
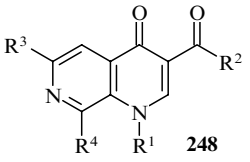
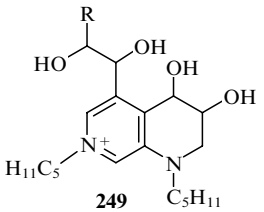
246 **247** **245**

1,7-Naphthyridone derivatives **248** were covered by patents as antibacterial agents.[164–166] Naphthyridinium derivatives **249** were covered by a patent as antidiabetic drugs.[167]



248

R^1 = H, Et, Bn; R^2 = OH, OAlk; R^3, R^4 = Hal, Me_2N, OAlk.



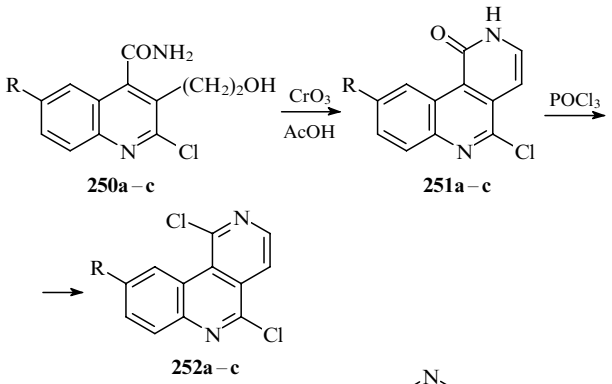
249

R = H, $HOCH_2CH(OH)$.

The data on different biological activities exhibited by a series of other 1,7-naphthyridine derivatives have also been reported in recent years.[157, 168–172]

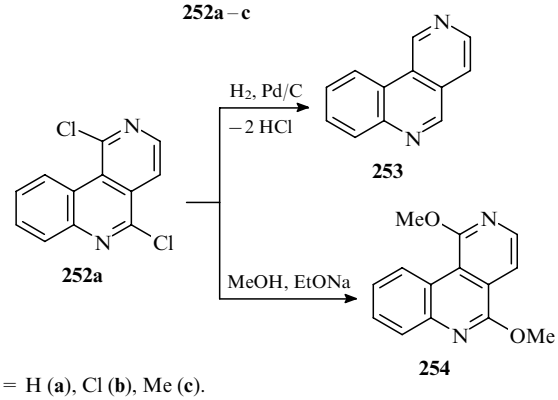
V. 2,6-Naphthyridines

Judging from the number of papers published over the last 15 years, the chemistry of 2,6-naphthyridines attracted much less attention than that of 1,5-, 1,6- or 1,7-naphthyridines. Of the synthetic procedures developed over this period, noteworthy is oxidative cyclisation of 4-carbamoyl-3-(2-hydroxyethyl)quinolines **250a–c** under the action of CrO_3 in glacial AcOH giving rise to benzo[*c*][2,6]naphthyridines **251a–c**. The latter were used in the synthesis of 2,6-naphthyridine derivatives **252–254**.[173]



250a–c **251a–c**

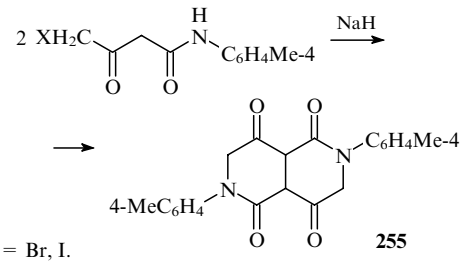
252a–c



252a **253** **254**

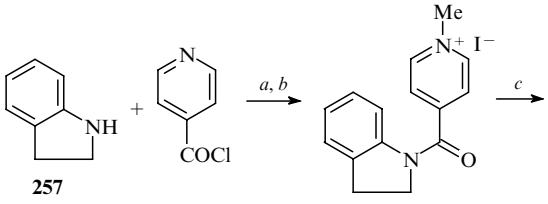
R = H (**a**), Cl (**b**), Me (**c**).

Treatment of toluidides of halogen-substituted acetoacetic acids with sodium hydride in dioxane led to intermolecular cyclisation to form completely hydrogenated 2,6-naphthyridinetetrone **255**.[174]

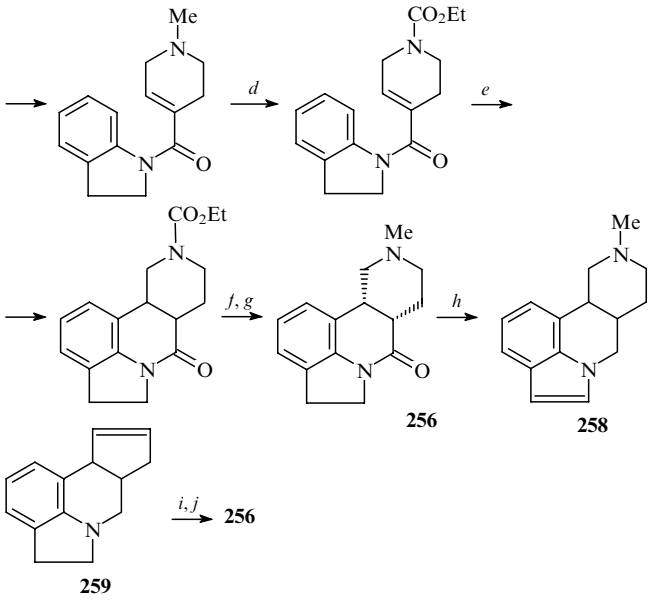


X = Br, I. **255**

Indolo[1,7-*bc*][2,6]naphthyridine **256** is a strong and selective antagonist of serotonin receptors of the 5-$HT_{2C/2B}$ subtypes possessing relatively weak affinity for 5-HT_{2A} subtype receptors.[175–177] The compound **256** was synthesised starting from indoline (**257**) and isonicotinoyl chloride.[175] Oxidation of the compound **256** with MnO_2 afforded indolonaphthyridine **258**. Yet another approach to the compound **256** involves oxidation of the double bond in compound **259** with ozone or osmium tetroxide followed by treatment with methylamine.[178] The indolonaphthyridines **256** and **258** were covered by patents as drugs for the treatment of appetite disturbance, obsessive states (phobia and depressions) and other diseases.[177, 178]

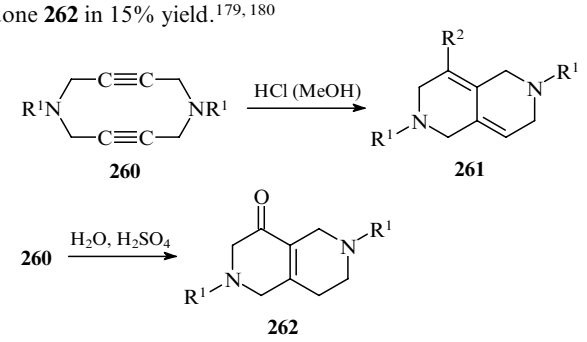


257



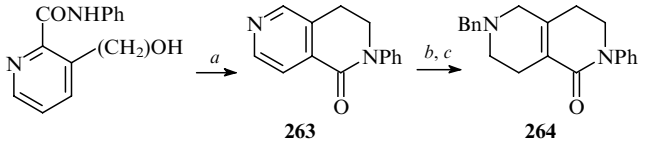
(*a*) Et_3N; (*b*) MeI; (*c*) $NaBH_4$; (*d*) $ClCO_2Et$; (*e*) *hv*; (*f*) AlH_3, THF; (*g*) (−)-di-*p*-tolyltartaric acid; (*h*) MnO_2; (*i*) O_3 (OsO_4); (*j*) $MeNH_2$.

The reactions of 1,6-dialkyl-1,6-diazacyclodeca-3,8-diynes **260** with different organic solvents (cyclohexa-1,4-diene, 9,10-dihydroanthracene or cyclooctane) as scavengers or with such reagents as HCl or MeOH proceed with high regioselectivity according to the Ad_E2 mechanism to give 1,2,3,5,6,7-hexahydro-2,6-naphthyridines **261** in quantitative yields. The reaction of the diyne **260** with H_2O in the presence of H_2SO_4 afforded naphthyridone **262** in 15% yield.[179, 180]



R^1 = Me, Et, Pr^i; R^2 = Cl, OMe.

Cyclisation of anilide of 3-(2-hydroxyethyl)pyridine-2-carboxylic acid occurred under the action of diethyl azodicarboxylate and Ph_3P. Subsequent treatment of the resulting 2,6-naphthyridine **263** with phenacyl bromide and then with sodium borohydride afforded octahydro-2,6-naphthyridine **264** covered by a patent as a medicine for prophylaxis and treatment of schizophrenia and depressions.[181]

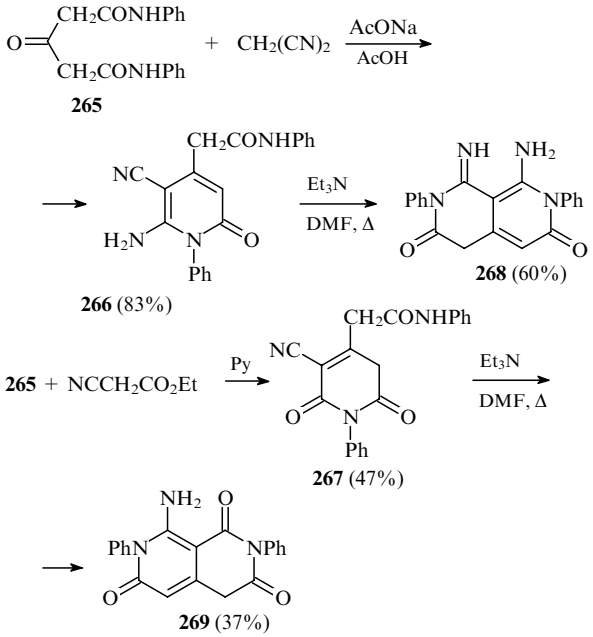


(*a*) $EtO_2CN{=}NCO_2Et$, Ph_3P, THF; (*b*) BnBr, PhMe; (*c*) $NaBH_4$, MeOH.

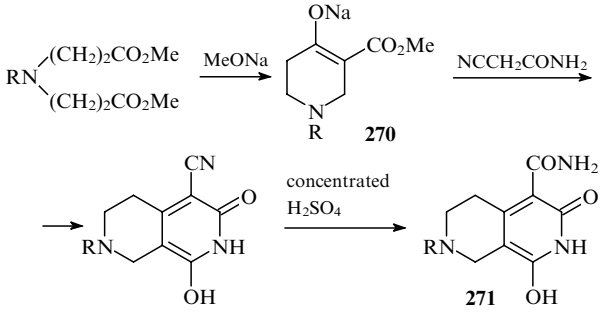
It was reported that 2-methoxy-12-methoxycarbonyl-2,6,8,9-tetrahydro-1*H*-indolo[7*a*,1*a*][2,6]naphthyridine isolated from seeds of *Erythrina melanacantha* Yarms can be used in the treatment of different forms of hypertonia and as an inhibitor of thrombocyte agglutination.[182]

VI. 2,7-Naphthyridines

Various approaches to the synthesis of 2,7-naphthyridines are available. Thus dianilide of 3-oxoglutaric acid **265** reacted with malononitrile in the presence of sodium acetate to give pyridone derivative **266**, whereas the reaction of the compound **265** with ethyl cyanoacetate in pyridine afforded tetrahydropyridinedione derivative **267**. The compounds **266** and **267** underwent cylcisation upon heating with triethylamine in DMF to form substituted 2,7-naphthyridine-3,6-diones **268** and **269**, respectively.[183]



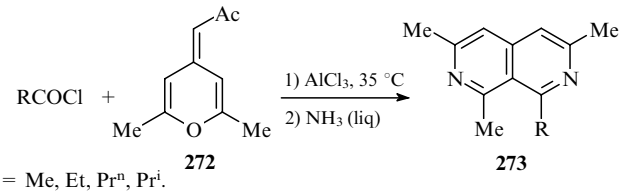
Dieckmann cyclisation of bis(2-methoxycarbonylethyl)alkylamines under the action of sodium methoxide gave rise to sodium salts of 4-hydroxy-3-methoxycarbonyltetrahydropyridines **270**. Condensation of the latter with cyanoacetamide afforded 4-cyano-1-hydroxy-5,6,7,8-tetrahydro-3-oxo-2,7-naphthyridines whose hydrolysis gave rise to 4-carbamoyl derivatives **271** exhibiting antiarrhytmic activity.[184]



R = Et, Bn.

One of procedures for the preparation of alkyl-substituted 2,7-naphthyridines involves acylation of alcohols, ketones or alkenes in the presence of $AlCl_3$ followed by treatment of the reaction mixture with ammonia. However, these reactions are not necessarily regioselective. Thus, the reactions of acetyl chloride with *tert*-butyl alcohol or isobutylene in the presence of $AlCl_3$ followed by treatment with NH_4OH gave rise to 1,3,6,8-tetramethyl-2,7-naphthyridine along with other reaction products.[185, 186]

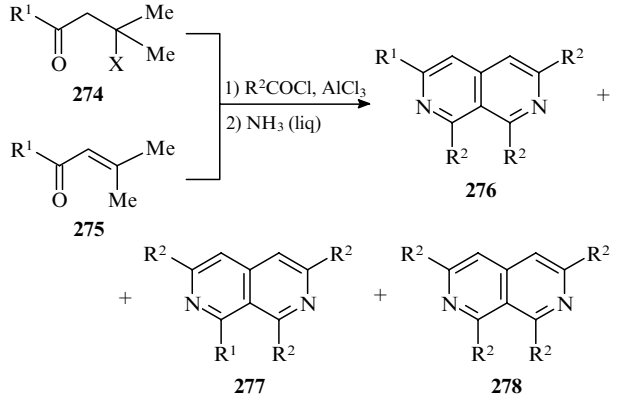
1-Alkyl-3,6,8-trimethyl-2,7-naphthyridines **273** were regioselectively prepared by the reactions of pyran **272** with an excess of fatty acid chlorides in the presence of $AlCl_3$ followed by treatment with liquid ammonia.[187]



272 **273**

R = Me, Et, Pr^n, Pr^i.

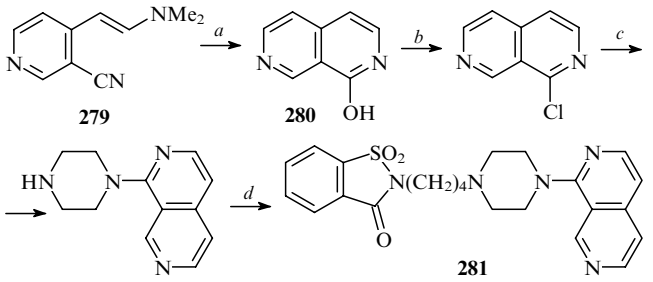
Acylation of ketones **274** or enones **275** in the presence of $AlCl_3$ proceeded nonselectively. Subsequent treatment with liquid ammonia afforded a mixture of 1,3,6,8-tetraalkyl-2,7-naphthyridines **276** and **277** along with symmetrically substituted naphthyridines **278** and picolines.[188]



274 **276** **275** **277** **278**

R^1, R^2 = Me, Et, Pr^i; X = OH, OMe.

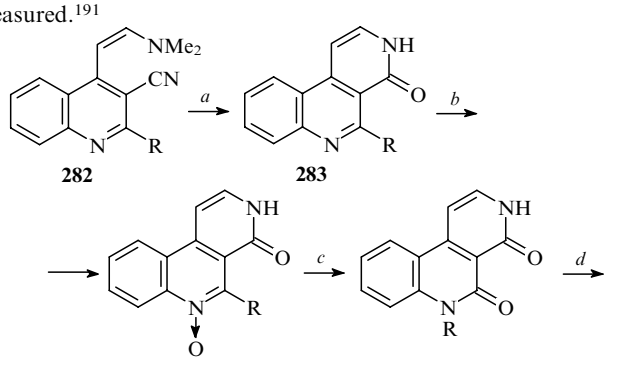
Yet another reaction used in the synthesis of 2,7-naphthyridine derivatives involves intramolecular cyclisation of enamino nitriles under the action of acid catalysts. Thus compound **279** underwent cyclisation to form 1-hydroxy-2,7-naphthyridine (**280**), which was used in the synthesis of sedative agent **281**.[189]



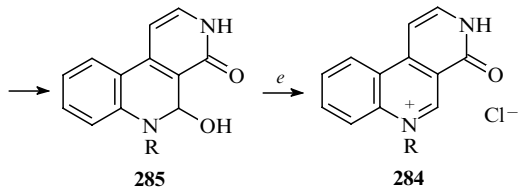
279 **280** **281**

(*a*) 30% HBr, AcOH; (*b*) $POCl_3$; (*c*) HN NH, Bu^tOK, Bu^tOH;

(*d*) 
Analogous cyclisation of enamino nitrile **282** in polyphosphoric acid afforded benzo[*c*][2,7]naphthyridine **283**, which was converted into perlolinium chloride (**284**) [herbaceous alkaloid perloline (**285**)].[190] The mass spectra of the compound **285** were measured.[191]



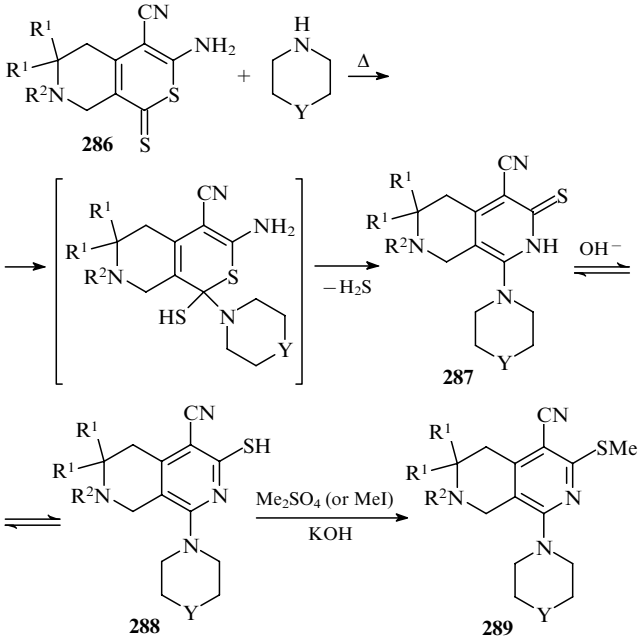
282 **283**



285 **284**

R = 3,4-$(MeO)_2C_6H_3$; (*a*) PPA; (*b*) 3-$ClC_6H_4CO_3H$; (*c*) *hv*, MeOH; (*d*) $[MeO(CH_2)_2O]_2AlH_2Na$; (*e*) HCl.

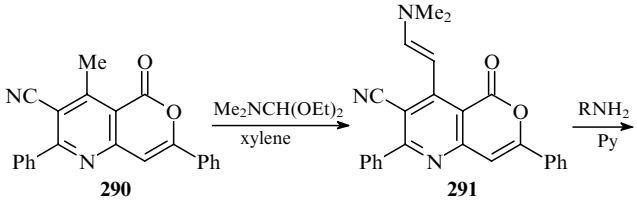
Yet another approach to the synthesis of 2,7-naphthyridines involves recyclisation of pyridinothiopyranothiones and pyridinopyranones. Thus recyclisation of thiopyranothiones **286** upon heating with morpholine, piperidine or piperazine in anhydrous ethanol proceeded through the nucleophilic attack of the amine on the thiocarbonyl group, the cleavage of the C(1)–S bond of the thiopyran ring and the rearrangement to form finally 2,7-naphthyridine-3(2*H*)-thiones **287**. It was demonstrated that the compounds **287** in the crystalline state exist in the equilibrium with the thiol form **288**. Their methylation with Me_2SO_4 or MeI in aqueous or ethanolic solutions of KOH produced thiomethyl derivatives **289** exhibiting antibacterial activity.[192]



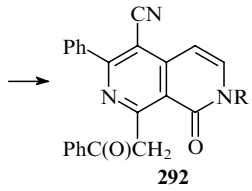
286 **287** **288** **289**

R^1 = H, Me; R^2 = Me, $CH_2CH=CH_2$; Y = O, CH_2, NH.

Condensation of substituted pyrano[4,3-*b*]pyridin-5-one **290** with dimethylformamide dimethyl acetal in xylene yielded enamine **291**, which underwent recyclisation to 2-alkyl-5-cyano-8-phenacyl-2,7-naphthyridin-1(2*H*)-ones **292** upon treatment with primary amines.[193] It was demonstrated that the change in the sequence of the addition of the reagents to the pyranone **292** (first, treatment with benzylamine and then condensation with dimethylformamide dimethyl acetal) resulted in 8-benzoyl-6-benzyl-3-cyano-4-(2-dimethylaminovinyl)-2-phenyl-1,6-naphthyridin-5(6*H*)-one (**293**).

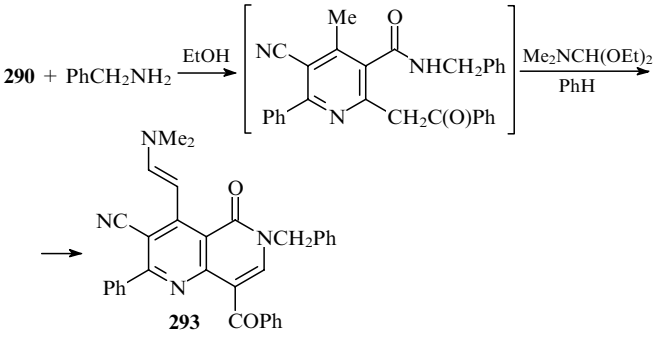


290 **291**



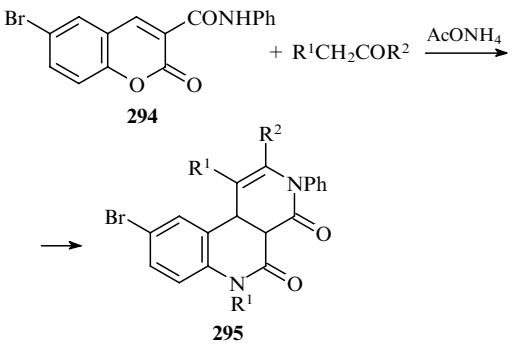
292

R = Pr, Bn.



293

The reactions of 3-(phenylcarbamoyl)coumarin (**294**) with ketones in the presence of ammonium acetate in ethanol at 20 °C or in the absence of a solvent at 170 °C yielded benzo[*c*][2,7]-naphthyridines **295**.[194]

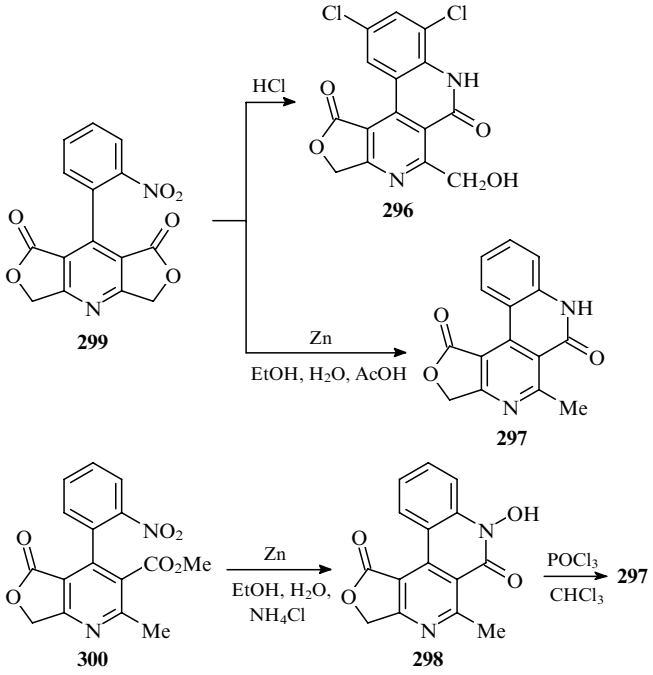


294

295

R^1 = H, Me; R^2 = Me, Et; R^1–R^2 = $(CH_2)_4$.

Fused tetrahydro-2,7-naphthyridine-1,6-diones (**296**–**298**) were also synthesised by reductive cyclisation of difuropyridine **299** and furopyridine **300**.[195]



296

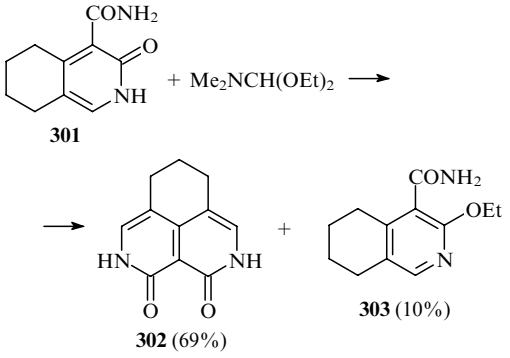
299

297

300

298

Annelated 2,7-naphthyridines were prepared according to a number of other approaches. Thus the reaction of hexahydro-3-oxoisoquinoline-4-carboxamide (**301**) with dimethylformamide diethyl acetal afforded a mixture of 4,5-trimethyl-1,2,7,8-tetrahydro-2,7-naphthyridine-1,8-dione (**302**) with another O-alkylation product **303**.[196]

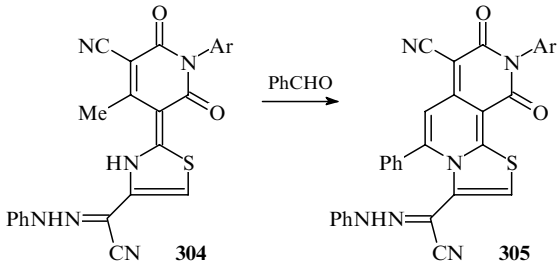


301

302 (69%)

303 (10%)

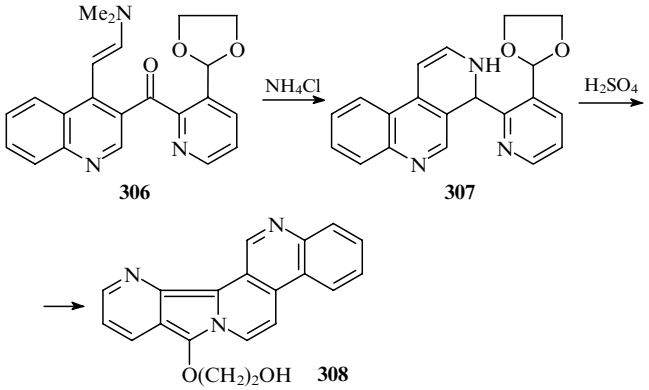
3-(2,3-Dihydrothiazol-2-ylidene)tetrahydropyridinedinone (**304**) underwent cyclocondensation upon treatment with benzaldehyde to form thiazolo[2,3-*a*][2,7]naphthyridine (**305**).[197]



304

305

Enamine **330** underwent cyclisation to give 2,7-naphthyridine **307** under the action of ammonium chloride. The compound **307** was converted into benzo[*f*]pyrido[2′,3′:3,4]pyrrolo[2,1-*a*]-[2,7]naphthyridine **308** on treatment with H_2SO_4.[198]

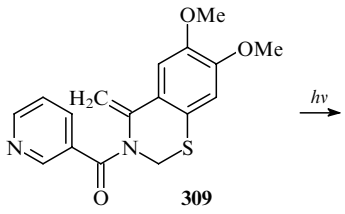


306

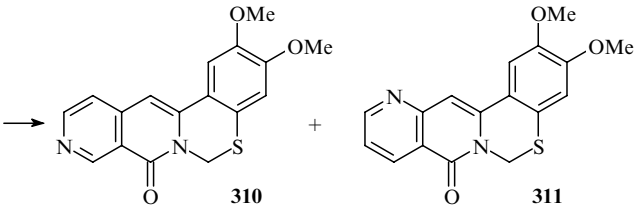
307

308

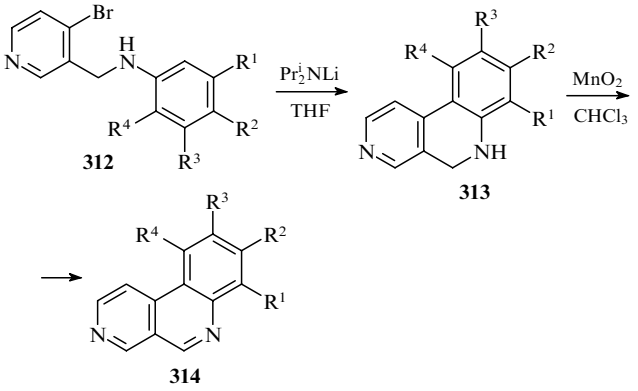
Photocyclisation (irradiation with a low-pressure mercury lamp, the power was 10 W, MeOH, N_2 atmosphere, 5 h) of 4-methylidene-3-nicotinoyltetrahydro-1,3-benzothiazine **309** gave rise to a mixture of isomeric 6*H*,8*H*-naphthyridino-1,3-benzothiazin-8-ones **310** and **311**.[187]



309

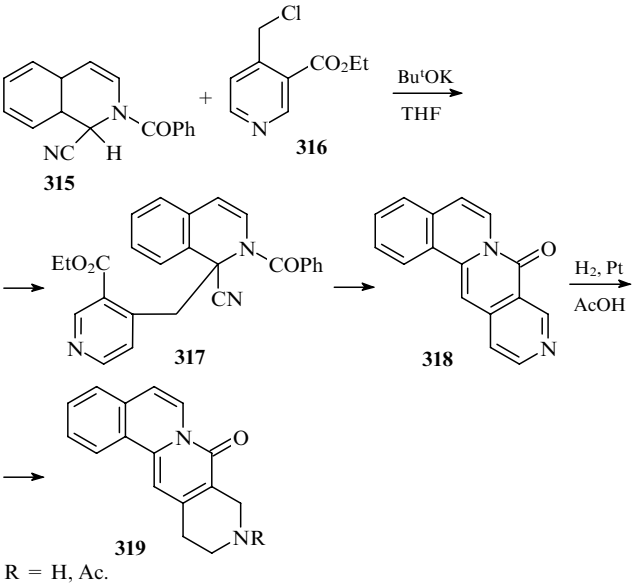


Intramolecular cyclodehydrobromination of substituted *N*-[(4-bromo-3-pyridyl)methyl]anilines **312** followed by dehydrogenation of intermediates **313** afforded benzonaphthyridines **314**.[199]



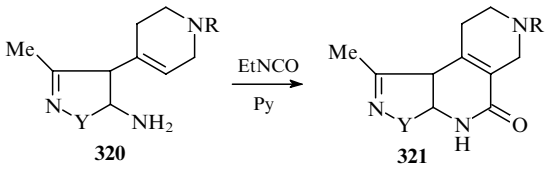
R^1, R^2, R^3, R^4 = H, Me, OMe.

Treatment of isoquinoline derivative **315** with ethyl 4-chloromethylnicotinate **316** in the presence of Bu^tOK gave rise to isoquinoline derivative **317**, which underwent cyclisation to form isoquinolino[2,1-*b*][2,7]naphthyridin-8-one (**318**).[200] The latter was not reduced with $NaBH_4$ or $NaBH_3CN$ in AcOH or Ac_2O, though this compound in AcOH was converted into derivatives **319** upon hydrogenation with hydrogen over Pt.



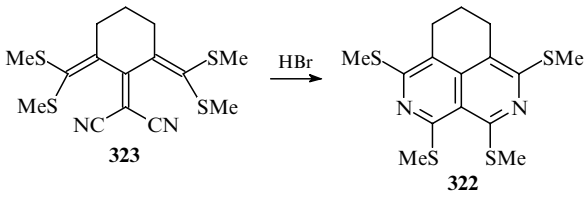
R = H, Ac.

Refluxing of substituted heterylamines **320** with a threefold excess of ethyl isocyanate in pyridine gave rise to partially hydrogenated fused 2,7-naphthyridines **321**.[201]

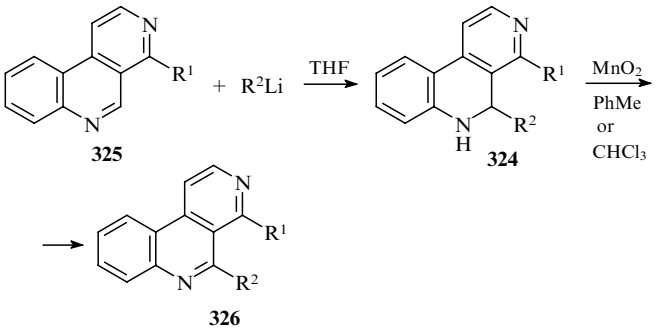


R = Me, Ac; Y = O, NMe.

An ingenious method for the preparation of annelated tetramethylthio-substituted 2,7-naphthyridine **322** is based on cyclisation of 2,6-bis[bis(methylthio)methylidene]cyclohexylidenemalononitrile (**323**) under the action of gaseous HBr.[202]

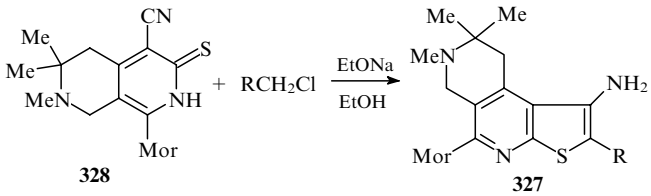


Dehydrogenation of 5,6-dihydro derivatives of 2,7-naphthyridines **324**, which were prepared by the addition of organolithium compounds to 4-substituted benzo[*c*][2,7]naphthyridines (**325**), afforded naphthyridines **326**.[203]



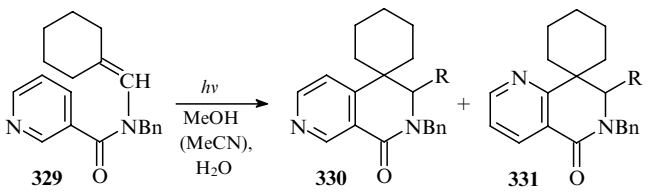
R^1 = F, Cl, $CONPr^i_2$; R^2 = Bu, Ar, Het.

Substituted tetrahydrothieno[2,3-*c*][2,7]naphthyridines **327** were prepared by the reaction of naphthyridinethione **328** with derivatives of chloroacetic acid in ethanol in the presence of sodium ethoxide (the Thorpe–Ziegler reaction).Their neurotrophic properties were investigated.[204]



Mor = ; R = CN, $CONH_2$.

UV irradiation of *N*-aroyleneamide **329** in methanol or aqueous acetonitrile afforded a mixture of regioisomeric spirocycloadducts **330** and **331**. The solvent was not involved in the reaction performed in cyclohexane, and R = H in the compounds **330** and **331**.[205]



R = OMe, OH.

In a number of studies, the structural 2,7-naphthyridine fragment was found to be a component of alkaloids alangimaridine (**332**),[206] isoalamarine (**333**),[207] alamaridine (**334**) and *epi*-alamaridine,[208] nauclefine (**335**),[209,210] naulafine (**336**),[211] normalindine (**337**),[212] eudistones **338**,[213] cystodytins **339**–**341**,[214] kuanoniamines **342**,[215] meridine (**343**) possessing fungistatic activity,[216] alkaloids **344** and **345** exhibiting high antifungal and anticancer activities [217] and other biological compounds, such as sampangine (**346**) possessing antibacterial activity,[218,219] the biosynthetic precursor of camptothecin **347** exhibiting anticancer activity,[220] an analogue of olivecin **348** [221] and benzo derivatives **349** suitable for the treatment of asthma and lowering of blood pressure.[222] The data on antispasmodic activity of 2,7-naphthyridine derivatives were also reported.[223]

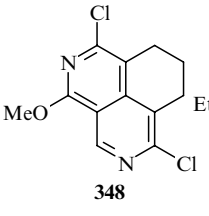
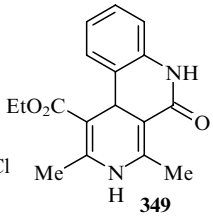
347



348



349

* * *

Analysis of the data on the synthesis, properties and biological activities of five isomeric pyridopyridines (1,5-, 1,6-, 1,7-, 2,6- and 2,7-naphthyridines) published over the last 15 years is indicative of a lively interest in different aspects of the chemistry of these heterocyclic systems. This interest is generally associated with the practical utility of their derivatives possessing a very broad spectrum of biological activities.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 99-03-32965).

Abstract. Data on the mechanism of thermal decomposition of silanes are generalised. The main stages of the process are distinguished and characterised. Attention is concentrated on the elementary homogeneous reactions, deposition of silicon from the gas phase and formation of aerosols. Various models of formation of aerosols are considered. The results of theoretical and experimental investigations of this process are discussed. Data on the chemical composition of the solid product of silane pyrolysis (wall deposit and aerosol particles) are presented. It is noted that the hydrogen content in the solid product varies over wide limits. The bibliography includes 211 references.

I. Introduction

Thermal decomposition (pyrolysis) of silanes is used in microelectronics to obtain polycrystalline silicon and amorphous silicon layers, which explains the researchers' interest in this process. Dozens of investigations devoted to pyrolysis of silane are published annually, however, it should be emphasised that this process has been studied to a much lesser extent than pyrolysis of their closest structural analogues, *viz*. alkanes. For example, it is known that the homogeneous pyrolysis (cracking) of alkanes follows a non-branched chain mechanism. Rice's quantitative scheme suggested back in the 1930s (Ref. 1) allows one to calculate the composition of cracking products for any individual hydrocarbon. The results of the calculations obtained by this scheme fit the experimental data. The study of the influence of heterogeneous factors on the pyrolysis of hydrocarbons [2] has led to a concept of the involvement of surface in both the stages of chain initiation and termination and the stages of chain propagation.

By now, the mechanism of silane pyrolysis (unlike that of hydrocarbon pyrolysis) has not been studied adequately. Due to the lower Si—H and Si—Si bond strengths in silanes in comparison to those of the C—C and C—H bonds in hydrocarbons, pyrolysis of silanes occurs at much lower temperatures and high-molecular-mass silane derivatives are not the final products, but rather intermediates. The final products of the thermal decomposition of silanes are gaseous hydrogen and the solid phase, *viz*., silicon

$$Si_nH_{2n+2} \longrightarrow n\,Si + (n+1)\,H_2\,. \qquad (1)$$

It should be noted that the reaction generally cannot go to completion due to the experimental conditions. So the solid product is usually hydrogenated (containing chemically bound hydrogen) rather than pure silicon. The lower the reaction temperature the higher the hydrogen content in the solid product. Besides, under real conditions, stable gaseous substances (Si_2H_6, Si_3H_8, Si_4H_{10}, *etc*.) are obtained in addition to hydrogen.

Silane pyrolysis is a complex process including numerous homogeneous and heterogeneous elementary steps. At lower pressure ($P < 1$ kPa), heterogeneous stages prevail [3–7] and the solid product deposits on the reactor walls, while at high pressures homogeneous elementary reactions dominate and the solid product is obtained mainly in the form of aerosol particles.[8,9] Usually, the thermal decomposition of silanes is studied in a static reactor ($600 < T < 750$ K),[10–19] in a flow reactor ($800 < T < 1000$ K) [10,14,20–29] and in shock tubes ($900 < T < 2000$ K).[30–35] The solid product is most often amorphous hydrogenated silicon. The content of hydrogen in the solid product expressed as the [H]/[Si] ratio varies from ~ 2 (Ref. 15) 0.5 (Ref. 27) and 0.15 (Ref. 8) at low temperature and a short reaction period to < 0.01 (Ref. 36) at high temperature and a long reaction time.

Under definite conditions, the intermediate solid product (hydrogenated silicon) formed in the course of pyrolysis influences the kinetics and mechanism of this process. In particular, such influence results in acceleration of the reaction when silicon with a highly developed surface (owing to the precipitation of aerosol particles) is obtained.[37,38] As the composition of the solid product changes during the reaction, its reactivity changes, *i.e*., a solid phase of variable composition is formed, which affects the kinetics and mechanism of the process.[3] This is the key feature of the pyrolysis of silanes.

In the present review, elementary reactions, the processes of silicon precipitation on the reactor walls, the formation of aerosols and elementary reactions occurring in the solid product in the pyrolysis are considered. It should be mentioned that certain aspects of the thermal decomposition of silanes have been

discussed in detail. Thus homogeneous elementary stages of the process have been described thoroughly in a number of publications.[39–44] In the reviews,[45,46] the data on chemical vapour deposition (CVD) are systematised and some peculiarities of this process are explained. The results of studies on aerosol formation in the silane pyrolysis have been analysed.[8,9,47] In the present review, we avoid repeating the above-mentioned publications; in particular, elementary homogeneous reactions and CVD processes are not considered in detail. The attention is concentrated on those aspects which, in our opinion, either require an additional discussion (for example, the contribution of radical reactions) or provide more complete information on the pyrolysis of silanes.

II. Thermal decomposition of monosilane

1. Primary decomposition of the monosilane molecule

The reactions of the thermal decomposition of monosilane have been described most thoroughly. There are many viewpoints on whether the process of primary decomposition of SiH_4 into SiH_2 and H_2 under different conditions is homogeneous or heterogeneous. Thus according to an investigation of the silane pyrolysis in a static reactor ($P = 5-30$ kPa, $T = 650-700$ K) where the initial reaction rate did not depend on the surface to the volume ratio (S/V), the authors came to the conclusion that the primary reaction proceeds homogeneously.[15] This process was studied in static and flow reactors [10] (under lower pressure) and a conclusion as to the heterogeneity of the primary pyrolysis reaction in the whole range of pressures from 1 to 10^4 Pa was made assuming that the rate of the initial decomposition of silane at $P = 10$ Pa is proportional to the S/V ratio. This conclusion [10] was the subject of criticism. In particular, O'Neal and Ring [48] on the basis of results obtained earlier [15] reinterpreted the data given in the paper cited [10]. Taking into consideration that the heterogeneous primary decomposition prevails at pressures below 100 Pa, they proved convincingly that under high pressure (> 1 kPa) the primary decomposition proceeds as a homogeneous process. Studies on monosilane pyrolysis by laser heating (without influence of the reactor walls) confirm this conclusion. The activation energy of the laser-induced monosilane pyrolysis at 2.7 kPa (Ref. 49) was measured to be 221 ± 29 kJ mol^{-1}, which corresponds to the results obtained earlier in shock tubes [30] and in a static reactor.[15] Investigations into the silane pyrolysis under continuous wave (c.w.) CO_2 laser radiation and a total pressure of the mixture equal to 4×10^4 Pa allowed representation of the effective rate constant for the silane pyrolysis as $10^{11.5\pm0.6}\exp[-219\pm8(\text{kJ mol}^{-1})/RT]$ (Ref. 50); the value of the activation energy obtained in this study agrees with those given elsewhere.[15,30,49]

At present, it is believed that at $P > 1$ kPa the primary monosilane decomposition occurs as a homogeneous reaction and at lower pressures it is heterogeneous.[5,51]

2. The role of radical reactions in the monosilane pyrolysis

A detailed study of the mechanism of the homogeneous monosilane pyrolysis in a static reactor was first carried out by Purnell and Walsh.[15] The kinetics of the pyrolysis was characterised in the initial (conversion below 3%) and middle (conversion of 10%–20%) stages of the process. In the initial stage, the reaction had the order $\sim3/2$ with respect to monosilane, and the stoichiometry was described by the equation

$$2.39\,SiH_4 = Si_2H_6 + 0.13\,Si_3H_8 + 1.26\,H_2\,.$$

The total pressure in the reactor did not change with time and the solid product was not deposited. In the intermediate stage, the reaction was first order with respect to monosilane, the total pressure in the reactor increased and the formation of the solid product was observed.

Two alternative mechanisms were suggested which explained the experimental result, *viz*., the molecular mechanism

$$SiH_4 \longrightarrow SiH_2 + H_2\,, \tag{2}$$

$$SiH_2 + SiH_4 \longrightarrow Si_2H_6\,, \tag{3}$$

$$SiH_2 + Si_2H_6 \longrightarrow Si_3H_8 \tag{4}$$

and the radical mechanism

$$SiH_4 \longrightarrow {}^{\bullet}SiH_3 + H^{\bullet}, \tag{5}$$

$$H^{\bullet} + SiH_4 \longrightarrow H_2 + {}^{\bullet}SiH_3\,, \tag{6}$$

$${}^{\bullet}SiH_3 + SiH_4 \longrightarrow Si_2H_6 + H^{\bullet}, \tag{7}$$

$$2\,{}^{\bullet}SiH_3 \longrightarrow Si_2H_6\,. \tag{8}$$

It was noted that the reaction order 3/2 can be explained both by the radical and the molecular mechanism (it is suggested that the process in the latter proceeds in the region of the dependence of the rate constant on pressure, *viz*., in the 'fall-off' regime). Later, the calculations of the reaction constant of the unimolecular decomposition of monosilane (reaction 2) by the Rice–Ramsperger–Kassel–Marcus (RRKM) method [30] confirmed the reaction order 3/2 observed by Purnell and Walsh. Nevertheless, the discussion on the possible role of radical reactions in the thermal decomposition of monosilane continues to be topical for the last two decades.

Cleavage of the Si–H bond rupture in the SiH_4 molecule (reaction 5) is the key reaction in the radical mechanism. The Si–H bond energy was measured both by the experimental and theoretical methods. For example, interpreting the experimental data on the kinetics of the reaction between I_2 and SiH_4 in the gas phase, Doncaster and Walsh [52] estimated the H_3Si-H bond energy as 378 ± 5.1 kJ mol^{-1}. The energy of this bond found in the investigation of the reaction of SiH_3 with HI (HBr) was 384 ± 2.0 kJ mol^{-1} (298 K),[53] and in the experiments on SiH_4 photo-ionisation at 150 K it was found to be equal to 372 ± 7 kJ mol^{-1} (Ref. 54).

It should be mentioned that the values of the H_3Si-H bond energy found experimentally agree with the theoretical values. Thus Sax and Kalcher [55] have calculated the enthalpies of formation and Gibbs energies of silicon hydrides containing up to three silicon atoms. According to these calculations, the dissociation energy of the H_3Si-H bond is 383.7 kJ mol^{-1}. The H_3Si-H bond energy obtained in the determination of atomisation energies for a series of AH_n hydrides (where A is an element of the I–VII groups of the second and third periods of the Periodic Table) is 384 kJ mol^{-1}.[56] According to the calculation carried out by Ho *et al*.,[57] the value of the energy is 384 kJ mol^{-1}, later,[58] it was established as 382 kJ mol^{-1}.

The average value of the H_3Si-H bond energy obtained in the above-mentioned studies is 381 ± 13 kJ mol^{-1}. This does not agree with the experimental activation energy (233 kJ mol^{-1}) of monosilane decomposition in the initial stage of the process.[15] (Besides, for the rate of the monosilane chain decay to fit the experimentally observed rates, the chain length should exceed 10^6, but as it follows from the experimental results obtained in shock tubes,[30] the average number of collisions of the monosilane molecule with the molecules of products does not exceed 50 under these conditions.) However, the activation energy value equal to 233 kJ mol^{-1} agrees with the calculated data on the activation energy of the reaction (2).[59–64]

At present, it is acknowledged that the primary stage of the monosilane decomposition is the dissociation of the SiH_4 molecule into SiH_2 and H_2 and not H_3Si-H bond cleavage; but the significance of the contribution of the radical reactions to the next pyrolysis stages still remains an open question. Numerous publications deal with the role of SiH_3 in the process of the thermal monosilane decomposition. Thus the pyrolysis of an equimolar mixture of SiH_4 and SiD_4 was studied in flow and static reactors.[14] The formation of mixed silanes and disilanes and the differences in the results obtained in static and flow reactors could be rationalised by the mechanism implying the involvement of SiH_3.

Thermal decomposition of monosilane in the presence of acetylene in a flow reactor at 690–710 K was studied by Haas

and Ring.[24] Based on the analysis of the reaction products, it was suggested that the silyl radicals were the major products of the initial decomposition.

In an investigation into the decomposition of monosilane in a single-pulse shock tube at 1200–1300 K, it was concluded [33] that the observed decomposition rate of monosilane cannot be explained by the radical mechanism; therefore, the primary act of the monosilane decomposition is the unimolecular elimination of H_2. The rate constants for the H_2 elimination from SiH_4 were calculated by the RRKM method. Comparison of the calculated and experimental [15] values showed that they differ more than forty-fold, which led to the conclusion that the chain mechanism is predominant under the static reactor conditions.

The thermal decomposition of SiH_4 in a static reactor in the presence of ethylene was carried out in order to determine whether the primary act of the monosilane decomposition occurs according to the molecular mechanism (*i.e.*, as the result of H_2 elimination from the SiH_4 molecule).[18] The analysis of the pyrolysis products suggested that the SiH_3 radicals formed in the slow heterogeneous process of the Si—H bond cleavage participate, though to a minor extent, in the pyrolysis of silane. This suggestion was confirmed by performing a pyrolysis of a SiH_4–SiD_4 mixture and detecting a rather high content of HD in the hydrogen fraction.

The initial acceleration of the silane pyrolysis in static and flow reactors in the range of pressures from 1 to 10^4 Pa was found,[10] which could be explained by the liberation of radicals from the surface into the gas phase or by the hydrogen atom elimination into the gas phase followed by chain reaction [processes (6) and (7)].

The gas-phase pyrolysis of monosilane in the mixture of Ar and SF_6 under c.w. CO_2-laser radiation was investigated.[50] The total pressure of the mixture was 4×10^4 Pa, while the partial pressure of monosilane was 10^2–10^3 Pa. The influence of propene additives as an inhibitor of radical reactions was studied experimentally. It was established that the effective rate constant for the silane pyrolysis decreases on the addition of propene. Presumably, in the presence of an inhibitor the reaction proceeds in accordance with the molecular mechanism and is characterised by an activation energy of 281.5 kJ mol^{-1}. In the absence of an inhibitor, the radical stages become sifnificant and the effective activation energy of this process decreases to 217 kJ mol^{-1}.

A series of experiments on the monosilane decomposition in the presence of alkenes and acetylene in a static reactor was carried out in order to find out whether silyl radicals take part in the pyrolysis of monosilane.[11] The analysis of the kinetics of the pyrolysis of the silane–acetylene mixture gave additional information on the nature of the monosilane thermal decomposition. According to the first-order kinetics obtained for this mixture, it was determined that silyl radicals do not participate in the decomposition under conditions examined. A possible scheme of the radical mechanism of monosilane decomposition in the presence of alkenes, according to which lower alkanes should be formed, was suggested. The absence of lower alkanes among the experimentally detected products led to the conclusion that the silyl radicals do not contribute considerably to the reaction.

The results of the investigation on the pyrolysis of a SiH_4–SiD_4 mixture under static conditions and under reduced pressures, in particular, the kinetic curves of the H_2, HD and D_2 formation, showed [12] that HD concentration in the initial stage of the process increased more slowly than in the following stages. The analysis of the formation of isotopic hydrogen molecules shows that the molecular mechanism of the monosilane decomposition is predominant. The sequence of the formation of mixed deuteriosilanes

$$\left.\begin{array}{l} SiH_4 \longrightarrow SiH_3D \\ SiD_4 \longrightarrow SiHD_3 \end{array}\right\} \longrightarrow SiH_2D_2,$$

was determined as being due to the exchange reactions involving the SiH_3 radical, *e.g.*

$$^{\bullet}SiH_3 + SiD_4 \longrightarrow SiH_3D + {}^{\bullet}SiD_3. \quad (9)$$

The concentrations of Si_2H_6, $Si_2H_2D_4$ and Si_2D_6 in the initial stage of the pyrolysis exceed those of other deuteriodisilanes. This fact proves the predominance of the disilane formation upon the reaction SiH_2 with SiH_4. Thus, the features of formation of isotopic hydrogen molecules and deuteriodisilanes points to the significance of the contribution made by the molecular mechanism.

In studies on the heterogeneous decomposition of monosilane at 0.5–4 Pa, the liberation of hydrogen atoms and SiH_3 radicals into the gas phase was observed.[61] The heated surface was placed directly close to the ionisation source in such a way that practically all the radicals evolved from the surface into the gas phase could reach the inlet of the ionisation chamber virtually without collisions with the gas molecules. At $T > 1800$ K, almost all the hydrogen obtained upon the decomposition SiH_4 is liberated as H atoms, while a part of hydrogen is liberated as H_2 molecules at $T < 1800$ K. The elimination of hydrogen in the temperature range 1300–1800 K is characterised by the activation energy 176 kJ mol^{-1}, while at $T < 1300$ K the activation energy is 46 kJ mol^{-1}. The effectiveness of the formation of SiH_3 radicals in the heterogeneous silane decomposition is 0.014–0.05. The liberation of SiH_3 radicals from the surface takes place as the result of the exchange of the hydrogen atom between the SiH_4 molecule and the free bond localised on the surface.

Direct detection of SiH_3 radicals in the thermal decomposition of monosilane in a flow reactor was investigated by the method of laser magnetic resonance.[28] A mixture of monosilane and argon (the total pressure was 60–500 Pa, the partial pressure of monosilane was 2.3–18 Pa) was used. The concentration of SiH_3 radicals changed from 10^{10} to 10^{12} cm^{-3} as the temperature of the reactor was raised from 830 to 1250 K (10% of SiH_4 at the total pressure of 400 Pa). It was suggested that SiH_3 radicals are formed in the heterogeneous processes.

The possibility of the chemical induction of the monosilane pyrolysis was shown.[19] This was carried out in a cylindrical metal reactor. A mixture of SiH_4 and O_2 with the oxygen percentage below 2% was introduced at room temperature and the reaction was initiated by spark ignition or by chemical ignition. The degree of conversion of monosilane was up to 60%. At definite concentration ratio of SiH_4 and O_2 and pressures, the mixture can ignite spontaneously even at room temperature, which is the chemical method of ignition. If the necessary $[SiH_4]:[O_2]$ ratio is established in a small volume of a reactor, self-ignition occurs. Then the burning front spreads over the whole volume, which results in the significant burnout of monosilane. The decomposition of silane presumably has branched-chain character under these conditions. Oxygen is required only in the stage of chain initiation. The atoms and radicals formed in this stage take part in the chain reactions of the monosilane decomposition, which results in significant consumption of monosilane. The average chain length is ~ 10.

Studies of the monosilane pyrolysis under static conditions at $P = 0.2$–5 kPa show that an increase in the specific surface (S/V) at $T = 669$ K gives rise to an increase in the decomposition rate, while at $T = 779$ K it results in its reduction.[4] The dependences obtained were interpreted in the terms of the radical chain mechanism and it was suggested that the rate of the heterogeneous decomposition of monosilane increases with the increase in the ratio S/V at low temperatures, while at high temperatures the rate of the heterogeneous chain termination increases.

It was supposed that the chain process plays a considerable role in the pyrolysis of monosilane [reactions (6) and (7)].[62] The activation energies obtained by *ab initio* quantum-chemical calculations were found to be 36 and 133 kJ mol^{-1} for these reactions, respectively.

Hydrogen atom formation during the monosilane pyrolysis in a shock tube was studied.[35] The reaction was followed by monitoring light absorption by the hydrogen atoms at the wavelength $\lambda = 121.6$ nm. An Ar/SiH_4 mixture was used (the total

pressure was 1 – 1.5 atm, the relative concentration of monosilane in the mixture was $\sim 10^{-5}$). The time dependence of the hydrogen atom concentration was obtained. The features of this dependence are as follows: the change in the concentration at low temperatures is S-shaped; the maximum concentration increases as the temperature increases to $\sim$ 1600 K and decreases as the temperature increases from 1600 to 2300 K. Furthermore, at $T \geqslant 1800$ K the two-stage formation of hydrogen atoms is evident, as the characteristic time of the accumulation of hydrogen exceeds significantly the decomposition time of SiH_4. These features confirm the complex character of the processes of the hydrogen atom formation

$$Si + SiH_2 \longrightarrow {}^{\bullet}Si(H)Si + H^{\bullet}, \quad (10)$$

$$Si + H_2 \longrightarrow {}^{\bullet}SiH + H^{\bullet}, \quad (11)$$

$$Si + Si(H_2)Si \longrightarrow {}^{\bullet}Si_3H + H^{\bullet}, \quad (12)$$

$$H_2 + M \longrightarrow H^{\bullet} + H^{\bullet} + M. \quad (13)$$

Thus, the monosilane pyrolysis results in significant amount of hydrogen (5% – 10% of the initial silane concentration) even under homogeneous conditions and at high dilution. The hydrogen atoms are formed not upon the decomposition of SiH_4 or SiH_2, but rather in the secondary bimolecular reactions. It was concluded that the hydrogen might take part in the chain process which includes the reaction (6) and

$$ {}^{\bullet}SiH_3 + M \longrightarrow {}^{\bullet}SiH + H_2 + M, \quad (14)$$

$$SiH_4 + SiH \longrightarrow {}^{\bullet}Si_2H_4 + H^{\bullet}. \quad (15)$$

The rate constants for the radical reactions should be determined to evaluate the importance of these reactions in the thermal decomposition of monosilane. Unfortunately, the information on these reactions in the literature is poor. The rate constants [63] for the reactions of SiH_3 with Si_2H_6, of SiH_3 with SiD_4 and of H with SiH_4 ($T = 300$ K) are $\leqslant (7\pm4)\times10^{-15}$, $\leqslant (4\pm2)\times10^{-14}$, $\leqslant (2.5\pm0.5)\times10^{-13}$ cm^3 s^{-1}, respectively.[63] According to the calculations of the activation energy, the rate constant for the reaction (7) should be $1\times10^{-10}\exp[-56.1(\text{kJ mol}^{-1})/RT]$ cm^3 s^{-1}.[64] The calculated activation energy for the reaction (7) is 133 kJ mol^{-1}.[62] For the reaction [65]

$$ {}^{\bullet}SiH_3 + SiH_4 \longrightarrow {}^{\bullet}Si_2H_5 + H_2 \quad (16)$$

the rate constant is

$$k_{16} = 2.94\times10^{-12}\exp\left[-\frac{18.4\ (\text{kJ mol}^{-1})}{RT}\right].$$

The values of the rate constant for reaction (5) calculated based on the variation theory of the transition state for the temperature range 200 – 1000 K (Ref. 66) agree with the experimental values.

The above-mentioned data show that the role of the radical reactions in the monosilane pyrolysis is not clear. Nevertheless, the following conclusions can be made. First, under the conditions of the homogeneous pyrolysis, the primary reaction of the silane decomposition is the dissociation of SiH_4 to H_2 and SiH_2 [reaction (2)]. Second, the conditions under which radical reactions make considerable contribution exist probably even at relatively high pressures (where homogeneous reactions are predominant). In static and flow reactors, the radicals are apparently formed in heterogeneous reactions.[67]

The later statement can be confirmed by the following data. Studies of monosilane pyrolysis in a flow reactor for a mixture of 5% SiH_4 and 95% Ar (the total pressure was 6.6 kPa) gave the constants of the decomposition of monosilane at 843 and 933 K, *viz*., 0.25 and 3.6 s^{-1}, respectively. Let us estimate the possible contribution of the radical reactions to this process. The concentration of SiH_3 radicals formed in the monosilane pyrolysis in a flow reactor for a mixture of 10% SiH_4 and 90% Ar (the total pressure was 400 Pa) was measured by the method of laser magnetic resonance and was found to be 1×10^{10} and 5×10^{10} cm^{-3} at 843 and 933 K, respectively.[28] The signal for SiH_3 was proportional to the total pressure squared (the content of the silane in the initial mixture was constant) and to the partial pressure of the silane (the total pressure was fixed). Extrapolating the results obtained [28] for the mixture of 5% SiH_4 and 95% Ar (the total pressure was 6.6 kPa), we obtain $[SiH_3] \approx 1\times10^{12}$ and 5×10^{12} cm^{-3} at $T = 843$ and 933 K, respectively. The ratio of the (Ref. 65) reaction rate to $[SiH_4]$ can be calculated using the rate constant for the reaction (16). At 843 and 933 K, this ratio is 0.2 and 1.37 s^{-1}, respectively. Thus the estimated rate of the reaction (16) is close to the rate of the monosilane decomposition measured experimentally. Unfortunately, the development of the expression for the rate constant for the reaction (16) has not been described in detail.[65] Thus, the estimate given may suggest that the contribution of the radical reactions to the process of pyrolysis can be significant.

3. The mechanism of homogeneous pyrolysis of monosilane

At present, it is believed (see *e.g*. Ref. 39) that the main contribution to the process of the homogeneous monosilane pyrolysis (at least, in the early stages) is made by the following reactions

$$\begin{aligned} &SiH_4 \rightleftharpoons SiH_2 + H_2, \\ &SiH_2 + SiH_4 \rightleftharpoons Si_2H_6, \\ &SiH_2 + Si_2H_6 \rightleftharpoons Si_3H_8, \\ &SiH_2 + Si_3H_8 \rightleftharpoons Si_4H_{10}. \end{aligned} \quad (17)$$

Silylene (SiH_2) formed in the reaction of primary monosilane decomposition reacts with another molecule of monosilane to give disilane. Silylene reacts consecutively with disilane to give trisilane, with trisilane to give tetrasilane, *etc*. The formation of polysilanes is accompanied by their dissociation and the formation of substituted silylenes

$$Si_2H_6 \rightleftharpoons H_3SiSiH + H_2, \quad (18)$$

$$Si_3H_8 \rightleftharpoons SiH_3SiH_2SiH + H_2. \quad (19)$$

The reactions of substituted silylenes with monosilane result in the formation of trisilane, tetrasilane, *etc*.

$$SiH_4 + H_3SiSiH \rightleftharpoons Si_3H_8, \quad (20)$$

$$SiH_4 + SiH_3SiH_2SiH \rightleftharpoons Si_4H_{10}. \quad (21)$$

In addition, the isomerisation reactions

$$H_3SiSiH \rightleftharpoons Si_2H_4, \quad (22)$$

$$SiH_3SiH_2SiH \rightleftharpoons Si_3H_6, \quad (23)$$

unimolecular elimination of hydrogen, *e.g*.,

$$Si_2H_4 \rightleftharpoons Si_2H_2 + H_2, \quad (24)$$

$$Si_2H_2 \rightleftharpoons Si_2 + H_2, \quad (25)$$

$$Si_3H_6 \rightleftharpoons Si_3H_4 + H_2, \quad (26)$$

etc, take place.

The intermediate product Si_2H_2 is represented by two isomers, $Si(H_2)Si$ being more stable.[39,68] The Si_3H_4 species also has two isomers.[47]

Transition from the initial stage of the pyrolysis to intermediate one is accompanied by the acceleration of the process. Devyatykh and coworkers [16] were the first to investigate this phenomenon. This transition was described in more detail by Purnell and Walsh,[15] and the first mechanism of the initial acceleration was suggested in their monograph (Ref. 69). The reactions are autocatalytic processes with SiH_3SiH as an intermediate product.

$$\begin{aligned} &SiH_2 + SiH_4 \rightleftharpoons Si_2H_6 \longrightarrow SiH_3SiH + H_2, \\ &SiH_3SiH + SiH_4 \rightleftharpoons Si_3H_8 \longrightarrow SiH_2 + Si_2H_6. \end{aligned} \quad (27)$$

The results of simulation [39] have shown that the initial acceleration observed under the conditions of a static reactor [15] agree with the mechanism involving reactions (27). It should be noted that the initial acceleration in the process of the monosilane pyrolysis in a flow reactor was also described based on the mechanism of the reactions (27).[27, 67]

An alternative heterogeneous mechanism of the initial acceleration of the silane pyrolysis under the conditions of a static reactor [15] was suggested.[13, 70] Modification of the surface during the reaction was supposed to be the reason for the initial acceleration. As the result, SiH_2 is liberated from the surface into the gas phase accelerating the homogeneous process. This mechanism was criticised,[39] as the pyrolysis rate and the product ratio did not depend on the S/V ratio.[15] Furthermore, the homogeneous mechanism of the initial acceleration was supported by the results obtained in the silane pyrolysis where the influence of the reactor walls was eliminated (shock tubes [30] and laser pyrolysis [49]).

At present, the rate constants for numerous homogeneous elementary reactions occurring in the monosilane pyrolysis have been established. In particular, for the numerical simulation of the monosilane pyrolysis, one can use the parameters of the Arrhenius equation

$$k = A\exp\left(-\frac{E}{RT}\right),$$

where A is a pre-exponential factor, E is the activation energy.

The parameters A and E for the initial decomposition of the monosilane molecule [reaction (2)] in the pyrolysis of undiluted silane for the range of pressures are given in Table 1.

Table 1. Parameters of the Arrhenius equation for the reaction of primary monosilane decomposition in the range of temperatures 800 – 1500 K.[60]

P /Pa	A /s^{-1}	E /kJ mol^{-1}
0.1	1.5×10^{7}	214.4
1.3	1.5×10^{8}	214.4
13	1.5×10^{9}	214.4
1.3×10^{2}	1.5×10^{10}	214.4
1.3×10^{3}	1.5×10^{11}	214.8
1.3×10^{4}	1.8×10^{12}	218.6
1.3×10^{5}	1.7×10^{13}	223.6
∞	3.4×10^{15}	250.4

Table 2. Parameters of the Arrhenius equation (A /cm^3 s^{-1} or s^{-1}; E /kJ mol^{-1}) for the reactions occurring in the silane pyrolysis.

Reaction	A	E	Ref.
$SiH_2 + H_2 \rightarrow SiH_4$	9.8×10^{-13}	−2.3	40
$SiH_4 + SiH_2 \rightarrow Si_2H_6$	1.3×10^{-10}	−3.0	40
$Si_2H_6 \rightarrow SiH_2 + SiH_4$	1.3×10^{15}	213	43
$Si_2H_6 + SiH_2 \rightarrow Si_3H_8$	3.1×10^{-10}	−1.9	40
$Si_3H_8 \rightarrow SiH_2 + Si_2H_6$	4.9×10^{15}	222	42
$Si_3H_8 + SiH_2 \rightarrow Si_4H_{10}$	3.7×10^{-10}	−2.0	40
$Si_4H_{10} \rightarrow Si_3H_8 + SiH_2$	6.31×10^{15}	223.6	70
$Si_2H_6 \rightarrow H_3SiSiH + H_2$	7.9×10^{15}	237	70
$H_3SiSiH + H_2 \rightarrow Si_2H_6$	2.8×10^{-10}	9.2	70
$Si_3H_8 \rightarrow SiH_3SiH_2SiH + H_2$	1.8×10^{15}	229	70
$SiH_3SiH_2SiH + H_2 \rightarrow Si_3H_8$	2.83×10^{-10}	9.2	70
$SiH_4 + H_3SiSiH \rightarrow Si_3H_8$	6.6×10^{-11}	−10.9	70
$Si_3H_8 \rightarrow SiH_4 + H_3SiSiH$	9.3×10^{14}	209	42
$SiH_4 + SiH_3SiH_2SiH \rightarrow Si_4H_{10}$	6.6×10^{-11}	−10.9	70
$Si_4H_{10} \rightarrow SiH_4 + SiH_3SiH_2SiH$	4.4×10^{15}	210.3	70
$H_3SiSiH \rightarrow Si_2H_4$	6.2×10^{9}	6.5	72
$Si_2H_4 \rightarrow H_3SiSiH$	1.3×10^{10}	52.7	72
$SiH_3SiH_2SiH \rightarrow SiH_3SiHSiH_2$	6.2×10^{9}	6.5	70, 71
$SiH_3SiHSiH_2 \rightarrow SiH_3SiH_2SiH$	1.3×10^{10}	52.7	70, 71

In order to apply the data of Table 1 to the mixture of monosilane and argon, the parameters of the Arrhenius equation for several other elementary reactions of the silane pyrolysis are given in Table 2.

III. Homogeneous pyrolysis of disilane

Possible elementary reactions occurring in the thermal decomposition of disilane are described in the theoretical studies (Refs 72 – 75), while experimental investigations into the pyrolysis of disilane and higher silanes are presented in other papers (Refs 32, 42 – 44, 76, 77). Chromatographic analysis of the pyrolysis products of disilane carried out under static conditions at $P = 3\times10^3 - 10^4$ Pa and $T = 560 - 610$ K shows that the products are monosilane, trisilane, two tetrasilane isomers and hydrogen.[76] The parameters of the Arrhenius equation for the reactions of formation of monosilane, trisilane and hydrogen were determined. The mechanism of decomposition of disilane is following: the initial stage is the Si_2H_6 dissociation into SiH_2 and SiH_4, SiH_2 reacts further with Si_2H_6 to form Si_3H_8 and with Si_3H_8 to form Si_4H_{10}, *etc*. The experimental data suggest that hydrogen is a secondary reaction product.

The kinetics of the disilane decomposition was studied in a single-pulse shock tube in the temperature range 850 – 1000 K and at $P = (3.1 - 3.6)\times10^5$ Pa.[44] It was considered that two primary reactions of the disilane decomposition, *viz*., the forward reaction (18) and the reverse reaction (3) occur simultaneously. The parameters of the Arrhenius equation for these reactions were found (see Table 2).

Thermolysis of disilane under static conditions was experimentally studied by Martin, Ring and O'Neal.[43] The dependences of rate constants for this process on temperature and pressure were obtained. The calculated parameters of the Arrhenius equation differ substantially from those found by Bowrey and Purnell.[76]

The experimental investigation of the thermolysis of disilane, as well as tri- and tetrasilane under the conditions of a static reactor was continued later.[42] The parameters of the Arrhenius equation for the primary decomposition reactions of these silanes were found.

Studies of the kinetics of the disilane thermal decomposition in a shock tube at 1000 – 3100 K have shown that disilane generally decomposes into SiH_2 and SiH_4.[32]

The process of the thermolysis of disilane at $T = 300 - 1000$ K and $P = 100 - 1000$ Pa was studied by resonance enhanced multiphoton ionisation (REMPI) and multiphoton ionisation (MPI) methods.[78] The formation of silicon atoms during the pyrolysis was detected by REMPI method.

Thus, according to the above-mentioned data, the reactions

$$Si_2H_6 \longrightarrow SiH_2 + SiH_4,$$

$$Si_2H_6 + SiH_2 \longrightarrow Si_3H_8,$$

$$Si_3H_8 + SiH_2 \longrightarrow Si_4H_{10} \quad etc.$$

are predominant in the primary stage of the disilane pyrolysis.

Furthermore, the formation of silylsilylene H_3SiSiH and hydrogen as a result of dissociation of disilane, *viz*., the forward reaction (18), takes place. Silylsilylene is in equilibrium with its isomer disilene Si_2H_4 [equilibrium (22)].

Silylsilylene reacts actively with disilane (and other silanes), for example,

$$H_3SiSiH + Si_2H_6 \longrightarrow Si_4H_{10}. \qquad (28)$$

Thus, pyrolysis of disilane can proceed with an acceleration of the process due to the additional consumption of Si_2H_6 as the result of its reaction with H_3SiSiH and other substituted silylenes.

IV. Heterogeneous decomposition of silanes

Silicon deposition on the surface as the result of the heterogeneous silane decomposition has been described in detail in several reviews (see *e.g.* 45, 46). Hence, the processes of CVD are considered only in brief in the present review. The publications on the heterogeneous pyrolysis can arbitrarily be divided into two groups: the first group includes studies on the rate of formation of silicon films depending on macroscopic conditions (such as temperature, pressure and composition of a gas mixture); the second group deals with investigations into elementary heterogeneous reactions on the well-characterised ideal surface of single-crystal silicon using modern methods of analysis of the surface.

1. Growth of silicon films upon heterogeneous decomposition of silanes

Studies on the rate of formation of silicon films by the CVD method are aimed at the search for the optimum deposition conditions. Generally, this is associated with technological demands for microelectronics. Experiments were mostly carried out at reduced pressures to avoid the formation of aerosol particles, the deposition of which on the surface of growing layers impairs the product quality. In majority of investigations into CVD, silane [5, 60, 79–93] and disilane [5, 60, 80, 81, 89, 94–99] served as precursors of silicon films. The conditions of deposition in these investigations were so chosen, that the contribution of the homogeneous reactions was negligible. Thus, using the data from these publications, one can determine the reaction sticking coefficient of monosilane (ε_s) and disilane (ε_{ds}). For instance, ε_s is calculated using the equation

$$\varepsilon_s = \frac{W\rho}{Zm}, \tag{29}$$

where W is the rate of the film growth (cm s^{-1}); ρ is the density of the growing silicon film ($\rho \approx 2$ g cm^{-3}); Z is the collision frequency of the monosilane molecules with the unit surface area; m is the mass of the silicon atom. The value of ε_{ds} is calculated by the same manner.

Summing up the results given in the above-cited papers, we derived the equations for the reaction sticking coefficient of monosilane and disilane for a wide range of temperatures and partial pressures of these substances ($750 < T < 1000$ K, $2 \times 10^{-4} < p_s < 2$ kPa, $1 \times 10^{-4} < p_{ds} < 1$ kPa) [27]

$$\varepsilon_s = 10^{3.0}\exp\left[-\frac{148\ (\text{kJ mol}^{-1})}{RT}\right](p_s)^{-0.59}, \tag{30}$$

$$\varepsilon_{ds} = 10^{1.6}\exp\left[-\frac{119\ (\text{kJ mol}^{-1})}{RT}\right](p_{ds})^{-0.70}, \tag{31}$$

where p_s and p_{ds} are partial pressures of silane and disilane, respectively. The dependences of the reaction sticking coefficient of mono- and disilanes on their partial pressures are shown in Figs 1 ang 2.

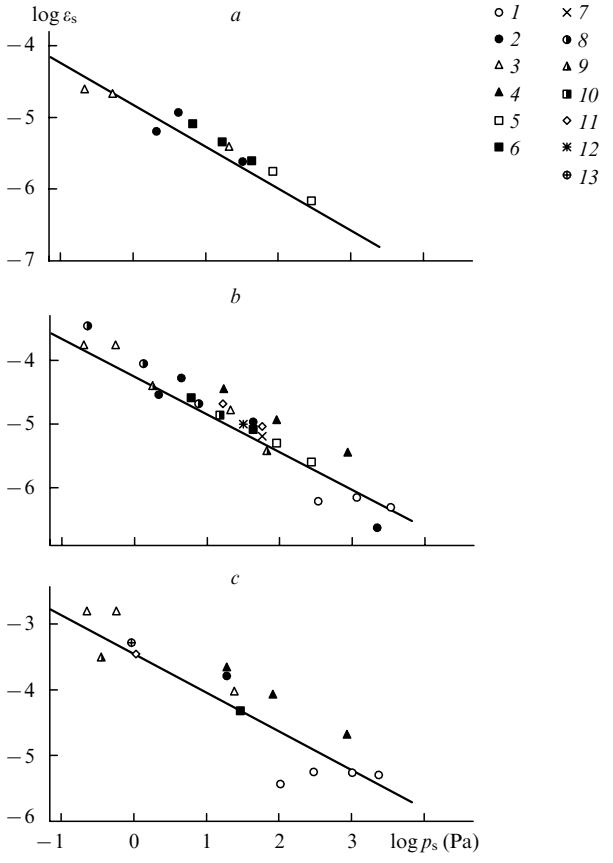

Figure 1. Dependence of the reaction sticking coefficient of monosilane on its partial pressure over the surface of the growing silicon layer at 813 (*a*), 863 (*b*) and 950 K (*c*).
Straight lines are plotted using the Eqn (30), the experimental points (*1*)–(*13*) are taken from Refs 92, 5, 81, 87, 86, 84, 88, 96, 95, 91, 85, 93 and 82, respectively.

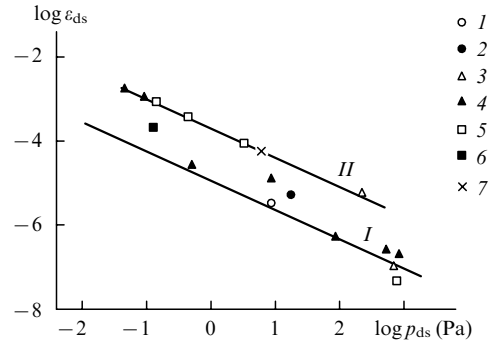

Figure 2. Dependence of the reaction sticking coefficient of disilane on its partial pressure over the surface of the growing silicon layer at 738 (*I*) and 863 K (*II*).
Straight lines are plotted using the Eqn (31), the experimental points (*1*)–(7) are taken from Refs 5, 96, 79, 99, 95, 91 and 94, respectively.

The reaction sticking coefficient of trisilane is approximately the same as those of disilane (for the same range of partial pressures).[89] It is noteworthy that the transport of the molecules from the gas phase to the reactor walls does not limit the process of film growth in the range of temperatures mentioned.[46] Using the Eqns (29)–(31), the growth rate of the silicon film in the heterogeneous decomposition of silane and disilane can be estimated for a wide range of temperatures and pressures.

2. Dissociative adsorption of silanes on the ideal surface of single-crystal silicon

Information on heterogeneous elementary reactions which occur in the pyrolysis of silane on the surface of a solid product formed, *viz.*, amorphous hydrogenated silicon is rather scarce. However, the mechanism of silicon growth on the well-characterised ideal Si(111) and Si(100) surfaces is discussed in numerous studies. Modern methods of the analysis of surface such as thermodesorption,[98] low-energy electron diffraction,[98, 100, 101] secondary-ion mass spectrometry,[102] scanning tunnelling microscopy,[103–108] reflection high-energy electron diffraction [109–111] are used in these investigations.

It was found that two neighbouring dangling bonds participate in elementary reactions of heterogeneous decomposition of mono- and disilane.[104, 107] The elementary reaction of the heterogeneous monosilane decomposition can be represented by the reaction [104, 108, 112–114]

$$SiH_4 + 2_ \longrightarrow \underline{H} + \underline{SiH_3}. \quad (32)$$

Hereinafter, the symbol _ denotes an active centre of the surface (dangling bond), $\underline{H}$ and $\underline{SiH_3}$ mean that H and SiH_3 are bound to the surface (mono- and trihydride groups, respectively).

The elementary reaction of the heterogeneous decomposition of disilane occurs as follows [105, 115, 116]:

$$Si_2H_6 + 2_ \longrightarrow \underline{SiH_3} + \underline{SiH_3}. \quad (33)$$

Alternatively, the following version is possible (Refs 115, 117, 118):

$$Si_2H_6 + 2_ \longrightarrow \underline{Si_2H_5} + \underline{H}. \quad (34)$$

Trihydride groups are unstable at high temperatures and decompose in the reaction presented below [105, 113, 116, 119–121]:

$$SiH_3 + 2_ \longrightarrow \underline{\underline{SiH_2}} + \underline{H}, \quad (35)$$

where $\underline{\underline{SiH_2}}$ is the group bound to two surface silicon atoms.

V. Aerosol formation in the pyrolysis of silanes

Three characteristic stages of aerosol formation in the pyrolysis of silanes can be distinguished: (1) nucleation, *i.e.*, the formation of nuclei which grow much faster than they decompose; (2) growth of single particles in the processes of 'condensation' and coagulation; (3) the formation of agglomerates consisting of individual primary particles. The stage of nucleation is the least studied.

1. Experimental investigation into aerosol formation

Aerosol formation can take place in the process of thermal decomposition of silane under certain conditions. The regimes of an epitaxial reactor which favour aerosol formation were studied by Eversteijn.[122] Mixtures of silane with hydrogen under atmosphere pressure were used. Aerosol formation occurred above certain critical concentration of silane, and this lower limit of silane concentration was registered at different temperatures. The critical silane concentration depended on the temperature of the reactor and changed from 0.248% to 0.002% as temperature increased from 1050 to 1410 K.

The process of aerosol formation in an epitaxial reactor was also studied by Murthy *et al.*[123] Mixtures of silane with argon under atmosphere pressure were used. If the concentration of silane at the reactor entrance exceeded 0.2%, 'smoke' was observed at the exit from the reactor at 1370 K. The onset of gas-phase nucleation was determined from 'smoke' formation. The critical concentration of silane decreased with the increase in temperature.

Investigations into aerosol formation in flow reactors were carried out.[9, 26, 124–129] Critical concentrations of silane in the decomposition of its mixtures with inert gases and hydrogen at low temperatures were determined by Slootman and Parent.[9] These experiments were carried out in a vertical flow reactor under atmosphere pressure. It was found that the critical concentration of silane for all carrier gases is inversely proportional to temperature. Homogeneous nucleation in inert gases began at relatively low temperatures. In the experiments with mixtures of silane with hydrogen, aerosol formation was observed at much higher temperatures. It is necessary to consider chemical reactions inhibiting the formation of aerosol particles to rationalise the increase in temperatures. It was suggested that the large excess of hydrogen influences kinetics of gas-phase processes, *viz.*, favours reverse reactions with silylene, which results in the decrease in the concentration of aerosol particle precursors.

Qian *et al.*[124] carried out experiments in a low-pressure flow reactor using pure silane. The residence time of silane in a hot zone was ~ 1 s. The beginning of the homogeneous nucleation was established by appearance of a weak smoke-forming flash. The critical concentration of silane (above which the nucleation was observed) increased ~ 1.26-fold on the increase in temperature from 970 to 1020 K.

The mechanism of deposition of polycrystalline silicon from silane was studied in a low-pressure flow reactor.[125] Mixtures of silane with nitrogen were used. The formation of aerosol particles was determined from laser light scattering. If the pressure of the silane exceeded the critical value (the initial content of silane in the mixture being the same), the intensity of the scattered light increased sharply. Thus for the initial mole fraction of silane equal to 0.3, the flow rate 400 $cm^3\ min^{-1}$ and temperature 1000 K, an abrupt increase in the intensity of the scattered light was observed at ~ 85 Pa. Electron microscopic studies of particles formed at 130 Pa suggest that these particles are single crystals with characteristic sizes from 5 to 10 nm.

Studies of the growth of silicon particles formed upon pyrolysis of silane in a multistage flow reactor followed by condensation, showed that the formation of the primary silicon particles as the result of homogeneous nucleation took place in the first stage.[126, 127] In the second stage, the primary particles served as the 'condensation nuclei' for the products of heterogeneous decomposition of silane and the intermediate products formed in the homogeneous pyrolysis. It was noted that the regime of spontaneous homogeneous nucleation can be realised provided such parameters as flow rate, silane concentration and temperature profile are properly selected. The morphology of the particles and their crystal structure were studied by electron microscopy. It was found that the particles are non-agglomerated spheres with the size of ~ 0.1 μm. The major part of the particles has crystal structures.

A method of synthesis of spherical particles homogeneous in size in a reactor with five heating zones was described.[128] The particle morphology was determined by electron transmission microscopy method and their crystal structures were determined by X-ray and electron diffraction.

Particles obtained in a flow reactor were shown to be clusters resulting from the homogeneous decomposition of silane, nucleation and coagulation.[26] The sizes of the clusters varied from 1 to 10 μm. X-Ray diffraction analysis revealed that the particles have crystalline structures.

The results of an experimental study of aerosol formation under static conditions were given in Refs 4 and 17. The formation of aerosols upon thermal decomposition of silane under pressure of 0.3–4.5 Pa and 750–830 K was investigated.[4] The aerosol particle formation was followed by monitoring changes in optical transmission at wavelengths of 515 and 755 nm. It was suggested that the precursors of aerosol are silicon atoms.

