CO)$ complex showed substantial back bonding between the 5*f* orbitals of U and the 2π orbitals of CO, which leads to stabilisation of the 5*f* atomic orbitals of uranium.[20, 119] Some uranium complexes containing carbonyl ligands were described in the study.[120] The relativistic effective core potentials of tris(cyclopentadienyl) actinide complexes were calculated by the *ab initio* quantum-chemical method. These complexes were examined also by gas-phase UV photoelectron spectroscopy.[121, 122]

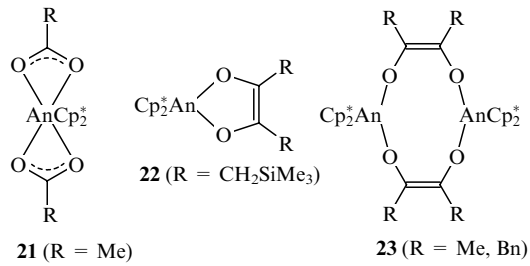
The Cp_3AnR^1 complexes tend to incorporate the CO, CO_2 and CNR^2 ligands to form η^2-acyl (**18**), η^2-carboxylate (**19**) and η^2-iminoalkyl (**20**) complexes, respectively.[20]

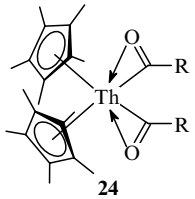


The Cp_3UX compounds containing the U–P, U–N, U–Si, U–Sn or U–Ge bonds were prepared from Cp_3UCl by the replacement of the chloride ligand.[24] In the crystal structures of $Cp_3U(OPh)$ and $Cp_3U(OSiPh_3)$, which were established by X-ray diffraction analysis, the U–O distances are shortened [2.119(7) and 2.135(8) Å, respectively] and the U–O–C and U–O–Si angles are 159.4(5)° and 172.6(6)°, respectively. These geometric parameters are indicative of strong π-bonding between the U and O atoms in oxygen-containing uranium complexes.[24] The bimetallic oxygen-bridged complex, *viz*., μ-*O*-bis[tris(cyclopentadienyl)uranium(IV)] was investigated.[123] The absolute enthalpies of the cleavage of the uranium–ligand bonds in complexes containing the U–S bonds of the L_3U-SR type (L = $C_5H_4Bu^n$, $C_5H_4SiMe_3$ or $C_9H_6SiMe_3$; R = Et or Bu) were determined.[124] The heteroatomic compound $UCp_2(\mu\text{-}Cl)_2Li[(Me_2NCH_2CH_2)_2$. .NMe] containing two chloride bridges provides yet another example of bimetallic complexes.[125]

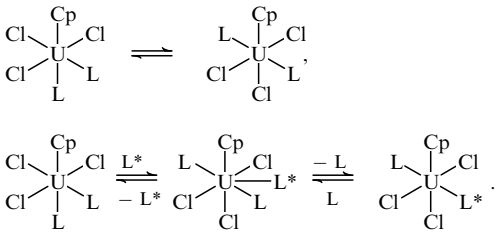
The electronic structure and configuration of the ground state of the monomeric alkyl uranium(III) complex η^5-$Cp^*_2UCH(SiMe_3)_2$ were studied.[126] The ground state of the molecule is $4A''[(a')^1(a'')^1(a'')^1]$, which corresponds to the $5f^3$ configuration of the uranium atom; its energy is close to that of the higher-lying $4A''(5f^26d^1)$ state. The uranium(III) ions free of ligands can adopt two different electronic configurations, *viz*., $5f^3$ and $5f^2d^1$ (see Ref. 126 and references cited therein). The ground state of the U^{3+} ions in the gaseous phase has the $5f^3$ configuration. According to the results of an EPR study of the Th[η^5-$C_5H_3(SiMe_3)_2]_3$ complex in the gaseous state, Th(III) in the ground state adopts the $6d^1$ configuration, whereas the free ion has the $5f^1$ configuration.[127]

The insertion of CO or CO_2 into the An–R bond in the $Cp^*_2AnR_2$ complexes gave rise to complexes **21**–**23** or carbene-like η^2-acyl complexes $Cp^*_2An(COR)_2$ (**24**, R = Alk).[20, 128–130]





The dynamic behaviour of $CpUCl_3L_2$ in solutions was examined.[24, 131] In toluene, rapid isomerisation and the ligand exchange were observed.[24]



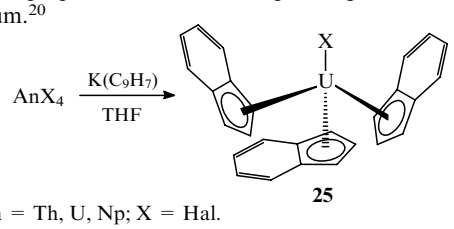
The tribromide complex $Cp^*ThBr_3(THF)_3$ (see Ref. 111 and Table 3) is a convenient compound for studying the chemistry of mono(pentamethylcyclopentadienyl) derivatives of thorium. Treatment of this complex with bases or Grignard reagents afforded aryloxide or alkyl derivatives.[111]

$$Cp^*ThBr_3(THF)_3 + KOAr \xrightarrow[18\ h]{THF} Cp^*ThBr_2(OAr)(THF) + KBr,$$

$$Cp^*ThBr_3(THF)_3 + 2\,KOAr \xrightarrow[18\ h]{THF} Cp^*ThBr_2(OAr)_2 + 2\,KBr,$$

$$Cp^*ThBr_2(OAr)_2 + MeMgBr \longrightarrow Cp^*MeTh(OAr)_2 + MgBr_2.$$

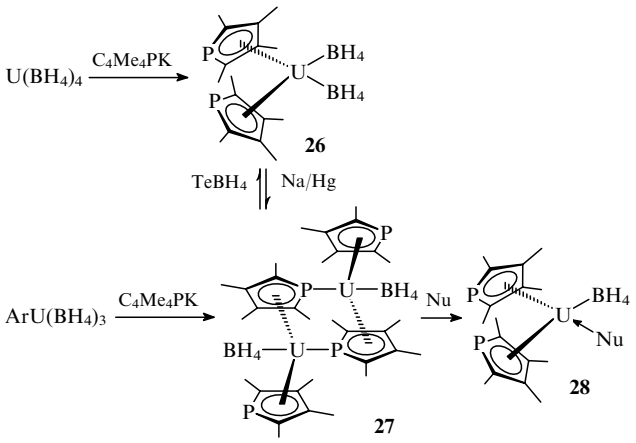
In 1971, the first indenyl derivative of actinides was prepared upon treatment of uranium tetrachloride with indenyl anions.[132] The indenyl uranium(III) complex $U(C_9H_7)_3$ was synthesised from UCl_3 and indenylsodium.[133] Indenyl actinide(IV) complexes **25** were prepared from the corresponding halides and indenylpotassium.[20]



25

An = Th, U, Np; X = Hal.

Uranium complexes **26**–**28** containing phosphacyclopentadienyl ligands were described.[24, 134]



Nu = THF, $OPPh_3$.

The structure of the first cycloheptatrienyl sandwich complex $[K(18\text{-}C\text{-}6)][U(\eta\text{-}C_7H_7)_2]$ was established.[135] The authors believed that the cycloheptatrienyl ligand can be formally considered as $C_7H_7^{3-}$ and the uranium atom occurs in the oxidation state +5.[135, 136] It was demonstrated that the C_7H_7 ligands in this compound are planar and are located parallel to each other and perpendicular to the axis passing through the uranium atom and the centres of the rings.[135]

Generally, cyclooctatetraene complexes of actinides have the composition $(COT)_2An$ or $(COT)AnX_2$ (X = Hal). Compounds of the mixed type (COT)AnCp can also be obtained. Some of these complexes contain solvent molecules, for example, THF.[20] Compounds of this type can be prepared, for example, according to the following procedures:

$$AnCl_4 + 2\,K_2(COT) \longrightarrow An(COT)_2 + 4\,KCl,$$

An = Th, Pa, U, Np;

$$(PyH)_2PuCl_6 + 2\,K_2(COT) \longrightarrow Pu(COT)_2 + 4\,KCl + 2\,PyHCl,$$

$$ThCl_4 + Th(COT)_2 \longrightarrow 2\,(COT)ThCl_2(THF)_2,$$

$$UCl_4 + COT + 2\,NaH \longrightarrow (COT)UCl_2(THF)_2 + 2\,NaCl + H_2.$$

[a] In this complex, six of seven CH_3 groups are involved in coordination to the $Li(TMEDA)^+$ cations, two groups being coordinated to each of the cations; TMEDA is tetramethylenediamine.

mixed ligands were prepared by treatment of $An(COT)(BH_4)$ with thiol.[137] Mono(cyclooctatetraene) amide uranium complexes $K[U(COT)(NEt_2)_2]$ and $U(COT)(NEt_2)_2(THF)$ were synthesised from tetrakis(diethylamine)uranium and bis(cyclooctatetraene)uranium, respectively. Oxidation of these complexes afforded a series of uranium(V) derivatives.[138]

As can be seen from Table 4, actinide π-complexes containing the cyclopolyene or arene ligands (see also Ref. 139) are more abundant than actinide complexes with other ligands.

VI. Hydride and hydroborate complexes of actinides

The first organoactinide hydrides were prepared by hydrogenation of $Cp^*_2AnR_2$.[20]

$$Cp^*_2AnR_2 + H_2 \longrightarrow Cp^*_2AnH_2 + 2\,RH$$

Both monomeric and oligomeric hydride complexes of actinides are available. Generally, these complexes contain OAlk, 1,2-bis(dimethylphosphino)ethane (dmpe) or cyclopentadienyl as additional ligands. Thus uranium and thorium tetrahydroborates are polymeric compounds, whereas neptunium and plutonium tetrahydroborates are monomeric. Methyltrihydroborate derivatives $An(MeBH_3)_4$ always occur as monomers.

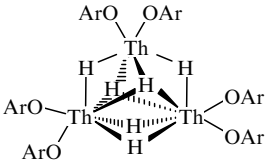
$$AnF_4 + 2\,Al(BH_4)_3 \xrightarrow{0\ ^\circ C} An(BH_4)_4 + 2\,AlF_2(BH_4)$$

The volatility of the complexes increases and their stability decreases on going from thorium to plutonium.[17]

Thorium, neptunium, plutonium and protactinium hydroborates and uranium tris(tetrahydroborate) possess similar properties. However, Th, Np, Pu and Pa hydroborates have a number of characteristic structural features.[44] The $UH(BH_4)_3(DME)$ complex contains the U–H bond. The $U(BH_4)_3[Ph_2P(Py)]_2$ complex was also described in the cited study.[44]

Trimeric thorium complex **29** provides a rare example of hydride complexes of early actinides, which are stabilised only by the aryloxide ligands.[90]

$$Th(OAr)_2(CH_2SiMe_3)_2 \xrightarrow[-\,SiMe_4]{H_2,\ PhP,\ 1.5\ atm,\ 7\ days} \longrightarrow$$



29

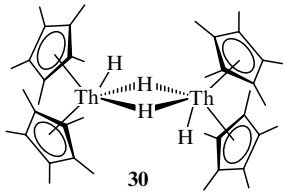
Ar = $C_6H_3Bu^t_2$-2,6

The complex **29** exhibits moderate catalytic activity in hydrogenation of hex-1-ene.[158] Alkoxide tetrahydroborate complexes of uranium(IV) were also described.[159]

Organoactinide hydrides are formed from the Ar_nAnR complexes through metathesis of σ-bonds.[20]

$$Ar_nAnR + H_2 \longrightarrow \begin{array}{c} \overset{\delta-}{H}\!-\!\overset{\delta+}{H} \\ Ar_nAn\text{----}R \\ \delta+\quad\ \delta- \end{array} \longrightarrow Ar_nAnH + RH$$

The structure of complex **30** was established.[20] The geometric parameters [the H–Th–Th and Th–H–Th angles are 58(1)° and 122(4)°, respectively; the distance between the thorium atoms is 4.007(8) Å] indicate that the metal–metal interaction in this complex is weak.



30

The unusual electron-deficient cyclopentadienyl complexes $(C_5H_4PPh_2)_2U(BH_4)_2$ and $(C_5H_4BH_3)_2U(BH_4)_2$ were described.[160]

Other cyclopentadienyl and related hydroborate complexes, for example, $[Na(THF)_6][Cp^*U(BH_4)_3]_2$,[161] were also synthesised.[161,162]

Selected examples of hydride and hydroborate complexes of actinides are listed in Table 5.

Table 5. Selected hydride and hydroborate complexes of actinides.

VII. Actinide complexes with macrocyclic ligands

Data on several actinide complexes with crown ethers and other macrocyclic ligands were published in the literature. Thus treatment of uranium and thorium tetrakis(diethylamides) $[An(NEt_2)_4]$ with free porphyrin (TPP) afforded the diporphyrin non-planar sandwich complexes $An(TPP)_2$.[17] Ultrafast electronic deactivation and the vibrational dynamics for the excited states of the uranium(IV) porphyrin sandwich complexes were examined.[169]

General procedures for the preparation of actinide complexes with macrocyclic Schiff's bases involve direct binding of the metal ion with the corresponding ligand and cyclisation in the presence of the metal ion. Thus phthalodinitrile reacted with anhydrous uranyl dichloride in DMF to give a 'superphthalocyanine' uranyl complex. Condensation of ethylenediamine with 2,6-dicarbonylpyridine in the presence of UO_2^{2+} gave rise to a hexaazamacrocyclic complex.[17] When irradiated with neutrons, the phthalocyanine complex $ThPc_2$ (Pc is phthalocyanine) entered into the nuclear reaction to give the corresponding protactinium(IV) complex.[17]

$$^{232}ThPc_2(n,\gamma)^{233}ThPc_2 \longrightarrow {}^{233}PaPc_2$$

The phthalocyanine complexes $AnPc_2$ were described in detail in a number of publications.[170–173]

Complexes with other polydentate ligands, for example, with chelating agents, can be used for efficient binding of actinide ions. These complexes are soluble both in water and organic solvents.[17] The higher the dentation of the ligand the more stable the complex. In the An^{4+}(EDTA) complexes (EDTA is ethylenediaminetetraacetic acid), the ligand is hexadentate and adopts a twist conformation.[17] Binding of plutonium and other radionuclides can be carried out with the use of cyclic and linear catecholamines.[174]

Actinide complexes with crown ethers are generally prepared from actinide salts. Complexes only with tri- and tetravalent actinide ions are known {for example, $[UCl_3(18\text{-}C\text{-}6)]_2 \cdot [UO_2Cl_3(OH)H_2O]$}. The hydrogen bonds between the oxygen atoms of the ether and the water molecules of coordination were found in the UO_2^{2+} complexes.[17] The IR spectra and the isotope effects for uranium complexes with crown ethers and the crystal structures of some of these compounds were published in the literature.[175]

Actinide complexes with crown ethers can be prepared also from organometallic compounds. Thus Cp_3UCl reacted with 18-C-6 in the presence of a sodium amalgam in THF to yield $(Cp_3UCl)[Na(18\text{-}C\text{-}6)]$ (see Ref. 24 and references cited therein).

VIII. Actinide complexes with nitrogen-containing ligands

Most of N-donor bases possess low affinity for actinides and act predominantly as proton acceptors. The An–N bonds with mono- and even bidentate N-donor ligands are rather weak.[17] The complex $UO_2(hfa)_2$ exhibiting high acidity forms a 1:1 complex only with ammonia. Like actinide alkoxides, actinide amides occur generally in the associated form. For example, these compounds react with chelating *N,N′*-dimethylethylenediamine to give the linear trimeric $[U(dmed)_2]_3$ complex and the square tetrameric $[U(dmed)_2]_4$ complex.[17,176] Dialkylamide and related complexes, such as $U[N(SiMe_3)_2]_3$, $[U(NEt_2)_3]BF_4$, $U(NPh_2)_4$, $UO_2[N(SiMe_3)_2]_2 \cdot (OPPh_3)_2$ and $UO_2CrO_4 \cdot 2\,MeCONEt_2$, were described in the literature.[97,177–182]

The structure of the $U[N(SiMe_3)_2\{N(SiMe_3)[SiMe_2-CH_2B(C_6F_5)_3]\}]$ complex was established by X-ray and neutron diffraction analysis. It was demonstrated that the electron deficiency on the uranium atom is effectively compensated by the formation of multicentre bonds between the U atom and the $SiCH_2$ groups of the amine ligands. The X-ray diffraction data are unambiguously indicative of μ^3-coordination of the BH_4 groups.[183] The structure of the unusual uranium(III) complex with a tripodal aromatic amine, *viz.*, tris[(2,2′-bipyridin-6-yl)]amine, was established by X-ray diffraction analysis.[184]

Protolysis of the U–N bond in amide complexes of uranium affords cationic complexes. This procedure was used for the synthesis of compounds containing the cations $[U(\eta\text{-}Cp)_3(THF)]^+$, $[U(\eta\text{-}Cp^*)(NEt_2)_2(THF)_2]^+$, $[(U\text{-}\eta\text{-}C_5R_5)_2 \cdot (NEt_2)(THF)]^+$, $[U(\eta\text{-}C_5R_5)(\eta\text{-}COT)(THF)_2]^+$ (R = H, Me),[185] $[U(NEt_2)_3]^+$, $[U(NEt_2)_2(THF)_3]^{2+}$, *etc.*[177] The resulting Th and U complexes with the silylated $N(CH_2CH_2NSiMe_3)_3$ ligand contain bonds between the metal atoms and the chlorine, carbon, hydrogen or oxygen atoms.[186] Chloro, pentamethylcyclopentadienyl and tetrahydroborate complexes of uranium containing the $N(CH_2CH_2NSiMe_3)_3$ ligand were characterised by the X-ray diffraction method.[186] The reactions of actinide amides were surveyed in a recent review.[187]

Only several imide complexes of actinides are known: $Me_3SiN=U^{V}[N(SiMe_3)_2]_3$, $Me_3SiN=U^{VI}F[N(SiMe_3)_2]_3$, $Cp_2.U(NC_6H_2Bu^t_3\text{-}2,4,6)$ and $U[N(CHMeCH=PPh_2Me)]Cp_3$.[188,189] In complexes of the $(C_5H_4Me)_3U=NR$ type (R = Ph or $SiMe_3$), both lone electron pairs of nitrogen are involved in binding with uranium.[24,190] Of the simplest nitrogen-containing ligands, the azide anion gives very stable complexes with uranium ($K_{diss} = 5\times10^{-3}$). The stabilities of the latter complexes are comparable with those of fluoride complexes.[17] The binuclear (U—Mo) heterocomplexes with N_2 were prepared.[191] IR spectroscopic and quasirelativistic theoretical studies of the coordination and activation of N_2 with the uranium and thorium atoms were carried out virtually at the same time.[192]

The mononuclear $UCp^*_2(NHR)_2$ complexes (R = 2,6-$Me_2C_6H_3$, Et or Bu) were synthesised, their structures were established and these complexes were demonstrated to catalyse hydroamination of terminal alkynes with ammonia.[193] The data on complex formation of uranium(VI) with neutral N-donors in DMSO were reported.[194]

An analogue of the uranyl ion was found in the crystal structure of the red complex $PPh^+_4\{UOCl_4[NP(C_6H_4Me\text{-}3)_3]\}^-$ (**31**).[195] The air-stable complex **31** was prepared from compound **32** by the replacement of the chloride ligand in the $[UOCl_5]^-$ anion accompanied by elimination of Me_3SiCl.

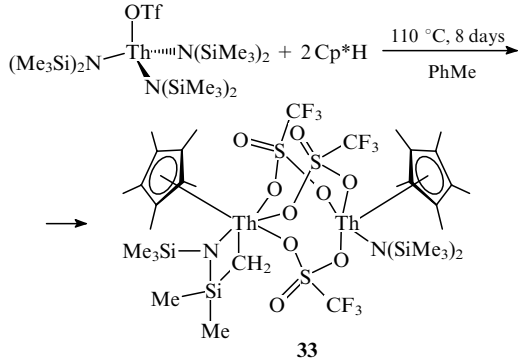
$$PPh^+_4[UOCl_5]^- + Me_3Si[NP(C_6H_4Me\text{-}3)_3] \xrightarrow[-Me_3SiCl]{CH_2Cl_2} PPh^+_4\{UOCl_4[NP(C_6H_4Me\text{-}3)_3]\}^-$$

32 → **31**

According to the data of X-ray diffraction analysis, the $\{UOCl_4[NP(C_6H_4Me\text{-}3)_3]\}^-$ ion contains the linear O=U=N group coordinated by four chlorine atoms.[195] The U—O distance (1.76 Å) is typical of the uranyl ion (see Ref. 195 and references cited therein). The U—N distance (1.90 Å) indicates that the bond order is no less than 2. The U—N—P group is nearly linear (171.9°), which suggests that the π electrons of the nitrogen atom are completely involved in bonding with uranium. The orders of the bonds between the uranium atom and each of the oxygen atoms in the uranyl ion can be equal to 3 due to the fact that the uranium atom bears simultaneously *f* and *d* valence orbitals.[195,196]

Other anionic actinide complexes can be prepared immediately from salts. For example, UF_5 and UF_6 react with nitrogen bases to give molecular or ionic compounds, such as $[(bipy)_2H]^+[UF_6]^-$, $UF_4(2\text{-}FC_5H_4N)$ and $U_2F_{12}(bipy)$.[197]

Thermolysis of the thorium derivative $Th(OSO_2CF_3).[N(SiMe_3)_2]_3$ in the presence of 1 equiv. of pentamethylcyclopentadiene afforded binuclear complex **33**.[111]



33

The actinide complex with 1,4-di-*tert*-butyl-1,4-diazabutadiene (DAB) **34** was prepared for the first time from the complex containing $N(CH_2CH_2NHSiMe_3)_3$ (tren) as a ligand.[198]

$$[(tren)ThCl]_2 + 2\,Li[Bu^t_2(DAB)_2] \xrightarrow[-80\ ^\circ C]{THF} 2\,(tren)Th[Bu^t_2(DAB)] + 2\,\{Li[Bu^t_2(DAB)]\}Cl$$

34

The complex **34** was obtained as red paramagnetic crystals (monoclinic, the space group is $P2_1/n$). The $N(CH_2CH_2NHSiMe_3)_3$ ligand ensures the optimum spatial environment for stabilisation of this complex. Since thorium(IV) compounds are diamagnetic, the diazabutadiene ligand in the paramagnetic complex **34** is subjected to one-electron reduction, *i.e.*, this ligand is present as the $[Bu^t_2DAB]^{-\bullet}$ radical anion.

The complex formation of neptunium(VI) with 3,3′-bis(diazaridine) derivatives[199] and of uranium(VI) with 8-hydroxyquinoline and its 5-halogen derivatives was studied.[200] In the latter case, the UO_2L and UO_2L_2 complexes (where L is a 8-hydroxyquinoline derivative) were obtained.[200]

Considerable recent attention has been given to uranium complexes with Schiff's bases (see, for example, the review[201]). Uranium(VI) complexes with Schiff's bases are used as organic oxidants (the catalytic modifications of these reactions were also developed).[202] Polystyrene-supported chelating resins incorporating U(VI) complexes with Schiff's bases are available.[203,204] Salicylaldehyde[205] and triethylenetetramine,[203] 3-formylsalicylic acid and *o*-hydroxybenzylamine[204] or salicylaldehyde and 1-amino-2-hydroxynaphthalene-4-sulfonic acid[206] were used as precursors of Schiff's bases. Uranium(VI) complexes with Schiff's bases exhibit photochromic properties. The kinetics and the mechanisms of photochromic conversions were examined.[207]

Examples of actinide complexes with nitrogen-containing ligands are given in Table 6.

Table 6. Selected actinide complexes with nitrogen-containing ligands.

Starting compound	Reagents	Reaction products	Ref.
UO_2Cl_2	$KN(SiMe_3)_2$, THF	$UO_2[N(SiMe_3)_2]_2\cdot(THF)_2$	208
$ThBr_4(THF)_4$	KNR_2	$Th(NPh_2)_4(THF)$ or $K[Th(NMePh_5)]$	44, 110
$UCl_3(THF)_3$	$NaN(SiMe_3)_2$, THF	$U[N(SiMe_3)_2]_3$	112
$U(NPh_2)_4$	L (L = Py, Et_2O, THF, $(EtO)_3PO$)	$U(NPh_2)_4\cdot L$	180
$(NSiMe_2)_2U\cdot CH_2SiMe_2NSiMe_3$	Ph_2NH	$U(NPh_2)_4$	44

IX. Complexes with phosphorus-containing ligands

A large number of actinide complexes, which bear oxygen-containing phosphorus ligands and in which the metal atom is

coordinated by the oxygen atom, are available.[17] Examples of phosphine complexes containing the An–P bond are few in number.[209] Thus thorium(IV) and uranium(IV) tetrahalides react with trimethylphosphine to give the 1 : 2 complexes $MCl_4(PMe_3)_2$ (M = U or Th).[17, 210] The $U[Me_2PCH_2CH_2PMe_2]_4$ complex containing an eight-coordinate uranium atom, which is isostructural to the thorium analogue, was described.[211] Uranium complexes with phosphorus donor ligands, procedures for their synthesis, structures and properties were considered in the study.[212]

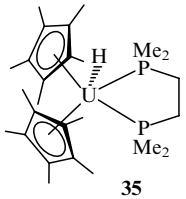
Ligands of the phosphacyclopentadienyl type serve as bridges, for example, in the dimeric uranium(III) complex **27**.[24, 134, 213]

The reactions of lithium salts of the potentially tridentate diphosphinoamide ligands $N(CH_2CH_2PR_2)^{2-}$ (R = Et or Pr^i) with uranium or thorium tetrachlorides afforded diphosphinoamide complexes of actinides. Ligands of this type are suitable for the preparation of various complexes of uranium(IV) (for example, $\{UCl_2[N(CH_2CH_2PEt_2)_2]_2\}_2$), uranium(V) and thorium(IV). Depending on the reaction conditions, these ligands can be mono-, bi- and tridentate. The character of the coordination compounds can be radically changed by varying the substituents at the neutral phosphine centre.[214]

Thorium and uranium complexes with diphosphazane dioxides were synthesised.[215] The crystal structure of the $UO_2(NO_3)_2[Ph_2P(O)N(Ph)P(O)Ph_2]$ complex was established. It was demonstrated that the metal atom is coordinated by diphosphazane dioxide in a bidentate fashion. Some other organophosphorus and related compounds of uranium were described in the studies.[216–219]

Actinide complexes containing simultaneously the phosphine and cyclopentadienyl ligands are few in number. Only the $Cp_2ThX_2(Me_2PCH_2CH_2PMe_2)$ complexes (X = Cl, Me or Bn)[179] and monomeric hydride complex of uranium(III) **35** were prepared.[220]

$$Cp^*_2UR_2 + Me_2PCH_2CH_2PMe_2 \xrightarrow[\text{autoclave, } -20\ ^\circ C]{\text{PhMe, } H_2}$$



R = Me, CH_2SiMe_3. **35**

The reactions of $U(BH_4)_3(THF)_x$ with some diphosphine ligands afforded the $U(BH_4)_3(L)_2$ complexes [L is dimethylphosphinoethane[221] or 2-(diphenylphosphino)pyridine[222]]. In these compounds, dynamic transformations are observed within the NMR time scale even at low temperature.

Table 7. Selected actinide complexes with phosphorus-containing ligands.

Substrate	Reagent	Product	Ref.
$AnCl_4$	$MP(CH_2CH_2PMe_2)_2$ M = Li, K	$An[P(CH_2CH_2PMe_2)_2]_4$ An = Th, U	211, 214
$ThCl_4$	$[N(CH_2CH_2PPr^i_2)]^{2-} \cdot Li^+_2$	$ThCl_2[NCH_2CH_2PPr^i_{0.5}]_2$	211, 214
UCl_4	$[N(CH_2CH_2PEt_2]^{2-} \cdot Li^+_2$	$\{UCl_2[N(CH_2 \cdot CH_2PEt_2)_2]_2\}_2$	211, 214
$[UOCl_5]^-$	$Me_3Si[NP \cdot (C_6H_4Me\text{-}3)_3]$	$[UOCl_4NP \cdot (C_6H_4Me\text{-}3)_3]^-$ (see [a])	189
$UO_2Cl_2 \cdot (Ph_3PO)_2$	$KOBu^t$	$UO_2(OBu^t)_2 \cdot (Ph_3PO)_2$	181
	$NaN(SiMe_3)_2$	$UO_2[N(SiMe_3)_2]_2 \cdot (Ph_3PO)_2$	181
$Cp^*_2UCl_2$	$HNPPh_3$	$Cp^*_2UCl_2(HNPPh_3)$ [b]	223

[a] The red salt containing the Ph_4P^+ cation is air-stable and is soluble in CH_2Cl_2 and MeCN; [b] the first complex of the *f* element with the phosphineimino ligand.

Examples of actinide complexes with phosphorus-containing ligands are given in Table 7.

X. Sulfur-containing actinide complexes

Being hard acids, actinides usually do not form stable complexes with S-donor ligands, which are soft bases. Only a few examples of complexes with sulfur-containing ligands are available in the literature, *viz*., $UCl_4(dmte)_2$ (dmte is 1,2-dimethylthioethane), $An(S_2CNEt_2)_4$ (An = Th, U, Np or Pu), $(NEt_4)[Np(S_2CNEt_2)_4]$, $(NMe_4)[UO_2(S_2CNEt_2)_3]$,[17] $U(SBu^n)_4$, $[U(SBu^n)_6]^{2-}$ and $[U(SPh)_6]^{2-}$;[224] $[Na(18\text{-}C\text{-}6) \cdot (THF)][U(COT)(C_4H_4S_4)_2]$ is the only known uranium(V) complex containing the metal–sulfur bond.[225] The reaction of UCl_4 with $Li_2(SCH_2CH_2S)$ in dimethoxyethane afforded[226] the first homoleptic dithiolate complex of an *f* element (**36**; the space group is $P2_1/n$).

$$UCl_4 + 4\,Li_2(SCH_2CH_2S) \xrightarrow{DME} [Li(DME)]_4[U(SCH_2CH_2S)_4] \cdot DME$$

36

The nature of the U–S bond in the complex **36** was estimated by the semiempirical Hückel method. It was found that the 6*d*, 7*s* and 7*p* orbitals of uranium are responsible for interactions with sulfur-containing ligands. The involvement of 5*f* orbitals is insignificant, and hence, the π interaction between uranium and sulfur is weak.[226] The authors also gave a brief review of the state of the art in the chemistry of actinide ions with sulfur-containing ligands.[226]

Derivatives of uranium(IV) tetrathiolate were prepared by treatment of $U(NEt_2)_4$, $U(BH_4)_4$ or $U(SBu^n)_4$ with thiols and by oxidation of metallic uranium with disulfides.[227] It was found that the reactions of the $U(SBu^i)_4$ complex with acids, I_2 and CS_2 proceeded at the U–S bond.[227]

The neptunium(V) complex with DMSO with composition $[(NpO_2)_2(DMSO)_7(H_2O)_2](ClO_4)_2 \cdot H_2O$ was structurally characterised.[228] The structure contains the dimeric complex $[(NpO_2)_2(DMSO)_7(H_2O)_2]^+$ cations, perchlorate anions, coordinated water molecules and water molecules of crystallisation. The IR and electronic spectra are indicative of the non-equivalence of the dioxo cations. Thus $Np(1)O_2^+$ acts as a monodentate ligand, whereas $Np(2)O_2^+$ serves as the coordination centre.[228]

Treatment of the $U(COT)(BH_4)_2$ complex with thiols or sodium thiolates (RSH or RSNa, where R = Bu^n, Pr^i or Bu^t) afforded first organouranium compounds containing the bridging disulfide $\{[U(COT)(\mu\text{-}S)_2]_2\}$ and thiolate $\{[U(COT)(\mu\text{-}SR)_2]_2\}$ groups. The structures of these compounds differ from those of their alkoxide analogues, which contain only two bridging OR groups.[229]

The reaction of $U(NEt_2)_4$ with Pr^iSH and $OP(NMe_2)_3$ gave rise to the first structurally characterised tetrathiolate complex of uranium $U(SPr^i)_4[OP(NMe_2)_3]_2$.[229] The uranium sulfur cluster $U_3(\mu_3\text{-}S)(\mu_3\text{-}SBu^t)(\mu_2\text{-}SBu^t)_3(SBu^t)_6$ was also described.[230]

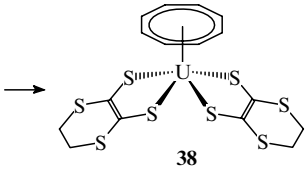
The $Cp^*_2U(dddt)$ complex (dddt is 5,6-dihydro-1,4-dithiin-2,3-dithiolate)[231] and the homoleptic uranium(IV) complexes $(THF)_3Na(\mu\text{-}SR)_3U(\mu\text{-}SR)_3Na(THF)_3$ (R = Bu^t or Ph) were synthesised.[232]

Recently, the first heteroleptic uranium(V) complex **38** was prepared by oxidation of complex **37** with $AgBPh_4$ in THF.[233]

$$(COT)UX_2(THF)_n + Na_2(dddt) \longrightarrow$$

$$\longrightarrow [(COT)U^{IV}(dddt)_2][Na(18\text{-}C\text{-}6)]_2 \xrightarrow[THF]{AgBPh_4}$$

37



38

X = BH_4, *n* = 0; X = I, *n* = 1.

Notwithstanding the fact that the available sulfur-containing actinide complexes are few in number, these compounds are of great interest in the coordination chemistry [230] and can find use for extraction of actinides.[232]

Examples of sulfur-containing uranium complexes are given in Table 8.

Table 8. Selected sulfur-containing uranium complexes.

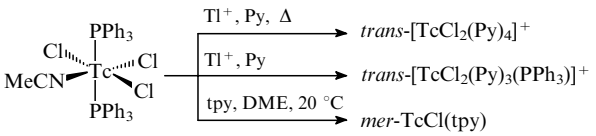
Starting compound	Reagents	Product	Ref.
UCl_4 or $U(BH_4)_4$	NaSR (R = Bu^t, Ph), THF	$(THF)_3Na(\mu\text{-}SR)_3U\cdot(\mu\text{-}SR)_3Na(THF)_3$	232
UI_4	DMSO DIBSO	$UI_4(DMSO)_n$ (n = 6, 8) $UI_4(DIBSO)_n$ (n = 6, 8)	104
$Cp^*_2UCl_2$	Na_2(dddt)	Cp^*_2U(dddt)	230
$U(NEt_2)_4$	Pr^iSH, $(Me_2N)_3PO$	$U(SPr^i)_4[OP(NMe_2)_3]_2$	233

XI. Technetium complexes

The chemistry of technetium becomes increasingly important, particularly, due to the fact that the short-lived ($T_{1/2}$ 6.015 h, γ irradiator) nuclide ^{99m}Tc is used in diagnostic medicine. This nuclide has been used over many years in bone scanning. Recently, ^{99m}Tc has found use in the treatment of various diseases of the heart, brain, kidney, liver and other organs as well as of tumour tissues. Technetium complexes are also of interest in the radiopharmaceutical industry.[234] Owing to the ideal energy of γ radiation (140 keV), lack of particulate radiation dose, the small half-life $T_{1/2}$ and the fact that ^{99m}Tc is readily accessible, this isotope is a radionuclide of choice for obtaining images in diagnostic nuclear medicine.[235, 236]

1. Complexes with nitrogen-containing ligands

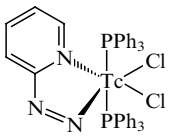
Complexes of Tc(III), Tc(II) and Tc(I) with pyridine ligands were prepared.[237] The authors were interested to prepare a coordinatively unsaturated low-valence electron-rich Tc metal centre surrounded by very weak π-donor ligands.



tpy is terpyridine.

The $TcCl_2(Py)_4$, $TcCl_3(PPh_3)_2$(TMEDA), $TcCl_3[Bu^t_3(tpy)]$ and [Tc(tpy)(Py)$_3$]Cl compounds were characterised by electrochemical and spectroscopic methods and by X-ray diffraction analysis.[237] According to the data of this investigation, π-back bonding is observed in the Tc(II) and Tc(I) complexes, unlike the Tc(III) complexes. In particular, the Tc–N bonds in pyridine complexes of Tc(II) are shortened by 0.04–0.06 Å and the Tc–N(internal) bonds in terpyridine complexes of Tc(I) are shortened by 0.09 Å compared to those in the analogous Tc(III) complexes.[237] These effects are favourable for stabilisation of low oxidation states of the metal atoms. The pyridine Tc(III) complexes give Knight-shifted ^{1}H NMR spectra. The visible regions of the spectra show transitions, which were empirically assigned to ligand-to-metal charge transfer transitions; multiple reversible electrochemical redox couples were found.[237]

Reduction of pertechnates (as well as perrhenates or permolybdates) with 2-hydrazinopyridine hydrochloride in methanol afforded complexes containing the M(η^1-$NNC_5H_4NH_x$)(η^2-$HNNH_yC_5H_4N$) core (M = Tc, Re or Mo).[238] In particular, the $TcCl_3(NNC_5H_4NH)(HNNC_5H_4N)$ complex was prepared. The latter was used for the synthesis of the $Tc(C_5H_4NS)_2$.$(NNC_5H_4N)(HNNC_5H_4N)$ complex (C_5H_4NS is pyridine-2-thiolate), which is a precursor of ^{99m}Tc-containing peptide reagents for medical investigations. The bifunctional hydrazine ligands used in the study [238] are efficient and versatile linkers for labelling antibodies and protein fragments. Other organic hydrazine complexes of ^{99m}Tc were also prepared. The reactions of $[TcOCl_4]^-$ with hydrazine hydrochloride (PhMe, 20 °C or CH_2Cl_2, 36 °C) gave rise to $[TcCl_2(C_8H_5N_4)(PPh_3)_2]\cdot 0.75\,PhMe$ and $[TcNCl_2(PPh_3)_2]\cdot 0.25\,CH_2Cl_2$, respectively.[239] The exchange reaction of $Tc(MeCN)(PPh_3)_2Cl_3$ with 2-hydrazinopyridine afforded Tc(III) complex **39**.[240]



39

Complexes with compositions *mer*-$[Cl_3(pic)_3Tc]$ and *mer*-$[Cl_3(pic)(PMe_2Ph)_2Tc]$ (pic is 4-picoline) were prepared by the reactions of $[TcOCl_4]^-$ with a series of phosphine ligands in 4-picoline. The process was accompanied by the oxygen atom migration. The resulting compounds were characterised by spectroscopic methods and X-ray diffraction analysis.[241]

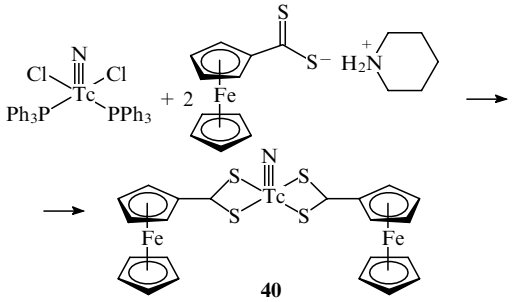
Complexes of high oxidation state technetium containing the $[Tc\equiv N]^{2+}$ core are more stable than the corresponding complexes of technecyl $[Tc=O]^{3+}$ and their properties resemble those of technecyl derivatives.

The technetium(V) complex $[TcN(L)(H_2O)]\cdot 2\,H_2O$ (L is the tetraazamacrocycle) was prepared by the reaction of $TcNCl_2(PPh_3)_2$ with the tetraazamacrocycle.[242] A complex with the $[Tc\equiv N]^{2+}$ core was synthesised using ancillary polydentate phosphorus- and nitrogen-containing ligands. The reaction of $[TcNBr_4]^-$ with 2,2′-bipyridyl in ethanol afforded the *cis*-octahedral $[TcNBr(bipy)_2]_2(TcBr_4)$ complex with the $[Tc\equiv N]^{2+}$ core containing the tetrahedral tetrabromo technetate(II) cation.[243]

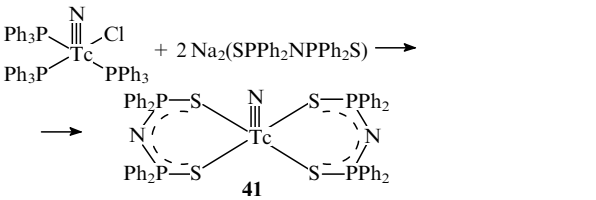
Other chelate nitride complexes of technetium(V) with the N_2S_2 ligand and the $[Tc\equiv N]^{2+}$ core were prepared by the reactions of $TcNCl_2(PPh_3)_2$ with $(HSCR_2CH_2NRCH_2)_2$ (R = Me or Et).[244]

Since the chemical behaviour of the Mo^VO complexes is similar to that of the $Tc^{VI}N$ complexes, pertechnate complexes can be synthesised according to the procedure developed for the preparation of analogous Mo^VO complexes. Thus chelate nitride complexes of technetium(V) with ligands of the N_2S_2 type and the $[Tc\equiv N]^{2+}$ core, *viz*., $[TcN(S_2CNEt_2)]_2(\mu\text{-}O)_2$, $[TcN.(S_2CNC_4H_8)]_2(\mu\text{-}O)_2$, $(AsPh_4)_2\{[TcN(CN)]_2(\mu\text{-}O)_2\}$ and $(AsPh_4)_2.\{[TcN(edt)]_2(\mu\text{-}O)_2\}$ [edt = $S(CH_2)_2S$], were prepared by the reactions of $\{[TcN(OH_2)_3]_2(\mu\text{-}O)_2\}^{2+}$ or $Cs_2(TcNCl_5)$ with precursors of the corresponding ligands in solutions of $Na_4P_2O_7$.[245]

The reaction of $TcNCl_2(PPh_3)_2$ with the piperidinium ferrocenyldithiocarboxylate gave rise to nitride complex **40**. According to the data of cyclic voltammetry,[246] two iron(II) atoms in the complex **40** act as independent redox centres linked through the $[Tc\equiv N]$ core. Chelate complexes **41** and **42** containing the same $[Tc\equiv N]$ core were also synthesised.[247]



40

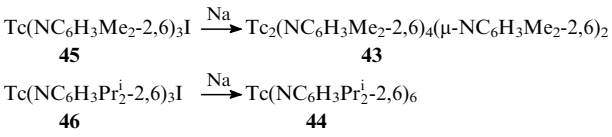


41

42

The possibility of radiopharmaceutical application of nitride technetium complexes with nitrogen-substituted amino acids, *viz*., derivatives of 2,5-dimethyldithiocarbamic acid, was reported.[248] Complexes with composition $TcN(L^n)(PPh_3)$, where L^n = Z-Gly-dtc (n = 1), Z-Ala-dtc (n = 2), Z-Phe-dtc (n = 3), Z-Val-dtc (n = 4) or Z-Leu-dtc (n = 5), were synthesised. All these complexes were characterised by spectral methods and X-ray diffraction analysis.

Binuclear complexes of Tc(VII) **43** and Tc(VI) **44** were synthesised by reduction of complexes **45** and **46**, respectively, with sodium.[249]



The crystal structure of the complex **43** consists of tetrahedra linked *via* shared edges, whereas the complex **44** has an 'ethylene-like' structure.[249] The reaction of the pertechnate ion with the salt of 3,6-bis(2′-pyridyl-1,2,4,5-tetrazine) (bptz · 2 HCl) in methanol or ethanol afforded binuclear complexes of the general formula $(\mu\text{-bptz})(TcO_3X)_2$ (X = Cl, OMe or OEt) containing Tc(VII), Tc(V) and the bridging bptz ligand. 4-Phenyl-3,6-bis(2′-pyridyl)-pyridazine (pppz) was used as a ligand for the preparation of mononuclear complexes from pertechnate and $TcOCl_4$ in an aqueous-ethanolic solution of HCl.[250] The binuclear polypyridyl oxo-bridged technetium(III) complex $\{(tpy)[Me_2(bipy)]Tc-O-Tc(tpy)[Me_2(bipy)]\}(OTf)_4$ was prepared by the reaction of $TcCl_3(tpy)$ with thallium triflate in the presence of water.[251]

The synthesis of diazene technetium complexes was described.[252] Thus the $TcCl(NNR)_2(PPh_3)_2$ complex (R = C_6H_4Cl-4), which was prepared from $TcOCl_4^-$ and monosubstituted hydrazine $RNHNH_2$ in methanol, reacted with the bidentate S_2CNR_2 ligand and maltol to give $Tc(NNR)L_2(PPh_3)$ and $TcCl(NNR)L(PPh_3)$ (L = S_2CNR_2) in high yields.[252]

The template synthesis from tetrabutylammonium pertechnate $(NBu_4)(TcOCl_4)$ or $(NH_4)_2(TcXO)$ (X = Cl or Br) followed by reduction by divalent tin afforded seven-coordinate Tc(III) complexes, for example, such as the monocapped adduct of boric acid with technetium(III) trisdioximate or $TcX(dioxime)_3BR$ (X = Cl or Br; dioxime = dimethylglyoxime or cyclohexanone dioxime; R = Me or Bu).[253]

A technetium(III) complex containing acetonitrile, *viz*., $TcCl_3(MeCN)(PR_3)_2$ (R = Ph or C_6H_4Me-3), was prepared by reduction of $TcCl_4(PPh_3)_2$ with zinc in acetonitrile in the presence of PPh_3. This complex is a convenient intermediate in the synthesis of other Tc(III) compounds. Its reactions with bipy, 1,10-phenanthroline (phen) and tpy afforded dicationic Tc(III) complexes, *viz*., $[Tc(bipy)_3]^{2+}$, $[Tc(phen)_3]^{2+}$ and $[Tc(tpy)_3]^{2+}$, respectively, as salts with BPh_4^- or PF_6^-.[254]

2. Complexes with sulfur- and oxygen-containing ligands

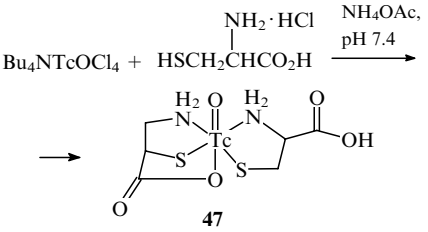
Reduction of $[Tc(OH)O(dmpe)_2]^{2+}$ in the presence of an excess of toluene-3,4-dithiol (H_2tdt) gave rise to the thiolate Tc(IV) complex $[Tc(tdt)(dmpe)_2](PF_6)$ (tdt = $MeC_6H_3S_2$-3,4).[255] Its structure was established by spectroscopic methods and X-ray diffraction analysis. The coordination polyhedron about technetium is intermediate between the octahedron and the trigonal prism [the Tc–S and Tc–P distances are 2.318(6) Å and 2.902(7) Å, respectively; the S–Tc–S angle is 84.49(4) °].

Refluxing of the salt $(NBu_4)(TcOCl_4)$ in alcoholic solution with dihydrooxazoles and dihydrothiazoles, for example, with 2-(2-hydroxyphenyl)-4,5-dihydrooxazole, 2-(2-hydroxy-3-methylphenyl)-4,5-dihydrooxazole or 2-(2-hydroxyphenyl)-4,5-dihydrothiazole, yielded the six-coordinate complexes $TcOClL_2$ (L is the corresponding (hydroxyphenyl)dihydrooxazole or -thiazole).[256]

The reaction of ammonium pertechnate with 3,5-di-*tert*-butylpyrocatechol (DBCat) in methanol afforded a mixture of the $Tc^{VI}(DBCat)_3$ and $Tc^{VI}(DBCat)_2(DBAP)$ complexes (DBAP is the amidophenoxide ligand).[257] The amidophenoxide ligand is formed through condensation of ammonia (from ammonium pertechnate) with pyrocatechol to give the Schiff's base. According to the data of EPR spectroscopy and X-ray diffraction analysis, technetium in the complex exists in oxidation state +6, which is very untypical. The DBCat ligand serves both as a reducing and chelating agent.

3. Complexes with nitrogen- and sulfur-containing ligands

The $HTcO(cysteine)_2$ complex (**47**) and its barium salt $Ba[TcO(cysteine)_2]_2$ were synthesised.[258] These compounds are of importance in biology and medicine. The properties of these complexes were studied.



47

The complex **47** can be synthesised starting from ammonium pertechnate and cysteine. All previous attempts to prepare technetium complexes with cysteine afforded products contaminated by polymeric compounds.[258] It was also reported[259–263] that chelation of technetium with polyfunctional ligands was accompanied by the formation of polymeric by-products. It is believed that an excess of the ligand causes decomposition of the initially formed chelate. The use of S-protective groups (for example, benzyl, acetylaminomethyl or benzoylaminomethyl) prevents the formation of undesirable polymeric products.[258]

The technetium (^{99m}Tc) analogue of oxorhenium bis-cysteinate possesses valuable biological properties. In particular, it is accumulated in kidneys,[264] which is useful in diagnostics of the morphological status of this organ.[258]

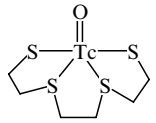
Potential radiopharmaceuticals for diagnostics of the renal function were synthesised with the use of chelating carboxyl-containing ligands bearing N- and S-centres . The carboxyl groups favour the renal uptake of these compounds.[264] The $^{99}TcO(ECH_3)$ complex was prepared based on the ammonium salt $NH_4(TcOX_4)$ (X = Hal) and (2*R*,7*R*)-2,7-dicarboxy-3,6-diaza-1,8-octanedithiol (ECH_3). In the isostructural rhenium(V) complex, one of the carboxyl groups in the *trans* position with respect to the oxo ligand is coordinated in an unexpected fashion.[265]

The choice of other ligands, *viz*., Schiff's bases, was governed by their tendency to be coordinated to technetium in various unusual oxidation states. The chemistry of technetium(I) complexes is poorly known. Only a few compounds were identified and characterised. The reaction of $(PPh_3)_2(CO)_3Cl$ with the lithium salt of Schiff's base, *viz*., *N-ortho*-hydroxybenzylidene-2-thiazolylimine, in boiling THF gave rise to the Tc(I) complex with composition $Tc(PPh_3)_2(CO)_2[(C_3H_2NS)N=CHC_6H_4O]$. This six-coordinate complex has a distorted octahedral structure with *trans*-PPh_3 and *cis*-CO groups and one chelating bidentate anion.[266]

Complexes containing biologically active molecules, such as peptides, proteins or antibodies, as ligands can be used as unique

target-specific radiopharmaceuticals in diagnostics. The reaction of $[TcO_4]^-$ with $SnCl_2$, sodium gluconate and RP 294 produced the $^{99}Tc(V)$ oxo complex with RP 294, which exists as the *syn* and *anti* isomers. The study of the crystal structure of the isostructural rhenium(V) complex demonstrated that the isomerism results from the positions of the CH_2OH groups in the serine residues. At room temperature, the isomers in solution undergo interconversion. The ^{99m}Tc and rhenium complexes with RP 294 exhibit similar chemical properties.[267]

The ^{99}Tc and ^{99m}Tc complexes with new tetradentate N_2S_2 and NS_2 ligands were prepared by refluxing a methanolic solution of $(TcOCl_4)(NBu_4)$ with the corresponding NS_3H_3 proligands. The technetium(V) complex $[TcO(NS_3)](NBu_4)$ (**48**) was obtained in high yield. However, compounds of this type are unstable and decompose in a matter of several hours or days. By analogy with the crystal structure of the related rhenium oxo complex, these compounds can be considered as square-pyramidal complexes containing the oxygen atom in the apical position.[268]



48

4. Complexes with phosphorus-containing ligands

Phosphine ^{99m}Tc-labelled derivatives can be used for obtaining images of internal organs, for example, heart images. Complexes of the $[TcO_2(PR_3)_3](BPh_4)$ (R = Et or Pr) type[234] have distorted trigonal-bipyramidal structures with two oxo ligands located in a single plane. Salts of the $[TcO_2(PR_3)_3]^+$ cations are convenient starting compounds for the synthesis of other complexes with mixed ligands.

$$[TcO_2(PR_3)_2]^+ \xrightarrow[MeOH]{Py} [TcO_2(PR_3)_2(Py)_2]^+$$

The trimethylphosphine derivative $[TcO_2(PMe_3)_2(Py)_2]^+$ can be prepared according to a one-pot procedure directly from pertechnates $[TcO_4]^-$. Apparently, this procedure can be adapted for the preparation of ^{99m}Tc radiopharmaceuticals in hospitals.

$$NH_4(TcO_4) \xrightarrow[MeOH]{Py,\ PMe_3} [TcO_2(PMe_3)_2(Py)_2]^+$$

The $[TcO_2(PR_3)_2(Py)_2]^+$ derivatives are diamagnetic, which is indicative of a noticeable deviation of their geometry from the ideal octahedron.[234]

The reactions of pertechnate with derivatives of phosphinocarboxylic acids afforded the TcL_3 complexes [L is 2-(diphenylphosphino)benzoic acid, 3-(diphenylphosphino)propionic acid or (diphenylphosphino)acetic acid]. According to the results of spectroscopic studies and X-ray diffraction analysis, these complexes possess a distorted octahedral geometry with the *mer* configuration in which the donor atoms of the same type are in *trans* positions with respect to each other and the phosphorus atom is in the *trans* position with respect to the oxygen atom.[269]

Complexes of the short-lived ^{99m}Tc isotope were prepared analogously. Their physical and chemical properties are similar to those of ^{99}Tc complexes. Biological assays revealed significant brain uptake of these compounds.

Chelate technetium(V) complexes with bis(*o*-hydroxyphenyl)-phenylphosphine and (*o*-hydroxyphenyl)diphenylphosphine were prepared by metathesis of the corresponding Tc(V) precursors or by reduction–ligand exchange with ammonium pertechnate.[270] These complexes combine a soft phosphine donor site and two hard phenoxide centres. It was expected that this fact would stabilise technetium in intermediate oxidation states.

The $[Tc(tu\text{-}S)_6]Cl_3 \cdot 4H_2O$ complex (tu-S is thiourea) was used as the precursor of $[Tc(dppe)_2(Bu^tNC)_2](PF_6)$ (dppe is diphenylphosphinoethane).[271] This complex can be prepared by mixing both ligands and a source of technetium(III) in ethanol followed by refluxing of the reaction mixture. This procedure is more convenient than the method involving a sodium amalgam, dppe and $TcCl_4(PPh_3)_2$. In the $[Tc(tu\text{-}S)_6]Cl_3 \cdot 4H_2O$ complex, the coordination polyhedron about the technetium atom is a distorted tetrahedron, the isocyanide ligands being in *trans* positions with respect to each other.

Treatment of $[TcO_4]^-$ with an excess of the corresponding S,P-bidentate phosphinothiolate ligands, such as 2-(diphenylphosphino)ethanedithiolate, 2-(diphenylphosphino)propanethiolate or 2-(diphenylphosphino)thiophenoxide, yielded neutral technetium(III) complexes.[272] These complexes have a trigonal-bipyramidal geometry, two phosphorus donor centres (consisting of two chelate rings) occupying axial positions and being in *trans* positions with respect to each other.

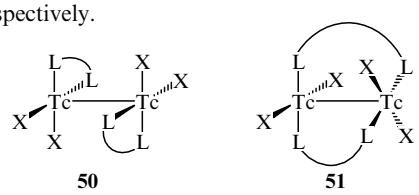
5. Complexes with the metal–metal bond, carbonyl complexes

The data on complexes containing multiple Tc–Tc bonds are scarce. Thus several diamagnetic phosphine ditechnetium(II) complexes of the $Tc_2Cl_4(PR_3)_4$ type (**49**) were described.[160] These complexes contain a triple bond between the metal atoms and provide the first examples of phosphine complexes possessing a multiple technetium–technetium bond.

$$TcCl_4(PR_3)_2 \xrightarrow[PhH,\ PhH,\ utrasonics]{PhMe,\ 50-55\ ^\circ C\ or} \underset{\mathbf{49}\ (>90\%)}{\text{image_ref 2}}$$

PR_3 = PEt_3, PPr^n_3, $PMePh_2$, PMe_2Ph.

The polymeric chain structure of $[Tc_2Cl_6]^{2n-}_n$ also contains triple metal–metal bonds.[273] The triple Tc≡Tc bond was found in the α and β forms of the $Tc_2Cl_4(dppe)_2$ complex.[274] The α isomer **50** adopts an eclipsed conformation; the Tc–Tc distance is 2.15(1) Å. In the β isomer **51**, the twist angle is 35(2)° and the Tc–Tc distance is 2.117(1) Å. These isomeric complexes were prepared by refluxing $Tc_2Cl_4(PR_3)_4$ (PR_3 = PEt_3 or PMe_2Ph) in toluene in the presence or in the absence of an excess of dppe, respectively.



50 **51**

L = dppe, X = Cl.

Complexes containing the multiple Tc–Tc bond of order 3.5 were synthesised in high yields by one-electron chemical oxidation of the $Tc_2Cl_4(PMe_2Ph)_4$ complex with ferrocenium hexafluorophosphate in acetonitrile.[275] In this study, the cationic $[Tc_2Cl_4(PMe_2Ph)_4](PF_6)$ complex was prepared.[275] Oxidation in the presence of bis(triphenylphosphine)iminium produced the neutral $Tc_2Cl_5(PMe_2Ph)_3$ complex.[275] The complexes $Tc_2Cl_4(PR_3)_4$ **49** (PR_3 = PEt_3, $PMePh_2$ or PMe_2Ph) reacted with molten diphenyl- or di-*p*-tolylformamidine to give mixtures of formamidine-bridged complexes of the general formula $Tc_2(L)_4Cl_n$ (n = 1 or 2) in moderate yields.[276] Complexes with the triple Tc≡Tc bond, for example $[Tc_2(MeCN)_{10}](BF_4)_4$,[277] in an acetonitrile solution can undergo photodissociation to give the $[Tc(MeCN)_6]^{2+}$ ions in almost quantitative yields.[278] A decaacetonitrile binuclear complex with the triple Tc≡Tc bond was obtained in good yield by acidification of a solution of $Tc_2Cl_4(PR_3)_4$ in a mixture of acetonitrile and dichloromethane using $HBF_4 \cdot Et_2O$.[277] The $[Tc_2Cl_8]^{n-}$ (n = 2, 3 or 4) and

$[Mo_2Cl_8]^{m-}$ ($m = 4$ or 5) clusters were studied by theoretical methods.[279]

Of other types of Tc complexes, noteworthy are Tc carbonyl derivatives.[280–282] The $Tc(CO)_5I$ complex, which is isostructural to the $Mn(CO)_5I$ complex, exists as orthorhombic crystals. Its crystal structure consists of $Tc(CO)_5I$ molecules. The crystals of $[Tc(CO)_4I]_2$ are monoclinic and are also built of individual $[Tc(CO)_4I]_2$ molecules. Complexes with composition $[M(CO)_4X]_2$ (M = Mn, Tc or Re; X = Cl, Br or I) are isostructural. The main types of technetium complexes are given in Table 9.

* * *

In spite of the difficulties associated with operations with radioactive elements, their complexes are being studied intensively. The development of the coordination chemistry of these compounds, particularly, of those containing radioactive elements in unusual oxidation states,[24] is dictated both by the possibility of their practical use and theoretical interest. Thus considerable recent attention has been given to bimetallic complexes of 5*f* elements in connection with a search for new unusual properties and molecular structures. Investigations and a search for new uranium(V) complexes remain to be of great importance. Information[166,167] on the unique activities of alkylcyclopentadienyl derivatives $Cp^*_2AnR_2$ (An = Th or U; R = H or Alk) as catalysts of alkene hydrogenation and polymerisation gave impetus to studies in this field of chemistry. These compounds proved to be ten times more active than traditional Pt/SiO_2 catalysts. Hence, actinide complexes are of interest from the viewpoint of extension of the scope of their use in catalysis, as the starting compounds in organometallic synthesis[17,24] and for separation and extraction of actinides.[283]

We are grateful to Professor M Ephritikhine (Service de Chimie Moleculaire, France) for permission to reproduce schemes from his articles and Professors A D Garnovskii (Rostov State University, Russia) and S S Berdonosov (Moscow State University, Russian Federation) for valuable advice.

Table 9. Synthesis of technetium complexes with oxygen-, sulfur-, nitrogen- and phosphorus-containing ligands.

Starting compound	Reagent and reaction conditions	Products	Ref.
Complexes with oxygen- and sulfur-containing ligands			
$KTcO_4$		$Tc(DBCat)_3$, $Tc(DBCat)_2(DBAP)$	257
$Tc(PPh_3)_2(CO)_3Cl$	$LiOC_6H_4CH=N(CSNC_3H_2)$, THF	$Tc(PPh_3)_2(CO)_2 \cdot [(C_3H_2NSC)N=CHC_6H_4O]$	266
$Tc(CO)_5X$ (X = Cl, Br, I)	H_2O	$[Tc(CO)_3(H_2O)_3]^+$	282
Complexes with nitrogen-containing ligands			
$Tc_2Cl_4(PR_3)_4$ (PR_3 = PEt_3, PMe_2Ph, $PMePh_2$)	(1) Bu_3SnH or Zn (2) MeCN, HBF_4	$[Tc_2^{II}(MeCN)_{10}](BF_4)_4$ (see [a])	277
$[TcCl_6]^{2-}$	(1) Bu_3SnH or Zn (2) MeCN, HBF_4	$[Tc_2^{II}(MeCN)_{10}](BF_4)_4$	277
$(Bu_4N)(TcOCl_4)$	Cys [b]	$HTcO(Cys)_2$	258
$TcCl_3(PPh_3)_2(MeCN)$	$Bu^t_3(tpy)$, DME	$TcCl_3[Bu^t_3(tpy)]$	237
NH_4TcO_4	 , MeOH	$TcCl_3(\eta^1\text{-}NNC_5H_4NH)(\eta^2\text{-}HNNC_5H_4N)$	238
Complexes with phosphorus-containing ligands			
$Tc_2Cl_4(PMe_2Ph)_4$	$(Cp_2Fe)(PF_6)$	$[Tc_2Cl_4(PMe_2Ph)_4](PF_6)$ [c]	275
$NH_4(TcO_4)$	PR_3, MeOH (R = Et, Pr) (see [d])	$[TcO_2(PR_3)_3]^+$	234
$[TcO_2(PR_3)_3]^+$ (R = Et, Pr)	PR_3, MeOH, Py (R = Et, Pr)	$[TcO_2(PR_3)_3(Py)_2]^+$	234
$TcCl_3(PPh_3)_2(MeCN)$	TMEDA, PhMe, DME	$TcCl_3(PPh_3)_2(TMEDA)$	237
	Py	*mer*-$TcCl_3(Py)_2$	241
$TcCl_4(PPh_3)_2$	PR_3 (R = Et, Pr^n), THF	$TcCl_4(PR_3)_2$	160
$TcCl_4(PEt_3)_2$	Zn, PhH, utrasonics	$Tc_2Cl_4(PEt_3)_4$	160

[a] The yield was 50%, the Tc—Tc multiple bond is present; [b] Cys is an aqueous solution of cysteine chloride monohydrate; [c] the multiple Tc—Tc bond is present; [d] the yield was 60%–70%; a ~10-fold excess of the ligand was used; there was no need for the use of reducing agents; the reaction was accompanied by the formation of NH_3.

Abstract. Data on the structure, synthesis, stability and reactivity of sulfur-containing reducing agents with C – S or S – S bonds — sodium dithionite, sodium hydroxymethanesulfinate and thiourea oxides — are surveyed. Reactions of anaerobic and aerobic decomposition of sulfur-containing reducing agents are discussed. The applications of these compounds in the studies of non-linear phenomena in chemical kinetics and in guanidine syntheses are considered. The bibliography includes 165 references.

I. Introduction

Compounds containing an S – S or C – S bond, namely, sodium dithionite, sodium hydroxymethanesulfinate (HMS, commercial name rongalite) and thiourea dioxide (TUDO), have long been used in chemistry and chemical technology as reducing agents. The traditional fields of application including printing and dyeing of textiles,[1] production of synthetic rubber,[2] manufacture of uranium and transuranium element compounds,[3] preparative organic[4] and inorganic[5] chemistry have been covered fairly comprehensively in monographs.[6,7] In recent years, some new fields of application appeared and the above-mentioned fields (mainly, organic synthesis[8,9]) have been further developed. In particular, increasing numbers of publications are devoted to the use of these compounds in biochemistry,[10–12] in organofluorine chemistry,[13] and in investigations of non-linear phenomena in chemical kinetics.[14,15] A promising field of application of thiourea dioxides and the products of their oxidation, trioxides, is the synthesis of guanidines.[16–20] The researchers' interest in the guanidine properties, which has increased in recent years,[21,22] is due to the discovery of an important biological function of nitrogen oxide, the precursor of which in an organism is L-arginine (2-amino-5-guanidinovaleric acid), and to the search for new medical drugs.[18,20] Thus, there is a need for a review that would reflect the state-of-the-art of the chemistry of sulfur-containing reducing agents.

II. The structure of molecules of sulfur-containing reducing agents

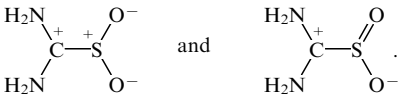
The molecular structures of sodium dithionite, HMS and TUDO have been studied in detail by IR and Raman spectroscopy and by X-ray diffraction analysis. The structure of sodium dithionite has aroused the greatest interest. Seemingly, the structure of the $S_2O_4^{2-}$ ion should resemble the structures of well-known sulfur-and-oxygen anions with the S – S bonds, *e.g.*, $S_2O_5^{2-}$ and $S_2O_6^{2-}$ (see Ref. 23). One might expect that $S_2O_4^{2-}$ and $S_2O_6^{2-}$ ions would correspond to D_{3d} and C_{2h} point groups of symmetry, respectively. This prediction came true only for the latter anion, while for sodium dithionite, unexpected results were obtained. According to X-ray diffraction data,[24,25] the $S_2O_4^{2-}$ ion belongs to the C_{2v} point group and contains an abnormally long S – S bond (2.39 Å). Later, it was shown by Raman spectroscopy[26,27] that in aqueous solutions of sodium dithionite, the structure of the $S_2O_4^{2-}$ ion changes, namely, it becomes centrosymmetrical and corresponds to the C_{2h} point group. The influence of the nature of the salt cation on the structure of the dithionite ion has been studied.[23] It was shown that the 'abnormal' eclipsed conformation (C_{2v}) of $S_2O_4^{2-}$ can be found in salts with small cations, for example, with sodium. In the salts with large cations, in particular, in tetraethylammonium dithionite, this anion is centrosymmetrical both in the solid state and in solution. Thus, the abnormal structure of sodium dithionite in the solid phase is due to the influence of the cation and to the associated packing effects[23] rather than to the properties of the $S_2O_4^{2-}$ anion itself. These experimental data were substantiated theoretically by the results of LCAO-X_α density functional calculations.[28] It was shown that the curve for the total energy *vs.* S – S bond length for dithionite ion, unlike these curves for $S_2O_6^{2-}$ or $S_2O_5^{2-}$ ions, has a very broad minimum. This indicates that the S – S bond length in $S_2O_4^{2-}$ depends appreciably on external factors, in particular, on the packing effects in the crystal. It was also found that the barrier to rotation in the dithionite ion is very low. This accounts for the easy dehydration of $Na_2S_2O_4 \cdot 2H_2O$ and the concomitant change in the dithionite structure (for example, the S – S bond length increases from 2.298 Å in the dihydrate to 2.393 Å in the anhydrous salt). Therefore, it can be expected that the properties of solid dithionites should depend on the nature of solvents from which they have been crystallised. Indeed, it has been demonstrated in relation to lithium dithionite[29] that the products isolated from aqueous and tetrahydrofuran solutions have different properties; in particular, the latter is extremely susceptible to oxidation and to self-ignition in air. When lithium dithionite is stored in a sealed capillary, its

crystal lattice is transformed giving rise to defects, and this accelerates solid-phase processes. A similar transformation but taking place at elevated temperatures was observed for the sodium salt. Thus, conditions used to prepare dithionites affect appreciably their properties. A substantial dependence of the stability on the nature of the solvent used for recrystallisation is also typical of solid sodium hydroxymethanesulfinate.[30]

Due to the long and rather weak S–S bond, dithionites tend to undergo homolytic decomposition giving rise to the $SO_2^{-\bullet}$ radical anions. The structural parameters of the $SO_2^{-\bullet}$ radical anion have been determined;[31] the (*r*) S–O distance is 1.523 ± 0.02 Å, the O–S–O angle (α_{O-S-O}) is $115.6 \pm 2.0^\circ$. The structures of the $SO_2^{-\bullet}$ radical anion and the $NaSO_2$ charge transfer complex were also determined by *ab initio* calculations.[32]

According to X-ray diffraction studies,[33] HMS is the sodium salt of hydroxymethanesulfinic acid, $HOCH_2SO_2Na$. The crystal lattice parameters of HMS and the interatomic distances in the $HOCH_2SO_2^-$ anion were determined; the C–S bond was found to be the longest one (1.838 Å).

X-Ray diffraction analysis of TUDO was first performed by Sullivan and Hargreaves;[34] later, the data were refined.[35,36] In the solid phase, TUDO exists as $(NH_2)_2CSO_2$. The CSO_2 group is pyramidal, the S–O and C–N bond lengths are 1.496 and 1.296 Å, respectively, and the C–S bond (1.867 Å) is much longer than this bond in the thiourea (1.716 Å) molecule. The bond lengths in the TUDO molecule found from X-ray diffraction data are in good agreement with the results of *ab initio* calculations.[36] It was suggested that TUDO is a combination of two zwitter-ion forms



In these ions, the negative charge is concentrated on the oxygen and nitrogen atoms and the positive charge is on the hydrogen, carbon and sulfur atoms, mainly, on sulfur. The results of calculations indicate that nucleophilic attack is directed at the carbon and sulfur atoms. The structure of thiourea dioxide depends substantially on the solvent. It was found[37] that after dissolution of TUDO in water, the acidity increases, a constant pH value being established very slowly. It was found in special experiments that these changes are not related to decomposition of TUDO or to the presence of oxygen. The ^1H NMR spectra of aqueous[38] and dimethyl sulfoxide[39] solutions of TUDO were found to vary with time. The peak observed initially in the TUDO spectrum is rapidly split into a doublet, these changes taking place only in the first minutes after dissolution of thiourea dioxide. Quantum-chemical calculations by the AM1 method for TUDO in the $(NH_2)_2CSO_2$ and $NH_2C(=NH)SO_2H$ (aminoiminomethanesulfinic acid) forms[40] showed that solvation with water or dimethyl sulfoxide decreases substantially the total energy of the system. Note that unlike the gas phase, in aqueous solutions, aminoiminomethanesulfinic acid is the thermodynamically more stable form. Thus, quantum-chemical calculations imply the possibility of TUDO tautomerisation in aqueous solutions. The tautomeric transformations of TUDO in aqueous solutions have been studied theoretically using the method of critical points on the potential energy surface.[41] The most probable mechanism of tautomerisation includes stages of successive intermolecular proton transfer in TUDO oligomers and decomposition of the oligomers to give solvated monomers of aminoiminomethanesulfinic acid.

The structure of thiourea trioxide (TUTO) has also been studied.[42] It was found that the C–N bonds in TUTO are virtually equivalent (1.298 and 1.297 Å) and are much shorter than the typical C–N single bond (1.470 Å), while the C–S bond length (1.815 Å) is slightly greater than the sum of the covalent radii of the S and C atoms (1.790 Å). The tetrahedral S atom forms three nearly equivalent S–O bonds (1.439, 1.431, and 1.446 Å). The structures of thiourea di- and trioxides are stabilised by intermolecular hydrogen bonds.[36,42] The unusually high density calculated[42] for TUTO, 1.948 g cm^{-3} (the density of thiourea dioxide is[36] 1.70 g cm^{-3}) points to a highly efficient packing of $(NH_2)_2CSO_3$ molecules in the crystal lattice. Apparently, the structure of TUTO is similar to that of TUDO.

The research into the structures of sodium dithionite, HMS and TUDO showed that each of these molecules contains an abnormally long bond, which is, hence, highly prone to rupture (S–S bond in the dithionite and C–S bonds in HMS and TUDO). It is this structural feature that accounts for the high reducing activities of these compounds. As will be shown below, the chemical reactivities of dithionites, HMS, TUDO and their analogues are governed by transformations of the same intermediates, namely, sulfoxylic acid H_2SO_2 or its anions and the $SO_2^{-\bullet}$ radical anion. This fact, together with the similarity of methods for the use of these compounds explain why they have been combined in one group.

III. Classification of sulfur-containing reducing agents and the fields of their application

The sulfur-containing reducing agents considered here (Table 1) can be classified into dithionites, α-hydroxyalkanesulfinates, and thiourea dioxides.

Thiourea trioxides are also included in Table 1. Data on α-aminoalkanesulfinates not reflected in the Table can be found in a monograph.[7] Note that the properties of most of compounds listed in Table 1 have been little studied. The only exceptions are sodium dithionite, HMS and TUDO, which have found wide practical use. Sodium dithionite and hydroxymethanesulfinate are used most often for the reduction of vat dyes in textile industry.[1] The processes involving these reducing agents form the basis of all industrial printing and vat dyeing techniques. The textile industry also makes use of zinc hydroxymethanesulfinates, which possess a lower reducing activity than HMS.[6] Conversely, α-hydroxyethanesulfinate is a stronger reducing agent than HMS.[7]

An important application of HMS and TUDO is the manufacture of synthetic rubber.[2] For instance, a mixture of HMS with isopropylbenzene hydroperoxide and ethylenediaminetetraacetatoferrate(III) initiates copolymerisation of butadiene with styrene. The Fe^{2+}–TUDO–H_2O_2 system is used to initiate polymerisation of various vinyl monomers.[59] Other effective initiating systems are TUDO–$KBrO_3$[60] and TUDO–$KMnO_4$.[61] In addition, TUDO is used for waste paper processing[62] and for wool bleaching.[63] Numerous publications have been devoted to the use of the reducing agents in question, mainly sodium dithionite, in biochemistry.[10–12,64–66] Sodium dithionite is used for the reduction of many natural and synthetic electron transfer agents including nicotinic acid derivatives, flavins and cytochromes;[64,65] TUDO is used for reduction of ferredoxin, cytochrome C and other substrates[66] and for inactivation and modification of cytidine triphosphate synthase.[11,12] *N*,*N*′-Dimethylthiourea is a highly efficient antioxidant, which has found wide use in biochemical and medical research.[67] Thus the reaction of hydrogen peroxide with *N*,*N*′-dimethylthiourea, resulting in the dioxide, can be used to determine the content of H_2O_2 in biological systems.[55]

Sulfur-containing reducing agents are widely used in organic synthesis. Thus sodium dithionite serves as the reagent for the reduction of nitro, nitroso, azido and azo compounds, aldehydes, ketones, keto esters, benzyls, quinones, heterocycles, and compounds with double bonds as well as for the synthesis of sulfones.[4] Hydroxymethanesulfinate and thiourea dioxide are used in similar processes, in particular, in the preparation of a light-stabiliser for plastics, Benazol P,[68] a stabiliser for motor oils called Diafen FP[69] and sulfones.[70–74] In recent years, the possibility of using these reducing agents in the chemistry of organofluorine compounds has been studied intensively.[13,75] Thiourea dioxide is also employed to reduce organosulfur compounds (sulfylimines, sulf-

oxides, disulfides),[76,77] for the preparation of a number of compounds of selenium and tellurium[78,79] and deoxygenation of various heteroaromatic *N*-oxides;[8] in addition, it serves as a convenient reductant in phase transfer catalysis.[76,80] Sodium hydroxymethanesulfinate is also utilised in the syntheses of various compounds of selenium and tellurium[81,82] and for the preparation of sultins.[9]

An important application of thiourea oxides is the synthesis of guanidines and their derivatives,[16–20,83–85] which consists in the reaction of thiourea oxides with primary[83] or heterocyclic secondary amines, for example, morpholine,[85] or with amino acids[84] and other amino compounds. The reactions of thiourea oxides with amines are carried out in organic solvents (methanol,[83] acetonitrile[85]), while the reactions with amino acids take place in aqueous solutions.[84] The mechanism proposed for this reaction includes the addition of the nucleophile (*i.e.*, amine) to thiourea oxide and decomposition of the intermediate giving rise to guanidine.[85] The use of trioxides is more convenient because it permits the preparation of guanidines[85] and guanidine acids[84] in high yields. Currently, thiourea trioxide is among the most important guanidylating agents used in the syntheses of guanidines with various structures.[18–20,86–98] Unfortunately, the kinetics of the reactions of thiourea oxides with amino compounds has not yet been studied, despite the fact that the interest in guanidines is very high due to the discovery of the crucial role of nitrogen oxide in functioning of the vascular system.[99–101] It was found that it is the guanidine fragment of L-arginine that is oxidised *in vivo* to give citrulline and nitrogen oxide (in a recent publication,[87] the possibility of using thiourea trioxide in the syntheses of L-arginine derivatives is demonstrated). Guanidines have proved efficient in the treatment of cardiovascular diseases.[100] Thus chemists of the Du Pont company have developed the Du P 714 preparation,[18] which prevents thrombus formation; this synthesis was a success only when thiourea dioxide was used to introduce the guanidine group. The attempts to synthesise this preparation using other guanidylating agents failed. Thiourea trioxide[86–98] and *N*-phenylthiourea trioxide[16] have also been employed for the preparation of other medicinal drugs. Thiourea trioxides are the initial compounds in the syntheses of aminoiminoethanenitriles, 5-aminotetrazoles, *N*-cyanoguanidines and *N*-hydroxyguanidines.[57] The reaction of $(NH_2)_2CSO_3$ with methyl anthranylate affords 5*H*-quinazolino[3,2-*a*]quinazoline-5,12(6*H*)-dione.[102]

Numerous studies have been devoted to the use of reduction reactions involving HMS and TUDO to produce metals — silver,[103] cadmium,[104] technetium,[105] nickel,[106] and metallic coatings on fibres.[107]

IV. Methods of synthesis of sulfur-containing reducing agents

Metal dithionites are prepared by the reduction of sulfur dioxide with zinc, sodium formate[44] or borohydrides.[43] A method for the synthesis of extra pure sodium dithionite containing 99% of the required substance has been developed.[108] A procedure for the preparation of tetraethylammonium dithionite using ion exchange resins is documented.[45]

Several methods for the synthesis of sodium hydroxymethanesulfinate are known.[6] The preparation of HMS by the reduction of sodium hydroxymethanesulfonate with disperse zinc is used most often.

Thiourea mono-, di- and trioxides are produced upon the oxidation of thiourea with hydrogen peroxide in a neutral medium.[7] The synthesis of TUDO is performed at 0–5°C. Unlike the dioxide, thiourea monoxide is quite unstable. More stable monoxides are formed from thiourea derivatives containing bulky substituents at the nitrogen atoms. Thus *N*-phenyl- and ethylenethiourea monoxides have been prepared.[109] The formation of these compounds in solution was proved by the test reaction with $FeCl_3$, typical of mono-*S*-oxygenated thioamides and thiocarbamates. Neutral aqueous solutions of the monoxides synthesised are stable over a period of 24 h at 0 °C; however, these compounds are exceptionally unstable in the solid state. *N*-Phenyl-, *N*,*N*′-diphenyl-, *N*-*o*-hydroxyphenyl- and *N*-*o*-methoxyphenylthiourea dioxides have been prepared by using sodium molybdate[51] to catalyse the reaction between the corresponding thiourea derivative and H_2O_2. Dioxides of other *N*-aryl-substituted thioureas have also been prepared.[53] Syntheses of *N*-aryl- and *N*-alkyl-substituted thiourea dioxides in 80%–90% yields without catalysts have been reported.[50,110] In order to prepare *N*-phenylthiourea dioxide containing ~100% of the required substance, the synthesis should be carried out at −7 to 12 °C.[17] An attempt to prepare *N*,*N*′-diphenylthiourea dioxide by a procedure proposed previously[53] failed.[17] Thiourea trioxides can be synthesised by treatment of thioureas or thiourea dioxides with three or one equivalent of peracetic acid, respectively.[56] An electrochemical procedure for the synthesis of thiourea trioxides has been proposed.[111]

The major products formed in the reaction of thiourea with hydrogen peroxide in strongly acidic media and in the presence of metal ions are formamidine disulfide salts.[112] There is no consensus of opinion on the mechanism of the reaction between thiourea and H_2O_2. The kinetics and the mechanism of the reactions of thiourea and *N*,*N*′-dialkylthiourea with hydrogen peroxide in acid media have been studied.[113] Presumably, in this case, these thioureas act as nucleophiles by replacing the peroxide oxygen, *i.e.*, the reaction does not involve free radicals. However, the use of spin traps, namely, *N*-benzylidene-*tert*-*N*-butylamine *N*-oxide and 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) allowed detection of the carbamidinothiyl radical $NH_2(=NH)CS^{\bullet}$ upon oxidation of thiourea with hydrogen peroxide.[114] The stability of this radical was found to depend substantially on the medium pH, the most intense EPR signal being observed at 2.5–3.0.

V. The kinetics and mechanisms of reactions involving sulfur-containing reducing agents

Decomposition of sulfur-containing reductants and their reactions with oxidants are closely interrelated because they proceed *via* the formation of the same intermediates. Therefore, we shall first consider the results of research into decomposition of sulfur-containing reducing agents. The stability of these compounds in aqueous solutions depends appreciably on the pH. Sodium dithionite and HMS are less stable in acid media.

Oxygen-free decomposition of sodium dithionite in acid solutions has been studied in detail.[115,116] Polarography was used to measure the time variation of the concentrations of dithionite and the products of its decomposition, which include sulfide, sulfite, thiosulfate, and active sulfur (S_a); the term 'active sulfur' implies atomic sulfur, the $S\cdot H_2O$ hydrate, the HSOH thioperoxide, the polymeric biradical and sulfur in a polysulfide chain.

Decomposition was found to be autocatalytic, active sulfur and sulfide functioning as the catalysts. The influence of sulfide, sulfite, thiosulfate and sulfur dichloride additives (and also of mixtures of these compounds) on the rate of dithionite decomposition has been studied.[115] On the basis of the results obtained, it was concluded that the following reactions are responsible for the dithionite decomposition:

— non-catalysed reaction proceeding during the induction period,

$$2\,H_2S_2O_4 \longrightarrow S_a + 3\,SO_2 + 2\,H_2O; \quad (1)$$

— autocatalytic reaction mainly proceeding at the fast decomposition stage,

$$3\,H_2S_2O_4 \longrightarrow H_2S + 5\,SO_2 + 2\,H_2O. \quad (2)$$

Simultaneously, a series of side reactions take place. On the basis of experimental data,[115] a mathematical model of the dithionite decomposition was proposed.[116] Calculations performed in terms of this model made it possible to estimate the

contribution of individual homogeneous reactions and to demonstrate that the proposed two-stage scheme is adequate to describe the real mechanism of decomposition.

Non-catalysed and catalysed decomposition of sodium dithionite in weakly acidic solutions in the presence of sulfur-containing admixtures has been investigated.[117] Particular attention is devoted to the influence of sulfite. In the opinion of the researchers cited,[117] in the case of a high sulfite concentration in the solution, decomposition of $S_2O_4^{2-}$ can follow two mechanisms, a heterolytic and a homolytic one. The former includes the following stages:

$$S_2O_4^{2-} + HSO_3^- \longrightarrow [O_2S(O_2)S-SO_2OH]^{3-}, \quad (3)$$

$$[O_2S(O_2)S-SO_2OH]^{3-} + H^+ \longrightarrow S_3O_6^{2-} + H_2O. \quad (4)$$

In this case, reaction (3) is the rate-determining stage. The trithionate formed in reaction (4) participates, together with the $SO_2^{-\bullet}$ radical ion, in the decomposition by the homolytic mechanism

$$S_2O_4^{2-} \rightleftharpoons 2\,SO_2^{-\bullet}, \quad (5)$$

$$HSO_3^- + SO_2^{-\bullet} \rightleftharpoons S_2O_5H^{2-\bullet}, \quad (6)$$

$$S_2O_5H^{2-\bullet} + S_3O_6^{2-} \longrightarrow SO_2 + HSO_3^- + SO_3^{2-} + S_2O_3^{-\bullet}, \quad (7)$$

$$S_2O_3^{-\bullet} + SO_2^{-\bullet} \longrightarrow S_2O_3^{2-} + SO_2. \quad (8)$$

The reaction between two dianions [reaction (7)] determines the rate of the whole homolytic process.

When the sulfite concentration in the solution is low, the process follows a third pathway

$$S_2O_4^{2-} + HSO_3^- \longrightarrow [O_2S(O_2)S-OSOOH]^{3-}, \quad (9)$$

$$[O_2S(O_2)S-OSOOH]^{3-} \longrightarrow S_2O_5^{2-} + HSO_2^-, \quad (10)$$

$$2\,HSO_2^- \longrightarrow S_2O_3^{2-} + H_2O, \quad (11)$$

$$S_2O_5^{2-} + H_2O \rightleftharpoons 2\,HSO_3^-. \quad (12)$$

Unlike the heterolytic mechanism mentioned above, in this pathway, the initial reaction is the transfer of an oxygen atom from the bisulfite ion to the dithionite sulfur atom.

A serious drawback of the mechanisms proposed by Holman and Bennett [117] [see reactions (3)–(12)] is that nothing is said about the role of sulfur or sulfides in the dithionite decomposition. This is explainable for a large excess of sulfite present because in acid media, HSO_3^- rapidly reacts with sulfur and sulfides, which virtually cancels out their effect on the dithionite decomposition. However, in the case of low initial concentrations of sulfite in the solution, the influence of sulfur or sulfide, which are the main products of dithionite decomposition in acid media, cannot be neglected.

Decomposition of sodium hydroxymethanesulfinate in acid media has been studied.[118, 119] This process is autocatalytic, being accelerated by active sulfur. The catalytic effect of S_a is attributable to its influence on the decomposition of sodium dithionite, which is one of the main intermediate compounds formed upon decomposition of HMS. The following sequence of reactions was proposed as taking place during oxygen-free decomposition of HMS in acidic aqueous solutions:

$$HOCH_2SO_2^- \rightleftharpoons HSO_2^- + CH_2O, \quad (13)$$

$$2\,HSO_2^- \longrightarrow S_2O_3^{2-} + H_2O, \quad (11)$$

$$S_2O_3^{2-} \rightleftharpoons S_a + SO_3^{2-}, \quad (14)$$

$$SO_3^{2-} + H^+ \rightleftharpoons HSO_3^-, \quad (15)$$

$$HSO_2^- + HSO_3^- \rightleftharpoons S_2O_4^{2-} + H_2O, \quad (16)$$

$$S_2O_4^{2-} \rightleftharpoons 2\,SO_2^{-\bullet}. \quad (5)$$

An important role in the mechanisms of decomposition of sodium dithionite as well as HMS and TUDO is played by reaction (5), *i.e.*, the homolytic cleavage of $S_2O_4^{2-}$.

The equilibrium constant of reaction (5) at 298 K is equal to 1.4×10^{-9} mol litre^{-1} (see Ref. 120). Studies of the temperature dependence of this equilibrium constant gave quite contradictory results. Thus it has been found [121] that an increase in the temperature from 298 to 353 K results in a 10-fold increase in the concentration of the $SO_2^{-\bullet}$ radical anion, which entails an increase in the equilibrium constant of reaction (5) by a factor of 10. A similar pattern of dependence of the constant on the temperature was also indicated by other researchers.[122] However, according to some other studies,[120, 123, 124] the increase in the equilibrium constant upon an increase in the temperature is much more gradual.

In view of the inconsistency of the data on the temperature dependence of the equilibrium constant, the thermodynamic characteristics of reaction (5) were determined using other methods.

The standard enthalpies of formation (Δ_fH°) of the $SO_x^{-\bullet}$ ($x = 2-4$) radical anions were calculated.[125] The $\Delta_fH^\circ(SO_x^{-\bullet}, 298)$ values in an aqueous solution were determined on the basis of thermodynamics data for liquid-phase decomposition of ions of the $[R-R]^{2-}$ type including the dithionite ion:

$$[R-R]^{2-} \rightleftharpoons R^{-\bullet} + R^{-\bullet}. \quad (17)$$

The standard enthalpy of formation of the product of this reaction can be estimated using the following relation:

$$\Delta_fH^\circ(R^{-\bullet}, 298) = 0.5\,\{\Delta_rG^\circ(298) + T\Delta_rS^\circ(298) + \Delta_fH^\circ([R-R]^{2-}, 298)\}, \quad (18)$$

where $\Delta_rG^\circ(298)$ and $\Delta_rS^\circ(298)$ are the change in the standard Gibbs energy and the standard entropy in reaction (17) at 298 K, respectively, $\Delta_fH^\circ([R-R]^{2-}, 298)$ is the standard enthalpy of formation of the $[R-R]^{2-}$ ion at 298 K.

The $\Delta_rG^\circ(298)$ (52.3 ± 1.3 kJ mol^{-1}) and $\Delta_fH^\circ(S_2O_4^{2-}, 298)$ (-753.7 kJ mol^{-1}) values for the decomposition of $S_2O_4^{2-}$ are known. The uncertainty in $T\Delta_rS^\circ(298)$ is due to the absence of data on the standard entropy of formation of the $SO_x^{-\bullet}$ anion at 298 K [$S_f^\circ(SO_x^{-\bullet}, 298)$]. These values were estimated using the empirical dependence of the standard entropy of the $[R-R]^{2-}$ oxy anion on its mass (M), charge (Z), the distance between the central atom and the peripheral oxygen atoms (r), and the empirical factor (f) that takes into account the ion geometry

$$S_f^\circ(298) - 6.3\,R(\ln M) = 276 - 338.6\,(Z/\rho), \quad (19)$$

where R is the universal gas constant, ρ is an empirical variable equal to r/f. For $SO_2^{-\bullet}$, the ρ value was found proceeding from the values $r = 0.151$ nm, $f = 0.87 \pm 0.11$. The $S_f^\circ(SO_2^{-\bullet})$ value at 298 K found on the basis of relation (19) amounted to 134 ± 25 J mol^{-1} K^{-1} [for the dithionite ion, $S_f^\circ(S_2O_4^{2-}) = 104.5$ J mol^{-1} K^{-1}]. The $\Delta_rS^\circ(298)$ value for reaction (5) corresponding to these parameters is equal to 163.5 ± 50 J mol^{-1} K^{-1}. The $\Delta_fH^\circ(SO_2^{-\bullet}, 298)$ value determined from Eqn (18) amounts to -326.5 ± 8 kJ mol^{-1}. The researchers cited [125] did not compare the resulting $\Delta_rH^\circ(298)$ (100.7 ± 17 kJ mol^{-1}) with the values found from the temperature dependence of the equilibrium constant of reaction (5). It is noteworthy that this value is close to $\Delta_rH^\circ(298) = 89.1$ kJ mol^{-1}, presented in a publication.[122] Unfortunately, the standard enthalpies and entropies of formation of the sulfoxylate ion SO_2^{2-} have not been determined yet.

Equilibrium (5) in aprotic media has been studied using tetraethylammonium dithionite.[45] It was shown by EPR and UV spectroscopy that the $S_2O_4^{2-}$ dimer dissociates to give the $SO_2^{-\bullet}$ radical anions in DMF, DMSO and acetonitrile, the equilibrium constants in non-aqueous solvents being 10^7 times as high as that in water. Thus, the equilibrium constant for reaction (5) depends appreciably on the nature of the solvent.

Unlike HMS or sodium dithionite, TUDO is much less stable in alkaline solutions than in neutral or acidic solutions.

Comparative investigation of the composition of the products of decomposition of thio- and *N*-phenylthiourea di- and trioxides

and *N*,*N*′-diphenylthiourea trioxide in neutral and alkaline solutions has been carried out.[17] Ureas are the major products of thiourea dioxide decomposition in alkaline media. Conversely, decomposition of thio- and *N*-phenylthiourea trioxides affords mainly cyanamides (pH 13–14) (*N*,*N*′-diphenylthiourea trioxide is mainly converted into *N*,*N*′-diphenylurea). In less alkaline solutions (pH 10), the percentage of ureas in the products of dioxide decomposition decreases, while the content of cyanamides increases. Under similar conditions, thiourea trioxide gives melamine in 52% yield; the formation of cyanoguanidine (dicyanodiamide) was also detected (the formation of substituted triazine related to melamine has been observed previously in the decomposition of *N*-propylaminoiminomethanesulfonic acid in the presence of *tert*-butylamine [16]). Presumably, a product of self-condensation of TUTO is formed intermediately in the reaction of melamine formation.

The essentially different decomposition mechanisms of thiourea dioxides and trioxides and, as a consequence, different compositions of the reaction products have been attributed,[17] first of all, to the different stabilities of $NH_2NHRCSO_2$ and $NH_2NHRCSO_3$ in alkaline media (R = H, Ph). The trioxide is assumed to be much more stable in solution than the dioxide; however no experimental evidence supporting this assumption is available. No data on the sulfur-containing products of decomposition of thiourea oxides are available either.

It has been assumed [126] that an important role in the decomposition of TUDO is played by dithionite ions and the $SO_2^{-\bullet}$ radical anions. The appearance of these species in alkaline solutions of TUDO was detected by polarography and interpreted as being due to the reaction

$$(NH_2)_2CSO_2 + OH^- \longrightarrow HSO_2^- + (NH_2)_2CO, \quad (20)$$

as well as reactions (5) and (16) presented above. Presumably,[126] decomposition of TUDO gives sulfoxylate as the primary product [however, it is not indicated what process is responsible for the formation of sulfite needed for the formation of dithionite by reaction (16)]. Yet another mechanism of TUDO decomposition has also been proposed;[104] according to this mechanism, the strong reducing properties of TUDO in alkaline media are due to the homolytic decomposition of the $H_2N(=NH)CSO_2^-$ anion to give reactive species, $SO_2^{-\bullet}$ and $(NH_2)_2C^{\bullet}OH$. It has also been suggested [127] that the $SO_2^{-\bullet}$ radical anion (in the aqueous alkali–ethanol system) is formed as the primary product of TUDO decomposition.

Unfortunately, in most of the above-mentioned studies, no integrated approach is used to investigate the processes of decomposition of sulfur-containing reducing agents. This is especially true for thiourea oxides. The transformations of their 'sulfur' and 'nitrogen' components have been studied independently by chemists working in different fields. The former, 'sulfur' part has been studied by inorganic chemists and specialists in chemical kinetics, while the latter, 'nitrogen' part has been an object of investigations of organic chemists and biochemists. These investigations have not been connected with one another and, moreover, the results have been published in journals of different disciplines. The fewness of kinetic data concerning the processes of decomposition of sulfur-containing reducing agents also appears surprising. Data on the decomposition mechanisms are fragmentary and often contradictory. Unfortunately, in many publications, no attention is paid to the role of oxygen in the decomposition of the compounds in question. Often, it is even impossible to grasp whether the reaction was carried out in an inert atmosphere or in air (this is especially typical of papers in organic chemistry). It will be shown below that it is the effect of oxygen on the composition of the intermediate and final products in the decomposition of sulfur-containing reducing agents that is the main reason for the contradictions mentioned above.

Let us consider the reactions of sulfur-containing reductants with oxygen. Creutz and Sutin,[128] who confirmed the previously proposed [120] mechanism of the dithionite reaction with oxygen,

$$S_2O_4^{2-} \rightleftharpoons 2\,SO_2^{-\bullet}, \quad (5)$$

$$SO_2^{-\bullet} + O_2 \longrightarrow \text{products}, \quad (21)$$

showed also that the process rate is determined by reaction (5), the rate constant for the forward reaction being virtually independent of the pH: $k = 2.5$ (pH 6.5) and 1.8 s^{-1} (pH 13). The researchers also determined the lower limit for the rate constant for reaction (21): $k_{21} \geqslant 1 \times 10^8$ litre mol^{-1} s^{-1}. Later, the value $k_{21} = 2.4 \times 10^9$ litre mol^{-1} s^{-1} was found.[129]

The kinetics of the reaction of sodium dithionite with hydrogen peroxide has been studied.[128] As in the case of oxygen, the $SO_2^{-\bullet}$ radical anion rather than the $S_2O_4^{2-}$ dithionite ion enters into the reaction with the oxidant. The influence of oxygen on the decomposition of HMS and TUDO has been studied.[119, 130] It was found that in the HMS decomposition under aerobic conditions, the appearance of dithionite is preceded by an induction period, which is missing when the experiment is carried out under an inert atmosphere.[119] Study of decomposition of HMS in the presence of superoxide dismutase, catalase and sodium formate showed that active forms of oxygen (superoxide, peroxide, hydroxyl radicals) have little influence on the rate of dithionite formation. Sulfite additives exert a much more pronounced influence under both anaerobic and aerobic conditions.

Decomposition of air-saturated alkaline solutions of thiourea dioxides is also accompanied by the formation of dithionite, preceded by an induction period.[130] However, unlike HMS, sulfite additives do not affect decomposition of TUDO. In addition, decomposition of thiourea dioxides under anaerobic conditions does not give dithionite. Thus, the $S_2O_4^{2-}$ ion and the $SO_2^{-\bullet}$ radical anion occurring in equilibrium arise upon the reaction of a sulfur-containing product of thiourea dioxide decomposition with oxygen. Apparently,[130] this sulfur-containing product is the sulfoxylate ion SO_2^{2-}. This species reacts with oxygen to give the $SO_2^{-\bullet}$ radical anion, which in turn reacts with oxygen [reaction (23)] and dimerises [back reaction (5)]:

$$SO_2^{2-} + O_2 \longrightarrow SO_2^{-\bullet} + O_2^{-\bullet}, \quad (22)$$

$$SO_2^{-\bullet} + O_2 \longrightarrow SO_2 + O_2^{-\bullet}, \quad (23)$$

$$S_2O_4^{2-} \rightleftharpoons 2\,SO_2^{-\bullet} \quad (5)$$

These reactions occur during the induction period. Since dithionite ion is accumulated after the completion of the induction period, *i.e.*, after oxygen has disappeared, the sulfur-containing species react with superoxide or with the product of its dismutation, peroxide. However, it is known that superoxide is quite stable in strongly alkaline media [131] (most experiments were carried out in a solution of NaOH with a concentration of 0.5 mol $litre^{-1}$) and is unlikely to undergo dismutation over the period of TUDO decomposition. Thus, the peroxide can be formed only upon the reduction of superoxide. This was proved by an independent research of the reaction of TUDO with potassium superoxide in the absence of oxygen. The shape of the resulting kinetic curves was similar to that typical of the curves of TUDO decomposition and dithionite accumulation in the presence of oxygen. The same regularities were also observed in the reaction of TUDO with peroxide under anaerobic conditions; this is due to reactions of the sulfoxylate (arising upon decomposition of TUDO deprotonated in a strongly alkaline medium) and the $SO_2^{-\bullet}$ radical anion with peroxide, giving rise to a hydroxyl radical [represented in Eqns (25) and (26) as the deprotonated form $O^{-\bullet}$]:

$$(NH)_2CSO_2 \longrightarrow SO_2^{2-} + NH{=}C{=}NH, \quad (24)$$

$$SO_2^{2-} + HO_2^- \longrightarrow SO_2^{-\bullet} + O^{-\bullet} + OH^-, \quad (25)$$

$$SO_2^{-\bullet} + HO_2^- \longrightarrow SO_2 + O^{-\bullet} + OH^-, \quad (26)$$

$$S_2O_4^{2-} \rightleftharpoons 2\,SO_2^{-\bullet}, \quad (5)$$

$$NH = C = NH + H_2O \longrightarrow (NH_2)_2CO. \quad (27)$$

Thus, study of the kinetics of reactions of thiourea dioxide with oxygen and its reduced forms made it possible to prove that

the sulfoxylate ion SO_2^{2-} rather than the $SO_2^{-\bullet}$ radical anion, as had been proposed previously,[104] is the primary sulfur-containing product of TUDO decomposition in strongly alkaline media. It is the formation of sulfoxylate that accounts for the strong reducing properties of TUDO in alkaline media.

The aerobic decomposition of *N*-methyl- and *N*,*N*′-dimethylthiourea dioxides follows regularities similar to those considered above for TUDO.[130] *N*,*N*′-Dimethylthiourea dioxide is the most reactive reductant, apparently due to the much higher stability of the intermediate formed primarily in its decomposition, namely, *N*,*N*′-dimethylcarbodiimide, compared to the stabilities of carbodiimide and *N*-methylcarbodiimide.[132] Conversely, the rates of the reactions of oxygen and its reduced forms with *N*-methylthiourea dioxide (MTUDO) are lower than those in the case of TUDO. Among the compounds considered, MTUDO is the most stable. *N*-Phenylthiourea dioxide (PTUDO) also exhibits a higher stability in solutions than TUDO.[133] Data on the reactivity of thiourea dioxides can be important for interpreting the toxicity of thioureas. Many thioureas, especially *N*-substituted ones, are known to be highly toxic. Thus lethal doses of α-naphthyl- and *N*-phenylthioureas amount to 0.5 and 5 mg kg^{-1}, respectively.[17] The toxicity of thioureas is supposed to be due to their oxidation [134–137] and the tendency of the resulting oxides to undergo desulfurisation;[17] the higher this tendency, the more toxic the compound. However, data of some publications [130, 133] are at variance with this conclusion:[17] the rates of desulfurisation of *N*-methyl- and *N*-phenylthiourea dioxides are lower than that of thiourea dioxide; nevertheless, *N*-methyl- and *N*-phenylthioureas are much more toxic than the unsubstituted thiourea. Apparently, there are also other reasons for the high toxicity of *N*-substituted thioureas. Therefore, the formation and the properties of adducts produced by thiourea oxides and proteins are being vigorously studied.[137]

In weakly alkaline solutions of thiourea dioxides, dithionite ions are accumulated much more slowly. Among other reasons, this is due to the sharp increase in the reactivity of hydrogen peroxide upon a decrease in the pH, which results in a change in the mechanism of interaction of H_2O_2 with TUDO. It was found that at pH < 13, TUDO reacts directly with the peroxide to give thiourea dioxide radicals and hydroxyl radicals.[138] The latter have been detected by EPR in the presence of DMPO. Yet another possible reason for the appreciable decrease in the rate of dithionite formation in solutions of thiourea dioxides is a change in the mechanism of their decomposition. To verify this, a comparative kinetic study [138] of the processes of TUDO decomposition and its reactions with oxygen at various pH has been carried out. The rate of the reaction of thiourea dioxide with oxygen at $[TUDO]_0 \gg [O_2]_0$ was found to be described by the equation $v = k[TUDO]$. In nearly neutral and in strongly alkaline media, the rate constants for both processes virtually coincide. However, in the pH range of 9–12, substantial differences are observed: the rate constant for TUDO decomposition increases much more rapidly and reaches a constant level at pH 10, whereas the rate constant for the reaction of thiourea dioxide with O_2 continues to grow even in the pH 10–13.7 range. The non-coincidence of the mechanisms of TUDO decomposition at pH 10 and 13 has been also discovered by other authors. Thus it has been found [139] that the reaction of glycine with TUDO in concentrated ammonium hydroxide solutions affords guanidinoacetic acid in 36% yield. When the reaction is carried out in a solution of K_2CO_3 with a concentration of 1 mol $litre^{-1}$ (pH 10), guanidineacetic acid is not formed.[17] In addition, ammonia was detected upon decomposition of TUDO in this solution [17] (ammonia is also formed when thiourea trioxide decomposes in weakly acidic media [42]). These facts led to the conclusion [138] that decomposition of thiourea dioxide at pH 9–12 follows two pathways. According to one of them, ammonia is eliminated (as this takes place, TUDO loses the guanidylating capacity towards glycine) but the C–S bond is not cleaved, the SO_2^{2-} anion is not formed, and the reaction with oxygen does not occur. Conversely, the second pathway includes a stage of formation of the SO_2^{2-} anion and the C–N bond remains intact; therefore, TUDO actively reacts with oxygen and glycine. It was found[138] that both pathways have a stage of TUDO ionisation. Since the dependence of the rate constant for the reaction of thiourea dioxide on pH is shifted to the region of high pH, the pathway involving the formation of sulfoxylate is assumed to result from decomposition of TUDO dianions. In the TUDO monoanion, the C–N bond is apparently much weaker than the C–S bond; hence, the primary decomposition stage yields ammonia.

In acid media, thiourea dioxide is very stable and barely decomposes at room temperature.[7] On heating in glacial acetic acid, TUDO and some its analogues decompose to give formamidine acetate and sulfur dioxide.[110]

The data presented here indicate that oxygen and active forms of oxygen (AFO) play an important role in the reactions with sulfur-containing reductants. Let us consider published data dealing with the reaction of the TUDO precursor, thiourea, with AFO (oxidation with peroxide has been mentioned above, in the discussion of the methods of synthesis of thiourea oxides). The strongest oxidant among the AFO is the hydroxyl radical.[140] The reaction of thiourea with the $OH^{\bullet}$ radicals proceeds at a very high rate [141] ($k = 1.2 \times 10^{10}$ litre mol^{-1} s^{-1}). The hydroxyl radicals also oxidise very effectively *N*,*N*′-dimethylthiourea [55] and tetramethylthiourea.[141]

The reactivity of the $O_2^{-\bullet}$ superoxide is substantially lower than that of $OH^{\bullet}$ radicals. In aqueous solvents, superoxide reacts with thiourea to give cyanamide.[142] It is assumed that TUDO is formed as an intermediate of this process. The reaction of superoxide with diarylthiourea follows a different pathway [143] giving rise to a substituted guanidine. In nonaqueous solutions, superoxide reduces sulfur dioxide

$$SO_2 + O_2^{-\bullet} \rightleftharpoons SO_2^{-\bullet} + O_2 . \qquad (28)$$

The equilibrium constant for this reaction, calculated on the basis of redox potentials (E°) of the $O_2/O_2^{-\bullet}$ and $SO_2/SO_2^{-\bullet}$ couples, equals 4.8;[144] however, experimental data indicate that reaction (28) proceeds virtually to completion. This is due to the subsequent transformations of the $SO_2^{-\bullet}$ radical anion, namely, dimerisation to give $S_2O_4^{2-}$ and complexation with SO_2. In the aqueous medium, superoxide does not reduce sulfur dioxide: the redox potential of the $O_2/O_2^{-\bullet}$ couple at pH 7 and pH 14 equals −0.16 V; that at pH 0 is +0.12 V;[145] E° of the $SO_2/SO_2^{-\bullet}$ pair is −0.26 V.[146]

In some studies,[147–149] electron transfer reactions in the $O_2/O_2^{-\bullet}$–metal complex systems are considered in terms of the Marcus theory. The equations derived

$$k_{12} = \sqrt{k_{11}k_{22}K_{12}f_{12}} , \qquad (29)$$

$$\log f_{12} = \frac{(\log K_{12})^2}{4\log(k_{11}k_{22}/z^2)} , \qquad (30)$$

where z is a factor taking into account the frequency of collisions of the reacting species in solution, were used to determine the rate constant for the electron exchange in the $O_2/O_2^{-\bullet}$ system (k_{22}) on the basis of known constants for electron exchange in metal complexes (k_{11}) and the experimental rate constants for the reduction of metal complexes by superoxide (k_{12}), for example

$$Co(NH_3)_6^{3+} + O_2^{-\bullet} \longrightarrow Co(NH_3)_6^{2+} + O_2 \qquad (31)$$

[in Eqns (29), (30), K_{12} is the equilibrium constant for reaction of type (31)].

However, the k_{22} values found in these calculations,[147] based on the data on the kinetics of reactions of $O_2^{-\bullet}$ with various metal complexes, varied in the range of 10^{-8}–$10^{5.7}$ litre mol^{-1} s^{-1}. In the opinion of the researchers cited,[145] the unsuitability of the Marcus theory for the calculation of k_{22} was due to the unequal solvations of O_2 and $O_2^{-\bullet}$. Later,[148] a different approach was used to determine the k_{22} values, namely, the kinetics of the reaction of metal complexes with oxygen

$$CrL_3^{2+} + O_2 \longrightarrow CrL_3^{3+} + O_2^{-\bullet}, \quad (32)$$

rather than with superoxide was studied (L is 2,2′-bipyridine, 1,10-phenanthroline and their derivatives).

The use of this approach provided the k_{22} values in the range of 1–10 litre mol^{-1} s^{-1} (in a later review,[150] a value of 10 litre mol^{-1} s^{-1} was recommended). The reasons for the so great difference between the k_{22} values calculated from the data on the kinetics of reduction of complexes with superoxide remain unknown. No corresponding data concerning the superoxide reduction to peroxide can be found from the literature.

Comparison of the rate constants for the reactions of the $O_2^{-\bullet}$ and $SO_2^{-\bullet}$ radical anions with identical oxidants, metal complexes, published in a study is of interest.[149] The ratio of the rate constants for the reactions involving $SO_2^{-\bullet}$ and $O_2^{-\bullet}$ was found to be approximately 10^3; it does not depend on the nature of the oxidant, which is consistent with the Marcus theory and the equation derived from it

$$\frac{k(SO_2^{-\bullet})}{k(O_2^{-\bullet})} = \sqrt{\frac{k(SO_2/SO_2^{-\bullet})}{k(O_2/O_2^{-\bullet})} \cdot 10^{16.9\,\Delta E}}, \quad (33)$$

where $k(SO_2^{-\bullet})$ and $k(O_2^{-\bullet})$ are the rate constants for the reaction of $SO_2^{-\bullet}$ and $O_2^{-\bullet}$ with the same substrate; ΔE is the difference between the reduction potentials of O_2 (−0.16 V) and SO_2 (−0.26 V), and $k(SO_2/SO_2^{-\bullet})$ and $k(O_2/O_2^{-\bullet})$ are the self-exchange rate constants of the $SO_2/SO_2^{-\bullet}$ and $O_2/O_2^{-\bullet}$ systems, respectively.

If we assume that $k(SO_2^{-\bullet})/k(O_2^{-\bullet}) = 10^3$, the $k(SO_2/SO_2^{-\bullet})/k(O_2/O_2^{-\bullet})$ ratio should be equal to $\sim 10^4$.

In most studies devoted to the electron exchange in the $SO_2/SO_2^{-\bullet}$ couple, dithionite served as the source of $SO_2^{-\bullet}$.[149] The $k(SO_2/SO_2^{-\bullet})$ values calculated for the outer-sphere oxidation of CrL_3^{2+} (L is bipyridine, phenanthroline, and their substituted derivatives) with sulfur dioxide were compared with the values determined previously in experiments using $SO_2^{-\bullet}$ as the reagent.[151] It was found that, unlike the $k(O_2/O_2^{-\bullet})$ values, the $k(SO_2/SO_2^{-\bullet})$ constants calculated from the kinetic data for reactions involving SO_2 and $SO_2^{-\bullet}$ are rather close: $k(SO_2/SO_2^{-\bullet}) = (1-18) \times 10^4$ litre mol^{-1} s^{-1} at 298 K. These values are approximately 10^4 times as high as the value $k(O_2/O_2^{-\bullet}) = 10$ litre mol^{-1} s^{-1} reported in a review,[150] which is consistent with the results cited above.[149]

Thus, the published data indicate that the Marcus theory is applicable to the $SO_2/SO_2^{-\bullet}$ and $O_2/O_2^{-\bullet}$ couples. It is noteworthy that the $SO_2^{-\bullet}/SO_2^{2-}$ couple in which $SO_2^{-\bullet}$ is the oxidised form has not been studied. Apparently, this is due to the difficulty of reduction of the $SO_2^{-\bullet}$ radical anion. Oxidation of sulfoxylate would be the preferred variant. The above data indicate that thiourea dioxides can be used as sources of SO_2^{2-}.

Let us consider data on the reactions of thioureas with yet another active form of oxygen, namely, singlet oxygen $^1O_2$. Thus oxidation of thiourea with photochemically generated singlet oxygen has been studied.[152] It was shown previously that solutions of thiourea do not undergo photolysis either in the absence or in the presence of oxygen even on prolonged exposure to UV light. Photooxidation of thioureas was observed when their alcohol solutions containing oxygen and a sensitiser (dye) were exposed to the visible light. The composition of photooxidised products depends on the nature of thiourea and, to a lesser extent, the dye. The major products formed in the reaction of thiourea with $^1O_2$ include SO_2, sulfur and TUDO (the sensitisers used are Methylene Blue or chlorophyll). In the presence of Rose Bengal, the formation of dicyanediamide was also observed.

Photochemical destruction of thiourea was discovered when titanium dioxide was used as the sensitiser.[153] The reaction yields cyanamide and dicyanamide.

The acid HOCl is also an active form of oxygen.[55] The kinetics of reactions of thiourea with oxohalogen compounds draws special attention.[14, 15, 154, 155] Until recently, studies of non-linear phenomena in chemical kinetics have been mainly related to the chemistry of halogens. However, at present, oscillators based on sulfur compounds are becoming more and more important. The combination of halogen and sulfur compounds in one reaction is rather attractive. However, data on the kinetics of such reactions are scarce.

One of the first chemical oscillators based on sulfur-containing compounds[156] is a mixture of sulfide, sulfite, oxygen and the Methylene Blue dye. It has been reported that the reaction between chlorite and thiourea is accompanied by oligo-oscillation.[154] Diverse non-linear effects have been discovered in the reactions of thiourea with iodate, bromate, chlorine dioxide, iodine and bromine.[155, 157, 158] However, the greatest attention of researchers is still attracted by the reaction with chlorite. Nevertheless, there is no consensus of opinion concerning the mechanism of the reaction between thiourea and chlorite. Thus it has been assumed[155] that the protonated form of the chlorite $HClO_2$ is much more reactive than the deprotonated form. However, other researchers[159] hold to the opposite opinion. They proposed a mechanism for the reaction of ClO_2 and $(NH_2)_2CS$, according to which two ClO_2 molecules successively transfer the oxygen atoms to $HOSCNHNH_2$ to give $HO_3SCNHNH_2$. However, other researchers[155] believe that the reaction between ClO_2 and the thiourea monoxide is accompanied by electron transfer giving rise to ClO_2^- and $H_2NNHCSO^\bullet$ (it has been assumed[60] that the reaction of thiourea dioxide with bromate also follows a radical mechanism). It was shown experimentally[155] that the rates of reactions of formamidine disulfide and thiourea dioxide with ClO_2 depend substantially on the time elapsed after the preparation of solutions of the sulfur-containing compounds. This was attributed[155] to accumulation of reactive aminoiminomethanesulfenic acid (thiourea monoxide) in the solution. However, this explanation can hardly be considered to be convincing because thiourea monoxide is exceptionally unstable at 298 K and can hardly be expected to accumulate in solution.

It was shown[158] that, among other reasons, non-coincidence of the kinetic data obtained by different researchers may be due to the influence of impurities of metal compounds, especially copper and iron compounds (Cu and Fe compounds are known to catalyse efficiently the processes of reduction by thiourea). However, the main reason for the inconsistency mentioned above is that no kinetic data concerning individual stages of the multistage reaction between thiourea and oxohalogen compounds have been available until recently. Only in 1993–1995, were reactions between an intermediate of $(NH_2)_2CS$ oxidation, *i.e.* thiourea dioxide, with iodate,[160] bromate[15] and chlorite[14] studied. The kinetic parameters thus found made it possible to correct (in some cases, the corrections were quite significant) the rate constants for the individual stages of thiourea oxidation published previously. However, the reported[14] ratios of the rate constants for reactions of thiourea di- and trioxides with the same oxidants raise doubts. Thus the rate constants for the reactions of TUDO and TUTO with HOCl are nearly equal (9.5×10^3 and 6.5×10^3 litre mol^{-1} s^{-1}) but those for the reaction with ClO_2 differ by a factor of 60 (6×10^2 and 10 litre mol^{-1} s^{-1}, respectively). The reasons for this discrepancy have not been elucidated. The interpretation[161, 162] of the results of kinetic studies of the reactions of hydroxymethanesulfinate with bromate and chlorite in acid media is even more objectionable. Presumably, the reactions of HMS with any oxohalogen compounds either present initially or formed at intermediate stages (BrO_3, $HBrO_2$, HOBr, ClO_2^-, HOCl, ClO_2, Cl_2O_2) afford hydroxymethanesulfonate.[161, 162] As a result of oxidation, this product gives sulfate, *i.e.*, as in the case of reactions involving thiourea, the C–S bond rupture takes place after the appearance of sulfonate. Meanwhile, it is known that hydroxymethanesulfonate is very stable in acid media and does not tend to participate in redox reactions.[7] Conversely, HMS rapidly decomposes in acid solutions, the products of its decomposition exhibiting strong reducing properties. Unfortunately, in the studies cited above,[161, 162] no mention is even made of the HMS decomposition or the role of its products —

sulfoxylate and formaldehyde (later, the same researchers demonstrated [163] that formaldehyde reacts with chlorite at a rather high rate). The results of study of Makarov *et al.*[164] made it possible to introduce substantial changes to the schemes of reactions of halogens and oxohalogen compounds with thiourea, thiourea dioxide and hydroxymethanesulfinate. It was shown [164] that the rates of oxidation of sulfonates (thiourea trioxide and hydroxymethanesulfonate) are much lower than the rates of oxidation of sulfinates (thiourea dioxide and hydroxymethanesulfinate) and even thiourea. Thus, it appears that thiourea trioxide and hydroxymethanesulfonate are not intermediates of the reactions of TUDO, thiourea and HMS with halogens and oxohalogen compounds. During the oxidation of sulfinates, rupture of the C–S bond takes place before the formation of sulfonates.[164] The active reducing agent thus formed, sulfoxylate, is then oxidised to sulfite and sulfate.

VI. Conclusion

The data on the properties of sodium dithionite, sodium hydroxymethanesulfinate and thiourea dioxides considered in the review provide a number of conclusions. An important feature common to these compounds is decomposition in solutions to give strong reducing agents. However, the opposite patterns of dependence of the stability of TUDO and HMS on the pH entail differences between the processes of their decomposition. Indeed, in solutions of HMS, the dithionite ion is formed predominantly according to an 'anaerobic' mechanism, whereas in solutions of TUDO, this occurs by an 'aerobic' mechanism. Sulfur-and-oxygen ions (sulfite, thiosulfate) barely affect the TUDO decomposition, whereas the mechanism of decomposition of hydroxymethanesulfinate largely depends on admixtures. Thus, in the case of HMS decomposition, the subsequent reactions of sulfur-containing compounds are much more significant than in the decomposition of TUDO. Decomposition of HMS is affected most appreciably by dithionite ions. The very low stability of these ions in acid media and the capability of decomposing in aqueous solutions by an autocatalytic mechanism account for the autocatalytic mode of HMS decomposition as a whole. The unique character of dithionite is due to the presence of the very long S–S bond. Therefore, insertion of monoatomic sulfur into the S–S bond becomes possible and, as a consequence, decomposition of dithionite and hydroxymethanesulfinate is accelerated. Conversely, in the thiourea dioxide molecule, direct insertion of sulfur into the shorter C–S bond is difficult. No conjugate pathway for dithionite destruction exists in the decomposition of TUDO (in alkaline solutions of thiourea dioxide under aerobic conditions, dithionite formation does take place but it is much more stable in these media than TUDO).

The following important circumstance should also be mentioned. Thiourea dioxides are the most convenient precursors of the little studied sulfoxylate ion (SO_2^{2-}). This sulfur-and-oxygen ion is quite interesting from both practical and theoretical standpoints. The need to study systematically its properties is due not only to its high reductive activity but also to the fact that sulfoxylate is the possible intermediate in the hydrogen sulfide oxidation.[165] The importance of this process as a part of natural sulfur cycle is beyond doubt.

Abstract. Data on applications of the most important rearrangements of sulfoxides and sulfones to stereoselective total syntheses of natural compounds are systematised. The bibliography includes 175 references.

I. Introduction

Rearrangements of sulfoxides and sulfones along with other reactions of these compounds (see the review [1]) are widely used in stereospecific total syntheses of natural compounds. The mechanisms of the rearrangements of sulfoxides and sulfones were detailed in the reviews.[2, 3] In the present review, syntheses of natural compounds involving these rearrangements as the key stages are surveyed.

In spite of the fact that the Mislow – Evans rearrangement of sulfoxides can be applied only to the construction of allylic alcohol fragments, whereas the Ramberg – Bäcklund rearrangement can be used only for the formation of C = C bonds, both these reactions are often utilised in the syntheses of complex natural compounds. An important point is that the sulfur-containing group is removed in both processes.

The Pummerer reaction is used much more extensively. This rearrangement was discovered in 1910 [4] and did not come to the attention of chemists for 50 years. Once Horner [5, 6] had demonstrated that this reaction has a general character, the Pummerer rearrangement gained wide acceptance. It should be noted that Pummerer appraised the essence of this reaction quite adequately and related it to the lability of the α-hydrogen atom and generation of the sulfenium cation.[4]

Later on, the assumptions made by Pummerer were supported by the fundamental studies of Oae *et al.*[7, 8] devoted to the mechanism of this process.

Different aspects of the synthetic applications of the Pummerer reaction were considered in many reviews, for example, in the reviews [9 – 13] published in the last decade. However, the data on the use of this reaction as well as of other rearrangements for the preparation of natural compounds have not been systematised. The only exception is the review [14] in which consideration was given to the use of additive Pummerer conversions of enantiomerically pure vinyl sulfoxides in asymmetric syntheses of natural compounds.

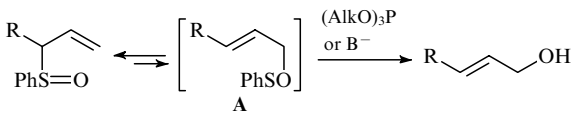
II. Syntheses involving rearrangements of sulfoxides into sulfenates and sulfenates into sulfoxides

The mechanisms of the rearrangements of sulfoxides into sulfenates and sulfenates into sulfoxides and the effects of the structures of the initial compounds and the reaction medium were detailed in a review.[2] Thermal rearrangements of benzyl sulfenates into sulfoxides, which proceed in nonpolar solvents by an ion-pair mechanism, did not find wide use in synthesis. On the contrary, rearrangements of β,γ-unsaturated aliphatic sulfoxides have assumed great importance. This is particularly true for the reversible allyl sulfoxide – allyl sulfenate Mislow – Evans rearrangement and, to a lesser extent, holds for the propargyl sulfenate – allenyl sulfoxide Braverman rearrangement.

1. Syntheses based on the reversible rearrangement of allyl sulfoxides into allyl sulfenates (the Mislow – Evans rearrangement)

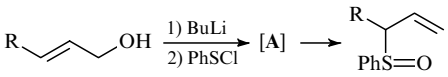
a. General observations

The thermal reversible rearrangement of allyl sulfoxides into allyl sulfenates proceeds as a intramolecular process through a five-membered transition state and is accompanied by migration of the double bond. This rearrangement is presently among the best-studied [2,3]-sigmatropic processes. The structure of allyl sulfoxide is thermodynamically more favourable than that of sulfenate due to which the equilibrium in the liquid phase under normal conditions is virtually completely shifted toward sulfoxide. The occurrence of this equilibrium was assumed [15] based on the fact that racemisation of optically active allyl sulfoxides proceeds much more rapidly than racemisation of saturated sulfoxides. This assumption was additionally supported by the fact that the reaction of allylic alcohol with sulfenyl chloride in the presence of a base afforded sulfoxide (rather than sulfenate).



A

† Dedicated to Academician O M Nefedov with appreciation and on the occasion of his seventieth birthday.

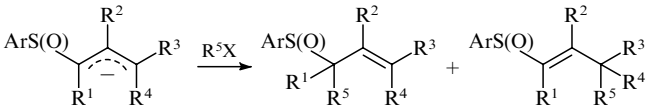


Both reactions proceeded through allyl sulfenate **A**, which is readily isomerised. The mechanism of the intramolecular completely concerted process was proved by kinetic data and by the results of experiments using labelled compounds.[15]

The Mislow–Evans rearrangement is used as a general procedure for the preparation of allylic alcohols.[16] Trimethyl phosphite was proposed as the thiophilic reagent of choice.[16] This reagent moves sulfenate off the equilibrium, which is virtually completely shifted toward allylic alcohol. In some cases, such bases as amines, thiolates or Na_2S are used as thiophiles.

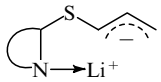
This procedure was later modified[17] so that it involved the one-pot synthesis of allylic alcohol by oxidation of allyl sulfide with 30% H_2O_2 in the presence of a catalytic amount of SeO_2 followed by treatment with 0.1 equiv. of TsOH (alcohols were obtained in ~70% yields).

For this procedure to be successfully employed in the synthesis of complex compounds, it was necessary to find appropriate conditions for α-alkylation of the simplest allyl sulfoxides. Evans and Andrews[16] revealed that selective α-alkylation ($\alpha/\gamma \ll 10$) took place only in the case of allyl sulfoxides that contain the double bond in the ring or bear two terminal alkyl substituents; otherwise noticeable amounts (up to 50%) of γ-alkylated products formed due to which the yield of the target allylic alcohol decreased substantially.



R^1, R^2, R^3, R^4 = H, Alk; R^5 = Alk.

To eliminate this problem, it was suggested[16] that alkylation of allyl sulfides bearing heterocyclic (for example, 2-pyridyl or 2-imidazolyl) substituents at the sulfur atom should be followed by oxidation of the resulting compounds to sulfoxides. These sulfides underwent predominantly α-alkylation due to the chelating effect of the heteroatom.



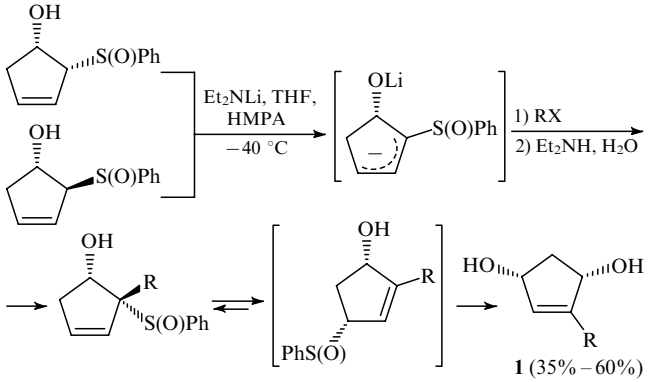
Evans and Andrews[16] also established that deprotonation with alkyllithium in the case of alkylation of allyl sulfoxides with weak electrophiles, such as long-chain halides, must be performed in aprotic solvents at below-zero temperatures.

The advantage of the allyl sulfoxide–allyl sulfenate rearrangement is the stereoselective formation of the (*E*)-C=C bond because the *trans* conformation (according to the nomenclature proposed by Mislow[15]) in the transition state is more favourable. Recently, *ab initio* calculations for 2-methyl-3-phenylsulfinylbut-1-ene confirmed that the formation of the (*E*)-C=C bond is energetically more favourable.[18] However, the difference between the energies of the *trans* and *cis* transition states is small. Hence, isomerisation of sulfoxides can afford up to 10% of the (*Z*)-isomer depending on the character of the substituents. If the double bond is involved in the corresponding ring, the product with the (*Z*) configuration can be obtained in quantitative yield. Recently, it has been demonstrated that distant functional groups exert efficient (*E*)-stereocontrol. Thus the presence of branched groups in the β position[19] or the hydroxy group in the γ position[20] of allyl sulfoxide is favourable for (*E*)-stereoselectivity (80%–99%).

Mislow was the first to note[15] that isomerisation of sulfoxides containing a chiral centre at the C(1) atom is accompanied by migration of this centre to the C(3) atom. The characteristic features of this asymmetric synthesis, which was called self-immolative, and the effects of the bulkiness and the character of the substituents were thoroughly investigated by Hoffmann.[21]

b. Syntheses of natural compounds involving the Mislow–Evans rearrangement

The [2,3]-sigmatropic Mislow–Evans rearrangement was first applied to the syntheses of prostaglandins.[22–27]

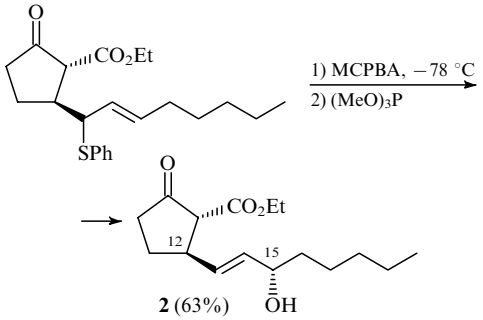


HMPA is hexamethylphosphoramide;

RX = $C_6H_{13}I$, BnBr, $\overline{OCH_2CH_2OCH}(CH_2)_6I$,

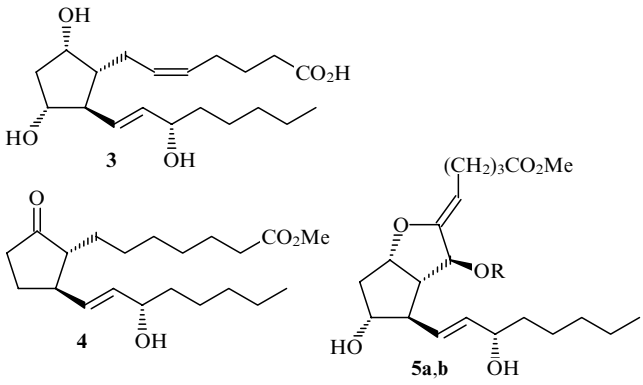
$Bu^tCO_2(CH_2)_2C{\equiv}CCH_2Br$, $Bu^tCO_2(CH_2)_6I$, $PhCH{=}CHCH_2Br$.

This procedure was used for the preparation of *cis*-cyclopentene glycols **1**, which are convenient starting compounds for preparing prostaglandins,[22] and the stereocontrolled construction of the chiral centre at the C(15) atom in compound **2** was carried out. The latter compound was utilised in the synthesis of prostaglandin PgA_2.[23]



MCPBA is *m*-chloroperbenzoic acid.

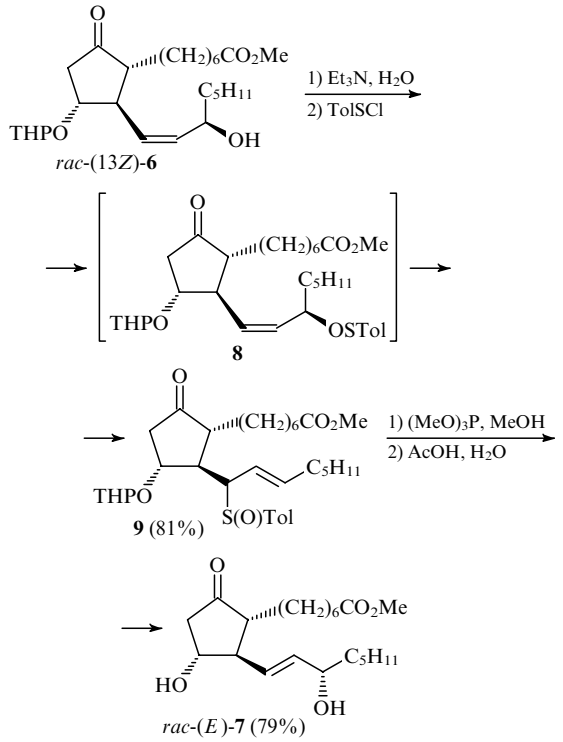
This methodology was also employed for the preparation of racemic products: prostaglandin $F_{2\alpha}$ (**3**),[24] methyl ester of 11-deoxyprostaglandin E_1 (**4**)[25] and stable analogues of prostaglandin PgI_2, *viz*., 7-hydroxy- and 7-acetoxy-PgI_2 (**5a**,**b**).[26]



R = H (**a**), Ac (**b**).

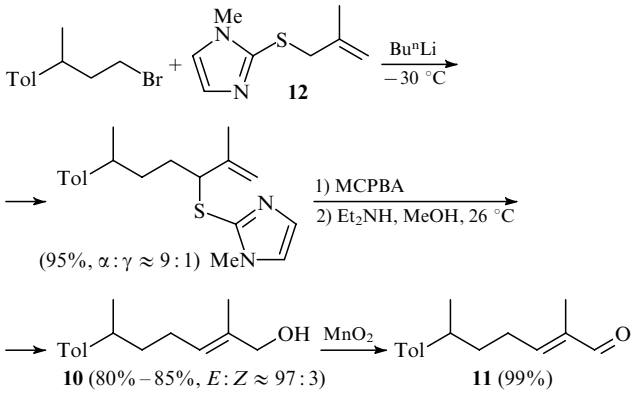
Of special interest is the study, which demonstrated high stereo- and enantioselectivity of the sigmatropic process.[27] The methyl ester of *rac*-PgE_1 (**7**), which is completely identical to the natural specimen, was prepared in high yield by a two-step

procedure starting from the readily accessible *rac*-(13*Z*)-prostaglandin (**6**) through unstable sulfenate **8** and sulfoxide **9**. In this study, both directions of the Mislow – Evans rearrangement were utilised.

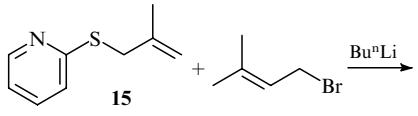


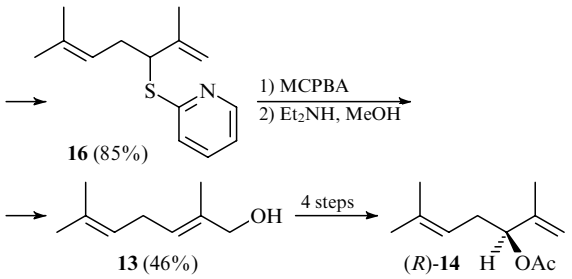
Tol = 4-MeC_6H_4, THP = .

Linear terpenoids and related compounds were synthesised using the above-mentioned alkylation at the stage of allyl sulfide. (*E*)-Nuciferol (**10**) and the terpenoid (*E*)-nuceferal (**11**) were prepared starting from methallyl imidazol-2-yl sulfide (**12**).[16]

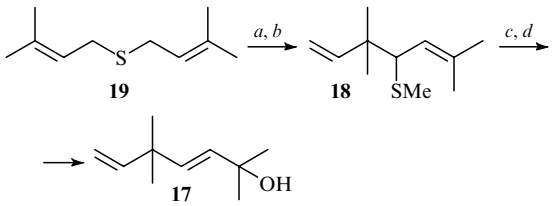


Alcohol (**13**), which is the key compound in the synthesis of the mealybug pheromone, *viz*., (*R*)-2,6-dimethylhepta-1,5-dien-3-ol acetate (**14**), was prepared in four steps starting from methallyl 2-pyridyl sulfide (**15**).[28] After oxidation of intermediate **16** and rearrangement, the alcohol **13** was isolated by chromatography. The pheromone (*R*)-**14** and its (*S*)-enantiomer were prepared in four steps involving asymmetric Sharpless epoxidation. This synthesis allowed the establishment of the absolute configuration of the natural pheromone.



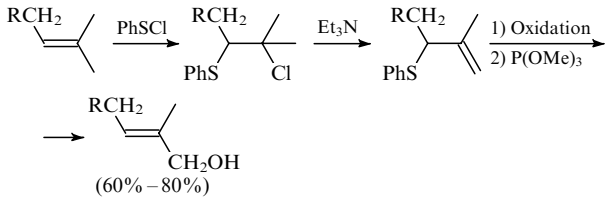


The ingenious short synthesis of yomogi alcohol **17** was carried out starting from sulfide **18**, which was prepared by alkylation of tetramethyldiallyl sulfide **19** with methyl iodide.[16]



(*a*) Bu^nLi, TMEDA (1,1,4,4-tetramethylethylenediamine); (*b*) MeI; (*c*) $NaIO_4$; (*d*) Et_2NH, MeOH, 25 °C, 24 h.

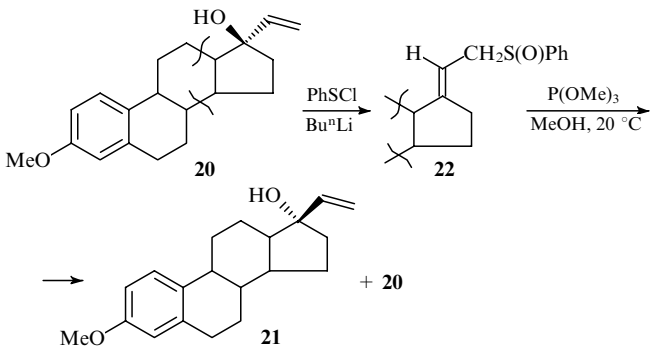
The sulfoxide – sulfenate rearrangement was also used for the functionalisation of the isopropylidene group of farnesol, related isoprenoids [29, 30] and compounds of the terpene – quinone series.[31]



Hence, the sulfoxide-sulfenate rearrangement can be performed as a one-pot procedure after oxidation of allyl sulfide to sulfoxide.

If quinones of the terpene series are used as the starting compounds, the functionalisation products containing ω-hydroxyprenyl or -geranyl chains can serve as convenient building blocks in syntheses of biologically important compounds, such as ubiquinone or vitamins K.[31]

The sulfoxide – sulfenate rearrangement made it possible to perform one-pot epimerisation of 17β-hydroxy-17α-vinylsteroids of type **20** to produce the previously unavailable epimers **21** with the 17α-hydroxy-17β-vinyl group through sulfoxide **22** (the total yield was 88%, the isomer ratio **21** : **20** = 86 : 14).[32]

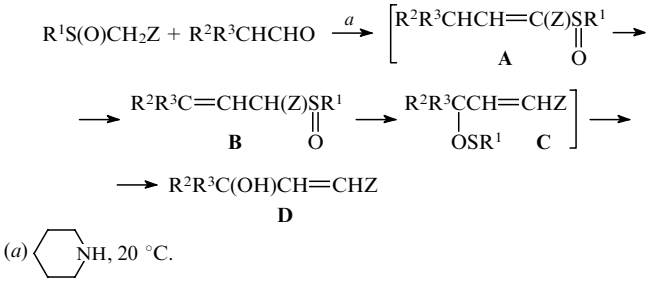


The reaction has a general character and can be applied to steroids containing the *A* rings with different structures.[32]

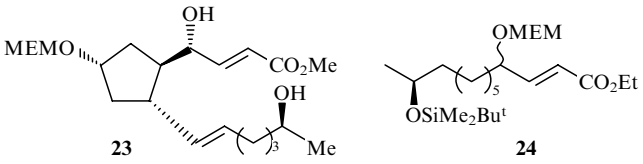
Tandem processes involving other procedures for the preparation of allyl sulfoxides were also described; among them the so-

called SPAC reaction (Sulfoxide Piperidine and Carbonyl)[33] is noteworthy.

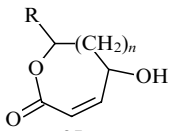
This reaction proceeds under very mild conditions and is typical of sulfoxides containing an electron-withdrawing group in the α position. It is believed that the reactions of the latter compounds with carbonyl groups in the presence of bases proceed according to a cascade mechanism, which involves the Knoevenagel reaction yielding substituted vinyl sulfoxide **A**, its isomerisation to allyl sulfoxide **B** and the subsequent Mislow–Evans rearrangement into sulfenate **C**. In the presence of a base, the latter compound gives the reaction product **D**.



The SPAC reaction and its use in syntheses of natural compounds were considered in detail in a review.[1] This procedure was followed in the preparation of compound **23**, which is a key intermediate in the synthesis of brefeldin A,[34,35] protected seco acid **24**, which is a precursor of (*R*,*R*)-pyrenophorin,[36] and macrocyclic lactones of type **25**.[37]



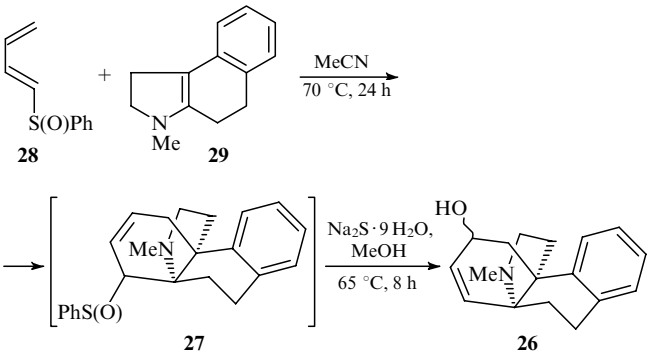
MEM = $MeO(CH_2)_2OCH_2$.



25 (R = H, Me; *n* = 7, 9).

Diene condensations of sulfinyl-substituted 1,3-dienes afford adducts containing the allylsulfinyl fragment due to which they can be used in tandem with the subsequent sulfoxide–sulfenate rearrangement of the adduct (see the review[38]).

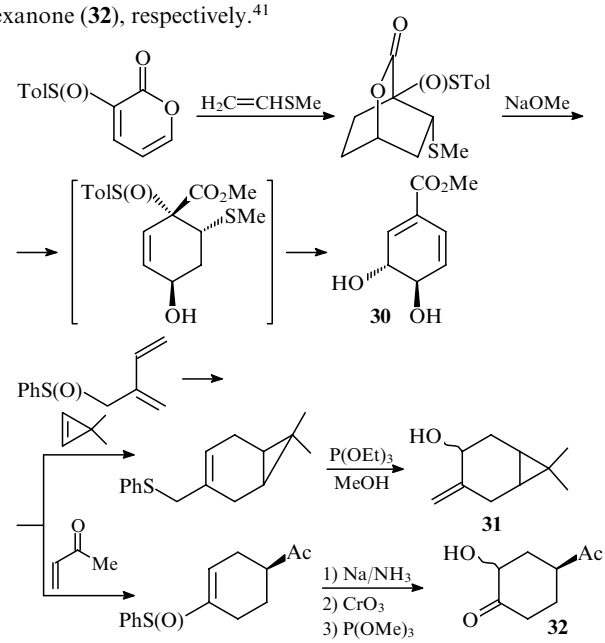
The first example of such a tandem process involving the Diels–Alder reaction and the sulfoxide–sulfenate rearrangement has been described in the early study of Evans *et al.*[39] The authors prepared compound **26** with the skeleton of the alkaloid hasubanan by the transformation (without isolation) of adduct **27**, which was synthesised by the stereoselective reaction of 1-phenylsulfinylbuta-1,3-diene (**28**) with tetrahdydrobenzoindole (**29**).



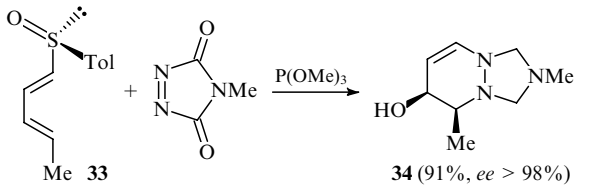
This combination of the reactions offers promise for the synthesis of biologically important substituted cyclohexenols, which cannot be prepared by other procedures.[39] However, this approach has received little use in the synthesis of natural compounds.

There are several examples of the reactions, which do not belong to tandem processes because they involve rearrangements proceeding with the participation of adducts isolated in the pure form.

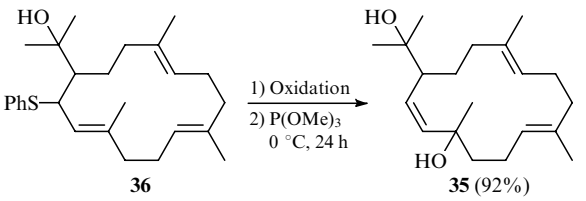
Thus compound **30**, which is a key intermediate in the total synthesis of chorismic acid, was prepared by the rearrangement of the adduct of 2-(tolylsulfinyl)pyrone with ethyl vinyl sulfide.[40] The rearrangements of the adducts of 2-phenylsulfinylbuta-1,3-diene with 3,3-dimethylcyclopropene or methyl vinyl ketone afforded carenols **31** (a mixture of the α- and β-isomers in a ratio of 7.5 : 1) and a mixture of isomers of 4-acetyl-2-hydroxycyclohexanone (**32**), respectively.[41]



The asymmetric tandem process consisting of the Diels–Alder reaction and the sulfoxide–sulfenate rearrangement can be performed with the use of enantiomerically pure 1-arylsulfinylbuta-1,3-dienes containing an electron-withdrawing substituent at position 4. Thus one-pot thermal reactions of such dienes with an excess of *N*-methylmaleimide gave rise to enantiomerically pure cyclohexene-containing compounds in high yields.[38] This methodology has not been extended to the synthesis of natural compounds. However, the recent study carried out by Carreño *et al.*[42] was devoted to the condensation of [S_R]-1-(1*E*,3*E*)-1-(tolylsulfinyl)penta-1,3-diene (**33**) with 4-methyldihydro-1,2,4-triazole-3,5-dione in the presence of trimethyl phosphite. This reaction proceeded in quantitative yield to form enantiomerically pure compound **34** serving as a key intermediate in the synthesis of optically active β-hydroxy-γ-amino acids.

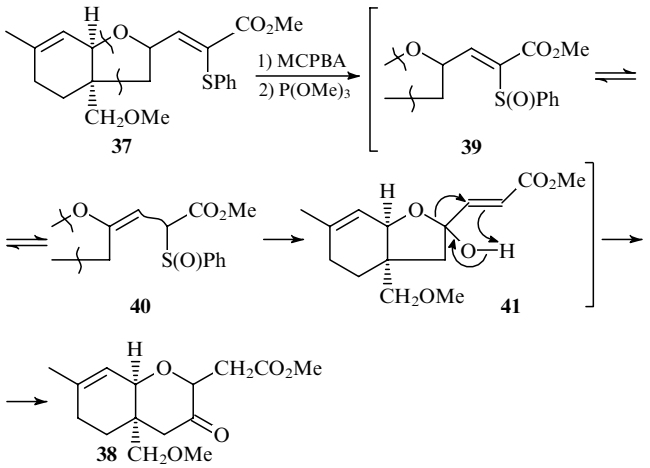


There are also other examples of the use of alcohols, which were prepared by the Mislow–Evans reaction, as key compounds in syntheses of natural products. Thus diol **35** was generated by the rearrangement of an epimeric mixture of sulfoxides, which was obtained by oxidation of sulfide **36**, and served as a key intermediate in the synthesis of cembranoids.[43]



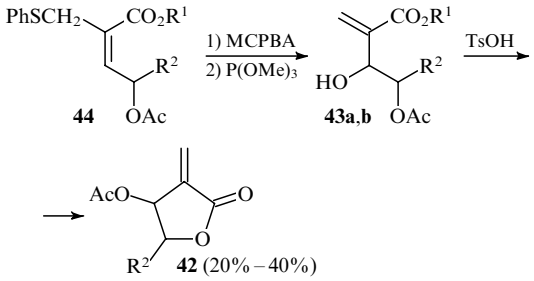
36 **35** (92%)

Bicyclic vinyl sulfide **37** was used for the preparation of derivative **38**,[44] which is a key compound in the facile synthesis of the sesquiterpenoid fragment of the active antitumour agent verrucarin. The scheme involves oxidation of the sulfide **37** to vinyl sulfoxide **39** followed by a cascade process consisting in the isomerisation of allyl sulfoxide **40** and the rearrangement of the latter into allylic alcohol **41**, which is spontaneously isomerised with the ring expansion to give the final product.



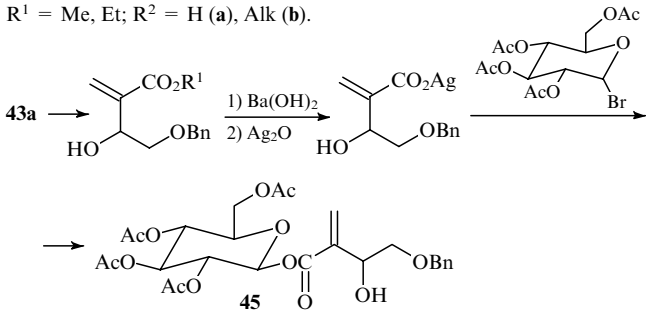
37 **39** **40** **41** **38**

The general procedure for the preparation of β-hydroxy- and β-acetoxy-γ-lactones **42**, which are precursors of compounds possessing allergic action, is based on cyclisation of susbtituted allylic alcohols of type **43**.[45] The latter were prepared by oxidation and the rearrangement of allyl sulfides **4**. This procedure was used in the first synthesis of tuliposide B, which is an agent of allergic dermatitis caused by prolonged contact with tulip bulbs. The precursor of tuliposide B **45** was synthesised starting from allylic alcohol **43a** and acetobromoglucose.



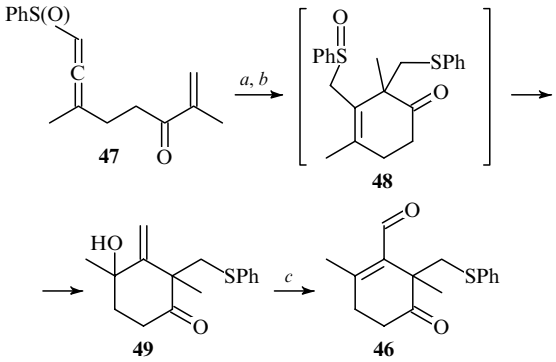
44 **43a**,**b** **42** (20%–40%)

R^1 = Me, Et; R^2 = H (**a**), Alk (**b**).



45

Compound **46**, which is a key intermediate in the route to the synthesis of an active antitumour drug taxol, was prepared starting from allenyl sulfoxide **47**. Its treatment with lithium phenoxide led to the cascade reaction accompanied by cyclisation and the rearrangement of intermediate **48** containing the allyl sulfoxide unit. Oxidation of the resulting tertiary allylic alcohol **49** afforded the target compound **46**.[46] It should be noted that the intermediate **48** was isolated in the reaction of the sulfoxide **47** with less basic nucleophile $PhMe_2Al$.



47 **48** **49** **46**

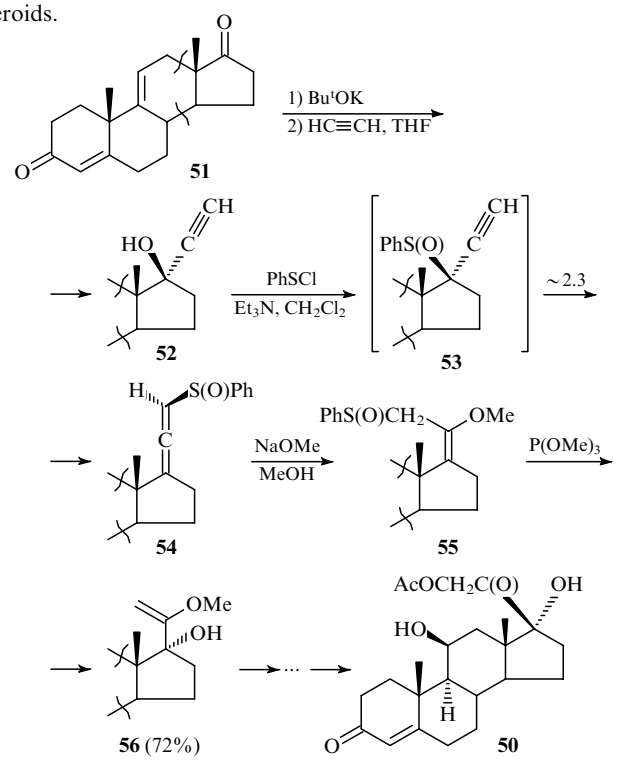
2. Syntheses involving the sigmatropic rearrangement of propargyl sulfenates into allenyl sulfoxides

The rearrangement of propargyl sulfenates into allenyl sulfoxides discovered by Braverman (see Ref. 2) has received little use in syntheses of natural compounds as compared to the Mislow–Evans rearrangement. The former rearrangement is a reversible [2,3]-sigmatropic reaction proceeding under mild conditions. This rearrangement is utilised in syntheses of natural products only as a convenient procedure for the preparation of allenyl sulfoxides starting from available propargylic alcohols. Allenyl sulfoxides can, in turn, be converted into substituted allyl sufoxides by the addition of a nucleophile at the activated C=C bond of allenyl sulfoxide.

A procedure was developed[47] for the preparation of the antiinflammatory agent hydrocortisone acetate (**50**) bearing the $COCH_2OH$ group at position 17β, which is typical of corticosteroids.

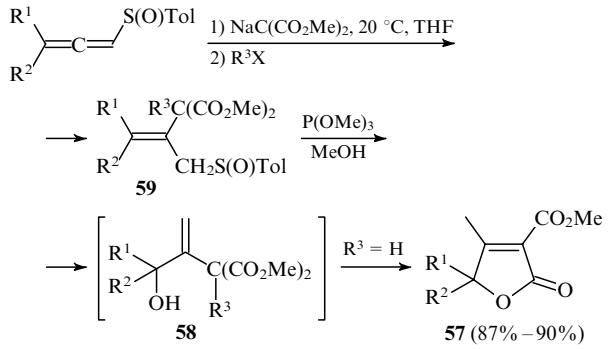


51 **52** **53** **54** **55** **56** (72%) **50**

Readily accessible androst-4,9(11)-diene-3,17-dione (**51**) was used as the starting compound. The reaction of alcohol **52**, which was prepared by the selective addition of acetylene to the carbonyl group at position 17 of compound **51**, with $PhSCl-NEt_3$ afforded sulfenate **53**. The latter is stable only below −40 °C and underwent the [2,3]-rearrangement to give allene sulfoxide **54** as a mixture of isomers. The addition of the methoxy group at the double bond of the sulfoxide **54** gave rise to an epimeric mixture of allyl sulfoxides **55**, which were isomerised into allylic alcohol **56** through the Mislow–Evans rearrangement. This process provides the basis for a general method for the conversion of ketosteroids to corticosteroids. The stereochemistry of all stages of this process was investigated.[47]

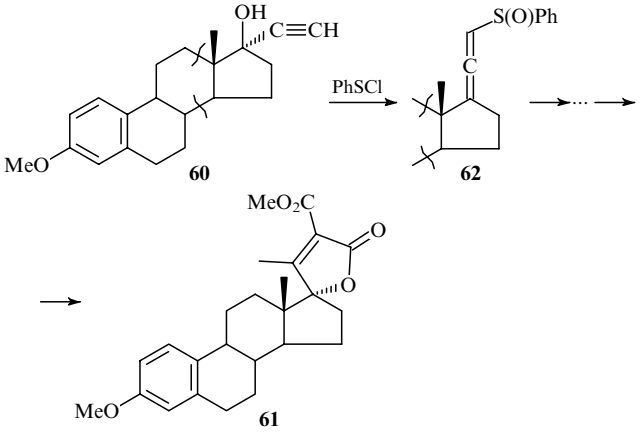
The addition of the alkyne fragment to the carbonyl group followed by desulfinylation of allenyl sulfoxides under the action of MeLi was used for the preparation of steroids containing allene substituents.[48, 49]

In the study,[50] allenyl sulfoxides were utilised as the starting compounds in the development of a general method for the preparation of 2,5-dihydrofuranones **57** by cyclisation of substituted allylic alcohols **58**, which are products of the [2,3]-rearrangement of allyl sulfoxides **59**. The compounds **59** were prepared by the addition of a sodium derivative of dimethyl malonate to allenyl sulfoxides.

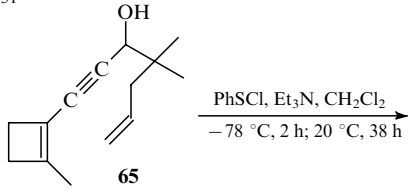


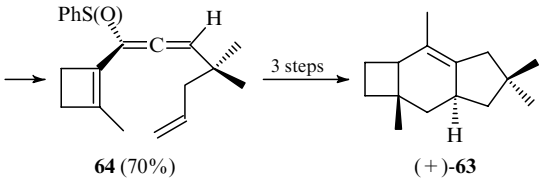
R^1 = H, Me; R^2 = Me; $R^1-R^2 = (CH_2)_5$.

This procedure was also employed for the conversion of mestranol **60** to spiro lactone **61** *via* allenyl sulfoxide **62**.[50]



In the synthesis of sesquiterpenoid sterpurene [(+)-**63**], the key tetraene sulfoxide **64** was derived from propargylic alcohol **65**.[51]

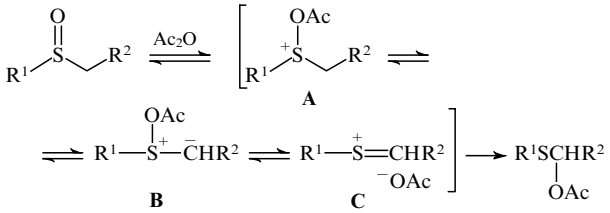




Other examples of the synthetic applications of vinylallenyl-containing sulfoxides prepared in a similar way were presented in a review,[52] which covered the use of vinylallenes in the synthesis of metabolites of vitamin D_3.

III. Syntheses based on the Pummerer reaction

The Pummerer reaction consists in the transformation of sulfoxides bearing at least one α-hydrogen atom under the action of electrophilic reagents. The reactions of saturated sulfoxides resulted in reduction of the sulfinyl group to the sulfide group and oxidation of an α-hydrogen atom. It is believed [7, 8, 11, 53] that the reaction proceeds through successive equilibrium stages of the formation of the acyloxy sulfonium ion **A**, ylide **B** and the sulfenium cation **C**. The reactions ended in the attack of an internal or external nucleophile on the cation **C**.



All three main experimental versions of this reaction are employed in syntheses of natural compounds.

The first version is the classical Pummerer reaction in which sulfoxides containing no unsaturated groups in the α,β positions react with acids or their derivatives (most often with anhydrides and sometimes in the presence of bases). As shown in the above scheme, these reactions afford α-acyloxy sulfides as the primary reaction products.

The second version involves the so-called sila-Pummerer reactions. In this case, the substrate or the electrophilic reagent possesses labile Si–X bonds due to which the reactions often proceed under milder conditions (generally at below-zero temperatures). Trimethylchlorosilane [54] or other silicon-containing electrophiles are used as silylating agents.

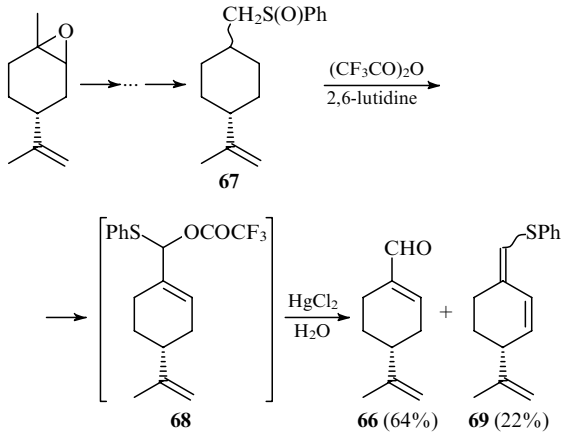
The third version of the Pummerer reaction consists in additive processes involving vinyl sulfoxides as substrates, which undergo Pummerer-like rearrangements under the action of various inorganic or organic electrophilic reagents.[55] The version proposed by Marino and Neisser [56] is of particular interest. In the latter case, dichloroketene generated *in situ* served as the electrophilic reagent.

Examples of the use of the Pummerer reaction in syntheses of biologically active compounds are systematised below according to the nature of the nucleophilic reagent involved in the reaction with the sulfenium cation.

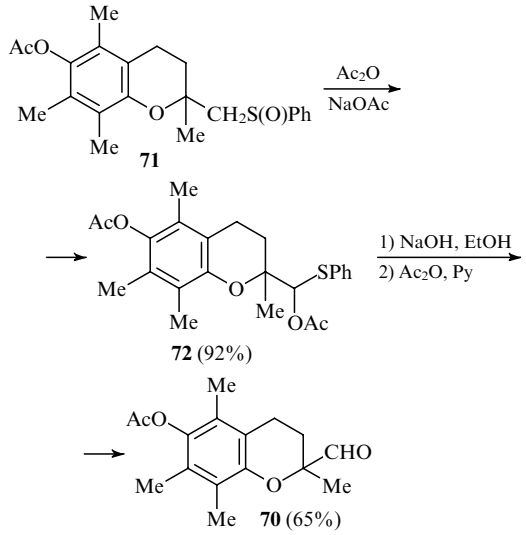
1. Syntheses based on hydrolytic cleavage of α-acyloxy sulfides

Hydrolysis of α-acyloxy sulfides generated in the course of the classical Pummerer reaction provides a convenient way of transforming sulfoxides into carbonyl compounds. These reactions are generally performed under the action of alkalis with the addition of salts, such as $HgCl_2$ or $CaCl_2$, which promote elimination of the RS group. This section is concerned with examples of the applications of this procedure to the construction of carbonyl groups in natural compounds or key intermediates for their syntheses.

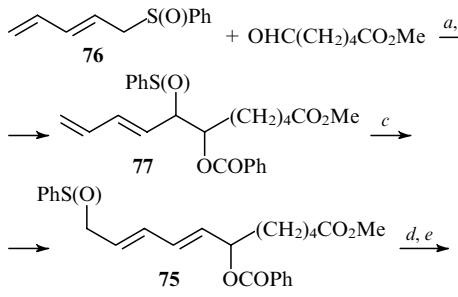
(*R*)-(+)-Perillaldehyde (**66**) was prepared [57] starting from an enantiomeric mixture of optically active sulfoxides **67** [which were synthesised in two steps from (+)-limonene epoxide] by hydrolysis of the Pummerer-reaction product **68** without its isolation. Side chain deacylation of the intermediate **68** afforded vinyl sulfide **69**.

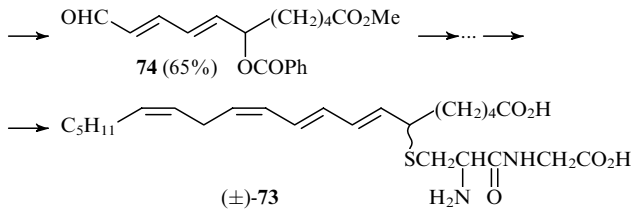


6-Acetoxy-2,5,7,8-tetramethylchroman-2-carbaldehyde (**70**), which is a key starting compound in the total synthesis of α-tocopherol, was derived [58] from sulfoxide **71** by hydrolysis of α-acyloxy sulfide **72** isolated in the individual form.



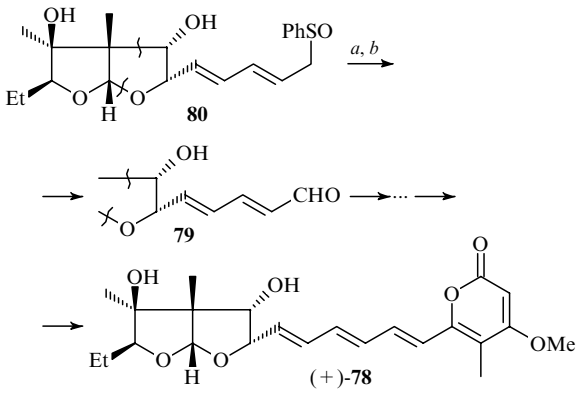
Racemic 5-desoxyleukotriene D [(±)-**73**] was synthesised with the use of aldehyde **74**, which was prepared from sulfoxide **75** without isolation of intermediate acyloxy sulfide. The scheme of the synthesis of the aldehyde **74** involves the reaction of 1-phenylsulfinylpenta-2,4-diene **76** with methyl 5-formylvalerate in the presence of butyllithium followed by migration of the sulfinyl group in benzoyl derivative **77**, which proceeds very readily through a two-step [2,3]-rearrangement.[59]





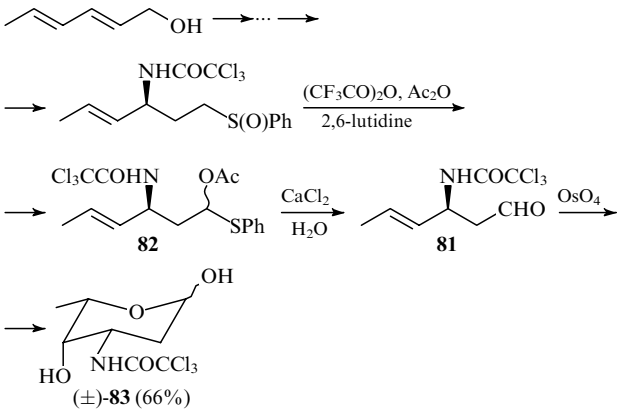
(*a*) Bu^{n}Li; (*b*) PhCOCl, −40 °C; (*c*) 25 °C, 3 h, (*d*) Ac_2O, 2,6-lutidine, $(CF_3CO)_2O$, NaOH; (*e*) $CaCO_3$, $HgCl_2$, MeCN – H_2O.

In the key stage of the total synthesis of asteltoxin [(±-**78**)], aldehyde **79** was generated from sulfoxide **80** also without isolation of intermediate acyloxy sulfoxide.[60]

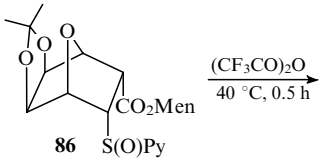


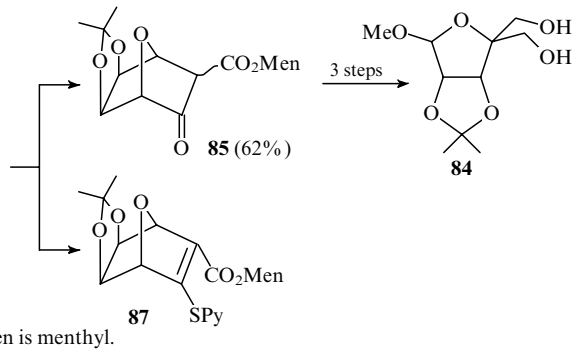
(*a*) $(CF_3CO)_2O$, Ac_2O, 2,6-lutidine; (*b*) $CaCl_2$, $HgCl_2$, MeCN – H_2O.

3-Trichloroacetylaminohex-4-enal (**81**) was synthesised starting from sorbinic alcohol. [61] In this case, acyloxy sulfide **82** was isolated as an intermediate. Hydroxylation of the aldehyde **81** with OsO_4 afforded the *N*-trichloroacetyl derivative of racemic daunosamine (**83**), which is a carbohydrate fragment of the antitumour antibiotic daunorubicin used in clinical practice. Variations of this procedure made it possible to synthesise the related carbohydrates, *viz*., racemic vancosamine and ristosamine.[61]



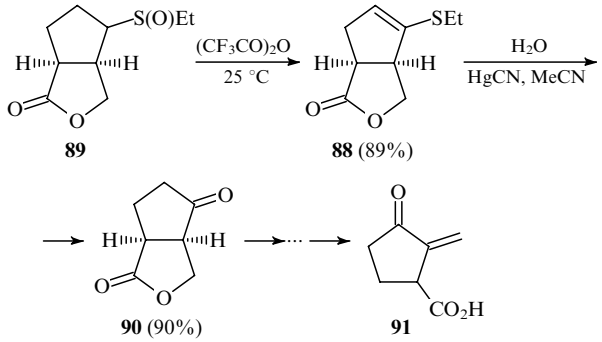
Branched sugar **84** was synthesised [62] in three steps from keto ester **85**. The latter was obtained as the major product of the Pummerer reaction of sulfinyl-substituted ester **86**, which was prepared by diene condensation of menthyl (*S*)-(2-pyridylsulfinyl)acrylate with furan.[63] The Pummerer reaction involving the sulfoxide **86** afforded vinyl sulfide **87** as a by-product. Acid hydrolysis of the latter gave rise to the keto ester **85** in low yield (< 25%).[62]



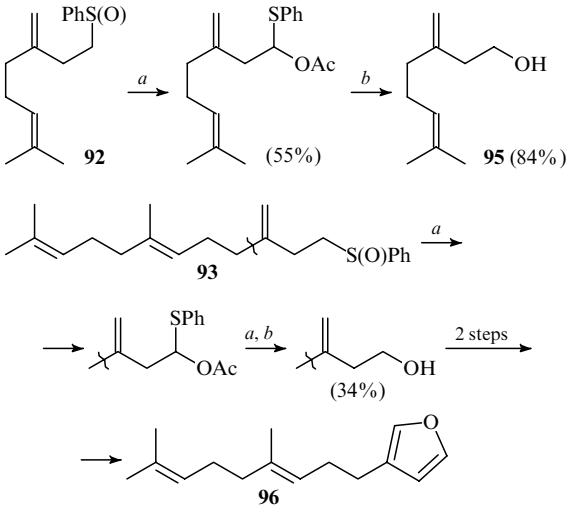


Men is menthyl.

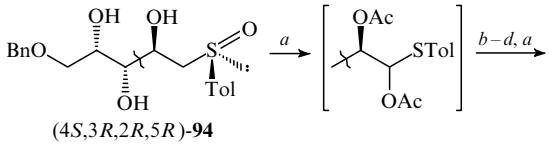
However, some of these reactions proceed readily; examples of such reactions were described in the literature. Thus vinyl sulfide **88**, which was prepared by the Pummerer reaction starting from sulfoxide **89**, was utilised in the synthesis of ketolactone **90**. The latter is the direct precursor in the synthesis of the antitumour agent sarcomycin (**91**).[64]

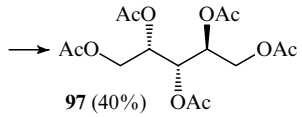


Below is given a scheme illustrating additional potentialities arising from a combination of the classical Pummerer reaction and the subsequent transformation of its products without their isolation. A combination of hydrolysis of acetoxy sulfide and reduction of the intermediate carbonyl compound starting from sulfoxides **92**–**94** made it possible to prepare labile compounds, such as γ-geraniol (**95**),[65] dendrolasin (**96**)[66] and enantiomerically pure penta-*O*-acetyl-L-arabinitol (**97**).[67]



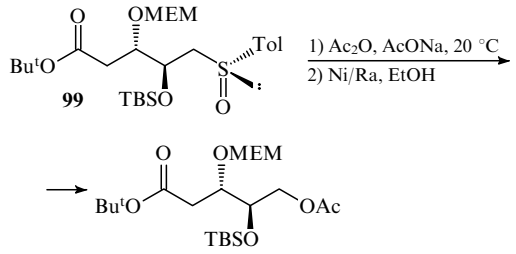
(*a*) Ac_2O, $(CF_3CO)_2O$ (cat); (*b*) $NaBH_4$, EtOH, H_2O.





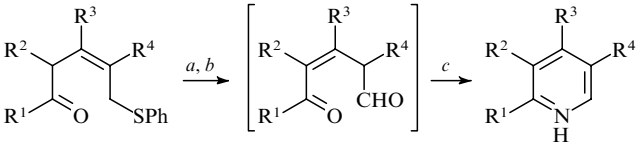
(*a*) Ac_2O, AcONa; (*b*) Bu^i_2AlH; (*c*) Ac_2O; (*d*) Pd/C, C_6H_{10}.

In more recent studies, for example, in the synthesis of 2-deoxy sugars[68] or in the construction of a fragment of the antibiotic nystatin A_1 containing five chiral alcoholic centres, Solladié *et al.*[69] used yet another modification of the acyloxy sulfide group. The Pummerer-reaction product, which was purified only by column chromatography, was immediately subjected to desulfurisation with Raney nickel. This procedure is exemplified by the preparation of derivative **98** of (2-deoxy-D-ribonic acid) starting from sulfoxide **99**.



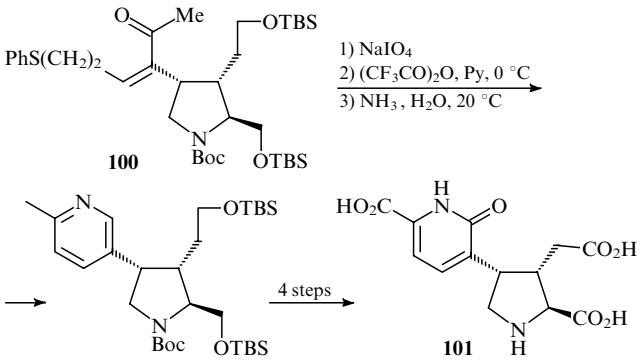
TBS = Bu^tMe_2Si.

The procedure developed for the synthesis of substituted pyridines[70] involves a combination of four reactions, *viz.*, oxidation of sulfide to sulfoxide, the classical Pummerer reaction, hydrolysis of α-acyloxy sulfide and the formation of the pyridine ring by the reaction of ammonia with intermediate 1,5-ketoaldehyde.



(*a*) $NaIO_4$, MeOH, H_2O; (*b*) $(CF_3CO)_2O$, Py; (*c*) NH_3, MeOH, H_2O.

This procedure made it possible[71] to synthesise natural neurotoxin, *viz.*, acromelic acid A (**101**), starting from phenylthio-substituted pyrrolidine **100**. Isomeric acromelic acid B was prepared analogously.[72] More complex synthetic schemes involving the Pummerer reaction as the key stage are considered at the end of the section.



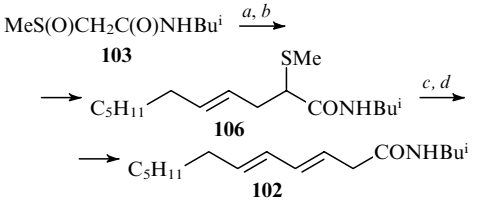
Boc = Bu^tOCO.

2. Syntheses based on intermolecular reactions of sulfenium cations with C = C bonds of alkenes

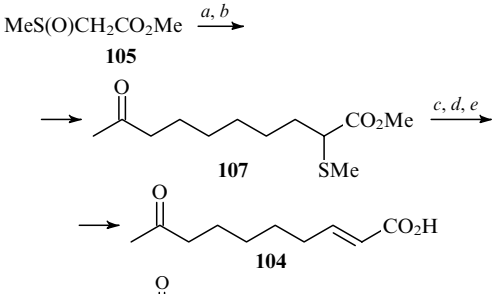
The sulfenium cation is a highly electrophilic reagent, particularly, if the initial sulfoxide bears activating electron-withdrawing

groups (most often carbonyl groups). This cation can react even with the weakly nucleophilic C=C bond. Analogous intermolecular processes were used in syntheses of predominantly linear unsaturated components of pheromones. In most studies, no consideration has been given to intermediates and hence, the mechanism of this reaction is unknown. Ishibashi and coworkers [73–77] proposed the ene-type mechanism involving the sulfenium cation.

The natural insecticide pellitorine (**102**) was prepared [73] by the reaction of oct-1-ene with the product of the Pummerer rearrangement of (methylsulfinyl)acetamide (**103**). (*E*)-9-Oxodec-2-enoic acid (the queen substance) (**104**) was synthesised analogously from methyl methylsulfinylacetate (**105**) and oct-1-en-7-one.[74] Additional C=C bonds were generated by thermolysis of sulfoxides prepared by oxidation of adducts **106** and **107**.



(*a*) $(CF_3CO)_2O$; (*b*) $C_6H_{13}CH=CH_2$; (*c*) $NaIO_4$; (*d*) Δ.



(*a*) $(CF_3CO)_2O$; (*b*)  ; (*c*) $NaIO_4$; (*d*) Δ; (*e*) OH^-.

p-Chlorophenylmethyl sulfoxide proved to be a particularly convenient starting compound in such reactions. The Pummerer reaction involving primary product **108** afforded numerous biologically active compounds, for example, the sex pheromone of red cotton moth (**109**) with the ratio of the (*E*)- and (*Z*)-isomers identical to that observed in the natural substance,[75] the pheromone of some tortricids **110** [76] and bicyclic *exo*-brevicomin **111**, which is the aggregation pheromone of fir moth (in a mixture with 11% of the *endo* epimer).[77]

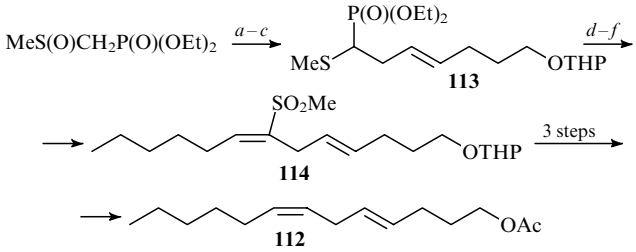
(±)-*exo*-**111**

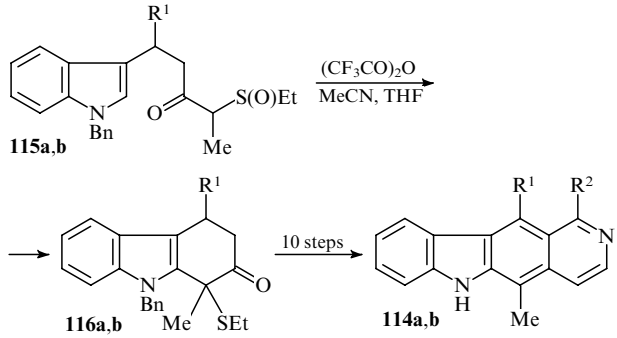
Trideca-(4*E*,7*Z*)-4,7-dien-1-ol acetate (**112**), which is the potato moth pheromone, was synthesised [78] starting from phosphorus-substituted sulfide **113**. The latter was derived from (methylsulfinyl)phosphonate by the Pummerer reaction followed by the reaction with 5-heptyl acetate. The synthesis ended in oxidation of the sulfur atom in the adduct to the sulfonyl group, chain elongation by the Horner–Wadsworth–Emmons reaction with hexanal and a three-step modification of intermediate **114**.



(*a*) $(CF_3CO)_2O$; (*b*)  ; (*c*)  , H^+; (*d*) MCPBA;
(*e*) Bu^nLi; (*f*)  .

3. Cyclisations based on intramolecular reactions of sulfenium cations with C=C bonds

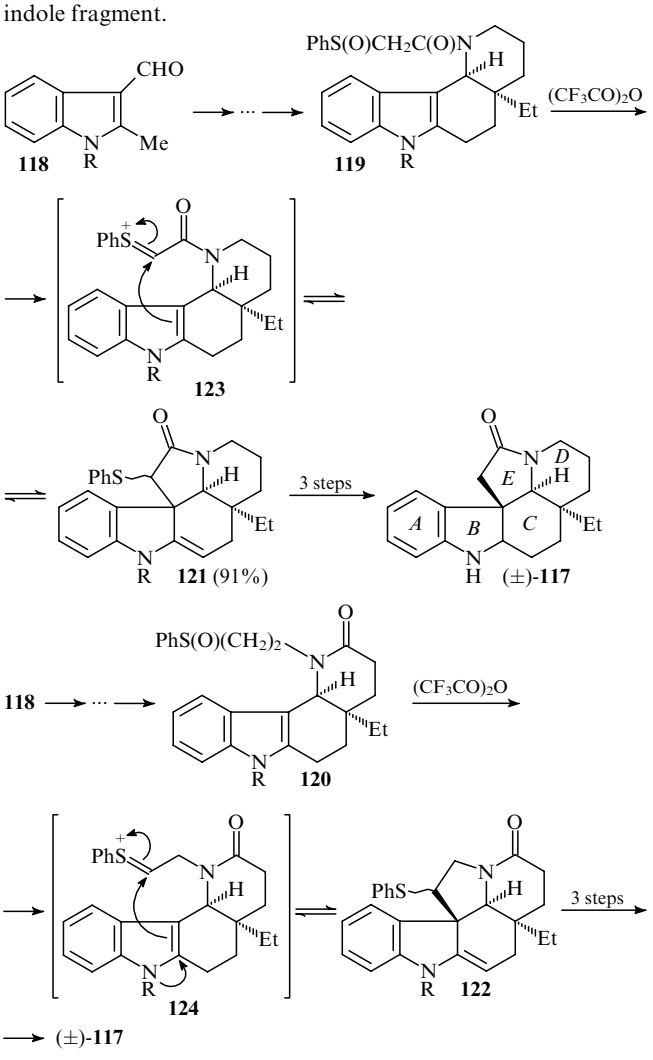
Intramolecular coupling of the Pummerer-reaction products and C=C bonds proved to be much more fruitful. The reaction of the sulfenium cation, which was derived from the sulfinyl fragment of compounds **115a**,**b**, with the C=C bond of the indole fragment was the key step in the synthesis of tetracyclic pyrido[4.3-*b*]carbazole alkaloids olivacine (**114a**) and ellipticine (**114b**). The target alkaloids **114a**,**b** were prepared in rather high yields by ten-step transformations of intermediates **116a**,**b**.[79]



Compound	R^1	R^2	Yield (%)
116a	H		51
116b	Me		55
114a	H	Me	28
114b	Me	H	23

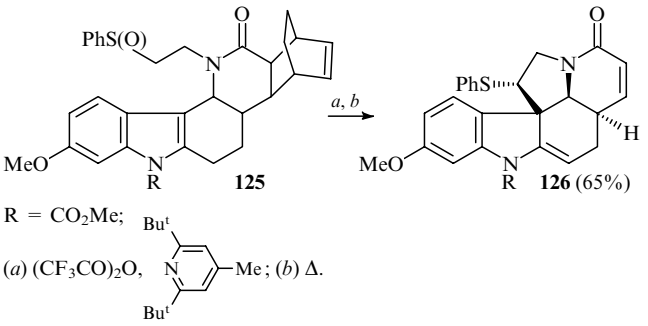
Magnus and coworkers carried out systematic research into the synthesis of polycyclic indole alkaloids (see the review [80]) and devised the [2,3]-quinodimethane strategy for constructing these alkaloids. (±)-Aspidospermidine (**117**), which is the simplest representative of pentacyclic alkaloids from *Aspidosperma sp.* plants, was a convenient compound for the development of the methodology. Gallagher *et al.*[81] synthesised tetracyclic precur-

sors, *viz*., substituted octahydro-7*H*-pyrido[3,2-*c*]carbazole **119** and **120**, starting from nitrogen-protected 3-formyl-2-methylindole (**118**). The compound **119** contains the sulfinyl-substituted exocyclic amide group, whereas the compound **120** bears the endocyclic amide group. Under the conditions of the Pummerer reaction, compounds **119** and **120** very readily undergo cyclisation to compounds **121** and **122** to form the *E* ring (apparently through intermediates **123** and **124**, respectively). After deprotection of the indole nitrogen atom and reductive removal of the carbonyl and sulfide groups, racemic aspidospermidine **117** was obtained through the compounds **119** and **120** in total yields of 6.3% of 11.7%, respectively. Cyclisation proceeded with exceptional stereoselectivity resulting in the natural *cis*-fusion of the rings. Cyclisation proceeded readily due to the close arrangement of the sulfenium cation and the π-electron system of the nucleophilic indole fragment.

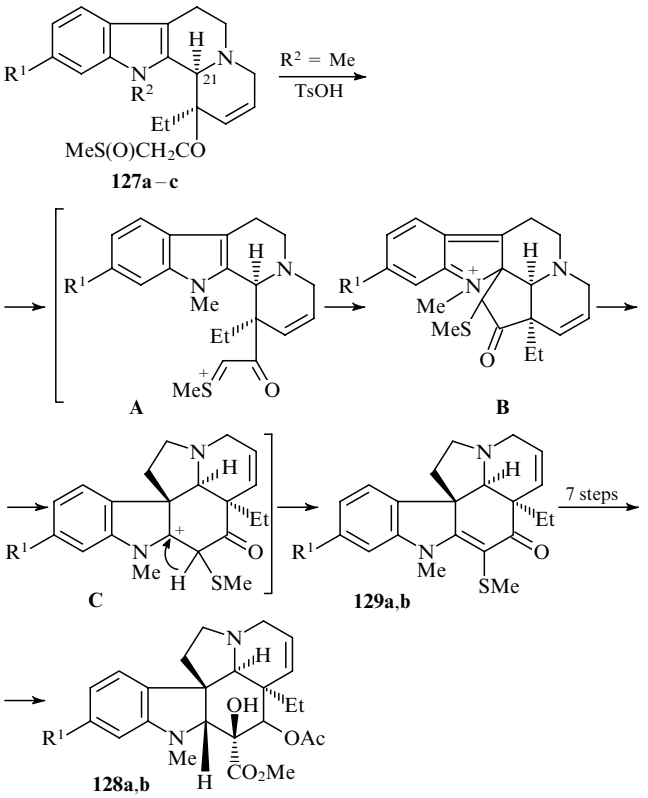


R = $SO_2C_6H_4OMe$-4.

The electronic or steric factors inhibiting the ring formation can (owing to the equilibrium character of this reaction) promote other conversions of a sulfenium-containing intermediate. Thus researchers failed to construct the *E* ring of indole alkaloids of the aspidospermine group under the standard conditions of the Pummerer reaction starting from model compound **125**, which contains the electron-donating methoxy group in the benzene ring typical of alkaloids of the vinblastine and vindoline groups. Cyclisation was successfully performed under the action of trifluoroacetic anhydride in the presence of 2,6-di-*tert*-butyl-4-methylpyridine as a base.[82] After thermolysis, compound **126** was obtained in rather high yield.



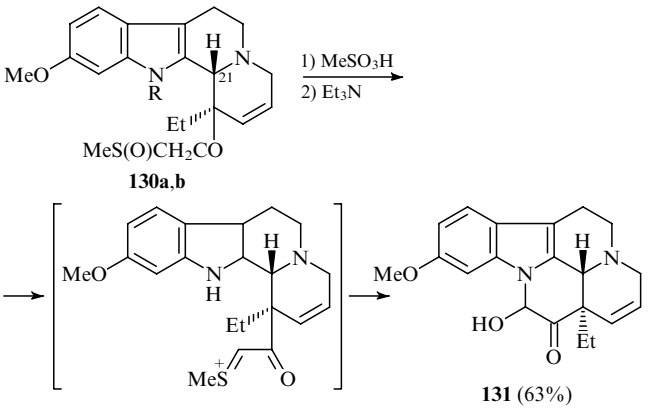
Magnus did not extend this discovery to natural alkaloids of the vinblastine and vindoline series, probably, because Langlois and coworkers [83] have reported an ingenious procedure for their preparation, which was also based on the Pummerer reaction but which utilised β-ketosulfinyl-containing tetrahydroindolo[2,3-*a*]-quinolizidines of type **127** as the starting compounds. Vindoline (**128a**) and vindorosine (**128b**) were prepared from the compounds **127a**,**b** in which the indole nitrogen atom was protected with the methyl group. Under the conditions of the Pummerer reaction, the compounds **128a,b** underwent a retrobiomimetic rearrangement *via* the intermediates **A** → **B** → **C**. The reaction started with the coupling of the sulfenium cation with the indole C=C bond and ended in the construction of the *E* ring in **129a**,**b**, which are key compounds in the synthesis of the target alkaloids. If the indole nitrogen atom is not protected (as in the precursors **127c** or **130a**), the indole C=C bond can couple with the nearby sulfenium cation (*via* the intermediate **D**) under the conditions of the Pummerer



Compound	R^1	R^2	Yield (%)
127a	OMe	Me	–
127b	H	Me	–
127c	H	H	–
128a	OMe		10 (total)
128b	H		–
129a	OMe		73
129b	H		70

reaction giving rise to eburn-type alkaloids, for example, to compound **131**. However, for this reaction pathway to become dominant, the indole C=C bond must be additionally shielded by the β-hydrogen atom at the C(21) atom as in indoloquinolizidine **130a**.[84]

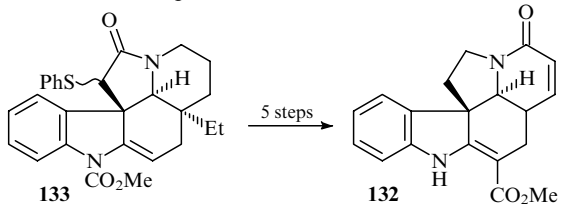
The Pummerer reaction involving the epimeric compound **127c**, which bears an α-hydrogen atom at the C(21) atom, afforded a mixture of aspidospermidine- and eburn-type alkaloids with the former predominating.[85]



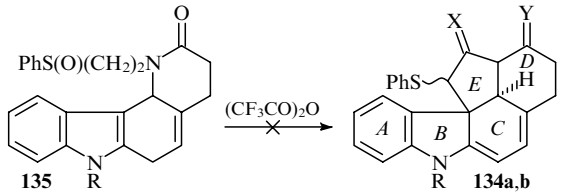
R = H (**a**), Me (**b**).

Vindoline **128a** can be prepared with equal ease from the C(21)-epimeric precursors **127a** or **130b**. It was assumed [84] that the compound **130b** was converted into the compound **127a** due to rapid reversible Mannich-type isomerisation. Apparently, this reversible process is also responsible for racemisation, which was observed in attempting to prepare enantiomerically pure alkaloids of this series from optically pure indoloquinolizidines.[84, 86]

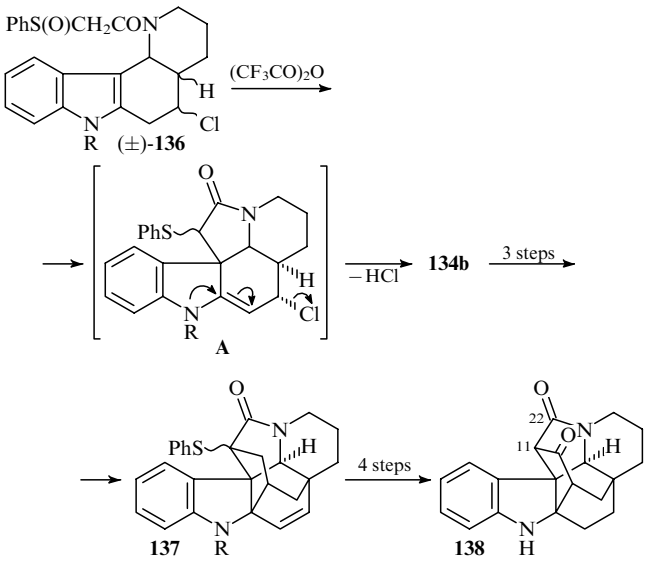
Further progress in studies on the synthesis of alkaloids of the aspidospermine group performed by Magnus and coworkers [87] was achieved owing to the employment of additional functionalisation of pentacyclic thio-containing amides. Thus racemic 8-oxotabersonine (**132**) was prepared [87] from pentacyclic compound **133** in five steps.



The synthesis of heptacyclic alkaloids of the kopsan series was a more complicated problem. For this purpose, key compound **134a** containing the diene system in the *C* ring was constructed. Under the conditions of the Pummerer reaction, aromatisation of the *C* ring competed with cyclisation due to which the use of the diene precursor **135** did not afford the target compound **134a**. The reaction involving chlorine-containing analogue **136** took the desired path [88] and the intermediate **A** readily underwent dehydrochlorination.



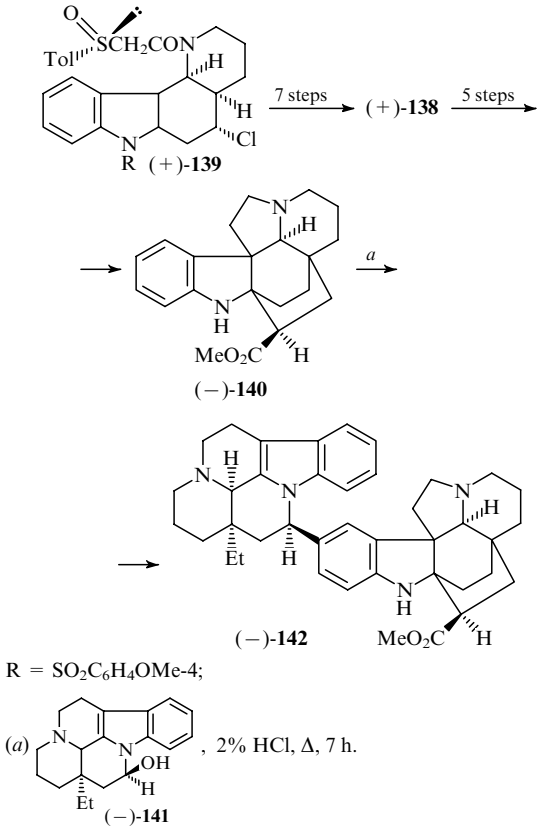
R = $SO_2C_6H_4OMe$-4; X = H, Y = O (**a**); X = O, Y = H (**b**).



R = $SO_2C_6H_4OMe$-4.

The one-pot synthesis of heptacyclic compound **137** containing all major elements of the kopsan system was carried out with the use of the pentacyclic compound **134b**. For this purpose, the starting compound was allylated at the C(11) atom followed by intramolecular diene condensation involving the diene system of the *C* ring. The key alkaloid of this series, *viz*., (±)-10,22-dioxokopsan (**138**), was synthesised from the compound **137** in four steps [the keto group at the C(22) atom was formed by the Pummerer reaction of the intermediate C(22)-sulfoxide]. C(22)-Oxokopsan and epimeric C(22)-kopsanols were readily derived from the compound **138**.

An analogous procedure was also used [89] for the preparation of optically active (+)-dioxokopsan [(+)-**138**] based on enantiomerically pure (taking into account the sulfinyl group) tetracyclic precursor (+)-**139**. In the cited study,[89] the data on the optical



R = $SO_2C_6H_4OMe$-4;

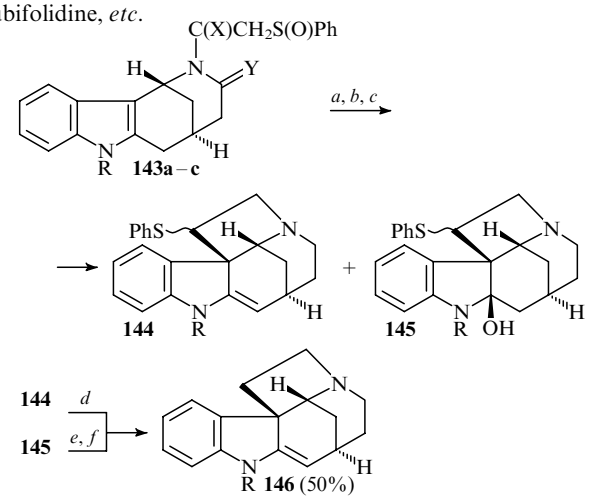
(*a*)

, 2% HCl, Δ, 7 h.

(–)-**141**

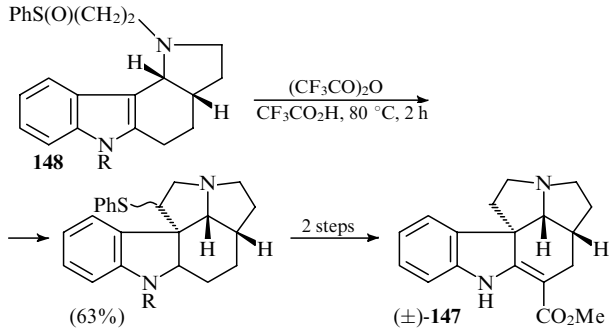
purity and absolute configurations of the products are lacking. However, the conversion into (−)-kopsinine (**140**) followed by its condensation with optically pure (−)-eburnamine [(−)-**141**] afforded bis-indole (−)-norpleiomutine [(−)-**142**] characterised by an optical rotation identical to that of the natural alkaloid.

The application of Magnus's procedure to the construction of the fifth ring of the more strained systems of alkaloids from plants of the *Strychnos* family utilising either precursor **143a**, which contains the exocyclic sulfinylamide group, or precursor **143b**, which is an endocyclic amide, has not met with success.[90] In the study of Bosch and coworkers,[91] steric hindrances to the favourable arrangement of the sulfenium ion relative to the indole C=C bond were overcome with the use of the more flexible sulfinylalkylamine group in tetracyclic precursor **143c**. In the latter case, after the standard treatment with trifluoroacetic anhydride, the process was terminated at the stage of formation of α-acyloxy sulfide, which was converted without isolation into cyclisation product **144** under the action of boron trifluoride etherate. The yield was insufficiently high because the undesirable hydration product **145** was simultaneously obtained. However, the cited study[91] can be considered as a facile synthesis of strychnine alkaloids. Compound **146** was obtained in 50% yield. It is a 20-deethylated analogue of the final intermediate (which was prepared previously[92]) in the synthetic pathway of the most important representatives of strychnine alkaloids, *viz*., tubifoline, tubifolidine, *etc*.



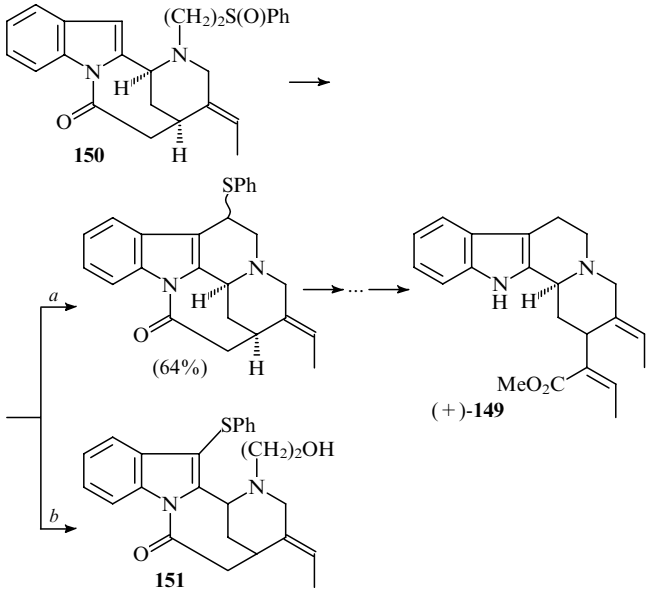
R = CO_2Me; X = O, Y = H_2 (**a**); X = H_2, Y = O (**b**); X = Y = H_2 (**c**); (*a*) X = Y = H_2, $(CF_3CO)_2O$; (*b*) $BF_3 \cdot Et_2O$; (*c*) CH_2Cl_2, Δ, 4 h; (*d*) Ni/Ra; (*e*) TsOH, 20 °C; (*f*) Ni/Ra.

Sulfinylalkylamines were successfully used in syntheses of other groups of alkaloids. (±)-Deethylibophyllidine (**147**) was prepared[93] according to the standard Pummerer reaction from tetracyclic compounds **148** by the construction of the fifth ring.



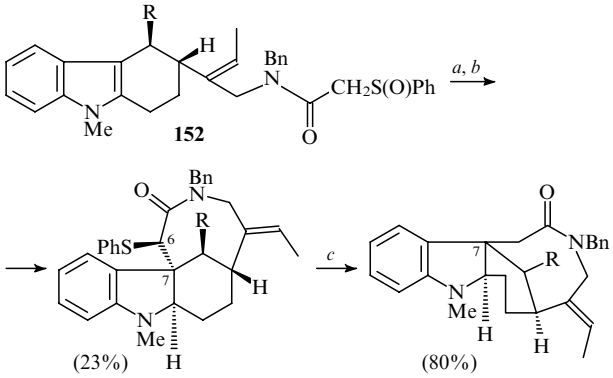
R = CO_2Me.

In the facile synthesis of (±)-geissoschizine (**149**) starting from precursor **150**, the six-membered ring was successfully constructed only under the conditions of the sila-Pummerer reaction.[94] Under the conditions of the classical Pummerer reaction, the unexpected formation of hydroxy sulfide **151** from the compound **150** was observed instead of cyclisation. In a special study,[95] it was demonstrated that such an anomalous Pummerer reaction is typical of C(3)-unsubstituted indole derivatives and is attributable to the prior formation of the seven-membered ring.



(*a*) Me_3SiOCF_3, 20 °C; (*b*) $(CF_3CO)_2O$, CF_3CO_2H.

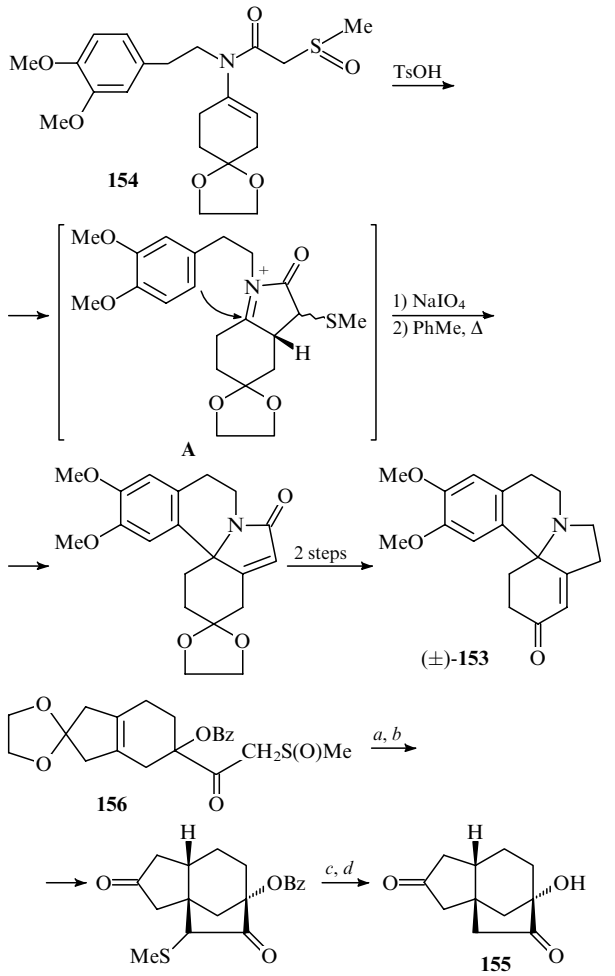
This research group[96] carried out the first synthesis of an alkaloid of the 3,4-secoakuammilan series by cyclisation of sulfoxide **152** under the conditions of the Pummerer reaction. In this synthesis, the strongly strained quaternary centre at the C(7) atom was generated through the formation of the eight-membered lactam ring.



(*a*) $(CF_3CO)_2O$, CH_2Cl_2; (*b*) $NaCNBH_3$; (*c*) Ni/Ra, EtOH.

4. Synthesis of cyclic compounds by intramolecular reactions of sulfenium cations with various nucleophilic traps

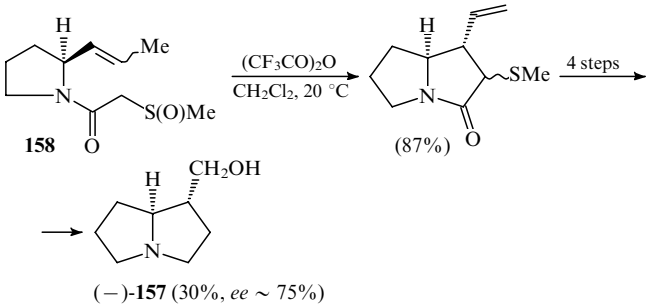
The Pummerer reaction is finding increasing use in the construction of various rings, including those present in natural compounds, primarily, of heterocycles (see the review[12]), and, to a lesser extent, of carbocycles. Natural heterocycles are constructed by intramolecular binding of the sulfenium cation to various nucleophilic traps. The C=C bonds other than those present in indoles can serve as nucleophiles as exemplified by the ingenious synthesis of the alkaloid (±)-3-demethoxyerythratidinone (**153**).[97] The latter was prepared starting from substituted sulfinylacetamide **154**, which was subjected to double cyclisation *via* intermediate **A**.



(*a*) $(CF_3CO)_2O$; (*b*) $SnCl_4$; (*c*) Ni/Ra; (*d*) H_2, Pd/C.

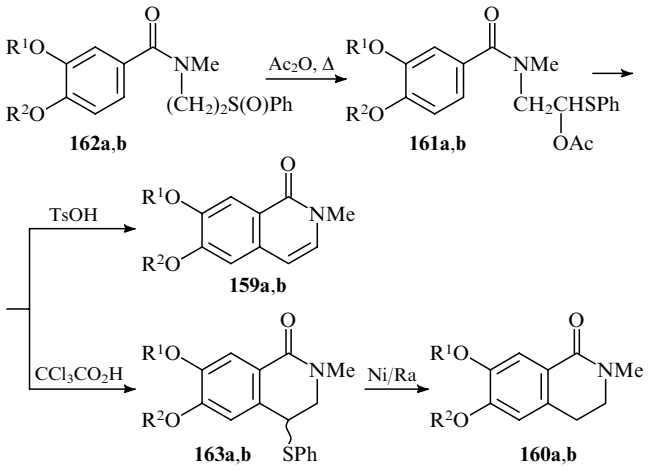
In the synthesis of the key starting compound **155** for the preparation of gibberellic acid, cyclisation also proceeded through the intramolecular coupling of the sulfenium cation with the double bond of compound **156**.[98]

Ishibashi and coworkers used the intramolecular coupling of the sulfenium cation with the C=C bond in the development of a general facile procedure for the synthesis of pyrrolizidine alkaloids [99] and in the construction of the optically active (−)-trachelanthamidine (**157**) from precursor **158**.[100]



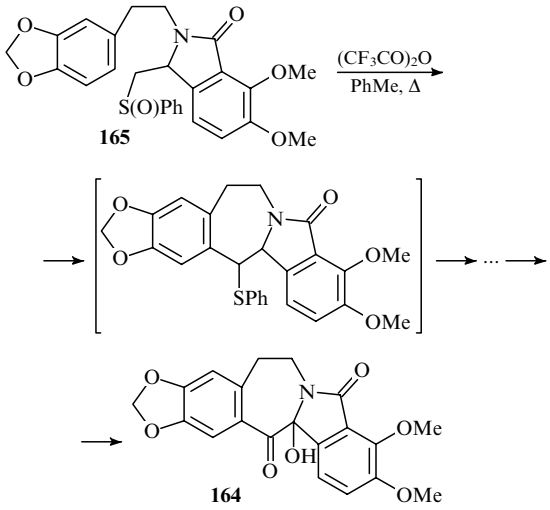
(−)-**157** (30%, *ee* ~ 75%)

Cyclisation can proceed through a Friedel–Crafts-like coupling of the sulfenium cation with the aromatic ring containing activating alkoxy groups. Thus isoquinolone alkaloids, *viz*., dimethoxymethylisocarbostyril (**159a**) and doryanine (**159b**), as well as *N*-methylcorydaldine (**160a**) and oxyhydrastinine (**160b**) were synthesised starting from common precursors **161a**,**b**.[101] The latter were prepared by the reactions of Ac_2O with alkylamides **162a**,**b**. Cyclisation of α-acetoxy sulfides **161a**,**b** under the action of TsOH afforded alkaloids **159a**,**b**, whereas treatment of the compounds **161a**,**b** with CCl_3CO_2H gave rise to intermediates **163a**,**b**, which were subjected to desulfurisation to form the compounds **160a**,**b**.

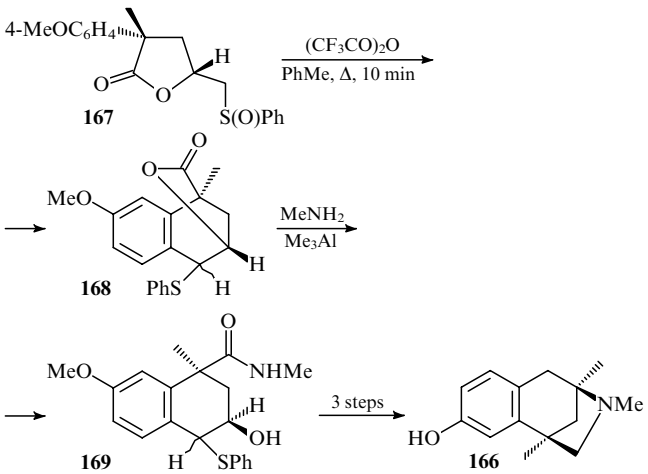


$R^1 = R^2 = Me$ (**a**), $R^1 - R^2 = CH_2$ (**b**).

Analogous procedures were used for the preparation of the tetrahydroisoquinoline alkaloid hydrohydrastinine from the corresponding aromatic amino sulfoxide [102] and for the facile synthesis of the polycyclic alkaloid chilenine (**164**),[103] the seven-membered ring of the latter being constructed upon cyclisation of precursor **165**.

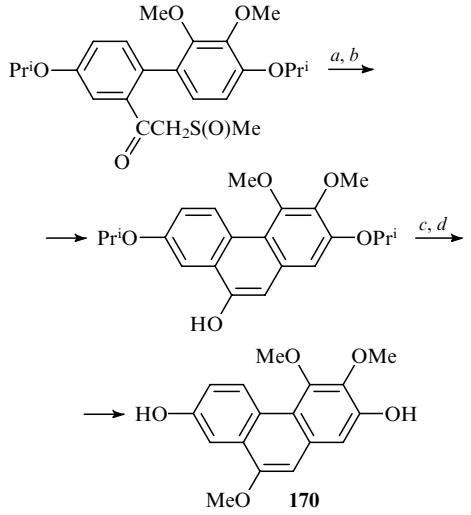


(+)-Aphanorphine (**166**), which exhibited specific optical rotation identical to that of the natural alkaloid, was synthesised [104] from optically active sulfinyl-substituted lactone **167**. The Pummerer reaction was accompanied by cyclisation to yield a



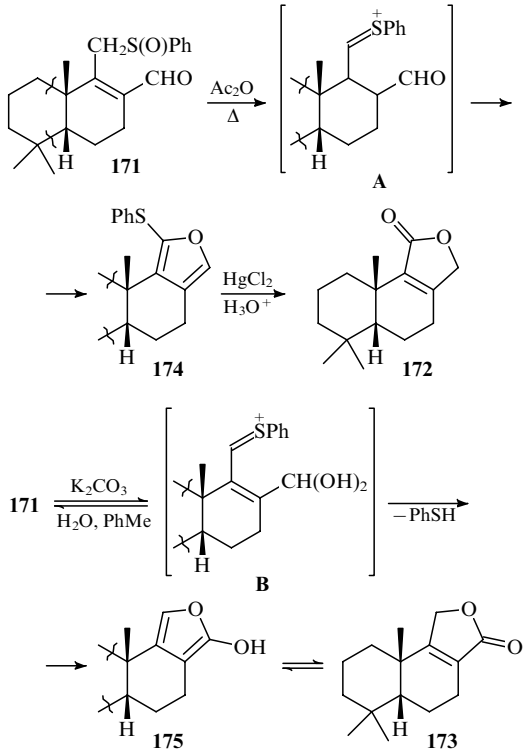
mixture of enantiomeric lactones **168**. The lactone-ring opening was performed under the action of methylamine and the resulting bicyclic intermediate **169** was converted into the target alkaloid **166** in three steps.

The short synthesis of gymnopusin (**170**),[105] which is the first representative of natural phenanthrenes with the oxygen-containing substituent at the C(10) atom, provides yet another example. It should be noted that the results of this synthesis proved the structure of natural gymnopusin.

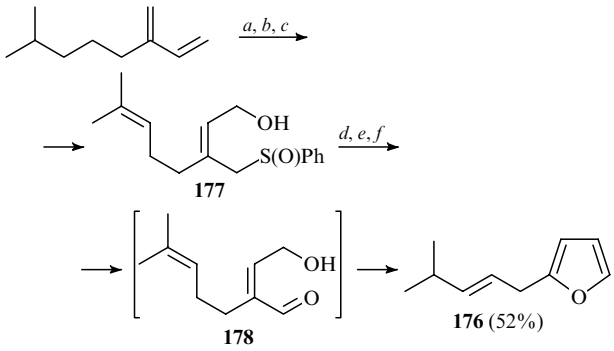


(*a*) $(CF_3CO)_2O$; (*b*) Na/NH_3; (*c*) $(MeO)_2SO_4$, $CaCO_3$; (*d*) BCl_3, CH_2Cl_2.

Oxygen-containing groups can also be involved in intramolecular coupling with the sulfenium cation to form oxacycles. Thus the involvement of the aldehyde group of sulfinyl-substituted α,β-unsaturated aldehyde **171** in cyclisation under the conditions of the Pummerer reaction made it possible to synthesise butenolides isodrimenin (**172**) or confertifolin (**173**) *via* intermediate compounds **174** or **175** containing substituted furan rings.[106, 107] The possible mechanism of this process involves the free (under the action of Ac_2O) or hydrated aldehyde group (upon heating in aqueous dioxane in the presence of K_2CO_3) (transition states **A** and **B**, respectively).

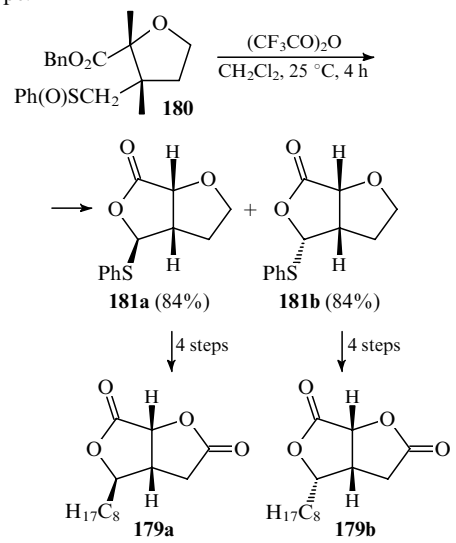


The short one-pot synthesis of furanoterpene perylene (**176**) (a component of insect communication pheromones) was carried out using the sila-Pummerer rearrangement of hydroxy-containing allyl sulfoxide **177**, which was readily derived from the adduct of β-myrcene with benzenesulfinyl chloride.[108] The authors of the cited study believed that the furan ring was generated from intermediate hydroxyaldehyde **178**.

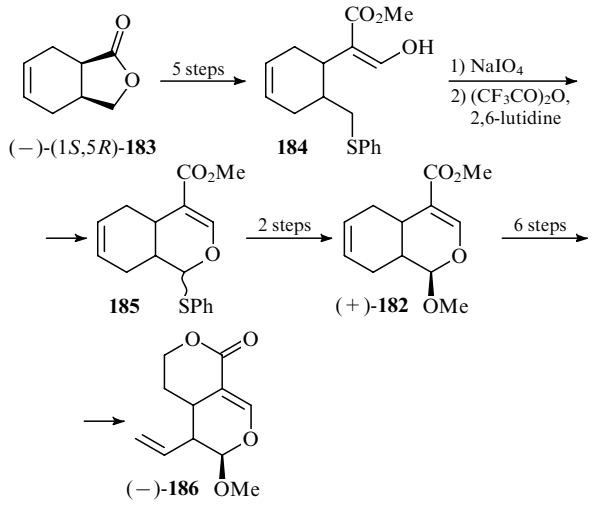


(*a*) PhSOCl, 5 kbar; (*b*) AcOK, AcOH; (*c*) H_2SO_4, MeOH; (*d*) Bu^nLi, −85 °C; (*e*) Me_3SiCl, −85 to 25 °C; (*f*) H_2O, C_5H_{12}.

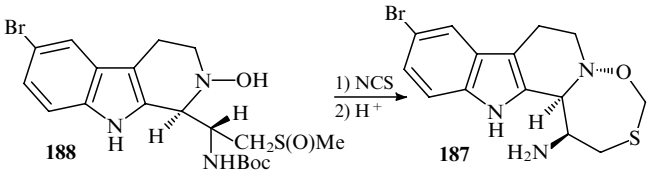
The synthesis of bicyclic lactones **179a**,**b**, which are 3-normethylene analogues of avenaciolide and isoavenaciolide, respectively, provides an example of the involvement of the ester group in cyclisation of the above-mentioned type.[109] The Pummerer reaction of optically active sulfenyl-substituted ester of tetrahydrofuranocarboxylic acid **180** afforded a mixture of diastereomeric bicyclic compounds **181a**,**b** in a ratio of 5 : 1. Both these compounds were converted into the target compounds **179a**,**b** in four steps.



The ring closure can occur with the participation of the OH group. Optically active pyran derivative (+)-**182** serves as the common key intermediate in enantiospecific syntheses of iridoid monoterpenes. This derivative was prepared[110] from bicyclic lactone **183** containing the required chiral centres. The compound **183** was converted into sulfide **184** by reactions in which the latter centres remained intact. Oxidation to sulfoxide and cyclisation, which occurred through the Pummerer reaction involving the enol hydroxy group, gave rise to compound **185** in which the SPh group was replaced by OMe. The methylacetal of iridoid aglycone sweroside **186** was prepared from the compound **182** in six steps.



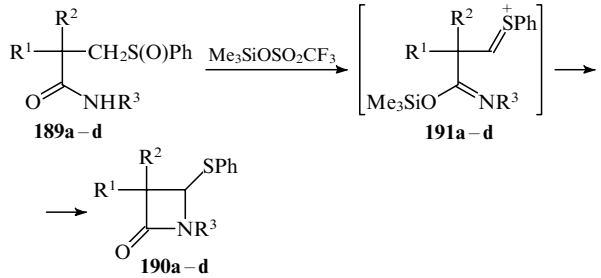
To construct the seven-membered oxathiazepine ring involved in the L-eudistamine molecule (**187**),[111] which shows activity against *Herpes simplex*, the Pummerer reaction was carried out with the use of intermediate **188** in the course of which the sulfenium ion was coupled with the adjacent N—OH group.



NCS is *N*-chlorosuccinimide.

The Pummerer reaction was used in the chemistry of penicilins and related biologically active lactams. This reaction allows one to convert rather inactive sulfoxides of the penam series into penem derivatives exhibiting high biological activities (see, for example, Refs 112 and 113).

The most interesting results were obtained on cyclisation of β-amido sulfoxides in which intramolecular coupling of the sulfenium cations with the nitrogen atom of the imino group occurred to form substituted lactams. Thus Kaneko [114] was the first to perform intramolecular cyclisation in mild conditions of the sila-Pummerer reaction under the action of silyl trifluoromethanesulfonate on β-amidosulfoxides **189a–d** and obtained 4-arylthio-substituted lactams **190a–d**. Kaneko demonstrated that the compound **189c** containing one β-alkyl substituent produced predominantly *cis*-3,4-disubstituted lactam **190c**, whereas enantiomerically pure precursors, *viz*., (*R*)- or (*S*)-**189d**, yielded optically active (*R*)- or (*S*)-lactams **190d** with *ee* ~ 67% (see Ref. 115).‡ These results provided supporting evidence for the assumption as to the correlation between the mechanism of the

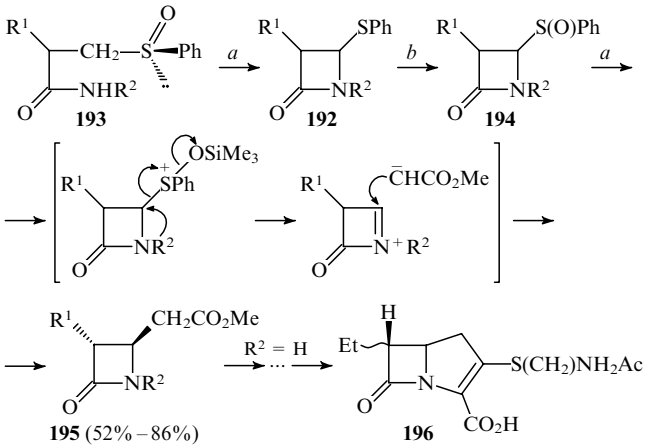


$R^1 = R^2 = Me$, $R^3 = OBn$ (**a**); $R^1 = R^2 = H$, $R^3 = OBn$ (**b**); $R^1 = Me$, $R^2 = R^3 = H$ (**c**); R^1, R^2, $R^3 = H$ (**d**).

‡ Unfortunately, the absolute configurations of the compounds used in the investigation [115] were not established.

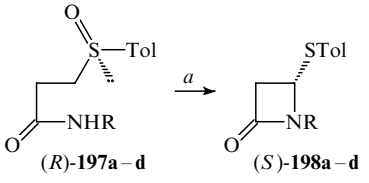
Pummerer reaction (involving sulfenium intermediate **191**) and the first stage of the biosynthesis of lactam antibiotics.

Kita and coworkers made a considerable contribution to the solution of the problems associated with the synthesis of β-lactams. The authors demonstrated that nitrogen heterocycles containing the thio group in the α position can be readily synthesised with the use of versatile silylating agents, *viz*., silyl ketene acetals.[116] This methodology was first examined for the Pummerer cyclisation of ω-amido sulfoxides to obtain intermediates utilised in the synthesis of pyrrolizidine and indolizine alkaloids.[117] Later on, this procedure was extended to the synthesis of β-lactam carbapenems starting from ω-amido sulfoxides.[118] 4-(Arylthio)-azetidin-2-ones **192**, which were prepared by the reactions of methyl(trimethylsilyl) ketene acetal with amido sulfoxides **193**, were used as the starting compounds. The compounds **192** were oxidised to sulfoxides **194**. Under the action of the same ketene acetal, the latter compounds were transformed into *trans*-disubstituted azetidin-2-ones containing ester groups at the C(4) atom [**195**, the ratio *trans*:*cis* = (89–95):(5–11)], which are the key precursors in the synthesis of β-lactam antibiotics, carbapenems. This procedure was employed for the preparation of racemic carbapenem PS-5 (**196**)[119] and β-methylcarbapenem.[120] The enantioselective synthesis of thienamycin was carried out starting from enantiomerically pure β-amido sulfoxide of the type **193**.[121]



(*a*)  , ZnI_2 (cat), MeCN, 20 °C, (*b*) oxidation.

Kita *et al*.[122] demonstrated that (*S*)-(tolylthio)lactams **198a–d** (*ee* 82%–83%) can be prepared in high yields starting from optically active β-amido sulfoxides, for example, from (*R*)-**197a–d**, whereas the corresponding (*R*)-lactams can be prepared with high enantioselectivity from (*S*)-**197a–d**. Hence, the authors of the cited study not only improved the enantioselectivity of this reaction compared to the method proposed by Kaneko,[114] but also proved unambiguously that cyclisation was accompanied by the transfer of the asymmetric centre from the sulfinyl group to the C(4) atom of the lactam ring.

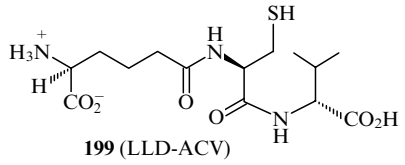


R = MeCHPh (**a**), Bn (**b**), $CHPh_2$ (**c**), 2-$BrC_6H_4CH_2$ (**d**);

(*a*)  , ZnI_2 (cat), MeCN, 20 °C.

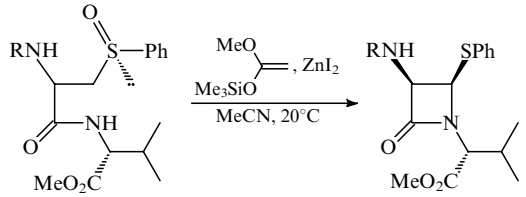
The mechanism of the first stage of the biosynthesis of penicillins consisting in the construction of the *cis*-disubstituted lactam ring by oxidative cyclisation of the tripeptide δ-(L-α-

aminoadipyl)-L-cysteinyl-D-valine (**199**) (LLD-ACV, which was assumed [123] as the direct precursor of isopenicillin N), has long been unknown.



199 (LLD-ACV)

Under the conditions of the sila-Pummerer reaction, amido sulfoxides **200a**,**b**, which contain substituents analogous to those in the compound **199**, were demonstrated [124] to give predominantly *cis*-disubstituted lactams **201a**,**b**. This fact was seemingly evidence in favour of the possible occurrence of the Pummerer sulfenium intermediate in the first stage of the biosynthesis of penicillins.



(*R*)-**200a**,**b** *cis*-**201a**,**b**

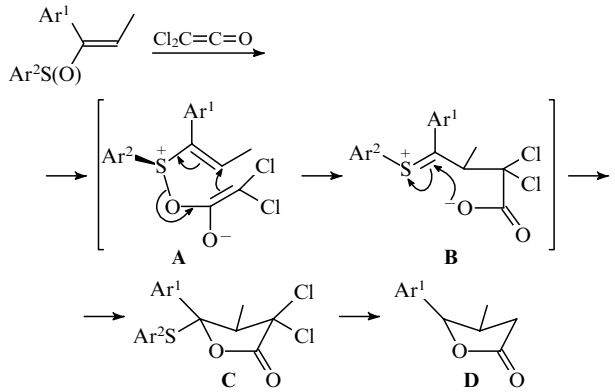
R = BnO_2C (**a**); BnO_2CHN (**b**).

However, the results of the recent investigation performed by Baldwin and coworkers [125] gave conclusive evidence that the biosynthesis of penicillins takes quite a different path. The key stage of this process involves the attack of the Fe-activated enzyme IPNS on the thiol group of LLD-ACV (**199**). When analysing this problem, Shibata and Kita [126] admitted that their strategy [124] has not elucidated the mechanism of the biosynthesis of penicillins, but led to substantial improvement in Pummerer-type asymmetric cyclisation and in the Pummerer reactions of nonracemic sulfoxides. In earlier studies (see the review [14]), high asymmetric induction was not achieved and *ee* was at most 30%.

5. Syntheses involving additive Pummerer reactions

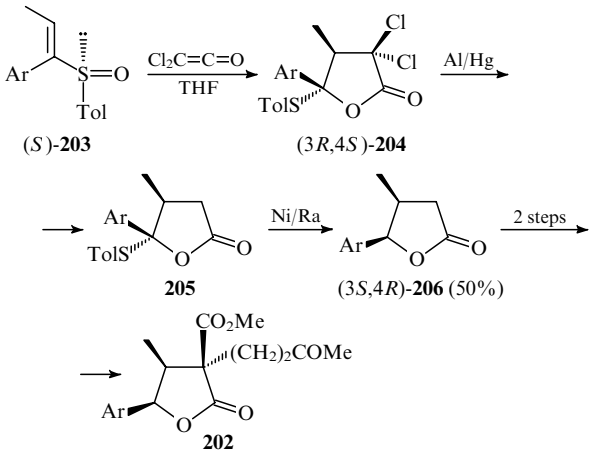
The most interesting results in the field of the asymmetric synthesis of natural compounds were obtained with the so-called additive Pummerer reaction (primarily using the procedure proposed by Marino). These investigations have been considered in detail in a previous review [14] and hence, they are only briefly outlined in the present review .

The mechanism of the additive Pummerer reaction involves the initial attack of electrophilic dichloroketene, which is prepared *in situ* by the reaction of the zinc–copper pair with trichloroacetyl chloride, on the sulfinyl oxygen atom [127, 128] as exemplified below



by disubstituted vinyl sulfoxide. Then the zwitterionic intermediate **A** is converted into the Pummerer sulfenium-cationic intermediate **B** through the [3,3]-sigmatropic rearrangement involving the vinyl C=C bond. The intermediate **B** is stabilised through the intramolecular reaction with the carboxylate anion to give 3-arylthio-5,5-dichloro-γ-lactone **C**.

After dechlorination and desulfurisation, 3,4-disubstituted lactone **D** is obtained. The configurations of the chiral centres in the latter compound are completely controlled by the configuration of the chiral sulfinyl group in the initial vinyl sulfoxide. The synthesis of the key precursor of the neolignane porosin **202** starting from (*S*)-(dimethoxyphenyl)prop-1-enyl tolyl sulfoxide (**203**) [128] is an example of the additive Pummerer reaction. Thiosubstituted dichlorolactone **204**, which was obtained in high yield, was dechlorinated with aliminium amalgam to obtain lactone **205**. The latter was desulfurised with freshly prepared Raney nickel at 0 °C. The resulting enantiomerically pure γ-lactone **206** was converted into the target compound (3*S*,4*R*)-**202** in two steps.



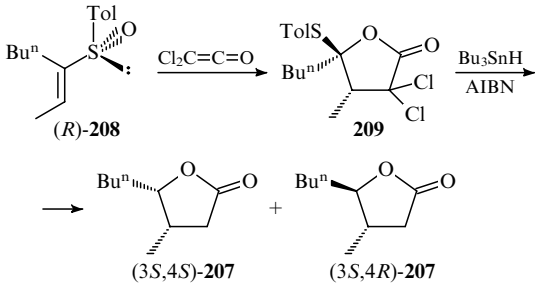
(*S*)-**203** (3*R*,4*S*)-**204**

205 (3*S*,4*R*)-**206** (50%)

202

Ar = 3,4-$(OMe)_2C_6H_3$.

Separation of the dechlorination and desulfation stages is important for a successful synthesis. For example, the synthesis of oak lactones **207** from (*E*,*R*)-3-(tolylsulfinyl)hept-2-ene (**208**),[127] which involved one-step dechlorination–desulfurisation of lactone **209** under the action of tributylstannane, afforded the final product as a mixture of enantiomers.

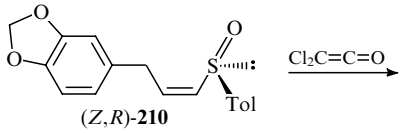


(*R*)-**208** **209**

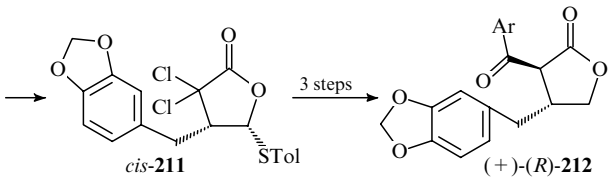
(3*S*,4*S*)-**207** (3*S*,4*R*)-**207**

AIBN is azodiisobutyronitrile.

The additive Pummerer reactions can be performed with various nonracemic α,β-unsaturated sulfoxides. Thus lactone (+)-(*R*)-**212**, which is the key intermediate in the syntheses of a broad spectrum of lignane lactones, was derived from (*Z*,*R*)-piperonylvinyl sulfoxide (**210**) *via* lactone **211**.[129]



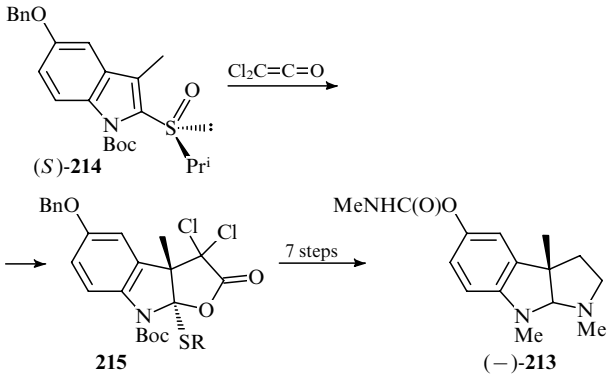
(*Z*,*R*)-**210**



cis-**211** (+)-(*R*)-**212**

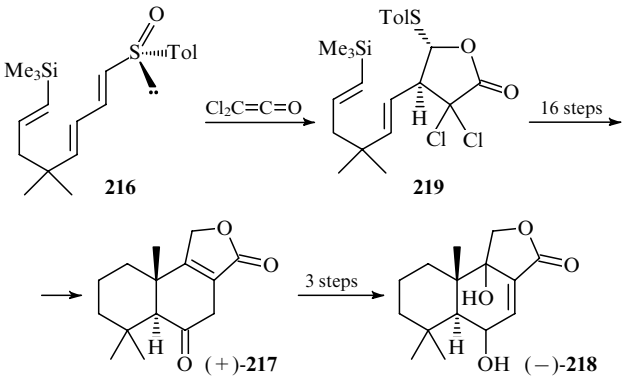
Ar = 3,4,5-$(OMe)_3C_6H_2$.

In the synthesis of (−)-physiostigmine (**213**) (the alkaloid used for the treatment of glaucoma), the reaction pathway was found to depend on the electronic and steric characteristics of the sulfinyl group and on the bulkiness of the protecting group at the nitrogen atom of the initial 2-sulfinylindole.[130] 5-Benzyloxy-3-methyl-2-(isopropylsulfinyl)indole [(*S*)-**214**] containing the protecting Boc group at the nitrogen atom proved to be the starting compound of choice. The reaction involving the above reagent proceeded through the tricyclic adduct with dichloroketene **215** to yield (−)-physiostigmine [(−)-**213**] exhibiting specific optical rotation identical to that of the natural compound.



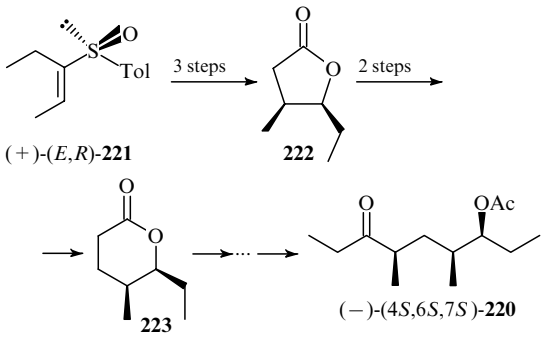
(*S*)-**214** **215** (−)-**213**

Sulfinyl-substituted triene **216** is an example of polyunsaturated sulfinyl precursors. This compound was utilised in the synthesis[131] of drimane-type sesquiterpenoids (+)-fragolide (**217**) and (+)-pereniporin (**218**). The process began with the addition of dichloroketene and the construction of *p*-tolylthiodichloro-γ-lactone fragment in compound **219**. The subsequent multistage transformation involved dechlorination and desulfurisation along with cationic cyclisation with the participation of the vinylsilane group.



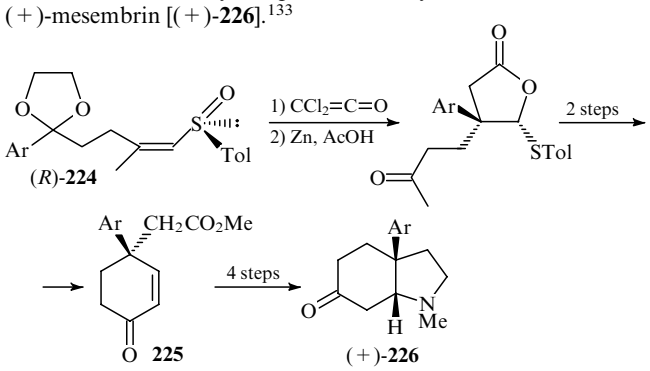
216 **219**

The advantages of the additive Pummerer reaction are the possibile subsequent transformations of primary γ-lactones, which can be used in enantioselective syntheses of compounds with various structures. For example, in the facile synthesis of the pheromone with the linear structure, *viz*., (7)-(4*S*,6*S*,7*S*)-serricornin (**220**),[132] starting from (*E*,*R*)-3-(tolylsulfinyl)pent-2-ene (**221**), γ-lactone **222** was converted into the key intermediate, *viz*., 4,5-disubstituted valerolactone **223**, with retention of the chiral centres.



(+)-(*E*,*R*)-**221** **222** **223** (−)-(4*S*,6*S*,7*S*)-**220**

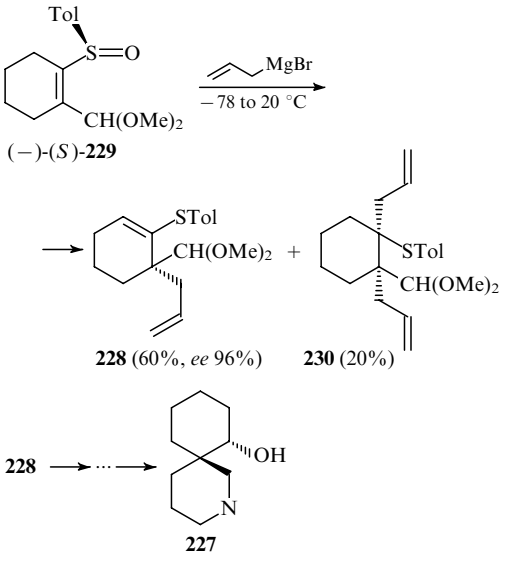
The product of the Pummerer reaction of β,β-disubstituted vinyl disulfoxide (*R*)-**224** with dichloroketene was dechlorinated *in situ* and then converted into 4,4-disubstituted cyclohexenone **225**, which was the key compound in the synthesis of the alkaloid (+)-mesembrin [(+)-**226**].[133]



(*R*)-**224** **225** (+)-**226**

Ar = 3,4-$(OMe)_2C_6H_3$.