The critical character of the dependence of aerosol formation on the silane pressure was rationalised as being due to competition of the homogeneous nucleation and silicon deposition on the reactor walls.[17]

The investigation of aerosol formation in the pyrolysis of mono- and disilane diluted with argon was carried out in a shock tube.[8] The aerosol particle formation was followed by monitoring the absorption of laser radiation at two different wavelengths. Information on the sizes, compositions and the number concentrations of particles was obtained. The investigation of the particles by such methods as electron diffraction, electron transmission microscopy and secondary-ion mass spectroscopy shows that the particles are spherical with their diameters ranging from 10 to 40 nm. These particles are weakly agglomerated and contain 15 at.% of hydrogen.

A number of investigations [130–135] was devoted to the study of aerosol formation upon heating of silane by laser radiation. The formation of particles in mixtures of silane with argon under the action of a CO_2-laser was investigated by Flint and coworkers.[130, 131] The sizes and number concentrations of the particles were determined from the results of the measurement of

scattered and passed radiation. It was concluded that silicon particles are formed as amorphous silicon with subsequent crystallisation on passing into hotter reaction zones.

The silicon powder obtained upon laser heating of silane was analysed.[133, 134] Physicochemical parameters of the powder were determined, using a number of methods: the sizes of the particles and crystallites were determined by electron transmission microscopy and scanning electron microscopy, while the density was determined by the method of helium pycnometry. The crystal structures and sizes of the crystallites were determined by X-ray diffraction (considering the width of X-ray diffraction lines using the Debye–Sherrer formula), electron diffraction and dark-field electron microscopy. It was found that both separate spherical silicon particles and chain agglomerates are formed in the laser pyrolysis. The sizes of the primary particles incorporated in these agglomerates are in the range 10–100 nm. The particles are built of separate crystallites with the size ~ 15 nm.

The morphology of aerosol silicon particles formed upon decomposition of silane is of particular interest. Coagulation of these particles results in agglomerates of irregular structures.[128, 136] Analogous agglomerates of Ag,[137, 138] TiO_2,[136, 139–144] SiO_2[141, 144–147] and soot[148–150] are formed in natural and industrial processes.[151] These structures can be characterised by the fractal dimension $D_f < 3$, which is the exponent in the ratio

$$M \propto \left(\frac{R}{a}\right)^{D_f}, \tag{36}$$

which relates the mass of the agglomerate M to its radius R, a is the average radius of the primary particles. The silicon agglomerates formed upon pyrolysis of monosilane at temperatures 800–1720 K had the fractal dimension $D_f = 1.5–1.7$ (Refs 29, 136).

2. The mechanism of aerosol formation

Much attention has been paid to the mechanism of aerosol formation in the thermal decomposition of silanes. A mechanism of the formation of particles from silicon atoms was suggested based on investigation of aerosol formation upon thermal decomposition of monosilane under static conditions in the range of temperatures 723–1070 K and pressures 66–1335 kPa.[17] Studies of thermal decomposition of silane at 770–1070 K have led to a conclusion that the particles could be formed from Si and Si_2 atoms.[21, 22] A model of homogeneous polymerisation in the gas phase for the conditions of low-pressure reactors was suggested.[125] According to this model, the particles are formed from SiH_2. A model of particle formation from disilane was considered by White *et al.*[13] and Ring and O'Neal.[70] An assumption was made that trisilane could be a precursor of the solid product in the processes of the deposition on the reactor walls and homogeneous polymerisation.[39] Decomposition of pentasilane was considered to be the initial stage of aerosol formation.[152] A model of aerosol formation in low-pressure reactors which allows identification of the conditions of homogeneous nucleation and those under which heterogeneous reactions predominate was suggested by Sladek.[153] This model is based on the competition of nucleation processes and diffusion of aerosol precursors to the reactor walls.

A model of aerosol formation upon silane pyrolysis was given.[154] The calculations for the temperature range 900–2400 K were made based on the classical nucleation theory and assumption that aerosols are formed from silicon atoms. The critical nucleus contained several silicon atoms at 900–2000 K. Yet another theoretical investigation of silicon nucleation in silane decomposition was made based on the classical nucleation theory.[155]

Simulation of the aerosol formation process in the silicon layer deposition from mono- and disilane at atmospheric pressure showed that the basis of the mechanism is the growth of aerosol particles as the result of the consecutive addition of silylenes.[77]

A kinetic model of aerosol formation in thermal decomposition of silane was described.[156] The essence of this model is that a nucleus of an $(SiH_m)_n$ particle is formed in the initial stage as the result of homogeneous reactions; its further growth occurs due to its reaction with silane.

A mechanism of the formation of silicon hydride clusters in the silane pyrolysis was discussed.[47] This model contains detailed chemical information on the relative stabilities and reactivities of different possible silicon hydride clusters. The model allows one to calculate the rate of the particle nucleation. Thermodynamic properties of the silicon hydride clusters were estimated. The mechanism includes reversible and irreversible formation of silicon hydrides: the former reactions involve particles containing up to 10 Si atoms, while the latter reactions involve particles containing 11–20 Si atoms. The key intermediates and reactions leading to the formation of the particles were determined, the dependence of their formation on the conditions of the reaction was studied.

A detailed kinetic model describing pyrolysis of the initial molecules and the homogeneous nucleation of the silicon particles under shock tube conditions was considered.[8] The kinetic scheme contains 117 elementary reactions and includes 42 types of molecules (from fully hydrogenated Si_nH_{2n+2} to unsaturated Si_nH_{2n}, Si_2H_2 and non-hydrogenated silicon Si_n clusters). The model describes the process of coagulation of aerosol particles and their growth due to the CVD process.

Numerical solutions of discrete-sectional equations of the aerosol dynamics, which take account of the interaction of separate clusters for various reactor types were described.[128, 157] Simplified equations of reaction and coagulation which permit one to predict rapidly the aerosol evolution were derived. The influence of the initial vapour concentration, reaction time, seeds and temperature profile on the properties of the highly dispersed particles formed in silane pyrolysis was estimated.

Numerical stimulation of aerosol formation under the heterogeneous-homogeneous thermal decomposition of silane was made.[67] The model allows one to calculate the following time-dependent parameters: the degree of silane decomposition, di- and trisilane concentration, the concentration and dispersity of aerosol particles formed, the hydrogen content and the concentration of active centers (in the form of dangling bonds) in particles. These data agree reasonably with the experimental results.

The results of the above-mentioned studies show that the modern concepts on the process of aerosol formation are contradictory and its mechanism is not sufficiently studied. A reason for the disagreement as to the mechanism of aerosol formation is the insufficiency of experimental data. As a rule, the experiment gives only some parameters of the process such as the sizes of the particles,[8, 128] or temperature and the concentration of silane required for the onset of homogeneous nucleation.[4, 9, 17, 122–126] Nevertheless, based on the available literature data general features of aerosol formation in the silane pyrolysis can be formulated. The initial stage of this process is the formation of Si_mH_n clusters. The thermochemical calculations[47] show that for small sizes of clusters ($m \leqslant 10$) the rate of their decomposition is relatively high, which leads to a decrease in the number of silicon atoms in the clusters

$$Si_{m+l}H_{2(n+k)} \longrightarrow Si_mH_{2n} + Si_lH_{2k}. \tag{37}$$

In other words, the concentration of this kind of clusters depends on a quasi-equilibrium between the formation reactions of these clusters due to the agglomeration of smaller clusters

$$Si_mH_{2n} + Si_lH_{2k} \longrightarrow Si_{m+l}H_{2(n+k)}, \tag{38}$$

and the decay of lager clusters [see reaction (37)], on one side, and involvement of these clusters in analogous reactions of agglomeration and decay, on the other side. The rate of cluster decomposition is relatively small for larger cluster sizes ($m > 10$); since the dissociation of a large cluster requires that larger numbers of the Si–Si bonds were cleaved than in the dissociation of a smaller

cluster. Thus, the clusters with $m > 10$ may be regarded as particles and the rate of the formation of clusters with $m > 10$, as the rate of nucleation.[47] Further, the rate of the particle growth is determined largely by coagulation.[67]

VI. The composition of the solid product

The detailed investigations on the chemical composition of aerosol particles formed in thermal decomposition of silane are virtually not documented and the data on the solid product of the reaction which deposits on the reactor walls during the silane pyrolysis are very scarce. Therefore, the experimental data concerning this aspect should be analysed in more detail than in the previous sections.

The solid product (a deposit on the reactor walls and aerosol particles) of thermal decomposition of silane represents polycrystalline silicon [8] (high temperatures and/or long reaction time) or amorphous hydrogenated silicon [3] (mild temperatures and/or short reaction periods). The content of hydrogen in the solid pyrolysis product vary over a wide range (see Section I).

The bound hydrogen present in amorphous hydrogenated silicon has been actively studied over the last three decades. Detailed information on the vibration modes of mono- (SiH) and polyhydride [SiH_2, $(SiH_2)_n$, SiH_3] groups present in amorphous hydrogenated silicon was obtained (see, *e.g.*, Refs 158–162). IR spectra contain three characteristic absorption bands in the range of frequencies 550–750, 800–950 and 1900–2300 cm^{-1} (Ref. 158). Two peaks at ~ 2000 and 2100 cm^{-1} can be found in the range of frequencies 1900–2300 cm^{-1}. A doublet with maxima at 845 and 880 cm^{-1} or a single peak with maximum at 880 cm^{-1} is most often observed in the range 800–950 cm^{-1}. The data allow one to compare different vibration modes with absorption bands observed in the IR spectra of silanes (Table 3).

Table 3. Vibration frequencies of the Si—H bond observed in the IR-spectra of silanes.

Group	Vibration type	Frequencies /cm^{-1}
SiH	stretching	2000
	bending	630
SiH_2	stretching	2090
	scissors	880
	oscillation	630
SiH_3	stretching	2120
	deformation	905, 860
$(SiH_2)_n$	stretching	2090–2140
	scissors	890
	oscillation	845
	the same	630

The absorption peak at ~ 2100 cm^{-1} has to be discussed separately. It was supposed earlier [163, 164] that the stretching vibrations of the monohydride groups manifest themselves only at ~ 2000 cm^{-1}. However, it is well known that the stretching vibrations of the monohydride groups localised on the surface of single-crystal (Refs 116, 165 and references cited therein) and amorphous silicon [166, 167] have the frequencies at ~ 2100 cm^{-1}. Furthermore, lines at 2140,[168] 2100,[169] 2085,[170, 171] 2068 cm^{-1} (Ref. 172) were found in the IR spectra of the amorphous hydrogenated silicon, while absorption at 800–950 cm^{-1} (corresponding to the polyhydride groups, see Table 3) was absent. Heating of amorphous hydrogenated silicon resulted in an increase in the absorption intensity at 2100 cm^{-1} without any absorption at 800–950 cm^{-1}.[173, 174] These results suggest that two types of monohydride groups, which have absorption lines at 2000 and 2100 cm^{-1}, are possible in amorphous hydrogenated silicon. Using aerosol particles of amorphous hydrogenated silicon as an example, it was shown that the SiH groups with the vibration frequency ~ 2000 cm^{-1} do not interact with atmospheric oxygen, unlike the groups with the frequency ~ 2100 cm^{-1} (Refs 3, 175). The interaction of the latter is characterised by a decrease in the line intensity at 2100 cm^{-1} and appearance of absorption in the region 2170–2300 cm^{-1}. The absorption in this region is generally ascribed to monohydride groups where the hydrogen and oxygen atoms are bound to the same silicon atom (Si—O—Si—H).[176–182]

The hydrogen evolution method is a most informative method used for the investigation of amorphous hydrogenated silicon.[183–194] This method allows one to obtain quantitative information on the content of hydrogen in groups of different structures. The essence of this method can be described in the following way. A sample of amorphous hydrogenated silicon is heated at a constant rate (20–40 K min^{-1}), which results in the evolution of hydrogen. The amount of the hydrogen evolved is determined by the increasing pressure or by mass spectroscopy. The sample is heated to the $T \sim 920$–950 K, where crystallisation takes place and all the hydrogen releases to the gas phase. The results of the hydrogen evolution are usually represented as the dependence of the rate of evolution on temperature. Two temperature regions, *viz.*, 570–770 and 770–920 K can be distinguished. In the former region one [185–191, 193, 194] or two [183, 186, 188, 189, 191] peaks are observed. The hydrogen evolution in this temperature region is described by the first-order process and is not diffusion-limited.[185, 190] It is supposed that the low-temperature peak in this region is associated with elimination of hydrogen from the polyhydride groups,[183, 187–189, 194] while the high-temperature peak is determined by elimination of hydrogen from the monohydride groups.[183, 188] In the region 770–920 K, a peak the location of which depends on the rate of heating is observed. Hydrogen evolution in this case is described by the kinetics with an order exceeding the first order.[185–187, 189, 192] This peak is associated with the elimination of hydrogen from the monohydride groups.[183, 185–189] In relation to the interpretation of the peaks in the evolution spectra of hydrogen, it is worthwhile to note the investigations into the thermal desorption of hydrogen from the (111) and (100) faces of silicon single crystal [113, 195–202] and from the surface of porous crystalline sample.[202] It was found [198, 202] that the desorption of hydrogen from di- and trihydride groups occurs at 640–715 K, while from monohydride groups, at 720–820 K.

Detailed comparison of the IR spectra and the hydrogen evolution spectra for the aerosol particles of amorphous hydrogenated silicon formed upon thermal decomposition of monosilane in a flow reactor was described.[36, 175] The evolution spectra of the samples of aerosol particles withdrawn from the flow contain two relatively sharp peaks with the maxima at 670 and 760 K and a broad peak with the maximum at 780 K. It was found that the sharp peaks are determined by the evolution of hydrogen from poly- and monohydride groups with the frequency of stretching vibrations 2000 cm^{-1}, while the broad peak is determined by the evolution of hydrogen from monohydride groups with the frequency of stretching vibrations ~ 2100 cm^{-1}.

The investigations into amorphous hydrogenated silicon by the proton magnetic resonance method (Refs 203–205) show that the spectra represent superposition of two lines, *viz.*, a broad (20–30 kHz) one and a narrow (3–4 kHz) one. The hydrogen giving the broad line is called the 'clustered' phase and hydrogen giving the narrow line is called the 'dilute' phase. Hydrogen atoms of the both phases are bound to silicon atoms by covalent bonds. The difference between these two phases is that hydrogen atoms of the 'clustered' phase are located close to each other, while the hydrogen atoms of the 'dilute' phase are isolated.

For the aerosol particles of the amorphous hydrogenated silicon obtained upon thermal decomposition of monosilane, the data of IR spectroscopy were compared to those of the hydrogen evolution, on one hand, and the data from NMR spectroscopy, on the other hand.[3] It was concluded that the hydrogen of the

'clustered' phase is a constituent of mono- (vibration frequency is 2000 cm^{-1}) and polyhydride groups. The hydrogen of the 'dilute' phase is a constituent of monohydride groups with the vibration frequency 2100 m^{-1}. Experimental results suggest that the SiH groups of the 'clustered' phase are localised inside the amorphous silicon network [206] as 'hydrogen complexes', *viz*., extended defects stabilised by hydrogen.[207–211] The monohydride groups of the 'dilute' phase are localised on the surfaces of interconnected microvoids and microchannels.

VII. Conclusion

Thermal decomposition of silanes is a complex process including different stages. Arbitrarily, the main components of the mechanism of this process are as follows:

1. Homogeneous elementary reactions.

2. Heterogeneous reactions occuring on the surface of the silicon deposited on the reactor walls.

3. The formation of precursors of aerosol particles (molecular clusters Si_mH_n, $m = 10-20$) which exist in the equilibrium with gaseous intermediate products.

4. Homogeneous nucleation, *i.e*., the formation of the smallest aerosol particles, the rates of forward growth reactions for which exceed substantially those of the reverse reactions.

5. Heterogeneous deposition of molecules and smaller clusters on the surface ('condensation').

6. Coagulation and coalescence of particles. In the initial stages where the rate of coalescence exceeds that of the coagulation, more or less spherical particles are formed. In the following stages where the coagulation becomes predominant, particle agglomerates (the so-called primary particles) are formed.

7. Agglomeration of primary particles, *i.e*., the transformation of several neighbouring particles into one primary particle.

8. Chemical and structural changes in aerosol particles.

To explain the pyrolysis mechanism in general each of the above-mentioned stages has to be investigated in detail because of their close relations and mutual influence on each other. Only thorough study with the help of modern physicochemical methods can give the detailed representation of this process.

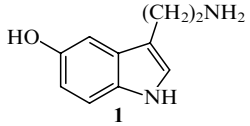
Abstract. The data on the structures of organic compounds active with respect to serotonin (5-hydroxytryptamine) receptors are systematised. Various aspects of their design are considered. The bibliography includes 296 references.

I. Introduction

The problems connected with the design of physiologically active compounds are discussed in the literature in terms of medicinal chemistry;† therefore, they are usually not very well known to a broad circle of organic chemists. The present review is aimed at the systematisation of the published data on the design of physiologically active compounds interacting with serotonin receptors and the analysis of effects of their chemical structures on their activities.

It is known that the physiological role of serotonin (5-hydroxytryptamine) (**1**, 5-HT) in the human brain consists in the regulation of various psychoemotional reactions. In addition, serotonin controls thermal regulation, sensory perception (particularly, pain sensitivity), *etc*. Recent studies have shown that disturbances in serotonin metabolism and/or functional activities of serotonin regulators are related to the pathogenesis of schizophrenia, depressive and anxiety states, alcoholism, drug abuse, *etc*.



1

These findings have stimulated the interest that emerged over the past decade in the design of chemical compounds involved in the neurotransmission mediated by serotonin.

We hope that this review, which generalises structural approaches to the design of compounds interacting with serotonin receptors, will inspire synthetic chemists to make a radically new contribution to this branch of medicinal chemistry.

II. Classification of serotonin receptors

Serotonin (**1**) is a biogenic amine which manifests an extremely broad range of biological activities with respect to the central nervous system and other body organs and tissues. In the human central nervous system, it acts as a neurotransmitter, *i.e*., a chemical compound which transmits information from one nerve cell to another.[3] In the course of transmission, neurotransmitter molecules are released into the space separating membranes of the interacting cells where they bind to the corresponding receptors on the surfaces of target cells. It is this event that represents perception of information. The specificity of neurotransmitter – receptor interactions is determined by the structures of both the receptor and the neurotransmitter.

Serotonin receptors represent proteins incorporated into cell plasmatic membranes, which transform molecular signals from serotonin and its analogues into specific cell responses. The capability of chemical compounds of binding to their specific receptors underlies their effects on serotoninergic transmission. The effects of the majority of compounds presently used for the treatment of mental disorders, anxiety, schizophrenia, obesity, migraine, *etc*., are thought to be based on their involvement in serotoninergic transmission. These compounds act as agonists (activators) or antagonists (blockers) of the corresponding receptors. It should be noted that the interactions of chemical compounds with receptors are considered from the standpoint of both affinity (*i.e*., binding ability) and intrinsic activity (*i.e*., the ability to produce a biological response by means of structural or conformational changes in the receptor). (Affinity is numerically expressed by the reverse value of the equilibrium dissociation constant of the ligand – receptor complex. Apparently, antagonists possess no intrinsic activities.) The existence of partial

† The subject of medicinal chemistry is the search for, and the structural design [1,2] of, physiologically active compounds (drugs), the elucidation of chemical structure – activity relationships and, finally, the solution of the opposite structure – activity problem, *viz*., the design of compounds with predetermined properties.

agonists, *i.e.*, those which cannot produce maximum activation of their specific receptors and, as a consequence, maximum biological effect irrespective of their concentrations, is also possible.

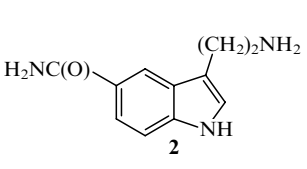
The discovery of an immense variety of serotonin receptors of different subtypes in the past decade has brought about significant changes in their classification and nomenclature. Here, we shall adhere to the classification proposed by a special IUPAC commission according to which the 14 presently known subtypes of serotonin receptors are further divided into seven groups ($5HT_1 - 5HT_7$) depending on their amino acid sequences and the similarity of their signal transmission mechanisms.[4–6] Activation of serotonin receptors triggers the mechanism which involves a cascade of membrane proteins interacting sequentially with one another. In a definite step, signal transmission involves secondary messengers, *i.e.*, molecules or ions endowed with the ability of inducing conformational changes in the proteins involved in specific cellular processes. $5HT_3$ receptors which form ionic channels and transmit signals directly from nervous cells by ionic currents are the only exception.

The discovery of various subtypes of serotonin receptors led to the conclusion that the majority of presently known drugs, influencing serotoninergic transmission, act simultaneously on several subtypes of 5-HT receptors. Therefore, the design of selective ligands aimed at more efficient treatment with minimum side effects has been and still remains the problem of paramount importance, to say nothing of the fact that the design of selective ligands may culminate in the elaboration of radically new treatment schedules.

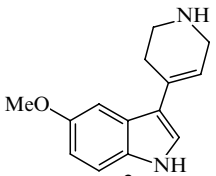
III. Ligands of serotonin 5-HT_{1A} subtype receptors

High concentrations of 5-HT_{1A} subtype serotonin receptors were found in the brain cortex where they are thought to play a crucial role in the processes associated with emotions. It has presently been demonstrated that these receptors are involved in the pathogenesis of various mental diseases, whereas ligands (especially agonists) interacting with these receptors were recommended as candidates for the treatment of various anxiety states, phobias, depressions, Alzheimer's disease (senile dementia), as analgesics, *etc.*[7–9] It is of note that 5-HT_{1A} receptors display a high degree of similarity to other receptor systems of the organism, such as adrenergic and dopaminergic systems, which significantly complicates the search for their selective ligands.

The simplest structural modifications of the serotonin molecule, *viz.*, the introduction of substituents into the benzene ring or restriction of the conformational mobility of the side chain, afforded several high-affinity 5-HT_{1A} agonists, *e.g.*, amines **2** and **3**. However, like serotonin itself, these compounds are not selective and interact with different subtypes of serotonin receptors (predominantly, with 5-HT_{1B}, 5-HT_{1D} and 5-HT_{2C}).[10,11]

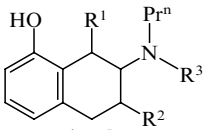


2



3

8-Hydroxy-2-dipropylaminotetralin (**4a**) was among the first most active and selective agonists of 5-HT_{1A} receptors,[12,13] the (+)-(*R*)-enantiomer being fully agonist and manifesting the highest affinity. The main structure–activity regularities for compounds of the type **4** are as follows. The presence of the hydroxy group in position 8 is essential for the binding and provides 500-fold higher selectivity with respect to serotonin receptors in comparison with dopamine receptors (the shift of the OH group into positions 5 or 7 sharply decreases the selectivity), while the hydroxy group in position 8 may be replaced by OMe, Ac or other groups (but not the carboxy group) without any loss in the affinity and selectivity, although the agonistic activity sometimes decreases noticeably, as in substitution by Ac.[14] The presence of two propyl substituents at the nitrogen atom is an optimum for affinity, selectivity and agonistic activity, although some variations in substituents, *e.g.*, replacement of one Pr^n group by $CH_2CH=CHI$ (compound **4b**),[15] enhance significantly the binding of the ligand to the receptor.

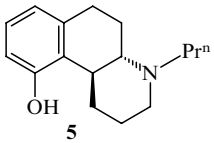


4a–d

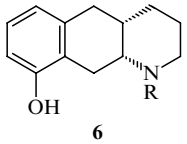
$R^1 = R^2 = H$: $R^3 = Pr^n$ (**a**),
$CH_2CH=CHI$ (**b**);
$R^1 = Me$, $R^2 = H$, $R^3 = Pr^n$ (**c**);
$R^1 = H$, $R^2 = Me$, $R^3 = Pr^n$ (**d**).

The introduction of small substituents (*e.g.*, Me) into positions 1 (compound **4c**)[16] or 3 (compound **4d**)[17] of the alicyclic fragment of the molecule results in compounds manifesting different activities. The tetralin (1*S*,2*R*)-isomer **4c** displays nearly the same affinity as compound **4a**, but is much inferior to the latter with regard to intrinsic activity and is a weak partial agonist. The derivatives containing a methyl group in position 3 bind less effectively to 5-HT_{1A} receptors, although some of them, *e.g.*, the (2*S*,3*S*)-isomer of the tetralin **4d**, manifest high intrinsic activities.[18]

The transition to tricyclic structures afforded several potent 5-HT_{1A} agonists (*e.g.*, the *trans*-isomer **5**),[19] whereas the synthesis of rigid octahydrobenzo[*g*]quinolines yielded weak 5-HT_{1A} agonists, among which the amine **6** was the most active compound.[17] Notice that these cyclic analogues were used for the preparation of pharmacophore models of compounds interacting with 5-HT_{1A} receptors.‡



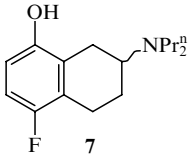
5



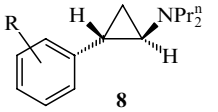
6

And, finally, it should be noted that the introduction of a fluorine atom into position 5 of compound **4a**, which gives compound **7**, changes quite unexpectedly the binding pattern. Thus the (*R*)-isomer of the tetralin **7**, is a full agonist and is somewhat less active than compound **4a**, while the (*S*)-isomer of compound **7** is a strong antagonist of 5-HT_{1A} receptors and its affinity is nearly an order of magnitude lower than that of the (*R*)-enantiomer.[20–22]

The amine **4a** was used as a prototype for the design of yet another structural class of 5-HT_{1A} agonists, *viz., trans*-(arylcyclopropyl)amines **8**.[16,23] The analysis of the structure–activity relationships in this series of compounds revealed that the introduction of electron-withdrawing substituents into the phenyl ring decreases the affinity for 5-HT_{1A} receptors, whereas electron donor or aromatic substituents (with the exception of bulky ones), *e.g.*, 2- or 3-thienyl substituents, enhance the affinity. Unlike the aminotetralin **4a**, compounds of this series are highly stereoselective, only (1*R*,2*S*)-isomers manifesting high activities.



7

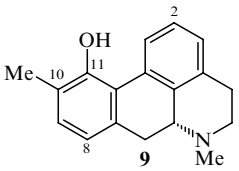


8

Yet another class of 5-HT_{1A} agonists, *viz.*, (*R*)-apomorphine analogues structurally close to aminotetralins **4** are known.

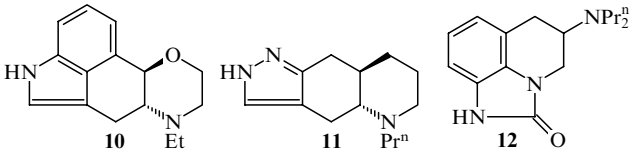
‡ The pharmacophore entails specific spatial arrangement of the binding groups essential for the optimum interaction with the receptor and causing (or blocking) a specific biological reaction. It is a purely structural concept which is neither a genuine molecule nor a genuine association of functional groups.

(*R*)-Apomorphine is a non-selective agonist of dopamine receptors. Structure–activity studies of its derivatives resulted in compounds which do not interact with dopamine receptors but are selective towards serotonin receptors. 11-Hydroxy-10-methylaporphine (**9**) with a methyl group in position 10 (instead of the hydroxy group in aporphine) is the most potent and selective compound. It is of note that only the (*R*)-enantiomer manifests agonistic activity, whereas the variations of substituents in positions 10, 11 and at the nitrogen atom reduce this activity in comparison with the amine **9**. These findings suggest that a hydrogen bond is formed between the hydroxy group in position 11 and serine-168 in the receptor protein and that a 'pocket' for the methyl group in position 10 exists in the binding site of the 5-HT_{1A} receptor.[24,25]



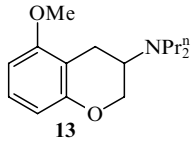
9

Compounds **10**–**12** provide other examples of cyclic systems that interact with 5-HT_{1A} receptors. Although these compounds are not selective, being active with respect to other receptors, they have been used for the construction of computer models of the ligand-binding site of 5-HT_{1A} receptors.[26–28]



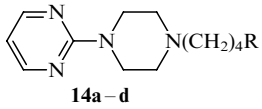
10 **11** **12**

Other structural variations in compound **4a** included the introduction of heteroatoms into the bicyclic fragment. For example, the 5-methoxy derivative **13** manifests the same high reactivity as aminotetralin (**4a**) and, which is more important, is more selective towards the 5-HT_{1A} receptor.[29] The main structure–affinity relationships for this class of compounds can be summarised as follows. Tertiary amines manifest higher affinity for the receptor than secondary and primary amines; substituents at the nitrogen atom can be rather bulky and the presence of MeO, CO_2Me and $CONH_2$ groups in position 5 provides both tight binding and the selectivity towards 5-HT_{1A} receptors.[30]

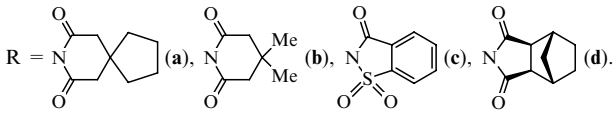


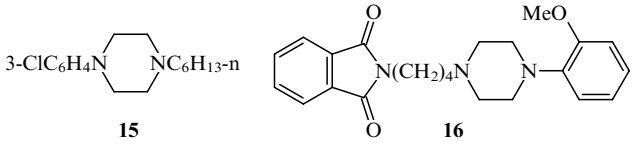
13

Buspirone derivatives constitute a large and very important structural class of 5-HT_{1A} receptor ligands.[31–33] Buspirone (**14a**) manifests high affinity for 5-HT_{1A} receptors and is endowed with agonistic activity. This is the only known compound specific for this subtype of receptor that has been recommended for clinical application as an antidepressant drug. Structural modifications of the imide and piperazine fragments and variations in the lengths of the alkyl chains were carried out aimed at a search for more active and selective buspirone analogues. These studies showed that the imide fragment of compound **14a** can be replaced by bioisosteric groups,§ *e.g.*, like those in gepirone (**14b**), ipsapirone (**14c**), tandospirone (**14d**), *etc.*[34–36] These groups should be lipophilic,[37–39] although the role of steric effects may also be significant.[40] Interestingly, some compounds, *e.g.*, substituted piperazine (**15**),[41] devoid of the cyclic amine fragment in the side chain, also manifest agonistic activities towards 5-HT_{1A} receptors. Heterocyclic substituents at the second nitrogen atom of the piperazine rings of buspirone and its analogues can be replaced by the phenyl substituent either non-substituted or containing an electron-withdrawing substituent in the *o*- or *m*-position to ensure higher affinity, *e.g.*, compound **16**.[42,43]



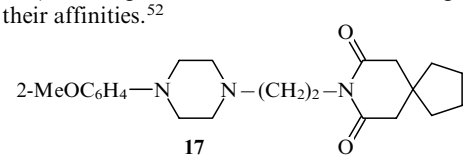
14a–d



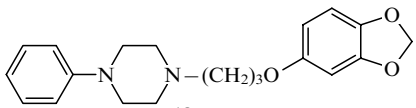


15 **16**

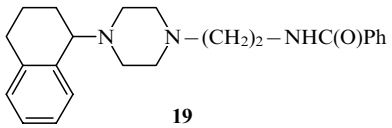
The optimum number of methylene groups in the linker needed for manifestation of maximum affinities of buspirone analogues for 5-HT_{1A} receptors is four, although some compounds with three and even two (less frequently) methylene groups also manifest noticeable affinities, *e.g.*, compound **17**.[44–46] Moreover, high affinity can persist upon substitution of heteroatoms for some methylene groups in the chain as is the case with ether **18**[47,48] or amide **19**.[49] Variations in the chain length and structure strongly affect its selectivity towards serotonin receptors in comparison with adrenoceptors and dopaminergic receptors.[50,51] Thus the selectivities of the bicyclohydantoin derivatives **20a**,**b** for 5-HT_{1A} can be improved by reducing the length of the intermediate alkyl chain to one methylene group ($n = 1$), although such modification causes a significant decrease in their affinities.[52]



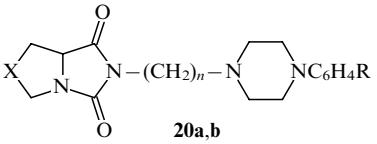
17



18



19



20a,**b**

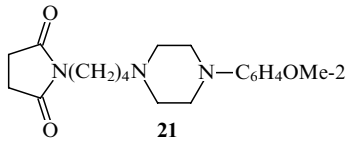
$n = 1–4$; X = CH_2 (**a**), $(CH_2)_2$ (**b**).

Computer simulation studies aimed at rationalisation of such an increase in the selectivities of the bicyclohydantoin derivatives **20a**,**b** revealed[53] that compounds with $n = 1$ and $n = 4$ bind differently to the receptor. The fact that the derivatives with $n = 1$ manifest agonistic activities towards 5-HT_{1A} receptors (albeit rather weakly) suggests[53] that the protein molecule has a 'non-pharmacophoric' pocket (*i.e.*, the site docking 'non-essential' fragments of the ligand molecule rather than the pharmacophore group), which docks the imide group of the ligand

§ A bioisoster is a compound prepared by the replacement of an atom or a group of atoms (*e.g.*, a functional group) by other structural fragments with 'preserved' biological activity. The bioisosteric equivalence rules were established experimentally and are widely used in medicinal chemistry.

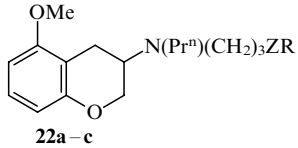
containing one methylene bridge. Its selectivity is attributed to the fact that adrenoceptors have no such pocket.

It is noteworthy that the majority of buspirone analogues mentioned above and buspirone itself, despite their high affinities for 5-HT_{1A} receptors, do not manifest any high intrinsic activities and are thus partial agonists. Moreover, some of them, *e.g.*, compounds **17** and **18** or the succinimide analogue **21** [54, 55] are sometimes classified as antagonists due to their very low intrinsic activities.



21

Studies aimed at the design of 5-HT_{1A} agonists containing simultaneously the groups constituting the essential fragments of the two main classes of 5-HT_{1A} ligands, *viz.*, aminotetralin (**4a**) and buspirone (**14a**) analogues, have become very popular in the past decade. An imide or a bioisosteric group, such as substituents R in buspirone (**14a**), gepirone (**14b**), ipsapirone (**14c**), *etc.*, were attached to the amino group of the benzopyran fragment of compound **13** through an alkyl chain, resulting in compounds **22**. Studies of structure–affinity relationships of these compounds revealed that compounds **22a–c** containing imide or sulfanylamide substituents manifested the highest activities and selectivities, whereas the preferred length of their side chains was four methylene groups, although sulfonylamide derivatives are also active even if their chains contain two methylene groups.[56]

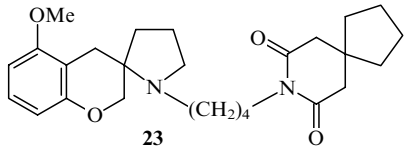


22a–c

Z = CH_2: R =  (**a**),  (**b**);

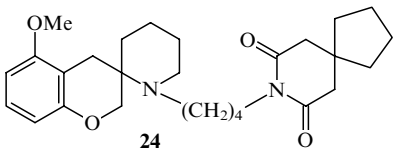
Z = CH_2NHSO_2, R = C_6H_4Me-4 (**c**).

High activities and selectivities of analogues of compounds **22** with limited mobilities of their side chains due to incorporation of the alkylamino groups into ring structures were predicted using the pharmacophore model of 5-HT_{1A} receptor agonists [17] and QSAR.¶ It should be noted that in many cases the restriction of conformational mobilities of functional groups is a classical approach in medicinal chemistry, since this allows stabilisation of the conformation which is the most suitable for the interaction with the receptors. The spiropyrrolidine- and spiropiperidinebenzopyrans **23** and **24** synthesised manifest high agonistic activities and selectivities with respect to 5-HT_{1A} receptors, though not exceeding those of compounds **22a–c**. In our opinion, it is expedient to carry out a detailed analysis of other types of restriction of conformational mobility in the side chains of such compounds. It is also noteworthy that compounds **23** and **24** are partial agonists of 5-HT_{1A} receptors and manifested the properties of antidepressant and anxiolytic drugs *in vivo*.[60]



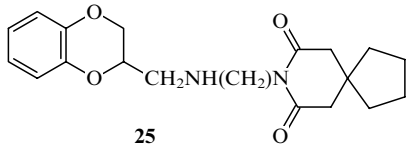
23

¶ QSAR is the abbreviation for 'quantitative structure–activity relationships'. This branch of medicinal chemistry is aimed at establishing the relationships between the properties (activities) and structural parameters of compounds (see, *e.g.*, Refs 2, 57–59).

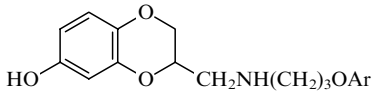


24

Benzodioxane derivatives which constitute another structural class of effective 5-HT_{1A} receptor ligands are being studied intensively. Compound **25** is one of the most potent and selective partial agonists.[61–63]



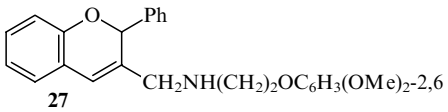
25



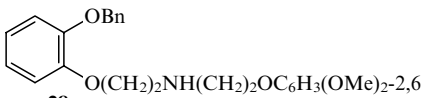
26

Ar = C_6H_4R, Het.

In such structures, as in any other buspirone (**14a**) analogues, the bridging chain may be elongated and modified, as in the case of the high-affinity partial agonists **26**, although such modification sometimes causes significant reduction in their selectivities.[64] Therefore, the search for structural modifications of benzodioxanes which might afford compounds endowed with the ability to distinguish among the binding sites of adrenoceptors and dopaminergic 5-HT_{1A} receptors was continued. It was found [65] that benzopyran (**27**), the unsaturated analogue of benzodioxanes, manifests high affinity for 5-HT_{1A} receptors and partial agonistic activity; the presence of a double bond in its ring and the absence of the oxygen atom in position 1 strongly depress its binding to adrenoceptors, which makes this compound more selective with respect to serotonin receptors. The acyclic benzodioxane analogue (compound **28**) is, contrariwise, less selective towards 5-HT_{1A} receptors than compounds **26**, although they retain their high affinities for these receptors.

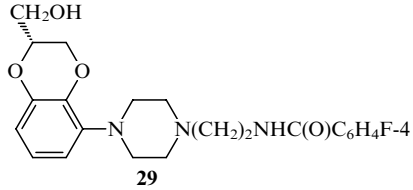


27



28

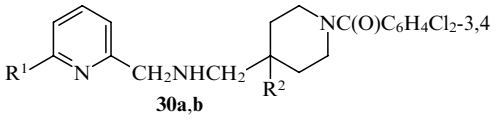
Benzodioxane derivatives with substituents in the benzene rings, *e.g.*, flesinoxan (**29**), also manifest high selectivities and agonistic activities.[66] Studies of structure–affinity relationships revealed that the main contribution to the binding of compound **29** to the receptor is made by the lipophilic substituent at the N(4) atom (the 4-fluorophenyl fragment may be replaced by the phenyl, thiophene or cyclohexane fragment without any loss in activity, but not by polar five- or six-membered heterocyclic substituents). Also, the amide group hardly takes part in the binding to the receptor but, rather, acts as a bridge and may therefore be replaced by other fragments. Structural modifications may also involve the



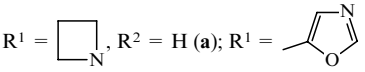
29

aryl substituent at N(1); these affect not only the affinities of the analogues but also their selectivities in comparison with dopamine receptors.[66]

An intensive search for 5-HT_{1A} receptor ligands characterised by high intrinsic activities is now in progress, since the majority of the known ligands are partial agonists. Full 5-HT_{1A} agonists were found in a new class of compounds, *viz*., 6-substituted pyridylmethylamine derivatives **30**. These ligands were selected using a special model of 5-HT_{1A} receptor activation according to which the intrinsic activities of 5-HT_{1A} ligands depend on their abilities to stabilise the positive charge generated on the receptor protein upon its binding to the agonist. The pyridine ring was chosen as a group endowed with this ability. Therefore, the pyridine derivatives of the type **30** were constructed in order to obtain full agonists of 5-HT_{1A} receptors.

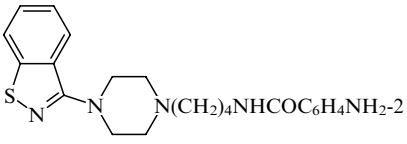


30a,**b**

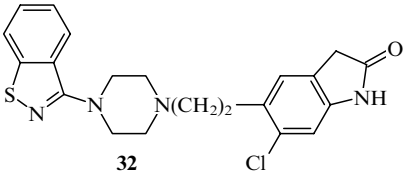


The results of QSAR studies suggest that the abilities of compounds to activate the corresponding receptors strongly depend on the nature and position of substituents in the pyridine ring. Thus a substituent (preferrably an electron-donor substituent) should be present in position 6. Compounds **30a**,**b** were finally found to be full agonists of 5-HT_{1A} receptors and possess the highest affinities and selectivities.[67] Moreover, the agonistic activities and selectivities of these compounds and some of their pharmacological characteristics can be improved by introducing the fluorine atom (R^2 = F).[68]

As shown above, structure–activity studies of 5-HT_{1A} receptor ligands are mainly directed at the search for selective compounds. However, special mention should be made of other relevant tasks, such as the search for compounds acting simultaneously as dopaminergic receptor antagonists and serotonin 5-HT_{1A} agonists. These compounds hold much promise in the therapy of schizophrenia and other mental disorders; some of them, *e.g*., the piperazine derivative **31**, are undergoing clinical trial.[69] Certain structurally related compounds, *e.g*., ziprasidone (**32**), manifest antagonistic activities towards 5-HT_2 receptors.[70]

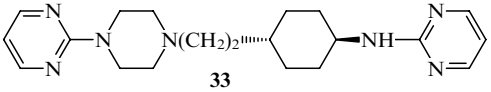


31



32

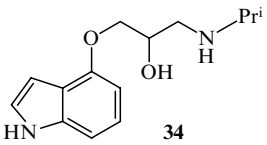
Since this review is aimed at the structural analysis of serotonin receptor ligands, their affinities, intrinsic activities and selectivities, we shall not dwell on the search for ligands for the related types of receptors, although in these studies 5-HT-selective ligands can also be found. Thus the search for ligands of dopaminergic receptors revealed that compound **33** possessed affinity and selectivity exclusively with respect to 5-HT_{1A} receptors.[71]



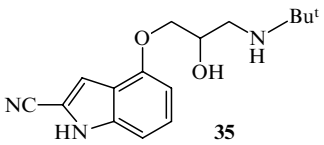
33

To complete the consideration of problems related to the design of 5-HT_{1A} agonists, it should be noted that although such ligands are rather numerous, all of them belong to a limited set of structural classes of compounds. Moreover, only some of these ligands interact with 5-HT_{1A} receptors in a selective manner and very few of them are full agonists. In this context, a search for agonists among novel classes of compounds is a very important task, since it helps elucidation of the structure–activity relationships for ligands and sheds more light on the structural peculiarities and functional roles of the corresponding receptors.

Antagonists of 5-HT_{1A} receptors have been studied in lesser detail, although they could in principle be used for the treatment of various diseases of the central nervous system. Some presently known β-adrenoceptor blockers, *e.g*., pindolol (**34**),[72,73] cyanopindolol (**35**),[74,75] *etc*., manifest antagonistic activities towards 5-HT_{1A} receptors, the (−)-(*S*)-enantiomers being more active. These compounds are also active with respect to other subtypes of serotonin receptors.

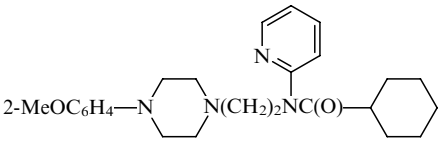


34

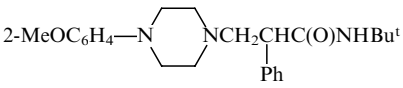


35

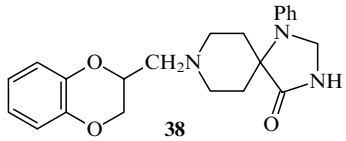
Numerous studies aimed at a search for selective antagonists of 5-HT_{1A} receptors have led to compounds **7** and **36**.[76,77] It was also found that many compounds previously assigned to 5-HT_{1A} antagonists, *e.g*., the piperazine derivative **37**,[78] spiroxatrine **38**,[79,80] *etc*., are in fact not genuine antagonists but manifest partial agonistic and low intrinsic activities.† It should be noted that the main approach to the design of compounds **36**–**38** consists in the introduction of bulky lipophilic substituents into the structures of 5-HT_{1A} receptor agonists. This approach is widely used in medicinal chemistry for the construction of antagonists, since the presence of additional hydrophobic interactions between the ligand and the receptor in the vicinity of the binding site increases the strength of binding to such an extent that the receptor appears to be completely blocked by the compound.



36



37

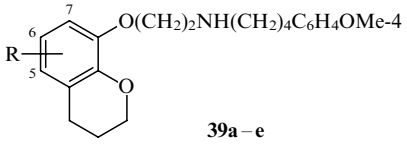


38

Until recently, there was no evidence in the literature concerning the differences in the structural requirements for agonists or antagonists of 5-HT_{1A} receptors.[18] Special mention should be made of investigations into effects of substituents on the intrinsic activities of chromanes of the type **39** which, like benzodioxanes **26**, represent high-affinity 5-HT_{1A} ligands.[81,82] Modifications of the benzene ring in their side chains revealed that the *p*-methoxy group plays a crucial role in both affinity and antagonistic activity of compound **39a**, whereas other substituents diminish both the

† The term 'silent antagonist' was specially introduced to distinguish among genuine antagonists, *i.e*., those devoid of agonistic activity, and partial agonists.

binding and the blocking properties. Modifications of the chromane ring showed that the introduction of F, Cl and OMe (but not OH and Me) into position 6 results in strong antagonists (compounds **39b**,**c**,**d**), whereas the introduction of analogous substituents into positions 5 and 7 yields partial agonists. The differences in the antagonistic activities of this series of compounds cannot be explained by different distribution of their electron densities, since the introduction of both electron-donor (*e.g.*, OMe) and electron-withdrawing groups (*e.g.*, Cl) affords full antagonists, whereas compound **39e** containing the hydroxy group manifests the properties of a partial agonist.



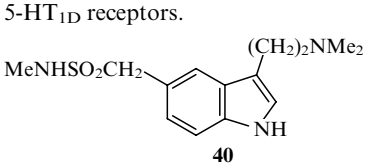
39a–e

R = H (**a**), 6-F (**b**), 6-Cl (**c**), 6-OMe (**d**), 6-OH (**e**).

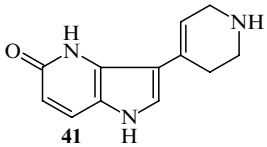
In all probability, the antagonistic properties of the majority of structural classes of 5-HT_{1A} ligands depend on many factors and not necessarily depend on those factors which determine the strength of binding of the ligand to the receptor, *i.e.*, affinity. This circumstance and the fact that even minor structural modifications of 5-HT_{1A} receptor antagonists often cause significant reduction in their affinities, selectivities and antagonistic activities call for further investigations using computer simulation of the receptor structure and ligand docking (in this context, docking is a molecular simulation technique aimed at a search for the optimum matching of the ligand to the binding site).[83] On the whole, the search for selective antagonists of 5-HT_{1A} receptors is a complicated but very urgent task, since no preparations of this class have been recommended for the clinical use thus far.

IV. Ligands of serotonin 5-HT_{1B} and 5-HT_{1D} subtype receptors

Serotonin 5-HT_{1B} and 5-HT_{1D} subtype receptors are rather densely localised in the human brain. They contain extremely similar amino acid sequences despite being encoded by two different genes. These two subtypes can pharmacologically be separated using several non-selective 5-HT_2 antagonists (*e.g.*, ketanserin, see below);[53,84–86] however, their functional roles in the organism have not been established yet because only a very small number of selective ligands to these receptors are known. It is known that blocking of 5-HT_{1B} receptors results in coronary vasodilation,[87] therefore, their selective antagonists can be used for the treatment of various cardiovascular disorders. They are also recommended for use as effective fast-acting antidepressant drugs.[88,89] Agonists of 5-HT_{1D} receptors are putative antimigraine drugs, since their activation causes the brain vasodilation, diminishes pulsation, *etc*. In recent years, 5-HT_{1B} and 5-HT_{1D} subtype ligands have attracted considerable attention in connection with the design of an efficient antimigraine drug sumatriptan (**40**), which appeared to be a 5-$HT_{1B/1D}$ receptor agonist.[90–93] Sumatriptan has very few side effects, but causes coronary vasodilation, which is controlled by 5-HT_{1B} receptors (see above). This, too, calls for the design of selective agonists of 5-HT_{1B} and 5-HT_{1D} receptors.

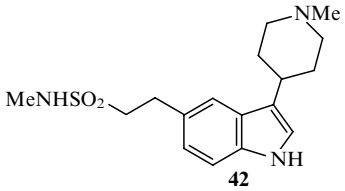


40

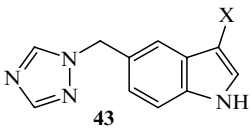


41

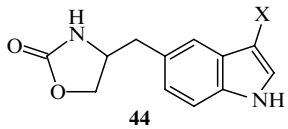
A fairly large group of 5-HT_{1B} and 5-HT_{1D} receptor agonists includes serotonin or tryptamine derivatives, such as amines **2** and **3**, which represent non-selective agonists of 5-$HT_{1B/1D}$ and 5-HT_{1A} receptors. Interestingly, the amine **41**,[94–96] which is a close analogue of compound **3**, is much more active and selective towards the 5-HT_{1B} receptor. Close serotonin analogues include sumatriptan (**40**) itself and its numerous derivatives, such as naratriptan (**42**),[97,98] rizatriptan (**43**),[97,99,100] zolmitriptan (**44**),[101,102] eletriptan,[103] avitriptan,[104] almotriptan[97,105] and frovotriptan (**45**).[85,106] The majority of these compounds are candidates for antimigraine drugs and have passed clinical trials or are in the final stages. Their structures vary largely by changing substituents in the indole fragment or by restricting conformational mobility of the side chain containing an amino group.



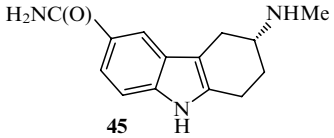
42



43



44

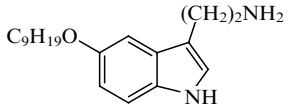


45

X = $(CH_2)_2NMe_2$.

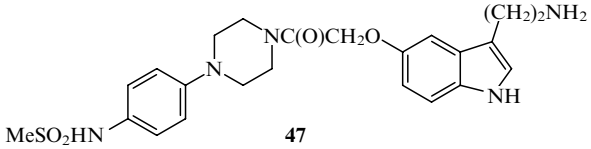
Compounds **42**–**45** possess high affinities for 5-HT_{1D} receptors. However, they are non-selective and only 1.5–3-fold less active with respect to 5-HT_{1B} receptors. Comparison of the structures obtained suggest that the basic amine, the indole fragment and the substituent in position 5 involved in the formation of a hydrogen bond as an acceptor or a donor are the key groups needed for their efficient binding to the receptor. QSAR studies aimed at improving the activities and selectivities of serotonin and tryptamine derivatives towards 5-HT_{1D} receptors included variations of substituents at the C(5) atom.

It was found[43] that in the case of alkoxy substituents the optimum length of the alkyl chain needed for the binding to 5-$HT_{1B/1D}$ receptors is 8 or 9 carbon atoms; with shorter chains, the selectivity is lost, while with longer chains, the affinity is decreased. Thus 5-nonyloxytryptamine (**46**) represents a high-affinity agonist, which is more selective towards 5-HT_{1B} than towards 5-HT_{1D} receptors and is practically inactive towards 5-HT_{1A} receptors. It should be noted, however, that no compounds capable of distinguishing 5-HT_{1B} and 5-HT_{1D} receptors with a high degree of selectivity could thus far be obtained by changing the lengths and degree of ramification of the alkoxy substituents.[43]

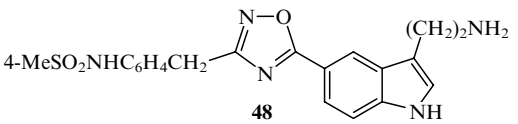


46

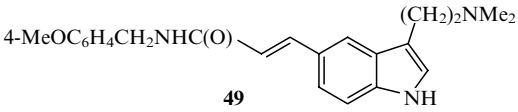
The variations in the substituents in position 5 revealed that the latter can be rather bulky as in the case of compounds **47**,[88,107] **48**[108–110] and **49**,[111–112] which are more selective towards 5-HT_{1D} than towards 5-HT_{1B} receptors. This is suggests the existence of a deep pocket in the binding site of 5-$HT_{1D/1B}$ receptor proteins adjacent to C(5) of the serotonin molecule. According to some data, it is in the size of this domain that 5-$HT_{1D/1B}$ receptors differ from the 5-HT_{1A} receptor,[113] although some of compounds mentioned, as expected, manifest low affinities for the latter.



47

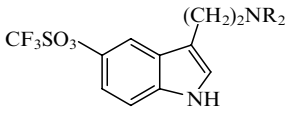


48



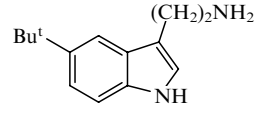
49

It is noteworthy that the introduction of a triflate group (compounds **50**), which is bioisosteric to the carboxy or the methoxy group,[114] increases the selectivity towards 5-HT_{1D} receptors 10 – 15-fold in comparison with 5-HT_{1B} receptors.[115]



50

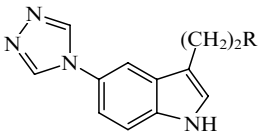
R = Me, Et.



51

It is of note that until recently the ability of the substituent in position 5 to be involved in the formation of a hydrogen bond was thought to be a necessary prerequisite for high affinity, since virtually all presently known 5-HT_{1D} receptor agonists have at least one heteroatom (N, O or S) in this position. However, the recently discovered 5-alkyltryptamine analogues devoid of heteroatoms in position 5 possess high affinities for 5-HT_{1D} receptors. This affinity increases as the size of the lipophilic group increases, reaching a maximum in the *tert*-butyl derivative **51**.[85] The resulting compounds are not highly selective, *viz*., their maximum selectivities towards 5-HT_{1D} receptors are only four times greater than towards 5-HT_{1B} receptors. The fact that the formation of a hydrogen bond involving the substituent at the C(5) atom of serotonin is not critical for the manifestation of its high affinity for 5-HT_{1D} receptors points to the hydrophobicity of the spacious pocket in the vicinity of C(5). This finding allows one to expand significantly the range of possible substituents at this atom.

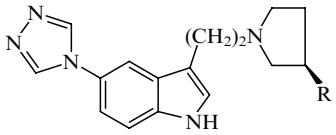
The variations in substituents in position 3 are much less documented. However, there are recent data to show that the selectivity towards 5-HT_{1B} and 5-HT_{1D} receptors can be enhanced by introduction of structurally more complex substituents in this position. Thus it was shown that the tryptamine analogue **52a** containing the pyrrolidine ring possesses an order of magnitude higher affinity for 5-HT_{1D} receptors than for 5-HT_{1B} receptors. On the other hand, the analogous *N*,*N*-dimethylamino derivative **52b** is non-selective.[116, 117]



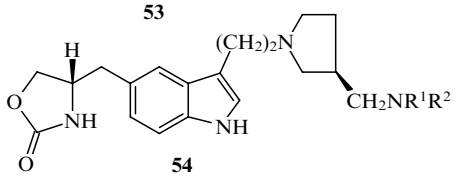
52a,**b**

R = (**a**), NMe_2 (**b**).

It is thought that the region in the receptor which binds the fragment at the C(3) atom contains an aspartic acid residue.[117] The steric requirements for the binding to this domain in both types of receptors can be determined by modifying this fragment.[117] Studies of series of compounds **53** and **54** revealed that 5-HT_{1D} receptors can bind bulky groups. It was therefore assumed that this domain contains a spacious binding pocket. At the same time, compounds containing smaller substituents bind more effectively to 5-HT_{1B} receptors. For example, compounds **53** or **54** which are full agonists of 5-HT_{1D} receptors manifest 100- and 140-fold higher selectivities towards them. Hence, the selectivity towards each of these two receptor subtypes can be provided by a correct choice of a substituent in the structural domain responsible for the binding to the aspartate residue. It is of note that the presence of a bulky substituent at C(3) can in principle increase the affinities for 5-HT_{1A} receptors (see above). However, the above-mentioned series includes compounds (*e.g*., **54**, $R^1 = CH_2Ph$, $R^2 = H$) which are selective with respect to both 5-HT_{1B} and 5-HT_{1A} receptors.[117]

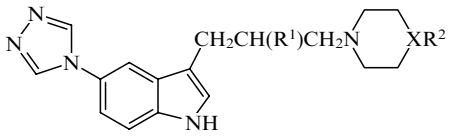


53



54

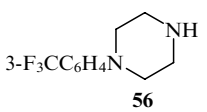
Many (3-piperazinopropyl)indoles, *e.g*., compound **55a**, also manifest high (up to 200-fold) selectivities towards 5-HT_{1D} *vs*. 5-HT_{1B} receptors.[118] The selectivity increases 300- to 500-fold upon introduction of the hydroxy group or the fluorine atom into the propyl chain (compound **55b**).[119] The distal nitrogen atom of piperazine does not seem to be essential for the binding to this receptor, since the corresponding piperidine analogues, *e.g*., compound **55c**, also manifest high affinities.[120] The distal nitrogen atom can also be displaced into the exocyclic position without any loss of its affinity,[120] as in the case of the 4-aminopiperidine derivative **55d**.[116] The selectivities of the ligands **55a** – **d** towards 5-HT_{1D} receptors suggest that these are less sensitive to changes in the position of the nitrogen atom than 5-HT_{1B} receptors despite close homology of these two proteins. This circumstance can further be used in the structural design.



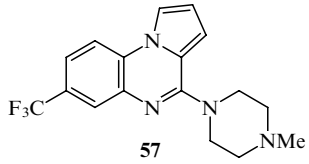
55a – **d**

R^1 = H, X = N, R^2 = $(CH_2)_2C_6H_4F$-3 (**a**); R^1 = OH, F; X = N, R^2 = Ph, C_6H_4F-3 (**b**); R^1 = H, X = CH, R^2 = Bn (**c**); R^1 = H, X = CH, R^2 = N(Me)Bn (**d**).

Among other full and partial agonists of 5-HT_{1B} and 5-HT_{1D} receptors structurally different from tryptamine, special mention should be made of arylpiperazines, *e.g*., compounds **56** [121, 122] and **57**,[121, 123] which display very low selectivities towards 5-HT_{1B} subtype receptors. As expected, these compounds possess high

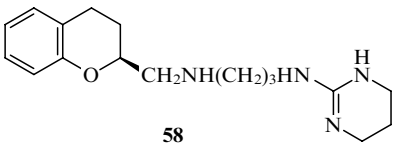


56

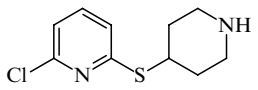


57

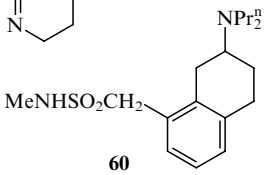
affinities with respect to the 5-HT_{1A} receptor. More recently synthesised compounds of this series include alniditane (**58**) [124] as well as compounds **59** [125] and **60**.[126]



58



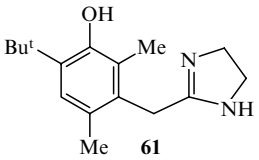
59



60

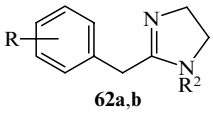
The adrenoceptor agonist oxymethazoline (**61**) manifests agonistic activity towards both 5-HT_{1B} and 5-HT_{1D} receptors

and is among the most promising lead compounds ‡ for the design of 5-$HT_{1D/1B}$ agonists.[127]

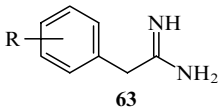


61

However, an analysis of structural requirements for the binding of benzylimidazolines of the general formula **62** to these receptors revealed that far from all substituents in the aromatic ring of compound **61** are necessary for the manifestation of high affinity. Thus the hydroxy group in position 3 of compounds **62** can be removed without any noticeable decrease in their affinities for 5-HT_{1D} subtype receptors. However, such modification decreases 50-fold the affinity for 5-HT_{1B} subtype receptors. Moreover, the contribution of the bulky substituent at the C(4) atom to the binding to 5-HT_{1D} receptors is greater. Therefore, some structural modifications of compounds **62** (*cf.*, *e.g.*, compounds **62a**,**b**) lead to a 100-fold increase in the selectivities towards 5-HT_{1D} receptors. Compounds **62a**,**b** are agonists, their affinities for adrenergic receptors are lower than that of compound **61**. It should be noted that the transition to amidines **63** decreases both their affinities and selectivities towards 5-HT_{1D} subtype receptors.[113]



62a,**b**

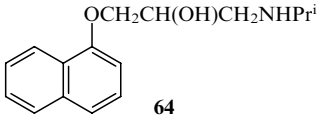


63

R^1 = 4-Bu^t (**a**), 6-Me (**b**).

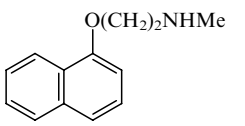
Thus, the overwhelming majority of agonists of 5-HT_{1B} and 5-HT_{1D} receptors represent tryptophan analogues; therefore, these types of new lead compounds could be useful in the search for the next generation of agonists able to distinguish between these two subtypes of receptors.

The main efforts of chemists engaged in the search for antagonists are directed at the synthesis of compounds more selective towards 5-$HT_{1B/1D}$ subtype receptors in comparison with other serotonin receptors. As mentioned above, some aryloxyalkylamines, such as the well-known β-adrenoceptor antagonist propranolol (**64**), are characterised also by low affinities for 5-HT_{1A} and 5-HT_{1B} receptors and usually represent antagonists or very weak partial agonists of these receptors.

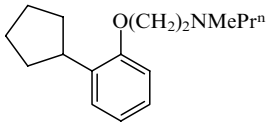


64

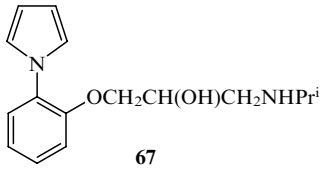
Studies of binding of their analogues to 5-$HT_{1D/1B}$ receptors [128] revealed that the presence of the hydroxy group in the side chain is not necessary, whereas the substitution of the CH_2 group for the oxygen atom in the ether group results in the loss of affinity. The affinity for 5-HT_{1B} subtype receptors can be increased by reducing the length of the side chain to two CH_2 groups or by using a primary or a secondary amine with smaller alkyl groups, *e.g.*, compound **65**. Replacement of the naphthalene fragment by a substituted phenyl ring is also possible, but in this case the affinity will decrease by an order of magnitude as in compounds **66** and **67**.[129] In our opinion, the structures of these lead compounds are not very suitable for the design of antagonists, since the compounds obtained interact with adrenoceptors, but are virtually non-selective towards 5-HT_{1B} subtype receptors in comparison with 5-HT_{1D} subtype receptors. Moreover, some high-affinity compounds, *e.g.*, compound **65**, lose their antagonistic properties and behave as agonists towards the corresponding receptors.



65

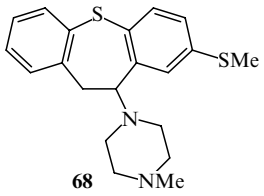


66



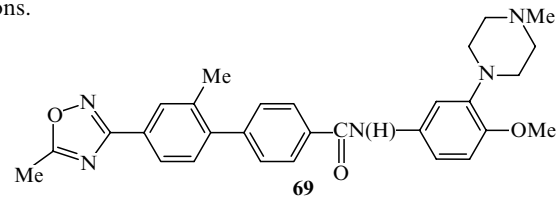
67

It is of note that until recently virtually no selective 5-$HT_{1B/1D}$ antagonists existed and studies into receptor binding were carried out with other compounds, *e.g.*, methiothepin (**68**), which interacts with other serotonin, dopaminergic and adrenergic receptors.



68

Benzanilide (**69**) is the first example of a selective 5-$HT_{1D/1B}$ antagonist, although it does not discriminate between the subtypes. This finding has played a crucial role in the characterisation of 5-$HT_{1D/1B}$ receptors. However, subsequent studies using cloned human receptors revealed that compound **69** is not a full antagonist, it rather acts as a partial agonist.[130,131] Therefore, the construction of selective antagonists required further investigations.

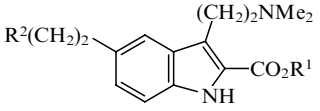


69

Sumatriptan (**40**), zolmitriptan (**44**) and other tryptamine analogues were used for the design of 5-$HT_{1B/1D}$ antagonists based on the corresponding selective agonists. QSAR studies of the factors affecting both the activity and selectivity as well as simulation using pharmacophore models of 5-$HT_{1D/1B}$ receptors [132] revealed that certain geometrical and conformational restrictions can result in the displacement of the indole nucleus from the site (which is arbitrarily termed as the aromatic binding site) specific, *e.g.*, for zolmitriptan (**44**). It was demonstrated that the retention of high affinity can be accompanied by a significant decrease in intrinsic activity. Later, it was shown that the antagonistic effect is manifested if only the pyrrole moiety of tryptamine (rather than the whole indole nucleus) is displaced. In other words, it was necessary to modify the structure of the agonist in such a fashion that the interaction of the pyrrole double bond with the π-electrons of the receptor in their specific domain would be blocked and the agonistic response would correspondingly be prevented. To achieve this, it was proposed to design an electron-deficient aromatic system by introducing electron-withdrawing substituents into position 2 of zolmitriptan (**44**). The presence of a substituent in position 2 not only makes the indole system electron-deficient, but also restricts the conformational mobility of the side chain. The alkyl chain in position 5 was also varied in order to confer greater mobility on this substituent.[132]

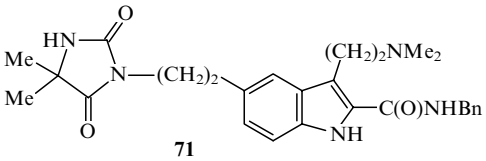
‡ The 'lead compound' is one of the basic concepts in medicinal chemistry which denotes a structural prototype for the future drug. The lead compound manifests definite physiological activity and its structure serves as the basis for the design of a new drug.[2]

This approach was successful, *viz*., the resulting tryptamine derivatives of the type **70** contain heterocyclic substituents comprising the carbonyl group R^2 (this group is critical for selectivity as compared with that of 5-HT_{2A} receptors)[133] and represent highly active full antagonists of 5-HT_{1B} receptors. These are also selective towards other serotonin receptors including sometimes compounds **70a**,**b** 5-HT_{1D} subtype receptors. Substitution of the amide group for the ester group in position 2 afforded less active and less selective antagonists; high affinities and selectivities were restored only after the introduction of bulky substituents to the nitrogen atom, *e.g*., compound **71**. It is believed[134] that this substituent can occupy the aromatic binding site in the receptor by pushing the indole nucleus out from this site.



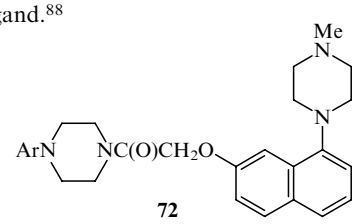
70a,**b**

R^1 = Et: R^2 =  (**a**),  (**b**).



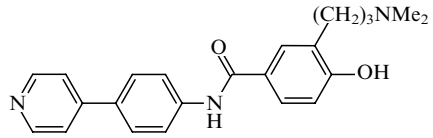
71

Yet another example is the design of 5-$HT_{1D/1B}$ receptor antagonists from the corresponding agonists.[88] Assuming that the tryptamine fragment in compound **47** is responsible for the intrinsic activity (by analogy with serotonin), while the arylpiperazine moiety is mainly responsible for the binding to the receptor, it was suggested to replace the tryptamine fragment in compound **47** by a non-selective ligand manifesting antagonistic activity towards 5-$HT_{1D/1B}$ receptors (in this particular case, the 1-naphthylpiperazine fragment) which would result in their selective antagonists. This was the case, *e.g*., for compounds **72**. Studies of these compounds showed that they are indeed selective towards 5-$HT_{1D/1B}$ receptors and many of them are full antagonists. However, the antagonistic activity depends on the aryl substituent of the arylpiperazine side chain and is maximum for Ar = 2-MeC_6H_4 or 2,3-$Me_2C_6H_3$. This suggests that the binding of this fragment also contributes to the intrinsic activity of the ligand.[88]

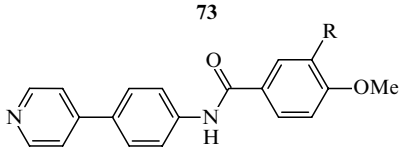


72

Recently, a series of antagonists based on the above-mentioned partial agonist **69**, which was successfully used as the lead compound in the design of compounds selectively blocking 5-HT_{1D} and 5-HT_{1B} subtype receptors, have been synthesised. These include primarily benzamide (**73**),[112,135] the structural analogue of compound **69**, which is a strong antagonist much more selective towards 5-HT_{1B} subtype receptors. Variations in the substituent R of its methylated analogues **74a**–**d** revealed that all these compounds bind to the receptor to approximately the same degree and in the same manner (like compound **73**) and manifest low affinities for 5-HT_{1A} and 5-HT_{1D} subtype receptors; their agonistic activities depend critically on the conformation of their side chains. Compound **74a** and the (*Z*)-alkenyl derivative **74b** act as strong antagonists resembling compound **73**, whereas the alkynyl derivative **74d** and the (*E*)-alkenyl derivative **74c** manifest pronounced agonistic activities.[89]



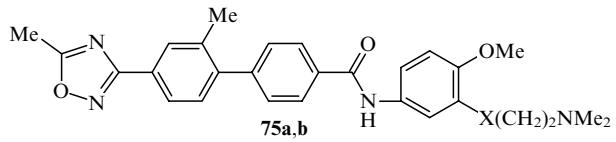
73



74a–**d**

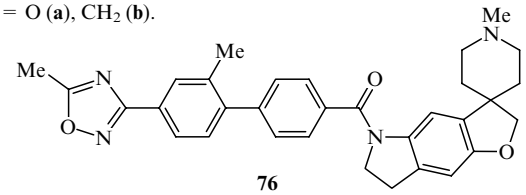
R = $(CH_2)_3NMe_2$ (**a**), (*Z*)-CH=$CHCH_2NMe_2$ (**b**), (*E*)-CH=$CHCH_2NMe_2$ (**c**), C≡CCH_2NMe_2 (**d**).

It should be noted that substitution of the flexible aminoalkyl side chain for the piperazine ring in compound **69** (compounds **75a**,**b**) decreases their intrinsic activities with respect to 5-HT_{1B} receptors.[89,136] These data demonstrate the significant role of the spatial orientation of the aminoalkyl fragment in the design of 5-HT_{1B} antagonists, although it is still impossible to describe this notion in terms of conformation, since some conformationally rigid analogues of compounds **69** can also act as full antagonists. Thus compound **76** is a selective 5-HT_{1B} antagonist; its design was based on the use of a computer model of 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, 5-HT_{2A} and 5-HT_{2C} receptors.[86,137]



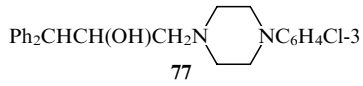
75a,**b**

X = O (**a**), CH_2 (**b**).



76

In conclusion, we shall refer to the structure of compound **77**, the recently discovered selective antagonist of 5-HT_{1D} receptors.[138] This compound possesses 60-fold higher affinity with respect to 5-HT_{1D} subtype receptors than to 5-HT_{1B} subtype receptors and is virtually inactive with respect to other serotonin receptors.



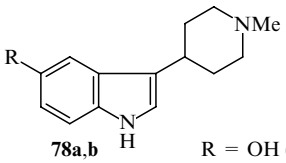
77

It is necessary to stress again that only a few compounds are known which interact with each of the above-mentioned subtypes with high selectivities, which is due to the structural similarity of 5-HT_{1B} and 5-HT_{1D} receptors. However, the present-day structural requirements for the design of such ligands are becoming more and more understandable and their number will be increasing.

V. Ligands of serotonin receptors of other 5-HT_1 subtypes

The 5-HT_{1E} and 5-HT_{1F} subtype receptors have been studied to a much lesser degree than those of other 5-HT_1 subtypes. It is known that they are present in large concentrations in brain and display high structural similarity as regards their amino acid sequences. The non-selective 5-HT_1 agonist, *viz*., the amine **2**, manifests *ca*. 1000-fold lower affinity for 5-HT_{1E} subtype recep-

tors than for the 5-HT_{1B} subtype receptors.[139,140] This is explained by the presence of the lysine–glutamic acid pair in the binding site of the 5-HT_{1E} receptor protein instead of the less polar isoleucine–serine (5-HT_{1B}) pair or the valine–serine pair (5-HT_{1D}). Presumably, this results in the formation of a salt bridge between lysine and the aspartate residue which plays the key role in the ligand binding. Compound **78a** is the agonist of 5-$HT_{1E/1F}$ receptors but does not discriminate between them and possesses low affinity. No selective or highly active ligands of 5-HT_{1E} receptors have been identified so far and the function of these receptors still remains to be established.



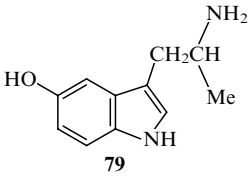
78a,**b** R = OH (**a**), 4-$FC_6H_4CONH_2$ (**b**).

Recently, studies of the functions and ligands for 5-HT_{1F} receptors have attracted the attention of many research groups due to the detection of high affinity of sumatriptan (**40**) for 5-HT_{1F} receptors (which was about an order of magnitude lower than for 5-HT_{1D} receptors). It was assumed that some (probably all) effects of sumatriptan in the alleviation of migraine symptoms are due to its binding to these receptors. The recently discovered indole derivative **78b** is their first and the only selective agonist;[141–143] no antagonists of 5-HT_{1F} receptors have been identified yet.

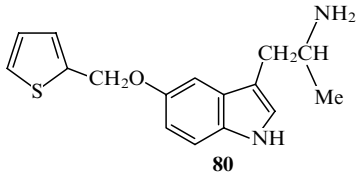
VI. Ligands of serotonin 5-HT_2 subtype receptors

The family of serotonin 5-HT_2 receptors is classified into three subtypes, *viz*., 5-HT_{2A}, 5-HT_{2B} and 5-HT_{2C}. The first two subtypes occur widely in peripheral tissues where they regulate muscle contraction; therefore, their ligands are used in the therapy of cardiovascular diseases. As for 5-HT_{2C} subtype receptors, they are localised exclusively in the central nervous system; their ligands produce psychotropic effects, *e.g*., their antagonists are used as anxiolytic and sedative drugs.

A series of 5-HT_2 receptor agonists were obtained by the simplest modifications of the serotonin structure. Thus α-methyl-5-hydroxytryptamine (**79**)[48,144,145] is a full high-affinity agonist of 5-HT_{2B} subtype receptors which manifests 10- and 100-fold lower affinities for 5-HT_{2C} and 5-HT_{2A} receptors, respectively. Similar selectivity profiles hold following the introduction of the thienylmethoxy substituent into position 5 (compound **80**).[146–148]

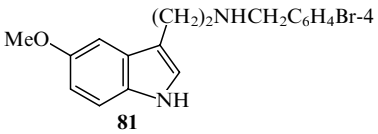


79



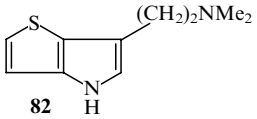
80

5-Methoxytryptamine also manifests higher affinity for 5-HT_{2B} receptors than for 5-HT_{2A} and 5-HT_{2C} receptors (25- and 400-fold, respectively), although it is non-selective towards other serotonin receptors. The introduction of a bulky bromobenzyl substituent into the amino group of 5-methoxytryptamine results in the ligand **81** which possesses high affinity and selectivity with respect to 5-HT_{2A} receptors,[149] but manifests the properties of a partial agonist.

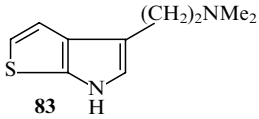


81

Bioisosteric substitution of thienepyrrole fragments for the tryptamine indole nucleus was undertaken in an attempt to design 5-HT_2 agonists. However, the resulting compounds **82** and **83** displayed somewhat lower activities towards 5-HT_2 receptors than the corresponding indole analogues (compound **82** is nearly 4 times more selective with respect to 5-HT_{2C} receptors than to 5-HT_{2A} and 5-HT_{2B} receptors). Moreover, this transformation increased significantly the affinity for 5-HT_{1A} receptors.[150] On the whole, these data corroborate the fact that different subtypes of serotonin receptors are highly sensitive to minor changes in the electronic characteristics of the aromatic systems.

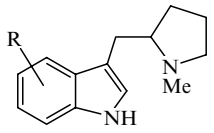


82

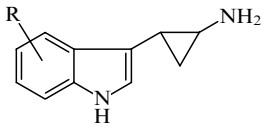


83

Studies of restriction of conformational mobility in the aminoethyl side chain of serotonin have led to the *N*-methylpyrrolidine derivative **84** (R = 5-OMe) and its analogues which manifested very high agonistic activities, being more selective towards 5-HT_{2A} subtype receptors. The activities of these compounds strongly depend on their stereochemistry, *viz*., (*R*)-enantiomers manifest *ca*. 30-fold higher affinities than (*S*)-enantiomers.[151,152]



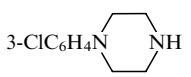
84



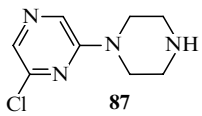
85

It is of note that conformationally rigid serotonin analogues containing cyclopropane fragments (**85**) in their side chains are somewhat more selective towards 5-HT_{2C} receptors, the fluoro derivative (**85**, R = 5-F) being the most active compound.[153,154] Noteworthy, the electron-withdrawing fluorine atom in the benzene ring not only decreases the affinity of this compound for 5-HT_{1A} receptors (see above) but also seems to be responsible for higher selectivity towards 5-HT_{2C} receptors in comparison with 5-HT_{2A} receptors. A similar dependence was demonstrated for other fluorotryptamines.[155]

The agonists manifesting higher selectivities towards 5-HT_{2C} subtype receptors were identified among halogeno derivatives of other structural classes, *e.g*., of piperazine. The diamine **86**, a partial agonist of 5-HT_{2C} receptors, which possesses 10-fold lesser affinity for 5-HT_{2A} receptors, is the most popular among them.[48,156–159] Structural variations in its molecule revealed that substitution of the pyrazine ring for the benzene ring increased significantly its selectivity and intrinsic activity; thus, the affinity of compound **87**,[160,161] a full agonist of 5-HT_{2C} subtype receptors, is 25 times higher than for 5-HT_{2A} subtype receptors.

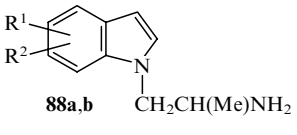


86

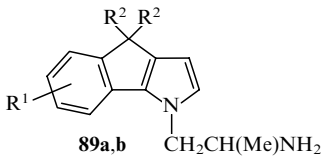


87

Agonists of 5-HT_{2C} receptors have recently been identified among indole derivatives manifesting high selectivities towards 5-HT_{2A} subtype receptors. Earlier, it was found[162] that isotryptamines (**88**) with the 2-aminopropyl side chain attached to the nitrogen atom are bioisosteric to the corresponding tryptamines as regards their binding to serotonin receptors. Affinity studies of a series of isotryptamines **88** and their analogues, *viz*., indenopyrroles **89**, revealed[155] that many of them, *e.g*., compounds **88a**,**b** and **89a**,**b**, are high-affinity full agonists of 5-HT_{2C} receptors which are 20- to 100-fold more selective towards 5-HT_{2A} receptors. It is noteworthy that the selectivities of *S*-isomers are higher than those of the corresponding *R*-isomers.[155] It should be noted that tryptamine structural isomers of some of these derivatives manifest nearly identical affinities but much lower selectivities with respect to 5-HT_{2C} receptors.



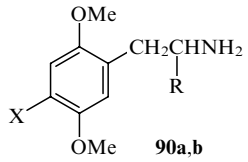
88a,**b**



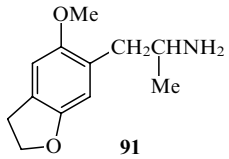
89a,**b**

R^1 = 5-F: R^2 = H (**a**), 6-Cl (**b**). R^1 = 7-OMe: R^2 = H (**a**), Me (**b**).

Phenylisopropylamines **90a** and phenylethylamines **90b** [163–165] which constitute a large group of high-affinity 5-$HT_{2A/2C}$ receptors have been the subjects of in-depth studies into the structure–activity relationships aimed at establishing the topologies of the binding sites of this particular subtype of serotonin receptors (see, *e.g.*, Refs 166–169). These studies demonstrated that high affinities for 5-$HT_{2A/2C}$ receptors require that certain structural requirements are fulfilled, such as the presence of a two-carbon chain between the amino group and the phenyl ring, the presence of methoxy groups in positions 2 and 5 of the aromatic ring and the presence of the hydrophobic substituent X in position 4. Assuming that the methoxy groups in compounds **90a**,**b** bind to two serine residues in the receptor protein, Nichols *et al.*[166,170] synthesised the cyclic derivatives **91**–**94** in order to study the geometry of this binding. It was found that compound **91** having a '*syn*-conformation' of the tetrahydrofuran ring relative to the aminoalkyl chain is practically inactive towards 5-$HT_{2A/2C}$ receptors, whereas the activity of the analogous compound **92** with the '*anti*-orientation' of these fragments is as active as that of the acyclic analogue **90a**.

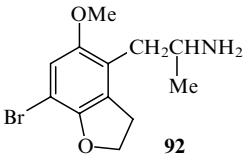


90a,**b**



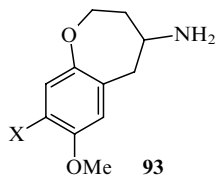
91

R = Me (**a**), H (**b**);
X = Alk, Hal, AlkS, F_3C *etc*.