Marino's procedure does not exhaust the synthetic possibilities of the additive Pummerer reaction. Iwata *et al.*[134] found that α,β-unsaturated sulfoxides, including cyclic sulfoxides, underwent the Pummerer-like reaction under the action of allylmagnesium bromide and applied this reaction to the enantioselective total synthesis of (−)-sibirine (**227**).[135] The monoallylation product **228** of cyclohexene sulfoxide (−)-(*S*)-**229**, which was readily separated from diallylated compound **230**, already contained the chiral quaternary carbon atom characteristic of (−)-sibirine **227**. The latter was prepared by a multistage transformation; its specific optical rotation corresponded to that of the natural alkaloid.



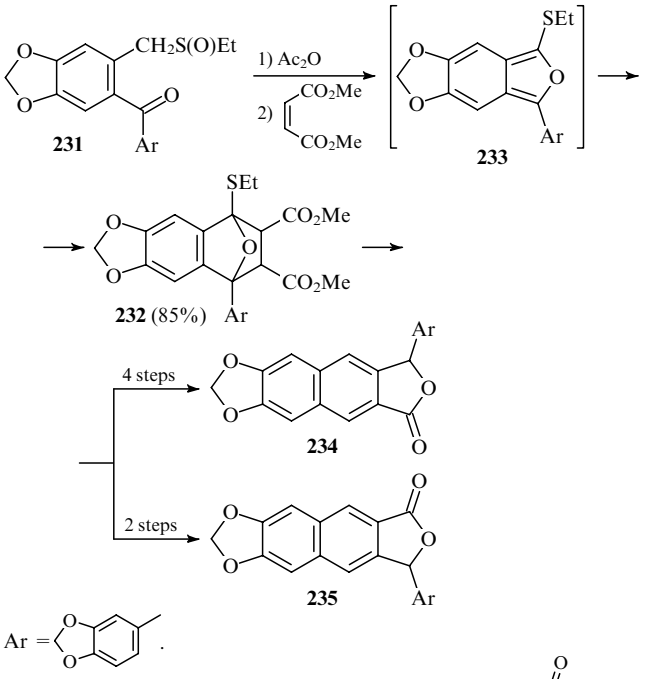
(−)-(*S*)-**229** **228** (60%, *ee* 96%) **230** (20%) **227**

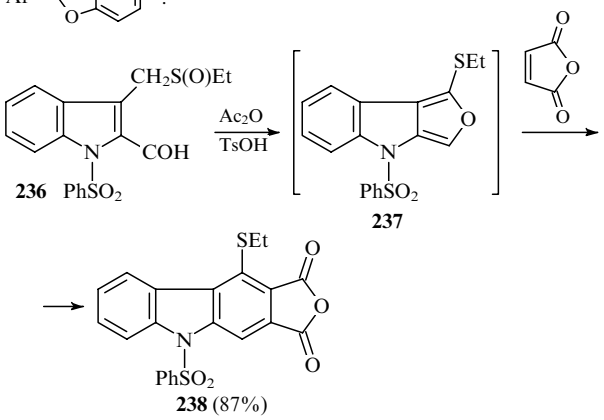
An analogous methodology was employed in the facile synthesis of the spirocyclic alkaloid (−)-perhydrohistrionicotoxin, which also contains the quaternary chiral centre.[136]

6. Syntheses based on cascade processes involving the Pummerer reaction

Examples of application of cascade processes involving the Pummerer reaction to syntheses of natural products were considered above. It should be noted that Padwa and coworkers have obtained particularly impressive results in recent years.[12, 137–139]

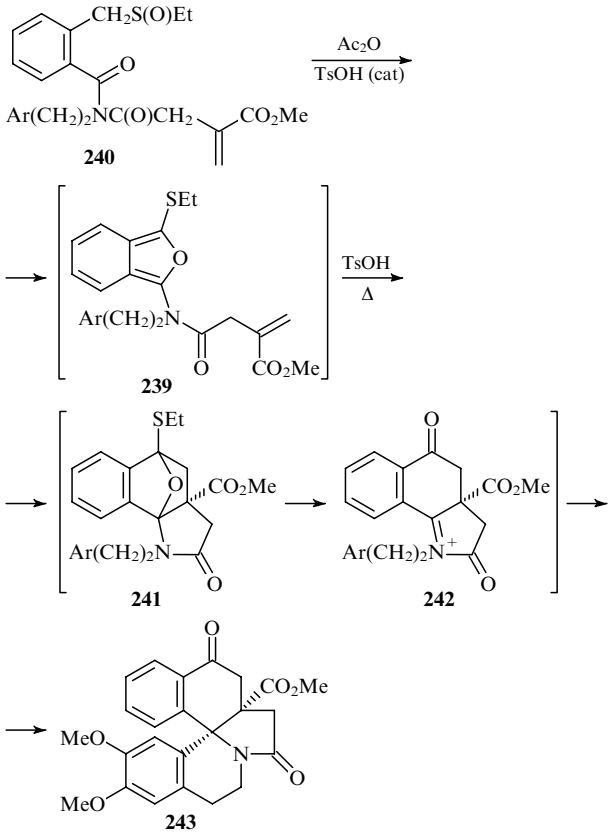
The tandem use of the Pummerer and Diels–Alder reactions made it possible to develop a versatile procedure for the construction of polycyclic molecules. Thus treatment of sulfinylmethyl-substituted diaryl ketone **231** with acetic anhydride and then with dimethyl maleate afforded [137] adduct **232** of the initially formed Pummerer-reaction product, *viz*., α-ethylthioisobenzofuran **233**, in high yield. Simple transformations of the adduct **232** gave rise to natural lactones of the naphthalene series, *viz*., taiwanin **234** and justicidin E **235**.





Kappe and Padwa [138] used *o*-formyl-substituted indole sulfoxide **236** as the starting compound. After the Pummerer reaction, the primary cyclisation product **237** was treated (without isolation) with maleic anhydride to obtain carbazole derivative **238** in high yield. This method can be used for the construction of natural carbazoles, for example, of ellipticine.[12]

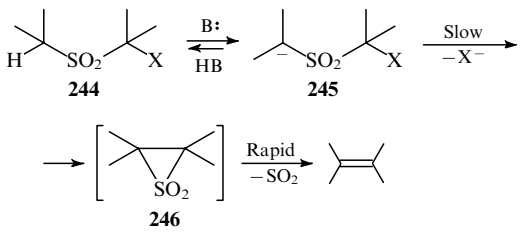
The one-pot synthesis of the five-membered cyclic skeleton of the alkaloid erythrinane is a particularly elegant cascade procedure.[139] For this purpose, compound **239**, which was derived from polysubstituted aromatic sulfoxide **240** under the action of Ac_2O in the presence of a catalytic amount of TsOH, was heated with an additional amount of TsOH. The process involved an intramolecular Diels–Alder reaction giving rise to adduct **241** followed by the oxabicycle opening yielding product **242** and, finally, cyclisation of the latter involving the *N*-acyliminium ion to give 3,4-benzoerythrinane **243** (the total yield was 70%). Padwa *et al*.[139] noted that the tandem process proceeded more or less readily depending on the reaction conditions. The best results were obtained with the use of Ac_2O in toluene in the presence of catalytic amounts of TsOH, which efficiently suppressed the formation of acetoxy sulfide (a normal product of the Pummerer reaction).



Ar = 3,4-$(MeO)_2C_6H_3$.

IV. Use of the Ramberg–Bäcklund rearrangement for the insertion of C=C bonds

The Ramberg–Bäcklund rearrangement (see the reviews [3, 141, 142]), which is the oldest reaction [140] of all known sulfonyl rearrangements, proceeds with the participation of sulfones of type **244** containing a substituent X in the α position as substrates. The substituent can be readily removed in the anionic form once carbanion **245** is generated through α-deprotonation. The mechanism of the process was confirmed by the results of numerous kinetic studies (see the review [3]).



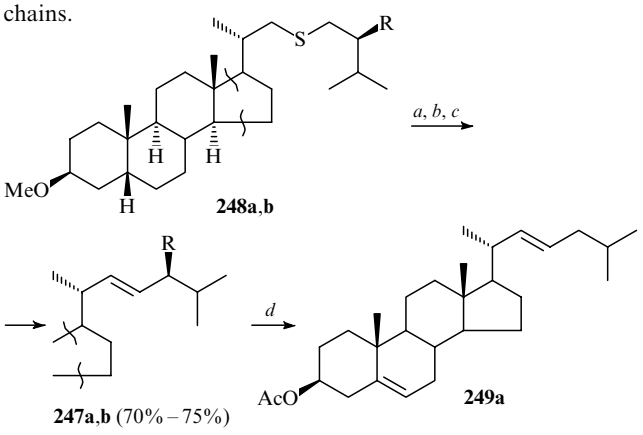
The reaction gives rise to the C=C bond in the strictly fixed site of the molecule through the formation of episulfone **246**, which readily eliminates SO_2. The involvement of the intermediate **246** in the rearrangement was long judged from indirect evidence. Recently, episulfones, which are stable only below −20 °C, were prepared by the reactions of Bu^tOK with some highly reactive α-iodosulfones primarily of the thiolane 1,1-dioxide series.[143]

The Ramberg–Bäcklund reactions are traditionally carried out with the use of α-Cl and α-Br-substituted sulfones as the starting compounds. Halogenation with soft reagents, for example, with *N*-halogenosuccinimides, is often performed at the stage of the initial sulfide before its oxidation to sulfone.

Meyers *et al.*[144] devised a convenient modification of this reaction, which allowed the one-pot preparation of α-chlorosubstituted sulfone and its subsequent rearrangement. In this version, sulfone was treated with powdered KOH in CCl_4–Bu^tOH. Unfortunately, this reaction is sometimes complicated by side processes, such as excessive halogenation or formation of chlorocarbene. To prevent these side reactions, Chen *et al.*[145] used KOH adsorbed on Al_2O_3 in Bu^tOH in the presence of CBr_2F_2, which does not generate carbenes.

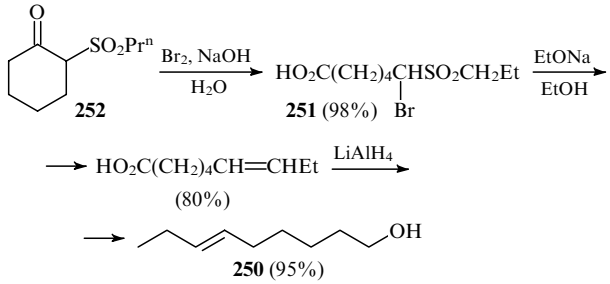
The Ramberg–Bäcklund reaction is actually a versatile procedure for the construction of the C=C bond; the configuration of the latter depends both on the structure of the initial sulfone and the reaction medium; in open-chain compounds, the resulting bond generally has the *E* configuration. The synthetic importance and applications of this reaction were covered in reviews.[141, 142, 146] However, the data on use of this process in syntheses of natural compounds is systematised for the first time in the present review.

Examples of the construction of isolated C=C bonds in open-chain natural compounds or in linear fragments of more complex molecules are considered below. Thus the Bu^tOK-induced rearrangement of α-chlorosulfone was used in the highly *E*-stereoselective synthesis of Δ^{22}-unsaturated steroids of types **247a**,**b** starting from sulfides **248a**,**b**, which were prepared based on 3α,5α-cyclo-6β-methoxypregnane.[147] The structure of the compound **247a** was proved by its conversion into the known steroid **249a**. This synthesis was carried out in view of the fact that many exotic steroids from plants and animals contain unsaturated side chains.

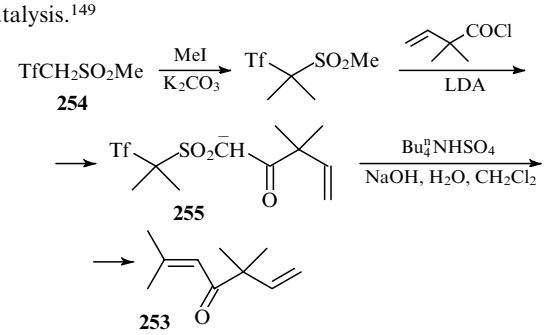


R = H (**a**), Et (**b**); (*a*) NCS, CCl_4; (*b*) MCPBA, $NaHCO_3$; (*c*) 3 equiv. of Bu^tOK; (*d*) R = H, $Zn(OAc)_2$, AcOH.

Non-6-en-1-ol (**250**), which is a pheromone of Mediterranean fruit flies,[148] was synthesised with the use of the rearrangement of linear α-bromosulfone **251**, which was prepared by the reaction of 2-(*n*-propylsulfonyl)cyclohexanone (**252**) with bromine and NaOH. This reaction provided the basis for a general procedure for the synthesis of α-bromosulfones. The scheme of the synthesis ended in reduction of the carboxyl group to the alcoholic group in the initially formed non-6-enoic acid.

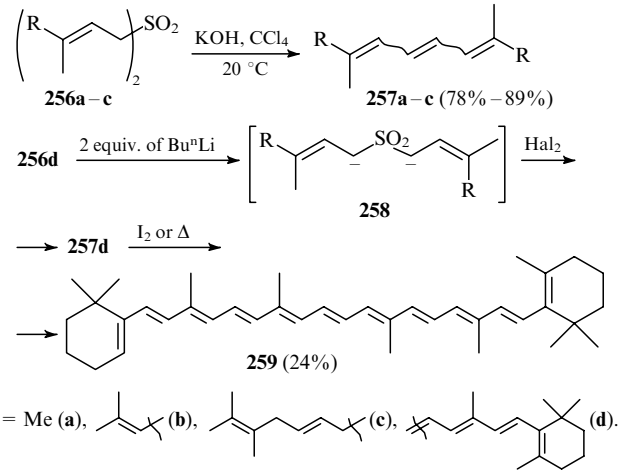


The short synthesis of natural artemisia ketone (**253**) (the total yield was 86%) starting from methyl trifluoromethylsulfonylmethyl sulfone (**254**) demonstrated that the triflate fragment is an excellent leaving group in the Ramberg–Bäcklund reaction. The rearrangement of ketosulfone **255**, which was prepared by alkylation followed by acylation of the sulfone **254**, was carried out at room temperature under conditions of phase transfer catalysis.[149]



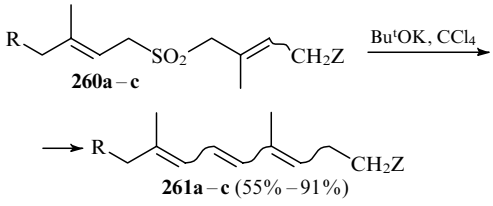
Tf = CF_3SO_2; LDA is lithium diisopropylamide.

Polyenes, including those containing conjugated C=C bonds, can be constructed by the Ramberg–Bäcklund rearrangement starting from substituted diallyl sulfones. In an early study,[150] sulfones **256a**–**d** were used for this purpose. It appeared that treatment of the sulfones **256a**–**c** with KOH and CCl_4 at room temperature afforded mixtures of stereoisomeric polyenes **257a**–**c** in high yields, whereas the retinyl sulfone **256d** did not enter into the reaction under these conditions. To prepare a mixture of polyenes from the latter compound, it was successively treated with butyllithium (it was assumed that dianion **258** was formed) and halogen. Isomerisation of a mixture of the compounds **257d** under the action of iodine or upon heating gave rise to natural all-*trans*-β-carotene (**259**).



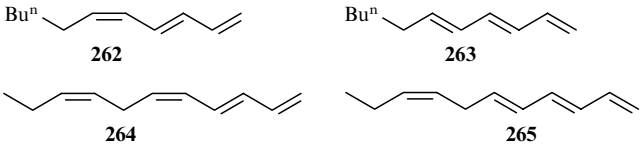
R = Me (**a**), (**b**), (**c**), (**d**).

Later, mixtures of substituted polyisoprenoids **261a**–**c** were obtained from diallyl sulfones **260a**–**c** containing polar substituents Z according to Meyers's procedure.[151]

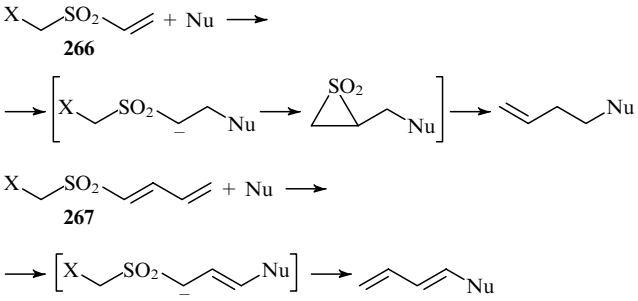


R = H, ; Z = OEt (**a**), CH_2COMe (**b**), $CH_2C(Me)(OH)CH=CH_2$ (**c**).

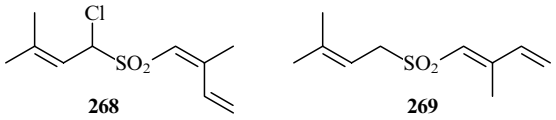
The synthesis of natural undecatrienes **262** and **263** and undecatetraenes **264** and **265** (the compounds **262** and **263** find use in perfumery) from the corresponding diallyl sulfones according to Meyers's procedure [152] also afforded mixtures of geometric isomers.



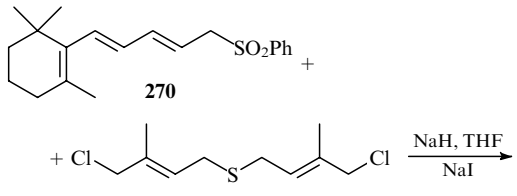
Burger *et al.* [153] failed to elaborate the stereoselective synthesis by decreasing the basicity of the reaction medium through the generation of the required anion by the addition of the sulfinate anion to α-halogenovinyl- (**266**) or butadienyl sulfones **267** [the so-called MIRB process (Michael Induced Ramberg–Bäklund)]. Starting from sulfones **268** and **269**, this procedure also yielded mixtures of stereoisomeric isoprenoinds.[153] The authors of the cited studies [150, 151, 153] did not examine the mechanisms of these processes. Hence, the stage at which *Z*-bonds are formed in the syntheses starting from all-*trans* compounds remains unknown.

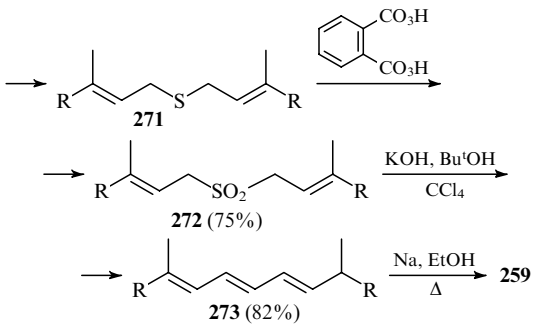


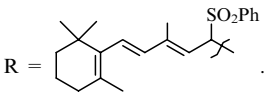
Nu = SO_2Ph; X = Cl, Br.



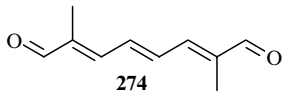
Recently, the problem of the construction of all-*trans*-polyene through the Ramberg–Bäcklund rearrangement has been successfully solved [154] in the synthesis of natural β-carotene **259**, which (along with its analogues) is finding increasing use as a food ingredient possessing simultaneously chemotherapeutic activity against some varieties of cancer. The scheme of the synthesis was based on alkylation of readily accessible sulfone **270** with dichlorodiallyl sulfide, which was prepared from isoprene in four steps. In the alkylation stage, NaI was added to the reaction mixture to form *in situ* more reactive iodide. Then intermediate **271** was converted into sulfone **272** and the latter was subjected to the rearrangement into compound **273** under very mild conditions (oxidation with peroxyphthalic acid formed *in situ* and Meyers's rearrangement under an atmosphere of argon). The sulfonyl groups were removed from the intermediate **273** by reduction. Starting from isoprene, β-carotene **259** (all-*trans*) was obtained in a total yield of 13%. Judging from the results obtained in the cited study, the Ramberg–Bäcklund rearrangement of the sulfone **272** gave rise exclusively to the (*E*)-C=C bond. The presence of sulfonyl groups in the radical R prevents isomerisation of the already existing (*E*)-C=C bonds.





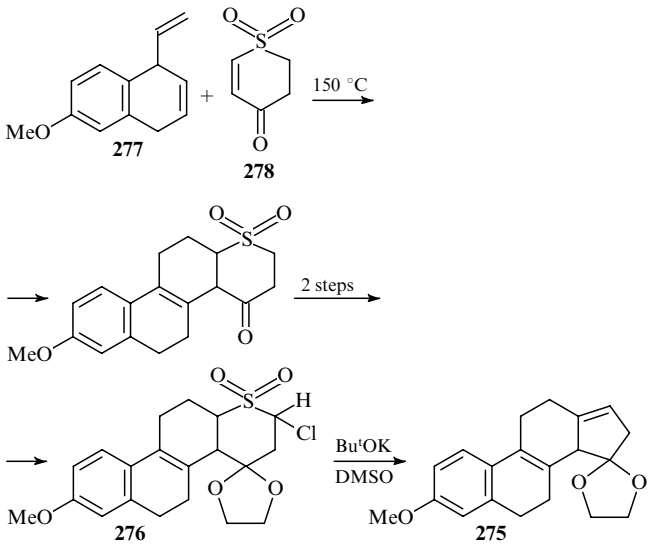


This procedure can also be used for the construction of other natural all-*trans*-polyenes. Thus, this procedure was employed [154] for the preparation of key intermediate **274** in the synthesis of carotenoids by the Wittig method.

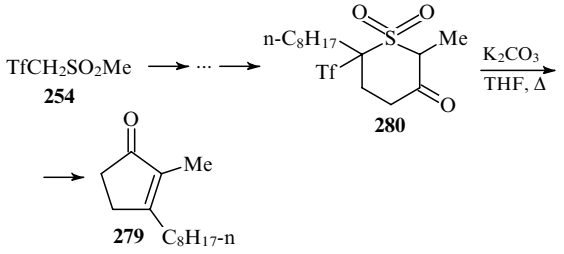


In his review, Paquette [141] emphasised that the construction of unsaturated rings of different sizes is one of the problems, which can be solved by applying the Ramberg–Bäcklund rearrangement. Examples of the use of this rearrangement in the synthesis of natural compounds are the preparation of both unsaturated carbocycles and oxygen-containing heterocycles.

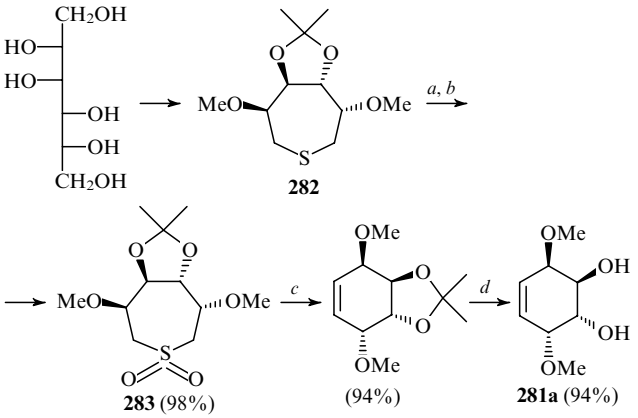
In the study,[155] the cyclopentene ring in steroid **275** was formed starting from tetracyclic α-chloro-substituted sulfone **276**, which was synthesised in two steps from the adduct of diene **277** and 2,3-dihydrothiopyran-4-one *S*,*S*-dioxide (**278**).



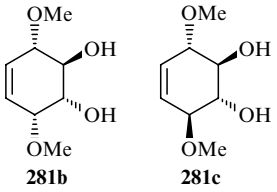
Dehydrojasmone **279** was synthesised starting from (trifluoromethylsulfonylmethyl)sulfone **254**. The latter compound was converted into cyclic ketosulfone **280** containing the triflate group, which was eliminated to give the target product **279**.[156]



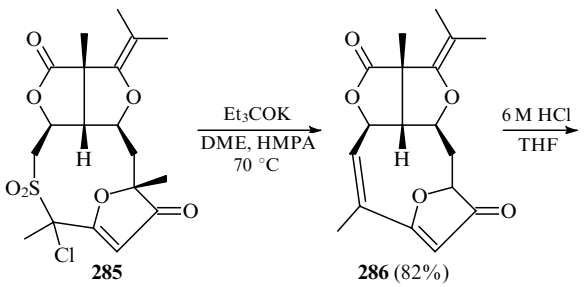
An interesting procedure was developed [157, 158] for the synthesis of enantiomerically pure cyclohexene alcohols of type **281a**–**c**, *viz*., conduritols containing four chiral alcoholic centres. These compounds are inhibitors of glycosidases and also serve as the key compounds in the preparation of agents, which show promise for AIDS treatment. These alcohols were synthesised starting from sugar derivatives containing the required chiral centres. The latter compounds were converted into thiepanes whose oxidation to sulfones followed by the rearrangement under Meyers's conditions gave rise to conduritols in high yields. This procedure was used for the preparation of (−)-conduritol E derivative (**281a**) [157] from Δ-mannitol through thiepane **282** and its sulfone **283**. All reactions proceeded in quantitative yields, the starting chiral centres remaining intact. Later, this procedure was extended [158] to the synthesis of derivatives of (−)-conduritol F (**281b**) and (+)-conduritol B (**281c**) starting from Δ-sorbitol and L-iditol, respectively. Conduritols (−)-F and (−)-E containing four unprotected hydroxy groups were obtained in 83% and 79% total yields, respectively, using readily removable benzyl instead of methyl as protecting groups.[158]

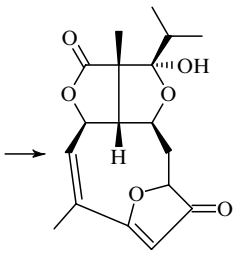


(*a*) MCPBA, 0 °C; (*b*) $Na_2S_2O_5$, CCl_4, 20 °C; (*c*) KOH, Bu^tOH, CCl_4, H_2O, 20 °C; (*d*) 0.1 N H_2SO_4.

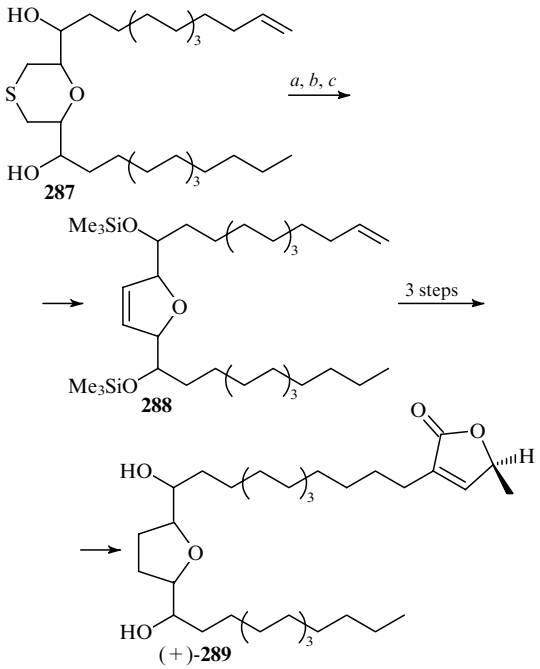


In the synthesis of the strained nine-membered oxygen-containing ring of (+)-eremantholide (**284**), which exhibits antitumour activity *in vitro*, the final stages were carried out with the use of α-chloro-substituted sulfone **285**.[159] The latter was unstable in the presence of strong bases due to which the rearrangement was performed under the action of the weakly basic alkoxide of 3-ethylpentan-3-ol. Under these conditions, intermediate **286** was obtained in quantitative yield and was converted into the final product in one step.



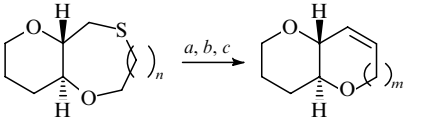


Meyers's method was successfully used [160] for the conversion of 1,4-oxathiane fragment of compound **287** (after oxidation of sulfide sulfur to sulfonyl sulfur) into the dihydrofuran fragment of compound **288**. The latter compound was converted in three steps into acetogenin (+)-solamine (**289**). This procedure is applicable to syntheses of other acetogenins possessing various biological activities.

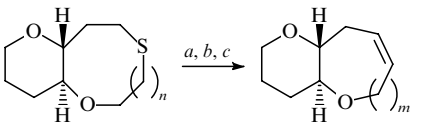


(*a*) MCPBA; (*b*) Me_3SiCl, Et_3N; (*c*) Bu^tOK, Bu^tOH, CCl_4.

In the course of the studies aimed at preparing polycyclic ciguatoxin, an efficient procedure was devised [161] for the preparation of dioxabicyclic systems. For this purpose, *trans*-fused bicyclic intermediates **290a**,**b** and **291a**,**b** generated by thioannelation were successively subjected to α-chlorination, oxidation to sulfones and rearrangement without isolation of intermediates. The resulting oxabicyclic compounds **292a**,**b** and **293a** containing



n = 2 (**290a**), 3 (**290b**); m = 1 (**292a**), 2 (**292b**).



n = 3 (**291a**), 4 (**291b**); m = 2 (**293a**), 3 (**293b**).
(*a*) NCS, CCl_4; (*b*) MCPBA; (*c*) Bu^tOK, THF.

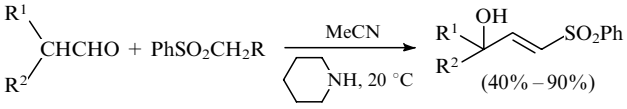
the newly formed six-, seven or eight-membered rings occurred as individual *trans*-fused molecules. Only compound **293b** with the nine-membered ring was obtained as a mixture of *cis* and *trans* isomers.

V. Conclusion

The data surveyed in the present review show that rearrangements of sulfoxides and, to a lesser extent, of sulfones find many varied applications in the total syntheses of natural compounds, including enantioselective processes.

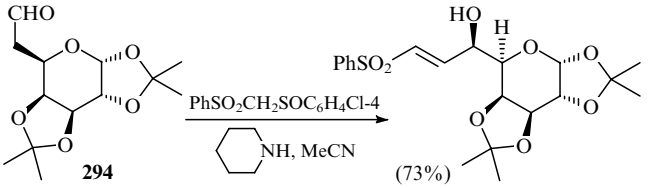
In the coming years, one would expect the wider use of cascade processes involving these rearrangements.

The extension of tandem processes, for example, the Diels–Alder reaction followed by the sulfoxide–sulfenate rearrangement involving enantiomerically pure sulfinyl-substituted dienes, to the synthesis of natural compounds has considerable promise.[162] The SPAC cascade process, which has been developed recently (by two research groups [163, 164] virtually simultaneously) and which provides a route to the synthesis of γ-hydroxy-α,β-unsaturated sulfones, can find application in functionalisation of natural compounds.

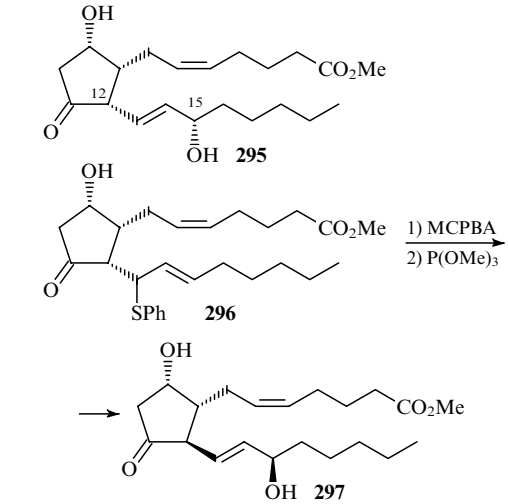


R = 4-MeC_6H_4, 4-ClC_6H_4.

In particular, Trost and Grese [164] demonstrated that this process occurred under very mild conditions, which allow the successful use of even such a labile compound, as galactose derivative **294**, as an aldehyde component.



However, the reagents used in a particular stage of the tandem process must be chosen with caution. Thus attempt was made to synthesise the ethyl ester of 15-D_{2c}-isoprostane (**295**) (which belongs to compounds structurally related to prostaglandins) starting from sulfide **296** through the Mislow–Evans rearrangement.[165] Generally (see Refs 23–26), the oxidation–rearrangement tandem processes give rise to the 'lower branch' of the product with correct stereochemistry. However, the last-mentioned process afforded C(12)-,C(15)-epimer **297** rather than isoprostane **295**.

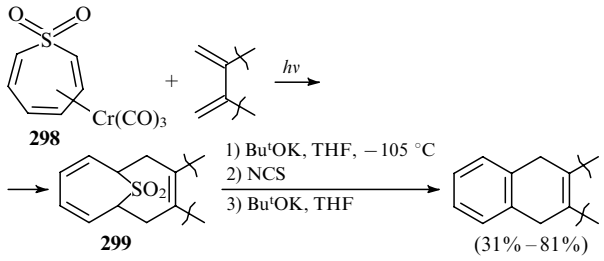


The authors believed that epimerisation was preceded by rearrangement under the action of residual amounts of *m*-chloroperbenzoic acid.

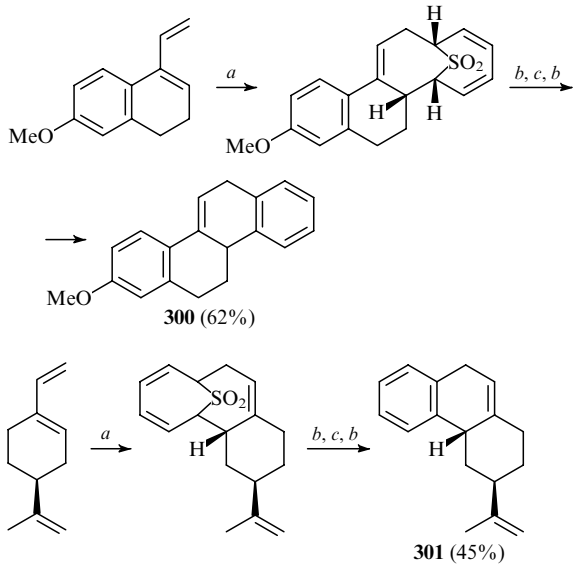
As for the Pummerer reaction, one would expect new examples of its application to the asymmetric synthesis of natural compounds both involving novel efficient inducing agents (for example, vinyl esters containing the ethoxy group in the α position proposed in recent years [166]) and by designing new reagents for the additive Pummerer process. Investigations carried out by Padwa and coworkers with the aim of devising new cascade processes hold much promise. For example, the tandem use of the Pummerer reaction and subsequent intramolecular [3 + 2]-cycloaddition has been applied.[167]

One would expect that the Ramberg–Bäcklund reaction will continue in use for the construction of unsaturated natural cyclic molecules.

It is likely that the recent cascade process,[168] which readily affords benzoannelated polycyclic molecules, will be extended to the synthesis of natural compounds. The process starts with the photochemical [6π + 4π]-cycloaddition of various dienes to the chromium tricarbonyl complex of 1,1-thiepin dioxide (**298**) and ends in the Ramberg–Bäcklund rearrangement of the resulting adduct **299**.



The characteristic feature of this process is that it makes possible both rapid assembly of the final polycyclic product (for example, in the synthesis of compound **300**) and the stereospecific synthesis (for example, in the synthesis of compound **301**) with the use of chiral nonracemic dienes.



(*a*) **298**, *hv*; (*b*) ButOK, THF, −105 °C; (*c*) *N*-iodosuccinimide, THF.

The investigations published in the very recent past [169–175] (after the present review had already been written) demonstrated that the rearrangements of sulfones and sulfoxides continue in use in syntheses of natural products. The investigations of Padwa and coworkers devoted to the application of cascade Pummerer cyclisation–deprotonation–cycloaddition processes to syntheses of alkaloids were summarised in a review.[169] Intramolecular Pummerer cyclisation was used as the key stage in the synthesis of bicyclic precursors for anthracyclinones.[170] The Pummerer

reaction was employed[171] in the stereoselective synthesis of 4β-thioribonucleosides. The procedure for the construction of the oxathiazepine ring using the modified Pummerer cyclisation[111] was extended to the synthesis of (−)-eudistamines C, E, F, K and L.[172]

Other rearrangements were used more rarely. Thus the Mislow–Evans reaction was employed in the synthesis of enantiomerically pure diastereomers of 8-F_{2t} isoprostane.[173] The Ramberg–Bäcklund reaction was utilised in the syntheses of (+)-estradiol[174] and exocylcic cisoid dienes, which served as the starting compounds for the preparation of natural substances.[175]

In conclusion, it should be emphasised that rearrangements of sulfoxides and sulfones other than the above-considered three processes were also described in the literature (see, for example, the reviews [2, 3]). There is still room for progress in the applications of these reactions to syntheses of natural molecules. This review will hopefully be found interesting and useful by chemists and contribute to progress in this field of chemistry.

(Het)aroylpyruvic acids and their derivatives as promising building blocks for organic synthesis†

S G Perevalov, Ya V Burgart, V I Saloutin, O N Chupakhin

Contents

I.	Introduction	921
II.	Methods of synthesis and tautomerism of (het)aroylpyruvates	921
III.	Chemical properties of (het)aroylpyruvates	923
IV.	Biological activities of (het)aroylpyruvates and the products of their heterocyclisation	935
V.	Conclusion	936

Abstract. Methods of synthesis of (het)aroylpyruvic acids and their acyclic derivatives (esters, amides and hydrazides), and their reactions with various C-, N-, O-, S-nucleophiles are described. Problems of tautomerism and biological activity of (het)aroylpyruvates and products of their transformation are briefly considered. The bibliography includes 191 references.

I. Introduction

(Het)aroylpyruvic acids [(H)APA] and their derivatives, (het)aroylpyruvates, [(H)AP] were discovered back in the XIX century.[1, 2] They proved to be interesting and useful synthons permitting the preparation of a very broad spectrum of products, in particular, diverse heterocyclic compounds many of which possess biological activities. At present, this class of compound still remains attractive for researchers.[3 – 9] The chemistry of (H)AP is fairly extensive but the current state of investigations in this field is not covered in the world literature. This review is meant to fill this gap.

Cyclic APA derivatives, 5-aryl-2,3-dihydrofuran-2,3-diones have been considered in reviews[7, 10] and will not be discussed here in detail. A review has been devoted to the chemistry of perfluoroaroylpyruvates;[3] therefore we note below only specific features of these compounds not found for non-fluorinated analogues.

II. Methods of synthesis and tautomerism of (het)aroylpyruvates

1. Methods of synthesis of (het)aroylpyruvates

The Claisen condensation of the corresponding (het)aryl methyl ketones **1** with dialkyl oxalates in the presence of sodium metal or sodium (potassium) alkoxides is the main and the most convenient method for synthesis of (H)APA esters **2** (Scheme 1). Alcohols, diethyl ether, benzene or toluene are used as solvents.[1, 2, 11 – 23] Pentafluorobenzoylpyruvates are prepared from pentafluoroacetophenone in the presence of lithium hydride.[3, 5, 24, 25] It is convenient to isolate and purify labile AP as their copper(II) chelates **3**.[1, 13, 14, 16] This is especially required in the case of pentafluorobenzoylpyruvates,[5, 24, 25] which cyclise very easily to chromone derivatives due to the presence of *ortho*-fluorine atoms in the benzoyl substituent. Hydrolysis of the esters **2** to the corresponding acids **4** is normally carried out in an acid medium,[1, 23, 26, 27] although examples of alkaline hydrolysis are also documented.[2, 11]

A method for the preparation of ethyl 4-(1,2-diaryl-4-hydroxy-5-oxo-1*H*-pyrrol-3-yl)-2-hydroxy-4-oxobut-2-enoates **5**

Scheme 1

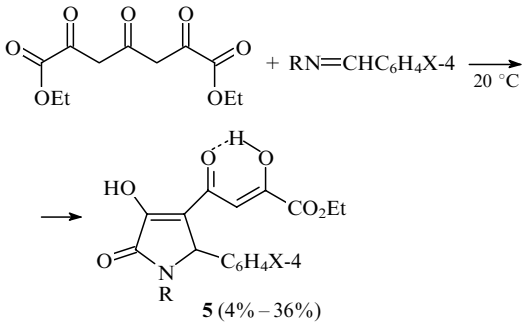
Uspekhi Khimii **70** (11) 1039 – 1058 (2001); translated by Z P Bobkova

† Dedicated to Academician O M Nefedov with appreciation and on the occasion of his seventieth birthday.

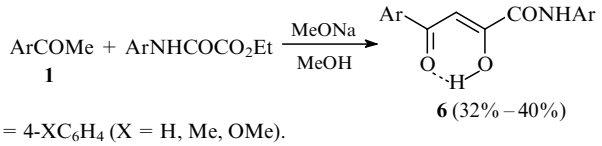
by the reaction of diethoxalylacetone with diarylazomethines was proposed not long ago.[28]



5 (4% – 36%)

R = Me, 4-YC$_6$H$_4$ (Y = H, Me, OMe, Br); X = H, OMe, Br, Cl.

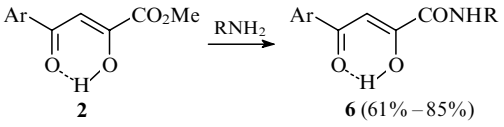
The condensation of acetophenones **1** with esters of oxanilic acids is used for the synthesis of APA amides **6**.[29]



6 (32% – 40%)

Ar = 4-XC$_6$H$_4$ (X = H, Me, OMe).

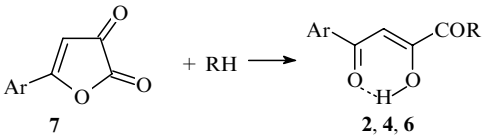
Preparation of the amides **6** from the APA methyl esters **2** and *N*-phenylethylenediamine[30] or 2-aminopyridine has been described.[31]



6 (61% – 85%)

Ar = 4-XC$_6$H$_4$ (X = H, Me, OMe, Br); R = (CH$_2$)$_2$NHPh, 2-pyridyl.

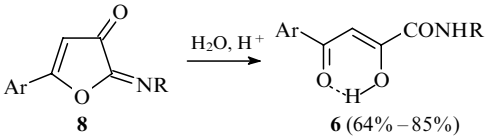
Methods for the synthesis of APA **4**,[32] the esters **2**,[32–37] the amides **6**,[30,31,37–64] and hydrazides [65–74] based on the reaction of the corresponding 5-aryl-2,3-dihydrofuran-2,3-diones **7**[38] with diverse nucleophiles have now become significant practically. The range of reagents used includes water,[32] alcohols,[32] oximes [33–36] and amides of 2-hydroxy acids;[37] amines,[30,31,37–39,41–44,48,51–64] 2-aminophenol,[37] ethanolamine,[37] amino acids,[40,49] thiols,[44,45] mercaptoethanolamine,[44] amides of thioacids,[50] acyl- and aroyl-hydrazides,[65,67–69,72,73] hydrazine,[66] and hydrazones.[70,71,74]



2, **4**, **6**

2: R = OAlk, OPh, ON = CR^1_2; **4**: R = OH;
6: R = NH$_2$, NHAlk, NHAr, NHHet.

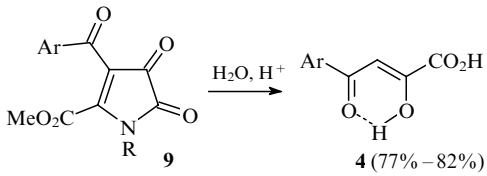
The APA amides and hydrazides **6** have been prepared by acid hydrolysis of 5-aryl-2-imino-2,3-dihydrofuran-3-ones **8**.[75–78]



6 (64% – 85%)

Ar = 4-YC$_6$H$_4$ (Y = H, Me, OMe, Cl, Br); R = CH$_2$SO$_2$C$_6$H$_4$Me-4, 1-adamantyl, N = CHCOPh.

Extensive hydrolysis of 1-aryl-4-aroyl-5-methoxycarbonyl-2,3-dihydropyrrole-2,3-diones **9** affords the APA **4**.[79]

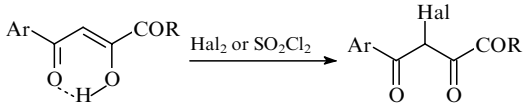


4 (77% – 82%)

Ar = 4-XC$_6$ H$_4$ (X = H, Me, OMe), R = Ar (X = H, Me, OMe, NO$_2$), *etc*.

3-Halogen-substituted esters **10** (R = OEt, OMe) and amides **11** (R = NHPh) of APA are prepared by halogenation of the corresponding AP **2** (see papers [18,80–84]) and **6**[39,85,86] (Scheme 2).

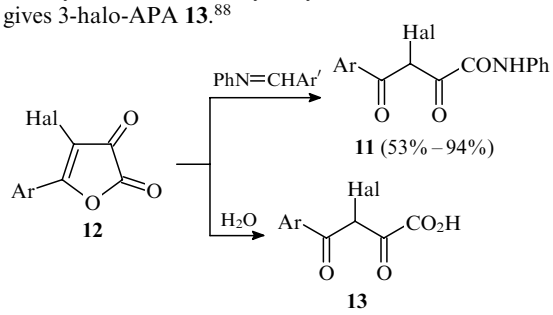
Scheme 2



10, **11** (83% – 98%)

Ar = 4-YC$_6$H$_4$ (Y = H, Me, OMe, F, Cl, Br), 2,4,6-Me$_3$C$_6$H$_2$, 2-naphthyl; Hal = Cl, Br; R = OEt, OMe, NHPh.

The amides **11** can also be synthesised from 5-aryl-4-halo-2,3-dihydrofuran-2,3-diones **12** by introducing them into a reaction with diarylazomethines.[87] Hydrolysis of the furandiones **12** readily gives 3-halo-APA **13**.[88]



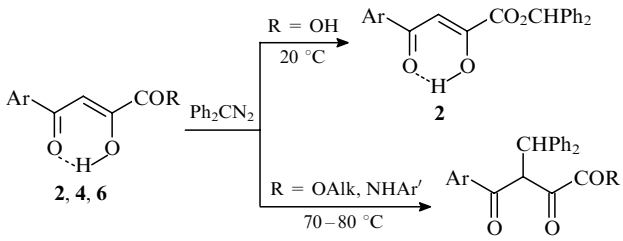
11 (53% – 94%)

13

Hal = Cl, Br; Ar = 4-YC$_6$H$_4$ (Y = H, Me, OMe, Cl).

The reaction of the APA esters **2** and amides **6** with diphenyldiazomethane gives rise to 3-diphenylmethyl-substituted AP **14**[81,89] and **15**.[90] It should be noted that APA **4** are esterified in this reaction to give the esters **2** (Scheme 3).

Scheme 3

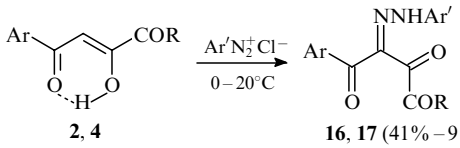


2, **4**, **6**

14, **15** (7% – 87%)

Azo coupling of the APA **4** [91–93] and the esters **2** [94–96] with aryldiazonium salts is used to prepare 3-arylhydrazones of 4-aryl-2,3,4-trioxobutanoic acids **16** and their esters **17** (Scheme 4).

Scheme 4



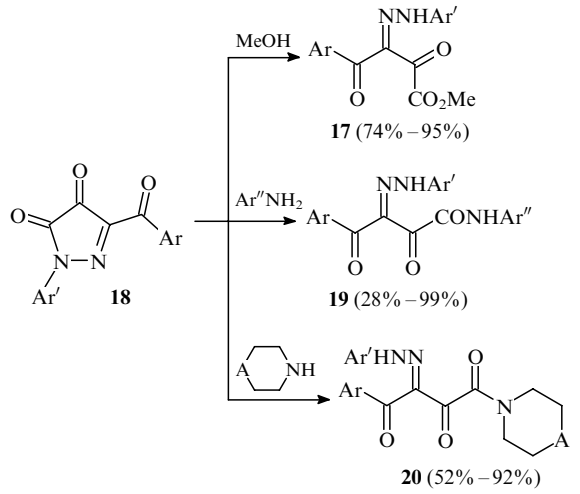
2, **4**

16, **17** (41% – 91%)

2, **17**: R = OMe, OEt; **4**, **16**: R = OH.

The esters **17** are also formed in the alcoholysis of 1-aryl-3-aroyl-4,5-dihydropyrazole-4,5-diones (**18**).[92] Treatment of the

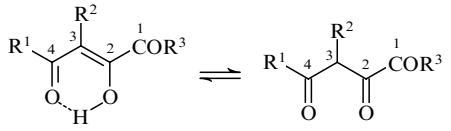
pyrazolediones **18** with amines yields 4-aryl-2,3,4-trioxobutyramide 3-arylhydrazones **19**[97,98] and **20**.[98]



2. Tautomerism of (het)aroylpyruvates

Tautomeric equilibrium has been studied for a series of (H)AP (Scheme 5). According to ^{1}H NMR data, the 3-unsubstituted (H)APA **4**, their esters **2** and amides **6** exist in solution as enols.[81,99,100] The enol structure of the benzoylpyruvic acid **4a** has also been confirmed by X-ray diffraction analysis.[101] Only ethyl 4-(3-indolyl)-2,4-dioxobutanoate in DMF-d_7 is a mixture of ketone and enol tautomers in a ratio of $\sim 1:1$.[20]

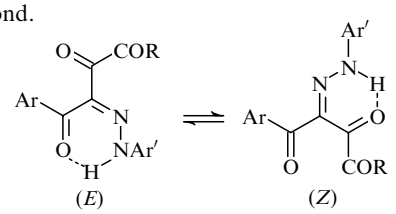
Scheme 5



R^1 = Ar, Het; R^2 = H, Cl, Br, N = NAr, Alk, Ar; R^3 = OR^4, NR^4_2, $NR^1NR^4_2$ (R^4 = H, Alk, Ar, COAlk).

In the case of 3-alkyl- and 3-halo-substituted AP **10**, **11**, and **13**–**15**, the ketone form predominates.[102–105] Apparently, the hampered formation and energetic destabilisation of the enol form are caused by the presence of bulky substituents at the 3-position.

The spectral data for the AP **16**, **17**, **19** and **20** available to date indicate that 3-arylhydrazone-substituted acids **16**,[92] esters **17**[92,96] and amides **19** and **20**[97,98] occur as equilibrium mixtures of *Z*- and *E*-tautomers of the ketone form relative to the C = N bond.



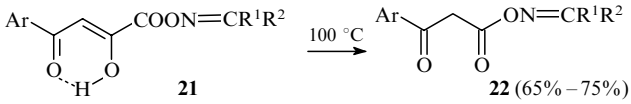
III. Chemical properties of (het)aroylpyruvates

(Het)aroylpyruvates contain three electrophilic centres, namely, the C(1) atom of the ester group and the C(2) and C(4) carbonyl atoms, and one nucleophilic centre, namely, the *meso*-position of the β-dicarbonyl fragment, *i.e.*, the C(3) atom (see Scheme 5). Therefore, the (H)APA **4**, their esters **2** and the amides **6** tend to react with nucleophilic reagents at the C(1), C(2) and C(4) atoms. In addition, (H)AP enter into reactions with electrophiles at the C(3) centre. These transformations are mainly considered in the previous Section concerned with the methods of synthesis of (H)AP (see Schemes 2–4). A typical feature of (H)AP is the susceptibility to thermal transformation. Some (H)AP are able to undergo intramolecular cyclisations.

1. Thermal transformations and intramolecular cyclisations of (het)aroylpyruvates

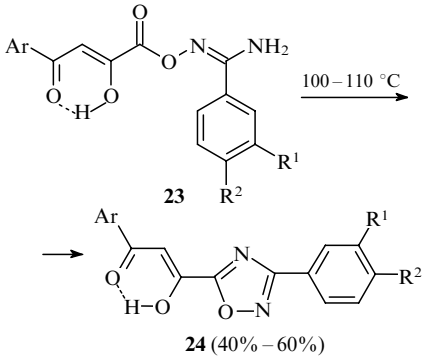
a. Thermal transformations

Virtually all (H)AP are fairly labile compounds. *O*-Aroylpyruvoyl oximes **21** undergo decarbonylation at 100°C giving rise to *O*-aroylacetyl oximes **22**.[34]



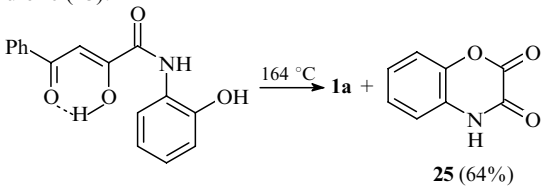
Ar = 4-XC_6H_4 (X = H, Me, Et, Cl); R^1 = H, Me; R^2 = Ph, 2-HOC_6H_4, 1-adamantyl.

Under similar conditions, *O*-aroylpyruvoyl oximes **23**, containing an amino group, cyclise to 3-aryl-5-(3-aroyl-1-hydroxypropenyl)-1,2,4-oxadiazoles **24**.[35]

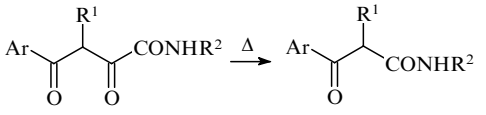


Ar = 4-XC_6H_4 (X = H, Me): R^1 = R^2 = H, OMe; R^1 = H, R^2 = NO_2.

Arylamides of the 3-unsubstituted APA **6** are stable even at 220 °C.[81,106] *N*-(2-Hydroxyphenyl)-3-benzoylpyruvoylamide is an exception; on refluxing in mesitylene, this compound decomposes into acetophenone **1a** and 3,4-dihydro-2*H*-1,4-benzoxazine-2,3-dione (**25**).[37]



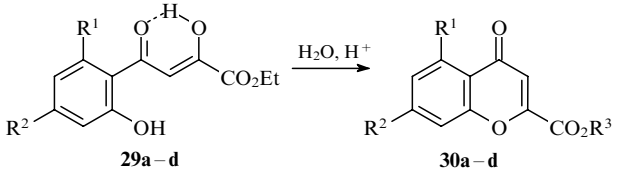
Meanwhile, 3-methyl- (**26**)[106] and 3-diphenylmethyl-substituted (**15**)[90] arylamides are decarbonylated on heating giving rise to *N*-aryl-2-methyl- (**27**) and *N*-aryl-2-diphenylmethyl-3-phenyl-3-oxopropanamides **28**.



26, **27**: Ar = Ph, R^1 = Me, R^2 = YC_6H_4 (Y = H, 3-OMe, 4-OMe); **15**, **28**: Ar = 4-YC_6H_4 (Y = H, Me); R^1 = $CHPh_2$, R^2 = Ph, 4-$MeOC_6H_4$.

b. Intramolecular cyclisations

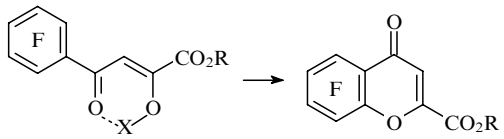
On refluxing in aqueous HCl, ethyl aroylpyruvates **29a**–**d**, containing a hydroxy group in the *ortho*-position of the benzene ring cyclise to give 4-oxachromene-2-carboxylic acids **30a**–**d**.[16]



R^3 = Et: R^1 = R^2 = H (**a**), OEt (**b**); R^3 = H, R^1 = H (**c**), OMe (**d**), R^2 = OMe.

Pentafluorobenzoylpyruvates **31a**,**b** cyclise either over a period of one month at 20 °C or rapidly on heating to give 2-alkoxycarbonyl-5,6,7,8-tetrafluoro-4*H*-chromen-4-ones **32a**,**b**.[3, 6, 24] Acid **31c** (R = H) is stable under these conditions.[27] It cyclises to be converted into chromone-2-carboxylic acid (**32c**) only after treatment with anhydrous ammonia or triethylamine in dioxane at 20 °C. The copper(II) chelates **31d**,**e** are also converted into chromones **32a**,**b** on heating in DMSO at 80 – 90 °C[3, 4, 6, 24] (Scheme 6).

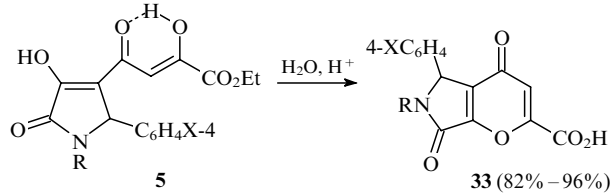
Scheme 6



31a – e **32a – e**

31: X = H: R = Et (**a**), Me (**b**), H (**c**); X = Cu/2, R = Et (**d**), Me (**e**);
32: R = Et (**a**), Me (**b**), H (**c**).

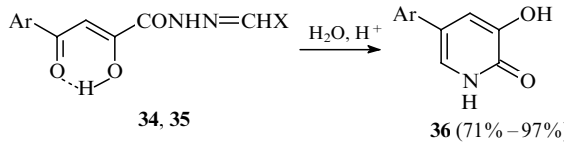
Under conditions of acid hydrolysis, the ethyl pyrrolylpyruvates **5** undergo cyclisation which involves the hydroxy group of the pyrrole fragment and gives 5,6-diaryl-2-carboxypyrano[2,3-*c*]pyrrole-4,7(4*H*,5*H*)-diones **33**.[107]



5 **33** (82% – 96%)

R = Me, Ph, 4-MeOC$_6$H$_4$, 4-BrC$_6$H$_4$; X = H, NO$_2$, Br.

Acid hydrolysis of APA *N*-benzoylmethylene- (**34**)[78] and APA *N*-benzimidenehydrazides **35**[108] results in the formation of the same 6-aryl-4-hydroxy-2,3-dihydropyridazin-3-ones **36**.

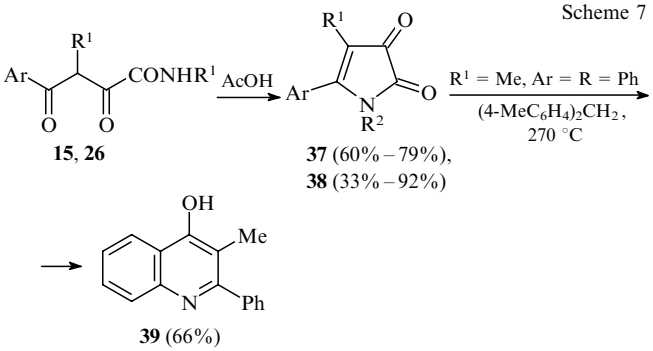


34, **35** **36** (71% – 97%)

Ar = 4-YC$_6$H$_4$ (Y = OMe, Cl, H, Me); X = COPh (**34**), Ph (**35**).

The amides **15** and **26** cyclise in boiling AcOH being thus converted into the corresponding 1,5-diaryl-4-diphenylmethyl-(methyl)-2,3-dihydropyrrole-2,3-diones **37**[90, 109] and **38**[110] (Scheme 7). The compound **37** (X = Me, Ar = R = Ph) recyclises on refluxing in ditolylmethane to afford 4-hydroxy-3-methyl-2-phenylquinoline (**39**).[110]

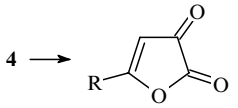
Scheme 7



15, **26** **37** (60% – 79%), **38** (33% – 92%) **39** (66%)

15, **37**: Ar = 4-YC$_6$H$_4$ (Y = H, Me), R^1 = CHPh$_2$, R^2 = Ph, 4-MeOC$_6$H$_4$, 4-ClC$_6$H$_4$;
26, **38** : Ar = Ph, R^1 = Me, R^2 = YC$_6$H$_4$ (Y = H, 3-OMe, 4-OMe, 4-Me, 4-OH, 2-OH, 4-Br).

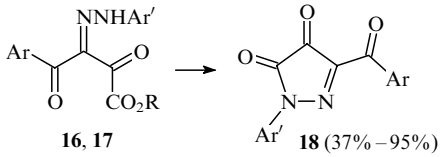
When heated in benzene with thionyl chloride (65 – 70 °C)[38] or acetic anhydride (60 – 70 °C),[111, 112] the acids **4** undergo dehydration to the furandiones **7**. The two methods provide similar yields of the compounds **7**.



7 (49% – 95%)

R = Ar, Het.

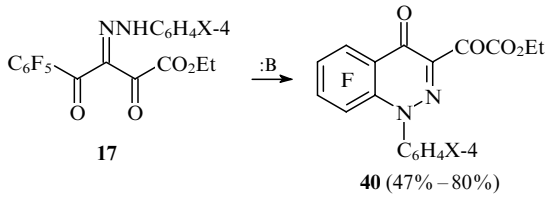
The APA 3-arylhydrazones **16** cyclise on treatment with thionyl chloride to give pyrazolediones **18**.[92, 93] The same compounds are produced on prolonged refluxing of the methyl esters **17** in acetic anhydride.[113]



16, **17** **18** (37% – 95%)

Ar = 4-YC$_6$H$_4$ (Y = H, Me, OMe, NO$_2$, Br, Cl); Ar′ = 4-YC$_6$H$_4$ (Y = H, OMe, Cl).

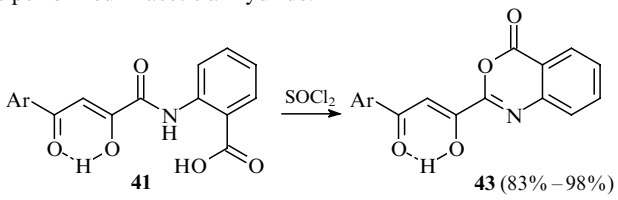
A distinctive feature of pentafluorophenyl-substituted arylhydrazones (**17**, Ar = C$_6$F$_5$) is their ability to undergo cyclisation either on heating with DMSO in the presence of potassium carbonate or in a mixture of triethylamine with chloroform; the reaction furnishes 1-aryl-5,6,7,8-tetrafluoro-3-ethoxalyl-1,4-dihydrocinnolin-4-ones **40**.[95, 96]



17 **40** (47% – 80%)

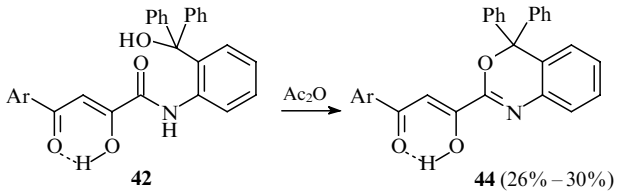
X = H, Me, OMe.

Cyclodehydration of APA arylamides **41**[49] and **42**[64] with participation of the amide group capable of enolisation gives benzoxazines **43**, **44**. In the case of the amide **41**, the reaction was carried out by heating the compound in benzene with thionyl chloride (with DMF as the catalyst),[49] and for the compound **42**, it was performed in acetic anhydride.[64]



41 **43** (83% – 98%)

Ar = 4-XC$_6$H$_4$ (X = OMe, OEt, Br, Cl).



42 **44** (26% – 30%)

Ar = 4-XC$_6$H$_4$ (X = H, Me, OMe).

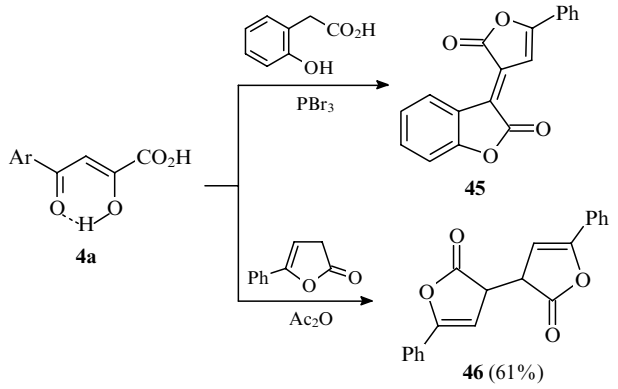
2. Reactions of (het)aroylpyruvates with mononucleophiles

Reactions with some C-, N- and O-mononucleophiles are known for the (H)APA **4** and their esters **2** and amides **6**.

a. Reactions with C-mononucleophiles

The reported reactions of AP with C-mononucleophiles are few in number because AP tend to decompose under conditions where nucleophiles are generated and/or are sufficiently reactive and heterocyclisation is precluded.

Mention should be made of condensations of **4a** with 2-hydroxyphenylacetic acid in the presence of PBr_3 resulting in the product **45** and with 5-phenyl-2,3-dihydrofuran-2-one in the presence of acetic anhydride to give the compound **46**.[114]

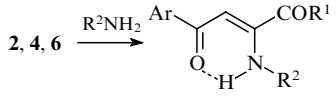


b. Reactions with O-mononucleophiles

Of the transformations of (H)AP in reactions with alcohols, only transesterification of the esters **2** is known. Most of the APA esters **2** (Ar is substituted phenyl) are unstable under conditions of alkaline hydrolysis and decompose yielding the corresponding acetophenone **1**, alcohol and oxalate.[1] The HPA esters **2** are more stable to this cleavage because the acids **4** [Ar = 2-thienyl,[2] 3-(2,4-dimethylpyrrolyl) [11]] can be prepared by alkaline hydrolysis of the corresponding esters **2**. However, ethyl 3-indolyl- and 3-(5-methoxyindolyl)pyruvates are readily cleaved by alkalis and are even partially cleaved during recrystallisation from ethanol.[20] Recently, ethyl pentafluorobenzoylpyruvate copper(II) chelate **31d** was reported to undergo transesterification into the chelate of the methyl ester **31e**. For the free AP **2**, this reaction is unknown.

c. Reactions with N-mononucleophiles

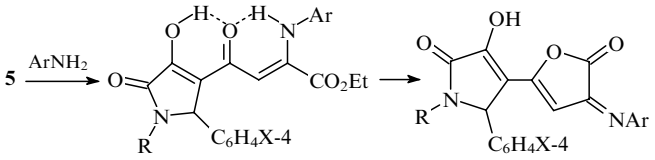
The esters **2** are known [115] to react with ammonium acetate on refluxing in an AcOH – benzene mixture; the reaction involves the carbonyl group at the C(2) atom and gives ethyl 2-amino-4-arylbut-2-en-4-onoates **47** in ~80% yield. Under mild conditions (at 20 – 50 °C), both the (H)APA **4** and their esters **2** add aniline and its derivatives at the carbonyl group giving rise to 2-arylamino-4-aryl-4-oxobut-2-enoates **48** (the yields vary from 9% to 83%).[79, 102, 116] Electron-withdrawing substituents and steric hindrance in the reactants result in lower yields of the products **48**. The structure of the compounds **48**, stabilised by an intramolecular hydrogen bond (IMHB) in the β-amino vinyl ketone fragment, was confirmed by NMR spectroscopy.[117] The APA arylamides **6** behave in a similar way in reactions with aniline, giving rise to arylamides of 4-aryl-4-oxo-2-phenylaminobut-2-enoic acids **49** in 60% – 93% yields.[29, 118]



47, **48**, **49**

2, **47**: R^1 = OEt; R^2 = H; **2**, **4**, **48**: R^1 = OH, OMe; R^2 = Ar′; **6**, **49**: R^1 = NHAr′; R^2 = Ph.

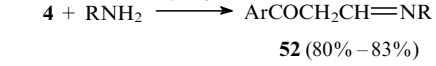
The pyrrolylpyruvates **5** are also converted into amino esters **50b – e** when heated with arylamines to 60 °C.[107] However, on stronger heating (150 – 220 °C), these products cyclise to give compounds **51b – e**.[107] The cyclisation is facilitated by electron-withdrawing substituents in the pyrrole ring of **5**. Indeed, 1-methylpyrrolylpyruvate **5a** readily cyclises with aniline at 20 °C giving rise to heterocycle **51a**; the intermediate compound **50a** cannot be isolated.[107]



50b – e (87% – 97%) **51a – e** (29% – 58%)

Ar = Ph, R = Me, X = H (**a**); Ar = R = Ph (**b – d**): X = H (**b**), Br (**c**), NO_2 (**d**); Ar = R = 4-BrC_6H_4, X = Br (**e**).

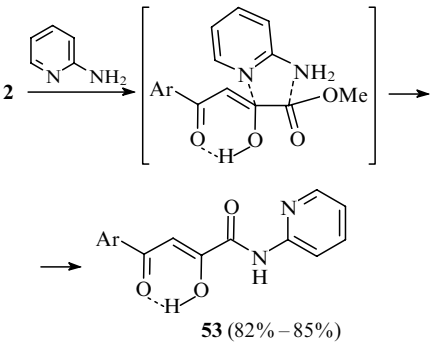
It has been reported that salts decarboxylated on refluxing in mesitylene (164 °C) to give 3-aryl-3-oxopropanal monoanils **52** can be isolated from the products of reaction between the APA **4** and aromatic amines at 20 °C.[119]



52 (80% – 83%)

Ar = 4-XC_6H_4 (X = H, Me, OMe, Cl, Br); R = 4-XC_6H_4 (X = H, OMe, Cl, Br).

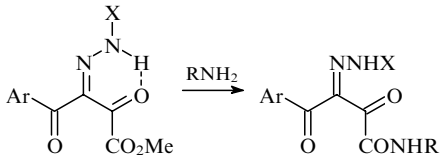
It is of interest that refluxing of methyl aroylpyruvates **2** in benzene with 2-aminopyridine results in APA 2-pyridylamides **53** instead of the 2-amino-derivatives such as **48**, **49**.[31] The unusual pathway of 2-aminopyridine addition to AP is due, apparently, to the fact that in the transition state, the highly basic pyridine nitrogen atom of the nucleophile is coordinated to the C(2) carbonyl atom of the AP and the amino group is coordinated to the C(1) atom.



53 (82% – 85%)

Ar = 4-XC_6H_4 (X = H, Me, OMe, Br).

Unlike 3-unsubstituted esters **2**, 3-arylhydrazones **17**, which are efficiently stabilised by an IMHB, react with arylamines on refluxing in benzene; the reaction involves the ester group and gives the arylamides **19**.[98]

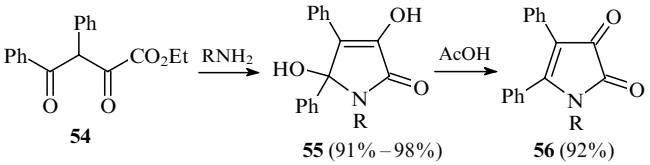


17 **19** (40% – 63%)

Ar = Ph, 4-$EtOC_6H_4$; R = 4-YC_6H_4 (Y = H, Me, Cl); X = Ph.

It is known [120] that APA arylamides containing a bulky group at the 3-position readily cyclise yielding 4-substituted 1,5-diaryl-2,3-dihydropyrrole-2,3-diones **37**, **38** (see Scheme 7).[90, 109, 110] The tendency toward cyclisation is sometimes so pronounced that it is not always possible to isolate arylamides formed in the reaction of APA esters with amines.[121] Indeed, the reaction of ethyl 3-phenylbenzoylpyruvate (**54**) with methyl- or benzylamine in chloroform at 20 °C yields immediately the products of cyclisation of intermediate amides, 1-alkyl-4,5-diphenyl-3,5-dihydroxy-2,5-dihydropyrrol-2-ones **55**. It is noteworthy that in this case, as for arylhydrazones **17**, it is the ester group that is involved in the

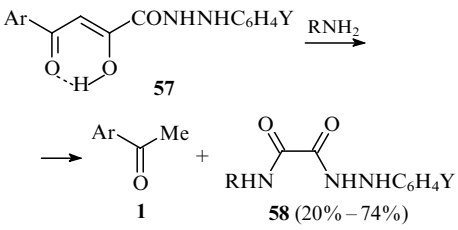
reaction with the amine. The products **55** are dehydrated to give 1-alkyl-4,5-diphenyl-2,3-dihydropyrrole-2,3-diones **56**.[103]



54 **55** (91% – 98%) **56** (92%)

R = Me, CH_2Ph.

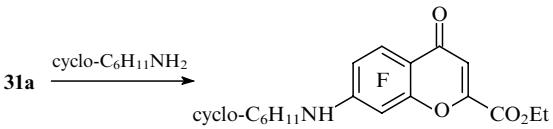
Unlike the amides **6**, APA β-aroylhydrazides **57** are cleaved by aromatic amines when fused together (160 – 165 °C); this gives rise to acetophenones **1** and mixed amidohydrazides of oxalic acid **58**.[67] Benzylamine splits the hydrazides **57** even at 60 – 65 °C.



57 **1** **58** (20% – 74%)

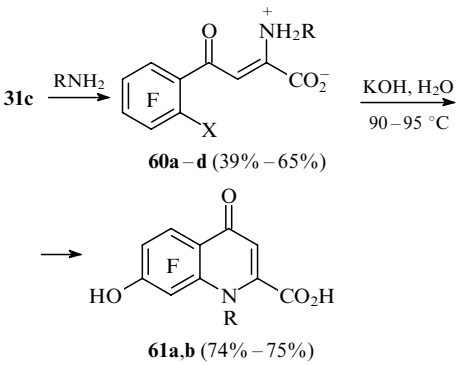
Ar = 4-XC_6H_4 (X = H, Me, OMe); R = 4-XC_6H_4 (X = H, Me, OEt), CH_2Ph; Y = H, 3-NO_2, 4-OMe.

Fluorine-containing AP behave quite differently in reactions with amines. Thus the pentafluorobenzoylpyruvates **31a**,**b** rapidly cyclise to the chromones **32a**,**b** when made to react with aqueous ammonia at 20 °C[3, 121] (see Scheme 6); the reaction of the pyruvate **31a** with cyclohexylamine on heating in DMSO does not stop at the cyclisation stage but proceeds as nucleophilic substitution with removal of the fluorine atom at the 7-position of the aromatic ring, thus yielding 5,6,8-trifluoro-7-cyclohexylamino-2-ethoxycarbonylchromen-4(4*H*)-one (**59**).[121]



59 (63%)

As noted above, the reaction of pentafluorobenzoylpyruvic acid (**31c**) with anhydrous ammonia or triethylamine in dioxane at 20 °C leads to chromone-2-carboxylic acid (**32c**) (see Scheme 6). Heating of the acid **31c** with aqueous ammonia and primary amines affords 2-(alkyl)amino-4-oxo-4-polyfluoroaryl-2-butenoic acids **60**.[26, 27] The acid **60a** cyclises reversibly into the chromone **32c** on heating in an acid medium. On treatment with aqueous alkali, the acids **60b**,**c** undergo cyclisation to give 1-alkyl-2-carboxy-7-hydroxy-5,6,8-trifluoroquinolin-4(4*H*)-ones **61**.[26, 27] The structure of the quinolone **61b** as DMSO adduct has been determined by X-ray diffraction analysis.[104]



60a – **d** (39% – 65%)

61a,**b** (74% – 75%)

60: X = OH, R = H (**a**); X = F: R = Pr^i (**b**), cyclo-C_6H_{11} (**c**), Ph (**d**); **61**: R = Pr^i (**a**), cyclo-C_6H_{11} (**b**).

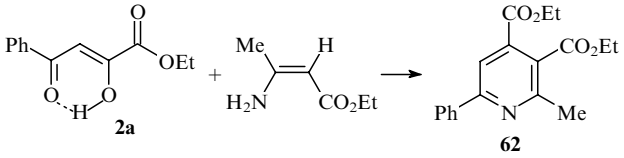
Thus, the reactions of APA **4**, their esters **2** and amides **6** with N-mononucleophiles mainly involve the oxo group at the C(2) atom, although in the case of esters having bulky substituents at the 3-position, the ester group becomes more reactive.

3. Reactions of (het)aroylpyruvates with dinucleophiles

The reactions of (H)AP with bifunctional nucleophiles are widely used in organic synthesis to prepare five-, six-, and seven-membered heterocycles and their fused derivatives.

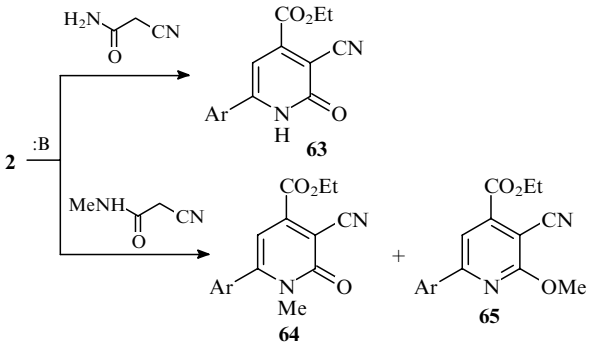
a. Reactions with C,N-dinucleophiles

Reactions with C,C-dinucleophiles are unknown. Of transformations of (H)AP on treatment with C,N-dinucleophiles, the reactions with ethyl 3-aminocrotonate and cyanoacetamide are documented. Under mild conditions (at 20 °C in the absence of bases), the pyruvate **2a** adds ethyl 3-aminocrotonate at the β-diketone fragment to give 3,4-bis(ethoxycarbonyl)-2-methyl-6-phenylpyridine (**62**).[105] The most electrophilic centre of AP [the C(2) atom] reacts with the C-nucleophilic centre of the crotonate and the C(4) atom reacts with the amino group.



2a **62**

The reaction of the (H)AP **2** with cyanoacetamide proceeds in a similar way giving rise to 6-aryl-3-cyano-4-ethoxycarbonyl-2-pyridones **63**.[13,14, 122] The reaction was carried out by refluxing the reactants in ethanol in the presence of piperidine[122] or diethylamine.[13, 14] The use of *N*-methylcyanoacetamide affords not only 6-aryl-3-cyano-4-ethoxycarbonyl-1-methyl-2-pyridones **64**, but also 6-aryl-3-cyano-4-ethoxycarbonyl-2-methoxypyridines **65** as side products.[13, 14]



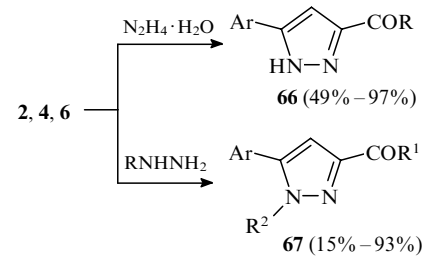
63 **64** **65**

2, **63**: R = Et, Ar = Ph, 2-furyl, 4-diphenylyl; **64**, **65**: Ar = 2-furyl, 4-diphenylyl.

b. Reactions with N,N-dinucleophiles

The reactions of (H)AP with N,N-dinucleophilic reagents possess the highest synthetic value; these reactions have been the best studied.

Reactions with hydrazine and its derivatives. The acids **4**, the esters **2** and the amides **6** react selectively with hydrazine at the β-dicarbonyl fragment [C(2) and C(4) atoms] to give 5-(het)arylpyrazole-3-carboxylic acid derivatives **66** in good yields.[3 – 5, 11, 13, 14, 16, 17, 20, 21, 23, 31, 53, 59, 62, 67, 72, 73, 123 – 126] The solvents used in these reactions are acetic acid, 1,4-dioxane, alcohols or water. The (H)AP **2**, **4** and **6** react with monomethyl and arylhydrazines in a similar way, the reaction proceeding regioselectively to give exclusively 1-methyl-[13, 14] and 1-aryl-5-(hetero)arylpyrazole-3-carboxylic acid derivatives **67**.[1 – 5, 13, 14, 20, 23, 67, 124, 127]

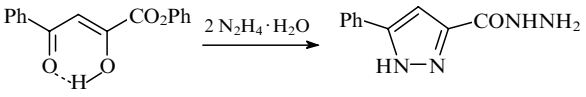


66: Ar = XC_6H_4 (X = H, 4-OH, 4-Me, 4-OMe, 4-OEt, 4-Br, 3-Br, 4-F, 4-Cl), 2,4-$Me_2C_6H_3$, 4-diphenylyl, 3-phenanthryl, C_6F_5, 2-furyl, 3-indolyl, cymantrenyl, 3-methyl-5-phenyl-2-thienyl, 4-methyl-5-oxazolyl, 2,4-dimethyl-5-oxazolyl, 5-(2,4-dimethylthiazolyl); R = OEt, OH, NHPh, $NH(CH_2)_2NHAc$, 2-pyridylamino, 3-pyridylamino, 2-bromo-5-pyridylamino, 2-thiazolylamino, 2-pyrimidylamino, 3-cyano-4,5-tetramethylene-2-thienylamino, NHNHCOAr′ (Ar′ = Ph, 4-$MeOC_6H_4$), NHNHCOCO-CH = PPh_3, $NHNHCOC_6H_4Y$ (Y = 2-methylphenylamino, 2-methyl-4-quinolyl);

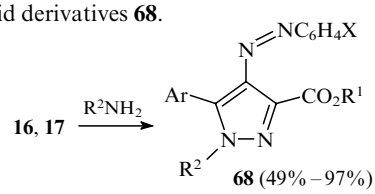
67: Ar = Ph, 4-MeC_6H_4, 4-diphenylyl, C_6F_5, 2-pyrrolyl, 2-furyl, 2-thienyl, 5-methyl-2-furyl, 3-methyl-2-phenyl-5-thienyl, 2,4-dimethyl-5-oxazolyl, 2,4-dimethyl-5-thiazolyl, 3-indolyl; R^1 = OH, OEt, OPr^i; 2(3)-pyridylamino, 5-bromo-2-pyridylamino, $NHNHCOC_6H_4Y$-4 (Y = H, OMe); R^2 = Ph, 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$, Me.

For the synthesis of pyrazoles **66**, the use of equimolar amounts of (H)AP and hydrazine hydrate or dihydrochloride is recommended.[14] Some examples of cleavage of (H)AP upon the use of excess hydrazine have been reported.[13, 20] In addition, under these conditions, the ester group in the final pyrazoles **66** is usually converted into a hydrazide group.[11, 13, 17] Thus the reaction of 2-furoylpyruvate **2c**[13] with excess hydrazine gives 5-(2-furyl)pyrazole-3-carbohydrazide together with the target pyrazole **66** (Ar = 2-furyl, R = OEt) even under mild conditions.

Note that the reaction of phenyl benzoylpyruvate with hydrazine involves both the β-dicarbonyl fragment and the phenoxycarbonyl group, resulting in 5-phenylpyrazole-3-carbohydrazide.[16]



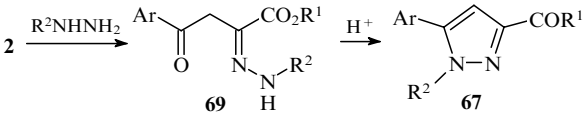
3-Arylhydrazono-APA **16**[128] behave in reactions with hydrazine and phenylhydrazine similarly to 3-unsubstituted analogues giving rise to 4-arylazo-(1-phenyl)-5-arylpyrazole-3-carboxylic acid derivatives **68**.



Ar = C_6H_4Y (Y = H, 4-Me, 4-OMe, 4-Cl); R^1 = H, Et; R^2 = H, Ph.

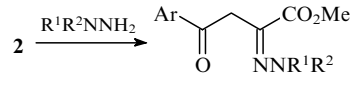
Conversely, the 3-chloroaroylpyruvates **10** are cleaved by hydrazine even under mild conditions without giving pyrazoles.[80]

Reactions of some esters of the (H)APA **2** with arylhydrazines at 20 °C catalysed by AcOH involve the C(2) = O group and result in the corresponding arylhydrazones **69** in good yields (87% for Ar = R^2 = Ph).[127] Upon heating in an acid medium (AcOH, AcOH + HCl), these products cyclise almost quantitatively (93% for Ar = R^2 = Ph)[127] to give pyrazoles **70**.[11, 20, 124, 127]



Ar = Ph, 3-indolyl, 2,4-dimethyl-3-pyrrolyl; R^1 = Et, Pr^i; R^2 = 2,4-$(NO_2)_2C_6H_3$, Ph.

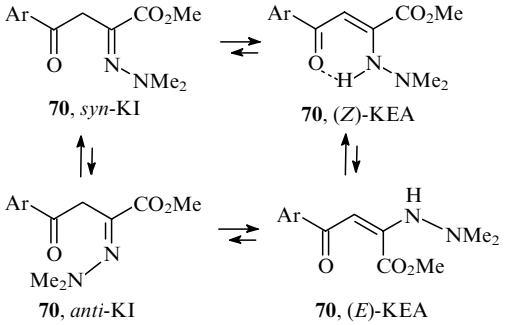
The reactions of methyl aroylpyruvates **2** with *N*,*N*-dimethyl-,[129] *N*-alkyl-*N*-arylhydrazines[130] and benzophenone and 9-fluorenone hydrazones[131] involve exclusively the C(2) centre and give AP *N*,*N*-dimethyl- (**70**) and *N*-alkyl-*N*-arylhydrazones **71** and AP *N*-(di)arylmethylenehydrazones **72**, respectively.



70 – **72** (27% – 69%)

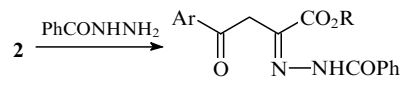
70: Ar = XC_6H_4 (X = H, 4-Me, 4-OMe, 4-Br, 4-Cl, 3-NO_2, 4-NO_2); R^1 = R^2 = Me; **71**: Ar = Ph; R^1 = Me, Et, Pr^i; R^2 = 4-XC_6H_4 (X = OMe, Me, H, Br, NO_2); **72**: Ar = XC_6H_4; R^1 + R^2 = CPh_2, 9-fluorenylidene.

It was shown by ^{1}H NMR spectroscopy[129] that the dimethylhydrazones **70** exist in solutions as equilibrium mixtures of β-ketoimine (*syn*-KI, *anti*-KI) and ketoenamine [(*Z*)-KEA, (*E*)-KEA] tautomers. In low-polarity aprotic solvents, the content of the KEA tautomer is higher. Electron-donating substituents X in the aromatic nucleus of the compounds **70** and an increase in the solvent polarity result in a higher content of the KI forms. The *syn*-KI form predominates in the KI pair, while in the KEA pair, the preferred form is (*Z*)-KEA, which is stabilised by an IMHB. The hydrazone **70** (X = H) was isolated from a solution as a mixture of the *syn*-KI and (*Z*)-KEA isomers, whereas other hydrazones **70** were obtained only as (*Z*)-KEA.



The *N*-alkyl-*N*-arylhydrazones **71** are isolated as the (*Z*)-KEA tautomers. However, they exist in chloroform and pyridine solutions as equilibrium mixtures of the (*Z*)-KEA and *syn*-KI forms.[130] In DMSO, the (*E*)-KEA form was also found. The influence of the nature of the solvent and the substituent X in the R^2 group on the tautomeric equilibria has been elucidated. On passing from chloroform to pyridine, the content of the tautomer (*Z*)-KEA increases, while in DMSO, the total content of the KEA isomers increase, the (*E*)-KEA form being the preferred one. The content of (*Z*)-KEA increases with the enhancement of the −M-effect of the group X on passing from OMe to NO_2.

The AP **2** react with benzoylhydrazine at the α-carbonyl group to give the corresponding hydrazones **73a**–**h**.[132]

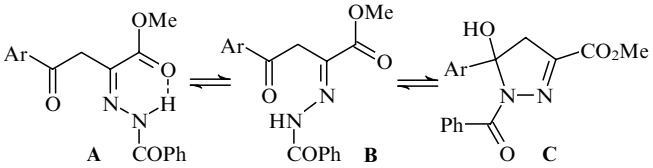


73a–**h** (70% – 86%)

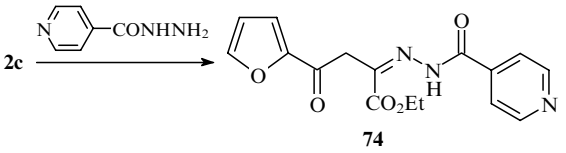
R = Me; Ar = XC_6H_4 (X = H (**a**), 4-Me (**b**), 4-OMe (**c**), 4-NMe_2 (**d**), 4-Cl (**e**), 3-NO_2 (**f**), 4-NO_2 (**g**)); R = Et, Ar = Ph (**h**).

A ^{1}H NMR study of the tautomerism in the series of benzoylhydrazones **73** has shown[133] that these compounds exist in solutions as equilibrium mixtures of three tautomers, namely, *Z*-(**A**) and *E*-(**B**) ketohydrazones and 5-hydroxypyrazoline (**C**). Their proportions depend on the nature of the hydrazone **73** and the solvent. The electron-donating substituent X in the aryl group of the hydrazone **73** promotes an increase in the content of ketohydrazone. In $CDCl_3$, *Z*-form **A** stabilised by IMHB is preferred, while in DMSO-d_6, *E*-form **B** predominates. The

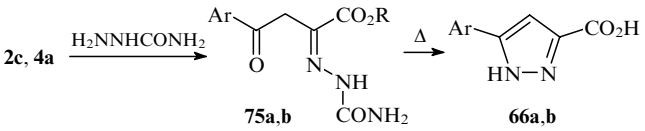
hydrazones **73e–g** with electron-withdrawing groups X predominantly exist in solutions as cyclic form **C**. The content of tautomer **C** is higher in DMSO than in $CDCl_3$. The benzoylhydrazones **73a–d** were isolated from methanol in form **A**, while **73e–g**, in form **C**.



The synthesis of 2-isonicotinoylhydrazone **74** from ethyl 2-furoylpyruvate **2c** and isonicotinic acid hydrazide has been reported.[33]

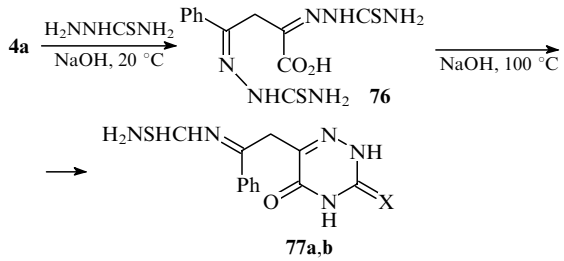


The reaction of the ester (H)AP **2c** [13] and the acid **4a** [134] with semicarbazide or its hydrochloride results in the formation of monosemicarbazones, which have, in our opinion, the structure **75a,b**. These semicarbazones undergo thermal decomposition giving the corresponding pyrazoles **66a,b**. On short-term refluxing in an aqueous solution of potassium carbonate, semicarbazone **75b** is converted into 5-(2-furyl)-3-carboxypyrazole **66b**.[33]



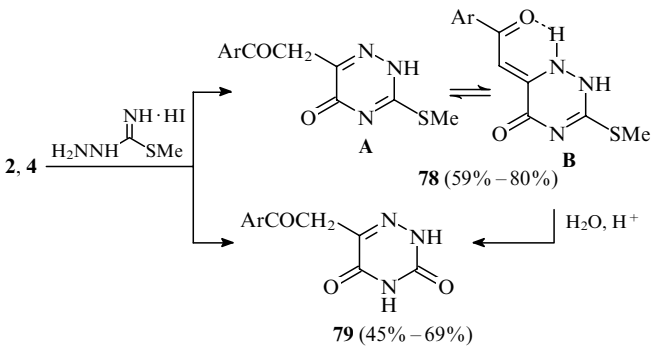
Ar = Ph, R = H (**4a**, **75a**, **66a**); Ar = 2-furyl, R = Et (**2c**, **75b**, **66b**).

The acid **4a** reacts with thiosemicarbazide with participation of both carbonyl groups to give bis(thiosemicarbazone) **76**. The alkaline hydrolysis of this product affords 1,2,4-triazine derivatives **77a,b**.[134]



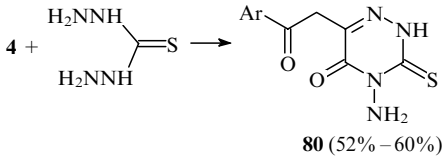
X = S (**a**), O (**b**).

The reaction of the APA **4** and their methyl esters **2** with *S*-methylisothiosemicarbazide hydroiodide involves the α-dicarbonyl fragment and affords 6-aroylmethyl-3-methylthio-1,2,4-triazin-5(2*H*)-ones **78** or 6-aroylmethyl-1,2,4-triazine-3,5(2*H*,4*H*)-diones **79**, depending on the nature of the aryl substituent and the reaction duration.[135, 136] Thus refluxing in ethanol for 2 h gives 3-methylthio-1,2,4-triazinones **78**; when the reaction time increases to 10 h, the products of their hydrolysis, 1,2,4-triazinediones **79**, are formed.[136] The compounds **78** are converted into the triazinediones **79** upon short-term refluxing in aqueous dioxane in the presence of catalytic amounts of HCl. According to the ^1H NMR spectra, the compounds **78** in DMSO-d_6 are mixtures of the imine (**A**) and enamine (**B**) tautomers in 4 : 1 ratio.[135, 136]



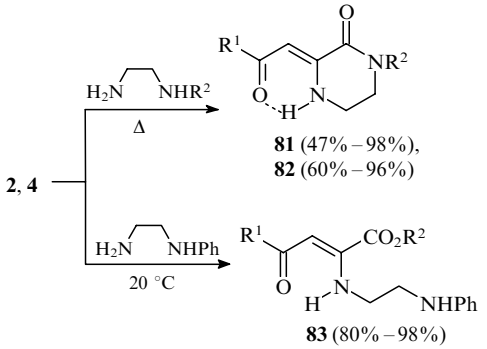
Ar = 4-XC_6H_4 (X = H, Me, OMe, Cl, Br, I, NO_2), 2,4-$Me_2C_6H_3$.

On refluxing in dioxane, the acids **4** add selectively thiocarbohydrazide at the α-ketocarboxyl fragment to give 4-amino-6-aroylmethyl-3-thioxo-2*H*,4*H*-1,2,4-triazin-5-ones **80**.[136]



Ar = 4-XC_6H_4 (X = H, Me, Cl).

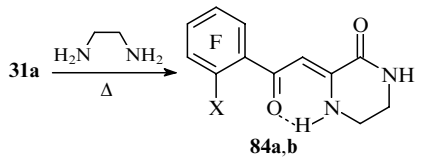
Reactions with 1,2-diaminoethane and its derivatives. Both the APA **4** [30, 137] and their esters **2** (see [21, 30, 137–141]) add 1,2-diaminoethane [21, 30, 138–140] or its mono-*N*-methyl-,[141] *N*-benzyl- [137] and *N*-phenyl-substituted [30, 141] derivatives in chemo- and regioselective reactions involving the α-dicarbonyl fragment [the C(1) and C(2) atoms] giving rise to 3-aroylmethylidenepiperazin-2-ones **81** or their 1-alkyl(aryl) derivatives **82**. The reactions are normally carried out on heating in toluene, ethanol or acetic acid. The piperazin-2-ones **81** can also be prepared by heating the sodium enolates of H(AP) **2** with 1,2-diaminoethane in glacial AcOH.[140] Under mild conditions (ethanol, 20 °C) the AP **2** and **4** react with *N*-phenyl-1,2-diaminoethane at the α-carbonyl group to give acyclic 4-aryl-4-oxo-2-(2-phenylamino)ethylamino-2-butenoic acids or their esters **83**.



81: R^1 = Ar, Het, ferrocenyl, R^2 = H; **82**: R^1 = Ar, Het, R^2 = Me, Ph, CH_2Ph; **83**: R^1 = Ar, Het, R^2 = H, Me, Et.

However, on refluxing in ethanol, the pyruvate **2b** reacts with *N*-phenyl-1,2-diaminoethane at the ester fragment [the C(1) atom] to give benzoylpyruvic acid 2-phenylaminoethylamide in 61% yield.[30] 1,2-Diphenylaminoethane does not react with AP.[30]

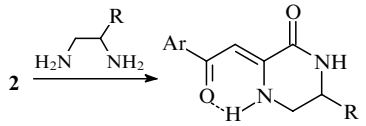
It is noteworthy that the reaction of pentafluorobenzoylpyruvate **31a** with 1,2-diaminoethane gives, depending on the conditions, either 3-pentafluorobenzoyl- (**84a**) or 3-(2-hydroxy-3,4,5,6-tetrafluoro)benzoyl-methylidenepiperazin-2-ones (**84b**).[3, 5] The piperazinone **84a** is formed when the pyruvate **31a** is treated with a large excess of ethylenediamine at 20 °C in a MeOH–AcOH mixture, and the product **84b** is produced on refluxing equimolar amounts of the reactants in methanol.



84a,**b**

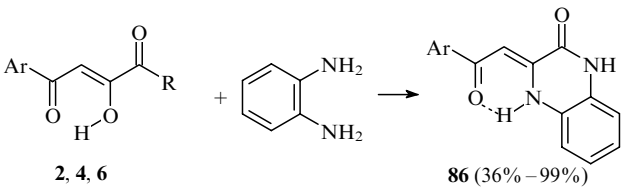
X = F (**a**, 43%), OH (**b**, 18%).

Non-symmetric 1-methyl- and 1-phenyl-1,2-diaminoethanes have been shown [142] to react selectively with the APA esters **2** on refluxing in an ethanol–acetic acid mixture to give the corresponding 6-methyl- or 6-phenyl-3-aroylmethylenepiperazin-2-one **85** as the only reaction product.



85 (58%–93%)

Reactions with 1,2-phenylenediamine and other arylenediamines. The major process involved in the reaction of the (H)APA **4**, their esters **2**, and the amides **6** with 1,2-phenylenediamine (PDA) is cyclocondensation at the α-dicarbonyl fragment [the C(1) and C(2) atoms] giving rise to the corresponding 3-aroylmethylidene-1,2,3,4-tetrahydroquinoxalin-2-ones (**86**).[3, 5, 8, 12, 21, 44, 46, 58, 62, 67, 107, 115, 123, 126, 143–149]



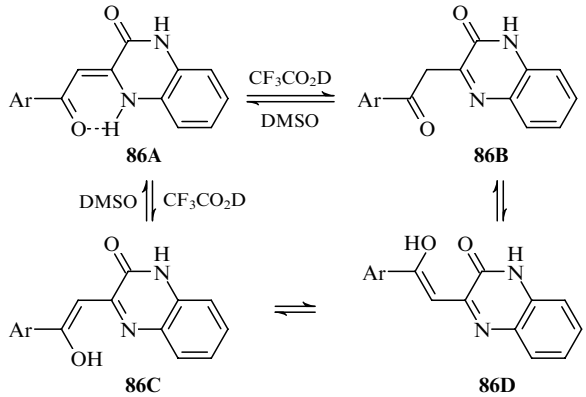
2, **4**, **6** **86** (36%–99%)

Ar = XC_6H_4 (X = H, 4-Me, 4-Et, OH, OMe, 4-Ph, 4-NO_2, 3-NO_2, 4-F, 4-Cl, 4-Br), 2,5-$Me_2C_6H_3$, 2,4,6-$Me_3C_6H_2$, C_6F_5, 1-naphthyl, 3-phenanthryl, 2-furyl, 2-thienyl, 4-pyridyl, 4-hydroxy-5-oxo-1,2-diphenyl-2,5-dihydroxypyrrol-3-yl, cymantrenyl;

2: R = OMe, OEt, OBu^t, SCH_2Ph; **4**: R = OH;

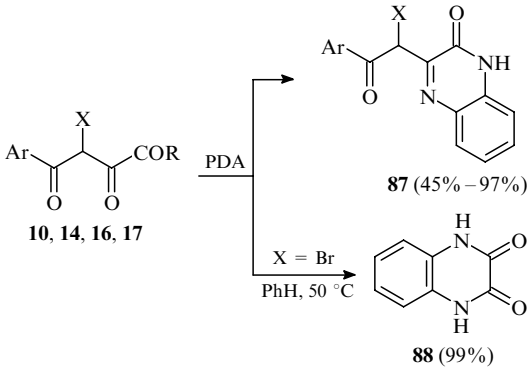
6: R = N(Ar′)C(Ph)=CH_2, NH_2, NHNHAr′, NHAr′, 3-pyridylamino, 2-pyridylamino.

Tautomerism of 2-quinoxalones **86** has been studied by spectroscopy.[145, 146] It was found that these compounds exist as IMHB-stabilised form **A** in the solid state and in solutions in DMSO-d_6. Noticeable amounts of forms **B**–**D** are found only in solutions in CF_3CO_2D.[145]



86A **86B** **86C** **86D**

3-Substituted APA and their esters react with PDA similarly to unsubstituted analogues to yield 3-(1-X-aroylmethyl)-1,2-dihydroquinoxalin-2-ones **87**.[80, 83, 89, 147] For instance, the 3-arylhydrazones **16**,[91] **17**[94–96] and 3-alkyl-substituted APA esters **14**[89, 147] readily react with PDA on refluxing in ethanol. The 3-halogen-containing AP **10** are more reactive and are converted into quinoxalinones **87** on treatment with PDA at 20 °C.[80, 83, 147] Heating of the reactants induces resinification [80] or formation of quinoxaline-2,3(1*H*,4*H*)-dione (**88**).[83]

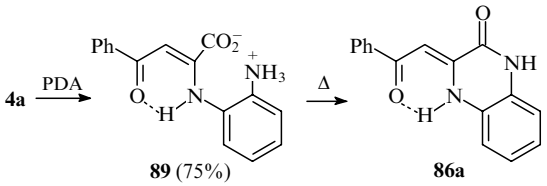


10, **14**, **16**, **17** **87** (45%–97%) **88** (99%)

10: X = Cl, Br; Ar = 4-YC_6H_4 (Y = H, Me, Br, OMe, F, Cl); R = OMe, OEt; **14**: X = Me, Et, $CHPh_2$; Ar = 4-YC_6H_4 (Y = H, Me, Br, Cl, NO_2); R = OMe, OEt; **16**, **17**: X = N = NAr′; R = OMe, OEt, OH; Ar = C_6H_4Y (Y = H, 4-Cl, 4-Br), C_6F_5; **87**: X = Me, Et, $CHPh_2$, Cl, Br, N = NAr′; Ar = 4-YC_6H_4 (Y = H, Me, Br, OMe, F, Cl, NO_2), C_6F_5.

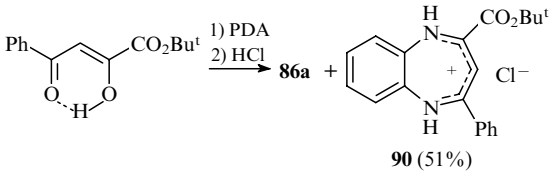
However, prolonged refluxing in ethanol of 3-bromo-substituted ethyl benzoylpyruvate **10a** (Ar = Ph, R = Et, X = Br) with PDA furnishes 3-benzoylmethylidenequinoxalinone **86a** containing no bromine.[150]

When the acid **4a** has been made to react with PDA under mild conditions (Pr^iOH, 20 °C), a labile intermediate, 2-(2-ammoniophenylamino)-4-oxo-4-phenyl-2-butenoate (**89**), has been isolated. On heating, this compound is quantitatively converted into quinoxalinone **86a**.[148]



89 (75%) **86a**

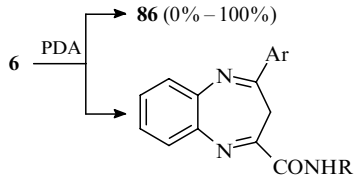
It is notable that *tert*-butyl benzoylpyruvate prepared *in situ* from the acid **4a** and isobutylene in the presence of H_2SO_4 reacts with PDA to give, apart from the quinoxalinone **86a**, 2-*tert*-butoxycarbonyl-4-phenylbenzo[*b*]-1,4-diazepine isolated as hydrochloride **90**. The product **90** results from the competing cyclocondensation of PDA at the β-dicarbonyl fragment of the pyruvate **4a**. The diazepine **90** easily recyclises into the quinoxalinone **86a** upon dissolution.[149]



90 (51%)

Unlike the APA **4** and their esters **2**, the APA arylamides **6** react with PDA to give, depending on the reaction conditions, 4-arylbenzo[*b*]-1,4-diazepine-2-carboxylic acid arylamides **91**[29, 151] instead of the expected quinoxalinones **86**,[115] or a mixture of these products.[62, 149] The formation of the quinoxalinones **86** is promoted by performing the reaction in EtOH–AcOH–H_2O–HCl mixtures at pH 2.4–4.6 and temperatures of 20–65 °C.[115] Meanwhile, short-term fusion of the reactants at 115–130 °C furnishes predominantly the benzodiazepines **91**.[29, 115, 149] It was noted that electron-donating substituents in the aryl group of the initial amide **6** lead to higher yields of the benzodiazepines **91**, while electron-withdrawing groups promote the formation of the quinoxalinones **86**.[149] The reaction of the 3-pyridylamide **6b** with PDA on refluxing in a Pr^iOH–AcOH

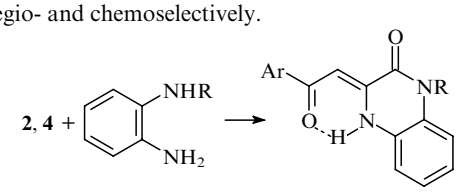
mixture affords both the quinoxalinone **86a** and the benzodiazepine **91** (R = 3-pyridyl).[62]



91 (39% – 99%)

86: Ar = XC_6H_4 (X = H, 4-Me, 4-OMe, 4-Cl, 4-Br, 4-NO_2, 3-NO_2);
91: Ar = 4-XC_6H_4 (X = H, Me, OMe, Br); R = 4-YC_6H_4 (Y = H, Me, OMe, Br), 3-pyridyl.

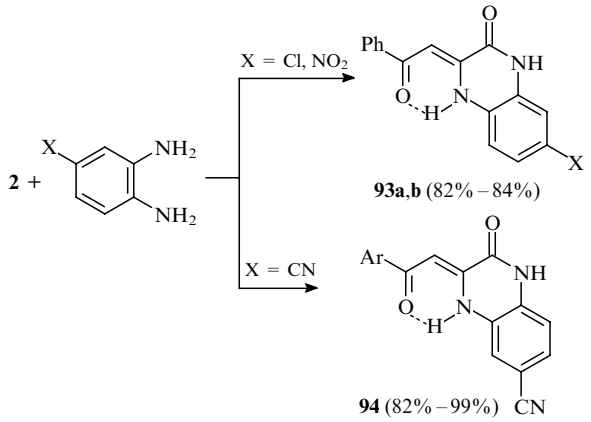
N-Monoalkyl(aryl)-1,2-phenylenediamines react with the AP **2** and **4** similarly to PDA giving rise to 1-alkyl(aryl)-3-aroylmethylidene-1,2,3,4-tetrahydroquinoxalin-2-ones **92** [8, 143, 152, 153] stabilised by an IMHB.[153] Note that these reactions proceed regio- and chemoselectively.



92 (40% – 84%)

Ar = 4-XC_6H_4 (X = H, Cl); R = Me, 4-XC_6H_4 (X = H, Me, OEt, Cl).

Heterocyclisations of the AP **2** with 1,2-phenylenediamines containing various substituents in the benzene ring have been described. The addition pattern depends on the nature of the substituent in the benzene ring of the nucleophile. 1,2-Diamino-chlorobenzene [145] and 1,2-diamino-4-nitrobenzene [8] provide 3-benzoylmethylidene-7-chloro- (**93a**) and 3-benzoylmethylidene-7-nitro-1,2,3,4-tetrahydroquinoxalin-2-ones (**93b**), whereas 3,4-diaminobenzonitrile forms 3-aroylmethylidene-6-cyano-1,2,3,4-tetrahydroquinoxalin-2-ones **94**.[51]

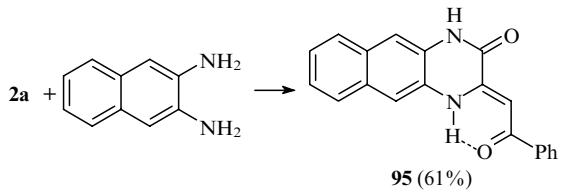


93a,**b** (82% – 84%)

94 (82% – 99%)

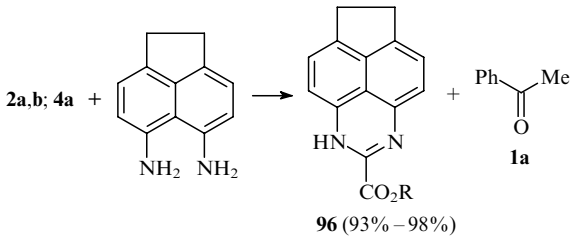
X = Cl (**a**), NO_2 (**b**); Ar = 4-YC_6H_4 (Y = H, Me, Cl).

2,3-Diaminonaphthalene reacts with the AP **2a** similarly to PDA to give 3-benzoylmethylene-1,2,3,4-tetrahydrobenzo[*g*]quinoxalin-2-one (**95**).[145]



95 (61%)

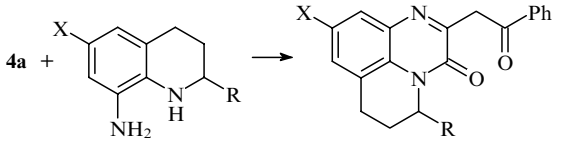
On treatment with 5,6-diaminoacenaphthene, the AP **2a**,**b** and **4a** are cleaved even under mild conditions (at 18 °C) to give 6,7-ethanoperimidine-2-carboxylic acid **96**.[154]



96 (93% – 98%)

R = H, Me, Et.

When the acid **4a** is refluxed with 2(6)-substituted 8-amino-1,2,3,4-tetrahydroquinolines **97a**,**b** in ethanol, 2-benzoylmethyl-4,5,6,7-tetrahydropyrido[1,2,3-*d*,*e*]quinoxalin-3(4*H*)-one derivatives **98a**,**b** are formed.[155]

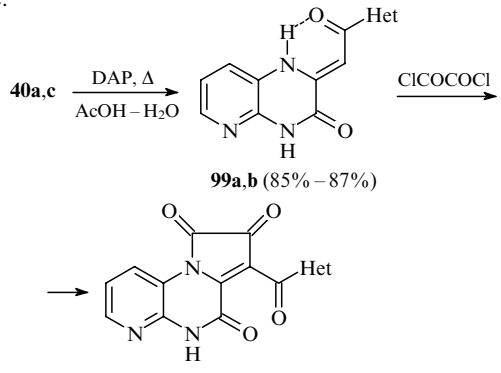


97a,**b** **98a**,**b** (39% – 68%)

R = Me, X = H (**a**); R = H, X = OMe (**b**).

Reactions with heterocyclic diamines. Known reactions of the (H)APA **4** and their esters **2** with heteroaromatic *ortho*-diamines result in the preparation of annelated pyrazin-2-one derivatives [156 – 162] (the products of addition at the α-dicarbonyl fragment of the AP) or [*b*]annelated 1,4-diazepines [160] (the products of cyclocondensation at the β-dicarbonyl part of the AP), depending on the nature of the reactants. In the case of non-symmetric diamines, these reactions proceed regioselectively. Moreover, in some cases, both possible series of regioisomers can be prepared.[157, 162]

It has been reported [156] that refluxing the HPA **4b**,**c** with 2,3-diaminopyridine (DAP) in an AcOH – H_2O mixture results in the formation of (*Z*)-2-heteroaroylmethylidene-1,2,3,4-tetrahydropyrido[2,3-*b*]pyrazin-3-ones **99b**,**c**. The researchers cited [156] confirmed the structure of the heterocycles **99** by converting them into 3-heteroaroyl-1,2,4,5-tetrahydropyrrolo[1,2-*a*]pyrido[2,3-*b*]pyridazine-1,2,4-triones **100** upon condensation with oxalyl chloride.[156]

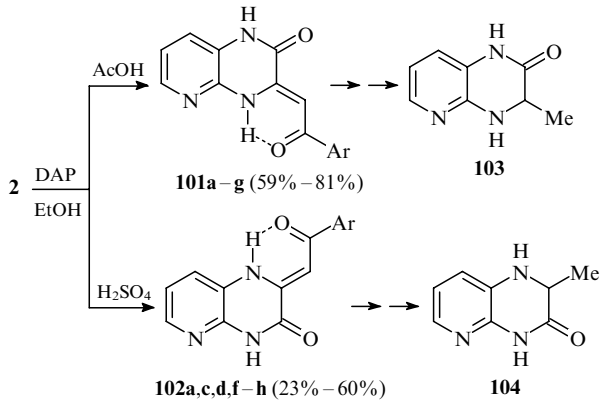


99a,**b** (85% – 87%)

100a,**b** (69% – 72%)

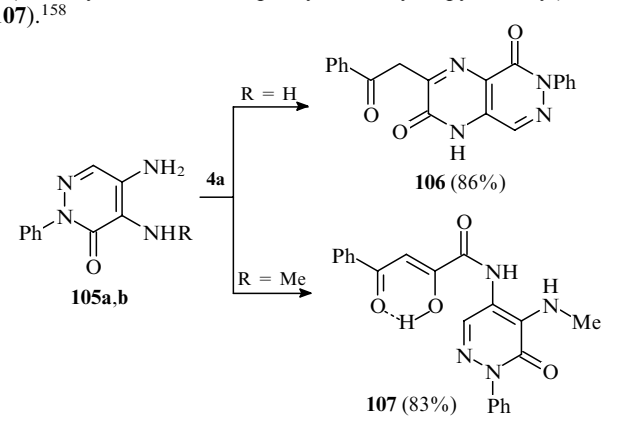
Het = 2-furyl (**4b**, **99a**, **100a**), 5-thiazolyl (**4c**, **99b**, **100b**).

Unlike the APA **4**, the esters **2** can yield two regioisomeric products, depending on the conditions, in the cyclocondensation with DAP. Thus 3-aroylmethylidene-1,2,3,4-tetrahydropyrido[2,3-*b*]pyrazin-2-ones **101** were prepared in an AcOH – EtOH – H_2O solvent mixture, whereas the use of an H_2SO_4 – EtOH – H_2O mixture gave 2-aroylmethylidene-1,2,3,4-tetrahydropyrido[2,3-*b*]pyrazin-3-ones **102**.[157] The structure of the heterocycles **101** and **102** was confirmed by hydrolysis of the compounds **101a** and **102a** followed by reduction to give the known methyltetrahydropyrido[2,3-*b*]pyrazinone **103**, **104** isomers.[163]



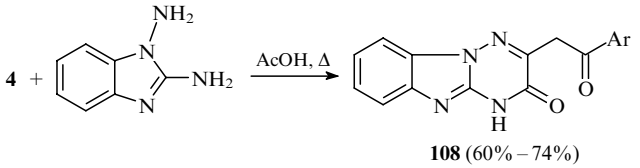
Ar = XC_6H_4 (X = H (**a**), 4-Me (**b**), 4-OMe (**c**), 3-OMe (**d**), 2-OMe (**e**), 4-OH (**f**), 4-Br (**g**), 2-OH (**h**)).

The reaction of the acid **4a** with 4,5-diamino-1-phenyl- (**105a**) and 4-amino-5-methylamino-1-phenyl-1,6-dihydropyridazin-6-ones (**105b**) in boiling ethanol has been described.[158] In the case of the diamine **105a**, the reaction gives the product of cycloaddition at the α-oxocarboxy group of the acid, 3-benzoylmethyl-6-phenyl-1,2,5,6-tetrahydropyrazino[2,3-*d*]pyridazine-2,5-dione (**106**), while the reaction with **105b** gives benzoylpyruvic acid *N*-(5-methylamino-6-oxo-1-phenyl-1,6-dihydropyridazinyl)amide (**107**).[158]



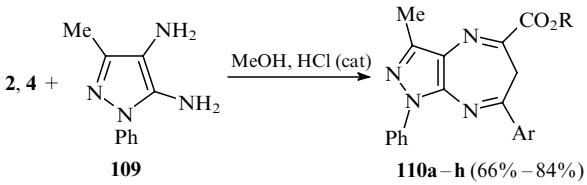
R = H (**a**), Me (**b**).

The reaction of the APA **4** with 1,2-diaminobenzimidazole in boiling AcOH occurs chemo- and regioselectively to yield 2-aroylmethyl-3,4-dihydro-1,2,4-triazino[2,3-*a*]benzimidazol-3-ones **108**.[159] Refluxing of the same reactants in methanol affords salts, which are formed, apparently, at the pyridine N(3) atom of the diamine (yields 80% – 85%). When refluxed in AcOH, the salts cyclise to give heterocycles **108** in 80% – 87% yields.[159]



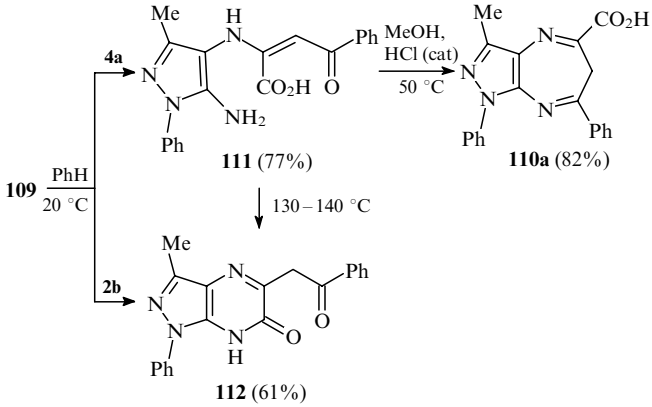
Ar = 4-XC_6H_4 (X = H, Me, OMe, Cl, Br).

The direction of the reactions of the AP **2**, **4** with 4,5-diamino-3-methyl-1-phenylpyrazole (**109**) depends on the conditions and on the nature of the α,β-tricarbonyl compound.[160] At 20 °C in methanol, in the presence of a catalytic amount of HCl, both the APA **4** and their esters **2** add selectively the diamine **109** at the β-dicarbonyl fragment giving rise to 7-aryl-5-carboxy(methoxycarbonyl)-3-methyl-1-phenyl-6*H*-pyrazolo[5,4-*b*]-1,4-diazepines **110**.

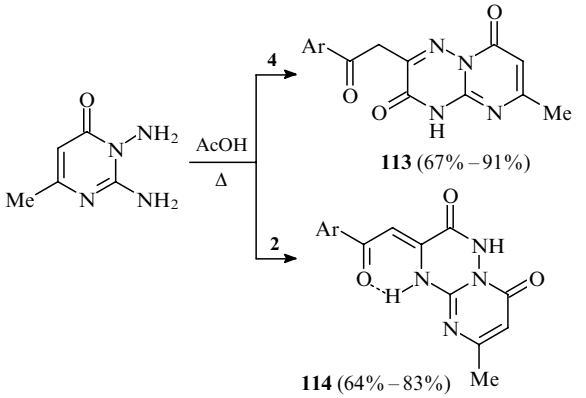


R = H (**a** – **c**), Me (**d** – **h**); Ar = 4-X C_6H_4 [X = H (**a**, **d**), Me (**b**, **e**), Cl (**c**, **f**), NO_2 (**g**)], 2,4-$Me_2C_6H_3$ (**h**).

When the reaction is carried out in benzene at 20 °C, the APA **4a** and diamine **109** form 2-(5-amino-3-methyl-1-phenylpyrazol-4-yl)amino-4-oxo-4-phenylbut-2-enoic acid (**111**), which cyclises to give pyrazolodiazepine **110a** when heated to 50 °C in methanol in the presence of HCl. Unlike the acid **4a**, the methyl ester **2b** adds selectively the diamine **109** at the α-oxoester fragment under similar conditions; this furnishes 5-benzoylmethyl-3-methyl-1-phenyl-6,7-dihydropyrazolo[4,5-*b*]pyrazin-6-one (**112**). The product **112** can also be obtained by heating the acid **111** without a solvent at 130 – 140 °C.[160]



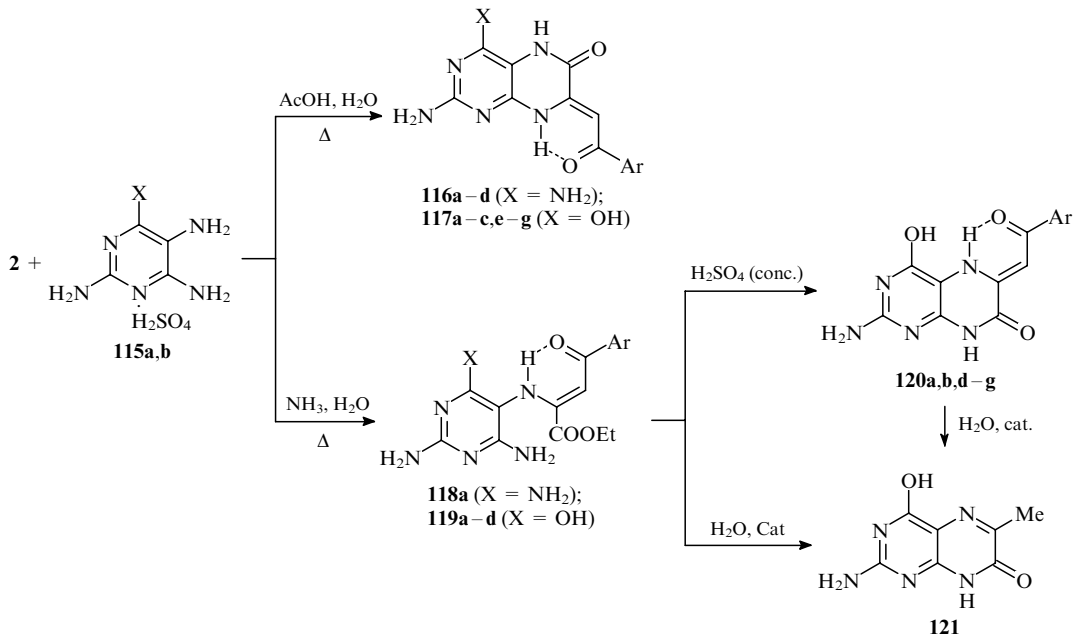
Although cyclocondensation at the α-dicarbonyl fragment is the major process in the reaction of both the APA **4** and the methyl ester **2** with 1,2-diamino-4-methyl-1,6-dihydropyrimidin-6-one on refluxing in AcOH, this process yields different regioisomers for these two types of substrate, namely, 2-aroylmethyl-6-methyl-4,8-dihydro-4*H*-pyrimido[1,2-*b*]-1,2,4-triazine-3,8-diones **113** and (*Z*)-3-aroylmethylidene-6-methyl-2,3,4,8-tetrahydro-1*H*-pyrimido[1,2-*b*]-1,2,4-triazine-2,8-diones **114**, respectively.[161]



Ar = 4-XC_6H_4 (X = H, Me, OMe, Cl, OEt, Br, NO_2).

Heterocyclic amines such as 2,4,5,6-tetraamino- (**115a**) and 4-hydroxy-2,5,6-triaminopyrimidines (**115b**) condense with the AP **2** similarly to *o*-diamines. When refluxed in a solution of AcOH, both amines react selectively with the AP **2** or with the corresponding sodium enolates at the α-oxoester fragment to give 2,4-diamino-7-aroylmethylidene-5,6,7,8-tetrahydropteridin-6-ones

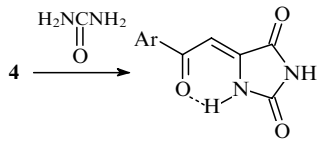
Scheme 8



116, **117**, **119**: Ar = 4-YC_6H_4 [Y = H (**a**), Me (**b**), CN (**c**), OH (**d**), Cl (**e**), Br (**f**), CO_2H (**g**)]; **118a**: Ar = 4-OHC_6H_4 .

116 in the case of the amine **115a** or 2-amino-7-aroylmethylidene-4-hydroxy-5,6,7,8-tetrahydropteridin-6-ones **117** in the case of **115b**.[162] When the reaction is conducted in aqueous NH_3 (1 mol litre^{-1}, pH 8), derivatives of 4-aryl-2-(5-heteroaryl)-amino-4-oxobut-2-enoic acids **118a** and **119a–d**, respectively, can be isolated.[162, 164] In concentrated H_2SO_4, the compounds **119** cyclise into 2-amino-6-aroylmethylidene-4-hydroxy-5,6,7,8-tetrahydropteridin-7-ones **120**, which are isomers of the pteridines **117**. The structures of the products **119** and **120** were proved by hydrolysis, which gave rise to known 2-amino-4-hydroxy-6-methyl-7,8-dihydropteridin-7-ones (**121**) and benzoic acids (Scheme 8).[162]

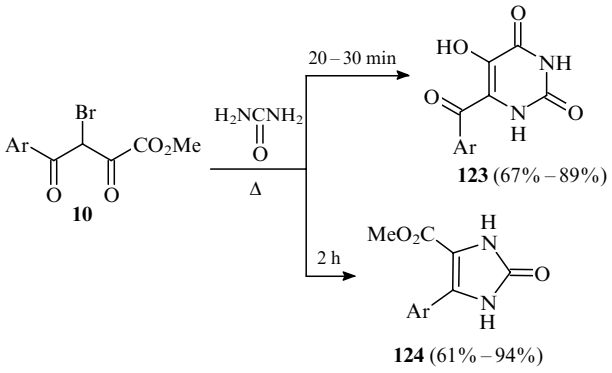
Reactions with urea and sulfamides. The aroylpyruvic acids **4** react with urea at the α-oxocarboxyl fragment on fusion (120–130 °C); this affords 5-aroylmethylidene-2,3,4,5-tetrahydroimidazole-2,4-diones **122**.[165]



122 (68%–96%)

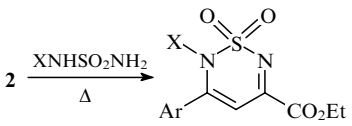
Ar = 4-XC_6H_4 (X = H, Me, Bu^t, OMe, F, Cl, Br).

The direction of reactions of methyl 3-bromoaroylpyruvates **10** (X = Br) with urea is determined by the reaction conditions. Fusion of equimolar amounts of the reactants for 20–30 min at 105–120 °C results in the formation of 6-aroyl-5-hydroxy-1,2,3,4-tetrahydropyrimidine-2,4-diones **123**, whereas the use of a great excess of urea and a longer reaction time (2 h) gives 5-aryl-4-methoxycarbonyl-2,3-dihydro-1*H*-imidazol-2-ones **124**.[166–168] The researchers proposed a mechanism for the formation of the heterocycles **123** and **124**, according to which the common first stage of the reaction is nucleophilic substitution of urea for the bromine atom in the initial AP **10**.[166]



R = Me, X = Br; Ar = 4-YC_6H_4 (Y = H, Me, OMe, F, Cl, Br).

The APA esters **2** react with sulfamide on refluxing in HCl-saturated ethanol at the β-dicarbonyl fragment to give 5-aryl-3-ethoxycarbonyl-2*H*-1,2,6-thiadiazine 1,1-dioxides (**125**).[169] Similarly, *N*-methylsulfamide cyclocondenses selectively with the AP **2** giving rise to only one series of regioisomers, the position of the methyl group in which is not indicated in the study cited.[133] The most probable structure is, apparently, **126**, *i.e.*, the structure of 6-methyl-substituted 1,2,6-thiadiazine dioxides **125**. The products of reactions of the compounds **125**, **126** with ammonia, primary amines and hydrazine possess biological activities.[133, 169]



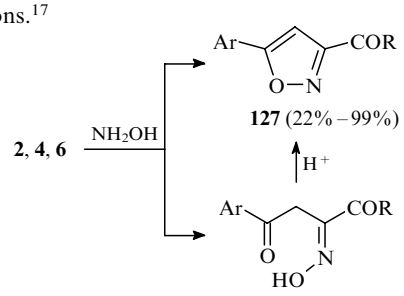
125 (X = H);
126 (X = Me)

Ar = 4-YC_6H_4 (Y = H, Cl, Me).

c. Reactions with N,O-dinucleophiles

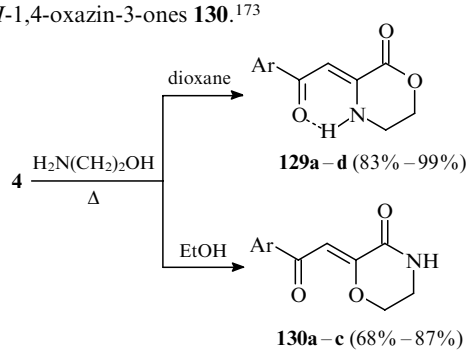
Reactions with hydroxylamine. The acids **4** and their esters **2** react with hydroxylamine hydrochloride at the β-dicarbonyl fragment to give isoxazoles of only one of the two possible regioisomer classes — 5-arylisoxazole-3-carboxylic acids **127**. The reactions are usually carried out by refluxing in aqueous ethanol [13–15, 123, 170, 171] or at 20 °C in the presence of Na_2CO_3 with subsequent short-term heating with either strong acids [15] or acetyl chloride.[2] Less reactive arylamides AP **6** are converted into the corresponding amides **127** (R = NHAr) on refluxing with hydroxylamine hydrochloride in ethanol in the presence of KOH,[62] while the AP hydrazides **58** produce hydrazides **127** (R = NHNHAr) in boiling dioxane.[67]

Under mild conditions (EtOH – H_2O, Na_2CO_3, 20 °C), it is sometimes possible to isolate 2-oximes **128** formed as intermediates in the reactions of the (H)AP **2**, **4** with hydroxylamine hydrochloride.[2, 13, 15] The oximes **128** readily cyclise into isoxazoles **127** on heating or on treatment with strong acids [13, 15] or with dehydrating agents such as acetyl chloride.[2] The formation of ethyl 3-pyridoylpyruvate (**128h**) requires more drastic conditions.[17]



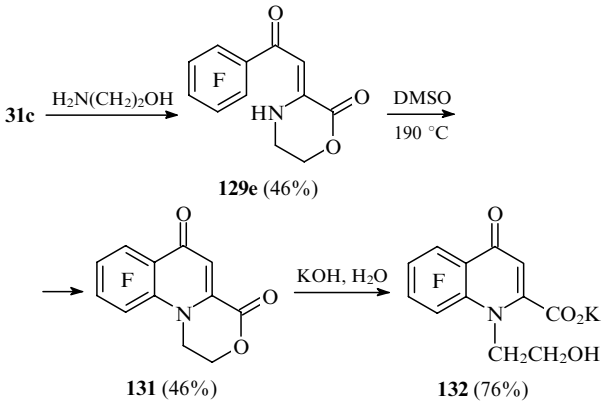
127: Ar = Ph, YC_6H_4 (Y = 4-Me, 4-Cl, 2-OMe, 4-AcNH), C_6F_5, 4-diphenyl, 3-phenanthryl, 2-pyrrolyl, 2-furyl, 2-thienyl, 5-methyl-2-thienyl; R = OH, OEt, 3-pyridylamino, $NHNHCOC_6H_4Z$ (Z = H, 4-OMe);
128: Ar = YC_6H_4 [Y = H (**a**), 2-NO_2 (**b**, **c**), 4-AcNH (**d**)], 2-furyl (**e**), 2-thienyl (**f**), 5-methyl-2-thienyl (**g**), 3-pyridyl (**h**); R = OH (**a**, **b**), OEt (**c** – **g**), OMe (**h**).

Reactions with 2-aminoethanol. The acids **4** add 2-aminoethanol at the α-oxocarboxyl fragment to give oxazine derivatives, the regiodirectivity of the reaction being dependent on the reaction conditions. The refluxing of the APA **4** with potassium 2-aminoethoxide in anhydrous dioxane yields 3-aroylmethylidene-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-ones **129**;[172] the reaction in anhydrous ethanol affords 2-aroylmethylidene-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-3-ones **130**.[173]

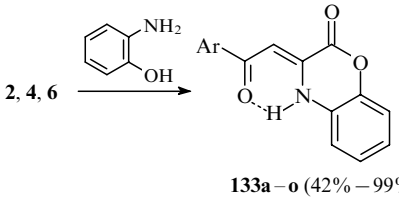


Ar = 4-XC_6H_4 [X = H (**a**), F (**b**), Br (**c**), Cl (**d**)].

The acid **31c** reacts with 2-aminoethanol in boiling dioxane also to give 3-pentafluorobenzoylmethylidene-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-one (**129e**). The structure of the compound **129e** was confirmed by the fact that on heating in DMSO, it cyclises to yield 7,8,9,10-tetrafluoro-1,2-dihydro-1,4-oxazino[4,3-*a*]quinoline-4,6(4*H*,6*H*)-dione (**131**). On treatment with aqueous KOH, this product undergoes opening of the lactone ring, which gives potassium 1-(2-hydroxyethyl)-5,6,7,8-tetrafluoro-4-oxo-1,4-dihydroquinoline-2-carboxylate (**132**).[26, 27]

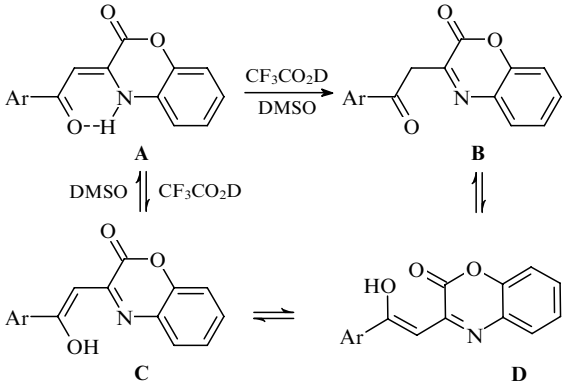


Reactions with 2-aminophenol and its derivatives. The reactions of 2-aminophenol with the APA **4**, their esters **2** and anilides **6** also involve the α-dicarbonyl fragment and give 3-aroylmethylidene-3,4-dihydro-1,4-benzoxazin-2(2*H*)-ones **133**.[3, 5, 9, 21, 29, 37, 44, 45, 53, 174–177]



2: R = OMe, OEt; **4**: R = OH; **6**: R = NHPh.
Ar = XC_6H_4 [X = H (**a**), 4-Me (**b**), 4-OMe (**c**), OH (**d** – **f**), 4-F (**g**), 4-Cl (**h**), 4-Br (**i**), 4-NO_2 (**j**)], 2,4,6-$Me_3C_6H_2$ (**k**), 2-furyl (**l**), 2-thienyl (**m**), 4-pyridyl (**n**), cymantrenyl (**o**);

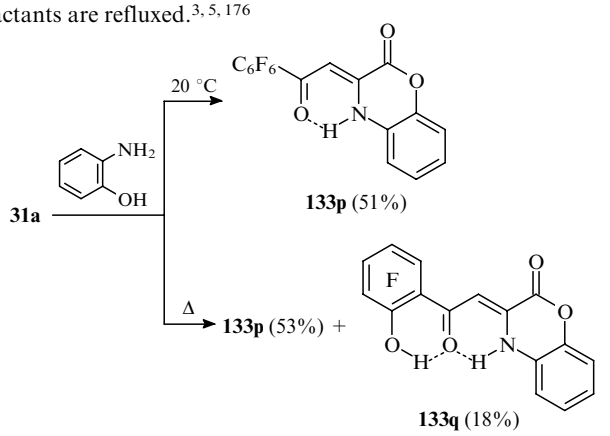
The tautomerism of benzoxazines **133** has been studied by spectroscopy.[145, 146] It was shown that in the solid state and in DMSO-d_6 solutions, they exist as form **A** stabilised by an IMHB. Noticeable amounts of forms **B** – **D** are present only in CF_3CO_2D.[145]



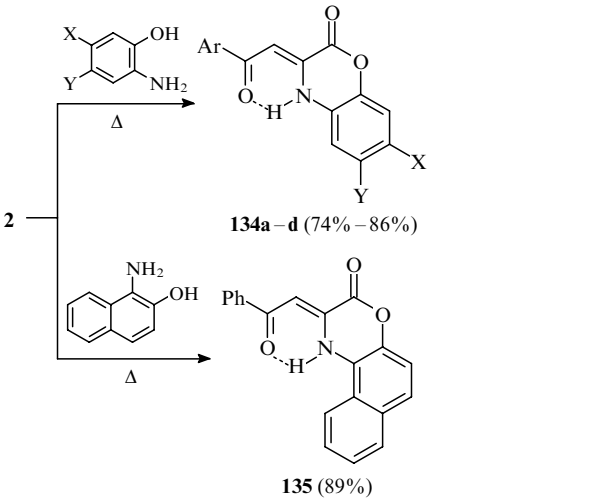
When the reaction of the acid **4a** with 2-aminophenol was carried out under mild conditions (ethanol, 20 °C), a salt was isolated. On heating, this salt readily cyclised to benzoxazin-2-one **133a**.[37] It has been shown [37] that benzoxazinones **133** are thermodynamically less stable than quinoxalones **86**. Thus the compound **133a** is converted into the quinoxalone **86a** almost quantitatively when fused with PDA; in solutions, this transformation occurs even at 20 °C.

Pentafluorobenzoylpyruvate **31a** can react with 2-aminophenol to give, unlike non-fluorinated analogues, not only 3-pentafluorobenzoylmethylidene-3,4-dihydro-1,4-benzoxazin-2(2*H*)-one (**133p**), but also its mixture with 2-hydroxy-3,4,5,6-tetrafluorobenzoylmethylidene-3,4-dihydro-2*H*-1,4-benzoxazin-2-one (**133q**). The compound **133p** is formed under mild conditions (at 20 °C)

in alcohol, while the product mixture is produced when the reactants are refluxed.[3, 5, 176]

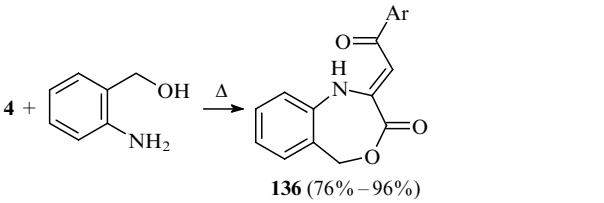


4(5)-Monosubstituted 2-aminophenols and 1-amino-2-naphthol react with the AP **2** similarly to 2-aminophenol yielding 6(7)-derivatives of 3-aroylmethylidene-3,4-dihydro-1,4-benzoxazin-2(2*H*)-ones **134a**–**d** and 3-benzoylmethylidene-3,4-dihydronaphtho[2,1-*b*]-1,4-benzoxazin-2(2*H*)-one (**135**), respectively.[145, 175, 177]

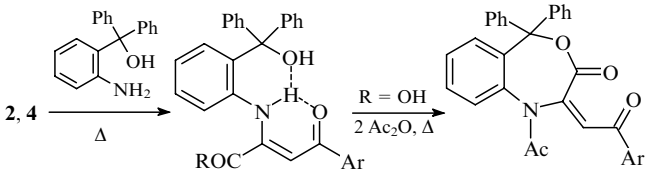


Ar = Ph (**a**–**c**), 4-MeC$_6$H$_4$ (**d**); X = H (**a**–**c**), Me (**d**); Y = Me (**a**), Cl (**b**), NO$_2$ (**c**), H (**d**).

The reaction of the APA **4** with 2-aminobenzyl alcohol carried out by refluxing in toluene gives 4-aroylmethylidene-3,4-dihydro-1*H*,5*H*-benzo[*e*]-1,4-oxazepin-3-one **136**.[178]



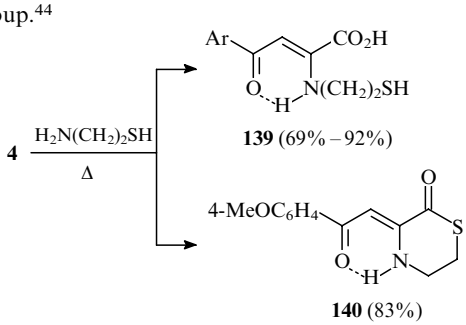
The reactions of the APA **4** and their methyl esters **2** with 2-aminophenyldiphenylmethanol carried out by refluxing in benzene do not result in cyclisation products but give instead 4-aryl-2-[2-(1-hydroxydiphenylmethyl)phenylamino]-4-oxo-4-but-2-enoic acids and their esters **137**. Unlike the ester **137d**, the acids **137a**,**b** cyclise when refluxed in acetic anhydride to 5-acetyl-4-aroylmethylidene-1,1-diphenyl-3,4-dihydro-1*H*,5*H*-benzo[*e*]-1,4-oxazepin-3-ones **138**.[64, 179]



Ar = 4-XC$_6$H$_4$ [X = H (**a**), Me (**b**, **d**), Cl (**c**)]; R = OH (**a**–**c**), OMe (**d**).

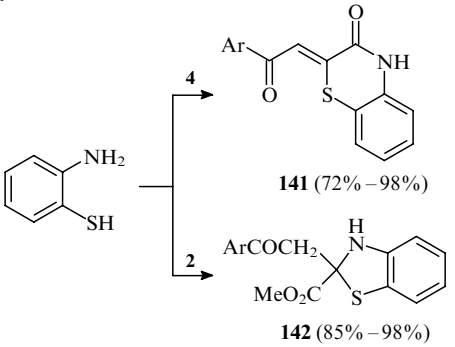
d. Reactions with N,S-dinucleophiles

Reaction with 2-mercaptoethylamine. The acids **4** react with 2-mercaptoethylamine in boiling ethanol to give acyclic 4-aryl-2-(2-mercaptoethylamino)-4-oxobut-2-enoic acids **139**, except for the APA having a methoxy group in the aryl substituent. In this case, the reaction yields cyclic 3-(4-methoxybenzoylmethylidene)-2,3,5,6-tetrahydro-1,4-thiazin-2(4*H*)-one (**140**), which is due, apparently, to the strong electron-donating effect of the methoxy group.[44]



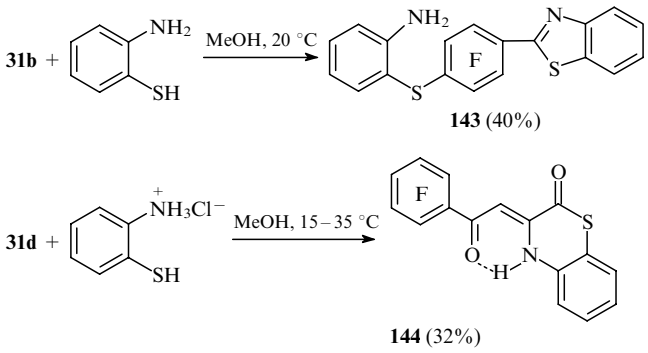
Ar = 4-XC$_6$H$_4$ (X = H, Me, Cl, Br, NO$_2$).

Reaction with 2-mercaptoaniline. The aroylpyruvic acids **4** react with 2-mercaptoaniline on refluxing in toluene; the reaction involves the α -oxocarboxyl fragment and affords 2-aroylmethylidene-3,4-dihydro-1,4-benzothiazin-3(2*H*)-ones **141**.[180] Unlike the acids **4**, their methyl esters **2** react with 2-mercaptoaniline on fusion to give the products of addition at the carbonyl group attached to C(2), *i.e.*, 2-aroylmethyl-2-methoxycarbonyl-2,3-dihydrobenzothiazoles **142**.[180, 181]



Ar = 4-XC$_6$H$_4$ (X = H, Me, OMe, Cl, Et, F, Br).

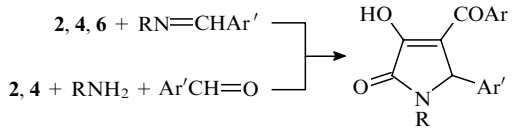
It is of interest that pentafluorobenzoylpyruvates **31b**,**d** behave in a different way towards 2-mercaptoaniline. The pyruvate **31b** is cleaved by the nucleophile under mild conditions (methanol, 15–25 °C) to give ultimately 2-[4-(2-aminophenylthio)-2,3,5,6-tetrafluorophenyl]benzothiazole (**143**). Under similar conditions, the copper(II) chelate **31d** reacts with 2-mercaptoaniline hydrochloride to give the product of selective cyclocondensation at the α-oxoester fragment, 3-pentafluorobenzoylmethylidene-3,4-dihydro-1,4-benzothiazin-2(2*H*)-one (**144**).[3, 6]



4. Miscellaneous reactions

A specific feature of the APA **4** and their esters **2** in the formation of heterocycles is the ability to react simultaneously at the nucleophilic C(3) atom and one electrophilic center.

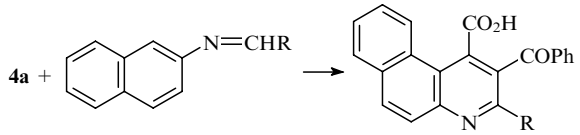
Fusion of ethyl benzoylpyruvate **2a** with benzylideneaniline is known [182] to result in the formation of 4-benzoyl-3-hydroxy-1,5-diphenyldihydropyrrol-2(5*H*)-one (**145**, Y = H, Ar = R = Ph). Borsche has shown [183] that the same pyrrol-2-ones **145** can be prepared from the APA **4** if an equimolar mixture of arylamine and aldehyde is used instead of *N*-arylaldimine. In subsequent studies dealing with the synthesis of pyrrolediones **145**, all the three components, namely, (H)AP, aldehydes and amines were varied over wide limits.[13, 184–187] These reactions are usually carried out in alcohol, AcOH or dioxane at 20–60 °C. The yields of the target products **145** can be increased by using an aldehyde – amine mixture, instead of the corresponding aldimine, and in the case where the AP **2**, **4** contain electron-withdrawing substituents. It is of interest that pyrrolediones **145** are easily (AcOH, 20 °C) formed also from benzoylpyruvic acid 2-pyridylamide **6** (Ar = Ph, R = 2-Py) and diarylaldimines.[187]



Ar = Ph, 4-XC_6H_4 (X = Me, OMe, OEt, Cl, Br, NO_2), 2-furyl;
R = Ph, 2-naphthyl, 4-MeC_6H_4, CH_2CO_2H, $(CH_2)_2NMe_2$;
Ar′ = C_6H_4Y (Y = H, 4-OMe, 4-I, 4-Cl, 4-Br, 4-OH, 2-OMe, 2-F, 2-Cl).

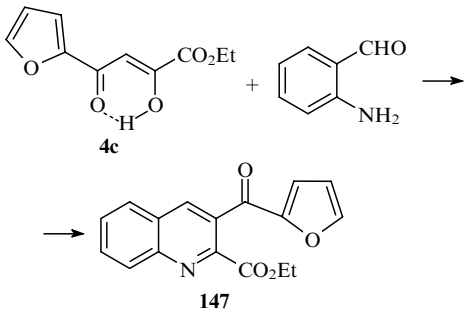
In the given reactions, the aldimine acts as an N-nucleophile and a C-electrophile with respect to AP. The enolysed structure of **145** has been confirmed by NMR spectroscopy.[184–186]

It is notable that when 2-aminonaphthalene (or the corresponding aldimines) are used as the amine component, the acid **4a** is not converted into pyrrolones **145** in boiling ethanol but forms (according to the Doebner condensation pattern) 2-substituted 3-benzoyl-4-carboxybenzo[*f*]quinolines **146**.[183, 188] In this case, the Schiff base acts as a C-nucleophile [the C(1) atom of the 2-naphthyl group] and a C-electrophile with respect to the AP.

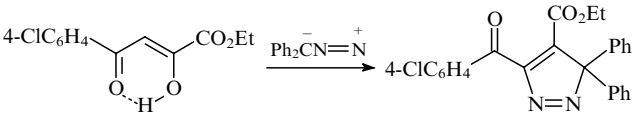


R = H, Me, Ph, 4-$MeOC_6H_4$, piperonyl.

The reaction of ethyl 2-furoylpyruvate **4c** with 2-aminobenzaldehyde gives 3-(2-furoyl)-2-ethoxycarbonylquinoline (**147**).[13]



It has been reported [89] that refluxing of ethyl 4-chlorobenzoylpyruvate with diphenyldiazomethane in benzene induces cycloaddition of the ester at the C(2) and C(3) atoms without elimination of nitrogen to give 3,3-diphenyl-5-(4-chlorobenzoyl)-4-ethoxycarbonyl-3*H*-1,2-pyrazole (**148**).



IV. Biological activities of (het)aroylpyruvates and the products of their heterocyclisation

The interest in the (H)AP chemistry is related, first of all, to the broad spectrum of biological activities exhibited by representatives of this group of compounds and the products of their heterocyclisation.

Thus sodium enolates derived from ethylbenzoyl- and 4-chlorobenzoylpyruvates possess an antimicrobial activity *in vitro*.[189] Hetaroylpyruvic acids [23] and their esters [22, 33, 34, 36] have been found to display antiaggregation,[23] antibacterial,[23, 33, 34] antiviral,[22] antiinflammatory [34] and analgesic [36] activities. 3-Halogenated esters of APA showed antibacterial [80, 84] and antifungal [18, 80] effects. The most diverse and the highest biological activities were found for (H)APA amides and hydrazides. Substances with analgesic,[31, 54, 59, 61, 62, 73, 94, 179, 190] antiinflammatory,[31, 42, 50, 54, 57–60, 62, 69, 70, 72, 73, 85, 94, 179] anticonvulsant,[43, 61] antiviral [69–71] and antibacterial [50, 51, 57, 58, 61, 62, 66, 69, 70, 73, 77, 86, 179, 190] activities have been found among this group.

Many heterocyclic compounds obtained from (H)AP possess various types of physiological activities. The pyrazoles **66** (R^1 = NHR^2) exhibit antiinflammatory,[31, 59, 62, 73] analgesic [59, 73] and antibacterial [62, 69, 128] activities with low toxicity. 5-(3-Pyridyl)-3-hydrazinocarbonylpyrazole (**66**, Ar = 3-pyridyl, R = $NHNH_2$) has been patented as an antitumour agent.[17] Antibacterial action has been discovered for a number of 1-phenyl-5-hetarylpyrazole-3-carboxylic acids **67**.[23] 3-Aroylmethylenepiperazin-2-ones **81** [137, 139, 191] and their 1-methyl- and 1-phenyl- **82**[141, 191] or 6-methyl- and 6-phenyl-substituted **85**[142] derivatives show antiinflammatory, anticonvulsant and analgesic activities in combination with low toxicity. Antiinflammatory [94] and analgesic [91, 94] effects of 3-(1-phenylazoaroylmethylene)-1,2,3,4-tetrahydroquinoxalin-2-ones **87** (X = N = NPh) have been reported. *N*-Aryl-4-arylbenzo[b]diazepine-2-carboxamides **91** were patented as analgesics.[151] Antibacterial and antiinflammatory activities have been found for 3-aroylmethylene-6-cyano-2-quinoxalinones **94**.[51] The tetrahydropyridoquinoxalinones **98** exhibited a tuberculostatic activity *in vitro*.[155] It was found that 4-aryl-2-(5-heteroaryl)amino-4-oxobut-2-enoic acid **119** stimulates the cell growth of some microorganisms.[162, 164] Some 5-aroylmethyleneimidazolidine-2,4-diones **122** possess an anticonvulsant activity while having low toxicity; they depress the central nervous system and, possibly, the activity of the microsomal liver enzymes.[165] A series of 5-aryl-1,2,6-thiadiazine-3-

carboxylic acid 1,1-dioxide derivatives **125**, **126** demonstrated antiviral and sedative activities.[133] The benzoxazepinones **136** show antimicrobial action.[178] An antibacterial activity has been noted for 4-aryl-2-[2-(1-hydroxydiphenylmethyl)phenylamino]-4-oxo-4-but-2-enoic acids and their esters **137**.[179] The benzothiazoline **142** (Ar = Ph) has an antiinflammatory activity.[181] In the case of some pyrrolones **145**, antibacterial[185, 186] and nootropic activities have been found.[185]

V. Conclusion

Analysis of the published data demonstrates that (H)AP represent an ample class of organic compounds containing carboxyl, ester, or amide functional groups. An indispensable structural feature of these substances is the presence of the β-dicarbonyl fragment. The structure of (H)AP accounts for their great synthetic potential. The availability of a wide range of (H)AP is ensured by facile and convenient procedures for their preparation, the main of them being the Claisen condensation or hydrolysis (alcoholysis) of 2,3-dihydrofuran-2,3-diones and -pyrrole-2,3-diones.

When comparing the reactivity of the APA **4**, the esters **2** and the amides **6**, one cannot but note that the amides **6** are somewhat less reactive. Indeed, similar reactions require more drastic conditions in the case of the APA amides **6**. In all the (H)AP **2**, **4** and **6**, the C(2) centre, *i.e.*, the α-carbonyl group, is the site of choice for the primary attack in the reactions with both mono- and dinucleophilic reagents (see Scheme 5). However, when a bulky substituent has been introduced at the 3-position of (H)AP, some reactions involve the ester group. The transformations of (H)AP on treatment with dinucleophiles arouse the greatest interest because these reactions serve as the basis for the synthesis of various heterocyclic systems. The reaction can involve either the α- or β-dicarbonyl fragment. In the reactions with α-dinucleophiles (hydrazines, hydroxylamine), the β-dicarbonyl moiety of (H)AP is involved in the process, while for most of other nucleophiles, the addition at the α-dicarbonyl residue is preferred. In the majority of cases, these processes are regio- and chemoselective, which allows (H)AP to be used for targeted synthesis of heterocycles.

Nevertheless, the chemistry of (H)AP is far from being exhausted. Further research into the properties of these compounds and into the prospects for using them in organic synthesis appears quite topical. These may be related, for example, to investigation of fluoro-containing (H)AP the chemistry of which has essential distinctive features. In addition, (H)AP with organometallic aryl groups are still unknown. The authors hope that this review will be favourable for the development of research into the biological activity of (H)AP and their heterocyclic derivatives, which has been studied only cursorily and fragmentarily.

Thus, (H)AP are readily available and convenient building blocks for the design of diverse acyclic and heterocyclic structures. They can be considered to be promising for further investigations in the fields of heterocyclic and medical chemistry.

This review was supported by the Russian Foundation for Basic Research (Project No. 00-03-32767a).

Abstract. The published data on the synthesis and photochemical properties of porphyrin-based molecular ensembles which represent models of natural photosynthetic light-harvesting complexes are generalised and systematised. The dependence of the transfer of excitation energy on the distance between donor and acceptor components, their mutual arrangement, electronic and environmental factors are discussed. Two mechanisms of energy transfer reactions, *viz*., 'through space' and 'through bond', are considered. The bibliography includes 96 references.

I. Introduction

Absorption of solar energy and its subsequent transformation by cells in the course of photosynthesis is the basis for the energy supply for vital activities of all living organisms. It is therefore not surprising that this problem arouses considerable theoretical and practical interest from investigators.[1–6] Spectroscopic and theoretical studies of photosynthetic processes are mainly focused on the fundamental analysis of photophysical and photochemical characteristics of biological energy-transforming systems and the construction of supramolecular ensembles for molecular photonics and optoelectronics.[7–10]

Chlorophylls and related pigments as well as quinones and carotenoid polyenes are the major components of natural photosynthetic systems. Their interactions are reduced to three basic photochemical processes, *viz*., singlet – singlet energy transfer, triplet – triplet energy transfer and photoinduced electron transfer. For example, antenna systems, which contain chlorophylls, carotenoids and other accessory pigments, collect light and transfer excitation energy to the reaction centres *via* a singlet – singlet energy transfer mechanism.[11,12] Carotenoids are responsible for photoprotection of living organisms from destructive effects of highly reactive singlet oxygen by rapid quenching of the triplet state of chlorophylls *via* a triplet – triplet energy transfer mechanism.[13] The excitation energy derived from antenna complexes is transformed into chemical energy in the course of photoinduced electron transfer mediated by chlorophylls and quinones, which, in turn, generates long-living states with transmembrane separation of charges.[14–16]

Recent studies have led to the synthesis of molecular systems which successfully simulate certain stages of natural conversion of solar energy, particularly, the above-mentioned singlet and triplet energy transfer reactions. The choice of pigments, donors and acceptors for such model systems is based of their spectral properties, which determine the energy characteristics of various excited states. Chromophores related to pigments involved in natural photosynthetic processes are the most promising components for such systems.

The choice of the working principle, which regulates interactions between the individual fragments of a system, is no less important. These interactions, which are controlled by the spatial arrangement of the photosynthetic components and the nature of the separating medium, strongly affect the rates and quantum yields of photochemical processes. The spatial arrangement of pigments, donors and acceptors in natural photosynthetic systems is provided by their interactions with protein subunits. One of the strategies in the construction of artificial photosynthetic systems consists of the substitution of covalent bonds for pigment – protein interactions.[1–3,6] An alternative strategy involves noncovalent assembly of supramolecular complexes, mostly by virtue of the formation of hydrogen and coordination bonds.[17] The construction, in the past few years, of models in which amino acids and peptides are used as connecting bridges (spacers) permitted one to study different regularities of energy and electron transfer in a protein matrix.[18]

The majority of supramolecular model systems described in the literature reproduce the photoinduced electron transfer step. Spectroscopic studies of donor – acceptor model systems have made it possible to establish the dependence of rates of photochemical charge separation reactions on structural factors, such as the distance between the system components and their orientation, on the interactions between the electronic systems of the donor and the acceptor, thermodynamic driving force of the electron transfer and environmental factors.[1–3,6]

Until very recently, much less attention was given to the development of model systems mimicking certain functional steps of light-harvesting antenna complexes.

Light-harvesting antenna complexes inherent in natural photosynthetic systems absorb low-intensity sunlight at wavelengths ~280 – 900 nm (up to 1040 nm in the case of some bacterial complexes) eventually resulting in the transfer of energy to the reaction centres. These complexes contain a large number of chlorophyll or bacteriochlorophyll molecules, carotenoid poly-

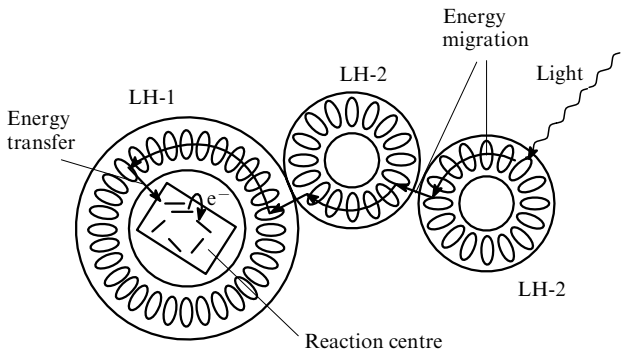

Figure 1. The structures of the bacterial light-harvesting complexes LH-1 and LH-2 responsible for the transfer of absorbed light energy to the reaction centres.[11]

enes and some other accessory pigments held at a small distance from one another by virtue of noncovalent interactions with the protein environment. Absorption of photons by pigments of antenna complexes is followed by migration of excited state energy generated by pigment ensembles until excitation reaches the reaction centre (Fig. 1). The energy can be transferred over sufficiently large distances at record-breaking high speed and with nearly quantitative quantum efficiency (quantum yields).[11, 12]

The complexity of supramolecular pigment–protein structures of natural antenna complexes hinders detailed investigations of light-harvesting reactions at the molecular level and does not provide unambiguous answers to the following questions. How do electronic, photophysical and photochemical properties of pigments influence the efficiency of light-harvesting processes? How does energy migration depend on the three-dimensional configuration of pigments (*viz.*, the distance between the components, their orientation, spatial packing, *etc.*)? What are the mechanisms of electronic interactions between pigments and the role of local environment? What are the effects of these interactions on the synthetic ensembles after substitution of covalent bonds for pigment–protein interactions between the components? What is the mechanism of functioning of the pigments as integral antenna systems within the ensembles and at what distances does energy migrate? Is it possible to increase the efficiency of energy migration in artificial systems by varying the system structure or energy gradients and what are the structural limitations for directional migration of energy? These questions are of crucial importance for the correct understanding of light-harvesting processes occurring in photosynthesising organisms and purposeful utilisation of solar energy. In this context, artificial model systems offer convenient subjects for the study of regularities of energy transfer in natural antenna complexes.

In this review, we consider the main principles of the construction of porphyrin-based model photosynthetic systems and the methods of their synthesis. The applications of these systems in the study of energy transfer in photosynthesis are also discussed.

II. Porphyrin dimers

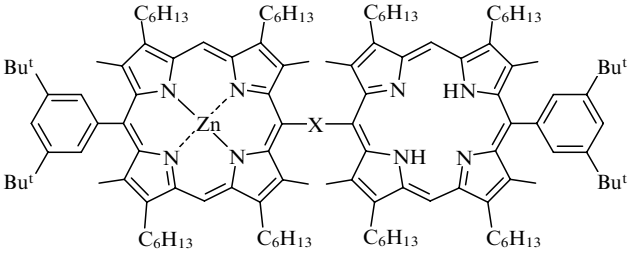
Porphyrin dimers present special interest for investigation of pairwise interactions between pigments in larger ensembles as the simplest models for energy transfer studies. According to the type of their binding, these compounds can be divided into three groups, *viz.*, covalently bound molecules with hydrocarbon spacers, complexes with amino acid and peptide spacers and systems linked by non-covalent bonds.

1. Porphyrin dimers with hydrocarbon spacers

a. Synthesis

The synthesis of covalently bound pigment ensembles is the most popular approach to the design of bisporphyrin model systems.

Covalently bound π-conjugated donor–acceptor systems are convenient models for the study of regularities of energy transfer at large distances. The polyyne- and polyene-bound bisporphyrins **1a–d** and **2a–d** are examples of such systems.[19] The strength of electron-exchange reactions between the donors and the acceptors in these compounds is largely determined by the 'centre-to-centre' distance between two porphyrin macrocycles. This, in turn, is strictly correlated with the number of unsaturated bonds in polyyne-bound systems and can be measured, with a high degree of precision, for polyene-bound molecules taking account of rotation of porphyrin rings around the single bonds.



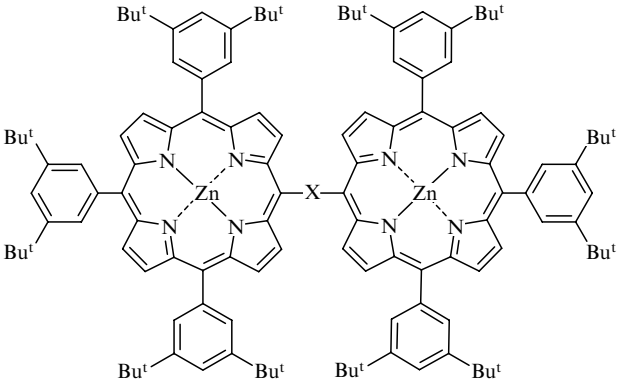
1a–d, **2a–d**, **3a–c**

1: X = *p*-C_6H_4–(–C≡C–)$_n$–C_6H_4-*p*; *n* = 1 (**a**), 2 (**b**), 3 (**c**), 4 (**d**);

2: X = *p*-C_6H_4–(–CH=CH–)$_n$–C_6H_4-*p*; *n* = 1 (**a**), 2 (**b**), 3 (**c**), 4 (**d**);

3: X = *p*-$C_6H_4C{\equiv}C{-}Ar{-}C{\equiv}C\,C_6H_4$-*p*; Ar = 1,2-$C_6H_4$ (**a**), 1,3-C_6H_4 (**b**), 1,4-C_6H_4 (**c**).

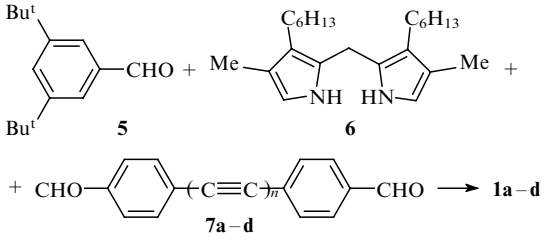
The efficiency of intramolecular singlet energy transfer in the dimeric porphyrins **3a–c** and **4a–c** containing bis(phenylethynyl)phenylene bridges is determined by both the distance and mutual arrangement of the pigments.[20, 21]



4a–c

X = *p*-$C_6H_4C{\equiv}C-Ar-C{\equiv}CC_6H_4$-*p*; Ar = 1,2-$C_6H_4$ (**a**), 1,3-C_6H_4 (**b**), 1,4-C_6H_4 (**c**).

The polyyne-bound bisporphyrins **1a–d** were obtained by trichloroacetic acid-catalysed condensation of 3,5-di-*tert*-butylbenzaldehyde (**5**), dipyrrolylmethane **6** and dialdehydes **7a–d**



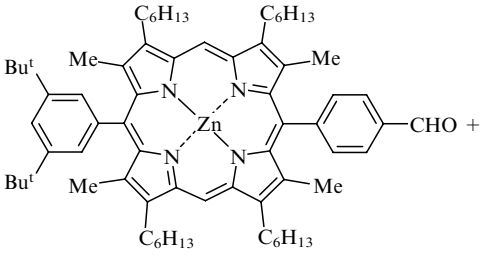
1a–d

n = 1 (**a**), 2 (**b**), 3 (**c**), 4 (**d**).

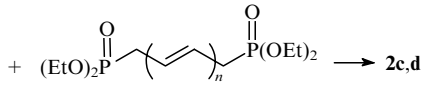
with subsequent oxidation with *p*-chloranil [22, 23] and metallation of one of the porphyrin rings. The yields of bisporphyrins ranged from 13% to 46%.[19] Similarly, the dimers **2a**,**b** and **3a**,**b** were synthesised by condensation of dialdehydes with compounds **5** and **6**.[19, 20]

This one-pot synthesis of bisporphyrins is both convenient and efficient. The formation of polymeric side products in the condensation is suppressed by a large excess of the terminal monoaldehyde; the polyyne and polyene groups, which are especially acid-sensitive, are not affected, since the reaction is carried out under mild conditions.[22, 23]

An alternative approach, which includes condensation of the formyl-substituted zinc-porphyrin monomer **8** with bisphosphonates **9a**,**b**, was used in the synthesis of bisporphyrins **2c**,**d**.[19]



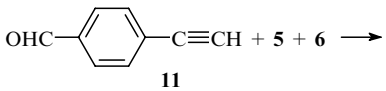
8



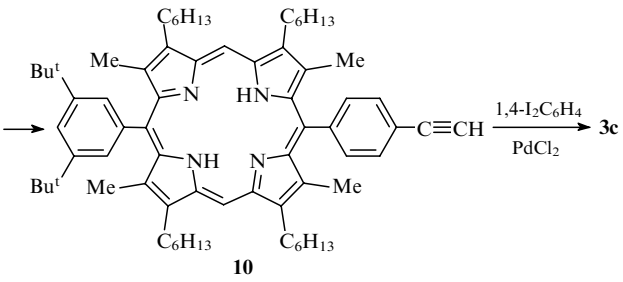
9a,**b** → **2c**,**d**

n = 1 (**a**), 2 (**b**).

Bisporphyrin **3c** was synthesised by palladium-catalysed condensation of ethynylporphyrin **10** [the latter was prepared by the reaction of 4-ethynylbenzaldehyde (**11**) with compounds **5** and **6** with subsequent oxidation by *p*-chloranil] with 1,4-diiodobenzene.[24, 25] The yield of the dimer **3c** was 35%.[20]



11

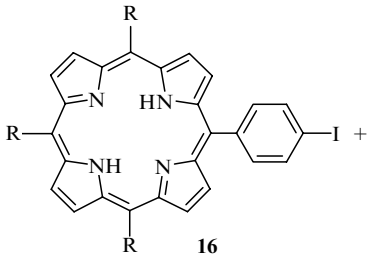


10

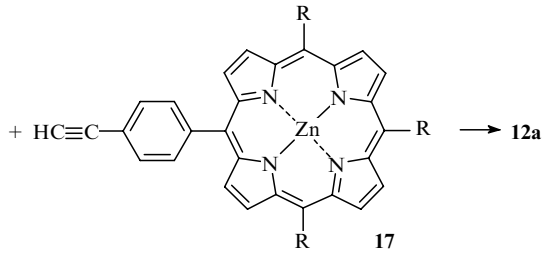
Similarly, bisporphyrins **4a**–**c** were synthesised in 49%, 55% and 84% yields, respectively, by the reaction of ethynyl-substituted tetraarylporphyrins with 1,2-, 1,3- and 1,4-diiodobenzene in the presence of tris(dibenzylideneacetone)dipalladium(0) and triphenylarsine.[21]

An approach to the construction of model light-harvesting systems has been developed, which makes use of porphyrin building blocks. Firstly, *meso*-substituted porphyrins are synthesised from aldehyde precursors (containing iodine atoms and ethynyl groups) and pyrrole (or dipyrrolylmethanes) with subsequent palladium-catalysed condensation optimised for mild coupling of the porphyrin building blocks. In this case, spacers between porphyrins are formed directly in the condensation step.[25–27] This block synthesis was used to prepare the dimeric ensembles **12a**–**i**,[27–31] **13a**–**c** [32] and **14a**,**b**.[33] These model systems were employed for the systematic analysis of structural and electronic factors and their effects on the degree of electronic interactions between tetrapyrrole macrocycles as well as for the synthesis of the amphiphilic porphyrin dimers **15a**,**b**.[34] The latter can be incorporated into lipid bilayer membranes for transmembrane energy transfer studies.

Condensation of the iodoporphyrin **16** free base and the zinc ethynylporphyrin complex **17** in the presence of tris(dibenzylideneacetone)dipalladium(0) and triphenylarsine in a 5 : 1 toluene–triethylamine mixture (35 °C) afforded the dimer **12a** with a diphenylethyne linker (yield > 70%).



16



17

R = 2,4,6-$Me_3C_6H_2$.

Bisporphyrins **12b**–**h** were synthesised analogously in 70%–80% yields.[27–31]

Since the palladium catalyst present in the reaction mixture is not involved in undesirable metallation reactions, free porphyrin bases can be used. If the reaction is carried out in neutral and weakly basic solvents at moderate temperatures, neither demetallation of zinc complexes nor oligomerisation of ethynyl-substituted porphyrins take place.[25, 27]

The diphenylethyne linkers in the systems **12a**–**i** ensure a sufficiently large (~20 Å) distance and relatively weak electronic interactions between the pigments, which excludes quenching of the excited state owing to the electron transfer, which competes with the energy transfer. However, in this case it is desirable to reduce the distance between the porphyrin chromophores in order to increase the rate of the energy transfer.

It was shown [35] that the distance between the porphyrin components of a dimer can be reduced to 13 Å if a *para*-phenylene linker is used, which significantly enhances their electronic interactions. Compounds **18a**,**b** were obtained by one-pot condensation of the corresponding aldehyde with terephthalaldehyde and pyrrole using boron trifluoride etherate as a catalyst and oxidation of the resulting product by 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

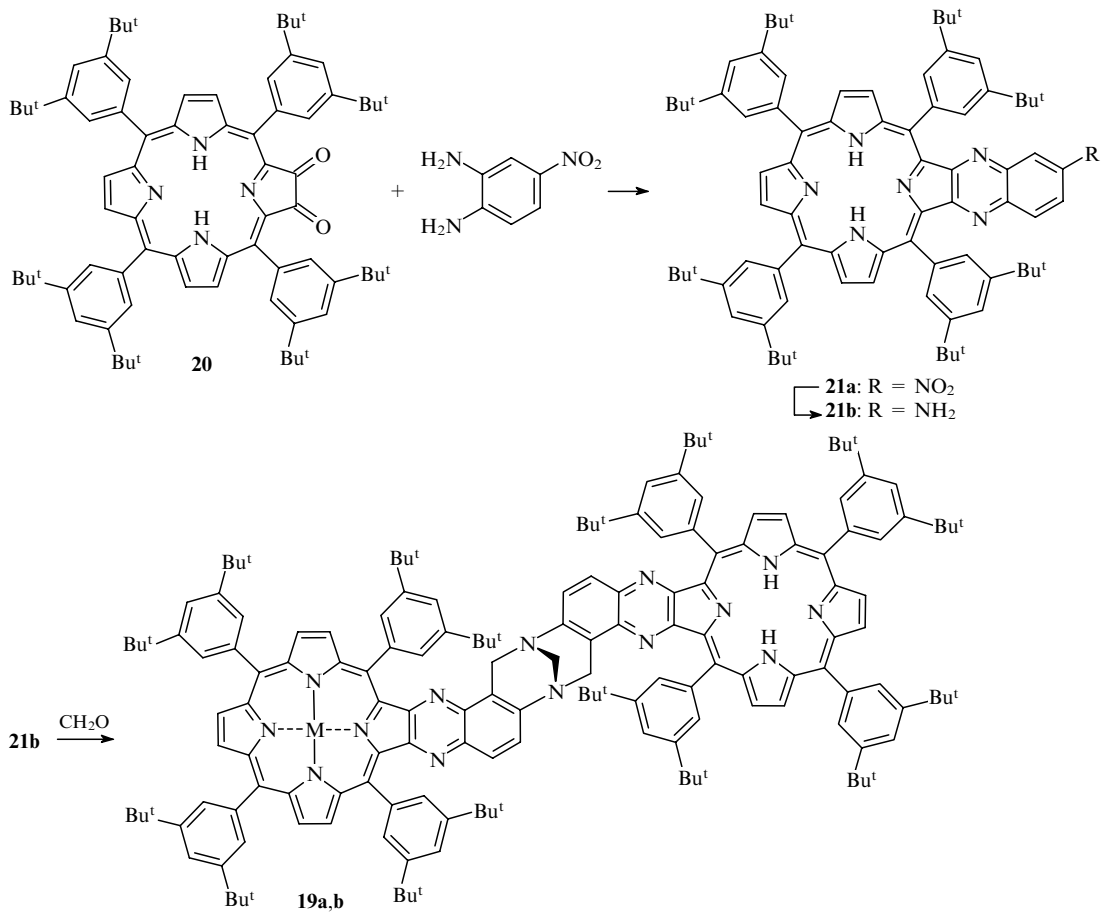
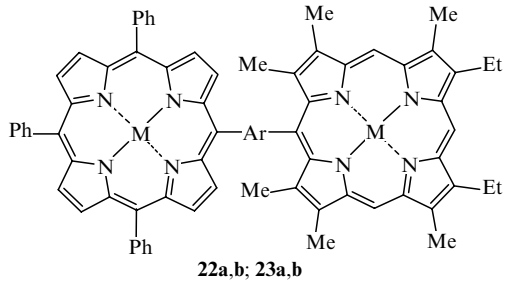
Scheme 1



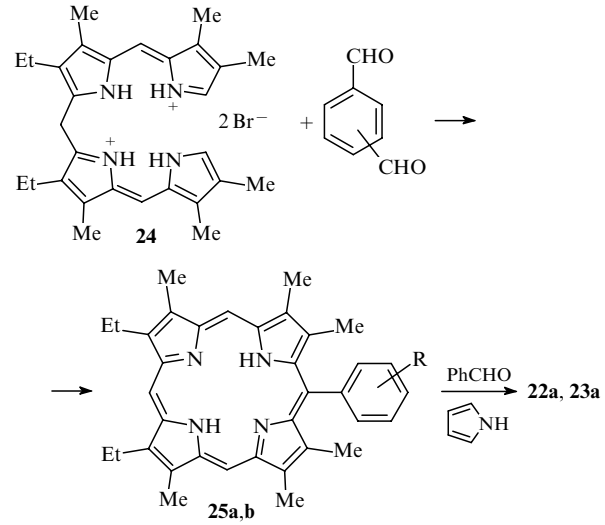
The 'centre-to-centre' distance between two porphyrin fragments in the dimers **19a**,**b** (Scheme 1) is equal to 16.5 Å, whereas their spatial configuration is fixed by two-point addition of each macrocycle to a rigid bridge in such a way that the angle between the planes is 96°. The synthesis of this system includes condensation of porphyrin-2,3-dione **20** with 1,2-diamino-4-nitrobenzene resulting in nitroquinoxalinoporphyrin **21a.** The latter is reduced by tin chloride in hydrochloric acid and the aminoquinoxalinoporpyrin **21b** formed reacts with formaldehyde. The yield of the dimer **19a** is 88%. Compound **19b** was obtained by metallation of bisporphyrin **19a** in 73% yield.[36]

Non-symmetrical porphyrin dimers containing two different macrocycles are promising models for the study of photosynthetic energy transfer. Studies into these compounds provide valuable information about the effects of electronic properties of porphyrin fragments on the yields and the direction of the energy transfer. For example, the covalently linked dimers **22a**,**b** and **23a**,**b** contain tetraphenylporphyrin and octaalkylporphyrin components; their π-systems possess different electronic properties. This allows their selective irradiation and elucidation of pathways of energy transfer following photoexcitation by light with an appropriate wavelength.



22: Ar = 1,4-C_6H_4; **23**: Ar = 1,3-C_6H_4; M = 2 H (**a**), Zn (**b**).

The non-symmetrical dimers **22a**,**b** and **23a**,**b** were synthesised in the following way. The condensation of 8,12-diethyl-2,3,7,13,17,18-hexamethylbiladiene-*a*,*c* dihydrobromide (**24**) with terephthalaldehyde resulted in porphyrin **25a** with the formyl group in the *para*-position. The reaction of the latter with pyrrole and benzaldehyde gave the dimer **22a**. Similarly, bisporphyrin **23a** was synthesised using isophthalaldehyde in the first step.[37]

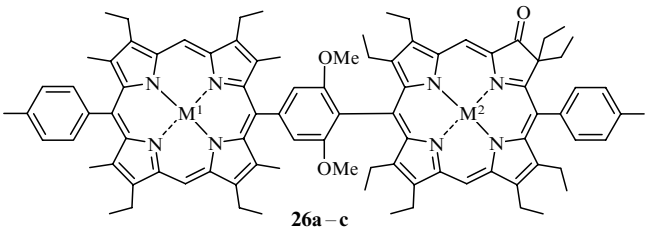


25: R = CHO (**a**), $CH(OEt)_2$ (**b**).

Despite the similarity of many structural, chemical and photophysical characteristics of synthetic porphyrins and natural chlor-

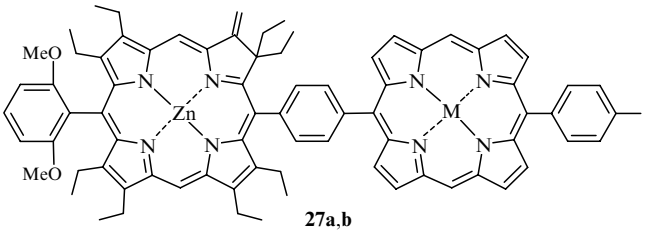
ins, their electronic properties differ considerably because of changes in the symmetry and conjugation pattern in chlorin due to the presence of a reduced pyrrole ring. The main difference between porphyrins and chlorophylls (or bacteriochlorophylls) constituting natural photosynthetic antenna complexes is in that the former absorb light strongly only in the blue region of the solar spectrum, whereas the latter absorb light in both blue and red regions. The orthogonal axes N–N in metalloporphyrins are degenerate (planar oscillator), whereas the dipole moment of the longwave transition in the metal complexes of hydroporphyrins is polarised along one of the N–N axes (linear oscillator), which favours directed transfer of energy. Therefore, the design of chlorin-containing donor–acceptor systems is a promising approach for the modelling of natural light-harvesting complexes.

In the ensembles **26a–c** and **27a,b**, the porphyrin and chlorin macrocycles are linked through rigid aromatic spacers, which fix the macrocycles in parallel planes at a fixed 'centre-to-centre' distance equal to ~12.8 Å.[38,39]



26a–c

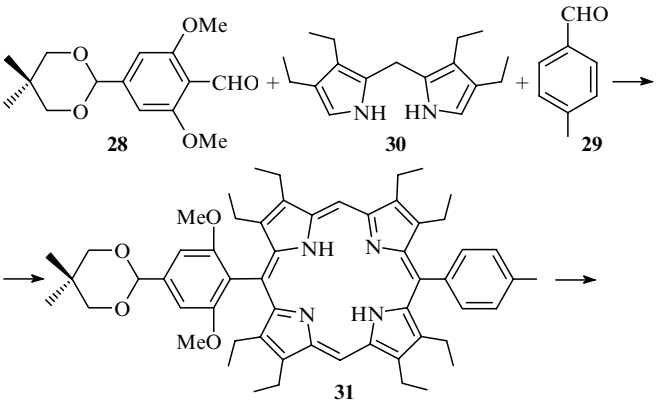
$M^1 = M^2 = 2H$ (**a**); M^1 = Zn, $M^2 = 2H$ (**b**); $M^1 = M^2$ = Zn (**c**).



27a,b

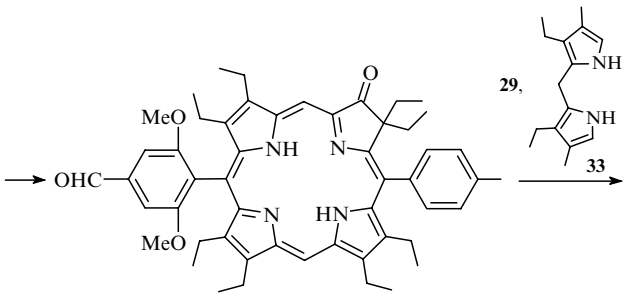
M = 2H (**a**), Zn (**b**).

The macrocyclic ensembles **26a–c** were synthesised in the following way. Condensation of the aldehydes **28** and **29** with 3,3′,4,4′-tetraethyldipyrrolylmethane (**30**) resulted in the porphyrin **31**; its hydroxylation with osmium tetroxide and treatment with trifluoroacetic acid gave the oxochlorin **32**. Condensation of compound **32** with *p*-tolualdehyde (**29**) and dipyrrolylmethane (**33**) and subsequent incorporation of zinc resulted in compound **26c** (yield 18%); demetallation of the latter by hydrochloric acid afforded the product **26a** in a quantitative yield. Treatment of the metal-free dimer **26a** with an equimolar amount of zinc acetate resulted in the selectively metallated bisporphyrin **26b** in quantitative yield.[38]



28 **30** **29**

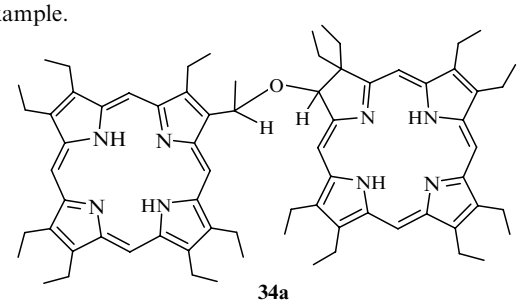
31



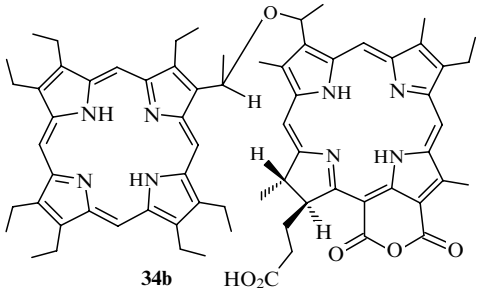
26c → **26a** → **26b**

The dimeric ensembles **27a,b** were synthesised in a similar way. The chlorin component was obtained by condensation of tetraethyldipyrrolylmethane **30** with 2,6-dimethoxybenzaldehyde and 4-(5,5-dimethyl-1,3-dioxan-2-yl)benzaldehyde. The resulting porphyrin was oxidised to oxochlorin, which was further converted into hydroxychlorin by treatment with methyllithium in ether according to Chang. Subsequent dehydration by boiling with trifluoroacetic acid in the presence of 2,2-dimethylpropane-1,3-diol gave methylenechlorin, which was condensed with dipyrrolylmethane and *p*-tolualdehyde following hydrolysis of the protective acetal group. The resulting metal-free dyad reacted with zinc acetate to give a mixture of mono- and dizinc-containing complexes **27a,b** (yields 15% and 30%, respectively).[39]

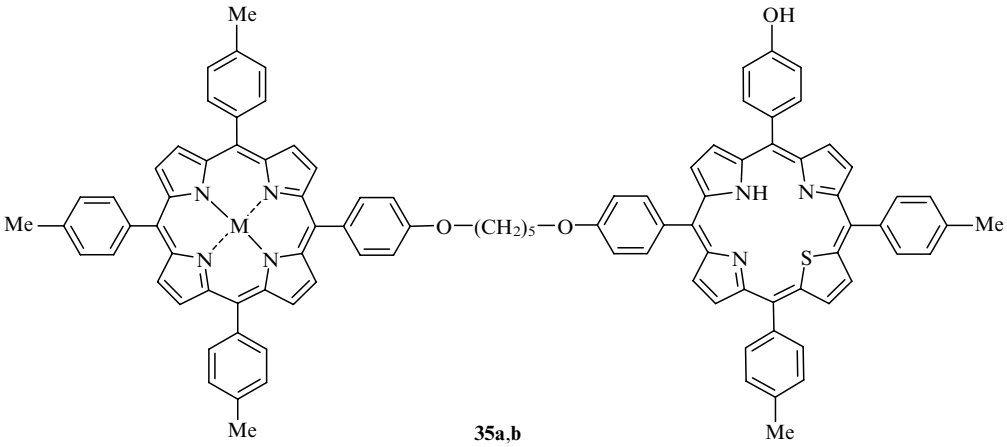
The porphyrin–chlorin heterodimers **34a,b** containing ether bonds between the macrocycles have also been synthesised. The dimer **34a** was prepared from 2-hydroxy-3,3,7,8,12,13,17,18-octaethyl-22*H*,24*H*-chlorin. This was treated with trifluoroacetic anhydride and the resulting trifluoroacetate reacted with 2-(1-hydroxyethyl)-3,7,8,12,13,17,18-heptaethylporphyrin.[40] The heterodimer **34b** was synthesised by condensation of the trifluoroacetylated porphyrin component with the corresponding hydroxychlorin in the presence of catalytic amounts of 4-dimethylaminopyridine.[41] Data from thin-layer chromatography, ^{1}H NMR spectroscopy and computer modelling studies suggest that these compounds exist as two stable isomers. One of them has a sterically hindered structure due to the spatial proximity of the porphyrin and chlorin macrocycles, while the tetrapyrrole fragments of the other isomer do not virtually overlap.[40–42] The effects of conformational mobility on spectroscopic and photophysical properties of the donor–acceptor systems were studied using the porphyrin–chlorin heterodimer **34a** as an example.



34a



34b HO_2C



35a,**b**

M = 2 H (**a**), Zn (**b**).

The dimeric ensembles **35a**,**b**, which contain an ordinary porphyrin and thiaporphyrin, have been synthesised.[43] The sulfur atom in one of their macrocycles changes the electronic structure of the porphyrin backbone; therefore, the properties of the tetrapyrrole fragments in the ground and excited states of these systems differ considerably.

The synthesis of the bisporphyrins **35a**,**b** included the preparation of a monomeric thiaporphyrin precursor by condensation of pyrrole and 2,5-bis(*p*-tolylhydroxymethyl)thiophene with *p*-hydroxybenzaldehyde and subsequent reaction of the resulting product with 5-[4-(5-bromopentyloxy)phenyl]-10,15,20-tritolylporphyrin.[43]

The ensembles in which the chromophores are linked through ethylene, ethyne or butadiyne linkers introduced directly into *meso*- or β-positions of the porphyrin macrocycles manifest interesting properties. These systems, in contrast to the above-described systems, are characterised by extraordinarily strong exciton and electronic interactions between the chromophores as can be evidenced from the significant changes in the electronic absorption spectra (splitting of the Soret band, pronounced bathochromic shifts, *etc*.).[8,44–49] As regards photosynthesis, these compounds can serve as spectral models of antenna pigments possessing absorption in the red spectral region.[44] However, dimers with conjugated ethylene, ethyne and butadiyne units between the chromophores are not used for the modelling of energy transfer; therefore, their synthesis and spectroscopic properties are not considered in this review.

b. Photochemical properties

Studies of photochemical properties of model compounds have shed light on the dependences of the rates and efficiencies of energy transfer reactions on the distance between donor and acceptor components,[19–21,35] their mutual arrangement[20,21,37] and extent of electronic interactions.[21,28,29]

Quenching of singlet excited states of porphyrin donors in the absence of acceptors can be effected in several ways (Fig. 2), *viz*., by radiative quenching through fluorescence emission with the rate constant k_F and by non-fluorescent quenching including intersystem transition to the triplet state, inradiative quenching to the ground energy state, *etc*., with the rate constant k_{NF}. For dilution commonly employed in photochemical studies ($\sim 10^{-6}$ mol litre^{-1}), intermolecular quenching can be neglected. Attachment of an acceptor to the porphyrin donor provides an additional route of quenching of its excited state, *viz*., intramolecular singlet energy transfer with the rate constant k_{EN}.[19]

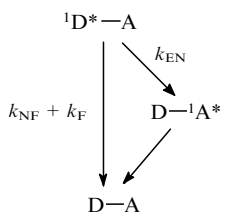


Figure 2. Possible ways of quenching of the singlet excited state of the donor (D, donor, A, acceptor).[19]

Emission spectra provide essential information about photoprocesses occurring in model systems. Quenching of fluorescence of a porphyrin donor concomitant with enhanced fluorescence of the acceptor implies an intramolecular transfer of singlet excitation energy.[19,50,51]

High efficiency of energy transfer is a prerequisite for the normal functioning of natural light-harvesting antenna complexes. The quantum yields (Φ) of the energy transfer can be correctly determined by several methods. One of them includes detailed comparison of steady-state absorption and fluorescence excitation spectra. However, high quantum fluorescence yields, significant overlap of the donor and acceptor fluorescence spectra and the presence of residual amounts of the original monomers do not allow reliable estimation of energy transfer efficiency in molecular ensembles by static measurements alone. An alternative approach consists in comparison of the rates of the energy transfer and competing quenching channels of the donor excitation (see Fig. 2).

The use of this method for the determination of quantum yields of the energy transfer from the zinc-containing porphyrin to the free base in the dimeric ensembles **12a**–**i** has demonstrated extremely high efficiency of this reaction (Φ = 87%–99%)[28–31,51] despite of the large distance (20 Å) and weak interactions between the chromophores. Similar results were obtained in the study of the model systems **18a**,**b** where the quantum yields of the energy transfer were $\geqslant$ 99%.[35] Efficient energy transfer from the octaalkylporphyrin to the tetraphenylporphyrin component was observed for the dimers **22** and **23** (Φ = 79%–99%).[37] Analysis of these systems did not reveal any competitive electron transfer reactions. Thus, the energy transfer is a predominant channel of decay of the excited states of porphyrin donors in these ensembles.

Energy transfer reactions follow two basic mechanisms. The first of them is the Förster 'through-space' mechanism, which is determined by the interactions between transient dipole moments. In this case, the reaction rate depends on the mutual donor and acceptor arrangement, the 'centre-to-centre' distance between them and the integral of spectral overlap of the donor emission and the acceptor absorption. The second route, *viz*., the Dexter 'through-bond' mechanism, is realised in the presence of strong electron-exchange interactions in the case of close contacts between the donor and the acceptor or the presence of a π-conjugated bridge between them.[52]

It was shown that linear π-conjugated polyyne and polyene spacers enhance the 'through-bond' electron-exchange interactions between two porphyrin macrocycles in donor–acceptor bisporphyrin systems.[19]

The values of rate constants for the intramolecular energy transfer in the systems **3b**,**c** containing porphyrin macrocycles in the *meta*- and *para*-positions of the aryl ring, are virtually identical despite the differences in the 'centre-to-centre' distances between the chromophores, which is a clear evidence of electronic 'through-bond' interactions in these compounds. Comparison of the energy transfer rates in the linear dimer **3c** ($k_{EN} = 5.7 \times 10^8$ s^{-1} for the 'centre-to-centre' distance of 26.2 Å) and the diphenylpolyyne-bound bisporphyrin **1d** ($k_{EN} = 1.9 \times 10^9$ s^{-1} for the 'centre-to-centre' distance of 27.0 Å) has demonstrated that the 1,4-bis(phenylethynyl)phenylene bridge is less active in 'through-bond' electronic interactions than diphenylpolyyne spacers of analogous lengths.[19,20]

At the same time, the rates of the energy transfer in the bisporphyrins **13a**,**b**, in which the arrangement of the porphyrin rings and the structures of spacers are similar to those in the dimer **3c**, are comparable with that calculated in the framework of the Förster approximation ($k_{EN} = 4.9 \times 10^8$ s^{-1}). This suggests that the electron energy transfer in these compounds follows the 'through-space' mechanism.[32] Probably, in this case both mechanisms contribute to the interactions between the electronic systems of these pigments.

The energy transfer in the diarylethyne-linked ensembles **12a**–**e** predominantly occurs by the 'through-bond' mechanism mediated by the π-electron system of the linker. This is supported by the fact that the rate constants for the energy transfer for all the dimers of this series (7.5×10^9 s$^{-1} < k < 4.2 \times 10^{10}$ s^{-1}) exceed markedly that predicted by the Förster theory for the 'through-space' mechanism (1.4×10^9 s^{-1}).

In terms of the Lindsey hypothesis, the dihedral angle between the porphyrin ring and the aryl rings of the linker is a critical structural parameter, which determines the possibility of the 'through-bond' energy transfer. Thus steric hindrances created by the introduction of *ortho*-substituents into the linker unit preclude coplanar arrangement of the aryl rings of the linker and the porphyrin rings. This diminishes orbital overlap and decreases fivefold the rate of the 'through-bond' energy transfer. In the dimer **12e**, this effect is predominant over other effects, such as withdrawal of the electron density and interactions of the π-orbitals of *ortho*-chloro-substituents with the *meso*- carbon atoms of porphyrins.[28,51]

Comparison of the rates of singlet–singlet energy transfer in two series of bis(phenylethynyl)phenylene-linked bisporphyrins **3a**–**c** and **4a**–**c** gave similar results. The β-alkyl groups in the dimers **3a**–**c** adjacent to the bridge attachment site hold the bridge in the virtually perpendicular position relative to the porphyrin planes, which minimises the electronic interactions between the porphyrins and the bridge. This conformational restriction is not so severe in the dimers **4a**–**c**, which is a reason for enhanced electronic interactions between porphyrins and increased rates of the 'through-bond' energy transfer in these systems in comparison with the bisporphyrins **3a**–**c**.[21]

The superexchange mechanism, which involves the binding chromophore, is also responsible for increased energy transfer rates in the systems **19a**,**b** characterised by strictly fixed mutual spatial arrangement of the porphyrin macrocycles and the bridge.[53]

At the same time, the decrease in the degree of conjugation between the π-electron systems of the linker and the porphyrins is accompanied by somewhat enhanced contribution of the 'through-space' energy transfer to the overall process. Thus the contribution of this mechanism to the energy transfer in the dimers **12d,e** where the rotation of the linker's aromatic rings is restricted by the substituents, exceeds 10%.[28,51]

The experimental values of the rate constants for the energy transfer for the dimers **22a** (2.4×10^8 s^{-1}), **23a** (8.5×10^8 s^{-1}) and **23b** (2.5×10^{10} s^{-1}) are in good accord with those predicted by the Förster theory. This can apparently be explained by the fact that the macrocycles in the above models cannot lie in the same plane with the binding phenylene groups due to steric hindrances; therefore, direct conjugation between the π-systems of the porphyrins and the linker is excluded while the contribution of the 'through-space' mechanism to the overal energy transfer process increases in accordance with the Lindsey hypothesis.[37]

Energy transfer in natural photosynthetic systems occurs at very fast rates. One of the ways to accelerate this process in synthetic ensembles is to reduce the distance between the porphyrins. Thus the rate constant for the energy transfer in the bisporphyrin **3a** exceeds by about an order of magnitude that in the dimer **3c**, which has an identical spacer, but the distance between chromophores is twice as long.[20] In the case of the dimer **4a** with closely located porphyrin fragments, the energy transfer rate is higher than in the system **4c**, but the effect is far less pronounced.[21]

The rates of the energy transfer in the *p*-phenylene-linked dimers **18a** (2.9×10^{11} s^{-1}) and **18b** (1×10^{11} s^{-1}) are much higher than in structurally similar ensembles containing the diphenylethyne linker, *viz*,. 4.2×10^{11} s^{-1} for **12a** and 4.2×10^9 s^{-1} for **12f**. The observed increase in the reaction rate is mainly due to enhancement of the electronic interactions between the porphyrin components which, in turn, is due to shortening of the distance between the chromophores in the former case.[35]

Analysis of spectral properties of the heterodimer **34a** revealed that the efficiency of the energy transfer in the 'folded' conformer characterised by spatial closeness of the two macrocycles (the 'centre-to-centre' distance determined by computer simulation studies is ~6 Å) is close to 100%. At the same time, the quantum yield of the energy transfer for the isomer having an 'open' conformation of the macrocycles (the distance between the chromophores is > 10 Å) is lower (74%) (see Ref. 54).

It was shown that direct dipole–dipole 'through-space' interactions become predominant in the energy transfer in the ensembles **3a**,[20] **18a**,**b** [35] and **34a** [54,55] with decreased distances between the donor and acceptor components.

Whereas the effects of steric factors on the rates and mechanisms of energy transfer have been studied in sufficiently great detail, the contribution of spacers to the electronic structure of the excited state has been studied to lesser extent. It is known, however, that the strength of the electronic interaction depends not only on structural parameters, such as the distance between the chromophores constituting the system and their mutual arrangement, but also on the relative orbital energies of the donor, the acceptor and the spacer group.

Investigation into the effect of the electronic structures of bridges on the rate of energy transfer has been carried out [32] with the systems **13a**–**c** with identical distances between the macrocycles, well-defined mutual arrangements of two porphyrin ring planes and minimum degree of conjugation between the donor, the bridge and the acceptor, which allowed consideration of the system components as individual chromophores.

Spectral studies of the model bisporphyrins **13a**–**c** revealed the strongest quenching of donor emission in the case of the anthracenylene-linked dimer **13c**, which suggests the higher efficiency of the energy transfer in this compound. Moreover, the rate constant for the energy transfer for the dimer **13c** ($k = 10^9$ s^{-1}) exceeds approximately twofold those for the bisporphyrins **13a**,**b** (5.8×10^8 and 5.4×10^8 s^{-1}, respectively) with phenylene- and naphthylene-containing spacers. These results indicate stronger electronic interactions in the dimer with anthracene-containing spacer, apparently due to the proximity of the energy levels of the lower singlet excited states of the donor, the acceptor and the anthracene chromophore (17 500, 16 000 and 21 600 cm^{-1}, respectively). However, splitting of the energy levels between the donor and the bridge as well as between the bridge and the acceptor is large enough to prevent stepwise energy transfer with the involvement of the intermediate excited state of the binding chromophore.[32]

Comparison of photochemical properties of the dimeric ensemble **12f** containing pentafluorophenyl groups in all the non-binding *meso*-positions of the tetrapyrrole macrocycle and its non-fluorinated analogue **12a** was carried out in order to elucidate the effects of electronic factors on the extent of interactions of the porphyrin components in the ground and excited states. The rate of the energy transfer in the bisporphyrin **12f** was 10 times lower than that in the dimer **12a** despite identical diphenylethyne linker in both compounds. The lower rate of the energy transfer in the former dimer is attributed to weakened electronic interactions between Zn-porphyrin and the free base in the S_1 excited state.

The degree of the 'through-bond' energy transfer between components of dimeric ensembles depends on the electronic and oscillation matrix elements. In the dimers **12a**,**f** possessing identical linkers, oscillator contributions are the same and interactions between the porphyrin components are predominantly determined by electronic factors. Their magnitude depends on the nature and distribution of the electron density of molecular orbitals involved in bonding. In compound **12a**, as in most *meso*-substituted porphyrins, HOMO has the a_{2u} symmetry characterised by considerable electron densities on *meso*-carbon atoms including those attached to the linker. In contrast, the pentafluorophenyl groups in the dimer **12f** stabilise the orbital with the a_{2u} symmetry, which changes the HOMO symmetry to a_{1u}. Such a change in the orbital ordering diminishes the electron density on the peripheral *meso*-atoms of the macrocycle where the linker is attached, and thus reduces the electronic matrix element. Thus, the rate of the energy transfer between the zinc-containing porphyrin and the free base of the dimer decreases. Redistribution of the electron density from the *meso*-carbon atoms of the a_{2u} orbital to the strongly electron-withdrawing pentafluorophenyl rings is yet another factor inducing appreciable decrease in the rate of the energy transfer in the dimer **12f**.[29]

In the case of the fluorine-containing dimer **18b**, a threefold decrease in the rate of the energy transfer was observed in comparison with the non-fluorinated analogue **18a** (1×10^{11} and 2.9×10^{11} s^{-1}, respectively). This effect correlates with the above-described fluorine-induced changes in the orbital characteristics of porphyrin components in the case of *meso*-diarylethyne-linked dimers.[35]

An opposite effect was observed for the β-linked dimers **14a**,**b** in which the presence of pentafluorophenyl groups in the non-binding *meso*-positions promotes stronger electronic interactions. As a result, the rate of the energy transfer in the dimer **14b** ($k = 4.2 \times 10^{10}$ s^{-1}) exceeds more than twofold that in the mesityl-substituted ensemble **14a** ($k = 1.8 \times 10^{10}$ s^{-1}). This, too, is due to enhanced contribution of the a_{1u} orbital characterised by higher electron density on the β-pyrrole atoms, where the linker is attached, to the wave function of the excited electronic state in pentafluorophenyl-substituted dimers.[33]

A 17-fold decrease in the rate of the energy transfer in the *meso*-diphenylethyne-linked β-alkyl-substituted dimer **1a** (see Ref. 19) in comparison with the *meso*-aryl-substituted bisporphyrin **12a** possessing the identical linker is mainly due to the electronic factors determined by the differences in the orbital ordering.[29] In particular, eight β-alkyl substituents and two aryl groups in the *meso*-positions of each porphyrin fragment in the dimer **1a** determined the a_{1u} HOMO symmetry characterised by the absence of electron density on the *meso*-carbon atoms to which the linker is attached. In addition, the steric hindrance due to the β-methyl groups in the pyrrole rings of the porphyrin macrocycle limit the rotation of the aromatic rings of the linker and prevent their coplanarity with the porphyrin macrocycles. This diminishes the conjugation of their π-electron systems and thus makes an additional contribution to the weakening of the electronic interactions between the dimer components.

The enhancement of 'through-bond' electronic interactions and the increase in the rate of singlet energy transfer upon substitution of the tetraarylporphyrin component in the systems **4a**–**c** for the 10,20-diaryloctaalkylporphyrin component in the dimers **3a**–**c** are explained in a similar way.[21]

Thus, the site of attachment of the linker should be chosen with due regard to the general pattern of substitution in the tetrapyrrole macrocycle in order to ensure optimum electronic interactions. For porphyrins with the a_{2u} HOMO symmetry, the strongest electronic interactions are provided by linkers attached to the *meso*-positions of the macrocycles, whereas stronger electronic interactions between the pigments with the a_{1u} HOMO symmetry are provided by spacers introduced into β-pyrrole positions. It should also be considered that the electron densities of the eight β-pyrrole carbon atoms with the a_{1u} orbital symmetry are much lower than those of the four *meso*-atoms with the a_{2u} orbital symmetry. Consequently, the electronic interactions through spacers connecting β-positions of the porphyrin macrocycles should be less efficient than those through spacers connecting *meso*-carbon atoms.[29, 33]

The LUMO characteristics also contribute to linker-mediated electronic interactions between chromophores. The electronic factor is determined by the overlap of the e_g orbitals of porphyrin with the d_π-orbitals of the metal. Thus an increase in the rate of the energy transfer in the cadmium-containing ensemble **12h** ($k = 6.7 \times 10^{10}$ s^{-1}) in comparison with the magnesium-containing dimer **12g** ($k = 3.2 \times 10^{10}$ s^{-1}) reflects the putative role of cadmium *d*-orbitals in the electronic interactions.[31] Stronger 'through-bond' interactions in the zinc-containing diporphyrin **19b** in comparison with its non-metallated analogue **19a** is thought[53] to be due to the interaction of the metal d_π-orbitals with the porphyrin ring, which increases the electron density on the pyrrole carbon atoms bearing the spacer group.[53]

The effect of the bridge topology on the electronic interactions between porphyrins in the ground and excited states was studied in the example of the conjugated dimers **36** and **37**. The energies of absorption maxima in the region of the Q-bands of the β,β-linked ensembles **36a**,**b** are essentially the same as those of the isolated zinc-containing tetraphenylporphyrin complex, which points to weak electronic interactions between the chromophores in the ground and the lowest singlet electron-excited states. Contrariwise, a pronounced bathochromic shift and enhanced low-energy absorption in the region of the Q-bands in the *meso*,*meso*-linked dimer **37** suggest the presence of strong electronic interactions between the porphyrin macrocycles. These data are in good agreement with the order of changes in the strength of the electronic interaction (*meso*,*meso* > *meso*,β > β,β) for *meso*-substituted porphyrins at a fixed twist angle between the tetrapyrrole planes predicted on the basis of the above-described analysis of the electronic structure. Moreover, the rotation barrier around the ethyne linker in the *meso*,*meso*-linked ensemble **37** is a minimum in comparison with β,β-linked dimers. This suggests that the conformers in which the components of the *meso*,*meso*-linked dimer have planar structures and maximum conjugation predominate in solutions at room temperature.[44, 45]

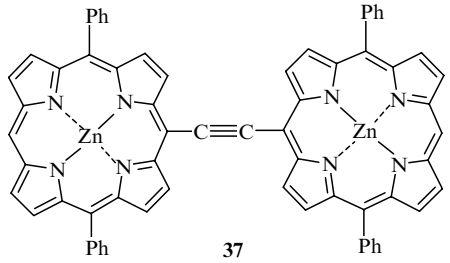
$n = 1$ (**a**), 2 (**b**).



37

These data suggest that the electronic structure together with steric factors are essential for efficient electronic interactions and high rates of the energy transfer in dimeric ensembles.

Zinc-containing porphyrin complexes analogous in structural, chemical and photophysical characteristics to those of chlorophylls and bacteriochlorophylls are widely employed in photosynthetic model systems. However, natural photosynthetic pigments contain magnesium atoms in their chlorin rings. Spectral properties of the ensembles **12a**,**g**,**h**, which contain zinc, magnesium and cadmium in one of their macrocycles, were compared in order to examine the effects of metal substitution on the photodynamic behaviour of bisporphyrins. The rates of the energy transfer for the three dimers were very close, which can be attributed to the similarity of electronic interactions between the chromophores in the magnesium-, zinc- and cadmium-containing bisporphyrins. However, the quantum yield of the energy transfer for the Mg-containing dimer (Φ = 99.7%) is higher than that for the Zn-containing dimer (Φ = 99%) due to the longer lifetime of the excited state of the Mg-porphyrin (10 ns) in comparison with that of the Zn-porphyrin (2 ns). Although this difference is insignificant in the case of the isolated dimer, this may be multiplied in multiporphyrin ensembles, which perform more energy transfer steps.[30] A more significant decrease in the efficiency of the energy transfer in the case of the cadmium-containing dimer (Φ = 87%) is almost exclusively due to the very short ($\sim$ 100 ps) lifetime of the Cd-porphyrin excited state, which, in turn, may be a result of acceleration of the singlet–triplet intersystem transition, which competes with the energy transfer due to the presence of a heavy metal.[31] Moreover, magnesium- and especially cadmium-containing bisporphyrins are more labile with respect to demetallation and photochemical oxidation and are more prone to electron transfer, whereas zinc-containing dimers are rather stable against these side reactions.

These data suggest that synthetic ensembles capable of highly efficient energy transfer may contain both Mg- and Zn-porphyrins; the choice of a metal should be made with due regard to all the factors mentioned above.[30] Moreover, the extremely high rate ($k = 1.1 \times 10^{11}$ s^{-1}) and the nearly quantitative efficiency of the energy transfer in the dimer **12i**, which contains Zn- and Mg-tetraarylporphyrin complexes, confer attractive properties on the combination of these complexes within a single ensemble. At the same time, the use of cadmium complexes in artificial energy-transforming systems is limited due to reduced efficiency of the energy transfer and lability of these compounds.[31]

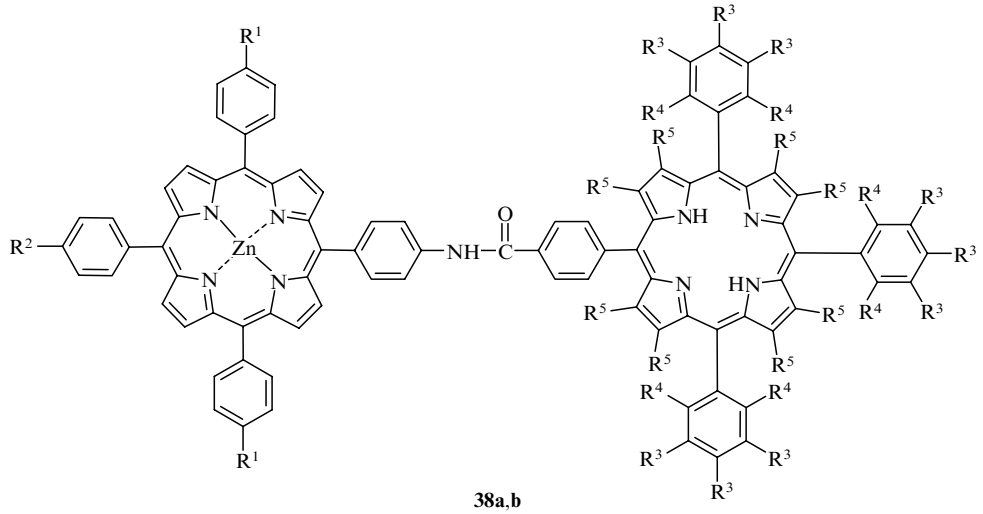
The effects of environmental factors, such as viscosity, solvent polarity and temperature, on the photodynamic behaviour of the diarylethyne-linked ensembles **12a**–**d** have been discussed.[51] These studies have shown that the rates of energy transfer in viscous media (*e.g.*, castor oil) are 1.3–1.9 times lower than in toluene. This can be explained by the fact that higher viscosity of the medium impedes probably the rotation of the aromatic rings of the linker around a single bond, which prevents their coplanarity with the porphyrins and thus weakens electronic 'through-bond' interactions between the porphyrin macrocycles.

With a decrease in temperature to 150 K, the rates of the energy transfer in these dimers show a slight decrease. Presumably, the mobility of the aromatic group and a concomitant change in the average dihedral angle between the linker and the porphyrin are also decreased due to freezing of the solvent. The degree of thermoinduced conformational changes depends on rotational restrictions of the linker. Therefore, the most appreciable (2.5-fold) decrease in the rate of the energy transfer is observed for the dimer **12a** where a broad range of dihedral angles is possible due to the lack of torsional restrictions. No such changes were observed for the ensemble **12d**.[51]

The dynamics of singlet–singlet energy transfer in the porphyrin–chlorin system **34a** containing ether bond between the macrocycles changes with temperature. At 293 K, the excitation energy migrates repeatedly between the interacting donor and acceptor components over the lifetime of acceptor fluorescence, since the rates of forward and reverse energy transfer reactions exceed the deactivation rates of S_1 states of porphyrin and chlorin by more than an order of magnitude. In contrast, the transfer of excitation energy from porphyrin to chlorin at 77 K is irreversible, for in this case the calculated rate of the reverse transfer is much lower than the deactivation rate of the acceptor S_1 state.[55]

It was shown that the polarity of the solvent affects only slightly the efficiency and rate of energy transfer in diarylethyne-linked dimers. However, significant quenching of fluorescence of the porphyrin free base in the dimers **12a**,**b** observed in polar solvents (*e.g.*, dimethyl sulfoxide) is ascribed to the charge transfer from the neighbouring metal complex.[51] Magnesium-containing ensembles are even more sensitive to this process due to increase in the driving force of the electron transfer process.[30]

Similar photoinduced electron transfer to the excited singlet state has also been observed in the hybrid porphyrin–chlorin dimer **26b** (see Ref. 38) and the bisporphyrins **38a**,**b** (see Ref. 56).



38a,**b**

R^1 = Me, R^2 = NHCOMe, R^3 = H, R^4 = R^5 = Cl (**a**); R^1 = R^2 = NMe_2, R^3 = R^4 = F, R^5 = H (**b**).

It should be emphasised that the charge transfer occurs after the excitation has reached the acceptor and has no appreciable influence on the energy transfer between the donor and acceptor components in the above-described ensembles.[51]

The fluorescence spectra of bisporphyrins linked by flexible hydrocarbon chains can be interpreted by the existence of two conformations, *viz*., the 'open' conformation where quenching of the donor fluorescence is fairly ineffective and the 'folded' conformation characterised by effective quenching of donor emission owing to the transfer of singlet energy to the acceptor.[57–59] Changes in the solvent polarity bring about transition of one form into another. Thus the 'open' conformation is predominant for solutions of bisporphyrins **35** in toluene, whereas in dimethylformamide the 'folded' conformation is preferable in which the 'centre-to-centre' distance between two porphyrin components is 18.7 Å. Such conformational transition results in the enhancement of the efficiencies and rates of energy transfer in polar solvents.[59]

The knowledge of regularities of the energy transfer depending on structural, electronic and environmental factors is useful for the design of more complex model donor–acceptor systems.

2. Porphyrin dimers with peptide spacers

All the bisporphyrins described above contain hydrocarbon spacers. However, chlorophyll and bacteriochlorophyll in photosynthetic antenna systems exist in a protein environment, which affects the photophysical properties.[11, 12, 60] Synthetic porphyrin dimers with the macrocycles linked through amino acid or peptide spacers represent convenient model subjects for the study of intramolecular interactions and energy transfer between tetrapyrrole chromophores within natural pigment–protein complexes.

a. Synthesis

The porphyrin dimers **39a**,**b** and **40a**,**b** linked through amino acid bridges served as models for the studies of spectral properties of chromophores in biological photosynthetic systems.[61] These compounds were synthesised in 10%–15% yields by condensation of 5-*o*-(2-bromoethoxy)phenyl-10,15,20-triphenylporphyrin with glycine or racemic phenylalanine in dimethylformamide in the presence of a phase-transfer catalyst.

39: R^1 = R^2 = H; **40**: R^1 = Bn (H), R^2 = H (Bn); M = 2H (**a**), Zn (**b**).

The porphyrin dimers with macrocycles covalently linked through cyclic dipeptides, *viz*., piperazine2,5-diones (compounds **41a**,**b** and **42a**,**b**),[62] β-folded oligopeptides (dimers **43a**,**b**, **44a**–**d**, **45a**,**b**)[63] and the oligo-L-proline spacers **46a**–**i** and **47a**–**i**,[64] were synthesised for studies of intramolecular interactions and energy transfer between the porphyrin components.

In these dimers, two porphyrin rings are held in specific conformations by rigid peptide spacers. Thus rigid β-folded structures of the dipeptides in the molecules **43a**,**b**, **44a**–**d** and **45a**,**b** are determined by the formation of hydrogen bonds between the carbonyl groups of the porphyrins and amino groups of amino acid residues of the peptides.[63] Due to the cyclic side chain, the oligo-L-proline spacers in the dimers **46a**–**i** and **47a**–**i** acquire fairly stable helical conformations provided the number of amino acid residues is no less than four.[18, 64]

The general strategy of the preparation of these compounds is based on the use of standard protocols of the peptide synthesis. The symmetrical bisporphyrins **41a**,**b** and **42a**,**b,** which are covalently linked to tyrosine residues by ether bonds to form piperazine-2,5-dione, were obtained from the zinc-containing porphyrins **48a**,**b**, which in turn were synthesised by the condensation of the corresponding aromatic aldehydes with methoxycarbonylbenzaldehyde and pyrrole followed by reduction of the ester groups to hydroxy groups, substitution of bromine for

hydroxy groups and introduction of zinc into the porphyrin rings.[62]

Condensation of benzyloxycarbonyl-protected L- or D-tyrosine with L-tyrosine methyl ether afforded dipeptides, which were converted into piperazine-2,5-diones following deprotection. Reactions of the latter with the porphyrins **48a**,**b** afforded the diastereomerically pure zinc-containing dimers **41b** and **42b**; their demetallation resulted in compounds **41a** and **42a**.[62]

An alternative approach was used in the synthesis of the porphyrin dimers **43a**,**b**, **44a–d** and **45a**,**b** linked through β-folded peptides. In this synthesis, 5-(*p*-carboxyphenyl)-10,15,20-tri-*p*-tolylporphyrin (**49**) and 5-(*p*-aminophenyl)-10,15,20-tri-*p*-tolylporphyrin (**50**) were used as the porphyrin components, while

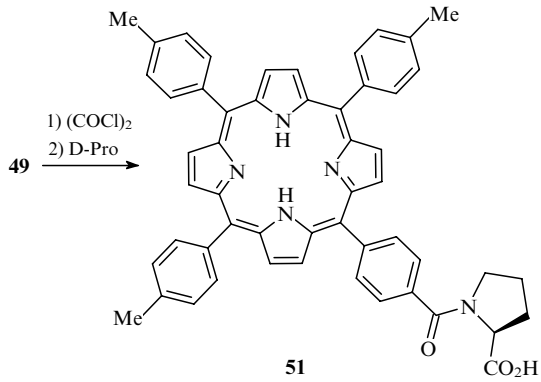
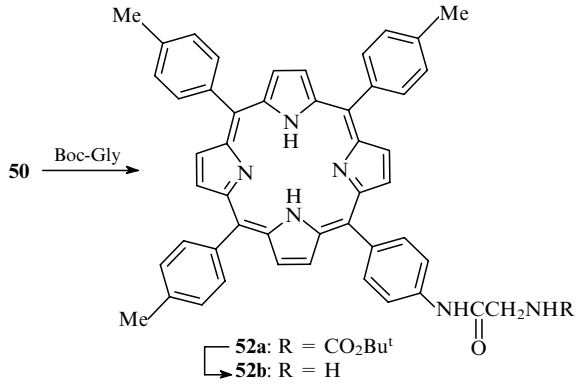
the amino acid sequences D-Pro-Gly and D-Pro-L-Asp were used as the β-folded peptide spacers. The acid **49** was converted into its acid chloride, which reacted with D-proline to yield compound **51**.



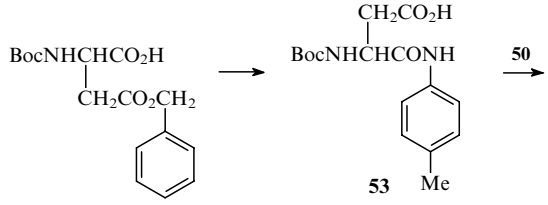
51

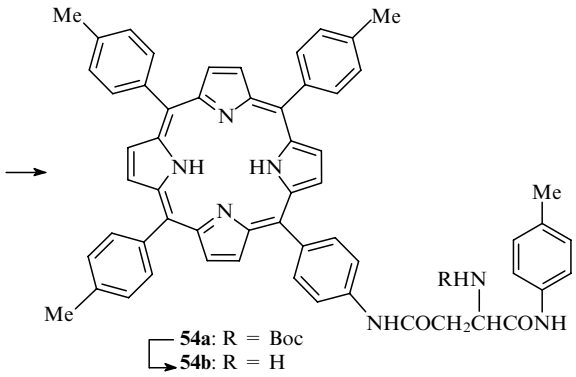
The reaction of the amine **50** with *tert*-butoxycarbonylglycine (Boc-Gly) using dicyclohexylcarbodiimide (DCC) as a coupling reagent resulted in the derivative **52a**. The last step included condensation of the acid **51** with the amine **52b** under the action of DCC in the presence of 1-hydroxybenzotriazole. This reaction afforded the porphyrin dimer **43a** linked through a β-folded dipeptide (yield 76%). The bisporphyrin **43a** was easily converted into the dizinc complex **43b** by treatment with an excess of zinc acetate.[63]



51 + **52b** ⟶ **43a** ⟶ **43b**

The dimers in which both porphyrin residues are linked to aspartic acid were synthesised in the following way. First, the β-carboxy group of Boc-L-Asp(OH)-OH was selectively protected followed by protection of the α-carboxy group. Subsequent hydrolysis of benzyl ester afforded the amino acid derivative **53** with a free β-carboxy group; its reaction with the amino acid component **50** yielded the derivative **54a**. Condensation of the acid **51** with the amine **54b** (obtained in 66% yield by deprotection of compound **54a**) gave the dimer **44a**, which gave further the complex **44b** (yield 58%).

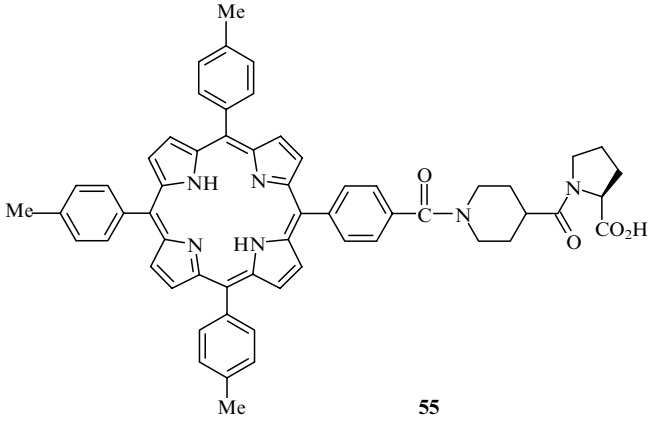




54b + **51** ⟶ **44a** ⟶ **44b**

The selectively metallated dimers **44c**,**d** were synthesised by the condensation of the zinc-containing porphyrin component with the porphyrin free base.[63]

The synthesis of the dimer **45a** included condensation of 5-(*p*-carboxyphenyl)-10,15,20-tri-*p*-tolylporphyrin (**49**) with piperidine-4-carboxylic acid, reaction of the product with D-proline to yield the amino acid derivative **55** and condensation of the latter with the zinc – porphyrin complex **54b** in the presence of DCC.[63]



55

The bisporphyrin **45b** was synthesised from the zinc complex of compound **55** and the porphyrin free base **54b** in a similar way.[63] This strategy was also used in the synthesis of the bisporphyrin donor – acceptor model systems **46a** – **i** and **47a** – **i** linked by oligoproline spacers.

Porphyrin components differing in the positions of their functional groups used in the synthesis of peptide-linked bisporphyrins made it possible to obtain *meso*-β-linked ensembles **56a** – **c**.[65,66] An interesting feature of these systems is that their spacers contain an aromatic amino acid, *viz*., phenylalanine. Incorporation of aromatic amino acids into model photosynthetic systems is an important issue, since it was found that such aromatic amino acids as tyrosine and tryptophan mediate interactions between tetrapyrrole chromophores by virtue of electronic coupling of their molecular orbitals. Substitution of aliphatic amino acids for aromatic ones enables one to establish the dependence of the strength of interchromophore interactions and the efficiencies of photoinduced processes on the nature of the amino acid components of the spacers. The bisporphyrins **56a** – **c** were synthesised from the amino acid derivatives of 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin and 2-(2-carboxy)-vinyl-5,10,15,20-tetraphenylporphyrin using the dicyclohexylcarbodiimide method.

The covalently linked mesoporphyrin dimers **57a-g** containing a lysine residue as the spacer were synthesised to study chlorophyll–protein interactions. UV-Vis and circular dichroism spectroscopic studies revealed that these dimers form complexes with polypeptides of natural light-harvesting systems owing to axial coordination of zinc and nickel atoms with histidine and the formation of hydrogen bonds between the ester groups of the dimer and the polar amino acid residues of the peptides. In the synthesis of the dimers **57a–g**, the mesoporphyrin IX monomethyl ester was condensed with Boc-L- or Boc-D-lysine using *N*-hydroxysuccinimide–DCC as the activating reagents. The product formed reacted with the second molecule of the mesoporphyrin monomethyl ester under identical conditions.[67]

b. Photochemical properties

Photochemical studies of the piperazine-2,5-dione-linked systems **41a**,**b** and **42a**,**b** revealed that the chromophores of the L,L-dimers **41a**,**b** having *p*-tolyl substituents interact more efficiently than the chromophores of the L,L-dimers **42a**,**b** with 3,5-di-*tert*-butylphenyl substituents. This difference is due to the fact that the bulkier 3,5-di-*tert*-butyl groups in the molecules **42a**,**b** disturb interactions of the porphyrin rings.

It was also found that the porphyrin components in the L,L-dimers **41a**,**b** and **42a**,**b** interact more efficiently in comparison with the D,L-dimers. This can be attributed to the localisation of both tyrosine phenylene groups in L,L-isomers on one side of the piperazine-2,5-dione plane, whereas in D,L-isomers these groups are localised on different sides of this plane. Thus the porphyrin components of the L,L-dimers are closer to each other than in the D,L-dimers. It thus follows that the strength of intramolecular interaction depends on the 'centre-to-centre' distance between the porphyrin rings.[62]

Evidence for the dependence of interactions between chromophores on the 'centre-to-centre' distance was also obtained for the dimers **43a**,**b** and **44a–d**.[63]

The efficiency of intramolecular energy transfer from zinc complexes to porphyrin free bases in the asymmetrical dimers **44c**,**d** (Φ = 86%) and **45a**,**b** (Φ = 76%) depends on the distance between tetrapyrrole components rather than on the nature of the spacer. The efficiency of quenching of the excited states of zinc-containing porphyrin complexes in compounds **46** and **47** decreases with an increase in the number of proline residues, *i.e.*, the average distance between the chromophores, in the course of energy transfer irrespective of its direction. These findings prompted a conclusion that singlet energy transfer in dimers linked by peptide spacers occurs predominantly 'through-space'.[63,64]

The dipole–dipole 'through-space' interaction described by the Förster approximation is the most probable mechanism of energy transfer from the zinc complex to the nickel-containing porphyrin in the dimer **57g**. The most efficient energy transfer was noted between the porphyrin rings that form coordination and hydrogen bonds with polypeptides of natural light-harvesting complexes. This suggests that polypeptides induce efficient intramolecular energy transfer between pigments in model photosynthetic compounds.[67]

3. Non-covalently linked bisporphyrin systems

The above-described methods for the construction of model photosynthetic systems are based on the formation of covalent bonds between chromophores, but they are not always suitable for the synthesis of muticomponent ensembles. An alternative approach consists in the assembly of supramolecular aggregates due to non-covalent interactions, such as the formation of hydrogen bonds, salt bridges and coordination bonds between metals and ligands.[17]

The strategy of synthesis of non-covalently linked ensembles consists first in the synthesis of chromophores possessing specific recognition sites and their subsequent self-assembly into highly ordered multicomponent structures. According to the type of their binding, these model systems resemble those discovered in the light-harvesting antennae.

The design of non-covalently linked supramolecular complexes can be based on pairwise interactions between complementary heterocyclic bases. The complex **58–59**, which is stabilised by hydrogen bonds between guanine and cytosine residues, was among the first ensembles of this kind described in the literature.[68]

However, high flexibility of this first-generation system prevented detailed studies of the energy transfer mechanism observed. The synthesis of the rigid dimeric porphyrin ensemble **60–61** in which the donor and the acceptor are linked directly to guanosine and cytidine residues through phenyl groups has been described.[69] The arrangement of its two porphyrin residues is such that the angle between the planes of their macrocycles is $\sim 90^\circ$ and the 'centre-to-centre' distance was estimated[69] to be ~ 22.5 Å. The porphyrin fragments can rotate by $\sim 45^\circ$ around the C–C bond linking the phenyl ring to the heterocyclic base.

The nucleoside-substituted porphyrin **60** was prepared by the Lindsey condensation of the guanosine-containing benzaldehyde **62** with benzaldehyde and 3,3′-dibutyl-4,4′-dimethyldipyrrolyl-

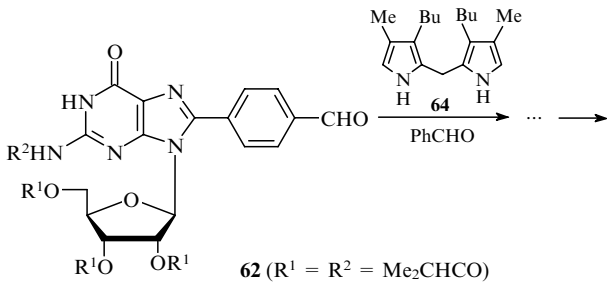
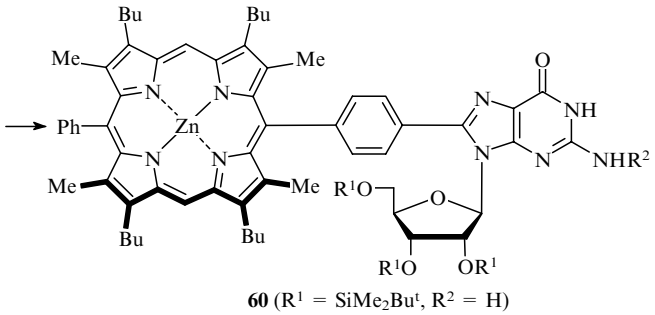
methane (**64**) with subsequent removal of the isobutyryl group, introduction of the *tert*-butyldimethylsilyl group and metallation.



62 ($R^1 = R^2 = Me_2CHCO$)

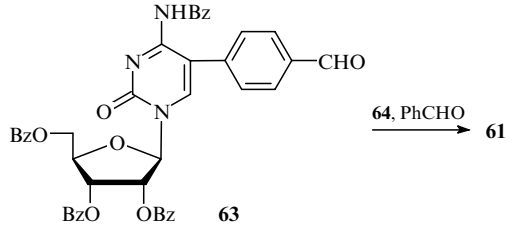


60 ($R^1 = SiMe_2Bu^t$, $R^2 = H$)

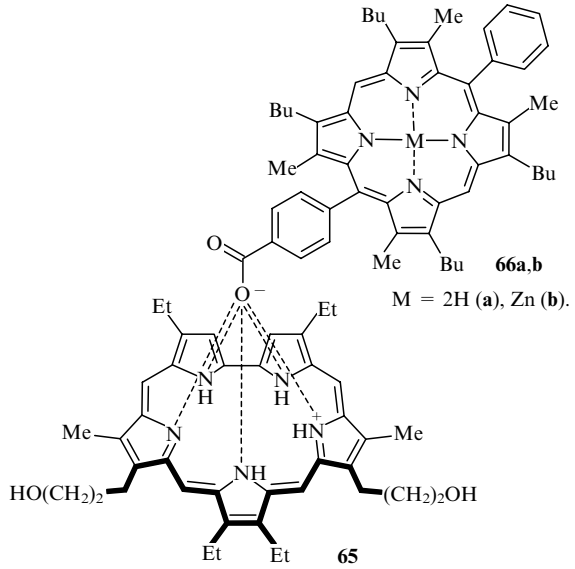
The nucleoside-substituted metal-free porphyrin **61** was synthesised in a similar way from the cytidine-containing benzaldehyde **63**.

The reaction of the cytidineporphyrin **61** with the guanosine-containing zinc complex **60** in dichloromethane results in the formation of a three-point hydrogen bond between the complementary bases. According to ^1H NMR spectroscopic data, the binding constants of the guanosine and cytidine derivatives in the ensemble **60**–**61** are equal to $22\,000 \pm 2000$ litre mol^{-1} (see Ref. 69).

The photoactive non-covalent complexes **65**–**66a** and **65**–**66b** (see Ref. 70) were assembled from carboxylate-containing porphyrins and the monoprotonated pentapyrrole chromophore sapphirine through the salt bridge formed. These systems are prepared by mixing porphyrin and sapphirine (in the form of a free acid and a free base) in dichloromethane; their binding constants determined by ^1H NMR spectroscopy are $\sim 10^3$ litre mol^{-1}. The two chromophores in these ensembles are oriented perpendicularly to each other in such a way that porphyrin is localised above the plane of sapphirine, while the 'centre-to-centre' distance between the chromophores is equal to 12.5 Å.



63 **61**



66a,**b**

M = 2H (**a**), Zn (**b**).

65

It was shown [69, 70] that the non-covalently linked bisporphyrin systems described above can be used as models in studies of photoinduced energy transfer between pigments.

The singlet–singlet energy transfer from the zinc complex to the porphyrin free base in the ensemble **60**–**61** is effected to a distance of ~ 22.5 Å and is characterised by the rate constant $k \approx 9.1 \times 10^8$ s^{-1} and 60% efficiency, which is consistent with the parameters calculated on the basis of the Förster approximation. These results suggest that dipole–dipole 'through-space' interactions are the most probable mechanism of singlet energy transfer. In this case, the role of hydrogen bonds between complementary bases is solely to bind chromophores and not to promote singlet energy transfer.

On the other hand, the triplet energy transfer in the ensemble **60**–**61,** which follows from the appearance of an absorption band at 545 nm characteristic of triplet states of metal-free porphyrins, seems to be effected through hydrogen bonds which play in this case a more active mediatory role.[69]

Irradiation of porphyrin subunits in the ensembles **65**–**66a** and **65**–**66b** induces singlet–singlet energy transfer from porphyrin to sapphirine within the complexes; this process is characterised by lower energy of the first excited singlet state. The calculated rate constants for the energy transfer in systems, which utilise metal-free bases and zinc–porphyrin complexes as donors, were equal to 4.3×10^{10} and 1.1×10^{11} s^{-1}, respectively, which is consistent with the Förster mechanism. Rapid energy transfer in the ensembles **65**–**66a** and **65**–**66b** is due to higher values of spectral overlap integrals of porphyrin emission and sapphirine absorption.[70]

The donor–acceptor ensembles described in this Section can be incorporated into more complex multicomponent systems mimicking natural light-harvesting complexes.

III. Multiporphyrin ensembles

Natural photosynthetic light-harvesting complexes contain several hundreds of pigments responsible for the migration and transfer of excitation energy to the reaction centres. Therefore, an ideal model system should include a great and strictly defined number of chromophores with known photophysical properties. The molecular organisation of such a system should allow accurate control over the mutual arrangement of pigments in the integral ensemble. This, in turn, will ensure efficient transfer of excited state energy.

Limited solubility of multiporphyrin ensembles is one of the main difficulties in their design. The approaches to the solution of this problem include incorporation of long alkyl groups into β-pyrrole positions and of alkyl, 3,5-di-*tert*-butylphenyl or *ortho*-disubstituted phenyl groups into more accessible *meso*-positions of terrapyrrole macrocycles. The porphyrins thus substituted are less susceptible to aggregation and, correspondingly, are more readily soluble in organic solvents, which facilitates the synthesis, chemical and spectroscopic analysis of the multiporphyrin ensembles based on them.[27]

Yet another problem is related to the quenching of excited states by photoinduced electron transfer which competes with the energy transfer. One of the ways to limit the energy transfer envisages the design of porphyrin ensembles with sufficiently long fixed 'centre-to-centre' distances where electronic interactions between the pigments are relatively weak.

1. Synthesis

Two promising approaches to the synthesis of multiporphyrin ensembles include building block synthesis of covalently linked systems and self-assembly of pigments possessing special recognition sites. Building block synthesis, which consists in condensation of substituted iodoaryl- and ethynylarylporphyrins under mild conditions in the presence of a palladium catalyst, was used for the preparation of linear trimers **67**[25] and **68**,[27] the linear amphiphilic ensemble **69**[34] and the star-like five-porphyrin ensemble **70**[30, 71] in which the macrocycles were linked through diarylethyne spacers.

The synthesis of a dithiaporphyrin (N_2S_2) block and its further use in the construction of the model light-harvesting system **71** have been reported.[72] The preparation of the N_2S_2-porphyrin includes the reaction of 4-(trimethylsilylethynyl)benzaldehyde (2 equiv.) with dilithiothiophene (1 equiv.), condensation of 2,5-bis[4-(trimethylsilylethynyl)phenyl(hydroxy)methyl]thiophene with pyrrole in the presence of boron trifluoride etherate and removal of trimethylsilyl protective groups. The reaction of the dithiaporphyrin formed with 5-(4-iodophenyl)-10,15,20-tris(3,5-di-*tert*-butylphenyl)porphyrin in the presence of a palladium catalyst and triphenylarsine affords the pentamer **71** in 37% yield.