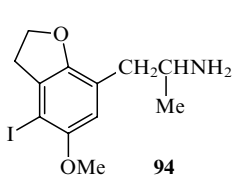


92

Substitution of the oxygen-containing heterocycle for the methoxy group in position 2 produces an opposite effect, *viz*., the '*anti*-analogues' of the type **93** compounds are inactive, whereas compound **94** is a potent agonist. As expected, structurally rigid compounds, *e.g*., compound **95** with two dihydrofuran fragments mimicking effectively active binding conformations of the methoxy groups in compounds **90a**,**b**, appeared to be high-affinity agonists of 5-$HT_{2A/2C}$ receptors. In this case, benzodihydrofuran-containing compounds represent effective conformationally restricted bioisosteres of aromatic methoxy groups.[169]

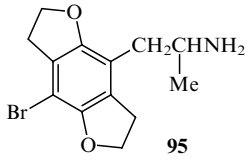


93

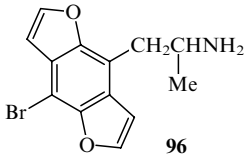


94

Substitution of furan fragments (see, *e.g*., compound **96**) [169] for dihydrofuran fragments made it possible to enhance also the agonistic activity with respect to 5-$HT_{2A/2C}$ receptors by an order of magnitude. Compounds of the type **96** manifest the highest affinities among other known ligands. Unfortunately, none of these compounds discriminate between 5-HT_{2A} and 5-HT_{2C} subtype receptors; the affinities of these compounds for 5-HT_{2B} receptors are severalfold lower because of similarities of the binding domains of the corresponding receptors.



95

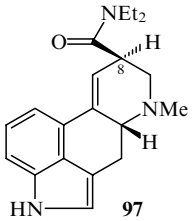


96

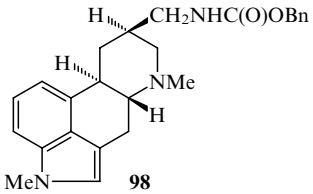
The attempts to lock the geometry of the aminopropyl side chain in compounds **90a**,**b** showed that its incorporation into the aminotetralin or the aminoindan rings results in the loss of activity towards 5-$HT_{2A/2C}$ receptors, whereas its introduction into the side chain of the cyclopropane ring, as in *trans*-2,5-dimethoxy-4-methylphenylcyclopropylamine, enhances the activity.[154,171]

As can be seen from the above survey, the structural classes of 5-HT_2 agonists are not very diverse and their design is poorly documented in the literature. This can probably be attributed to the strong hallucinogenic effect of these agonists,[172] which makes them unsuitable as therapeutics. Antagonists of 5-HT_2 subtype receptors can be used as drugs in treatment of ischemia and other vascular disorders.[173]

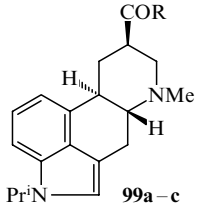
So far, several structural classes of 5-HT_2 antagonists have been identified. The most prominent position is occupied by ergolines and related compounds which manifest the properties of partial agonists or antagonists with respect to the corresponding receptors [174] [the former include the classical hallucinogenic agent, *viz*., lysergic acid diethylamide (LSD, **97**)].[174–176] Numerous antagonists of 5-HT_2 receptors have been synthesised based on ergolines and related compounds; the main strategy consisted in the introduction of various substituents [most frequently, at C(8)] assuming that this might enhance the antagonistic activity due to their additional binding to the receptor. This resulted in potent 5-HT_2 antagonists, such as compounds **98**,[177,178] **99a**–**c**, *etc*.[176,179–182]



97



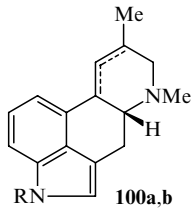
98



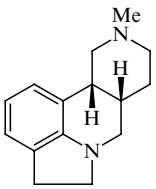
99a–**c**

R = O–⟨⟩–OMe (**a**), HN–⟨⟩ (**b**), HO–⟨⟩–HN (**c**).

Subsequent computer simulation of the binding of ergolines to 5-HT_2 receptors [174] showed that the presence of an aromatic ring in the vicinity of phenylalanine-340 of the receptor is an essential structural feature which ensures high-affinity binding owing to π- or hydrophobic interactions. This prompted synthesis of a series of ergolines and related compounds of the type **100a**,**b** devoid of the acyl fragment at C(8). Indeed, the resulting compounds manifested high affinities for 5-HT_2 antagonists and high selectivities as regards other subtypes of serotonin receptors. Thus, the ergoline structure of 5-HT_2 antagonists can in principle be reduced to a simple tetracyclic indoloquinoline system without any detriment to the affinity and antagonistic activity.[182]



100a,b



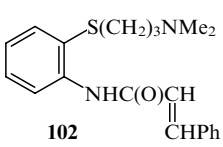
101

R = H (**a**), Pr^i (**b**).

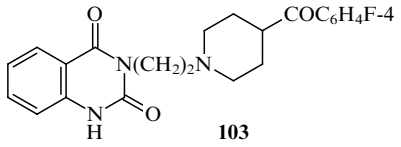
Other structural modifications of ergoline analogues included variations of substituents at the nitrogen atom of the indole moiety. It was shown that the introduction of small alkyl substituents, including branched ones, into this position is possible.§ In some cases, the antagonistic activity is enhanced due to the presence of a double bond in positions 9 and 10 present also in lysergic acid.[182] The literature data on the role of substituents in position 4 of the cyclohexane ring are controversial: in some cases, the methoxy group at C(4) of the cyclohexane ring significantly enhances the antagonistic activity,[187] but has no effect in other cases.[182]

The majority of ergoline derivatives are active with respect to serotonin 5-HT_1, adrenergic and other receptors, but are non-selective towards 5-HT_2 subtype receptors. However, recent systematic screening of ergoline-related compounds disclosed the naphthyridine (**101**),[188–190] a highly selective antagonist of 5-$HT_{2B/2C}$ receptors which does not interact with 5-HT_1 receptors. This compound will probably serve as a prototype for the design of novel selective ligands.

Distant analogues of the long-known non-selective ligand **102**,[191,192] such as ketanserin (**103**)[193,194] and its derivatives which manifest certain selectivities towards 5-HT_{2A} receptors, constitute another large structural class of 5-HT_2 antagonists.[191,192] Ketanserin (**103**) is used in the clinical practice as an antihypertensive drug.

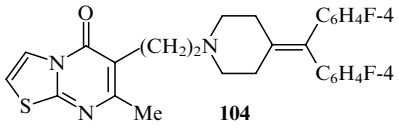


102

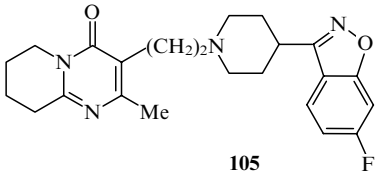


103

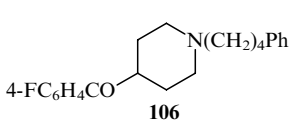
Studies of the structure–activity relationships in ketanserin derivatives have revealed the following features. The carbonyl group in position 2 of quinazoline can be replaced by the thiocarbonyl group, and a phenolic hydroxy group can be introduced into position 6. The two-carbon side chain can be replaced by the $(CH_2)_4$, but not by the $(CH_2)_3$ chain, which decreases the activity 100-fold.[195] Piperidine ring-opening also decreases the affinity. Although the 4-fluorobenzoyl group is present in the majority of ketanserin analogues, it can be replaced by the benzylidene [as in the case of ritanserin (**104**)] or a similar group. However, the benzylic carbon atom should be sp^2-hybridised [*cf.* the carbonyl group in ketanserin (**103**) or the double bond in ritanserin (**104**) and risperidone (**105**)]. Although a certain role in the affinity for 5-HT_{2A} receptors is played by the quinazoline-2,4-dione fragment,[195] this may be replaced by the pyridopyrimidine or thiazolopyrimidine fragment[196] or structurally simplified, as in compound **106**.[197] The latter modification is more appropriate because it affords 120-fold enhancement of selectivity towards 5-HT_{1C} receptors for which ketanserin manifests high affinity. It is of note that some ketone **106** analogues having a shortened bridging chain, *e.g.*, compound **107**,[198] are also potent selective antagonists of 5-HT_2 receptors. However, none of the above-mentioned compounds distinguish among different subtypes of 5-HT_2 receptors.



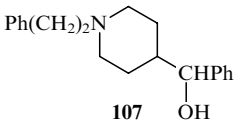
104



105

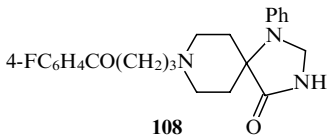


106



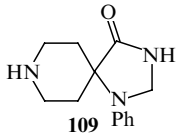
107

Variations in the quinazolidinedione fragment of ketanserin analogues have led to a large family of 5-HT_2 antagonists, *viz.*, triazaspirodecanones; their classical representative is spiperone (**108**).[197,199] This compound manifests rather high affinity for dopaminergic and 5-HT_{1A} receptors, and is also one of the few ligands binding more selectively (*ca.* 1000-fold) to 5-HT_{2A} subtype receptors than to 5-HT_{2C} subtype receptors.

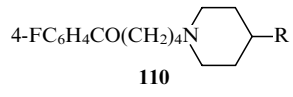


108

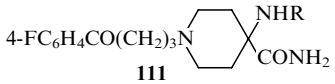
Molecular 'dissection' of this compound into its two basic fragments revealed that 1,3,8-triazaspirodecanone (**109**) is absolutely inactive towards 5-HT_1 and 5-HT_2 receptors, while the piperidine derivative **110** (R = H) manifests moderate affinity for 5-HT_{2A} receptors, which is 150-fold lower than that of spiperone (**108**), but is inactive towards 5-HT_1 and 5-HT_{2C} receptors. The introduction of the anilino group into position 4 of piperidine (**110**, R = NHPh) increases its affinity for 5-HT_{2A} receptors; however, the resulting compound manifests 150-fold lower selectivity towards 5-HT_{2C} receptors than spiperone (**108**).[200] These findings are suggestive of the important role of the imidazolidinone fragment in the reactivity and selectivity of spiperone (**108**). This conclusion is corroborated by the fact that the spiperone derivatives **111** containing geminal amino groups and an amide group instead of an imidazolidine ring are less selective towards 5-HT_{2A} receptors. Moreover, the affinities of some spiperone analogues decrease dramatically after the removal of the lactam carbonyl group, which points to its significance for the binding to the receptor.



109



110

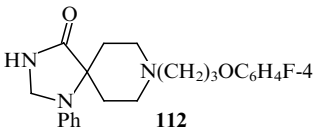


111

Other modifications of the spiperone (**108**) structure showed that substitution of the cyclohexyl fragment for the phenyl substituent at the N(1) atom increases its affinity twofold, whereas the substitution of alkyl groups decreases it. However, the

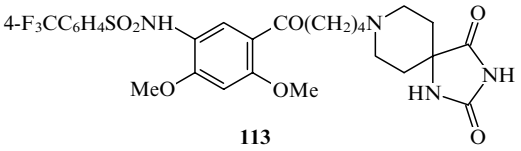
§ It should be noted that ergolines non-substituted at N(1) manifest higher affinities for human 5-HT_2 receptors than for the corresponding rat receptors,[183,184] although the only structural difference between these receptors is associated with the amino acid 242 residue (serine in humans and alanine in rats).[185,186] Presumably, serine and the NH group of indole in non-substituted ergolines form a hydrogen bond, whereas hydrophobic interactions occur between alanine and the alkyl group of the substituted ergolines.

selectivity towards 5-HT_{2A} subtype receptors increases in comparison with 5-HT_{2C}, 5-HT_{1A} and dopaminergic receptors.[201] Contrariwise, analogous substituents at the N(3) atom significantly decrease the selectivity.[201,202] It was shown also that the carbonyl group in the spiperone (**108**) molecule may be replaced by the ether group (compound **112**) with the preservation of activity and a small increase in the selectivity towards 5-HT_{2A} receptors in comparison with 5-HT_{2C} receptors. Such analogues can further be used as new structural prototypes in the search for affinity ligands to 5-HT_{2A} receptors.[200,201]



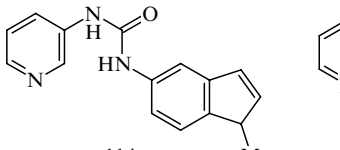
112

The sulfonylamide derivative **113** assayed recently among spiperone analogues (**108**) is attractive, because unlike compound **108** it manifested antagonistic activity and 100-fold higher selectivity towards 5-HT_{2C} receptors in comparison with 5-HT_{2A} and 5-HT_{2B} receptors. Moreover, this compound virtually did not bind to other serotonin receptors.[203,204]

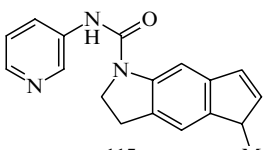


113

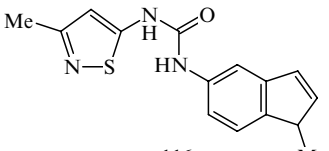
Progress has also been achieved in the design of selective antagonists of 5-HT_{2B} receptors. It was found that the indole derivative **114** manifests 150-fold higher affinity for 5-HT_{2B} receptors than for 5-HT_{2A} receptors, but is non- selective with respect to 5-HT_{2C} receptors.[205] The selectivity to the latter was virtually unenhanced upon partial restriction of conformational mobility of the linking chain (compound **115**); however, this approach makes it possible to increase the affinity for 5-HT_{2B} receptors and to decrease the affinity for 5-HT_{2A} receptors. A highly selective antagonist of 5-HT_{2B} receptors was obtained by substitution of the methylisothiazole fragment for the pyrimidine fragment (**114** → **116**), but the activity of the resulting compound is not very high.[206,207]



114

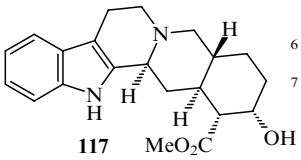


115

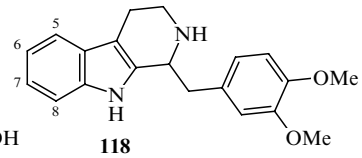


116

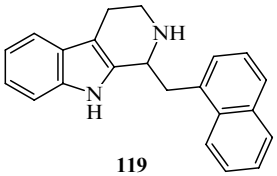
More active and selective (with respect to 5-HT_{2B} receptors) compounds were prepared based on the alkaloid yohimbine (**117**), which exhibits low affinity for this type of receptor itself. Elucidation of the key elements essential for the antagonistic activity of this alkaloid towards 5-HT_{2B} receptors was carried out by sequential simplification of its structure, resulting in high-affinity derivatives **118** and **119**. The affinities of these compounds and some of their analogues for 5-HT_{2B} receptors were 100–200-fold higher than for 5-HT_{2A} and 5-HT_{2C} receptors; these were practically inactive with respect to adrenergic receptors (in contrast to the original alkaloid **117**).[173] Structure–activity studies revealed an unusual and interesting fact, namely, it was found that the introduction of the methoxy substituent into position C(6) of compound **118** [which corresponds to position C(5) of the serotonin molecule] decreases the affinity, whereas the introduction of two methyl substituents into positions C(7) and C(8) increases it to a unique extent.[173] This suggests that the direct structural analogies of serotonin and the corresponding fragments of compounds **118** and **119** do not reflect their actual orientation during their binding to the receptor and demands further investigation.



117



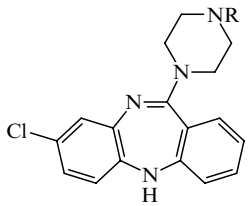
118



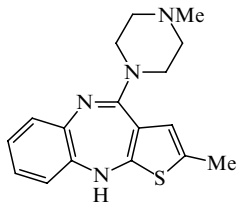
119

A new structural class of 5-HT_2 antagonists based on 5-HT_{2A} agonists of the type **90a** has recently been found. Compound **90a** (X = $CH_2CH_2CH_2Ph$) containing a phenylpropyl substituent in position 4 has become the first representative of this class. Structure–activity studies of some of its analogues established a surprising fact, *viz*., that the presence of methoxy groups in the ring is not a necessary prerequisite for their high affinities. However, this feature holds only for antagonists (for agonists, see above). This indicates that the phenylpropyl substituent can change the binding profile to the receptor.[165,208] Further developments in this field can be expected in the nearest future.

And finally, there exists a vast class of compounds manifesting nearly identical antagonistic activities towards serotonin 5-HT_2 and dopamine receptors which can be used as efficient antischizophrenic drugs. The neuroleptic drug clozapine (**120a**) is a classical representative of these compounds.[165,209,210] This possesses somewhat higher selectivity towards serotonin receptors of the 5-HT_{2A} subtype, whereas its desmethyl derivative **120b** manifests higher affinity for 5-HT_{2C} receptors.[211,212] A large number of their presently known analogues comprise a lipophilic tricyclic system,[213] which may contain additional heteroatoms (*e.g*., compound **121**) or be devoid of them (*e.g*., compound **122**).[214,215] Tetracyclic analogues such as mianserin (**123**) are also known.[216,217] A detailed survey of the work devoted to the design of compounds similar to compounds **120**–**123** or mixed-type antipsychotic drugs belonging to other structural classes is beyond the scope of the present review, which considers only compounds selective towards serotonin receptors.

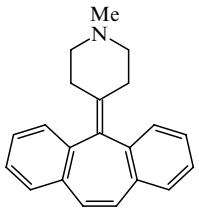


120a,**b**

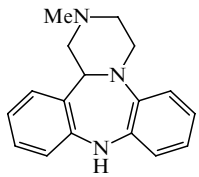


121

R = Me (**a**), H (**b**).



122



123

It should be stressed that the selectivities of antagonists towards serotonin 5-HT_2 receptors as opposed to dopaminergic (D_2) receptors are difficult to achieve. This problem was the central issue in special studies aimed at comparative structural analysis of binding sites of both types of receptors (see, *e.g.*, Ref. 218). Although the structural requirements for the affinities of both receptors are very close, they have certain steric differences, which makes it possible to predict the selectivities of various compounds to 5-HT_2 receptors.

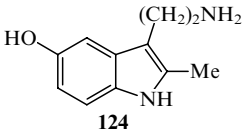
To conclude this chapter, it should be emphasised that the search for 5-HT_2 ligands employed mainly simple screening procedures, without recourse to computer simulation or pharmacophore hypotheses. Nevertheless, the design of such ligands entails efficient structural approaches. Moreover, the use of pharmacophore and receptor models developed in the last few years and modern QSAR methods [174, 218, 219] leaves hope that progress in this area will finally be achieved.

VII. Ligands of serotonin 5-HT_3 subtype receptors

Receptors of the 5-HT_3 subtype are the only serotonin receptors that form ion channels penetrable for monovalent cations and calcium ions. The ligands interacting with this type of receptor have been in the focus of attention in the past decade, primarily in connection with the design of antagonists, some of which proved to be efficient antiemetic drugs. Antagonists of 5-HT_3 receptors can also be used for the treatment of schizophrenia and other mental disorders. The putative therapeutic role of 5-HT_3 agonists is based on their ability to control the release of the neuromediator acetylcholine in the brain, which makes these compounds promising for the treatment of neurodegenerative diseases associated with cholinergic transmission disturbances. In addition, 5-HT_3 agonists can be used as antidepressant and analgesic drugs.

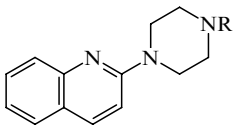
Since the mechanism of signal transmission by 5-HT_3 receptors is different from those of other serotonin receptors, its ligands often possess unique structures and manifest high selectivity. Thus quaternary amines of the type *N*,*N*,*N*-trimethyl-5-hydroxytryptamine do not bind to any other subtypes of serotonin receptors.

Agonists of 5-HT_3 receptors have been studied less thoroughly than their antagonists and are less numerous. The most well-known of them is 5-hydroxy-2-methyltryptamine (**124**) which possesses lower affinity than serotonin but much higher selectivity towards 5-HT_3 subtype receptors and preserves simultaneously agonistic activity.[145, 220, 221]

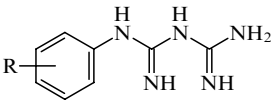


124

The other two structural groups of 5-HT_3 subtype agonists include arylpiperazines and arylbiguanides; their classical representatives are quipazine (**125a**) [222, 223] and 1-phenylbiguanide (**126**, R = H).[224] These compounds had been neglected for a long time, apparently because of the high selectivity but low affinity of phenylbiguanide for 5-HT_3 receptors. At the same time, arylpiperazines of the general formula **127** display higher affinities for 5-HT_2 receptors but are less selective and are active with respect to a vast variety of other serotonin receptors (see above). The number of publications devoted to the design of arylpiperazine and arylbiguanide analogues has increased markedly over the past decade; studies in this field were designed to increase the affinities of arylbiguanides and the selectivities of arylpiperazines.

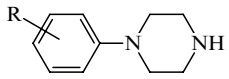


125a,**b**



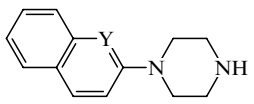
126

R = H (**a**), Me (**b**).

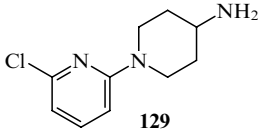


127

For the first trend, the key hypothesis was that both classes of compounds occupy the same aromatic binding site on 5-HT_3 receptors; therefore, the structure–activity dependences for arylpiperazines **127** can be extrapolated to arylbiguanides. The main structure–activity regularity for arylpiperazines **127** is that the chlorine atom in the *m*-position of the benzene ring is the only substituent (R) studied which produces a significant increase in affinity. This cannot be replaced by any other electron-withdrawing substituent (*e.g.*, CF_3). Substitution of the naphthyl substituent (compound **128a**) for the phenyl substituent, the introduction of the nitrogen atom into the benzene or the naphthalene fragment (compound **128b**) and the conversion of the NH group of piperazine into an exocyclic amino group (compound **129**) also affords high-affinity compounds.[225–227] It should be noted that the majority of these compounds manifest pronounced antagonistic activities and behave as partial agonists.¶



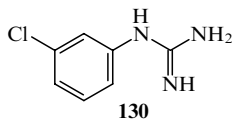
128a,**b**



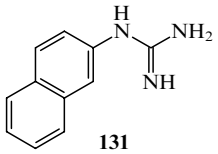
129

Y = CH (**a**), N (**b**).

In contrast, all the arylbiguanide derivatives under study are full agonists of 5-HT_3 receptors and manifest high selectivities towards them. As in the case of piperazine compounds, the introduction of the chlorine atom into the *m*-position affords the high-affinity compound **126** (R = 3-Cl), and 2-naphthylbiguanide binds 100 times more effectively than 1-phenylbiguanide.[229–233] These data unambiguously demonstrate the validity of the hypothesis about the similarity of binding profiles (or binding sites) of arylpiperazines **127** and arylbiguanides **126**. It is of note that the affinities of 3-chlorophenyl- (**130**) and 2-naphthylguanides (**131**) which also act as 5-HT_3 receptor agonists manifest the highest (by one or two orders of magnitude) affinities among other structurally related arylguanides [233] and can thus be regarded as representatives of a new structural class of serotonin receptor agonists.



130



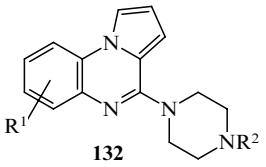
131

Investigations into the increase in the selectivities of arylpiperazines towards 5-HT_3 receptors have led to the synthesis of a vast variety of effective ligands endowed with a broad range of intrinsic activities, *viz.*, from full agonists to full antagonists. In the majority of studies, quipazine (**125a**) was used as the structural lead; its simplest modifications showed that the *N*-methyl analogue **125b** [225] manifests nearly identical affinity for 5-HT_3 recep-

¶ Some arylpiperazine derivatives manifest complex activity profiles with respect to 5-HT_3 subtype receptors. Thus the intrinsic activity of quipazine (**125a**) depends on the type of the cells comprising these receptors. It was shown that quipazine behaves as an agonist for some of these receptors and an antagonist for other receptors.[228]

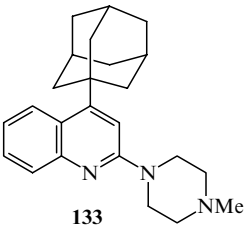
tors but does not bind to 5-HT_{1B} receptors (according to more recent data, the *N*-methyl substituent is the most suitable substituent for many quipazine analogues [234]).

Earlier, it was shown that the 5-HT_{1B} receptor ligand **57** which contains a pyrrole ring and is inactive towards 5-HT_3 receptors acquires high affinity for these receptors upon removal of the trifluoromethyl group. Therefore, a vast majority of studies aimed at modification of the quipazine structure include the introduction of a condensed pyrrole ring into the quinoline system.[234–236] Among compounds of the general formula **132**, the derivatives manifesting the highest affinities for 5-HT_3 receptors possess the properties of partial (R^1 = H, 6-, 7- or 9-F; R^2 = H, Alk, CH_2 = $CHCH_2$) and full (R^1 = 9-Me, R^2 = Me; R^1 = 7-OH, R^2 = Me) agonists, the latter being the strongest 5-HT_3 agonists presently known.[237]

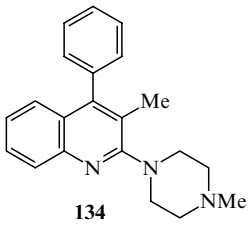


132

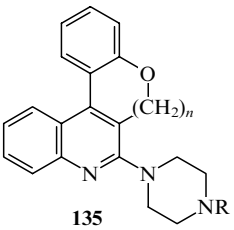
The introduction of lipophilic groups into the quipazine molecule yields the derivatives **133**–**135**, which behave as antagonists of the corresponding receptors or partial agonists endowed with low intrinsic activities, *e.g.*, compound **136**.[228]



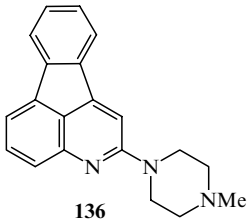
133



134



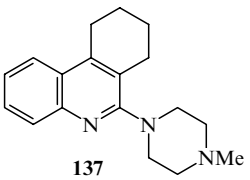
135



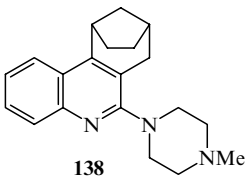
136

n = 0–2, R = H, Alk.

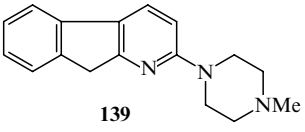
QSAR studies of quipazine derivatives containing various heteroaromatic fragments revealed several compounds (*e.g.*, compounds **137**–**139**) manifesting high activities, high selectivities and different intrinsic activities with respect to 5-HT_3 receptors. Thus compound **137** is the partial agonist, compound **138** is the antagonist, while compound **139** is the agonist of the corresponding receptors.[238]



137

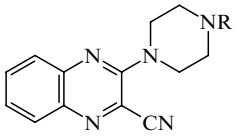


138



139

This finding was used in the design of a binding model of quipazine derivatives (both agonists and antagonists) to 5-HT_3 receptors.[238, 239] According to this model, the high-affinity interaction with the receptor involves the formation of a hydrogen bond between the protonated terminal nitrogen atom of piperazine and the carboxylate anion of the amino acid residue in 5-HT_3 receptors (there is conformational restriction for the bulk of the substituent at this nitrogen atom), the formation of a hydrogen bond between the nitrogen atom in the heterocycle and the corresponding hydrogen bond donor in the receptor and, finally, the specific interaction between the aromatic ring and the corresponding amino acid residue of the receptor (there is a size restriction of substituents in the region of aromatic ring fusion). Presumably, the first two interactions make a weighty contribution to affinity.[240] Moreover, favourable van der Waals interactions which are supposed [238] to be critical for the modulation of intrinsic activities with respect to 5-HT_3 receptors (*cf.* structures **137**–**139**) can be triggered in that domain of the receptor molecule which corresponds to the quinoline fragment. However, the structural determinants responsible for the intrinsic activities of quipazine derivatives are in fact more complicated, since the changes in their activities can be provoked even by any apparently insignificant changes in the heterocyclic backbone of quipazine. Thus compounds **140a**,**b** which contain neither bulky, nor lipophilic substituents in their nuclei behave nevertheless as 5-HT_3 antagonists.[240, 241]

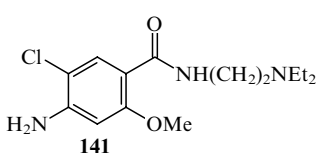


140a,**b** R = H (**a**), CH_2 = $CHCH_2$ (**b**).

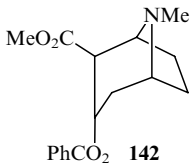
QSAR studies aimed at the search for effective 5-HT_3 agonists and antagonists based on quipazine give an insight into the molecular fragments essential for the strong binding of the ligands to the receptors and allow the prediction of novel high-affinity compounds. However, elaboration of structural requirements for their agonistic and antagonistic activities is hardly possible without detailed computer simulation studies.

As indicated above, the main progress in the design of 5-HT_3 ligands is associated with the synthesis of its selective antagonists some of which have already found application in clinical practice. The majority of 5-HT_3 antagonists represent aryl- or hetarylamide derivatives. We shall briefly summarise the main concepts and results of structure–activity studies of 5-HT_3 antagonists with special emphasis on the latest data.

The first potent and selective 5-HT_3 antagonists prepared were based on the non-selective dopamine receptor ligand metoclopramide (**141**), which had long been used as an antiemetic drug. Studies from the early 1980's showed that metoclopramide and some cocaine (**142**) analogues manifest relatively weak antagonistic activities towards one of the serotonin subtype receptors [242] further identified as 5-HT_3.[243] This activity is responsible for the antiemetic effect of metoclopramide. Further modifications of metoclopramide structure as well as of the structures of analoguous and lead compounds consisted in conformational restriction of the side chain, modification of the amide fragment and substitution of an oxygen-containing ring for the *o*-alkoxy group.



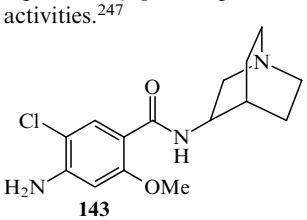
141



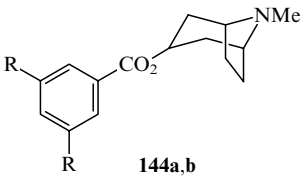
142

The introduction of the quinuclidine residue into the side chain of metoclopramide (**141**) afforded zacopride (**143**), which is a potent selective antagonist of 5-HT_3 receptors.[244, 245] Modifications including the introduction of a tropane fragment and variations of substituents in the ring give compound **144a** which is also a potent selective antagonist of this subtype of receptors.[246] Its analogue **144b** containing two methyl groups possesses virtually the same activity. It should be noted that side chain

modifications included the variations in its 'mobile' fragment. Thus phenylurea derivatives containing an alkoxy group in the *o*-position (*e.g.*, compound **145**) manifested high antagonistic activities.[247]

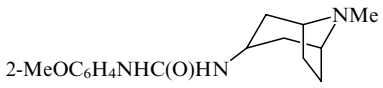


143



144a,b

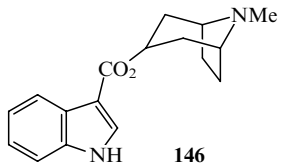
R = Cl (**a**), Me (**b**).



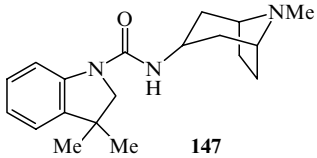
145

The benzene ring of these compounds was subjected to structural modification. Thus substitution of the indole ring for the disubstituted benzene ring in compounds **144a,b** which affords tropisetron (**146**) [144] significantly increases the affinity. A similar effect is observed upon the replacement of the aryl substituent in the urea derivative **145** by hetaryl substituents (compounds **147** and **148**).[248, 249]

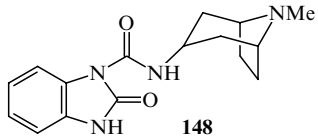
Tropisetron (**146**) is a selective 5-HT_3 ligand used in clinical practice as an antiemetic drug, like its more active structural analogue granisetron (**149**) containing a 9-azabicyclo[3.3.1]nonane residue in the side chain.[250]



146

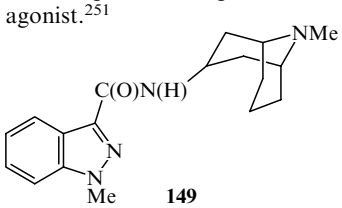


147

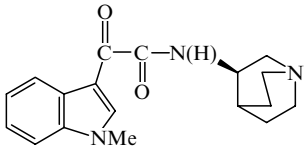


148

Modification of the 'mobile' fragment of the side chain resulted in the ketoamide (**150**), a high-affinity and selective 5-HT_3 ligand although manifesting the properties of a partial agonist.[251]

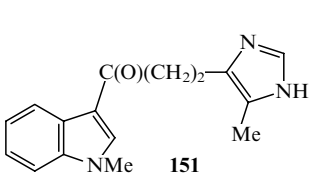


149

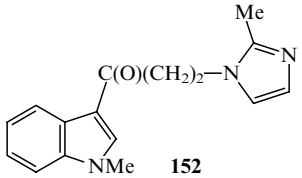


150

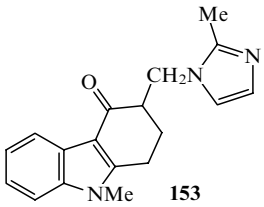
It is of note that these modifications were carried out together with the search for effective 5-HT_3 ligands among indole derivatives. Thus compounds **151** and **152** containing an imidazole fragment in their side chains were synthesised [252] and ondansetron (**153**),[253] the conformationally rigid analogue of compound **152**, a potent selective antagonist of 5-HT_3 receptors. Ondansetron (**153**) is the most well-known 5-HT_3 antagonist widely used as an antiemetic drug in combined therapy of tumour diseases.[254]



151

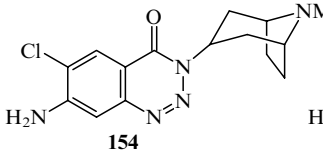


152

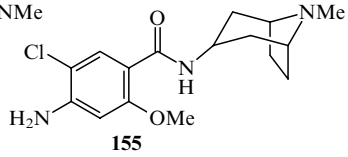


153

A modification of the amide group of metoclopramide (**141**) included the formation of the benzotriazine fragment (compound **154**). Since this modification increases the activity in comparison with the 'open' analogues of the type **155**, it is assumed that the active conformation of benzamides in the 5-HT_3 receptor should involve a planar arrangement of the carbonyl group.[255] Similar results were obtained for a series of ondansetron analogues (**153**) in which ketones fused to the indole fragment were 4 times as active as the non-cyclic analogue **152**.[255]

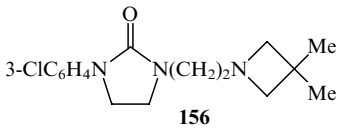


154

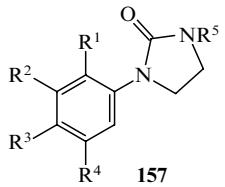


155

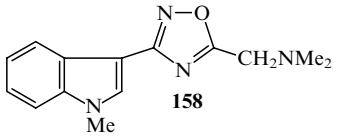
Yet another version of cyclisation is the incorporation of an amide group into a new ring in the side chain. The idea of this transformation stems from bioisosterism of benzamide and phenylimidazolidin-2-one fragments. Comparison of the structures of metoclopramide (**141**) and the dopamine receptor antagonist zetidoline (**156**) prompted an idea about the introduction of azabicyclic or other equivalent structural fragments of 5-HT_3 antagonists into the phenylimidazolidinonalkyl group. Indeed, several high-affinity antagonists of the 5-HT_3 receptor were identified among a series of compounds of the general formula **157**, and a compound with $R^1 = R^3 = R^6 = R^7 = H$, $R^2 = R^4 = Cl$, $R^8 = Me$ is characterised by unusually high affinity.[256] It should be noted also that the indole derivative **158** containing an oxadiazole residue mimicking the amide group instead of the bicyclic substituent is a specific antagonist of 5-HT_3 receptors.[257]



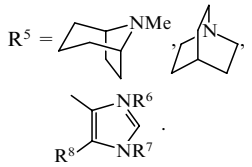
156



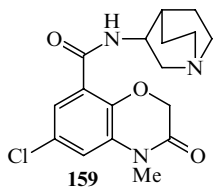
157



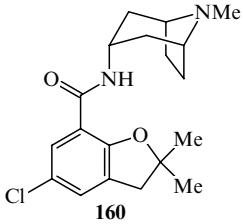
158



Substitution of a fused oxygen heterocycle for the *o*-alkoxy group is also a modification of the metoclopramide (**141**) structure. This modification resulted in several high-affinity selective 5-HT_3 antagonists, *e.g.*, the quinuclidine derivative **159** [258, 259] and zatosetron **160**.[260] In all these cases, the presence of the chlorine atom is a necessary prerequisite for the high activities of these compounds.

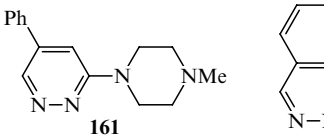


159

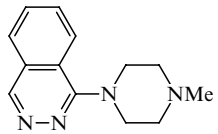


160

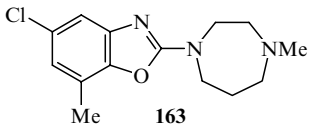
Many pharmacophore models have been suggested for 5-HT_3 antagonists. The differences between them originate from different models and different 5-HT_3 ligands used in their development. Critical analysis of five pharmacophore models [247, 248, 251, 261–263] disclosed the following essential components required for manifestation of high affinity, *vis*., the presence of an aromatic ring, the carbonyl group directly attached to the aromatic ring and a basic amine. The aromatic ring can represent a structural element of benzoate, benzamide, indole or imidazole fragments. As mentioned above, the carbonyl group can be replaced by an equivalent bioisosteric group, *e.g*., the 1,2,4-oxadiazole or the imidazolidin-2-one fragment. The presence and accessibility of the amine nitrogen plays a significant role in certain models,[261–263] although the details of this binding are still unknown.[264] It should be stressed, however, that some antagonists (*e.g*., compound **157**) do not fit into these structural models. The lack of correlation brought forth the necessity for modification of the binding profile of the receptor, *viz*., two additional hydrophobic binding sites were identified in the domain surrounding the aromatic ring.[257, 265] Pharmacophore models have proved to be a useful tool for the rational design of 5-HT_3 antagonists. Thus these models were used to predict high affinities of 3-aminopyridazines **161** and **162** containing a piperazine fragment for 5-HT_3 receptors.[265]



161



162



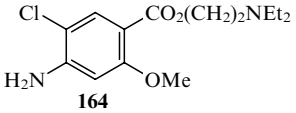
163

It should finally be noted that the number of publications devoted to the design of 5-HT_3 antagonists has presently lessened, presumably due to progress already achieved in this area. Nevertheless, the search for novel structural classes of 5-HT_3 antagonists is a vital problem in the endeavour to go far beyond the scope of tryptamine, metoclopramide and arylpiperazine derivatives. In novel compounds, such as compound **163** containing a seven-membered ring, modifications involve the same fragments. Compound **163** is a high-affinity partial agonist of 5-HT_3 receptors with low intrinsic activity.[266, 267]

VIII. Ligands of serotonin 5-HT_4 subtype receptors

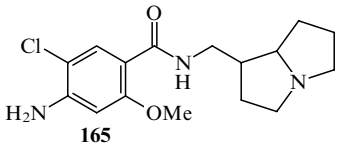
Serotonin 5-HT_4 subtype receptors were discovered in the late 1980's and cloned in 1995;[268] their molecular structures and some functional characteristics have not been described until very recently.[269] Various therapeutic applications for their agonists and antagonists, *e.g*., in the treatment of intestinal disorders, arrhythmias and diseases associated with the loss of the cognitive ability, are based on the localisation of this receptor in gastrointestinal tract, atrium and urinary bladder tissues as well as in the central nervous system.

Some non-selective antagonists of serotonin receptors, mostly of 5-HT_3 receptors, *e.g*., metoclopramide (**141**), possess partial agonistic activities towards 5-HT_4 receptors. Therefore, metoclopramide (**141**) and its ester analogue **164**[270] manifesting the properties of a weak antagonist and 30-fold selectivity towards 5-HT_4 receptors than to 5-HT_3 receptors were used as the lead compounds in the design of more selective 5-HT_4 ligands.

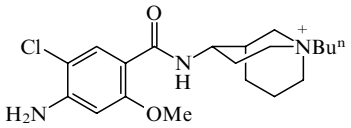


164

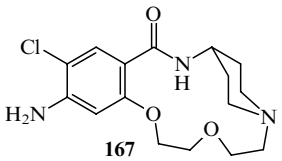
The general scheme of the design of these ligands resembles in many features that for 5-HT_3 antagonists and includes, in the first place, different versions of restriction of conformational mobility and modification of the amine side chain. The agonist **165**[271] and the antagonist **166** (a quaternised butyl analogue of renzapride (which is a partial agonist of the 5-HT_3 receptor) were among the first compounds manifesting somewhat higher selectivity towards 5-HT_4 receptors in comparison with 5-HT_3 receptors. This modification is based on a significant decrease in the activities of quaternary salts of 5-HT_3 antagonists with substituents bulkier than the methyl group at the nitrogen atom.[272, 273] Special mention should also be made of the original macrocyclic benzamide (**167**) which represents a partial agonist twice as selective towards 5-HT_4 receptors as towards 5-HT_3 receptors, which does not interact with other receptors.[274]



165

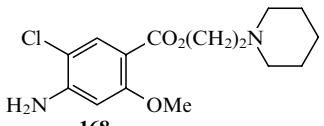


166

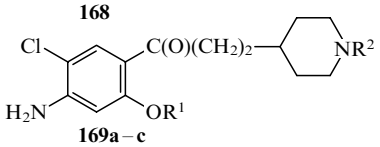


167

The close structural analogues of compound **164**, *viz*., the piperidine derivatives **168** and **169a**,**b**, are potent selective partial agonists of 5-HT_4 receptors (their intrinsic activities are 50% – 60%).[275–277] The classical approach to decrease the intrinsic activity of compound **169b** by introducing bulky lipophilic substituents proved to be successful. Thus the derivative **169c**[275, 278] manifests high antagonistic activity and 100-fold higher selectivity towards 5-HT_4 receptors than towards other serotonin receptors. It is of note that the changes in the structural activity of compound **168** from the agonistic to the antagonistic one is achieved by less significant structural modification, *viz*., through the introduction of two methyl groups into positions 3 and 5 of the piperidine ring. For the derivative **169a**, the decrease in the intrinsic activity is achieved through structural simplification, whereas the analogue **170** containing an additional carbon atom in the side chain but devoid of the lipophilic butyl substituent is a full 5-HT_4 antagonist manifesting high affinity and noticeable selectivity.[279, 280]

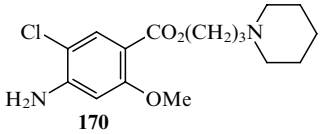


168



169a–c

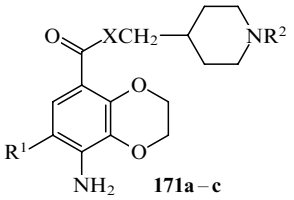
R^1 = Me: R^2 = Bu (**a**), $(CH_2)_2NHSO_2Me$ (**b**); R^1 = $CH_2C_6H_3(OMe)_2$-3,5, R^2 = $(CH_2)_2NHSO_2Me$ (**c**).



170

These and some other examples of this kind, *e.g*., the fact that metoclopramide (**141**) is a partial agonist of 5-HT_4 receptors and its ester analogue **164** is a 5-HT_4 antagonist, suggest that even minor structural changes may provoke dramatic changes in the intrinsic activities of 5-HT_4 ligands. A hypothesis of the existence of two binding sites in the 5-HT_4 receptor was developed to rationalise this fact.[277]

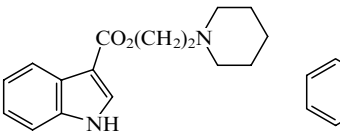
Substitution of an oxygen-containing ring for the *o*-alkoxy group in the piperidine-substituted metoclopramide derivatives (**141**) was efficient in the design of both 5-HT_3 and 5-HT_4 antagonists. Thus chlorine-substituted benzodioxanes **171a**,**b**[281] and the iodo derivative **171c**[282,283] proved to be selective 5-HT_4 antagonists with affinities exceeding that of compound **164** 1000-fold and even more.



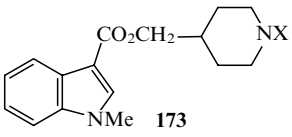
171a–c

R^1 = Cl, R^2 = Bu^n, X = O (**a**); R^1 = Cl, R^2 = $(CH_2)_3C_6H_3(OMe)_2$-3,4, X = CH_2 (**b**); R^1 = I, R^2 = Bu^n, X = O (**c**).

Substitution of the indole fragment for the benzene rings in many metoclopramide derivatives mentioned above was also effective. Compounds **172** and **173**[284,285] and their tricyclic analogue **174**[285] proved to be high-affinity selective 5-HT_4 antagonists. The attempts to modify the indole fragment revealed that benzoimidazoles **175** containing the piperazine fragment in their side chains manifest high affinities for 5-HT_4 receptors. Interestingly, compound **175** (where R = cyclo-C_3H_5) behaved as a potent antagonist, whereas that with R = Pr^i was a partial agonist manifesting very high intrinsic activity.[286] This is yet another example of reversal of the pharmacological profile of structurally related compounds, which provides additional evidence in favour of the hypothesis postulating the existence of two binding sites in the 5-HT_4 receptor.

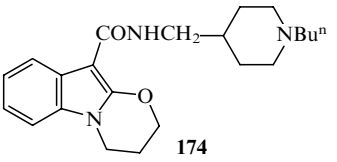


172

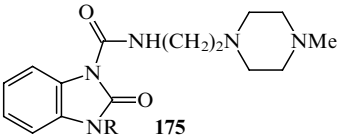


173

X = $(CH_2)_2NHSO_2Me$.



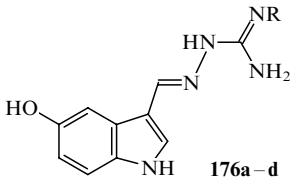
174



175

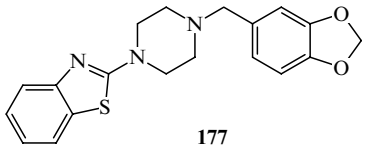
Conformational analysis of serotonin and zacopride (**143**) which also manifests agonistic activity towards its receptor disclosed very potent and selective 5-HT_4 agonists among indole derivatives close to serotonin and made it possible to propose a model of a binding site for 5-HT_4 agonists corresponding to the serotonin analogue **176a**. The latter appeared to be a high-affinity full agonist of 5-HT_4 receptors towards which it was more selective than to other serotonin and dopaminergic receptors.[287,288] The affinity of this compound can be increased through the introduction of lipophilic substituents into the side chain. Thus the derivatives **176b**,**c** are full agonists with the affinities exceeding that of serotonin severalfold. Compound **176d** binds to the receptor 300 times more effectively than serotonin but manifests the properties of a partial agonist. These compounds are among the most potent and selective 5-HT_4 agonists presently available.[287,288]

Some 5-HT_4 ligands were found among the derivatives of quipazine (**125a**), which also represents a 5-HT_3 ligand. The majority of compounds of this kind, *e.g.*, compound **177**, manifest partial agonistic activity towards 5-HT_4 receptors and simultaneously act as 5-HT_3 antagonists[289] which makes them promising candidates for gastrokinetic agents.



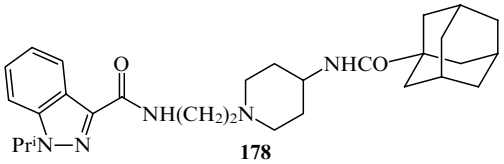
176a–d

R = H (**a**), C_5H_{11} (**b**), $(CH_2)_2Ph$ (**c**), $(CH_2)_2C_6H_3Cl_2$-3,4 (**d**).



177

It should be stressed in conclusion that despite the construction of a fairly large number of potent and sufficiently selective 5-HT_4 ligands, they manifest predominantly antagonistic activities. Full selective agonists are fewer in number, but are therapeutically more valuable. Moreover, very many 5-HT_4 ligands do not possess high pharmacodynamic characteristics needed for their clinical application. It is for this reason that the main attention has presently been focussed on those modifications of the ligand structure which might improve their pharmacodynamic characteristics. To this end, amide, carbamate or ketone groups are introduced into the side chains of compounds **170** instead of ester groups.[290,291] Among compounds with improved pharmacodynamic characteristics, compounds **171b** and **174** and the recently prepared compound **178**,[290,292] a long-acting, potent and selective 5-HT_4 antagonist, deserve special mentioning.

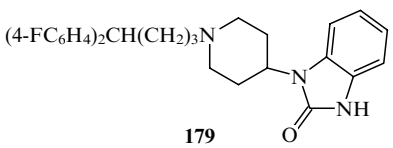


178

IX. Ligands of serotonin receptors of other subtypes

Among other subtypes of serotonin receptors, 5-HT_5 (further classified into 5-HT_{5A} and 5-HT_{5B}), 5-HT_6 and 5-HT_7 receptors are the least known. Highly selective ligands to 5-HT_5 and 5-HT_6 receptors have not been identified yet; therefore, their functional and, perhaps, therapeutic values have been studied relatively little. It is suggested that 5-HT_7 receptors play a role in the pathophysiology of certain sleep disturbances, depressive states and schizophrenia; also their stimulation causes vasodilation.

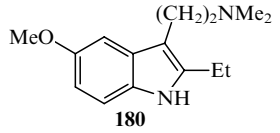
Studies of the effects of many classical ligands of serotonin receptors on these subtypes revealed that 5-carboxamidotryptamine (**2**) and LSD (**97**) manifested high, whereas compound **4a** manifested moderate, affinities for 5-HT_{5A} and 5-HT_7 receptors.[293] Many non-selective 5-HT_2 antagonists, such as methiothepin (**68**), methergoline (**98**), ritanserin (**104**), *etc.*, bind to 5-HT_6 and 5-HT_7 receptors manifesting high or moderate affinities. Very strong binding is observed in the interaction of some mixed-action antipsychotic drugs, *e.g.*, clozapine (**120a**) and pimozide (**179**), with these receptors.[294]



179

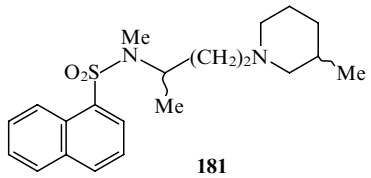
It is not until very recently that a series of studies devoted to the design of selective ligands of some of the above-mentioned receptor groups have been published.[295,296] Thus it was found that 5-HT_6 receptors match small alkyl substituents in position 2 of the indole ring of serotonin. The ethyl derivative **180** which represents

a full 5-HT_6 agonist manifests the highest affinity and binds to the receptor 5 times more strongly than serotonin. Compound **180** manifests only moderate affinity for some other types of serotonin receptors, being the most selective 5-HT_6 agonist known so far. Substitution of the phenyl group for the ethyl substituent does not influence the affinity but decreases dramatically the intrinsic activity. These data suggest that 2-substituted tryptamines can be used in the design of both selective agonists and antagonists of 5-HT_6 receptors.[296]

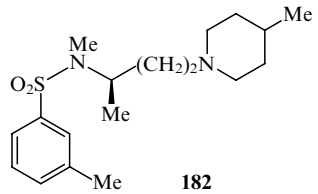


180

A selective ligand of 5-HT_7 receptors was prepared based on sulfamide **181**, which has been found as a result of wide screening and manifesting moderate affinity and weak selectivity towards 5-HT_7 receptors; its *R*,*R*-configuration was found to be important for binding. Modifications of compound **181** revealed that the methyl group in the piperidine ring may be shifted to position 4, whereas the naphthalene ring may be replaced by other aromatic substituents. Thus sulfamide **182** appeared to be two orders of magnitude more selective towards 5-HT_7 receptors than to other serotonin receptors. Compound **182** is the first example of an effective selective ligand endowed with 5-HT_7 antagonistic activity, although its affinity for these receptors is not very high.[295]



181



182

* * *

A vast variety of compounds interacting with serotonin receptors with high affinity have been prepared by the methods employed in medicinal chemistry. Selectivity is the major problem in the design of new ligands, since the family of serotonin receptors is characterised by a large set of structurally similar subclasses. Although this problem can successfully be overcome for some of 5-HT subtypes, for other 5-HT receptors, particularly for 5-HT_{1E}, 5-HT_{1F}, 5-HT_{5A}, 5-HT_{5B}, 5HT_6 and 5-HT_7, the design of selective ligands presents a challenge. Its successful solution will help better understanding of the functional roles of receptors in the organism. Obviously, progress in the search for ligands to serotonin receptors will depend on further advances in X-ray diffraction analysis, which will provide a basis for refining of computer models and docking studies of ligands pertaining to different structural classes.

V.	Conclusion	370

Abstract. Data on the application of the chromaticity method in chemical analysis and in various branches of industry are surveyed. The potential of the method is demonstrated and the prospects of its further development are discussed. The bibliography includes 196 references.

I. Introduction

Chromaticity is a science that deals with methods for colour measurement and its quantitative characterisation. The chromaticity method involving calculation of colour characteristics from the available spectral parameters of a test sample makes it possible to both differentiate between spectrally similar compounds and obtain additional information about them. In view of this, researchers are interested in the informative potential of the method, its field of application and limitations.

A great number of studies on the elaboration of visual detection systems and image processing have been published to date; most of these are comprehensive specialised monographs that mostly deal with the traditional methods for colour measurement and data processing.[1–5] However, so far this perfect mathematical apparatus has been little employed in analytical chemistry, although there are a number of computerised spectroscopic analytical procedures that use colour measuring systems.[4]

The appearance of a characteristic colour upon a chemical reaction is normally used in qualitative analysis for the detection of elements. It is well known that our vision is very sensitive to small absolute light intensity and distinguishes hues rather well. Not only can an eye compare two radiations but it can also determine which one is more (or less) intense. Colorimetric systems are designed and perfected for the quantitative evaluation of radiation. For some time, their practical use was hindered by the complexity of the hardware required. The need for determination of the compositions of complex dye mixtures used in the textile industry has served as an impetus for the development of the chromaticity method. The solution of this problem has made it possible not only to develop compact light-measuring instruments but also to create a mathematical apparatus for the calculation of concentration dependences from the colour changes in the test samples.

There are two basic methods for colour measurement which differ in the calculation procedure: one is based on the spectral composition of radiation and the other is based on the number of individual colours in a mixture resulting in the colour to be determined. According to this classification, all colorimetric instruments and procedures for the calculation of chromaticity coordinates can arbitrarily be divided into two types, depending on the quantity to be measured:

1. The chromaticity coordinates are calculated from the known spectral composition of radiation from a test compound (absorption and reflectance spectra, *etc*.). This method is believed to be the most accurate.[6]

2. The measured general function of colour addition (which in many cases corresponds to the sensitivities of photocells) is used to determine directly the chromaticity coordinates of the required component. The development of this method is hampered due to the difficulty of manufacturing photocells with the required spectral sensitivities.

The measurement inaccuracy of a colorimetric instrument is predicted as a function of the principle of its operation.[7–10]

Chromaticity measurements are successfully used in spectrophotometric titration,[11–13] as well as for characterisation of the forms in which indicators exist.[14–17] Chromaticity measurements are even more promising in chemical analysis in the absence or with minor use of instrumentation. Owing to the development of visual-detection express methods, the problem arises of determination of the content of a compound from the overall change in the colour of a test sample (the so-called test-methods); this problem can only be solved by chromaticity measurement methods which approximate most exactly the characteristics of human vision.

The methods of objective colour measurement with computer data processing are popular in many branches of industry, *e.g*., in the printing and paint industries,[18,19] textile industry,[20–22] glass industry[23,24] and pharmaceutical industry.[25,26] In addition, colour is an important parameter of the quality of food.[27,28] There are so many application fields of chromaticity measurement methods that they cannot all be listed.

To our knowledge, only one review on the application of the chromaticity method has appeared over the last ten years.[14] However, more than 200 publications on various aspects of the method have been published over the same period. These vast literature data are scattered, which hampers the studies, especially for those scientists who just start working in this field. In view of this, the purpose of our review is to discuss the analytical

capabilities and practical applications of the chromaticity method and to estimate the major trends and prospects in this field.

II. The main chromaticity characteristics and relationships between them

In essence, spectroscopic methods of analysis involve the detection of optical radiation parameters of a test sample. As a rule, these are the space–time distributions of radiation, its amplitude, frequency, phase, polarisation and coherence ratio. Measurement of the analytical signal is based on changes in these parameters due to interaction of the optical radiation with the object that is analysed (light absorption, reflection, dispersion) and on changes in the characteristics of the object itself upon exposure to light due to photochromism, electrooptical effects, luminescence and other phenomena.[6] The main informative parameters of optical monitoring in analytical chemistry include amplitude-related parameters, such as optical density (A), diffuse reflection coefficient (R), luminescence intensity (I_{lum}), *etc*. Integral characteristics (the total colour differences measured photometrically) are almost never used for this purpose.

According to Grassman's laws,[1] colour determination requires that three parameters be measured independently; two of them characterise the colour and the third one, the intensity. However, these parameters are used extremely seldom in analytical chemistry because of certain specific features of quantitative measurements.

Spectroscopic analysis does not allow direct determination of the chemical composition of a compound. It gives indirect information in the form of a suitable measurable physical quantity, such as optical density, diffuse reflectance, *etc*. An additional independent parameter, such as wavelength or frequency, is introduced in order to describe the spectrum. Chemical analytical techniques are mostly based on the amplitude-related characteristics and the values of these independently measured parameters. A similar approach is used for measurement of chromaticity characteristics.[29]

The mathematical description of colour in colorimetry is based on the experimental fact that each colour can be represented as a mixture (sum) of certain amounts of three linearly independent colours.[2] The basic colours include red (R), green (G) and blue (B), *i.e*., three monochromatic radiations with wavelengths (λ) of 700, 546.1 and 435.8 nm, respectively.[30]

The colour gamut diagram in this system is shown in Fig. 1. The point S_1 corresponds to a colour within the colour gamut, while S_2 corresponds to a colour outside the gamut. It is most convenient to illustrate this representation geometrically. The three basic colours serve as axes in the orthogonal coordinate system, while any colour determined by three chromaticity coordinates is reflected by a vector **S** (see Fig. 1)

$$\mathbf{S} = R\mathbf{R} + G\mathbf{G} + B\mathbf{B}, \qquad (1)$$

where R, G and B are the red, green and blue chromaticity coordinates, respectively; **R**, **G** and **B** are the unit vectors of these colours that are mixed. Connection of the unit basic colour points ($R = 1$, $G = 1$, $B = 1$) with each other gives a triangle located in the unit plane. A remarkable feature of this plane is that the colour vectors having different lengths but the same direction cross it in the same point S, which characterises the colour saturation. In order to establish the position of the point S on the unit plane, the chromaticity coordinates r, g, b are introduced; these are related to the chromaticity coordinates R, G, B as follows:

$$r = \frac{R}{R+G+B}; \quad g = \frac{G}{R+G+B}; \quad b = \frac{B}{R+G+B}. \qquad (2)$$

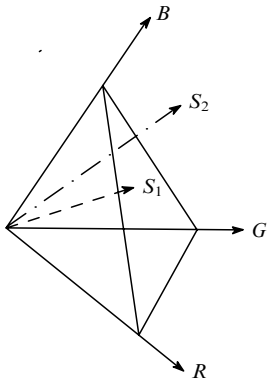

Figure 1. The RGB three-coordinate colour space.[30]

It follows from relationships (2) that $r + g + b = 1$, *i.e*., two chromaticity coordinates are sufficient to determine unambiguously the position of a point on the unit plane.

The colour perception by humans is taken into account based on experiments with colour mixing. In these experiments, one has to equalise visually pure spectral colours of equal intensity (which correspond to monochromatic lights with various wavelengths) with mixtures of the three basic colours produced by an analytical instrument. To make the comparison, pure spectral light and a mixture of the three basic colours are arranged alongside on two halves of the photometric comparison field. Upon equalisation, the amounts of the three basic colours are measured and their ratios to the unit amounts of these colours are determined. The values obtained are the chromaticity coordinates of the colour that is equalised in the selected chromaticity coordinate system. This procedure does not allow equalisation of the majority of pure spectral colours with mixtures of the three basic colours provided by the instrument. In such cases, a certain amount of one of the basic colours is added to the colour to be equalised, *i.e*., the chromaticity coordinate is allowed to be negative. Based on the estimates given by several observers, one calculates the averaged amounts of the three basic colours (specific chromaticity coordinates) which produce a mixture visually indistinguishable from the pure spectral colour. The graphic plots of the basic colour amounts on the wavelength represent the so-called colour addition curves. Based on these curves, one can calculate the fractions of the basic colours required to obtain a mixture visually indistinguishable from a colour with a complex spectral composition. For this purpose, the colour of a complex radiation is represented as a sum of pure spectral colours corresponding to its monochromatic components (with account of their intensities). The possibility of such representation is based on one of Grassman's laws, according to which the chromaticity coordinates of the colour of a mixture are equal to the sums of the corresponding coordinates of all of the colours mixed.

The addition functions are positive for the colours included in the RGB colour gamut. However, if a colour is outside the gamut, the addition functions become negative, which is inconvenient for calculations. In order to overcome this drawback, the International Commission on Illumination (CIE) summarised the known colour properties and formulas for colour variation calculations. As a result, a non-orthogonal three-colour system (XYZ) was created, which describes the spectral properties of a test object as three-dimensional vector coordinates.[2] The integral separation of the light radiation intensity into three components is convenient for correlation with human vision (due to the existence of red-, green- and blue-sensitive fibres in the eye retina).

The XYZ coordinate system is based on the following assumptions:

— the XYZ chromaticity coordinates are always positive for all real colours;

— the Y coordinate defines the colour brightness;

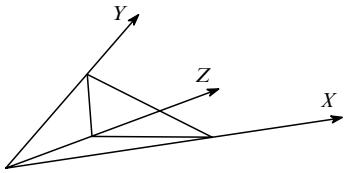

Figure 2. The XYZ three-coordinate colour space.[2]

— the chromaticity coordinates of white equal-energy radiation correspond to the centre of gravity of a triangle located in the unit plane (Fig. 2).

The following relationships are used for conversion from the RGB system of basic colours to the XYZ system:

$$\mathbf{X} = X_R\mathbf{R} + X_G\mathbf{G} + X_B\mathbf{B}, \tag{3}$$

$$\mathbf{Y} = Y_R\mathbf{R} + Y_G\mathbf{G} + Y_B\mathbf{B}, \tag{4}$$

$$\mathbf{Z} = Z_R\mathbf{R} + Z_G\mathbf{G} + Z_B\mathbf{B}, \tag{5}$$

where X_R, X_G, X_B, Y_R, Y_G, Y_B, Z_R, Z_G and Z_B are coordinates of the basic colours in the three-coordinate RGB space. It should be noted that these values have also been standardised. The chromaticity coordinates in the new colour space will have the form

$$x = \frac{X}{X+Y+Z}, \quad y = \frac{Y}{X+Y+Z}, \quad z = \frac{Z}{X+Y+Z}, \quad x+y+z = 1. \tag{6}$$

A unit plane is a right-angled triangle called the chromaticity plot; its vertices are located in the intersection points with the vectors of the basic colours. The vectors of spectral colours cross the unit plane along the pure spectral colour line (Fig. 3), which limits the region of existence of the real colours.

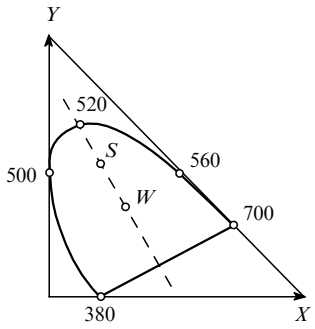

Figure 3. A unit plane in the XYZ system and the line of pure spectral colours (the solid curve).[2]
The S and W points correspond to the chromaticity coordinates of a given colour and white colour. The numbers indicate the irradiation wavelengths (λ /nm).

In addition to the X, Y, Z coordinates, there are other characteristics such as hue [$T(\lambda)$] and colour purity (P), which define unambiguously the radiation chromaticity. Obviously, any real colour can be obtained by additive mixing of white radiation with the appropriate monochromatic radiation. The hue is determined by the intersection point of the straight line which passes through the chromaticity coordinates of a given colour and the white colour (see points S and W in Fig. 3) with the pure spectral colour line (Fig. 4). The colour purity shows the ratio in which the monochromatic and white colours are mixed; the purity of monochromatic radiation is equal to unity and that of white radiation is equal to zero.

It should be noted that the use of the colour plot in the XYZ system (CIE, 1931) meets certain difficulties. For example, some

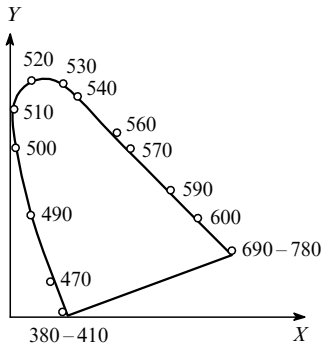

Figure 4. A colour diagram in the XYZ system.[2]
The numbers indicate the irradiation wavelengths (λ /nm).

distances between pairs of points in the plot (see Fig. 4) do not correlate with the visual perception of humans, since the scale of the plot is non-uniform. In addition, it does not give information regarding the colour lightness. The systems considered above provide only a quantitative estimate of the colour, but one cannot estimate visually the difference between two colours using these systems, since the distances between points in the colour space do not correspond to a difference reliably visible by eye. Several attempts have been undertaken to create such an equicontrast space where the distance between two points would correlate with visible colour variation. However, none of these attempts have been successful to date. The International Commission on Illumination has proposed several quasi-equal contrast systems of this kind; *CIELAB* (1976) is most popular of these systems. The L, A, B coordinates in this system are related to the X, Y, Z coordinates by the following relationships:

$$L = 116\,(Y/Y_W)^{1/3} - 16, \tag{7}$$

$$A = 500\,(X/X_W)^{1/3} - (Y/Y_W)^{1/3}, \tag{8}$$

$$B = 200\,(Y/Y_W)^{1/3} - (Z/Z_W)^{1/3}, \tag{9}$$

where L is lightness; A and B are the chromaticity coordinates (A is used for the red-green axis; B, for the yellow-blue axis); X_W, Y_W, Z_W are the coordinates of the white colour in the XYZ system; the axes A and B lie in a plane perpendicular to the L axis (Fig. 5).

The distance between two points in the three-coordinate LAB colour space characterises the total colour difference (ΔE) calculated using the formula

$$\Delta E = \sqrt{(\Delta L)^2 + (\Delta A)^2 + (\Delta B)^2}. \tag{10}$$

The hue (T) and saturation (S) are determined by the following relationships:

$$S^2 = A^2 + B^2, \qquad T = \operatorname{arctg}(B/A). \tag{11}$$

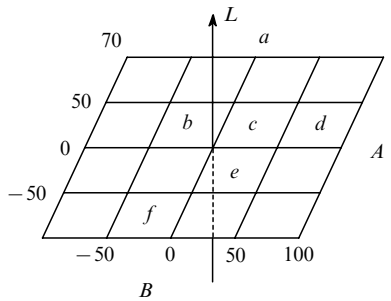

Figure 5. The LAB three-coordinate colour space. The white (a), green (b), grey (c), yellow (d), purple (e) and blue (f) regions.[30]

The yellowness (G) and whiteness (W) are expressed by the equations

$$G = \frac{100(1.28X - 1.06Z)}{Y}, \quad W = 100 - \Delta E. \tag{12}$$

The *CIELAB* colour space is most suitable for calculations, since equal distances between the points corresponding to different colours in any part of this coordinate system correlate with visual perception, enabling one to introduce a convenient measure for the quantitative determination of colour differences. In practice, the chromaticity coordinates in the *XYZ* and *CIELAB* systems and the colour characteristics of the objects of interest are obtained, *e.g.*, from the diffusion reflectance spectrum, as follows:

$$X = k \sum_{\lambda} S(\lambda)\bar{x}(\lambda)R(\lambda)\Delta\lambda, \tag{13}$$

$$Y = k \sum_{\lambda} S(\lambda)\bar{y}(\lambda)R(\lambda)\Delta\lambda, \tag{14}$$

$$Z = k \sum_{\lambda} S(\lambda)\bar{z}(\lambda)R(\lambda)\Delta\lambda, \tag{15}$$

where k is the normalising coefficient; $S(\lambda)$ is the radiation spectral density from one of the standard light sources A, C or D_{65} in relative units; $\bar{x}$, $\bar{y}$ and $\bar{z}$ are the colour addition functions; $R(\lambda)$ is the measured diffuse reflection coefficient. For self-luminous objects:

$$k = \frac{100}{\sum_{\lambda} S(\lambda)\bar{y}(\lambda)\Delta\lambda}.$$

Upon introduction of the factor k, the chromaticity coordinates for non-self-luminous objects are expressed in the scale where $Y = 100$.

Thus, chromaticity characteristics are more informative than the spectral ones, although they cannot be used without analysis of diffuse reflection spectra. The use of chromaticity characteristics in analytical chemistry expands the possibilities of studying processes that occur in test samples. The colorimetric instruments and calculation methods created for this purpose make it possible to detect colour changes and to use colour measurements for the analysis of objects.[31–33]

III. The theoretical aspects of the chemical chromaticity method

The most common task in the broad range of analyses carried out with the use of chromaticity involves the determination of metal ions. It is easy to understand that the essence of the method requires that the metals be transformed into coloured compounds, in most cases into complexes with organic ligands. These compounds can be analysed both in solution and in solid state (in the form of sorbates); in the latter case, the detection limit can be lowered by pre-concentration. Metals are mostly transformed into coloured compounds using the classical organic reagents employed in conventional spectrophotometry. Chromaticity studies on the properties of these organic reagents (optical and chromaticity parameters, *etc.*) is an important but insufficiently studied stage in the development of analytical procedures.

1. Studies of the state of organic reagents in solution and in the sorbent phase

Studies of the properties of organic reagents are important for expanding the analytical capabilities of chromaticity.[34] In view of this, the optical and chromaticity characteristics of Arsenazo III in solution and in the adsorbed state on an AV-17 anion-exchange resin have been studied. The chromaticity functions (CF) of Arsenazo III, namely the chromaticity coordinates x, y, z in the *XYZ* system, lightness (L), chromaticity coordinates A, B in the *CIELAB* system, colour saturation (S), yellowness (G), hue (T), as well as colour differences with respect to saturation (ΔS), lightness (ΔL) and tint (ΔT), were measured relative to a white colour standard with a diffuse reflection coefficient R equal to 0.98. It is assumed for an absolutely white body that $R = 1$, $W = 100$, and both ΔE and G equal zero. The functions R, W, L, X, Y, Z should be lower and ΔE should be higher for coloured compounds that absorb and reflect light simultaneously; these differences are the more significant the more intense the coloration of compounds. In agreement with this, the values of the functions R, W, L, X, Y, Z for sorbates, the coloration of which is more intense than that of solutions due to concentration, are lower, namely, they vary from 20 to 40 (for R in the range 0.2–0.4), whereas for solutions they vary from 80 to 70 (for R in the range 0.8–0.7). Of the CF, the yellowness provides the most abundant colour information. For an absolutely white body, $G = 0$; for yellow and red bodies, $G > 0$, while for green and blue ones, $G < 0$. The inflexion points in the plots (Fig. 6) correspond to regions of transition between the forms. Changes in the magnitude and sign of G in the inflexion points can indicate the state of the organic reagent in the test medium. In Arsenazo III solutions at pH < 5, the yellowness becomes positive as they contain H_8R molecules and ions such as H_7R^- (pH < 2), H_6R^{2-}, H_4R^{4-} (pH ≈ 4.6), which are red. At pH > 9.6, the yellowness is negative (−10), since the blue ions (HR^{7-} and R^{8-}) dominate in the solution. On the contrary, the G values are positive and rather high (from 40 to 120) for all sorbates and reach a maximum (120) at pH 12. It was inferred from these data that only the red ions, most likely the single-charged H_7R^- ions, are sorbed on the anion-exchange resin. Sorption of two- and multicharged ions is hampered or impossible due to steric hindrance. Ivanov *et al.*[34] suggested the use of molar CF coefficients (the ratio of the signal of a given CF to the concentration of the complexing agent expressed in mol litre^{-1}) which increase in the series: $R < G < B < L$, $X < S$, $A < W < \Delta E < Z < Y$. It was also found that the molar CF coefficients are 1.5–2.5 orders higher than the molar absorption coefficients (ε). This suggests that the

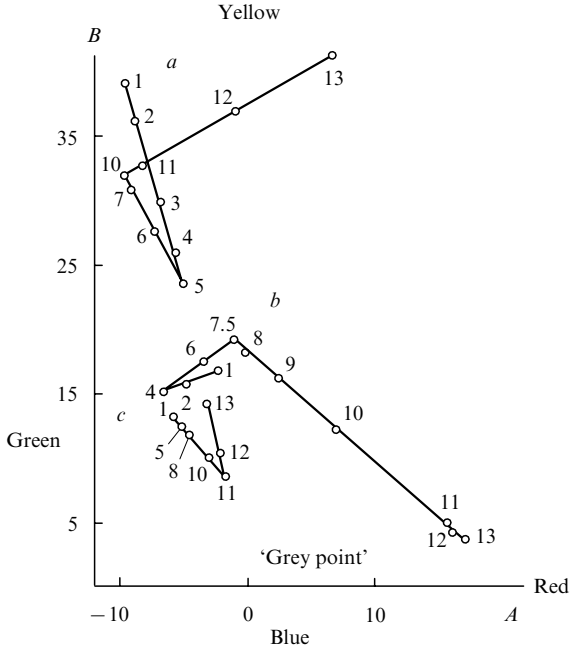

Figure 6. Changes in the A and B chromaticity coordinates (*CIELAB*) of 4-(2-pyridylazo)resorcinol (PAR) (*a*), 4-(2-thiazolylazo)resorcinol (TAR) (*b*) and 1-(2-pyridylazo)-2-naphthol (PAN) (*c*) solutions as functions of the medium acidity.[41]
Solution concentrations ($10^5 c$ /mol litre^{-1}): (*a*) 5, (*b*) 1.5, (*c*) 2.5. Acetone concentration (vol.%): (*a*) 0, (*b*) 10, (*c*) 20; the ionic strength (I) equals 0.1. The numbers indicate the pH of the solutions.

use of CF is promising for an increase in the sensitivity of determinations.

2. Studies of acid – base properties of reagents

In the majority of studies, spectrophotometric methods are used to determine the dissociation constants of organic reagents. In these methods, dependences of optical density on the solution pH are obtained and then processed graphically or by semi- or bilogarithmic computational methods. A correct choice of wavelengths is very important when measuring the optical density. They normally correspond to the maxima of light absorption by various ionic and molecular forms of the reagents. The situation becomes more complicated if the positions of the maxima differ insignificantly and especially if tautomeric equilibria exist and are imposed on the dissociation equilibria.

Changes in the properties of the equilibrium states of a reagent can be recorded using the chromaticity coordinates of the *CIELAB* equicontrast chromaticity system.[30] These values provide data on the integral distribution of light absorption in an equilibrium system tested in a broad range of wavelengths (380 – 720 nm). This allows one to avoid inaccuracies associated with a wrong choice of the range of the reagent absorption spectrum where the measurements are carried out. Thus, the reliability of the results obtained increases considerably.

Two methods exist for the determination of the equilibrium constants (pK_a).

1. Colour saturation (S) is plotted *versus* the solution pH at various reagent concentrations, then pK_a is determined graphically or calculated using the equation

$$pK_a = pH_1 + \frac{(pH_2 - pH_1)(\Delta S_1' - \Delta S_1)}{(\Delta S_2 - \Delta S_2') + (\Delta S_1' - \Delta S_1)}, \qquad (16)$$

where pH_1 and pH_2 are pH values around the assumed pK value; ΔS_1, ΔS_2, $\Delta S_1'$ and $\Delta S_2'$ are the changes in saturation depending on whether the equilibrium is shifted from alkaline to acid or from acid to alkaline medium, respectively.[35]

2. Differential plots of the reagent colour on the medium acidity are used:

$$SCD = \frac{\Delta S}{\Delta pH},$$

where the *SCD* (specific colour discrimination) parameter characterises the change in the colour saturation upon a change in pH.

The latter method is more accurate and has proved itself well in titrimetric methods.[36–39] Its application in complexonometric titration is discussed in detail elsewhere.[30,40] Of considerable interest was the use of the differential method for the determination of dissociation constants in spectroscopic analytical methods (diffuse reflection spectroscopy, solid-phase spectrophotometry). Heterocyclic azo compounds, namely, PAN, PAR and TAR, have been chosen,[41] since these are well studied as metallochromic indicators.

a. Determination of dissociation constants in solutions

It is known that PAR, TAR and PAN can exist in three main forms, *viz*., protonated at the nitrogen atom, neutral (molecular) and anionic (formed due to dissociation of the hydroxy groups) depending on the medium acidity.[42]

The variations of the chromaticity coordinates A and B (*CIELAB*) of model solutions of PAR, TAR and PAN at various pH values are shown in Fig. 6. It follows from the general character of these dependences that there are discrete pH values where the colour changes proportionally to the content of the form in which the reagent exists in the solution, and the differential plots of the colour of PAR, TAR and PAN *versus* the medium acidity should contain maxima corresponding to the pK values of the reagents. Differential curves of this type are usually analysed using the *SCD* parameter.[43,44] Morozko *et al*.[41] made calculations based on the numerical values of colour saturation. The dissociation constants found by the graphical method were found to be close to those obtained by the method of isosbestic points (Table 1).

Table 1. Dissociation constants of PAR, TAR and PAN in water – acetone solutions determined by chromaticity method and the method of isosbestic points ($I = 0.1$).

Reagent	Acetone concentration (vol.%)	Constant	pK_i obtained by	
			chromaticity method [a]	method of isosbestic points
PAR	0 [b]	pK_{NH}	2.7 ± 0.1	2.55 ± 0.15 (see [42])
	0 [b]	p$K_{p\text{-OH}}$	5.3 ± 0.2	5.47 ± 0.09 (see [45])
	0 [b]	p$K_{o\text{-OH}}$	11.5 ± 0.2	11.36 ± 0.08 (see [46])
TAR	10	pK_{NH}	1.0 ± 0.2	–
	10	p$K_{p\text{-OH}}$	5.8 ± 0.2	5.9 (see [47])
	10	p$K_{o\text{-OH}}$	9.5 ± 0.2	9.4 (see [48])
	20	pK_{NH}	1.0 ± 0.1	–
	20	p$K_{p\text{-OH}}$	6.3 ± 0.1	6.15 ± 0.22 (see [49])
	20	p$K_{o\text{-OH}}$	9.8 ± 0.2	9.68 ± 0.19 (see [49])
	40	pK_{NH}	0.8 ± 0.2	–
	40	p$K_{p\text{-OH}}$	7.1 ± 0.2	7.33 ± 0.17 (see [45])
	40	p$K_{o\text{-OH}}$	12.1 ± 0.2	12.32 ± 0.18 (see [45])
PAN	10	pK_{NH}	2.1 ± 0.2	2.32 ± 0.04 (see [50])
	10	pK_{OH}	11.9 ± 0.2	12.0 ± 0.03 (see [50])
	20	pK_{NH}	1.9 ± 0.2	1.90 ± 0.03 (see [51])
	20	pK_{OH}	12.0 ± 0.2	12.22 ± 0.05 (see [51])
	40	pK_{NH}	1.7 ± 0.2	2.09 ± 0.08 (see [52])
	40	pK_{OH}	12.2 ± 0.2	12.63 ± 0.06 (see [52])

[a] Reported data;[41] [b] measurements in water.

In a number of studies on acid – base equilibria in solutions of heterocyclic azo compounds,[53,54] it was noted that the region of existence of the reactive molecular form of an organic reagent expands with a decrease in the dielectric constant (ε) of the medium. This statement has been checked by the chromaticity method for model water – acetone solutions of PAN, PAR and TAR.[41] Figure 7 shows these dependences for TAR. The character of changes in the pK_{NH} and pK_{OH} constants makes it possible to conclude that as the content of the organic solvent increases, the reaction occurs in a more acidic medium (pK_{NH} decreases with a decrease in ε), whereas the stability of the complex increases (pK_{OH} increases with a decrease in ε).

The effect of the solvent on the pK_{NH} and pK_{OH} values for TAR was demonstrated by measuring the half-widths of *SCD* peaks (Table 2). The narrower the peak the closer the pK value

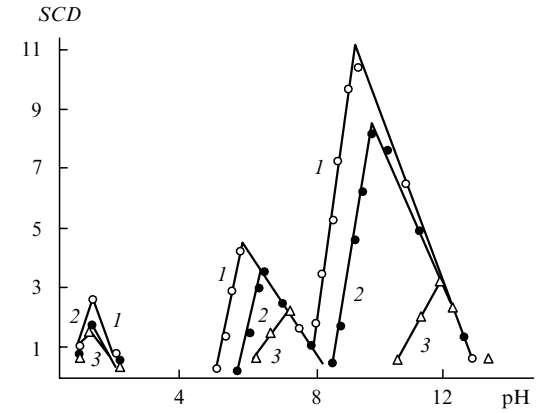

Figure 7. Variation of *SCD* of a TAR solution ($c = 10^{-5}$ mol litre^{-1}) as a function of acetone concentration and pH.[41] Acetone concentration (vol.%): (*1*) 10, (*2*) 20, (*3*) 40.

Table 2. Peak half-widths *SCD* ($\Delta p_{0.5}H_i$) as a function of acetone concentration.[41]

Parameter	$\Delta p_{0.5}H_i$ at acetone concentrations (vol.%)		
	10	20	40
$\Delta p_{0.5}H_{NH}$	0.4 ± 0.1	1.2 ± 0.2	0.3 ± 0.1
$\Delta p_{0.5}H_{p\text{-OH}}$	1.0 ± 0.2	1.2 ± 0.2	0.5 ± 0.2
$\Delta p_{0.5}H_{o\text{-OH}}$	1.2 ± 0.2	1.3 ± 0.2	0.6 ± 0.2

found graphically to that found by calculation. The results obtained suggest a sharper colour change of the reagent forms existing in solution upon both the variation of the medium acidity and the increase in the content of the polar solvent.

b. Determination of dissociation constants in the sorbent phase

The chromaticity approach to the determination of the state of organic reagents has been well proved for solutions.[55, 56] On the other hand, studies of protolytic reactions of these organic compounds on sorbent surfaces are no less important for investigation of the properties of the modified sorbents. First, protolytic equilibria characterise the reactivities of compounds, because this type of reaction is restricted to a larger extent than, *e.g.*, complexation processes. Hence, the data obtained allow one to estimate rather reliably the reactivities of different functional groups of the sorbent and of the organic compound immobilised thereon. In addition, the knowledge of the acid–base properties of reagents is necessary for the quantitative description of the stability of complexes on sorbent surfaces.

The state of TAR in the phases of silica (Silochrom C-120) and an anion-exchange resin with styrene–divinylbenzene matrix (AV-17 × 8) was studied[41] by diffuse reflectance spectroscopy (DRS) and by solid-phase spectrophotometry (SPS). The TAR dissociation constants have been found using the graphical and chromaticity calculation methods based on Fig. 8: the values of pK_{NH}, $pK_{p\text{-OH}}$ and $pK_{o\text{-OH}}$ were 1.5 ± 0.2, 6.6 ± 0.2 and 10.8 ± 0.2 for Silochrom C-120 and 1.0 ± 0.2, 5.7 ± 0.2 and 9.4 ± 0.2 for the anion-exchange resin AV-17 × 8, respectively.

Let us note that the above values of the TAR dissociation constants on AV-17 × 8 are close to those obtained for solutions. For TAR sorbed on silica, the dissociation equilibrium is shifted to the more alkaline region in comparison with solutions. This can probably be explained by specific interactions in the sorbate–sorbent system and by destruction of the silica skeleton (at pH > 10)[57] and possible dissociation of silicic acid ($pK_1 = 9.9$, $pK_2 = 11.8$, $pK_3 = 13.7$).[58]

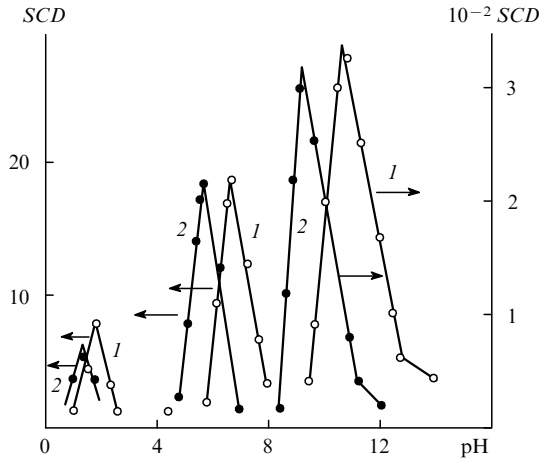

Figure 8. Variation of *SCD* of modified sorbents as a function of medium acidity.[41]
Systems: (*1*) SG–TAR, $c = 20$ μmol g^{-1} (DRS method); (*2*) AV-17 × 8–TAR, $c = 10$ μmol g^{-1} (SPS method). Sorbent fractions 200–350 μm.

It can be concluded that the quantitative description of equilibrium in the sorbent phase is a much more complicated task which usually involves a number of simplifications and assumptions that cannot be verified strictly. In spite of this, studies of equilibria on solid phase surfaces by the chromaticity method not only facilitate experimental procedures but are also of undoubted interest for researchers, as complex-forming sorbents are widely used in analytical chemistry.

3. Increasing the sensitivity of determination of metal ions

It is important to know the chromaticity parameters of complexes in order to expand the determination capabilities of chromaticity methods for elements. The use of chromaticity coordinates can increase both the determination selectivity and its sensitivity, as CF vary over broader limits than optical density or the diffuse reflectance coefficient.

Complexation of a series of transition metals, *viz.*, Cu^{II}, Zn^{II}, Ni^{II}, Mn^{II}, Fe^{III}, Cr^{III}, Co^{II}, Co^{III}, with PAN immobilised on silica gel (SG–PAN) was studied.[59, 60] It was found that the chromaticity coordinates of the SG–PAN surface in the air-dry state are strictly constant, *viz.*, $A = 77.0 \pm 0.5$ and $B = 34.0 \pm 0.5$. Basically, the chromaticity coordinates should remain constant. However, since various masking substances (for example, sodium thiosulfate for masking copper and sodium fluoride for masking iron) were added and the medium acidity was changed during the experiments, the initial chromaticity coordinates of SG–PAN changed also. These changes were particularly pronounced in the case of Mn^{II} and Cr^{III}, because the determination was carried out at pH 10.0, *i.e.*, near the critical acidity of the sorbent (pH 11.0) where it undergoes decomposition (depolymerisation). Owing to cleavage of hydrogen bonds and desorption of PAN, the chromaticity coordinates in the reference experiment are close to the 'grey point'. An increase in the absolute content of a metal ion in the solution changes the chromaticity coordinates of the complex proportionally and linearly; the saturation point of SG–PAN remains virtually constant. This means that the saturation point can serve as an individual characteristic for the detection of elements in solution. This point is usually determined using such parameters as the hue and saturation. In this case, the hue allows one to judge to which primary colour the given colour corresponds. For example, the hue of zinc is 625 nm, *i.e.*, a red colour. Saturation shows to what degree the hue is expressed in the given colour. The higher the saturation the brighter the colour of a complex adsorbed by SG–PAN.

The optimum conditions for the complexation of rare-earth metal (REM) ions, *viz.*, La, Nd, Sm, Tb, Dy, Ho, Er, Yb, with PAR were determined.[61] For all of the complexes, correlation equations for the dependence of CF on the REM concentration in the range of 0.4–2.0 μg ml^{-1} were obtained. As an example, Fig. 9 presents such dependences for erbium pyridylazoresorcinate; for the other REM studied, similar dependences were observed. It was shown that of all CF studied, the chromaticity coordinate A, the yellowness (G) and the hue (T) have the maximum magnitudes; the use of these quantities allows one to increase the determination sensitivity 35–50-fold in comparison with the sensitivity that can be achieved by spectrophotometry. Unfortunately, no correlations between the optical (such as molar absorption coefficients) or chromaticity characteristics and the properties of metal ions (for example, ionic radii) could be found.[61]

Later,[62] the features of complexation of some REM with organic reagents of various classes were studied. In particular, the complexation of lanthanum, terbium and erbium with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PAAP) was studied with and without cationic (dodecyltrimethylammonium bromide), anionic (sodium dodecylsulfate) and non-ionic (OP-7) surfactants at various concentrations of organic solvents. The majority of CF depend linearly on the element concentration in

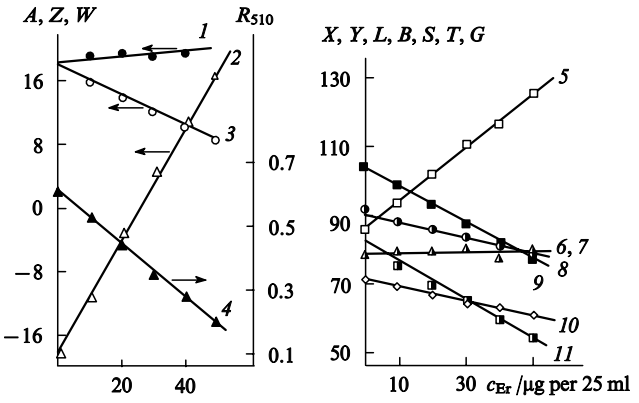

Figure 9. Dependence of the colour functions of erbium 4-(2-pyridylazo)resorcinate on the erbium concentration:[61]
(*1*) whiteness (*W*), (*2*) the chromaticity coordinate *A* in the *CIELAB* system, (*3*) the chromaticity coordinate *X* in the *XYZ* system, (*4*) diffuse reflectance coefficient at $\lambda = 510$ nm (R_{510}), (*5*) yellowness (*G*) (*6*) the chromaticity coordinate *B* in the *CIELAB* system, (*7*) saturation (*S*), (*8*) the *L* coordinate in the *CIELAB* system, (*9*) hue (*T*), (*10*) the *X* coordinate and (*11*) the *Y* coordinate in the *XYZ* system.

solution. However, for some functions, *e.g.*, for *T*, *Z*, *A* and *W*, this proportionality is violated, though the reasons for these anomalies are as yet unclear. The molar absorption coefficients were compared to the molar CF coefficients of the complexes under optimal complexation conditions. The *G*, *S* and *B* values were found to be the most sensitive characteristics. For complexes of lanthanum, erbium and terbium, the molar CF coefficients decrease in the series $G > S > B > W > Y > X > Z > L$, $B > G > S > Y > A > W > X > L$ and $B > S > W > Y > A > X > L$, respectively.

It was also shown that the use of CF provides an essential increase in the sensitivity of REM determination, *viz.*, by a factor of 25 – 100 in comparison with photometric methods (*cf.* Ref. 61).

Similar studies were carried out for complexes of erbium with Arsenazo I, Arsenazo III and Chlorophosphonazo III.[63] The molar CF coefficients for these complexes decrease in the series $G > B > Y > X > Z > L > W > A$ for Arsenazo I, $T > A > S > G > W > X > B > Y > L$ for Arsenazo III and $T > G > S > A > W > B > Y > X$ for Chlorophosphonazo III.

A study on the dependence of colour functions on the optical path length showed that all of them, except hue, change proportionally with the increase in the optical path, but the proportionality coefficient does not correlate with the molar coefficients of these functions. In addition, the sign of the change in a CF does not always coincide with the sign of its molar coefficient. These anomalies are explained [63] by the existence of complex non-linear relationships between the CF. Thus, the CF should be measured at the same layer thicknesses rather than be referred to 1 cm, as is common in photometry according to the Bouguer – Lambert – Beer law.[64] The main chemical-analytical characteristics of complexes in solutions used for the determination of metals by the chromaticity method are listed in Table 3.

A study of indium complexation with PAR,[66] PAN [67] and 5-Br-PAAP [68,69] showed that the CF depend linearly on the In content in the same concentration range (0.07 – 0.53 μg ml^{-1}) as in a study by the DRS method.

Eriochrome cyanine R (ECR) was used for the determination of trace amounts of aluminium [70–72] and beryllium [73,74] by DRS and chromaticity methods. Study on the effect of the sorbent nature on the sorption of complexes showed that the sorption ability of aluminium complexes increases in the following series of sorbents: AV-17 × 8 < silica gel < Chromaton-N-Super < cellulose. The sensitivity and reproducibility are better for colour functions than for the diffuse reflectance coefficient. The sensitivity of functions in the aluminium determination decreases in the series $G > Y > L > B > W > S > A > R$ for Chromaton-N-Super and $G > Y > B > L > S > W > A > R$ for cellulose.

Table 3. Chemical and analytical parameters of complexes in solutions in metal determination by chromaticity ($c_{min} = 0.1$ mg litre^{-1}).

Reagent	Element	pH	CP [a] range /mg litre^{-1}	Ref.
PAR	La	8.1 – 8.9	0.4 – 2.0	61
	Nd	8.0 – 9.0	0.4 – 2.0	61
	Sm	8.3 – 9.1	0.4 – 2.0	61
	Tb	8.0 – 8.6	0.4 – 2.0	61
	Dy	8.0 – 9.0	0.4 – 2.0	61
	Ho	8.5 – 9.1	0.4 – 2.0	61
	Er	8.0 – 9.5	0.4 – 2.0	61
	Yb	7.0 – 8.0	0.4 – 2.0	61
Arsenazo I	Er	6.0 – 8.5	0.4 – 2.4	63
Arsenazo III	Er	2.5 – 4.5	0.4 – 1.6	63
Chlorophosphonazo III	Er [b]	2.0 – 5.0	0.025 – 0.800	63
Lumogallion	Mo^{VI}	2.0 – 3.5	0.23 – 0.90	65
Magnezone	Mo	2.0 – 4.9	0.23 – 0.90	65

[a] CP is the linear region of the calibrating plot; [b] $c_{min} = 0.01$ mg litre^{-1}.

Beryllium interferes in the determination of aluminium; however, the beryllium – ECR complex is not sorbed by cellulose, which allows selective determination of aluminium in the presence of beryllium. The detection limit for aluminium with cellulose as the sorbent was found to be 0.004 mg litre^{-1}. The procedures developed were used for the determination of aluminium in natural water and in sodium acetate.

The complexation of nickel with dimethylglyoxime (DMG) and benzyldioxime (BD) was studied.[75] The complexes obtained were sorbed on silica gel. It was found that the optical and chromaticity characteristics form the following series in terms of determination sensitivity for nickel: $R < S < A < L < Y$ for SG – BD – Ni and $R < L \approx S < A < Y \approx T$ for SG – DMG – Ni.

Thus, the diffuse reflectance coefficient is the least sensitive colour function of coloured immobilised nickel complexes. The highest error of nickel determination is observed if the chromaticity coordinate *A* and saturation are used. The sorption of nickel complexes with DMG and BD on microcrystalline cellulose (MCC) was also studied.[76] It was found that the sensitivity of the CF increased as follows: $R < B < G < L < S < T < A < W = \Delta E < Y$ for MCC – DMG – Ni and $R < B < S < L < T < A < W = \Delta E < G < Y$ for MCC – BD – Ni.

One can see that if MCC is used, a greater number of the CF depend linearly on the nickel concentration and the order in the sensitivity series changes. Simultaneously, the detection limit becomes lower.

The CF of molybdenum(VI) complexes with *o*,*o*′-dihydroxyazo compounds [lumogallion (LG) and IREA Magnezon (MG)] and with heterocyclic azo compounds (PAR, 5-Br-PAAP) in the presence or in the absence of a third component (hydroxylamine) were determined.[65] In all cases, the three-component systems are not inferior, and in most cases superior, to two-component systems with respect to optical characteristics.

Microquantities of Co^{II}, Ni^{II}, Fe^{II} and Fe^{III} in the form of complexes with nitroso-R-salt (NRS) were determined by measurement of chromaticity coordinates of a membrane filter after concentration of metal complexes on it; the detection limits were 0.1 – 0.4 μg.[77] This reagent was also used to find conditions for the separate determination of Fe^{II} and Fe^{III} ions (see Ref. 78). The chemical and analytical characteristics of adsorbed metal complexes determined by the chromaticity method are listed in Table 4.

Three-coordinate chromaticity was used in a study of the behaviour of the $Fe(bipy)_2(CN)_2$ complex (where bipy indicates bipyridyl) in 17 different organic solvents.[81] The chromaticity

[a] Indium oxide was used as the subject of the study; [b] 1-(2-thiazolylazo)-2-naphtol; [c] natural water was used as the subject of the study.

coordinates allow one to compare all spectral changes occurring in a system on going from one solvent to another. In particular, the hue was used as the basic characteristic. Equations relating the T values with the acceptor numbers of the solvents (AN), the Dimroth–Reichardt parameter (Et) and the Kosover parameter (z) were found:

$$AN = (-29.15 \pm 3.68) + (0.20 \pm 0.01)T, \quad (17)$$

$$T = (151.66 \pm 8.79) + (4.71 \pm 0.30)\,AN, \quad (18)$$

$$T = (73.29 \pm 58.24) + (75.55 \pm 1.22)Et, \quad (19)$$

$$T = (167.02 \pm 55.89) + (6.15 \pm 0.77)\,z. \quad (20)$$

The results obtained make it possible to predict the acid–base properties of solvents based on the hue.

Thus, the chromaticity method provides a considerable increase in the determination sensitivity of microquantities of metals, especially if pre-concentration is used. In view of this, it would be of interest to survey the chromaticity characteristics of complexes used in analytical chemistry, first of all, in photometry. Based on this systematisation, one could try to find regularities of the effect of the reagent structure on chromaticity functions (as has already been made in photometry [42]) in order to select the most valuable organic reagents and hence to develop new determination procedures. In our opinion, this task is made much easier owing to the fact that, with rare exceptions, the optimum complexation conditions found by optical methods (including DRS) coincide with the optimum conditions for chromaticity analysis.

4. Increasing the determination selectivity of metal ions

Photometric methods are promising for the determination of mixtures of elements which form complexes with the same reagent either under different conditions (pH, temperature) or with different positions of their light absorption maxima. In the latter case, derivative spectrometry or two-wave spectrometry is used. Sometimes, this lowers the detection limit;[82] the latter can also be lowered by pre-concentration of complexes, including coloured compounds, on various sorbents or by changing the method for signal recording (for example, DRS). The greatest effect is usually achieved by a combination of analytical procedures with selection of the method for signal recording. However, selective signal recording is still an issue of topical interest.

On the other hand, the chromaticity method makes it possible to increase the determination selectivity of metal ions. For example, the chromaticity method enables separate determination of microquantities of copper and zinc in water after concentration by sorption on SG–PAN.[83] The equations for the calculation of the content of metal ions are derived using vector addition of the analytical signals

$$\Delta A_\Sigma = \sqrt{\sum_i \Delta A_i^2}\,, \quad (21)$$

where ΔA_i is the colour difference with respect to lightness (ΔL), saturation (ΔS) or shading (ΔE). This set of fourth-order equations is solved by the decahotomy method using the SVI.LAB program created by Morozko and Ivanov,[83] which allows determination of no more than two metals based on the total change in the chromaticity coordinates of a sample. Quite satisfactory results were obtained; however, determination of copper and zinc should be carried out in separate aliquots of the test solution.

In a development of this approach, the possibility of separate determination of cobalt and palladium in mixtures after concentration by chromaticity analysis with subsequent calculation of the amounts of these metals using the equations by Ivanov *et al.*[79] was studied. Cobalt and palladium were chosen due to the anomaly of the colours of their complexes with PAN (green to bluish-green) in comparison with complexes of other elements (reddish-violet) rather than by the similarity of their chemical and analytical properties, and also because they can be used to demonstrate the advantages of chromaticity as an analytical method.

Due to the closeness of the absorption (reflection) maxima of both complexes, cobalt and palladium cannot be determined separately by the DRS method because of overlap of the signals. Therefore, the effect of the sorption conditions on their chromaticity characteristics was studied.

Heterocyclic azo compounds immobilised on silica form green complexes with cobalt and palladium which differ in hue (yellowish-green and bluish-green, respectively). Recording of the colour change *versus* the content of metal ions in a solution with the use of the chromaticity coordinates A and B provides the possibility of using these differences for the separate determination of the ions in a mixture by measuring the signal at one wavelength. For example, Fig. 10 shows such dependences for complexes adsorbed on SG–PAN. If the absolute content of a metal ion in the solution (and, hence, in the sorbate) increases, the chromaticity coordinates of the sorbate surface change proportionally; the saturation point of the sorbate with respect to each metal does not change upon further increase in concentration of the corresponding ion in the solution.

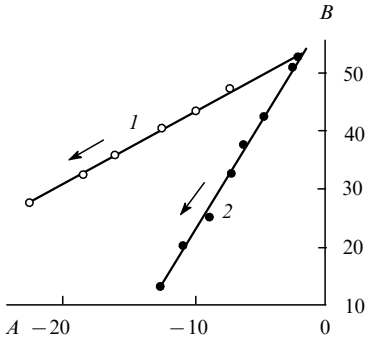

Figure 10. Effect of cobalt (*1*) and palladium (*2*) concentration on the chromaticity coordinates A and B of sorbates on SG–PAN at pH 3.[79] The arrows show the increasing metal concentration.

The equations derived for the change in the chromaticity coordinates of the sample (Table 5) are used to find conditions for separate determination of metal ions in solutions. It was suggested to use the signal separation factor (α) as a measure of completeness of separation; it is calculated using the following equations:

$$\begin{aligned} &\alpha = |\operatorname{arctg} K_{M_1} - \operatorname{arctg} K_{M_2}|, \\ &\text{if } |\operatorname{arctg} K_{M_1} - \operatorname{arctg} K_{M_2}| < 90^\circ; \\ &\alpha = 180^\circ - |\operatorname{arctg} K_{M_1} - \operatorname{arctg} K_{M_2}|, \\ &\text{if } |\operatorname{arctg} K_{M_1} - \operatorname{arctg} K_{M_2}| \geqslant 90^\circ, \end{aligned} \quad (22)$$

where K_{M_1} and K_{M_2} are the slopes of plots of the chromaticity coordinates A and B of the sorbent on the concentration of metal ions M_1 and M_2, respectively.

The magnitude of α is affected by the error of determination of the analytical signal (chromaticity coordinates). It was found experimentally for the Spectroton colorimeter that separate determination of two metals is satisfactory for $\alpha \geqslant 25^\circ$.

For all of the sorbents studied, dependences of the chromaticity coordinates A and B on the content of cobalt and palladium in solution were obtained and the following signal separation factors were found:

Sorbent	SG–PAN	SG–PAR	SG–TAN	SG–TAR
α	27°	21°	20°	15°

Table 5. Chromaticity coordinates of cobalt(III) and palladium(II) complexes on the sorbent surface.

Ion	Reagent	Equation of the sorbent colour change	Range of the sorbent colour change,[a] $(A_i, B_i)-(A_j, B_j)$	Saturation point /μg of ion
Co^{III}	TAR	$B = (28 \pm 0.1)A + (28.3 \pm 0.7)$	(7.0, 48.0)–(−7.5, 8.0)	10.97
	TAN	$B = (1.8 \pm 0.05)A + (29.5 \pm 0.4)$	(−0.5, 28.5)–(−14.0, 4.0)	18.00
	PAR	$B = (4.7 \pm 0.1)A + (19.6 \pm 0.3)$	(1.3, 25.5)–(−2.5, 8.0)	8.40
	PAN	$B = (3.9 \pm 0.05)A + (62.3 \pm 0.2)$	(−2.5, 52.5)–(−12.5, 13.0)	18.00
Pd^{II}	TAR	$B = (1.15 \pm 0.05)A + (38.5 \pm 0.5)$	(7.0, 48.0)–(−18.0, 11.0)	21.10
	TAN	$B = (1.1 \pm 0.1)A + (30.1 \pm 0.6)$	(−0.5, 28.5)–(−19.0, 9.0)	21.00
	PAR	$B = (1.5 \pm 0.1)A + (23.7 \pm 0.1)$	(1.3, 25.5)–(−10.0, 8.5)	13.10
	PAN	$B = (1.2 \pm 0.05)A + (55.6 \pm 0.2)$	(−2.5, 52.5)–(−14.0, 4.0)	35.60

[a] Saturation was used as the reference experiment.

It was concluded on the basis of the data obtained that the separation factor increases on going from thiazole azo compounds to pyridine ones and from resorcinol to naphthol. Only SG–PAN complies with the criterion of satisfactory separation ($\alpha \geqslant 25^\circ$). So this sorbent was chosen for the concentration of cobalt and palladium followed by their determination by the chromaticity method.

The concentrations were calculated using the following set of equations:

$$\Delta L_\Sigma^2 = (a_{11} + b_{11}x_1)^2 + (a_{12} + b_{12}x_2)^2,$$
$$\Delta S_\Sigma^2 = (a_{21} + b_{21}x_1)^2 + (a_{22} + b_{22}x_2)^2, \quad (23)$$

where ΔL_Σ and ΔS_Σ are the lightness and saturation, respectively, for the sum of the two metals; a_{ij} and b_{ij} $(i, j = 1, 2)$ are the factors of the calibration plot for the dependence of the chromaticity coordinates A and B on the metal ion concentrations (see Table 5); x_1 and x_2 are the unknown concentrations of the cobalt and palladium ions, respectively.

This fourth-order set of equations has four different parameters (four x_1 and x_2 pairs) which, in the general, case satisfy the solution. The sets of equations were solved on a personal computer using the Newton method. The amounts of cobalt and palladium (in 20 ml of solution) were varied from 0.5 to 5.0 μg and from 2.0 to 20.0 μg, respectively. Satisfactory results of separate determination of these metals in model mixtures were obtained; they were close to the data of analysis by the DRS method on the SG–TAR sorbent.

Of the greatest interest is the possibility of increasing the selectivity in the determination of metal ions which form reddish-violet complexes, since it is impossible to determine individual metals in a mixture in this spectral region by other methods (DRS, SPS) without masking or separation. TAR was selected as the reagent.[80] The possibility of separate determination was studied for copper, nickel and zinc in the presence of iron and cobalt. The optimum conditions for the sorption of these metals are indicated in Table 4.

The detectability of colour changes depending on the content of metal ions in solution with the use of chromaticity coordinates A and B implies that it is possible to carry out separate determination of ions in two- and three-component mixtures. Figure 11 shows such dependences for sorbates of complexes on SG–TAR. The data obtained were processed by the least-squares method.

Based on the calibration plots for the dependences of the chromaticity coordinates A and B on the content of copper, nickel, zinc and cobalt, the following signal separation factors were found:

M_1-M_2	Cu–Zn	Cu–Ni	Zn–Ni
α	23°	13°	37°

One can see that the nickel–zinc pair satisfies the criterion of separate determination. It should be noted that copper interferes in the simultaneous separate determination of nickel and zinc,

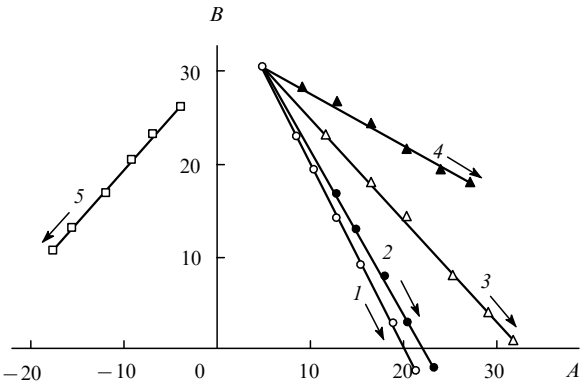

Figure 11. Dependence of the chromaticity coordinates A and B of sorbates on SG–TAR on the content of cobalt(II) (*1*), nickel (*2*), copper (*3*), zinc (*4*) at pH 7.0 and cobalt(III) (*5*) at pH 2.0.[80]
The arrows show the increasing metal concentration.

therefore it is masked with sodium thiosulfate. The ΔL and ΔS values obtained were used to calculate nickel and zinc concentrations using the set of Eqns (23).

Separate determinations of nickel and zinc in the presence of copper and cobalt were carried out similarly, except that the concentrations were calculated using a modified set of equations:

$$\Delta L_\Sigma^2 = (a_{11} + b_{11}x_1)^2 + (a_{12} + b_{12}x_2)^2 + d_1,$$
$$\Delta S_\Sigma^2 = (a_{21} + b_{21}x_1)^2 + (a_{22} + b_{22}x_2)^2 + d_2, \quad (24)$$

where x_1 and x_2 are the unknown concentrations of nickel and zinc ions, respectively; d_1 and d_2 are constants describing the contribution of cobalt to the set of equations.

The contribution of cobalt was estimated by determining its content at $\lambda = 610$ nm. The procedures described above were used to determine nickel, zinc and cobalt in a standard soil sample SP-3.

The above version of chromaticity analysis allows separate determination of 0.03–0.30 μg ml^{-1} cobalt and 0.013–0.130 μg ml^{-1} palladium, as well as 0.05–1.00 μg ml^{-1} nickel and 0.15–5.00 μg ml^{-1} zinc. The advantages of chromaticity for increasing the selectivity of determination of metal ions in two-, three- and four-component mixtures have been shown.

IV. Practical applications of the chromaticity method

1. Application of the chromaticity method in chemical analysis

Let us dwell on the most interesting practical applications of chromaticity. At present, the test procedures are becoming more and more popular. A test metal ion is usually identified by the colour of a complex it forms with a test reagent.[84] In the case of

acid – base indicators, the colour change upon decrease or increase in the medium pH is recorded. General-purpose test paper (pH 1 – 10) or reactive test papers used for qualitative and semi-quantitative analysis can serve as obvious examples.[84, 85] A colour change of the paper (sorbent) after a reaction indicates the presence of the ion in question in the test solution. Only the colour change is usually observed while the laws of this process are not recorded.

Construction of calibration test scales for the visual determination using the known dependence of the total colour difference (ΔE) on the content of the test element allows minimisation of inaccuracy of a test technique and quantitative description of not only the intensity but also of the colour change. Since one colour discrimination threshold corresponds to one ΔE unit in the equicontrast colorimetric system (*CIELAB*), the concentrations of the test element are chosen in accordance with a certain ΔE step to be determined most precisely by a human eye.

Even before the equicontrast *CIELAB* system had been developed, it was noticed that the difference in intensity of luminous fluxes is felt reliably if they differ by approximately 10% (see Ref. 6). The total colour difference is measured in the range of 0 – 100 arbitrary units, hence 10% corresponds to a step of $\Delta E = 10$. If colour is to be recognised from the surface of a reactive paper (sorbent) by a human, it is recommended to create test scales with $\Delta E \geqslant 10$ (see Ref. 86).

If a test sample loses its own colour or discolours due to the analytical reaction and the colour of the test sample support is close to white (for example, in the case of silica), the test scale should better be constructed using the inverse quantity, *viz*., the whiteness of the test sample, $W = 100 - \Delta E$ (see Ref. 68).

The dependence of the variation of the W and ΔE parameters of a test sample on the content of the test microelement has the shape of a logarithmic curve.[59] Thus, for a constant step $\Delta E = 10$ the concentration of a given microelement in a test sample changes in a geometrical progression, which is often suggested for the construction of a visual test scale.[87] In this case, the total colour difference of 10 arbitrary units between the original test sample (E_0) and a test sample following reaction of the microelement to be tested (E) is considered as the lowest determination threshold: $E - E_0 = 10$ (or $W - W_0 = 10$).

It was shown convincingly that the use of heterocyclic azo compounds immobilised on various sorbents makes it possible to achieve low detection limits in sorption-spectroscopic analyses in combination with high sensitivity and good reproducibility of results. In some cases, selective express techniques for the determination of microelements can be created using such reagents.

According to the general ideology of test methods for the environmental control, three basic rules were used as a guide in the development of sorption-spectroscopic procedures.[86]

1. The identification and determination of microelements in the environmental objects should be carried out quickly. This is achieved by comparing the indicator test sample with a standard scale.

2. It is necessary to provide the documentation of the test or the possibility of performing post-instrumental chemical analysis, which is realistic only for stable test samples.

3. The reactions should be contrasting.

The chromaticity method allows one to create an equicontrast chromaticity test scale well discernible by the human's eye. Based on the functional relationship between ΔE and the content of a test element in an object with a colour difference threshold $\Delta E \geqslant 10$, it is possible to construct a calibration test scale with a minimum error. Therefore, the descriptions of sorption-spectroscopic determination procedures involve the $\ln(\Delta E) = f(c)$ dependences in a mathematically processed form.

The non-selective colour difference parameter based on lightness (ΔL) is applicable for the post-instrumental determination of the content of a microelement in a test sample, provided that the chemical reactions which can be used for the sorption-spectroscopic analysis occur selectively and the reaction products are extracted quantitatively. The latter can be predicted to a certain extent based on the regularities of the sorption extraction of reagents by sorbent surfaces that we have studied.

The potential of the chromaticity method with the use of chromaticity coordinates is demonstrated in this study (Ref. 86) for the development of selective sorption-spectroscopic procedures for the separate simultaneous determination of cobalt(III) and palladium(II), copper(II) and zinc(II) using TAR immobilised on silica gel (SG – TAR). The capacity of the sorbent with respect to the reagent determined from saturation curves for metals was 20 μmol g^{-1} (see Refs 79, 80).

An advantage of the sorption version of testing is that it allows one to change the sensitivity of determination of a microelement by varying the sample volume, which is impossible if reagent test papers are used.

When a coloured compound formed and the sorbent sedimented, its colour was compared with the standard calibration colour scale for microelement determination, using the step $\Delta E = 10$ for making the test scale. The sorbates for the test scale were placed in test tubes with a diameter of 4 mm. The test scale obtained in this way is stable for at least five years.

2. Application of the chromaticity method in other fields of science and industry

a. Food chemistry

The greatest number of studies deal with the use of the chromaticity method for monitoring the production of foodstuffs, quality of cultures grown and in wine-making.

The effect of the growth conditions (greenhouse or open air) of hot pepper on its chromaticity characteristics[88] showed that the amount of pigments in pepper grown in a greenhouse can be predicted using the chromaticity coordinates A and B and the ratio A/B. For pepper grown in the open air, a similar correlation is observed for the values L and A/L.

The *CIELAB* system was used to estimate the quality of tomatoes,[89] tinned mushrooms[90] and potato chips.[91] It was found that the angle between the coordinates A and B depends on the colour of vegetables. A similar correlation with the L coordinate is not always observed. In particular, a study on the darkening of cut-off lettuce *versus* time[92] did not show such a dependence.

The *XYZ* chromaticity system can be used to classify honeys[93] and to estimate the natural sweetener from the cactus tree.[94] In this case, some other characteristics (viscosity, glucose content, *etc*.) were used along with the chromaticity coordinates. The chromaticity coordinates were also used to monitor production of sausages,[95, 96] in particular, to study the effect of the content of soybean proteins on the colour characteristics of the product.[95]

The three-coordinate colour system was used to study the first phase of milk turning[97, 98] and to estimate the colour of milk prepared from powder.[99] A theory allowing the preparation of emulsions with certain colour characteristics has been developed.[100] In this case, the chromaticity coordinates are calculated from the diffuse reflectance coefficient (R). The theoretical calculations are in good correlation with the experimental results. The variations of the chromaticity characteristics of soybean milk during the grinding of soy beans have also been studied.[101]

The chromaticity systems *CIEXYZ*, *CIELUV* and *CIELAB* were successfully employed for the characterisation of anthocyans isolated from red grapes,[28, 102] raspberry[103] and strawberry.[104] The effect of an atmosphere enriched with carbon dioxide on the decomposition of strawberry after harvesting was studied.[104]

Two hundred and twenty four model solutions of cyanine copigmented with rutin were studied. The procedure is based on measurements of the total colour difference and the copigment : pigment ratio. The strongest effect is reached at pH 3 – 5 and low copigment : pigment ratio (1 : 1).[105] The chromaticity system *CIELAB* is the best to describe the colour changes observable by a human eye.

The kinetics of colour changes in apples, bananas, beets and potatoes in the course of drying (convective and vacuum drying at 50, 70 and 90 °C) was studied.[106]

The effect of pasteurisation on the chromaticity characteristics of grapefruit juice [107] and pear juice [108] was studied. It was shown that the strongest changes are observed for the saturation and the chromaticity coordinate *B*, in particular, this allows one to monitor the decrease in the content of vitamin C and the discoloration of orange juice during storage at 4–24 °C (Ref. 109).

Two reviews are devoted to the spectrophotometry of wines.[110, 111] It was noted that the *CIELAB* chromaticity system is most promising as it allows one to create any colour scales, quickly compare the results of different operators in various flow points and is advantageous as it requires simple equipment. For port as an example, the effects of temperature, pH, sugar content and time on the colour characteristics of wines was studied.[111, 112] A simpler method for the calculation of the chromaticity coordinates of white, red and pink wines and brandy [27, 33] based on the measurement of the reflectance signal at three fixed wavelengths (440, 540 and 610 nm) was suggested. The method was tested for 690 wine samples.

The effect of pH and content of anthocyans on the chromaticity characteristics of a number of wines was studied.[113–117] Satisfactory correlations were found between the degree of ionisation of anthocyans and the wavelength of absorption maximum (λ_{max}) and between the degree of ionisation of anthocyans and the colour intensity.[114] It was noted that a decrease in the medium acidity increases the colour intensity and the degree of ionisation of anthocyans.[113]

The effect of pretreatment of red table wine with sulfur dioxide on their colour, phenolic composition and quality was studied.[118] It was shown that wines untreated with SO_2 darken faster than the treated wines.

b. Textile industry

The chromaticity method is used for the selection of colours in the dyeing of natural and synthetic fibres, for the control of fading of coloured cloths and fibres and for monitoring the formation of brown spots on paper-based materials.

The observed colours are produced by subtractive and additive methods. In subtractive synthesis, colour appears due to selective absorption of a portion of radiation from a light beam falling on an object. This occurs upon successive passage of a light beam through a series of differently coloured media (for example, colour films) or upon passage of light through a solution containing several dyes. Subtractive synthesis is the basis of the modern methods of colour photography, cinematography and three-colour printing. Required colours of materials formed by several dyes are obtained using this method.

The subtractive synthesis method makes it possible to blend various colours by using triads of dyes whose colours correspond to three linearly independent colours in various ratios. The painting compounds most suitable for these purposes have yellow, light-blue and purple colours. A particularly wide scale is obtained in the case where these are 'ideal' colours. A characteristic feature of the spectra of such dyes is that radiation of each of the three spectral zones is either absorbed completely or transmitted completely. The dyes that have such spectra are ideal for various processes of colour reproduction and allow one to blend virtually any colour.

If real dyestuffs are used, their transmission spectra are characterised by the absence of complete transmission in any of the zones, and the palette of the colours obtained becomes narrower and reproduction of high-purity colour is impossible. Therefore, a number of studies was devoted to the development of dyes the properties of which approached those of ideal dyes.

Several regression models for the optimal selection of dyes for various fibres have been developed.[20, 22, 119, 120]

Three 9-phenylxanthene derivatives were synthesised and used for dyeing polyacrylonitrile and polyamide cloths. All of the products were subjected to chromaticity characterisation.[121] Aqueous extracts of black tea were used for dyeing cotton and jute fibres.[21] The fibre colours were monitored using the *CIELAB* system.

The effect of the solvent system $CCl_3COOH-CH_2Cl_2$ on the ability of cotton yarn to undergo dyeing was studied. The chromaticity characteristics of dyes were studied by varying the concentration and duration of treatment of yarn with the solvent.[122]

A number of natural dyes were used for the colouring of synthetic fibres (polyester, nylon, acrylic and acetate fibre).[123] It was noted that the fibre colour saturation increased with the increase in the treatment temperature and this effect is especially strong in the case of nylon fibres.

The dependence of the chromaticity characteristics of nylon fibres on the conditions of its heating was studied.[124] The temperature was varied from 150 to 180 °C; the time was varied from 2 to 10 h.

The resistance of 15 dyes for cotton fibres and their mixtures to fading was studied.[125] The samples were irradiated with a xenon arc lamp. It was shown that the fibres dyed with a combination of dyes always faded less than the samples dyed with just one dye.

The effect of pH of the starting cochineal solution on the chromaticity characteristics of fibres was studied.[126] The pH values were set using solutions of hydrochloric, sulfuric, nitric and phosphoric acids. It was found that the chromaticity coordinate *B* decreases with the increase in pH of the starting solution; in addition, the coordinates *L*, *A*, *B* decrease regularly on storing the solutions from 1 to 21 days. This effect was most pronounced if phosphoric acid was used for setting the pH.

New synthetic polyoxyalkylene–polyurethane water-repellent fibres were obtained.[127] Polarising fibres from poly(vinyl alcohol) which possess constant light absorption in the visible region were described.[128] Such fibres can be used for making liquid-crystal displays and polarising screens.

The so-called fluorescent (or optical) whiteners are known, *i.e.*, compounds that absorb radiation with wavelengths of 340–400 nm and transform it into radiation with wavelengths of 415–466 nm (in the visible region of the spectrum). Depending on the wavelength of the absorbed light, fluorescence of different colours is observed, *viz.*, violet (the fluorescence maximum is observed at 415–429 nm), dark blue (at 430–440 nm) and light-blue (at 466 nm). The most popular optical whiteners have light-blue fluorescence (radiation with wavelengths of 400–500 nm). Unlike optical whiteners, fluorescent dyes absorb light in the visible spectrum region, like ordinary dyes. As a consequence of fluorescence of dyes, their brightness increases. Optical whiteners are used like ordinary dyes and are often referred to as white dyes.

White paper, cellulose and other cloths and fibres partially absorb light in the shortwave part of the spectrum and thus become yellowish. If optical whiteners are applied on such yellowed objects, the former radiate light with wavelengths of 400–500 nm and hence compensate for the absorbed part of visible light and complement the spectrum of the reflected light. As a result, the degree of whiteness of the objects increases, *i.e.*, an optical (fluorescent) whitening effect is observed. Optical whiteners are widely used for whitening natural and synthetic materials (cotton, wool, viscose, hair, silk, cellulose acetates, polyamides, polyurethanes, polyacrylonitrile, polypropylene, polyester), paper, plastics, for improvement of colour of dyed cloths, *etc.* The *CIELAB* system was used to study the reasons for the appearance of brown spots on materials based on paper (ancient books, paintings).

Optical whiteners are added to washing powders and compositions for dry cleaning. They should have good light resistance, resistance against acids and bases, oxidants and reducing agents and should not form complexes with metals. Bleaching with such substances is similar to dyeing with direct and acid dyes: cellulose fibres are treated with suitable optical whiteners in neutral or weakly alkaline media, while polyamide fibre, silk and wool are

treated in weakly acidic media. Dispersion whiteners are used for polyester and acetate fibres, and cationic whiteners, for polyacrylonitrile fibres.

The synthesis and properties of some unsubstituted triazinylstilbenes as fluorescent whitening agents were described.[129] The spectral and thermal characteristics, the whitening effect for cotton and the chromaticity coordinates were determined. Fluorescent dyes based on naphthalene-1,8-dicarboxylic anhydride suitable for the dyeing of polyamide fibres and epoxy resins were synthesised. The relationship between the dye structure and the colour characteristics was discussed.[130]

The effect of fluorescent additives on the colour saturation of fibres was studied.[131] For this purpose, a cotton fibre was dyed using eight dye types with five various saturation levels. The fibres obtained were treated with two types of fluorescent additives. It was shown that the addition of fluorescent compounds increased the saturation of red and dark blue hued fibres and decreased that of yellow hued fibres.

The total colour difference was used to characterise a coated antibacterial polyester fibre.[132]

A new composition based on esters was suggested for dry cleaning of cotton cloths.[133] The efficiency of laundry disks in the removal of spots from cotton and polyester fibres with the use of detergents in the absence of water was studied.[134] It was shown using chromaticity characteristics that these detergents are not superior to the compounds used for 'wet cleaning'.

c. Geochemistry and mineralogy

The *CIELAB* system allows one to distinguish the hues of precious stones (the alexandrite effect).[135] Depending on the hue, precious stones can be grouped as follows: type 1 — alexandrite, fluorite, spinel, tourmaline; type 2 — glass; type 3 — sapphire; type 4 — garnet. Such functions as lightness and saturation can be used for documentary characterisation of the differences observed.

The microscopy and photometry of ores over the period of 1890–1998 was reviewed.[136] In particular, it was emphasised that identification of ore materials includes plotting of chromaticity diagrams as an obligatory stage.

The chromaticity characteristics of a rare sulfide deposit with the composition Cu_5FeS_6 were obtained.[137]

The chromaticity coordinates ware applied to determine the nature of the colour of the Mozambiquean beryls. It was found that the green colour appears due to the presence of chromium ions in the aluminium crystal lattice, while the purple colour is due to the presence of manganese ions.[138]

A method for non-destructive determination of metal corrosion products with the use of the chromaticity characteristics of the *CIELAB* system was suggested.[139] Studies of alloys based on copper, zinc and aluminium showed that an increase in the content of zinc and aluminium first increases the lightness and yellowness to a certain value and then decreases these values.[140, 141] The results obtained have enabled the creation of differently coloured alloys, *viz*., copperish-red, goldish-yellow, brown, purple and, finally, silverish-grey.

The colour characteristics have been utilised for the description of protective and decorative coatings from chromium and titanium[142–144] and for painted steel panels.[145]

d. Production of glasses and ceramics

The chromaticity characteristics were used to control the colour range of glasses[146–149] and ceramics.[150–152] Twenty five antique glass samples were studied. It was shown that the three fragment types, *i.e*., bluish-green, light-blue and yellowish-green, result from the combinations $Fe^{II}-Fe^{III}$, $Fe^{II}-Co^{II}$ and $Fe^{II}-FeS$, respectively.[148] It was suggested to make grey and bronze glasses[149] by using combinations of such additives as Co_3O_4, Nd_2O_3 and V_2O_5, MnO_2, Er_2O_3. The resulting glass colour was monitored using chromaticity characteristics.

A series of studies was devoted to the effect of temperature–time modes on the synthesis of pigments.[23, 150–153] It was found that the heat treatment temperature is the most important factor determining the colour of the pigments obtained. An optimal temperature should hinder the formation of colourless or weakly coloured compounds. The formation of significant amount of a glassy phase resulting in dissolution of coloured crystal phases is also undesirable.[23, 150–152]

A procedure for the preparation of ceramics by coprecipitation of hydroxides was suggested. The particle sizes of the resulting polymeric hydroxides are comparable to those of colloid species. Such compounds can be transformed into ceramics of a certain colour at lower temperatures compared to those employed in the oxide technology.[152]

A study on the effect of temperature on the colour stability of series of differently coloured ceramic samples showed that the yellowish-brown ceramics are most unstable.[24]

e. Pharmacology and fabrication of cosmetics

In the pharmaceutical industry, chromaticity is used as a reliable method to control the production of dental compositions, to check the uniformity of coatings on pills, *etc*. For example, the hue of silver-containing alloys was made similar to the colour of human tooth enamel by adding cerium dioxide, which discolours silver, to the alloys. The addition of 0.1% CeO_2 causes an essential (threefold) discoloration of the alloys without any loss of strength.[25]

The relationship between the colour of dental cement and paste was studied using chromaticity characteristics.[154] Metal ceramics for tooth crowns were created and characterised by chromaticity.[155, 156]

The value of total colour difference was utilised to control the uniformity of coatings on pills.[157]

The absorption and diffuse reflection spectra of structural isomers of riboflavin tetrabutyrates were obtained.[26] The specific feature of these compounds is that their colour characteristics in the solid state differ depending on the type of the structural isomer, whereas in solution, all of the spectra are identical. This is explained by intramolecular reactions occurring in the solid phase, which result in hydrogen bond formation. The chromaticity method allows one to distinguish one isomer from another.

Tinted powders for correction of face colour were created; they consist of micas covered with granular metal oxides (titanium, iron and their mixtures) and have definite values of the chromaticity coordinates.[158] Studies of the reaction of Methylene Blue with natural white mica and with synthetic sodium-type mica[159] showed that Methylene Blue reacts with both types of mica on heating in the absence of a solvent; as a result, the chromaticity coordinates change strongly (the purple colour changes to light-blue). The resulting compounds are water-insoluble due to immobilisation of Methylene Blue on mica.

Chromaticity characteristics were used to compare a number of sunscreens.[160]

f. Electronic industry, preparation of colour coatings, radio-engineering and photo-engineering

A series of studies dealt with the development of light-emitting diodes.[161–168] It was found that green sources provide a long life of electron-beam tubes and improve the radiating characteristics.[163] A chromaticity-based method for the correction of the electron-beam tube characteristics was developed.[164]

It was suggested to use bathocuproin[161] and triphenyl amine derivatives[169] as blocking layers for organic light-emitting diodes. The diodes were characterised by the chromaticity coordinates X and Y; it was proven on this basis that the source has pure red, dark blue or green radiation.[170–172]

New sources for three-coordinate chromaticity[173] containing red and green reverse lenses were created. Sources based on polymers and oligomers[174] cover a broad spectral range, *viz*., from dark blue through white to green. A series of powder radiation sources were synthesised.[175–178] The effect of the content of Sm^{III} (see Ref. 179), Zn^{II} (see Ref. 180) and Tm^{III} (see

Ref. 181) added to fluorescent powders on the chromaticity characteristics of irradiation was studied.

Resins based on an aromatic polyester with improved colour characteristics were created;[182, 183] the advantages of copolymers of *N*-vinylcarbazole and *N*-phenyl-2-(2-thienyl-5-vinyl)-5-(2′-thienyl)pyrrole were shown.[184]

The synthesis of new copolymers containing electron- and hole-conducting elements (oxadiazole and carbazole, respectively) and an irradiator (naphthalimide) was reported.[185] Their luminescence spectra were studied and the chromaticity coordinates were calculated.

A new process for obtaining a photographic image consisting of an absorbing dye and a sensitive dye was created; the dyes were selected in such a manner that their λ_{max} values were equal. This made it possible to improve the image characteristics in the red spectral region.[186] A uniform image in the blue spectral region was obtained using silver halide grains (95 mol.% AgCl).[187] A material containing photosensitive microcapsules that included fuchsine was used to form the purple layer of the photographic image.[188]

Coatings for steel sheets resistant against changes in weather conditions were developed;[189] they can be suitable for roofs, cars, doors and mechanisms. A mixture of yellow pigments for traffic signs with good reflection properties has been developed.[190] The theory and practice of colour measurement for powder coatings were covered in a review [18] which provided recommendations on controlling the colour of these coatings. A method for the creation of coloured powders by mixing dry powders was suggested.[191] Blending the required powder colour is simplified by plotting the colour diagrams.[192]

A computer-aided method for blending the colour of paints was reported.[193] The panels are coated with various mixtures of a colour and white paints; the reflection signal is measured, and the chromaticity coordinates are calculated. The values obtained are compared with those in a standard database. Such a technique simplifies the colour blending and increases its accuracy.

The optical properties of paint coatings formed on a surface depend on the nature of the pigment and the film-forming agent, on the volume concentration of the pigment and on the surface geometry.[19] The changes in the spectral composition of the light reflected by samples upon increase in their brightness due to application of a polymeric layer were estimated by changes in the optical characteristics in the *CIELAB* system (L, S, T, ΔE). Upon application of the first layer 10–20 μm thick, a sharp decrease in reflection coefficients and increase in lightness are observed; further increase in the layer thickness affects these characteristics only slightly. For light-blue and light-green coatings, the hue decreases continuously with the increase in the layer thickness: the colour vector turns clockwise. The hue of orange samples remains unchanged. This results from the fact that light dispersion is stronger in the short-wave spectral region.

V. Conclusion

Over many years, the progress in colour-measuring systems was restrained by the low technological level. Therefore, simultaneously with development of the equicontrast colorimetric system (*CIELAB*) by the International Commission on Illumination, colorimetric instruments and calculation methods were created which made it possible to record colour and use colour measurements in the analysis. Today, the chromaticity method, especially combined with computer programs for processing spectral data, has become widely popular in polygraphy and in the paint, textile, glass, pharmaceutical and food industries and in a number of other branches of industry.

One can hope that the chromaticity method will be used more widely in analytical chemistry, especially in the cases where the analytical signal is directly related to the colour of the compound to be determined, for example, in the approximate evaluation of the content of a compound from the colour intensity. Test methods, which basically do not require complicated instruments, are promising for fast batch analysis. The use of chromaticity systems which approach as much as possible the colour characteristics of human vision should favour the development of express analysis methods.

In our opinion, chromaticity will also be used more widely in spectroscopic analysis, since the use of optical radiation as the information carrier seems to be undoubtedly promising.

Along with broadening of the scope of the method, one should note two important directions of its development. First, these are studies devoted to the methodology and metrology of the chromaticity processing of spectra, as well as development of the theoretical basis. Publications on this topic have already appeared.[194–196] Second, broadening of the scope of chromaticity can serve as an impetus for improvement of the available instruments and development of new ones and for the creation of databases and software.

Abstract. Modern modifications of the conventional X-ray methods of physicochemical analysis (X-ray and electron spectroscopy, diffraction methods, *etc*.) and new combined techniques using X-ray synchrotron radiation are considered. Unique characteristics of synchrotron radiation are noted, namely, continuous spectrum, exceptionally high intensity, polarisation, coherence, pulse nature, *etc*. The key trends in the use of combined methods in chemistry and materials science including studies of substances under extreme conditions, the study of rapid processes, studies with high spatial resolution are discussed. The achievements in the applications of synchrotron radiation are illustrated by examples from various fields of chemistry and related sciences. The bibliography includes 405 references..

I. Introduction

Development of modern science relies to a great extent upon the set of available investigation tools. Many methods of physicochemical analysis commonly applied in chemistry are based on interaction of a substance under study with electromagnetic radiation of various spectral ranges. Several independent groups of methods can be distinguished based on the spectral range used, *e.g*., infrared, visible, ultraviolet and X-ray radiation. Radiation in the required spectral range is usually generated using special sources (such as gas discharge tubes, lamps, lasers, X-ray tubes) characteristic of classical versions of each method. Each source type requires its own experimental methodology, which takes into account the specific features of the interaction of this radiation with matter.

Integration of natural sciences over the last decade of the XXth century affected the techniques of physicochemical analysis stimulating their convergence. A unified approach to the generation of electromagnetic radiation of different spectral ranges is based upon a fundamental principle of electrodynamics: the electromagnetic radiation is generated by a charged particle moving with an acceleration. In particular, electrons or positrons, which move along a curved trajectory in a magnetic field with a velocity close to the velocity of light, generate a flux of photons in a broad spectral range, *i.e*., synchrotron radiation (SR) (Fig. 1).

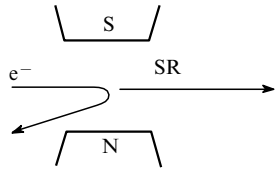

Figure 1. Generation of synchrotron radiation upon movement of an electron in a magnetic field.

Accelerators of charged elementary particles (typically, electrons or positrons) operating in a stationary regime of a storage ring can conveniently serve as powerful SR sources. In such large-scale facilities, ultrarelativistic electrons,† moving along a closed-loop orbit in an evacuated chamber of a storage ring with curvature radius of a few tens of meters, emit extremely intense electromagnetic radiation with a continuous spectrum ranging from far infrared to hard X-ray (Fig. 2). The energies of electrons in storage rings of different constructional designs can vary from hundreds of eV up to several GeV. Upon an incremental increase in the electron energy, the spectral maximum of the SR generated shifts from ultraviolet through hard ultraviolet (vacuum ultraviolet, VUV) and soft X-ray up to hard X-ray, respectively.[1–8]

Modern SR sources gradually become collective use research centres. Such centres accommodate up to a few tens of experimental stations, which function in the 24×7 mode shift by shift servicing specialists from various institutions and fields of science — from nuclear physics to molecular biology and materials science. Along with synchrotron modifications of established and widely accepted methods using traditional X-ray sources, unique purely synchrotron-based specialised techniques are rapidly developing. Applications of SR in industry are also expand-

† The term ultrarelativistic particles is commonly referred to those, the kinetic energy of which $E \gg m_0c^2$, where m_0 is the rest mass of the particle and c is the velocity of light. Velocities of such species are virtually constant and very close to the velocity of light; thus any increase in their kinetic energies leads to the increase in their relativistic masses.

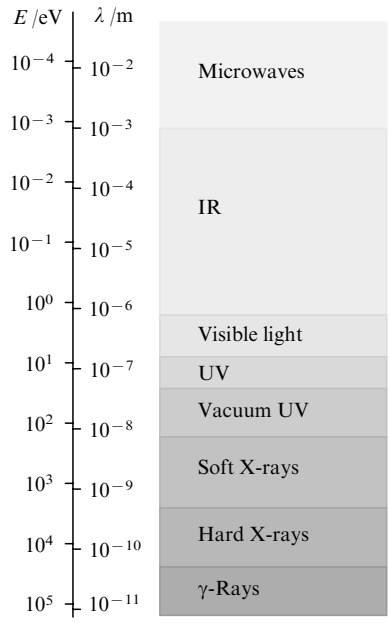

Figure 2. Spectral ranges of electromagnetic radiation, which can be generated by modern synchrotron radiation sources.

ing, in particular, in the manufacture of microelectronics (microchips, printed circuit boards, *etc*.) and micromechanics (micromotors, micropumps) devices. In this connection, applied industrial methods, such as deep X-ray lithography and LIGA technology (German acronym for a 3-stage technological process of microfabrication including lithography, electrodeposition and moulding), have made tremendous progress.[9] Medical applications utilising SR are evolving as well, especially ones aimed at early diagnostics and radiotherapy of various diseases, including cancer and at imaging of human internal organs and tissues with high contrast and spatial resolution (mammography, angiography, radiography).[10] Synchrotron techniques are successfully used in environmental studies, *e.g*., for detection of trace amounts of heavy metal pollutants in industrial wastes, aerosols, soils and in biological objects — plants, living tissues, *etc*.[11]

Currently, there are about 40 operating SR sources worldwide and more than 10 new sources are under construction. In Russia, starting from the late 70's, the Siberian Synchrotron Radiation Centre (SSRC) continuously functions on the basis of the VEPP-3 ‡ storage ring (2 GeV) at the G I Budker Institute of Nuclear Physics of the Siberian Branch of the Russian Academy of Sciences in Novosibirsk.[12] Recently, a new upgraded VEPP-4 storage ring (6 GeV) has been put into operation in the SSRC. Construction of a dedicated storage ring 'Sibir'-2' (2.5 GeV) has been finished at the Kurchatov Synchrotron Radiation Source (KSRS) in the Russian Research Centre 'Kurchatov Institute' in Moscow;[13] two new synchrotron centres in Dubna and Zelenograd are in the construction phase.

An important benefit of storage rings is their environmental safety,§ which distinguishes such facilities advantageously from, for example, neutron sources, *viz*., nuclear reactors. Even a major accident on an electron storage ring cannot result in any radiation pollution of the environment. Work at a synchrotron radiation centre does also not imply any health risk for researchers provided that they obey elementary safety rules and regulations.

All of the main methods utilising electromagnetic radiation are represented at the modern synchrotron radiation centres. A substantial organisational advantage of the SR sources is that all the state-of-the-art techniques and advanced instrumentation are concentrated in one centre and even in one building. This makes it possible to conduct comprehensive studies with the use of a broad range of complementary experimental techniques as well as stimulates mutual influence and integration of different experimental approaches and ideas.

This review is devoted to applications of SR in chemistry and related disciplines, *viz*., chemical materials science, biochemistry and molecular biology. Since it is virtually impossible to cover all modern trends in the SR applications, we have confined ourselves to discussion of only instrumental techniques based on X-ray part of the synchrotron radiation spectrum. For the same reason, we did not consider such technological applications of SR as X-ray lithography and the methods in which synchrotron radiation is used for triggering physicochemical processes, *e.g*., photochemical reactions and radiation-induced degradation (to get familiar with this field one may see, for example, Ref. 14, where synthesis of amino acids from a gaseous mixture of nitrogen, water and carbon dioxide at atmospheric pressure under irradiation by intense photon beams is described). For a detailed review of modern technological applications of SR see Ref. 15. Among non-X-ray synchrotron methods we should mention various types of UV spectroscopy [5] and synchrotron IR spectroscopy, which have been actively developed over the last years, especially its varieties with high spatial (microspectroscopy) [16] and time resolution.[17]

X-Ray-based instrumental techniques, which are most important for chemistry, include X-ray diffraction methods (in particular, single-crystal X-ray crystallography), X-ray and electron spectroscopy. In 'classical' laboratory versions of these methods, allowing detailed exploration of atomic and electronic structures of substances, traditional X-ray sources, *viz*., X-ray tubes, are used. However, synchrotron radiation sources have several significant advantages. Synchrotron X-ray beams are more intense than radiation of the high-energy X-ray tubes with rotating anodes by several orders of magnitude. Such a gain in intensity allows one to shorten the data acquisition time and investigate fine effects which would require very lengthy experiments with traditional sources. A considerable portion of energy emitted by an X-ray tube lies in a narrow spectral range (anode characteristic radiation), whereas the high intensity of synchrotron radiation is uniformly distributed over the entire X-ray spectral range. With 'white' synchrotron radiation, it is possible to select the wavelength most appropriate in each particular case or scan over a certain wavelength range during the experiment, which extends significantly the potential of traditional X-ray techniques. Yet another advantage of SR is relatively small cross-section and low divergence of X-ray beams, which can further be focused and collimated using X-ray optics. This approach is successfully applied in X-ray microprobe methods and in studies of substances under extreme ¶ conditions (it has to be mentioned, however, that focusing X-ray optics is now frequently used in laboratory devices as well). Pulse structure, polarisation and coherence of synchrotron radiation are other factors, which are of great interest and potential for applications.

II. Design of a storage ring and parameters of synchrotron radiation

1. Building blocks of a storage ring

A storage ring is an accelerator of charged light particles (electron or positrons) in which ultrarelativistic particles move along a closed-loop trajectory with velocity close to the velocity of light emitting an intense photon flux. The energy lost by electrons during each revolution as emitted radiation is compensated in a special electromagnetic acceleration system, *viz*., radiofrequency

‡ Russian acronym for electron-positron colliding beams.

§ In this respect, it is indicative that several storage rings are constructed in residential areas of large cities, *e.g*., BESSY (Berlin) and KSRS (Moscow).

¶ The term extreme condition refers here to the limiting achievable (high and low) temperatures and superhigh pressures, which are created using specialised instruments to apply to substances under study.

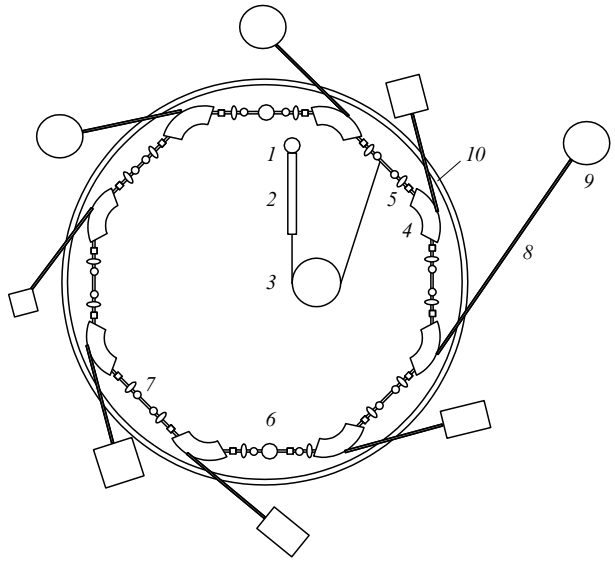

Figure 3. Design of a storage ring, the SR source: (*1*) is an electron gun, (*2*) is a linear preaccelerator (linac), (*3*) is a ring preaccelerator (booster), (*4*) is a bending magnet, (*5*) is a system of 'magnetic lenses', (*6*) is a radiofrequency resonator, (*7*) is a straight section suitable for accommodation of specialised insertion devices, (*8*) is a channel, (*9*) is an experimental station, (*10*) is a biological protection concrete wall.

resonator. The storage ring is designed to maintain a stationary regime of particles' movement rather than to generate a single pulse of particles with the maximum energy (as in the case of elementary particle accelerators in nuclear physics).

A storage ring includes the following indispensable components (Fig. 3):

— an electron source (*1*), which is, as a rule, a standard high-power electron gun based on the thermoelectric emission;

— a system for preacceleration and injection of electrons: linear (linac) (*2*) or ring (booster) (*3*) preaccelerators;

— a hollow torroidal chamber of the accelerator where the beam of ultrarelativistic electrons moves. High vacuum has to be maintained in this chamber (10^{-9}–10^{-10} Torr) in order to reduce energy losses of the electrons due to collisions with background molecules;

— a system of bending magnets (magnetic dipoles) (*4*), which define closed-loop trajectory of the electrons' movement. Between the bending magnets the particles move linearly. It is in the bending magnets that the synchrotron radiation directed tangentially to the beam trajectory is generated (see Fig. 1);

— a system of magnetic lenses (*5*), *viz*., magnetic quadrupoles and higher-order magnets, which is used for the electron beam focusing;

— an electromagnetic system (*6*) is used for the acceleration of electrons up to ultrarelativistic velocities as well as for compensation of energy losses due to emitted radiation (radiofrequency resonator);

— specialised magnetic devices (insertion devices) (*7*), *viz*., undulators and wigglers, are inserted in straight sections between the bending magnets. These devices are used for the generation of SR with enhanced characteristics compared to the bending magnet radiation. Though these are optional components of a storage ring, they are installed in the majority of modern storage rings;

— a biological protection concrete wall (*10*) adsorbs background radiation of the storage ring. Photon beams are guided by evacuated channels (*8*) through the biological protection wall to the experimental station (*9*), where experimental stations and all devices for investigations and other works based on SR utilisation are situated.

2. Design parameters of a storage ring and characteristics of synchrotron radiation

The main parameters of a storage ring as an SR source are as follows: the orbit radius R, along which the electrons move (in modern facilities, it is typically 10–30 m), electron energy E (1–6 GeV), magnetic field (B) in bending magnets (1–2 T) and their number and electron current I, which is an integral measure of the total number of electrons in the storage ring chamber (50–500 mA). These parameters are interlinked by the following relations:[4–7]

$$R = \frac{E}{eB}\,, \tag{1}$$

where e is the electron charge;

$$I = \frac{2\pi e N_e R}{c}\,, \tag{2}$$

where c is the velocity of light and N_e is the total number of electrons in the chamber.

The stability of an electron (or positron)† beam is characterised by a beam lifetime, which is the time required for the electron current to decrease by a factor of $\sim$2.7 (it corresponds to a decrease in $\ln I$ by unity). Beam lifetime depends primarily upon the vacuum quality in the chamber and can range from a few to a few tens hours. This governs the frequency of electron re-injections to the storage ring chamber required in order to maintain the intensity of SR at the appropriate level.

Design parameters of a storage ring determine the characteristics of SR it generates. Spectral distribution of the SR is commonly characterised by a critical wavelength λ_c or critical energy

$$E_c = \frac{hc}{\lambda_c}\,,$$

(h is the Plank constant); λ_c is chosen so that the total energy emitted by the source at the wavelengths longer than λ_c was equal to the total energy emitted at shorter wavelengths.

Size of a synchrotron radiation source is defined by the emittance ε; this quantity is the product of a linear size of the emitting area of the electron beam by the divergence angle of the photon beam. Typical values of the vertical and horizontal emittances of modern SR sources lie in the range of 10^{-10}–10^{-8} and 10^{-8}–10^{-6} m rad, respectively.

The intensity of SR is characterised by its brilliance, which is determined as number of photons emitted in 1 s from the emitting surface unity into the solid angle unity within the certain photon energy bandwidth (BW). Usually, the bandwidth is chosen to be equal to 0.1% of E_p (E_p is the photon energy), the so-called 0.1% BW. Thus, the unit of measure of the brilliance is photon s^{-1} mm^{-2} rad^{-2} (0.1% BW)$^{-1}$. Other intensity characteristics include spectral flux, which is obtained by multiplication of the brilliance by horizontal and vertical emittances, and total flux, which is obtained by integration of the spectral flux over the entire range of the wavelengths emitted.

Total power W emitted by the electron beam per revolution and the critical wavelength depend on the electron energy in the beam, electron current and the orbit radius:

$$W \sim \frac{I\gamma^4}{R}\,, \tag{3}$$

where $\gamma = E/m_0c_2$ is the relativistic (Lorentz) factor of an electron (m_0 is the rest mass of the electron) and

† Positron beams are used, for example, in the DCI storage ring (Orsay, France). The design of all storage rings in the SSRC (VEPP series) allows physical experiments using colliding electron–positron beams (which are accelerated in opposite directions within the same chamber). Similar principles are implied in the German PETRA accelerator (Hamburg, Germany): its name stands for Positron-Electron Tandem Ring Accelerator.

$$\lambda_c = \frac{4\pi eR}{3\gamma^3}. \quad (4)$$

Most widespread types of insertion devices are undulators and wigglers. These are multipole magnetic systems with an intense magnetic field B (0.1 – 10 T depending on the device type) and alternating polarity. The trajectory of electrons becomes strongly curved in the magnetic field of insertion devices, thus the synchrotron radiation with specially selected characteristics can be generated (Fig. 4). Spectral distribution of synchrotron radiation emitted by a bending magnet, wiggler and undulator is shown in Fig. 5; the spectrum from a 'classical' X-ray tube is also given for comparison. Yet another type of specialised magnetic insertion devices is long undulators or free-electron lasers (FEL), which act as sources of coherent monochromatic SR. Currently, more than 100 insertion devices are in operation in the synchrotron radiation centres world-wide.

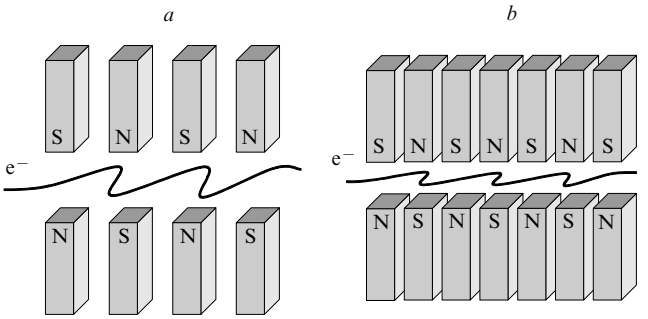

Figure 4. Specialised insertion devices: wiggler (*a*) and undulator (*b*)

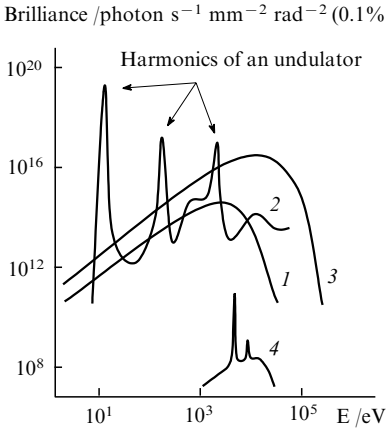

Figure 5. Spectral distribution of SR generated by bending magnet (*1*), undulator (*2*) and wiggler (*3*). For comparison, emission spectrum of an X-ray tube is also shown (*4*).

Adjacent curved sections of the electrons' trajectory within an N-pole wiggler emit independently, which leads to an increase in the intensity of SR by a factor of N compared to radiation of a bending magnet. Yet another advantage of wigglers is that they allow for creation of magnetic fields much stronger (5 – 10 T) than in a bending magnet since in the latter the value of B is linked to the orbit radius [see Eqn (1)], which results in a shift of the critical wavelength to higher energy. This is achieved by using superconducting magnets, which induce transverse 'beats' of the electrons' trajectory with amplitude of a few tenths mm. One wiggler may contain from several up to several tens of magnetic poles.

Compared to wiggler, an undulator is characterised by a larger number of magnetic poles, smaller separation between them and a weaker magnetic field ($\sim$1 T). The operation parameters of an undulator are chosen so as to achieve interference of the emission by adjacent curved trajectory sections. As a result of this interference, spectral distribution of the SR generated exhibits intensity maxima, *i.e.*, the so-called undulator harmonics. The intensity of the harmonics, which is proportional to N^2 is much higher than that generated by both bending magnets and wigglers. Furthermore, the radiation emitted by an undulator is more directed, *i.e.*, its emittance is diminished.[18] Due to differences in physical background and underlying mathematical formalism, synchrotron and undulator radiation are considered separately in the high-energy physics.

An important parameter of the SR is its polarisation, *i.e.*, the existence of preferred directions of the electric field vector. There are two types of the 'pure' polarisation, *viz.*, linear polarisation (the electric field vector oscillates in a certain plane) and circular one (the electric field vector precesses clockwise or counter-clockwise in the plane perpendicular to the direction of the wave propagation). In contrast to X-rays generated by X-ray tubes, synchrotron radiation is always completely polarised. The bending magnet radiation is linearly polarised in the plane of electrons' movement. Upon deviations from this plane up or down, the radiation becomes partially circularly polarised (elliptic polarisation). The synchrotron radiation generated in insertion devices (wigglers or undulators) also exhibits linear or circular polarisation depending on the design of the corresponding device (for example, for generation of circularly polarised SR, helical undulators or elliptic multipole wigglers can be used).

Yet another important characteristic of SR is its coherence, *i.e.*, correlation in oscillations of the electromagnetic field at different space points and at different time moments. The coherence determines the ability of radiation to produce an interference pattern; the planned fourth-generation SR sources approach lasers in this respect. There are two types of coherence, *viz.*, temporal (longitudinal) coherence, which depends mostly on monochromaticity of the SR beam and is characterised by the longitudinal coherence length, and spatial (transverse) coherence, which is, first of all, determined by the emittance of the source.

Synchrotron radiation has a pulse structure. Due to relativistic effects, the electron beam in the storage ring is split into separate moving clusters (bunches), each bunch is of a few cm in length. Therefore, electron current through a bending magnet is not continuous and the SR generated contains periodic pulses with duration of a few tens ps with nanosecond intervals between them. Under certain injection conditions, it is possible to achieve the state where only one bunch of electrons moves in the storage ring (single-bunch mode). In this case, both pulse durations and intervals between them are highly regular, which can be of great importance for time-resolved studies of fast processes.

The key parameter of a SR source is its emittance. It is the emittance, which depends upon perfection of the magnetic system of the source, that reflects most clearly the level of industrial technology involved in the construction of the storage ring. As a rule, the emittance is correlated with the brilliance: the smaller the emittance the higher the brilliance. In addition brilliance depends on the electron current. According to the value of emittance, all the operating synchrotron centres (Table 1) can be conventionally subdivided into generations. First-generation storage rings built in the 60's have the emittance of 100 – 500 nm rad. They were designed and constructed within the scopes of nuclear physics research programmes and thus were not optimised for applications based on utilisation of the synchrotron radiation and such applications took only small portion of the all available beamtime. SR studies on the first-generation storage rings were often conducted in parallel to the main studies on high-energy physics of the electron, positron, or electron – positron colliding beams (in the so-called 'parasitic' mode). In the 80's, the second-generation storage rings with emittance of the order of 50 – 150 nm rad appeared. These accelerators were specialised for SR applications, so they are often referred to as dedicated sources. Most of storage rings which are in operation nowadays belong to the second

Table 1. Characteristics of several storage rings.

Storage ring name (city, country)	Circumference /m	Energy /GeV	Maximum current /mA	Emittance /nm rad	Number of stations	Startup year [a]

[a] In parentheses, the year of last large update of the storage ring is specified.

generation. Several most modern storage rings built in the 90's are classified as third-generation storage rings. They are characterised by emittance of the order of 1 – 10 nm rad and, as a constructive design feature, contain many straight sections in their vacuum chamber between bending magnets for installation of insertion devices. Brilliance of SR sources increases by 2 – 3 orders of magnitude with each new generation.[19] For example, brilliance [photon s^{-1} mm^{-2} rad^{-2} $(0.1\%\ BW)^{-1}$] of first-generation SR sources is $10^9 - 10^{12}$, of second-generation SR sources, it is $10^{12} - 10^{15}$, of third-generation SR sources, it is $10^{18} - 10^{23}$ and $> 10^{24}$ as expected for X-ray free-electron lasers. For comparison, brilliance of standard X-ray tubes and X-ray tubes with rotating anode is only $10^6 - 10^7$.

The modern SR sources generate radiation, which is more intense than that of X-ray tubes by a factor of $10^8 - 10^{14}$. Further modernisation of third-generation storage rings will soon lead to a 'diffraction limit' of a single electron emittance (ε_0)

$$\varepsilon_0 = \frac{\lambda}{2\pi}$$

(where λ is the wavelength of emitted photons), which is equal to 16 pm at $\lambda = 1$ Å ($E = 12$ keV). Thus the currently exploited SR sources are close to the physical limit of brilliance 10^{24} photon s^{-1} mm^{-2} rad^{-2} $(0.1\%\ BW)^{-1}$. The advent of fourth-generation sources with emittance of the order of 0.01 nm rad is related to new technological schemes, such as utilisation of linear accelerators or multi-ring recuperator accelerators and FELs.[12]

3. Components of experimental stations

Special channels guide synchrotron radiation generated in bending magnets, wigglers or undulators to experimental stations (see. Fig. 3). High vacuum should be maintained in these channels, as in the main chamber, in order to minimise losses and radiation background due to absorption of photons by molecules of gases within the channel. Though exact instrumentation of each station largely depends on the specificity of the method used, several main components are common for most stations. These are X-ray optics elements, X-ray monochromators and X-ray detectors.[20]

Virtually in all the cases, optical transformation of the primary SR beam is necessary for experiments, *viz*., collimation (transformation of a divergent beam into a parallel one) and focusing (transformation of a divergent or parallel beam into a convergent one). X-Ray beams with small linear sizes are widely used in X-ray microprobe techniques, X-ray microscopy and microspectroscopy. X-Ray monochromators, which allow one to extract a narrow spectral band with certain (and variable in most cases) wavelength from 'white' synchrotron radiation, are also often considered as X-ray optical elements.

The main tasks of the X-ray optics development include the increase in the energy and spatial resolution and the decrease in the intensity losses associated with the interaction of the respective elements with SR beams. Optical schemes for focusing and monochromatisation of visible light beams (and also, to a great extent, in IR and soft UV spectral ranges), *viz*., lenses, prisms, *etc*., are based on the dispersion phenomenon, *i.e*., the dependence of the refraction coefficient on the wavelength. However, the refraction coefficient for X-rays in most of materials is very close to unity and virtually independent of the wavelength (see below). Besides, soft X-rays are strongly absorbed by virtually all materials (including air). Thus alternative basic principles are used in X-ray optics, such as total external reflection at incidence angles less than 0.1° (grazing incidence), Fresnel scattering and Bragg diffraction.

Most typical optical elements aimed at collimating and focusing the synchrotron X-ray beams include: grazing incidence concave mirrors (toroidal, spherical, cylindrical, *etc*.), curved single crystals, Fresnel zone plates (FZP), Bragg Fresnel lenses (Bragg Fresnel optics, BFO) and tapered capillaries (Fig. 6). Minimal linear size of an X-ray beam achieved in modern SR centres using microcapillary techniques is 20 – 50 nm. The disadvantage of tapered capillaries is strong divergence of the focused beam after the focal point, so they should be mounted very closely to the sample under investigation. FZP and BFO allow one to produce virtually parallel X-ray beams with linear sizes of the order of 1 μm. In applications which do not require very high spatial resolution, concave X-ray mirrors are most commonly used. Generally, an X-ray mirror represents a glass or silicon support coated with a fine and extremely smooth layer of non-oxidisable noble metals (Rh, Pt or Au). A focusing mirror allows amplification of SR beam intensity by 1 – 2 orders of magnitude at the costs of decrease in its linear size.

Some of the aforementioned optical elements (curved crystals, FZP, BFO) can also play a role of a monochromator. In addition, multilayer periodical structures and coatings as well as gratings are often used as monochromators for soft X-rays. Multilayer X-ray mirrors produce sufficiently high intensity of the reflected

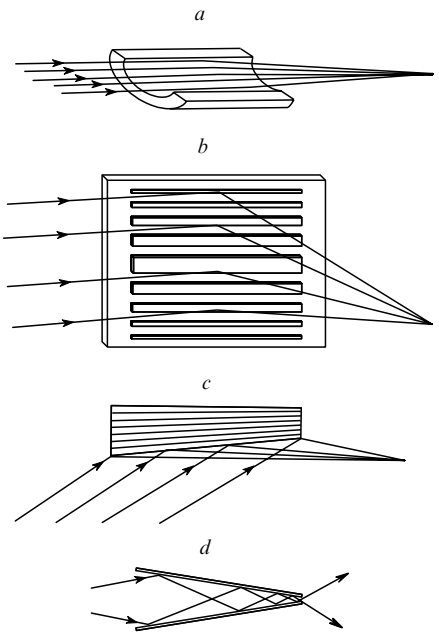

Figure 6. Main types of optical elements for collimating and focusing X-ray SR:
(*a*) X-ray mirror, (*b*) Bragg trensel lens, (*c*) focusing multilayer mirror, (*d*) tappered capillary.

beam even at usual incidence angles (up to a few degrees) and simultaneously focus and monochromatise the primary beam.

In the hard X-ray range, single crystals oriented in a diffracting position by one of its crystallographic planes are most typical monochromators. Among such monocromators, flat single-crystal plates, channel-cut monochromators and more advanced double crystal monochromators with two independent drives are well known. Upon variation of an incident radiation wavelength, the exit-axis of a channel-cut monochromator can drift by a few millimeters, whilst the independent drives of two single crystals make it possible to fix the spatial direction of the monochromatised beam.

The most important characteristic of a monochromator is its energy (or wavelength) resolution $\Delta E/E$ (or $\Delta\lambda/\lambda$). For example, energy resolution of a monochromator based on a flat mosaic graphite crystal with the diffracting plane [002] is $\sim 10^{-2}$; for double crystal monochromator with Si [111] crystals, this value is $\sim 10^{-4}$. Higher resolution can be achieved by utilising low-intensity reflections from higher-order crystallographic planes along directions almost perpendicular to the crystal surface (back reflections). For instance, monochromators with Si [13 13 13] crystals in the back reflection geometry allow one to reach a $\Delta\lambda/\lambda$ resolution of $\approx 10^{-8}$. For experiments requiring very high energy resolution, systems of nested double crystal monochromators are often applied (Fig. 7). A very promising direction in the field of X-ray monochromatisation is the utilisation of the resonance nuclear diffraction phenomenon, which allows one to reach resolutions down to 10^{-10}. It has to be noted that monochromatisation of a 'white' SR beam (extraction of a narrow spectral band) is always accompanied by great losses in intensity.

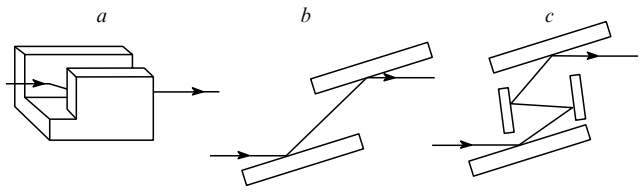

Figure 7. Examples of X-ray monochromators: (*a*) channel-cut monochromator, (*b*) double-crystal monochromator with independent drives for both crystals, (*c*) a system of two nested double-crystal monochromators.

An X-ray beam monochromatised using Bragg diffraction from a single crystal is always contaminated with higher harmonics, *i.e.*, radiation components with an energy multiple of the main component. In order to reject these harmonics, grazing incidence mirrors are often used with parameters adjusted so that the total reflection condition holds for the main component only; higher harmonics in this case pass without changing direction. In double-crystal monochromators, the harmonic rejection can be achieved by slight detuning of the two diffracting crystalline planes (this is however accompanied by noticeable losses in the main component intensity).

In some methods, (*e.g.*, in the energy-dispersive modification of XAFS spectroscopy, see below), similar X-ray optical elements based on Bragg diffraction (in particular, curved single crystals) are used not for monochromatisation but for decomposition of the 'white' beam into spectral components and defining certain spatial directions for photons with different energies (crystal-polychromators).

For control and modification of SR polarisation properties, a specialised polarised optics is used: crystal-polarisers, X-ray quarter-wave plates, phase retarders, *etc*. The state-of-the-art of modern X-ray optics is discussed in detail in a number of reviews (see, for example, Refs 1–4, 20–22).

Virtually any experiment utilising X-ray radiation requires measurement of beam intensities (primary, transmitted through a sample, fluorescent, *etc*.). For this purpose, X-ray detectors are used. Basic characteristics of an X-ray detector are sensitivity, linearity range, maximum load, counting rate, energy and spatial resolution. The following types of detectors are most often used in modern synchrotron radiation centres: photographic films and plates, ionisation chambers, proportional counters, scintillation detectors, solid state semiconducting detectors and charge-coupled devices (CCD).

Depending on spatial resolution, all detectors can be subdivided into point and position-sensitive detectors (PSD). In turn, the latter can be linear (1*D*) or two-dimensional (2*D*). PSDs allow registration of X-ray intensity distribution over a certain spatial area. Of them, multichannel (multiwire) proportional counters, detectors of the type Image Plates (which transform X-rays into visible light in recurring cycles 'energy storage as crystalline lattice defects – stimulated emission in the visible spectral range upon laser irradiation') and CCDs are most popular.

Scintillation counters and ionisation chambers are 'classical' X-ray detectors. They possess extremely high sensitivity (down to registration of single photons). Ionisation chambers are often used as primary beam monitors due to their wide linearity range and ability to operate under conditions of very intense X-ray beams. For some specific tasks (such as imaging, small angle scattering, sample adjustment in a beam), photofilm and photosensitive paper are still in use.

Solid-state semiconducting detectors exhibit high energy resolution. They are applied in cases where a spectral distribution analysis of the detected X-ray radiation is required. Avalanche photodiodes (APD), where each photon coming into the semiconducting diode generates an 'avalanche' of electron – hole pairs are the fastest of the modern X-ray detectors. Such detectors allow intensity measurements for very short pulses of SR (~ 0.1 ns), so they are widely adopted in time-resolved studies of fast processes.