As mentioned previously, one of the main tasks in photosynthetic modelling is the construction of molecular ensembles which, like natural antenna complexes, are characterised by high molar absorption coefficients in both blue and red regions of the visible spectrum and significant overlap of absorption spectra of the acceptor and emission spectra of the donor. These properties are inherent in systems containing porphyrins and phthalocyanines, which differ in their electronic characteristics. Yet another attractive feature of the combination of porphyrin and phthalocyanine chromophores within a single ensemble is that the energy of the first singlet excited state of phthalocyanine is lower than that for porphyrin.

The light-harvesting complexes **72** and **73** contain four and eight porphyrin components, respectively, which are covalently linked to phthalocyanine to form a star-like structure. The use of a phenylethyne linker between the porphyrin and phthalocyanine components makes it possible to reduce the distance and to enhance interchromophore electronic interactions in the above systems in comparison with their structural analogues, *viz*., the diphenylethyne-linked pentamers **70** and **71**.

The ensembles **72a**,**b** were synthesised in 45% and 15% yields by cyclotetramerisation of ethyne-linked porphyrin–phthalonitrile in pentan-1-ol in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene and $MgCl_2$ or $Zn(OAc)_2$, respectively. Subsequent selective demetallation and metallation reactions afforded the pentads **72c**–**e**, which contain different metals in their tetrapyrrole macrocycles.[73]

A similar approach was used for the synthesis of the ensembles **73a**–**c**. In this case, cyclotetramerisation was preceded by palladium-catalysed preparation of the porphyrin dimer containing a phthalonitrile fragment.[74]

Miller *et al*.[75] have carried out the synthesis of the linear chromophore ensemble **74**, containing perylene, bisporphyrin and phthalocyanine components, which manifests enhanced light-harvesting properties owing to strong absorption in all the visible region of the spectrum. This system can function as a cascade transferring excitation energy towards the acceptor. The ensemble **74** was synthesised in four steps: (1) synthesis of *trans*-substituted AB_2C-porphyrin building blocks, each possessing only one non-substituted *meso*-position; (2) oxidative *meso,meso*-condensation of the porphyrin monomers to yield the bisporphyrin containing the phthalonitrile and iodophenyl fragments; (3) synthesis of bisporphyrinphthalocyanine ensembles by mixed cyclisation of the bisporphyrin and 4-*tert*-butylphthalonitrile and (4) palladium-catalysed condensation of the resulting product with ethynylperylene.

X-Ray diffraction analysis of antenna complexes of photosynthesising bacteria revealed that these consist of two concentric circular ensembles of bacteriochlorophyll molecules non-covalently bound to apoproteins (see Fig. 1).[11] The planes of overlapping bacteriochlorophyll *a* molecules in the inner ring containing two thirds of all chromophores are perpendicular to the plane of the tylakoid membrane, whereas the planes of chromophores in the outer ring are almost parallel to the membrane surface. Such spatial arrangement ensures the most efficient energy transfer through dipole–dipole resonance interactions between pigments in the photosynthetic subunit.

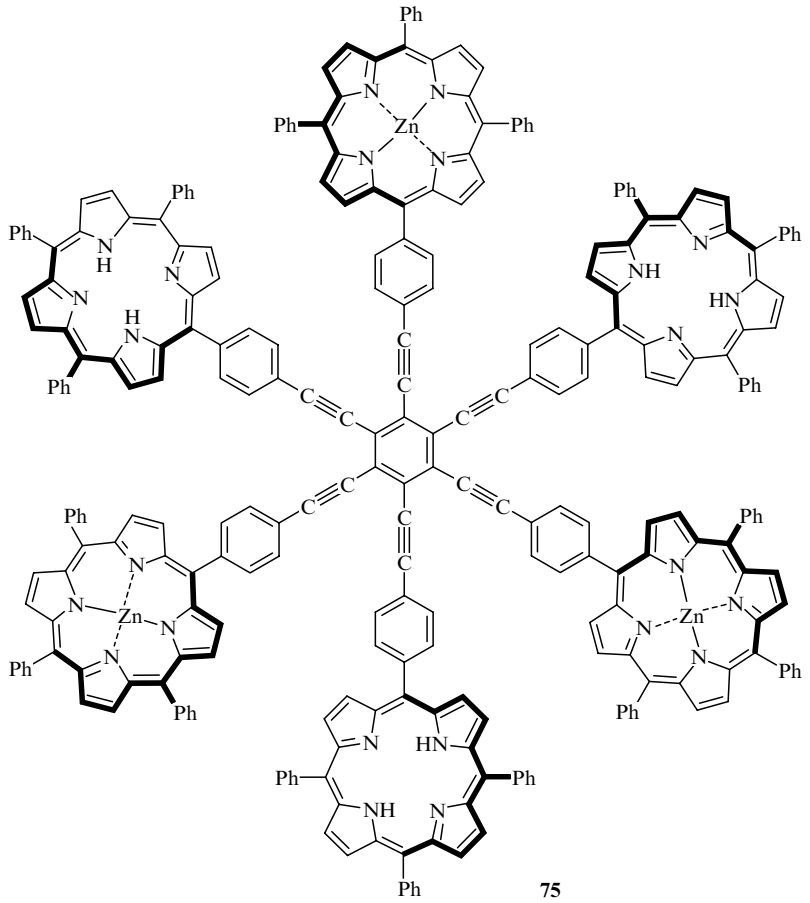
74



75

The multiporphyrin ensemble **75** was designed for simulation of spatial arrangements of chromophores in the inner rings of natural antenna complexes. In this model, six porphyrin rings are covalently linked through rigid ethynyl linkers to six positions of the benzene ring, which functionally replaces protein matrices of natural complexes. The diameter of the cyclic ensemble **75** is 46.7 Å and the 'centre-to-centre' distance between chromophores is 13.2 Å, *i.e.*, it is higher than the average distance (~9 Å) between magnesium ions of bacteriochlorophylls in natural systems.

The three-step synthesis of the hexaporphyrin ensemble **75** includes reaction of the zinc-containing complex of 5-(4-iodophenyl)-10,15,20-triphenylporphyrin with the 1,3,5-tris(trimethylsilyl) derivative of hexaethynylbenzene in the presence of a palladium catalyst under standard conditions, removal of protective groups and reaction of the star-like trimer formed with a large excess of the metal-free porphyrin. The total yield of the resulting ensemble **75** is 11%.[76]

The hexagonal cyclic ensembles **76a**,**b** have been described[77] in which the six porphyrin rings are linked rigidly through six *meta*-diethynylphenyl bridges to form a cavity with an internal diameter of ~ 46 Å. A multistep synthesis of these ensembles is based on the use of only one building block (**77**) in which two protected, reactive positions, *viz*., the ethynyl group and the carbon atom of the phenyl ring, can be activated selectively (Scheme 2). Cross-condensation of porphyrins **78a** and **79**, which are readily prepared from compound **77** by treatment with methyl iodide or sodium hydroxide, respectively, in the presence of a palladium catalyst results in the bisporphyrin **80a**. Iteration of this three-step reaction sequence yields porphyrin tetramers; their condensation with dimeric fragments and cyclisation result in the formation of the hexameric ensembles **76a**,**b**.

Eight chromophores in the system **81** are linked to the polypeptide chain, which may form a secondary α-helical structure after certain degree of oligomerisation. This conformation is determined by the natural trend of porphyrins for aggregation and is characterised by overlap of the chromophores, which ensures electronic interactions sufficient to enhance migration of excitation energy within the ensemble.

The synthesis of the octamer **81** is based on the use of the L-lysine-containing porphyrin **82**, which was prepared by condensation of carboxy and amino components in the presence of DCC and 1-hydroxybenzotriazole (HOBT) (yield 94%). The strategy of oligomer synthesis involves selective removal of protective *tert*-butoxycarbonyl and allyl groups under mild conditions (Scheme 3). Thus treatment of the porphyrinlysine **82** with a solution (1 mol litre^{-1}) of chlorotrimethylsilane and phenol in dichloromethane results in the removal of the protective Boc group (yield 91%). Removal of the allyl protection from the carboxy group of compound **82** was carried out in a dimethylacetamide–piperidine mixture in the presence of tetrakis(triphenylphosphine)palladium in 84% yield. The dimer **83** was synthesised by condensation of the amine and the acid in the presence of DCC and HOBT. Iteration of this three-step procedure affords the tetramer **84** and the octamer **81** in 86% and 80% yields, respectively.[78]

A strategy based on an ordered assembly of chromophores owing to specific non-covalent interactions, was used in the design of a model photosynthetic system **85**. This is formed as a result of pairwise interactions between complementary heterocyclic bases upon mixing of guanosine and cytidine porphyrin derivatives in dichloromethane.[69]

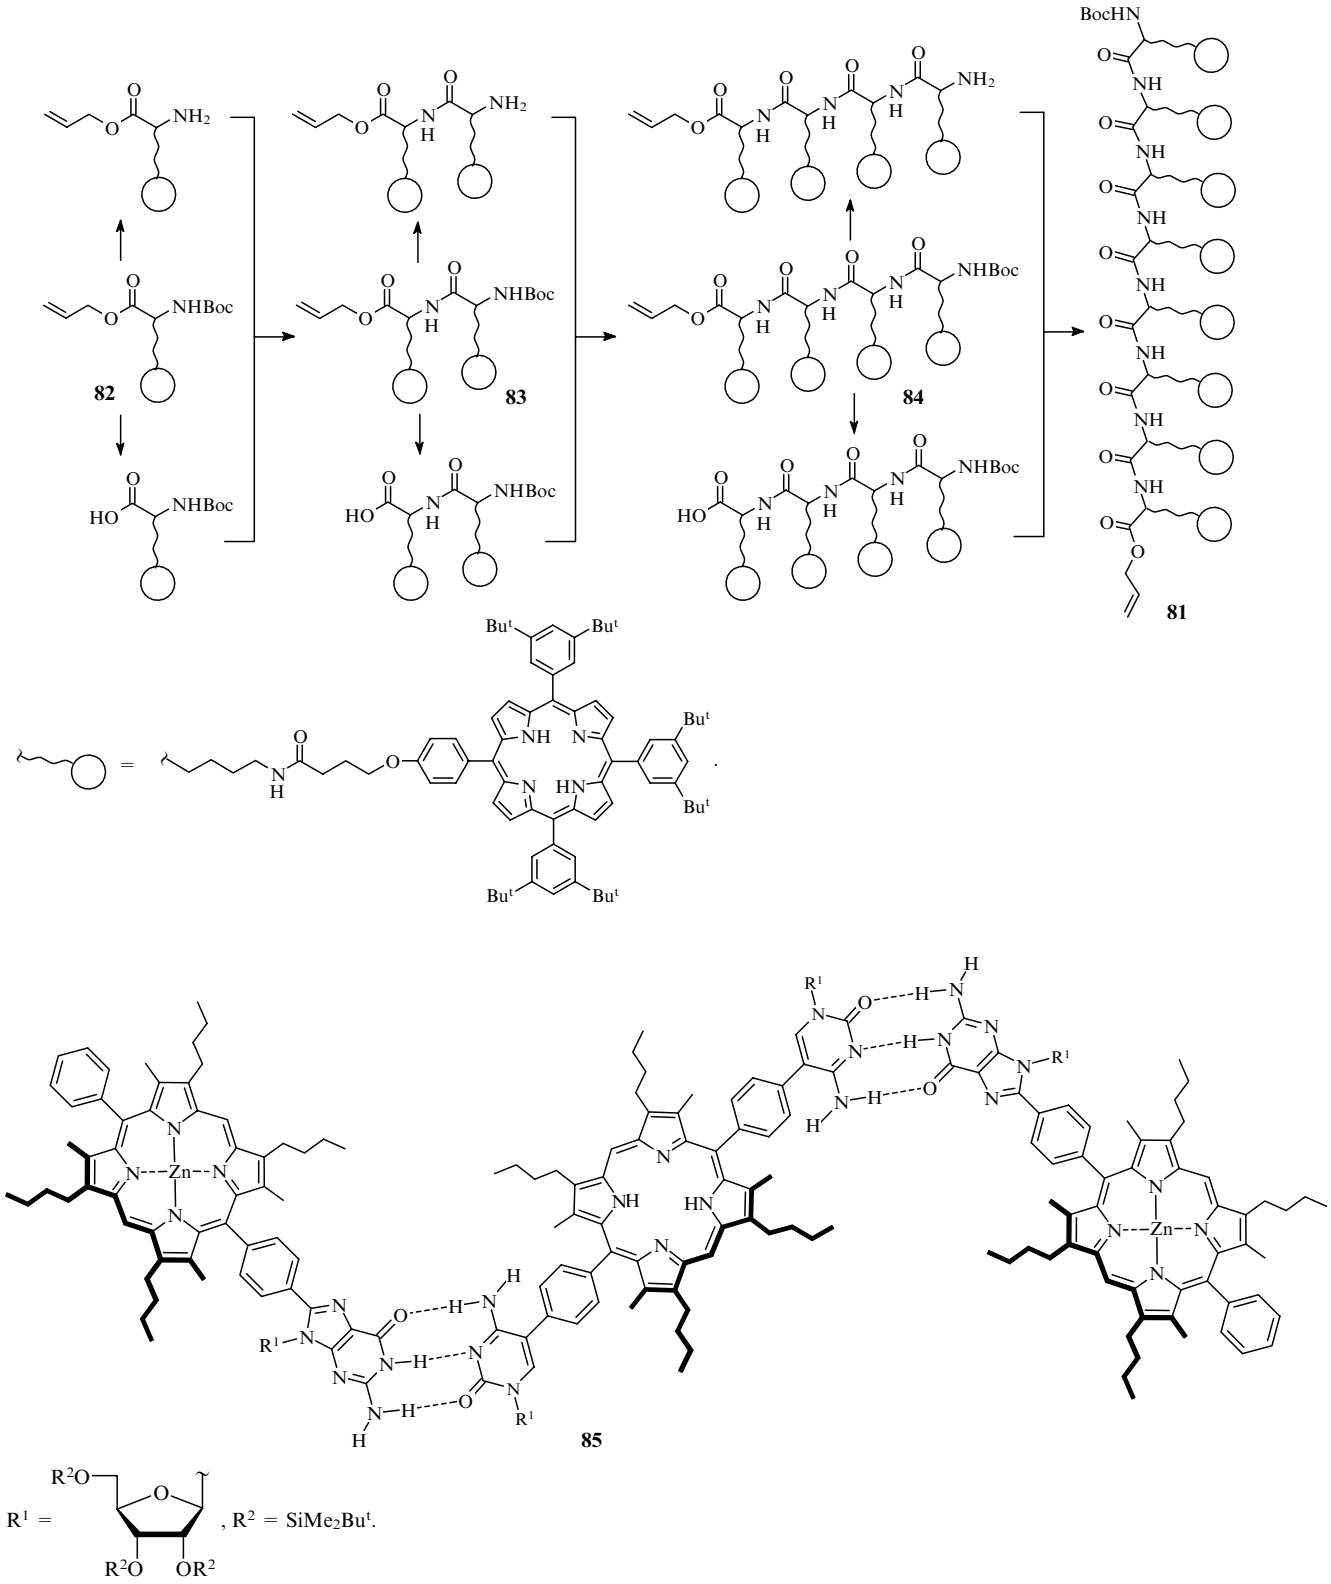
Scheme 3



2. Photochemical properties

Photochemical studies of the system **70a** have shown that the emission from the central porphyrin free base predominates in the fluorescence spectrum. The quantum yields of emission of zinc-containing complexes within the ensemble (Φ = 0.38%) were 12-fold smaller than that of the corresponding monomeric zinc-porphyrin complex. At the same time, the presence of four peripheral metal-containing porphyrin fragments virtually did not influence the emission yield of the central porphyrin free base (Φ = 12%). It was noted also that the whole fluorescence excitation spectrum coincided almost completely with the absorption spectrum. Based on these data, the yield of the energy transfer from the peripheral zinc complexes to the porphyrin free base was estimated to be equal to 90%. Thus, the pentamer **70a** can accumulate and concentrate the energy of photons in the centre of the ensemble.[71]

Similar results were obtained for the ensembles **71a**,**b** where the efficient energy transfer occurs from the peripheral porphyrin fragments to the central dithiaporphyrin subunit.[72]

The quantum yields of the energy transfer from the photoexcited porphyrin components to the central phthalocyanine in the model systems **72b**–**e** exceed 99%. However, the efficiency of energy transfer in the ensemble **72a** is decreased by 40%, which is attributed to the contribution of the charge transfer from the excited porphyrin to the ground state of phthalocyanine due to probable easier oxidation of magnesium-containing porphyrins in comparison with zinc-porphyrin complexes and free bases.[73]

An approach to the targeted transfer of energy to the terminal acceptor includes a cascade of energy transfers along the ensemble of pigments linked in succession. Studies of spectral properties of the linear molecular system **74** revealed an ultrafast ($k \geqslant 3.3 \times 10^{11}$ s^{-1}) and nearly quantitative cascade-like energy transfer from perylene to bisporphyrin and further to phthalocyanine. The directional energy transfer in this rigid structure is determined by the nature of the donor and acceptor chromophores, type of spacers and strong electronic interactions between the pigments in the bisporphyrin energy-transferring subunit. In addition, the ensemble **74** is characterised by significant overlap of absorptions of the components in the visible region of the spectrum, which determines its high light-harvesting capacity.[75]

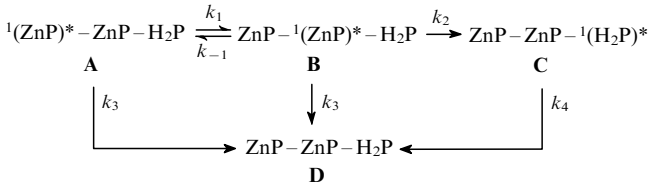
The effective transfer of singlet excitation energy from zinc-containing complexes to porphyrin free bases was observed in the ensembles **75** ($\Phi = 98\%$) and **76a** ($\Phi = 91\%$) in which the spatial configuration of the chromophores mimicks the mutual arrangement of pigments in light-harvesting complexes of natural photosynthesising organisms.[76,77] At the same time, the energy transfer from five zinc-containing chromophores to the single acceptor in the hexamer **76b** occurs with the quantum efficiency of 40%.[77] Such a significant difference is explained by the increase in the number of non-productive stages in the energy transfer between zinc-containing porphyrins in the ensemble **76b**.

In contrast with the above-described systems, the singlet energy transfer in the non-covalently linked ensemble **85** where two zinc complexes and one porphyrin free base are held at a distance of 22.5 Å from one another due to pairwise interactions between guanine and cytosine follows the Förster 'through-space' mechanism ($k \approx 9 \times 10^8$ s^{-1}) with a 60% efficiency. The quantum efficiency of the energy transfer in this system can be optimised by reducing the distance (by ~ 5 Å) between the porphyrin components.[69]

Fast migration of excitation energy between isoenergetic pigments takes place in natural light-harvesting complexes. It was of interest to determine the rate of this process. In an attempt to study the dynamics of this process and the feasibility of a reversible energy transfer, Hsiao *et al.*[51] have performed computer-assisted simulation of the photodynamic behaviour of the trimer **68** with some admissions. First, considering that absorption characteristics of two zinc-containing chromophores are identical, the authors admitted that primary excitation is distributed uniformly between these two porphyrins. Second, it was assumed that the two-photon absorption was negligible under the conditions used. Third, it was suggested that the rate of energy transfer from the terminal zinc porphyrin (ZnP) to the central one (k_1) is equal to that of the reverse process (k_{-1}). And, finally, the rate of the energy transfer between the central zinc-containing complex and the porphyrin free base (H_2P) (k_2) was taken to be equal to the rate measured for the analogous dimer **12c** (Scheme 4).

The temporal evolution of the energy transfer between the chromophores in the trimer is described by a system of differential equations which, for a fixed value of k_1 with a time interval of 0.5 ps, is solved with respect to the concentrations of singlet excited states for each of the three individual chromophores at a given moment of time. The decay curves constructed on the basis of the calculated values should correlate with the experimental monoexponential curves of absorption bleaching of the metal-free

Scheme 4



porphyrin in the ground energy state and of decay of the singlet state of zinc-containing porphyrins. The rate constant for the energy transfer between two isoenergetic zinc-containing porphyrins estimated in this way, $k_1 = k_{-1} = (2.2 \pm 0.8) \times 10^{10}$ s^{-1}, is comparable to that for the energy transfer between a zinc-containing complex and the free base.[51]

The total quantum yields of energy transfers in multicomponent porphyrin ensembles are difficult to predict, even if the efficiencies of individual steps of these processes are known. As the synthesis of such ensembles is very time and material consuming, rational design of efficient energy-transmitting molecular structures demands reliable prediction of their properties.

Van Patten *et al.*[79] have developed a general analytical technique for simulation of the kinetics of energy migration in weakly bound multipigment ensembles containing several donors but only one terminal acceptor. This approach is based on the system of differential equations which describe the temporal evolution of the energy transfer between the neighbouring chromophores. Thus in the case of the trimeric porphyrin ensemble **68**, these processes include energy migration between the donors (k_1, k_{-1}), energy transfer to the terminal acceptor (k_2), relaxation of the singlet state of the donors (k_3) and the terminal acceptor (k_4) (see Scheme 4). In this specific case, it is necessary to consider four configurations the interaction of which is described by the following system of differential equations:

$$dA/dt = (-k_1 - k_3)A + (k_{-1})B,$$

$$dB/dt = k_1 A + (-k_{-1} - k_2 - k_3)B,$$

$$dC/dt = k_2 B - k_4 C,$$

$$dD/dt = k_3 A + k_3 B + k_4 C,$$

where $A - D$ are the concentrations of states **A**–**D**, respectively.

In the general case, the energy transfer for a multiporphyrin ensemble $ZnP_{N-1}-H_2P$ can be regarded as an analogous first-order task for a series of reactions with N + 1 configurations. These equations are constructed with allowance for irreversibility of the energy transfer to the acceptor, whereas excitation energy migrates between isoenergetic donors in both directions (see Scheme 4).

By varying the initial conditions for excitation and the empirical data for the rates of energy transfer in all stages, it is possible to find solutions for the given system with respect to the concentrations of singlet excited states for each particular chromophore at a given moment of time. Their subsequent summation in time makes it possible to determine the general quantum efficiency of the energy transfer, *i.e.*, the percentage of ensembles in which the excitation reaches the terminal acceptor. This method allows prediction of the quantum efficiency depending on the rates, lifetimes of excited states and structures of ensembles.

The results of these calculations showed that the quantum efficiency of the energy transfer to the terminal acceptor in linear ensembles during random excitation of isoenergetic donor pigments with fixed rates of the energy transfer in each step decreases rapidly with an increase in the molecule length. The quantum efficiency strongly depends on the changes in the rates of the energy transfer between isoenergetic pigments. For example, the quantum efficiency of excitation capture for a linear twenty-porphyrin ensemble (the rate constant for the energy transfer between its isoenergetic pigments, k_1, is 2×10^{10} s^{-1}) is as low as 35%. However, with an increase in the transfer rate

($k_1 = 1 - 10^{12}\ s^{-1}$) the quantum yield of the energy transfer for this ensemble increases to 70%, whereas that for the linear fifty-porphyrin ensemble is 43%. Thus, the increase in the rate of the energy transfer results in a significant increase in the quantum efficiency.

The energy transfer becomes more efficient provided the migration of energy competes successfully with relaxation of the excited state. With this in mind, van Patten *et al.*[79] have studied the dependence of the efficiency of the energy migration in linear ensembles on the lifetime of the singlet excited states. A comparative study for different rates of competing deactivation has demonstrated that the quantum efficiency increases significantly with an increase in the lifetime (τ) of the excited singlet state of the donor. Calculations have shown that the quantum yields for ten-component linear ensembles containing zinc- and magnesium–porphyrin complexes as donors (τ = 2.4 and 9 ns, respectively) are 62% and 85%, respectively. Qualitatively similar results were obtained in simulation of linear ensembles where the excitation and energy capture occur at different ends of the molecule.

Since the quantum yields are determined by the competition between the energy migration and relaxation of the excited state, the efficiency of the energy transfer increases significantly in cyclic and branched ensembles with the minimum number of non-productive energy transfer steps. For example, the quantum efficiency for a tri-branched ten-component ensemble shown in Fig. 3 *c* (Φ = 91%) is similar to that for a linear tetramer, whereas that for a linear ensemble comprising nine zinc-containing porphyrins and one free base is as low as 63%.[79]

It should be noted that the quantum efficiency estimated for a cyclic porphyrin decamer with an integral acceptor (Φ = 84%, see Fig. 3 *b*) exceeds markedly the experimental value for the hexamer **76b** with an identical structure (Φ = 40%). There are several explanations for this phenomenon: (1) different sizes of the macrocyclic ensembles in theoretical and synthetic models; (2) decreased (in comparison with theoretical value) rate of intramolecular energy transfer in the synthetic ensemble where porphyrin subunits are linked through *meta*-positions of aromatic rings of the linkers; (3) predominant excitation, under the experimental conditions, of only one zinc-containing chromophore in each multiporphyrin ensemble with the resulting loss of excitation energy in the reversible energy transfer between neighbouring zinc porphyrins and (4) possible rotation of porphyrin chromophores in the synthetic hexamer.[77]

Introduction of different types of donors into model systems increases the ratio of rates of forward and reverse energy transfer processes between the donors ($k = k_1/k_{-1} > 1$), which, in turn, leads to a directed energy transfer (Fig. 4) and sharp increase in the quantum efficiency. Modelling of such cascade ensembles demonstrated that a twofold decrease in the rate of the reverse reaction (k = 2) results in an increase in the quantum efficiency which is commensurate with a 50-fold increase in the rate of direct energy transfer in the linear ensemble under conditions of random migration of the excitation energy.[79]

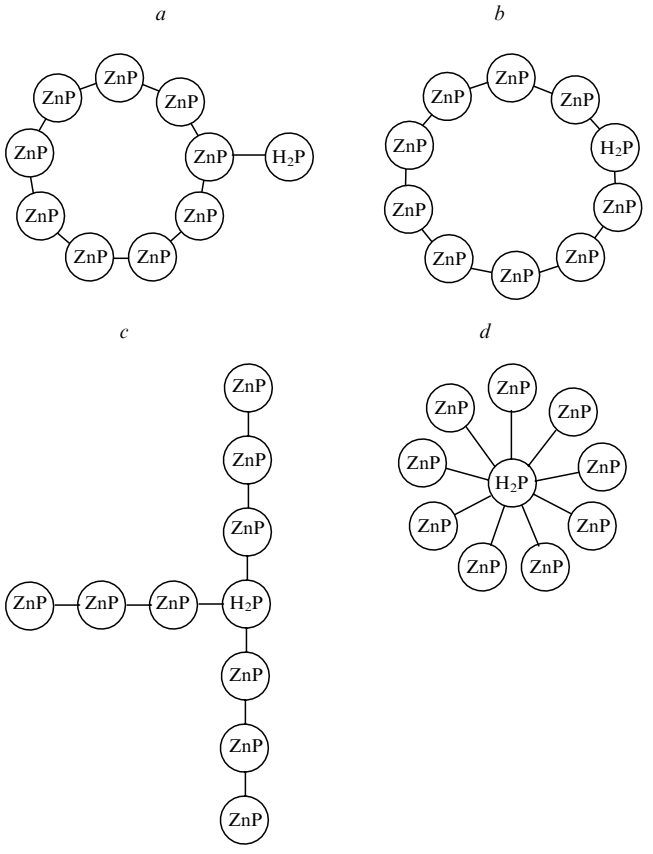


Figure 3. The effect of architecture on the quantum yields (Φ) of energy migration to a single acceptor in cyclic (*a*, *b*) and branched (*c*, *d*) ensembles containing nine donor pigments. All donor pigments have similar absorption patterns: $k_1 = k_{-1} = 2 \times 10^{10}\ s^{-1}$, $k_2 = 2.1 \times 10^{10}\ s^{-1}$, $k_3 = 4.2 \times 10^{8}\ s^{-1}$; Φ = 76% (*a*), 84% (*b*), 91% (*c*), 98% (*d*).[79]

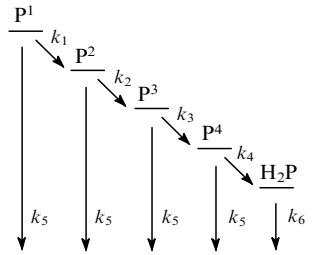

Figure 4. A five-membered cascade ensemble containing several types of donor pigments ($P^1 - P^4$) and an acceptor (H_2P).[79] (Here and in Figs 5 and 6 k_i are the rate constants of the corresponding energy transfer).

An important characteristics of light-harvesting model systems is their antenna effects, which represent products of the number of donor pigments in an ensemble with the quantum efficiency of the energy transfer. For example, the dimer **12a** and the corresponding star-like pentamer **70** have identical quantum efficiencies (98%),[51, 71] but the antenna effect of the former ensemble is 0.98, whereas that of the latter is 3.92, which points to a higher light-harvesting capacity of the pentamer.[79]

The antenna effect provides a possibility for the choice of strategies in the design of multicomponent ensembles. From the standpoint of energy capture by the acceptor, the most efficient architecture of the ensemble is the one which ensures maximum antenna effect. Thus the addition of three donors to a ten-component tri-branched ensemble (see Fig. 3 *c*), which manifests an antenna effect of 8.19 and a quantum efficiency of 91%, can be effected in two ways. Attachment of one zinc-containing porphyrin each to the ends of branches decreases the quantum efficiency to 87%, while the antenna effect increases to 10.44. An alternative route consists in direct addition of the fourth linear ensemble consisting of three zinc-containing porphyrins to a free base resulting in the formation of a symmetrical cross-shaped structure. This procedure does not influence the level of quantum efficiency, since all the four linear branches are independent structures, but enhances the antenna effect to 10.92. These calculations have shown that the appearance of a new individual route for the direct energy transfer from additional donors to the acceptor does not increase the number of non-productive energy transfers in the existing set of donors and is therefore the most efficient way to enhance the light-harvesting properties of the ensemble. Systems with star-like architecture (see Fig. 3 *d*) manifest the best light-harvesting properties, their quantum efficiencies are comparable with those of the corresponding dimer and the

antenna effect depends linearly on the number of the attached donors.

The results of theoretical modelling pave the way to the synthesis of multicomponent ensembles with anticipated high efficiency of the overall energy transfer process.[79]

IV. Porphyrin – carotenoid compounds

Carotenoids (Car) are present in the composition of antenna complexes and reaction centres of natural photosynthetic systems. They function as light-harvesting pigments by absorbing light in the spectral regions where the extinction coefficients of chlorophylls (Chl) and bacteriochlorophylls (BChl) are low and by supplying the excitation energy to these pigments through a fast singlet – singlet transfer.[12, 80–82]

$$Car + h\nu \longrightarrow {}^1Car^*,$$

$${}^1Car^* + Chl\ (BChl) \longrightarrow Car + {}^1Chl^*,$$

$${}^1Chl^* \longrightarrow Chl + h\nu\ (\text{fluorescence}).$$

Contrariwise, in the case of high light intensity carotenoids dissipate excesse energy through singlet energy transfer from chlorophyll to the carotenoid and thus control the intensity of singlet energy flow to photosynthetic reaction centres.[83]

In addition, carotenoids fulfil the photoprotective function. Upon irradiation of photosynthetic complexes with high-intensity light, primary electron donors (special pairs) obtain excitation energy from antenna systems and effect primary electron transfer prior to regeneration of the quinone component of the electron transport chain. Under these conditions, the primary charge-separated state, which involves the radical cation of the special pair and the radical anion of bacteriopheophytin (BPh), is not subject to ordinary conversions and undergoes recombination with the formation of the triplet state of the special pair. Triplet states of chlorophylls are usually long-living and are highly energetic. They can also react with other compounds, particularly, with molecular oxygen to generate singlet oxygen. Sensitisation of singlet oxygen represents an energy transfer from the triplet state of chlorophyll to the ground state of oxygen according to an electron-exchange mechanism.

$$BChl \xrightarrow{h\nu} {}^1BChl^*,$$

$${}^1BChl^* + BPh \longrightarrow BChl^{+\bullet} + BPh^{-\bullet},$$

$$BChl^{+\bullet} + BPh^{-\bullet} \longrightarrow {}^3BChl^* + BPh,$$

$${}^3BChl^* + O_2 \longrightarrow BChl + {}^1O_2^*.$$

Singlet oxygen is known to be extremely reactive and causes the destruction of plant tissues.

Carotenoid polyenes prevent the deleterious effects of singlet oxygen by quenching the triplet states of chlorophylls and bacteriochlorophylls prior to their reaction with oxygen. This represents a triplet – triplet energy transfer and results in the formation of a low-lying triplet state of a carotenoid, which is harmless for plant tissues.

Studies of the temperature dependences of the decay rate of the triplet state of the primary donor and the quantum yield of the triplet carotenoid have led to the discovery of a transient excited state which was attributed to the triplet state of the monomeric bacteriochlorophyll localised on the inactive side of the reaction centre. Thus, the triplet energy is transferred from the special pair to the neighbouring bacteriochlorophyll in a thermally activated step; the triplet state of bacteriochlorophyll generated in this process is rapidly quenched by the carotenoid.[84]

$${}^3(BChl_2)^* + BChl + Q \longrightarrow BChl_2 + {}^3BChl^*,$$

$${}^3BChl^* + Car \longrightarrow BChl + {}^3Car^*,$$

$${}^3Car^* \longrightarrow Car + Q,$$

where Q is heat.

Carotenoids behave also as photoprotectors by directly quenching singlet oxygen.[84, 85]

$$Car + {}^1O_2^* \longrightarrow {}^3Car^* + {}^3O_2,$$

$${}^3Car^* \longrightarrow Car + Q.$$

Biomimetic model compounds containing porphyrin or chlorophyll derivatives covalently linked to carotenoid polyenes have been developed for the study of photochemical characteristics of carotenoids, particularly, their photoprotective and antenna functions.

1. Synthesis

The carotenoid – tetraarylporphyrin dyads **86a**,**b** linked by the ester bond, were described in 1980. With these compounds it was shown for the first time that the efficient intramolecular singlet – singlet energy transfer from carotenoids to porphyrins requires that strict conformational demands be met.[86, 87] The models **86c** – **f** were subsequently prepared for the study of singlet – singlet and triplet – triplet energy transfer between carotenoids and porphyrins.[2, 85]

R^2 = NHCOX (**d**); X = 
The synthesis and investigation into photodynamic behaviour of the dyads **87a** – **k** and **88a** – **k** in which the carotenoid and the porphyrin are linked through aromatic groups have been reported.[88] Owing to steric repulsion between the *meso*-aryl rings and methyl groups in the adjacent β-pyrrole positions, the aromatic bridge occupies an almost perpendicular position relative to the porphyrin plane and the 'centre-to-centre' distances between the pigments in the majority of models are fixed. These conformational restrictions permit one to establish the dependences of the rates of dynamic processes of the photoexcited state on geometric parameters of the molecules. Yet another essential feature of these models is conjugation of carotenoid and porphyrin π-electronic systems in the systems **87a** – **g** and **88a** – **g** containing phenylene, naphthylene and biphenylene spacers, which help realisation of considerable 'through-bond' electronic interactions between the chromophores.

The dyads **87a** – **k** were prepared by trichloroacetic acid-catalysed condensation of the carotenoid-substituted aromatic aldehydes **89a** – **k**, which in turn were synthesised by the Wittig reaction from the corresponding arylphosphonium salt and β-apo-8′-carotenal, with 4-methoxycarbonylbenzaldehyde (**90**) and dipyrrolylmethane **6** (Scheme 5). Despite the lability of the carotenoids in acidic media, this method afforded carotenoid-linked porphyrins in quite acceptable yields. Metallation of

compounds **87a–k** by zinc acetate results in the model systems **88a–k**.[88]

The carotenoid–pyropheophorbide dyads **91–95** (see Refs 89–91) were prepared to study the interactions of the carotenoid and chlorophyll in the excited state. The natural carotenoids fucoxanthin and zeaxanthin used in these model studies fulfil different functions in the photosynthetic apparatus. It was found that fucoxanthin transfers energy to chlorophyll *a* in natural systems with high efficiency, whereas zeaxanthin, which is a member of the xanthophyll cycle, quenches excess energy during intense illumination. Studies of electronic interactions of these carotenoids with chlorin-type pigments are important for gaining insight into the mechanisms of photochemical processes underlying biological functions of natural carotenoids. The use of different pyropheophorbide components allows one to vary the energy levels of their S_1 states and the extent of 'through-bond' electronic interactions between the two pigments.

The dyads **91–95** were prepared by the reaction of chlorophyll *a* derivatives with fucoxanthin and zeaxanthin in the presence of 4-dimethylaminopyridine using 2-chloro-1-methylpyridinium iodide as a condensing reagent. These reactions occurred with acceptable yields (15%–30%) without formation of side products and *cis–trans*-isomerisation of the carotenoid component. According to ^{1}H NMR spectroscopic data, these dyad molecules have extended conformations in solution.

2. Singlet–singlet energy transfer

Despite the large number of publications devoted to the studies of light-harvesting function of carotenoids in photosynthesising organisms, the detailed mechanism of the transfer of solar energy to chlorophylls is still obscure. Among a variety of factors hampering the understanding of singlet–singlet energy transfer mechanisms mediated by carotenoids, special mention should be made of the following: (1) experimental problems connected with determination of energy levels of the lowest excited singlet states of carotenoids; (2) fast time scale of the energy transfer; (3) difficulties in estimation of the energy transfer rate constants for individual chromophore pairs within multicomponent ensembles; (4) lack of detailed information about the structures of light-harvesting antenna complexes.

A characteristic feature of carotenoids is the presence of two low-lying singlet excited states. Intense colour of carotenoids, *e.g.*, β-carotene, is due to a strictly allowed electric dipole transition to the second excited singlet state S_2. The radiative rate constant for

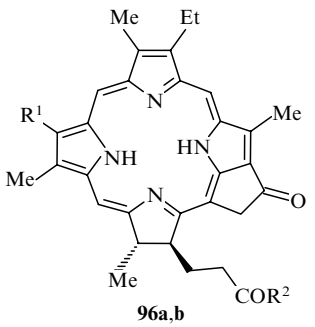
this state is rather high, but its lifetime is ~ 200 fs and, correspondingly, the quantum yield of fluorescence is very low. The first excited singlet state S_1 is characterised by a longer lifetime (~ 10 ps), but is strictly forbidden and is seldom detected in ordinary absorption spectra. The radiative rate constant for this state and quantum yield of fluorescence are usually very low.[80] As a consequence, spatial requirements for effective singlet–singlet energy transfer from carotenoids to chlorophylls or porphyrins are very strict, which imposes strong limitations on molecular structures of artificial photosynthetic systems.

The very first studies of energy transfer in porphyrin–carotenoid compounds revealed that sreric factors influence strongly the efficiency of this process. Thus the carotenoid unsaturated chain in the dyad **86a**, which contains tetraarylporphyrin linked to the carotenoid through the *para*-position of the *meso*-aryl ring, is removed from the tetrapyrrole macrocycle as a result of which singlet–singlet energy transfer does not take place. At the same time, the folded carotenoid chain in the *ortho*-isomer **86b** lies above the porphyrin macrocycle with an interchromophore distance of ~ 4 Å and the π-electron systems of the two chromophores are in contact with one another. In this case, the singlet–singlet energy transfer occurs with ~ 25% efficiency (see Refs 2, 86 and 87).

Singlet–singlet transfer of excitation energy from carotenoids to porphyrins can be studied by fluorescence excitation spectroscopy. In these studies, the fluorescence intensity of porphyrin depends on the excitation wavelength. If porphyrin fluorescence is induced by the light absorbed by the carotenoid, the energy transfer from the carotenoid to porphyrin follows the singlet–singlet mechanism.[2] The use of this technique has made it possible to detect this type of intramolecular energy transfer in compounds **87a**–**k**. The efficiency of this process was estimated from the ratio of excitation to absorption spectra and is equal to 9%–35% (see Ref. 88). The energy transfer from the carotenoid to pyropheophorbide in the fucoxanthin-containing compounds **91a**–**95a** occurs with the quantum efficiency of 12%–44% (see Ref. 91).

Elucidation of the mechanism of the singlet–singlet energy transfer from the carotenoid to chlorophyll in photosynthesising organisms is a topical problem in the study of the light-harvesting function of carotenoids. The existence of close orbital contact needed for the singlet–singlet energy transfer in the dyad **86b** calls into question the applicability of the Förster dipole–dipole approximation, which has been formulated for complexes where the distances between chromophores are larger than their sizes. Thus, the probability of energy transfer through electron-exchange interactions which demand orbital overlap becomes higher. In the carotenoid–porphyrin dyad **86c**, the chromophores are linked by a partially conjugated amide bond and the energy transfer yield is ~ 13%. This is rather high, especially with reference to a very short lifetime of the excited singlet state of the carotenoid. Electron-exchange interactions caused by partial overlap of π-electron systems of carotenoid and porphyrin through the amide bond appeared to play a crucial role in the energy transfer in this model system.

Similar results were obtained for the dyads **96a**,**b** in which the carotenoid is linked to the pyropheophorbide derivative. The quantum yield of the energy transfer in compound **96a** is < 5%; the lifetime of the corotenoid singlet state (16 ps) remains unchanged upon attachment of pyropheophorbide. In contrast, the lifetime of the carotenoid S_1 state in the dyad **96b** decreases to 7 ps due to energy transfer to pyropheophorbide which occurs with the quantum efficiency of ~ 50%. These results are interpreted by the fact that in the molecule **96a** saturated carbon atoms separate the π-orbitals of the two chromophores and thus prevent electron-exchange interactions required for effective singlet energy transfer. In the molecule **96b**, partial conjugation of the π-electron systems of the carotenoid and porphyrin through the amide bond ensures electron-exchange interactions; therefore, energy transfer occurs with high efficiency.[2,85]



96a,**b**

R^1 = CH=CH_2, R^2 = NHX (**a**), R^1 = CONHX, R^2 = OMe (**b**);

X = 
In the model compounds **87a**–**g**, the conjugation of the π-electron system of the carotenoid with the porphyrin macrocycle through the aryl bridge enhances electronic interactions between the chromophores. The rates of singlet–singlet intramolecular energy transfer in these dyads depend on the site of attachment of the carotenoid to the aromatic spacer. Thus comparison of the energy transfer rates in the dyads **87a**,**b** revealed that this process occurs faster in a *para*-linked structure than in the *meta*-isomer ($k = 5 \times 10^{10}$ and 3×10^{10} s^{-1}, respectively). This can be rationalised by stronger electronic interaction between chromophores in the former case due to much greater orbital density in the *para*-position. Analogously, distribution of the electron density on the molecular orbitals of spacers provides an explanation for the observed dependence of the rate of the energy transfer on the carotenoid-binding site in naphthylene- and biphenylene-bound systems. The results obtained suggest that 'through-bond' electronic interactions represent the most essential mechanism of intramolecular singlet–singlet energy transfer. This conclusion is consistent with the dipole-forbidden nature of the carotenoid S_1 state, since energy transfer involving such forbidden states can only be effective in the presence of electron-exchange interactions in the system.[88]

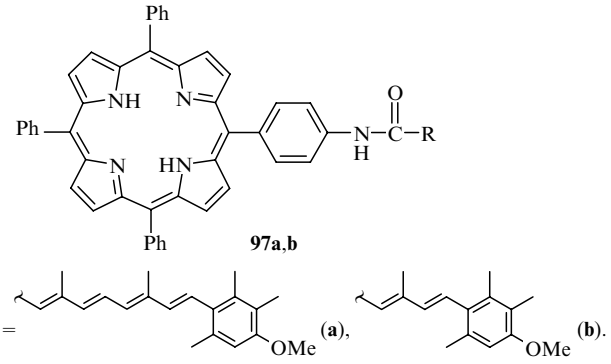
Effective orbital overlap, is possible where chromophores are in van-der-Waals contact. In the case of bound chromophores (see above), orbital overlap occurs in folded conformations, where the π-systems of the donor and the acceptor are in direct contact with one another. The orbitals of the linkers and the environment (*e.g.*, the solvent or a protein) also take part in electron-exchange interactions. Orbital contacts of non-bound pigments in solution require molecular collisions; therefore, the rates of electron-exchange interactions depend directly on the rate of diffusion. However, the lifetime of the S_1 state of carotenoids is so short (tens of picoseconds) that no collisions with the expected energy acceptors (*viz.*, porphyrins or chlorophylls) can take place. It thus follows that carotenoids are inefficient donors of the singlet state energy in non-bound systems in solution.[85]

The results illustrating the necessity of electron exchange for singlet energy transfer from carotenoid pigments are very important for the design of more complex photosynthetic model systems in which chlorophylls and carotenoids are bound to the protein. Functioning of carotenoids as antennae in the transfer of singlet excitation energy to chlorophylls requires that two protein-bound pigments were in a van-der-Waals contact with one another.

Although the predominance of electron-exchange interactions in 'through-bond' singlet energy transfer from the carotenoid to porphyrin has been confirmed experimentally, one should not rule out some contribution of dipole–dipole interactions. The two π-electron systems in the fucoxanthin–pyropheophorbide dyads **91a**–**95a** are separated by at least five saturated carbon atoms and there is no evidence of folded conformation. In this case, direct orbital overlap required for 'through-bond' electron-exchange interactions is insignificant and its contribution to the singlet–

singlet energy transfer observed is very low. However, in non-symmetrical carotenoids, such as fucoxanthin, the S_1 state can 'borrow' oscillating dipole energy from the S_2 state and thus become weakly dipole-allowed. The rate constants and the efficiencies of energy transfer in the dyads **91a**–**95a** estimated with the use of the Förster approximation are in good agreement with the experimental results. These studies suggest that dipole–dipole interactions play a crucial role in the intramolecular singlet–singlet energy transfer from fucoxanthin to pyropheophorbide in these compounds.[89, 91]

According to Sadovnikova *et al.*,[92] the energy transfer in model compounds **97a**,**b** is also described in terms of the Förster theory. The efficiency of energy transfer in these systems varies depending on the lengths of the conjugated bonds in the polyene and changes from 33% to 55% on going from compound **97b** to compound **97a**, apparently due to the increased spectral overlap integral of the donor fluorescence and the acceptor absorption in the latter case.



Elucidation of the role of two excited singlet carotenoid states in the energy transfer is yet another important problem, which attracts keen attention of investigators. An analysis of time resolved fluorescence spectra showed that the quenching time of the carotenoid S_1 state in compound **96b** (7 ps) coincides with the time of formation of the singlet state of the pyropheophorbide component.[85] A similar phenomenon was observed for the fucoxanthin-containing dyads **91a**–**95a**. Besides, the decrease in the efficiency of the energy transfer in the series **92a** > **91a** > **93a** is commensurate with the decrease in the spectral overlap between the fluorescence of the S_1 state of fucoxanthin and Q_y-absorption of pyropheophorbide.[88–90] The lifetime of the carotenoid S_2 state does not exceed several hundreds of femtoseconds and therefore cannot contribute to the energy transfer, which proceeds on a picosecond time scale. These findings point to the involvement of the carotenoid S_1 state as an energy donor in the singlet energy transfer.[80, 85, 89]

The energy transfer from the carotenoid S_2 state is also possible as was the case with the light-harvesting antenna complex B800-850 of the purple bacterium *Rhodobacter sphaeroides*; however, in this case the process proceeds on a femtosecond time scale.[80]

The S_1 state of zeaxanthin in the dyads **91b**–**95b** is energetically lower than the singlet state of pyropheophorbide and cannot therefore take part in the energy transfer to pyropheophorbide. An alternative route of the energy transfer from the singlet-excited state to pyropheophorbide is that from the S_2 state of zeaxanthin. This hypothesis is corroborated by the fact that the fluorescence spectrum from the S_2 state of zeaxanthin overlaps with the high-energy absorption Q_x-band of pyropheophorbide. The quantum yields of the energy transfer from the S_2 state of the carotenoid to the S_1 state of pyropheophorbide in compounds **91b**–**95b** do not exceed 15%. The strictly allowed nature of the $S_2 \rightarrow S_0$ transition permits the contribution of dipole–dipole interactions to this mechanism. However, the rate constants for the energy transfer estimated with the use of the Förster model correlate weakly with experimentally determined values. The Förster theory of dipole–dipole interactions assumes that the excitation is followed by oscillatory relaxation of the donor state prior to its deactivation through energy transfer. However, no complete oscillatory equilibrium can be reached in zeaxanthin-containing compounds in which the rapid energy transfer is effected from the short-lived S_2 state. Therefore, the use of the Förster model for the description of the energy transfer mechanism is not correct in this case. It should be noted, however, that the carotenoid and pyropheophorbide components of the dyads **91b**–**95b** are separated by fewer saturated carbon atoms in comparison with the components of the corresponding fucoxanthin-containing compounds **91a**–**95a**. This structural difference can favour somewhat stronger 'through-bond' electronic interactions in those cases where the energy is transferred from zeaxanthin to pyropheophorbide.[89–91]

Thus, highly efficient transfer of excitation energy from carotenoids to chlorophylls can follow several mechanisms. Their detailed study in each concrete case depends on the structures of the carotenoid and chlorophyll and their mutual arrangement in the protein environment.

Efficient singlet–singlet energy transfer is thermodynamically possible in those cases where the singlet state energy of the donor (carotenoid) exceeds that of the acceptor (chlorophyll or bacteriochlorophyll). In the case of partial degeneracy of excited singlet states of the carotenoid and chlorophyll, the overall efficiency of the energy transfer may depend on the lifetimes of their singlet states. The reduction of the lifetime of the S_1 state of chlorophyll in natural photosynthetic systems owing to the fast electron transfer to an additional acceptor, *e.g.*, accessory chlorophyll, can enhance the efficiency of the energy transfer from the carotenoid to chlorophyll. On the other hand, in the absence of additional fast photochemical processes, which quench the singlet state of chlorophyll, the efficiency of the energy transfer from the carotenoid to chlorophyll can be less than optimum.[85]

In addition to the key light-harvesting function discussed above, an opposite process, *viz.*, photochemical quenching of the first excited singlet state of porphyrin or chlorophyll by the carotenoid, was discovered in the studies of carotenoid-containing model compounds. This phenomenon is similar to energy dissipation after excessive irradiation of chlorophylls *in vivo*. A comprehensive analysis of mechanisms of quenching of porphyrin fluorescence by carotenoids will shed additional light on the ability of the latter to control the intensities of singlet energy fluxes to photosynthetic reaction centres.

Spectroscopic studies of the dyads **91b** and **94b** have demonstrated that zeaxanthin diminishes the intensity of pyropheophorbide fluorescence by 20% and 45%, respectively, and noticeably reduces the lifetime of the excited singlet state of pyropheophorbide (5.6 and 3.9 ns, respectively) in comparison with dimethyl esters of free pyropheophorbides (6.8 and 7.8 ns, respectively). This points to the existence of an additional pathway of quenching of the singlet excited state of pyropheophorbide in carotenoid-containing systems.[89] A possible explanation of this phenomenon is electron transfer from the carotenoid to the singlet excited state of pyropheophorbide with subsequent ultrafast recombination of charges.[93] An alternative mechanism of quenching of pyropheophorbide fluorescence consists in reverse singlet–singlet energy transfer from the excited S_1 state of pyropheophorbide to zeaxanthin. This route is thermodynamically allowed, since the S_1 state of zeaxanthin possesses lesser energy than that of pyropheophorbide. The ability of zeaxanthin to quench the singlet excited state of pyropheophorbide corresponds with the role played by this carotenoid in the quenching of excess energy of chlorophyll under conditions of the excess irradiation *in vivo*.[89, 90]

Similar quenching of porphyrin fluorescence by the carotenoid was observed in the dyads **87a**–**k** and **88a**–**k.** Thus the lifetime of porphyrin fluorescence in compound **87a** decreases to 850 ps, *i.e.*, becomes close to the time of formation of the carotenoid S_1 state (930 ps), which reflects the intramolecular energy transfer from the excited singlet state of porphyrin to the carotenoid. The carotenoid S_1 state generated is subjected to reversible energy transfer to porphyrin, which competes with its

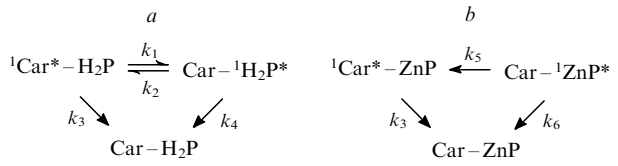


Figure 5. A scheme of singlet energy transfer in the porphyrin – carotenoid compounds **87a** – **k** (*a*) and **88a** – **k** (*b*).[88]

fast internal transition to the ground state. The singlet – singlet energy transfer between the carotenoid and the metal-free porphyrin in compounds **87a** – **k** is reversible (Fig. 5 *a*) assuming that the S_1 states of the two chromophores are nearly isoenergetic. At the same time, the unidirectional singlet – singlet energy transfer from zinc porphyrin to the carotenoid (Fig. 5 *b*) observed in systems **88a** – **k** indicates that the S_1 state of the carotenoid is energetically lower than that of the zinc – porphyrin complex.[88]

The above-described approach, which is based on the changes in positions of the S_1 energy level of porphyrin or chlorophyll induced by chemical modifications, *e.g.*, metallation, introduction of appropriate substituents and changes in the π-electron system, makes it possible to estimate the true localisation of the non-radiative S_1 state of carotenoids provided the lifetime of the singlet excited state is determined exclusively by the intramolecular energy transfer between the carotenoid and the tetrapyrrole pigment.[89]

3. Triplet – triplet energy transfer

Photoprotection of plant tissues from the destructive action of singlet oxygen is provided by quenching of triplet states of chlorophylls through the transfer of energy to carotenoids. In contrast to singlet – singlet energy transfer, triplet – triplet transfer is forbidden as regards the dipole – dipole mechanism and occurs exclusively in the presence of electron-exchange interactions, which demand orbital overlap of the donor and the acceptor.

The triplet – triplet energy transfer in porphyrin – carotenoid dyads can be studied by monitoring the quenching of transient absorption of the triplet state of porphyrin around ~ 440 nm and the concomitant increase in the carotenoid triplet absorption at ~ 550 nm.

The triplet – triplet energy transfer in the isomeric dyads **86c**,**d** in which the carotenoid is linked to porphyrin through the *para*- and *meta*-position of the *meso*-aryl group, respectively, was studied in order to determine structural and photophysical parameters of effective photoprotection. In these systems, electron-exchange interactions are mediated by π-electrons of the amide bonds. The rate constants for the triplet energy transfer in compounds **86d** and **86c** determined by laser-flash spectroscopy for solutions of these compounds in toluene were equal to 2×10^7 and 1×10^8 s^{-1}, respectively. The calculated yield of the singlet oxygen generated by the triplet state of porphyrin in the *meta*-linked dyad **86d** was 30%; singlet oxygen was not formed in the case of the *para*-isomer **86c**. These findings suggest that in the former case the carotenoid fails to entrap the bulk of the singlet oxygen sensitised by the attached porphyrin. As a result, singlet oxygen avoids direct contacts with the quencher even if the former is localised in immediate proximity to the latter. It thus follows that the triplet energy transfer from porphyrin to the carotenoid should proceed at a very fast rate in order to suppress completely the formation of singlet oxygen. Thus the triplet of the special pair of bacteriochlorophyll in the reaction centres of *Rhodobacter sphaeroides* is quenched by the energy transfer to the carotenoid with the rate constant $k > 10^8$ s^{-1}.

In the absence of conjugation between the chromophores, rapid triplet transfer takes place in a molecule with a folded conformation in which all the π-electron systems are in close contact with one another. Fast triplet – triplet energy transfer was observed in the porphyrin – carotenoid system **86b** characterised by good spatial orbital overlap of the two chromophores.[2,85]

The energy transfer from the triplet excited state of pyropheophorbide (Ppd) to the attached carotenoid was observed in model compounds **91a**,**b** and **94a**,**b**. It was found that the rates of energy transfer in these systems did not depend on the type of the carotenoid, but were determined by the flexibility of the bond linking the chromophores. In this case, 'through-bond' electron-exchange interactions are weak due to the presence of saturated carbon atoms between the π-systems of the chromophores and the orbital overlap required for such triplet transfer should be effected 'through-space'. However, according to ^{1}H NMR data the extended conformations of these dyads are the most stable where the carotenoids are spatially separated from pyropheophorbide. Folded conformations may appear exclusively in the case of intramolecular mobility of chromophores in solution. The molecular structures **91a**,**b** are little flexible. To some extent, this restricts their intramolecular movement, which would bring the π-systems of the two chromophores into close contact. Correspondingly, the rates of the triplet – triplet energy transfer in these compounds are lower than those in the more flexible molecules **94a**,**b**.[89]

The triplet – triplet energy transfer mediated by intramolecular movements was also observed in the porphyrin – carotenoid dyad **86f** containing flexible polymethylene spacer between the chromophores.[2] This dynamic process is similar to that observed between non-bound donors and acceptors upon collision in solution.

Fast quenching of the triplet state of the special pair in *Rhodobacter sphaeroides* is a two-step process, which includes a triplet energy transfer from the bacteriochlorophylls of the special pair to the auxiliary bacteriochlorophyll with its subsequent transport to the carotenoid.[84]

The photochemical properties of the molecular triads **98a**,**b** and **99**, which consist of a carotenoid covalently linked to porphyrin, which, in turn, is linked to a pyropheophorbide derivative (Car – P – Ppd) in the system **98** and the fullerene (Car – P – C_{60}) in the system **99**, were studied in order to elucidate the structural and dynamic parameters of multistep triplet energy transfer.[94,95]

The excitation of porphyrin or pyropheophorbide in compound **98a** dissolved in acetone results in the population of the first excited singlet state of pyropheophorbide, which accepts singlet energy from the excited porphyrin with ~ 100% efficiency (Fig. 6). Subsequent intersystem transition gives rise to the triplet state of pyropheophorbide (the quantum yield is ~ 1), which sensitises the formation of singlet oxygen in air ($k \approx 2.5 \times 10^9$ s^{-1}).

The quantum yield of the singlet oxygen in the triad **98a** (Φ = 36%) is much lower than that for the free pyropheophorbide (Φ = 80%), which reflects competitive quenching of the triplet state of pyropheophorbide in the triad by intramolecular energy

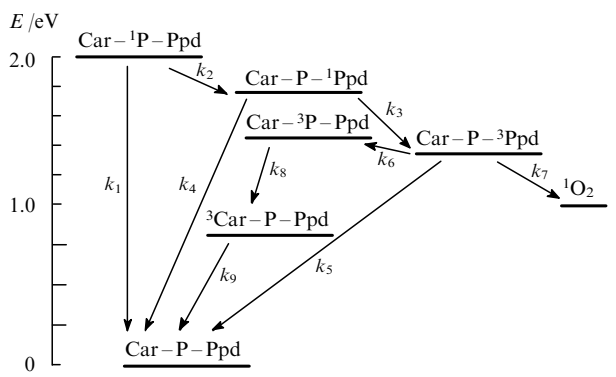

Figure 6. A scheme of energy transfer in the triad Car – P – Ppd.[94]

transfer with the formation of a carotenoid triplet state. The rate constant for this triplet transfer, k_6, is equal to 2.9×10^6 s^{-1}. The linear structure of the triad prevents the appearance of conformations where orbital interactions of the carotenoid with pyropheophorbide required for the triplet–triplet energy transfer are possible. It was suggested[94] that intramolecular triplet energy transfer in compound **98a** is a two-step process. Its first step consists in the energy transfer from the triplet state of pyropheophorbide ($\sim$ 1.33 eV) to the attached porphyrin, while the second step includes fast quenching of the porphyrin triplet state formed (1.44 eV) by the carotenoid ($k_8 > 10^8$ s^{-1}) (see Fig. 6). The rate of the overall process is determined by the endoergic step of the triplet energy transfer from pyropheophorbide to porphyrin.

The temperature dependence of the formation of the carotenoid triplet state was studied in order to gain an insight into the two-step mechanism of triplet energy transfer. No triplet absorption of the carotenoid was observed upon excitation of cooled (to 77 K) solution of compound **98a** in butyronitrile, which points to the lack of the energy transfer. Consequently, this process requires sufficient activation energy for its realisation, which correlates with the putative two-step mechanism of the triplet energy transfer with the first endoergic step.

The height of the potential barrier in such endoergic transfer can be varied by chemical modification of the system. The presence of a zinc atom in the porphyrin macrocycle of the triad **98b** increases the triplet state energy of porphyrin from 1.44 to 1.59 eV with a concomitant increase in the activation energy by 0.15 eV. In this case, the transfer of triplet energy is too slow to compete with sensitisation of singlet oxygen. As a result, the carotenoid loses its ability to afford photoprotection by quenching the triplet state of pyropheophorbide.[85,94]

The quantum yield of singlet oxygen in the triad **98b** is commensurate with that obtained for the corresponding pyropheophorbide–porphyrin dyad. Consequently, in the absence of energy transfer the proximity of the carotenoid to the site of singlet oxygen generation does not provide effective photoprotection. This clearly demonstrates that rapid quenching of the triplet state of the sensitiser is a much more efficient means of photoprotection than deactivation of singlet oxygen that has already formed.[94]

The triplet excitation energy in the fullerene-containing triad **99** is transferred from the fullerene component (Car–P–$^3C_{60}$) to the carotenoid polyene resulting in the generation of state ^{3}Car–P–C_{60}. As in the previous case, the activation energy E_a = 0.17 eV is necessary for the energy transfer, which is consistent with the two-step mechanism where the energy migrates from the excited triplet state of fullerene to porphyrin with the formation of Car–^{3}P–C_{60} in a slow thermally activated step, fast transfer of energy from the porphyrin triplet to the carotenoid culminates in the generation of the terminal state.[95]

Thus, there are several strict structural and energetic limitations for the stepwise triplet energy transfer, *viz*., electronic interactions between the donor chromophore, the intermediate porphyrin and the carotenoid should be sufficiently strong; in addition, the thermodynamic barrier to migration of the triplet energy should not be too high.

In contrast to the triplet state of chlorophyll, the excited triplet state of the carotenoid does not sensitise singlet oxygen, which is a prerequisite for photoprotection. Thermodynamic analysis of this process suggests that the energy of the lower triplet state of a potential sensitiser should exceed that of the singlet oxygen (0.98 eV) for the latter could be formed. The published data on the energy of the triplet states of carotenoids are very scarce, which can be attributed to the difficulties in the detection of phosphorescence of the carotenoid chromophore.

Moore *et al*.[85] have carried out a series of photoacoustic laser-flash experiments using the dyad **86c** as an example and calculated the energy of the lowest triplet state of the carotenoid by measuring heat energy released upon relaxation of ^{3}Car–P into the ground state in solution. The triplet energy of the carotenoid determined in this way (0.64 $\pm$ 0.04 eV) is much lower than that of chlorophyll ($\sim$ 1.3 eV) and bacteriochlorophyll ($\sim$ 1 eV) in photosynthetic reaction centres. This allows directed transfer of triplet energy to the carotenoid trap, which makes the transfer fast and irreversible. Low triplet energy of carotenoids also explains the lack of sensitisation of singlet oxygen by the triplet state of the carotenoids needed for effective functioning of natural photoprotective systems.

V. Conclusion

The porphyrin-containing ensembles described in this review are convenient models for the study of photoinduced energy transfer. These data suggest that optimisation of efficiency of electronic interactions between pigments and the rates of energy transfer in these models should take into account structural characteristics altogether, such as mode and the character of substitution in macrocycles, the type of coordination metal ions, the nature and binding site of the linker, *etc*. By varying these features, it is possible to gain control over electronic and steric factors, which determine various parameters of photodynamic processes and to obtain compounds with predetermined spectral characteristics and energy levels of excited states of pigments. The data on the structure of natural light-harvesting antenna complexes combined with fundamental energy transfer theories provide a basis for the construction and fine tuning of model molecular photosynthetic systems.[2,29,35]

The use of the multistep energy transfer strategy is an efficient approach to the reproduction of natural photosynthetic processes.

The development of novel methods for the synthesis of covalently linked ensembles [27] and the principles of non-covalent self-assembly of pigments [17] has made possible the synthesis of a great variety of multicomponent structures. Preliminary reliable estimation of expected photochemical properties of each target structure allows the design of highly efficient model photosynthetic systems.[79]

The synthesis of multicomponent clusters with several isolated sets of donors which provide independent routes of energy transfer to the terminal acceptor is a promising approach to the modelling of energy transfer. Such systems possess the most efficient light-harvesting properties, although their application is limited for steric reasons. Yet another promising strategy consists in incorporation of several types of donor pigments into a single ensemble, which may lead to directed energy transfer and a sharp increase in the quantum efficiency of energy migration. The construction of such cascade ensembles has become possible owing to fine tuning of energy levels of excited states of pigments. For example, cascade ensembles may include linear compositions of porphyrin, chlorin and bacteriochlorin pigments; their longest wavelength absorption bands are shifted from 646 to 740 nm.[79]

Synthetic light-harvesting complexes reproduce only some of the structural and functional characteristics of natural objects, which opens up new possibilities for their investigation. Further approximation of artificial photosynthetic schemes to biological transmembrane energy-transducing processes is aimed at reaching a definite level of supramolecular organisation of cofactors, which is controlled by polypeptide subunits of natural photosystems. Elucidation of factors providing effective control over the rates and mechanisms of biological energy transfer occurring in the protein matrix still continues to be a central problem. Only a few synthetic models containing peptide-linked chromophores have been designed so far in order to elucidate the effects of protein components on interpigment interactions and regularities of energy transfer processes.[67, 78] However, the usefulness of this approach demands further investigations.

And, finally, it seems very tempting to use multiporphyrin ensembles in non-biological objects, such as molecular photonic and optoelectronic devices. The feasibility of incorporation of such systems into highly ordered structures, *e.g.*, liposomes, micelles, polymers and monolayers deposited onto conducting supports, significantly increases the efficiency of molecular devices due to limited intramolecular migrations of pigments. Multicomponent ensembles able to function as molecular photonic wires and optoelectronic switches have already been devised.[10, 96] Hence, the basic principles of photosynthesis can successfully be employed in the design of synthetic molecular devices. Their versatility and main characteristics are comparable to, and sometimes surpass, those of the natural systems.

Abstract. The data on the use of silica gel in organic synthesis are presented. Some specific features of cyclisation (both intra- and intermolecular) reactions, rearrangements, reduction, oxidation, condensation, formylation, hydration and dehydration, protection of functional groups, *etc*., in the presence of silica gel, are discussed. The bibliography includes 96 references.

I. Introduction

Silica gel represents a uniform, non-deformable, three-dimensional network consisting of densely packed colloidal silicon oxide particles.[1] It contains substantial amounts of water which is retained tenaciously in the gel network even after drying, which points to the presence of hydrates or silicic acids.

Owing to its highly developed surface (5 – 800 $m^2\ g^{-1}$) and high porosity, silica gel is generally used as a sorbent for dehydration of gases and fluids, chromatographic separation of organic compounds, as a catalyst support, an enhancer of thixotropic properties of fluids, *etc*. Various chemical applications of silica gel have been described in the monograph of Vail.[2]

In addition, silica gel plays an important role in fine organic synthesis. Chemical reactions catalysed by silica gel usually proceed under mild conditions and with high chemo-, regio- and stereoselectivities and involve operationally more simple procedures for the isolation of final products in comparison with the corresponding homogeneous reactions.

A vast number of papers published over the past 20 years have been devoted to the use of silica gel in organic synthesis (see, *e.g*., Ref. 3), and their number is steadily increasing. This review is an attempt to generalise the published data. The overwhelming majority of studies in this area were aimed at obtaining maximum yields of target products rather than at elucidating mechanisms underlying catalytic (or any other) effects of silica gel in these reactions.

Although this review does not give an exhaustive account of reactions on silica gel, it sheds more light on its usefulness for organic synthesis.

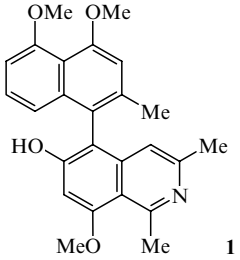
II. Cyclisation reactions

Most of the studies published over the past 20 years and devoted to various applications of silica gel in organic synthesis provide a description of various cyclisation reactions. This can be explained by the fact that these reactions have found wide application in the synthesis of diverse physiologically active compounds, particularly, of alkaloids.

1. Intramolecular cyclisation reactions

A simple procedure for the synthesis of isoquinoline and naphthalene fragments of an unusual alkaloid, *viz*., ancistrocladein (**1**), has been proposed by Bringmann.[4]

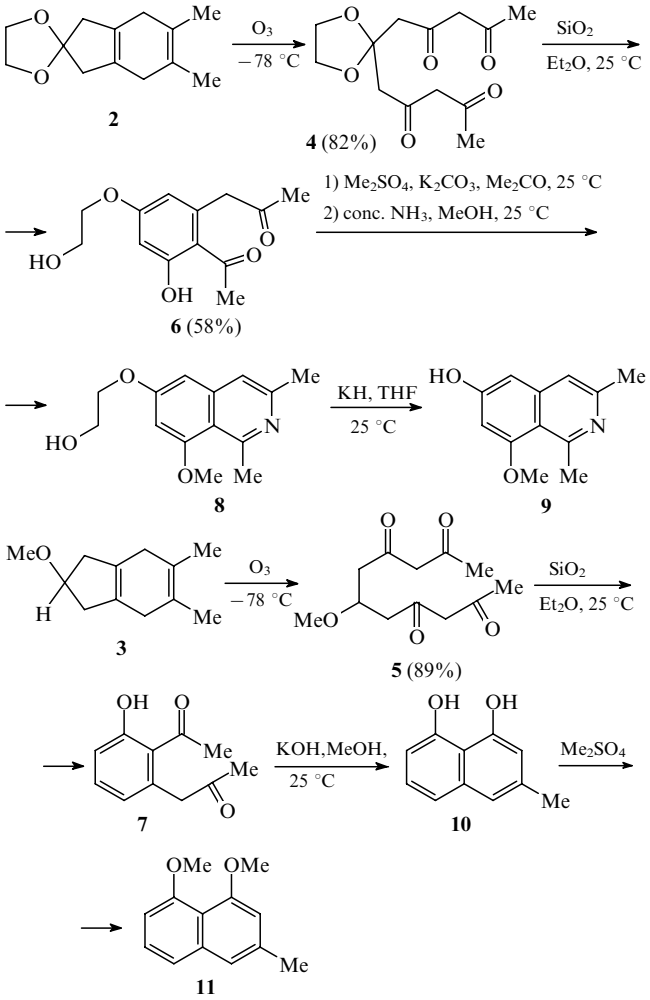


1

This synthesis employed the indan derivatives **2** and **3** as the starting compounds. They were converted into the corresponding polyketones **4** and **5** by mild ozonolysis (in the absence of oxygen) followed by cyclisation into the phenolic derivatives **6** and **7** in the presence of silica gel.†

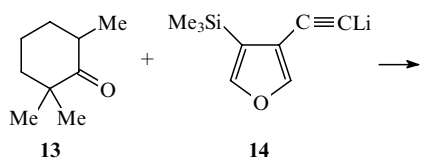
† The possibility of cyclisation of polyketone **4** under the action of bases was postulated long ago by Birch *et al*.,[5] however, the reaction products have not been studied.

The conversion of phenol **6** into the isoquinoline derivative **8** was carried out by consecutive methylation by dimethyl sulfate and cyclisation by concentrated ammonia in methanol. Selective removal of the 2-hydroxyethyl group afforded 6-hydroxy-8-methoxy-3-methylisoquinoline (**9**). In turn, treatment of the phenol **7** with a base resulted in 1,8-dihydroxy-3-methylnaphthalene (**10**);‡ its methylation by dimethyl sulfate gave the dimethoxy derivative **11**. Further reaction of isoquinoline **9** with naphthalene **11** resulted in ancistrocladein **1**.

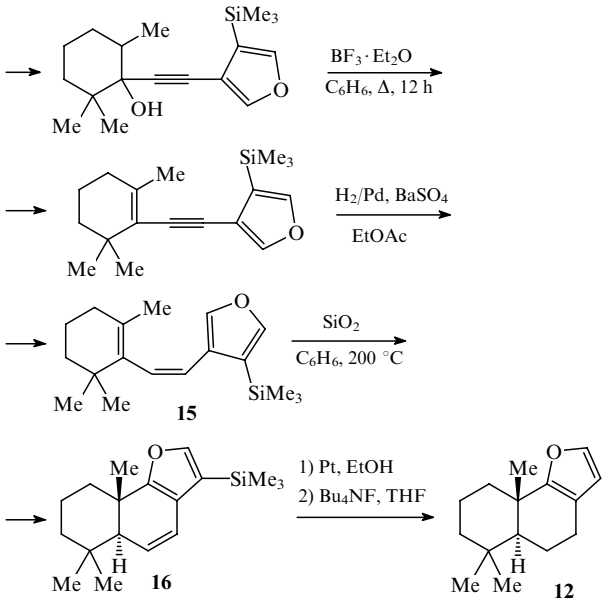


2 **4** (82%) **6** (58%) **8** **9** **3** **5** (89%) **7** **10** **11**

The use of silica gel in the synthesis of the sesquiterpene pallescensin A (**12**) has been described.[6] Trimethylcyclohexanone **13** and furylacetylenide **14** were used as the starting compounds. The addition of acetylenide **14** to cyclohexanone **13** and subsequent dehydration of the reaction product followed by hydrogenation over Lindlar's catalyst yield the derivative **15**; its cyclisation on silica gel affords the *trans*-fused tricyclic product **16**. Selective hydrogenation and desilylation of the product **16** yield pallescensin A (**12**). It is of note that hydrogenation is accompanied by partial reduction of the furan ring.



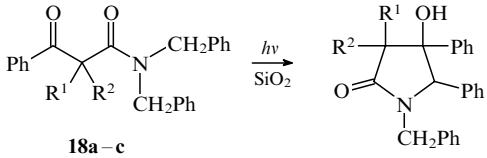
13 **14**



15 **16** **12**

In this reaction, silica gel not only facilitated the cyclisation of the furyl derivative **15** but also ensured control over the stereochemistry of ring fusion, which made this procedure attractive on the whole.

The synthesis of five-membered lactams **17a**–**c** by photocyclisation of *N*,*N*-dibenzyl-2-benzoylcarboxamides **18a**–**c** adsorbed on silica gel has been reported.[7]



18a–**c** **17a**–**c**

Compound	R^1	R^2	Yield of **17** (%)	
			C_6H_6	SiO_2
a	H	H	80	83
b	Me	H	90	91
c	Me	Me	65	63

It is suggested that this reaction, similar to that performed in solution,[8] occurs as an intramolecular 1,3-hydrogen shift towards the carbonyl oxygen atom.

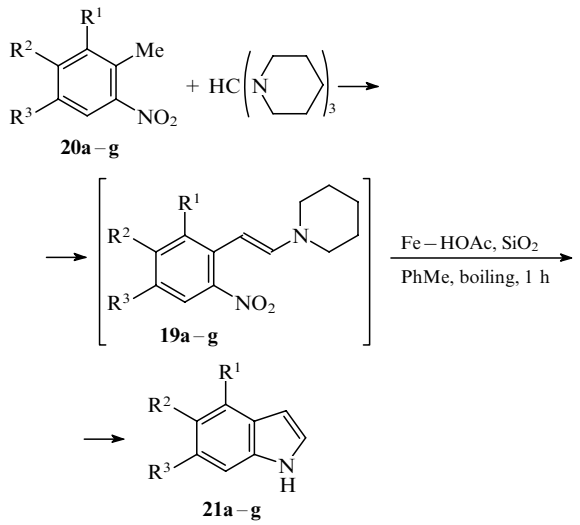
The rate of consumption of the starting β-oxo amides **18a**–**c** depends on their surface densities, *i.e.*, the amount of β-oxo amide adsorbed per g of silica gel. If solid β-oxo amides are irradiated in the absence of silica gel, the yields of lactams are low.

The use of silica gel as adsorbent in photoconversions of β-oxo amides is very effective, since it ensures uniform distribution of the latter over the whole surface of silica gel. The yields of lactams **17a**–**c** obtained by photocyclisation on silica gel are comparable to those obtained in solutions.[9]

Reductive cyclisation on silica gel of a series of 2-nitro-β-piperidinostyrenes **19a**–**g** prepared§ by condensation of substituted 2-nitrotoluenes **20a**–**g** with tripiperidinomethane has been described.[10] In this study, the Fe–AcOH system was used as the reducing agent and toluene as the solvent. The yields of the reaction products, *viz.*, indoles **21a**–**g**, were 62%–94%.

‡ The derivative **10,** which is extremely sensitive to oxidation, was found in the berries *Diospyros mollis* possessing anti-helminthic activity.

§ This procedure for indole synthesis is a modification of the Leimguber–Batcho method,[11] which includes aminovinylation of 2-nitrotoluenes followed by reductive cyclisation of *trans*-β-dialkylamino-2-nitrostyrenes formed.



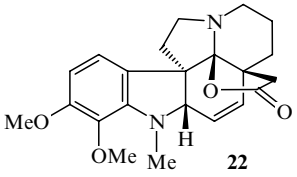
Compound	R^1	R^2	R^3	Yield of **21** (%)
a	H	H	H	82
b	F	H	H	87
c	H	H	Cl	90
d	OMe	H	H	94
e	OCH_2Ph	H	H	85
f	H	H	OMe	81
g	H	OCH_2Ph	OCH_2Ph	62

In the absence of silica gel, the yields of indoles are much lower, which can be ascribed to intramolecular reactions involving β-dialkylamino-2-nitrostyrenes.[12]

This approach was successfully employed in the synthesis of 5,6-bis(benzyloxy)-4-fluoro-, 5,6-bis(benzyloxy)-7-fluoro- and 4,7-difluoro-5,6-diphenylmethylenedioxyindoles (yields 61%, 53% and 53%, respectively); these products are intermediates in the synthesis of halogeno-substituted analogues of pharmaceutically useful neurotoxins, *viz*., 5,6- and 5,7-dihydroxytryptamines. If $TiCl_3$–$AcONH_4$ and Ni-Raney–N_2H_4 are used as reducing agents in the condensation, the yields of indoles are much lower. Thus the yields of 5,6-bis(benzyloxy)-7-fluoroindole were as low as 19% and 23%, respectively, apparently due to side reactions,[13] whereas these undesirable intramolecular reactions are suppressed in the processes carried out in non-polar solvents (*e.g*., toluene) in the presence of silica gel.

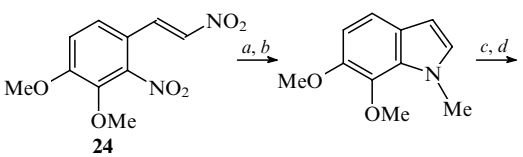
It is noteworthy that the use of silica gel together with toluene increases sharply the yields of indoles in reductive cyclisation with Fe–AcOH. Thus the yield of indole **21a** was 82%, while that obtained with the Fe–AcOH system in ethanol was as low as 17%.

The system mentioned (iron + acetic acid, toluene and SiO_2) was used by Corey *et al*.[14] in the synthesis of a substituted tryptamine, a starting compound in the synthesis of the indole alkaloid aspidophytin **22**.

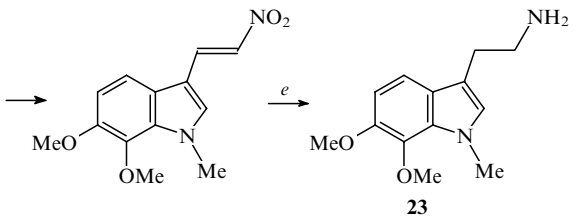


22

Dinitrostyrene **24** was used as the starting compound in the synthesis of tryptamine **23**.



24

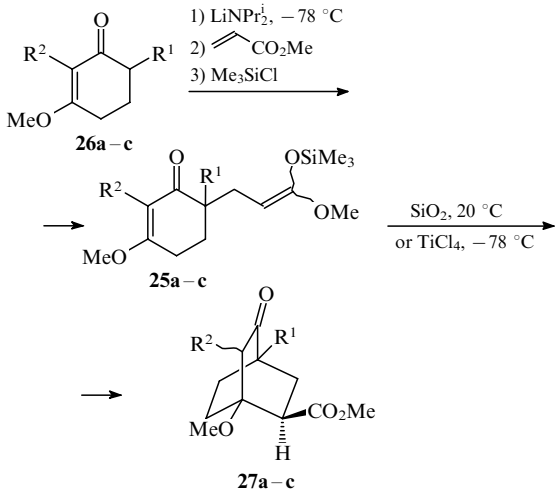


23

(*a*) Fe–HOAc, SiO_2, MePh, Δ; (*b*) MeI, KOH, Bu_4NI, THF, 23 °C; (*c*) $POCl_3$, DMF, 35 °C, 1 h, NaOH(aqueous), Δ; (*d*) $MeNO_2$, NH_2OAc, Δ, 1 h; (*e*) $LiAlH_4$, THF, Δ, 1 h.

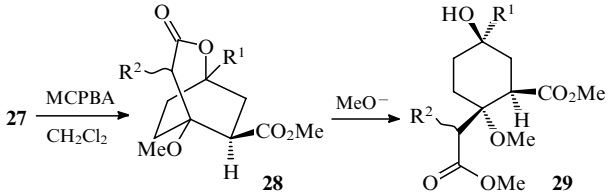
The use of silica gel for cyclisation of several ketene acetals resulting in polyfunctional bicyclo[2.2.2]octanones has been described.[15]

Ketene mixed acetals **25a**–**c** were prepared from 3-methoxycyclohex-2-enone (**26a**) and its 6-methyl- (**26b**) and 2,6-dimethyl derivatives (**26c**). To this end, cyclohexenones following treatment with lithium diisopropylamide (LDA) at low temperature reacted with methyl acrylate with subsequent silylation. In this case, the reaction of cyclohexenones with methyl acrylate was stopped in the step of formation of mixed ketene acetals **25a**–**c**; no twofold Michael addition products were detected. The cyclisation of acetals **25a**–**c** was carried out in two ways, *viz*., by passage through a short column packed with silica gel and by treatment with titanium tetrachloride at low temperature. In the former case, the reaction is stereoselective and the yields of the corresponding bicyclo[2.2.2]octanones **27a**–**c** exceed 98%. The yields of reaction products prepared by an alternative route are much lower.



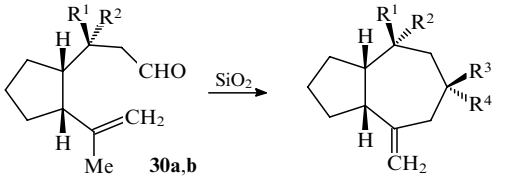
Compound	R^1	R^2	Yield of **27** (%)	
			SiO_2	$TiCl_4$
a	H	H	> 98	72
b	Me	H	> 98	83
c	Me	Me	> 98	54

Bicyclooctanones **27** present certain interest as precursors of cyclic products having several asymmetric centres. To this goal, compounds **27** are converted into lactones **28** by regioselective Baeyer–Villiger oxidation. Opening of the lactone ring affords the cyclic products **29**, which contain three asymmetric centres with defined configurations.



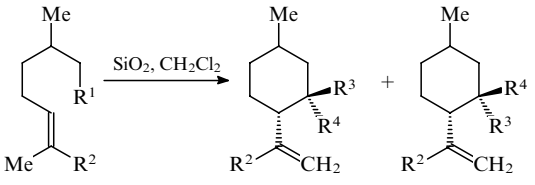
Later, Schinzer and Kalesse[16] used this method to obtain other bicyclo[2.2.2]octanone derivatives. 3-Vinyl- and 3-(*N*-methyl-*N*-tosylamino)-substituted cyclohex-2-enones were used as the starting compounds. It was found that the former derivative reacts with methyl acrylate similarly to the 3-methoxy derivative, *viz*., first, the corresponding ketene acetal is formed, which is then cyclised on silica gel into the final vinyl-substituted bicyclo[2.2.2]octanone. On the other hand, the amino derivative affords directly bicyclooctanone at −78 °C as a result of twofold Michael addition.

Acid-catalysed cyclisation of unsaturated carbonyl compounds in the presence of Lewis acids has been studied in sufficiently great detail (see, *e.g*., the review[17] and references cited therein). This approach is very attractive in the generation of a new C−C bond. However, the use of ordinary Lewis acids does not always ensure high selectivity, the reactions are accompanied by the formation of side products. The use of silica gel as a catalyst for this reaction has been recommended by Marshall *et al*.[18] Thus, silica gel catalyses efficiently the cyclisation of unsaturated aldehydes **30**.[19,20]



30a: R^1 = Me, R^2 = H, R^3 = H, R^4 = OH (from **30a**),
30b: R^1 = H, R^2 = Me, R^3 = OH, R^4 = H (from **30b**).

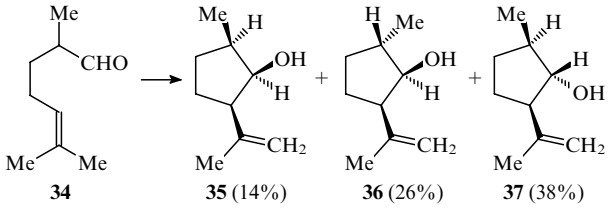
The results of studies[21] of different reagents absorbed on silica gel provide convincing evidence that silica gel always contains some amount of bound water molecules, particularly as silicic acid. It is known that high pressure increases the pK_a of acids. Although we still have no direct proof of the effect of high pressure on the acidity of silica gel, it can be assumed, with a high degree of certainty, that the acidity of silica gel will increase with pressure. According to Dauben and Hendricks,[22] oven-dried silica gel efficiently catalyses the cyclisation of various unsaturated carbonyl compounds. Acid-catalysed cyclisation on silica gel as a mild acid catalyst under a pressure of 15 kbar was used in the synthesis of six- and five-membered carbocycles.



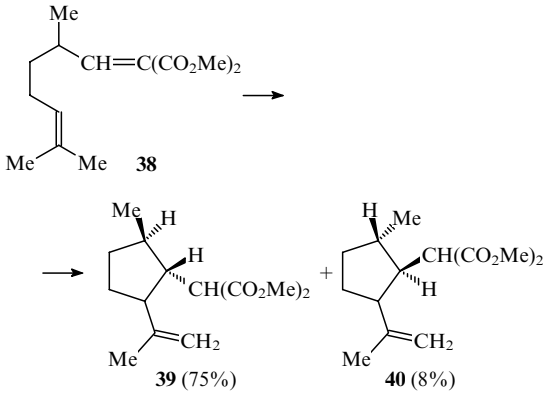
Compound	R^1	R^2	R^3	R^4	Yield (%)	
					32	**33**
a	CHO	Me	OH	H	58	15
b	CHO	H	OH	H	5	20
c	COMe	Me	OH	Me	46	20
d	CH=C$(CO_2Me)_2$	Me	CH$(CO_2Me)_2$	H	66	7

The cyclisation of unsaturated carbonyl compounds **31a**–**d** yields the six-membered stereoisomeric cyclic products **32a**–**d** and **33a**–**d**. The yields of the carbocyclic products from compounds **31a**, **31c** and **31d** on silica gel at 15 kbar are comparable to those obtained previously with Me_2AlCl[23] and $ZnBr_2$.[24,25] In the case of the aldehyde **31b**, the yields of the cyclisation products **32b** and **33b** are low (5% and 20%, respectively), whereas the yield of the product **32b** prepared with Me_2AlCl is 90%. Under normal pressure, compound **31c** is not cyclised on silica gel; compound **31a** is cyclised but the yields of the reaction products are < 10% after 7-day exposure on silica gel. No cyclisation of compounds **31a** and **31d** takes place at 15 kbar in the absence of silica gel.

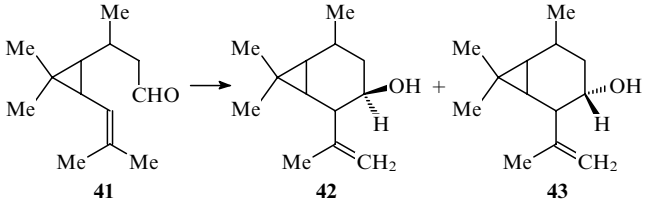
The unsaturated aldehyde **34** undergoes cyclisation on silica gel at 15 kbar to yield a mixture of five-membered cyclic products **35**–**37**. The methyl ketone homologue of the aldehyde **34** is not cyclised under these conditions.



The unsaturated ester **38** yields the cyclic derivatives **39** and **40** under identical conditions.

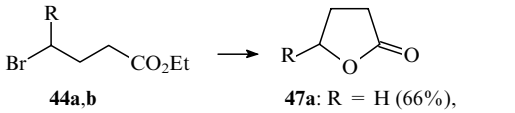


The use of silica gel in combination with a pressure of 15 kbar was also found to be helpful in the cyclisation of the labile vinylcyclopropane-containing aldehyde **41** into compounds **42** and **43**. An attempt to cyclise compound **41** under the action of zinc bromide failed, the products **42** and **43** were detected but in trace amounts.

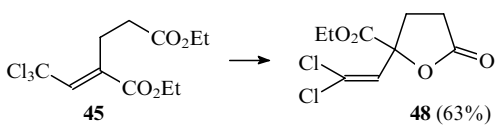


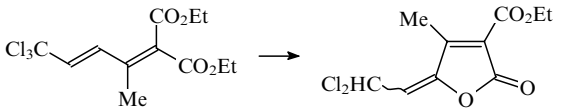
It was shown[22] that the yields and selectivities in ene-type cyclisations on silica gel at 15 kbar are comparable to those obtained by other methods (see, *e.g*., Refs 26 and 27). The conditions mentioned proved to be of choice in certain cases, as in the cyclisation of the aldehyde **41**.

Treatment of γ-halogeno-substituted esters **44a**,**b** and their vinylogues **45** and **46** with silica gel in xylene results in high yields of γ-butyrolactones **47a**,**b**, **48** and **49**, respectively.[28]



47a: R = H (66%),
47b: R = n-C_6H_{13} (79%).





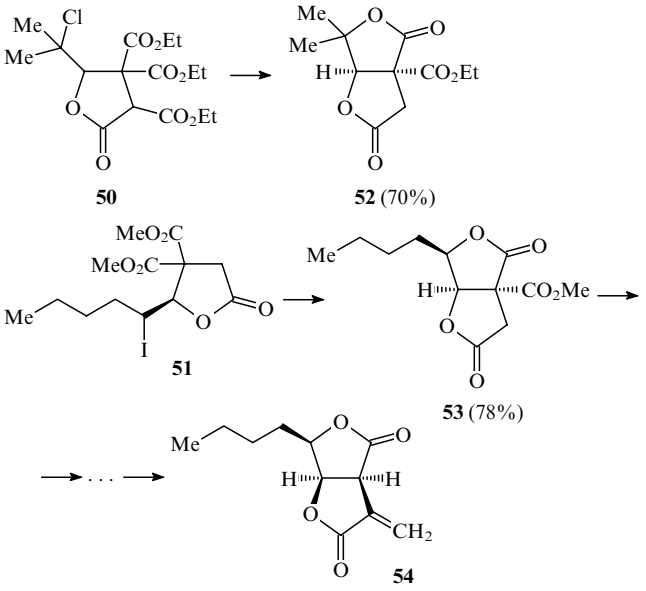
46 **49** (46%)

The silica gel used in this reaction was dried for 3 h at 200–250 °C and 20 Torr. The reactions were performed by heating the substrates with silica gel in xylene for 3–15 h.

The efficacy of silica gel was demonstrated in the conversion of ethyl 4-bromobutyrate (**44a**) as an example. Boiling of compound **44a** in xylene in the presence of SiO_2 results in γ-butyrolactone **47a** in 66% yield, whereas heating of the haloester in xylene in the absence of silica gel affords no lactonisation product.

Acid-catalysed lactonisation of γ-halogeno-substituted carboxylic acids is one of the most attractive methods for the synthesis of γ-butyrolactones. However, this is inapplicable to substrates containing easily hydrolysable functional groups. The use of silica gel not only lifts these restrictions, but also increases the yields of the target products. Previous reports describe moderate yields of γ-butyrolactones prepared upon heating of γ-halogeno esters in the absence of solvents. It is of note that the conditions for this reaction (170–180 °C) are more drastic than those used for the lactonisation on silica gel.

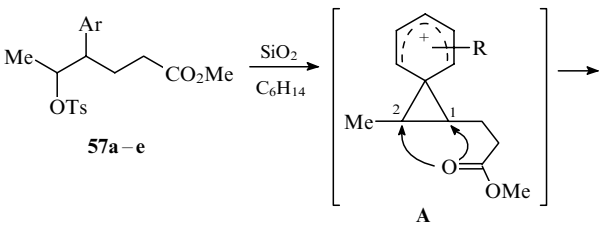
This method was also used in the synthesis of bis-γ-butyrolactones. Thus the triester **50** and the diester **51** are converted into dilactones **52** and **53** in high yields by treatment with silica gel.



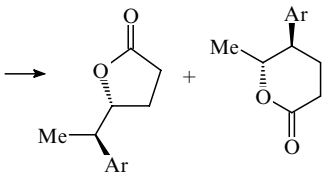
50 **52** (70%) **51** **53** (78%) **54**

Compound **53** is the key intermediate in the synthesis of (+)-canadensolide (**54**), a metabolite isolated from *Penicillium canadense*.

A novel method of the synthesis of γ- (compounds **55a–e**) and δ-lactones (compounds **56a–e**) by conversion of methyl 4-aryl-5-tosyloxyhexanoates **57a–e** in the presence of silica gel in hexane has been reported.[29]



57a–e **A**

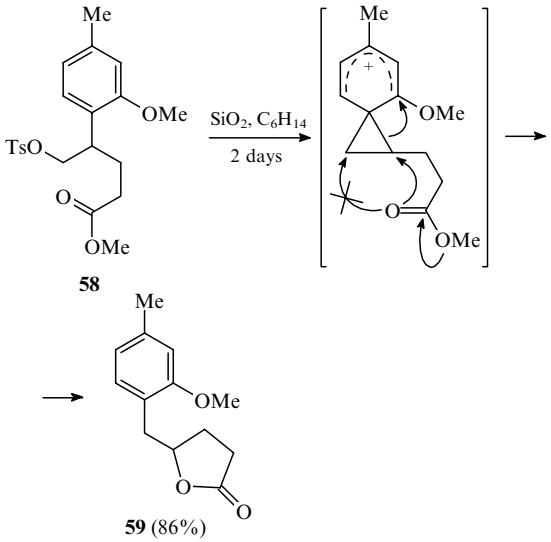


55a–e **56a–e**

Compound	Ar	Yield (%)	
		55	**56**
a	4-$MeOC_6H_4$	30	42
b	2-$MeOC_6H_4$	11	67
c	3,4-$(MeO)_2C_6H_3$	34	36
d	4-MeO-2-MeC_6H_3	7	73
e	2-MeO-4-MeC_6H_3	14	68

The structures of the resulting lactones were determined from spectroscopic data. In all cases studied, the yields of δ-lactones exceeded those of γ-lactones.

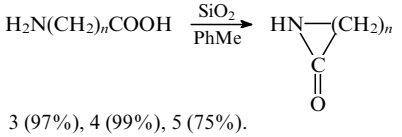
The stereochemistry of δ-lactones **56a–e** suggests that these compounds, like γ-lactones **55a–e**, are formed *via* an intermediate phenonium ion (**A**), rather than by direct substitution of the tosyloxy group by the ester group. It was concluded that the regioselectivity of the lactonisation reaction, which proceeds *via* the intermediate phenonium ion (**A**), is controlled by electronic factors. It was also found that the lactonisation of compounds **57a–e** under conditions of thermodynamic control is selective and yields γ-lactones **55a–e**, whereas that under conditions of kinetic control yields predominantly δ-lactones **56a–e**. It should be noted that methyl 4-(4-methyl-2-methoxyphenyl)-5-tosyloxypentanoate (**58**) is converted exclusively into γ-lactone **59** upon lactonisation on silica gel in hexane.



58 **59** (86%)

We believe that lactonisation on silica gel will find broad application in synthetic organic chemistry.

A simple procedure for lactam synthesis, which includes cyclodehydration of the corresponding amino acids by treatment with silica gel in boiling toluene, has been described.[30]



n = 3 (97%), 4 (99%), 5 (75%).

The corresponding lactams are formed in very high yields. This reaction proceeds smoothly on alumina as well.

An efficient procedure for the synthesis of nitrogen heterocycles, which includes cyclisation of *N*-(Δ^4- or Δ^5-alkenyl)carbamates under the action of PhSeCl in the presence of silica gel, has been developed (Table 1).[31] Presumably, this reaction proceeds in two steps, *viz*., initial rapid addition of PhSeCl in CH_2Cl_2 to the double bond of the urethane and subsequent cyclisation of the adduct formed on the surface of silica gel.

The PhSe-groups were removed by treatment of the selenides with triphenyltin hydride in boiling toluene.

It was noted that the ring closure occurs more easily in the presence of predried silica gel (Merck 60 PF-254) and the yield of the target products (the corresponding pyrrole and piperidine derivatives) is increased (Table 1). In the case of *N*-ethoxycarbonyl-2-(3-methylbut-2-enyl)aniline both 5-*exo*- and 6-*endo*-cyclisation products were obtained.[32]

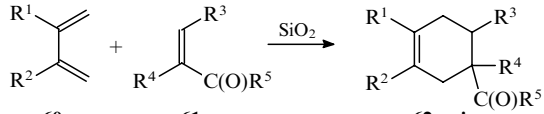
This method provides a reasonable alternative to Hg^{2+}-induced cyclisation commonly used in the synthesis of nitrogen heterocycles and a good supplement to palladium-assisted cyclisation, which affords products at a different level of hydrogenation.

Table 1. Cyclisation of urethanes.

Urethane	Product	Yield (%)	
		in solution	on SiO_2
		77	93
		73	85
	 + 	–	76
		59	82
		52	87
		–	94
		–	83
		–	84
		–	35

2. Intermolecular cycloaddition reactions

The efficiency of silica gel in intermolecular cycloaddition reactions has been described in numerous papers (see, *e.g*., reviews [3,21] and references cited therein). Here we shall consider only some of the most interesting studies devoted to [4 + 2]-cycloaddition reactions (the Diels – Alder reaction). A new methodology for [4 + 2]-cycloaddition of dienes **60** to dienophiles **61** on the surface of chromatographic adsorbents (*e.g*., SiO_2, $MgO \cdot SiO_2$, Al_2O_3) under solvent-free conditions has been described.[33,34]



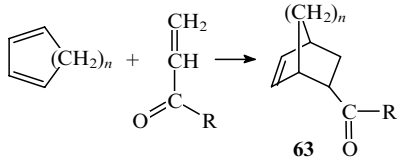
60 **61** **62a – i**

Compound	R^1	R^2	R^3	R^4	R^5	Yield of **62** (%)
a	H	H	H	H	Me	85
b	H	H	H	H	H	67
c	Me	H	H	H	Me	72
d	Me	H	H	H	H	56
e	Me	Me	H	H	Me	92
f	Me	Me	H	Me	H	89
g	Me	Me	Me	H	H	83
h	$(CH_2)_2CH=CMe_2$	H	H	H	Me	73
i	$(CH_2)_2CH=CMe_2$	H	H	H	H	66

With SiO_2, the yields of the [4 + 2]-adducts **62a – i** were 56% – 92%. Condensation of these compounds in the liquid phase in the absence of catalysts usually requires drastic conditions (120 – 160 °C, 3 – 6 h). If the reaction is carried out on SiO_2 without solvents, the temperature can be decreased considerably (*e.g*., by 50 – 100 °C). In some cases, the Diels – Alder diene products are obtained in higher yields. Presumably, the role of silica gel is to ensure polyfunctional catalysis (due to multicentre adsorption), and the absence of a solvent favours formation of pre-reaction complexes due to weak van-der-Waals interactions of adsorbed substrates devoid of shielding solvation shells. If the reaction is carried out on the surface of SiO_2 in the presence of solvents (*e.g*., C_6H_{14}, CH_2Cl_2), the efficiency of cycloaddition decreases considerably, presumably due to partial desorption of the reactants from the surface of SiO_2.

It is suggested that the activity of silica gel depends critically on the water content. The highest yields were obtained with silica gel dried at 200 °C for 6 h in order to remove physically adsorbed water. Florisil ($MgO \cdot SiO_2$, Florisil) tested in this reaction appeared to be less efficient. With $MgO \cdot SiO_2$, the reaction temperature had to be increased by 20 – 30 °C in order to make the yields of [4 + 2]-adducts comparable to those obtained with dried SiO_2.

The main advantage of this method is that cycloaddition reactions on silica gel in the absence of solvents are highly regio- and stereoselective, whereas reactions in liquid media yield mixtures of isomers. Thus the SiO_2-catalysed addition of methyl vinyl ketone and acrolein to cyclopenta- and cyclohexadienes results in the predominant formation of the *endo*-isomers **63**, whereas the liquid-phase reaction involving these substrates yields a mixture of isomers where the *exo*-isomer content is > 20%.

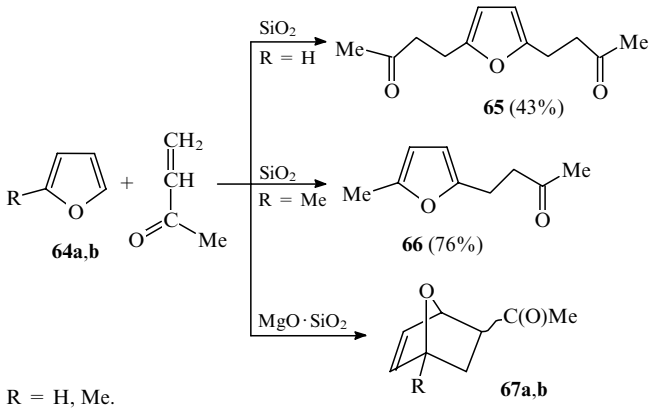


63

R = H, Me.

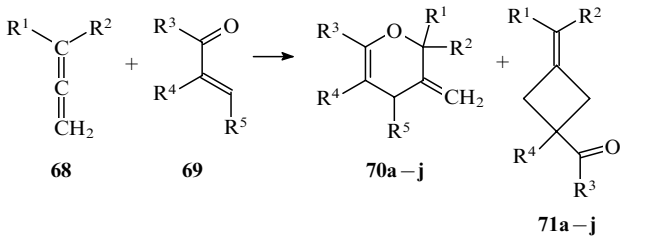
The reaction of furan (**64a**) and silvane (**64b**) with methyl vinyl ketone occurs differently under these conditions. This reaction is fast, but yields exclusively addition products, *viz*., compounds **65**

and **66**, respectively. This can be attributed to high lability of methyl vinyl ketone on such a sorbent as silica gel. At the same time, the use of florisil ($MgO \cdot SiO_2$) as a sorbent affords the expected [4 + 2]-cycloaddition products **67a**,**b**.



R = H, Me.

An illustrative example of the high efficiency of the dry-adsorption method is provided by the hetero-Diels–Alder synthesis.[35] It was found that the cycloaddition of alkoxyallenes **68** to α,β-enals and α,β-enones **69** results in the [4 + 2]-adducts **70**.



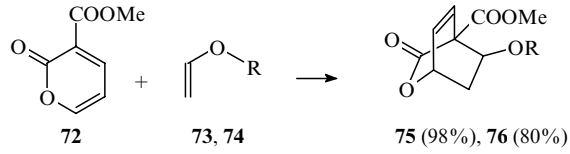
Compound	R^1	R^2	R^3	R^4	R^5	Yield of **70** + **71** (%)
a	EtO	H	H	H	H	71 (with predominance of **70**)
b	EtO	H	Me	H	H	68 (with predominance of **70**)
c	EtO	H	H	Me	H	58 (with predominance of **71**)
d	EtO	H	H	H	Me	< 5
e	MeO	Me_3Si	H	H	H	47 (**70**) + 26 (**71**)
f	MeO	Me_3Si	Me	H	H	47 (with predominance of **70**)
g	MeO	Me_3Si	H	Me	H	38 (**70**) + 43 (**71**)
h	MeO	H	H	H	H	47 (with predominance of **70**)
i	MeO	H	Me	H	H	65 (with predominance of **70**)
j	MeO	H	H	Me	H	82 (1 : 1)

In addition to the dihydropyran derivatives **70**, which represent [4 + 2]-cycloaddition products, this reaction affords a small amount of [2 + 2]-cycloaddition by-products, *viz*., the cyclobutane derivatives **71**.

The highest yields of the [4 + 2]-cycloaddition products were obtained when dried silica gel deactivated with triethylamine (0.2% – 0.5%) was used. It is of note that the acidity of ordinary silica gel is a factor which is responsible for the destruction and polymerisation of cycloaddition products. The use of more basic florisil as a medium for the hetero-Diels–Alder reaction helps avoid undesired side reactions,[34] but the reaction rate decreases. Alumina manifests no catalytic activity in this reaction.

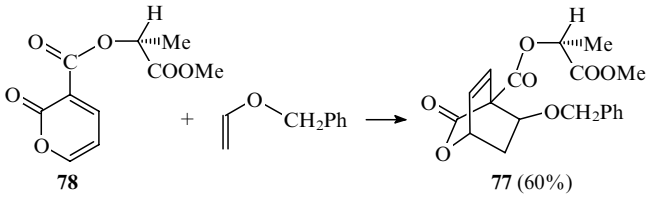
The 2-alkoxy-5-methylidene-3,4-dihydro-2*H*-pyrans **70** formed are the starting products in the synthesis of valuable derivatives of glutaraldehyde.

According to Posner *et al*.,[36] preparative [4 + 2]-cycloaddition of commercial 3-methoxycarbonyl-2-pyrone (**72**) to vinyl ethers **73** and **74** is strongly accelerated under the action of silica gel (EM Science 60) at room temperature, resulting in *endo*-bicyclic products (**75** and **76**) diastereoselectively and in extremely high yields.



R = Bu^n (**73**, **75**), $PhCH_2$ (**74**, **76**).

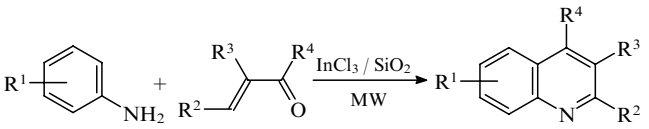
The *endo*-adducts **77** (the diastereomer ratio is ~4 : 1) are also formed upon cycloaddition of benzyl vinyl ether (**74**) to the enantiomerically pure (*R*)-methyl pyrone-3-carbonyl lactate **78**. This reaction was carried out on dried (200 °C, 16 h) silica gel (Syloid 221) in toluene.



No [4 + 2]-cycloaddition products are formed in the absence of silica gel.

The above-described silica gel-catalysed cycloaddition reactions are operationally simple, stereoselective methods for the synthesis of bicyclic lactones and represent 'atom-economical' procedures[¶] in which all the atoms of both reactants are incorporated into the final products.

Despite the immense diversity of synthetic methods used to obtain nitrogenous heterocycles, the interest of investigators in simple and convenient procedures does not fade, since nitrogenous heterocycles are constituents of many physiologically active compounds. Recently, Ranu *et al*.[37] have developed a simple and efficient method for quinoline synthesis from anilines and alkyl vinyl ketones by treatment with indium(III) chloride on silica gel under microwave irradiation without any solvent.



Compound	R^1	R^2	R^3	R^4	Yield of **79** (%)
a	H	H	H	Me	85
b	2-Me	H	H	Me	81
c	3-Me	H	H	Me	84
d	4-Me	H	H	Me	85
e	2-OMe	H	H	Me	80
f	4-OMe	H	H	Me	83
g	3-OH	H	H	Me	81
h	3-Cl	H	H	Me	87
i	4-Cl	H	H	Me	80
j	4-Br	H	H	Me	80
k	2-Me-4-I	H	H	Me	83

n	3-Cl	Me	H	*p*-$MeOC_6H_4$	83
o	H	Pr^n	Et	Me	55

¶ This term was originally suggested by B Trost.

This method allows one to obtain quinolines **79a–o** in high yields irrespective of the nature of substituents in the anilines and alkyl vinyl ketones. This reaction includes the Michael addition of aniline to vinyl ketone followed by cyclisation and aromatisation catalysed by $InCl_3/SiO_2$. When $InCl_3$ is used without silica gel, the reaction is sluggish, while imines are formed on silica gel in the absence of $InCl_3$.

The same authors have developed a convenient one-step method for the synthesis of polysubstituted pyrroles.[38] It was found that the reaction of α,β-unsaturated carbonyl compounds with amines and nitroalkenes on the surface of silica gel (HF 254) under microwave irradiation without any solvent affords various polysubstituted pyrroles **80a–p**.

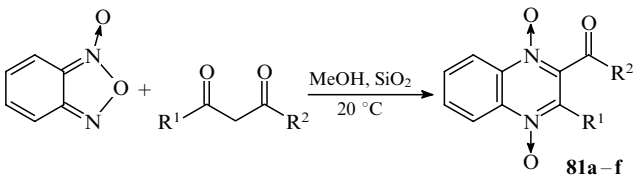
o	Ph	H	H	Bu^n	61	32
p	$-(CH_2)_4-$		Me	Bu^n	68	40

Heating of mixtures of starting compounds in the absence of silica gel results in resinification. When this reaction is carried out in solution (*e.g.*, boiling in THF), the yields of the reaction products decrease significantly, whereas the reaction time increases.

In our opinion, the one-step syntheses of quinolines and pyrroles from readily available compounds developed by Ranu *et al.*[37,38] are among the best methods presently available. To obvious advantages of these methods one can relate simple procedures, high product yields, high reaction rates and the possibility to obtain a broad array of quinolines and pyrroles.

A convenient procedure for the preparation of quinoxaline di-*N*-oxide derivatives **81a–f** from β-dicarbonyl compounds and benzofuroxan in methanol in the presence of silica gel has been proposed.[39]



81a–f

Compound	R^1	R^2	Enol content (%)	Yield of **81** (%)
a	OMe	OMe	0	0
b	Me	OMe	12.6	16
c	Ph	OEt	27	63
d	Me	Me	84	58
e	Ph	Ph	90–100	66
f	Me	Ph	94	88

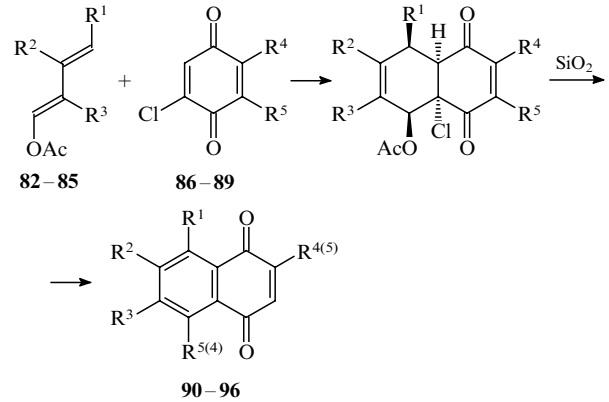
This reaction is carried out as follows. Benzofuroxan and the β-dicarbonyl compound are dissolved in methanol, the solution is mixed with silica gel and concentrated at 20 °C. The resulting mixture containing the adsorbed reagents is kept at room temperature for 1–2 weeks without drying after which the corresponding quinoxaline di-*N*-oxide is isolated. The efficacy of this reaction strongly depends on the type of silica gel used. Convenient gels are Wako gel C-200 (Wako Pure Chemical Industries) and Silica gel 60 (Merck).

It is assumed that the yields of the products **81a–f** correlate with the per cent content of the enol form of the carbonyl compound. When alumina (basic, neutral or acidic) was used instead of silica gel, the yields of quinoxaline di-*N*-oxides **81a–f** were much lower. In all cases studied, the main product appeared to be contaminated with side products.

III. Rearrangements

Many organic compounds undergo diverse molecular rearrangements under the action of acids and bases. The papers published before 1979 provide examples of interesting rearrangements of certain classes of organic compounds, such as aminopyrrolidines,[40] hydroxycyclopropanes,[41] oxazolidines[42] and aldehydes, on silica gel.[18] A great variety of interesting rearrangements induced by silica gel have been described in the review of McKillop and Young,[21] therefore we shall omit them from consideration and shall confine ourselves to a few cases only.[43–45]

Thus multiple passage of addition products of methyl-substituted 1-acetoxybuta-1,3-dienes **82–85** to chlorobenzoquinones **86–89** through a column with silica gel leads to rearrangement and concomitant aromatisation leading to naphthoquinones **90–96**.[43]



82–85 **86–89**

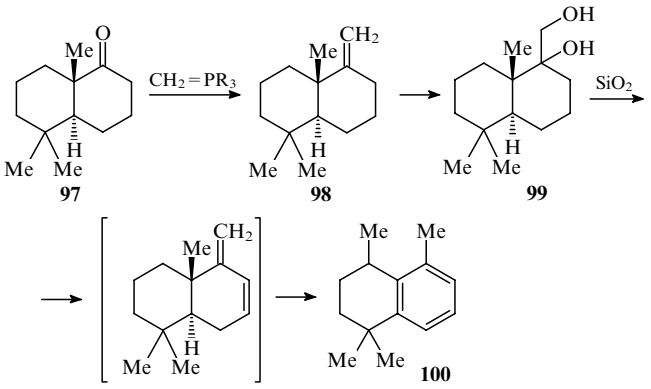
90–96

Reaction	Product	R^1	R^2	R^3	$R^{4(5)}$	$R^{5(4)}$	Yield (%)
82+**87**	**90**	H	H	H	Cl	H	92
83+**86**	**91**	H	H	Me	Cl	H	79
83+**87**	**92**	H	H	Me	(H)	(Cl)	65
84+**86**	**92**	H	Me	H	Cl	H	88
84+**87**	**91**	H	Me	H	(H)	(Cl)	80

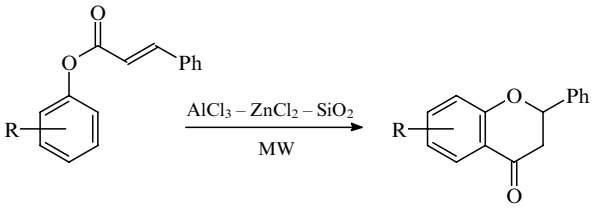
Reaction	Product	R^1	R^2	R^3	$R^{4(5)}$	$R^{5(4)}$	Yield (%)
85 + 86	**93**	Me	H	H	Cl	H	80
85 + 87	**94**	Me	H	H	(H)	Cl	90
84 + 88	**95**	H	Me	H	OMe	H	96
84 + 89	**96**	H	Me	H	(H)	(OMe)	79

This method is especially convenient for the synthesis of substituted naphthoquinones which represent fragments of many natural alkaloids.

Yet another interesting rearrangement coupled with aromatisation has recently been observed in studies of the conversion of ketone **97**.[44] This was first transformed into alkene **98** by the Wittig reaction and then into the target diol **99** by treatment with Woodward's reagent (MeCOOAg, I_2, MeCOOH, H_2O) followed by alkaline hydrolysis. An attempt to purify the diol **99** on a column with silica gel (Silica gel 60, Merck) gave unexpectedly tetralin **100** in 90% yield. Apparently, during its passage through the column diol **99** first undergoes dehydration and then rearrangement.



A simple procedure for flavanone synthesis from esters (the Fries rearrangement) has been proposed.[45] This rearrangement is effected by microwave irradiation in the presence of the catalytic system $AlCl_3 - ZnCl_2 - SiO_2$.



IV. Reduction

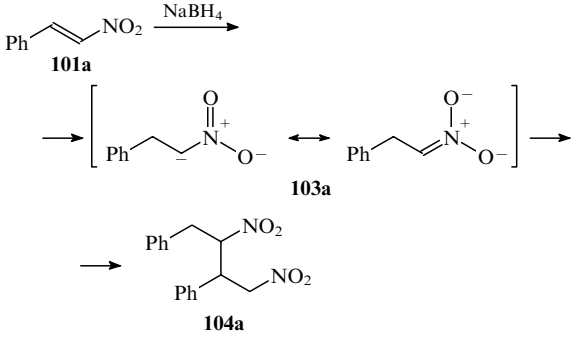
Reduction of nitrostyrenes **101a – e** to nitroethylbenzenes **102a – e** was carried out by treatment with sodium borohydride in chloroform – isopropyl alcohol in the presence of silica gel.[46]

$$R^1C_6H_4CH{=}CR^2NO_2 \xrightarrow[SiO_2]{NaBH_4} R^1C_6H_4CH_2CHR^2NO_2$$

101a – e **102a – e**

Compound	R^1	R^2	Yield of **102** (%)
a	H	H	93
b	H	Me	93
c	2-Me	H	99
d	4-Me	H	92
e	3-Me	H	92

The reduction results in highly polar negatively charged intermediates **103**. In the absence of silica gel, such intermediates bind a proton or a second molecule of the original styrene resulting in a mixture of products **102** and **104** in a nearly equal ratio. The formation of the dimer **104a** in solution shown in the scheme below is an example.