III. Interaction of X-rays with matter

Upon interaction with the matter, X-ray radiation can be scattered or absorbed. These processes as well as combined phenomena of inelastic and anomalous scattering form the basis of X-ray methods of physicochemical analysis.

When a photon is scattered on a particle of a medium and changes its directions, its energy can either be conserved (elastic scattering) or partially transferred to the matter (inelastic scattering). Inelastic scattering can be due to various channels of energy transfer including excitation of collective vibrations of atomic nuclei in a crystalline lattice (phonons) or charge carriers, *viz*., electrons and holes in a conduction zone (plasmons); excitation of electrons from valence zone to vacant energy levels with creation of electron – hole pairs; ionisation of core level electrons of light elements (the so-called X-ray Raman scattering).

For standard energy of a primary beam of ~ 10 keV, inelastic losses due to phonon excitations have the order of a few meV, plasmon losses and losses due to electron – hole pairs creation lie in the range of 0.5 – 10 eV, ionisation of core electron levels may lead to losses of several tens or hundred eV (depending on the binding energy of the excited level). In the case of very hard X-ray radiation, the energy of which is much larger than the binding energies of electrons in atoms, the dominant channel of inelastic scattering is the Compton scattering of X-ray photons on quasi-free electrons (without quantum restrictions on the momentum and energy transfer). Harder γ-radiation with energy starting from several MeV (which usually is not produced by standard SR sources and thus is not considered in detail in this review ‡) interacts with the matter through the mechanisms of elementary particles' transformation, for example, by generation of electron – positron pairs.

Elastic (coherent) scattering of X-ray photons depends primarily on their interaction with electron shells of atoms (Thomson scattering). Since the energies (*i.e*., the wavelengths) of all the scattered photons are the same, elastic scattering can lead to diffraction, *i.e*., a spatial redistribution of the scattered beam intensity as a result of interference of waves coming from different atoms. When atomic arrangement has a translational symmetry (as in crystals), diffraction reflections, *i.e*., narrow maxima of the scattered wave intensity arise at certain directions. Furthermore, a persistence of a mean local atomic order even in amorphous substances gives rise to sinusoidal oscillations of the smooth (without sharp maxima) elastically scattered background as a function of the scattering angle. Diffraction phenomena form the basis of a number of experimental techniques which allow studies of fine details in the structure of the matter, including local atomic environment, supramolecular arrangement and periodicity elements (types of partial ordering).[23, 24]

Absorption of X-ray photons leading to attenuation of the photon beam as it propagates in a medium is primarily related to the photoelectric effect, *i.e*., photoionisation of inner electronic shells of atoms. In this case, a vacancy (hole) in the respective core electron level and a free electron are generated. All the methods of X-ray absorption spectroscopy are based on the analysis of X-ray absorption coefficient as a function of the energy of incident photons. Energy and spatial distribution of the photoelectrons generated in this process are the main subject of X-ray photoelectron spectroscopy techniques.[25]

The excited state with a vacancy in the core level (X-ray term), to which an atom transfers upon absorption of an X-ray photon, is metastable with a lifetime not longer than 10^{-15} – 10^{-16} s. The photoionised atom tends to diminish its energy by filling the core level hole with an electron from higher-lying levels. This can be achieved either through emission of an X-ray photon of lower energy (X-ray fluorescence) or through a radiationless two-electron process involving a transition of one electron from a higher electronic level to the core level vacancy with simultaneous detachment of a second electron (the Auger process). X-Ray fluorescence is the dominant direction of decay of an X-ray term with a *K*-shell hole (*K*-term) for atoms with atomic numbers $Z > 20$ and with $Z > 90$ for an *L*-term (Fig. 8).

‡ Recently, generation of hard γ-rays using Compton back scattering of a laser light on ultrarelativistic electrons has been developed in several synchrotron radiation centres (see, for example, Ref. 12).

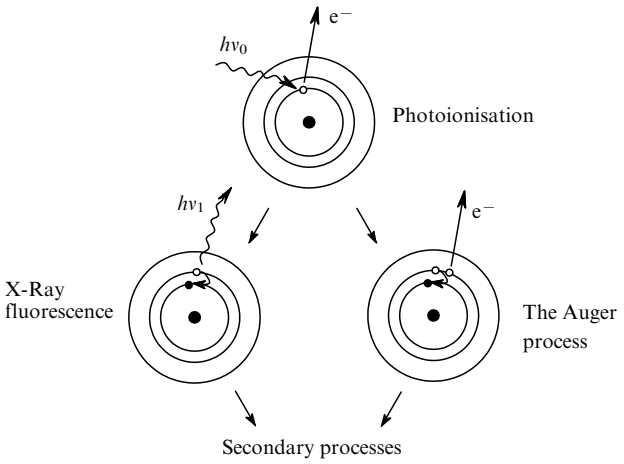

Figure 8. The main processes occurring in matter upon absorption of an X-ray photon.

X-Ray fluorescence and the Auger process result in new holes and thus evoke a cascade of secondary processes, such as emission of secondary electrons, fluorescence in the longer wavelength region, *etc*. In particular, secondary processes can lead to the appearance of luminescence in the visible light range. This phenomenon forms the physical background of the XEOL (X-ray excited optical luminescence) method. Energy transferred to the system from the absorbed X-ray photon can result in cleavage of chemical bonds and detachment of molecular fragments (photostimulated ion desorption, PSID). X-Ray absorption by semiconducting materials is accompanied by an increase in concentration of charge carriers in the conduction zone and thus by an increase in their conductivities. Secondary processes initiated by absorption of X-ray photons are widely utilised in various techniques like X-ray fluorescence spectroscopy, Auger electron spectroscopy, secondary electron spectroscopy, *etc*.

Absorption of X-ray photons in matter can also occur due to nuclear excitations. In particular, the Mössbauer spectroscopy is based on this phenomenon. Generally, this technique is not considered as a sort of X-ray spectroscopy but rather referred to as a distinct field, *viz*., γ-spectroscopy. However such a discrimination is arbitrary: the energy of the nuclear transition in the ^{57}Fe isotope, most often exploited in the Mössbauer spectroscopy (14.4 keV) is close and even slightly less than the energy of characteristic radiation produced by an Mo K_α X-ray tube, which is most popular in X-ray diffraction experiments (17.4 keV). The energy of nuclear excitations for many other isotopes commonly studied by Mössbauer spectroscopy lies also in the range of 10 – 100 keV attainable with modern SR sources. As in the case of electron excitations, excited nuclear states are metastable (however their lifetimes are substantially longer than that of electronic states, *viz*., $\sim 10^{-7}$ s) and the excited nucleus reverts back to its ground state with emission of an X-ray photon of the corresponding energy. The energy of emitted photon may be equal to (elastic or coherent nuclear scattering), or slightly less (inelastic scattering) than, that of the initial radiation. Due to longer lifetime of excited nuclear states, absorption and emission bands associated with nuclear transitions are exceptionally narrow.[26]

When X-ray beam strikes an interface, X-ray reflection occurs with the reflection angle equal to the incidence angle. However, in contrast to, for example, visible light, the probability of the X-ray reflection decreases rapidly with an increase in the incidence angle and for large incidence angle common for visible light optics, the X-ray beam simply crosses the interface not changing its direction. Noticeable X-ray reflection can be observed only at very small grazing incidence angles ($\sim 0.1\,^\circ$) under conditions of the so-called total external reflection. Under this condition, the penetration

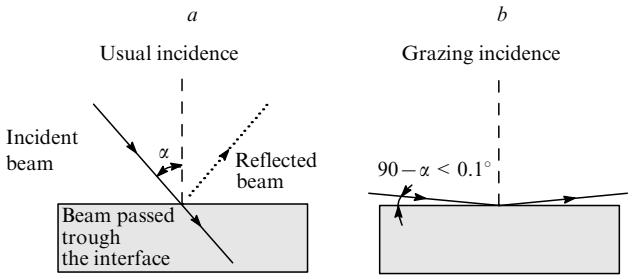

Figure 9. Reflection of an X-ray beam from a surface under conditions of usual (*a*) and grazing (*b*) incidence.

depth of X-ray radiation into the matter is only of a few atomic layers (Fig. 9). This phenomenon has to be taken into consideration in design of X-ray mirrors and focusing microcapillaries; moreover, it is the basis of a number of surface investigation techniques.

IV. X-Ray methods of physicochemical analysis

All X-ray-based research methods can be classified based on the processes which accompany interaction of X-rays with the matter. According to this principle, the following groups of methods can be formulated: X-ray spectroscopy, X-ray electron spectroscopy, X-ray diffraction and X-ray inelastic scattering. Additional independent groups include methods utilising effect of the resonance nuclear scattering (Mössbauer spectroscopy) and imaging techniques.

1. X-Ray spectroscopy

a. X-Ray absorption spectroscopy

The subject of X-ray absorption spectroscopy is the analysis of the X-ray absorption coefficient (μ) as a function of the incident photons energy $\mu = \mu(E)$. In the most common transmission mode, the linear absorption coefficient is determined by the formula

$$\mu = \ln\frac{I_0}{I_t}, \qquad (5)$$

where I_0 and I_t are intensities of the incident X-ray beam and the beam transmitted through the sample. This formula coincides with the respective relations for linear absorption coefficients in other spectral ranges (UV, visible, IR), since X-ray absorption also obeys the Bouguer – Lambert – Beer law, which links attenuation and optical path of radiation propagating in a medium. The major part of modern X-ray absorption spectroscopy studies is performed using SR, since they require scanning the incident beam energy over a broad spectral range.

The X-ray absorption coefficient increases sharply for certain values of incident radiation energy superimposed on a smooth $\mu(E)$ curve monotonically decreasing with an increase in the energy. This resonance absorption induced by photoionisation of atoms of a certain element (see above) define 'triangular' shape of X-ray absorption bands (Fig. 10 *a*). Near the absorption edge, the $\mu(E)$ manifests a fine structure. The fine structure is subdivided into two types, *viz*., X-ray absorption near-edge structure XANES (Fig. 10,*b*) and extended X-ray absorption fine structure expressed as $\psi(k)$ EXAFS (Fig. 10 *c*). XANES covers the energy range from ~50 eV before the absorption edge up to 100 – 150 eV after it. This fine structure is composed of relatively narrow resonance bands generated by electron transitions from the core level to vacant energy levels up to complete ionisation (*i.e*., photoionisation) along with broader bands associated with electron transitions to quasi-bound states (multiple scattering). The oscillatory structure EXAFS, which appears as a result of a free photoelectron scattering on the local atomic environment, is observed in the energy range of 100 – 1000 eV above the absorption edge.

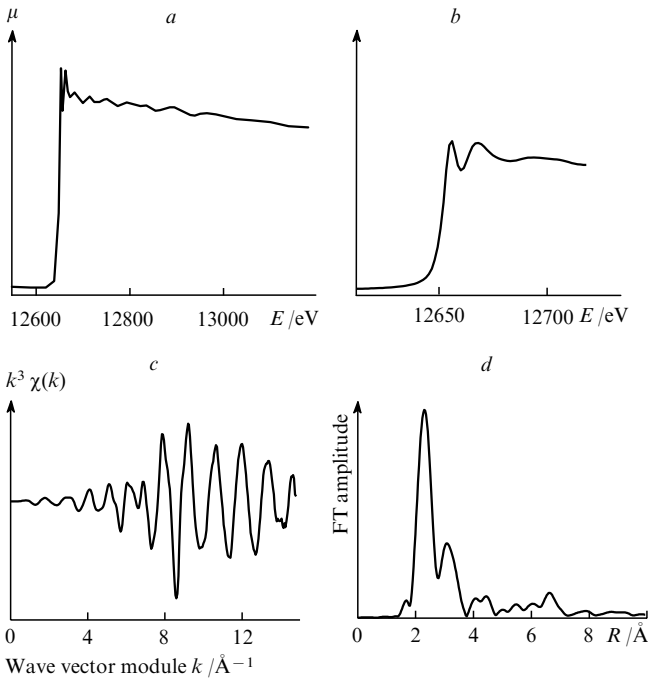

Figure 10. Steps of an EXAFS data processing:
(*a*) an experimental X-ray absorption spectrum; (*b*) the amplified XANES region; (*c*) the normalised EXAFS curve, *i.e*., the oscillating part of the X-ray absorption coefficient; (*d*) the Fourier transform (FT) of the normalised EXAFS curve, the maxima of the Fourier transform correspond to the coordination spheres around the central atom.

XANES spectroscopy is used in studies of electronic structure of substances, including determination of the energy and symmetry of vacant orbitals in molecules or unoccupied zones above the Fermi level in solids. In particular, using this method, information on the oxidation state and coordination symmetry of the central atom can be obtained.[27,28] Analysis of EXAFS gives additional structural information on the local order around the absorbing atom, including the type and the number of closest neighbours as well as interatomic distances within a sphere with the radius of 5 – 6 Å (see Fig. 10 *d*).[29,30] In addition to the interatomic distances, bond angles can be found using such modern approaches as the assessment of multiple photoelectron scattering or simultaneous fitting of spectra measured at the absorption edges of several elements in the sample. In modern X-ray absorption spectroscopy, a common term XAFS (or XAS), which covers both EXAFS and XANES, is often used.

Since the intensities of all the secondary processes are determined by the number of X-ray photons absorbed (*i.e*., by the number of holes generated in the core level), the quantum yields of these processes are proportional to the X-ray absorption coefficient and their energy dependencies exhibit XAFS-like fine structures. For example, such a fine structure is manifested in the dependence of the X-ray fluorescence intensity I_f on the energy of incident photons. Due to substantially higher signal-to-background ratio, the fluorescence yield defined as the ratio of I_f to the intensity of the excitation radiation I_0

$$\mu(E) = \frac{I_f}{I_0},$$

is 10 to 100-fold more sensitive to the oxidation state and local atomic environment of the photoionised atom than the X-ray absorption coefficient measured in the transmission mode.

XAFS in the fluorescence yield mode can be used for the analysis of the oxidation state and coordination of admixture atoms (in concentrations down to 0.1% – 0.2%).[31] Registration of the total or the Auger electron yield

$$\mu(E) = \frac{i_e}{I_0},$$

(where i_e is the electron current) as a function of incident photon energy leads to enhancement of EXAFS sensitivity to surface layers of the sample since the escape depth of electrons does not exceed 50–100 Å.[32] The optical luminescence yield in XEOL [33] or the ion yield in PSID [34] can be used in a similar way.

XAFS allows investigations of substances in any aggregate state. Therefore, it is applicable to the solution of a broad range of structural chemical problems related to the electronic state and local atomic surroundings of a certain element. Methods of X-ray absorption spectroscopy proved to be efficient in structural investigations of semiconductors,[35] superconductors,[36] amorphous glasses and alloys,[37] polymeric electrolytes,[38] ceramics,[39] metallocentres in biomolecules,[40–42] supported catalysts,[43–45] metallic nanoclusters,[46–48] *etc*. XAFS studies of solutions reveal information on structural rearrangements of molecules,[49] solvation mechanisms and structures of solvate shells of ions.[50,51] This method can be used for structural monitoring of reactions in solutions (*e.g*., electrochemical processes).[52] Structural studies of melts give important information on the nature of the interatomic interactions.[53]

In the soft X-ray range at the absorption edges of light elements, such as B, C, N, O and F (the excitation energies from 100 to 1000 eV), the X-ray absorption fine structure is usually referred to as NEXAFS (near-edge X-ray absorption fine structure).[54] Soft X-rays are strongly absorbed in matter (photon free path is only a few tens of nm), therefore NEXAFS is a surface-sensitive technique. The corresponding spectra are generally recorded in vacuum or in a helium atmosphere in the total electron yield mode. The NEXAFS spectroscopy is widely applied for characterisation of polymers,[55] chemisorbed molecules,[56] adsorbed monolayers,[57] Langmuir–Blodgett films, *etc*. For example, thin films of higher fullerenes, which are available only in minute quantities, have been characterised using this method.[58] Though extended oscillating structure is not very prominent in NEXAFS spectra, they are sensitive to the long-range atomic ordering,[57,58] which allows identification of, for example, conformations of long-chain hydrocarbon fragments or individual atomic clusters C_n with $n \leqslant 96$ (Fig. 11).[58]

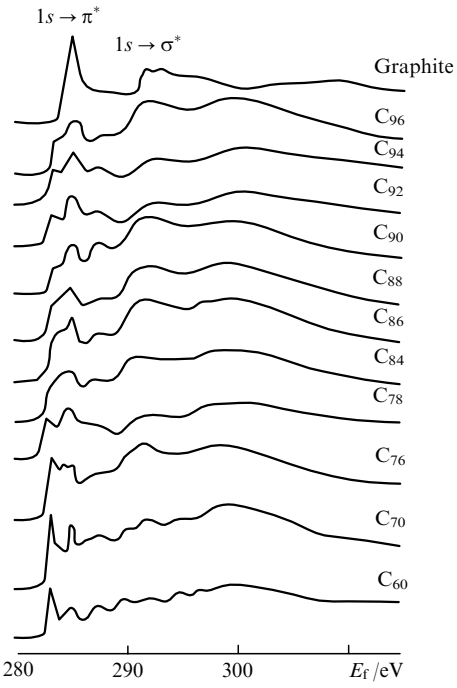

Figure 11. Carbon *K*-edge NEXAFS spectra for a series of fullerenes C_n ($n = 60–96$). Electronic transitions making principal contributions into the respective absorption bands are shown.[58]

Recently, significant attention has been drawn to XAFS spectroscopy in the energy range of 1.5–3 keV, which is intermediate between hard (> 5 keV) and soft (< 1 keV) X-rays.[59] Such techniques require expensive ultrahigh vacuum equipment, which is generally utilised in the soft X-ray region, but methodological approaches developed for hard X-ray studies can be applied to them. As an example, SOEXAFS (soft EXAFS) may be mentioned. The aforementioned energy range covers *K* absorption edges of such key elements as magnesium (~1.30 keV), aluminium (~1.56 keV) and silicon (~1.84 keV), which form the base for many building materials and composites, natural minerals, supports for catalysts, organometallic reagents, *etc*.[60–62] Furthermore, *K*-edges of phosphorus (2.14 keV) and sulfur (2.47 keV), which are constituent of many organic molecules, also belong to this region.[63]

b. X-Ray fluorescence spectroscopy

Methods of X-ray fluorescence (emission) spectroscopy (XRF) are based on detection and spectral analysis of the secondary radiation emitted by a substance following absorption of monochromatic or 'white' synchrotron radiation. They are in active use for elemental analysis of specimens of various origin.[64] An X-ray emission spectrum in XRF analysis measured usually in a broad energy range (typically up to a few tens keV) presents a set of characteristic emission lines corresponding to electron transitions from occupied levels to core holes. Modern synchrotron radiation-based X-ray fluorescence analysis is one of the most sensitive and accurate non-destructive methods for the determination of trace element concentration. In routine multi-element analysis, the lowest detection limit for a broad range of elements from calcium to actinides reaches the level of 0.1 ppm (*i.e*., 10^{-7} g g^{-1});[65] ~0.1 mg of a sample is required to carry out the measurement and the measurement itself takes a few minutes. This enables compositional analysis of samples available only in very small amounts, such as in the case of microelement distribution in lunar rock probes (Fig. 12).[66] In dedicated studies optimised for quantitative analysis of a single element or a limited range of elements, the sensitivity as high as ~1 ppb (*i.e*., 10^{-9} g g^{-1}) and even several ppt (*i.e*., 10^{-12} g g^{-1}) in the analysis of aerosols pumped through a filter, can be achieved.[67]

High-resolution X-ray fluorescence spectroscopy is an established technique for characterisation of the electronic structure of matter, *viz*., for the determination of energy distribution of occupied electronic states below the Fermi level. Information on the electronic structure collected by this method is complementary

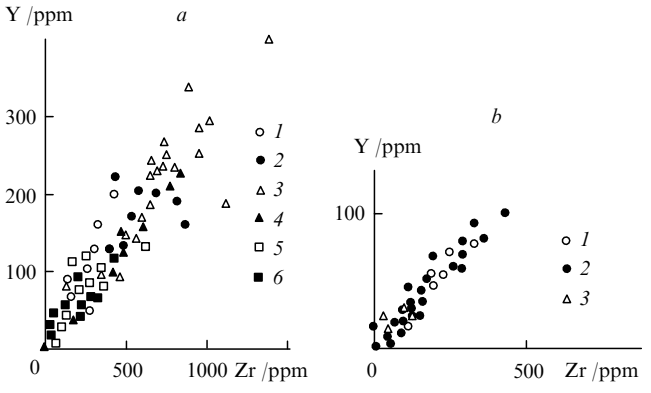

Figure 12. Zirconium *vs*. yttrium concentration correlations in samples of lunar rocks collected in 'Apollo' (*a*) and 'Luna' (*b*) space missions as determined using synchrotron X-ray fluorescence analysis.[66]

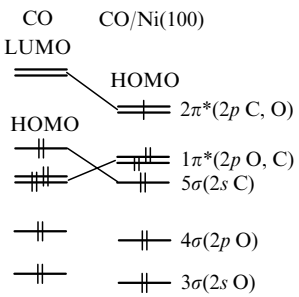
X-ray C K_α fluorescence: (*1*) perpendicular to the surface of Ni(100) face (π-components make major contribution); (*2*) parallel to the adsorbed layer. X-ray O K_α fluorescence: (*3*) parallel to the adsorbed layer; (*4*) perpendicular to the adsorbed layer; (*5*) usual XPS spectrum.

to that obtained using X-ray absorption spectroscopy. Exact positions of X-ray fluorescence lines recorded with high precision depend upon the oxidation state and coordination environment of the element under study.[68] High-resolution XRF spectroscopy can thus be considered as an analogue of the X-ray photoelectron spectroscopy (see next section), which does not require recourse to ultrahigh vacuum equipment. X-Ray fluorescence spectroscopy in the soft X-ray region is particularly informative in studies of organic molecules.[69–71] Resonant photoionisation of atoms of a certain element achieved using monochromatic radiation with the specially adjusted energy (resonant X-ray emission) enhances selectively the intensities of transitions to the vacant level generated in this process and of all the transitions in the cascade of associated secondary processes. This leads to a substantial increase in the sensitivity.[72] For instance, in a study of CO chemisorbed on metallic Ni, this approach allowed one to demonstrate experimentally donation of electrons from the Ni atoms to the $2\pi^*$ molecular orbital of CO (Fig. 13 and Scheme 1).

Scheme 1



(LUMO is the lowest unoccupied molecular orbital; HOMO is the highest occupied molecular orbital).

Recent achievements in the field of applications and instrumentation of synchrotron X-ray fluorescence spectroscopy are discussed in reviews.[64, 73, 74]

c. X-Ray electron spectroscopy

In traditional methods of X-ray electron spectroscopy, the energy distribution of electrons knocked out of the sample by an X-ray beam is analysed. There are several types of X-ray electron spectroscopy, such as X-ray photoelectron spectroscopy (XPS, sometimes also referred to as ESCA, *i.e.*, electron spectroscopy for chemical analysis), Auger electron spectroscopy (AES), secondary electron spectroscopy (SES), *etc.* All the electron spectroscopy techniques are used for surface studies since the electron escape depth in the energy range typical of these methods does not exceed 50 – 100 Å.

XPS and AES are common methods for quantitative analysis of the surface chemical composition. Positions of lines in the XPS spectra correspond to binding energies of the corresponding electron levels, *i.e.*, they give information on the electronic state of atoms at the surface (chemical shift of core levels) and energy structure of the valence zone. Several other effects are manifested in XPS and give additional information, *viz.*, spin-orbit splitting of lines into multiplets, two-electron excitation processes (low energy shake-up and shake-off satellites), inelastic energy losses of photoelectrons (characteristic bulk and surface plasmons). The use of SR increases the sensitivity and energy resolution of the method noticeably due to high intensity of SR and availability of strictly monochromatic X-ray beams, respectively.[75] Variation of the excitation energy, for example, allows one to distinguish photoelectron and the Auger lines in complex spectra (the positions of the Auger lines, in contrast to photoelectron ones, do not depend on the excitation energy).[25, 76]

As in the case of XRF, additional information can be obtained from XPS spectra provided that the excitation energy is chosen close to one of the edges of resonance absorption (resonant photoemission). This method, in particular, can be used for the determination of contributions of certain atomic orbitals to molecular orbitals, which is important for chemical bonding description, for example, in transition metal complexes with π-ligands (Fig. 14).[77, 78] By varying energy of the incident beam, incidence angle or electron escape angle, one may reconstruct concentration *vs.* depth profiles of the elements under study.

A new promising branch of photoelectron spectroscopy, *viz.*, angular-resolved X-ray photoelectron spectroscopy (ARXPS),[79]

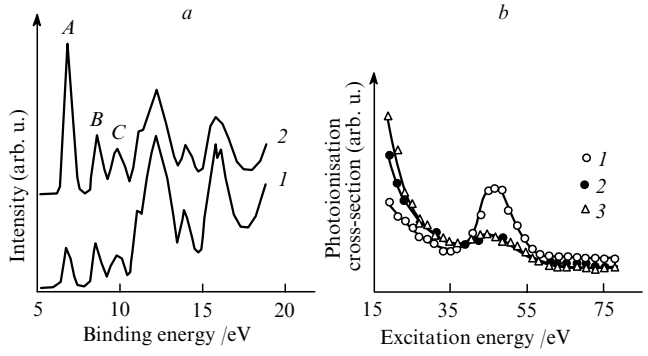


Figure 14. Valence zone photoelectron spectra of the π-complex $Ti(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_5H_5)$ for two different excitation energies (*a*) and dependence of relative photoionisation cross-sections for bands *A*, *B* and *C* upon the excitation energy (*b*).
(*a*) Excitation energy /eV: (*1*) 33, (*2*) 48; (*b*) band: (*1*) *A*, (*2*) *B*, (*3*) *C*. Sharp increase in the band *A* intensity for the excitation energy of ~48 eV due to approach of the excitation energy to the $M_{II,III}$ absorption edge of Ti ($3p \rightarrow 3d$ resonance) indicates that this band is mostly composed of Ti $3d$ atomic orbital; bands *B* and *C* correspond to molecular orbitals with significant contribution of the ligand orbitals.[77]

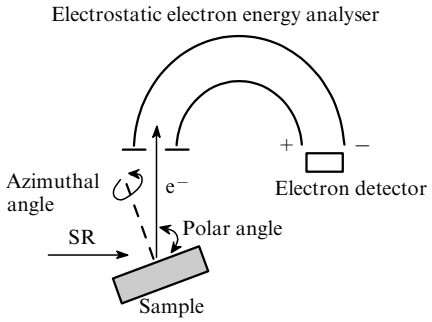

Figure 15. A scheme of a photoelectron spectrometer for recording angular-resolved spectra.

is actively developing in modern SR centres over the last years. This method is based on registration of a spatial distribution of photoelectrons with certain kinetic energies (Fig. 15). Analysis of this distribution allows one to extract the contribution of photoelectron scattering on local atoms surrounding the photoionised atom, *i.e.*, the effect of the photoelectron diffraction. In contrast to other techniques utilising electron diffraction, such as low-energy electron diffraction (LEED) or reflected high-energy electron diffraction (RHEED), the photoelectron diffraction is observed in systems both with and without long-range atomic ordering of a surface. ARXPS, like XAFS, allows studies of local atomic environment of photoionised atoms in samples with disordered or partially ordered surface structure. In particular, this method proved its effectiveness in studies of sorption–desorption processes. This allows one to reveal positions and orientations of diatomic or more complex molecules adsorbed on crystallographic faces of metal single crystals and to estimate adlayer–support distances as a function of adsorbate concentration. Photoelectron diffraction can be applied to structural characterisation of various surface systems, *viz.*, thin films, epitaxial deposits, surface alloys, metal–semiconductor interfaces, oxide layers, supported metal nanoclusters, products of ion-implantation, as well as processes like growth of interfaces and surface phase transitions including melting.[80–82]

Further development of the theory and instrumentation of ARXPS has lead to appearance of a new method for surface structural studies, *viz.*, photoelectron holography. Photoelectron holography is based on mathematical processing of large body of data on the intensities of photoelectron lines obtained by varying the sample orientation relative to the incident beam and detector (both azimuthal and polar scans) and excitation X-ray radiation energy. Holographic processing of ARXPS data allows complete reconstruction of spatial arrangement of atoms within the sphere with a radius of 5–20 Å around the photoionised atom with an accuracy in atomic positions of 0.02–0.05 Å.[83] Similar approaches are being developed in Auger electron spectroscopy and X-ray fluorescence spectroscopy.[84]

2. X-Ray diffraction methods

a. Single crystal X-ray diffraction

X-Ray diffractometry is a most important experimental method of modern structural chemistry. This allows one to determine the atomic structure of a single crystal (including unit cell parameters, space group, coordinates and types of atoms within the unit cell and parameters of their thermal vibrations). Based on atomic coordinates, any structural characteristics like interatomic distances, bond and torsion angles, *etc.*, can easily be calculated. In contrast to the majority of structural methods, X-ray diffractometry allows complete objective determination of a crystal structure without prior knowledge of any of its structural characteristics and even chemical composition.

The set of experimental data measured by X-ray diffractometry includes angle coordinates and intensities of reflections generated by diffraction of X-rays on a single crystal. The scattering of X-rays occurs primarily on electron shells; thus, mathematical processing of the experimental data (Eulerian angles and intensities of reflections) allows reconstruction of the electron density distribution $\rho(r)$ in the unit cell. In routine diffraction experiments, distinct maxima of the $\rho(r)$ function corresponding to the centres of atoms, are revealed with the accuracy of 0.01–0.02 Å. Based on high-precision data, fine features of the electron density distribution functions, such as valence electrons redistribution due to formation of chemical bonds, as well as other physicochemical characteristics of a crystal related to $\rho(r)$ can be analysed. Qualitatively, the redistribution of electron density can be visualised in deformational electron density maps $\Delta\rho(r)$ obtained by subtraction of the promolecule's electron density [composed of spherically symmetric non-interacting atoms whose positions are determined from the 'high-angle' refinement of the structure versus reflections with high $(\sin\theta)/\lambda$ ratio, where θ is the diffraction angle and λ is the wavelength] from the total experimental $\rho(r)$ function.

Currently, the most popular technique in chemical X-ray crystallography is the conventional single crystal diffractometry based on diffraction of monochromatic X-ray beam on a single crystal. X-Ray tubes are most often used as an X-ray source. A serious disadvantage of this method is very strict requirements to the quality of a sample under study. It has to be a well-formed single crystal with linear dimensions of approximately 0.1–1 mm and a sufficient diffraction power at a fixed wavelength (typically, characteristic Mo K_α $\lambda = 0.71$ Å or Cu K_α $\lambda = 1.54$ Å radiation). If a crystal is smaller than the dimensions mentioned or it is of poor quality (due to domain misorientation, static or dynamic disorder of molecules or molecular fragments in the unit cell, *etc.*), the routine structure solution becomes very complicated or even impossible. Such accompanying phenomena as X-ray absorption, anomalous dispersion, multiple diffraction and extinction (deviations of X-ray reflection intensities from the values predicted by the kinematic X-ray scattering theory) further decrease accuracy of the X-ray diffraction results.[23,24]

The use of SR in X-ray crystallography eliminates many restrictions of this method. Due to high intensity of SR beams with a capability of their further focusing and collimation by X-ray optics, it is possible to collect reflection sets of satisfactory quality for weakly diffracting and very small crystals. Low divergence of SR beams leads to improvement of angle resolution in high-precision diffraction experiments.[85–88]

Routine synchrotron X-ray crystallographic studies of low-molecular-weight compounds are now developing in two principal directions, *viz.*, investigations of samples not applicable to laboratory diffractometry (*e.g.*, due to a weak diffraction power)[89,90] and experimental investigations of electron density distribution in crystals.[91] Nowadays, crystals with linear dimensions down to several micrometers can be characterised by X-ray diffraction in synchrotron centres.[92,93] Such crystals are commonly formed in a chemical synthesis[94] and they are particularly typical in geology and mineralogy.[95,96] For mounting of such small crystals onto a diffractometer, special methods and devices (for example, on the stage of an electron microscope) are required.[97,98]

In the 90's, systematic studies of electron density distribution in crystals based on high-precision diffraction experiments were started in synchrotron radiation centres. Data acquisition time required for these studies shortened down to 15–20 hours from 10–15 days needed with laboratory equipment. Furthermore, requirements for the quality of single crystals for the studies also became not so strict as, for example, in high-precision studies (Fig. 16).[99–102] Application of hard X-ray radiation reduces absorption and extinction and increases the resulting accuracy due to larger number of observed reflections with high $(\sin\theta)/\lambda$ ratio. In high-precision laboratory experiments, Ag K_α line of X-ray tubes ($\lambda = 0.56$ Å) is used whereas several studies with synchrotron radiation wavelengths as short as 0.3–0.1 Å have been reported.[103–105]

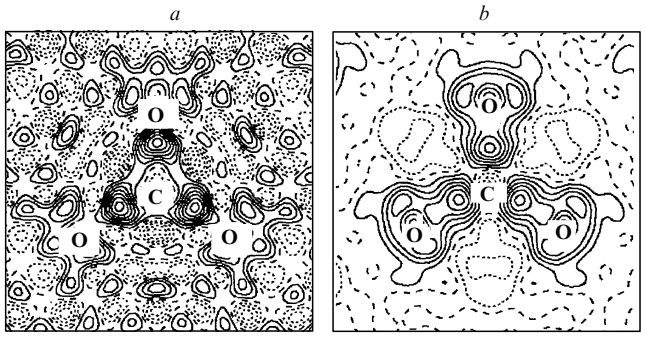

Figure 16. Static deformational electron density maps $\Delta\rho(r)$ reconstructed in high-precision X-ray diffraction studies of $MnCO_3$ single crystal (section in the plane of the carbonate group, solid lines correspond to positive and dashed lines to negative deformational electron density; contours are drawn with a step of 0.1 e $Å^{-3}$): (*a*) data collected on a laboratory diffractometer, (*b*) SR data (Photon Factory, Tsukuba, Japan).[100]

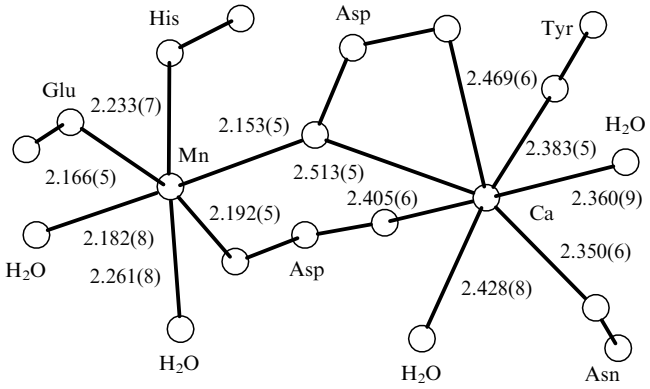

Figure 17. Geometry of the metallocentre in the protein concanavalin A determined using synchrotron X-ray single-crystal diffraction with accuracy typical of low molecular-weight compounds (the synchrotron centre CHESS, Ithaca, USA, $\lambda = 0.92$ Å). Only the atoms of amino acid fragments coordinated to the metal atoms are shown. The crystallographic parameters are as follows: orthorhombic, $a = 89.55(2)$ Å, $b = 86.46(2)$ Å, $c = 62.11(1)$ Å, space group $I222$, 116923 observed reflections, 19158 least-squares parameters refined for 2134 independent non-hydrogen atoms, $R_F = 12.2\%$.

In processing of high-precision synchrotron X-ray diffraction data, the most advanced computational techniques are applied, *viz*., multipole refinement and topological analysis of the $\rho(r)$ function.[99,106] Comparison of SR-based and laboratory approaches shows that the accuracy of synchrotron diffraction experiments is at least not lower than that obtained using laboratory diffractometers and is noticeably higher in many cases (see Fig. 14).[100,107,108] For example, one of the most accurate structures ever solved from single crystal X-ray diffraction data is racemic DL-serine: data collected at HASYLAB (Hamburg, Germany) at the wavelength of 0.45 Å.[99]

Currently, X-ray crystallography is widely applied in studies of biological macromolecules (proteins, nucleic acids, polysaccharides, viruses, *etc*.).[109] Single crystals of biopolymers possess large unit cells with parameters of 50 – 500 Å containing up to several hundred thousand independent atoms. For this reason, measurement and structure solution techniques applied in this field have to be noticeably altered. The 'classical' X-ray diffraction study allows one to reconstruct the electron density map of the crystal of a biopolymer with a relatively low resolution (3 – 5 Å), in which typical functional groups or fragments rather than single atoms can be seen on a partially resolved background of hydration water molecules (which can occupy 15% – 20% of the crystal volume). Furthermore, large and well formed single crystals of biopolymers are extremely difficult to grow and they easily decompose under X-ray irradiation, since the standard data acquisition can take several weeks on a laboratory diffractometer.

Distinct advantages of synchrotron radiation-based techniques caused a very fast growth of their application to crystallographic studies of proteins and other biopolymers.[100–113] According to Biosync (an international organisation of SR users in the field of structural biology), the fraction of SR in all diffraction studies of new crystal structures of biological macromolecules has grown from 18% in 1990 to 44% in 1996.[114] Presently, almost a half of all studies in protein crystallography is performed using SR sources. In a number of cases, the use of SR allowed one to achieve the resolution comparable to the standard resolution in small-molecule X-ray crystallography. Thus in an X-ray diffraction study of the protein concanavalin A (molecular weight 25 000), the resolution of 0.93 Å has been reached, which made it possible to reveal and refine the positions of all 2134 non-hydrogen atoms within the unit cell in the anisotropic approximation.[115] Since the ratio of the number of independent reflections *vs*. refined parameters was relatively high, accuracy comparable to that of small-molecule crystallography has been obtained (Fig. 17). Even higher resolution of 0.54 Å has been achieved in the diffraction study of the oligopeptide cramine and the deformation electron density map has been analysed for the first time for a protein molecule (data collected at HASYLAB).[116]

As a recognition of great importance of structural biology for the modern science, the 1997 Nobel prize in chemistry was awarded to the international team including J E Walker (UK), P D Boyer (USA) and J C Skou (Dennmark) for the determination of the enzymatic mechanism of the intercellular synthesis of adenosine triphosphate (ATP). The key stage of the investigation was the single crystal structure study of the enzyme complex F1-ATPase using SR diffraction data collected in Daresbury Laboratory (UK).

This enzyme is a constituent of the ATP-synthase complex, which catalyses the last stage of the intercellular ATP synthesis by oxidative phosporylation of adenosine diphosphate. The solution of the structure of F1-ATPase (molecular weight 371 000, orthorhombic, unit cell parameters $285 \times 108 \times 140$ Å, space group $P2_12_12_1$) took 12 years. To date, it is the largest non-centrosymmetric crystal structure solved from X-ray diffraction data.[117]

In addition to conventional diffractometry, the Laue diffraction method is widely applied in synchrotron crystallographic studies of proteins. In this method, the diffraction pattern is obtained by 'white' X-ray beam scattering on a rotationally fixed single crystal. Combined utilisation of intense synchrotron radiation and area detectors allows investigations of extremely small single crystals (with a volume of ~ 0.1 μm^3) with a very short data acquisition time (several ns). The unprecedented volume for a single crystal of gold studied by this method[118] is $\sim 10^{-3}$ μm^3. During recent years, special techniques for data recording and processing have been developed in this field, which allow at present the *ab initio* (*i.e*., without any *a priori* structural models) solution of relatively simple structures solely from Laue diffraction data[119,120] and refinement of structures of any complexities.[121]

Yet another direction in the development of synchrotron X-ray crystallography is magnetic scattering. The incorporation of relativistic effects gives corrections of the X-ray scattering amplitude due to interaction of X-ray photons with magnetic moments of electrons. In a classical X-ray diffraction studies, scattering of photons on magnetic moments is several orders of magnitude weaker than that on charge density. However, the magnetic component increases in the case of very hard X-rays (80 – 100 keV). Furthermore, the magnetic scattering intensity can be substantially enhanced (by 3 – 4 orders of magnitude) when the scattered wavelength approaches an absorption edge of an element with unpaired electrons in the sample (the so-called X-ray

resonance exchange scattering). In this case, the intensity of magnetic scattering of photons achieves the intensity of scattering on electron charge density.[122]

Magnetic X-ray scattering leads to the appearance of forbidden diffraction maxima (extinction condition violations) and superstructure reflections corresponding to the sublattice of magnetic atoms. With synchrotron X-ray sources of high intensities it is possible to record magnetic reflections both in the resonance region and far from the absorption edges.[123,124] It allows investigations of magnetic structures of paramagnetic crystals. In this respect, magnetic scattering of SR turns into an important alternative for the traditional technique in this field, *viz*., magnetic scattering of polarised neutrons. Magnetic X-ray scattering is widely used for studies of magnetic ordering in compounds of *f*-elements (lanthanides and actinides).[125] One of the first demonstrations of research capabilities of the technique has been the confirmation of helical magnetic structure (*i.e*., heliomagnetism, a particular case of antiferromagnetic ordering) in a number of rare-earth metals, in particular, in holmium.[126]

Yet another emerging trend of synchrotron X-ray crystallography is the so-called perturbation crystallography, covering structural investigations of crystals in an external perturbing field, such as mechanical deformation, electrostatic or magnetic field and crystals of substances in excited states.[127] For instance, an X-ray diffraction study has been performed for a single crystal of 2-methyl-4-nitroaniline (exhibiting non-linear optical and piezoelectric properties) in an external electric field (NSLS, Stony Brook, USA). Changes in unit cell parameters and intensities of selected reflections for the crystal placed into the electrostatic field of 3.9×10^6 V m^{-1} have been explained by rotation of the molecules tending to align their dipole moments with the direction of the external field.[128] Changes in unit cell parameters and electron charge density redistribution have been observed in a crystal of deuterated potassium dihydrophosphate KD_2PO_4 (manifesting segnetoelectric and piezoelectric properties) in the electrostatic field of 1.3×10^6 V m^{-1}. Upon application of the external field, a phase transition with alteration of space group and syngony ($I42d \rightarrow Fdd2$) has been detected.[129]

A combined study using IR and X-ray diffraction data for a single crystal of the $Na_2[Ru(NO_2)_4(NO)OH] \cdot 2H_2O$ photochromic complex with excitation by a laser pulse has been carried out in ESRF (Grenoble, France).[130] An excited state of the molecule (with relative population of 0.2–0.3) has been detected and structurally characterised. The excitation is accompanied by elongation of the N–O bond by 0.19(5) Å and decrease in the Ru–N–O bond angle by 6(2)°. Earlier, a non-zero population of an excited state with changed geometry of the MNO fragment has been observed for (η^5-C_5H_5)NiNO by XAFS spectroscopy.[131]

b. X-Ray powder diffraction

Techniques of X-ray powder diffraction (XRD) or X-ray phase analysis are the main fast methods for structural characterisation of polycrystalline samples. In XRD, the dependence of scattering intensity as a function of a single scattering angle 2θ, is measured. Compared to single crystal X-ray diffractometry, X-ray powder diffraction methods are much more versatile allowing studies of a broader range of samples including compact workpieces, partially ordered multiphase systems, polymers, thin films, layered nanocomposites, minerals and so on. XRD is applicable to solution of such problems as qualitative identification and semi-quantitative analysis of crystalline phases in mixtures, estimation of degree of crystallinity and sizes of crystallites in polymers, analysis of preferred orientation and textures in materials, investigations of phase transitions and equilibria in solids, determination of unit cell parameters as a function of the phase chemical composition or external conditions (pressure, temperature), structural monitoring of solid-phase reactions, *etc*.

XRD is routinely used in laboratories with X-ray tubes as the X-ray source. However, during the last decade measurement of XRD patterns in synchrotron centres (especially for samples with low diffracting power and substances available in small amounts) become more and more common (Fig. 18). Most important areas of the SR X-ray powder diffraction are high-precision and high-resolution diffractometry, which allows *ab initio* structure solution in combination with the structure refinement using the full-profile analysis (Rietveld method) solely from powder diffraction data; diffraction investigations of partially ordered and amorphous samples; time-resolved studies of processes in solids.[12,20,132] As in synchrotron X-ray crystallography, position-sensitive detectors are widely utilised in SR-based XRD (typically, curved linear 1*D* PSDs capable of simultaneous full pattern registration in the 2θ range from 0° up to 165–170°).

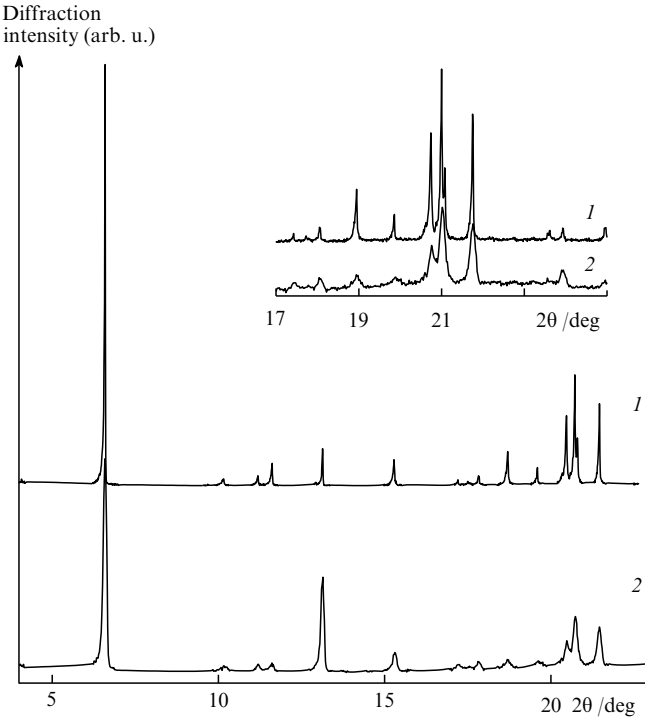

Figure 18. X-Ray powder diffraction patterns for radical-ion salt $BEDTTTF^+ \cdot C_{60} \cdot I_3^-$ (BEDTTTF stands for bis-ethylenedithiotetrathiafulvalene).
(*1*) – SR pattern (VEPP-3 storage ring, Novosibirsk, λ = 1.5402 Å, angle step 0.01°, exposure time 1 h); (*2*) – laboratory pattern (DRON-3 diffractometer, X-ray tube Cu K_α, $\lambda \approx$ 1.5418 Å, 45 kV × 20 mA, angle step 0.02°, exposure time 20 h).

Depending on the instrumental setup, two methods of XRD can be distinguished: conventional angle-dispersive diffraction (when a fixed-wavelength monochromatic X-ray beam is used) and energy-dispersive diffraction (when the scattering intensity is measured at the constant scattering angle and the wavelength of the incident beam is varied).[133] Energy-dispersive X-ray powder diffraction can be accomplished only on SR sources; this modification of XRD is very useful in structural investigations of matter under extreme conditions. In the case of angle-resolved diffractometry, due to high collimation and degree of monochromaticity of X-ray beams, resolution of weak reflections is substantially better than that obtained using laboratory diffractometers; the profiles of reflections are narrower and more regular. Using SR, it becomes possible to achieve good signal-to-noise statistics for very short time intervals (down to ms); thus it allows registration of minor crystalline phases present in the sample in very low concentration ($\sim$0.1%).[134] All these factors substantially facilitate data processing including full-profile analysis of powder patterns by the Rietveld method. The latter is used to refine positions of atoms within the unit cells by fitting the calculated intensity profile $I(2\theta)$ to the experimental curve; the

accuracy of this procedure may approach that of single crystal X-ray crystallography.[135]

The main unsolved problem in the powder crystallography is the selection of the initial approximation, *i.e.*, structure solution. In synchrotron XRD patterns, up to a few hundred individual reflections can be revealed. Thus it turns possible to solve *ab initio*, in a routine mode, relatively complex structures with up to several tens of independent atoms in the unit cell. For structure solution, both algorithms widely adopted in crystallography of small-molecular-weight compounds (direct methods, the Patterson method) and *ad hoc* techniques (maximum entropy, maximum likelihood and Monte Carlo methods, trial-and-error search among sterically allowed orientations of a fragment with known geometry in the unit cell with variation of selected structural parameters such as torsion angles, *etc.*) are used. The reliability of the Rietveld refinement results can be enhanced by fitting the structural model *versus* several independent experimental data sets (for example, *vs.* synchrotron diffraction patterns measured at different wavelengths). Recently, the Rietveld refinement combined with trial-and-error search for most probable atomic configurations proved to be very efficient in structure solution from powder diffraction data.[136–139]

The number of various structures of organic,[140–142] inorganic,[143–146] and organometallic[147,148] compounds solved *ab initio* based on synchrotron XRD data has now reached several hundreds. Synchrotron XRD is actively employed in structural studies of fullerene derivatives,[149] such as endohedral metallofullerenes $Sc@C_{82}$,[150] $Y@C_{82}$, $Sc_2@C_{84}$ (which are available only in a few mg),[151] dimeric azafullerene $(C_{59}N)_2$,[152] low-temperature modification of fullerene bromide $C_{60}Br_{24}\cdot 2Br_2$ (see Ref. 153), *etc*. In certain cases, this method allows one to solve independently several components of a multiphase system without their separation. For example, it was possible to determine crystal structures of two polymorph modification of cyclopentadienyl rubidium from synchrotron powder diffraction pattern of their mixture (Fig. 19).[154] The electron density distribution revealing features at the subatomic level for a series of simple inorganic solids, *viz.*, BN, Mg, Be, was successfully reconstructed based on synchrotron X-ray powder diffraction and using the maximum entropy method (MEM).[155–157]

Structural investigations of textured samples, which can be considered as an intermediate step between a single crystal and a polycrystalline powder with random orientation of crystallites, can also be facilitated if SR is used up to the possibility of routine structure solutions by direct methods.[158] In this case, a typical routine includes measurement of an XRD pattern at different orientations of the sample in the X-ray beam. In contrast to synchrotron experiments, such a procedure with the laboratory diffractometers usually leads to a substantial line broadening due to high divergence of the incident beam produced by an X-ray tube.

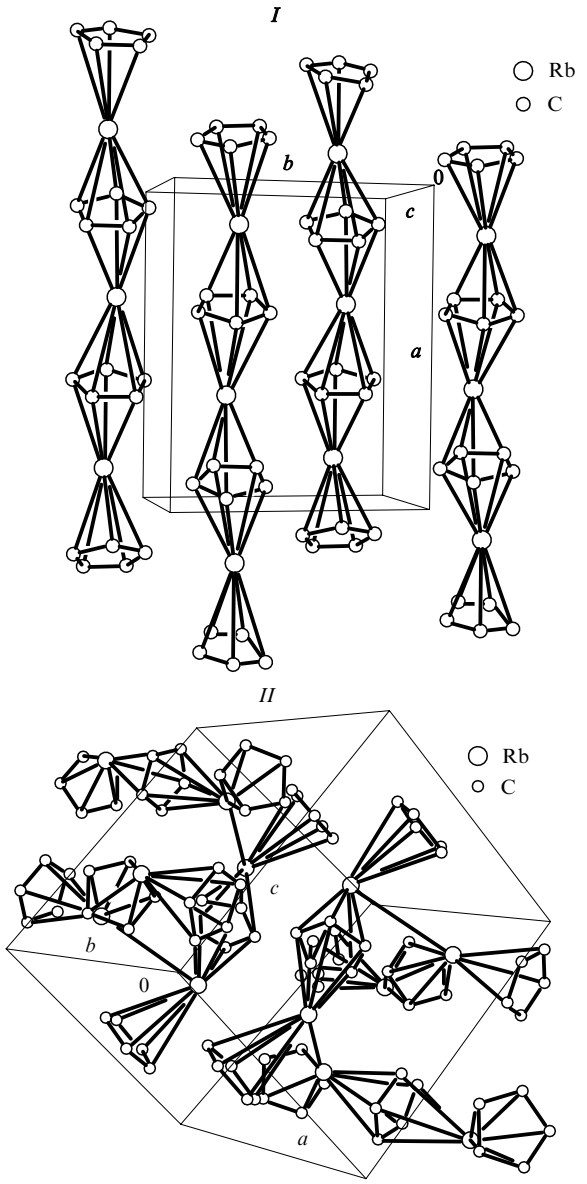

Figure 19. Crystal structures of two polymorphic modifications of $Rb(C_5H_5)$ differing from each other in spatial arrangement of infinite Cp – Rb – Cp chains. The structures have been solved *ab initio* based on the synchrotron powder diffraction pattern for their mixture.[154]
(*I*) Space group *Pnma*, a = 10.799 Å, b = 8.962 Å, c = 5.706 Å (chains are arranged along the a axis); (*II*) space group *Pbcm*, a = 9.340 Å, b = 10.967 Å, c = 10.549 Å (chains are arranged along both the b and c axes).

c. X-Ray scattering by amorphous and partially ordered samples

When X-ray radiation is scattered by a completely amorphous solid or by a liquid, the dependence of intensity on the scattering angle exhibits no sharp diffraction maxima. The Fourier transformation of smooth oscillations observed in this dependence gives rise to a radial distribution function (RDF). The maxima in this curve correspond to interatomic distances. A classical version of this method § has a limited applicability, since the interpretation of results for systems more complex than monocomponent or binary is often ambiguous. For example, noncrystalline scattering of synchrotron X-rays with the energy of 101.2 keV (HASYLAB centre) has been utilised for the analysis of RDF in normal and heavy water. In this study, small systematic differences in interatomic distances between oxygen atoms forming H-bonds with different hydrogen isotopes (the Ubbelohde effect) have been revealed.[159]

Noncrystalline scattering of hard X-rays is a promising technique for structural characterisation of glasses and other inorganic materials with disordered structures, since in this case, the amplitudes of scattering on light atoms become negligible and thus only interatomic distances related to heavy atoms are seen in RDF, which facilitates substantially their interpretation. Analysis of oscillations in the noncrystalline X-ray scattering curves up to high values of the diffraction vector

$$Q = \frac{4\pi \sin\theta}{\lambda}$$

allows determination of interatomic distances with the accuracy of *ca.* 0.01 Å.[160,161] For instance, in a study of a short-range order around barium atoms in $BaSi_2O_5$ using non-crystalline scattering

§ This method is also often referred to as the method of radial electron density (RED), wide-angle X-ray scattering (WAXS), or partial distribution functions (PDF).

of synchrotron X-rays with the energy of 150 keV over the Q range of 0.8 – 38.7 Å^{-1}, long Ba – Ba distances at 4.5 – 4.8 Å have been revealed.[162] For measurements of this kind, intense SR beams produced by insertion devices (wigglers and undulators) in third-generation storage rings are most suitable.

In substances with partially ordered structures (defect-rich, disordered and dynamic phases, liquid crystals, thin films, intercalation compounds, polymers, *etc.*) as well as in phases with non-crystallographic ordering (modulated and incommensurate phases, quasi-crystals), the types of spatial symmetry can be different for different directions and/or components of the sample. Intercalation compounds of layered matrices (such as transition metal dichalcogenides, graphite, *etc.*) may be mentioned as examples of partially ordered systems. They often exhibit a strictly parallel stacking of alternating 'guest/host' layers, long-range order within host layers combined with the possibilities of phase transitions in two-dimensional guest layers and orientational disorder of adjacent layers. Powder diffraction patterns for such systems often contain relatively narrow reflections together with wide diffuse features. Important structural information can be extracted in this case from the analysis of shapes and widths of diffraction lines [133, 135] and diffuse scattering.[163, 164]

A variety of partial ordering is particularly typical of biopolymers and other biological systems.¶ In SR-based studies of such systems, two-coordinate detectors are conveniently used. The measured patterns are usually adjusted to fit some *a priori* model, which corresponds to a structure of a segment of polymer chain, conformation of the chain, fibre orientation, *etc.*[165, 166]

d. Small-angle X-ray scattering

Small-angle X-ray scattering (SAXS) is based on the scattering of X-rays on optical inhomogeneities of the sample (atomic aggregates, cavities) with the size of the order of several tens of nm. Experimentally, scattering intensity is registered as a function of scattering angle in the region of small angles from several angular minutes up to a few degrees, *i.e.*, for diffraction vector moduli $0 < Q \leqslant 0.2$ (see Refs 167 – 169). In such small angle diffraction patterns, usual diffraction maxima corresponding to reflections from long-periodicity atomic planes with interplanar distances 10 – 50 nm (100 – 500 Å) can be observed. A periodic structure can also be formed by packing of supramolecular objects (polymer globules, nanoparticles, *etc.*). By analysing the scattering intensity decrease function for a sample with completely irregular structure, one may retrieve information on the mean particle size (or inhomogeneity regions) in the sample as well as estimate the shape and size distribution of such particles (Fig. 20).

SAXS plays a very important role in characterisation of polymer morphology (including biopolymers), conformations of macromolecules in solutions,[170, 171] colloid systems,[172] submicro- and nanoparticles as well as in studies of such processes as phase segregation in amorphous glasses, gelation, nucleation, crystal growth, amorphisation, *etc.*[173 – 175] Small divergence of synchrotron X-ray beams extends the capabilities of the technique enabling collection of scattering data at very small angles corresponding to interplanar distances up to ~1000 nm [ultra-small angle X-ray scattering (USAXS)].[176 – 178]

¶ Studies of biological objects using X-ray crystallography, non-crystalline diffraction, small angle scattering (see below) and XAFS are often merged under the common term 'structural biology'.

3. Inelastic X-ray scattering

Analysis of energy distribution of scattered X-rays forms the basis of a number of methods.[179 – 181] As has been mentioned above (see Section III), inelastic losses accompanying X-ray scattering are due to several distinct physical processes (Fig. 21). Processing of phonon and plasmon loss spectra allows one to reconstruct dynamic structural factors (which describe the collective dynamics of a multiparticle system) for nuclei and electrons, respectively. The dynamic factor of nuclei is linked with many important characteristics of materials, such as strength, compressibility, sound velocity, *etc.*

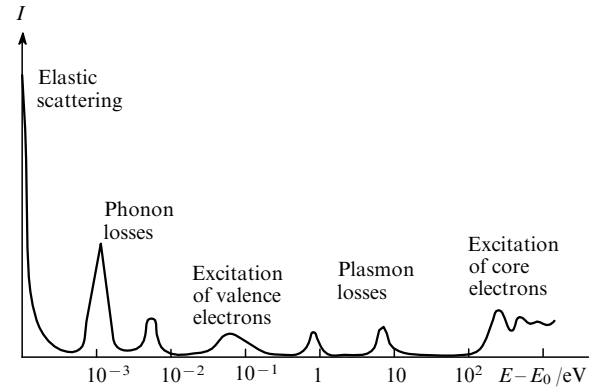

Figure 21. Characteristic energy losses in inelastic X-ray scattering spectra.

Phonon spectra of solids are close analogues of vibrational molecular IR spectra. For studies of phonon structure of crystals, inelastic neutron scattering is traditionally used. However, application of synchrotron X-rays has a number of advantages, in particular, for small crystals as well as for amorphous or liquid samples.[182, 183] In order to study atomic vibrations using inelastic X-ray scattering, a very high degree of the incident beam monochromaticity is required, so development of this method has become possible after the appearance of third-generation SR sources, systems of nested monochromators and monochromatisation techniques based on resonance nuclear diffraction (see Section IV.4).

Spectra of plasmon vibrations of electrons in the conduction zone for such solids as metals, semi- and superconductors contain important information on microscopic mechanisms of conductivity and other electrophysical properties. Spectra of energy losses corresponding to electron excitations allow determination of electron transitions, *i.e.*, studies of energy band structure of solids (similarly to the analysis of electronic states of molecules by UV spectroscopy).[184, 185] The Compton scattering profiles can be transformed into the Fermi surface maps, which reveal the distribution of electron moments in the conduction zone.[186] Many electrophysical characteristics of metals and semiconductors can be calculated based on this distribution.

X-Ray Raman scattering becomes increasingly important in chemical studies.[187, 188] Similarly to conventional Raman scattering employed in Raman spectroscopy, X-ray Raman satellites are produced by a quantified transfer of energy from photons to the sample under study. However, it is phonon loss spectra that are the closest analogues of molecular Raman spectra, whereas X-ray Raman scattering has several special features. First of all, the energy lost by an X-ray photon is consumed to induce photo-

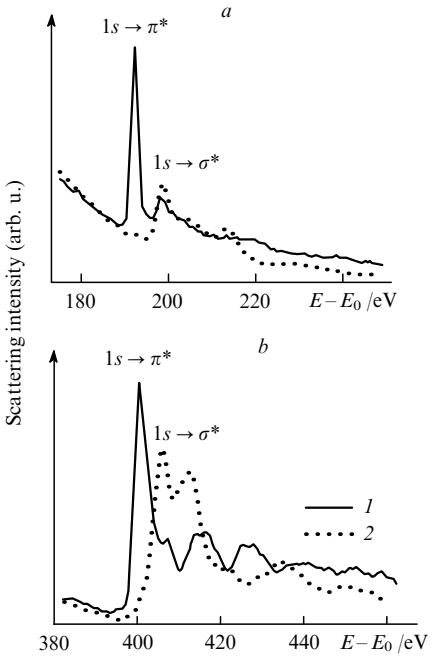

Figure 22. Boron (*a*) and nitrogen (*b*) *K*-edge X-ray absorption fine structures according to X-ray Raman scattering on a boron nitride single crystal in transmission (*1*) and reflection (*2*) modes.[180]
(*1*) The scattering vector is parallel to the *c*-axis of the crystal; (*2*) scattering vector is perpendicular to the *c*-axis of the crystal; excitation energy ~7 keV.

ionisation of light elements rather than excitation of vibrational modes and thus the respective amount of energy transfer exceeds the energy of vibrations by 5–6 orders of magnitude. Second, only low-energy satellites are observed in X-ray Raman scattering which represent triangular-shaped extended bands with an edge rather than narrow resonance maxima (Fig. 22).

Low-energy Raman satellites observed in inelastic scattering of a hard monochromatic X-ray beam (~10 keV) due to photoionisation of 1*s* shells manifest XAFS-like fine structure. Thus, X-ray Raman scattering allows one to measure XAFS spectra for the elements, the absorption edges of which lie in the soft X-ray region (50–500 eV), if one operates with ordinary hard X-ray radiation in air. This technique allows one to obtain the same information on the electronic state and local atomic environment of light elements as is given by NEXAFS or electron energy loss spectroscopy (EELS) under ultrahigh vacuum conditions. This technique is particularly promising for investigations of substances under extreme conditions, since such experiments usually require sample environment non-transparent for soft X-rays. X-Ray Raman scattering has been applied to study electronic structure of light elements, such as Li, Be, C, *e.g.*, in graphite intercalation compounds with alkaline metals (carbon 1*s*-edge) as well as in LiC_6 intercalate (lithium 1*s*-edge).[189–191]

When the energy of inelastically scattered X-ray radiation is close to resonance absorption of one of elements in the sample, the so-called resonant inelastic X-ray scattering (RIXS) is observed. The physical background of RIXS is very similar to that of resonant X-ray emission (see above). The difference in these two processes is reflected in their quantum description: the RIXS is a one-stage process; meanwhile in the resonant X-ray emission, two stages can be distinguished, *viz.*, absorption and re-emission (during lifetime of the excited state, part of the information on absorbed photon, such as its initial moment, can be lost due to internal conversion processes). The RIXS method can be efficiently used to explore fine features of electronic structures of solids: many electron transitions (excitation channels) non-detectable in absorption or non-resonant inelastic scattering spectra clearly manifest themselves in RIXS.[192, 193]

4. Synchrotron radiation Mössbauer spectroscopy

Transitions of atomic nuclei to low-lying quantum excited states for many elements lie in the hard X-ray region of the energy range 10–100 keV. When the energy of the incident X-ray radiation coincides with the energy of a nuclear transition, resonance nuclear absorption occurs, also known as nuclear γ-resonance or the Mössbauer effect. Each Mössbauer isotope (possessing low-lying excited states) is characterised with its own distinct set of nuclear transitions. Nuclear absorption bands are very narrow, their widths are usually 10^{-8}–10^{-10} eV ($\Delta E/E \approx 10^{-14}$). For comparison, the width of absorption bands associated with valence electron transitions is $\sim 10^{-7}$ eV ($\Delta E/E \approx 10^{-8}$) and that with core electron transitions is 1–10 eV ($\Delta E/E \approx 10^{-3}$). In this connection, measurements of resonance nuclear absorption are possible only with X-ray beams of the extremely high degree of monochromaticity. In the conventional laboratory modification of Mössbauer spectroscopy, excited nuclei of the isotope under study produced upon a radioactive decay are normally used as an excitation energy source; for example:

$$^{57}Co \rightarrow {}^{57}Fe^{*} \rightarrow {}^{57}Fe + \gamma. \qquad (6)$$

Other techniques of strictly monochromatic γ-rays generation, such as target activation with a neutron beam or collision of atoms with high-kinetic-energy ions (Coulomb nuclei activation) are available in nuclear research centres.†

Isotopic (or chemical) shift of the nuclear excited level energy and quadrupole splitting of the level are the parameters that are measured in Mössbauer spectra. Furthermore, hyperfine magnetic splitting of spectral lines is observed for magnetically ordered systems. These parameters represent fingerprints for each individual compound; so these allow rather straightforward and unambiguous determination of the oxidation states of an element, symmetry of coordination environment and degree of its distortion.

A major disadvantage of the conventional Mössbauer spectroscopy is a limited number of monochromatic γ-sources available. The predominant part of all Mössbauer studies is performed for a few elements which have convenient γ-active isotopes, such as ^{57}Fe, ^{119}Sn, ^{121}Sb, ^{151}Eu. In principle, utilisation of SR eliminates this restriction since X-ray radiation with continuous energy distribution up to 100 keV and higher is made available (this is particularly true for the third-generation SR sources and insertion devices). The Mössbauer effect on synchrotron radiation was first observed in the mid 80's.[194] Now, experimental stations for the experiments in this field are installed in several SR centres, such as HASYLAB, ESRF, APS, SPring-8.[195, 196]

Single crystal X-ray monochromators do not provide the degree of monochromaticity required for the convenient modification of Mössbauer absorption spectroscopy. In this relation, the so-called nuclear forward scattering (NFS) technique is under active development in the field of synchrotron Mössbauer spectroscopy. In this method, a sample is irradiated by a very fast pulse of monochromatised SR with energy close to the energy of resonance nuclear absorption and photons scattered in the direction of the primary beam (forward scattering) are registered.[197]

Under such experimental conditions, a fast-decaying background signal of X-rays elastically scattered by electrons is observed immediately after the excitation pulse followed by a coherent nuclear scattering (nuclear fluorescence) with a delay of the order of 100 ns, corresponding to the lifetime of a nuclear

† In the classical version of Mössbauer spectroscopy, the energy difference between the incident radiation emitted by nuclei of a source and resonance absorption of target nuclei is compensated by movement of a sample due to the Doppler effect; thus shifts of Mössbauer spectral lines are usually measured in velocity units (mm s^{-1}).[26]

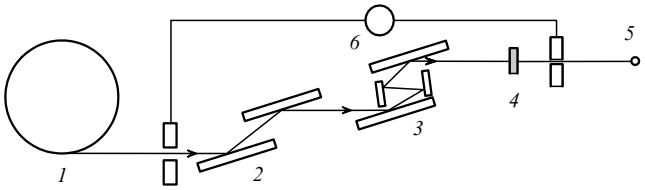

Figure 23. A scheme of a device for measurement of Mössbauer spectra in the NFS mode with utilisation of pulsed synchrotron radiation.
(*1*) Pulsed SR source, (*2*) pre-monochromator ($\Delta E/E \simeq 10^{-4}$), (*3*) high-resolution monochromator ($\Delta E/E \simeq 10^{-7}$), (*4*) sample, (*5*) APD, (*6*) delay circuit (~ 100 ns).

excited state (Fig. 23). In this signal extracted with a specialised delay circuit and measured with a fast-counting detector, such as an avalanche photodiode (APD), decaying oscillations of the scattered beam intensity (quantum beats) are observed. Quantitative parameters of these oscillations can be transformed into normal Mössbauer characteristics [197] implying that the information similar to that of conventional Mössbauer spectra can be obtained (sometimes with higher accuracy).

Up to now, first experiments have been conducted on 'exotic' Mössbauer nuclei, which however are potentially important for chemistry, such as ^{67}Zn, ^{61}Ni, ^{40}K, ^{73}Ge and a number of lanthanides and actinides. Synchrotron Mössbauer spectroscopy is a promising research tool in bioinorganic chemistry [196, 197] and structural materials science (materials under high pressures,[198–200] time-resolved studies of fast processes, magnetic properties [201, 202]).

Coherence of nuclear scattering can be violated as a result of various dynamic processes involving excited nuclei.[203] For instance, diffusion of excited nuclei leads to a faster decay of quantum beats. This phenomenon (quasi-elastic nuclear scattering [204–206]) is used in NFS studies of single crystals for determination of length and direction of elementary diffusion jumps. Energy distribution of nuclear fluorescence at non-zero scattering angles relative to the excitation beam (inelastic nuclear scattering [207]) gives information on phonon structure of a crystal lattice, *i.e.*, on collective dynamics of nuclei in the time scale comparable to the lifetime of excited states.[208]

Yet another important trend in development of synchrotron Mössbauer spectroscopy is the so-called resonance nuclear diffraction.[209] When a single crystal containing a Mössbauer isotope (for example, yttrium iron garnet enriched with ^{57}Fe isotope) is irradiated by a synchrotron X-rays with the energy close to resonance excitation of the nucleus (under Bragg's conditions), all the inelastic nuclear scattering processes are suppressed and the beam reflected becomes highly monochromatic. X-Ray monochromators based on the resonance nuclear diffraction provide the highest energy resolution available to date allowing one to extract exceptionally narrow spectral lines corresponding to energies of Mössbauer nuclei resonance absorption from incident beams of a medium degree of monochromaticity. Such high-resolution monochromators are used in Mössbauer studies and in phonon structure studies of solids by means of inelastic X-ray scattering.[210]

5. Imaging techniques

Synchrotron X-ray radiation (as well as electromagnetic radiation of other spectral regions) can be used for production of magnified images of various objects. SR-based imaging techniques include X-ray microscopy, X-ray diffraction topography, computed tomography along with methods widely adopted in medical applications, such as radiography, subtraction angiography, mammography, *etc*.

With respect to spatial resolution, X-ray microscopy occupies an intermediate position between optical and electron microscopy. Synchrotron radiation-based X-ray microscopy benefits from the possibility of varying such characteristics of the incident X-ray beam as energy and polarisation. Besides, utilisation of hard X-rays (7–30 keV) does not require an ultrahigh vacuum analytical chamber (in contrast to all modifications of electron microscopy). This enables *in vivo* studies of biological systems and strongly facilitates investigations of large objects. Standard spatial resolution of hard X-ray microscopy is ~ 0.25 μm. Utilisation of soft X-rays (0.2–1.2 keV) in combination with advanced X-ray optics, such as FZP and BFO, makes spatial resolution of 30–50 nm attainable. Penetration depth of soft X-rays into a condensed matter is higher than that of electrons, thus, the samples which are opaque for transmission electron microscope can be studied by X-ray microscopy. Furthermore, the use of electron beams induces greater radiation damage of the sample compared to synchrotron X-rays.

Yet another advantage of X-ray microscopy is the possibility to achieve element and even valence contrast by varying the incident radiation wavelength and using absorption edges. Studies of biological objects are usually performed in the energy range referred to as the 'water window', *viz*., 280–550 eV. In this range, absorption by oxygen atoms (and thus by water molecules always abundantly present in biological samples) is relatively weak. By varying the beam energy within the 'water window' it becomes possible to achieve contrast in visualisation of, for example, carbon and nitrogen atoms and thus independently estimate the spatial distribution of proteins and nucleic acids in the sample. X-Ray microscopy can be subdivided into contact, projection and scanning modifications depending on mutual orientation of SR source, sample and detector.[211–214] Recent achievements in the field of synchrotron X-ray microscopy are considered in detail in the monograph.[215]

X-Ray diffraction topography is a method of defect imaging in crystals. It is based on the analysis of intensity distribution of scattered radiation within the diffraction spot.[216] Using X-ray topography it is possible to visualise point defects and dislocations with spatial resolution of 2–3 μm, to analyse their dynamics upon application of a mechanical stress (for example, in piezoelectric crystals), as well as to study local distortions, deformations, inhomogeneities and microcracks in nearly perfect crystals.[217] Diffraction topography is sensitive to gradients of unit cell parameter deformations $\Delta a/a$ of the order of $\sim 10^{-7}$. This method can be used efficiently in studies of large single crystals which are opaque for visible light. The principal field of application of this technique is technological control of perfect crystals, for example, in manufacturing semiconductors. Utilisation of SR in this field leads to increase in the spatial resolution and decrease in exposure times (and therefore radiation damage to the sample).[216–219] X-Ray topography can be utilised as a fast preliminary test of single crystal quality. This can be particularly important in protein crystallography where diffraction experiments are very expensive and time-consuming.

X-Ray computed tomography allows visualisation of internal structure of samples in different cross-sections. The image is reconstructed by mathematical processing of transmitted intensity profiles for various mutual orientations of the sample and radiation source.[220, 221] This method is used for characterisation of such objects as technological workpieces, biological and geological samples (*e.g.*, microcavities and micropores in minerals). For image reconstruction, parallel or divergent, 'white' or monochromatic synchrotron X-ray beams can be used. The spatial resolution of X-ray tomography is a few micrometers.[222] As in the case of X-ray microscopy, the contrast of reconstructed images can be noticeably enhanced if incident radiation wavelength is chosen close to the absorption edges of certain elements in the sample. For instance, distribution of light and heavy elements throughout the sample may be independently reconstructed from X-ray tomography data collected at two strongly different wavelengths [dual photon absorptiometry–computed tomography (DPA-CT)].

In modern imaging techniques, utilisation of the coherent properties of SR acquires increasing importance. In this connection, coherent synchrotron X-ray radiation of third-generation SR sources allows one to achieve phase contrast besides standard absorption contrast in images. Absorption contrast is obtained as a result of differences in X-ray absorption coefficients of different points in the sample, whereas phase contrast is due to phase shifts of scattered coherent radiation, which gives rise to an interference pattern superimposed on the sample image. This interference pattern depends upon sample-to-detector distance and therefore very high contrast images may be obtained by adjusting this distance.[223–225]

Coherent properties are also utilised in a new SR-based visualisation technique, *viz*., X-ray photon correlation spectroscopy (XPCS) or intensity fluctuation spectroscopy. This method is an X-ray analogue of visible light dynamic scattering, which is widely used in studies of colloid systems. The X-ray photon correlation spectroscopy is based on observation of a real-time evolution of the speckle interference pattern produced by scattering of coherent X-ray radiation on disordered samples. Using this method, it is possible to study low-frequency dynamic processes (10^{-3}–10^{6} Hz) in the sample and visualise short-range density fluctuations within the distances range of the order of 1 nm.[226] This method has been successfully applied to study Brownian motion of metal nanoparticles[227] and copolymer micelles in solutions,[228] dynamics of charge density waves, critical fluctuations near the point of order–disorder phase transitions in amorphous alloys,[229] conformational dynamics of polymers upon glassification,[230] *etc*.

6. Other methods

a. Utilisation of anomalous scattering

In the theoretical description of X-ray scattering on atoms, the atomic scattering factor f_0 (sometimes also referred to as atomic form factor) is of key importance. The atomic scattering factor is a smooth function of scattering angle θ, monotonically decreasing with an increase in θ from 0° to 180°. Atomic scattering factors for adjacent elements in the D I Mendeleev Periodic Table are close. Over a wide range of wavelengths, f_0 is virtually independent of incident radiation energy.

However, if incident radiation energy approaches an X-ray absorption edge of an element in the sample, a wavelength-dependent correction to f_0 has to be introduced into the scattering formalism. This correction term is commonly referred to as anomalous dispersion (Fig. 24). In the energy range of X-ray resonance absorption, scattering is accompanied by intensity attenuation. In this case, the total atomic scattering factor $f(\theta,\lambda)$ formally acquires a complex value

$$f(\theta,\lambda) = f_0(\theta) + f'(\theta,\lambda) + if''(\theta,\lambda), \tag{7}$$

where f_0 is the wavelength-independent part of atomic scattering factor (rapidly decreasing with an increase in scattering angle);

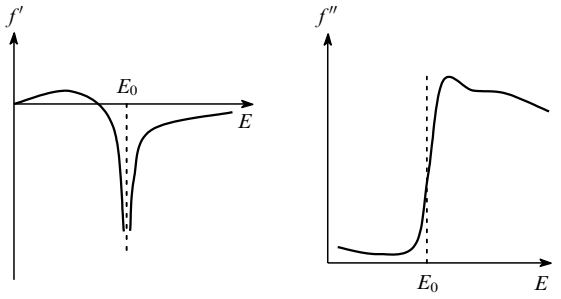

Figure 24. Real (f') and imaginary (f'') parts of anomalous dispersion correction to the atomic scattering factor as functions of the radiation energy.

f' and f'' are real and imaginary parts of the anomalous dispersion, respectively. The imaginary part of the anomalous dispersion is directly proportional to the X-ray absorption cross-section, *i.e*., to X-ray absorption coefficient μ, and its real part is linked with the imaginary part by the Kramers–Kronig dispersion relation

$$f'(\omega) = \frac{2}{\pi}\int_0^\infty \frac{\omega' f''(\omega')}{\omega^2 - (\omega')^2}\,\mathrm{d}\omega', \tag{8}$$

where ω is the radiation frequency.

An anomalous dispersion contribution may substantially distort scattering intensities compared to values calculated on the base of f_0 only. In contrast to f_0, the f' and f'' terms only weakly depend on the scattering angle, so the relative contribution of anomalous dispersion is higher for large scattering angles. As a rule, the energies of X-ray absorption edges for adjacent elements in the D I Mendeleev Periodic Table differ from each other by a few hundreds of eV, consequently, account for anomalous dispersion leads to substantial differences in atomic scattering factors (and thus to different X-ray scattering patterns) for such elements when the scattered radiation wavelength is close to an X-ray absorption edge of one of these two elements. Moreover, due to different chemical shifts of X-ray absorption edges in different compounds of one element, atomic scattering factors can become noticeably different even for atoms of one element in different chemical environment or charge state (valence contrast). Advanced techniques based on application of anomalous scattering and respective experimental diffraction results are thoroughly discussed in a number of recent publications.[231–233]

The anomalous scattering combines X-ray absorption and scattering phenomena. In order to utilise it in diffraction experiments, it is necessary to collect diffraction data with incident radiation of continuously variable wavelength (which is possible only with synchrotron sources) or to carry out a series of diffraction experiments at several wavelengths, at least one of which being close to an X-ray absorption edge of an element in the sample. In the latter case, the difference between two diffraction patterns in the proximity of the edge and apart from it will be primarily caused by scattering on the absorbing atoms.

Anomalous scattering of synchrotron radiation is widely used in powder X-ray diffraction. Using this approach, atoms of certain elements can be precisely located in the unit cell, which substantially facilitates structure solution. This technique is often referred to as resonance X-ray diffraction. In studies of amorphous samples using anomalous wide-angle X-ray scattering (AWAXS), partial radial distribution functions may be determined separately for each heavy element.[232] This makes interpretation of experimental results much more reliable and unambiguous. A similar approach is adopted in anomalous small-angle X-ray scattering (ASAXS), for example, for determination of mean size and size distribution of particles in supported metal catalysts and nanoparticles stabilised in polymer matrices or for analysis of metal distribution in bimetallic nanoclusters.[234–236]

In conventional single crystal X-ray crystallography, account for anomalous dispersion can be used in determination of the absolute configuration of a non-centrosymmetrical (chiral) crystal and its constituent molecules. When SR is used, data collection at the wavelength of resonance absorption allows unambiguous establishment of the chemical nature of anomalously scattering atoms as well as charge states for crystallographically non-equivalent atoms of one element in mixed-valence complexes, the so-called valence contrast X-ray crystallography. Capabilities of this technique has been demonstrated for a series of inorganic substances in which atoms of one element in different oxidation states occupy crystallographically non-equivalent positions, *e.g*., Fe_3O_4,[237] $GaCl_2$,[238] $NbSe_3$,[239] as well as for a number of mixed-valence polynuclear complexes.[240, 241]

Utilisation of anomalous dispersion in X-ray crystallography is most logically implemented in the multi-wavelength anomalous diffraction (MAD) method, which becomes increasingly popular in protein crystallography.[242–245] For a single crystal containing atoms of heavy elements, it is possible to estimate experimentally the phase of any reflection based on its intensity at three different wavelengths before, directly at and above the X-ray absorption edge of the corresponding element. Thus, MAD helps to overcome the key problem of single crystal X-ray crystallography, the so-called problem of initial phases: in order to transform the set of diffraction data into the target electron density distribution map, it is necessary to assign certain phases (which cannot be directly determined from standard diffraction experiment) to experimentally measured intensities of reflections. In small-molecule crystallography, reliable direct methods of statistical estimation of the initial phases have been developed, whereas in protein crystallography, the search for initial phases remains very complicated and not always solvable problem.

Determination of reflection phases using MAD is a much more laborious procedure than common diffraction measurements, however the information obtained is often worth the time spent. The MAD method gradually displaces multiple isomorphous replacement (MIR) method in protein crystallography. This formerly popular but much less versatile method is based on comparison of diffraction data sets for crystallographically isomorphous derivatives of a protein with different heavy substituents. Many biological macromolecules in their native form contain heavy elements (iron, molybdenum, zinc, copper, manganese, *etc.*) and thus the MAD-phasing procedure is directly applicable to them. Recently, first experiments have been undertaken, which demonstrated in principle the possibility of MAD application in the soft X-ray region at the absorption edges of sulfur and phosphorus. However technical problems arose related to rapid radiation-induced decomposition of the sample due to strong X-ray absorption.[246, 247]

Heavy anomalously scattering atoms can be introduced into samples under study by chemical methods. For instance, calcium or magnesium ions in biological molecules can be replaced by heavier lanthanide ions; zinc ions, by mercury, *etc.* In this case, the substituted derivative does not have to be crystallographically isomorphous to the native protein (which is a prerequisite for MIR), it is sufficient that the primary amino acid sequence and the main conformation of the protein molecule are conserved. Heavy elements can be introduced into biological molecules as labelling fragments, which are chemical analogues of their native building blocks. Among such labels, selenomethionine for proteins (MAD at the Se *K*-edge) and brominated uracil for nucleic acids (MAD at the Br *K*-edge) are most often used. Yet another route for incorporating heavy elements into crystals is to perform a diffraction experiment under pressure of Xe. In this case, Xe atoms replace water molecules in cavities of the crystal lattice without disturbing the general structure of the biopolymer, and MAD-phasing at Xe *K*-edge is then applied.[248]

Anomalous dispersion can be efficiently used to enhance research capabilities of X-ray absorption spectroscopy.[249] In this connection, the diffraction anomalous fine structure (DAFS) method, which can be considered as a diffraction modification of XAFS, is actively developing. In the DAFS method, the intensity of a selected diffraction reflection is measured while varying the incident radiation energy so as to pass across an X-ray absorption edge of a certain element. Since imaginary part of the anomalous dispersion is directly proportional to the X-ray absorption coefficient μ, the dependence of reflection intensity upon the incident radiation energy manifests XAFS-like fine structure.