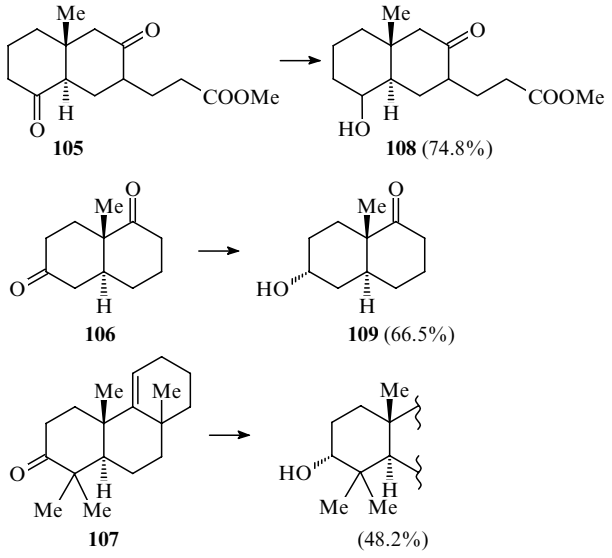


In the presence of silica gel, the intermediates **103** are formed most probably on the surface. In this case, the addition of the second styrene molecule is hindered, and the reaction yields nitroethylbenzenes **102** as the main products.

The use of chloroform as a solvent in this reaction is more preferable than the use of dichloromethane, ether or benzene. The reason is that the dissolution of the intermediate in this solvent is minimal due to the low dielectric permeability of chloroform, whereas its high density favours uniform distribution of silica gel in the reaction mixture.

For the same reasons, the use of isopropyl alcohol is more preferable than the use of methanol and ethanol, for it dissolves sodium borohydride to a lesser extent and, correspondingly, the formation of the dimeric side products **104** is less probable.

The reduction of bicyclic diketones **105** and **106**, tricyclic ketone **107** and several steroidal ketones (5α and 5β-androstane-3,17-diones, methyl esters of di- and trioxocholanoic acids, *etc.*) by treatment with the $BH_3 \cdot NMe_3$ complex has been described.[47] It was shown that the reaction carried out in the presence of silica gel impregnated with $FeCl_3 \cdot 6H_2O$ or $ZnCl_2$ resulted in selective reduction of only one keto group. Thus diketones **105** and **106** are reduced to the corresponding hydroxy ketones **108** and **109** in good yields; this reaction does not require protection of the second carbonyl group.



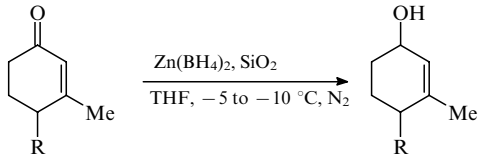
The presence of a small amount of water (5%) in silica gel accelerates the reaction, apparently due to enhanced adsorption of the amine.

Compounds containing several carbonyl groups can be regioselectively adsorbed on silica gel. Thus IR-spectroscopic studies of 5α- and 5β-androstane-3,17-diones revealed that during adsorption of these steroids on silica gel one of the carbonyl groups, *viz.*, C(17)O, forms stronger hydrogen bonds with the OH groups

present on the surface of silica gel in comparison with C(3)O. Thus, the former becomes protected from reduction with the $BH_3 \cdot NMe_3$ complex. In the cases of all steroidal ketones studied, it was the carbonyl group at position 3 that underwent reduction preferentially to the carbonyl groups at positions 7, 12, 17 and 20.

Three catalytic systems, *viz*., $SiO_2 \cdot FeCl_3 - PhH$, $SiO_2 - ZnCl_2 - PhH$ and $ZnCl_2 - PhH$, were tested in the reduction of 5α- and 5β-androstane-3,17-diones with $BH_3 \cdot NH_3$. All these reactions afforded mixtures of 3α- and 3β-hydroxy derivatives. The catalytic system $SiO_2 - FeCl_3 - PhH$ proved to be the best as the reaction was complete within 2 h, whereas reduction in the presence of the other two systems required 18–20 h. It should be noted also that in the absence of silica gel (the third catalytic system) the yields of steroid alcohols were very low.

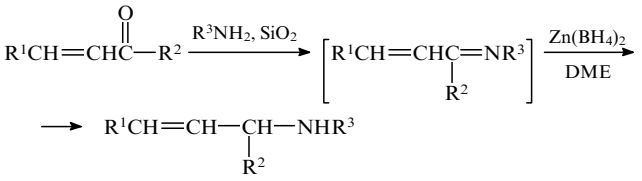
Ranu and Das[48] have proposed an excellent method for the synthesis of cyclic and acyclic allylic alcohols by reduction of the corresponding conjugated unsaturated ketones and aldehydes by zinc borohydride supported on silica gel. This reaction was carried out with unsaturated aldehydes (crotonic aldehyde, citral, *etc*.) and ketones (substituted 3-methylcyclohex-2-enones, α-ionone, pent-2-enone, *etc*.); in most cases, the yields of the corresponding allylic alcohols were quantitative. Thus the yields of alcohols in the reduction of substituted 3-methylcyclohex-2-enones exceeded 80%.



R = H (80%), COOEt (82%), COOMe (85%).

Zinc borohydride manifested high selectivity in hydrogenation, which affected exclusively carbonyl groups, but no double bonds.

Later, Ranu *et al*.[49] recommended this reagent for use in reductive amination of conjugated aldehydes and ketones in the presence of silica gel (substitution of the amino group for the carbonyl group is a very important process in organic synthesis).



R^1, R^3 = Alk, Ar; R^2 = H, Alk.

Attempts to use other catalysts, *e.g*., $BF_3 \cdot Et_2O$ or $ZnCl_2$, in this reaction were unsuccessful; good yields (75%–90%) of the corresponding imines were obtained only in the case when the reaction was carried out on silica gel.

Among other recent studies devoted to hydrogenation of carbonyl compounds, special mention should be made of the one[50] where the reduction of ketones and aldehydes into the corresponding alcohols was effected with sodium borohydride in the presence of silica gel in an aprotic solvent (hexane). The main advantages of this reaction are easy availability, low cost of reagents and catalysts, mild reaction conditions, ease of isolation of final products and, which is even more important, high yields.

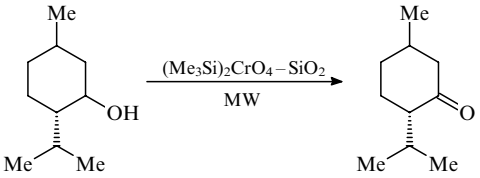
V. Oxidation

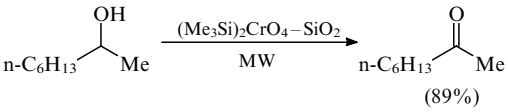
The use of inorganic oxidants in organic synthesis is often limited by their poor solubilities in low-polar media. One of the most popular oxidants is ozone. Dry ozonisation in the presence of silica gel for the insertion of oxygen atoms into non-activated C–H bonds has been described in sufficiently great detail by Basyuk;[3] therefore, we shall not discuss this process in this chapter and shall confine ourselves to the consideration of some other inorganic oxidants.

1. Oxidation of alcohols

The use of bis(trimethylsilyl) chromate supported on silica gel for the oxidation of some alcohols to carbonyl compounds has been described.[51] This reaction is initiated by microwave irradiation and takes place in the absence of solvents.

R = *p*-MeC_6H_4 (98%), n-C_7H_{15} (86%).



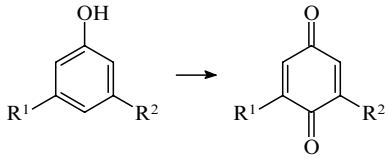


The reaction is complete within a short period of time. High yields of carbonyl compounds, simple methodology, easy isolation of reaction products and stability of the oxidant make this procedure especially attractive for synthetic chemists.

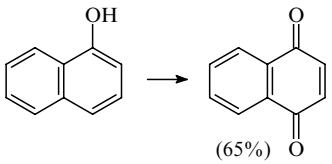
Oxidation of alcohols in CH_2Cl_2 with bis(trimethylsilyl) chromate supported on silica gel had been described earlier.[52]

2. Oxidation of phenols

Despite the great diversity of methods employed in quinone synthesis, studies in this field are currently under way, since many quinones possess biological activities and some of them are valuable semi-products in the synthesis of medicinal drugs. Recently, Hashemi and Bni[53] have proposed a very convenient, from our point of view, procedure for quinone synthesis which consists in oxidation of phenols with oxygen in the presence of a mixture of manganese and cobalt salts of 4-aminobenzoic acid supported on silica gel.



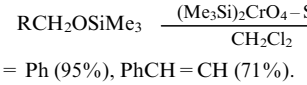
$R^1 = R^2 = H$ (64%); R^1 = Me, R^2 = H (53%); $R^1 = R^2$ = Me (57%)



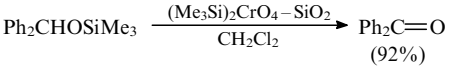
Benzene, toluene and ethylbenzene can be used as solvents in this reaction.

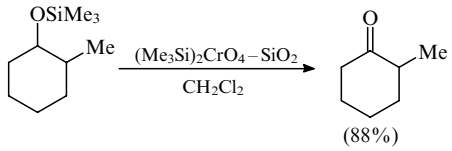
3. Oxidation of silyl ethers

Bis(trimethylsilyl) chromate supported on silica gel was also used for the oxidation of trimethylsilyl ethers of primary and secondary alcohols.[54] This reaction was run in dichloromethane.



R = Ph (95%), PhCH=CH (71%).





It is worth noting that in addition to the expected cinnamic aldehyde, the oxidation of 3-phenylallyl silyl ether yielded an appreciable amount (28%) of benzaldehyde, which points to the vulnerability of the double bond under these conditions.

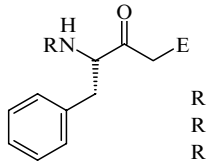
Special mention should be made of the oxidation of trimethylsilyl ethers by atmospheric oxygen which is catalysed by manganese and cobalt salts of 4-aminobenzoic acid supported on silica gel.[55] This reagent is also effective in the transformation of acetals and ketals into the corresponding carbonyl compounds.

4. Oxidation of sulfides

An effective procedure for the synthesis of sulfoxides by oxidation of sulfides in the absence of solvents has been developed.[56] The oxidation is carried out with manganese dioxide in the presence of a catalytic system, $H_2SO_4-SiO_2$.

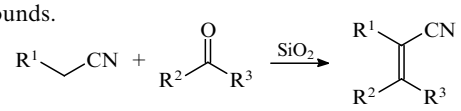
VI. Condensations

Silica gel is an efficient catalyst for the Knoevenagel condensation. The condensation of peptidylacetonitriles derived from *N*-acetyl-L-phenylalanine, *N*-acetyl-L-leucyl-L-phenylalanine and *N*-acetyl-L-leucyl-D-phenylalanyl-L-phenylalanine with aromatic aldehydes and ketones has been described.[57]



R = Ac: E = CN, CO_2Me, NO_2;
R = *N*-Ac-L-Leu, E = CN;
R = *N*-Ac-L-Leu-D-Phe, E = CN.

When this reaction is performed under homogeneous conditions, it requires weak bases, but even in this case the yields of reaction products are moderate. High yields can be achieved in heterogeneous conditions, *viz*., on silica gel. It is assumed that silica gel, which is acidic, catalyses enolisation of cyanomethyl ketones R^1CH_2CN and activates electrophilic carbonyl compounds.



R^1	R^2	R^3	Yield (%)
L-PhCH$_2$CH(NHAc)C(=O)–	H	4-$MeOC_6H_4$	100
	H	Ph	85
	H	4-$Me_2NC_6H_4$	58
	H	4-$O_2NC_6H_4$	37
	H	2-$HO_2CC_6H_4$	97
	H	3-MeO-4-HOC_6H_3	93
	$-(CH_2)_5-$		46
	$-(CH_2)_4-$		35
	Me	Me	44
	$HOCH_2$	Me	80
	MeC(OH)H	Me	61
L-PhCH$_2$CH(NH-*N*-Ac-L-Leu)C(=O)–	H	4-$MeOC_6H_4$	98
L-PhCH$_2$CH(NH-*N*-Ac-L-Leu-D-Phe)C(=O)–	H	4-$MeOC_6H_4$	94

This reaction holds great promise in the synthesis of peptide inhibitors of α-chymotrypsin by virtue of its operational simplicity, high yields of the reaction products and the fact that it is not accompanied by epimerisation. The condensation of (*N*-acetylphenylalanyl)acetonitrile with 2-formylbenzoic acid and vanillin has demonstrated that no preliminary protection of functional groups is necessary when this reaction is performed on silica gel. These data altogether suggest that silica gel is a mild selective acidic catalyst of the Knoevenagel reaction.

In addition to peptidylacetonitriles, other compounds, such as R^1CH_2E (E = CN, CO_2Me, NO_2; R = CN, NO_2, C(O)Ph, CO_2Me, CO_2Et and SO_2Ph) containing activated methylene groups, were tested in this reaction. It was found that the reaction takes place only if compounds with E = CN and R^1 = CN, NO_2 and C(O)Ph are used; compounds with E = CO_2Me and R^1 = CO_2Me, CO_2Et and SO_2Ph do not enter into this reaction, presumably, due to steric hindrances.

The reaction of malonic acid with carbonyl compounds is an important synthetic route to the preparation of valuable unsaturated acids. α,β-Unsaturated acids are formed upon heating of the starting compounds in the presence of bases (pyridine and piperidine). The Knoevenagel condensation catalysed by SiO_2 was recommended for the synthesis of β,γ-unsaturated acids.[58] This reaction was performed under microwave irradiation without any solvent.

110 – 118 **119 – 127**

R = Et (**110**, **119**, 84%), Pr^n (**111**, **120**, 83%), Bu^n (**112**, **121**, 84%), n-C_5H_{11} (**113**, **122**, 84%), n-C_6H_{13} (**114**, **123**, 88%), n-C_7H_{15} (**115**, **124**, 86%), n-C_8H_{17} (**116**, **125**, 90%), Ph (**117**, **126**, 92%), Bn (**118**, **127**, 89%).

Thus the reactions of aldehydes **110**–**118** with malonic acid afforded unsaturated acids **119**–**127**. The target products are formed in high yields and are stereochemically pure. The method is distinguished by the ease of preparation and rapidity.

VII. Formylation

The Vilsmeier–Haack reaction is widely employed for the introduction of aldehyde groups into aromatic rings. Taking into account the great importance of this reaction in organic synthesis, Paul *et al*.[59] made an attempt to find optimum conditions for its performance. It was found that irradiation in a conventional microwave oven of substituted aromatic compounds and the Vilsmeier–Haack reagent ($POCl_3$–DMF) supported on silica gel affords maximum yields of the corresponding aldehydes and decreases reaction time to 1.5–2.5 min (Table 2).

The amount of the reagent is crucial for achieving maximum yields. For liquid substrates supported on silica gel, the amount of the Vilsmeier-Haack reagent may not exceed 2 equiv., whereas formylation of solid substrates requires no less than 3 equiv. The amount of silica gel pre-irradiated for 5 min at 700 W needed for the formylation also depends on the amount of the reagent. Evidence for the important role of microwave irradiation in this reaction follows from the fact that the yields of aromatic aldehydes formed upon microwave irradiation exceed significantly those obtained upon conventional heating of the reactants at the same temperature.

The use of microwave irradiation in combination with silica gel is an excellent procedure for the rapid (within 1.5–2.5 min) and quantitative Vilsmeier–Haack reaction.

Table 2. The Vilsmeier – Haack reaction.

VIII. Hydration and dehydration reactions

Dehydration of alcohols resulting in the formation of alkenes and the inverse reaction, *viz*., hydration of alkenes, are valuable synthetic conversions widely applicable in organic synthesis.

A general method for the selective anti-Markownikoff addition of water to alkenes in the presence of silica gel has been described in detail by Ranu.[60] An alkene supported on preactivated silica gel (200 °C, reduced pressure) was treated with a solution of $Zn(BH_4)_2$ in 1,2-dimethoxyethane (DME) at room temperature and then hydrolysed. This reaction gives good yields of primary and secondary alcohols (Table 3).

Table 3. Anti-Markownikoff addition of water to alkenes.

Starting compound	Product	Yield (%)
$Me(CH_2)_6CH{=}CH_2$	$Me(CH_2)_6CH_2{-}CH_2OH$	95

		90
		80
	cis : *trans* = 3 : 7	
		70
	cis : *trans* = 1 : 3	
		70
	cis : *trans* = 3 : 7	

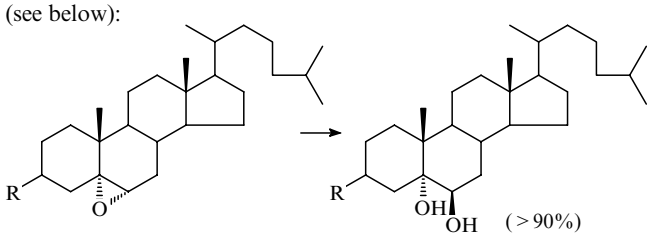
The obvious advantages of this method include ease of performance, mild conditions, lack of side reactions and high yields of reaction products. The reaction mechanism is not quite clear, but the authors exclude the possibility of conventional hydroboration – oxidation.

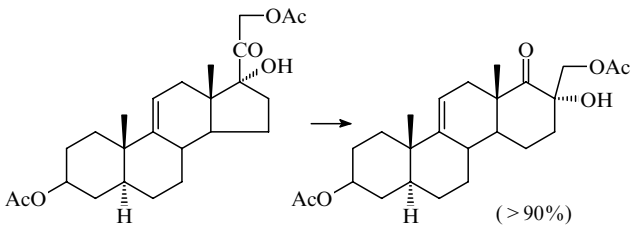
The efficiency of silica gel in the dehydration of alcohols is determined by the acidic properties of its surface (SiO_2 is a weak Lewis acid).

Thus application of iron(III) chloride hexahydrate dissolved in a volatile solvent (methanol, ether, *etc*.) onto the surface of commercial silica gel (Kieselgel 60, Merck) and subsequent evaporation of the solvent under high vacuum (0.1 Torr) yield a catalyst for selective dehydration of tertiary, allylic and sterically hindered secondary alcohols.[61] The corresponding alkenes are obtained in quantitative yields (Table 4).

This reaction is carried out under mild conditions using ether and acetone as solvents. The content of water affects the catalytic activity: the addition of H_2O (2 mass %) to the dry catalyst changes only slightly the catalytic activity, whereas at higher water content (> 10%) the activity is completely lost.

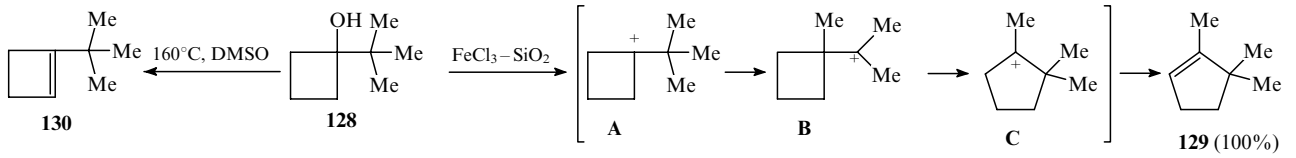
The $FeCl_3 \cdot 6H_2O - SiO_2$ system containing 2% of water also catalyses the epoxide ring opening and certain rearrangements (see below):



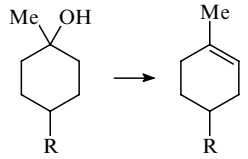


Later, the $FeCl_3 - SiO_2$ system prepared from anhydrous iron chloride by simple grinding of components was recommended for dehydration of alcohols.[62] This system proved to be efficient in

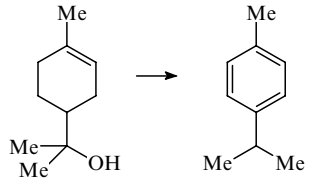
Scheme 1



dehydration of tertiary alcohols where the yields of reaction products were quantitative.



R = Me (95%), Bu^t (91%).



(90%)

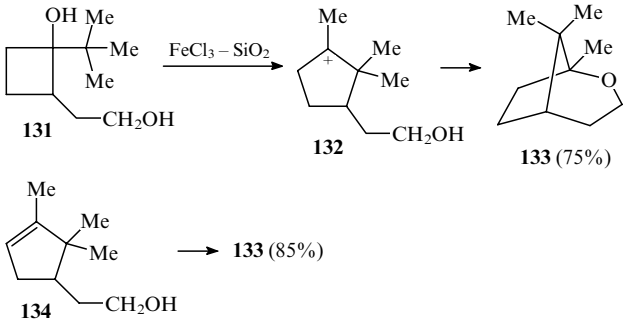
The reaction is carried out in the absence of the solvent. 1-*tert*-Butylcyclobutan-1-ol **128** undergoes an interesting rearrangement with ring enlargement and formation of 1,5,5-trimethylcyclopentene (**129**) (Scheme 1). In this case, the dehydration occurs *via* carbocations **A**, **B** and **C**.

If the dehydration of the alcohol **128** is carried out under different conditions, *viz*., by heating in DMSO at 160 °C, compound **129** is formed in low yield (5%), while the yield of the alkene **130** reaches 95%.

Table 4. Selective dehydration of alcohols by iron(III) chloride on silica gel.

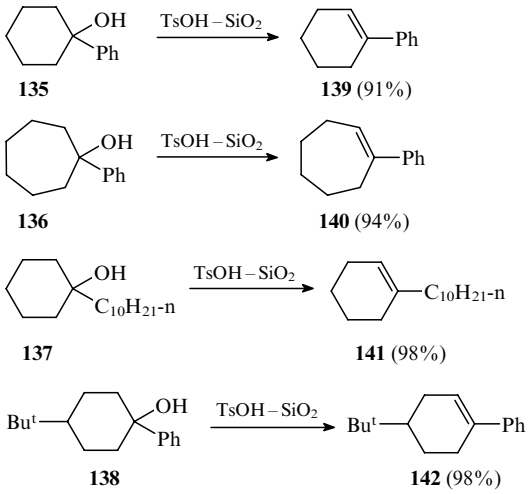
Starting compound	Product	Yield (%)
		>90
		>90
		>90
		>90
		>90

The dehydration of the alcohol **131** in the presence of the $FeCl_3 - SiO_2$ system also proceeds *via* the intermediate cyclopentyl cation **132** and results in the cyclic ether **133**. The same product (**133**) is obtained in good yield upon dehydration of the alcohol **134** under identical conditions.

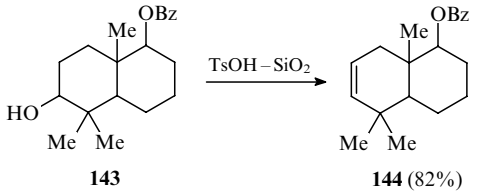


Thus, the $FeCl_3 - SiO_2$ system catalyses efficiently both dehydration reactions and rearrangements including ring enlargement. Some rearrangement products are key precursors in the synthesis of sesquiterpenoids.

Toluene-*p*-sulfonic acid supported on silica gel is an excellent catalyst in dehydration of secondary and tertiary alcohols (primary alcohols do not react under these conditions).[63] Thus alcohols **135** – **138** are converted into alkenes **139** – **142** in high yields.

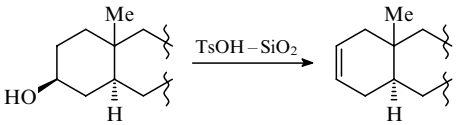


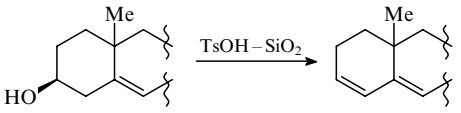
Dehydration of the alcohol **143** gave alkene **144** in somewhat lower yields under identical conditions.†



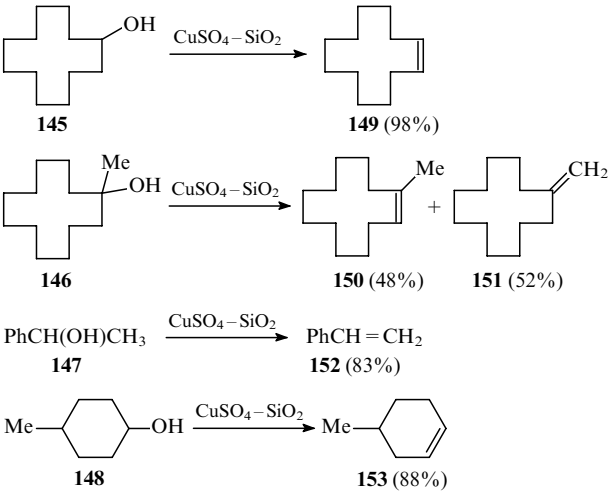
This system was also used for dehydration of 3-hydroxysteroids. The reaction occurred *via* carbocations and resulted in Δ^2-alkenes and $\Delta^{3,5}$-dienes.

† The authors' unpublished data.





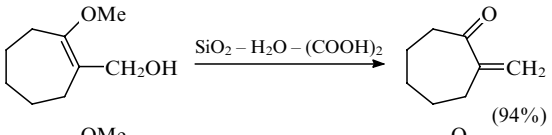
It was found [64] that silica gel-supported copper(II) sulfate is an efficient catalyst in smooth dehydration of secondary and tertiary alcohols into alkenes. The catalyst was prepared by mixing chromatographic silica gel with an aqueous solution of copper(II) sulfate with subsequent evaporation by heating at 2 Torr. The catalytic activity depended on the evaporation time and temperature and was maximum when the catalyst was dried at 200 °C for 3 h or at 240 °C for 1 h. With a further increase in the evaporation temperature (300 °C, 1 h), the catalyst lost its activity completely. The dehydration rate depended on the $SiO_2 : CuSO_4$ ratio (the optimum ratio is 4 : 1). Under these conditions, alcohols **145** – **148** are converted into alkenes **149** – **153** in high yields.

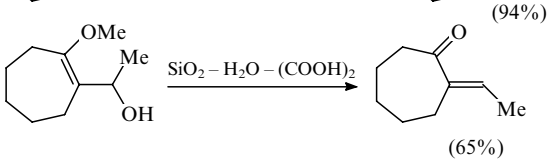


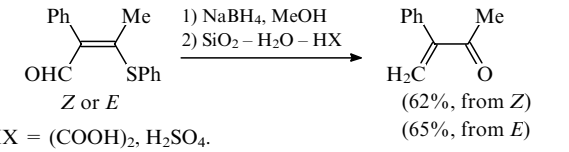
Tertiary alcohols are dehydrated more easily than secondary ones. The mechanism of this reaction is still unclear, but it is reasonable to assume the formation of carbenium cations, since dehydration rates of tertiary alcohols are higher than those of secondary and primary ones. This system can also be used for dehydration of 3-hydroxysteroids.

Special mention should be made of a detailed study [65] of dehydration of various primary, secondary and tertiary alcohols catalysed by transition metal sulfates supported on silica gel. The activities of various brands of silica gel in this reaction have been compared. The highest activity was manifested by Silica gel BW-300 (Fuji-Davidson). The catalytic activities of metal sulfates supported on silica gel decreased in the following order: Fe(III) = Ce(IV) = Ti(IV) > Sn(IV) > Al(III) > Cu(II) > Zn(II) > Co(III) > Ni(II) > Fe(II) > Mn(II) > Cd(II). The optimum conditions (time, temperature) for treatment of catalysts providing maximum yields of dehydration products have been found.[65] The effects of solvents, reagent ratios and reaction conditions on the product yields have been investigated. Some suggestions on the possible mechanism of this reaction have been put forward.

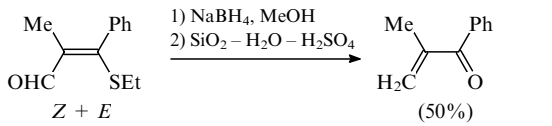
Interesting examples of the preparation of α-methylidenecarbonyl compounds from derivatives of cyclic β-(hydroxyalkyl)-vinyl ethers, β-alkylthio- and β-arylthioacroleins have been described,[66] which involved dehydration of intermediate alcohols in the presence of silica gel as one of the steps. The following catalytic systems, *viz.*, $SiO_2 - H_2O - HOOCCOOH - HgCl_2$, $SiO_2 - H_2O - HOOCCOOH$ and $SiO_2 - H_2O - H_2SO_4$ and dichloromethane as a solvent, were employed.







HX = $(COOH)_2$, H_2SO_4.



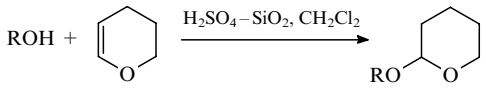
IX. Protection of functional groups

The use of silica gel as a catalyst for introduction of protective groups is a popular procedure in organic synthesis.

1. Tetrahydropyranylation of alcohols

The tetrahydropyran-2-yl group (THP) is one of the most popular groups used for the protection of alcohols and phenols. Many methods have been devised for its introduction.

It has been found [67, 68] that sulfuric acid adsorbed on silica gel can be used as a catalyst in tetrahydropyranylation of alcohols and phenols. Dichloromethane is generally used as a solvent in this reaction.



R = Ph (95%), $PhCH_2$ (96%), α-$C_{10}H_7$ (98%), $PhCH{=}CHCH_2$ (96%), $PhOCH_2\underset{|}{C}HC{\equiv}CH$ (94%).

This simple and inexpensive method gives the reaction products, as a rule, in high yields.

Recently, this reaction has been carried out [69] using microwave irradiation in the presence of the same catalyst but without solvent. This permitted one to obtain reaction products in a pure state and in high yields. The absence of solvents makes it possible to run this reaction under mild conditions. Other advantages include short reaction time (10 – 15 min), omission of the aqueous workup and environmental safety.

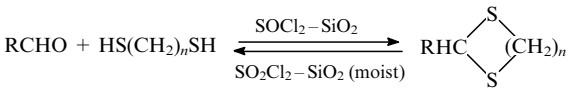
2. Thioacetalisation and acetalisation

Protection of carbonyl groups as acetals or thioacetals is a common procedure in the synthesis of organic compounds, in particular, of complex polyfunctional compounds. However, protic and Lewis acids and some silicon reagents [70] commonly used in (thio)acetalisation do not afford selective protection of aldehyde groups in the presence of keto groups.

Silica gel treated with thionyl chloride effects their protection. It was found that this silica gel effectively catalyses thioacetalisation ‡ of many aldehydes and ketones by 1,2-ethanedithiol or 1,3-

‡ The inverse reaction occurs upon treatment with sulfuryl chloride in the presence of wet silica gel.

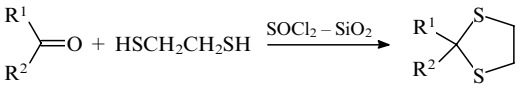
propanedithiol and affords selective protection of aldehyde groups when both these groups are present simultaneously.[71]



R	*n*	Yield of thioacetal (%)
C_6H_{13}	2	99
	3	99
PhCHMe	2	100
$H_2C=CH(CH_2)_8$	2	100
MeCH=CH	2	100
PhCH=CH	2	97
	3	100
Ph	2	100
	3	97
4-MeC_6H_4	2	98
4-ClC_6H_4	2	99
4-$MeOC_6H_4$	2	98
4-HOC_6H_4	2	88
4-$HO_2CC_6H_4$	2	98
4-$Me_2NC_6H_4$	2	98
2-$O_2NC_6H_4$	2	93

By itself, silica gel (without $SOCl_2$) does not manifest any noticeable catalytic activity in thioacetalisation of aldehydes. Treatment of heptanal with 1,2-ethanediol afforded the corresponding 1,3-dithiolane in as low a yield as 11%.

The reaction with ketones in benzene proceeds very slowly; however, this can be completed within 24 h in boiling toluene.



R^1	R^2	Yield (%)
Ph	Me	91
$-(CH_2)_5-$		100
$PhCH_2$	$PhCH_2$	93
Ph	Ph	31

The difference in the rates of thioacetalisation of aldehydes and ketones permits selective protection of aldehydes in the presence of ketones (Table 5) as well as selective thioacetalisation of oxo aldehydes.

Table 5. Thioacetalisation of mixtures of aldehydes and ketones in the presence of $SOCl_2-SiO_2$.

Aldehyde	Ketone	Conversion	
		aldehyde	ketone

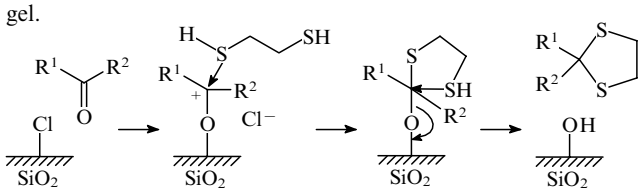
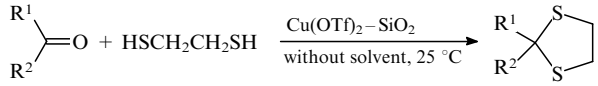
	Ph	3	92

All these reactions proceed with high selectivity and do not require complex equipment. The unusual chemoselectivity of this method can be attributed to the differences in spatial interactions of the aldehyde and ketone groups with the porous surface of silica gel.



This method holds especially great promise for multistep syntheses of complex molecules.

The synthesis of thioacetals from aldehydes (or ketones) and 1,2-ethanedithiol in the presence of catalytic amounts of copper(II) trifluoromethanesulfonate supported on silica gel in the absence of solvents has been described.[72] All thioacetals were obtained in high yields.



R^1	R^2	Yield (%)

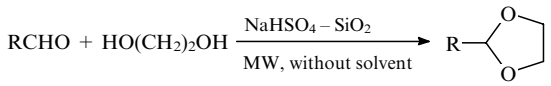
$-CH_2CH(CO_2Me)CH(CO_2Me)CH_2-$		93

In most cases, the reactions proceed selectively and at room temperature. This reaction can also be performed in the presence of the $CuCl_2-SiO_2$ system (in the absence of solvent), however, in this case the reaction rate and the product yields are lower.

In addition to thioacetals, cyclic acetals, which are stable in alkaline or weakly acidic media, are used to protect aldehydes and ketones in multistep syntheses.[73] The reaction of aldehydes with ethylene glycol in the presence of strong protic or Lewis acids is a common procedure for their synthesis; however, this method is characterised by low yields and long reaction time. Other methods for acetal synthesis require drastic conditions, the use of expensive or hazardous reagents, sophisticated synthetic and isolation procedures, *etc*.

An efficient method for protection of the aldehyde and ketone groups by treatment with ethylene glycol with microwave irradiation without any solvent has been developed.[74] Here, metal sulfates [$Ce(SO_4)_2$, $MgSO_4$ and $NaHSO_4$] supported on silica gel are used as catalysts.



R = Ph (85%), 2-$O_2NC_6H_4$ (98%), 2-$MeOC_6H_4$ (82%), 2-ClC_6H_4 (90%), 3-NCC_6H_4 (97%), 3-$PhOC_6H_4$ (85%), 3-$BnOC_6H_4$ (81%), PhCH(CN) (90%), β-$C_{10}H_7$ (87%), 4-[PhC(O)CH_2O]C_6H_4 (75%),

PhCH=CH (81%), [X = O (94%), S (81%)],

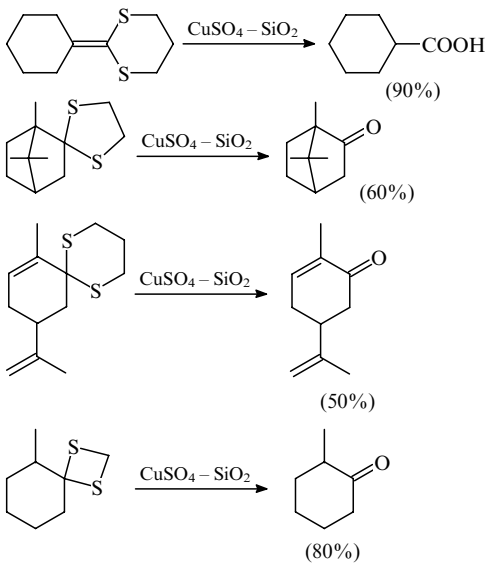
MeCH=CH (82%), MeC(O)CH_2CH_2 (82%), n-C_6H_{13} (90%), n-$C_{10}H_{21}$ (87%), $ClCH_2CH$=CH (78%), $MeO_2C(CH_2)_4$ (85%).

This technique provides selective protection of aldehyde groups in the presence of keto groups (the latter proved to be fairly resistant to microwave irradiation).

X. Deprotection of functional groups

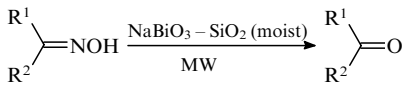
There is a vast body of evidence concerning the use of silica gel as a catalyst in hydrolytic reactions aimed at removal of protective (trityl, ketal, ester, *etc.*) groups.[3,21] Some examples of these reactions will be given below.

Very good yields of carbonyl compounds were obtained upon removal of the thioacetal group by boiling the dithioacetals in organic solvents with silica gel-supported copper(II) sulfate.[75]



The reaction is generally completed in 2–20 h. Its mechanism is still unclear.

Many oximes are converted into the starting carbonyl compounds under the action of chromium trioxide supported on silica gel.[76] These reactions occur on heating in such solvents as toluene, benzene or ether. Mitra *et al.*[77] have proposed to use sodium bismuthate supported on moist silica gel for removal of the oxime protective group. This reaction is initiated by microwave irradiation.



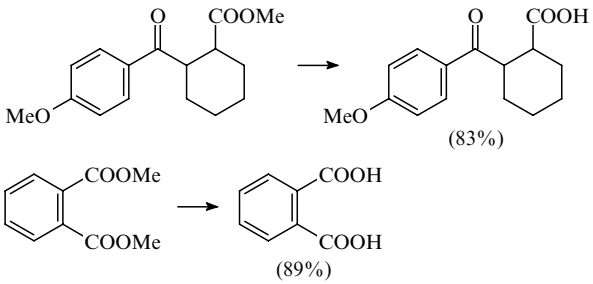
R^1	R^2	Yield (%)
Bu^i	Me	81
$-(CH_2)_5-$		73
Ph	Ph	90
$C_{10}H_7$	Me	90
Ph	Me	89
4-MeC_6H_4	Me	85
4-$MeOC_6H_4$	Me	94
4-$O_2NC_6H_4$	Me	82

This reaction is quantitative and is completed within several minutes at normal pressure.

Later, the same authors used this reagent to convert semicarbazones into the original carbonyl compounds.[78]

Hydrolysis of esters, which is usually carried out by heating in aqueous solutions of acids or bases, is one of the most common reactions in organic synthesis. These conditions can result in hydrolysis of compounds containing acid- or base-sensitive groups. Therefore, studies in this field are aimed at the search for conditions of ester hydrolysis in neutral media. An original procedure for ester hydrolysis by microwave irradiation on moist silica gel impregnated with indium triiodide has been proposed recently.[79] This approach made it possible to hydrolyse various acyclic and carbocyclic esters to the corresponding acids in high yields.

R = $PhCH_2$ (92%), n-$C_{17}H_{35}$ (70%), Ph_2CH (70%).



The duration of this reaction was 25–80 min. This reaction proceeded smoothly even in the case of sterically hindered esters and diesters. Mild reaction conditions make this reaction suitable for hydrolysis of compounds containing additional functional groups, *e.g.*, keto and hydroxy groups, as well as C=C bonds.

XI. Miscellaneous reactions

Among other reactions, we shall consider the Nef, Ritter, Wittig and Prins reactions as well as acylation, substitution, halogenation and ring-opening reactions. These types of conversions will be outlined below.

1. The Nef reaction

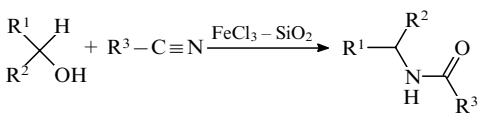
The use of silica gel in the Nef reaction has been described.[80] Nitroalkanes were converted into the corresponding carbonyl compounds in high yields by treatment with sodium percarbonate in the presence of silica gel in aqueous DMF (40 °C, 1 h).

R^1	R^2	Yield (%)
$-(CH_2)_4-$		73
$-(CH_2)_5-$		68
n-C_5H_{11}	H	65
$PhCH_2$	Me	81

In the absence of silica gel, the reaction proceeds at a slow rate (12–15 h). If sodium carbonate is used instead of percarbonate, the reaction does not take place.

2. The Ritter reaction

The Ritter reaction of benzyl alcohols with nitriles initiated by iron(III) chloride supported on silica gel results in the corresponding amides in high yields.[81]



R^1	R^2	R^3	Yield (%)
Ph	Ph	Me	94
Ph	Me	Me	95
Ph	Ph	$PhCH_2$	92
4-$MeOC_6H_4$	H	Me	80
4-ClC_6H_4	H	$ClCH_2$	91
4-$O_2NC_6H_4$	H	Ph	–

This reagent has a number of advantages over concentrated sulfuric acid commonly used in this reaction; it is non-hygroscopic and does not require any special precautions. All reactions were conducted under solvolytic conditions using nitrile as a solvent. The iron salt and the substrate were used in equimolar amounts. *p*-Nitrobenzyl alcohol does not enter into the reaction under these conditions.

3. The Wittig reaction

The Wittig reaction with the use of silica gel[82] allows one to selectively synthesise α,β-unsaturated carbonyl compounds in high yields from stable phosphorylides and aldehydes. Thus irradiation of mixtures of ethoxycarbonylmethylidenetriphenylphosphorane with aldehydes in a microwave oven in the presence of silica gel yielded esters of the corresponding α,β-unsaturated carboxylic acids.

$$RCHO + Ph_3\overset{+}{P}-\overset{-}{C}HCOOMe \xrightarrow[n\text{-}C_6H_{14},\ MW]{SiO_2} RCH{=}CHCOOMe$$

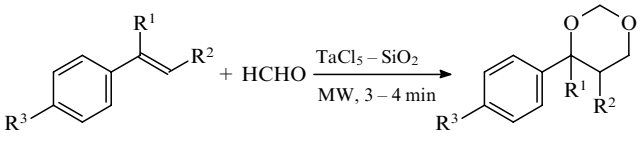
R = Pr^n (87%), Bu^t (78%), cyclo-C_6H_{11} (90%), $MeOCH_2$ (85%).

The use of silica gel not only accelerates the reaction, but also promotes the separation of the triphenylphosphine oxide formed. As a result, target products are formed in high yields and do not contain admixtures. In addition to aldehydes, ketones can also be involved in the reaction.

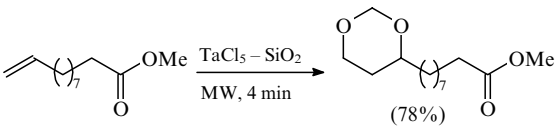
4. The Prins reaction

The Prins reaction, which includes condensation of alkenes with aldehydes (usually, formaldehyde), affords 1,3-diol derivatives. This reaction is catalysed by mineral acids, soft Lewis acids and solid catalysts, such as ion-exchange resins, zeolites and clays (montmorillonite K-10).

Recently, the Prins reaction has been carried out with microwave irradiation under solvent-free conditions using $TaCl_5$ supported on silica gel as a catalyst.[83] Under these conditions, alkenes were converted into 1,3-diol derivatives in high yields.



R^1	R^2	R^3	Yield (%)
H	H	H	90
Me	H	H	88
H	Me	H	86
H	H	Me	88
H	H	Cl	85
H	H	NO_2	80
H	Me	Me	90
H	Ph	H	85



These reactions are usually completed within 3–4 min, whereas under conventional conditions (in dioxane) it takes 10–13 h and the yields do not exceed 80%.

5. Substitution reactions

Thioamides were converted into the corresponding amides under mild conditions by treatment with Caro's acid (peroxymonosulfuric acid) supported on silica gel. The reaction was carried out in acetonitrile at room temperature in air.[84]

$$R^1C(S)NHR^2 \xrightarrow{H_2SO_5-SiO_2} R^1C(O)NHR^2$$

R^1	R^2	Yield (%)
Ph	CH_2Ph	84
4-$O_2NC_6H_4$	CH_2Ph	76
Ph	Bu^n	82
Me	C_6H_4Me	87

This reaction is operationally simple. However, it is not suitable for conversion of primary thioamides which yield a mixture of products difficult to identify. Despite this limitation, Caro's acid supported on silica gel allows mild conversion of secondary and tertiary thioamides into amides in the yields comparable and sometimes exceeding those described previously. This reaction is successfully employed in the chemistry of thio analogues of nucleic acids and nucleosides.[85]

6. Synthesis of nitriles from aldehydes

Nitriles are used as starting components in the synthesis of many biologically active compounds; therefore, elaboration of effective methods of their synthesis is a topical problem. The conversion of aldehydes into the corresponding nitriles represents an important transformation of functional groups. A simple and efficient procedure for the synthesis of nitriles from aldehydes and hydroxylamine using microwave irradiation in the presence of $NaHSO_4$ supported on silica gel has been described.[86]

$$RCHO \xrightarrow[NaHSO_4-SiO_2,\ MW]{NH_2OH-HCl} RCN$$

R = Ph (84%), 4-HOC_6H_4 (90%), 4-$MeOC_6H_4$ (91%), 3-Me-4-HOC_6H_3 (96%), 3-HOC_6H_4 (91%), 3,4-$(MeO)_2C_6H_3$ (97%), 3,4-$(CH_2O_2)C_6H_3$ (95%), PhCH=CH (85%), n-C_7H_{15} (81%), n-C_8H_{17} (80%).

This reaction proceeds very fast (1–3 min) and final products are formed in high yields. Presumably, the aldehyde is converted into the corresponding aldoxime which is immediately dehydrated to yield the nitrile.

7. Acylation, alkylation and esterification

The use of solid adsorbents in organic synthesis provides high selectivity in many chemical reactions including alkylation, acylation, esterification, *etc*. The most essential feature of these reactions is that they can be applied for selective protection of one functional group in bi- and polyfunctional compounds. Thus acetylation of a series of symmetrical 1,*n*-diols adsorbed on silica gel (Wako gel C-200, Wako Pure Chemical Industries) by heating with acetyl chloride in cyclohexane resulted in monoacetyl derivatives in quantitative yields.[87]

$$HO(CH_2)_nOH \xrightarrow[2\text{ h, boiling}]{AcCl,\ cyclo\text{-}C_6H_{12}} AcO(CH_2)_nOH$$

n	Yield on SiO_2 (%)		Yield in the homogeneous reaction (%)
	mono	bis	
4	99.5	0	52.3
6	99.5	0	58.6
8	99.8	0	54.3
10	99.8	0	56.5
12	99.0	1.0	66.5
16	99.9	0	30.2

n	Yield on SiO_2 (%)		Yield in the homogeneous reaction (%)
	mono	bis	
HO—⬡—OH	29.9	40.8	32.6
$HOCH_2$—⬡—CH_2OH	36.0	47.5	52.5

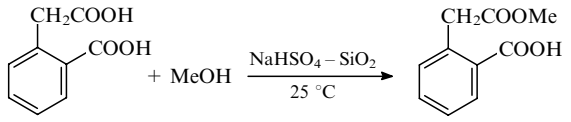
Under identical conditions, cyclic diols [cyclohexane-1,4-diol and 1,4-bis(hydroxymethyl)benzene] yield predominantly diol diacetates. The dependence of reaction selectivity on temperature was studied in the example of cyclohexane-1,4-diol; the yields of monoacetylated and bisacetylated products at 80 °C were 29.9% and 40.8% and at 0 °C, 52.4% and 19.3%.

The silica gel used in this reaction seems to play a protective role for one of hydroxy groups of the diol which is adsorbed on the silica gel surface. It is thought that the diol is adsorbed on the surface of silica gel resulting in the formation of a monomolecular layer, which has been demonstrated in the methylation of alcohols (1-decanol, geraniol and cyclohexanol), phenol, α- and β-naphthols, 2,6-di-*tert*-butylphenol, *etc*., by diazomethane.[88] Presumably,[88] it is alcohols (in the form of alkoxides) adsorbed on the surface of SiO_2 that enter into the reaction. This reaction does not take place in the absence of silica gel. Ogawa *et al*.[88] determined the maximum amount of the alcohol adsorbed on silica gel beyond which the reaction rate does not change further. For 1-decanol, it was equal to 4 mmol g^{-1} SiO_2, which corresponds to the formation of a monomolecular layer of the alcohol molecules on the surface of silica gel. It was found that 2,6-di-*tert*-butylphenol, which cannot be adsorbed on the surface of SiO_2 due to steric hindrances, is not methylated under these conditions.

An alternative procedure[89] for selective monoacylation of diols by reaction with esters (ethyl acetate, ethyl formate, methyl propionate, methyl isobutyrate) has been developed;[89] this reaction is catalysed by metal sulfates [$NaHSO_4$, $Ce(SO_4)_2$] supported on chromatographic silica gel. This method was used to prepare monoesters of ethylene glycol, butane-1,4-diol, pentane-1,5-diol and hexane-1,6- and -2,5-diols.

The reaction occurs in the presence of hexane at the controllable hexane : ester ratio of ~1 : 4. The yields of monoesters decrease with the increase in this ratio. This phenomenon is attributed to the effect of solvent polarity on the adsorption of alcohols and esters. With the above ratio, only alcohols are adsorbed, which are more polar than the monoesters.

A selective procedure for esterification of aliphatic carboxylic acids in the presence of aromatic acids has been developed;[90] an interesting example of selective esterification of dicarboxylic acid **154** into the monoester **155** has been described.



154 **155** (96%)

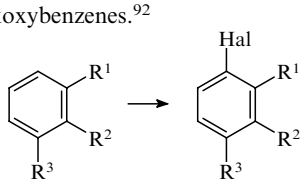
8. Halogenation of aromatic compounds

Preparation of novel effective reagents for electrophilic chlorination of aromatic compounds has been described.[91] It was found that many chlorine-containing organic compounds acquire strong electrophilic properties in the presence of silica gel, although they differ substantially in reactivities. The systems based on *N*,*N*-dichlorourethane, dichloramine-T and *tert*-butyl hypochlorite appeared to be the most active. They quantitatively chlorinate aromatic compounds under controlled conditions. The *tert*-butyl hypochlorite – chromatographic silica gel (BDH) system proved to be very convenient for monochlorination of some aromatic compounds.[91] In some cases, the yields of *ortho*- and *para*-chlorinated derivatives reached 100%.

R	Yield (%)	*ortho* : *para* Ratio
Me	100	65 : 35
Et	86	57 : 43
Pr^i	100	44 : 56
Bu^t	70	15 : 85
OMe	100	30 : 70
Ph	70	56 : 44

This reaction has significant advantages over classical electrophilic chlorination reactions involving chlorine and sulfuryl chloride and is characterised by high yields, ease of isolation of reaction products and the absence of HCl. The nature of silica gel is very important for the successful implementation of this reaction. Satisfactory results were obtained exclusively with strongly acidic (pH < 5) chromatographic silica gel dried at 120 °C. The dichlorourethane – silica gel system in acetonitrile was used for chlorination of benzene and the dichloramine – silica gel system in carbon tetrachloride was used for chlorination of toluene.

The addition of silica gel to *N*-bromosuccinimide in carbon tetrachloride resulted in a catalytic system, which allows selective monobromination (presumably, in the *para*-position) of some alkoxybenzenes.[92]



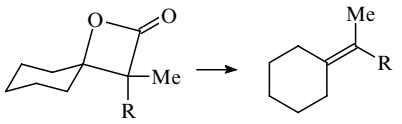
R^1	R^2	R^3	Yield (%)
OMe	H	OMe	99
OMe	OMe	H	98
Me	H	OMe	87
Pr^i	H	OMe	78
Et	H	OMe	90
H	H	OMe	90
H	H	OEt	96

Thus bromination of *m*-alkylmethoxybenzenes (Alk = Me, Et, Pr^i) occurs exclusively in the *para*-position relative to the methoxy group. 4-Bromo-3-*tert*-butyl-1-methoxybenzene is the major product even in the case of *m*-(*tert*-butyl)methoxybenzene. Quite unexpectedly, the ratio of 4-Br- to 6-Br-derivatives was found to be equal to 74 : 26, considering the large size of the *tert*-butyl substituent (bromination of this compound in the presence of Fe-catalysts yields exclusively the 6-Br derivative). The rate of this reaction strongly depends on the amount of silica gel and the mixing rate; this points to the heterogenous character of the reaction. No bromination occurs in the absence of silica gel. Many types of silica gels manifest catalytic activities in this reaction; noteworthy, acidic silica gels are more reactive, whereas neutral and basic ones are more selective. The acidic chromatographic silica gel Microbead 3A (Fuji – Davidson) exhibited the highest efficiency. Availability of the commercial reagent, ease of performance, excellent yields of reaction products and the absence of hydrogen bromide make this method especially attractive.[92]

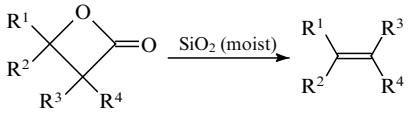
This reagent has been used in previous studies for the bromination of indoles and benzoimidazoles.[93]

9. Ring opening

A convenient method for the synthesis of high-boiling alkenes (b.p. = 250 °C) from β-lactones by heating the latter in benzene or cyclohexane in the presence of chromatographic silica gel has been proposed.[94]



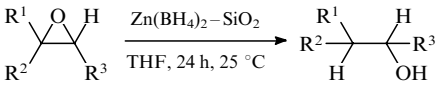
R = H (90%), Me (88%), CO_2Et (97%), CH_2OH (77%).



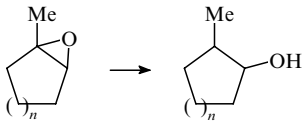
R^1	R^2	R^3	R^4	Yield (%)
Me	$Ph(CH_2)_2$	Me	Me	95
Me	$SiMe_2Bu^t$	H	H	93
Me	cyclo-C_6H_{11}	Me	H	95
Pr^i	H	n-C_7H_{15}	H	75

Distillation of lactones over moist silica gel is the best procedure for the preparation of alkenes with b.ps < 200 °C.[95] Silica gel was used to accelerate the decarboxylation of β-lactones; this is an excellent procedure for stereoselective synthesis of alkenes. Anhydrous silica gel fire-dried *in vacuo* is not always suitable for decarboxylation, since this may cause isomerisation of alkenes formed. In the above-described experiments, silica gel was used in the amount of 10 mass %, since the amount of water released in the course of distillation decreases with the silica gel dose.

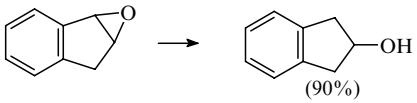
Zinc borohydride supported on silica gel proved to be a convenient reagent for the regio- and stereoselective opening of epoxides.[96] The least substituted alcohols are prepared by *anti*-opening of the rings.



R^1	R^2	R^3	Yield (%)
n-C_7H_{15}	H	H	88
$ClCH_2$	H	H	85
Ph	H	H	90
Ph	Me	H	91
Ph	H	Ph	88



n = 1 (84%), 2 (85%).



The main advantages of this method include high regioselectivity of epoxide opening, low toxicity and availability of the reagents.

Abstract. Organic molecules, the structural parameters of which (carbon – carbon bond lengths, bond and torsion angles) differ appreciably from the typical most frequently encountered values, are discussed. Using many examples of 'record-breaking' molecules, the limits of structural distortions in carbon compounds and their unusual chemical properties are demonstrated. Particular attention is devoted to strained compounds not yet synthesised whose properties have been predicted using quantum-chemical calculations. Factors that ensure the stability of such compounds are outlined. The bibliography includes 358 references.

I. Introduction

The experimentally determined lengths of carbon – carbon bonds of one type in the molecules of various organic compounds are usually very close. Thus the lengths of single and multiple carbon – carbon bonds usually deviate only slightly (as a rule, by less than 0.01 – 0.02 Å) from the values obtained by averaging over a large number of experimentally determined bond lengths. These values are often referred to as 'typical' or 'standard' geometric parameters. Some standard lengths of carbon – carbon bonds determined by X-ray diffraction analysis are listed in Table 1.[1–4] The same is true, although to a lesser extent (due to the smaller values of the corresponding force constants), for the bond angles the departure of which from the standard values is normally several degrees. The torsion angles usually vary over broader limits than bond angles; however, in some cases, in particular, for fragments with multiple bonds, these angles are also characteristic parameters.

The standard molecular geometric parameters are fundamental values used in stereochemistry.[5] The invariance of these parameters underlies various types of molecular models and various methods for structure calculation, in particular, molecular mechanics methods.[6]

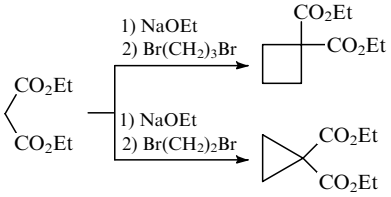
Table 1. Typical (averaged) lengths of some carbon – carbon bonds.

Type of bond	Length /Å
Single bond	
$C(sp^3)-C(sp^3)$	1.53
$C(sp^3)-C(sp^2)$	1.51
$C(sp^3)-C(sp)$	1.47
$C(sp^2)-C(sp^2)$	1.48
$C(sp)-C(sp)$	1.38
Double bond	
$C(sp^2)=C(sp^2)$	1.32
$C(sp^2)=C(sp)$	1.31
$C(sp)=C(sp)$	1.28
Triple bond [a]	
$C(sp)\equiv C(sp)$	1.186

[a] The data of Ref. 4.

Meanwhile, in the molecules of some compounds, the bond (or torsion) angles and the bond lengths sharply deviate from the typical values. The synthesis of such compounds is often stimulated by a chemist's desire to overstep the limits of the existing theoretical views and concepts. A vivid example is the synthesis of four- and three-membered carbocyclic compounds performed successfully by W H Perkin at the end of the XIX century,[7,8] despite the opinion of scholars of authority in those days who considered the synthesis of small rings to be impossible.[9]



A different tendency has been observed in recent years: one can name a number of compounds with appreciably distorted molecular geometry the successful synthesis of which was pre-

ceded by theoretical predictions of their possible existence and calculations of their spectral properties. In any case, synthesis and study of these compounds were favourable for the accumulation of knowledge on the nature of the chemical bond and mechanistic details for reactions of organic compounds.[10] Research along this line has resulted in the development of new original methods of synthesis and experimental techniques which made an invaluable contribution to modern synthetic organic chemistry.[11,12] The non-trivial syntheses of highly deformed molecules, together with many total syntheses of natural compounds,[13] can be regarded as classical achievements of modern chemical science.

What properties are inherent in substances the molecules of which have highly distorted bond lengths and angles? What is the degree of distortion of the molecular geometry of organic compounds that results in a qualitative (discontinuous) change in their properties? What is the maximum attainable degree of distortion of bond lengths and bond (torsion) angles and do calculations reproduce the observed structural characteristics? In this review, we consider the recent publications concerned with these problems.†

The literature on the synthesis and structural studies of compounds with distorted geometric parameters of molecules is very extensive. This review does not claim to be an exhaustive analysis of all these studies; the author's goal was to illustrate the limits of the possible geometric distortions of organic molecules using a number of interesting examples. Among the vast material, studies devoted to 'record-holder' molecules with the greatest distortions of bond lengths and bond and torsion angles either observed experimentally or calculated are discussed. However, structural chemistry is so rapidly developing that any unusual molecule soon loses the record-breaker title.[18]

The review discusses compounds the molecules of which are stable despite substantial distortions of the molecular geometry. The structures of these compounds are studied by physical methods, most often by X-ray diffraction analysis. Therefore, first, it is pertinent to discuss the specific features of the structures of strained molecules which allow them to reach the stability needed to study them by physical methods.

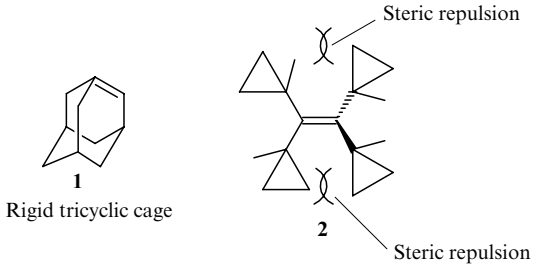
II. Stability of strained molecules

Organic molecules with abnormal geometric parameters possess increased energy. A usual quantitative characteristic of these molecules is strain energy, which is defined as the difference between the experimental standard enthalpy of formation of the molecule and the enthalpy calculated for the 'strainless' (often hypothetical) molecule containing the same number of atoms and the same sequence of bonds between them but no distortion of bond lengths or bond angles and no non-valence intramolecular interactions (for example, steric repulsion).[19] The concept of molecular strain is widely used in chemistry, although it is not exact because the calculation schemes for the enthalpies of formation of strain-free molecules are arbitrary and often different.[20] Therefore, when comparing strain energies, one has to be sure that they have been calculated by the same methods. Normally, calculations involve summation of the strain increments known for the structural fragments present in the molecule.[19]

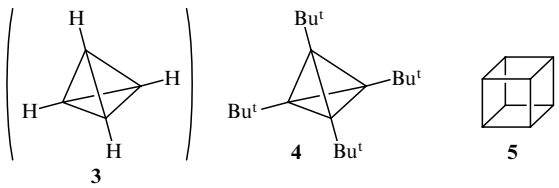
Molecules for which this enthalpy difference is great are referred to as strained. It should be noted that the criteria for regarding one or another structure as strained are quite arbitrary. Even the adamantane molecule with a strain energy of 7.6 kcal mol^{-1} can be regarded as 'strained', although its molecular model seems misleadingly unstrained.[14,15] We shall discuss molecules with strain energies many times exceeding that of adamantane. Such molecules are often reactive and susceptible to intra- and intermolecular reactions which are not typical of strainless analogues. The combination of these properties is associated with the qualitative notion of 'instability', while the factors due to which the chemical transformations of strained molecules can be retarded or entirely avoided are associated with 'stability' of the molecules.

Most highly strained 'record-breaker' compounds known to date exist owing to kinetic stability. Despite the substantial strain energy of the molecules of these compounds, their structures correspond to minima on potential energy surfaces (PES),[21] indicating the possibility of preventing decomposition and relaxation of the geometrically distorted fragments to the unstrained state.

The stability against structural changes that bring a fragment with distorted bonds and angles to the 'normal' state is provided most often by the fact that this fragment is incorporated into a ring or a rigid polycyclic cage. Alternatively, steric repulsion of bulky groups, especially *tert*-butyl substituents, also helps to avoid relaxation of a distorted fragment to an unstrained state.[22] The molecules of compounds **1** and **2** with a twisted double bond can serve as examples of strained molecules having a distorted fragment within a polycycle or bulky groups.



To attain stability of strained molecules, it is necessary to prevent them from entering reactions either with one another (oligomerisation, polymerisation) or with other potential reactants (solvents, oxygen, moisture, *etc.*). These reactions can be prevented by creating steric restrictions around the reaction centres. For example, tetrahedrane **3** is so reactive that it has not been prepared until now, in spite of considerable effort,‡ whereas tetra-*tert*-butyltetrahedrane (**4**), in which the strained C_4 core is shielded, has been isolated and studied, in particular, by X-ray diffraction analysis.



The instability of strained molecules is also related to their tendency to undergo intramolecular rearrangements. Kinetic stability due to electronic factors is an effective method for preventing these rearrangements. A classical example is cubane (**5**) in which the possible rearrangement pathways are forbidden by the orbital symmetry rules. The strain energy of molecule **5** is very high (157 kcal mol^{-1}; determined using data on the heat of

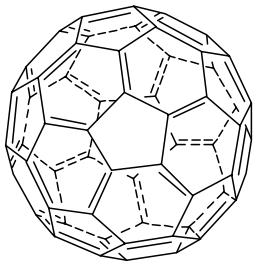
† This review covers studies published before the beginning of 2001. Analysis of publications on this topic up to mid-1970s was carried out by Greenberg and Liebman.[14,15] The publications for this review were collected using the STN electronic databases (Scientific Technical Network,[16] first of all, the REGISTRY database, which contains information on more than 18 000 000 organic and inorganic compounds), *Chemical Abstracts* and *Beilstein* as well as the Cambridge Structural Database (CSDB; the version of April 2001 presents structural information on more than 233 000 compounds).[17]

‡ From here on, the formulae of compounds not obtained experimentally are drawn in parentheses.

combustion of cubane [23]);§ however, cubane does not decompose even at temperatures above the melting point (130–131 °C).[26]

The strain energy of compound **5**, as well as that for other molecules described below, is markedly higher than that required for rupture of the C–C bond. However, the stability of cubane is secured by even distribution of the steric strain over the whole carbon skeleton.

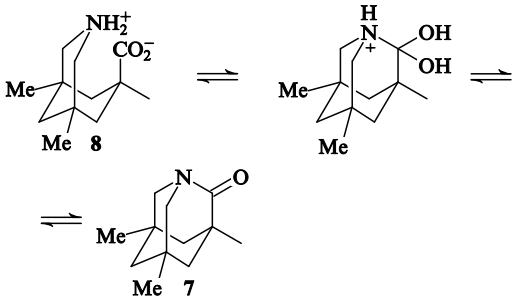
The exceptionally stable C_{60} fullerene (**6**) in the molecule of which strain is uniformly distributed over all the 90 carbon–carbon bonds can serve as yet another example of stable but very strained molecules. The heats of combustion of C_{60} and C_{70} fullerenes and their standard enthalpies of formation, which can be used to estimate the strain energy, have been determined experimentally.[27]



6

In some cases, the concept of thermodynamic stability of strained molecules is discussed but this term is often used improperly. For example, it has been claimed [28] that coordination of a metal atom to a distorted fragment can ensure 'thermodynamic stability' of strained ligands, in particular, *trans*-cycloalkenes. The overlap of molecular π orbitals of a strained alkene with the vacant orbitals of the transition metal and interaction of the occupied *d* orbitals of the metal with the π* orbital of the double bond (dative bond) finally stabilise the complex. However, in our opinion, this is a case of kinetic stability. Thermodynamic stability implies reversible transformations, for example, those between a complex with a ligand containing a distorted structural fragment and a complex with a strain-free analogue of the same ligand. Most transformations of strained molecules are irreversible; therefore, their thermodynamic stability is seldom encountered.

An example is provided by compound **7**, stable in methanol.[29] The driving force of the spontaneous formation of compound **7**, the molecule of which contains a strained twisted amide fragment, in equilibrium with zwitter-ion **8** is the steric strain in the bicyclic system, which decreases upon cyclisation.



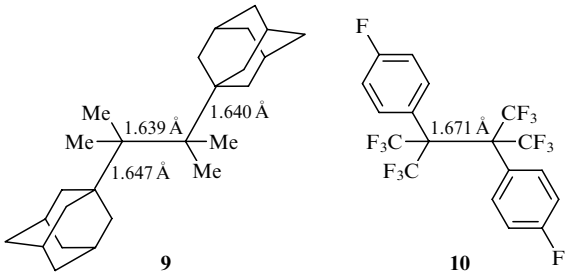
It makes sense to discuss the stability of a compound when conditions for its isolation or investigation are known. For example, a large number of compounds unstable at room temperature have been studied in inert matrices at 4–77 K.[30] Low-temperature isolation in solid matrices of inert gases prevents diffusion and, hence, excludes intermolecular reactions of the compounds under study. Moreover, intramolecular transformations, even those having an energy barrier of only several calories per mole are also retarded.[31]

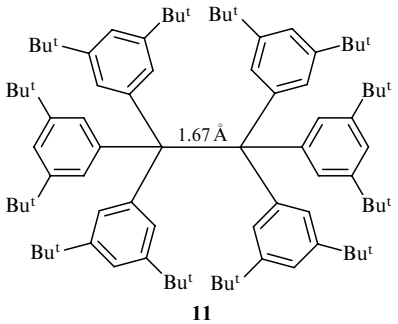
One more method that provides a sufficient (in particular, for spectroscopic studies at room temperature) lifetime of reactive species should also be mentioned, namely, preparation of these species inside cavities of large macromolecules — carcerands and hemicarcerands. In recent years, several studies have been published (see below) devoted to spectroscopic and chemical properties of compounds the isolation and investigation of which at room temperature could not even be discussed before the advent of this method, for example, cyclobutadiene and dehydrobenzene.[32]

III. Abnormally long and short C–C bonds

The characteristic lengths of C–C, C=C and C≡C bonds (see Table 1) can be regarded as fundamental parameters in chemistry. Deviations from 'normal' values are seldom encountered, and they serve as an indicator for the occurrence of steric or electronic effects.

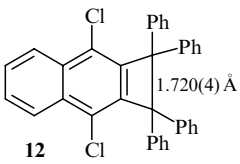
The quest for the longest $C(sp^3)-C(sp^3)$ bond has been called a 'real Odyssey.' [33] Considerable attention was devoted to hexaalkyl- and hexaarylethanes such as **9**–**11**,[34–36] in the molecules of which the central C–C bond is longer than 1.64 Å.

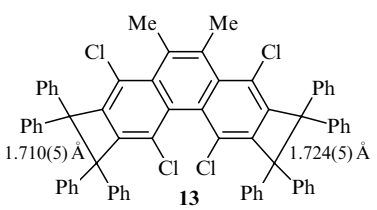




The main cause for bond elongation is steric repulsion between bulky groups. The elongated bonds are weakened, which accounts for the thermal instability of these hydrocarbons.[34] In the case of compound **9**, molecular mechanics (MM2) calculations¶ for the molecular geometry were carried out and good agreement between experimental and calculated values was obtained.

In 1996, Toda *et al.*[37] have reported exceptionally long C–C bonds in two benzocyclobutane derivatives, **12** (1.720 Å) and **13** (1.710 and 1.724 Å).

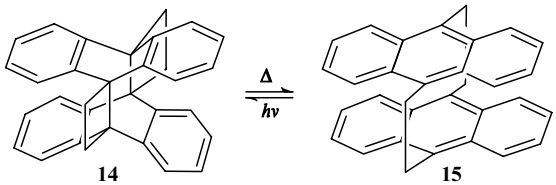




§ These data are somewhat outdated; however, more precise values have not yet been reported. The strain energy of the cubane molecule presented here is consistent with rough values determined from the heats of combustion of various cubane derivatives and with calculated values.[24, 25]

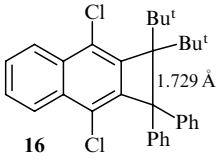
¶ Most of the calculation methods mentioned in the review are described in a book by Jensen.[21]

These values are almost 0.18 Å greater than the standard length of a single carbon–carbon bond; therefore, it is not surprising that some doubts have been cast upon the X-ray diffraction data published. Before the study by Toda *et al.*,[37] examples of compounds with even longer C–C bonds had been reported; however, a thorough verification showed the results of structural studies of these compounds to be incorrect. Thus the lengths of the central bonds in the molecule of compound **14**, a photoisomer of [2.2]tetrabenzoparacyclophane **15**, have been reported [38] to be 1.77 Å. Later, it was found that the measurements were carried out for a mixture of the photoisomers **14** and **15** rather than for a crystal of pure **14**.[39] In subsequent studies of a pure sample of **14** at 170 K, the lengths of the central bonds were found to be 1.648 Å.[40]



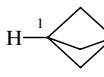
14 **15**

Repeated studies [41] of the compound **12** have confirmed, nevertheless, the validity of the previously obtained data,[37] and quantum-chemical calculations (B3LYP/6-31G*) reproduced them satisfactorily.[42] Model calculations [B3LYP/DZ(2d,p)] for the 1,1,2,2-tetraphenylbenzocyclobutene molecule also provided a Ph_2C-CPh_2 bond length consistent with the value found experimentally [37] in compound **12**. These calculations demonstrated the importance of taking into account the electron correlation in order to obtain correct values for geometric parameters of the strained molecules. It was also shown [41] that satisfactory interpretation of the observed elongation of the C–C bond requires that only steric effects (repulsion between bulky groups) be taken into account without considering hyperconjugation effects.[43] This conclusion is also confirmed by recently published data on the synthesis and X-ray diffraction analysis of the even more sterically hindered compound **16**.[44,45] The C–C bond length in the four-membered ring of **16** equals 1.729 Å, *i.e.*, it is longer than those in the molecules **12** and **13**.

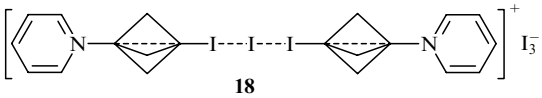


16

The distance between the carbon atoms formally not bound to each other in bicyclo[1.1.1]pentane (**17**) and its derivatives is close to the lengths of the 'stretched' C–C bonds given above. The C(1)–C(3) distance in this simple hydrocarbon measured by electron diffraction [46] is 1.874 Å (or 1.845 Å according to another publication [47]). The search through the CSDB for the shortest C(1)–C(3) distance among the bicyclo[1.1.1]pentane derivatives gave a value of 1.80 Å in bis(3-iodobicyclo[1.1.1]pentan-1-ylpyridinium)iodide triiodide **18**.[48] In this case, the X-ray diffraction data can best be interpreted by assuming that structures containing [1.1.1]propellane contribute to the resonance hybrid. In the molecules of bicyclo[1.1.1]pentane derivatives, the non-bonded bridging carbon atoms are so close to each other that the 'through-space' electronic interaction is clearly identified.[49]



17

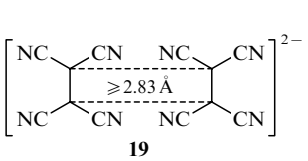


18

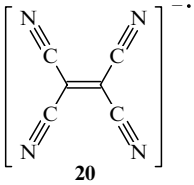
The above-mentioned studies raise the question of what is the longest distance between carbon atoms in a molecule that enable the existence of a chemical bond between them.

Proceeding from the empirical definition of the chemical bond † proposed by Pauling [50] without restricting the consideration to saturated systems, one can find examples of structures with formal C–C bonds longer than 1.729 Å, which is the value established for molecule **16**.

For example, a distance between carbon atoms equal to 2.83 Å has been found recently in the crystal of dimer **19**, formed by two tetracyanoethylene radical anions (**20**). Nevertheless, the results of structural, magnetic, and spectroscopic studies are consistent with the existence of a chemical bond between them.[51] This two-electron four-centre bond results from the π–π binding interaction between the radical anions **20** and the Coulomb repulsion between them. It was shown that the dimers are metastable species, *i.e.*, their formation is an endothermic process; in the solid phase, they can be stabilised upon interaction with metal cations.



19



20

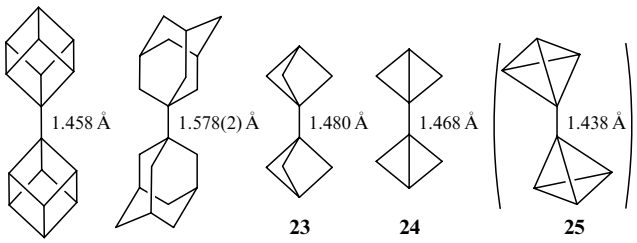
Apparently, it is impossible to establish the limiting bond length of any type on the basis of merely geometric criteria such as 'longer (or shorter) than..'; it is necessary to invoke conceptual models of chemical binding including new ones. Some new approaches to the determination of the nature of the chemical bond could be provided by Bader's theory.[52] This theory is based on the mathematical analysis of topological characteristics of the total molecular electron density function either found experimentally or calculated. In terms of this theory, it is possible to give strict criteria for the occurrence of a bonding interaction between a pair of atoms, irrespective of the distance between them.

A number of studies have been devoted to the search for strained molecules with short carbon – carbon single bonds. For example, the length of the exocyclic bond in bicubane **21** was found to be 1.458 Å,[53] which was explained by rehybridisation of the carbon orbitals. The exocyclic bonds in cubane have a greater *s*-character and, therefore, they are shorter than the standard $C(sp^3)-C(sp^3)$ bonds. The steric strain that could result in elongation of the central C–C bond in compound **21** is insignificant, unlike that in the molecule of 1,1′-biadamantane **22** (the length of the central bond in **22** is 1.578 Å [54]).

The central bond in bicubane can be compared with that in butadiene, the length of which is 1.383 Å, according to electron diffraction data;[55] however, in the latter compound, this bond is further shortened due to conjugation.

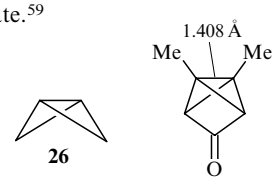
Schleyer and Bremer [56] not only compared the experimental and calculated (MNDO, MP2/3-21G, 6-31G*) lengths of the central bonds in molecules **23**–**25**, similar to the bicubane molecule, but also carried out model calculations for ethane (MP2/3-21G) with variation of the C–C–H bond angle. It was shown that an increase in this angle to 150° entails energy redistribution between molecular orbitals, resulting in strengthening of the C–C bond. The calculated (MP2/6-31G*) length of the C–C central bond in bitetrahedrane **25** is 1.438 Å. The compound **25** has not yet been synthesised; however, Ermer *et al.*[57] believe that the hexa-*tert*-butyl derivative of this compound could be prepared.

† According to Pauling, '... there is a chemical bond between two atoms or groups of atoms in the case that the forces acting between them are such as to lead to an aggregate with sufficient stability to make it convenient for the chemist to consider it as an independent molecular species.'



21 **22** **23** **24** **25**

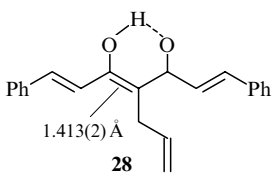
The angle strain in the cyclopropane molecule is known to result in shortening of the formally single C–C bonds (1.499 Å).[58] In the bicyclobutane (**26**) molecule, which is the smallest one among the molecules of bicyclic hydrocarbons, two cyclopropane rings are fused; the central C–C bond exhibits properties of the double bond (for example, electrophilic reagents readily add at this bond to give cyclobutane derivatives) and is abnormally short (1.497 Å). X-Ray diffraction study of bicyclobutane derivatives showed that the length of the central bond depends on the angle between the planes of the three-membered rings. In the compound **26**, this angle is ~122.7°, while in its derivatives **27**, this angle is much smaller (~87°) and the C(1)–C(3) bond is much shortened (1.408 Å), *i.e.*, this is one of the shortest single bonds known to date.[59]



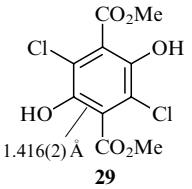
26 **27**

IV. Elongated and shortened C=C bonds

Analysis of the structures deposited in the CSDB shows that abnormally long formally double C=C bonds are found in systems containing long chains of conjugation (see, for example, compound **28**).[60] In aromatic derivatives (see, for example, compound **29**),[61] the C=C bonds can also be elongated. The shortest formally double carbon – carbon bonds have been found in a number of strained molecules (for example, in molecule **30**).[62] Exceptionally long carbon – carbon double bonds have also been found in twisted alkenes. The elongation of these bonds is due to a decrease in the degree of π-bonding.

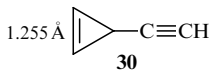


28

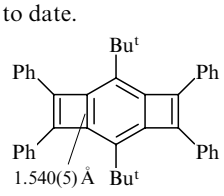


29

Let us consider the compounds the molecules of which incorporate the shortest (**30**) and the longest (**31**)[63] $C(sp^2)=C(sp^2)$ bonds known to date.



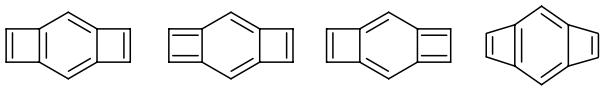
30



31

The length of the double bond in ethynylcyclopropene **30** is approximately an average between the bond lengths found in strain-free alkene and alkyne molecules — 1.255 Å. Even very high-level calculations provide overestimated lengths for the C=C bond in this molecule.[62]

Ab initio (HF/3-21G, 6-31G*) calculations for benzo[1,2:4,5]-dicyclobutene **32** predicted[64] two types of isomerism, one type being due to different bond lengths (**32a** and **32b**, **32c**) and the other type being due to different positions of the double bonds (**32b** and **32c**). X-Ray diffraction analysis[63] of the compound **31** did not confirm the results of calculations reported earlier.[64] The structural parameters found experimentally for **31** and those determined by quantum-chemical calculations for the hydrocarbon **32** (B3LYP/6-31G*, MP2/6-31G*) correspond to the structure **32d** with elongated bonds in the benzene ring. However, it should be emphasised that in this case, we are dealing with aromatic bonds rather than purely double bonds (as in alkenes).



32a **32b** **32c** **32d**

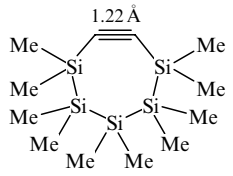
V. Variations of the triple carbon – carbon bond lengths in organic compounds

The deviations of the lengths of triple carbon – carbon bonds in organic compounds from typical values are less pronounced than similar deviations in the case of single or double bonds. For example, according to analysis of the CSDB data,[4] the difference in the C≡C bond lengths in acetylene and its alkyl derivatives is less than 0.05 Å.

It is noteworthy that triple bond lengths determined by electron or neutron diffraction are often greater than those found by the conventional X-ray diffraction technique for the same compound (the difference can reach 0.02 Å or even more). This is due to the fact that X-rays are scattered by the electron density of the object and the electron density maxima (centroids) identified as 'atoms' in the X-ray diffraction method do not always coincide with the positions of the atomic nuclei. The electron density maxima can be displaced towards each other in the case of high concentration of the electron density in the interatomic space, which is often the case for multiple bonds including triple bonds. However, in modern X-ray diffraction software packages, this effect can easily be taken into account. Nevertheless, statistic analysis covering only those parameters in the CSDB which have been determined by electron diffraction in the gas phase results in an even smaller scatter of the C≡C bond lengths, namely, 0.012 Å.[4]

As a rule, elongation or shortening of triple bonds is mainly due to electronic factors. For example, this bond is shorter in the molecules of acetylene derivatives containing electron-withdrawing substituents at the triple bond.[65] (Note that this is equally true for double carbon – carbon bonds.) Elongated C≡C bonds have been found in conjugated systems, for example, in butadiyne[55] [1.2176(6) Å], although the lengths of these bonds in vinylacetylene and propynal molecules exceed only slightly the average value. The steric factors in linear alkynes in which substituents at the C≡C bond are far from each other are minimised.

It can be suggested that the loss of π-bonding caused by bending of the X–C≡C–X fragment (X is any substituent) in cycloalkynes would result in elongation of the triple bond. Nevertheless, in most of the known strained molecules of cycloalkynes, the length of the triple bond is close to the typical value. For example, in compound **33**, despite the substantial bending of the Si–C≡C–Si fragment, the C≡C bond length is equal to 1.22 Å, which virtually coincides with the average value (1.201 Å) for silyl-substituted alkynes.[66]



33

VI. Distortions of bond angles at the tetrahedral carbon atom

The modern theory of the structure of carbon compounds is underlain by the hypothesis advanced independently by Van't Hoff [67] and LeBel [68] in 1874 stating that a tetracoordinated carbon atom has a tetrahedral or a nearly tetrahedral configuration. Later, the results of numerous studies including X-ray diffraction analysis have confirmed Van't Hoff's and LeBel's hypothesis based on empirical data, and the sp^3-hybridisation concept has explained simply and conveniently the stability of the tetrahedral configuration. However, as soon as somewhat more than a decade after the publication,[67, 68] Baeyer, who considered distortions of the tetrahedral configuration of the carbon atom, stated the foundations of strain theory.[69]

The types of distortion of bond angles at the sp^3-hybridised carbon atom are illustrated in Fig. 1. First of all, this is a decrease/increase in one bond angle (the angle between the other two bonds usually correspondingly increases/decreases; this is the so-called scissors distortion) as well as distortions leading to flattening of the carbon configuration, *i.e.*, tetrahedral compression and digonal twist. Special mention should be made of configurations in which all atoms attached to a given carbon atom are located on one side of the plane passing through it, namely, inverted and pyramidal configurations to which an umbrella-type distortion leads. Rigorous mathematical analysis of the disortions of the CX_4 fragment has been reported.[70–72]

It should be noted that in experimental or theoretical study of the electron density distribution in the molecules characterised by highly distorted bond angles at carbon atoms, the regions of increased electron density between the atoms ‡ do not lie on the straight lines connecting the atomic nuclei but are displaced from these lines. These bonds have been referred to as curved (banana) bonds; a classic example of these bonds is found in the cyclopropane molecule. The displacement of the maxima of DED (covalent electron density) outwards the ring in cyclopropane derivatives reaches 0.2 Å or more. An even greater shift of the DED maxima away from the internuclear lines, up to 0.5 Å, was found in tetrahedrane derivatives. Banana bonds are found not only in the molecules with small rings but also in highly strained cage systems.[74]

Subsequently, in particular in the analysis of structural data for cyclic and strained cage molecules, the notion of bond path was defined as the interatomic line along which the total electron density is a maximum relative to any 'lateral' displacement and has a minimum in the so-called saddle point.[52, 73–75] A bond path is not necessarily a straight line; the presence of this line implies a chemical bond between the given atoms.[76] These and some other definitions constitute the foundation of the modern quantum theory of interatomic interactions and chemical bonding, developed by Bader.[52]

In Bader's theory, the bond path angle at an atom is determined by the angle between the tangents to two neighbouring bond paths. In strained molecules, the bond paths are curved, as indicated above. In particular, in a cyclopropane molecule, the bond path angle is ~78.8° rather than 60°, which has been confirmed by a number of X-ray diffraction studies of the electron density distribution in this type of system. Therefore, in the case of strained molecules, it would be more appropriate to discuss the bond path angles.

‡ Normally, this is so-called deformation electron density (DED), which characterises the difference between the electron density of the molecule and that calculated as a sum of the electron densities of isolated spherical atoms located at the same distance from each other.[73]

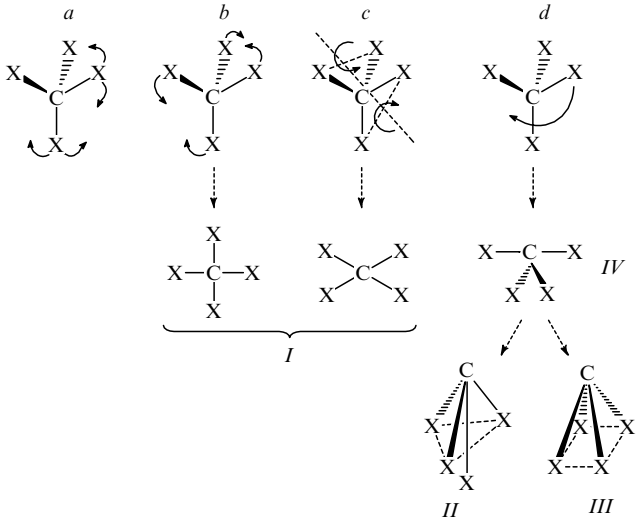


Figure 1. Distortions of bond angles at the tetrahedral carbon atom: scissors (*a*), tetrahedral compression (*b*), digonal twist (*c*), umbrella (*d*). Carbon atom configuration: (*I*) planar, (*II*) inverted, (*III*) pyramidal, (*IV*) intermediate between the tetrahedral and pyramidal.

A number of publications have been devoted to the study of electron density distribution in organic molecules. In these studies, the term 'bond angle' is used to imply the angle between the bond paths and not between the straight lines connecting the atomic nuclei. However, the vast majority of structural studies discuss the angles between the internuclear straight lines. Therefore, in this review, we also consider the latter type of angle unless otherwise indicated.

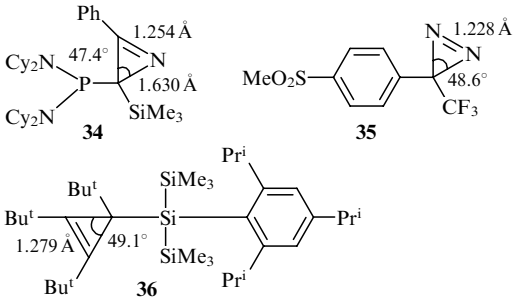
It should be noted that the Bader's topological approach and definition, in terms of its rigorous theory, of the bond path and some other key concepts of the molecular structure theory are drawing increasing attention of researchers. In particular, the classical term 'bond length' (the distance between the nuclei) is replaced in this theory by the notion of 'bond path length.' In the case of a strained molecule, the bond path length would naturally be longer than the internuclear distance. For example, in the cyclopropane molecule, the distance between the carbon nuclei (bond length) is 1.499 Å,[77] and the bond path length between them is ~1.53 Å, *i.e.*, it is nearly equal to the typical C–C bond length (see Table 1). An even greater inconsistency between the internuclear distances and the bond path lengths is found for cage systems, in particular, for icosahedral carboranes.[78]

1. Scissors type distortion: a decrease in the C–C–C bond angle

A considerable decrease in the C–C–C bond angle is found in molecules of cyclic compounds with small rings. A lot of information on the methods of synthesis and properties of these compounds has been accumulated to date. Many fundamental theoretical concepts, for example, the concept of steric strain and banana bonds, have been developed upon investigations of molecules with three- or four-membered carbocycles.[14, 26, 79–81] We shall consider several prominent examples of research along this line.

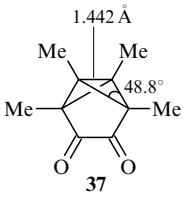
In the CSDB, we found eighteen structures with a bond angle at a saturated carbon atom smaller than 50°. The molecules of these compounds contain three-membered rings, and most of them contain multiple bonds in the rings. The smallest A–C–A angles (A is any atom) are typical of compounds with C=N and

N=N bonds in the three-membered rings. In compounds **34**[82] and **35**,[83] the angle at the saturated carbon atom is somewhat smaller than that in cyclopropene derivatives (for example, in compound **36**).[84] This is due to the fact that the C=N or N=N double bonds are shorter than the C=C bond, and the C−N single bonds are longer than the C−C bonds in cyclopropane (the C−C bond length in cyclopropane is 1.499 Å).[77] Both factors result in a decrease in the angle between the single bonds in unsaturated three-membered heterocycles.



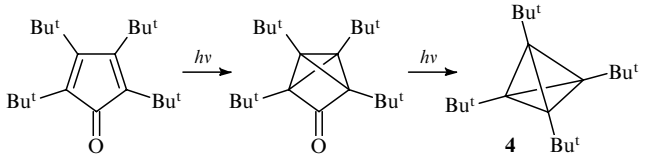
Cy is cyclohexyl.

Among the compounds containing saturated three-membered carbon rings with reduced C−C−C angles, bicyclobutane derivative **37** should be mentioned.[85] In the molecule of this compound, the bond between the bridging carbon atoms is shortened and, therefore, the opposing C−C−C angle in the three-membered rings is reduced.



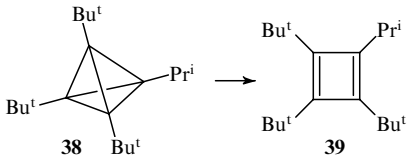
Compounds with reduced bond angles at saturated carbon atoms exhibit unusual reactivity due to the strain in their molecules. As an example, we shall consider derivatives of a hydrocarbon which has not yet been synthesised, tetrahedrane **3**.

Ab initio quantum-chemical calculations of different levels (SCF/4-31G,[86] G2 [87]) give a strain energy of 129–137 kcal mol^{-1} for the unsubstituted tetrahedrane molecule. This value is greater than the dissociation energy of a single C−C bond (72–117 kcal mol^{-1})[88] and exceeds (in relation to one carbon atom) the molecular strain in other hydrocarbons studied to date. It is not surprising that numerous early attempts to synthesise tetrahedrane and its derivatives have failed.[14, 89, 90] Only in 1978, did Maier *et al.*[91] synthesise the first tetrahedrane derivative, tetra-*tert*-butyltetrahedrane **4**, by photochemical transformations of tetra-*tert*-butylcyclopentadienone.



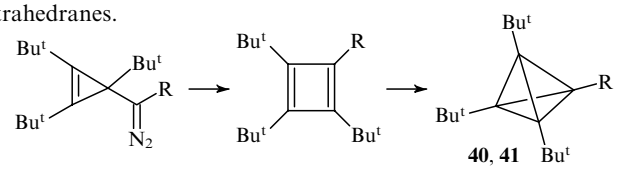
The seeming simplicity of the reaction scheme conceals great efforts of researchers aimed at selecting the optimal conditions for the preparation of a compound the possibility of isolation of which seemed unlikely at that time. The compound **4** is a stable crystalline substance isomerising into tetra-*tert*-butylcyclobutadiene only at 130 °C. Stability is attained owing to the presence of bulky *tert*-butyl substituents, which ensure the steric shielding (so-called 'corset effect') of the central strained fragment of the molecule by shielding it from the attack by reagents and preventing intramolecular rearrangements. The *tert*-butyl groups in the molecule **4** are remote from each other as far as possible but in the transformations of compound **4**, they approach each other, which results inevitably in an increase in the strain energy.

Tri-*tert*-butylisopropyltetrahedrane (**38**) proved to be much less stable than the compound **4**: its thermal isomerisation to cyclobutadiene **39** proceeds over several minutes at 80 °C.[92]



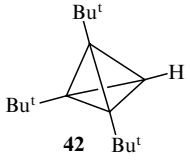
For a long period, researchers did not succeed in preparing other tetrahedrane derivatives.

It was another 10 years after the synthesis of **4** before a new derivative was prepared; this was tri-*tert*-butyl(trimethylsilyl)tetrahedrane (**40**).[93, 94] The approach to substituted cyclopropenyldiazomethane proposed by Masamune *et al.*[95] permitted Maier and co-workers to prepare other silyl- [96] and alkyl-substituted [92] tetrahedranes.



R = $SiMe_3$ (**40**), $SiMe_2OPr^i$ (**41**).

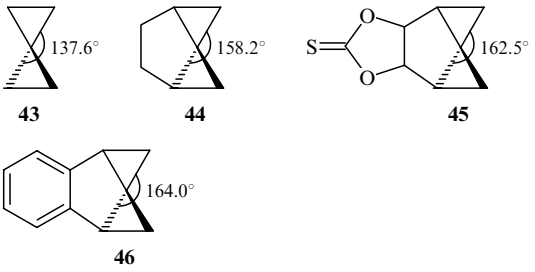
The reaction of compound **41** with the fluoride ion affords highly reactive trisubstituted tetrahedrane **42**.[96]



X-Ray diffraction data for the compound **4** showed that the C−C bond length in it (1.485 Å)[97] is shorter than the typical value (1.53 Å) and is even shorter than the C−C bond length in cyclopropane (1.499 Å).[77] This is due to rehybridisation of the cage atoms and bond bending. Early molecular mechanics calculations (MM2) showed that, due to the steric repulsion of the *tert*-butyl groups, the chiral structure (group of symmetry T) is energetically more favourable (by 2–6 kcal mol^{-1}) than the achiral structure (T_d).[98] This conclusion was confirmed by *ab initio* quantum-chemical calculations [B3LYP/6-311+G(d)//B3LYP/6-31G(d)].[99] The difference between the energies of these forms was 0.5–2.0 kcal mol^{-1}. The chemical properties of the compound **4** have also been studied. Besides the above-mentioned thermal rearrangement of the substituted tetrahedrane **4** into tetra-*tert*-butylcyclobutadiene, protonation with gaseous HCl and oxidation into the corresponding radical cation are known.[100]

2. Scissors type distortion: an increase in the C−C−C bond angle

Increased bond angles in the molecules with tetrahedral carbon atoms are observed, naturally, in the same cases where substantially reduced bond angles are found. For example, in the tetra-*tert*-butyltetrahedrane molecule discussed in the preceding Section, the angles between the exocyclic bonds and the bonds in the tetrahedral cage are 144.7 °, according to X-ray diffraction data.[97] A search through the CSDB provided examples of structures with even larger C−C−C angles. The vast majority of these compounds are spiropentane (**43**) or bicyclobutane (**26**) derivatives. According to X-ray diffraction analysis, the bond angles at the spiro carbon atom in the spiropentane molecule amount to 137.6 ° and 136.7 °.[101] The largest C−C−C bond angles were found in bridged derivatives of **43** — molecules **44**–**46** (the greater of the two increased bond angles is given for each molecule).[102]

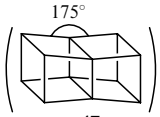


43 **44** **45**

46

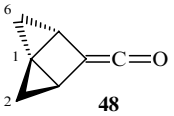
Analysis of DED maps for spiropentane and its derivatives has been carried out.[101] In all cases, substantial exocyclic dispacement of DED maxima in the planes of the three-membered rings was found.

An increase in one bond angle at the tetracoordinated carbon atom to 180° would result in a configuration intermediate between the tetrahedral and pyramidal ones (see Fig. 1 *d*). The carbon atoms in dicubane **47** may have a similar configuration. The possibility of synthesis of dicubane has been discussed.[103] The C−C−C bond angle in this molecule was calculated to be ~175°.



47

According to calculations (MP2/6-31-G*, HF/6-31G*),[104] a carbon configuration with a C(2)−C(1)−C(6) angle of ~180° is also possible in the molecule of compound **48**.



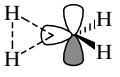
48

This highly reactive tricyclo[3.1.0.0^{1,3}]hexane derivative was detected by IR spectroscopy in an inert matrix at 15 K.[105]

3. Planar configuration of a tetracoordinated carbon atom

In recent years, researchers have devoted particular attention to types of distortion such as tetrahedral compression and digonal twist, resulting in a flattened CX_4 fragment.[106–110]

The search for compounds with such an unusual structure was stimulated by a publication by Hoffmann *et al.*,[111] in which the molecular orbitals in a hypothetical planar methane molecule were analysed and suggestions were made about possible ways of stabilisation of the planar configuration of carbon. According to qualitative analysis of the electronic structure of the planar methane molecule, the carbon atom in this molecule should be sp^2-hybridised. This atom should have two electrons in a non-hybridised *p* orbital and should form two two-electron two-centre C−H bonds and one two-electron three-centre H···C···H bond.



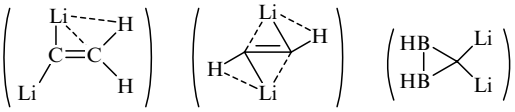
The strain energy of this molecule substantially exceeds the C−H bond dissociation energy; the energy difference (MP2/6-31-G*//6-31G*) between the tetrahedral (T_d) and planar (D_{4h}) methane configurations amounts to 159.7 kcal mol^{-1}. The possibility of existence of the planar structure, even as the transition state in the methane inversion, has been called in question.[112] Calculations[113] [MCSCF/6-31G(d,p), 6-31+G(d,p), TZV++G(d,p)] showed that the planar structure with D_{4h} symmetry does not match any minimum on the PES, whereas the planar structure with C_s symmetry corresponds to a saddle point on the PES. A molecule with this symmetry could represent a transition state formed in the methane inversion: its energy is almost 40 kcal mol^{-1} lower than the energy of the molecule with D_{4h} symmetry (nevertheless, its strain energy is still greater than the energy of C−H bond rupture by 7 kcal mol^{-1}). The same conclusion has also been drawn by other researchers,[114] who used extended basis sets [6-311+G(3df,2p), 6-311G*] to analyse the problem of methane inversion.

Hoffmann *et al.*[111] were the first to consider stabilisation factors of a planar configuration of the formally tetracoordinated carbon atom. One of these factors is electronic stabilisation caused by substituents exhibiting σ-donor and/or π-acceptor properties; the former provide the deficient σ-electron density, while the latter delocalise the increased π-electron density. Delocalisation of the lone electron density of the carbon atom with a planar configuration in the $(4n+2\pi)$-system should also facilitate stabilisation.

The idea of electronic stabilisation has been further extended by Schleyer and coworkers,[115] who found by RHF/STO-3G calculations that the energy of 1,1-dilithiocyclopropane molecule with a planar carbon (**49a**) is lower by 7 kcal mol^{-1} than the energy of the corresponding molecule with the tetrahedral carbon configuration (**49b**).

49a **49b**

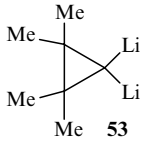
Later, Sorger and Schleyer[110] made calculations for a number of molecules that may have a planar configuration of a tetracaroordinated carbon atom stabilised by σ-donor and/or π-acceptor substituents. These include, for example, 1,1- and 1,2-dilithioethylenes (**50** and **51**, respectively) and 3,3-dilithio-1,2-diboracyclopropane (**52**).



50 **51** **52**

According to calculations (B3LYP/6-31G*), for the last-mentioned compound, the energy of the molecule with a planar carbon configuration is 18.7 kcal mol^{-1} lower than that in the case of tetrahedral configuration.

1,1-Dilithio-2,2,3,3-tetramethylcyclopropane (**53**) has been synthesised;[116] however, its structure has not been determined. The structural studies for this type of compound are complicated by the high degree of aggregation.



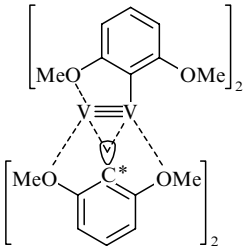
53

Spectroscopic detection of the $[CAl_4]^{2-}$ dianion has been reported.[117] It was suggested that the planar (according to B3LYP/6-311+G* calculations) $[CAl_4]^{2-}$ dianion can be stabilised in the solid phase by an appropriate counter-ion, for example, Na^+.

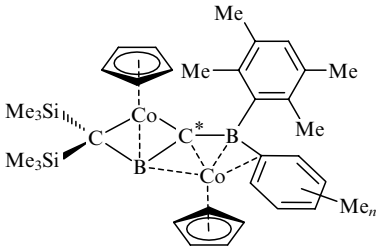
Organometallic compounds of transition metals the molecules of which contain a tetracoordinated carbon atom with a planar configuration are also known. Complex **54** was the first crystallographically characterised compound of this type.

It is of interest that only two years after the publication of the paper by Cotton and Millar[118] reporting the structural data for complex **54**, Keese *et al.*[119] noticed the unusual planar environment of the carbon atom (marked by an asterisk) in this compound. Quite a few other complexes of this type are also known;[107] however, the mechanisms of stabilisation of the planar configuration of the carbon atom in them are different.[108] In most of the molecules, the carbon atom under interest is a part of an unsaturated (often, aromatic) system, which is an additional stabilising factor. Molecules in which a tetracoordinated carbon

atom with a sum of bond angles equal to ~360° is stabilised only by σ-donor and π-acceptor substituents (as has initially been suggested for planar methane analogues) are found rather rarely; among them, compounds **55**, **56** were the first to be characterised and studied [108] (the carbon atom having a planar configuration is marked by an asterisk).



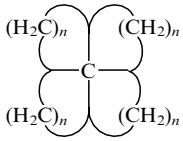
54



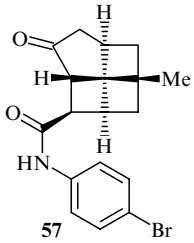
n = 4 (**55**), 3 (**56**)

Stabilisation of a planar methane molecule can be attained by oxidation to give a mono- or di-cation. As shown by calculations [ST4CCD/6-311 + G(2df,2p)],[120] the carbon atom in CH_4^{2+} has a planar environment (the symmetry group is C_{2v} rather than D_{4h}). This cation has been detected experimentally in mass spectra.[121]

The attempts to synthesise compounds in which the carbon atom with a planar configuration would be embedded into a rigid carbon cage have not yet been crowned with success. Hoffmann *et al.*[111] suggested that this type of carbon atom could exist in [*n.n.n.n*]fenestranes



Numerous studies have been devoted to the synthesis of fenestranes; elegant strategies for their synthesis have been developed.[106] However, fenestranes with *trans*-fused five- and four-membered rings (the case in which the greatest distortions of the bond angles at the central carbon atom are expected) have not yet been obtained. Of the fenestranes studied by X-ray diffraction analysis, the greatest distortion has been found in the molecule of [4.4.4.5]fenestrane derivative **57**,[122] in which the opposing bond angles at the central carbon atom are 128° and 129°.

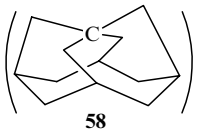


57

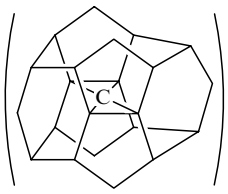
A highly distorted tetrahedral, although still not perfectly planar, configuration of the central carbon atom is also expected in the hypothetical structure **58**, which was called bowlane; initially, a pyramidal configuration of the central carbon atom was suggested for this compound.[123]

Ab initio calculations (HF/6-31G*) have shown [124] that the bowlane molecule should have C_{2v} symmetry and a distorted tetrahedral configuration of the central carbon atom with maximum sizes of the opposing angles at this atom of 170.9° and 148.1°. The predicted strain energy of the molecule **58** (RMP2/6-31G*, 166 kcal mol^{-1}) is approximately the same as that found experimentally for cubane (157–181 kcal mol^{-1});[23] therefore, the synthesis of bowlane appears quite possible.[125] However, it is beyond doubt that the reactivity of the distorted CC_4 fragment accessible to attack by reagents from outside would hamper the synthesis. Even in the case of [4.4.4.5]fenestranes (in which the distortion of this fragment is less pronounced), the reactivity is still rather high. Many thermal and photochemical reactions of [4.4.4.5]fenestranes proceed with cleavage of the bonds at the central carbon atom.[126]

The first and not yet synthesised neutral saturated hydrocarbon with a predicted perfectly planar configuration of the carbon atom the structure of which corresponds to a minimum on the PES is dimethanospiro[2.2]octaplane (**59**).



58



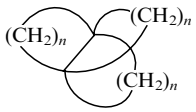
59

The MP2/6-31G(d) calculations predict for the compound **59** a structure with D_{2h} symmetry and a perfect planar configuration of the central carbon atom.[127,128] The highest occupied molecular orbital in **59** is represented by the *p* orbital of the central atom with a lone electron pair. Unusual physical properties of the octaplane **59** were predicted, in particular, a low ionisation potential (~5 eV) comparable with those of alkali metals. In this compound, the planar carbon atom is shielded by the hydrocarbon cage, which may decrease the reactivity.

4. The inverted and pyramidal configurations of the tetracoordinated carbon atom

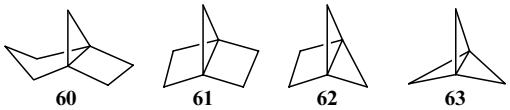
Now we shall consider examples of molecules containing a carbon atom with bonds located on one side of the plane that passes through this atom (see Fig. 1 *b*,*c*). Inverted and pyramidal configurations should be distinguished.[123,129] The inversion means that one bond of the carbon atom points to a direction opposite to its direction in the tetrahedral configuration, resulting in a fragment with C_{3v} symmetry (see Fig. 1 *b*). In the pyramidal CX_4 fragment, the carbon atom occupies a vertex of a tetragonal pyramid with C_{4v} symmetry (see Fig. 1 *c*).

The existence of inverted configurations was first discussed in relation to propellanes, *i.e.*, structures in which two bonded carbon atoms are additionally connected by three bridges.

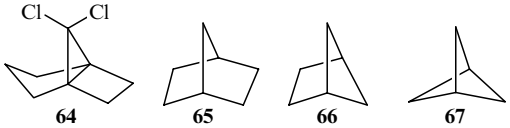


[*n*, *n*, *n*]propellanes

The first representative of small-ring propellanes, [3.2.1]propellane (**60**), was synthesised in 1969.[130] At about the same time, discussion concerning the inverted configuration of the carbon atom was initiated. It was suggested that in small-ring propellanes such as **60**–**63**, unusual configuration of the central atoms is possible. The results of X-ray diffraction analysis of 8,8-dichlorotricyclo[3.2.1.0^{1,5}]octane (**64**) provided the first evidence supporting this hypothesis.[131]



60 **61** **62** **63**



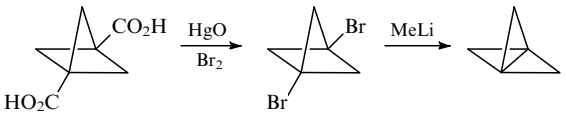
64 **65** **66** **67**

[3.2.1]Propellane **60** proved to be thermally stable but still extremely reactive (it reacts with oxygen and enters into diverse radical addition reactions).[130] An even more strained propellane (**61**) was stabilised only in an argon matrix at 29 K.[132] It appeared that the simplest [1.1.1]propellane **63** could hardly be expected to

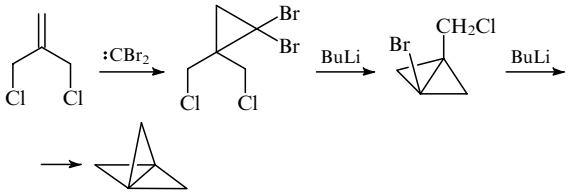
be more stable. However, in 1982, Wiberg and Walker [133] predicted theoretically the possibility of synthesis and the highest stability, among the compounds **61**–**63**, for [1.1.1]propellane and later they synthesised it. For the compound **63**, not only the possibility of synthesis and stability were predicted, but also the enthalpy of formation and photoelectron and IR spectra were calculated. The [1.1.1]propellane molecule is the first polyatomic molecule for which correct theoretical predictions preceded the synthesis.[134]

The relative stability of **63** is interpreted in the following way.[134] The molecules **61**–**63** have approximately equal strain, while the strain of the corresponding bicyclic hydrocarbons **65**–**67** with no bond between the central carbon atoms sharply increases on passing from [2.2.1]bicycloheptane (**65**) to [1.1.1]bicyclopentane (**67**).[135] Since the reactions of propellanes include rupture of the bond between the bridging carbon atoms to give species having the skeleton of the corresponding bicyclic hydrocarbons, the energy barrier to the reactions of [1.1.1]propellane is higher than the corresponding values typical of its homologues.

[1.1.1]Propellane was first synthesised from 1,3-dibromobicyclo[1.1.1]pentane, which is difficult to obtain.



Later, a procedure for the synthesis of the propellane **63** from more easily accessible precursors was developed;[136] this allows the preparation of tens of grams of this compound.

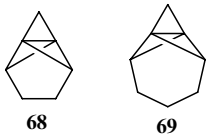


A similar approach has been used to prepare substituted [1.1.1]propellane derivatives.[137] The latest achievements in the synthesis, study of the chemical properties and application of [1.1.1]propellanes are covered in a review.[138]

The structure of [1.1.1]propellane was determined using vibrational spectroscopy,[139] gas-phase electron diffraction [140] and X-ray diffraction analysis.[141] The results of investigations by these methods confirmed the presence of the inverted configuration of the carbon atoms at the bridgehead in the structure of this compound.

The nature of the bond between the central carbon atoms in the compound **63** was the subject of numerous theoretical studies.[134] The energy of this bond was estimated (based on MP2/6-31G* calculations) to be approximately 70% of the energy of a single C–C bond (59 kcal mol^{-1}).[142]

Experimental information on the nature of the central bond in propellanes are provided by studies on the electron density distribution from X-ray diffraction data. Studies of this type have been attempted;[141, 143] however, the accuracy of experimental data proved to be inadequate to draw ultimate conclusions. The most accurate results of X-ray structure determination (at 81 K) and electron density distribution have been reported [143] for two [1.1.1]propellane derivatives, compounds **68** and **69**.

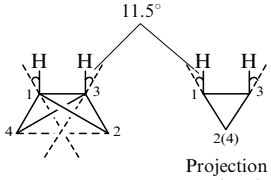


68 **69**

As expected, the DED maxima for non-bridging bonds proved to be concentrated outside the three-membered rings, which is typical of bent (banana) bonds. However, the DED values between the central carbon atoms are negative for both molecules. Nevertheless, this fact alone does not prove the absence of bonds between these atoms and does not contradict the results of the electron density calculation carried out by Wiberg.[144]

The negative DED values on the lines connecting atoms are encountered quite often; this is due to over-subtraction of the electron density of the 'pro-molecule' (combination of spherical non-interacting atoms) from the total density. This is due to the nature of the DED maps — they are differential. Therefore, in investigations of these bonds, a more promising approach includes analysis of the electron distribution topology and construction of non-differential maps, in particular, the Laplacian (the second derivative) of the experimental and theoretical electron density.[75]

The inverted configuration of the bridgehead carbon atoms was also observed in bicyclobutane derivatives (the structure was determined by microwave spectroscopy [145]).

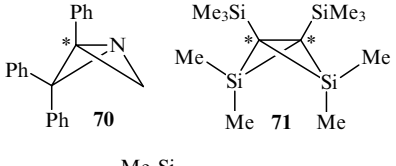


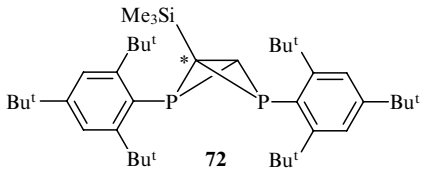
Projection along the straight line passing through C(2) and C(4)

In this molecule, the C(1)–H and C(3)–H bonds form an angle of 11.5° with the plane passing through the C(1), C(2) and C(4) atoms.

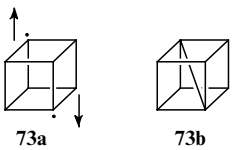
X-Ray diffraction data for other bicyclobutane derivatives with inverted configurations of bridgehead carbon atoms have also been published.[146–148]

The Cambridge Database contains also structural data on bicyclobutane heteroanalogues which also incorporate carbon atoms with inverted configurations. Examples are provided by compounds **70**–**72** (the carbon atoms with inverted configurations are marked by asterisks).[149–151]



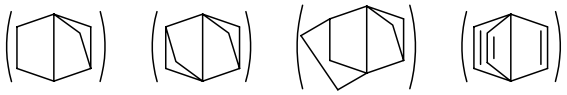


The presence of carbon with inverted configuration in 1,4-dehydrocubane has been doubted based upon the results of theoretical (*ab initio* 6-31G*) and experimental data.[152–154] It is more likely that this highly unstable molecule exists as singlet biradical **73a** and contains no diagonal bond, as shown in **73b**.



73a **73b**

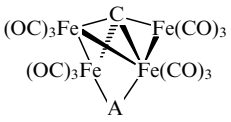
Theoretical calculations have been performed for the molecules of polycyclic hydrocarbons **74**–**76** [MP2/6-31G(d,p), 6-311++G(d,p), B3LYP/6-31G(d,p)][155] and [2.2.2]propellatriene **77** (CASSCF/6-31G*),[156] in order to find other structure types where existence of 'inverted' carbon atoms is possible.



74 **75** **76** **77**

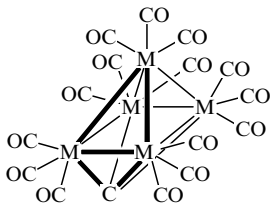
The pyramidal configuration of the carbon atom (see Fig. 1 *d*) is more exotic than the inverted one, and calculation methods still remain the most efficient tool for the investigation of compounds with this type of atom. Noteworthy are studies by Minkin *et al.*,[157, 158] who were the first to demonstrate that among the possible non-tetrahedral configurations of the carbon atom in methane, the pyramidal rather than planar configuration is energetically most favourable. The researchers cited discuss the factors that stabilise the pyramidal configuration; they are similar to those for the planar configuration, namely, the presence of σ-donor or π-acceptor substituents as well as incorporation of a pyramidal carbon atom in a rigid polycyclic cage, especially in small rings.

Known and structurally characterised systems with a pyramidal configuration of carbon (as well as compounds with the planar configuration of carbon) are represented exclusively by organometallic compounds of transition metals. Some of these structures are deposited in the CSDB; most of them are carbido clusters of iron, ruthenium, or osmium in which the carbon atom occupies an open cavity formed by metal atoms. The most frequently encountered types of structures are those present in compounds **78**, **79** (with the so-called butterfly geometry [159, 160]) and compounds **80**, **81**, in which the carbon atom lies below the base of the tetragonal pyramid formed by the metal atoms.[161, 162]



78, **79**

A = H^+ (**78**), CO (**79**)

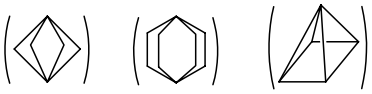


80, **81**

M = Fe (**80**), Ru (**81**)

In recent years, interest in these clusters has substantially increased because they were shown to be the key intermediates in the catalytic reduction of CO with hydrogen to give hydrocarbons, *i.e.*, the Fischer – Tropsch synthesis.[163] The first complex of this type was prepared as a side product of the reaction of $Fe_3(CO)_{12}$ with alkynes;[161] at present, preparative procedures for the synthesis of these compounds in high yields have been developed.[164] The carbon atoms in carbido clusters form σ- and π-bonds involving transition metal *d* orbitals; this stabilises the clusters. Similar complexes containing no carbido (interstitial) ligands are less stable.

Numerous theoretical studies of hypothetical organic molecules having the carbon atoms with pyramidal configuration have been carried out. About 10 years ago, the lack of computer resources and the absence of advanced software did not allow sufficiently accurate and reliable determination of the structural parameters of strained molecules. Many structures calculated at that time have later (according to the results of more advanced methods of calculation) proved unreal, *i.e.*, either not matched by minima on the PES or inaccurate. For example, [1.1.1.1]- and [2.2.2.2]paddlanes (**82**, **83**), which were initially supposed to have pyramidal configurations of carbon atoms, did not correspond to minima on the PES calculated by modern *ab initio* methods.[124]

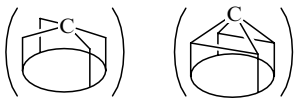


82 **83** **84**

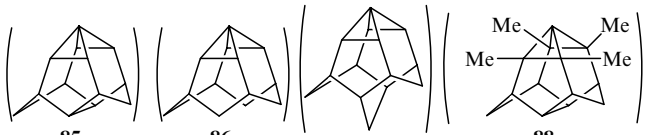
The molecular mechanics calculations for bowlane **58** had also showed the presence of a carbon atom with pyramidal configuration, but *ab initio* calculations carried out later refuted this conclusion.