The DAFS method can be applied to studies of both single crystals and polycrystalline powders. In particular, it is useful for investigations of mixtures of polycrystalline powders since it allows registration of XAFS spectra at the edge for a certain element separately for each phase. Furthermore, since crystallographically non-equivalent atoms of one element make different contributions to the intensity of different reflections, DAFS data measured for several diffraction reflections allow one to extract contributions into XAFS spectrum from each crystallographically independent group of atoms of a certain element. Capabilities of DAFS have been demonstrated on such classes of substances as spinels, complex oxides, superconductors, *etc.*[250–252]

b. X-Ray standing waves

In addition to anomalous dispersion, X-ray absorption and diffraction phenomena are manifested simultaneously in the method of X-ray standing waves (XSW).[253] Under conditions of a specular reflection or Bragg's diffraction in a nearly perfect single crystal, the intensity of the electromagnetic wave is redistributed so as to form a standing wave. Differences in local intensities of the electromagnetic field in points of nodes and antinodes of the standing wave lead to different absorption and thus to different yield of all secondary processes, such as X-ray florescence, photo- and Auger electron emission, *etc.* in the corresponding atomic layers.[254, 255] Experimentally, it is manifested in a strong dependence of intensity of respective secondary processes on the incidence angle of the X-rays on the crystal or on the wavelength of the X-rays at constant incidence angle. In the latter case, the geometry of normal incidence of radiation to the surface of the crystal is often selected; this technique is referred to as normal incidence X-ray standing waves (NIXSW).[256]

The XSW method, among very few other instrumental techniques, allows structural investigations of amorphous near-surface layers of crystals with thicknesses from several nm to several μm. It is also used for precise measurement of layer thickness in multilayer periodic structures as well as for localisation of impurity atoms in crystal lattices, *e.g.*, dopant atoms in semiconducting single crystals, implanted ions, guest metal ions in biomembranes, *etc.*[257–259] For example, XSW has been applied to study gallium arsenide single crystals with a surface doped with silicon using various techniques. As has been shown in the case of molecular beam epitaxy, all silicon atoms occupy the gallium positions of the crystal lattice. In contrast, in the case of ion implantation followed by annealing (or thermally activated diffusion), only 30% of Si atoms regularly occupy the gallium positions, the rest of Si atoms occupy random positions and of them $\sim$6% occupy the As positions.[260] Modern theoretical concepts underlying the XSW method, its instrumentation and applications are discussed in recent reviews.[256, 261]

c. Surface study methods in the geometry of grazing incidence

X-Ray reflectometry method is based on the analysis of X-ray reflectivity coefficient as a function of the X-ray incidence angle. In a number of cases, this method gives important information on the atomic structure of near-surface layers.[262] As has been mentioned above (see Section III), under conditions of total external reflection, the ratio of reflected radiation approaches unity and the incident radiation does not penetrate deep into the sample interacting only with the thin near-surface layer ($\sim$10 nm). This effect can be used in order to increase surface sensitivity of 'classical' bulk X-ray methods (such as X-ray spectroscopy and diffraction). In particular, total reflection X-ray fluorescence (TRXRF) is used for quantitative analysis of trace atoms (including light elements starting from boron) in near-surface regions of semiconductors, materials modified by ion implantation, *etc.*[263–265] Due to small penetration depth of X-rays into the sample under total reflection conditions, the method is extremely sensitive: the lowest detection limit expressed as absolute mass of an admixture is of the order of femtograms (10^{-15} g).[266] This method is used for admixture level control in such very pure objects as semiconducting single crystals.[267]

Grazing-incidence X-ray diffraction (GI-XRD) is used in studies of single crystal surfaces and other materials with atomically ordered surfaces, in particular, those with specific two-dimensional ordering. Recently, this method has been applied to such objects as self-assembled monomolecular layers, Langmuir–

Blodgett, epitaxial, atomic deposition and CVD films, as well as two-dimensional crystals of lipophilic systems (fatty acids and their salts, ω-amino acids, phospholipids) at the water–air interface.[268–275]

Grazing incidence small-angle X-ray scattering is used for characterisation of thin films and supported catalysts.[276] Measurement of X-ray reflectivity coefficient as a function of incident radiation energy at the incidence angle close to the angle of total external reflection allows registration of XAFS spectra for near-surface layers: X-ray reflectivity coefficient is correlated with complex refraction coefficient, imaginary part of which is directly proportional to the absorption coefficient $\mu(E)$ [see Eqn (7)]. This technique is commonly referred to as Refl-EXAFS. The term SEXAFS (surface EXAFS) is also sometimes used but it combines an entire set of surface-sensitive techniques for EXAFS registration including, in addition Refl-EXAFS, total electron yield, yield of photon stimulated ion desorption and so on.[277–279]

d. The use of polarisation of synchrotron radiation

The use of polarisation of electromagnetic radiation in physicochemical analysis of substances with anisotropic atomic structures is based on dichroism, *i.e.*, the dependence of optical properties of substances on the direction of the electric vector in the electromagnetic wave propagating through the substance. For instance, plane-of-polarisation rotation angle per optical path unit is a key characteristic of substances with asymmetric (chiral) atomic structures; meanwhile, circular dichroism (CD) spectra give important information on mutual orientation of chromophore groups in molecules.

In contrast to X-ray radiation produced by traditional sources, *viz.*, X-ray tubes, synchrotron radiation is always completely polarised. Similarly to visible light optics, two types of dichroism, *viz.*, linear and circular, can be distinguished in the X-ray region. Polarisation of SR is most widely used in X-ray spectroscopy, since it primarily affects the probability of electron transitions. In the case of molecule excitation by a linearly polarised SR, the probability of an electronic transition of a certain symmetry depends on the mutual orientation of the electronic transition dipole moment (difference between dipole moments of the molecule in the ground and excited states) and polarisation direction of the excitation radiation. Upon resonant photoionisation of an atom by linearly polarised X-rays, the photoelectron wave generated does not possess spherical symmetry: the probability of the photoelectron propagation is the maximum in the plane of polarisation and is equal to zero in the perpendicular plane. In EXAFS, in particular, this results in the situation where atoms from the local environment lying exactly in this plane dominate in the Fourier transforms.[280]

A prerequisite for manifestation of linear X-ray dichroism is ordering and strict orientation of the sample under study relative to the incident SR beam. For example, adsorbed monolayers, which exhibit strong anisotropy of properties in the directions parallel to the layer (interaction within the layer) and perpendicular to the layer (adsorbate–support interactions), can be efficiently studied using polarisation-dependent NEXAFS spectroscopy. This anisotropy causes a distinct dependence of X-ray absorption spectra on the incidence angle of the polarised SR beam or on the polarisation direction at the constant incidence angle. In particular, in the case of grazing-incidence, σ and π polarisations of the incident beam are often used, which probe interactions parallel and perpendicular to the sample surface, respectively.[281] Utilisation of linear polarisation of SR in X-ray microscopy with element contrast allows one to determine real-space orientation of atomic fragments in polymeric fibres, since the shape of the absorption edge (NEXAFS spectrum) becomes sensitive to the orientation of certain chemical bonds, such as C=C and C=O, which have a pronounced π*-resonance.[54, 212, 282]

Intercalation compounds into layered matrices (such as graphite and its chemical derivatives, transition metal dichalcogenides, phosphates, *etc.*) constitute another group of objects for which the application of X-ray spectroscopy with linearly polarised SR is particularly informative. These systems in many cases manifest virtually ideal texture with the layers of matrix strictly parallel to the surface of the sample. Thus, using polarisation-dependent XAFS it is possible to determine, for instance, orientation of molecules within the intercalated layers.[283, 284]

Analysis of polarisation-dependent EXAFS spectra for potassium niobate (perovskite type) made it possible to determine crystallographic directions of niobium atom shifts out of centres of octahedra formed by oxygen atoms in the phase transition.[285] Studies of distortions in planar square CuO_4 fragments in single crystals of high-temperature superconducting phases gave additional information on the mechanism of superconductivity.[286, 287]

In quantum mechanical description of polarised light properties, the term photon spin is often used. A photon, being a boson, possesses spin quantum number $S = 1$ and two allowed spin moment projections $m_S = \pm 1$ (the projection $m_S = 0$ is prohibited for a photon due to its zero rest mass). A beam of photons with $m_S = 1$ corresponds to the right and with $m_S = -1$ to the left circular polarisation. The electrons with a defined spin direction (coinciding with the photon spin) are excited upon absorption of circularly polarised photons (spin polarisation). If in the substance under study, all atomic magnetic moments are co-aligned (this is the case for a one-domain ferromagnetic or for a paramagnetic placed in a magnetic field), a distinct dependence of X-ray absorption coefficient on mutual orientation of the sample macroscopic magnetic moment and circular polarisation direction of the synchrotron radiation is manifested in XANES spectra (Fig. 25). This phenomenon first observed in 1987[288] was called X-ray magnetic circular dichroism (XMCD). Over recent years, the field of XMCD experienced rapid development since using this technique it is possible to analyse magnetic properties of materials at the atomic level, *viz.*, with element specificity determine magnetic moments of atoms and identify spin and orbital contributions.[289, 290]

XMCD (its realisation is possible only in synchrotron radiation centres) has already become an established technique for characterisation of magnetic materials: thin films of 3*d*-metals

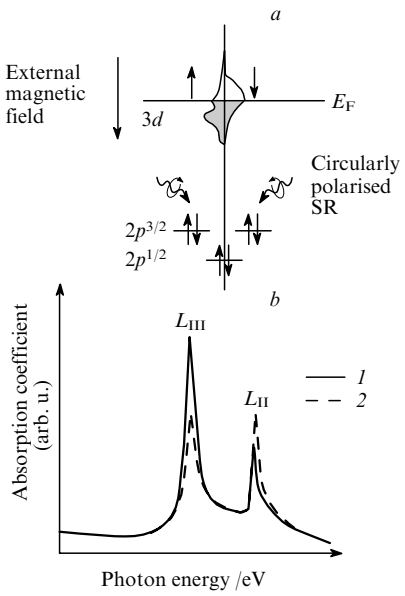

Figure 25. Scheme of the origin of circular dichroism in X-ray absorption spectra (*a*) and typical XMCD spectrum at $L_{II,III}$-edges of 3*d*- and 4*d*-metals (*b*).
Circular polarisation of the incident beam is chosen so as to excite electrons with spins parallel (*1*) and antiparallel (*2*) to the external magnetic field.

(Fe, Co, Ni), lanthanide and actinide derivatives, materials with giant magnetoresistance (strong dependence of conductivity on the applied magnetic field), *etc*. Giant magnetoresistance is typical, for instance, of multilayers with alternating ferro- and diamagnetic layers. Such materials are promising in information storage technology.[291–294]

In 1995, X-ray natural circular dichroism XNCD (*i.e*., X-ray circular dichroism, which is manifested without application of external magnetic field) was observed in some chemical systems, *e.g*., in chiral paramagnetic crystals.[295–297] Soft X-ray circular dichroism spectroscopy is widely used for characterisation of helical protein structures.[298]

The EXAFS spectra measured with circularly polarised SR produce RDF curves where atoms with non-zero magnetic moments dominate (spin-polarised or 'magnetic' EXAFS) (Fig. 26).[299, 300] The X-ray circular dichroism is actively employed in modern versions of spin-resolved photoelectron spectroscopy.[301, 302]

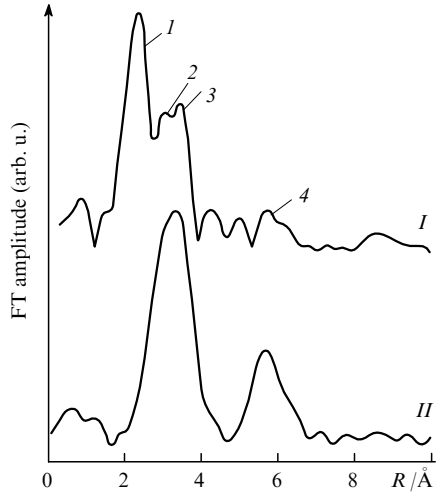

Figure 26. Normal (*1*) and magnetic (*2*) EXAFS spectra taken at Ho L_{II}-edge for $Ho_3Fe_5O_{12}$.
(*1*) Ho–O 2.3–2.4 Å; (*2*) Ho–Fe 3.0–3.7 Å; (*3*) Ho–Ho 3.7 Å; (*4*) Ho–Ho 5.6 Å.[299]

In contrast to X-ray spectroscopy, polarisation properties of SR have not found broad applications in X-ray diffraction techniques, though many phenomena accompanying diffraction exhibit polarisation dependence, which can be used for extraction of additional information. Besides, polarisation has to be taken into consideration in development and optimisation of X-ray optical elements designed for experiments with SR. Thus when linearly polarised X-rays with energy close to an X-ray absorption edge of an element in the sample is scattered by a low-symmetry single crystal, the dependence of atomic scattering factor on the scattering angle becomes anisotropic. This anisotropy is due to the fact that the absorption coefficient for the crystal (and thus corrections to the atomic scattering factor owing to the anomalous dispersion) will be different for non-equivalent crystallographic directions. In particular, this leads to the appearance of diffraction reflections forbidden by extinction conditions. This phenomenon is called anisotropic anomalous scattering (AAS) or forbidden reflection near-edge diffraction (FRNED). It can be used for determination of positions of anomalously scattering atoms within the unit cell.[303–305] For such forbidden reflections, the polarisation type and direction of the scattered wave can be different from those of the incident SR, this change being dependent on the specific crystal structure.[306] Utilisation of circularly polarised SR in X-ray crystallography makes determination of absolute configurations of chiral molecules in single crystals more reliable. X-Ray topography with circularly polarised SR is used for visualisation of magnetic domains.[307] Polarisation dependence of reflection intensities in magnetic scattering allows separation of total magnetic moment density into spin and orbital contributions.[308]

V. The main trends of applied studies using synchrotron radiation

1. Combined X-ray techniques

In majority of cases, application of only one, even quite powerful instrumental method, appears insufficient to get insight into the atomic and electronic structure of real objects (a probable exception is X-ray crystallography of small molecules). Therefore, complex SR-based studies with involvement of a number of complementary X-ray techniques are more desirable. The organisational structure of synchrotron centres itself (concentration of highly skilled staff and advanced instrumentation in one building) promotes such a convergence stimulating interchange of ideas between different experimental techniques. Moreover, a limited number of experimental stations installed at modern international synchrotron radiation centres is used by numerous research groups with diverse scientific interests. Under such operational conditions, each experimental station has to be sufficiently flexible and versatile and allow solution of a wide range of research problems with minimum hardware modifications.[309–312]

Among many advanced combined techniques routinely applied in SR centres to the studies of short- and long-range atomic order in various materials, the following combinations are most popular: XRD/XAFS (simultaneous registration of powder diffraction pattern and EXAFS spectrum) and XRD/DAFS (simultaneous registration of powder diffraction pattern and diffraction anomalous fine structure spectrum).[313–315] Specialised software has been developed for simultaneous refinement of crystal structure parameters from the experimental data of both methods.[316] For structural characterisation of semi-crystalline and amorphous polymers, SAXS/XRD or SAXS/WAXS combinations are used.[317] Protein crystallography is often supplemented with EXAFS data in order to determine exact geometry of metal centres.[318] Besides, in experiments based on the MAD method, measurement of X-ray absorption spectrum from the very same crystal as used in the diffraction experiment is required for the calculation of f' and f'' anomalous dispersion terms [see Eqn (8)] used in the phasing procedure. An ultrahigh vacuum chamber is the most expensive part of any device designed for surface studies. In order to use it with maximum efficiency, the respective device should be equipped with a broad range of functionality, for example, for utilisation of angular resolved photoelectron spectroscopy, X-ray standing waves, SEXAFS, *etc*.[319] A similar consideration is applicable to techniques based on utilisation of circularly polarised SR, where combination of magnetic scattering, XMCD, spin-polarised EXAFS, spin-resolved X-ray photoelectron spectroscopy, *etc*., in one device could be required.

Synchrotron radiation-based methods are often combined with traditional laboratory analytical methods, for example, XRD can be combined with differential scanning calorimetry for studies of phase transitions,[317, 320] the combination 'Quick-EXAFS/IR' can be used for the characterisation of matrix synthesis products.[321] Laboratories for chemical, biological and materials science studies in modern SR centres are equipped with the modern instruments for realisation of traditional analytical techniques. The availability of traditional facilities (chromatographs, lasers, presses, scanning tunnelling and transmission electron microscopes, *etc*.) is particularly important for investigations of such complex objects as surfaces, advanced materials, biological systems, *etc*.

The trend to combine several different techniques in one device is realised in a new SR-based method, *viz*., event correlation or coincidence spectroscopy. In this method, several types of secondary emissions (fluorescent photons, photoelectrons, Auger

electrons, secondary ions) initiated by resonance absorption of X-ray photons are simultaneously detected using specialised electronic circuits. As an example of this approach, mention can be made of photoelectron-photoion coincidence (PEPICO) spectroscopy, which implies simultaneous registration of photoelectrons and ions (with a time-of-flight mass spectrometer) produced by photoionisation of a free molecule by an X-ray photon. Other event correlation methods, such as Auger-photoelectron coincidence, photoelectron-fluorescent photon coincidence, *etc*., are also developing. These methods are used in investigations of photochemical reactions, determination of electronic structure and lifetime of excited states, studies of dynamics of photoionisation and photodissociation of chemical bonds in free molecules or ions in the gas phase.[322–327]

2. Studies of substances under extreme conditions

Studies of matter under extreme conditions are of great importance for many fields of modern materials science, condensed state physics, geochemistry, mineralogy and geology. A key component of devices for high-pressure researches is a diamond anvil cell (DAC), which allows production of pressures up to a few hundreds GPa at areas of several square micrometers (Fig. 27). The choice of diamond as the material for such a high-pressure cell is dictated by its unique properties, such as extremely high mechanical strength combined with transparency for hard X-rays. A disadvantage in this case is unavoidable presence of glitches due to Bragg's reflections from walls of the cell. For local heating of the sample, a laser beam can be used and for cooling, a flow of liquid helium. The temperature and pressure inside the DAC can be monitored using structural (unit cell parameters, bond lengths) or spectral characteristics of an internal standard. A ruby crystal is often used as an internal standard with the shift of optical luminescence line as a parameter enabling monitoring. Experimental stations capable to achieve conditions ($T \approx 6000$ K, $P \approx 200$ GPa) close to that in the Earth's core ($T \approx 5000$ K, $P \approx 300$ GPa) are in routine operation for several years in a number of synchrotron radiation centres.[328–333]

Along with static studies, dynamic investigations of substances and materials under microsecond impacts or in propagating blast waves are of significant practical importance. The usefulness of synchrotron radiation in studies of this kind relates primarily to its high intensity (which allows beam penetration through the sample environment) and to the temporal beam modulation in the single-bunch mode of the storage ring operation.

XRD (especially its energy-dispersive modification), X-ray crystallography, EXAFS and X-ray topography are most commonly applied for characterisation of substances under high pressures. High-pressure studies using synchrotron Mössbauer spectroscopy are also under rapid development over recent years.[199, 200] It has to be stressed that on most of specialised devices for high-pressure studies, several physical techniques are

P /GPa: (*1*) 77, (*2*) 85, (*3*) 88, (*4*) 96, (*5*) 101, (*6*) 105, (*7*) 110, (*8*) 116. At $P \sim 96$ GPa, a structural phase transition associated with oxygen metallisation occurs.

realised.[333, 334] Recently, equations of state for such substances as molecular hydrogen, helium, oxygen, carbon and water have been determined up to pressures > 100 GPa (Fig. 28) based on results obtained using SR. Phase diagrams of compounds which form the Earth's mantle and thus are very important in order to achieve understanding of geochemical processes (metallic iron, silicon, quartz, silicates and aluminosilicates) have been studied in a broad range of temperatures and pressures.[335–337] Results on structural monitoring of catalytic graphite–diamond transformation in the presence of magnesium carbonates and metallic nickel[338] and structural transition of carbon dioxide into polymeric quartz-like structure and further to metallic state have been reported.[339] In the last years, metallic states of substances and their mixtures which are gaseous under normal conditions (H_2, NH_3, CH_4, *etc*.), have become attainable, which allows simulation of the state of the matter in cores of distant planets of the Solar system: Saturn, Uranus and Neptune.[340–342]

A large part of all experiments with substances under extreme conditions is devoted to detection of unusual chemical properties and to studies of structure and properties of compounds not existing under normal temperatures and pressures. In particular, single crystals of molecular complexes formed in the hydrogen–methane system under high pressures, *viz*., $(CH_4)_2H_2$ and $(CH_4)(H_2)_2$, have been studied by synchrotron X-ray crystallography.[342] In another study, structural behaviour of potassium under high pressures has been investigated.[343] It has been shown that K forms intermetallides with 3*d*-metals, which implies that its chemical properties approach those of transition metals. Pressure-induced phase transitions in semiconducting, superconducting and magnetic materials often become subjects of SR-based studies.[344–347] Such transitions are sometimes accompanied by a change of coordination type or charge state of one of elements in the sample with preservation of overall stoichiometry.[348, 349] Structures and transformations of substances in supercritical media are widely studied. In particular, in a series of studies,[350–352] structural changes of hydration shells of such ions as Rb^+, Sr^{2+} and Br^- upon transition of water into a supercritical state have been monitored and a decrease of mean coordination number in the first coordination sphere has been revealed as a common effect.

3. Studies with high spatial resolution

Modern X-ray optics is capable of producing soft X-ray beams with linear size of several tens nm and hard X-ray beams of

submicron size. Technical progress in this field stimulates development of X-ray microprobe techniques: spatial resolution of such techniques has approached that of classical microprobe techniques utilising beams of charged particles, *viz*., electrons, protons or ions.[353–355] At the same time, synchrotron radiation gives access to a broader range of experimental techniques due to the possibility of detecting secondary radiation of various types, varying excitation energy, using polarisation and so on.‡

Microdiffraction (especially in the Laue modification) is used in studies of single grains and intergrain regions in compact polycrystalline materials (metals, composites, ceramics, semi- and superconductors),[362, 363] in analysis of local ordering areas in liquids or systems with a heavy disorder, in X-ray crystallographic investigations of submicron single crystals (clays, micas, zeolites)[364] and in structural characterisation of microscopic mineral inclusions in biological tissues.[365] Single fibre molecules are studied with synchrotron X-ray microdiffraction.[366] Spatially resolved X-ray fluorescence spectroscopy allows one to map the distribution of elements in a sample with resolution of the order of micrometers. Microprobe modifications of X-ray absorption spectroscopy (EXAFS, XANES, NEXAFS) give additional information on the chemical state and local environment of atoms in the sample under study (Fig. 29).[212, 367] Microprobe modification of XPS (sometimes referred to as 'Super-ESCA') is actively used for characterisation of minute amounts of hardly accessible or hazardous substances. For instance, an XPS study of curium oxide available in the amount of ~ 1 μg has been performed at the ALS synchrotron radiation centre (Berkley, USA).[368] The average beam size in this experiment was ~ 50 μm and the mass of the sample actually irradiated and contributing to the spectrum is estimated by the authors as only 4 ng. Spatially resolved information on supramolecular organisation of various objects can be obtained using microprobe modification of SAXS.[369, 370]

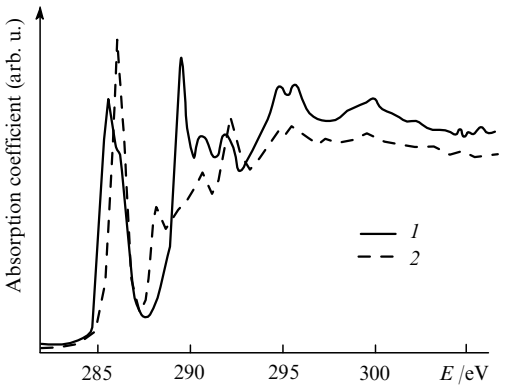

Figure 29. Micro-NEXAFS spectra (carbon *K*-edge) for thin polymeric films with area of 0.1 μm^2 on a scanning X-ray microscope (NSLS, Stony Brook, USA).[212]
(*1*) Polyethylene terephthalate; (*2*) polycarbonate.

Synchrotron X-ray microprobe techniques are routinely used for characterisation of spatially inhomogeneous objects including biological systems (cells, living tissues, bones), natural samples (microinclusions in minerals, coals, soils), advanced materials (ceramics, nanocomposites) as well as for environmental control of industrial wastes. Recently, the use of X-ray microdiffraction has been suggested as an express diagnostic tool for multilayer optoelectronics devices.[371] A set of synchrotron microprobe techniques (X-ray fluorescence, diffraction, XANES) with spatial resolution of 3×20 μm^2 has been used for determination of chemical composition, crystal structure and charge states of atoms in thin phosphor films of $MAlO_3$ (M is a rare-earth metal) grown by combinatorial synthesis.[372] Convergence of SR-based microprobe spectroscopic techniques and X-ray microscopy (see Section IV) during the last decade has lead to emergence of a new research area, *viz*., spectromicroscopy.[356]

‡ Instrumental realisation of X-ray microprobe techniques in modern synchrotron radiation centres and results of recent applications of these techniques are thoroughly discussed in a special issue of *Journal of Electron Spectroscopy and Related Phenomena*,[356] as well as in a number of books and reviews (see, for example, Refs 215, 357–361).

4. Time-resolved studies of processes

Evolution of SR sources and instrumentation, *viz*., gain in brightness, focusing optics optimisation, design of fast and sensitive detectors, development of specialised techniques for data collection and processing, has lead to a substantial decrease in the time required for conduction of an X-ray experiment with SR. Collection of XRF, EXAFS or SAXS data on facilities of modern SR centres may take only a few milliseconds. This approach is of great interest for chemistry, since it makes real-time studies of reaction dynamics possible. SR intensity is sufficiently high to obtain reliable results when the beam passes through walls of a chemical reactor (reaction chamber) or sample environment of another type. That is why most of synchrotron radiation-based methods can be realised *in situ* (see, for example, a special issue of *MRS Bulletin* dedicated to *in situ* studies of materials using synchrotron techniques[373]).

Real-time diffraction (the term 'diffraction cinema' is sometimes used) allows one to investigate dynamics of solid-state reactions, to detect formation of crystalline intermediates and, in the case of heterogeneous reactions, to follow the movement of the reaction front (interface).[20] Hydrothermal synthesis is one of the most promising fields in modern inorganic chemistry. This allows simulation of geochemical processes of natural mineral synthesis and preparation of new micro- and mesoporous materials, which can be applied as molecular sieves, ion-exchange resins, adsorbents, *etc*. The applicability of synchrotron real-time X-ray powder diffraction to studies of hydrothermal synthesis reactions is discussed in Refs 374, 375.

Changes in local environment of a reacting centre in the course of a chemical reaction can be analysed by means of Quick-EXAFS. In particular, such an approach has been utilised for detection of changes in local atomic order in active centres of catalysts.[376, 377] Time-resolved EXAFS can be used as well for structural monitoring of chemical transformations in solutions.[378, 379] Under the term Quick-EXAFS, the techniques with a rapid rotation of a standard crystal monochromator or so-called energy-dispersive EXAFS with a fixed crystal polychromator and a linear detector, are usually meant.[380–382]

Recently,[383] a new method aimed at a decrease in the XAFS data acquisition time has been proposed. It is based on a variation of the electron beam trajectory within insertion devices by adjusting operational parameters of the electromagnetic focusing system (Fig. 30) In this case, the crystal monochromator remains immobile and the beam intensity can be measured with a 'point' detector, *i.e*., ionisation chamber, which has better characteristics (such as counting rate, accuracy and sensitivity) compared to modern linear detectors. As an alternative of the aforementioned instrumental techniques of Quick-EXAFS, a stop-flow method can be used. This implies withdrawal of samples from a reaction mixture at required time intervals followed by their instant freezing and investigation using standard techniques.[384]

Time-resolved X-ray photoelectron spectroscopy enables investigations of chemical reactions at surfaces. For instance, this technique has been applied in studies of kinetics of NO reduction by molecular hydrogen on a single crystal face (553) of rhodium.[385] Data collected at the Super-ESCA station of the ELETTRA synchrotron centre allowed authors to detect intermediate unstable species (atomic nitrogen, atomic hydrogen, NH_x) and suggest a mechanism explaining the oscillatory dynamics of this reaction.

Time-resolved studies of biological processes give insights into mechanisms of key biochemical processes. For example, over the

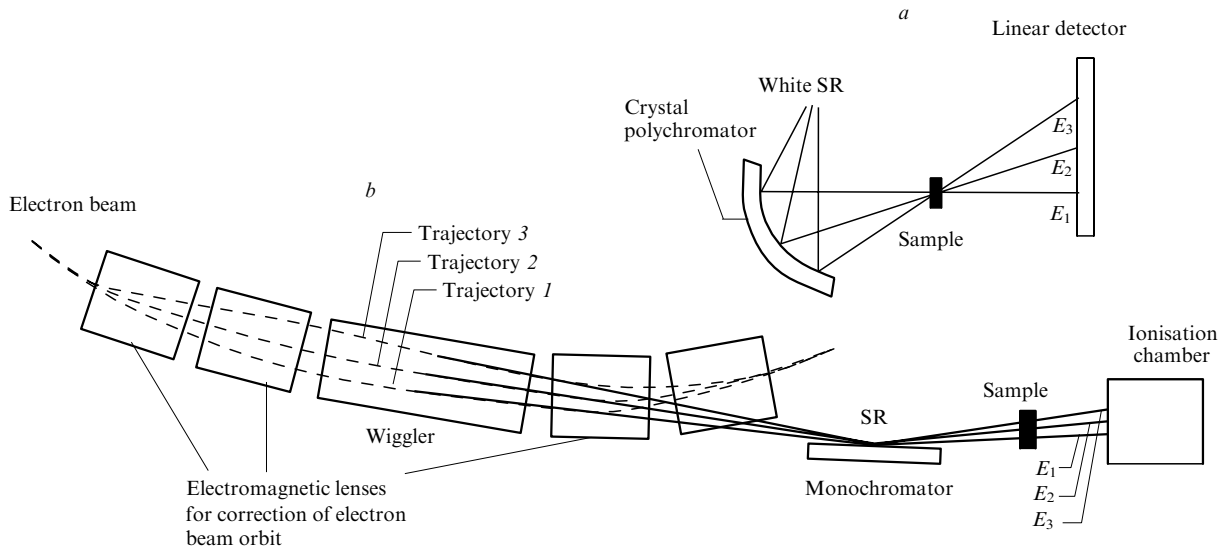

Figure 30. Experimental schemes for Quick-XAFS registration.[383]
(*a*) Energy-dispersive XAFS, (*b*) fast registration of XAFS by varying the electron trajectory within the channel of a storage ring.

last years, a substantial progress has been reached in understanding molecular mechanisms of muscle functioning thanks to SR-based studies of conformational transitions and supramolecular organisation changes of muscles under contraction and relaxation. Systematic real-time diffraction and SAXS studies of muscles are carried out in several international SR centres.[386, 387]

A combination of powerful third-generation SR sources and fast-counting 2*D* position-sensitive detectors opens new avenues in dynamic structural studies by means of Laue diffraction. Within this approach, a method of single crystal X-ray crystallography with time resolution down to tens of picoseconds is realised for biological macromolecules.[388, 389] In this modification of the 'diffraction cinema', a series of Laue patterns is registered during successive pulses of SR with a storage ring operating in the single-bunch mode. This approach is of great potential importance for investigations of enzymatic reactions. As one of the first applications of this technique, structural changes occurring in a single crystal of carboxy-myoglobin upon visible light-induced decarbonylation (Fig. 31) have been investigated.[390–392]

Capabilities offered by storage rings operating in the single-bunch mode are far from full realisation. A traditional method in this field is optical luminescence excited by X-ray pulse: its spectrum and decay dynamics are the key parameters in characterisation of new semiconducting and scintillating materials.[393] With a high level of confidence, we may suggest that in the immediate future, the interest of researchers in temporally modulated SR will increase, since this can supplement research capabilities of many of the aforementioned techniques with time resolution.

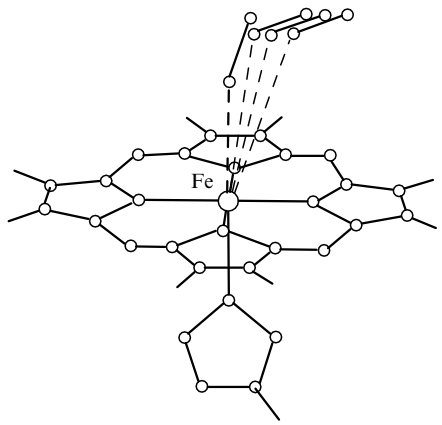

Figure 31. Migration of CO (dashed lines) in the initial stages of carboxy-myoglobin decarbonylation initiated by a visible light flash (ESRF). Atomic positions are determined by refinement of a common initial structural model *versus* a series of successive Laue-diffractograms measured for a single crystal of the substance with time resolution of ~ 10 ps.[392]

VI. Conclusion

Research capabilities of SR in chemistry and related sciences are wide and yet not fully realised. Over the last 30 years, introduction of synchrotron radiation into physicochemical analysis has resulted in substantial improvement of the accuracy and sensitivity of a few tens of physical methods. New synchrotron radiation centres are being constructed and the user community of the existing ones expands rapidly. The number of research papers reporting results obtained with the use of SR is thousands per year.

Starting from 1994, the International Union of Crystallography publishes a dedicated *Journal of Synchrotron Radiation*, in which over 1000 papers on various synchrotron radiation-related topics have already been published.

Key international and Russian national conferences with a dominant or major portion of synchrotron studies in their scope that took place over the period of 1994–2000, are listed in Table 2.

In certain fields of modern science (such as protein crystallography or XAFS), the synchrotron techniques has taken a leading position. And in such directions as development of MAD applications in crystallographic studies of biological polymers or time-resolved structural studies using Laue-diffraction, the last few years can be considered as a real breakthrough. Investigations of magnetic properties of materials using circularly polarised X-ray SR play an important role in modern technology.

Instrumentation of SR studies is under constant upgrade and sophistication. SR sources are evolving leading to even higher brilliance and stability and lower divergence of SR beams. According to predictions of machine R&D groups from several synchrotron centres [SSRL (Stanford, USA), ESRF, NSLS], fourth-generation SR sources may come into reality in the immediate future. In parallel, new ideas in the field of X-ray optics are emerging, which allows production of highly intense narrow-focus beams. Progress in this field is based to a great

extent on the latest achievements of X-ray lithography applications, which is also under active development in synchrotron centres. New fast, precise and sensitive X-ray detectors as well as X-ray monochromators with higher energy resolution appear. With improvement of coherent properties of SR, essentially new directions, such as X-ray holography, become possible. A breakthrough in imaging techniques can be expected with development of X-ray free-electron lasers.

Therefore, we may conclude that synchrotron radiation is one of the most promising points of growth for modern science. Starting from the 90's, the main SR centres turned into a new type of economic enterprises aimed at production of complex physical data. The overwhelming part of studies in modern centres have applied character and are tightly linked to technology. Despite the essentially profitless nature of 'photon factories' (for instance, costs of 1 h of beamtime on an EXAFS station, which is one of the 'cheapest' synchrotron techniques, is US \$200 – 400), contribution of synchrotron studies into modern competitive production is substantial. It explains, why the bulk of synchrotron studies in developed countries steadily increases and why many commercial companies tend to construct own stations at third-generation SR sources (for example, see review [405] on the use of synchrotron methods for characterisation of microelectronics materials prepared by the IBM R&D division on the basis of experimental results obtained at the NSLS).

Up to the 80's, the Soviet Union has been one of the world leaders in the field of synchrotron radiation theory and instrumentation. Many important steps in maturation of synchrotron radiation as a research tool have been made in the USSR. One of the first synchrotrons was constructed in 1964, experimental observation of synchrotron radiation dates back to 1971, undulators were designed in 1977, superconducting multipole wigglers in 1979 and helical undulators — sources of circularly polarised quasi-monochromatic radiation in 1983. Presently, G I Budker Institute of Nuclear Physics, where Siberian Synchrotron Radiation Centre (SSRC) operates, maintains a leading position in this field. Insertion devices, position-sensitive detectors and other high-tech devices designed and produced in BINP are used in many SR centres over the world: CAMD (Baton Rouge, USA), HASYLAB (Hamburg, Germany), Photon Factory (Tsukuba, Japan), PLS (Pohang, South Korea).

Meanwhile, the level and the volume of the applied synchrotron studies in Russia is noticeably lower than those in the largest world centres in USA, Japan and Western Europe. To the date of publication of this review, there is only one routinely operating national SR centre, Siberian synchrotron radiation centre (SSRC) in Novosibirsk, with a first-generation storage ring VEPP-3. Kurchatov synchrotron radiation source with the dedicated 'Sibir'-2' storage ring is on the stage of startup already for several years. Neither of the advanced complex techniques discussed above is involved in routine studies, which directly determine the level of modern science instrumentation. The authors hope that this review will draw attention of Russian researchers to this hot area of modern science.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 99-03-

32810), International Center for Diffraction Data (ICDD) and INTAS (Y V Z Grant YSF00-4095). We would like to thank our colleagues A A Ulyanov (Department of Geology, Moscow State University) and V A Strel'tsov (University of West Australia), who have kindly provided the results of their studies used as illustrations in this review, and O A Belyakova who provided us with materials of School on Synchrotron Radiation (Trieste, Italy, December 1997). The authors also express deep gratitude to D I Kochubey, B P Tolochko and specialists of SSRC for help in collaboration for many years.

Abstract. The published data on the chemistry of intermolecular 1,3-dipolar cycloaddition of nitrile oxides to different types of alkene derivatives are systematised. Various aspects of stereo- and regiochemistry of this reaction are considered. The bibliography includes 182 references.

I. Introduction

1,3-Dipolar cycloaddition of nitrile oxides to unsaturated systems is commonly used in the synthesis of heterocyclic compounds.[1–5] This is due to at least two reasons. First, nitrile oxides react with a great diversity of dipolarophiles by virtue of their high reactivities [1] and, second, the reaction products, *viz*., isoxazoles and 4,5-dihydroisoxazoles, can be used as starting compounds for various synthetic transformations including synthesis of natural compounds and their analogues.[2,3]

This review summarises the published data on 1,3-dipolar cycloaddition of nitrile oxides to alkenes. Problems of regio- and stereochemistry of intermolecular cycloaddition (as a rule, to non-cyclic dipolarophiles) are considered in more detail.

Nitrile oxides are usually generated by treating hydroximoyl chlorides with triethylamine, by dehydrating primary nitro derivatives with isocyanates or by oxidising aldoximes with *N*-chlorosuccinimide.[6–8] New effective approaches to the generation of nitrile oxides have been developed in recent years, *e.g*., from aldoximes under the action of sodium hypochlorite,[9] from hydroximoyl chlorides in the presence of silver(I) acetate [10] or from conjugated nitroalkenes under the action of titanium(IV) chloride.[11] The latter approach allows preparation of α-functionalised nitrile oxides.

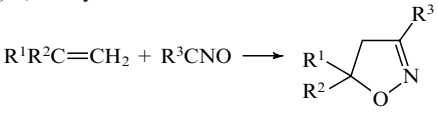
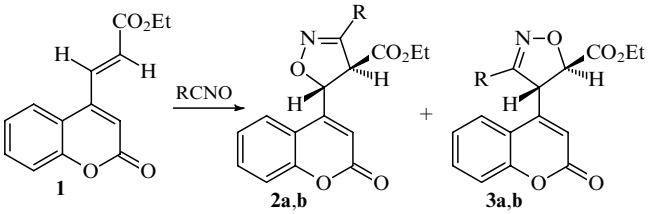
Usually, it is only regiochemistry that is the matter of discussion in the cycloaddition of nitrile oxides to terminal alkenes, *viz*., the formation of a single regioisomer, *i.e*., 3,5-disubstituted ($R^1 = H$) or 3,5,5-trisubstituted (R^1 = Alk, Ar, *etc*.) 4,5-dihydroisoxazole.[12–17]



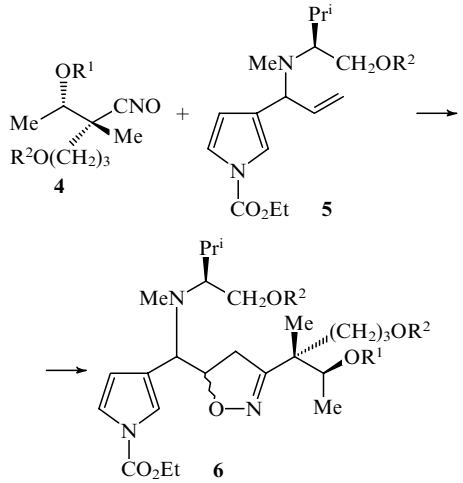
The analysis of stereochemical aspects of these reactions points to their low stereoselectivities [18,19] unless carried out under special conditions (see below).

Non-symmetrical 1,2-disubstituted alkenes usually give two regioisomers.[20–24] However, reactions of certain compounds manifest high regioselectivities with nitrile oxides. Thus the addition of acetonitrile oxide to the coumarin derivative **1** gave the regioisomeric dihydroisoxazoles **2a** and **3a** in a 75 : 3 ratio, whereas 4-methoxybenzonitrile oxide afforded exclusively the regioisomer **3b**.[25]



R = Me (**a**), 4-$MeOC_6H_4$ (**b**).

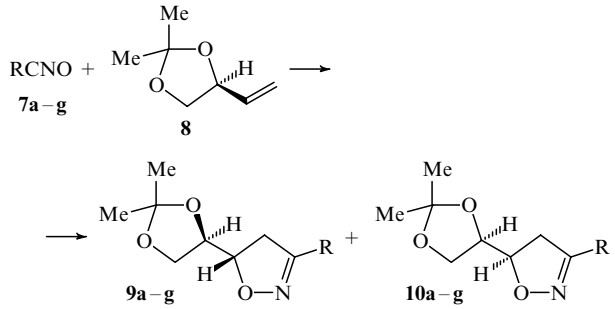
Attempts at performing asymmetric 1,3-dipolar cycloaddition using chiral alkenes or nitrile oxides have been undertaken, however, stereoselective introduction of a new asymmetric centre using chiral nitrile oxides was only partly successful.[26–29] Thus the reaction of the optically active nitrile oxide **4** with the alkene **5** afforded a mixture of diastereomers **6** in a 2.5 : 1 ratio.[30] Reactions with other nitrile oxides yield nearly equimolar mixtures of diastereomers.



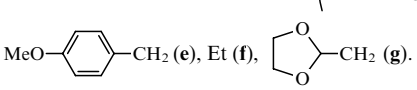
$R^1 = CH_2OMe$; $R^2 = Bu^tMe_2Si$.

II. Cycloaddition of nitrile oxides to allylic and homoallylic alcohols and their derivatives

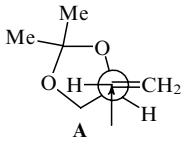
Allylic alcohols and their esters with a chiral centre in the α-position are often used as dipolarophiles; however, the diastereoselectivity of these reactions is not always high. As a rule, reactions of nitrile oxides with allylic alcohols give predominantly *syn*-isomers.[31,32] Cycloaddition of alkenes containing protected hydroxy groups in the α-position to the double bond increases the stereoselectivity.[33–36] The reaction of the nitrile oxide **7a** with (*S*)-(+)-*O*-isopropylidenebut-3-ene-1,2-diol (**8**) is among the first examples of regioselective cycloaddition of nitrile oxides to allylic alcohols; this resulted in the *anti*-adduct **9a** (**9a** : **10a** = 4 : 1) as the main product.[35] In this case, the stereochemistry of the cycloaddition reaction is governed by the oxygen-containing substituent in the allylic position.



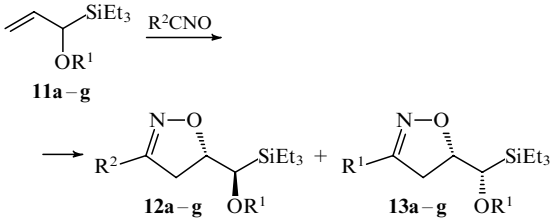
R = EtO_2C (**a**), Me (**b**), $THPOCH_2$ (**c**) (THP =), Ph (**d**),



Nitrile oxides **7b–g** also react with compound **8** with high diastereoselectivities with the predominant formation of *anti*-addition products (80%–94%); the selectivity of this reaction is only weakly dependent on the structure of the nitrile oxide.[34] But-3-ene-1,2-diol containing unprotected hydroxy groups manifests low diastereoselectivity in reactions with nitrile oxides, this is somewhat higher with dioxolanes analogous to compound **8**.[33] The highest diastereoselectivity is achieved with spiroketals of vicinal diols.[36] It is assumed[34] that the cycloaddition proceeds predominantly *via* the transition state corresponding to the conformer **A** (the Kozikovsky model). Nitrile oxide attacks the C=C bond on the side opposite to the C–O bond (indicated by an arrow). Thus, the allylic oxygen atom displays an *anti*-directing (the so-called antiperiplanar) effect. According to the calculations made by Houk *et al.*,[37] this is due to minimisation of secondary interactions of the non-bonding orbitals.



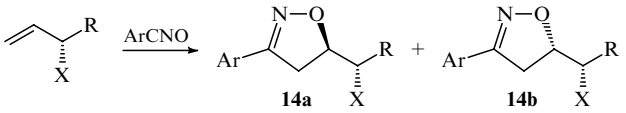
The cycloadditions of pivalo- and benzonitrile oxides to α-hydroxyallylsilane (**11a**) and its *O*-derivatives **11b–g** have been studied.[31,38] Compound **11a** yields a mixture of *syn*- and *anti*-adducts with a small excess of the *syn*-isomer **13a**; with different acylated derivatives, the stereoselectivity of this reaction is weakly affected, whereas silyl ether **11b** gives predominantly the *anti*-addition products **12b** (yield 94%).



R^1 = H (**a**), $SiMe_2Bu^t$ (**b**), COMe (**c**), CO_2Me (**d**), 4-$MeOC_6H_4CO$ (**e**), COPh (**f**), 4-$NO_2C_6H_4CO$ (**g**); R^2 = Bu^t, Ph.

It was shown[31] that the *syn*-selectivity of cycloaddition of nitrile oxides, which is characteristic of the majority of allylic alcohols studied so far, decreases with the increase in the proton-accepting capacity of the solvent used.

The stereochemistry of cycloaddition of benzonitrile oxides to allylic alcohols and their ethers, allylic chlorides and 3,3-diphenylprop-1-ene has been studied in detail.[39,40]



R = Me, Ph, Et, Bu^t; X = OH, OMe, OBn, OTHP, $OSiMe_2Bu^t$, Cl, Ph, Me; Ar = Ph, 4-$NO_2C_6H_4$.

In this case, too, allylic ethers react with nitrile oxides in a stereoselective manner to give the *anti*-addition products **14a** (up to 95% for X = OMe, $OSiMe_2Bu^t$); the selectivity of this reaction increases with the increase in the size of the substituent R. Alcohols yield predominantly the *syn*-addition products **14b**, albeit with low selectivity. The replacement of the ether allylic substituent by Cl, Ph or Me results in a complete or partial loss of stereoselectivity. It is of note that the ratio of the diastereomers strongly depends on the nature of the substituent in the nitrile oxide. Such a behaviour of allylic halides has been described by other authors.[41,42]

Based on the experimental data[37,43,44] and the calculations of transition state models of 1,3-dipolar cycloaddition of nitrile oxides to alkenes, it was suggested that the majority of transition states are structurally close to that shown in Fig. 1*a*. In this case, the substituents in the allyl position can be localised outside, inside or in the *anti*-position with respect to the C–O bond formed.

The main product is formed from the transition state **A** where the largest substituent (L) is in the *anti*-position, whereas the medium substituent (M) is located inside (Fig. 1*b*). The transition state **B** (Fig. 1*c*) yields the minor isomer. The outside position is more sensitive to steric factors due to the interaction of nitrile oxide with the oxygen atom. The electronic characteristics of substituents play a prominent role. Since cycloaddition of nitrile oxides is related to weakly electrophilic reactions, the donor substituent in the allylic position of the transition state is preferably in the *anti*-position, while the acceptor substituents are

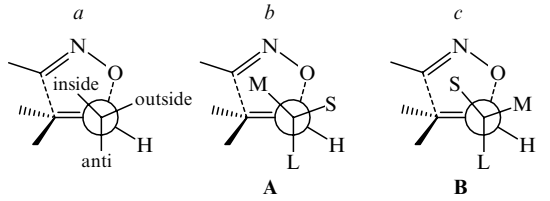


Figure 1. The transition state models in the reaction of 1,3-dipolar addition of nitrile oxides to alkenes.[43,44]
Designations for substituents: L is large, M is medium, S is small.

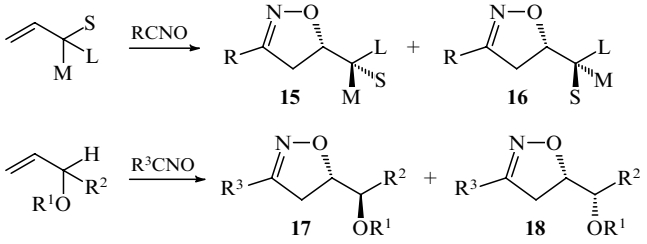
localised either inside or outside (in order to minimise electronic interactions).[39]

This transition state model commonly referred to as the Houk model provides a rationale for the effects of substituents on the stereochemistry of 1,3-dipolar cycloaddition.

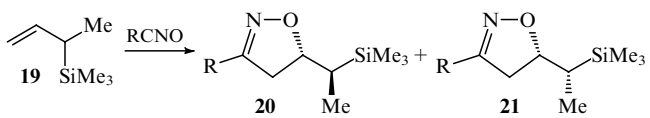
The formation of a hydrogen bond between the oxygen atom of the nitrile oxide and the hydroxy groups of cyclic allylic alcohols results in stabilisation of the *threo*-transition state **A** (Fig. 1*b*). The relatively low stereoselectivities in the case of acyclic allylic alcohols can be assigned to the fact that conformations **A** and **B** compete with one another in the transition state.[43,44]

It is of note that the increase in stereoselectivity with the increase in the size of the substituent R in the allylic alcohol fits well the Houk model, but cannot be explained in terms of the Kozikovsky transition state model.[34]

Thus the cycloaddition of nitrile oxides to terminal alkenes with different sizes of substituents in the allylic positions gives predominantly the diastereomers **15**. The stereoselectivity depends on the relative sizes of the medium (M) and large (L) groups and varies from very low (M = Me, L = Et, **15**:**16** = 1:1) to moderate (M = Me, L = Bu^t, **15**:**16** = 4:1). The same tendency is observed where M = AlkO group, although the stereoselectivity is somewhat higher in this case. The *anti*-diastereomer **17** usually predominates over the *syn*-diastereomer **18** (~3:1). For R^2 = Bu^i, it is the *anti*-isomer that is predominantly formed. The ratios of *syn*- to *anti*-products in these reactions change little with the change in steric and electronic factors in both the nitrile oxide substituent R^3 and the oxygen atom substituent R^1.[39]



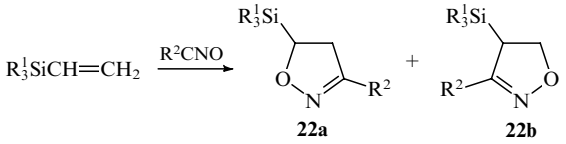
Assuming that the steric and electronic effects of the trimethylsilyl group[43] in the allylic position favour the formation of *anti*-cycloadducts, the behaviour of silanes of the type **19** has been studied in the reaction with nitrile oxides.[45]



R = Ph, Bu^t.

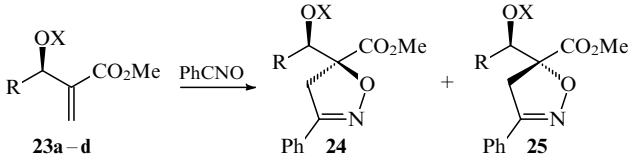
However, the diastereoselectivity of this reaction was low, although the main product **20** (60% – 65%) was formed in accord with the Houk model. Thus, high diastereoselectivity is difficult to achieve in the absence of an oxygen-containing substituent in the allylic position,.

Recent studies have shown[46] that the ratio of 5- and 4-silyl-substituted adducts **22a** and **22b** obtained by cycloaddition of nitrile oxides to trialkoxy(vinyl)silanes depends on the nature of substituents at the silicon atom and the method used to generate nitrile oxides. This reaction is especially selective for R^1 = Me$_3$SiO and R^2 = Me (**22a**:**22b** = 10:1).



R^1 = MeO, EtO, Me$_3$SiO, $\overline{\text{NCH}_2\text{CH}_2\text{O}}$; R^2 = Me, Et, Ph.

It was shown[47] that cycloaddition of nitrile oxides to 1,1-disubstituted alkenes **23** containing a hydroxy- or an alkoxy group in the allylic position (the so-called Baylis – Hillman adducts) gives predominantly the *syn*-isomers **24**, the stereoselectivity of the reaction being dependent on the substituent R.



Compound **23**	R	X	Ratio **24**:**25**	Compound **23**	R	X	Ratio **24**:**25**

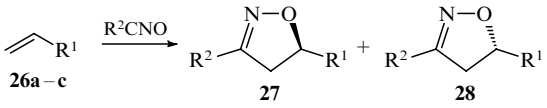
		Bu^{t}Me$_2$Si	7:1			Bu^{t}Me$_2$Si	4:1
		Ac	3:1			Ac	1:1

III. Cycloaddition of nitrile oxides to unsaturated amines, amides and related compounds

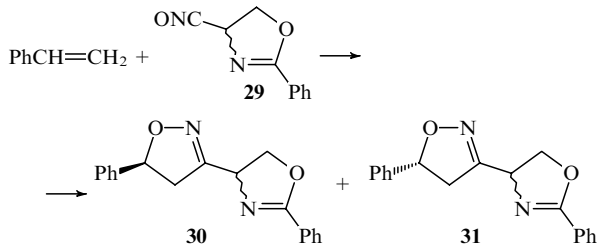
The directing effect of the nitrogen atom in the allylic position has been studied in less detail than that of the oxygen atom. Cycloadditions of nitrile oxides to vinylglycine and 2-aminobut-3-en-1-ol have been described;[48–50] the selectivities of these reactions were low. Reactions of nitrile oxides with (*R*,*S*)-4-vinyl-2-phenyl-4,5-dihydrooxazole (**26a**), *N*-benzyloxycarbonyl-(4*R*)-vinyl-2,2-dimethyloxazolidine (**26b**) and (2*R*)-(*N*-benzyloxycarbonyl)but-3-enol (**26c**) have been studied.[51] It was found that the selectivities of the reactions of the cyclic compounds **26a**,**b** are higher than that of the acyclic analogue **26c**; the *erythro*-isomers of the 4,5-dihydroisoxazoles **27** are the main products. The reaction of alkene **26a** with EtO$_2$CCNO oxide occurs with the highest selectivity (the **27**:**28** ratio is 82:18).



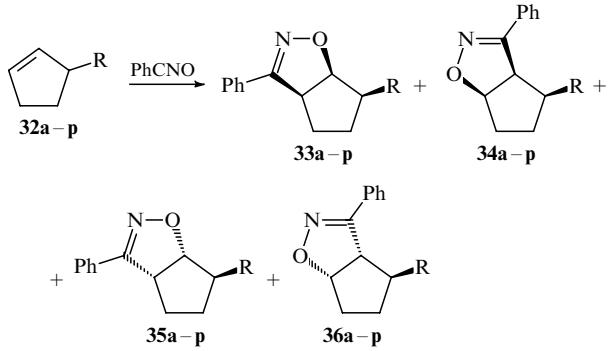
R^1 =  (**a**),  (**b**),  (**c**);

R^2 = Ph, EtO$_2$C, Br.

The effect of introduction of an asymmetric centre into the nitrile oxide component has been studied.[52] Cycloaddition of, *e.g.*, 4,5-dihydrooxazole-4-carbonitrile oxide **29**, to styrene yields a 1:1 mixture of 5-phenyl-4,5-dihydroisoxazoles **30** and **31**. This phenomenon is attributed to the large distance between the asymmetric centre of the molecule and the newly formed centre.

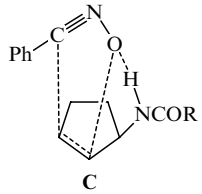


A series of 3-substituted cyclopentenes **32a–p** including amides **32f–p** have been studied as dipolarophiles;[53] variation of the amide acyl group made it possible to change the acidity of the proton in the amide substituent



R = Me (**a**), NMe_2 (**b**), OMe (**c**), OAc (**d**), OH (**e**), NHCOPh (**f**), NMeCOPh (**g**), NHCOMe (**h**), $NHCOCF_3$ (**i**), $NHCOC_4F_9$ (**j**), NHCSMe (**k**), $NHCOC_6H_4OMe$-4 (**l**), $NHCOC_6H_4CF_3$-3 (**m**), $NHCOC_6H_4NO_2$-4 (**n**), $NHSO_2Me$ (**o**), $NHSO_2CF_3$ (**p**).

The content of cycloadducts formed as a result of the nitrile oxide attack on the alkene on the *anti*-side with respect to the substituent *R* exceeded 92% for compounds containing a methyl (**32a**), a dimethylamino (**32b**), a methoxy (**32c**) or an acetoxy (**32d**) group in the allylic position. The reaction of compound **32e** containing an allylic hydroxy group in diethyl ether afforded the adduct **33e** in 30% yield. This adduct was formed due to the formation of a hydrogen bond in the transition state of the reaction. If the reaction is carried out in benzene, which binds a proton more weakly than ether, the yield of the product **33e** increases to 50%. It is assumed that the hydroxy derivative **32e** forms a hydrogen bond with the solvent in ether and with nitrile oxide in benzene. The cycloaddition of the allylic benzamide **32f** yielded the adducts **33f** and **36f** (9 : 1), which can also be ascribed to the formation of a hydrogen bond in the transition state **C** of the cycloaddition.



C

The model proposed sheds more light on the effects of solvents and amide substituents on the reaction rate. The product **33f** is predominantly formed in accordance with the model **C**, since the energy of its transition state decreases due to the formation of a hydrogen bond, while the energies of the transition states leading to the other three products are not changed. Therefore, the alkene **32f** should be more reactive than compounds unable to form hydrogen bonds with the nitrile oxide. Indeed, experiments on competitive reactions of compounds **32f**,**g** with pivalonitrile oxide yielded three products all of which were formed by cycloaddition of nitrile oxide to the alkene **32f** and the yield of the adduct of the type **33** reached 85%.

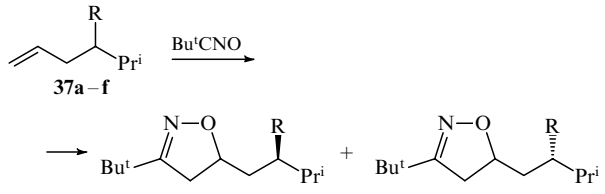
Competitive cycloadditions in benzene, 1,2-dimethoxyethane, dimethylformamide and hexamethylphosphoramide (HMPA) have been studied in order to establish the role of the solvent in this reaction.[54] It was found that the tertiary amide **32g** is much less reactive than the amide **32f**. In the case of the amide **32g**, the nature of the solvent influences neither the degree of conversion of the starting compounds, nor the ratios of the reaction products. Contrariwise, in the case of the amide **32f** the concentration of the reaction product **33f** increases significantly with the increase in the proton-donor capacity of the solvent; while the degree of conversion of the starting compounds changes only slightly. When the reaction was carried out in HMPA, the distribution of the reaction products was similar for both amides, which can be explained within the framework of the model **C**. Substitution of nitrile oxide for the solvent as a hydrogen-bonding acceptor decreases the rate of formation of the adduct **33f**, but the rates of formation of other reaction products change little, as a result of which the total degree of conversion decreases.

The model **C** suggests also that the yields of cycloadducts of the type **33** depend on the ability of the amide to form a hydrogen bond. Thus studies of amides **32h–p** revealed a marked tendency of an increase in the reaction selectivity with increase in the acidity of the amide proton. It is of interest that the sulfonamide group for which the acidity of the proton is the highest in this series, does not manifest high selectivity. In all probability, the bulky sulfonyl group prevents the formation of the transition state **C**. The effects of other factors should not be ruled out either.

These data show that the introduction of a disubstituted amide substituent into the allyl position of alkenes can change both the regio- and stereoselectivity of cycloaddition of nitrile oxides. The formation of hydrogen bonds in the transition state also plays a significant role in this effect.

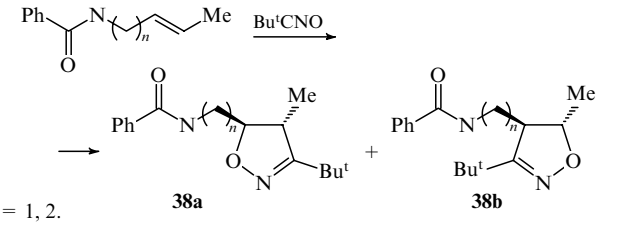
It is of note that the selectivities of cycloaddition reactions with acyclic allylic amides studied earlier [55–58] are low. However, it was shown [59] that amide substituents influence the selectivity of cycloaddition stronger than the allylic hydroxy groups, this effect being especially well-pronounced in the case of cyclic amides.

The stereoselectivity of cycloaddition of the homoallylic amides **37a–d** to nitrile oxides is low in all cases, being comparable to that of the homoallylic alcohol **37e** and amine **37f**.



R = NHCOMe (**a**), $NHCOCF_3$ (**b**), $NHSO_2Me$ (**c**), $NHSO_2CF_3$ (**d**), OH (**e**), NH_2 (**f**).

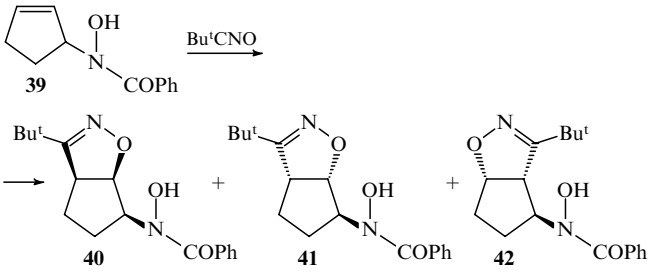
The regioselectivity of cycloaddition of pivalonitrile oxide to allylic and homoallylic acyclic amides containing a disubstituted double bond is also low, *e.g.*, the regioisomers **38a** and **38b** are formed in a ~2 : 1 ratio.[59]



n = 1, 2.

At 20 °C, the cycloaddition occurs slowly; after 5 days, 70% of the original alkene remains unconsumed. At 80 °C, the yield is higher, but the regioselectivity is still very low. It was concluded [59] that the formation of a hydrogen bond in the transition state of acyclic systems is not critical, otherwise the amount of the regioisomer **38a** would have been much higher.

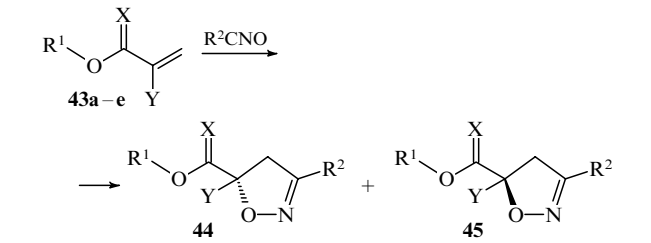
The hydroxy group plays the role of a proton donor when hydroxamic acid **39** is used as a dipolarophile. This reaction gave three isomers (**40** : **41** : **42** = 11 : 2 : 4). This suggests that the hydroxy group of hydroxamic acid is a better directing group than the hydroxy groups of alcohols and produces an effect comparable to that of the NH groups.[59]



IV. Cycloaddition of nitrile oxides to acrylates, crotonates and acrylamides

An efficient approach to optically active dihydroisoxazoles might become both an alternative to the well-known aldol-type reactions and a new method for the synthesis of enantiomerically pure primary amines. Two approaches to asymmetric induction in the cycloaddition of nitrile oxides were used, *viz*., the introduction of an allylic asymmetric centre into a dipolarophile [34, 35] or the use of a chiral nitrile oxide.[27] The attempts at developing efficient procedures for diastereoselective 1,3-dipolar cycloaddition of nitrile oxides using menthyl ethers of allylic alcohols [60] were unsuccessful.

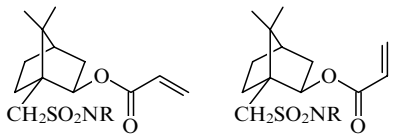
Thus 1,3-dipolar cycloaddition of 4-nitrobenzonitrile oxide with optically active acrylate **43a** and allylic ether **43b** yielded a mixture of the diastereomers **44** and **45**, the diastereomeric excess in favour of the latter was only 4%. The selectivity of the reaction of 4-nitrobenzonitrile oxide with the bornyl ester **43c** was somewhat higher. Pronounced stereoselectivity was observed only in the reaction of the sulfonamide derivatives **43d**,**e** with isobutyronitrile oxide and cyclohexanonitrile oxide. The diastereomers **44** having *S*-configurations of the newly formed chiral centres were the main isomers in these reactions.[61]



R^1	X	Y	Compound **43**	R^2	Ratio **44** : **45**
	O	H	**a**	4-$NO_2C_6H_4$	1 : 1
	CH_2	H	**b**	4-$NO_2C_6H_4$	1 : 1
	O	H	**c**	4-$NO_2C_6H_4$	1 : 1
	O	H	**d**	Bu^t	1 : 3
	O	H	**d**	Ph	1 : 4
	O	Me	**e**	4-$NO_2C_6H_4$	1 : 2
	O	Me	**e**	Bu^t	1 : 1
	O	Me	**e**	Ph	1 : 1

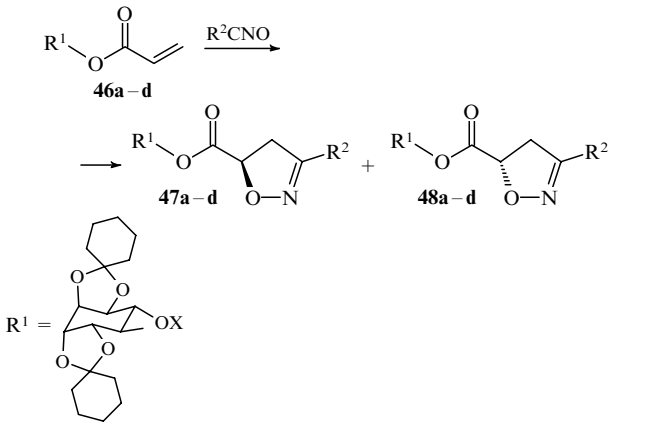
R^3 = Pr^i, C_6H_{11}

It is assumed [61] that the major diastereomers **44** result from the cycloaddition of the nitrile oxide to *s-cis*-confomers **A** of acrylates **43d**,**e**, whereas minor diastereomers are formed by addition to the *s-trans*-conformers **B**.



Later it was demonstrated [5] that the acrylates **43d**,**e** containing sulfonamide groups enter into other cycloaddition reactions predominantly in the *s-cis*-conformations.

Optically active 4,5-dihydroisoxazoles were synthesised by Akiyama *et al*.[62, 63] who added nitrile oxides to chiral acrylates where cyclitols played the role of auxiliary chiral substituents. The acrylates **46a**–**d** gave mixtures of dihydroisoxazoles **47** and **48** in the reactions with benzonitrile oxide (R^2 = Ph). The diastereoselectivities in the case of esters containing methoxymethyl (**46a**) and benzyl (**46b**) substituents were low, whereas the presence of bulky *tert*-butyldimethyl- and *tert*-butyldiphenylsilyl substituents in esters **46c**,**d** provided high π-facial selectivity. This stereochemical result is due to the fact that the major isomer **47** is formed from the *s-cis*-conformer of the acrylate. The bulky *tert*-butyldiphenylsilyl group effectively blocks the attack from the opposite side of the double bond. The maximum diastereoselectivity was achieved when the reaction was carried out in benzene.



Compound **46**	X	R^2	Ratio **47** : **48**	Compound **46**	X	R^2	Ratio **47** : **48**
a	CH_2OMe	Ph	1 : 2	**d**	Bu^tPh_2Si	Me	10 : 1

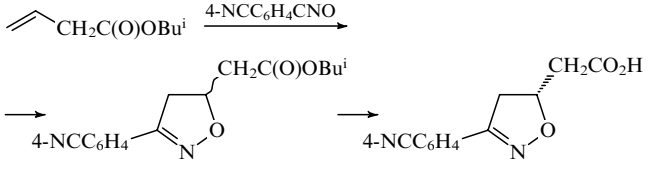
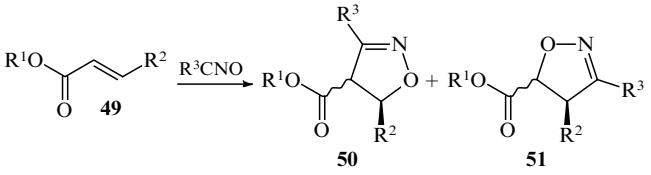
d	Bu^tPh_2Si	Ph	19 : 1	**d**	Bu^tPh_2Si	Bu^t	10 : 1
				d	Bu^tPh_2Si	4-ClC_6H_4	9 : 1

The cycloaddition of 4-cyanobenzonitrile oxide to isobutyl vinylacetate affords a racemic mixture of dihydroisoxazoles.[64] It was found that the hydrolysis of this mixture using the lipase PS30 gave optically pure [4,5-dihydro-3-(4-cyanophenyl)isoxazol-5-yl]acetic acid with the *R*-configuration of the chiral centre.



The addition of nitrile oxides to bornyl crotonates **49** (R^2 = Me) gave two regioisomeric cycloadducts **50** and **51**, each representing a mixture of diastereomers.[65]

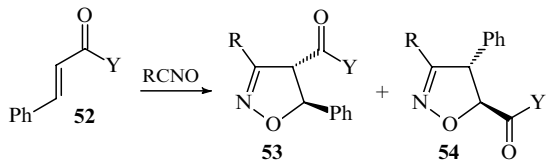


R^1	R^2	R^3	Yield of adducts (%)	
			50	**51**
	Me	Ph	65	22
	Me	Me	75	25
	Me	Ph	56	26
	Me	Me	46	25
	H	Me	–	79
	Me	Ph	63	28
	Me	Me	76	24
	H	Me	–	94

The diastereoselectivity of this reaction is > 80%. The diastereomers were separated and enantiomerically pure 4,5-dihydroisoxazoles were obtained after the cleavage of the ester bond. The regioselectivity of this reaction does not depend on either the substituent in the bornyl residue or the nature of nitrile oxide.

The addition of nitrile oxides to acrylates **49** (R^2 = H) results in an almost overriding formation of the sterically preferrable products **51**. The diastereoselectivity of this reaction is comparable to that of crotonates, which points to the similarity of the transition states generated by the attack of the dipole at the least shielded side of the alkene having an *s-cis*-conformation.[66]

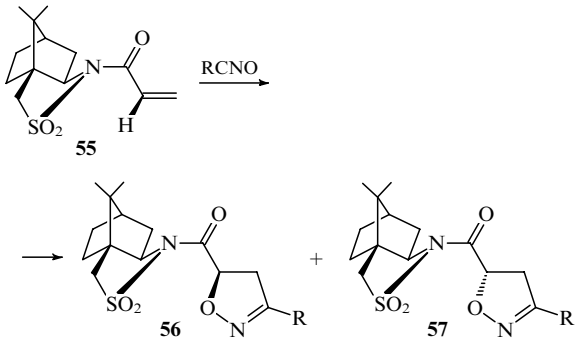
The reaction of methyl cinnamate **52a** with nitrile oxides affords a mixture of regioisomeric dihydroisoxazoles **53a** and **54a** (4 : 1).[67] Quite unexpectedly, the use of other cinnamic acid derivatives, *e.g.*, the tertiary amides **52b–f**, changed the regioselectivity of this reaction, whereas in the case of primary and secondary amines the regioselectivity was the same as with esters. It is also surprising that the substituent at the nitrogen atom virtually did not affect the regiochemistry of the reaction. Hence, its regioselectivity can be varied using different cinnamic acid derivatives and different nitrile oxides.



Compound **52**	Y	Ratio **53** : **54**
a	OMe	4 : 1
b	NEt_2	1 : 3
c	$N(Me)CH_2CO_2Me$	1 : 2
d	$N(Ph)CH_2CO_2Me$	1 : 2
e	L-proline methyl ester	see [a]
f	$N(CH_2CO_2Et)_2$	1 : 3

[a] Compound **54** is the main reaction product.

The use of chiral acrylamides as dipolarophiles has been reported;[68–73] acrylamides can have two low-energy rotamers due to rotation around the C–N bond. Cycloaddition of nitrile oxides to the optically active acryloylsultam **55** gives a mixture of diastereomers **56** and **57**; however, the diastereoselectivity of this reaction is rather high, especially in non-polar solvents.[68]



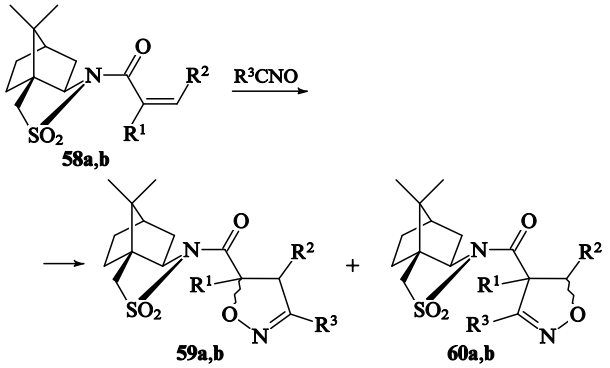
R	Solvent	Ratio **56** : **57**
Bu^t	C_6H_{14}	19 : 1
Bu^t	PhMe	9 : 1
Bu^t	CH_2Cl_2	4 : 1
Ph	C_6H_{14}	19 : 1
Me	C_6H_{14}	9 : 1
Et	C_6H_{14}	9 : 1
	PhH	7 : 1

These results prompted a transition state model the existence of which was confirmed by X-ray diffraction analysis of compound **55**.[68]

According to calculations,[74] the dipole–dipole interaction of the C=O and S=O groups and, as a consequence, steric destabilisation, are absent only in the *s-trans*-conformer. However, this model cannot be applied to reactions promoted by Lewis acids, since the predominant conformation changes upon chelation.[74]

The results of quantum-mechanical calculations of the energy and geometrical parameters of various transition states suggest [75] that Coulomb interactions are the main factor which determines diastereofacial differentiation. The Coulomb interactions of the oxygen atom of the nitrile oxide with the sultam oxygen *endo*-atom and, to a lesser degree, with the sulfur atom determine the energy predominance of the transition states during the approach of nitrile oxide to the double bond above the sultam ring which affords compounds of the type **56** (although the approach of the nitrile oxide to the double bond under the sultam ring is sterically more favourable and results in the formation of isomers **57**).

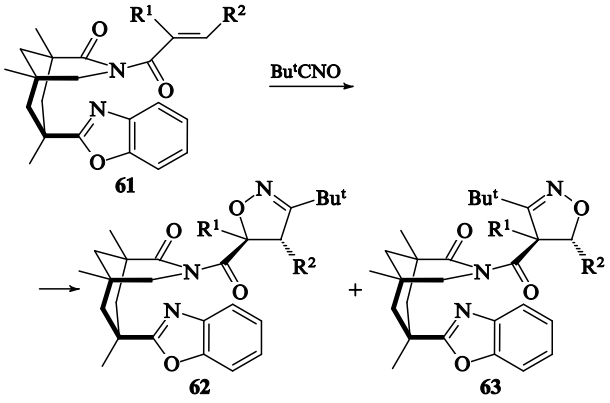
It was shown [21,76] that methacryloylsultam **58a** is inactive in the reaction with nitrile oxides and provides low asymmetric induction, whereas this reaction is completely regiospecific (the ratio of diastereomers **59a** is ~2 : 1; the stereochemistry of the major reaction product was not determined).



R^1 = Me, R^2 = H (a); R^1 = H, R^2 = Me (b); R^3 = Et, Bu^t, Ph.

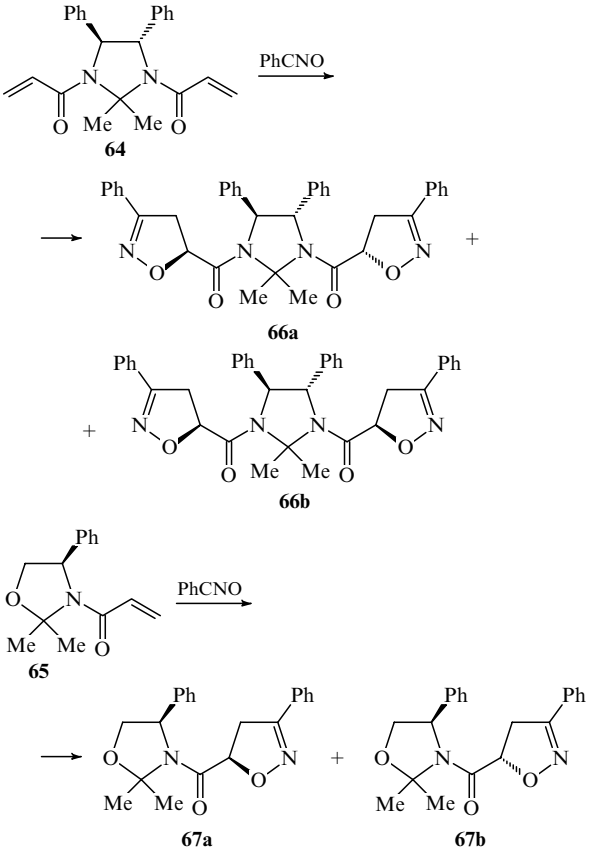
Crotonoylsultam **58b** ensures high diastereoselectivity (the diastereomer ratio is 9 : 1); however, the regioselectivity of this reaction is rather low and four products are formed. The regioisomers **59b** and **60b** are formed in nearly equal amounts.

High selectivity is also reached with the Rebek benzooxazolimides **61**,[77] which manifest a unique ability to control the selectivity of the reaction owing to the U-shape of the molecule. The ratio of the regioisomers **62** : **63** reaches 99 : 1.



R^1 = H, Me; R^2 = H, Me, Ph, CO_2Et.

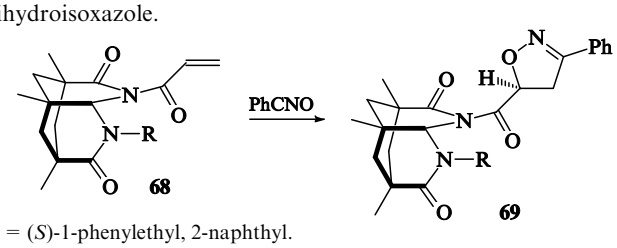
The addition of nitrile oxides to acrylamides[69] and α,β-unsaturated esters[78] containing a symmetrical chiral imidazolidine substituent in the β-position is characterised by extremely high diastereoselectivity. However, the former are difficult to obtain, while the latter manifest low regioselectivities. The reactions of 2,2-dimethyl-(4*S*,5*S*)-diphenyl-*N*,*N*′-diacryloylimidazolidine (**64**) and 2,2-dimethyl (4*R*)-phenyl-*N*-acryloylisoxazolidine (**65**) with benzonitrile oxide are highly diastereoselective.[79] Compound **64** yielded a mixture of the diastereomeric cycloadducts **66a** and **66b** in a ~ 5 : 1 ratio, whereas the reaction with compound **65** afforded a mixture of dihydroisoxazoles **67a** and **67b** (~ 4.5 : 1).



In both cases, hydrolysis of the reaction products leads to the corresponding dihydroisoxazoles possessing high optical purity. Based on the structure of the products **66a**,**b** and **67a**,**b**, it may be concluded that acrylamides **64** and **65** have an *s-cis*-conformation in the transition state, and benzonitrile oxide attacks the double bond from the side opposite to the phenyl substituent.

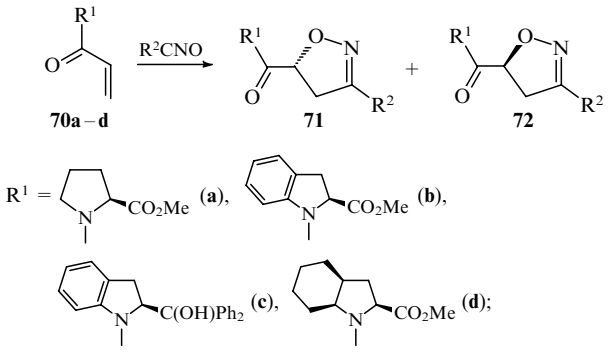
Studies of reactions of unsaturated compounds with benzonitrile oxide by the method of competing reactions[21] made it possible to construct an approximate scale of alkene reactivities, *viz*., activated monosubstituted > activated 1,1-disubstituted > non-activated 1,1-disubstituted = activated *trans*-1,2-disubstituted.

A high level of diastereoselectivity was achieved using compounds **68** which represent Kemp's triacid derivatives with chiral centres at one of the nitrogen atoms as dipolarophiles.[69,76] The adducts **69** with the *R*-configuration of the newly formed chiral centre are formed in more than 98% diastereomeric excess. It was noted that the pseudoenantiomeric alkene gives a C(5′)-isomeric dihydroisoxazole.



R = (*S*)-1-phenylethyl, 2-naphthyl.

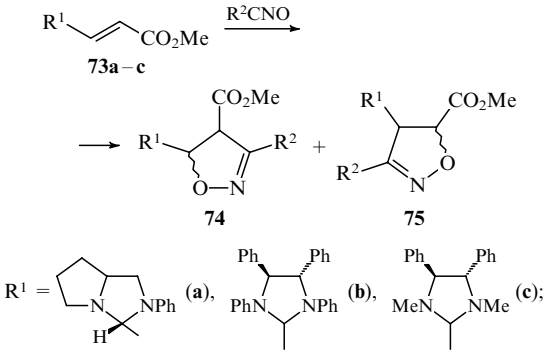
1,3-Dipolar cycloaddition of nitrile oxides to the chiral acrylamides **70a**–**d** derived from (*S*)-proline and (*S*)-indoline-2-carboxylic acid yields chiral 4,5-dihydroisoxazoles **71** and **72**.[80] The stereoselectivity of this reaction is largely determined by the structure of the dipolarophile and is practically independent of the solvent used but varies depending on the nitrile oxide structure. The dipolarophiles **70a**–**d** differ in their steric characteristics. The largest steric factor is inherent in compound **70c** due to the presence of two phenyl rings, whereas the steric factor in the rigid molecule of alkene **70d** is determined by the effect of the cyclohexane ring. In the latter case, the stereoselectivity is the highest (up to 95% of the isomer **71d** is formed).



R^2 = Me, Et, Ph, 3,5-$Cl_2C_6H_3$, 4-MeC_6H_4.

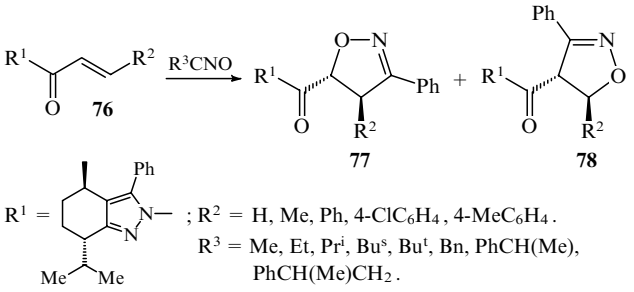
The asymmetric cycloaddition to α,β-unsaturated esters **73a**–**c** containing chiral imidazolidine substituents in the β-position has been studied.[78] With methyl acrylate **73a**, the regio- and stereoselectivity of the reaction is low, *viz*., the *trans*-isomers **74** are formed in small excess. The addition of the unsaturated esters **73b**,**c** containing a symmetrically substituted imidazolidine unit was regio- or diastereoselective depending on the nature of the substituent at the nitrogen atom of the heterocycle. Thus the reaction of the acrylate **73b** was regiospecific and afforded different regioisomers depending on the nature of the nitrile oxide. However, in all cases studied the products represented mixtures of diastereomers [~(3–2) : 1]. With compound **73c**, this reaction occurred with low regioselectivity [the ratio of the regioisomers

74 : 75 was (3 – 2) : 1]; however, each regioisomer in this mixture represented an individual (4*S*,5*S*)-diastereomer.



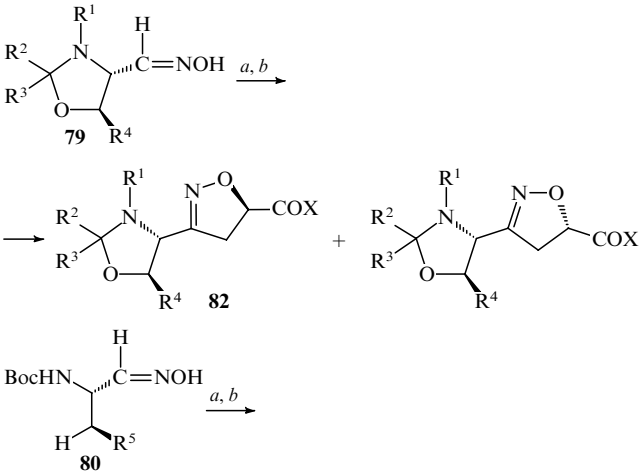
R^2 = Ph, 4-MeOC$_6$H$_4$.

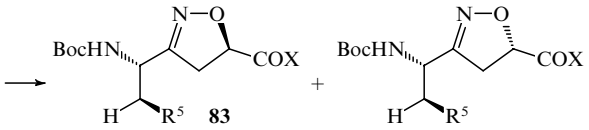
The reactions of acrylates **76** with a (4*R*,7*S*)-7-isopropyl-4-methyl-4,5,6,7-tetrahydro-2*H*-indazol-3-yl fragment as an auxiliary chiral substituent have been studied.[81] Mixtures of two regioisomers **77** and **78** were obtained, the regioselectivity decreased if the reaction was carried out in more polar solvents. The nature of the substituent R^2 in the dipolarophile weakly affected the yield and the regioselectivity.[82] The acrylate **76** (R^2 = H) gives predominantly the cycloadduct **77** with benzonitrile oxide, whereas the corresponding cinnamate (**76**, R^2 = Ph) yields a mixture of the regioisomers **77** and **78**.



R^1 = ; R^2 = H, Me, Ph, 4-ClC$_6$H$_4$, 4-MeC$_6$H$_4$.
R^3 = Me, Et, Pr^i, Bu^s, Bu^t, Bn, PhCH(Me), PhCH(Me)CH$_2$.

Reactions of nitrile oxides prepared from oximes **79** or **80** with *N*-acryloyl-(2*R*)- or -(2*S*)-bornane-10,2-sultams **81a**,**b** have been successfully used in the synthesis of pseudodipeptides.[83] (5*R*)-Diastereomers of dihydroisoxazoles **82** or **83** containing a chiral fragment XCO in position 5 were formed predominantly from 89% to 100%.



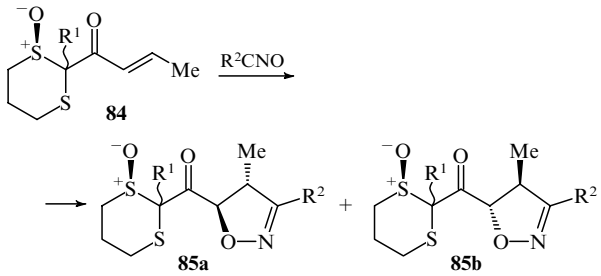


R^1 = Boc, OCOBn; R^2 = H, R^3 = Bu^t; R^2 = R^3 = Me; R^4 = H, Me; R^5 = OSiBu^{t}Me$_2$, CHMe$_2$, Ph;

(*a*) *N*-bromosuccinimide;

(*b*) XCOCH=CH$_2$ (**81a**,**b**), where X = 
As can be seen from the data presented, in the majority of cases the addition of nitrile oxides to substituted alkenes results in the adducts containing substituents in position 5. However, there are exceptions to this rule. Thus 1,3-dipolar cycloaddition of 4-*tert*-butylbenzonitrile oxide to 6^A-acrylamido-6^A-deoxy-β-cyclodextrin gives predominantly 4-substituted dihydroisoxazole[84] (the regioisomeric ratio is 4 : 1). This effect is due to the formation of an intermediate 'host – guest' complex between the cyclodextrin fragment and nitrile oxide.

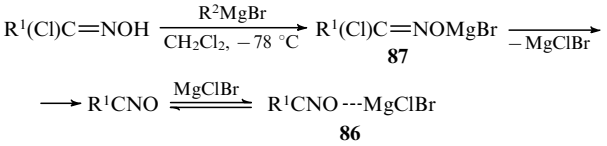
An efficient method for regio- and stereocontrol over the addition of nitrile oxides to the double bond of α,β-unsaturated diketones which makes use of chiral *S*-oxides of their cyclic dithioketals, *viz*., the diastereomeric 2-R-2-crotonoyl-1,3-dithiane *s*-oxides **84**, has been proposed.[85] The reaction with nitrile oxides is regioselective for both *syn*-**84** and *anti*-**84**; the former reacts with benzonitrile oxide to give products **85a** and **85b** in a 5 : 1 ratio, whereas for the latter the ratio is 1 : 3.



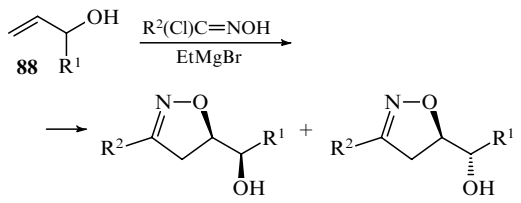
R^1 = Me, Et; R^2 = Me, Bu^i, Ph, Mes.

V. Cycloaddition of nitrile oxides to alkenes in the presence of Lewis acids

Lewis acids catalyse cycloaddition reactions of nitrile oxides to alkenes.[86–89] Thus the reaction of hydroximoyl chlorides with Grignard reagents yields the nitrile oxide complexes **86**. The first step includes *O*-metallation to give the intermediate **87** which undergoes 1,3-elimination of metal halide to give the nitrile oxide which further reacts with metal halide to give the complex **86**.



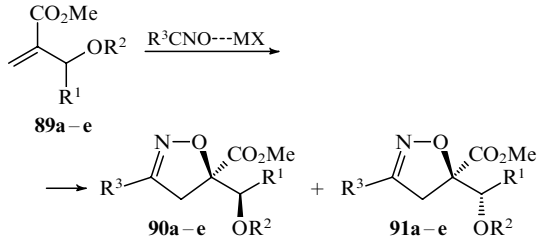
In the presence of ethylmagnesium bromide[86] the reaction rate of hydroximoyl chlorides with allylic alcohols **88** increases; no side products, *e.g*., nitrile oxide dimers, are hereby formed. Cycloaddition occurs in a *syn*-selective manner (up to 95%). Free nitrile oxides generated under the action of triethylamine manifested only weak *syn*-selectivities.



R^1 = Me, Et; R^2 = Ph, 4-$MeOC_6H_4$.

The nitrile oxide complexes of the type **86** can be generated under the action of other organometallic compounds (*e.g.*, Bu^nLi, Et_2Zn, Et_3Al); however, stereoselectivities of reactions are much lower in these cases. The complexes formed in the reaction with Et_2AlCl and $EtAlCl_2$ did not react with allylic alcohols **88** at all.[86]

The cycloaddition of nitrile oxides coordinated to Lewis acids to 1,1-disubstituted alkenes **89a–e** has been studied.[89] The formation of 4,5-dihydroisoxazoles always proceeds with high yields. The cycloaddition of acrylates **89a–d** with hydroxy groups in their chiral centres to free nitrile oxides is accompanied by the formation of a mixture of the diastereomers **90a–d** and **91a–d**, the *anti*-addition products **91a–d** being the main isomers. The proportion of the *anti*-adducts **91** decreases if nitrile oxides are used as complexes with LiCl, whereas magnesium and zinc complexes yield predominantly the cycloadducts **90a–d**. The highest *syn*-selectivity (98%) is observed in the presence of a twofold excess of magnesium alkoxide.

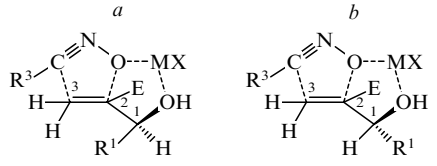


MX = $MgBr_2$, $ZnEt_2$, LiCl, $Mg(OAlk)_2$.

Compound **89**	R^1	R^2	R^3
a	Me	H	Ph
b	Me	H	4-$MeOC_6H_4$
c	Me	H	Bu^t
d	Et	H	Ph
e	Me	$SiMe_3$	Ph

A transition state model which accounts for the formation of *syn*- and *anti*-cyloaddition products has been proposed (Fig. 2).[89]

According to this model, the metal atom in the nitrile oxide–Lewis acid complex is coordinated to the hydroxy group of the dipolarophile. The transition state represents a system of condensed five-membered rings bent along the C(2)–O bond. Localisation of the substituent R^1 at the chiral centre inside the bent condensed system (Fig. 2 *a*) produces significant steric hindrances. Therefore, this reaction occurs *via* a sterically less hindered *syn*-transition state (Fig. 2 *b*). This model explains the effect of the coordinative capacity of the metal atom on the stereoselectivity of this reaction. Lithium and zinc form no stable complexes. In the presence of magnesium salts, dipolarophiles undergo ionisation to produce stronger complexes with metals, as a result of which their *syn*-selectivities increase.



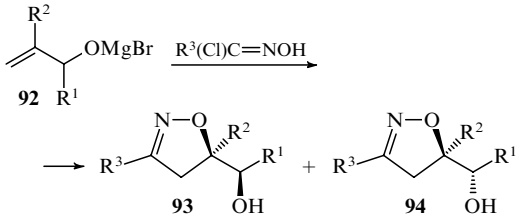
E = CO_2Me.

Figure 2. The transition states of the reaction of cycloaddition of nitrile oxides to chiral homoallylic alcohols **89a–d**.[89]
(*a*) *anti*-transition state, (*b*) *syn*-transition state; E = CO_2Me.

If the hydroxy group is protected by a bulky trimethylsilyl substituent (compound **89e**), the formation of a chelate complex in the transition state is less favourable; therefore, the alkene **89e** yields the *anti*-isomers **91** with moderate stereoselectivities (73%–79%) irrespective of the method used for the generation of nitrile oxides.

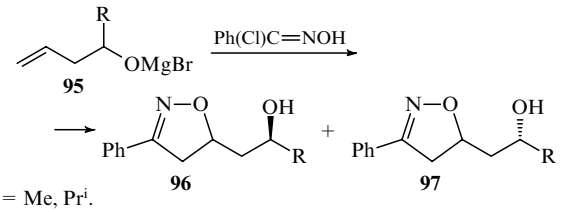
An alternative approach to increase in the stereoselectivity of nitrile oxide addition to alkenes is the use of magnesium alkoxides obtained by the reaction of allylic alcohols [86] or α,β-unsaturated ketones [90] with organomagnesium compounds. This reaction occurs in a *syn*-stereoselective manner. The maximum selectivity is reached with 2 equivalents of the alkoxide and decreases when the reaction is carried out in THF.

In the case of magnesium alkoxides **92** prepared from the corresponding allylic alcohols, the cycloaddition is regioselective and affords the cycloadducts **93** and **94**; with 2 equivalents of alkoxides **92** the *syn*-addition products **93** are predominantly formed.[86]



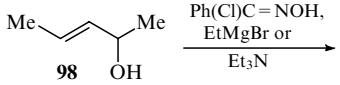
R^1	R^2	R^3	Ratio **93** : **94**
Me	H	Ph	96 : 4
Et	H	Ph	99 : 1
Et	H	4-$MeOC_6H_4$	89 : 11
Pr^i	H	Ph	97 : 3
Bu^n	Me	Ph	96 : 4

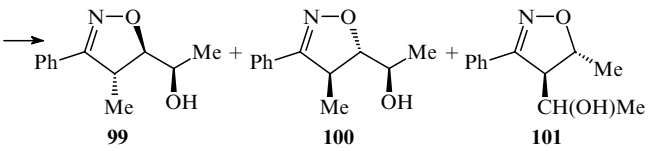
The application of this methodology to alkoxides of homoallylic alcohols resulted in the exclusive formation of the regioisomers **96** and **97** from terminal alkenes with no or very small diastereoselectivity.[86]



R = Me, Pr^i.

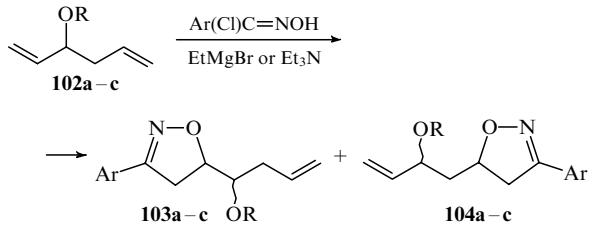
It should be noted that the control over the selectivity of 1,3-dipolar cycloaddition by coordination to metals proved to be efficient in those cases where internal alkenes were used as dipolarophiles. The cycloaddition of nitrile oxides to allylic alcohols **98** in the presence of ethylmagnesium bromide is regiospecific with the predominant formation of the *syn*-adduct **99** (94%), whereas the nitrile oxide generated under the action of triethylamine gave a mixture of compounds **99** and **100** in a 55 : 12 ratio and up to 18% of diastereomers of 4,5-dihydroisoxazole **101**, the total yield of the reaction products being much lower.





99 **100** **101**

The cycloaddition of nitrile oxides to dienes which contain a hydroxy group in both the allylic and homoallylic positions has been studied.[91] Thus the reaction of hexa-1,5-dien-3-ol (**102a**) with benzonitrile oxide generated under the action of Et_3N gives a mixture of the cycloadducts **103a** and **104a** (the diastereomeric ratios were 2 : 1 and 3 : 2, respectively), *i.e.*, under these conditions, the double bond of the allylic fragment was only a little more reactive than that of the homoallylic fragment.



102a–c **103a–c** **104a–c**

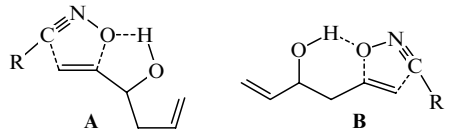
R = H (**a**), Ac (**b**), $SiMe_2Bu^t$ (**c**); Ar = Ph, 2,6-$Cl_2C_6H_3$.

When EtMgBr is used to generate nitrile oxide, the reaction is chemoselective with respect to the allylic fragment, the *syn* : *anti*-diastereomeric ratio in compound **103** being 99 : 1. Thus the magnesium alkoxide methodology proved to be more efficient for allylic alcohols than for homoallylic alcohols.

The influence of hydrogen bond formation on the cycloaddition of 2,6-dichlorobenzonitrile oxide to compounds **102a–c** has been studied.

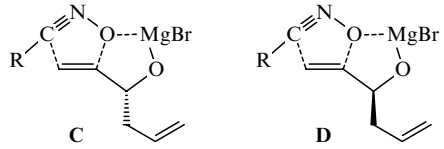
In weakly polar solvents, such as benzene or dichloromethane, nitrile oxide forms a hydrogen bond with the hydroxy group of the alcohol **102a** and coordinates to the double bond of the allylic fragment (the transition state **A** is more favourable than **B**), compound **103a** being the main product. The use of polar solvents, *e.g.*, DMF, prevents the formation of the hydrogen bond, and thus the product **104a** becomes predominant.

In the case of a protected hydroxy group (compounds **102b**,**c**), no hydrogen bond can be formed; therefore, acetate **102b** gives predominantly the adduct **104b** irrespective of the polarity of the solvent used. In addition, the homoallylic double bond in the acetoxy derivative **102b** becomes more reactive as a dipolarophile due to steric repulsion between the acetoxy group and nitrile oxide. For compound **102c**, the yield of dihydroisoxazole **104c** increases even more due to significant steric hindrances.



A **B**

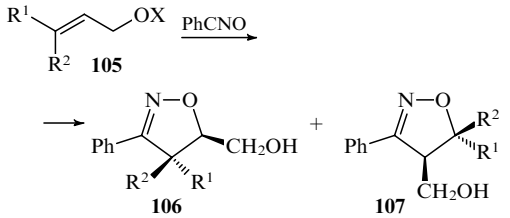
High *syn*-selectivity in the addition to the double bond of the allylic fragment of magnesium alkoxide prepared from the alcohol **102a** can be explained in terms of the reaction mechanism. Magnesium alkoxide forms five-membered intermediates **C** or **D**, the latter being much less stable due to steric hindrances created by the propenyl substituent.



C **D**

Thus the allylic double bond is relatively more reactive in the reaction of 1,3-dipolar cycloaddition of nitrile oxides to hexa-1,5-dien-3-ols than the homoallylic bond due to the formation of a hydrogen bond. In acetyl or silyl derivatives of the alcohol **102a**, it is the isolated homoallylic bond that is more reactive. Chelation with magnesium derivatives results in high regio- and diastereoselectivity. It should be noted that the products of simultaneous addition at two bonds were also isolated.

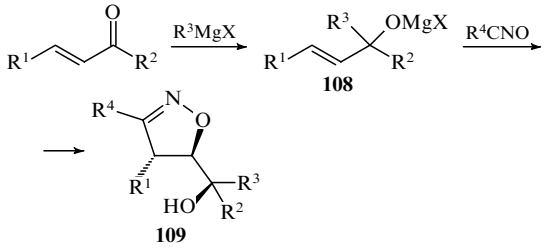
Reactions of 1,3-dipolar cycloaddition of benzonitrile oxide with 3,3-disubstituted allylic alcohols **105** proceed with very low regioselectivity; the nature of the substituent practically does not influence the ratio of the cycloadducts **106** and **107**.[92] In the case of magnesium alkoxides (X = MgBr), the reaction rate increases considerably and so does the regioselectivity,[93,94] this effect being observed exclusively with more than 1 equivalent of magnesium alkoxide. Similar results were obtained for mesitylenecarbonitrile oxide.[94]



105 **106** **107**

R^1 = H, Me, Pr^i, Ph; R^2 = H, Me, Pr^n; X = H, MgBr.

The cycloaddition of 2,6-dichlorobenzonitrile oxide to magnesium alkoxides **108** obtained by treatment of α,β-unsaturated aldehydes and ketones with Grignard reagents has been studied.[90] This reaction is regio- and diastereoselective and results in the *syn*-adducts **109**.



108 **109**

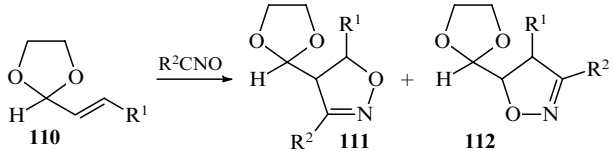
R^1 = H, Me; R^2 = H, R^1-R^2 = CH_2CH_2; R^3 = Me, Et; R^4 = 2,6-$Cl_2C_6H_3$.

Encouraging results were also obtained with cyclopentenone; however, the attempts to carry out an analogous reaction with cyclohexenone were without success.

VI. Cycloaddition of nitrile oxides to unsaturated aldehyde derivatives

Cycloaddition to cinnamaldehyde is one of few examples of cycloaddition of aceto- and benzonitrile oxides to α,β-unsaturated aldehydes.[95] In addition to the expected products, *e.g.*, 4-formyl-5-phenyl-3-R-4,5-dihydrooxazoles, bis-adducts were isolated due to the cycloaddition of nitrile oxide to the carbonyl group of the primary cycloadducts. Therefore, in subsequent experiments the carbonyl groups of α,β-unsaturated aldehydes were protected prior to their cycloaddition to nitrile oxides.

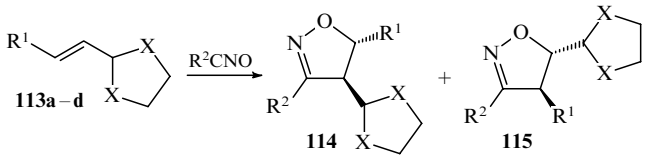
The reactions of cyclic acetals **110** with nitrile oxides[96] gave predominantly the adducts **111**. The desired regioselectivity can be attained by varying the nitrile oxide structure. For example, for R^1 = CO_2Et and R^2 = Ph the **111** : **112** ratio is 99 : 1.



110 **111** **112**

R^1 = Ph, CO_2Et, Et; R^2 = Ph, Me, Pr^i.

The compositions of cycloaddition products in the case of β-substituted α,β-unsaturated aldehyde derivatives depend on the nature of the protective groups.[97] The cycloaddition to cyclic acetals **113a**,**b** yields predominantly the regioisomers with an acetal substituent in position 4, whereas for dithioacetals **113c**,**d** the regioselectivity is opposite. Calculations led to a conclusion that the orientation in this case of the dithioacetal group is determined by the steric factor, whereas that in the case of the acetal group is determined by the interaction of the frontal orbitals.

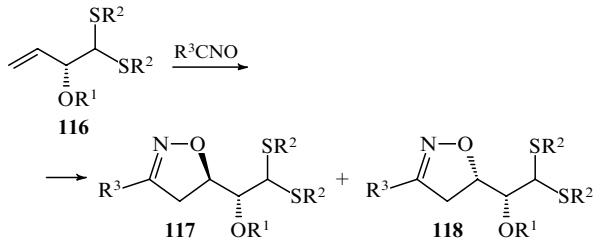


113a–d **114** **115**

Compound **113**	R^1	X	R^2	Ratio **114** : **115**
a	Ph	O	Ph	91 : 9
	Ph	O	4-$MeOC_6H_4$	17 : 1
b	Me	O	$PhCH_2$	9 : 1
c	Ph	S	Ph	17 : 83
	Ph	S	4-$MeOC_6H_4$	27 : 73
d	Me	S	$PhCH_2$	3 : 7

Thus, by varying the protecting group in the α,β-unsaturated aldehyde, one can change the regioselectivity of the reaction resulting in substituted 4,5-dihydroisoxazoles with the formyl substituent in different positions.

High stereoselectivity is achieved in the addition of nitrile oxides to 2-hydroxybut-3-enal dithioacetal derivatives.[98] Thus the diastereoselectivity of the cycloaddition of nitrile oxides to 2-silyloxybut-3-enal dithioacetals **116** virtually does not depend on either the size of the protective group at the oxygen or the sulfur atoms or the nature of the substituent. The *anti*-isomers **117** are formed as the main products and the maximum diastereoselectivity (96%) is achieved with the bulky dithioacetal group ($R^2 = Bu^t$). However, the yield of this reaction depends, to some extent, on the nature of the nitrile oxide; the total yield of the cycloadducts **117** and **118** is low (25%–26%) with $R^1 = SiMe_2Bu^t$, $R^2 = Bu^t$ and $R^3 = CO_2Et$ or CH_2OBn.



116 **117** **118**

R^1 = Bn, $SiMe_2Bu^t$; R^2 = Ph, $(CH_2)_3$, Bu^t; R^3 = Me, Ph, 4-$MeOC_6H_4$,

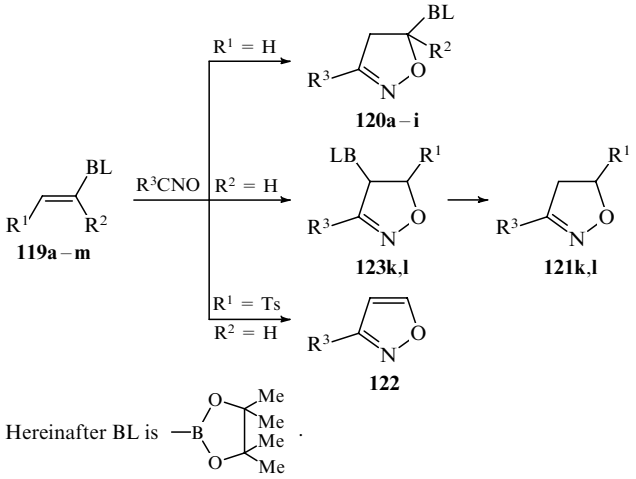
, CO_2Et, CH_2OBn.

Deprotection of the aldehyde group occurs with high yields and without epimerisation of the chiral centres, which apparently makes this method especially attractive from the synthetic point of view.[98]

VII. Alkenylboronates in cycloaddition reactions with nitrile oxides

Organoboron derivatives, particularly alkenylboronate derivatives are readily available and are often used in synthetic practice as convenient building blocks.[99] The possibility of the use of alkenylboronates as dipolarophiles in cycloaddition with nitrile oxides has been studied.[100–102] It is of note that an attempt at enhancing the reactivity of the double bond in alkenylboranes by introducing stronger electron-withdrawing groups, such as borabicyclononyl, catecholboryl or $BHal_2$ groups, has not led to the desired effect.[103]

It was found that the vinylboronates **119a–g** react with nitrile oxides in a regiospecific manner to give 4,5-dihydroisoxazoles **120a–g**, their yields being only little dependent on the changes in the nitrile oxide structure. α-Substituted alkenylboronates **119h**,**i** gave also 4,5-dihydroisoxazoles **120h**,**i** containing a boronate residue in position 5 as the reaction products, while the trisubstituted compound **119j** gave no cycloadducts. β-Substituted alkenylboronates **119k–m** do not afford products similar to compounds **120**; this reaction gave 4,5-dihydroisoxazoles **121k**,**l** or isoxazole **122** containing no boronate substituent.



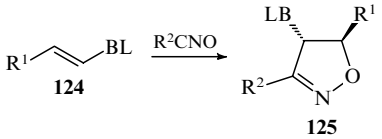
119a–m **120a–i** **123k**,**l** **121k**,**l** **122**

Hereinafter BL is .

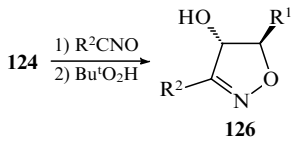
Substrate **119**	R^1	R^2	R^3	Reaction product
a	H	H	4-ClC_6H_4	**120a**
b	H	H	Me	**120b**
c	H	H	Bu^t	**120c**
d	H	H	CO_2Et	**120d**
e	H	H	COMe	**120e**
f	H	H	$(CH_2)_3CO_2Me$	**120f**
g	H	H	$CH_2CH(OMe)_2$	**120g**
h	H	Me	4-ClC_6H_4	**120h**
i	H	Ph	4-ClC_6H_4	**120i**
j	$(CH_2)_4$		4-ClC_6H_4	–
k	Bu	H	4-ClC_6H_4	**121k**
l	MeOCO	H	4-ClC_6H_4	**121l**
m	Ts	H	4-ClC_6H_4	**122**

A mechanism of cycloaddition has been proposed [101] based on the results of the reaction of vinylboronates with diazo compounds.[104] According to this mechanism, nitrile oxide is added regioselectively to *cis*-alkenylboronates **119k–l** to give 4,5-dihydroisoxazoles **123** with a boronate residue in position 4. Similar compounds were isolated and characterised in previous studies.[105] Spontaneous 1,3-migration of the boronate residue and subsequent hydrolysis give 4,5-dihydroisoxazoles **121**. Elimination of TsOH in the case where R^1 = Ts results in isoxazole **122** (R^3 = 4-ClC_6H_4).[106]

An effective procedure for the synthesis of 4-hydroxy-4,5-dihydroisoxazoles using vinylboronates has been proposed.[105] Thus 1,3-dipolar cycloaddition of nitrile oxides to 2-substituted *trans*-alkenylboronates **124** gives 4,5-dihydroisoxazoles **125** with a boronate substituent in position 4 as the main regioisomers. Treatment of the reaction mixture with Bu^tO_2H gives *trans*-hydroxy-4,5-dihydro-4-isoxazoles **126** in high yields (75%–88%).

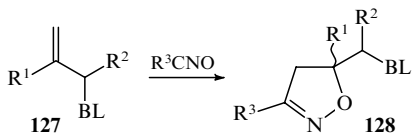


124 **125**



R^1 = Pr^n, CH_2OAc, Ph, Bu^n, CO_2Me, $(CH_2)_3Cl$; R^2 = Ph, 4-$MeOC_6H_4$.

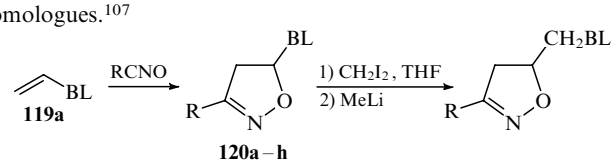
The cycloaddition of nitrile oxides to allylboranes **127** has been studied.[101] As in the case of alkenylboranes, one regioisomer **128** is formed. Allylboranes containing a chiral centre in the α-position yield a nearly equimolar mixture of diastereomers with nitrile oxides; their stereochemistry has not been established.



R^1 = H, Me; R^2 = H, Cl, C_6H_{13}, C_5H_9; R^3 = Bu^t, 4-ClC_6H_4.

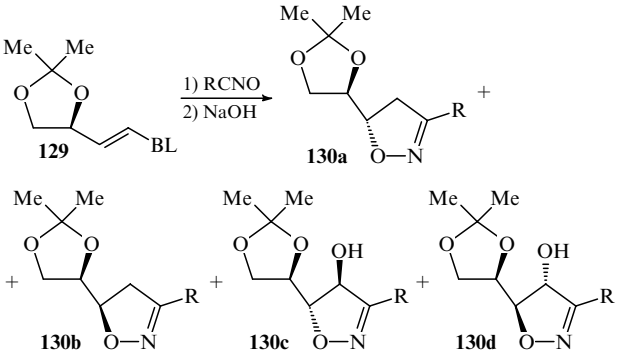
Thus, 1,3-dipolar cycloaddition of nitrile oxides to alkenyl- or allylboronates and subsequent oxidative deborylation of the adducts formed is a direct route to 4-hydroxy- or 5-hydroxyalkyl-4,5-dihydroisoxazoles.

The reaction of [3-R-4,5-dihydroisoxazol-2-yl]boranes **120a**–**h** with diiodomethane in the presence of MeLi yields their homologues.[107]



R = 4-ClC_6H_4 (**a**), Me (**b**), Bu^t (**c**), CO_2Et (**d**), COMe (**e**), Ph (**f**), $(CH_2)_2CO_2Me$ (**g**), CMe_2OSiMe_3 (**h**).

Cycloaddition of nitrile oxides to the optically active alkenylboronate **129** gives four products; the total yield of 4,5-dihydroisoxazoles **130a**,**b** is ~50%, whereas that of (4*S*,5*S*)- and (4*R*,5*R*)-4-hydroxy-4,5-dihydroisoxazoles **130c**,**d** is ~45%, *erythro*-isomers being predominant in both cases.[108] Thus, this reaction occurs in a regiospecific manner but with moderate stereoselectivity. Compounds **130a**,**b** are formed as a result of deborylation of the primary 4,5-dihydroisoxazoles which contain a boronate substituent in position 4 (like compounds **123a**,**b**).

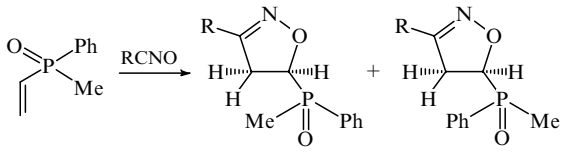


R = Ph, 4-ClC_6H_4.

Compounds **130c**,**d** were the only reaction products (**130c** : **130d** ≈ 4 : 1) when *tert*-butyl peroxide was used for the generation of nitrile oxide.

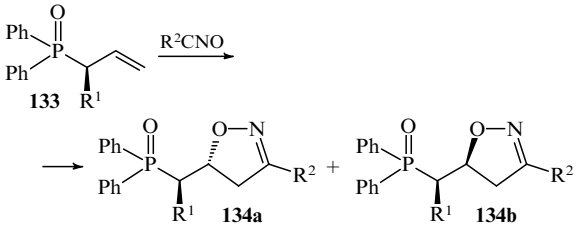
VIII. Vinyl- and allylphosphine oxides in cycloaddition reactions with nitrile oxides

1,3-Dipolar cycloaddition of nitrile oxides to racemic methylphenylvinylphosphine oxide results in phosphorus-containing 4,5-dihydroisoxazoles **131a**,**b** and **132a**,**b** in good yields.[109] The isomers **131a**,**b** with a phosphine oxide substituent in position 5 either predominate or are the only reaction products. The cycloaddition occurs with a significant (~40%) diastereofacial selectivity. According to X-ray diffraction data, compound **131a**, which exists in an *erythro*-configuration, has a conformation in which the C–O and P=O bonds are in the *anti*-position.



R = Ph, Me.

1-R-Propenyldiphenylphosphine oxides **133** were studied in the reaction of 1,3-dipolar cycloaddition.[110]



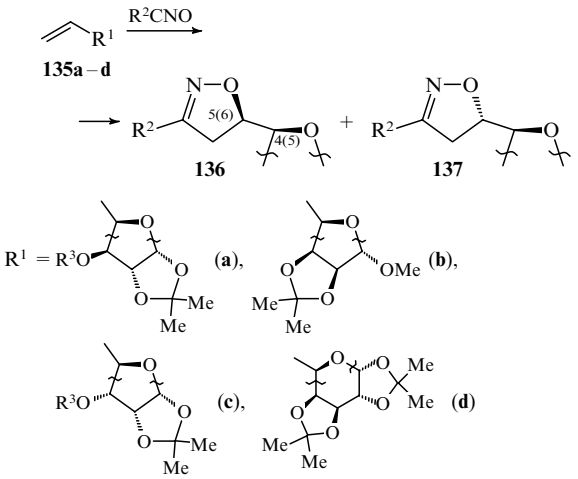
R^1 = Me, Et, Pr, C_6H_{11}, $C_{11}H_{23}$, CO_2Et, $(CH_2)_nCO_2Me$;
R^2 = H, Me, Et, Pr, Bu^i.

Cycloadducts are not formed, if nitrile oxides contain a bulky substituent R^2. In other cases, the reaction proceeds at a very slow rate. The *anti*-addition products **134a** are predominant in all cases. This is one of the few examples of cycloaddition reactions where the substituent in the nitrile oxide has a stronger influence than the substituent R^1 in the allylic position. It was suggested [110] that the extremely bulky phosphorus-containing substituent in the Houk transition state occupies a position opposite to that of the ring which is formed, whereas the R^1 group and the allylic hydrogen atom are localised inside and outside, respectively. Branched substituents R^2, *e.g.*, Pr^i, are too bulky for these positions; therefore, alkenes **133** do not form cycloadducts with such nitrile oxides.

IX. The nitrile oxide method in carbohydrate chemistry

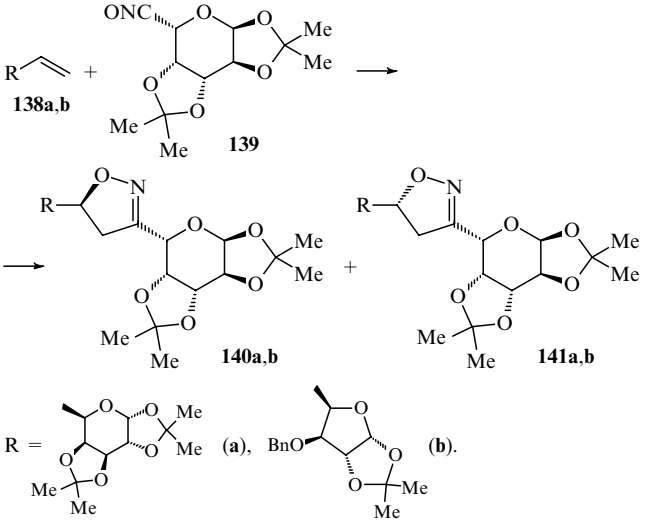
Cycloaddition of nitrile oxides to alkenes is used in the synthesis of various sugar derivatives. The nitrile oxide method proved to be a convenient procedure for the elongation of a carbon chain in the synthesis of higher sugars. The 1,3-dipolar cycloaddition of the simplest nitrile oxides to the double bonds of the sugar derivatives **135a**–**d** has been studied.[111–116] The reaction of compounds **135a**,**b**,**d** with nitrile oxides is regioselective and gives 4,5-dihydroisoxazoles **136** and **137** which contain the sugar moiety in position 5 (74 : 26 and 97 : 3, respectively). The major diastereomers of the adducts **136** have the *R*-configurations of the newly formed chiral centres. Quite a different result is obtained for the corresponding D-ribose derivative **135c**,[113,115] which represents an epimer of compound **135a** as regards the homoallylic C(3) atom. In this case, the *syn*- and *anti*-adducts **136** and **137** are formed in approximately equal amounts. This reaction is the first

example of the dependence of the composition of nitrile oxide cycloaddition products on the configuration of the chiral centre in the homoallylic position.

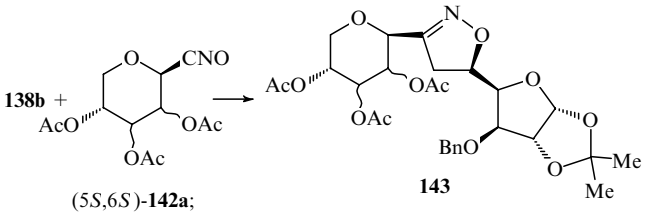


R^2 = Ph, CO_2Et; R^3 = H, OH, OMe, OBn, Ac, Ar.

The 1,3-dipolar addition of ω-unsaturated heptoses and hexoses **138a**,**b** to the nitrile oxide **139** was used in the synthesis of 7-deoxytrideca- and 6-deoxydodecadialdoses.[117] It should be noted that this reaction is one of the few examples of asymmetric induction by a chiral nitrile oxide. Both alkenes react regiospecifically and with high diastereoselectivity to give predominantly the *anti*-adducts **141a**,**b** (**141** : **140** = 4 : 1 and 14 : 3, respectively).

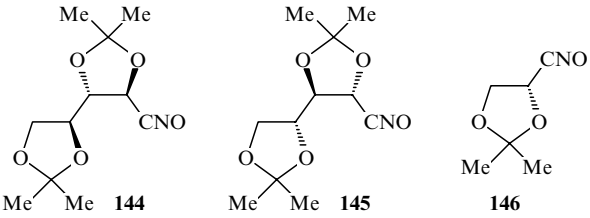


The stereo-controlled cycloaddition of the alkene **138b** to nitrile oxides derived from D-xylose (**142a**) or D-arabinose (**142b**) has been carried out. In both cases, the reaction is regiospecific and diastereoselective with the predominance (up to 80%) of the diastereomers **143** having *R*-configurations of the newly formed chiral centres.[118]

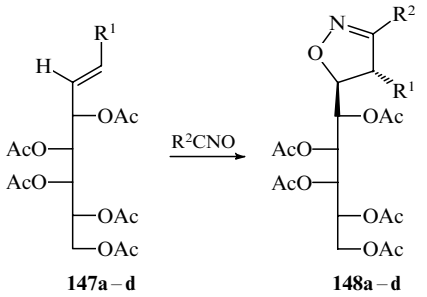


(5*S*,6*S*)-**142a**;
(5*R*,6*R*)-**142b**.

Similar results were obtained with L- or D-arabinonitrile (**145**),[119] oxide derivatives **144** and glyceronitrile oxide (**146**).[115]

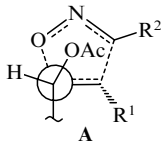


The 1,3-dipolar cycloaddition of nitrile oxides to nitroalkenes and α,β-unsaturated carbonyl compounds **147a**–**d** containing a sugar moiety has been studied. For alkenes **147b**–**d**, this reaction is regio- and stereoselective and yields exclusively the diastereomers **148** with the *trans*-configuration of substituents at the C(4) and C(5) atoms.[120]

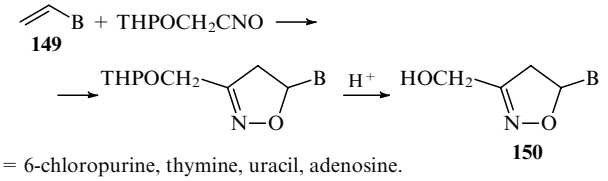


R^1 = NO_2 (**a**), Ac (**b**), CO_2Me (**c**), CO_2Et (**d**); R^2 = Me, Ph, Mes, Br.

Based on molecular-mechanical models and the structure of the reaction products, it was suggested [120] that in this case it is the stable transition state **A** that is realised. This conclusion is in good agreement with the anti-periplanar effect of the acetoxy group in the allylic position.



The regioselective cycloaddition of tetrahydropyranyloxyacetonitrile oxide to the nitrogen bases **149** containing vinyl groups results in the nucleoside aza analogues **150** possessing antiviral activities.[121, 122]

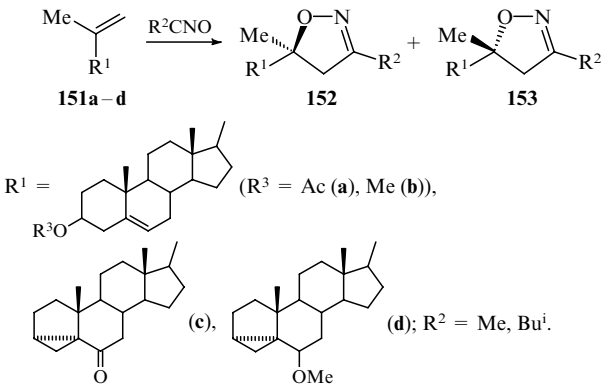


B = 6-chloropurine, thymine, uracil, adenosine.

X. Steroid alkenes as dipolarophiles in cycloaddition reactions with nitrile oxides

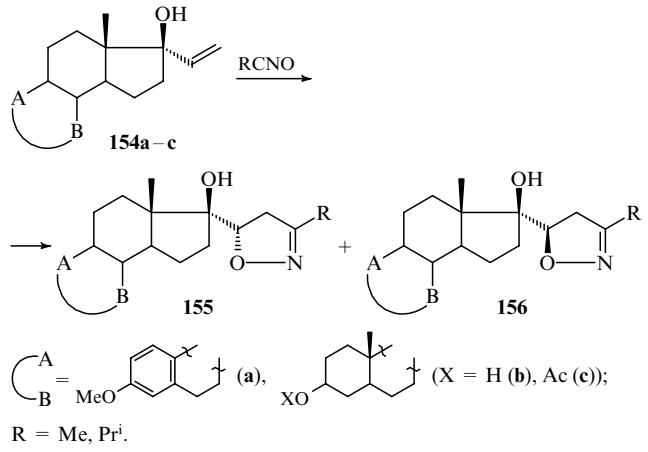
1,3-Dipolar cycloaddition of nitrile oxides to steroid alkenes has been studied using compounds with a double bond in both the cyclic part of the molecule (*e.g.*, $\Delta^{5(6),16(17)}$-steroids) and the side chain.

The addition of nitrile oxides to the disubstituted double bond of the steroids **151a**–**d** occurs at a slow rate and sometimes requires a large excess of nitrile oxide; its result does not change upon modification of the steroid skeleton but strongly depends on the nature of the substituent R^2 of the nitrile oxide.[123] No cycloaddition products were found for R^2 = Pr^i.

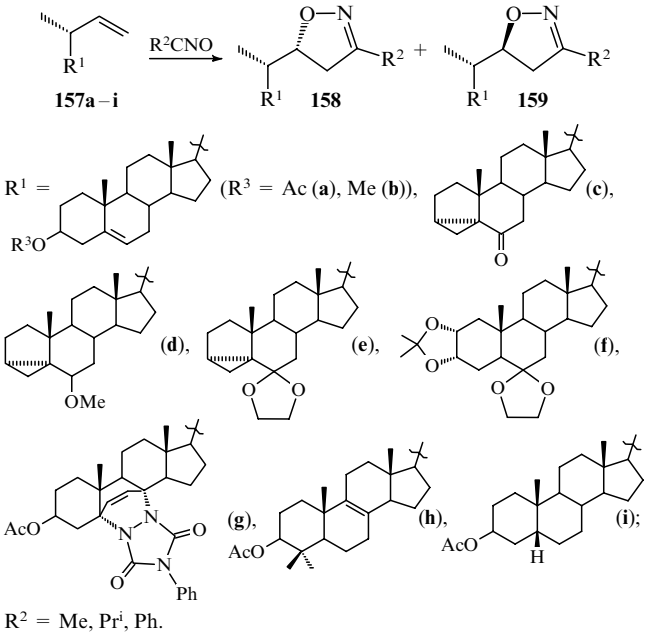


This addition is regiospecific leading exclusively to the formation of 4,5-dihydroisoxazol-5-yl derivatives and stereoselective (**152** : **153** = 3 : 1). The main epimer is formed as a result of an attack of the nitrile oxide at the double bond from the sterically less hindered side (the α-region of the steroid).

1,3-Dipolar cycloaddition of nitrile oxides to the 17β-hydroxy-17α-vinyl estrone derivative **154a** proceeds in a regiospecific and stereoselective manner [**155** : **156** = (10 – 15) : 1]. The stereoselectivity of the reaction decreases on going to the steroids of the androstane series **154b,c** (**155:156** = 1:1) for R^2 = Me and 3 : 1 for R^2 = Pr^i.[124, 125]

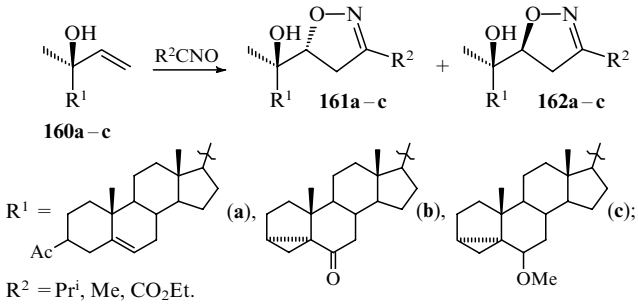


The steroid derivatives **157a** – **i** containing a but-2-enyl substituent in the ring *D* have been studied in the reaction of 1,3-dipolar cycloaddition to nitrile oxides.[126 – 132] In all cases, this

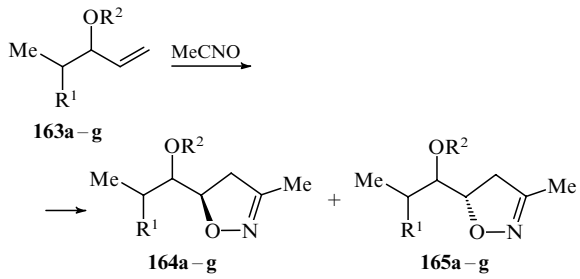


reaction gave a mixture of the 5′-epimeric 4,5-dihydroisoxazol-5-yl steroids **158** and **159**. The ratio of the epimers (5′*R*)-**158** and (5′*S*)-**158** depends on the structures of both the nitrile oxide and the steroid. In some cases, the reaction possessed pronounced stereoselectivity, *e.g.*, the **158** : **159** ratio in the reaction of compound **157h** with benzonitrile oxide is 4.5 : 1, whereas the reaction of the alkene **157f** with isobutyronitrile oxide is not selective. The reaction of compound **157g** with nitrile oxides is a special case, for it gives only one reaction product **158** (R^2 = Me, Pr^i).

1,3-Dipolar cycloaddition of nitrile oxides to steroidal allylic alcohols **160a** – **c** [126, 132, 133] affords the adducts **161** and **162**; the *threo*-isomers **161** are formed with high stereoselectivities. The cycloaddition of EtO_2CCNO to compound **160b** gave only one diasteromer, *viz.*, 4,5-dihydroisoxazole **161b** (R^2 = CO_2Et), albeit in a low yield.



The stereochemistry and the ratio of the reaction products in the cycloaddition of nitrile oxides to the Δ^{23}-steroids **163** is determined by the nature of the oxygen-containing substituents in the α- and β-positions to the double bond and the configuration of the C(20) and C(22) centres in the starting dipolarophile (Table 1).[134 – 138]



The cycloaddition of acetonitrile oxide to the steroid **163a** containing a (22*S*)-hydroxy group occurs in a regio- and stereoselective manner with the predominant formation of the *threo*-isomers **164a**. The ratio of the epimers formed in the reaction with (22*S*)-acetoxy derivative **163b** was 1 : 1 (with a concomitant decrease in the degree of conversion). The use of the (20*S*,22*R*)-hydroxy derivative **163c** also resulted in the predominant formation of the *threo*-isomer **165c**, whereas in the case of the (22*R*)-acetoxy derivative **165d** the epimers were formed in a 1 : 1 ratio and the degree of conversion was also decreased. This reaction becomes stereospecific upon protection of the hydroxy group by a bulky *tert*-butyldimethylsilyl substituent (compound **163e**), however, the (22*R*,5′*S*)-diastereomer **165e** is formed in a low yield. The (22*S*,5′*S*)-diastereomer **165f** was predominant upon cycloaddition of the (20*R*,22*R*)-22-hydroxy derivative **163f**, but the stereoselectivity of this reaction was not very high. When the (20*R*,22*R*)-22-acetoxy derivative **163g** is used as a dipolarophile, the *syn*-cycloaddition product **165g** is formed in a large excess which is in contrast to the reactions with the acetoxy derivatives **163b** and **163d**.

These reaction patterns differ basically from those for non-steroid compounds and suggest the possible formation of a transition state (an intermediate complex) including nitrile oxide and the allylic hydroxy group of the steroid molecule.[2] The structure of the transition state depends on the nature of the

Table 1. The stereochemistry and ratios of reaction products in the reaction of acetonitrile oxide with the steroids **163**.

R^1	R^2	Compound **163**	Configuration of the C(20) and C(22) centres	Total yield	Ratio of adducts **164** and **165**

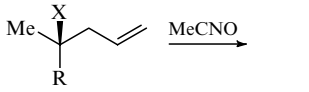
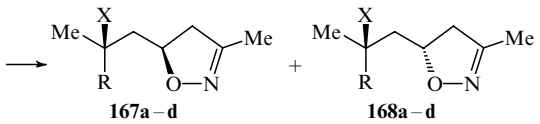
steroid fragment and the configuration of the allylic and homoallylic centres.

The reaction of acetonitrile oxide with the 20-hydroxy-20-propenyl steroids **166b**,**d** containing the homoallylic hydroxy groups occurs without any noticeable stereoselectivity to afford approximately equal amounts of the epimeric 4,5-dihydroisoxazoles **167b**,**d** and **168b**,**d**.[139]



166a–d



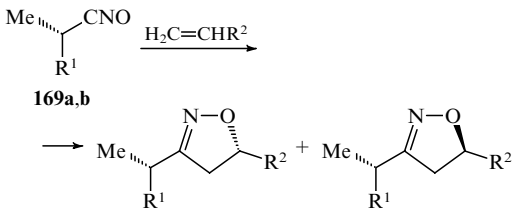
167a–d **168a–d**

R =  : X = H (**a**), OH (**b**);

R =  : X = H (**c**), OH (**d**).

This reaction is also non-stereoselective with the steroid alkenes **166a**,**c** devoid of hydroxy groups.[140]

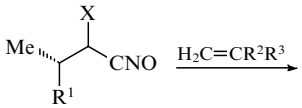
The first attempts to use steroidal nitrile oxides **169a**,**b** and **170a–d** [141–144] as dipoles in reactions with alkenes revealed that the cycloaddition which occurs in a regioselective manner yields one regioisomer in the form of epimeric pairs of 4,5-dihydroisoxazol-3-yl steroids. However, this reaction is non-stereoselective for both C(22)- (**169a**,**b**) and C(23)-nitrile oxides (**170a–d**).



169a,**b**

R^1 =  (**a**),  (**b**);

R^2 = CH_2OH, CH_2OAc, CMe_2OH, Ac, CH_2Br, Pr^i.



170a–d

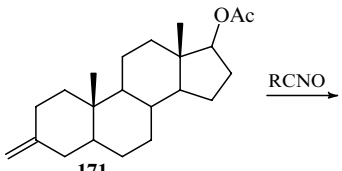
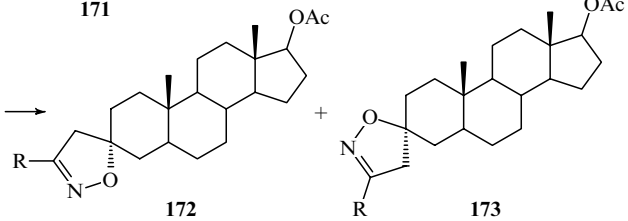
The reactions of 3-methylidene-17-acetoxyandrostane (**171**) with aceto- and benzonitrile oxides gave mixtures of 3α- and 3β-isomers of the spiro derivatives **172** and **173** with the predominance of the former isomers (2.5–3) : 1.[145,146] The reactions of the steroid **171** with nitrile oxides RCNO, where R = $EtCO_2$, 2,4,6-$Me_3C_6H_2$, always give the only cycloaddition products, *viz*., the 3α-isomers **172** (yields 60% and 25%, respectively). The addition of triphenylacetonitrile oxide to alkene **171** yields a 1 : 1 mixture of two epimeric 4,5-dihydroisoxazoles in a total yield of 87%.[147]



171



172 **173**

R = Me, Ph, Mes, CO_2Et, Ph_3C.

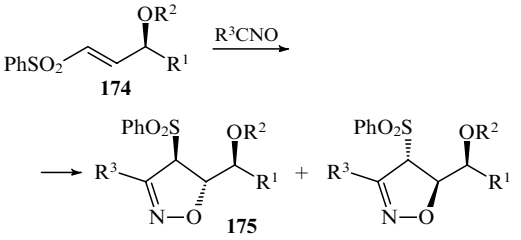
It was reported [145] that 1,3-dipolar cycloaddition of nitrile oxides to 17-methylidene steroids gives regioisomeric 4,5-dihydroisoxazoles *spiro*-conjugated to the steroid fragment in position 17. However, the configuration of the C(17) centre of the steroid has not been established (yield 60% – 70%).[145]

The stereochemistry of 1,3-dipolar cycloaddition of nitrile oxides to steroidal compounds with an endocyclic double bond is usually determined by the attack of the nitrile oxide from the less protected α-region of the steroid. Thus cycloaddition of arenecarbonitrile oxides to the spirost-5-ene derivatives [148] is regio- and stereoselective and results in 3′-substituted [5α,6α-*d*]-4,5-dihydroisoxazoles.

The published data concerning the addition of nitrile oxides to the Δ^{16}-bond of steroids are controversial.[149–155] In some cases, only [17α,16α-*d*]-4,5-dihydroisoxazoles or [16α,17α-*d*]-4,5-dihydroisoxazoles are exclusively formed, but the formation of two regioisomers was also reported. The composition of reaction products depends on the structure of the 1,3-dipole and the method used for its generation. It is of note that sometimes the Δ^5-bond and the cross-conjugated (3-oxo-1,4-diene) system are not involved in this reaction.

XI. Other examples of cycloaddition of nitrile oxides to acyclic alkenes

It was noted [105, 156, 157] that 1,3-dipolar cycloaddition of some achiral vinyl sulfones to nitrile oxides studied previously proceeds without any noticeable regioselectivity.

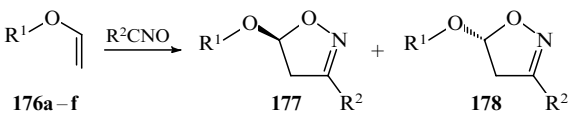


174 **175**

R^1 = Et, Pr^i; R^2 = Ac, MOM, Bu^tMe_2Si; R^3 = Me, Ph.

The reaction of the chiral vinyl sulfones **174** with nitrile oxides does not go to completion even in the presence of a large excess of the 1,3-dipole (the conversion is 36% – 68%).[158] In this case, only the regioisomers with the phenylsulfonyl group at C(4) are formed. The stereoselectivity of this reaction depends on the nature of substituents in both the alkene and nitrile oxide, however, the *anti*-adducts **175** are always predominant and in the case of the bulky substituents R^1 and R^2 they are virtually the only isolated products,[158] which is in agreement with the Houk model.

The first attempts at cycloaddition of nitrile oxides to the homochiral vinyl ethers **176a–f** [159] resulted in reaction products in low yields and with low diastereoselectivities.[160]

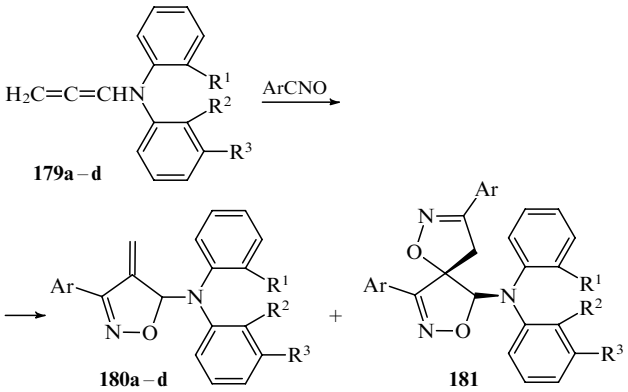


176a–f **177** **178**

R^1 = (–)-menthyl (**a**), 8-phenylmenthyl (**b**), (1*S*)-*endo*-bornyl (**c**), (*R*)-PhCH(CO_2Me) (**d**), (*S*)-1-(2-naphthyl)ethyl (**e**), (*S*)-1-phenylbutyl (**f**);
R^2 = Me, Et, Pr^n, Bu^t, Ph, $Ph(CH_2)_2$, 4-$NO_2C_6H_4$.

The best results were obtained for the vinyl ether **176e**,[161] *viz*., the ratio of the isomers **177** : **178** is (3–4) : 1 in reactions with almost all nitrile oxides. X-Ray diffraction data suggest that compounds **177** with the *R*-configurations of the newly formed chiral centres at the C(5) atoms are the predominant isomers.

1,3-Dipolar cycloaddition of nitrile oxides to allenes yields several reaction products.[162] The reaction of *N*,*N*-diarylamino allenes **179** with 1 equiv. of 3,5-dichloro-2,4,6-trimethylbenzonitrile oxide gives the adduct **180** with the involvement of the α,β-double bond and a small amount of the spirobisadduct **181**.[163]

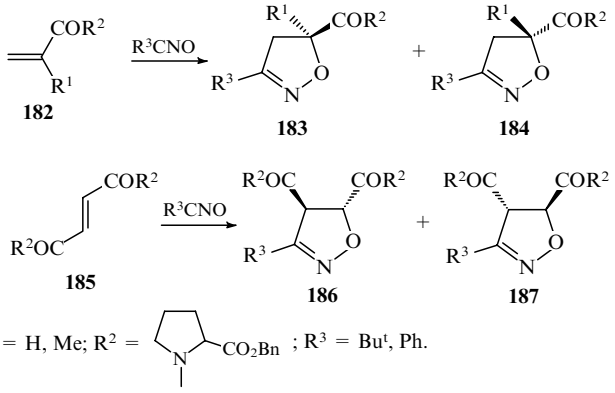


179a–d **180a–d** **181**

R^1 = R^2 = R^3 = H (**a**); R^1 – R^2 = $(CH_2)_2$, R^3 = H (**b**);
R^1 – R^2 = CH = CH, R^3 = H (**c**); R^1 = R^2 = H, R^3 = Me (**d**);
Ar = 3,5-Cl_2-2,4,6-Me_3C_6.

The reaction of the allenes **179** with 2 equivs. of the nitrile oxide gives only spiro compounds **181**. The α,β-double bond in the allenes **179** is more reactive due to the activating and polarisation effects of the nitrogen-containing substituent, which also controls the regio- and stereoselectivity of this reaction.

It was shown [164] that the fragment of proline benzyl ester plays the role of an effective chiral auxiliary group in the asymmetric addition of nitrile oxides to the alkenes **182**. This gives a mixture of the isomers **183** and **184** with the predominance of the former isomer. The regioselectivity does not depend on the reaction temperature and the nature of the substituent R^1. The reaction of the alkene **185** with benzo- and pivalonitrile oxides yields the adducts **186** and **187** in 10 : 1 and 9 : 1 ratios, respectively.[164]

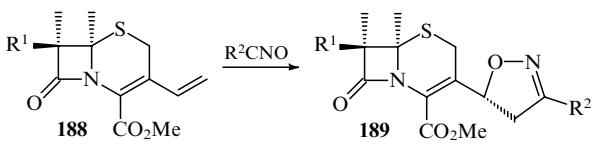


182 **183** **184**

185 **186** **187**

R^1 = H, Me; R^2 = ; R^3 = Bu^t, Ph.

3-Vinylcephalosporins **188** were used in the synthesis of novel 3-substituted cephalosporins **189**.[165] It was found that compounds **188** do not react with nitrile oxides generated from nitroalkanes under the action of phenyl isocyanate in the presence of triethylamine or *N*,*N*,*N*′,*N*′-tetramethylurea.

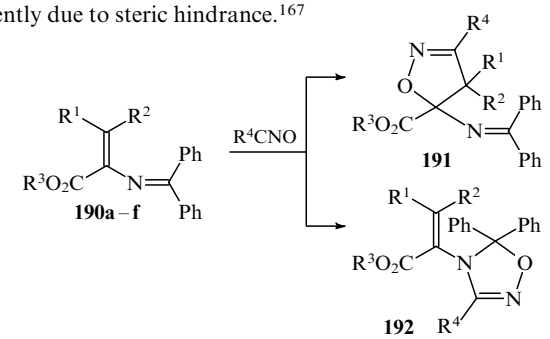


188 **189**

R^1 = BnCONH, $PhOCH_2CONH$; R^2 = Me, Et.

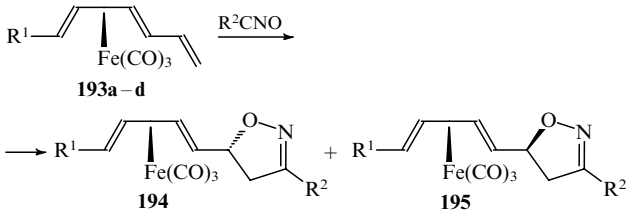
4,5-Dihydroxyisoxazoles **189** could be synthesised by the reaction of alkenes **188** with silyl nitronates as synthetic equivalents of nitrile oxides. These reactions result in *N*-silyloxyisoxazolidines which undergo spontaneous elimination of the trimethylsilanol group to yield 4,5-dihydroisoxazoles **189**; this reaction is regio- and stereoselective.

The simultaneous presence of C=C and C=N bonds in the molecule poses the problem of chemoselectivity.[166] Thus benzonitrile oxide and pivalonitrile oxide react with the heterodienes **190a**,**b** containing a terminal C=C bond to give the substituted 4,5-dihydroisoxazoles **191** in good yields. The cycloaddition of benzonitrile oxide to the β-substituted substrates **190c**–**e** involves exclusively the C = N bond resulting in 4,5-dihydro-1,2,4-oxadiazoles **192**. In this case, *E*-isomers react faster than *Z*-isomers. Compounds **190c**–**f** do not react with pivalonitrile oxide, apparently due to steric hindrance.[167]



$R^1 = R^2 = H$: R^3 = Me (**a**), Et (**b**); R^1 = Me, $R^2 = H$, R^3 = Me (**c**); $R^1 = H$, $R^2 = R^3$ = Me (**d**); R^1 = Ph, $R^2 = H$, R^3 = Me (**e**); $R^1 = H$, R^2 = Ph, R^3 = Me (**f**); R^4 = Ph, Bu^t.

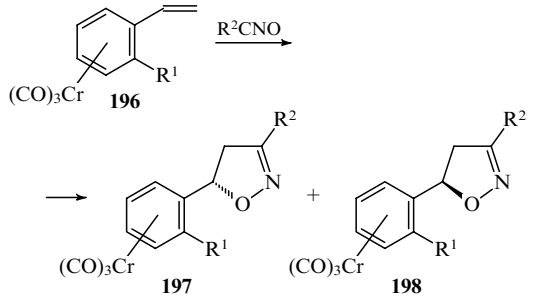
The irontricarbonyl complexes **193a**–**d** can be used to prepare 4,5-dihydroisoxazoles with a high degree of stereoselectivity.[168] This reaction results in the predominant formation of the epimers **194** [**194** : **195** = (7–9) : 1]. It is noteworthy that the formation of the isomers **195** is explained [168] by the presence of *cis*-rotamers in the original complexes **193**.



R^1 = Me (**a**), Et (**b**), Bu^t (**c**), Ph (**d**); R^2 = Me, CO_2Me, $CH_2OSiPh_2Bu^t$.

The chiral synthesis of (+)-(*S*)-[6]-gingerol was performed using the complex **193a**.[169]

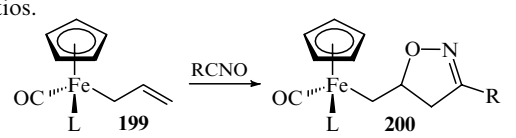
It was shown that the use of the chromiumtricarbonyl complexes of the styrene derivatives **196** in the reaction with 3,5-dichloro-2,4,6-trimethyl-benzonitrile oxide results in the stereoselective synthesis of the adducts **197** with the *S*-configurations of the newly formed chiral centres at the C(5) atoms.[170] It is of note that the reaction of nitrile oxides with styrene proceeds in a non-stereoselective manner.



R^1 = OMe, Me, Cl; R^2 = 3,5-Cl_2-2,4,6-Me_3C_6.

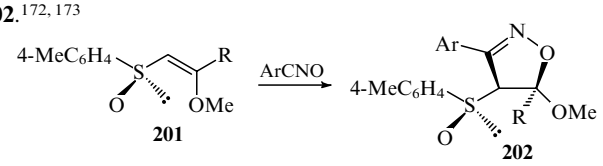
R^1	Ratio **197** : **198**
OMe	80 : 20
Me	98 : 2
Cl	96 : 4

The cycloaddition of nitrile oxides to the η^1-allyliron complexes **199** [171] yields mixtures of 4,5-dihydroisoxazoles **200**. In the case of the chiral complexes **199b**,**c**, mixtures of diastereomeric 4,5-dihydroisoxazoles **200b**,**c**,**e**,**f** are formed in (59–93) : (41–7) ratios.



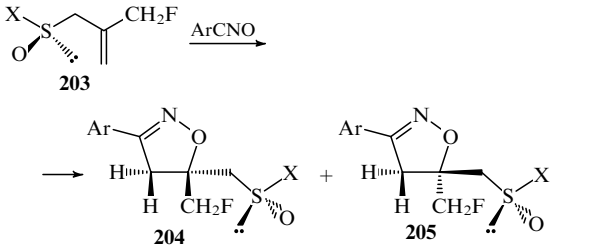
R = Ph: L = CO (**a**), (**b**), PPh_3 (**c**); R = Mes: L = CO (**d**);  (**e**), PPh_3 (**f**).

The 1,3-dipolar addition of arenecarbonitrile oxides to the chiral vinyl sulfoxides **201** occurs with high regio- and stereoselectivity and results in (4*S*,5*R*,R_S)-4,5-dihydroisoxazoles **202**.[172, 173]



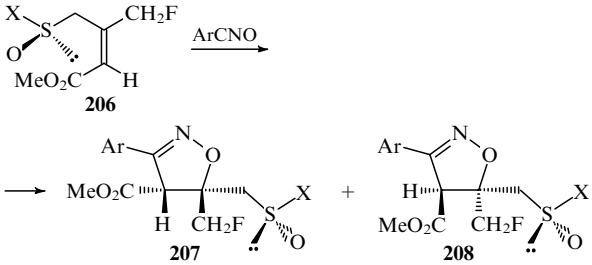
R = CH_2F, CHF_2, CF_3, C_2F_5;
Ar = Ph, 2,6-$Cl_2C_6H_3$, 3,5-Cl_2-2,4,6-Me_3C_6.

The effect of the sulfinyl group is much less pronounced if the latter is in the β-position relative to the double bond.[174] This reaction is characterised by full regioselectivity but moderate stereoselectivity and results in the formation of chiral 4,5-dihydroisoxazoles. Thus, the addition of 3,5-dichloro-2,4,6-trimethylbenzonitrile oxide to the allylic sulfoxide **203** results in the diastereomers **204** and **205** in a 1.4 : 1 ratio.[174]



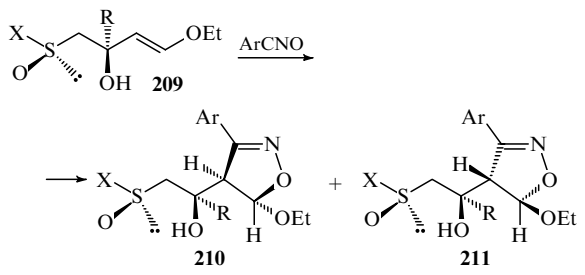
X = 4-MeC_6H_4; Ar = 3,5-Cl_2-2,4,6-Me_3C_6.

A mixture of the diastereomers **207** and **208** (2 : 1) is formed in the reaction of (*Z*)-allylic sulfoxide **206** with 3,5-dichloro-2,4,6-dimethylbenzonitrile oxide.



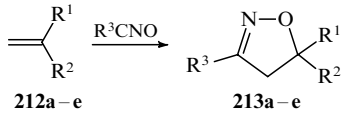
X = 4-MeC_6H_4; Ar = 3,5-Cl_2-2,4,6-Me_3C_6.

The dipolarophiles **209** have two chiral centres, *viz*., the sulfinyl group and the oxygen-containing substituent in the allylic position. Both functional groups influence the stereochemistry of the 1,3-dipolar cycloaddition.[175] The reactions of compounds (3*S*,R_S)-**209** with arenecarbonitrile oxides give mixtures of 4,5-dihydroisoxazoles **210** and **211**. In all cases studied, the epimers **210** were predominant (up to 67%).



X = 4-MeC$_6$H$_4$; R = CF_3, CF_2Cl;
Ar = 3,5-Cl$_2$-2,4,6-Me$_3$C$_6$, 2,6-Cl$_2$C$_6$H$_3$.

It was found [176, 177] that baker's yeast *Saccharomyces cerevisiae* are effective chiral catalysts in reactions of asymmetric cycloaddition of nitrile oxides. Thus the addition of nitrile oxides to alkenes **212a–c** in the presence of baker's yeast and cyclodextrin gives 4,5-dihydroisoxazoles **213a–c** with high stereoselectivity.



212a–e **213a–e**

R^1 = H: R^2 =  (**a**), (**b**), (**c**);

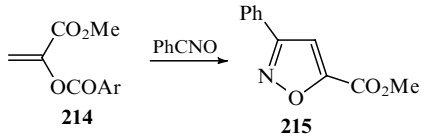
R^1 = Me: R^2 = CN (**d**), CO_2Me (**e**);

R^3 = Mes, 2,6-Cl$_2$C$_6$H$_3$, 2,4,6-(MeO)$_3$C$_6$H$_2$;

The electron-deficient dipolarophiles **212d,e** also gave optically active 4,5-dihydroisoxazoles **213d,e**.[178]

However, some authors [179] argue against this conclusion assuming that the isolation of only one enantiomer is due to the loss of the second enantiomer in the recrystallisation.

It was noted that cycloaddition of nitrile oxides to captodative alkenes **214** occurs in a regioselective manner and results in the isoxazoles **215**.[180] Here, alkenes **214** behave as acetylene equivalents.



214 **215**

* * *

Thus, 1,3-dipolar cycloaddition of nitrile oxides to the double bond can be applied to various classes of compounds. In the majority of cases, this occurs with good yields and high regio- and, sometimes, stereoselectivity which allows its use for the solution of complex problems of organic synthesis. The reaction products, *viz*., 4,5-dihydroisoxazoles, present interest from the standpoint of their biological activities.[181, 182] In our opinion, further investigations into the cycloaddition of nitrile oxides to alkenes will be associated with the search for novel catalysts and chiral substituents for regio- and stereo-controlled addition.

Problems of control of the reactivity of macroradicals and the growth of polymer chains

D F Grishin, L L Semyonycheva

Contents

I. Introduction 425
II. Coordination interactions of organic compounds of Group II and III elements with macroradicals and their influence on chain propagation 425
III. Growth of the polymer chain in the presence of stable radicals and iniferters 435
IV. Characteristic features of homo- and co-polymerisation of vinyl monomers in the presence of organoelement compounds derived from Group V elements 441
V. Conclusion 443

Abstract. Data on the influence of stable radicals, iniferters, organoelement compounds and other active additives on the reactivity of macroradicals and the elementary steps of the (co)polymerisation of acrylic and some other monomers are generalised. New approaches to the control of the lifetime of the polymer chain and of the chain propagation stage are analysed. The problems of synthesis of compositionally homogeneous homo- and copolymers by radical polymerisation are considered. The bibliography includes 247 references.

I. Introduction

Polymerisation involving radical species has long been and still remains the key method for the synthesis of polymers. Obvious advantages of radical polymerisation are the methodical and technical simplicity of its implementation and good reproducibility of the results. A significant drawback of the method which somewhat delays its practical use is the difficulty of controlling the kinetics of polymerisation and compositional homogeneneity of the products, caused by the fact that the reactivity of free radicals participating in the polymerisation barely depends on the medium composition or other conditions.[1–4]

In this connection, development of effective methods for controlling the growth and the lifetime of a polymer chain is a topical task. This problem could be solved if it were possible to change the reactivity of the chain-propagating radicals in the required manner.

In recent years, several new approaches for controlling the growth of a polymer chain under the conditions of radical polymerisation have been proposed. These approaches include reversible inhibition by stable radicals, the use of iniferters as controlling initiators of a new type and the use of catalytic amounts of stable radicals or coordinatively unsaturated organoelement compounds (OEC) as reactive additives, *etc*. These methods have been used to develop effective methods for the synthesis of compositionally uniform polymeric materials with a specified set of properties. This review is devoted to the analysis of these methods.

II. Coordination interactions of organic compounds of Group II and III elements with macroradicals and their influence on chain propagation

The search for the ways of target-directed change in the reactivity of monomers and chain-propagating radicals directly during polymerisation is one of the most important aspects in the studies on the methods of synthesis of polymeric materials of a particular structure with specified properties.

In the 1970 – 1980s, the vigorous studies concerning the use of protic and aprotic Lewis acids (halides of Group II and III elements and some transition metals) for controlling the reactivity of vinyl and, especially, acrylic monomers carried out in a number of leading scientific schools of the world gave rise to a new line of research in the synthetic chemistry of polymers, namely, coordinated radical polymerisation.[5–7]

It was found that Lewis acids, which are strong electron acceptors, can substantially influence the electron density distribution over the monomer π-bond and functional group and are thus able to change the kinetic parameters of homo- and copolymerisation and the relative activities of monomers. On the basis of this approach, original methods for the synthesis of alternating and compositionally homogeneous copolymers, physiologically active high-molecular-mass compounds, graft and block copolymers, and a number of promising composite materials have been developed.

The main drawback of this method for modification of polymeric materials is that the controlling additive is introduced, as a rule, in a substantial excess with respect to the initiator (1% – 5% relative to the monomer). This leads to contamination of the resulting polymer. The cost of its purification is high; therefore, this method for the control of the composition and structure of polymers does not have prospects in industry.

The use of OEC as initiators has laid the foundations of a new stage in the development of the synthetic chemistry of polymers.

The Ziegler – Natta catalysts proposed for the synthesis of homo- and copolymers of alkenes and dienes are of limited utility for (co)polymerisation of vinyl monomers, especially acrylates,

because these monomers are highly reactive towards the components of these organometallic catalysts.[8]

Conversely, initiating systems based on alkyl derivatives of non-transition elements and oxidants including organic and organoelement peroxides (OEP) not only initiate efficiently radical homo- and copolymerisation of a broad range of monomers but also control the composition of copolymers and the kinetics of processes; they also change noticeably the properties of polymers. Based on the analysis of the characteristic features of polymerisation kinetics and unusual properties of macromolecules synthesised in the presence of organoelement initiators, it was initially suggested and later convincingly proved that the features mentioned above are related to the coordination interaction of the OEC with the growing radical. This interaction promotes an increase in the electron-withdrawing properties (electrophilicity) of the macroradical.[9–11]

1. The effect of coordinatively unsaturated organoelement compounds on the polymerisation kinetics of vinyl monomers and on the molecular-mass characteristics of polymers

Among organoelement initiators of the redox type, it is necessary first of all to distinguish compositions based on alkyl derivatives of boron and aluminium, which possess a number of advantages over the conventional radical initiators.[11–20] In particular, boron and aluminium alkyl derivatives in combination with organic and organoelement peroxides permit one to carry out polymerisation of vinyl monomers, which occurs at a high initial rate over a broad temperature range,† from 0 to 50 °C,[13–15] and copolymerisation of vinyl monomers with alkenes and allylic monomers.[23–25] Polymers and copolymers prepared in the presence of these organoelement initiators have unusual properties such as stability against thermal treatment and unusual molecular-mass characteristics; copolymers possess a number of unique mechanical properties.[13–29]

In view of the fact that the rates of chain propagation during the synthesis are high and based on the studies of some physicochemical properties of the prepared polymers, it has been suggested [14,27–29] that components of an organoelement initiator not only participate in the stage of generation of chain-propagating radicals but also influence the chain propagation and termination stages.

It is known that unsaturated compounds including monomers are able to be coordinated to OEP.[30–32] In these compounds, monomers act as electron density donors. On the one hand, complex formation increases the rate of peroxide decomposition and, hence, increases the initiation rate, while, on the other hand, it favours redistribution of electron density on the monomer π-bond and thus changes the reactivity of the monomer including that with respect to radicals. Similar complexes of vinyl monomers with Lewis acids (metal halides) have long been known and studied in detail.[5] It was shown reliably by IR [33–36] and NMR [37] spectroscopy that metal halides are coordinated to the carbonyl group of the monomer. The constants of complex formation of organic compounds of Group III elements with methyl methacrylate (MMA) and acrylonitrile (AN) were estimated taking organoaluminium compounds as examples.[38]

If the concentration of the OEC used as the initiator amounts to 0.01 mol.% – 0.05 mol.%, the formation of OEC complexes with radicals,[39–41] including polymeric radicals, appears more likely.[28,33] Upon the OEC – radical coordination interaction, the electron-withdrawing properties of the growing macroradical are enhanced and its reactivity with respect to the multiple bonds in monomers increases. This interaction results in a higher rate constant for chain propagation. In addition, due to steric factors and the enhanced electrophilicity of the species, the rate constant for chain termination decreases.

† For vinyl chloride (VC), this range is −60 to 50 °C.[15,19,21,22]

In a series of studies,[17–19,40,41] it was demonstrated that the addition of catalytic amounts of OEC derived from Group II and III elements in a polymerising mixture which contains peroxide and azo initiators entails an increase in the rate of polymerisation of (meth)acrylic and some vinyl monomers and markedly influences the properties of the resulting polymers (Table 1).

Table 1. Influence of triisobutylborane (TIBB) on the rate of polymerisation (V) of vinyl monomers and the molecular mass (MM) of polymers (T = 313 K).

Monomer	Initiator (0.1 mol.%)	TIBB (mol.%)	$10^4 V$ /mol litre^{-1} s^{-1}	10^{-3} MM

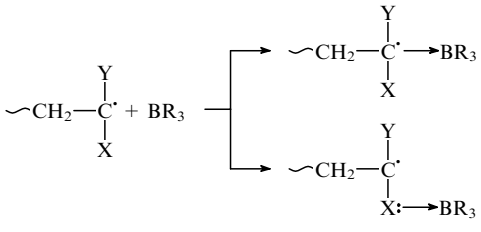
		0.3	3.7	1660

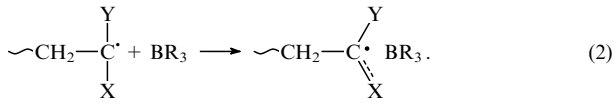
Note. The following designations are used: VA is vinyl acetate, AIBN is azobisisobutyronitrile; BA is butyl acrylate, DCHPD is dicyclohexyl peroxydicarbonate, AA is acrylamide, St is styrene.

Thus the rate of polymerisation of AN and butyl acrylate (BA) increases by almost two orders of magnitude upon introduction of trialkylborane in the system. Meanwhile, although organoboron compounds are capable of initiating homolytic decomposition of hydroperoxides,[42,43] they do not exert catalytic action on the decomposition of acyl peroxides [in particular, benzoyl peroxide (BP)[44] or dicyclohexyl peroxydicarbonate (DCHPD)],[18] or other compounds,[45] used in the studies cited as initiators. The researchers concluded that the accelerating influence of trialkylboranes on the polymerisation of polar vinyl monomers can be due exclusively to the coordination interaction of the growing macroradicals with the boron atom in the OEC. This interaction occurs either directly at the reaction centre (with participation of the unpaired electron), or at the functional group



(1)

(where X is a functional group, Y is the hydrogen atom or a methyl group), or simultaneously at both sites with delocalisation of the unpaired electron

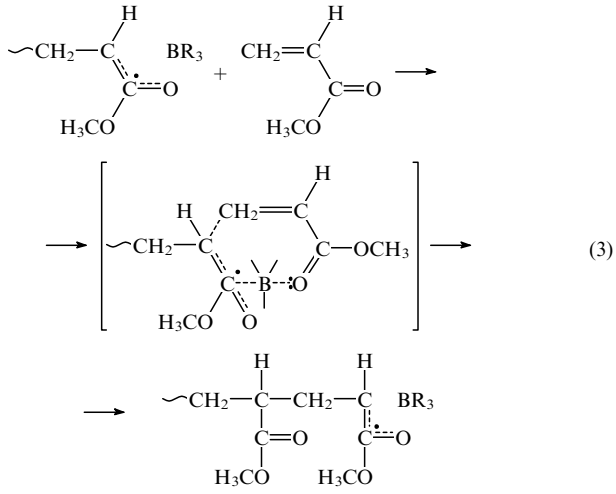


(2)

On the basis of studies of copolymerisation of MMA with electron-donating monomers involving binary trialkylborane–OEP initiators,[11,14] it was suggested that the Lewis acid might be involved in the coordination interaction with the poly(methyl methacrylate) (PMMA) radical; this hypotheisis was proved by EPR spectroscopy[28,46] and confirmed by quantum-chemical calculations.[47] In addition, it was shown by quantum-chemical calculations[48] that in the case of radicals containing a C=O group in the α-position to the reaction centre, the reaction centre is delocalised over three atoms.