The C_{4v} structure of pyramidane (**84**) with the pyramidal configuration of a carbon atom corresponds to a local minimum on the PES (MINDO/3,[165] HF/STO-3G [166] and HF/6-31G* [124]).

Rasmussen and Radom [167] have reported results of *ab initio* calculations (B3LYP/6-31G(d)//MP2/6-31G(d)) for hemialkaplane (bowlane **58** is a representative of this class of polycyclic hydrocarbons) and hemispiroalkaplane molecules; according to their data, the central carbon atom has a pyramidal configuration. The general formulae of hemialkaplanes (on the left) and hemispiroalkaplanes (on the right) are shown below:



On the basis of calculations of the molecular strain and the so-called apical strain (which characterises the strain of the separate molecular fragment containing the carbon atom with the pyramidal configuration), the researchers concluded that hemispirobioctaplane **85**, hemispirooctaplane **86** and hemispirobinonaplane **87** are the most promising synthetic targets. Analogues of the systems **85** – **87** containing methyl groups (for example, compound **88**) might prove to be easier to prepare because the presence of methyl groups contributes to the kinetic stability of the molecule. The compounds **85** – **88** were predicted to be highly basic.[167]



85 **86** **87** **88**

The existence of rigid polycyclic organic molecules, for which the presence of a carbon atom with a pyramidal configuration had been predicted, was later proved experimentally. For example, Wiberg *et al.*[168, 169] have detected one of them, namely, highly reactive tricyclo[2.1.0.$0^{1,3}$]pentane **89**.

89

VII. Distortions of bond and torsion angles at the double bond in alkenes

The research into the distortions of the bond and torsion angles in the molecules of alkenes has a long-standing history. Back in 1890, Baeyer [170] arrived at the conclusion that substantial strain should be expected in the *trans*-cyclohexene molecule and, therefore, isomerisation of *cis*-cyclohexene into the *trans*-isomer is unlikely. Later, when analysing the strain in unsaturated bicyclic molecules, Bredt,[171, 172] formulated a rule according to which the cage of camphane, pinane or other related compounds cannot have a double bond to a bridgehead position. At present, vast theoretical and experimental material on this point has been accumulated and reflected in numerous reviews (see, for example, studies [28, 173 – 176]).

The types of distortion of a planar alkene fragment are illustrated by Fig. 2.

Mathematical analysis of the distortions of the bond and torsion angles in the ethylene molecule has been described in detail in the literature (see, for example, reviews [28, 177]).

Distortions of only one type are seldom encountered in alkene molecules. However, in most cases, the prevailing type of distortion can be distinguished, which determines the total strain of

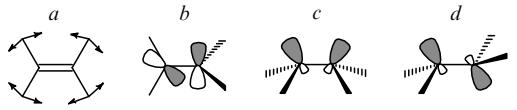


Figure 2. Types of distortion of the planar alkene fragment: (*a*) in-plane distortions; (*b*–*d*) out-of-plane distortions: (*b*) twist, (*c*) *syn*- and (*d*) *anti*-pyramidalisation.

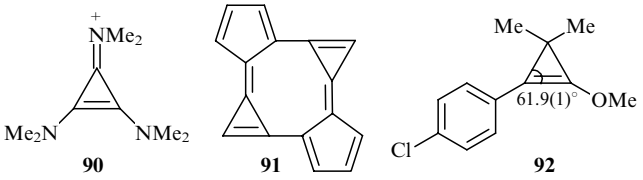
the alkene.[28] Below we consider compounds in which the strain of the molecule is mainly due to the contribution of one type of distortion.

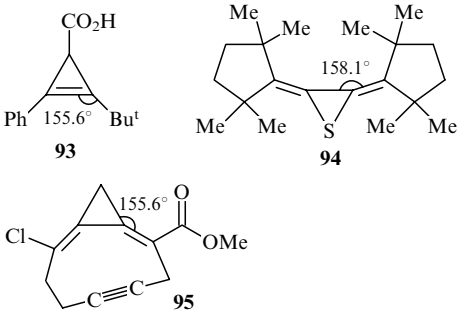
1. In-plane distortions of an sp^2-hybridised carbon atom

The bond angles at the sp^2-hybridised carbon atom can differ appreciably from the ideal value, equal to 120°. Indeed, the internal C–C=C angle in cyclopropene derivatives can be twice as small. The results of a search through the CSDB demonstrated that this angle is about 60° in the molecules of cyclopropene derivatives that also contain an exocyclic double bond (there are 10 structures of this type), for example, **90**, **91**.[178,179]

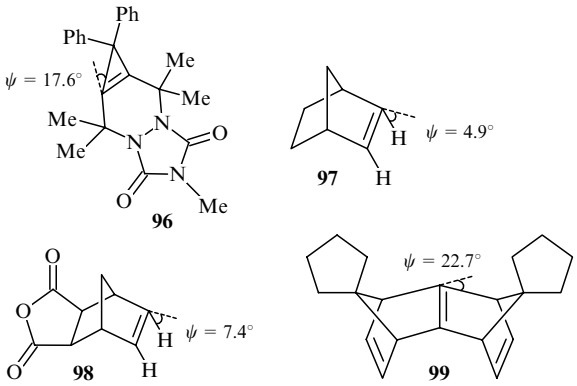


In these molecules, a major contribution to the resonance hybrid is made by canonical forms with the cyclopropenylium cation. In other cyclopropene derivatives, the internal C–C=C angle is close to 60°; for example, in molecule **92** this angle is 61.9°.[180]

The external R–C=C angles in cyclopropene derivatives can be greater than 150° in the case of bulky R substituents, for example, the angle is 155.6° in molecule **93**.[181] Bond angles exceeding 150° have also been found at exocyclic double bonds in compounds with saturated three-membered rings. The deviations of these angles from 150° are caused by steric repulsion of bulky groups (as in compound **94**)[182] or by the fact that double bonds are incorporated in rings (as, for example, in compound **95**).[183]



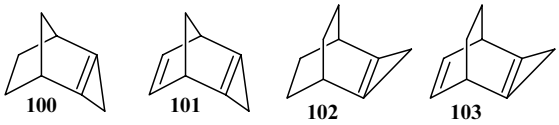
A decrease in the R–C=C angle results in pyramidalisation of the carbon atoms of the double bond. This fact was predicted theoretically:[184] model calculations (RHF/STO-3G) showed that if the H–C=C angles in the planar ethane molecule are less than 100°, pyramidalisation becomes energetically favourable. X-Ray diffraction analysis of compound **96** confirmed this fact experimentally.[185] In molecule **96**, the C–C=C angles in the cyclopropene fragment amount to 64.8° and 65.3°, and the ψ angle characterising pyramidalisation equals 17.6°.



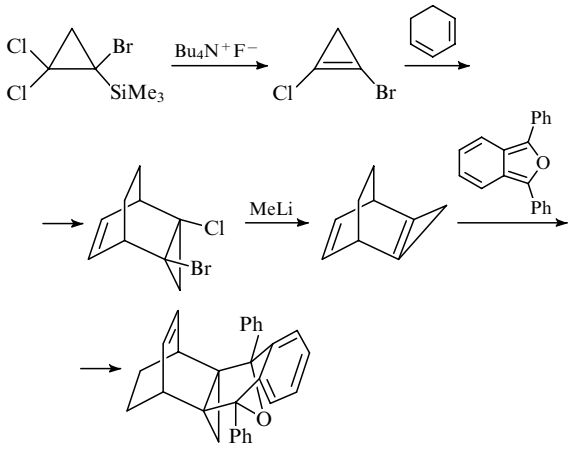
For the norbornene molecule (**97**), pyramidalisation of the carbon atoms of the double bond was predicted theoretically (for example, according to the STO-3G *ab initio* calculations,[186] the hydrogen atoms at the double bond are displaced in the *endo*-direction and the ψ amounts to 4.9°). X-Ray diffraction data for norbornene have not been obtained.

In a norbornene derivative, anhydride of *exo*,*exo*-2,3-norborn-5-enedicarboxylic acid (**98**), the structure of which has been determined by neutron diffraction, the ψ angle proved to be 7.4°.[187] In compound **99**, as shown by X-ray diffraction analysis, the fusion of two norbornyl cages (and, probably, steric repulsion between the cyclopentane rings) accounts for quite a noticeable pyramidalisation: ψ = 22.7°.[188,189]

An exceptionally high pyramidalisation of the carbon atoms at the double bond can be expected, according to calculations (HF, TCSCF, MP2, B3LYP, B3PW91/6-31G*),[190] in compounds **100**–**103**, the synthesis of which has been reported.[191–195]



It follows from calculations that each of the tricyclic structures **100**–**103** is matched by two minima on the PES, which correspond to the *endo*- and *exo*-isomers. In the case of the compounds **100** and **101**, a lower energy is found for *endo*-isomers (their energy is 2.2–7.5 kcal mol^{-1} lower than that of the corresponding *exo*-isomers), whereas for the compound **103**, the *exo*-isomer is lower in energy (by 2.2–3.3 kcal mol^{-1}). The carbon atoms of the double bonds in the compounds **100**–**103** should be strongly pyramidalised (ψ > 40°). Experimental verification of these theoretical conclusions would be a complicated task because the strained molecules **100**–**103** are highly reactive (for example, the existence of the compound **103** can only be proved by analysing the products of reactions involving this molecule).[193]



2. Twisting of the double bond

The loss of π-bonding upon distortion of the torsion angles at the double bond (twist) is partially counterbalanced by rehybridisation of carbon atoms, resulting in their pyramidalisation.[196–198] Therefore, when comparing the degree of twisting of double bonds in the molecules of different alkenes, it is not always legitimate to use the dihedral angle between the *a*C(1)*b* and *c*C(2)*d* planes (Fig. 3). Therefore, the so-called twist angle τ was introduced, which is found as the arithmetic mean of the *a*C(1)C(2)*d* and *b*C(1)C(2)*c* dihedral angles.

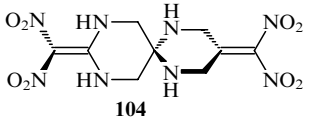
$$\tau = \frac{a\mathrm{C}(1)\mathrm{C}(2)d + b\mathrm{C}(1)\mathrm{C}(2)c}{2}.$$

This angle is equal to the angle between the *a*C(1)*b* and *c*C(2)*d* planes in the case where no pyramidalisation takes place. The degree of pyramidalisation of the C(1) and C(2) atoms is evaluated from the departure of the *a*C(1)C(2)*c* and *b*C(1)C(2)*d* dihedral angles from 180° and from the pyramidalisation angles $\chi_{C(1)}$ and $\chi_{C(2)}$:

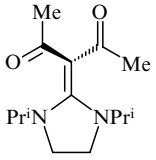
$$\chi_{C(1)} = b\mathrm{C}(1)\mathrm{C}(2)c - b\mathrm{C}(1)\mathrm{C}(2)d + \pi,$$

$$\chi_{C(2)} = a\mathrm{C}(1)\mathrm{C}(2)d - b\mathrm{C}(1)\mathrm{C}(2)d + \pi.$$

The results of theoretical investigations demonstrate that twisting of the molecule of an alkene with all electron-donating or all electron-withdrawing substituents by 90° (τ = 90° or −90°) should give rise to a singlet biradical,[199–201] and the maximum twisting in the molecules of non-symmetrical alkenes (so called push – pull alkenes) yields bipolar species.[202] Twisted systems correspond to the transition state of the *cis–trans*-isomerisation of alkenes. For simple alkenes, the activation free energy of the *cis–trans*-isomerisation found experimentally lies in the range from 51 to 67 kcal mol^{-1} (see Refs 203 – 205). For push – pull alkenes, this barrier is substantially lower.[202] This is why the 'record-holder' molecules in which the τ angle for the C=C bond is close to 90° (or −90°) are represented in the CSDB by push – pull alkenes. For example, according to X-ray diffraction data, in the molecules **104** and **105**, the τ angles are 85.1° and 84.3°, respectively.[206, 207]



104



105

When the double bond is conjugated with other π-bonds or aromatic systems, the barrier to the *cis–trans*-isomerisation also decreases. Among the structures of compounds with conjugated double bonds, numerous examples can be found in which the |τ| values are close to 90°. Thus in the octaisopropylcyclooctatetraene molecule (**106**), the τ angles for all multiple bonds exceed 64°.[208]

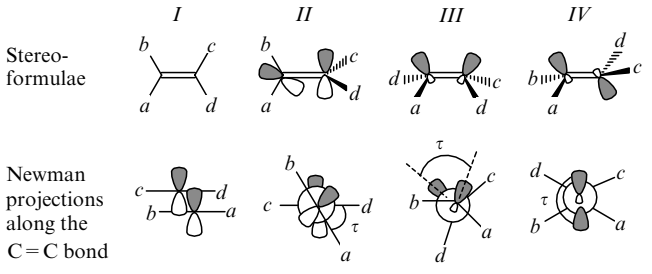


Figure 3. Twist distortion of the C=C bond and definition of the twist angle τ: (*I*) unstrained double bond; (*II*) twisting of double bond without pyramidalisation of the carbon atoms; (*III*, *IV*) twisting + pyramidalisation; *a–d* are substituents.

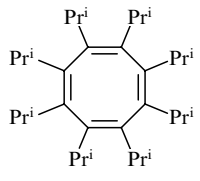
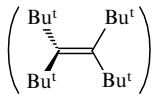


106

If push – pull alkenes and compounds with conjugated double bonds are excluded from consideration, the number of structures with τ angles lying in the range of 20° < |τ| < 90° included in the CSDB sharply decreases. Considerable twist-type distortions of the C=C bond were found both in acyclic and in cyclic or polycyclic compounds.

a. Acyclic twisted alkenes

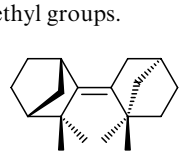
In acyclic alkenes, twist distortions take place if bulky substituents are present at the double bond. The largest twist of the double bond not incorporated in a ring or a polycyclic system and bearing only hydrocarbon substituents is expected in the tetra-*tert*-butylethylene molecule (**107**). Numerous attempts at synthesising this compound were undertaken; however, they have not yet met with success. *Ab initio* (BLYP/DZd) calculations for the molecule **107** [209] predict a singlet ground state (D_2 symmetry) with τ = 45°, slight pyramidalisation and a strain energy of 93 kcal mol^{-1}. The energy of the triplet state of **107** with τ ≈ 87° would be 12 kcal mol^{-1} higher than the energy of its singlet state.



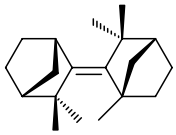
107

The alkenes **2**, **108**, and **109** have been prepared by methods used in the attempts to synthesise the compound **107**. In the molecules of these compounds, as in the molecule of **107**, the quaternary carbon atoms are linked directly to the double bonds. However, the steric repulsion in the molecules **2**, **108** and **119** is weaker than that in tetra-*tert*-butylethylene due to the presence of additional bonds between substituents.[210–213]

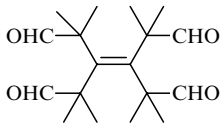
Krebs *et al.* [214, 215] approached very closely the synthesis of the compound **107**; they succeeded in synthesising tetrakis(2-formylpropan-2-yl)ethylene (**110**) (τ = 28.6°, according to X-ray diffraction data). However, the formyl groups proved to be so nonreactive that the researchers were unable to reduce them to the methyl groups.



108



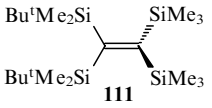
109



110

The relatively low reactivity of the double bond in the compounds **2** and **108**–**110** should also be mentioned. In all probability, this is due to the shielding of the π-system by bulky substituents. The *cis–trans*-isomerisation of strained alkenes proceeds much more readily than isomerisation of unstrained compounds (the energy barrier can be almost twice as low in the former case). This was used in a study [205] to estimate the energy barrier to the isomerisation of alkenes. Since isomerisation of strained alkenes takes place at relatively low temperatures, side reactions do not complicate the kinetic measurements. The standard enthalpies of formation (with an applied correction for steric effects found by MM2 calculations) of these alkenes were employed to calculate the activatiom barrier to the *cis–trans*-isomerisation (69.5 ± 0.9 kcal mol^{-1}), which does not depend on the nature of substituents at the double bond.

According to the results of a search through the CSDB, the greatest twist distortion of the double bond among acyclic compounds is found in compound **111**.[216]

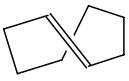


111

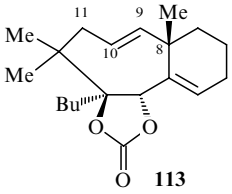
In the tetra(trialkylsilyl)ethylene **111**, the τ angle equals 49.6° (note that this value is greater than that predicted for tetra-*tert*-butylethylene **107**), no pyramidalisation of the carbon atoms of the C=C bond takes place, and the double bond length (1.370 Å) exceeds the typical value (1.32 Å).

b. *trans*-Cycloalkenes

Among monocyclic compounds, a substantial distortion of the double bond (mainly twist-type distortion) can be attained in *trans*-cycloalkenes in which the number of carbon atoms in the ring does not exceed nine. *trans*-Cyclooctene (**112**) is the unsubstituted compound with the smallest ring that can be isolated in a pure state at room temperature.[217, 218] The structure of *trans*-cyclooctene was determined by electron diffraction.[219] According to these studies, the C–C=C–C dihedral angle in the molecule **112** amounts to 136°. For a derivative of *trans*-cyclooctene, compound **113**, X-ray diffraction data have been published.[220] The C(8)–C(9)–C(10)–C(11) dihedral angle in the molecule **113** is 139.3°.



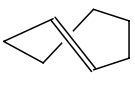
112



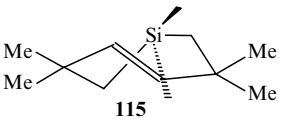
113

Further contraction of the ring containing a *trans*-double bond results in a substantial increase in the reactivity and the tendency for isomerisation to the *cis*-form. *trans*-Cycloheptene (**114**) can be synthesised at low temperatures.[221] Complexes of **114** with transition metals stable at room temperature have also been obtained.[222] Unsubstituted *trans*-cyclohexene (like *trans*-cyclopentene) has not been experimentally detected yet.

Monocyclic compound **115** with the smallest-possible ring containing a *trans*-double bond and stable at room temperature contains a silicon atom in the seven-membered ring and methyl groups in the α-positions relative to the double bond.[223] This compound proved to be sufficiently stable to be studied by X-ray diffraction analysis. The kinetic stability is ensured by the methyl group, while the presence of two C–Si bonds, which are longer than C–C bonds, makes the strain in the molecule **115** lower than that found in *trans*-cycloheptene.



114

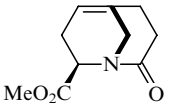


115

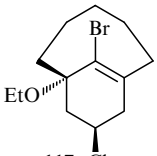
A substantial distortion of the double bond in **115** is reflected in the size of the C–C=C–C dihedral angle, which is 130.97°. It is of interest that the H–C=C–H dihedral angle is 173°, and pyramidalisation of the carbon atoms in the molecule **115** is insignificant. The C=C bond length (1.330 Å) deviates only slightly from the typical value, despite the substantial distortion of the dihedral angles. It should be noted that *trans*-cycloalkenes are chiral; the racemic **115** was partially resolved by column chromatography using a chiral adsorbent.

c. Polycyclic compounds with twisted double bonds: anti-Bredt alkenes

Among numerous anti-Bredt alkenes deposited in the CSBD, one can find structures in whose molecules a *trans*-double bond is incorporated into an eight-membered ring. As examples, one can mention compounds **116** and **117** (the molecule of **116** contains also a twisted amide bond [224]).



116



117

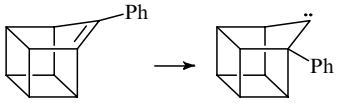
The following parameters have been found for the molecule **116**:[225] the angle τ = 10.8°, the average degree of pyramidalisation of the carbon atoms at the double bond χ = 28.45°.

The size of the τ angle attests to an even greater twist distortion of the double bond (τ = 29.3°) in the molecule **117**, although the degree of pyramidalisation in this molecule is lower, χ = 17.1°.[226]

The alkene **117** is very sensitive to moisture and atmospheric oxygen; the compound **116** is less reactive.

Anti-Bredt alkenes with a *trans*-double bond incorporated in rings containing not more than seven carbon atoms are known. The substantial strain in the molecules of these compounds accounts for their enhanced reactivity. The exceptionally reactive alkene **1** contains a *trans*-cyclohexene ring.[227, 228] This compound was stabilised in a solid argon matrix, and the IR absorption frequency for its double bond was determined. The unusually low frequency (1481 cm^{-1}) indicates that the π-bonding has been considerably reduced as a result of angle distortion in the molecule of **1**.

An even more strained molecule of 9-phenyl-1(9)homocubene (**118**) contains a *trans*-'double' bond in the five-membered ring. No spectroscopic or structural characteristics have been obtained so far for this compound because of its high reactivity.[229] The compound **118** rearranges into carbene **119** even at low temperatures.



118 **119**

This reaction is uncommon for alkenes (the reverse transformation takes place much more often); the fact that this reaction does proceed implies that the properties of the double bond change substantially upon geometric distortion.

Although the compounds **1** and **118** can be regarded as 'record-breaking twisted alkenes', the *p* orbitals of their 'double' bonds are not orthogonal: the calculated τ values are much smaller than 90° (for example, τ = 64° in the molecule of **1**).[227, 228] Due to the pyramidalisation of non-bridging carbon atoms of the C=C bonds, the orbital overlap is partly restored and the τ value decreases. Perhaps, an ideally orthogonal arrangement of the π orbitals could be realised in 'fixed betweenenes' (or orthogonenes) **120**, **121** (MM2 and semiempirical calculations; no *ab initio* calculations for these structures have been carried out).[230] Tentative results on the synthesis of orthogonenes have been published.[231]

120, **121**

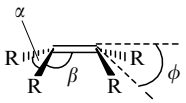
n = 0 (**120**), 1 (**121**).

3. Out-of-plane distortions of angles at the C=C bond: pyramidalisation

It is well-known that alkenes in which the double bond occurs in a non-symmetric environment are often characterised by a pyramidal configuration of the double-bond carbon atoms. This pyramidalisation is slight; the reasons for it are discussed in the

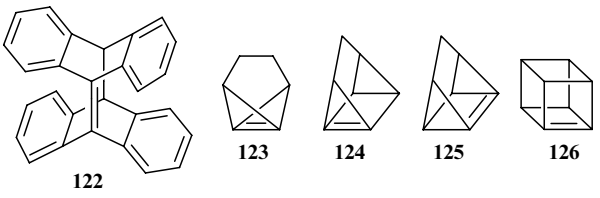
literature (see, for example, the reviews [232, 233]). Pyramidalisation accompanies also in-plane and twist distortion of a double bond (see above). Calculations [234] have shown that *anti*-pyramidalisation of the carbon atoms of the double bond is energetically more favourable than *syn*-pyramidalisation. However, this conclusion requires verification by means of more advanced methods of calculations than those used in the study cited.[234]

In this Section, we consider compounds the structural features of which impose pronounced *syn*-pyramidalisation. As a rule, these compounds contain a rigid polycyclic cage having two mutually perpendicular planes of symmetry one of which accommodates the double bond.[175] Examples of non-symmetric molecules have also been reported.[235] When discussing pyramidalisation in these molecules, in addition to χ, it is convenient to use the angle ϕ

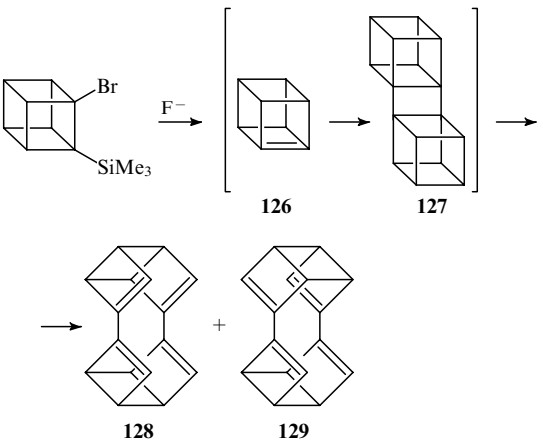


$$\cos\phi = -\frac{\cos\beta}{\cos(0.5\alpha)}$$

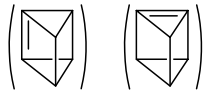
The first synthesised compound with a considerable pyramidalisation of the carbon atoms at the double bond (**122**) was reported more than 30 years ago;[236] at present, dozens of compounds of this type are known, for example, **123**,[237, 238] **124**,[239–241] **125**[242] and **126**.



In the cubene molecule (**126**), the angle ϕ, according to the SCF/3-21G calculations, is equal to 84.1°.[243] The possibility of synthesis of the compound **126** was predicted theoretically and then realised in practice.[244] Rough thermodynamic data for cubene [245] and the first results of the study of chemical properties of this highly reactive compound [246] have been published. The calculations showed that, despite the pronounced pyramidalisation of the double-bond carbon atoms, the overlap of the *p* orbitals in the molecule **126** is sufficient for regarding this compound as an alkene rather than a biradical (TCSCF/6-31G* for the singlet state, ROHF/6-31G* for the biradical).[153] This is also indicated by an observed reaction typical of alkenes with highly pyramidalised carbon atoms of the double bond,[247] namely, cubene dimerisation to give the corresponding propellane **127** with subsequent transformation into tetraenes **128** and **129**.



The attempts to synthesise derivatives with even more pyramidalised carbon atoms of the C=C bond, prismene, have so far been unsuccessful.[248] Both prismene isomers, **130** and **131**, have been studied theoretically [HF/6-31G(d), MP2/6-31G(d)].[249] According to calculations, the energy of the molecule **131** is lower than the energy of **130**.



VIII. Distortions of the bond and torsion angles in the molecules of aromatic compounds

Cyclic unstrained aromatic systems are normally planar. The benzene structure,[250] which serves as a sort of standard in discussion of the nature of aromaticity,[251] has been studied in the gas phase (spectroscopic methods and electron diffraction) with high accuracy: the molecule has D_{6h} symmetry, the carbon atoms form a regular hexagon, and the C–C bond length is 1.399 ± 0.001 Å.

The types of distortion investigated for benzene derivatives include changes in the bond angles in the aromatic ring plane and out-of-plane distortions; compounds with 'conformations' similar to those of cyclohexane, *i.e.*, a chair, a boat, and a twist 'conformation,' have been obtained (Fig. 4). Below we consider only benzene derivatives (strained molecules of aromatic heterocyclic compounds have received much less attention in the literature).

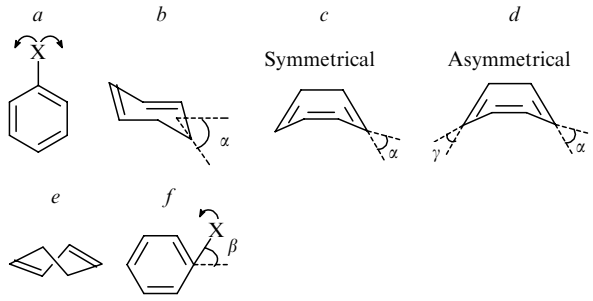


Figure 4. Bond angle distortions in benzene derivatives. (*a*) in the ring plane; (*b*–*f*) out-of-plane distortions: (*b*) chair, (*c*) symmetrical boat, (*d*) asymmetrical boat, (*e*) twist, (*f*) deviations of the C–X bond from the ring plane. The angles characterising the degree of distortion are marked.§

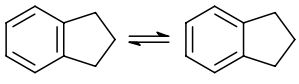
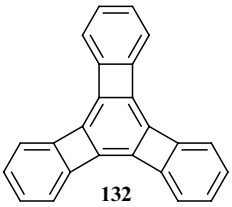
1. Changes in the bond angles in the plane of the benzene ring

The C–C–X bond angles at the carbon atoms of the benzene ring can markedly depart from the ideal value, equal to 120°. These distortions may be caused, in particular, by annelation of small rings to benzene. Mills and Nixon [252] postulated that annelation of cyclopentane to benzene shifts the equilibrium between the two Kekule structures.

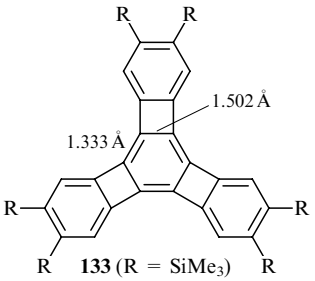


Later, the hypothesis of the existence of an equilibrium between the Kekule structures in benzene derivatives was admitted to be faulty;[50] however, localisation of the double bonds induced by annelation of strained rings was actually discovered.[253] The first experimental proof of this phenomenon was provided by the synthesis of cyclohexatrienes **132** and **133**.[254]

§ These designations of angles are used only in this Section.

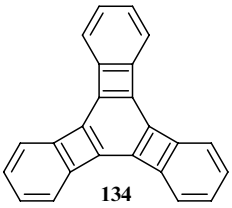


132

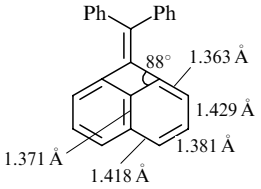


133 (R = $SiMe_3$)

The compound **133** contains, according to X-ray diffraction analysis, noticeably alternating bonds in the central ring. The unusually easy hydrogenation of the central ring in **132** also points indirectly to a substantial localisation of the double bonds.[255] Thermochemical data for this reaction have been published.[256] However, in this type of compound, localisation of the double bonds can be interpreted by assuming a smaller contribution of the structure **134**, with antiaromatic cyclobutadiene rings, to the resonance hybrid. Calculations (B3LYP/6-31G*) demonstrated that it is the bond localisation caused by annelation rather than other π-effects (aromaticity – antiaromaticty) that is responsible for the structure of these compounds.[257]



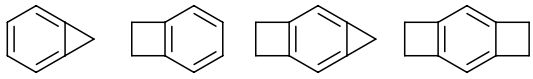
134



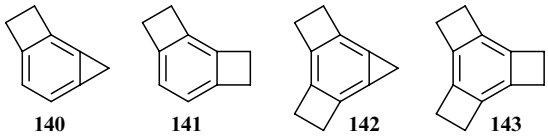
135

The clear-cut bond alternation has been found by X-ray diffraction analysis [258] in the molecules of naphthalene derivative **135**. The bond angles at the carbon atom at the *peri*-positions of the naphthalene ring differ appreciably from 120°.

Alternation of single and double bonds was to be expected in dehydrocyclobuta- and cyclopropabenzenes. It proved to be very difficult to perform the synthesis and X-ray diffraction analysis of strained compounds such as **136**–**143**. However, unexpectedly, no noticeable bond alternation was found in the molecules of these compounds.[259]

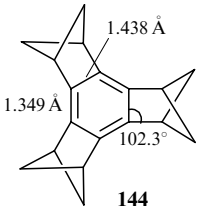


136 **137** **138** **139**

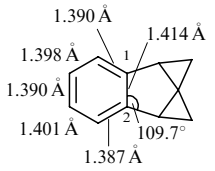


140 **141** **142** **143**

On the one hand, these results are at variance with the calculations (MP2/3-21G, HF/6-31G*) for model systems (benzene molecules with distorted C–C–H bond angles), according to which the decrease in the C–C–H angle to 90° is accompanied by pronounced localisation of the double bonds.[260] However, on the other hand, clear-cut alternation of bonds was found in the benzene ring annelated to bicyclic fragments. In the most strained molecule of this type of compound, tris(tetrahydrobicyclo[2.1.1]-hexa)benzene (**144**), noticeable bond alternation was found, first, by *ab initio* calculations [6-31G(D)(LDF)],[261] [MP2/6-31G(D)],[262] and then by X-ray diffraction analysis.[263] The C–C–C angle in the structure **144** is equal to 102.3° (which is much smaller than 120°). The reason for the observed bond alternation in the structure **144** is currently under discussion.



144



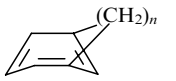
145

The alternation might be caused by the strain in the bicyclic fragments of **144**, which results in elongation of those bonds in the benzene ring at which the bicyclic fragments are annelated. A similar effect was observed for the compound **145**.[101]

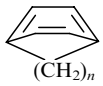
2. Out-of-plane distortions of the benzene ring

a. Compounds with benzene rings in the boat 'conformation'

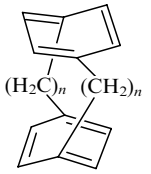
Among the molecules in which the benzene rings are distorted to form a boat 'conformation' typical of the cyclohexane ring, cyclophanes should be mentioned first of all.[264] In recent years, strained molecules of meta-, para- ([*n*]- and [*n.n*]-) cyclophanes have been vigorously studied. The synthesis and properties of these compounds have been considered in detail in reviews.[265–268]



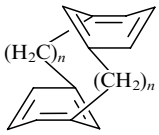
[*n*]metacyclophanes



[*n*]paracyclophanes



[*n,n*]paracyclophanes



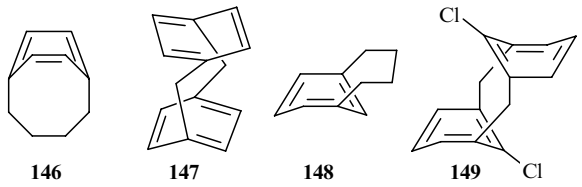
[*n,n*]metacyclophanes

The interest in these compounds, like that in the benzene derivatives **133**–**143** described above (cyclobuta- and cyclopropabenzenes can be treated as [*n*]orthocyclophanes), is related to some extent to the discussion of the nature of aromaticity.

In the case of [*n*]paracyclophanes, the benzene ring is not strained when $n = 9$; however, with a decrease in the bridge length, the ring becomes non-planar; in addition, the exocyclic C–C bonds are also distorted, in particular, they decline from the plane of the two adjacent bonds of the benzene ring (see Fig. 4 for the definition of the α and β angles characterising these distortions). Analogous distortions of the benzene rings in [*n*]metacyclophanes take place when $n \leqslant 7$. In [*n.n*]para- and -metacyclophanes, the benzene rings deviate substantially from the planar configuration at $n \leqslant 3$.

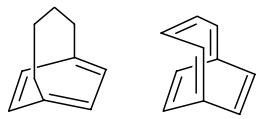
[2.2]Metacyclophane was synthesised in 1899,[269] and [2.2]paracyclophane was prepared in 1949 [270] by closure of the bridge. In the case of homologues with smaller *n* values, [*n*]paracyclophanes with $n \leqslant 7$, or [*n*]metacyclophanes with $n \leqslant 6$, this classical approach is inapplicable. The syntheses of cyclophanes with small *n* values include isomerisation of appropriately substituted valence isomers of benzene as the key stage. Six isomers of this type can be conceived (if only the CH fragments are combined, while charged species are excluded).[267] Different research groups have used four isomers,[271] most often, 3,3′-bicyclopropenyl derivatives.[265]

A decrease in the length of the bridge in cyclophane molecules results in a dramatic increase in their reactivity. The unsubstituted cyclophanes with the smallest *n* (with a saturated bridge) known to date, [4]paracyclophane (**146**) [272,273] and [1.1]paracyclophane (**147**),[274] can be stabilised only in inert matrices at low temperatures, while [4]metacyclophane (**148**) [275] and an extremely unstable [1.1]metacyclophane derivative (compound **149**) [276] were detected as short-lived intermediates.



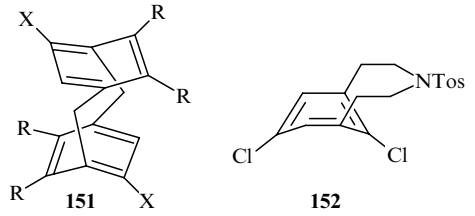
146 **147** **148** **149**

A highly unstable and, apparently, the most strained among the known [*n*]paracyclophanes, bicyclo[4.2.2]decapentaene, has been synthesised.[277] The results of experimental and theoretical studies (MP2, taking account of electron correlation)[278] suggest that the compound has the structure **150a**, which has a lower energy than the other isomer (**150b**).



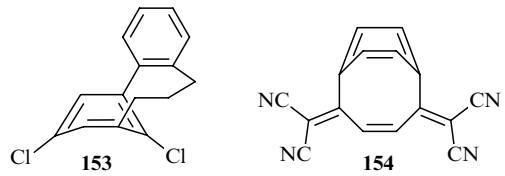
150a **150b**

To study the chemical and spectral properties and the structure of these compounds, it is necessary for them to be stable under experimental conditions. Sufficient stability was attained for strained cyclophanes having electron-withdrawing substituents or bulky groups shielding the most reactive centres, *i.e.*, bridging carbon atoms. Among the known stabilised cyclophane derivatives, the molecules of compounds **151**–**154** contain the most distorted benzene rings.[279–282]



151 **152**

R = CH_2SiMe_3, X = $CONMe_2$, Tos is *p*-toluenesulfonyl.

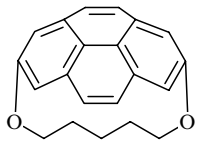


153 **154**

X-Ray diffraction data are available for the compounds **151** and **152**. Appreciable distortion of the benzene ring is indicated by the α and β angles: in the molecule **151**, $\alpha = 25.6°$ and $24.3°$, $\beta = 26.8°$ and $22.9°$, while in the molecule **152**, these parameters are even greater: $\alpha = 27.4°$, $\gamma = 12.3°$, $\beta_{max} = 48.7°$. The distance between the opposing bridging carbon atoms in the cyclophane derivative **151** is equal to 2.376(5) Å. Despite this heavy distortion of the aromatic rings, no bond alternation was detected in the compounds **151** and **152**, and the bond lengths fall in the ranges typical of unstrained benzene derivatives.

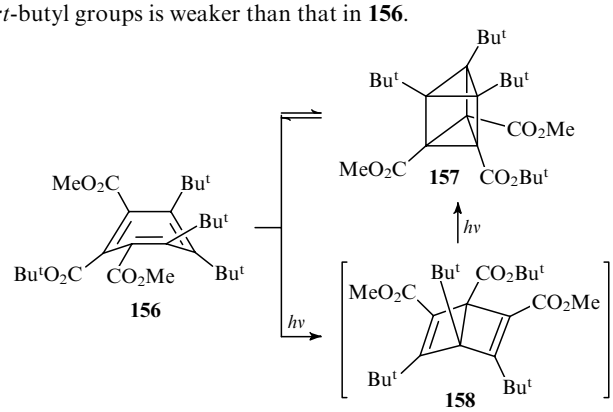
The presence of π-electron delocalisation is also indicated by NMR studies of strained cyclophanes including compounds **153** and **154**. The ^1H and ^{13}C NMR signals are exhibited in the chemical shift regions characteristic of aromatic compounds. Thus, despite the substantial distortions, the strained molecules of cyclophanes can still be regarded as aromatic. The system of π-bonds in these molecules is an 'observer' rather than a 'manager' and adapts itself to changes in the σ-core. This was confirmed by *ab initio* calculations for strained [*n*]metacyclophanes.[283] The benzene ring distortion of up to $\alpha = 30°$ is not accompanied by noticeable bond alternation. It may seem that these conclusions contradict the data on the chemical properties of strained cyclophanes, most of all, the data on the ability of these compounds to enter readily into Diels–Alder and nucleophilic substitution reactions.[266] However, one should take into account the fact that the molecules of compounds with non-planar benzene rings possess substantial strain. The reactions of the compounds result in strain relief, which is the driving force of their unusual chemical transformations.[265]

Distorted benzene rings serve as structural blocks of fullerenes; therefore, studies of strained cyclophanes are related to fullerene chemistry. Particular interest was aroused by the synthesis of compounds with fused non-planar aromatic rings, fullerene fragments,[284] for example, of 1,7-dioxa[7](2,7)pyrenophane (**155**).[285] In accordance with X-ray diffraction data, the pyrene residue in this compound is distorted to a greater extent than the similar fragment in C_{70} fullerene; the planes of non-annelated benzene rings make an angle of 109.2°.



155

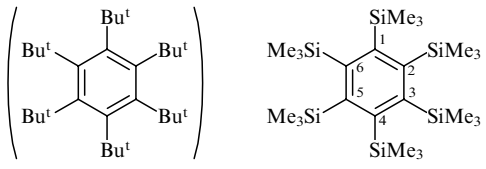
In conclusion, it should be noted that distortions of the benzene rings to a boat 'conformation' can be found not only in cyclophanes. In the molecules of 1,2,3-trisubstituted benzene derivatives, this conformation results in a decrease in the steric strain if the substituents are sufficiently bulky. According to analysis of CSDB structures, among benzene derivatives with bulky substituents in the 1,2,3-positions, the molecule **156** has the most distorted benzene ring.[286] The angle values $\alpha = 30.1°$, $\gamma = 11.6°$, and $\beta_{max} = 16.4°$ are comparable with the sizes of these angles in the cyclophane derivative **152**. Nevertheless, in compound **156**, no double bond localisation is found either. The strain in **156** accounts for the unusual reactivity of this compound, first of all, the tendency for isomerisation into prismane **157** [with the intermediate formation of the corresponding derivative of the Dewar benzene (**158**)], in which the steric repulsion between the *tert*-butyl groups is weaker than that in **156**.



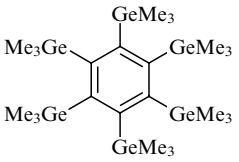
156 **157** **158**

b. Twist and chair 'conformations' of benzene rings

Due to steric repulsion of bulky substituents, the benzene ring can assume twist and chair 'conformations'. According to calculations, the chair 'conformation' can be found in the benzene ring of hexa-*tert*-butylbenzene (**159**).[287] This compound has not been synthesised so far but its less strained silyl-[288] and germyl-containing[287] analogues **160** and **161** are known.

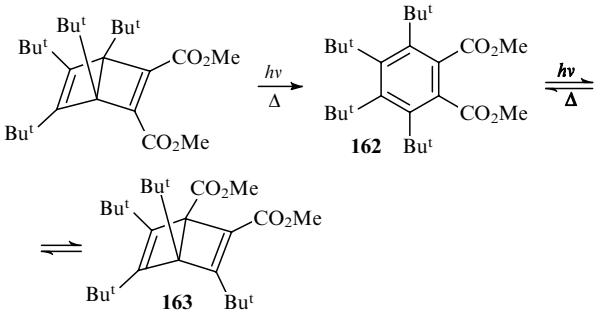


159 **160**

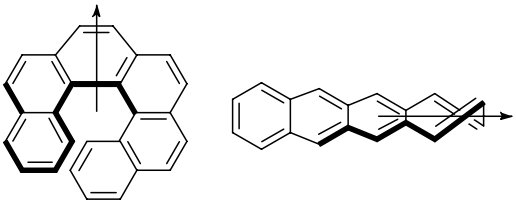


161

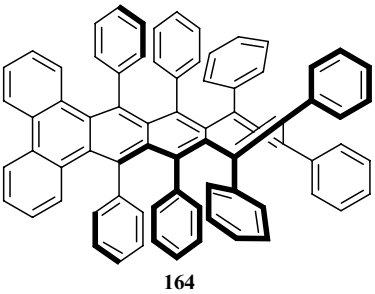
X-Ray diffraction analysis of the compound **160** showed that four carbon atoms of the benzene ring [C(1), C(3), C(4), C(6)] are located approximately in one plane, whereas the C(2) atom lies above this plane by ~0.1 Å and the C(5) atom is ~0.1 Å below this plane. The mean value of the C−C−C−C dihedral angle amounts to 9.8° and the C−Si bond deflects from the plane of the benzene-ring bonds adjacent to it by 22.2°. Despite the considerable distortions of the bond angles comparable to the distortions in the molecules **151**–**154**, the bond lengths in the benzene ring are normal for aromatic compounds. Analysis of the spectroscopic properties of the compound **160** shows that the compound can be considered to be aromatic but having an unusually high reactivity. The molecule **160**, similarly to the molecule **156**, is readily rearranged on exposure to radiation giving rise to a Dewar benzene derivative, hexakis(trimethylsilyl)bicyclo[2.2.0]hexa-2,5-diene (further [2 + 2]-cycloaddition to a substituted prismane was not observed). The rearrangement of the compound **160** occurring on heating resulted in benzene ring cleavage; in this case, 1,1,3,4,6,6-hexakis(trimethylsilyl)-1,2,4,5-hexatetraene was isolated. Interestingly, the benzene derivative **162** containing four *tert*-butyl groups in the adjacent positions is thermodynamically less stable than the isomer **163**, which is a Dewar benzene derivative.[289]



The twist 'conformation' of the benzene ring has been observed in molecules of fused aromatic compounds. Typically, these molecules contain an aromatic polycyclic system twisted to form a helix the axis of which is either perpendicular or parallel to the benzene-ring planes.



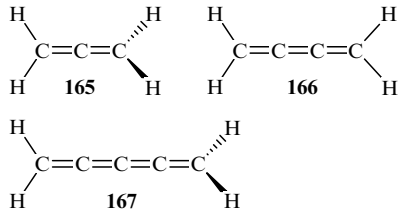
In the molecule **164**, the angle between the terminal bonds of the linear polybenzene system is 105°. Despite the steric strain, the compound **164** is exceptionally stable: it does not decompose on heating to 400 °C.[290]



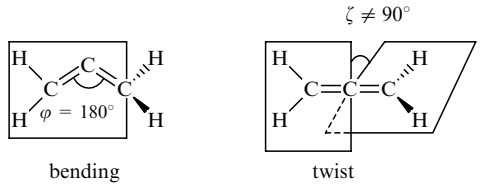
164

IX. Distortions of cumulated double bonds

Cumulenes are hydrocarbons containing two (or more) double bonds with shared carbon atoms. Strain-free cumulene molecules, for example, allene (1,2-propadiene) (**165**), 1,2,3-butatriene (**166**) and 1,2,3,4-pentatetraene (**167**) have a linear carbon skeleton of cumulated double bonds. The four substituents are located either in mutually perpendicular planes (for an even number of cumulated double bonds) or in one plane (for an odd number of these bonds).

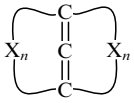


Distortions of cumulenes can include bending and twisting of the linear system of bonds. For allene, these distortions can be represented as follows:



bending twist

Below we consider only allene and 1,2,3-butatriene derivatives in which cumulated double bonds are incorporated in a ring. In the molecules of these compounds, the cumulene fragment is not only bent; twist type distortion is also always observed. The properties of strained cyclic allenes have been analysed in several reviews (see, for example, reviews [291, 292]). Only few publications have been devoted to the study of molecules with predominating twist distortion such as [*n.n*]betweenallenes. In the known betweenallenes, the ζ angle between the planes formed by substituents at the terminal C(sp^2) atoms deviates insignificantly from 90°.[293, 294]



[*n*,*n*]betweenallenes

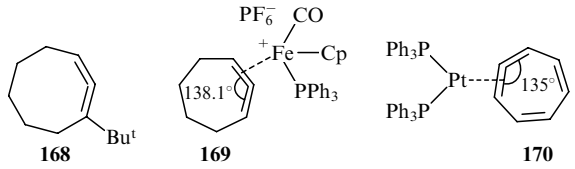
Even strain-free molecules of cumulenes are highly reactive (reactions involving them readily give stabilised intermediates).[295] Molecular distortions result in a further increase in reactivity and even in a qualitative change in the chemical properties of cumulenes.

1. Strained cyclic allenes

If the allene fragment is incorporated in a carbocycle that consists of not more than ten atoms, it inevitably becomes bent and, in addition, substituents tend to be arranged in one plane, which implies twist distortion. Model calculations showed that bending is always accompanied by twist — optimisation of an artificially bent system of two cumulated double bonds results in a twisted structure.[296] The strain energy of the molecules of cyclic allenes gradually increases up to $\varphi = 20°$ (by ~4 kcal mol^{-1}, according to the SCF/4-31 + G calulations);[297] however, subsequently it rises very steeply.

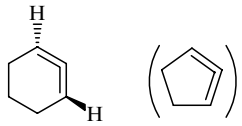
Even slight angle distortions in allene molecules entail a pronounced increase in the compound reactivity, which is anyway rather high, first of all in the tendency for polymerisation. 1,2-Cyclooctadiene the strain energy of which is calculated to be only

14 kcal mol^{-1}, has not yet been isolated in a pure state.[291] Bulky substituents at double bonds ensure the kinetic stability of allenes; the *tert*-butyl derivative of 1,2-cyclooctadiene **168** represents the smallest-ring carbocyclic allene that has been isolated at room temperature.[298] A cyclic allene with a smaller ring, 1,2-cycloheptadiene, has been stabilised in metal complexes. For compound **169**, X-ray diffraction data have been published,[299] pointing to a substantial distortion (bending and twist) of the allene fragment. Among metal complexes of this type deposited in the CSDB, the most pronounced bending of the allene fragment is found in the molecule of compound **170**, in which the φ angle is 135°.[300]



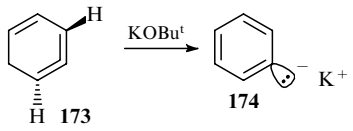
168 **169** **170**

1,2-Cyclohexadiene (**171**) has been known since 1968 when this compound was detected as a short-lived intermediate.[301] Later, it was detected by IR spectroscopy in an argon matrix at 11–170 K.[302] The compound **171** has now been thoroughly studied; according to calculations, the φ angle in this molecule is 138° (MINDO) or 134.8° (HF/6-31G**).[291] The attempts at synthesising 1,2-cyclopentadiene (**172**) have not yet met with success.[303]



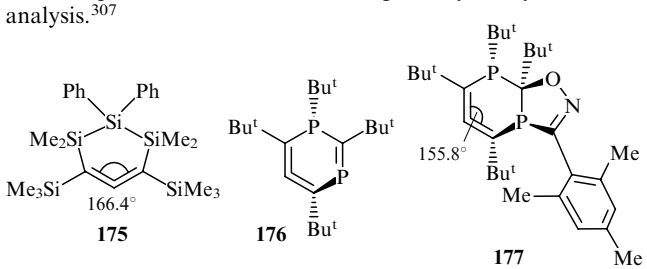
171 **172**

Cyclohexa-1,2,4-triene ('isobenzene') (**173**) has also been studied.[304] There is evidence that deprotonation of the compound **173** gives rise to the phenyl anion (**174**).[305]



173 **174**

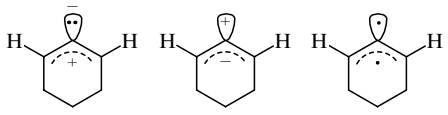
Stable six-membered heterocyclic compounds with a 1,2-diene fragment containing two or three heteroatoms, silicon and phosphorus, have been synthesised. The allene fragment in the cyclic allene **175** is less distorted than that in the six-membered carbocycle **171**; however, the former is stable, which allowed X-ray diffraction analysis of this compound.[306] According to X-ray diffraction data, the allene fragment is bent (φ = 166.4°) and the ζ angle between the Si—C(1)—C(2) and Si—C(3)—C(2) planes is 64.6°. Among stabilised cyclic compounds, the most distorted 1,2-diene group is found in diphosphaisobenzene **176**. A derivative of **176**, compound **177**, has been investigated by X-ray diffraction analysis.[307]



175 **176** **177**

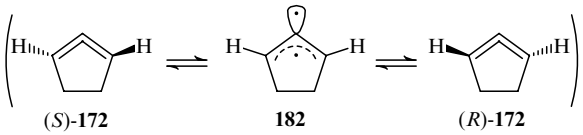
The values for the φ (155.8°) and ζ (40.7°) angles in the molecule **177** significantly depart from the ideal values (180° and 90°, respectively); steric shielding of the central fragment caused by the *tert*-butyl groups is responsible for the rather low reactivity of compound **177**.

The accumulated knowledge makes it possible to form a picture of molecular and electronic structures of highly strained allenes. Several variants of the spatial and electronic structures of these compounds can be suggested. For example, for 1,2-cyclohexadiene, apart from the chiral allene **171**, structures with the planar HC(1)C(2)H fragment and a non-bonding sp^2-hybridised orbital located in the plane of this fragment are also possible, *i.e.*, zwitter-ions **178**, **179**, and singlet (**180**) and triplet (**181**) biradical.



178 **179** S- **180**, T- **181**

The MCSCF/3-21G [308] and HF/6-31G* [309] calculations and experimental data [302, 309, 310] favour a non-planar chiral structure, at least, in 1,2-cycloheptadiene and 1,2-cyclohexadiene. The calculated τ angle at each double bond amounts to ~20°; this is sufficient for effective overlap of *p*-orbitals.[309] In the case of the 1,2-cyclopentadiene **172**, *ab initio* (STO, MP2/3-21G) calculations predict a relatively low energy barrier to racemisation (which might involve the intermediate formation of singlet biradical **182**) — 2–5 kcal mol^{-1} (see Ref. 311). This low value is within the error of the calculation techniques; therefore, experimental data are required to verify the results of theoretical methods.

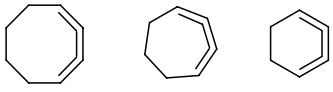


(*S*)-**172** **182** (*R*)-**172**

As regards the chemical properties of cyclic allenes, one should mention their enhanced tendency to enter into cycloaddition reactions, which were used in experiments on trapping short-lived molecules such as 1,2-cyclohexadiene. Strained allenes undergo the Diels–Alder reactions even with dienes having very low reactivity. These reactions are regioselective and *endo*-stereoselective; however, in the case of chiral allenes, no diastereoselectivity was observed. This fact was interpreted using the results of *ab initio* calculations (B3LYP/6-31G*),[312] which showed that in this case, the mechanism involving biradicals is preferred over the synchronous mechanism.

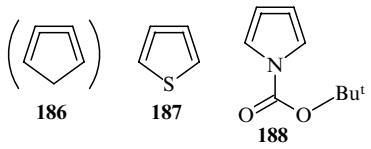
2. Cyclic butatrienes

The unstrained 1,2,3-butatriene fragment can be incorporated into a carbocycle if the number of carbon atoms in it is more than ten. Ring contraction causes bending of the linear C=C=C=C fragment, resulting in rehybridisation of carbon atoms and a substantial increase in the reactivity. Tentative experimental results showed [313] that, among unsubstituted cyclic 1,2,3-butatrienes, the minimum size of the ring which allows isolation of this compound at room temperature, is found in 1,2,3-cyclooctatriene (**183**). Homologues with smaller rings, 1,2,3-cycloheptatriene [314] (**184**) and a benzene isomer, 1,2,3-cyclohexatriene [315] (**185**), are highly reactive short-lived intermediates; only the products of cycloaddition of these species to dienes have been isolated.



183 **184** **185**

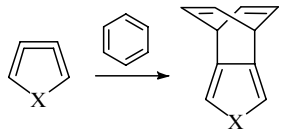
1,2,3-Cyclopentatriene (**186**) has not been prepared to date; however, its heterocyclic analogues, 3,4-didehydrothiophene (**187**) [316] and 1-*tert*-butoxycarbonyl-3,4-didehydro-1*H*-pyrrole (**188**),[317] have been synthesised, and their chemical properties have been studied using trapping reactions.



186 **187** **188**

The compound **187** was prepared and identified without substantial difficulties, although it is highly reactive. Meanwhile, the high reactivity of the heterocyclic triene **188** became a serious obstacle in the attempts to prove its existence. Among the strained butatrienes known currently, the geometry of the C=C=C=C system of bonds deviates most appreciably from linearity in the molecule **188**.[317]

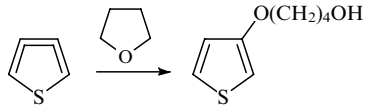
Cyclic 1,2,3-butatrienes, like highly strained allenes, readily react with dienes. The high reactivity of the compounds **187** and **188** can be illustrated by their reaction with benzene, which affords cycloadducts **189** and **190**.



189, **190**

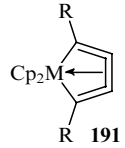
X = S (**189**), NCO_2Bu^t (**190**).

It was suggested that rehybridisation of the carbon atoms of the bent C=C=C=C system of bonds (like pyramidalisation of double bonds, see above) changes the electronic properties of the compounds **187** and **188** so dramatically that they can be regarded as biradicals. To support this, the researchers cited [316] reported the reaction of the heterocyclic triene **187** with tetrahydrofuran.



However, an ionic mechanism of this reaction is also possible. It has been shown above in relation to cubene that, even in the case of a very strong pyramidalisation of the carbon atoms of the double bond, alkenes do not exhibit properties of biradicals. Therefore, the conclusion that the compounds **187** and **188** are biradicals appears unlikely and requires further analysis.

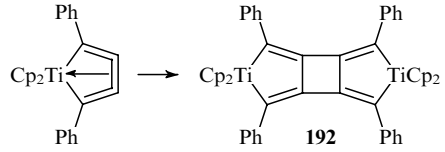
Among isolated and structurally characterised cyclic butatrienes, we shall consider metallacyclocumulenes (**191**) with a five-membered ring consisting of a 1,2,3-butatriene fragment and a metal (titanium or zirconium).[318]



191

M = Ti, R = Bu^t, Ph; M = Zr, R = Bu^t.

The stability of compounds of the type **191** is attributable to the additional stabilisation upon the coordination of the central double bond to the metal. This coordination changes the electronic structure of cumulenes; nevertheless, for some of the complexes **191**, dimerisaition to give radialene (**192**) has been observed.[319]

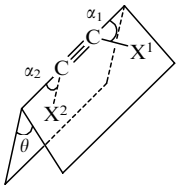


192

This reaction is also characteristic of purely organic strained cumulenes.[320] Metallacyclocumulenes have been investigated by X-ray diffraction analysis. The data obtained indicate that the central double bond is elongated and that the cumulene fragment deviates substantially from the linear geometry: the φ angle varies from 147° to 150°.

X. Bending of the $X^1-C\equiv C-X^2$ fragment

The unstrained $X^1-C\equiv C-X^2$ fragment is linear. The deviations of the bond angles at the carbon atoms from 180° are similar to the analogous deviations found in allene and butatriene molecules. The geometric distortions of the $X^1-C\equiv C-X^2$ fragment can be characterised by variation of the α_1, α_2 and θ angles.

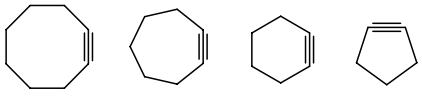


Below, we shall discuss the *cis*- ($\theta = 0°$) and *trans*- ($\theta = 180°$) bendings. Note that it is the *cis*-bending that is found in each organic molecule with a strained triple bond. The calculations showed, however, that *trans*-bending requires less energy than *cis*-bending (in a similar way as *anti*-pyramidalisation of the double bond is energetically more favourable than *syn*-pyramidalisation).[234] Probably, the lower energy of the transition state which contains a *trans*-bent fragment with a triple bond can account for the preferential *trans*-attack of alkyne molecules by nucleophilic reagents. This hypothesis has not been verified experimentally because no organic molecules with a *trans*-bent $X^1-C\equiv C-X^2$ fragment have been synthesised to date.

1. *cis*-Bending

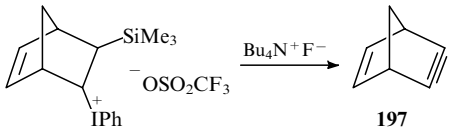
The only known way of realisation of *cis*-bending is incorporation of the $X^1-C\equiv C-X^2$ fragment into a ring or a polycyclic cage.[292, 321] This fragment is bent in carbocyclic alkynes with the number of carbon atoms not exceeding ten. The first strained cyclic alkyne, cyclooctyne (**193**), was synthesised in 1938;[322] later, it was isolated in a pure state.[323]

Cyclooctyne is smallest-ring carbocyclic alkyne stable at room temperature. Cycloheptyne (**194**) polymerises in less than 1 min even at −25 °C in dilute solutions (at −76 °C, it is stable over several hours).[324] Homologues with smaller ring sizes, cyclohexyne (**195**)[325, 326] and cyclopentyne (**196**),[327–333] are highly reactive. They have been detected as intermediates and studied in inert matrices.



193 **194** **195** **196**

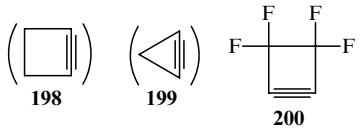
The highly strained molecules **194**–**196** can be prepared using elimination and cycloelimination reactions and by carbene rearrangements.[321] Elimination from appropriate precursors, hypervalent iodine compounds, has proved effective for this purpose.[334] Using this reaction, it was possible to prepare, perhaps, the most strained known (according to MP2/6-31G* calculations) carbocyclic molecule with a bent C−C≡C−C fragment, namely, bicyclo[2.2.1]hept-2-en-5-yne (**197**) molecule.[335]



197

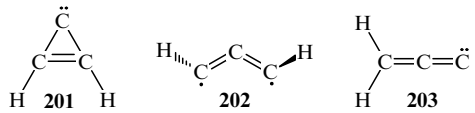
Cyclobutyne (**198**) and cyclopropyne (**199**) have not yet been synthesised. The results of calculations (MCSCF(4,4)/6-31G*, MP4/6-31G*//MP2/6-31G*) indicate that the compound **198** is

highly susceptible to a rearrangement to cyclopropylidenemethylene;[336] apparently, this makes this molecule 'elusive'. The existence of perfluorocyclobutyne (**200**) as an intermediate, possibly, more stable than **198**, has now been proven experimentally.[337] Metal complexes with cyclobutyne acting as a two-electron ligand have been prepared; however, cyclobutyne itself was not formed as an intermediate during the synthesis of these complexes.[338, 339]



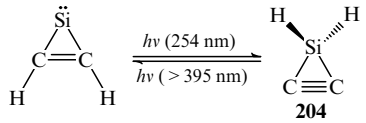
198 **199** **200**

The structure of cyclopropyne (unlike cyclobutyne) does not correspond to a minimum on the PES, even when the PES is calculated using advanced quantum-chemical techniques [such as SCF, TCSCF, CISD, TC-CISD/DZP; CCSD(T)/TZ(2df,2dp)];[340] Cyclopropyne is the only C_3H_2 isomer that has not yet been prepared. The other three isomers — cyclopropenylidene (**201**), propargylene (**202**) and propadienylidene (**203**), have been synthesised and studied in inert matrices.[341] It should be noted that investigation of the potential energy surface of C_3H_2 arouse considerable interest, among other reasons, due to the fact that the molecules **201** [342, 343] and **203** [344] were found in the interstellar space.



201 **202** **203**

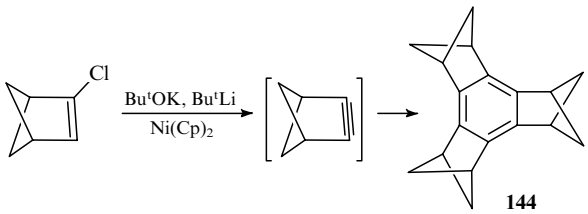
Maier *et al.*[345, 346] synthesised a heteroanalogue of cyclopropyne, silacyclopropyne (**204**).



204

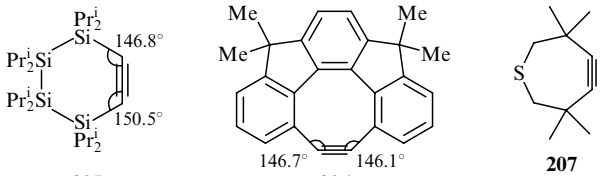
The identification of the compound **204** was at variance with the results of SCF/DZ calculations published previously, which indicated that the silacyclopropyne structure has properties of a saddle point rather than a minimum on the PES.[347] Maier *et al.*, who used higher-level calculations (MP2/6-31G**) demonstrated that the structure of **204** still corresponds to a local minimum on the PES; however, the IR frequencies they obtained differed somewhat from those observed experimentally. Only recent calculations [340] have given vibration frequencies on the basis of which the compound **204** was identified. The necessity of using advanced quantum-chemical methods for the prediction of properties of strained molecules such as **204** was demonstrated once again. The difference between the stabilities of cyclopropyne and silacyclopropyne can be explained by the difference between the energies of the carbenes and silapropadienylidenes $^{\cdot\cdot}C=C=XH_2$ (X = C, Si), which are formed presumably upon decomposition of the compound **199** and **204**. The energy of this species with X = Si is higher than the energy of the initial molecule **204**, whereas in the case where X = C, calculations predict the opposite situation.[346]

Cycloalkynes with a bent $X^1-C\equiv C-X^2$ fragment are susceptible to addition reactions with electrophiles, nucleophiles, and radicals.[321] Cycloaddition and oligomerisation also proceed with these molecules much more easily than with strain-free alkynes. Indeed, whereas cyclotrimerisation of strain-free alkynes requires catalysts (transition metal compounds), a similar reaction in the case of cyclic strained alkynes proceeds easily without catalysts. Moreover, the detection of benzene derivatives in the products of elimination reactions of cyclic alkenes can serve as evidence for the formation of highly strained alkynes as intermediates.[348] Trimerisation gave the above-discussed benzene derivative with annelated bicyclic fragments (**144**).



144

Cyclic alkynes stable due to either bulky substituents at the α-position relative to the C≡C bond (for example, as in molecule **205** [292]) or annelation of benzene rings (for example, as in molecule **206** [349]) have been studied by X-ray diffraction analysis. The search through the CSDB showed that in the molecules characterised by the most bent $X^1-C\equiv C-X^2$ fragment, the α_1 and α_2 angles approach ~30°.

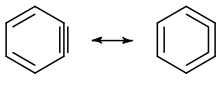


205 **206** **207**

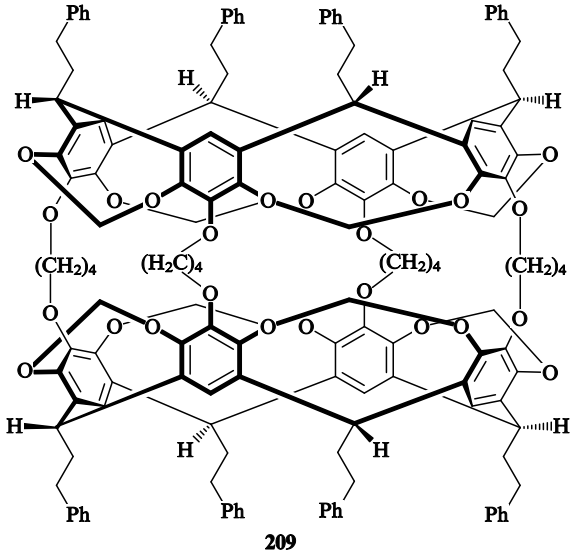
The structure of compound **207** has been studied by electron diffraction in the gas phase.[350–352]

The α_1 and α_2 angles in the molecule **207** are 34.2° and 30.7°, which is somewhat greater than those in **205** or **206**. Despite the pronounced bond angle distortions, the C≡C bond lengths in the compounds **205** and **207** remain within the limits typical of acyclic linear alkynes. Only in some cases (for example, in the molecule **206**), was the triple bond elongated (1.20–1.23 Å).

Finally, we should mention a new, original method of stabilisation of strained molecules and reactive intermediates, which allows one to gain spectroscopic data for these species in solutions at room temperature. The idea of this approach is to generate unstable molecules inside 'molecular vessels' — carcerands and hemicarcerands. Cyclobutadiene [353] and 1,2-dehydrobenzene (**208**) [354, 355] have been fixed in this way. Warmuth [354] has tackled the question whether the molecule **208** should be assigned to strained alkynes or to bent cumulenes. 1,2-Dehydrobenzene was prepared by exposure to UV light of benzocyclobutenedione inside hemicarcerand (**209**). For the compound **208** stabilised in



208a **208b**



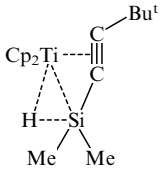
209

this way, it was possible to record the ^{1}H and ^{13}C NMR spectra before the compound has reacted with the host molecule.

Analysis of the NMR spectra led to quite an unexpected conclusion: the spectroscopic data are best described by a hybrid of two contributing structures, **208a** and **208b**, with a predominant contribution of **208b**. This interpretation, however, is inconsistent with the results of other studies (see, for example, Ref. 356).

2. *trans*-Bending

Synthesis of a molecule with a *trans*-bent $X^1-C\equiv C-X^2$ fragment is a difficult task: the shortage of substituents at a triple bond precludes creation of such a bending. However, *trans*-bending of an alkyne ligand can be attained in metal complexes. The first complex of this type **210** was prepared in 1995.[357]



210

A whole series of titanium and zirconium complexes of this type are currently known.[358] In the compound **210**, the agostic Si···H···Ti interaction ensures the *trans*-arrangement of substituents at the C≡C bond coordinated to titanium. The angles $\alpha_1 = 30.5°$ (for Si−C≡C) and $\alpha_2 = 44.8°$ (for C−C≡C) indicate a substantial distortion of bond angles at a triple bond. However, it should be noted that metal coordination also changes substantially the properties of a triple bond, for example, in the complex **210**, the bond length is increased to 1.275(9) Å.

The author is grateful to professors M Yu Kornilov and R R Kostikov, colleagues S P Verevkin, V V Burlakov and V I Tararov for critical remarks, corrections and assistance in preparing the manuscript, and to a colleague, mathematician O B Pikhurko, for consultation and help in the solution of mathematical problems. The author is especially grateful to Corresponding Member of the Russian Academy of Sciences M Yu Antipin for constructive criticism and discussion of the manuscript. This review was written with financial support of the Alexander von Humboldt Foundation (Germany).

Abstract. Data on organic chemosensors published over recent years are surveyed and described systematically. The bibliography includes 165 references.

I. Introduction

The creation and development of highly sensitive and reliable methods for the quantitation of various elements and their compounds in the environment (atmosphere, hydrosphere and lithosphere) is of current interest in chemistry. Success in solving this task requires that scientific studies be carried out to find the most selective reactions of atoms, ions or molecules which make it possible to determine qualitative and quantitative parameters of an object under study. The search for a selective reaction implies that one needs to find the transformation of the object being studied from a series of other transformations, which converts the substrate into the most convenient form with specific physical characteristics.

Of the many methods used to analyse substrates based on their physical properties (atomic absorption spectroscopy, ion-selective pM-metry (where pM is the negative logarithm of the metal ion concentration), electron microprobe analysis, neutron activation analysis, *etc.*), a special place belongs to electron spectroscopic methods,[1] fluorescence analysis being the most sensitive of these methods.[2]

An organic analytical reagent employed in fluorescence analysis should have a receptor which reacts selectively with the substrate, a signal-generating fragment and a conductor (bridge) between these parts of the molecule.[3] Such a system is called a chemosensor. If a fluorophore is the signal-generating part of a chemosensor, then this is a fluorescent chemosensor. Interaction of the receptor with the substrate followed by transfer of the energy of this interaction through the bridge to the fluorophore changes the spectral signal of the fluorophore, which allows one to make conclusions about the nature of the substrate. It became obvious while developing chemosensors that the set of fluorophores is rather limited, whereas the types of receptor are rather diverse. The most common chemosensors are represented by ionofluorophores; of these, reagents for various cations are used most widely.

Figure 1 shows a schematic diagram of the operating principle of chemosensor for cations.[4] The receptor of such a chemosensor is an electron donor (D), whereas the fluorophore is an electron acceptor.[5,6]

Excitation of the fluorophore results in electron transfer from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). This enables electron transfer from the HOMO of the donor (receptor) to the HOMO of the acceptor (fluorophore), thus quenching the fluorescence of the latter. This phenomenon is known as the PET (Photoinduced Electron Transfer).[7] Once a cation (shown as a ball in Fig. 1) has been attached to the receptor, the HOMO energy level of the latter becomes lower than that of the fluorophore, the PET is no longer possible, and the sensor starts to fluoresce.

The majority of fluorescent sensors fit this scheme. However, a different PET mechanism is possible in the case of transition metal cations. In this case, the electron transfer is directed from the fluorophore to the bound metal ion.[8]

If the fluorophore of the sensor incorporates an electron-donor fragment in addition to the electron-withdrawing one, then the so-called PCT mechanism (Photoinduced Charge Transfer) is also observed due to the interaction between the similarly or oppositely charged poles of the fluorophore and the receptor. This effect is observed as a bathochromic or hypsochromic shift of

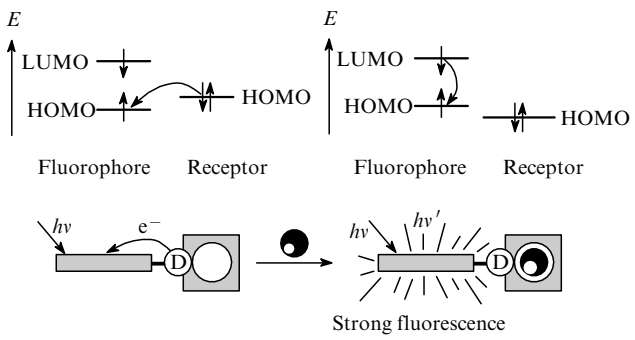

Figure 1. Schematic diagram of cation recognition fluorescent PET sensor.[4]

absorption and emission bands in the spectra, and also as changes in the extinction parameters.[4]

Fluorescence of sensors may get enhanced or quenched if exciplexes † or excimers ‡ appear due to the formation of complexes between the receptor and the substrate.[4]

Fluorescent sensors have certain advantages over other optical chemosensors. The fluorescence method is very sensitive (in certain cases, a few molecules of an object can be detected). These experiments are inexpensive and easy to perform; the method has high resolving power in the wavelength and time measurement scales. Furthermore, luminescence spectra are quite sensitive to both structural changes in the sensor and substrate molecules and the external conditions.[6, 9–12]

Thus, the fluorescence method makes it possible to both solve purely analytical problems and control chemosensor processes.

When Fabbrizzi and Poggi [10] introduced the concept of 'switchable sensors', they distinguished such systems that can be triggered or blocked by changing the pH or the concentration of metal ions in the environment, by applying an external redox potential, *etc*.

The original photo-switching method is based on the photochromism phenomenon. If the sensor is associated with one state of a bistable photochromic device, the sensor function can be reversibly switched on or off by means of a photoreaction.

In this review, recent achievements in the development of organic chemosensor systems are classified and generalised. Fluorescent sensors are considered in the most detail.

II. Fluorescent cation sensors

According to a classification by de Silva,[11, 13] fluorescent cation sensors can be subdivided into four types.

1. Organic molecules that emit light due to the presence of a metal ion.

2. Organometallic complexes containing a metal which emits light.

3. Organometallic complexes which emit light due to interaction with a different metal ion.

4. A complex of two organic compounds which emits light in the presence of an organic 'guest'.

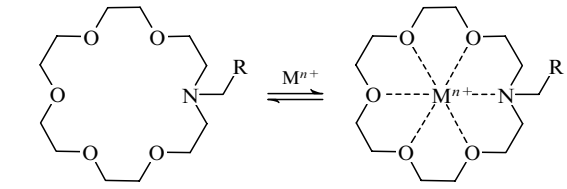
Although this classification of sensors is quite versatile, the need arose recently to expand it and make it more specific, because many new publications have appeared in the field of chemosensors. Detailed reviews have been published in which chemosensors were classified according to the type of interaction between the coordinating, luminescent and conducting parts of the system,[14, 15] as well as reviews dealing with the fundamentals of designing ionofluorophores for general analysis of cations,[4] transition metal ions,[16] anionic substrates,[17, 18] *etc*.

In this review, we have tried to emphasise the role of the receptor as the most functional part of a chemosensor molecule and to show the sensor capacities of various reactive series of compounds containing the same molecular receptors.

1. Azacrown ethers

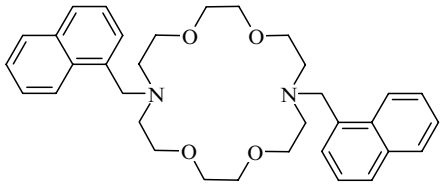
Chemosensors in which crown ethers serve as receptors belong to the most popular type of cation sensors of various metals. In order to enhance the efficiency of the crown ether receptor, the macrocycle is usually modified by incorporating nitrogen atoms, which are potent complexation centres.

Compound **1a** is the simplest azacrown-containing PET sensor.[19]



1a–c

R =  (**a**),  (**b**), (**c**).



2

For example, if compound **1a** coordinates the K^+ ion, its fluorescence quantum yield in methanolic solutions increases from 0.003 to 0.14. Incorporation of several (more than three) methylene units between the nitrogen atom of the azacrown ether and the aromatic substituent, *i.e*., between the receptor and the fluorophore, results in an abrupt decrease in the PET.[20]

Aza(diaza)-18-crown-6 ethers bound to fluorophores (polynuclear aromatic hydrocarbons) through an *N*-methylene bridge (**1b**,**c** and **2**) were used in order to discriminate between mono- and divalent metal ions.[15, 21] The nature of the solvent and the type of anion in the salt being analysed may affect considerably the character of coordination, and hence the strength of the PET.[22, 23]

The interaction of the sensor **1c** with thiocyanates of mono- and divalent metals can serve as an example; the spectral pattern of this interaction is shown in Fig. 2.[15] Divalent and ammonium cations display the standard PET with luminescence enhancement. Conversely, coordination of monovalent cations results in luminescence quenching. This anomaly can be rationalised by the existence of specific coordination of monovalent cations with the

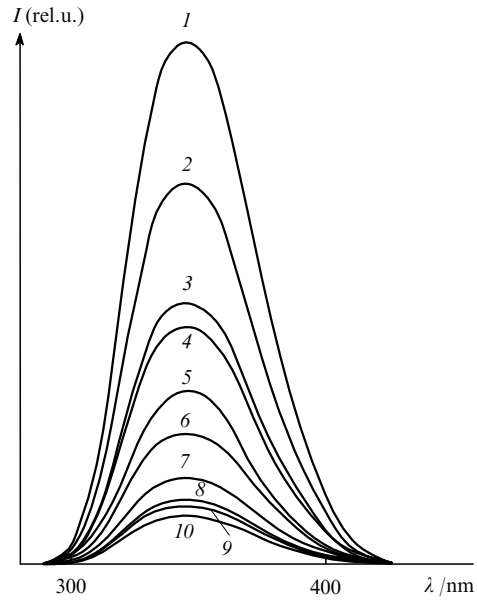


Figure 2. Fluorescence spectra of compound **1c** and its complexes with various metal ions in methanol;[15]

† An exciplex is an excited molecular complex. It is formed upon association of two molecules (which may be similar or different), one of which is in the ground state while the other is in an excited state.

‡ An excimer (a specific case of an exciplex) is an excited dimer formed from two similar molecules, one of which is in an excited state while the other one is in the ground state.

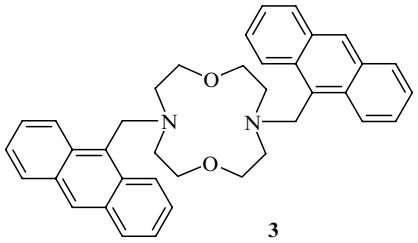
azacrown ether and the thiocyanate anion, providing additional transfer of electron density from the anion to the naphthalene chromophore.[15]

Using electronic spectra, ^1H and ^{13}C NMR spectra and X-ray diffraction analysis, it was shown that the PET affects the physical characteristics of complexation for a number of sensor series. For example, enhancement of fluorescence in the presence of various 'guest' cations occurs in derivatives of diazacrown ethers containing two, three, or four oxygen atoms in the ring and two fluorescent substituents. There are two reasons that can explain this phenomenon.

1. Quenching of fluorescence in the chemosensor molecules due to intramolecular electron transfer between the fluorescent 'pendants' and two nitrogen atoms of the ring. As a result, coordination of a cation by the crown ether enhances light emission.

2. Coincidence between the steric parameters of the receptor and the substrate and a suitable rate of cation exchange between the free ligand and the complex in the ground state.

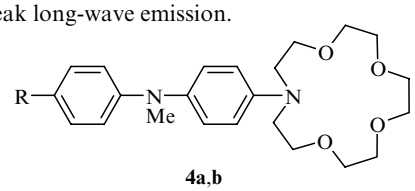
It was found[15] that Zn^{2+} ions are coordinated to both nitrogen atoms of the ring, which results in enhancement of luminescence of diaza-12-crown-4 ether **3** by a factor of 182.



3

It was shown[15] that diaza-18-crown-6, which has two 1-pyrenyl substituents, can be used as a fluorescent sensor for alkali metal ions.

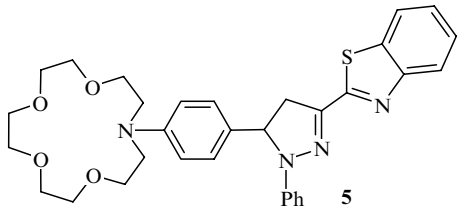
Ionofluorophores **4a**,**b** are suitable for the quantitative determination of Ca^{2+} ions in solutions based on changes in luminescence spectra upon complexation,[24] but they behave differently. For example, the $Ca^{2+} \cdot$ **4a** complex displays an intense fluorescence band, unlike the $Ca^{2+} \cdot$ **4b** complex which is characterised by weak long-wave emission.



4a,**b**

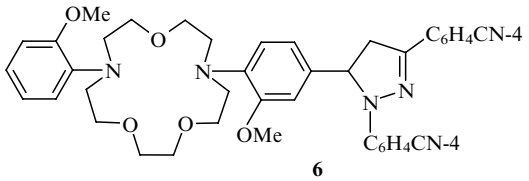
R = H (**a**), NMe_2 (**b**).

The *N*-aryl receptor of the azacrown sensor **5** with decreased basicity of the nitrogen atom of the crown macrocycle is characterised by strong luminescence enhancement (by a factor of 28) upon interaction with the Ca^{2+} ion in acetonitrile,[25] the fluorescence life time being increased from 0.28 to 3.6 ns.



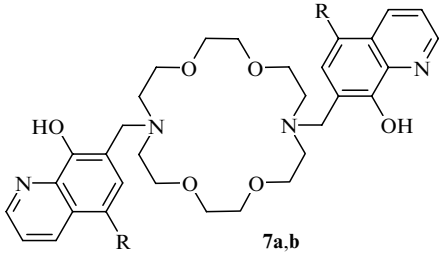
5

The coordination sphere of crown ethers can be expanded by introducing substituents containing additional donors. For example, the sensor **6** is a good fluorescent reagent for 'softer' sodium ions[13] due to involvement of the electron pairs of the *o*-methoxy groups in coordination.



6

Additional coordination sites are also present in compound **7a**, which is a highly selective luminescent sensor for magnesium ions effective in solutions with pH > 6.[26]

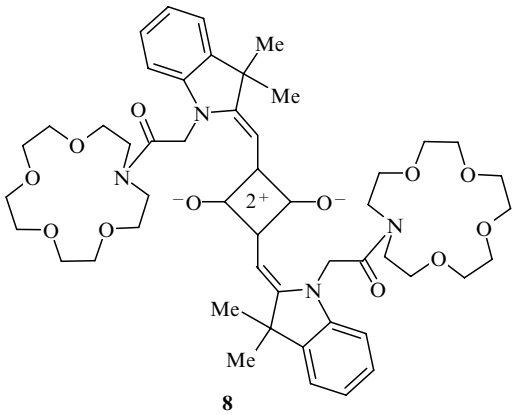


7a,**b**

R = Cl (**a**), NO_2 (**b**).

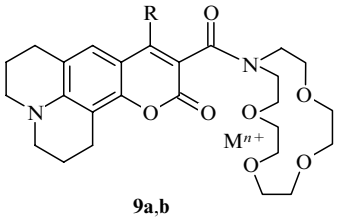
An analogous ion-selective chemosensor ligand **7b** has high sensitivity and affinity for Hg^{2+} ions over a wide range of pH.[27]

Yet another way to enhance the efficiency of sensors is to incorporate zwitter-ionic fragments. For example, excess electron density on the oxygen atoms of the central zwitter-ionic fragment in the luminescent sensor **8** makes it highly efficient with respect to lithium ions in acetonitrile – dichloromethane system.[28]



8

Similarly, the efficiency of chemosensors **9a**,**b** for divalent metal ions (Ca^{2+}, Mg^{2+}, Ni^{2+}, Zn^{2+}, Cu^{2+}) can be explained by the presence of a quinolizine and coumarin nuclei in the fluorophore.[29, 30] It was shown[30] that charge transfer from the nitrogen atom of the quinolizine part of the molecule to the carbonyl group of the coumarin part occurs in compounds **9a**,**b**. A strong PCT effect is realised in these molecules, and the electronic spectra manifest bathochromic shifts.[30]

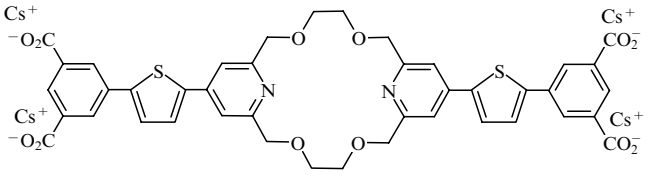


9a,**b**

R = H (**a**), CF_3 (**b**).

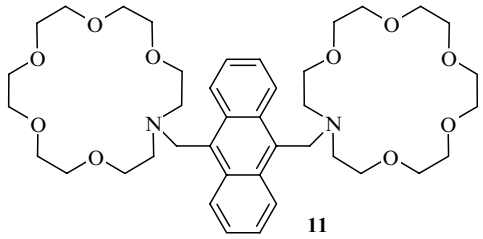
Yet another approach to specific chemosensors is the introduction of extra functional groups into the known sensors resulting in alteration of their properties. For example, introduction of carboxyl-containing thiophene derivatives as fluorophores into dipyridino-crown ether makes the resulting caesium tetracarboxylate **10** water-soluble, which is very important for practical use. The fluorescent sensor itself has high selectivity for potassium

ions, because the bulky caesium cations do not compete with potassium ions in solution for the coordination by the cavity of this dipyridinocrown ether.[31]



10

Modification of compound **1a** by addition of one more azacrown fragment results in the sensor **11** which can recognise dications. For example, ammonium groups located at α- and ω-carbon atoms of the substrate alkane chains enhance considerably the fluorescence of the sensor **11**; they are probably incorporated into both fragments of the crown ether.[32]

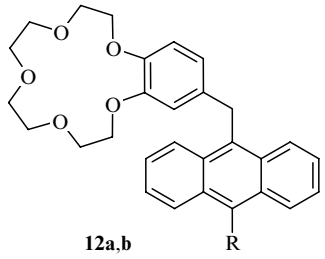


11

Azacrown ethers are characterised by rather a high basicity of the nitrogen atoms. On the one hand, the high basicity of the nitrogen atom increases the chemosensor efficiency and provides a stable PET; on the other hand, undesirable protonation occurs in acidic solutions. Crown-ether ligands are devoid of this drawback.

2. Crown ethers

Benzocrown ether **12a** was one of the first to be suggested as PET sodium ion sensor. When this compound is coordinated by the sodium cation in suitable solvents, fluorescence is enhanced.[33, 34]



12a,**b** R

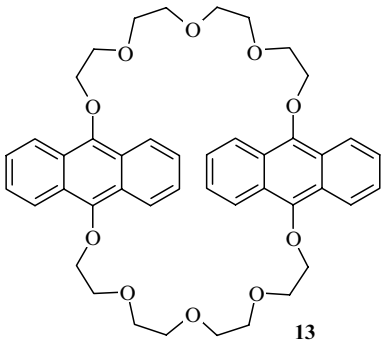
R = CN (**a**), CH_2N O (**b**).

Compound **12b** is a so-called 'switchable' fluorescent sensor which operates in acidic media, where the electron-donating morpholine substituent is protonated in the first stage.[35]

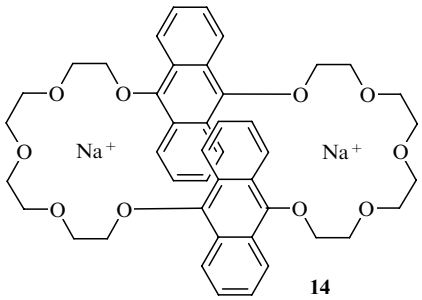
Other fluorescent indicators for the Na^+ and K^+ ions based on benzocrown ethers have been synthesised and studied (see Ref. 36).

1,8-Anthraceno-18-crown-5 is a luminescent sensor for ions of alkali and alkaline-earth metals.[37] Fluorometric titration was used to determine the stability constants of its complexes and their dependences on the cation parameters.

Bis(anthracene-9,10-diyl)coronand **13** is a sensor for Na^+ and K^+ ions. It was shown[38, 39] that gradual addition of sodium perchlorate to solutions of compound **13** in methanol or acetonitrile gives a stable excimer complex **14** with the composition 1 : 2, which is the reason for enhancement of the corresponding luminescence. K^+ ions form a 1 : 1 complex.

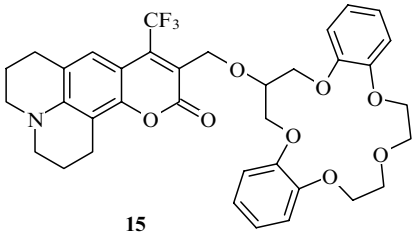


13



14

Combination of the coumarin fluorophore with benzocrown receptors results in efficient chemosensors. For example, strong substituent polarisation in sensor **15** in an excited state results in additional coordination of alkali and alkaline-earth metal ions with the carbonyl group of the coumarin fragment.



15

This effect is observed in luminescence spectra as a bathochromic shift of the bands (Fig. 3);[4] the strongest quenching is observed in the presence of the Ca^{2+} ion. The selectivity of Ca^{2+}

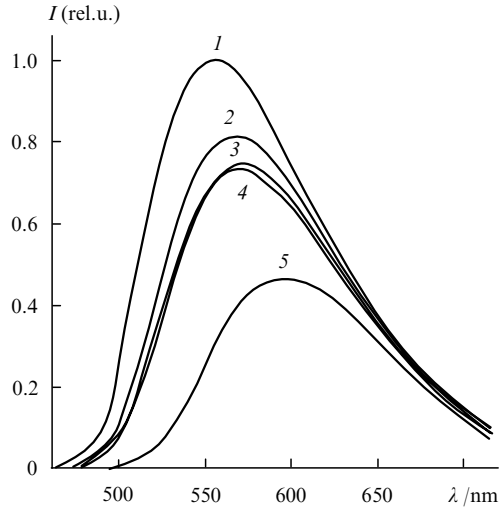


Figure 3. Fluorescence spectra of compound **15** and its complexes with metal ions in acetonitrile;[4]
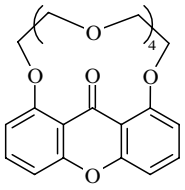
(*1*) the ligand; (*2*) K^+ complex; (*3*) Na^+ complex; (*4*) Li^+ complex; (*5*) Ca^{2+} complex.

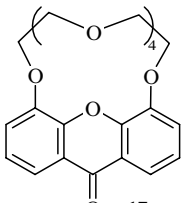
sensor **15** is very high: the ratio of stability constants of the complexes is $k(Ca^{2+}):k(Mg^{2+}) = 12\,500$; $k(Na^{+}):k(K^{+}) = 16$.

A few other sensors containing the coumarin fragment are known. For example, 4-substituted benzo-α-pyronebenzo-12-crown-4, -15-crown-5, and -18-crown-6 in acetonitrile are luminescent sensors for Li^{+}, Na^{+}, K^{+}, and Mg^{2+} ions (see Refs 40 and 41). The effect of the macrocycle size on the extent of fluorescence quenching during the formation of 1 : 1 complexes was studied.[42]

The crown ethers **16** and **17** containing the dihydroxyxanthone fragment have different properties: compound **16** has high affinity for barium ions, whereas the cavity in compound **17** binds selectively potassium ions. In the former case, luminescence is enhanced as the ion concentration increases; in the latter case, it is quenched.[43]

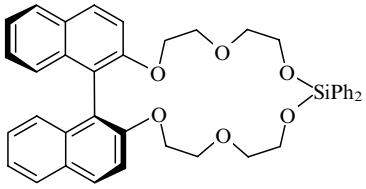


16

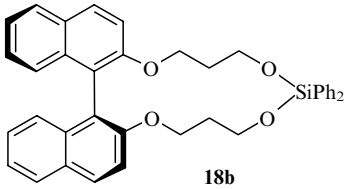


17

Unusual fluorescent sensors, namely, optically active silacrown ethers **18a**,**b** were synthesised.[44] Compound **18a** is a selective reagent for lithium ions and viologen bromide, while compound **18b** reacts with the latter to give rotaxane-like structures.

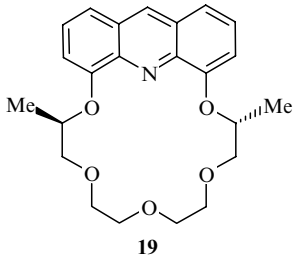


18a



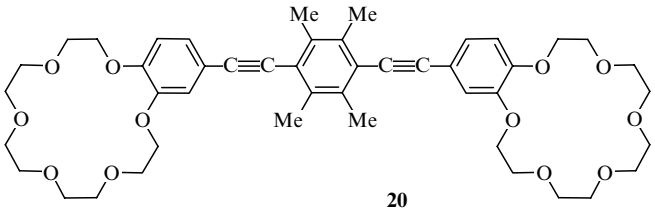
18b

The enantiomerically pure chiral ligand, *viz*., acridinodimethyl-18-crown-6 (**19**), displays high enantioselectivity and gives luminescent complexes with chiral ammonium ions in acetonitrile.[45] The authors of this study give well-reasoned evidence that it is possible to design a series of efficient enantioselective chemosensors for chiral substrates.

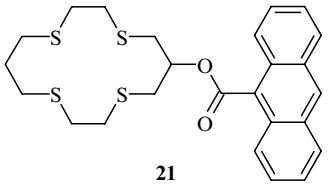


19

Xia *et al.*[46] described the synthesis of the luminescent sensor **20** containing 1,4-di(phenylethynyl)tetramethylbenzene as the chromophore and 18-crown-6 as receptors and discussed its photochemical properties. The chromophore luminescence is considerably quenched only by those lanthanide ions which have large ionic radii and in which *f*–*f* transitions occur (Ce^{3+}, Pr^{3+}, Nd^{3+}). Ions of alkali and alkaline-earth metals, as well as lanthanide ions with smaller radii, do not greatly affect the emission spectra of this sensor.



20



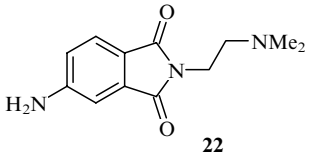
21

Thiacrown ether **21** is selective for Cu^{2+} ions. It is interesting that a 'reverse' PET operates in this complex, and fluorescence quenching occurs due to electron density shift from the anthracene substituent to the copper cation possessing strong oxidising properties.[47]

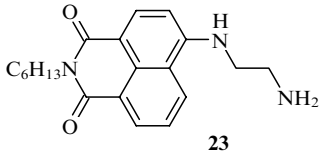
Thus, depending on the ring size and configuration, crown ethers may be selective for ions of alkali, alkaline-earth, or rare-earth metals.

3. Sensors with polyamine receptors

Even compound **22**, which is a rather simple diamino derivative, can form complexes with Cr^{3+}, Fe^{3+}, Co^{2+}, Ni^{2+}, and Cu^{2+} ions; it manifests the PET and acts as a chemosensor with 30-fold fluorescence enhancement.[48] The sensor **23** acts in a similar way but with higher selectivity for copper ions.[49]

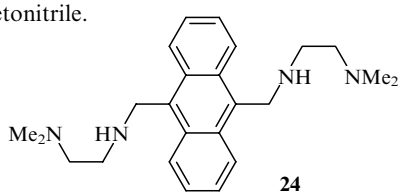


22



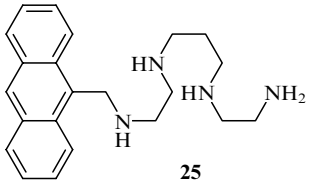
23

The anthracene derivative **24** was the first example of a chemosensor with a short polyalkylamine chain, which forms chelate complexes with transition metal ions.[50] The ligand fluorescence, which is very weak due to the PET process, becomes 1000 times more intense upon addition of zinc chloride in acetonitrile.



24

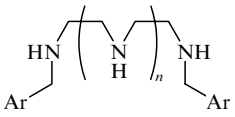
The action of chemosensors of the type **25** depends on the nature of the substrate cations and on the acidity of solutions. Coordination of Cu^{2+} and Ni^{2+} ions with compound **25** does not result in intense light emission in weakly acidic and neutral solutions (pH > 4) where the amino groups are not protonated and the PET operates. This results from deactivation of the excited state *via* the energy levels of the metal centre.



25

On the contrary, a complex of compound **25** with Zn^{2+} luminesces strongly due to the d^{10} configuration of the Zn^{2+} ion and an increase in the oxidation potential of amines.[51]

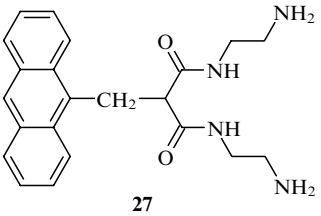
A large series of open-chain and cyclic *N*-mono- and *N*,*N*-diarylpolyalkylamines has been synthesised and analysed.[52] Compounds **26** are chemosensors for proton and transition metal ions: Co^{2+}, Ni^{2+}, Cd^{2+}, Pb^{2+}, Cu^{2+}, Zn^{2+}. Protonation or coordination of cations change the fluorescence accordingly. Sensors **26** where Ar are terminal anthracene substituents can form excimers.



26

$n = 0-4$.

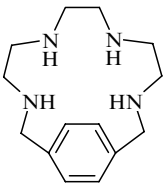
Ligands containing aminoethylamide fragments (*e.g.*, compound **27**) are effective in recognition of Ni^{2+} and Cu^{2+} cations. It is believed that photoexcitation involves electron transfer from the metal ions to the ligand.[53]



27

Fluorescent complexes with the composition ML_2^{2+} [where L is 6-(9-fluorenyl)-1,4,8,11-tetraazaundecane-5,7-dione and M is a divalent ion of copper, nickel or cobalt] were studied in non-aqueous and aqueous media.[54]

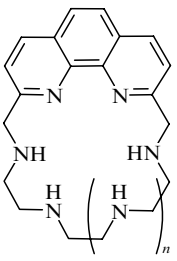
It was found that open-chain polyamines are more efficient sensors than cyclic polyazacyclophanes **28**.[52]



28

In a molecule of compound **28**, the polyamine chain is arranged as a strained arch above the benzene ring plane. As a result, simultaneous coordination of both benzyl nitrogen atoms by a single metal ion becomes impossible. However, the PET can still operate in the complex.

The situation changes if the ring size increases or if additional nucleophilic centers are introduced. For example, macrocyclic ligands **29a**,**b**, in which the receptor ring contains a 1,10-phenanthroline fragment, are chemosensors for hydrogen and zinc cations.[52]

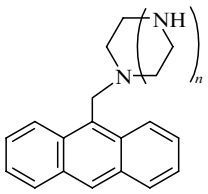


29a,**b**

$n = 1$ (**a**), 2 (**b**).

Compound **29a** forms only a mononuclear complex with zinc, whereas compound **29b** forms both mono- and binuclear complexes. Thus, fluorescence spectra depend on the degree of protonation and complexation.

Rather efficient chemosensors for Zn^{2+}, Cd^{2+}, and Hg^{2+} were obtained based on anthracene-substituted polyazacrown ethers **30** (see Ref. 55).

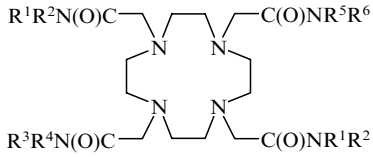


30a–**e**

$n = 1$ (**a**), 2 (**b**), 3 (**c**), 4 (**d**), 5 (**e**).

The luminescence of compounds **30c**,**e** is pH-dependent and increases abruptly upon complexation with Zn^{2+} or Cd^{2+} in water. On the contrary, Hg^{2+} ions quench the residual fluorescence of compounds **30a**–**e**.

The fluorescent properties of macrocyclic ligands **31a**–**d**, containing *N*-(β-naphthylmethyl)amide groups as fluorophores, were studied in water and acetonitrile. All ligands **31** display the typical fluorescence of the naphthalene chromophore (λ_{max} = 337 nm); however, it is weakened due to the PET. The emission spectra of compounds **31b**–**d** contain additional broad bands typical of the naphthalene excimer (λ_{max} = 397–401 nm). The ligands show different luminescent properties in the presence of quenching ions (Pb^{2+}, Ni^{2+}, Cu^{2+}, Eu^{3+}) and ions that cause luminescence enhancement (Zn^{2+}, Cd^{2+}).[56]



31a–**d**

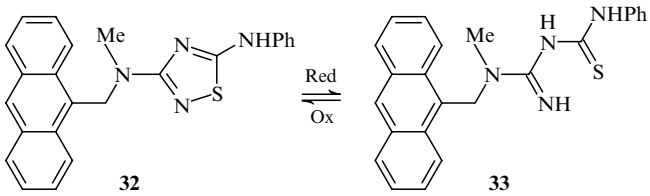
$R^1 = R^3 = R^5 = H$, $R^2 = R^4 = Me$, $R^6 = 2\text{-}CH_2C_{10}H_7$ (**a**);
$R^1 = R^3 = R^5 = H$, $R^2 = R^4 = R^6 = 2\text{-}CH_2C_{10}H_7$ (**b**);
$R^1 = R^3 = H$, $R^2 = R^4 = Me$, $R^5 = R^6 = 2\text{-}CH_2C_{10}H_7$ (**c**);
$R^1 = H$, $R^2 = Me$, $R^3 = R^4 = R^5 = R^6 = 2\text{-}CH_2C_{10}H_7$ (**d**).

When the ligand **31a** is coordinated with zinc or cadmium ions, the emission intensity increases by a factor of two; addition of Pb^{2+} salts quenches fluorescence by 25% (the heavy atom effect), while addition of Cu^{2+} quenches it by 95%. In the $Tb^{3+}\cdot$**31a** complex, fast deactivation processes predominate, which complicate spectroscopic studies. If Cd^{2+} ions are added, the intensity of the short-wave radiation of protonated sensor **31b** in acetonitrile increases, whereas the excimer band disappears quickly. Similarly, emission is quenched by Pb^{2+} ions. The reason for this is that naphthyl excimers cannot be formed in these complexes because of spatial hindrance. Complexation of the ligand **31c** with metal ions (Zn^{2+}, Cd^{2+}, Pb^{2+}, Ni^{2+}, Cu^{2+}, Eu^{3+}) occurs quickly even in aqueous solutions. Its behaviour in the presence of various ions resembles that of compound **31a**. Coordination of compound **31d** (which is more strained spatially) with metal ions is hindered. The Zn^{2+} and Cd^{2+} ions affect very weakly both the total intensity of fluorescence of the ligand **31d** and the ratio of emission from the monomer and excimer. On the other hand, the Pb^{2+}, Ni^{2+} and Cu^{2+} ions decrease the total emission (by 36%, 37% and 86%, respectively) by affecting considerably the excimer band.

Various physical methods were used to study whether it is possible to determine copper, nickel, zinc, cadmium, mercury, and lead cations using a series of polyaza- and oxazacycloalkanes (14 to 18 units) containing peripheral anthrylmethyl fluorophores. It was found that all metals studied form stable complexes with these ligands in dioxane–water and THF–water media.[57] Copper(II) ions selectively quench the fluorescence of sensors in neutral and acid media; the intensity of luminescence of the 1,4,10-trioxa-7,13-

diazacyclopentadecane ligand increases selectively in the presence of mercury(II) ions in basic medium.

Novel fluorescent chemosensors **32** and **33** for heavy metal ions were suggested.[58] Since the reduced form **33** is readily transformed into the oxidised form **32**, these compounds may be considered as two components of a switchable redox system.



32 **33**

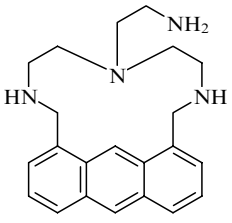
The oxidised form **32** binds mercury ions with a 44-fold increase in fluorescence; the carbamimidoylthiourea fragment of molecule **33** interacts with cadmium ions with a six-fold increase in the fluorescence intensity.

In the majority of fluorescent chemosensors considered above, which incorporate monocyclic or open-chain receptors containing nucleophilic atoms such as O, N, and S, the structures and electronic properties are affected by substrates (in most cases, cations). Nitrogen-containing podands and rings have sensor properties only with respect to hydrogen and transition metal ions. Incorporation of oxygen receptor atoms makes it possible to expand the range of cations that can be analysed (alkali and alkaline-earth metals; rare-earth elements; ammonium ions) and to improve selectivity. The selectivity and sensitivity of chemosensors increase upon transition from two-dimensional molecules to three-dimensional systems that coordinate substrate species in a 'host – guest' fashion in molecular cavities of specific sizes.

4. Tetraaminoalkyl three-dimensional sensors

Some planar chemosensors contain functional substituents which fix a cation or some other substrate outside the plane. As an example, the molecules **6** – **9a**,**b**, **15**, and **31a** – **d** have additional complexation sites located outside the main coordination plane. A tertiary nitrogen atom in a pyramidal configuration often serves as a vertex of a complex molecular frame forming a cavity.

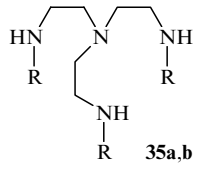
For example, compound **34** containing four nitrogen atoms is a selective sensor for Cu^{2+} and Hg^{2+}. In neutral media, its fluorescence is quenched due to formation of chelates with copper (18-fold) or mercury cations (fourfold).[59]



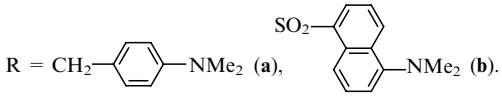
34

The sensor **35a** containing *p*-*N*,*N*-dimethylaminobenzyl fluorophores has an emission band at $\lambda = 360$ nm.[60] The fluorescence of sensor **35a** in solution in the presence of Cu^{2+} ions reaches a maximum at pH 3.8 (protonated form); as the pH is increased and protons are replaced by copper ions, fluorescence is progressively quenched and disappears at pH 5.5. Thus, the system **35a** – Cu^{2+} is an efficient switchable pH-dependent sensor.

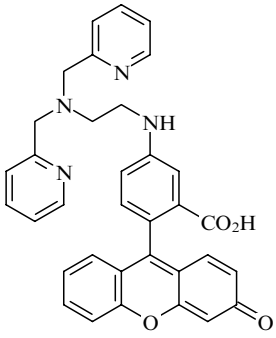
The fluorescence of compound **35b**, which contains 5-dimethylaminonaphthalenesulfonyl (dansyl) substituents as chromophores, does not depend on the pH of the medium in the range from 3 to 11. However, complexation with such ions as Cu^{2+}, Co^{2+}, Zn^{2+}, and Cd^{2+} at pH 9.5 affects strongly the luminescence: Cu^{2+} and Co^{2+} quench luminescence, whereas Zn^{2+} and Cd^{2+} enhance it. At pH 6, only Cu^{2+} ions form a complex, which makes compound **35b** a highly selective sensor for copper ions under physiological conditions.[61]



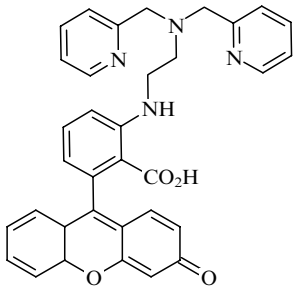
35a,**b**



In certain sensors, some of the nitrogen atoms may be involved in heterocycles; for example, this is the case for the sensor **36a** which has high selectivity for zinc ions and may be used to analyse biological objects. Its isomer **36b**, in which the polyamine substituent is at position 6 of the benzene ring, is also highly selective for Zn^{2+} ions. The fluorescence of original starting compounds is almost independent of the medium acidity; it is virtually absent at pH 7.5. However, the fluorescence of compound **36a** becomes 17 times more intense as zinc ions are added, whereas that of the 6-substituted isomer **36b** becomes 51 times more intense.[62]

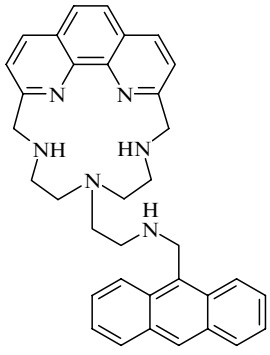


36a



36b

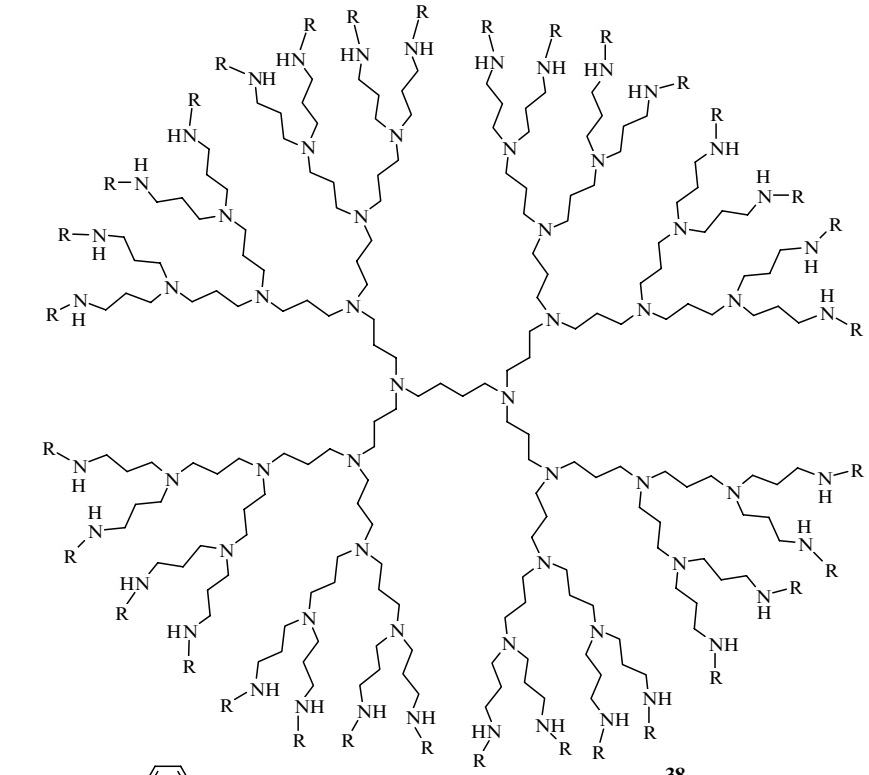
The fluorescence of the sensor **37** is quenched owing to the PET. At appropriate pH values and concentrations of the coordinating Zn^{2+} ions, reversible formation (decomposition) of the exciplex occur because the phenanthroline and anthracene parts of the molecule become closer (or farther, respectively). This allowed Bencini *et al.*[63] to classify this system as a 'molecular machine' controlled by pH and light.



37

Balzani *et al.*[64, 65] used polymeric compositions (dendrimers) based on polypropyleneamine with dansyl end groups (*e.g.*, compound **38**) as luminescent Co^{2+} sensors.

The amine fragments create a polycellular internal cavity which coordinates the cations. The formation of the complex with the Co^{2+} ions does not affect the absorption spectra, but it strongly quenches the radiation from the peripheral fluorophores; one cell of the dendrimer reversibly coordinates one cation. Zinc ions do not affect the properties of dendrimers; in the presence of Cu^{2+} cations, the macromolecule undergoes irreversible changes.

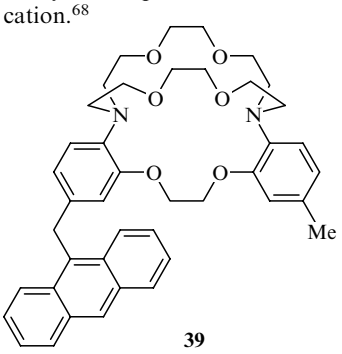


38

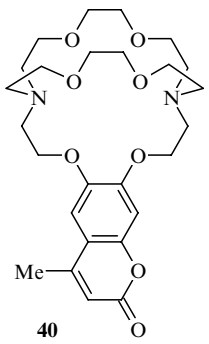
R = —SO_2— NMe_2

5. Cryptands

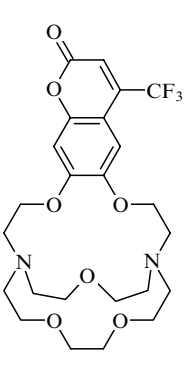
Attachment of an out-of-plane bridge to azacrown ethers results in cryptands, which represent sensors with enhanced receptor capacity.[66] For example, the PET is observed in the molecules of cryptands **39**–**41**. The cavity size in these compounds governs the selectivity: the parameters of the receptors in compounds **39** and **40** match the diameter of the K^+ ion (see Ref. 67), whereas the cavity in compound **41** is suitable for coordinating the sodium cation.[68]



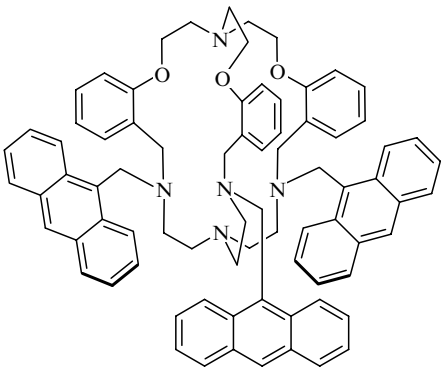
39



40



41



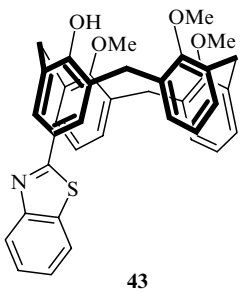
42

In order to determine transition metal ions, it was suggested to use cryptand sensors of the type **42**, which form 1 : 1 adducts with Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and Pb^{2+} cations in THF with an accompanying strong increase in the sensor fluorescence.[69] Of these cations, the strongest effect is observed in the case of Zn^{2+}. Silver and mercury ions, which have larger ionic radii, cannot form complexes. The properties of compounds **40**–**42** are strongly pH-affected.[4, 70]

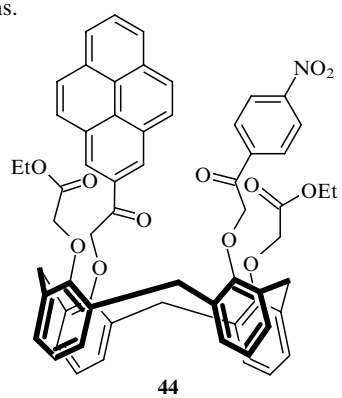
6. Calixarenes

Various calixarene and -hetarene derivatives can also be used as efficient sensor systems. Spatially hindered calixarenes are not very good ligands to form stable complexes; however, they can serve as a supramolecular base for adding diverse receptors and fluorophores. This results in sensors containing cavities with different sizes and properties suitable for several types of 'guest' species.

One of the first simple calix[4]arene systems **43** containing a benzothiazole fluorophore showed selective properties as a sensor for lithium ions.[71] The Li^+ cations replace the phenol proton and coordinate the methoxy groups, thus causing a bathochromic PCT-shift of the fluorescence band. This system shows no response to Na^+ and K^+ ions.



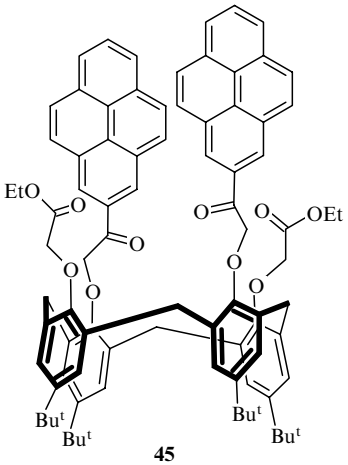
43



44

The cavity of yet another calix[4]arene sensor **44**, which incorporates ester groups, matches the size of Na^+ (see Ref. 72). Coordination with Na^+ breaks the spatial contact between the pyrene and nitrophenyl rings, which results in disappearance of the PET and enhances fluorescence by a factor of six.

Calixarene **45** is also suitable for the identification of Na^+ (see Ref. 73). Incorporation of the cation into the inner sphere of the sensor prevents the formation of an excimer from the pyrene units; as a result, only the monomer fluorescence remains in the spectrum of the complex. The selectivity factor [the ratio $k(Na^+):k(K^+)$] is 154; the presence of lithium cations does not disturb the system.



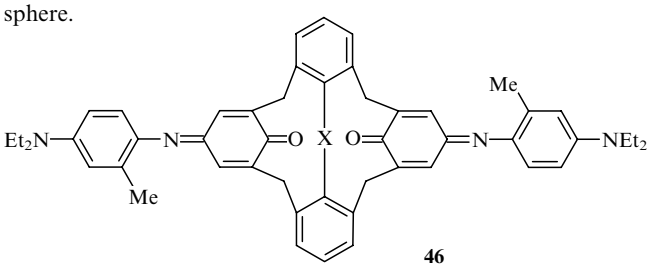
45

Ionophore **45** has recently been modified [74] by introducing a 9-anthroyloxyphenyl fluorophore into the molecule.

The electronic interactions in a series of calix[4]arene crown ethers and their complexes with alkali metal ions were studied. Absorption and emission electron spectroscopies have been used to reveal the effects of π-binding between the cations and the ligand; it was assumed that they have a major effect on the luminescent properties of the fluorophore.[75]

Many calixarene sensors contain crown ether fragments as receptors.

For example, calix[4]crown ether **46** is a strong ionochromophore.[76] If Ca^{2+} ions are added, they enter the cavities and interact with the electrons of the imino, keto, and crown-ether groups; a bathochromic shift occurs, which changes the colour of the compound from blue to green ($\Delta\lambda$ = 112 nm). This phenomenon is not observed in the presence of potassium ions; if the latter are coordinated with compound **46**, the spectrum of the latter is restored due to displacement of calcium ions from the inner sphere.



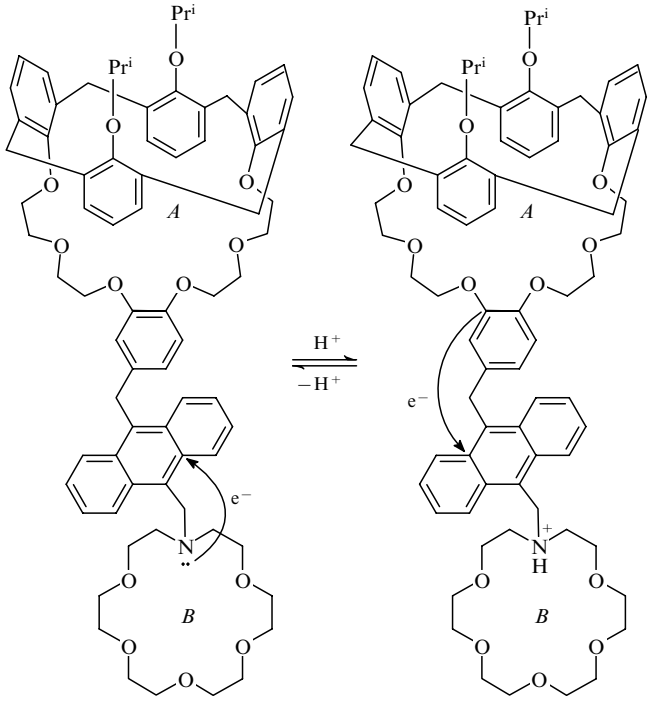
46

X = $OCH_2(CH_2OCH_2)_3CH_2O$.

Alkali metal cations affect strongly the excitation spectra of other calix[4]crown ethers containing two peripheral acetamidoanthraquinone residues.[77]

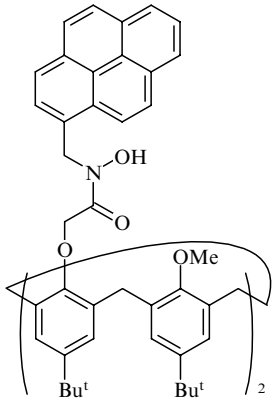
1,3-Alternating calix[4](9-cyano-10-anthrylmethyl)benzocrown-6 and its dideoxygenated analogue showed high selectivity towards the caesium ion when it was determined in the presence of a tenfold excess of potassium and rubidium cations.[78]

A more complicated calix[4]arene system **47** containing two crown receptors was suggested as an integrated sensor for the determination of potassium cations in alkaline medium and caesium cations in acidic medium.[79] The PET in alkaline solutions results in a very weak residual fluorescence of the anthracene fluorophore. Addition of caesium ions, which are coordinated by the cavity *A*, does not change the spectral characteristics. On the contrary, K^+ cations are incorporated into the cavity *B* of the crown ether, quench the PET and cause a sevenfold increase in fluorescence. In acidic media, where the nitrogen atom of the ring *B* is protonated, the PET is supported by the crown ether fragment *A*, and the fluorescence intensity is low. In this case, the ring *B* cannot coordinate potassium cations. Addition of Cs^+ ions to the solution results in their coordination by the ring *A* and a fourfold increase in fluorophore emission. Li^+ and Na^+ ions do not compete with each other in these processes, but rubidium cations display an effect resembling that of potassium cations in alkaline medium and that of caesium cations in acidic media.



47a **47b**

The range of cations that can be determined by sensors based on calixarenes is rather wide. Such sensors are suitable for analysis of not only alkali but also transition metal cations. For example, the bispyrenyl calix[4]arene **48** with two hydroxamic acid linkers is a good Cu^{2+} and Ni^{2+} sensors (see Ref. 80).

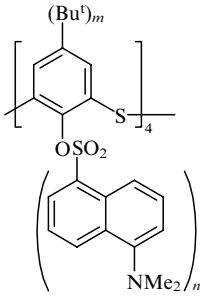


48

In solutions, compound **48** generates a double fluorescence spectrum, which corresponds to the monomeric and excimeric states of the pyrene rings. Addition of copper or nickel salts to the solution quenches abruptly a part of the fluorescent irradiation

depending on the solution acidity. In the opinion of Bodenant *et al.*,[80] the excimer photosensitivity of the ligand makes it possible to consider this system as a new type of chemosensor for the selective determination of transition metal ions in aqueous media.

The selectivity of sensors based on calixarenes may be enhanced by replacing the oxygen atoms in the calixarene skeleton by sulfur atoms. For example, water-soluble thiacalix[4]arenes **49** modified by dansyl fragments were suggested for the first time as fluorescent chemosensors for Co^{2+}, Ni^{2+}, and Cd^{2+}.[81]



49

$m = 0-4$; $n = 2-4$.

tert-Butyl groups decrease the sensitivity of sensor molecules. The thiacalixarene **49** containing one *tert*-butyl group ($m = 1$) and three dansyl residues ($n = 3$) was found to be the most efficient. The complexation constants of this compound with Co^{2+} and Cd^{2+} are 2380 and 1510, respectively. For comparison, the corresponding constants for the chemosensor **49** containing four *tert*-butyl groups ($m = 4$) and three dansyl residues ($n = 3$) are 130 and 250.

Calix[4]arene systems can be luminescent chemosensors for medium-radius lanthanides.

The recently obtained macrocyclic water-soluble tetra-*p*-sulfonylmethylcalixresorcin[4]arenes coordinated with Nb^{3+} or Eu^{3+} ions show a triplet transition with an analytical frequency of 24 400 cm^{-1} (see Ref. 82). In acetonitrile, the same ions form highly luminescent complexes with calix[4]arene crown ethers containing a 2,2′-bipyridine fragment.[83]

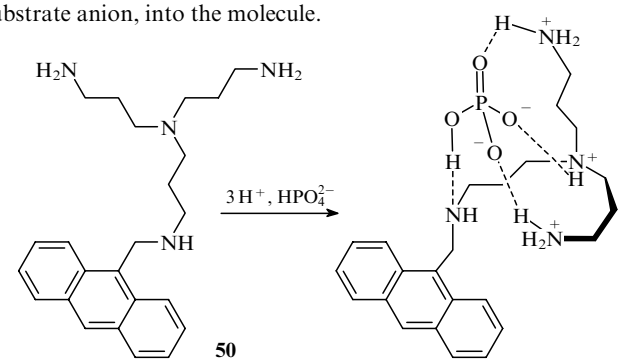
III. Fluorescent chemosensors for anions

The main types of sensor used for the determination of anions have been considered in detail in reviews [17, 18] and in a monograph,[84] hence here it is appropriate to dwell on the general principles for constructing such chemosensors and to discuss recent publications.

Design of luminescent sensors for anions is a more complex task than that for cations, for the following reasons.

1. Anions are usually larger than cations, hence the receptor should have a larger coordination space; in addition, because of a low charge density on the anion, the receptor should form rather strong bonds with the anion (at the hydrogen bond level).

2. Receptors for anions are commonly constructed on the basis of cation receptors by incorporating strong electrophiles (protons, metal cations) enabling reversible coordination of the substrate anion, into the molecule.

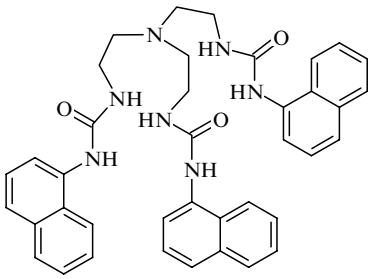


50

The system **50** was the first example of a fluorescent molecular sensor for anions.[85]

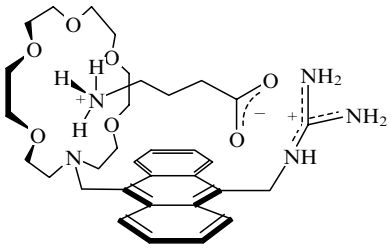
In aqueous solutions at pH 6, only three nitrogen atoms are protonated (the nitrogen atom closest to the anthracene fragment remains non-protonated), therefore the PET is effective and emission of the anthracene ring is small. If an HPO_4^{2-} anion is coordinated, the fourth H—N bond appears and fluorescence is enhanced.

Such anions as $H_2PO_4^-$ and HSO_4^- can be detected using the fluorescent system **51**, which incorporates three naphthylurea residues. The sensor **51** forms a 1 : 1 complex with $H_2PO_4^-$ in which the ligand fluorescence is enhanced owing to the PET.[86]



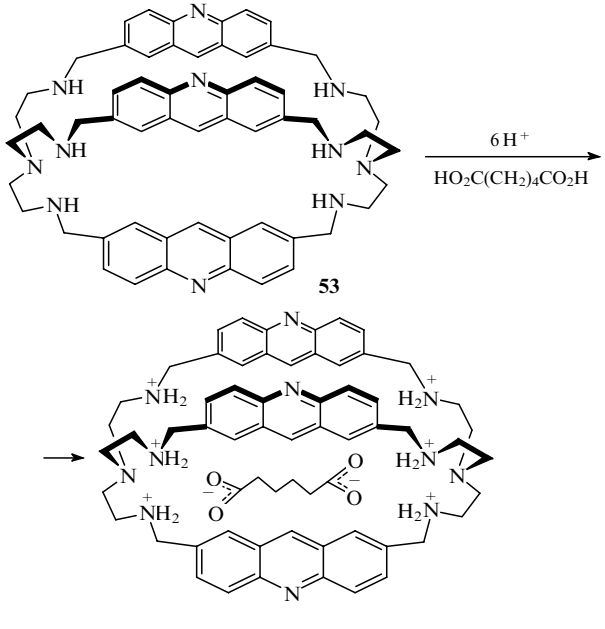
51

Compound **52** is an example of molecular sensor for amino acids.[87] In this compound, the bifunctional receptor is suitable for coordinating a zwitter-ionic amino acid molecule. The fluorescence of the anthracene fragment increases severalfold due to complexation.



52

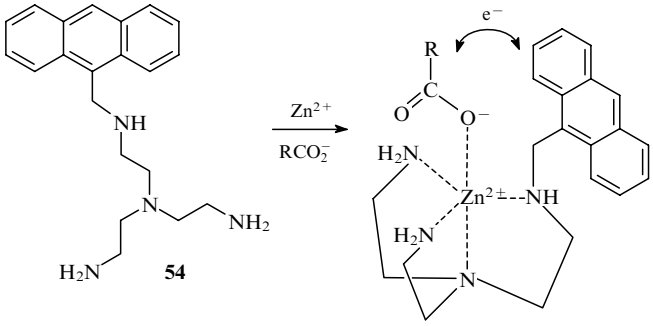
Polyazacycles are commonly used as selective sensors for anions. At pH 6, six of the eight nitrogen atoms in the cage of compound **53** are protonated (except the two apical ones). In this case, the fluorescence of the acridine fragment is quenched almost completely. When a dicarboxylate anion of suitable size is incorporated into such a protonated cell, intramolecular isolation



53

of the acridine rings occurs; the latter can no longer form an excimer and hence show strong one-ring fluorescence.[88]

An anion may also be fixed by a cation incorporated into the receptor and capable of coordination. For example, the tetramine **54**, which is a well-known chemosensor for zinc ions, displays secondary sensor capabilities in the presence of aromatic carboxylate anions.[89]

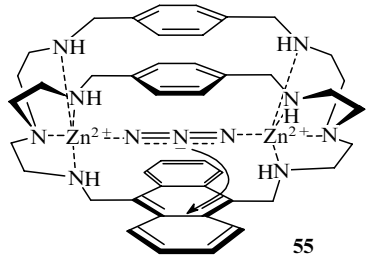


The fluorescence of the excited anthracene fragment is quenched when the carboxylate anion is bound with Zn^{2+}, which is explained [89] by electron transfer between the aromatic moiety of the carboxylic acid and the anthracene fluorophore.

The SO_4^{2-} ions can be determined selectively in acidic aqueous media using a complex of 1,4,8,11-tetrakis(naphthylmethyl)-1,4,8,11-tetraazacyclotetradecane with Cu^{2+}. The fluorescence intensity of this system increases in the presence of sulfate ions.[90]

A number of calix[4]pyrroles bound with anthracene moieties were synthesised and used as fluorescent chemosensors for anions (F^-, Cl^-, $H_2PO_4^-$).[91, 92]

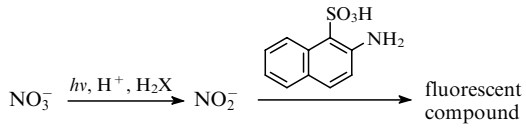
A bulky dizinc octamine complex **55** suitable for the selective determination of a number of anions was synthesised.[93] At pH 8 this complex reacts with ambident anions to give stable 1 : 1 adducts. The cavity of the molecule containing two zinc cations can accommodate linear anions such as N_3^- (2.34 Å), NCO^- (2.42 Å), and (partially) NCS^- (2.75 Å). If any of these anions is added to the sensor, fluorescence of the anthracene moiety is quenched due to electron density transfer.



55

Certain other anions, such as NO_3^-, HCO_3^-, SO_4^{2-}, Cl^- and Br^-, do not affect the fluorescence intensity of the anthracene moiety even if they are present in tenfold excess.

Other, less bulky molecular systems can also be effective for the determination of anions. In particular, Sharma and Street [94] reported a fluorescent determination method for nitrate and nitrite ions in water using simple photoreactions resulting in a fluorescent compound with unknown structure. This method is used for monitoring the content of NO_3^- anions in tap water.



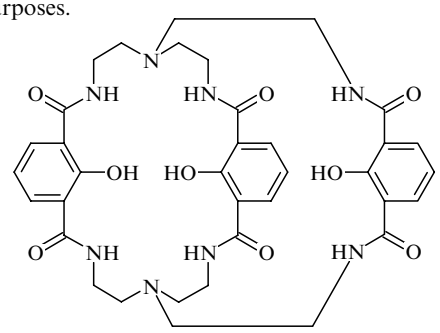
X = S^{2-}, SO_3^{2-}.

A method for the quantitative determination of nitrite ion in water and foodstuffs was elaborated [95] based on quenching of the indole fluorescence upon its interaction with nitrite ions in acidic medium. The detection limit is 2.5 mg per litre of the solution.

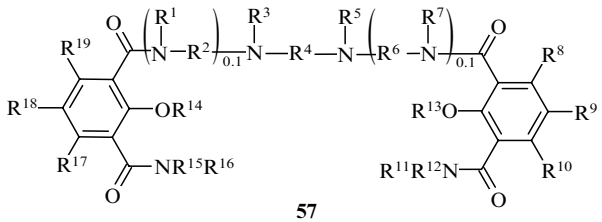
IV. Luminescent sensors for molecules

In Section III, we have already considered luminescent sensors for the determination of amino acids in acidic media [87] and dicarboxylic acids in alkaline solutions.[88] Recently, intense development of methods for the analysis of neutral organic molecules belonging to various classes has started. A number of sensors based on cationic and anionic receptors have been created for their determination.

For example, the luminescent sensor **56** has been patented; its non-cyclic analogue **57** has also been synthesised.[96] Complexes of these compounds with lanthanide cations are luminescent; the active cavities and diverse radicals $R^1 - R^{19}$ at the periphery of the macromolecules make it possible to detect a number of organic compounds, including peptides, nucleic acids and enzymes, and also to use these systems as luminescent markers for various purposes.

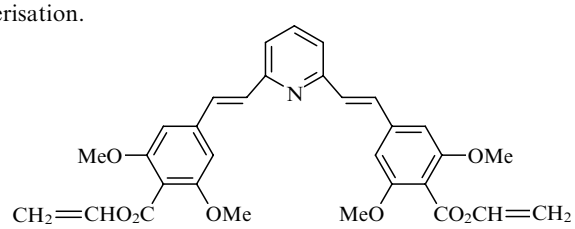


56



57

The fluorescent monomer **58** has been developed for the selective determination of phenols and anilines in non-polar solvents, even in the presence of aliphatic alcohols and amines, oxygen, and water.[97] The monomer can be involved in copolymerisation.



58

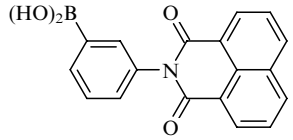
A new sensitive fluorimetric method for the determination of formaldehyde is based on the quenching of fluorescence of the aluminium complex of a tetra-substituted aminophthalocyanine in the presence of sulfite and formaldehyde. The latter can be determined at a concentration of 0.040 – 1.19 μg ml^{-1}, the detection limit being 7.5 ng ml^{-1} (see Ref. 98).

In order to determine traces of aldehydes and ketones in water, a fluorescent sensor was suggested, *viz*., 2-aminooxy-*N*-(3-dansylaminopropyl)acetamide.[99] It can be used for identification of formaldehyde, acetaldehyde, acetone, and other aldehydes and ketones at concentrations < 1 μmol $litre^{-1}$. The very low detection threshold makes this method suitable for the analysis of snow, ice and water in clouds for the content of carbonyl compounds.

The content of hydrogen peroxide in snow and ice can be determined with high accuracy using a new chemiluminescent reagent, *viz*., 7-(4,6-dichloro-1,3,5-triazinylamino)-4-methylcoumarin.[100] The chemiluminescence intensity is directly proportional to the concentration of H_2O_2 in the range 1×10^{-1}–4×10^{-4} mol litre^{-1}. The majority of non-transition metals do not interfere with this analysis.

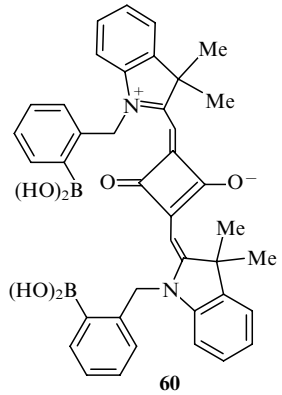
The first fluorescent sensor for the determination of boronic acids based on an anthracene fluorophore was created; a diethanolamine fragment was used as the receptor in this sensor. Complexation increases fluorescence by a factor of 19 due to the PET.[101]

Synthesis of a new water-soluble reagent **59** for carbohydrates based on 3-aminophenylboronic acid and naphthalene-1,8-dicarboxylic anhydride was reported.[102] Naphthalimide is the fluorophore in compound **59**. Significant change in the irradiation intensity ($I/I_0 = 0.25$) makes compound **59** a useful sensor in neutral media.[102]



59

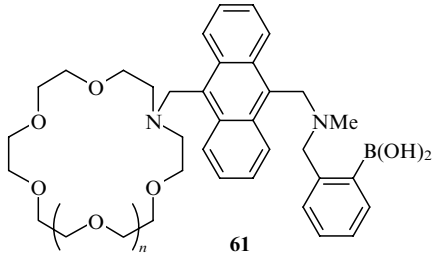
The symmetrical molecule **60** with two phenylboronic acid residues allows one to detect carbohydrates in aqueous solutions owing to a considerable enhancement of fluorescence.[103] Its characteristic feature is a low-frequency range; $\lambda_{max} = 645$ nm, with a shoulder at $\lambda = 695$ nm.



60

A fluorescent sensor for certain choline phospholipids was obtained based on squaramide.[104]

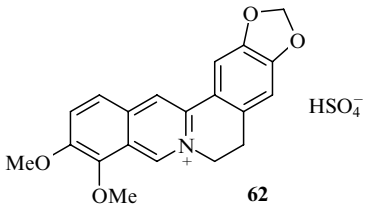
The selective fluorescent sensor **61** for D-glucosamine contains two receptors per molecule: monoaza-18-crown-6 (or monoaza-15-crown-5) and a boronic acid residue.[105]



61

$n = 0, 1$.

Fluorescent sensors were found even for such chemically inert organic compounds as hydrocarbons. For example, alkanes increase the fluorescence of berberine sulfate **62** under monochromatic UV irradiation. This effect was explained [106] by ion–dipole interaction of the hydrocarbon with berberine sulfate.

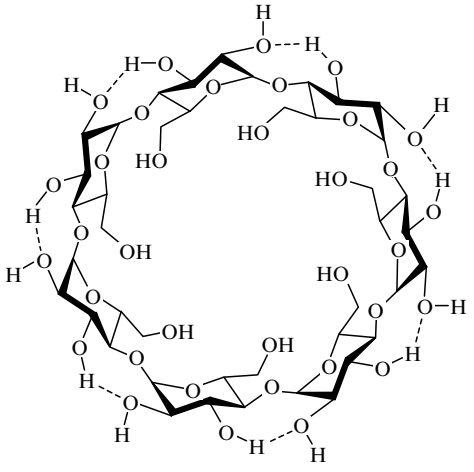


62

A method for selective determination of certain polycyclic aromatic hydrocarbons was suggested, involving the recording of the phosphorescence of sodium dodecyl sulfate micelles in the presence of acridine dyes (as donors of triplet energy) and polycyclic compounds (pyrene, anthracene, *etc*.) as acceptors.[107]

Cyclodextrins (CD) are also of considerable interest as chemosensors. A cavity in a cyclodextrin has low polarity, and its size is suitable for many 'guest' molecules. The properties of the substrate in the complex change considerably; this is reflected in the absorption and emission electronic spectra. Cyclodextrins are valuable sensors, as they often form water-soluble complexes owing to the presence of hydroxy groups; this expands considerably their scope.

More than 30 years ago, an inclusion complex was obtained, consisting of β-cyclodextrin **63** and 8-amino-1-naphthalenesulfonic acid. The molecules of the latter in the bound state showed intense fluorescence.[108] Later, a series of fluorescent sensors were obtained on the basis of this complex.



63

Two types of fluorescence, namely, monomer and excimer fluorescence, were studied for inclusion complexes of various naphthalene derivatives with β-CD.[109] Excimer fluorescence predominates for equimolar concentrations of naphthalene and β-CD. Complexes of 2,7-dimethylnaphthalene and 2-benzylnaphthalene with β-CD do not show excimer fluorescence.

Structures of various complexes of β-CD with naphthalene, phenanthrene, fluorene and cyclohexane were studied both by experimental and theoretical methods.[110–112] The complexation energy ranges within 9–12 kcal mol^{-1}.

Long-lived fluorescence at room temperature was found and studied for 2 : 2 complexes of β-CD with naphthalene.[113]

De la Pena *et al*.[114] studied the effect of various factors on the phosphorescence of the complex of α-CD with 6-bromo-2-naphthol in deaerated aqueous solutions at room temperature. Emission maxima were detected at $\lambda = 500$ and 535 nm. The determination threshold of bromonaphthol is 0.26 mg litre^{-1} with a standard deviation of 4%.

It was found subsequently that the addition of small amounts of various non-polar liquids (particularly cyclohexane) results in a very strong enhancement of phosphorescence. However, the presence of reducing agents (sodium sulfite) quenches the signal.[115]

Hydroxypropyl-β-CD in aqueous media forms a supramolecular inclusion compound with 8-anilino-1-naphthalenesulfonic

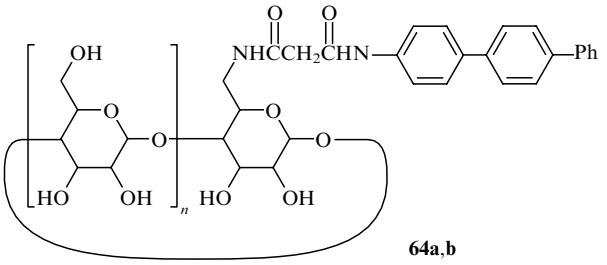
acid, which results in significant luminescence enhancement of the latter.[116]

Triethylenetetraminebis(β-CD) was synthesised from hydroxypropyl-β-CD and triethylenetetramine; after modification by Cu^{2+} ions, it showed specific luminescence upon interaction with 'guest' molecules, such as 6-(*p*-toluidino)-2-naphthalene- and 8-anilino-1-naphthalenesulfonic acids.[117]

A naphthol-modified β-CD was successfully used as a fluorescent sensor in the determination of trace amounts of CCl_4 and 2-methylisoborneol in water.[118]

β- and γ-Cyclodextrins modified by pyrrolinone residues are fluorescent chemosensors for a number of carboxylic acids, terpenoids and bile acids.[119] The cyclodextrin 'host' has a fluorescence band at $\lambda = 472$ nm, the intensity of which decreases if adamantane-1-carboxylic, *p*-aminobenzoic, benzoic, phthalic or cyclohexenecarboxylic acid is added as the substrate in aqueous medium at pH 5.90. However, if these acids are added in a buffer solution with pH 9.09, fluorescence is enhanced. The same effect is achieved if terpenoids, amino compounds and bile acid salts are added as the 'guests'.

The sensitivity of the cyclodextrin 'host' to the nature of the 'guest' molecules can be varied by changing the cavity size in the 'host'. For example, the terphenyl-substituted β-cyclodextrin **64a**, which has a smaller cycle than the γ-cyclodextrin derivative **64b**, 'recognises' well small terpenoid molecules, especially in the dimethyl sulfoxide–water medium (1 : 9). Bulkier bile acids are detected with lower sensitivity. It is interesting to note that the radiation intensity of cyclodextrin **64a** increases due to interactions with 'hosts', whereas that of compound **64b** decreases.[120]



64a,**b**

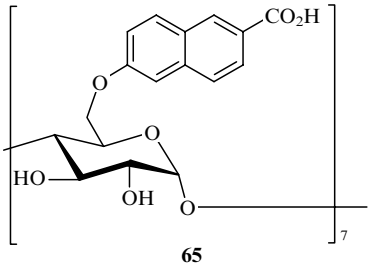
$n = 6$ (**a**), 7 (**b**).

Dansyl- and tosyl-modified β- and γ-CD are used as chemosensors for bile acids and terpenoids.[121] The luminescence of β-CD is quenched in the presence of 'guest' molecules, while that of γ-CD is enhanced as a result of interactions with monocyclic and non-cyclic molecules. Chenodeoxycholic acid, ursodeoxycholic acid, and (−)-borneol can be recognised with high sensitivity using β-CD, while γ-CD can be used to recognise lithocholic acid and (−)-borneol.

A system comprising a peptide, γ-CD and naphthalene fragments can also respond to the presence of various cholic acids due to the formation of a luminescent excimer.[122]

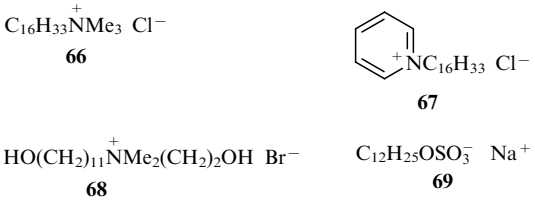
Mono[6-deoxy-6-(1-methyl-2-pyrrolidinylidenesulfamido)]-β-CD synthesised recently is also a promising sensor.[123]

A highly sensitive water-soluble fluorescent sensor system **65** was obtained; this is a β-CD (receptor) substituted with 2-naphthoic acid (fluorophore).[124]



65

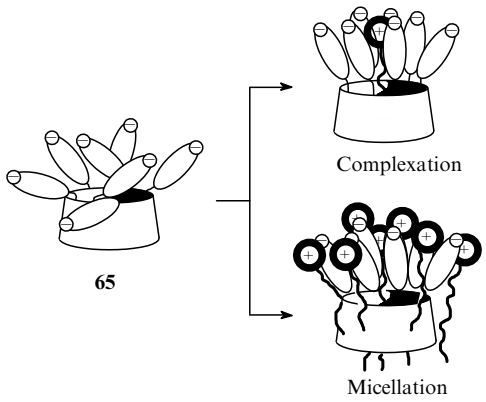
The sensor **65** was used to detect surfactants (mostly cations) of the types **66**–**69** with long hydrocarbon chains.



66 **67**

68 **69**

The fluorescence spectra of the sensor **65** undergo specific changes upon micellation or complexation.



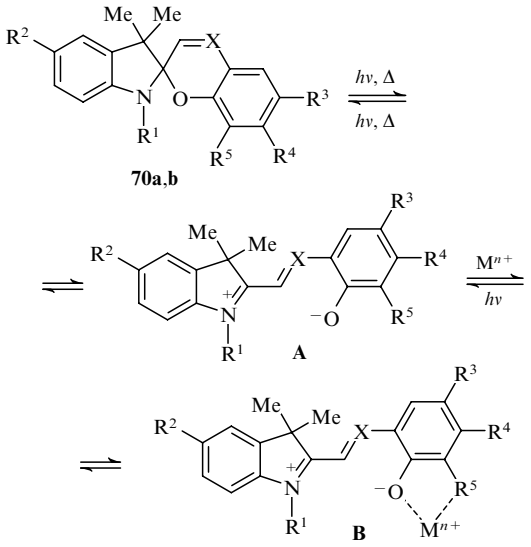
65

The nature of many sensor molecules involves a mechanism to control them, which makes it possible to turn on and off or switch the sensor process. When such systems are exposed to external factors (change in temperature, polarity, pH of the medium, concentration of metal ions, electromagnetic potential, chemical reactions), they undergo intramolecular rearrangements affecting the sensor properties. The following luminescent sensors can serve as examples: pH-controlled ones (azacrown ethers, polyaza compounds), those controlled by redox reactions (compounds **32**, **33**), pK^+- (compound **46**) and pNa^+-dependent (compound **44**).

V. Photochromic chemosensors

New highly sensitive photodynamic fluorescent sensor systems (*i.e.*, those that can be turned on and/or off upon irradiation of a solution) can be created based on photochromic spirocyclic compounds, such as spiropyrans **70a** and spirooxazines **70b**.

The general scheme of these transformations is shown below.



70a,**b** **A** **B**

X = CH (**a**), N (**b**); R^1–R^4 are various substituents, R^5 is complex-forming group.

Exposure of photochromic spirans **70a,b** to short-wave irradiation results in the merocyanine form **A**. The latter can undergo

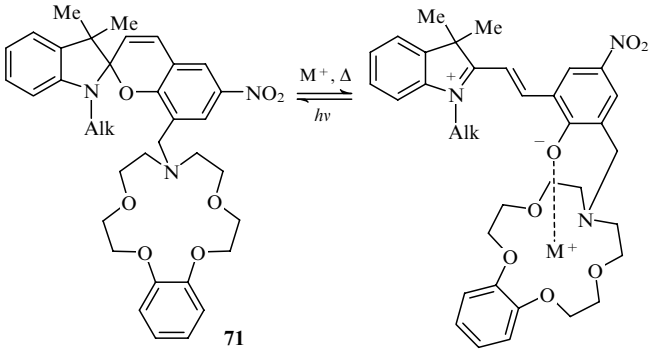
coordination with metal ions M^{n+} to give the complex **B** having specific absorption and fluorescence spectral characteristics different from those of the form **A**.

Studies of these systems as chemosensors started in the 1960s.[125,126] It was shown that complexes of such ions as Zn^{2+}, Co^{2+}, and Cu^{2+} with the spiropyrans **70a** have characteristic spectral bands in solution and can be used in analytical chemistry.

In 1982–1988, a number of papers were published (see, *e.g.*, Refs 127 and 128) reporting detailed studies on the complexation of various metal ions (Pb^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Cu^{2+}, Ce^{3+}, La^{3+}, *etc.*) with molecules of spiropyrans **70a** (R^1 = Me, R^2 = H, R^3 = H, NO_2, R^4 = H, R^5 = OMe) in organic solvents. The complexes **B** have characteristic bands in the absorption and emission electronic spectra. Certain cations coordinate the oxygen atom of the methoxy group and thus stabilise the open form. The open form **B** is also stabilised for $R^3 = NO_2$.

In solutions of spiropyrans **70a** with $R^1 = (CH_2)_2CO_2^-$ or $(CH_2)_2SO_3^-$, $R^2 = NO_2$, $R^3 = R^4 = R^5 = H$, the merocyanine form **A** is strongly stabilised by divalent metal ions (Zn^{2+}, Ca^{2+}). Specific fluorescence of solutions in acetone was noted.[129] Spiropyrans **70a** with R^1 = Me, R^2 = H, R^3 = H, NO_2, R^4–R^5 = N=CHCH=CH, which form **B**-type strongly fluorescent complexes with Mg^{2+}, Ca^{2+}, Ba^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and other cations, were found to be very sensitive sensors for these cations.

Incorporation of crown ether fragments as receptors into the molecules of spiro compounds changes the properties of these photochromic compounds. For example, nitrobenzospiropyran **71** containing monoazabenzo-15-crown-5 is a good Li^+ and Na^+ sensor with pronounced negative photochromism.[130]



71

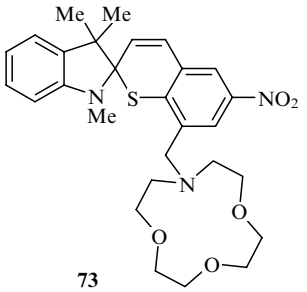
M = Li, Na, K.

Spiropyrans **70a** and spirooxazines **70b** with polyfunctional receptors undergo more complex transformations.[131–134] For example, for compounds **72a–c** there are two competing complexation pathways (Scheme 1) involving free alkaline-earth or rare-earth cations (structure **A**) or the same cations bound with the crown ether fragment (structures **B**, **C**). Each type of coordination is characterised by appropriate changes in the electronic spectra.

Complexation can be monitored coulometrically, by femtosecond spectrochromatography,[135] or this monitoring can be combined with mass spectrometric determinations.[136]

Light-sensitive membranes based on polyvinyl chloride with built-in fragments of lipophilic crown-containing spirobenzopyrans were obtained and studied. The photochromic parameters in such systems depend on the pH of the medium and on the concentration of alkali metal ions.[137]

The spirobenzothiapyran **73** containing the aza-12-crown-4 residue can form a complex with Li^+. The coloured photoinduced form of this compound has enhanced thermal stability, partially owing to stabilisation upon complexation.[138,139]

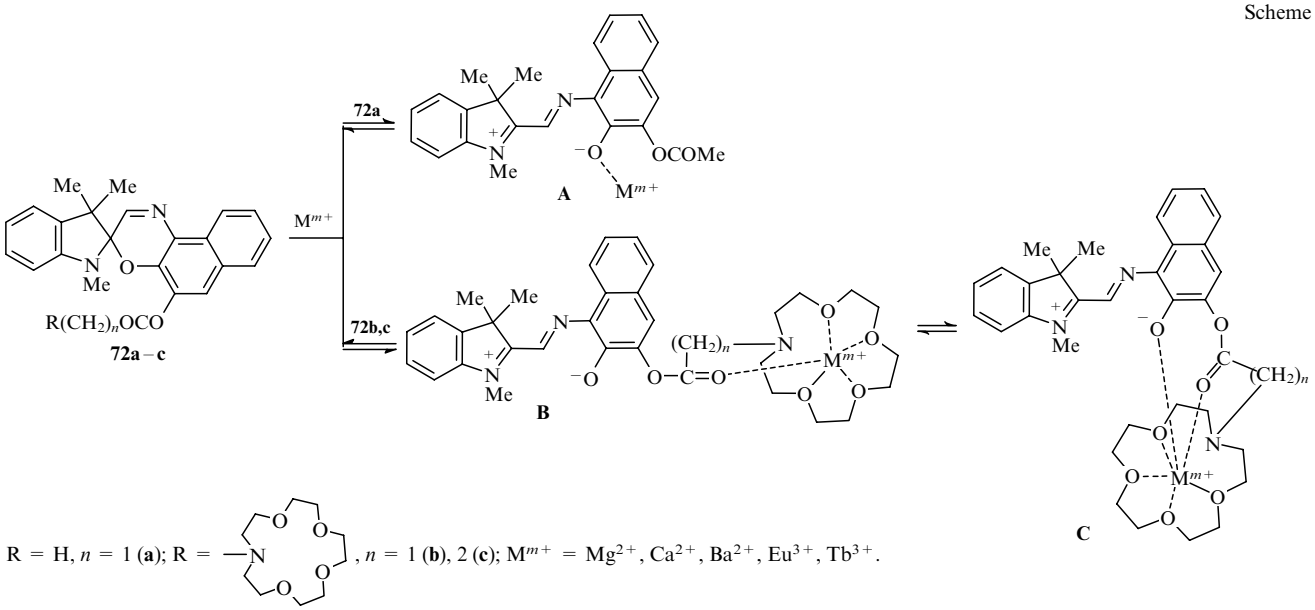


73

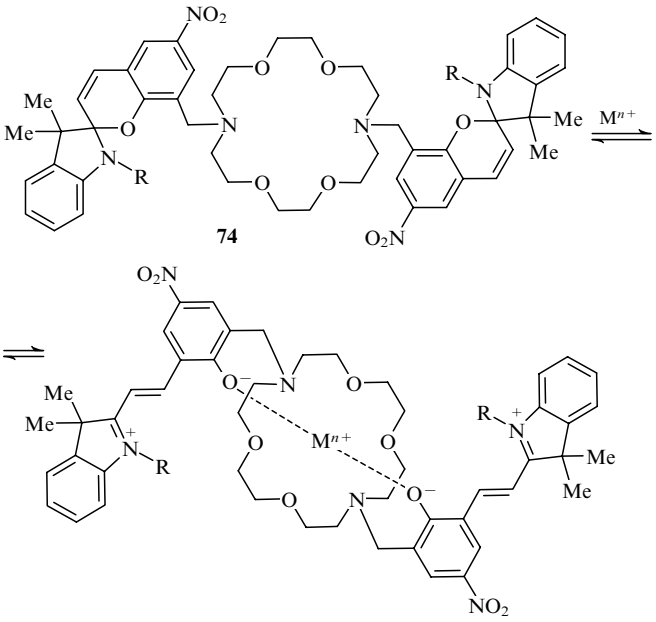
Stabilisation of an open merocyanine fragment also accompanies the complexation of Li^+ and especially Ag^+ with analogues of compound **73** containing monoaza-15-crown-5 and -18-crown-6.[139]

The two spirobenzopyran fragments linked with diaza-18-crown-6 (compound **74**) bind the Ca^{2+} ions more strongly than alkali metal cations due to an apical coordination of divalent cations by the anionic oxygen atoms of the ligand. This type of calcium complexation can be controlled by irradiation.[140]

Scheme 1

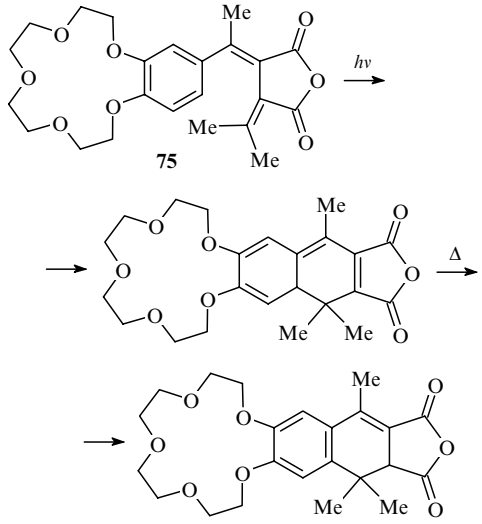


R = H, n = 1 (**a**); R = , n = 1 (**b**), 2 (**c**); M^{m+} = Mg^{2+}, Ca^{2+}, Ba^{2+}, Eu^{3+}, Tb^{3+}.



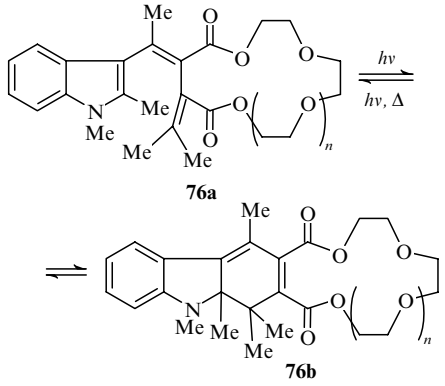
74

Upon complexation with Na^+, K^+ and alkaline-earth metal cations, the shift of the short-wave absorption band of phenylfulgide **75** containing a benzo-15-crown-5 fragment fused to the benzene ring was 28, 12, and > 40 nm, respectively, both in the open and cyclic forms.[141, 142]



75

Indolylfulgides **76** containing 14-crown-4, 17-crown-5 and 20-crown-6 fragments are sensors for Li^+, Na^+ and K^+, respectively; in this case, both the *E*- and *Z*-isomers of the open forms **76a** are more sensitive for alkali metal ions than the totally cyclic system **76b**.[143]

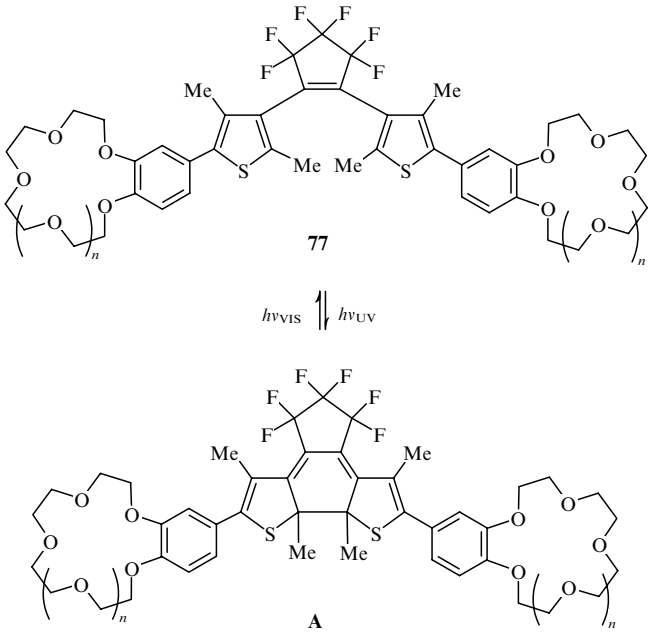


76a

76b

n = 1–3.

Dihetarylcyclopentenes **77** containing crown-ether fragments were synthesised and studied as photochromic sensors. These compounds can decrease considerably the degree of coordination of K^+, Rb^+ and Cs^+ when exposed to UV irradiation at a wavelength of $\lambda = 330 \pm 70$ nm (picrates in aqueous-organic media were analysed).[144–146] This phenomenon was explained by the ability of the original compound **77** to coordinate these cations by both crown-ether fragments simultaneously, whereas the more rigid photoreaction product, *viz*., isomer **A**, is devoid of this ability. The possibility of selective coordination of cations with certain radii is provided by the crown ether ring sizes.

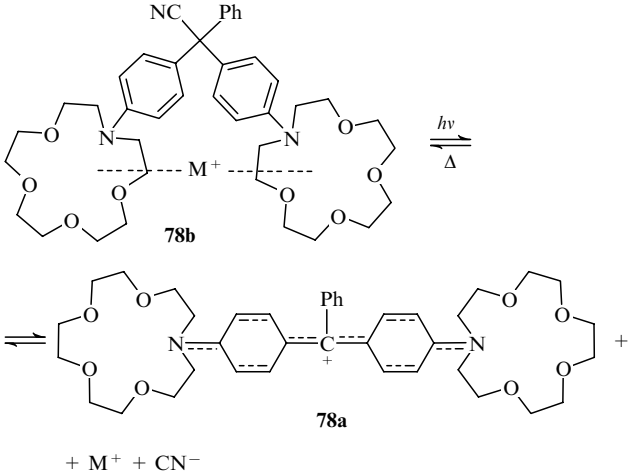


77

A

n = 0–2.

The novel photochromic compound **78a** based on a Malachite Green analogue containing two crown-ether fragments was synthesised.[147] Colourless complexes **78b** with metal cyanides are leuconitriles; their solutions are coloured reversibly under irradiation due to photodissociation.[147] The system **78** is a chemosensor for metal cyanides.

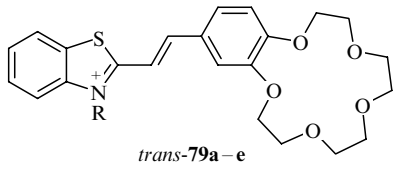


78b

78a

Alfimov *et al.*[148–152] described crown-containing styryl dyes **79**, **80**, which are fluorescent sensors for alkaline-earth metal cations (Mg^{2+}, Ca^{2+}, Ba^{2+}).

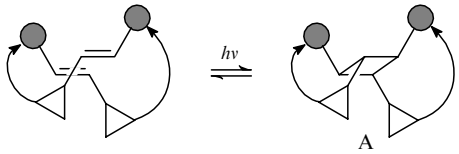
Compounds **79b–e** with *trans*-configuration of the double bond



trans-**79a–e**

R = $EtClO_4^-$ (**a**), $(CH_2)_2SO_3^-$ (**b**), $(CH_2)_3SO_3^-$ (**c**), $(CH_2)_4SO_3^-$ (**d**), $CH_2C_6H_4SO_3^-$ (**e**).

form (depending on the type of the substituent R, which serves as a spacer, and the nature of the counter-ion) either monomolecular complexes, in which the metal ion located within the crown is additionally coordinated by the sulfonic group oxygen, or type **A** dimers resulting from reversible [2 + 2]-cycloaddition.[148]



A

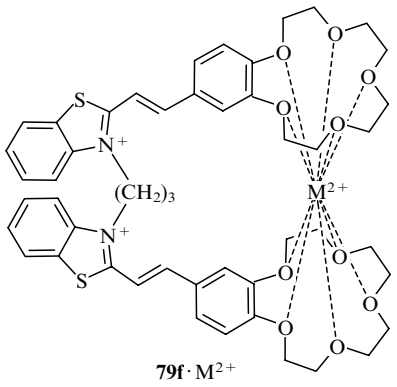
● — benzo-15-crown-5 fragment with a metal cation;

△ — benzothiazole residue; ↷ — $(CH_2)_nSO_3^-$ (n = 3, 4).

Illumination with light at a wavelength of 436 nm results in isomerisation of *trans*-complexes **79**·M^{2+} to give *cis*-complexes. The toluenesulfonic acid residue in the complex (*cis*-**79e**)·M^{2+} is arranged above the crown-ether plane to give a molecule 'capped' with the anion.[150]

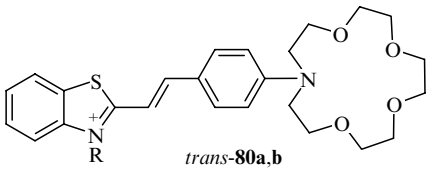
For dimeric molecules **79f** with a trimethylene bridge connecting the benzothiazole residues, the most stable configuration of the complexes is the structure **79f**·M^{2+} (see Ref. 149).

Quantum-chemical calculations of the energies of ground and excited electronic states of the molecules **79a–f**, their dimers and complexes confirmed the conclusions based on the experimental studies.[151]



79f·M^{2+}

The *trans*-**80a** dye containing the *N*-phenylaza-15-crown-5 fragment manifests a considerable ionochromic effect registered in electronic spectra (Fig. 4),[148] which, according to the calculated complexation constants, implies the usual complex structure where the Ca^{2+} cation is coordinated in the azacrown fragment.



trans-**80a,b**

R = $EtClO_4^-$ (**a**), $(CH_2)_3SO_3^-$ (**b**).

The data obtained for the complexation of compound *trans*-**80b** with Ca^{2+} and Zn^{2+} can be visualised schematically by the following sequence of equilibria

$$S{-}C + M \rightleftharpoons S{-}CM,$$

$$S{-}C + M \rightleftharpoons MS{-}C,$$

$$M(S{-}C)_{n-1} + S{-}C \rightleftharpoons M(S{-}C)_n,$$

$$MS{-}C + M \rightleftharpoons MS{-}CM,$$

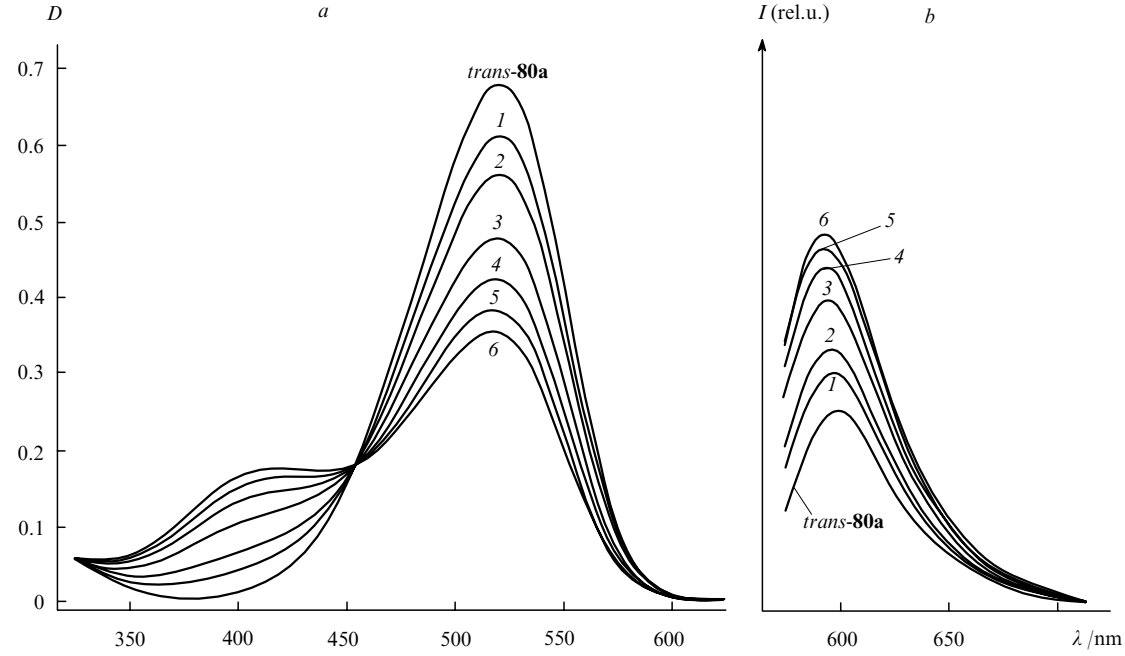


Figure 4. Dependence of absorption spectra (*a*) and fluorescence spectra (*b*) of ligand *trans*-**80a** ($c_{\mathbf{80a}} = 1.0 \times 10^{-5}$ mol litre^{-1}) in MeCN on the Ca^{2+} concentration at a constant concentration of ClO_4^- (0.01 mol litre^{-1});[148]
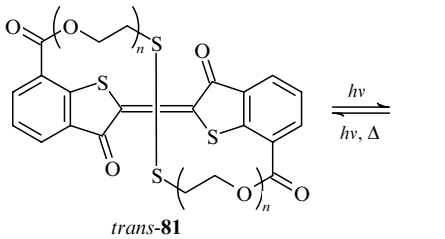
$c_{Ca2+} : c_{\mathbf{80a}}$ = 50 (*1*), 100 (*2*), 200 (*3*), 300 (*4*), 400 (*5*), 500 (*6*).

where S–C is a *trans*-**80b** molecule (S is a sulfonic group, C is an azacrown ether fragment); M is a metal ion, $n = 2-4$.

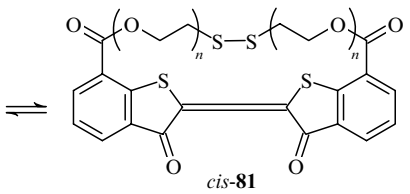
This means that, in addition to 1 : 1 complexes, the betaine **80b** forms aggregates comprising four dye molecules and one M^{2+} ion. Probably, the interaction between the metal cations with the sulfonic groups of the molecules makes the major contribution to the stability of these aggregates.[148]

Studies of ion exchange processes involving amphiphilic photochromic compounds **79** in the 'monolayer–aqueous phase' system showed that the Na^+, Ca^{2+} and Mg^{2+} ions increase the strain in the monolayer, whereas the K^+ ions decrease it considerably.[153, 154]

Compound **81**, which comprises thioindigo and dithiocrown-ether fragments, is a novel photochromic sensor for alkali metal cations and Ca^{2+}.[155] It exists as *cis*- and *trans*-isomers, each isomer having characteristic bands in the absorption spectra: $\lambda_{max} = 485$ and 545 nm for *cis*- and *trans*-**81**, respectively. The *trans*-isomer of compound **81**, which has weak coordinating properties, is transformed into the *cis*-isomer upon exposure to light with a wavelength of 550 nm;



trans-**81**

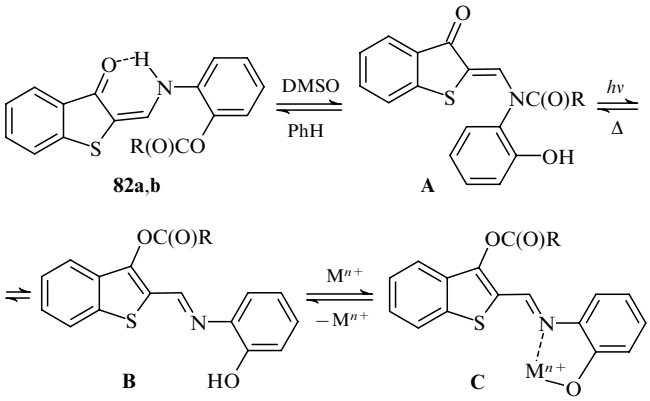


cis-**81**

$n = 2, 3$.

the *cis*-isomer can coordinate a 'guest' cation. The complexation equilibrium constants of metal ions, determined by the extraction method, suggest a high sensitivity of the *cis*-isomer for Na^+, Cs^+ and Ca^{2+}; however, such ions as Hg^{2+}, Cd^{2+}, Cu^{2+}, Co^{2+} and Ag^+ do not form these complexes. The lifetime of the *cis*-isomer is hundreds times longer than that of its analogue (*cis*-thioindigo), even in the absence of metal ions.

We obtained and studied[156, 157] 2-(2-acyloxyphenylamino-methylene)-2,3-dihydrobenzo[*b*]thiophen-3-ones **82a**,**b**. These are solvato- and thermochromic compounds undergoing the following transformations.



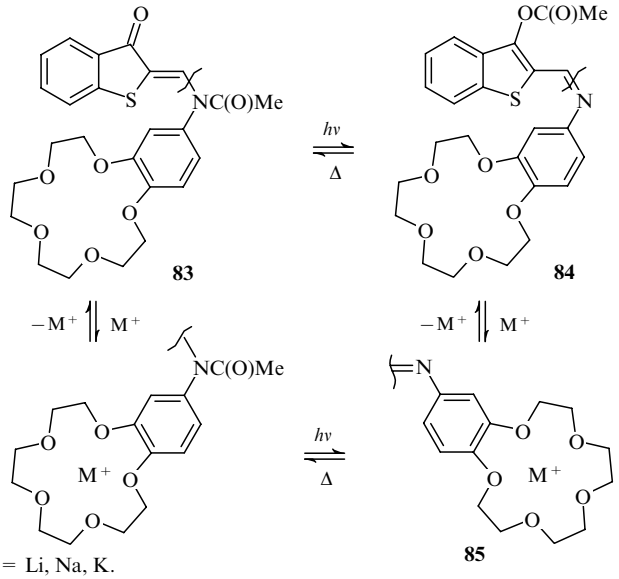
82a,**b** **A** **B** **C**

R = Me (**a**),  (**b**).

Under irradiation, the form **A** is transformed into the form **B**, thus creating conditions for the formation of the complex **C** with a metal ion; the spectral characteristics of the latter differ from those of compounds **A** and **B**, *i.e.*, the system **82** manifests metal-sensor properties. The acyl moiety can contain a fluorophore group, *e.g.*, the residue of 4-methylcoumarin-7-yloxyacetic acid (compound **82b**). It was shown by ^1H NMR and electronic spectroscopy[158] that an equilibrium is established in solutions between the original compound **82b** and the form **A**; the content of the latter increases with the solvent polarity. Illumination of the equilibrium mixture with light at 436 nm results in transfer of the acyl group from the nitrogen atom to the thiophene fragment. This produces an (*E*)-C=N bond. The absorption spectra of the system **82b** change if the solution contains Ca^{2+}, Mg^{2+}, Zn^{2+} or Ni^{2+} cations. However, the fluorophore residue does not behave as a luminescent indicator, probably because of preferential deactivation of excited molecules.

The system **83** comprising not only a benzothiophene fragment and an *N*-acyl residue but also an annelated crown ether can be used as a photochromic sensor for alkali metal ions.[159]

Illumination of compound **83** and its complexes with alkali metals with light at 436 nm results in migration of the acyl group from the nitrogen atom to the oxygen atom to give *O*-isomers **84** and **85**, respectively. Complexation with lithium ions results in the biggest changes in the absorption spectra.



83 **84** **85**

M = Li, Na, K.

Figure 5 shows a plot of the optical density of a solution of the complex **85** *versus* the concentration ratio of LiI and the ligand **84**

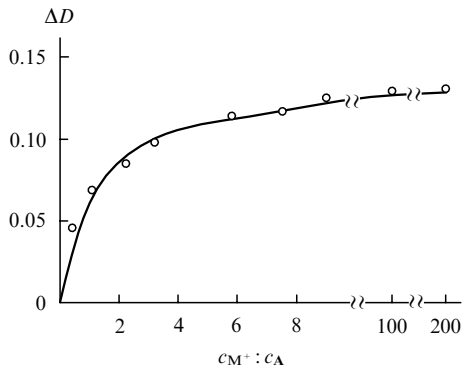


Figure 5. Dependence of the optical density variation (ΔD) of a solution of the complex **85** on the LiI (c_{M^+}) and the ligand **84** (c_A) concentration ratio.[159]

at the absorption wavelength of the complex ($\lambda = 357$ nm) upon addition of lithium iodide to an illuminated solution of the *O*-acetyl form of **85** (at a concentration of 6.55×10^{-5} mol litre^{-1}). The maximum extinction is reached at a tenfold excess of LiI. This specific behaviour of this system and its high sensitivity for Li^+ make it possible to place it among photochromic sensors.[160]

VI. Conclusion

Thus, recent studies demonstrate a considerable interest in the creation of novel chemosensor systems applicable to the analysis of inorganic and organic substrates. Table 1 shows the characteristics of certain organic sensors.

Table 1. Characteristics of certain organic sensors.

Compound	Substrate	Detection threshold /mol litre^{-1}	Analytical fluorescence wavelength /nm	Ref.

α-CD	6-bromo-2-naphthol	0.04 [c]	500	115

[a] Absorption band; [b] μg litre^{-1}; [c] mg litre^{-1}.

Currently, diverse types and classes of both organic and inorganic compounds are used as abiotic sensors or substrates. The use of crown-ether compounds as receptors stimulated the creation of chemosensors based on complex three-dimensional systems, including polyamines, dendrimers, calixarenes, cyclodextrins and their combinations.

Fluorescent chemosensors with high sensitivities and selectivities have been synthesised; the action of these sensors is based on specific but reliable intramolecular interaction mechanisms (the PET and PCT effects; excimers and exciplexes). Studies aimed at the external controlling of sensor processes are of current interest. The search for new types of molecular 'switches' is under way. Some chemosensor systems are created using elements of supramolecular chemistry and nanotechnologies; this makes it possible to create sensors with unique capabilities, *e.g.*, properties of molecular machines [52, 161] or artificial memory elements.[14, 52, 79]

The scope of application of fluorescent sensors expands: from routine laboratory reagents for cations and anions, they grow into systems for identifying complex organic molecules, analysing various biological substrates,[35, 55, 61] pesticides,[162] and foodstuffs,[163] monitoring the state of the atmosphere and oceans,[29, 164] *etc*.

Although the theory of chemical sensors has certain achievements,[165] it is developing somewhat more slowly than experimental and applied studies. The general theory of chemosensors requires new data on the mechanisms of intramolecular electronic interactions in the systems receptor – conductor – fluorophore, on the effects of external factors on the properties of sensors, on the nature of complementarity of receptors and substrates, *etc*.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 00-15-97320), the Ministry for Education of the Russian Federation, and CRDF (REC-004).

Abstract. The present-day published data on the relationships between the structures of rhodium, iridium, ruthenium, nickel and cobalt catalytic complexes and substrates in homogeneous asymmetric hydrogenation, hydrosilylation and cross-coupling reactions are systematised. The optimum ratio between the number of coordination vacancies in the complex and the number of functional groups of the substrate has been characterised in terms of a criterion of maximum enantioselectivity of the catalytic complex. The relationships between the configurations of the complexes and the products formed in the reactions are analysed. In the case of C_2-symmetrical chiral diphosphine complexes as catalysts (some structural elements of their ligands represent an incomplete turn of a helix surrounding the central metal atoms), substrates of the same kind form the products having definite configurations characteristic of the particular orientation of the helix. For example, rhodium complexes with ligands that form an incomplete *P*-helical turn around metal atoms catalyse the formation of (*R*)-amino acids from the corresponding precursors. If the ligands contain fragments of *M*-helices around rhodium atoms, it is (*S*)-amino acids that are formed. The bibliography includes 234 references.

I. Introduction

Considerable recent interest in asymmetric synthesis is explained not only by the objective logic of organic chemistry, but also by the fact that in the past decade the pharmaceutical industry has largely concentrated on the preparation of drugs in an enantiomerically pure form. Therefore, a search for relatively simple and inexpensive techniques for separation of enantiomers or the synthesis of compounds in the form of individual enantiomers has become a very urgent problem. In this respect, priority is given to asymmetric catalysis, which allows one-step synthesis of products (or intermediates) from prochiral compounds with high enantiomeric excess (*ee*). The latter is expressed in per cent as the ratio of the difference in the yields of two enantiomers to their total yield (the terms 'optical yield' and 'enantiomeric purity' are also used to describe stereoselectivity). The costs of enantiomeric products are sometimes close to those of racemates, since the concentrations of expensive chiral metal complex catalysts in the reaction mixture are usually low and the substrate : catalyst ratios are rather high (up to 70 000).

The progress in asymmetric metal complex catalysis has been documented in numerous publications (see the monographs [1–4] and the reviews [5–19]), and their number is steadily increasing. However, the 'catalyst – substrate – product' structural and configurational relationships remain relatively little-studied. Analysis of these relationships is the first step in the elucidation of the mechanism of a transfer of asymmetry from the catalyst to the reactive substrate, *i.e.*, asymmetric induction.

Most probably, the crucial role in asymmetric induction belongs to chiral ligands of metal complexes. It is these ligands that determine the chiral environment of metal atoms [20] in the catalyst. Therefore, special attention in the analysis of general regularities of 'catalyst – substrate – product' structural and configurational relationships should be given to reactions where the greatest number of different ligands have been used. These reactions include hydrogenation, hydrosilylation and cross-coupling. These were chosen for two additional reasons. First, in these reactions very high enantiomeric excesses of the products have been achieved. Second, this minimum set of reactions allows one to obtain chiral products with the largest number of functional groups (*e.g.*, alcohols, amines, organic acids, amino alcohols, amino acids, hydroxy acids and hydrocarbons), which is of considerable value in the synthesis of drugs and synthons.

By now, a vast variety of ligands, which represent components of C_1- and C_2-symmetrical chiral complexes (see, *e.g.*, reviews [20–32]), have been synthesised and analysed in these and some other reactions. Configurational relationships of chiral complexes having C_2 symmetry axes can be systematised most easily. Complexes with five- and seven-membered chelate cycles formed by bis(diphenylphosphine) ligands (from the simplest [33] to exotic [34, 35]) shown below manifest the highest enantioselectivities.

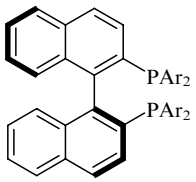
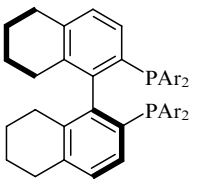
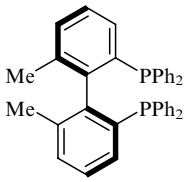
Substrates, such as α-acetamidocinnamic acid, which allow coordination by metals in the catalytic complexes both at the double bonds and at two additional functional groups, are especially suitable for the synthesis of chiral products by hydrogenation. Thus the *ee* of the hydrogenation product reaches 99% (see Ref. 36). The enantioselectivity of this reaction decreases dramatically upon removal of at least one functional group. Ruthenium complexes with atropoisomeric diphosphine ligands of the binap type are most suitable reagents for hydrogenation of such substrates.[37–41]



Ar = Ph: (*S*)-binap
Ar = *p*-MeC_6H_4: (*S*)-Tolbinap



(*S*)-H_8-binap



(*S*)-biphemp

In the presence of these complexes, the maximum value of *ee* exceeds 99.5% (see Ref. 40). The enantioselectivity of hydrogenation of substituted ketones in the presence of these complexes is at the same level.[42–50]

Asymmetric hydrosilylation of ketones[3,4]

$$R^1R^2C{=}O + HSiR_3 \xrightarrow{ML_n^*} HR^1R^2COSiR_3 \xrightarrow{H_3O^+} R^1R^2CHOH + HOSiR_3$$

M = Rh, Ir, Ru; L_n^* = P*, ; the chiral fragment or the asymmetric atom is marked with an asterisk

can be regarded as a variant of their asymmetric hydrogenation, since the silyl ether formed can be hydrolysed into an alcohol with retention of the configuration of the asymmetric carbon atom.[51–53] Very often, the same catalysts manifest similar efficiencies in both reactions, which also suggests their similarity.[54] However, specific hydrosilylation catalysts are known[55–57] which result in a maximum *ee* of 97.6% (see Ref. 58).

Asymmetric cross-coupling of organometallic compounds ($R^1M'X$) with alkenyl or aryl halides and related compounds (R^2Y)

$$R^1M'X + R^2Y \xrightarrow{ML_n^*} (R^1{-}R^2)^*$$

M′ = Mg, Zn *etc.*; X = Hal; M = Ni, Pd; Y = Hal, OR, OH, *etc.*;

L_n^* = P*,

results in the formation of a C*−C bond in the product; its enantiomeric purity reaches 95%. In terms of enantioselectivity, this reaction is somewhat inferior to hydrogenation and hydrosilylation, however, cross-coupling combined with allylic alkylation arouses considerable interest,[59–63] since it gives rise to chiral hydrocarbons.

II. Catalyst–substrate structural relationships

In a search for the most suitable substrates for performing their conversions on metal complexes containing structurally different ligands, enantiomeric purity of the product serves usually as the main criterion. Asymmetric hydrogenation on rhodium–phosphine complexes is certainly one of the most extensively studied reactions of this kind.

The *ee* values of hydrogenation products of various substrates depending on the structures of the ligands of the catalytic complexes are listed in Table 1. As can be seen from these examples, any substitution of the alkyl radical for the coordination-active substituent at the double bond results in a drastic decrease in the reaction enantioselectivity. Hence, the double bond should contain at least two groups of the type NHCOR or CO_2R. However, if a catalytic complex contains the bppm ligand, which can be coordinated by three groups (also in the presence of Et_3N), replacement of the acetamido group in the substrate by a group with weaker coordination ability has a smaller effect on the enantioselectivity in comparison with reactions catalysed by complexes with bidentate ligands. Similarly, the number of coordination-active groups in the substrate can be reduced to one (with the exception of C=C) on going from the planar Rh(I) complexes to the octahedral Ru(II) complexes containing ligands of the binap type (Scheme 1).†

† Hereinafter we give the best or close to best parameters cited in the relevant publications.

ee > 99.5% (*R*) [41]

These and some other data [70–73] suggest that high enantioselectivity of hydrogenation of substrates, such as tiglic acid in the presence of complexes of the $Ru(OAc)_2$[binap] type is provided by only one coordination group, which is located in the α-position relative to the double bond. Interestingly, hydrogenation of α-acetamidocinnamic acid on such catalysts is less enantioselective than that in the presence of rhodium complexes with binap ligands.[74] Thus for ruthenium complexes, the presence of two coordination-active groups at the double bond of the substrate is excessive and does not favour maximum enantioselectivity.

Simple ketones R^1COR^2 (R^1 = Ar, Alk, R^2 = Alk) are hydrogenated on chiral rhodium diphosphine complexes with low enantioselectivities. This can be improved by addition of an acid or a base to complexes which have proved to be efficient in asymmetric hydrogenation of enamide substrates. Thus in the presence of Rh/camp/Pr^iCO_2H, where camp is the ligand synthesised from camphor, *ee* = 12% (*R*) (see Ref. 75) and in the presence of Rh/(*S*,*S*)-diop/Et_3N, *ee* = 68% (*R*) (see Ref. 76). An alternative approach to increase enantioselectivity consists in the introduction of groups into α- or β-positions of ketones which can coordinate the metal. For example, hydrogenation of the ketone $ArCOCH_2NEt_2$ proceeds with high enantioselectivity without any base [in the presence of Rh/(*S*,*S*)-diop, *ee* = 93% (see Ref. 77)].

Presumably, complexes with bidentate diphosphine ligands (or diamino ligands in hydrogen-transfer hydrogenation reactions) do not provide a sufficiently high level of 'chiral recognition' of simple ketones due to small molecular sizes of the latter, nor do they favour their enantioselective hydrogenation. The results of hydrogenation of various ketones on such complexes

are presented in Table 2. It can be seen that the enantioselectivity increases considerably with an increase in the size of the fragment of the substrate involved in coordination. If an additional coordination-active group of a ketone is blocked by a bulky substituent, *e.g.*, NHBu^t, or cannot compete with an achiral ligand of the catalytic complex for vacancies (*e.g.*, in the presence of the β-ester group in the substrate and the carboxyl ligand in the Ru(AcO)$_2$. .[binap] complex), the enantioselectivity of this reaction at room temperature approximates a level characteristic of unsubstituted ketones [*ee* = 4% (*S*)]; however, at high temperatures the situation is different.[48] The introduction of an additional coordination-active group into a ketone can change both the value and the sign of enantioselectivity (as in reactions of ruthenium catalysts with the binap ligands (see Table 2), which points to the change in the mechanism of asymmetric induction.

Enantioselectivity can be increased by using complexes with ligands coordinated to metals by three groups.[86]

bpe is bis(phospholano)ethane.

Special mention should be made of a group of highly enantioselective catalytic complexes, which are active at atmospheric pressure of H_2. These complexes have the *in situ* composition $\{RuCl_2[binap(or\ biphemp)]\}_2 \cdot MeCOMe$ and are used for hydrogenation of β-oxo esters,[91] β-oxo phosphonates, β-oxo thiophosphonates[92] and phenylthio ketones.[93] Other catalytic complexes of this kind are also known.[34, 94 – 100] The hydrogenation of α- and γ-substituted ketones occurs less enantioselectively.[101 – 103]

Ruthenium complexes with tri- and tetradentate ligands, such as the ligands **1** – **8** and the complex **9**, are used as catalysts for increasing the enantioselectivity of hydrogen-transfer hydrogenation of simple ketones.

The effects of these complexes on the enantioselectivities of different hydrogenation reactions are demonstrated in Table 3 in the example of acetophenone.

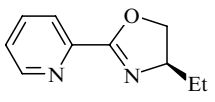
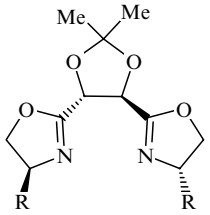
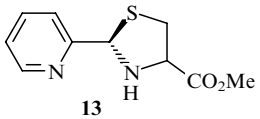
In order to achieve maximum enantioselectivity of hydrosilylation, bi-, tri- or tetradentate ligands should be taken in 2–13-fold excess with respect to the metal. This is sufficient to provide the substitution of at least four coordination vacancies in a catalytic complex. But even in this case achiral ligands should sometimes be added. The necessary ratios of the chiral ligands **10**–**16** to rhodium in catalysts for acetophenone hydrosilylation are shown in Table 4.



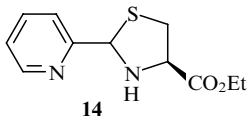
10



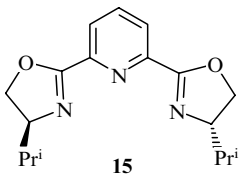
11: R = Pr^i
12: R = Bu^t



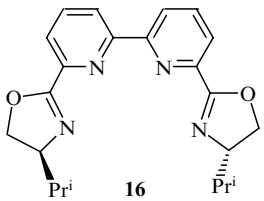
13



14



15



16

Thus, the maximum enantioselectivity will be provided by catalysts which ensure the minimum degree of freedom in the coordination of substrates in the intermediate complexes.

The dependence of enantioselectivity on the ligand structures of catalytic complexes is well studied and is not considered in this review. Until very recently, most of the studies devoted to asymmetric metal complex catalysis were aimed at obtaining maximum enantiomeric excesses of reaction products by simple search for all possible variants of ligand structures. A great body of evidence has been accumulated in this field, the effect of such structural parameter of a complex as symmetry deserves special mentioning.

Apparently, it is the difference in the symmetries of structurally related complexes, *viz*., {Rh[(*S,S*)-chiraphos](nbd)}ClO_4 (**I**) and {Rh[(*R*)-prophos](nbd)}ClO_4 (**II**), that can explain different enantioselectivities of hydrogenation in the presence of these catalysts (Table 5).

Table 5. The enantiomeric excess of the product in asymmetric hydrogenation of enamides on complexes (**I**) and (**II**).[33, 120, 121]

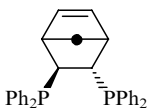
Substrate (S)	**I** (S : Rh = 100)		**II** (S : Rh = 250)	
	THF	EtOH	THF	EtOH
AcΔPhe	74 (*R*)	89 (*R*)	91 (*S*)	90 (*S*)
AcΔTyr	80 (*R*)	88 (*R*)	92 (*S*)	89 (*S*)
AcΔDOPA	80 (*R*)	83 (*R*)	89 (*S*)	87 (*S*)
AcΔLeu	100 (*R*)	93 (*R*)	87 (*S*)	87 (*S*)
BzΔPhe	99 (*R*)	95 (*R*)	93 (*S*)	91 (*S*)
BzΔLeu	87 (*R*)	72 (*R*)	87 (*S*)	87 (*S*)

Note. Hereinafter, the following designations were used: AcΔPhe is (*Z*)-α-acetylaminocinnamic acid; BzΔPhe is (*Z*)-α-benzoylaminocinnamic acid; AcΔTyr is *N*-acetyldehydrotyrosine; AcΔDOPA is 2-*N*-acetyl-β-(4-hydroxy-3-methoxyphenyl)-α-dehydroalanine; AcΔLeu is *N*-acetyldehydroleucine; BzΔLeu is *N*-benzoyldehydroleucine.

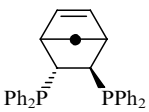
As can be seen from the table, the enantioselectivities achieved with the asymmetric complex **II** are less prone to variation than with the C_2-symmetrical chiral complex **I**. The *ee* value in the reactions catalysed by the former is virtually independent of the solvent or the nature of the substituent in the substrate.

III. Catalyst – product configurational relationships in reactions on C_2-symmetrical chiral metal complexes

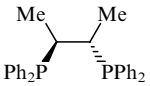
A search for relationships between configurations of catalytic complexes and products of asymmetric reactions is best carried out for complexes with ligands of the same type. Chiral bis(diphenylphosphine) ligands which form C_2-symmetrical complexes or C_2-symmetrical chelate rings (without substituents) meet these requirements.



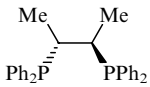
(*S,S*)-norphos



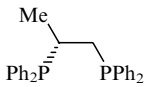
(*R,R*)-norphos



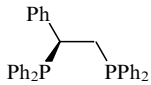
(*S,S*)-chiraphos



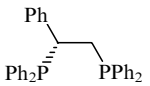
(*R,R*)-chiraphos



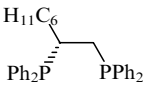
(*R*)-prophos



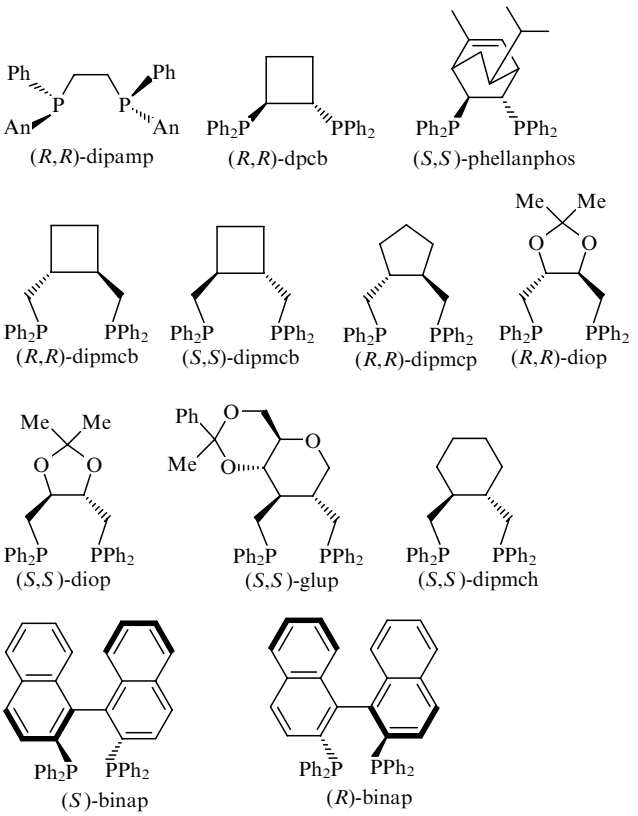
(*S*)-phenphos



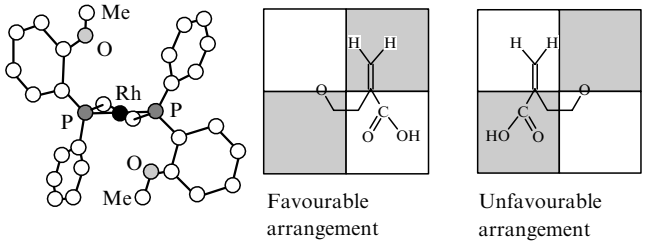
(*R*)-phenphos



(*R*)-cycphos

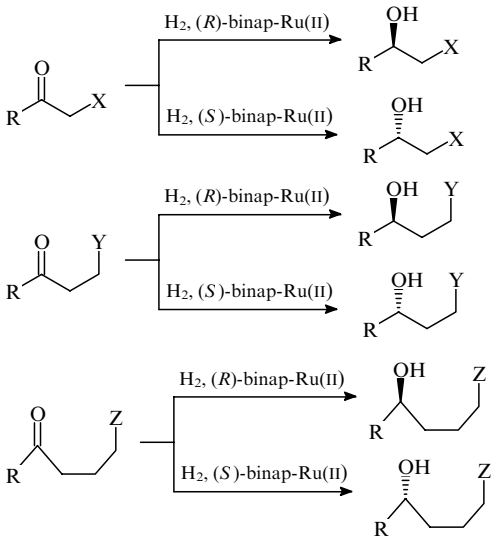


Regular relationships between the configurations of products and catalytic complexes in hydrogenation reactions on rhodium – phosphine catalysts have been established only for complexes with C_2-symmetrical chelate rings. Formal configurational relationships between catalysts and products are not always related to concrete reaction mechanism. A mnemonic dependence was proposed by Knowles in 1983.[122]



This dependence follows the 'quadrant rule' ‡ which relates the structure of the rhodium complex containing the dipamp ligand to the orientation (or coordination) of the substrate in the intermediate complex. It is assumed that the substituents occupying the hatched quadrants (*i.e.*, those blocked by the phenyl groups edge facing the viewer; the metal atom is located in the centre of the coordinates), experience larger steric hindrances. Therefore, the bulky carboxy group occupies preferably the unhatched quadrant. It is in this orientation that the formation of a particular enantiomer is experimentally observed. These graphical representations were used to describe the enantioselective behaviour of binap [14] and duphos [bis(phospholano)benzene] [124] complexes in asymmetric hydrogenation reactions.

The use of such graphical representations implies that the asymmetric induction step coincides with the coordination of the substrate in the intermediate complex. However, this conclusion demands further verification. The scheme proposed for the description of catalyst – product configurational relationships in the hydrogenation of α-, β- and γ-substituted ketones on ruthenium complexes containing binap ligands is even more formal. The configuration of the product depends exclusively on the configuration of the complex, rather than on the position of the functional group in the ketone.[14]

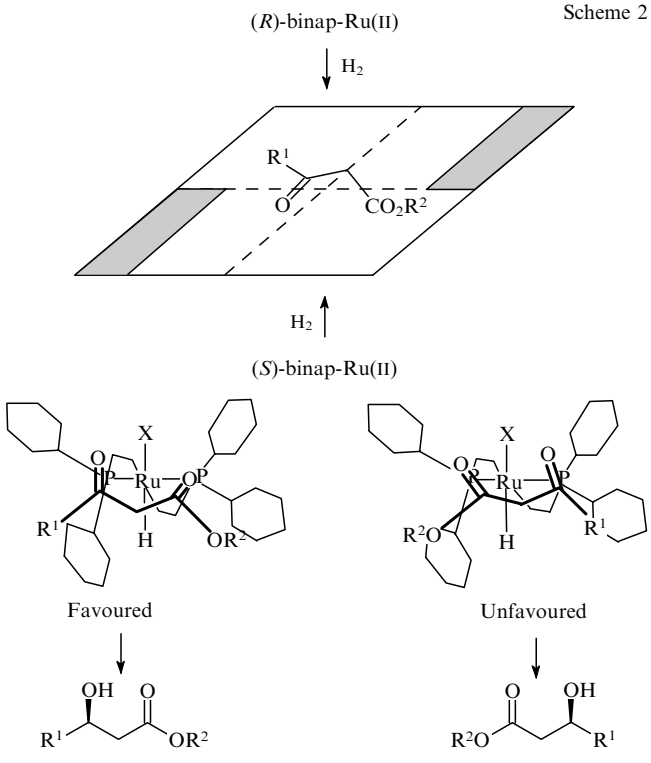


where X, Y, Z are N, O or Hal.

This has led to the development of a formal scheme for the formation of an intermediate complex using hydrogenation of a β-oxo ester as an example (Scheme 2).

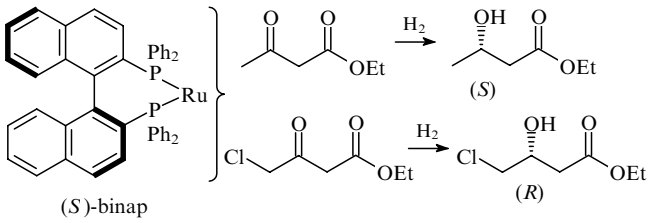
A similar scheme of configurational relationships has been proposed for hydrogenation of substituted β-oxo esters.[125] The configuration of the product does not depend on the nature of the substituent at the carbonyl group, whereas the change in the order of priority changes the configuration symbol.

Scheme 2

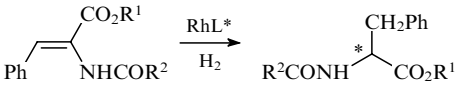


X = Hal.

‡ For the first time, this structural approach in the form of the 'octant rule' has been used to describe the chiral environment of carbonyl groups in steroids.[123]

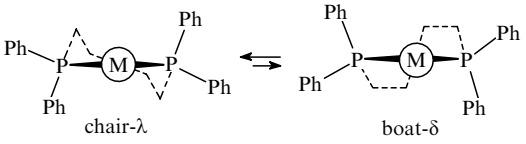


A large body of evidence has been gained concerning the application of rhodium complexes with these ligands as catalysts in hydrogenation of the same kind of substrates, *viz*., α-acetamidocinnamic acid derivatives.



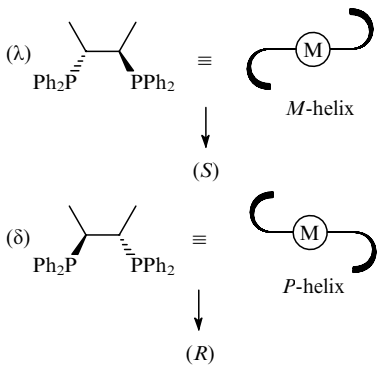
L* = 
Earlier, it was suggested that enantioselective effects of such complexes are related to chiral arrangements of the phosphine phenyl groups.[120] We suppose that the arrangement of phenyl groups forming the chiral environment of the metal atoms can be related to the sign of helicity or the conformation of the chelate complex (Scheme 3) (view from the side of the metal atom; the chelate complex without substituents is shown by a dotted line). The schematic representations of the helix turns are shown in the right part of the Scheme, where the *P*-helix moves off clockwise, while the *M*-helix moves off anti-clockwise.

The analysis of molecular models has demonstrated that the conformations of λ- or δ-five-membered chelate complexes can be distorted to some extent, but their interconversions are either impossible (*e.g*., for chelates based on cyclic 1,2-diphosphines, such as norphos, phellanphos, dpcb, *etc*.) or result in the formation of chelate complexes with unfavourable axial positions of substituents [126–128] (*e.g*., prophos, chiraphos, cycphos, phenphos, *etc*.). In the case of seven-membered chelate complexes, a change in the sign of chirality in the orientation of the phenyl groups is also accompanied by the transition from the favourable chair-λ (or -δ) conformation to the unfavourable boat-δ (or -λ) conformation. However, in this case the advantage is less apparent.



A correlation between the conformations of five-membered chelate rings of rhodium catalytic complexes with bis(diphenylphosphine) ligands and the configurations of the hydrogenation products of acetamidocinnamic acid and its derivatives was found in 1982 simultaneously and independently by two groups of authors (see Refs 129–131 and 132).§ The λ-conformation of the chelate complex determines the formation of (*S*)-, whereas the δ-conformation determines the formation of (*R*)-products. Quite naturally, this effect is directly related to the chiral positions of the phosphine phenyl groups corresponding to these conformations rather than to the conformations themselves. The conformations and the conformational rigidities of chelate rings in catalytic complexes play a crucial role in stabilisation of chiral positions or helical chiralities of the phosphine phenyl groups.

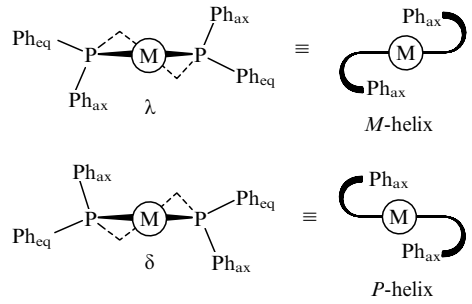
In a simplified form, this regularity may be described by the formula: λ-(*S*), δ-(*R*).[140,141] Another representation of this rule appears to be more complete:



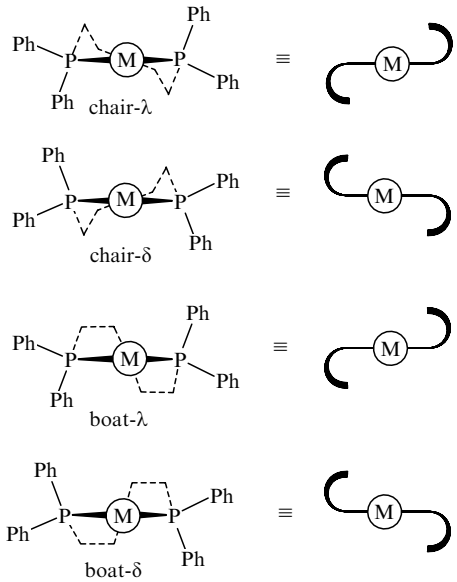
Some known ligands of rhodium complexes and the results of hydrogenation of α-acetylamidocinnamic acid derivatives in the presence of these complexes are shown in Table 6.

As can be seen, the results of hydrogenation in the presence of five-membered chelate rhodium complexes obey the λ-(*S*), δ-(*R*) rule [140,141] irrespective of whether the C_2 symmetry axis is inherent

Five-membered chelate complexes Scheme 3



Seven-membered chelate complexes



§ There are many examples of simultaneous publications by different research groups of experimental results concerning asymmetric hydrogenation on rhodium phosphine catalysts in which the same catalyst (ligand) was used or, as in our case, the same regularity of the reaction was established (see, *e.g*., Refs 133 and 134; 135,136 and 137; 138 and 139, *etc*.).

Table 6. Arylphosphine ligands forming five-membered rhodium chelate complexes and hydrogenation of α-acetylaminocinnamic acid and its derivatives in the presence of these complexes.

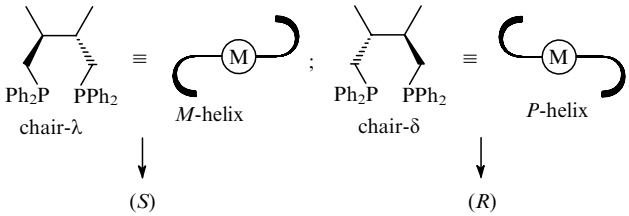
Note. Hereinafter, the following designations are used. For the substrate: AcΔPheOMe is (*Z*)-α-acetylaminocinnamic acid methyl ester; AcΔAla is α-acetylaminoacrylic acid; for the type of the catalytic complex: N is neutral including that formed *in situ*; C is cationic; for the solvent: M is methanol; E is ethanol; B is benzene; T is tetrahydrofuran.

[a] Data from X-ray diffraction analysis.

in the whole complex or in its chelate ring without substituents. The implementation of this rule is not influenced by the nature of substituents and experimental conditions. The situation is more complicated in the case of seven-membered ¶ chelate rhodium complexes in which the conformational transitions chair-λ – boat-δ and chair-δ – boat-λ are possible (other intermediate conformations have also been described [158]). Such transitions change the helicity sign of the phosphine phenyl groups, as a result of which the configuration of the product also changes. Unfortunately, X-ray diffraction analysis does not provide any unambiguous information about the conformations of the corresponding molecules in solution and especially in the intermediate catalytic complex, since the factors involved in crystal formation are stronger than those inducing conformational changes. Indeed, the conformations acquired by the diop ligand in Ir[(*S*,*S*)-(+)-diop](cod)Cl [159] and [(*R*,*R*)(−)-diop]$NiCl_2$ [160] crystals differ from the more favourable ideal conformations chair-λ and chair-δ. In the case of [(*R*,*R*)(−)-diop]$NiCl_2$, the distortions are so great that the position of the phenyl groups relative to the metal becomes close to symmetrical. If such conformations were maintained in solution, this would contradict the Curie – Pasteur principle ('there is no asymmetry without asymmetry') and would be in conflict with the very logic of asymmetric catalysis. The same complex, *viz*., [(*R*,*R*)-(−)-diop]$NiCl_2$, manifests high enantioselectivity in various cross-coupling reactions;[161] hence, its phenyl groups occupy chiral positions relative to the metal.

Therefore, the opposite statement, *viz*., if the λ-(*S*), δ-(*R*) rule is observed, the true conformations of the ligands in the complexes are close to the predictable chair conformation, seems to be more applicable to seven-membered chelate rhodium complexes.

Some examples of fulfilment of the chair-δ-(*R*), chair-λ-(*S*) rule are given in Table 7,[130, 140] *viz*.:



It is easy to ascertain that in the case of both seven-membered chelate complexes with second-order symmetry axes and complexes where only chelate rings without substituents possess C_2 symmetry the chair-λ-(*S*), chair-δ-(*R*) rule [or the boat-λ-(*S*),

¶ Six-membered chelate complexes have been studied relatively little, apparently due to their low efficiencies in asymmetric reactions resulting from conformational labilities of six-membered compounds. However, one such complex, *viz*., Rh(*S*,*S*)-skewphos [skewphos is 2,4-bis(diphenylphosphino)pentane], manifests high enantioselectivity [AcΔPhe, 93% (R)].[157]

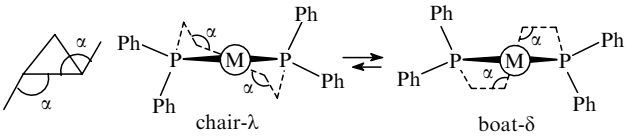
[a] Data from X-ray diffraction analysis. [b] The positions of the phosphine phenyl groups characteristic of the boat-δ conformation (in this case, boat-λ and boat-δ cannot be mutually interconverted without the bond cleavage) is associated with considerable steric hindrances.

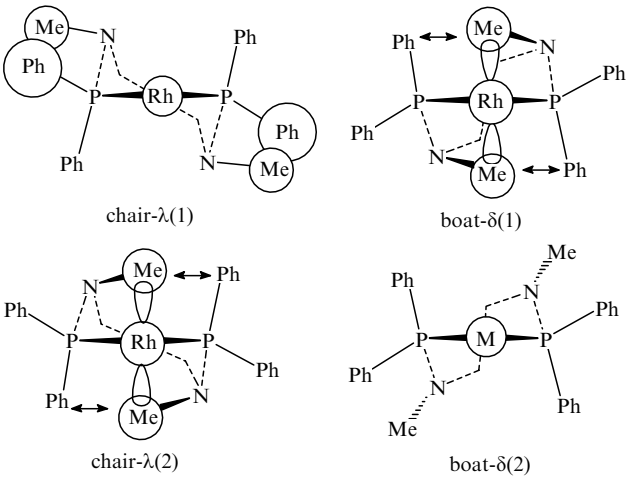
boat-δ-(*R*) for the atropoisomeric binap ligands] is obeyed.[140, 141] Thus, the intermediate catalytic complexes have predominantly the chair-λ and chair-δ conformations in solution. In the chelate complexes, the atropoisomeric ligands binap exist in the only possible boat-λ, boat-δ conformation.

The ligands which form complexes with seven-membered chelate rings, but do not formally follow the chair-λ-(*S*), chair-δ-(*R*) rule are shown in Table 8.

Let us consider molecular models. In the ligands based on *trans*-disubstituted cyclopropane, the α-angles between the planes of the rings and the substituents are close to 123°.



The boat-δ conformation of the chelate ring based on this ligand is preferable to the chair-λ conformation, since the α-angles are closer to 123°, and the λ-(*S*), δ-(*R*) rule is not violated in this case. The structures of the following four ligands, *viz*.:

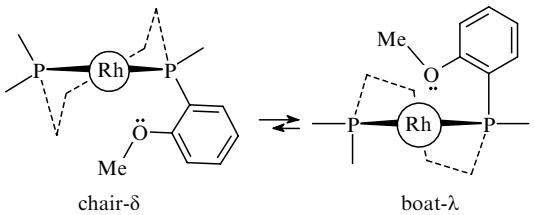


are of the same kind. In our opinion,[140] these ligands can theoretically have four conformers, *viz*., chair-λ(1), boat-δ(1), chair-λ(2) and boat-δ(2), owing to the well-known ability of pyramidal nitrogen atoms to invert.

Of the four possible conformers of the ligand (*S*,*S*)-Mediop(N), the boat-δ(2) conformer is the most sterically favourable. The chair-λ(1) conformation is characterised by spatial proximity of the Ph and Me groups, whereas in the chair-λ(2) and boat-δ(1) conformations non-bonding interactions of the methyl groups with the apical orbitals of rhodium atoms in planar-square complexes are observed.

Another disadvantage of the chair-λ(2) and boat-δ(1) conformations is the interaction of Me and Ph groups (they are marked by bidirectional arrows). We have carried out a series of non-empirical quantum-chemical calculations for the interactions of isolated fragments of these structures.[140] It was found that the boat-δ(2) conformation (or its mirror-opposite boat-λ(2) conformation) is more favourable for NMe-ligands taking into account the interaction between the Me and Ph groups. In the presence of complexes with these conformations of ligands, the reaction should proceed according to the δ-(*R*) [or λ-(*S*)] rule as is actually the case in experiment.

Formally, the *o*-$MeOC_6H_4$-phosphine diop analogue does not conform to this rule, which can also be explained by stabilisation of the 'unfavourable' conformation. The conformational equilibrium in complexes containing this ligand seems to be shifted towards the boat conformation due to the interactions of the electron pairs of the methoxy group oxygens with the apical orbitals of the rhodium atoms.



The existence of similar coordination bonds between the *o*-$MeOC_6H_4$ groups and rhodium atoms in complexes with dipamp ligands has been confirmed by X-ray diffraction analysis.[64] The boat-λ conformation is geometrically more fit for the formation of such bonds than the chair-δ conformation. It can therefore be assumed that the λ-(*S*), δ-(*R*) rule is also applicable to the rhodium complex with this ligand. The catalytic system containing the phosphinite ligand $[Rh(nbd)_2]ClO_4/CuCl$ (see Table 8) cannot be considered as an exception to this rule, since it is possible that it is a bimetallic cluster or a complex where the necessary stereochemistry that manifests the catalytic activity under the reaction conditions is violated.

Examination of molecular models of the other two ligands leads to a conclusion that only the boat-λ conformation in the strained bridged structure of 9,10-dihydro-9,10-ethanoanthracene enables the formation of seven-membered chelate complexes with a metal, *viz*., in this case, the λ-(*S*) rule is fulfilled. In the case of 1,4-bisdiphenylphosphino-(2*S*,3*S*)-diphenylbutane, the boat-δ conformation of the chelate complexes, in which both phenyl rings occupy equatorial positions and thus give an additional gain in energy, is more favourable.[127] Therefore, the λ-(S), δ-(R) rule holds true for complexes containing this ligand.

Five-membered chelate rhodium complexes based on alkylphosphine ligands with second-order symmetry axes (Table 9), conform also to this rule,† however, in its basic 'helical' form.

It is impossible to isolate the helical component of the rhodium complex with the (***S***,*S*)-Pr^i-cnrphos ligand without recourse to X-ray diffraction analysis. However, the *P*-helical structure can be predicted from the configuration of the hydrogenation product.

The data presented in Table 9 suggest that the product configuration is determined by the helical component present in all complexes with alkylphosphine ligands.

Sometimes, the enantioselectivity of reactions in the presence of bisdiphenylphosphine complexes is associated with chirality, which is determined by a definite inclination of the planes of the phenyl groups relative to one another.[194] However, the values and the signs of enantioselectivity in complexes with alkylphosphine ligands,[124, 191–193] cyclodiop [166] and Cydiop,[195] which are devoid of such chirality, do not differ from the corresponding parameters of complexes with bisdiphenylphosphine ligands. Therefore, the helical component makes the main contribution.

An experimental proof of the effect of the helical component on enantioselectivity follows from the enantioselective properties of the complex the achiral ligands in which form helices around the metal ions.[196]

The ligands forming eight- and nine-membered chelate complexes with C_2 symmetry axes (with the exception of atropoisomeric non-substituted aminophosphines [197–200]) are not very effective in the majority of asymmetric hydrogenation reactions. Enantioselectivity can be increased either through the use of bimetallic complexes or through a decrease in reaction temperature.

There is no reason to suppose that the above-considered rule concerning the conformation of five- or seven-membered bis(diphenylphosphine) chelate complexes with the C_2 symmetry axes is only applicable to hydrogenation reactions. Presumably, similar rules exist for other reactions, too. Indeed, the hydrosilylation of acetophenone by diphenylsilane in the presence of rhodium complexes proceeds in accordance with the λ-(*S*), δ-(*R*) rule (Table 10).

† In our opinion, the critical attitude [190] to the conformational expression of this rule, *viz*., λ-(*S*), δ-(*R*), is too formal.

Table 8. Arylphosphine rhodium complexes with seven-membered chelate rings which do not formally obey the chair-δ(*S*), chair-δ(*R*) rule.

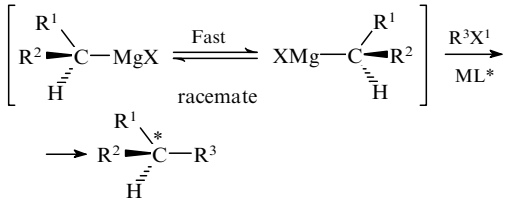
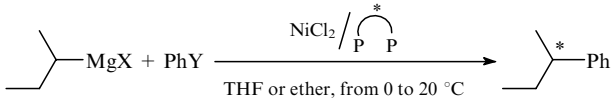
[a] Data from X-ray diffraction analysis.

The cross-coupling reaction has been most studied for secondary alkyl or arylalkyl Grignard reagents which react in the following way:[59]



(1)

The cross-coupling of Bu^{s}MgX with PhY in the presence of bis(diphenylphosphine) nickel complexes:



obeys the rule λ-(*R*), δ-(*S*) (Table 11).

Table 10. Hydrosilylation of acetophenone by diphenylsilane on chiral rhodium complexes.

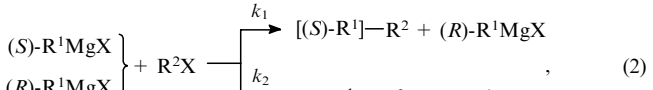
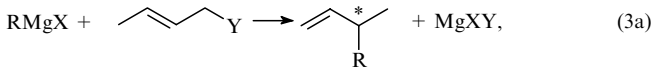
	chair-δ	214, 217	–	17.0 (*R*) [b]	218

[a] Presumably, the (*S*) conformation is indicated erroneously, since more recent studies by the same authors [209, 211] suggest the formation of (*R*)-products in analogous experiments. [b] In this case, X = Br, Y = Cl.

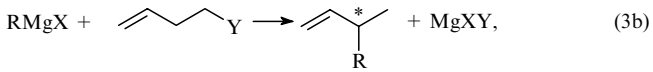
The following catalytic reactions also represent cross-coupling:



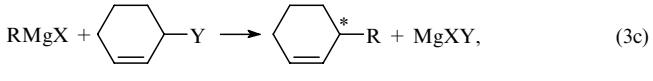
(*S*)-R^1MgX / (*R*)-R^1MgX + R^2X → (k_1) [(*S*)-R^1]—R^2 + (*R*)-R^1MgX; (k_2) [(*R*)-R^1]—R^2 + (*S*)-R^1MgX, (2)



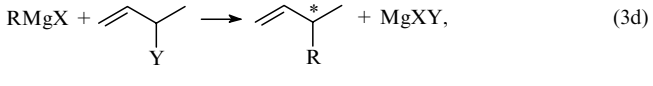
RMgX + + MgXY, (3a)



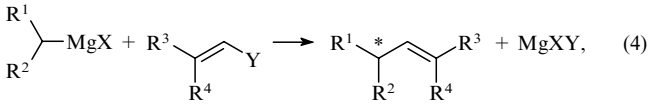
RMgX + + MgXY, (3b)



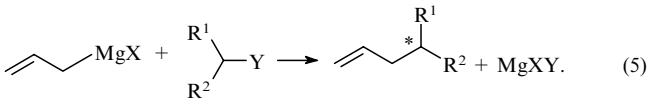
RMgX + + MgXY, (3c)



RMgX + + MgXY, (3d)



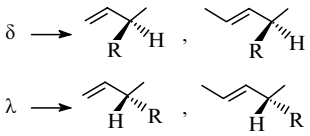
$R^1R^2CHMgX + R^3CH=CHCH_2Y \rightarrow R^1R^2C^*CH=CHR^3 + MgXY$, (4)



$CH_2=CHCH_2MgX + R^1R^2CHY \rightarrow CH_2=CHC^*R^1R^2 + MgXY$. (5)

The reaction of a vinyl halide with a non-racemisable Grignard reagent also belong to the type of reaction (2).[218–220] In this case, the resolution of the racemic Grignard reagent occurs due to different reactivities of the enantiomers of the racemate in the presence of chiral catalysts (kinetic resolution). This enantioselective reaction results in the enrichment of the non-consumed Grignard reagent with one of the enantiomers.

The results obtained in the study of reaction (3c) are given in Table 12. The data concerning reactions (3a), (3b) and (3d) (Table 13) illustrate the applicability of this rule:



δ →

λ →

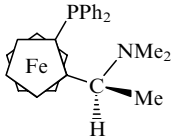
Tables 11 and 12 each contain one entry where the λ-(*S*){(*R*)}, δ-(*R*){(*S*)} regularities are not fulfilled. These examples may be regarded as the exceptions that corroborate the rule.

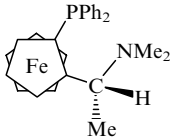
More generally, if we consider the helical structure of a ligand around the central metal atom rather than the conformation of the chelate complex, this rule can be formulated as follows.[125] In homogeneous asymmetric catalytic hydrogenation, hydrosilylation and cross-coupling reactions C_2-symmetrical chiral complexes with ligands in the form of an incomplete turn of a helix around the central metal atom catalyse, from the same kind of substrates, the formation of products having strictly specific configurations characteristic of this particular helicity sign, the metal and the reaction. For example, (*R*)-amino acids are the products of hydrogenation of amino acid precursors on rhodium complexes in which the ligands form incomplete turns of *P*-helices around the rhodium atoms. If the ligands in such complexes form a part of *M*-helices around the rhodium atoms, (*S*)-amino acids are formed.

IV. Catalyst – product configurational relationships in reactions on asymmetric metal complexes

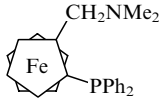
With respect to asymmetric catalytic reactions catalysed by chiral complexes devoid of any symmetry elements (with the exception of C_1), the regular catalyst – product configurational relationships have been gained exclusively in the cross-coupling reactions catalysed by nickel ($NiCl_2$/L*) and palladium ($PdCl_2$/L*) complexes with ferrocene-based (amino)diphenylphosphine ligands (L). The structural formulae of such complexes are given below.



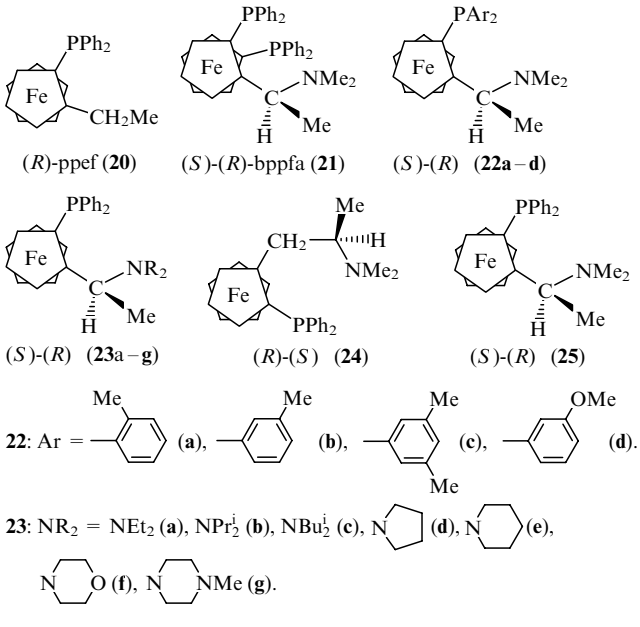
(*S*)-(*R*)-ppfa (**17**)



(*R*)-(*R*)-ppfa (**18**)



(*S*)-fcpn (**19**)



Examination of the cross-coupling reaction (1) (Table 14) demonstrates that the configurations of the products obtained on nickel and palladium complexes containing the same ligand are identical. Moreover, even the value of enantioselectivity virtually does not change. The introduction of *ortho*-substituted aryl radicals at the phosphorus atoms into the ligands decreases the enantioselectivity in comparison with complexes with non-substituted (phenyl) or *meta*-substituted radicals. The absence of amino groups in the ligands, the introduction of bulkier (in comparison with methyl) substituents at the nitrogen atoms and removal of the amino functional groups at a distance of one CH_2 group from the ferrocenyl ring decrease drastically the optical yields of the target products. Therefore, any disturbances in the optimum structures of ligands in catalytic complexes have negative effects on the enantioselectivity of the reaction.

Reaction (4), which proceeds in the presence of (amino)-diphenylphosphine nickel and palladium complexes, is a somewhat more complicated version of reaction (1). The corresponding experimental data ‡ are presented in Table 15. The coincidence of configurations and optical yields of reaction

‡ The catalyst – product configurational relationships have not been analysed in Refs 219, 220, 227–231.

[a] At −20 °C. [b] At 50 °C.

products in the presence of catalytic complexes $NiCl_2$/(*S*)-(*R*)-ppfa and $PdCl_2$/(*S*)-(*R*)-ppfa (entries 4 and 5), $PdCl_2$/(*S*)-(*R*)-ppfa and $PdCl_2$/(*S*)-(*R*)-bppfa (entries 5 and 6) as well as $NiCl_2$/(*S*)-(*R*)-ppfa (entries 1 and 3), prompt a conclusion about the same type of their structures. Thus the bppfa ligand is coordinated through a metal atom (Ni, Pd) to the PPh_2 and NMe_2 groups belonging to the same five-membered ring of ferrocene (the second PPh_2 group in bppfa is hardly involved in coordination). The palladium catalyst $PdCl_2$/(*R*)-(*S*)-ppfa can be used for the synthesis of optically active allylsilanes (entries 7–15), being much more enantioselective than the $PdCl_2$/(*R*)-(*S*)-bppfa complex (entry 8). In the presence of $PdCl_2$/(*R*)-(*S*)-ppfa, the (*E*)-isomers of alkenyl bromides generate products of higher optical purity than the (*Z*)-isomers (entries 10, 11, 13 and 14). Substitution of the phenyl group for the methyl group in the Grignard reagent $Me_3Si(PhCH)MgBr$ (entries 7–11 and 12–15) has no effect on the configuration of the product, since substitution of the (*S*) symbol for the (*R*) symbol reflects the changes in the order of priority of the substituents only.

The actual configurations of products do not change in reactions involving vinyl bromide and phenylethynyl bromide (entries 7 and 16). The substitution of zinc for magnesium in the Grignard reagent does not affect the product configuration either (entries 2 and 17).

The analysis of configurational relationships between the catalytic complex and the product (Table 16) shows that the Ni- and Pd-complexes with ferrocenyl(amino)diphenylphosphine ligands belonging to the (*S*)-(*R*) and (*R*)-(*S*) configurational series catalyse the formation of enantiomeric products or products with different actual configurations in reactions (3) and (4).

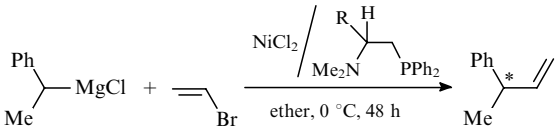
(*R*)-*t*-leuphos	Bu^t	83 (*R*)
		94 (*R*) [a]

[a] The optical yield is adjusted for the optical purity of the ligand.

Reaction (5) has been studied relatively little. In this reaction, asymmetric catalytic effects are produced by complexes (*R*)-(*S*)-$C_5H_5FeC_5H_3(CHMeNMe_2)$·(SR)$PdCl_2$, where R = Me, Pr^i, Ph, *p*-Tol, 4-ClC_6H_4. The optical purity of the product does not depend on the nature of the radical R (*S*-configuration, *ee* = 26%, 22%, 18%, 25% and 16%, respectively).[232]

Interesting relationships were found between the configurations of the metal complexes and the products as well as between the enantioselectivities and the structures of complexes for cross-coupling under the action of chiral nickel complexes with aminophosphine ligands based on amino acids (Table 17).[233, 234]



In this reaction, the configurations of the products depend on the configuration of the ligand. Special mention should be made of the stable tendency of enantioselectivity to increase with an increase in the molecular size of the radical R in the ligand.

Reaction (2) of a vinyl halide with a non-racemisable Grignard reagent proceeds with low enantioselectivity [218–221, 234] and does not present special interest from the standpoint of configurational relationships.

V. The structure of the intermediate complex

Knowing the configurations of the catalytic complexes and the products in cross-coupling reactions of Grignard reagents with allylic derivatives, one can conjecture upon the structure of the intermediate complex.[125]

Cross-coupling of Grignard reagents with allyl phenyl ethers gives rise to an intermediate compound.[221]

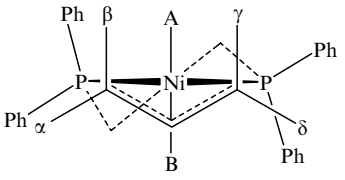


Figure 1. The intermediate compound in the cross-coupling reaction (see Scheme 4), a view from the side of the coordinated allylic group.

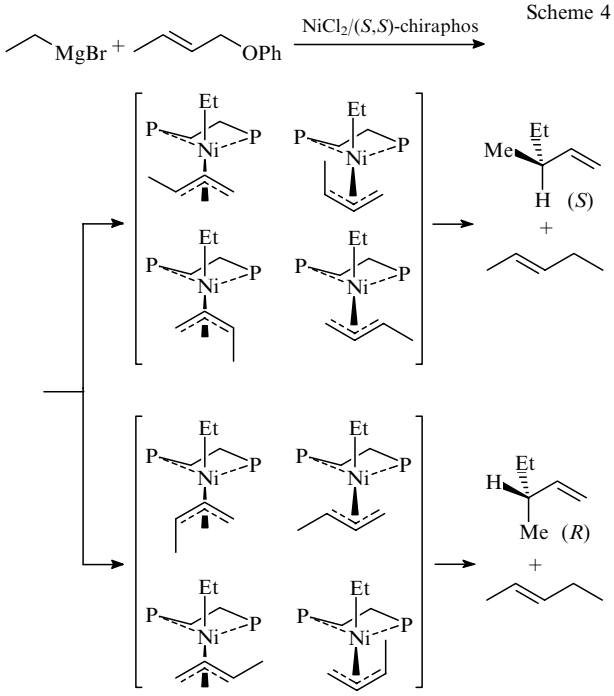
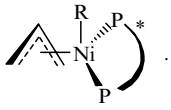
Scheme 4





Thus the formation of eight intermediates may be expected resulting in two enantiomers of the product (Scheme 4).

Figure 1 shows a structural scheme for the intermediate compound with a fixed position of the allylic fragment (a view from the side of the coordinated η^3-allylic group). The four positions of the methyl substituent in the allyl group are marked by the letters α, β, γ and δ, whereas the two positions of the apical radical at the nickel atom are designated by the letters A and B (in total, eight possible intermediates).

All these variants as applied to different reactions of the same kind and analysed in terms of their stereochemical properties have been compared with the known experimental data. The α-position of the Me group is unfavourable at any position of the apical substituent at the nickel atom (A and B), because of the unfavourable ('eclipsed') position of this radical relative to the phosphine equatorial phenyl group. Position β is also unfavourable due to the spatial proximity of the Me group to the phosphine axial phenyl group; if a radical of the Grignard reagent occupies position A, this is proximal to the Me group, too. Position γ is unfavourable only in the case where the apical substituent at the nickel atom occupies position A. And, finally, position δ is favourable at any position (A or B) of the apical radical. Thus only three out of eight intermediates are theoretically more or less preferred. An attack of the radical R(Et) from A or B at the nickel atom on the prochiral allylic carbon atom results in the formation of products with (*S*)-, or (*R*)- and (*S*)-configurations, respectively. In general, a small preference (2/3) goes to the (*S*)-configuration, which is consistent with the experimental data.[221] This simple analysis demonstrates a good coincidence with experimental results, which, in turn, corroborates the correctness of the statement about the structure of the intermediate complex (*cf.* Table 18).

Table 18. Relationships between the experimentally determined product configurations of cross-coupling reaction of alkyl (aryl) Grignard reagents with allylic compounds and those predicted from stereochemical models.

Note. Designations: C is configuration of the product formed from the intermediate (Fig. 1); PC is predicted preferential configuration of the product.

[a] The introduction of Ar into the allylic positions (α,β) is less favourable, being sterically more hindered than that into positions (γ,δ) [eclipsed conformation of the C(α,β) – Ar and the P – Ph bonds of the ligand].

VI. Conclusion

The analysis of experimental data presented in this review suggests that the highest enantiomeric excess of the target product can be reached if an optimum correlation is established between the number of coordination vacancies on the metal complex catalyst accessible to the substrate and the number of coordination-active functional groups of the substrate.

Presumably, the nature of asymmetric catalysis is such that high enantioselectivity is ensured with the minimum degree of freedom of the substrate where the latter is coordinated to the catalyst through all of its functional groups. For example, high enantioselectivity in asymmetric hydrogenation of acetamidocinnamic acid, which contains coordination-active groups in addition to the double bond, is attained with rhodium catalytic complexes with bidentate ligands. In hydrogenation of simple ketones, which are coordinated exclusively through one carbonyl group, this is insufficient and catalytic systems with tridentate ligands should be used which produce a chiral catalytic complex devoid of any symmetry elements other than C_1, where one of the vacancies is additionally blocked by an achiral monodentate ligand (*e.g.*, Et_3N, CF_3CO_2H, $PriCO_2H$, *etc.*). But even in such complicated catalytic systems, the most enantioselective hydrogenation is observed for ketones possessing additional coordination-active groups in the α- or, which is better, the β-position relative to the carbonyl.

The ratios of coordinating and coordination-active vacancies of the catalyst and the substrate should be an optimum. For example, substrates of the tiglic acid type, which contain only one coordination-active group (in addition to C=C), are hydrogenated with much higher enantioselectivity on $Ru(OAc)_2$[binap] complexes than on Rh complexes containing the binap ligand. Contrariwise, the hydrogenation of α-acetamidocinnamic acid occurs with higher enantioselectively in the presence of rhodium complexes. If the hydrogenation is carried out on octahedral ruthenium complexes with the binap ligand, substrates with two coordination-active groups seem to be less optimal as regards enantioselectivity than those with only one coordination-active group.

A similar situation is observed in hydrosilylation reactions where rhodium complexes with tri- and tetradentate ligands manifest the maximum enantioselectivity in hydrosilylation of simple ketones.

Simple graphical dependences between the structures of catalytic complexes and the configurations of the reaction products can be useful for predicting the configurations of reaction products at the design stage of asymmetric catalytic synthesis. The relationships between the configurations of reaction products and the signs of the helical components of the complexes seem to suggest the similarity of asymmetric induction mechanisms of all reactions which obey these regularities.

The analysis of putative structures of intermediate complexes based on stereochemical concepts further corroborates the similarity of asymmetric induction mechanisms of certain reactions. This approach, which enables one to predict the configuration of the product, differs from the graphical plots mentioned above. In this case, we deal with the actual structures of the intermediates.

The analysis of stereochemical relationships between chiral metal complex catalysts, substrates and products in asymmetric homogeneous catalytic hydrogenation, hydrosilylation and cross-coupling reactions illustrates the important role of steric factors in asymmetric catalysis. Additional evidence for the extreme importance of asymmetric catalysis can be derived from the fact that the three leading specialists in asymmetric homogeneous catalysis, *viz.*, W S Knowles, K B Sharpless and R Noyori, were awarded the Nobel Prize for Chemistry in 2001.