Unlike metal halides (Lewis acids), organometallic additives introduced in the system in amounts comparable with the initiator concentration (0.1 mol.% – 0.5 mol.% with respect to the monomer), influence appreciably the growth of the polymer chain. This fact indicates unambiguously that an increase in the polymerisation rate in the presence of these compounds is due to complex formation of the OEC exactly with the macroradical rather than with the monomer.

It has been suggested[49] that one OEC molecule can participate consecutively in several chain propagation steps, while retaining the growing macroradical in its coordination sphere. In this case, chain propagation occurs in a cyclic reaction complex which incorporates the growing macroradical, the monomer, and the complex-forming agent.



(3)

A similar mechanism involving an eight-membered reaction complex has been proposed by Kabanov[50] to interpret the increase in the propagation rate constant in the polymerisation of MMA in the presence of metal halides and by Smirnova and coworkers,[51,52] who studied copolymerisation of acrylic acid with VA (vinyl acetate) in the presence of germanium salts. In our opinion, the above-presented reaction complex [see Eqn (3)], which includes the allylic delocalised macroradical is thermodynamically and geometrically more stable.

It was found[53] that the addition of trialkylborane accelerates processes with monomers containing a polar substituent. In the case of styrene, organoelement additives have little influence on the polymerisation. Apparently, this is due to the fact that the St macroradical contains no functional groups capable of being coordinated to trialkylborane; therefore, the additive almost does not change the electrophilicity of the growing macroradical. The coordination directly to the reaction centre, namely, to the carbon atom carrying the unpaired electron is relatively unlikely. Moreover, this interaction can create steric hindrance to chain propagation. It is not by chance that the St polymerisation rate is lower in the presence of some organic compounds of Group III elements than without any complex-forming additives.[49]

The features of electronic and spatial structures of the growing macroradical play a crucial role in the chain propagation stage of coordinated radical polymerisation. On the one hand, coordination of an OEC molecule to a macroradical increases the electrophilicity of the latter and thus enhances its reactivity with respect to the monomer π-bond. It is evident that this effect is more pronounced in the case of polymerisation of sterically nonhindered monomers such as BA, AN and VA. On the other hand, upon the coordination interaction of the radical with OEC, the size of the reaction centre increases and additional steric hindrance to the chain propagation can arise. In the case of bulky radicals, for example, those of PPMA or polystyrene (PS), steric factors are, naturally, more significant in the chain propagation step than in the case of the BA or VA macroradicals. This is why the activating effect of Group III element alkyl derivatives is manifested most clearly in the polymerisation of esters and other functional derivatives of acrylic acid (amides, nitriles). The effect involved in the polymerisation of methacrylates, for example, MMA and butyl methacrylate (BMA) is much less pronounced.

The structure of OEC also influences the reactivity of the chain-propagating radicals and, hence, the kinetic parameters of polymerisation of acrylic monomers. For example, replacement of the alkyl radical in the trialkylborane molecule by a halogen atom [dibutylboron bromide (DBBB)] deteriorates the coordination capacity of boron due to the partial blocking of its vacant *p* orbital ($p_\pi - p_\pi$ conjugation). As a consequence, DBBB is less active as a controller of acrylate polymerisation than TIBB (triisobutylborane).[49]

Similar regularities can be observed in the case of phenyl derivatives of boron. Triphenylborane and dibutylphenylborane[53] were found to accelerate polymerisation of acrylic monomers to a smaller extent than TIBB.

This can be due both to the steric restrictions involved in the coordination of triphenylborane to the growing polymer radical and to the conjugation of one phenyl group of the substituent with the vacant *p* orbital of boron. Consequently, as in the case of DBBB, the electron-withdrawing capacity of the central atom in the OEC decreases. These results do not contradict the published data on the relationship of the reactivities of alkyl and phenyl derivatives of boron.[54]

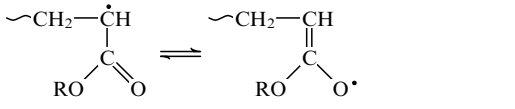
The alkyl derivatives of boron analogues — aluminium, gallium and indium — also increase somewhat the rate of polymerisation of acrylic monomers and VA;[49] however, as in the case of DBBB, their influence on the chain propagation stage is less pronounced than that of TIBB. The difference between the effects of organoboron compounds, on the one hand, and organoaluminium, -gallium and -indium compounds, on the other hand, is, apparently, due to different coordination capacities of the central atoms in the OEC and, as a consequence, their dissimilar influence on the reactivity of the macroradical. A similar consideration can be used to interpret the lower efficiency, compared to that of trialkylboranes,[53] of zinc and cadmium alkyl derivatives as controllers of the polymer chain growth in the polymerisation of acrylic monomers.

Thus, alkyl derivatives of boron exert a greater influence on chain propagation in the radical polymerisation of vinyl monomers than other coordinatively unsaturated OEC derived from Group II and III elements.[54]

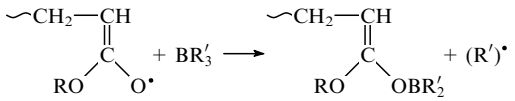
The participation of OEC in the elementary steps of polymerisation (chain propagation, transfer, termination) opens broad opportunities for controlling the MM of the resulting polymers. The introduction in the polymerisate of boron alkyl derivatives in amounts commensurable with the concentration of the initiator decreases substantially the MM. The calculated constants for the chain transfer to TIBB are 1×10^{-2} for MMA and 2.2×10^{-2} for VA.[53] The addition of TIBB also influences markedly the MM of poly(butyl acrylate) when polymerisation is carried out in an ethyl acetate solution.[49] The molecular mass of the polymer decreases with an increase in the OEC concentration; upon the introduction of 0.8 mol % of trialkylborane, it decreases by more than an order

of magnitude. The calculated constant for chain transfer to the organoboron compound is 7.4×10^{-2}; this is somewhat higher than the constant for chain transfer to TIBB during MMA polymerisation and appreciably higher than the chain transfer constant to BA (0.3×10^{-4}).[55]

The high constants of chain transfer to trialkylboranes can be due to two processes involving the macroradical and the OEC. One process is free-radical substitution of the growing polymer radical for the alkyl radical in OEC



(4)

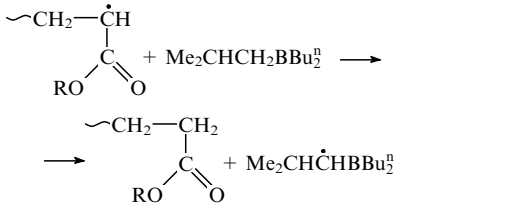


(5)

R, R′ is alkyl (isobutyl, ethyl, n-butyl).

Using EPR spectroscopy and quantum-chemical calculations, it has been shown [48] that (meth)acrylate macroradicals are prone to exist in a state typical of alkyl radicals, *i.e.*, the reaction centre is delocalised to give both carbon- and oxygen-centred radicals [Eqn (4)]. However, the rate constant for the replacement of alkyl radicals in trialkylborane by oxygen-centred radicals [Eqn (5)] is rather high, $\sim 10^5$ litre mol^{-1} s^{-1}.[56]

The second process which is also favourable for the control of the polymer MM is the abstraction of a hydrogen atom from the α-methylene unit of an alkyl group in OEC by the growing macroradical.



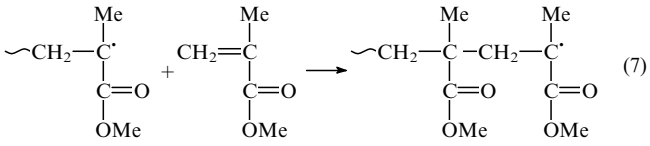
(6)

The occurrence of this reaction was proved unambiguously by EPR using the spin trap technique in a study of the influence of small additives of methyl acrylate (MA) and other acrylic monomers on the polymerisation of MMA with organoelement initiators.[57] The rate constant for this reaction in the case of triethylborane is $\sim 10^4$ litre mol^{-1} s^{-1}.[56]

In the polymerisation of styrene (St), the MM of the product barely changes, which is consistent with the results of kinetic measurements and indicates that OEC does not interact with the growing macroradical of PS.[49, 53]

The influence of added OEC on the molecular-mass distribution (MMD) of polymers has been studied by gel permeation chromatography (GPC).[58] In the presence of AIBN as the initiator, a unimodal MMD curve is observed; however, when TIBB is added to the system, the curve becomes clearly bimodal. As a consequence, the polydispersity of samples increases somewhat. Evidently, in the presence of TIBB, the growth of the polymer chain occurs in parallel by two mechanisms, namely, coordinated radical and radical mechanisms.

On the one hand, OEC is coordinated to the growing macroradical, thus increasing its electrophilicity and, hence, its reactivity with respect to the monomer. As noted above, chain propagation takes place in a cyclic reaction complex [see, for example, Eqn (2)]. This interaction changes the chain propagation and termination rate constants and decreases the MM of the polymer. On the other hand, growth of the polymer chain occurs simultaneously by the classical radical mechanism



(7)

A bimodal MMD curve is also observed when polymerisation of MMA is carried out with a binary initiator, TIBB–di-*tert*-butylperoxytriphenylantimony (DPA), which is an efficient low-temperature initiator controlling polymerisation of vinyl monomers.[13, 15, 19, 22, 32, 44]

The conclusions drawn confirm indirectly the results of studies of the MMD of PS samples synthesised in the presence of various OEC derived from Group II and III elements.[52] The introduction of these compounds barely influences both the general pattern of the MMD curve and the degree of polydispersity of samples. It has been noted above that OEC do not react with the growing polystyrene radical due to electronic and steric factors.[49, 58] Therefore, in the polymerisation of St, chain propagation follows only the traditional radical mechanism without participation of the complex-forming agent.

Thus, the data outlined above indicate that organic compounds of Group III elements provide effective control of the molecular-mass characteristics of polyacrylates. This way of controlling polymerisation of acrylic monomers opens up new opportunities for the synthesis of polymers with novel physicochemical and practical properties. A certain drawback of the proposed method is the higher polydispersity of the resulting polymers, caused by the fact that polymerisation in the presence of organoelement additives follows two parallel mechanisms.

2. Specific influence of phenolic inhibitors on homo- and copolymerisation of vinyl monomers in the presence of organic compounds of Group III elements

Hydroquinone, ionol, diphenylolpropane and some other phenols are known inhibitors of radical polymerisation; they are traditionally used as stabilisers for the storage of vinyl monomers. The inhibiting efficiency substantially increases in the presence of oxygen; this may be due to oxidation of phenols to quinones, which retard chain propagation more appreciably.[59]

According to the most popular viewpoint,[59, 60] the inhibitory influence of hydroquinone is due to the easy abstraction of the active hydrogen atom from the phenol molecule giving rise to a phenoxyl radical.

$$R^{\bullet} + ArOH \longrightarrow R-H + ArO^{\bullet}. \qquad (8)$$

The phenoxyl radical, which exhibits a low reactivity towards the monomer multiple bond, is unable to initiate a radical process (polymerisation).

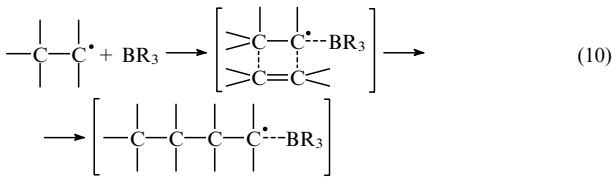
Back in the 1960s, it was found [61–64] that the addition of some OEC derived from Group III elements makes it possible to carry out polymerisation of MMA in the presence of BP or AIBN to a high degree of conversion, despite the presence of comparable amounts of hydroquinone. Apparently,[56] in the presence of OEC, the phenoxyl radicals undergo a fast S_R2 substitution reaction.

$$ArO^{\bullet} + MR_3 \longrightarrow R^{\bullet} + ArOMR_2 \qquad (9)$$

M is a Group II or III metal.

The alkyl radicals formed in this reaction can subsequently initiate polymerisation. It is in these processes that organoboron compounds can act as chain transfer agents in the polymerisation of acrylates. As noted above, the rate constants for the chain transfer in peroxide-initiated polymerisation of MMA are equal to 0.015 for tri-n-butylborane and 0.01 for TIBB.[20]

A somewhat different interpretation of the absence of inhibitory influence of phenols on polymerisation in the presence of OEC was proposed by Arimoto,[62] who suggested that trialkylborane is coordinated to the growing macroradical through the unpaired electron of the latter.

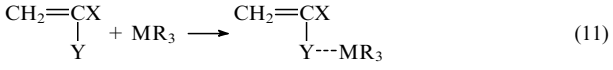


(10)

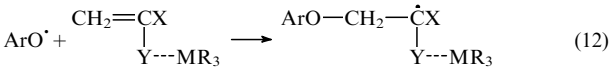
As a consequence, the reaction centre of the radical becomes blocked and the interaction with phenol is made impossible. It should be noted that Grotewold *et al.*[61] cast doubt on the experimental results obtained by Arimoto.

In some studies published in the 1990s,[16–18, 65] it was shown that diphenylolpropane and hydroquinone are not merely inactive as inhibitors of radical polymerisation of acrylates in the presence of trialkylboranes but, conversely, accelerate it. Indeed, the rates of MMA and AN polymerisation markedly increase in the presence of organic compounds of Group III elements, the effect becoming more pronounced with an increase in the contents of OEC and the above-mentioned diphenols. Similar data have also been obtained for reactions carried out in the presence of alkylalkoxy boron derivatives.[44]

This unusual accelerating effect can be due to some extent to the occurrence of chain transfer to the OEC [Eqn (9)]. However, this fact alone cannot account for the absence of the inhibiting effect in the polymerisation of MMA, AN, and MA in the presence of substantial concentrations of hydroquinone and diphenylolpropane (an order of magnitude higher than the initiator concentration) or for the absence of inhibiting effect after the introduction of Lewis acids in the system which undergoes polymerisation.[66–68] The unusual behaviour of phenols can be explained in terms of the coordinated radical mechanism of (co)polymerisation of acrylic monomers on organoelement initiators. In the presence of electron acceptors such as Lewis acids, the macroradical and the monomer are coordinated to components of the initiator. The complex formation of OEC with the monomer activates the monomer;[58] this enables initiation of the polymerisation by phenoxyl radicals.



(11)



(12)

M is a Group III metal.

The coordinated macroradical, unlike the non-coordinated one, exhibits enhanced electrophilicity with respect to the monomer π-bond, which results in a higher propagation rate constant.[5, 11, 18]

The occurrence of reaction (12) is also confirmed by the fact that IR- and UV-spectroscopic studies show the presence of phenoxy groups in the MMA polymer. This view on the kinetics of polymerisation of acrylates in the presence of OEC and inhibitors is indirectly supported by the absence or attenuation of the inhibiting effect in MMA polymerisation in the presence of Group III metal halides.[66–68] In this case, S_R2 reactions [Eqn (9)] are impossible in principle; therefore, the effect observed can be interpreted in terms of either the Arimoto scheme, or reactions (11) and (12), or the cyclic mechanism of chain propagation [see Eqn (3)].[7, 20, 49] The same trialkylborane molecule can be involved in several consecutive chain propagation events, while retaining the growing macroradical in the coordination sphere of the boron atom and 'receiving' (coordinating) new monomer molecules. Chain propagation in the cyclic reaction complex hampers the interaction of the growing macroradical with the inhibitor.

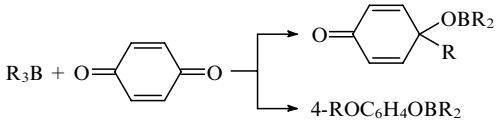
It is the processes considered above that account for the increase in the rate of MMA, AN and MA polymerisation in the presence of organic compounds of Group III elements and phenols such as hydroquinone and diphenylolpropane. However, in the case of ionol, which is a sterically hindered phenol, polymerisation rate somewhat decreases.[7, 16] This appears to be due to the fact that reactions (9) and (12) are much less efficient for ionol than for hydroquinone or diphenylolpropane.

In view of the foregoing, it can be assumed that the vacant orbitals of TIBB accept electron density through coordination to the macroradical. This increases the electrophilicity of the coordinated poly(methyl methacrylate) radicals; therefore, they become relatively 'inert' with respect to the abstraction of a hydrogen atom from phenol. In addition, chain propagation takes place in the cyclic reaction complex, which also hampers the reaction of the macroradical with the active hydrogen atom of the phenol hydroxy group. As a consequence, polymerisation of MMA proceeds up to a high degree of conversion in the presence of a 10-fold excess of the inhibitor with respect to OEC.

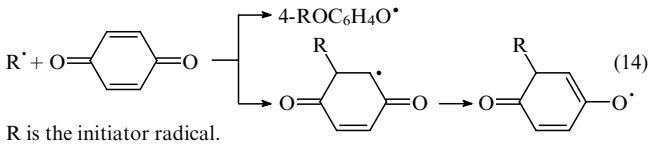
Phenolic inhibitors have also a certain influence on the polymer MM.[7, 16, 49, 65] In particular, the molecular mass of PMMA decreases upon the introduction of phenols. However, this influence is not so pronounced (as could be expected) as that observed in the absence of OEC or in the presence of conventional chain transfer agents.

Oxygen plays an important role in the mechanism of inhibition of radical polymerisation by various phenols. According to one view,[59] the influence of oxygen reduces to the oxidation of phenol to the corresponding stable radical or quinone. In the presence of organic compounds of boron or aluminium or of benzoquinone, polymerisation of MMA proceeds without an induction effect.[40, 61–64] The inhibitory effect of benzoquinone after the addition of TIBB depends on the [TIBB] : [benzoquinone] molar ratio. If the amount of benzoquinone is smaller than that of TIBB, the inhibitory action has virtually no effect on the polymerisation kinetics. The process occurs up to a high degree of conversion and the molecular mass of PMMA changes insignificantly. In the absence of OEC, benzoquinone efficiently inhibits polymerisation of acrylates: the rate of polymerisation in the initial stages is close to zero, the limiting degree of conversion is less than 0.5%.[49, 58]

As the benzoquinone concentration increases, the rate of polymerisation decreases. However, even with a twofold excess of benzoquinone with respect to alkylborane, it is markedly higher than that in the absence of OEC. Analysis of the publications cited and data on the reactivity of organoboron compounds and quinones point to efficient consumption of trialkylborane and quinone.[69–74]

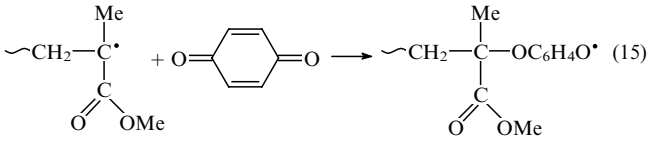


(13)



(14)

R is the initiator radical.



(15)

Reaction (14) and the regularities of inhibition of alternating copolymerisation by quinones have been studied comprehensively by EPR spectroscopy by Golubev,[70] who used the reactions of benzoquinone, naphthoquinone, and fluoranil with organic radicals of different electrophilicity as examples to demonstrate that the abnormally slight influence of quinoid-type radical inhibitors on the alternating copolymerisation is related to substantial polar effects involved in this reaction. In accordance with this concept, the increase in the electrophilicity of macroradicals upon the coordination to OEC should substantially influence the reactivity

of the macroradical with respect to the quinone [chain termination, Eqns (13)–(15)].

It is beyond doubt that in the presence of OEC in a polymerising system, the factor of polarity would play a vital part in the attenuation of the inhibiting effect of quinones. In particular, the phenoxyl radicals generated in processes (13)–(15) enter into S_R2 substitution to give alkyl radicals able to initiate polymerisation once again [see Eqn (9)]. Judging from the average chain length, two chain transfers to the trialkylborane molecule take place.[63]

The influence of organoaluminium compounds on the polymerisation of acrylates in the presence of benzoquinone is equally efficient.[58] The rate of polymerisation increases with an increase in the [triethylaluminium]:[benzoquinone] ratio, passes through a maximum, and then decreases. This was attributed[64] to the occurrence of two mechanisms of initiation; one of them is related to the decomposition of the initiator into radicals and the other, to the generation of radical centres upon decomposition of the triethylaluminium complex with quinone. In view of the analysis of products of the reaction of organoaluminum compounds with quinones, the latter mechanism seems quite debatable.

Apparently, in this case, as for trialkylborane, both the heterolytic reaction [Eqns (13)–(15)] and the homolytic transfer of the reaction centre to the metal atom in OEC [see Eqn (9)] take place. In addition, whereas in the case of TIBB, the reaction can involve two alkyl groups, in the case of triethylaluminium, only one group is involved[64] (the rate constant for chain transfer is equal to 89 litre $mol^{-1} s^{-1}$; for comparison, the rate constant for chain propagation is 576 mol $litre^{-1} s^{-1}$.[75]).

Organoelement compounds formed by Group III elements and the inhibitors chosen accelerate not only homo- but also copolymerisation of MMA with a number of vinyl monomers, including St, VA, and methacrylic acid (MAA).[7] Similar features have also been found for the MAA–VA pair of monomers. It was shown in relation to the copolymerisation of these monomers in the presence of hydroquinone and OEC that the inhibitor participates in the chain propagation and termination stages and influences the dependence of the copolymer composition on the composition of the monomer mixture.[17] For MAA contents in the monomer mixture ranging from 20 mol.% to 80 mol %, the addition of hydroquinone virtually does not change the composition of the MAA–VA copolymer, which does not depend on the composition of the monomer mixture. In the Kelen–Tudoc calculation of the copolymerisation constants, the intermediate calculated parameters (η and ψ) are found to deviate from the linear dependence; this is evidence supporting the coordinated radical mechanism of copolymerisation.

3. The coordinated radical copolymerisation of vinyl and some other monomers in the presence of organoelement initiators

At present, copolymerisation is an important method for the preparation of polymers with a specified set of chemical and physical properties because it is difficult in most cases to control the properties of homopolymers. Meanwhile the need to control these properties is a topical task in preparing materials for various purposes.[4, 76]

Copolymerisation normally affords random copolymers, the composition and properties of which are determined by the composition of the monomer mixture and the reactivity of monomers and chain-propagating radicals. However, there exist monomer pairs copolymerisation of which gives polymers with regular alternation of the units. As a rule, strict alternation of monomer units is observed if one monomer is a clear-cut donor of electron density, and the other one is an acceptor. Since the number of monomers with clearly defined electron-withdrawing properties is small [maleic anhydride and its derivatives, sulfur(IV) dioxide], the number of monomer pairs that can form alternating copolymers is also few.

The main method for controlling the composition of copolymers is introduction of special additives, usually, protic and aprotic acids, into the system. The latter are coordinated to the monomers or to the chain-propagating radicals and thus enhance their electron-withdrawing properties and provide the possibility of preparing alternating copolymers.[5, 77, 78] The main drawback of this method of modification of polymer materials is that the controlling additive is introduced in a large excess with respect to the initiator (1–3 orders of magnitude), which results in contamination of the polymer formed. The cost of polymer purification is high; therefore, the use of this method to control the polymer composition on an industrial scale is non-expedient.

The use of organoelement initiators based on Group III element organic compound and peroxides eliminates this drawback because the controlling influence of these additives on chain propagation manifests itself, as noted above, when catalytic amounts of the initiator are used (0.01 mol %–1.00 mol %).

The complex formation effects in the radical copolymerisation in the presence of Lewis acids are largely determined by the electronic structure of the monomer.[6, 79] In the possible limiting cases, either one monomer or both monomers react with the complex-forming agent. Both situations are analysed below.

It has been shown in relation to a number of monomer pairs that an organoelement initiator influences directly the variation of the copolymer composition and the copolymerisation rate *vs.* the composition of the monomer mixture. The controlling influence of OEC is most pronounced in the copolymerisation of (meth)acrylates with electron-donating monomers.[7, 58] For instance, in the copolymerisation of MMA with allyl chloride (AC) with a classical radical initiator AIBN, the copolymer is enriched in the more active monomer, MMA, in each section of the composition curve (the relative activities of the monomers are $r_{MMA} = 3.05$; $r_{AC} = 0.05$).[23, 77] The rate of copolymerisation decreases with an increase in the content of AC in the monomer mixture. When a binary initiator, TIBB–DPA, is used,[80] the composition curve is S-shaped. A section in which the copolymer composition does not depend on the composition of the monomer mixture can be clearly seen in the curve; in this case, the trend for the alternation of monomer units is close to its limiting value.

The relative activities of both monomers become much less different and smaller than unity (Table 2); the product $r_1 r_2 \rightarrow 0$, pointing to a coordinated radical mechanism of (co)polymerisation.[5, 6] This is also indicated by the deviation from linearity of the calculated parameters in the determination of the copolymerisation constants by the Kelen–Tudoc method.

Organoelement initiators, even present in low concentrations (0.01 mol %–0.10 mol %), have a noticeable controlling influence on the composition and structure of the MMA–AC copolymer. This is due to the coordination of the growing macroradical to the components of the initial system. Studies of the separate effects of the initiator components on the dependence of the copolymer composition on the composition of the monomer mixture indicate that TIBB, which contains a boron atom with a vacant *p* orbital, plays the most active role in the complex formation with the macroradical.[80] Its coordination to the growing poly(methyl methacrylate) radical induces electron density redistribution in the radical, increases the radical electrophilicity, and enhances its reactivity towards the π-bond of the electron-donating monomer AC.

The variation of the rate of copolymerisation of AC with MMA as a function of the initial composition of the monomer mixture has a clear-cut maximum at a monomer ratio close to the equimolar ratio. This is evidence in favour of the coordinated radical mechanism of copolymerisation and also provides grounds for believing that the monomers and macroradicals form a cyclic reaction complex in the chain propagation stage.

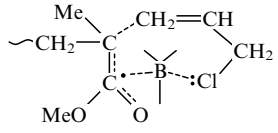


Table 2. Effective values for the relative activity of monomers.

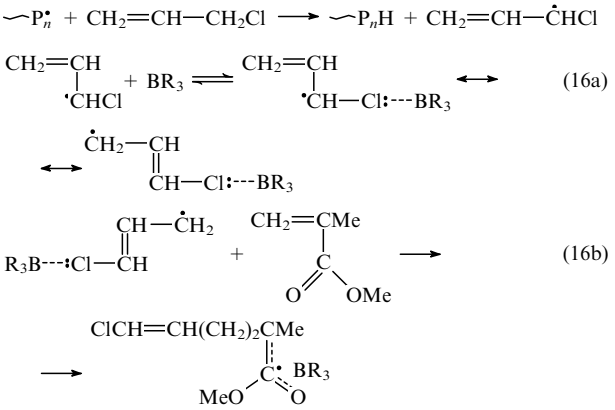
Note. The following designations are used: VDC is vinylidene chloride, AA is acrylic acid, VPD is vinylpyrrolidone, TBP is *tert*-butyl peroxide; TBPT is *tert*-butylperoxytriethyltin; TBPG is *tert*-butylperoxytriethylgermane; TBPS is *tert*-butylperoxytriphenylantimony; TBPS is *tert*-butylperoxytrimethylsilane.

The cyclic mechanism of propagation prevents the destructive chain transfer to the allylic monomer; this accounts for the high degree of conversion in the copolymerisation of AC with acrylates.

The presence of fragments with double bonds in the MMA – AC copolymer ($\sim$4% – 5%) can be explained by assuming that allyl-type radicals formed upon abstraction of a hydrogen atom from AC can again initiate polymerisation in the presence of OEC by the following scheme:



(16a)

(16b)

Coordination of OEC to an allyl type radical increases the radical electrophilicity and reactivity with respect to the π-bond of the monomer. The coordinated allylic radical, unlike a non-coordinated one, is able to re-initiate polymerisation [Eqn (16b)].

The possibility of initiating polymerisation by an allylic macroradical in the presence of Lewis acids (metal halides) was also mentioned in other publications. [5, 81, 82]

The NMR spectra of MMA – AC copolymers and syndiotactic PMMA coincide,[80] which confirms the radical mechanism of the copolymerisation of MMA with AC.

A thermomechanical study of MMA – AC copolymers showed [80] a sharp decrease in the glass transition temperature and a decrease in the ultimate strength and in the modulus of elasticity of copolymers with respect to the corresponding characteristics of the MMA homopolymer prepared both with the DPA – TIBB initiating system [83] and with a classical radical initiator.[84] Hence, the presence of AC (10 mol % – 15 mol %) in the copolymer has a substantial influence on its properties.

The decrease in the glass transition temperature of the MMA – AC copolymer noted above extends the temperature range of the highly elastic state of the copolymer and thus increases its frost resistance, which is significant for practical purposes.

Copolymerisation of AC with the electron-donating VA monomer in the presence of organoelement initiators proceeds to a lower degree of conversion (less than 10% over a period of 7 days)[85,86] than copolymerisation of AC with acrylates. This copolymer was also found to contain fragments with double bonds, which can serve as evidence for initiation of the polymerisation by allyl-type radicals in the presence of OEC [see Eqns (16a,b)].

In the copolymerisation of AN and AC, the formation of a cyclic reaction complex is impossible for steric reasons;[87] therefore, the influence of an organoelement initiator on the dependences of the copolymer composition and copolymerisation rate on the composition of the monomer mixture is less pronounced.[80] In all sections of the composition curve, the copolymer is enriched in AN, which is more reactive ($r_1 > 1$, $r_2 < 1$), although the relative activities of the monomers found in AIBN- and OEP-initiated reactions differ somewhat from each other.

Conversely, copolymerisation of MMA with an electron-donating monomer (St) is subject to regularities[27,88] similar to those observed in the copolymerisation of the MMA – AC pair, namely, the variation of copolymerisation rate as a function of the initial composition of the monomer mixture passes through an extremum (this may also imply the formation of a reaction complex in the chain propagation stage) and the relative activities of both monomers are much smaller than unity.

According to NMR study of the MMA – St copolymers synthesised using DCHPD and organoelement initiators, the microstructures of the specimens obtained are markedly different.[88] The copolymer synthesised in the presence of DCHPD shows a good agreement of the calculated content of triads with that found experimentally. However, in the case of the copolymer prepared in the presence of an organoelement initiator, the discrepancy between the experimental and theoretical values is substantial, indicating that the Mayo – Lewis scheme is inapplicable under these conditions. The ratio of triads calculated from the relative activities in accordance with the pre-terminal unit model showed that the Mertz – Alfrey – Goldfinger equation describes the polymerisation process much more adequately. It can be seen from the data presented that the effect of the pre-terminal unit is not the only factor able to change the copolymer composition. This indicates once again that complex formation between the monomer and the initiator and especially, between the initiator and the macroradical contributes significantly to the change in the monomer relative activities.

Analysis of the dependences of the instantaneous and gross compositions of MMA – St copolymers on the degree of conversion shows that the product of copolymerisation in the presence of DCHPD is enriched in MMA at high degrees of conversion. Initiation by the TIBB – OEP system gives rise to a copolymer with a narrower composition distribution of fractions.[88]

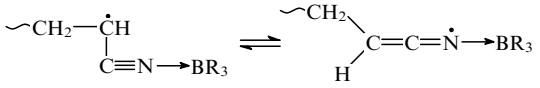
Hirai *et al.*,[89,90] who studied the controlling influence of boron compounds on the composition of the MMA – St copolymer, demonstrated that photoinitiation in the presence of 1 mol % of boron trichloride or ethylboron dichloride gives rise to an alternating St – MMA copolymer. On the basis of kinetic measurements and study of the microtacticity of copolymers, it was concluded that copolymerisation involves the ternary complex 'MMA – St – organoboron compound'. It was noted that diethylboron chloride and triethylborane have a weaker effect on the composition of the MMA – St copolymer than trialkylboranes. In the presence of boron trifluoride, homopolymerisation of styrene takes place.

It has been proposed[91] to use a mixture of alkylboron halides for the synthesis of alternating copolymers of acrylates with alkenes over a broad temperature range (−150 to 100 °C) and at a relatively low pressure (< 100 atm). The degree of conversion reaches 70% over 5 – 6 h. However, the controlling effect of the organoelement additive shows itself only when the amount of the additive is comparable with the monomer concentration. In this case, the influence of OEC on the copolymer composition is likely to be due to the coordination interaction of the OEC with the monomer rather than with the macroradical.

Blends based on organoelement derivatives of Group II elements in combination with Group IV element halides influence the composition of copolymers in a similar way.[92]

An efficient controlling influence of the binary initiator trialkylborane – OEP can be traced in the copolymerisation of AN with VA.[14,93,94] In the case of the classical radical initiator AIBN, the AN – VA copolymer is enriched in AN, which is the more reactive monomer ($r_{AN} = 4.05$, $r_{VA} = 0.06$) at any composition of the monomer mixture. When the organoelement initiator TIBB – OEP is employed, the composition curve is S-shaped. A section in which the copolymer composition barely depends on the composition of the monomer mixture can be clearly distinguished on the curve; this suggests the trend for alternation of the monomer units in the copolymer and points to the coordinated radical mechanism of copolymerisation. The same is indicated by equalisation of the relative activities of the monomers: $r_{AN} = 0.35$; $r_{VA} = 0.42$ (for comparison, r_1 and r_2 found in terms of the $Q-e$ scheme are 4.27 and 0.06, respectively) and by the deviation from linear dependence of the calculated parameters in the Kelen – Tudoc determination of the copolymerisation constants.

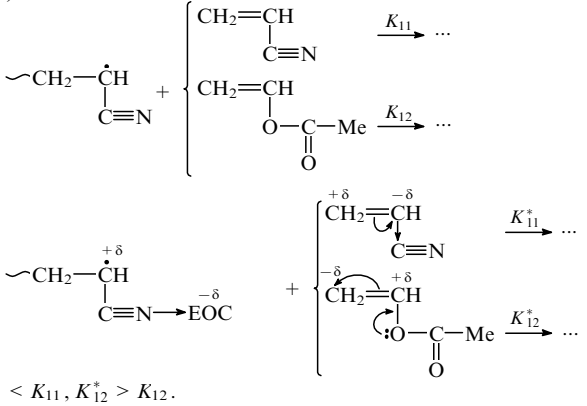
In our opinion, the very pronounced influence of low concentrations of the initiator (0.1 mol % – 1.0 mol %) is due to the coordination interaction of the growing macroradical with the components of the initiating system. Important roles should be played by both trialkylborane, which has a vacant orbital at the boron atom, and the organoelement peroxide. This interaction results in electron density redistribution and contributes to the stabilisation of the species



The decrease in the relative activity of AN, found as the ratio of the rate constant for the reaction of the radical with the like monomer (K_{11}) to the rate constant for its reaction with the foreign monomer (K_{12})

$$r_{AN} = \frac{K_{11}}{K_{12}},$$

in the presence of OEC can be related to either a decrease in K_{11}, or an increase K_{12}, or a simultaneous change of both rate constants in the above-indicated directions. These changes can be brought about by an increase in the electron-withdrawing properties of the polyacrylonitrile radical coordinated to the OEC. It is evident that an increase in the electrophilicity decreases the reactivity of the macroradical towards the π-bond of AN (the monomer with a strong electron-withdrawing group) and increases the reactivity towards VA (the electron-donating monomer).



$K^*_{11} < K_{11}$, $K^*_{12} > K_{12}$.

These changes result in a substantial decrease in the relative activity of acrylonitrile ($r^*_{AN} < r_{AN}$).

The rate constant for the addition to VA of the poly(vinyl acetate) radical coordinated to the OEC increases, while that for the addition to AN decreases. As a consequence, the relative activities of the monomers which undergo copolymerisation (AN and VA) become nearly equal and smaller than unity (see Table 2), which generates the trend for alternation of the monomer units. The relative activity of AN changes more sharply than the copolymerisation constant of VA; this indicates that complex formation of OEC with the polyacrylonitrile radical is the governing factor in this system.

The dependence of the rate of copolymerisation of AN with VA in the presence of organoelement initiator on the composition of the monomer mixture has a clear-cut maximum, as in the case of the MMA – AC monomer pair.[14] This points to a coordinated radical character of the process. Similar features have been found for the copolymerisation of AN with MAA, acrylic acid and MMA.[7] As for the AN – VA pair of monomers, the composition curve has a section in which the copolymer composition virtually does not depend on the composition of the monomer mixture. It can be seen from the data of Table 2 that the relative activities of the monomers in the presence of organelement initiators differ markedly from the values calculated using the $Q-e$ scheme or published data. The observed levelling of the relative activities of monomers entails the compositional uniformity of the resulting polymer.

The influence of the components of organelement initiators on the dependence of the copolymer composition on the composition of the monomer mixture in the case of MMA – MAA monomer pair is equally significant.[95] When copolymerisation of these monomers is carried out without OEC additives (AIBN initiation, see Table 2), the copolymer is enriched in the more active monomer, MAA, at any composition of the monomer mixture. In the case of a binary organoelement initiator, TIBB – DPA, the composition curve follows an S-shaped pattern, and the relative activities of both monomers are substantially smaller than unity. The product of the copolymerisation constants tends to zero, pointing to the alternation of monomer units in the copolymer.

Studies of the separate influence of components of the binary organoelement initiator on the chain propagation[27] demonstrated that the addition of 0.2 mol % of TIBB (the concentration of the AIBN initiator is 0.1 mol %) results in substantial levelling of the relative activities of the monomers (see Table 2). The addition of an organosilicon peroxide to AIBN also influences appreciably the reactivities of the monomers and the chain-propagating radicals — the copolymer is enriched in MMA in each section of the curve. The effective values of the relative activities of MMA and MAA are also subject to the controlling influence of DPA, which is an efficient co-initiator for trialkylboranes.[13–15] Thus, both components of the organoelement initiator (alkylborane and OEP) have a controlling influence on the copolymerisation of acrylic monomers.

Copolymerisation of MMA with an electron-donating monomer (St) is influenced by components of an organoelement initiator in a different way.[88] For the polymerisation of these monomers initiated by organoelement initiators, the composition curve is also S-shaped. The relative activities of both monomers are smaller than unity, their numerical values being slightly dependent on the initiator. However, for the MMA – St monomer pair with the use of organoelement initiators, the dependence of the copolymerisation rate on the composition of the monomer mixture has a clear-cut maximum at a nearly equimolar monomer ratio, which is indicative of a coordinated radical copolymerisation mechanism and of the participation of the initiator components in the propagation stage.

The different effects of OEC as weak Lewis acids on the copolymerisation of MMA with MAA and with St are due to the fact that in the former case, the two monomers (MMA and MAA) are similar in structure and electron-withdrawing properties and thus both can react with the complex-forming agent, whereas in the latter case (MMA and St), only one monomer, namely, MMA, reacts with the Lewis acid.

These conclusions are in good agreement with the results of kinetic studies of the copolymerisation of AN with VA and with (meth)acrylates.[7,93–95]

The effect of the heteroatom of the organoelement peroxide on the copolymer composition and the copolymerisation rate was also found for the AN – St pair of monomers at 343 – 353 K,[96] although it is less pronounced than in the case of a binary organoelement initiator.

A quantitative estimate of the change in the reactivity (including electrophilicity) of macroradicals and monomers induced by coordination to the components of an organoelement initiator is provided by the $Q-e$ parameters of the Alfrey – Price equation.[97,98] These parameters are known to have a clear physical meaning and to correlate with the energy of localisation, the order and the π-electron density of the monomer double bond. Comparative analysis of the published Q and e values for various vinyl monomers and the values of these parameters calculated using the relative activities of monomers for the case of organoelement initiators shows that the introduction of organoelement additives changes these values appreciably. Indeed, judging by the Q and e parameters, in the presence of the binary TIBB – OEP initiator, *N*-vinylpyrrolidone acts as an electron density acceptor ($e = 0.94$) rather than an electron density donor ($e = -1.0$), as usual.[97]

Similar regularities have been observed for other vinyl monomers (Table 3): the parameter e, which characterises the electronic structure of the monomer, substantially increases.

Table 3. The parameters Q and e for several vinyl monomers.

Monomer	Q	e	Monomer	Q	e
St	1.0	0.8	MA	0.74	0.40
	1.0	0.8		0.76	0.45
AN	0.60	1.20	VC	0.04	0.20
	0.90	1.33		0.94	0.97
VPD	0.20	−1.00	VDC	0.22	0.36
	1.31 [a]	1.89 [a]		0.29	1.07
AA	1.15	0.77		0.33	0.94
	0.34	1.03		0.50 [d]	0.34 [d]
MAA	1.50	0.68		0.50 [e]	1.50 [e]
	0.86	1.39	VA	0.03	−0.22
	0.74 [b]	0.40 [b]		0.85	−0.06
	1.15 [c]	0.53 [c]			

Note. The values obtained in the absence of initiators are given above the stroke; those in the presence of the organoelement initiator TIBB – DPA are below the stroke.

Additives: [a] tin tetrachloride, [b] dimethylformamide, [c] Lewis base, [d] TBPG – TIBB, [e] acetic acid.

An increase in the numerical value of e in (meth)acrylates attests to an increase in the energy of conjugation and a decrease in the electrophilicity of the double bond. This means an increase in the reactivity of the monomer π-bond towards elctrophilic radicals.

It has been found within the empirical Alfrey – Price scheme that an increase in the parameter e, which is related to the polarity of the monomer double bond, entails an increase in the rate constant for propagation and, hence, in the rate of homo- and copolymerisation.[97,98] As noted above, this is actually observed in the study of the kinetics of homo- and copolymerisation of (meth)acrylates in the presence of catalytic amounts of organoelement compounds.

The efficient controlling influence of organoelement initiators based on trialkylboranes and Group IV – V element peroxides is also manifested in those cases where both monomers involved in copolymerisation are electron donors but contain functional

groups able to be coordinated to Lewis acids. These monomers can be represented, for example, by VPD and VA.[99] The results of studies of the kinetic dependences for the composition and structure of copolymers point unambiguously to a coordinated radical mechanism of copolymerisation. The monomers form a reaction complex with the components of the initiator during the chain propagation stage: the dependence of the copolymerisation rate on the composition of the monomer mixture has an extremum in the region of equimolar amounts of monomers in the initial mixture.

An organoelement initiator has a substantial influence on the copolymerisation of VPD with VDC, which are 'naturally alternating' comonomers.[99,100] The composition curve is S-shaped when DCHPD is used as an initiator. When copolymerisation of this pair is carried out with a binary initiator, TIBB–OEP, the resulting copolymer is enriched in VDC.

Organosilicon peroxides have a controlling influence on the copolymerisation of acrylates in the presence of sulfuryl chloride and phosphorus trichloride;[101,102] however, for the monomer pairs considered in the studies cited, this influence is less pronounced than that in the case of Group III element OEC; this is undoubtedly due to the difference between the electron-withdrawing properties of the modifiers.

Thus, catalytic amounts of coordinatively unsaturated OEC not only effectively initiate low-temperature polymerisation of vinyl monomers but also have a controlling effect on the kinetic parameters of copolymerisation of a broad range of monomers and the composition of copolymers.

The compositional uniformities of macromolecules for one– and two-centre copolymerisation are substantially different.[103] Therefore, important information on the chain propagation mechanism can be gained by performing copolymerisation of a broad range of monomers.

It was found in relation to copolymerisation of MMA with MAA that the integral curves for the distribution over composition for MMA–MAA copolymers synthesised in the presence of a conventional organic (DCHPD)[104] and organoelement (TIBB–DPA)[105] initiators are different. The curve for DCHPD is unimodal,[104] while that obtained with organoelement initiators is bimodal.[105]

When acrylates are made to copolymerise with alkenes, the controlling effect of OEC is not so pronounced as in the copolymerisation of vinyl monomers with each other. The rates of copolymerisation of AN with cyclohexene and hex-1-ene, MMA with ethylene, and VA with ethylene [106] decrease linearly with an increase in the alkene content in the monomer mixture. The degree of conversion does not exceed 30%. The relative activities still differ somewhat from those found for classical radical initiators but this difference is less significant than in the case of copolymerisation of two vinyl monomers.[7] Apparently, this is due to the fact that alkenes and, especially, chain-propagating radicals derived from them, are less prone to form complexes than monomers containing functional groups or atoms with lone electron pairs.

In should be noted that low-pressure radical copolymerisation of ethylene and α-olefins with polar vinyl monomers is quite a topical problem in polymer chemistry. This is especially true for the synthesis of VC copolymers with α-olefins.

Vinyl chloride and α-olefins are known to undergo efficient polymerisation at low pressure according to different mechanisms, namely, polymerisation of VC follows a radical mechanism, while ethylene and its homologues polymerise by a coordination mechanism in the presence of Ziegler–Natta catalysts.[107,108] It is impossible to synthesise VC–olefin copolymers with a high degree of conversion under technologically beneficial conditions in the presence of conventional initiators. The highest degree of conversion on the Ziegler–Natta catalysts does not exceed 24% (in the presence of electron-donor additives, 30%),[109] that in the presence of AIBN is 17%.[110]

It should be noted that physicochemical properties of VC copolymers with ethylene or α-olefins, *e.g.*, good processability, great elongation at rupture, enhanced specific impact strength, *etc.*, make them promising as plastics. In addition, the introduction of even 5%–10% of ethylene units in poly(vinyl chloride) markedly decreases the cost of manufacture of the polymer. The absence of efficient initiators holds up large-scale production of these copolymers.

As shown above, the coordination-radical initiators based on OEC with Group III elements and OEP with Group IV elements, due to the specific features of their structure, occupy an intermediate position between the traditional radical initiators and Ziegler–Natta catalysts. With these initiators, copolymerisation of VC with ethylene and with α-olefins can be carried out at high rates and high degrees of conversion with minimum energy expenditure.[106,111,112]

The degree of conversion in the homopolymerisation of alkenes initiated by these compounds does not exceed 3%–5%, which may be due to the specific features of radical formation in the TIBB–OEP systems.[57,113] However, copolymerisation of ethylene and other alkenes with vinyl monomers can be performed in the presence of the TIBB–OEP systems over a broad range of compositions and with high yields.

Using the vinyl acetate–ethylene and AN–hex-1-ene monomer pairs as examples, the activation energies for copolymerisation on the TIBB–*tert*-butylperoxytetraphenylantimony binary initiator were estimated to be 25.8 and 36.4 kJ mol^{-1}, respectively.[29,106] These values are much lower than the activation energies found for the use of diazo compounds and acyl peroxides as initiators and are close to the data for homopolymerisation of vinyl monomers with organoelement initiators.

The rate of copolymerisation of alkenes with vinyl monomers and the degree of conversion depend substantially on the composition of the monomer mixture and the number of carbon atoms in the alkene molecule. Thus in the case of the VC–ethylene pair, the yield of the copolymer reaches 90% over a period of 5–6 h.[112]

As the alkyl chain length in the alkene increases, the rate of polymerisation and the degree of conversion decrease; in the case of oct-1-ene, the yield of the copolymer does not exceed 20%. Additional introduction of an initiator results in only a slight increase in the yield. The reason for the decrease in the degree of conversion on passing from ethylene to α-olefins is probably related to the chain termination involving the active hydrogen atoms in the α-position relative to the alkene double bond.

In the case where traditional radical initiators or Ziegler–Natta catalysts are used in the VC copolymerisation with alkenes, the possibility of varying the copolymer composition is quite limited. The course of the composition curves and the relative activities of the monomers indicate that the copolymer is enriched in one monomer at any composition of the initial mixture. This is due to the considerable difference between the reactivities of VC and alkenes. The use of the trialkylborane–OEP systems results in substantial equalisation of the copolymerisation constants. Thus the composition curve for VC copolymerisation with ethylene or other alkenes follows an S-shaped pattern; for alkene contents in the monomer mixture ranging from 30 mol.% to 70 mol.%, the copolymer composition is virtually constant and does not depend on the composition of the mixture.[112]

The introduction of alkene units in vinyl polymers influences the physicochemical properties of the product in a definite manner. In particular, in the case of the ethylene–VA pair of monomers, the intrinsic viscosity of the copolymer increases with an increase in the alkene fraction. Conversely, the intrinsic viscosity (and MM) of the ethylene–VC copolymer decreases with an increase in the ethylene mole fraction. We calculated the Fickentcher constant (K_F), characterising the MM of poly(vinyl chloride) for a number of VC–alkene copolymer specimens.[114] The constant proved to be much lower (K_F = 40–70) than in the case of poly(vinyl chloride) synthesised with these initiators.[22] A decrease in the Fickentcher constant is known to facilitate

processing and to enhance the plasticity of the polymeric product.[14] It is worthy of note that an increase in the concentration of the initiator for an invariant ratio of the monomers in the mixture decreases the viscosity of the copolymers and slightly (by 5% – 6%) increases the degree of conversion.[106]

Thus, the use of coordinatively unsaturated OEC able to change the reactivity of macroradicals in a desired manner is an efficient technique for controlling the growth of the polymer chain under conditions of radical polymerisation. One more way of controlling the lifetime of a polymer chain aimed at synthesising compositionally uniform polymers is the use of stable radicals.

III. Growth of the polymer chain in the presence of stable radicals and iniferters

In recent years, a new concept of controlled processes called 'pseudo-living'-chain ‡ (or 'living'-chain) radical polymerisation has been vigorously developing. This polymerisation is of considerable interest as a simple and reliable method for the synthesis of polymers with a definite structure and specified properties.

The essence of the 'pseudo-living' polymerisation is as follows.[76, 117 – 120] The polymerisate contains catalytic amounts of active additives of a specific type (for example, stable radicals or their sources, complex ions of variable-valence metals, and other chain propagation controllers), able to undergo a reversible reaction with chain-propagating active radicals ($R^{\bullet}$) to give a labile adduct [R–X], which decomposes under certain conditions to recover the same chain-propagating macroradical.

$$R^{\bullet} + {}^{\bullet}X \rightleftharpoons RX. \qquad (17)$$

An important feature of 'pseudo-living' radical processes is alternation of the periods of chain propagation, termination and re-initiation. An obvious advantage of this approach is that the polymer chain grows step-by-step, *i.e.*, it becomes possible to control the lifetime of the growing radical. This brings about the following specific features of both the polymerisation kinetics and the properties of the resulting polymer:

— the number of polymer chains and active centres remains constant at any degree of conversion;

— starting from a low degree of conversion, the polymer MM continuously increases, the number-average MM value (M_n) increasing linearly with the degree of conversion;

— a narrow polydispersity (M_w/M_n, where M_w is the weight-average MM) of the polymer is observed at any degree of conversion;

— the isolated products of polymerisation can also act as macroinitiators; the addition of a new portion of the monomer results in further polymerisation and an increase in the polymer MM;

— when two or more monomers are added successively, block copolymers are formed.

Although the 'pseudo-living' radical polymerisation is a relatively new line in the research dealing with controlled radical processes, quite a few organic and organoelement compounds which permit radical polymerisation to be carried out in the 'living' regime have been proposed to date. Currently, more than a hundred publications devoted to this topic appear annually, and this flow does not decrease.§

‡ The process has been called 'pseudo-living' radical polymerisation because it has some features peculiar to the ionic 'living' polymerisation in which no chain termination takes place and chain propagation is continued until the monomer is exhausted.[115, 116]

§ Suffice it to say that in the section 'Radical Polymerisation' of the World Congress 'IUPAC MACRO-2000,' the problems of 'pseudo-living' polymerisation were the most vigorously discussed topic: of 36 oral reports and 51 posters, 17 reports and 20 posters were related to 'pseudo-living' polymerisation; and 18 posters were presented at the separate poster session on 'pseudo-living' polymerisation.[121]

Depending on the active additives (chain propagation controllers) used, the processes carried out in the 'living'-chain regime can be classified into the following types:

— polymerisation involving stable carbon-centred radicals and nitroxides, first of all, 2,2,4,4-tetramethyl-1-piperidinoxyl (TEMPO) and its analogues;

— polymerisation in the presence of spin traps and other potential sources of stable radicals;

— polymerisation using iniferters, controlling initiators of a new type;

— polymerisation in the presence of OEC, mainly, transition metal halides (atom transfer radical polymerisation — ATRP).

1. 'Pseudo-living'-chain polymerisation with participation of carbon-centred radicals and nitroxides

Examples of using stable radicals for controlling the kinetic parameters of radical polymerisation are well known and have been described fairly comprehensively not only in original publications but in relevant monographs.[76] Stable radicals, for example, galvinoxyl, phenoxyl and nitroxide spin adducts are active acceptors of free radicals, including polymeric radicals, over a broad temperature range. In recent years, in relation to the development of the reversible inhibition concept,[122 – 124] the interest in these compounds, especially nitroxides, has substantially increased as they can be used to control the chain propagation.

An important feature of some nitroxides is reversible interaction with a number of growing polymeric radicals at temperatures above 100 °C. This opens up some prospects for controlling the growth and, mainly, the lifetime of the polymeric chain. Over a fairly short period, the studies on the influence of nitroxides [76, 118 – 120, 125 – 136] and alkoxyamines [76, 118 – 120, 137 – 139] have occupied a prominent place in the research on 'pseudo-living' polymerisation.

The compounds used most often to control the lifetime of the growing chain include TEMPO [125 – 133] and its substituted analogues such as 4-methoxy-2,2,6,6-tetramethyl-1-piperidinoxyl,[137] 4-hydroxy-2,2,6,6-tetramethyl-1-piperidinoxyl,[135] *etc.* These nitroxides are used both as such (in the case of thermally initiated polymerisation) and in combination with traditional radical initiators (BP, AIBN, *etc.*).[125 – 136, 140] 'Pseudo-living' polymerisation in the presence of nitroxides based on TEMPO is normally carried out at temperatures of 95 – 130 °C; it is most typical of St and its derivatives (4-bromostyrene,[137] 3- and 4-chloromethylstyrenes,[140] *etc.*), as well as some acrylic monomers.[127, 135] However, it should be noted that in the case of acrylates, nitroxide spin adducts are much less efficient. In all probability, this is due to the fact that the bond (C – O – N) formed according to reaction (17) between the growing macroradical and the nitroxide is stronger, and hence, less labile in the case of polyacrylate radicals than in the case of styrene. Thus, dissociation of this bond requires more energy and, correspondingly, a higher temperature. However, raising the temperature of the synthesis can result in irreversible transformation of the terminal fragment into hydroxylamine.[120, 141] This may account for the fact that in the case of acrylates and other vinyl monomers, 'pseudo-living' mechanism could not be induced by increasing polymerisation temperature to 150 °C.[130, 135, 142, 143] Nevertheless, poly(butyl acrylate) with M_n = 10 500 – 27 000 and M_w/M_n = 1.53 has been prepared in the presence of 2,2,6,6-tetramethyl-4-hydroxy-1-piperidinoxyl at 150 °C.[135] Copolymerisation of St with BA in the presence of TEMPO using an azeotropic monomer mixture (St : BA = 7 : 3) at 120 °C also proceeds by a 'pseudo-living' mechanism.[144]

Kuchanov [124] has studied the effect of nitroxides on block polymerisation of St carried out at 120 °C, with different initial concentrations of TEMPO and without initiators.[124] In the presence of an initiator, polymerisation follows a 'pseudo-living' mechanism,[129, 144, 145] as indicated by the absence of a gel effect and low polydispersity coefficients of the resulting polymer as well

as by the increase in MM following an increase in the degree of conversion. 'Pseudo-living' copolymerisation of St with BA was carried out under similar conditions.[144]

In the presence of TEMPO, block copolymers of St with MMA and with butyl methacrylate have been synthesised.[128,146] It was shown that PS macromolecules are capable of re-initiating polymerisation. Yoshida and Sugita[147] combined cationic and radical polymerisation to prepare a biterminal polymer, poly-(styrene-β-tetrahydrofuran), with two terminal TEMPO radicals, which subsequently undergoes copolymerisation with St to give triblock copolymer.

A detailed and thoroughly justified description of the kinetic features of the 'living'-chain polymerisation in the presence of nitroxides has been reported.[120]

In addition to nitroxides, stable radicals of other classes have also found use in 'pseudo-living' radical polymerisation processes. In particular, the influence of the triphenylmethyl (trityl) radical, formed upon homolytic decomposition of hexaphenylethane (HPE)

$$Ph_3C-CPh_3 \longrightarrow 2\,Ph_3C^{\bullet}, \quad (18)$$

on the polymerisation of acrylic monomers has been studied. It was shown[148,149] in relation to the AIBN-initiated polymerisation of MMA at 80 °C that in the presence of excess HPE ([HPE] : [AIBN] > 5), the process switches to the 'pseudo-living' regime, which is characterised by successive increase in the polymer MM and suppression of the gel effect at high degrees of conversion. However, unlike nitroxides (TEMPO and its analogues), which do not react with the monomer double bond, the triphenylmethyl radical can itself initiate polymerisation.[148,150] Therefore, radical polymerisation of MMA in the presence of HPE has a number of specific features.

It was shown[148,150] that polymerisation of MMA at 80 °C with the addition of HPE and in the absence of AIBN proceeds very slowly (polymerisation time up to a high degree of conversion at [HPE] = 0.1 mol % is ~50 h; for the same AIBN concentration, it is 2–3 h) and exhibits features of a 'pseudo-living' process. In particular, gel effect is scarcely observed, the MM of the polymer linearly increases with an increase in the degree of conversion, and the polydispersity decreases with an increase in the degree of conversion of the monomer. The researchers cited[150] convincingly demonstrated that in this case, polymerisation of MMA follows a two-stage 'pseudo-living' mechanism.

The first stage is due to fast consumption of the trityl radicals in chain initiation and termination. At this stage, a reactive PMMA oligomer containing trityl groups at both ends of the chain is formed and rapidly accumulated

$$Ph_3C^{\bullet} + MMA \longrightarrow Ph_3C-MMA^{\bullet}, \quad (19)$$

$$Ph_3C-MMA^{\bullet} + {}^{\bullet}CPh_3 \longrightarrow Ph_3C-MMA-CPh_3\,. \quad (20)$$

The terminal bond in this oligomer remains labile. The PMMA oligomer re-initiates polymerisation at the second stage of the process, giving rise to a polymeric product in the system. During polymerisation at the second stage, the average MM continuously increases due to the formation of the polymer with a higher molecular mass and gradual consumption of the oligomer.

By analysis of the molecular-mass characteristics of the synthesised PMMA, interesting features of this process were identified.[148,150] The products formed at the first stage show a bimodal MMD. The position of the low-molecular-mass mode corresponding to oligomers virtually does not change during the process; however, its area gradually decreases. The high-molecular-mass mode shifts to higher MM with an increase in the degree of conversion, and its area increases. At high degrees of conversion, the oligomer mode virtually disappears, and the chromatogram becomes unimodal. Similar changes in the MMD of the final product — PMMA — were also observed when MMA polymerisation was carried out in the presence of specially synthesised and isolated oligomer.

Taking into account the experimental data considered above on the polymerisation of MMA in the presence of HPE, the following mechanism of the AIBN-initiated formation of PMMA was proposed.[148,150] Hexaphenylethane dissociates at 80 °C to afford trityl radicals, which initiate polymerisation; the rate constant for this reaction is 1×10^{-3} litre mol^{-1} s^{-1} (the rate of initiation at [HPE] = 5.0×10^{-3} mol litre^{-1} is 5×10^{-5} mol litre^{-1} s^{-1}). In parallel with this process, initiation at a rate of 5×10^{-8} mol litre^{-1} s^{-1} due to the thermal decomposition of AIBN takes place. It is clear that initiation caused by decomposition of AIBN at the beginning of the process can be neglected. The resulting oligomers re-initiate polymerisation; the parallel polymerisation due to initiation by AIBN also continues. The ratio of the rates of these processes is determined by the ratio of the initial concentrations of HPE and AIBN (the rate constants of these reactions are close[1]). If excess HPE is used (for example, [HPE] : [AIBN] > 50), the mechanism of this process is close to the 'pseudo-living' polymerisation mechanism.

In the opinion of the researchers cited,[148–150] HPE can be regarded as an iniferter because in the absence of a reactive competing agent, initiator (in this case, AIBN), the relatively inert trityl radical has time to attack the monomer and participates in the step of initiation of polymerisation; however, the rate of polymerisation with HPE is much lower than the rate of the AIBN-initiated process.

The diphenylmethyl and (trimethylsilyloxy)diphenylmethyl radicals, formed upon decomposition of tetraphenylethane[117,151–154] and bis(trimethylsilyloxy)tetraphenylethane,[117,155] respectively, behave similarly to the trityl radical in the 'pseudo-living' thermal polymerisation. In the first stage consisting of initiation and termination of the growing chains, the radicals formed upon thermal decomposition are rapidly consumed, and the reactive oligomeric product is accumulated. This product re-initiates polymerisation in the second stage of the process, which gives rise to the polymeric product. The polymers formed in the first stage are characterised by a bimodal MMD. The position of the low-molecular-mass mode, corresponding to oligomers, barely changes during the process; however, its area gradually decreases.

Study of copolymerisation of vinyl monomers in the presence of stable carbon-centred radicals is of obvious interest. The first data on the mechanism of copolymerisation involving carbon-centred radicals were obtained back in 1985.[156,157]

The use of *O*,*O*′-diisopropyl xanthogen sulfide (DXS) as a controlling additive made it possible to perform 'pseudo-living' copolymerisation of St with MA at 120–140 °C.[158,159] A specific feature of this process is a substantial decrease in the copolymerisation rate. Apparently, this is due to the fact that the rate of re-initiation in this system is lower than the rate of initiation;[159] this is obviously due to the difference between the energies of the S–S bond in the dissociating DXS and the C–S bond in the terminal group of the copolymer

$$Pr^iO-\underset{\underset{S}{\|}}{C}-S-S-\underset{\underset{S}{\|}}{C}-OPr^i \longrightarrow 2\,{}^{\bullet}S-\underset{\underset{S}{\|}}{C}-OPr^i \quad (21)$$

$$\sim CH_2\underset{\underset{R}{|}}{CH}-S-\underset{\underset{S}{\|}}{C}-OPr^i \longrightarrow \sim CH_2\underset{\underset{R}{|}}{CH}^{\bullet} + {}^{\bullet}S-\underset{\underset{S}{\|}}{C}-OPr^i \quad (22)$$

It can be seen from Eqn (22) that under these conditions, the stable S-centred radical formed acts as both an initiator and a chain propagation controller, similarly to carbon-centred radicals such as the trityl[148–150] or diphenylmethyl radical.[151–155] The copolymers considered are gradient polymers the properties of which differ from the properties of random polymers.[159]

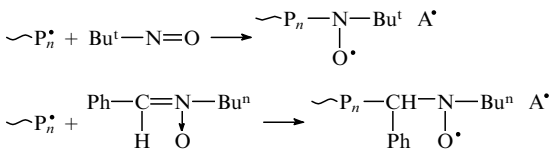
2. Controlled radical polymerisation in the presence of spin traps and other sources of stable radicals

As noted above, a substantial drawback of the control of chain propagation by stable radicals is that the use of these species allows one to perform 'pseudo-living' radical polymerisation only at relatively high temperatures, above 100 °C. It is clear that development of effective methods for conducting polymerisation in the 'living'-chain regime at lower temperatures, normal for radical polymerisation of vinyl monomers under industrial conditions (50–80 °C), is a topical problem of synthetic polymer chemistry.

In this respect, the use of peroxides and azo compounds (typical radical initiators) in combination with active additives able to generate stable radicals, chain propagation controllers, directly in the polymerisation system (*in situ*) appears to be promising for performing controlled polymerisation. Nitroso compounds, nitrones, and other acceptors of free radicals used as spin traps in the studies of homolytic processes in organic and polymer chemistry can be used for this purpose.[160] For example, the use of *C*-phenyl-*N*-*tert*-butylnitrone (PBN) and 2-methyl-2-nitrosopropane (MNP) as effective controllers of the lifetime of a polymer chain for a number of vinyl monomers of various structures has been proposed.[161–169] These compounds exert an effective controlling influence on the polymerisation of various monomers in the temperature range of 50–80 °C.

On the basis of analysis of experimental data on the reactivity of nitrones and nitroso compounds, the following scheme of chain propagation in the presence of these additives was proposed.[161–163]

At the first stage, MNP (or PBN) react with the growing macroradical ($\sim P_n^{\bullet}$) to give a stable nitroxide.



(23)

The nitroxide spin adduct $A^{\bullet}$ further reacts with the chain-propagating radical $\sim P_n^{\bullet}$ to give a labile bond

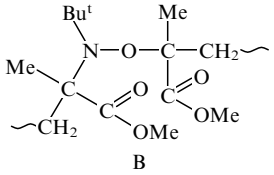
$$\sim P_n^{\bullet} + {}^{\bullet}A \rightleftharpoons [\sim P_n\text{---}A]. \quad (24)$$

The reversible reaction (24) results in alternation of the 'sleeping' and 'living' periods of the polymeric radical: the monomer (M) molecules add successively to the macroradical; thus, the polymer chain grows.

$$[\sim P_n\text{---}A] + M \longrightarrow [\sim P_{n+1}\text{---}A]. \quad (25)$$

The lability (relative instability) of the resulting $[\sim P_{n+1}\text{---}A]$ bond under conditions of polymerisation of vinyl monomers (50–80 °C) is due to both high stability of the nitroxide spin adduct ($A^{\bullet}$) and specific features of the structure of the polymeric radical ($\sim P_n^{\bullet}$). In particular, the energy of the R^1-O bond in the R^1-O-N bridge of the $R^1-O-N(R^3)R^2$ type nitroxide adducts formed according to Eqn (23) depends appreciably on the nature of radicals surrounding the N–O group, especially on their spatial structure. Thus in the case of TEMPO, a known controller of chain propagation, or the methyl radical, the bond energy is ~30 kcal mol^{-1}. Apparently, this is why TEMPO and its analogues are able to control efficiently the radical polymerisation of St and some acrylic monomers only at relatively high temperatures (100–130 °C). For a more bulky ethyl radical, the energy of this bond is ~25 kcal mol^{-1}, and in the case of sterically hindered *tert*-butyl or polyacrylate radicals, it is even lower (~20 kcal mol^{-1}).

When vinyl monomers are made to polymerise in the presence of PBN (or MNP), the nitrogen atom in the $R^1-O-N(R^3)R^2$ nitroxide adduct is linked to even more bulky and sterically hindered radicals. For example, in the case of MMA and MNP, it is linked to a *tert*-butyl radical (from MNP) and two polyacrylate radicals, having a high-molecular-mass 'tail'.



B

The strength of this bond is much lower than that in the case of TEMPO; naturally, it will dissociate rather easily at lower temperatures to give the initial radicals.

Moreover, since the nitroxide adduct B is formed initially upon the interaction of two bulky radicals directly during the synthesis of the polymer at a temperature of 50–80 °C, it cannot be ruled out that the chemical bond between the chain-propagating radical ($\sim P_n^{\bullet}$) and the nitroxide spin adduct ($A^{\bullet}$) is a vibrationally excited molecule (an analogue of a radical pair in the $[\sim P_n\text{---}A]$ solid matrix) even at the instant of formation.

To date, 'pseudo-living' polymerisation in the presence of PBN has been accomplished for a number of vinyl monomers, namely, MMA,[161–164, 166–168] butyl methacrylate, BA, St, and VC.[165–167] The main process parameters and the properties of polymers prepared in the presence of PBN are listed in Table 4. Some common features of the mechanism of the 'pseudo-living' radical polymerisation in the presence of PBN can be distinguished.

In particular, the introduction of a controlling additive results in an appreciable decrease, down to complete suppression, of the gel effect and allows conduction of the polymerisation to high degrees of conversion (80%–90%). It is very important for practical purposes that the time of polymerisation increases insignificantly (with respect to that for the process without an additive), as a rule, not more than twofold (see Table 4). The duration of polymerisation of St and MMA by the 'pseudo-living'

Table 4. Some kinetic parameters for the polymerisation of vinyl monomers in the presence of PBN and molecular-mass characteristics of polymers (initiator AIBN, 0.1 mol.%).

Monomer	[PBN] (mol.%)	T /°C	$10^4 V$ /mol litre^{-1} s^{-1}	Time /h	Degree of monomer conversion (%)	$10^6 M_\eta$	M_w/M_n	Ref.
MMA	–	50	1.2	8	91	4.3	>2.0	161, 162
	0.80	50	0.8	17	75	1.2	1.7	
BA	–	65	2.1	2	98	–	>2.0	169
	0.02	65	0.1 [a]	7	65	0.7 [b]	1.7	
BMA	–	50	1.1	12	99	10.7	–	169
	0.2	50	0.8 [a]	24	78	6.5	–	
VC	–	50	9.1	3	92	70 [c]	2.5	165
	0.01	50	0.6	5	89	66 [c]	1.7	

[a] The rates are given for [PBN] = 0.1 mol.%. [b] The M_n value. [c] The Fickentcher constants are given.

radical mechanism is known to increase severalfold in the presence of TEMPO,[125–136] triphenylmethyl radicals[148–150] or other radicals. The PBN concentration at which the gel effect is suppressed depends on the structures of the monomer and, especially, the growing macroradical; in any case, this concentration is commensurable with the content of the initiator (0.01 mol.%–0.80 mol.%).[161, 162, 164, 169]

The number-average and viscosity-average (M_η) molecular masses of the polymer prepared in the presence of PBN follow a linear dependence on the degree of conversion, which is typical of polymerisation by the 'pseudo-living' mechanism. The shift of the low-molecular-mass shoulder and the whole mode to higher molecular masses with an increase in the degree of conversion of the monomer can be clearly seen in the MMD curves.[161, 162, 169]

An important feature of the proposed controller is the fact that stable radicals able to control chain propagation are formed directly during polymerisation as a result of interaction of the macroradicals with an additive introduced to the system, which effectively controls the synthesis of macromolecules even at 50–80 °C.

A shortcoming of this method for controlling the growth of a polymer chain is that the MMD of the resulting polymer is broader than, for example, in the case of ATRP.[76, 119, 120] In our opinion, this is due to the inhomogeneity of high-molecular-mass nitroxides formed by reaction (23) as chain propagation controllers.

It should be noted that the structures of the macroradical and the monomer have a substantial influence on the polymerisation kinetics and the polymer MM under the conditions of reversible inhibition in the presence of PBN. Thus comparison of acrylic monomers, namely, MMA, butyl methacrylate and BA, shows that the process involving BA occurs at higher temperature (> 65 °C) and at much lower concentrations of the active additive and has a longer induction period than the processes with MMA or butyl methacrylate.[166–169]

The differences in the regularities of polymerisation of MMA and butyl methacrylate, on the one hand, and BA, on the other hand, are undoubtedly due to specific features of the structure of growing macroradicals and the reactivity of the macroradicals towards nitroxide spin adducts. Thus, from a thermodynamic standpoint, sterically hindered PMMA and poly(butyl methacrylate) macroradicals (tertiary radicals) form a weaker and, hence, a more labile bond with the nitroxide used as a chain propagation controller [reaction (23)]. In the case of polymerisation of BA, the bond between the nitroxide spin adduct and the growing macroradical of poly(butyl acrylate) (secondary radical) is stronger and more stable against dissociation. As a consequence, in the case of polymerisation of BA, the 'living'-chain mechanism can be accomplished at a higher temperature. In addition, the rate constant for the acceptance of secondary and tertiary radicals by a spin trap (PBN) are known to differ by almost an order of magnitude. In our opinion, this can account for the long induction period in BA polymerisation and for the possibility of using lower concentrations of nitrone as a controller of the chain propagation than those required in the polymerisation of MMA and butyl methacrylate.[166–169]

The foregoing is confirmed by the data on the polymerisation of VC[165, 166, 168] and St[166, 168] in the presence of PBN: the growing polymer radicals derived from these monomers are secondary radicals; hence, as in the case of BA, the controlled process takes place at a lower PBN concentration.

It was shown in relation to the polymerisation of MMA that the use of MNP as a controlling additive entails effects similar to those observed with PBN; in the latter case, the control of the polymer chain propagation requires lower concentrations of the additive (0.005 mol.% – 0.01 mol.%). Apparently, this is due to higher constants for the acceptance of macroradicals by nitroso compounds than by nitrones.[163, 166–169]

3. Iniferters as controlling initiators of polymerisation of a new type

Yet another elegant method for performing controlled radical polymerisation proposed in recent years is based on the use of a special class of initiators called iniferters.¶ These compounds decompose rather readily to give free radicals ($A^\bullet$) and ($B^\bullet$)

$$A-B \rightleftharpoons A^\bullet + B^\bullet. \quad (26)$$

One radical is reactive ($A^\bullet$), it can react with the monomer and thus initiate the chain propagation. The second radical ($B^\bullet$) is reactive only with respect to the growing macroradical and can react with it according to the reversible inhibition pattern

$$A^\bullet + M \longrightarrow A-M^\bullet, \quad (27)$$

$$A-M^\bullet + {}^\bullet B \rightleftharpoons A-M-B. \quad (28)$$

Chain termination *via* recombination of the growing macroradical with the primary radical of the iniferter [reaction (28)] occurs much faster than chain termination *via* recombination or disproportionation of the growing radicals. In addition, iniferter participates in chain transfer reactions.

In terms of their chemical nature, the iniferters known to date can be conventionally divided into three groups.

In the iniferters of the first group, homolytic decomposition of both the initial and the resulting macromolecular initiator involves a labile bond of the same chemical nature. Examples of these iniferters are alkoxyamines[76, 118–120, 137–142] and alkylthiocarbamates.[170–174]

In the case of second-group iniferters, the steps of decomposition of the initial and macromolecular initiators involve bonds of different chemical natures. This group of iniferters includes, for example, phenylazotriphenylmethane[117, 148, 175, 176] and some thio iniferters.[117]

Binary redox systems based on organic and organoelement compounds and the corresponding oxidants (sterically hindered quinones, oxytriazenes, *etc*.) can be classified as the third type of iniferters.[177–182]

Alkoxyamines, which are used most often as iniferters, are compounds of the $R-M_n-X$ type, where R is the radical formed upon decomposition of a conventional initiator of radical polymerisation (BP, AIBN, DCHPD[135, 183–189]), M is the monomer (most often, St), X is a nitroxide (as a rule, TEMPO or its analogue).

It has been noted above that the parameters of polymerisation in the presence of TEMPO are close to the parameters of 'living' ionic processes; this is due to the high re-initiation constant by reaction (17). In this connection, vigorous studies into the use of alkoxyamines as iniferters are being carried out.

Numerous publications have been devoted to the synthesis of new alkoxyamines[189–195] and their application in the polymerisation processes. The results of these studies can be used to select the compounds $R-M_n-X$ the half-life of which is shorter than the period of complete polymerisation transformation by factors of tens or even hundreds;[120] this, in turn, can increase the efficiency of a nitroxide as a 'pseudo-living' polymerisation agent. An important indication of a 'living' process is polydispersity. If ordinary quadratic termination does not take place, the polydispersity of the polymer should be equal to unity. Polystyrene samples with polydispersity values close to unity have been obtained with a number of alkoxyamines.[120]

The results of kinetic studies of the mechanism of 'living' radical polymerisation of St in the presence of alkoxyamines and of analytical calculation studies were considered in detail in a review.[120] Polymerisation in the presence of alkoxyamines occurs by the following scheme:

¶ The term iniferter is composed of the names of elementary steps of radical polymerisation: ini (initiation), fer (transfer), ter (termination).[117, 124]

$$\begin{aligned} &R-R \longrightarrow 2\,R^{\bullet}\ \text{(initiation)},\\ &R-X \longrightarrow R^{\bullet} + X^{\bullet},\\ &R^{\bullet} + X^{\bullet} \longrightarrow R-X,\\ &R^{\bullet} + M \longrightarrow R-M^{\bullet},\\ &R^{\bullet} + R^{\bullet} \longrightarrow R-R. \end{aligned} \qquad (29)$$

The process kinetics has the following specific features: the rate of polymerisation is proportional to the monomer concentration and does not depend on the alkoxyamine concentration; the polymer MM increases linearly with an increase in the degree of polymerisation (this regularity holds, at least, up to $M_n = 20\,000 - 30\,000$); the polydispersity of the polymer normally first decreases with an increase in the degree of conversion and then increases; the polydispersity coefficient fluctuates depending on the process conditions but, as a rule, it remains less than 1.3; the concentration of the stable nitroxide (EPR detection) is equal to 0.1% – 1.0% relative to the initial concentration of the alkoxyamine throughout the whole process.[196]

Computer analysis of the kinetic data and the molecular-mass characteristics[197–199] made it possible to establish correlations between reaction parameters (temperature, concentration of the reactants) and the properties of 'living' polymerisation agents [the rate constants for the forward and back reactions (28)]. These results can be used to choose the optimum conditions for performing polymerisation of St with a particular iniferter.

However, it should be noted that, similarly to the polymerisation in the presence of TEMPO (and, evidently, for the same reasons), these compounds can be used at temperatures above 100 °C and only for polymerisation of St and its analogues[137,140,198,200,201] and copolymerisation or preparation of block copolymers of St with other monomers, most commonly, acrylates.[202–204]

Dissociation of alkoxyamines at high temperatures (above 135 °C) has been studied in detail in relation to 1-methylbenzyloxy-2,2,6,6-tetramethyl-1-piperidine[205] and its derivatives resulting from decomposition of BP in St.[141] The process follows two pathways, one to give a reactive hydrocarbon radical and a stable nitroxide (it is this reaction that is responsible for the 'living' polymerisation mechanism) and the other, giving rise to an unsaturated hydrocarbon and hydroxylamine (hydride transfer).

Alkoxyamines based on TEMPO have been used[206–209] to synthesise densely cross-linked glassy polymers by 'pseudo-living' radical three-dimensional polymerisation; copolymerisation of St with MA was taken as an example. Due to the 'pseudo-living' polymerisation mechanism, the point at which a continuous network was formed was shifted appreciably towards higher degrees of conversion (> 17% – 35%) compared to that observed for conventional three-dimensional radical polymerisation.

Block copolymerisation of St and its analogues with acrylates has proved to be a more efficient method for the extension of the scope of application of alkoxyamines. Block copolymers based on PS or on St copolymers with acrylates with high St contents prepared in the presence of alkoxyamines have been considered in detail in reviews[120,210] and monographs.[76,119]

The use of derivatives of thiocarbamates as photoiniferters has been studied extensively.[124,170–174] Unlike the iniferters which decompose at high temperatures, thiocarbamates tend to decompose on exposure to UV radiation at much lower temperatures than alkoxyamines. The polymerisation of St in the presence of these reagents has all the main features of 'pseudo-living' polymerisation.[173,174]

An EPR study of the photo decomposition of *S*-benzyl *N*,*N*-diethyldithiocabamate and PS containing a terminal dithiocarbamate group induced by UV radiation (λ = 365 nm, 25 °C) has shown[120,211] that decomposition follows the same mechanism with rupture of the C – S bond to give reactive benzyl (or polystyrene) and stable *N*,*N*-diethyldithiyl radicals.

$$\mathrm{BnSC(S)NEt_2} \xrightarrow{h\nu} \mathrm{Bn^{\bullet}} + {}^{\bullet}\mathrm{SC(S)NEt_2} \qquad (30)$$

$$\sim\!\mathrm{CH_2CH(Ph)SC(S)NEt_2} \longrightarrow \sim\!\mathrm{CH_2CH^{\bullet}(Ph)} + {}^{\bullet}\mathrm{SC(S)NEt_2} \qquad (31)$$

By assuming that decomposition of these compounds occurs by the same mechanism, one can explain the fact that the regularities of polymerisation in the presence of low- and high-molecular-mass iniferters — *S*-benzyl *N*,*N*-diethyldithiocabamate and the PS containing a terminal dithiocabamate group — prove to be qualitatively the same.

Research into the photo and thermal decomposition of thio iniferters showed[212–215] that decomposition of symmetric molecules involves either the S – S bond

$$\mathrm{RSSR} \xrightarrow{h\nu} 2\,\mathrm{RS^{\bullet}} \qquad (32)$$

R = Ph, $\mathrm{C(S)NAlk_2}$,

or both the S – S and C – S bonds

$$\begin{aligned} &\mathrm{RSSR} \xrightarrow{h\nu} 2\,\mathrm{RS^{\bullet}},\\ &\mathrm{RSSR} \xrightarrow{h\nu} \mathrm{R^{\bullet}} + {}^{\bullet}\mathrm{SSR} \end{aligned} \qquad (33)$$

R = C(O)Ph.

In the case of nonsymmetric dithiocarbamates and dithiocarbonates $\mathrm{R(CH_2)_nSC(S)NAlk_2}$ and $\mathrm{R(CH_2)_nSC(S)OAlk}$ (R = Ph, R′CO), the formation of dithiyl (stable) radicals needed to induce 'pseudo-living' polymerisation takes place only for the compounds $\mathrm{BnSC(S)NAlk_2}$, BnSC(S)OAlk and AlkCOO. $\mathrm{.CH_2SC(S)NAlk_2}$.[216–218]

Other compounds that can be attributed to the class of iniferters in question include HPE,[148–150] tetraphenylethane[117,151–154] and bis(trimethylsilyloxy)tetraphenylethane,[117,155] which do decompose under polymerisation conditions to yield symmetric inert radicals but only in the case where they are added without an initiator. In the absence of an active competing agent, initiator, the low-reactivity radical has time to attack the monomer and participates in the initiation of polymerisation. However, the rate of polymerisation in the presence of HPE or related tetraphenylethane or bis(trimethylsilyloxy)tetraphenylethane is much lower than that of the process initiated by AIBN or an organic peroxide.

Another type of iniferters includes phenyl azotriphenylmethane (PAT); the use of this compound as the initiator of 'pseudo-living' polymerisation of MMA was first described by Otsu and Matsumoto.[117]

The thermal decomposition of PAT occurs at a high rate with rupture of the C – N bond; it is accompanied by evolution of nitrogen and gives rise to phenyl and triphenylmethyl radicals according to the following scheme

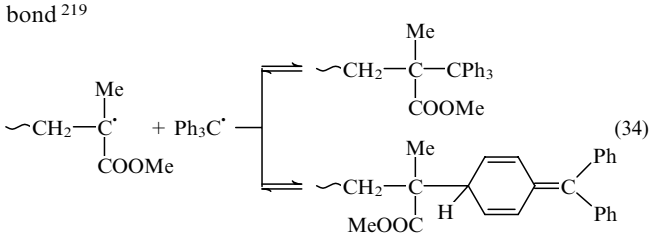
$$\mathrm{Ph-N=N-CPh_3} \longrightarrow \mathrm{Ph^{\bullet}} + \mathrm{N_2} + {}^{\bullet}\mathrm{CPh_3}.$$

The reactive phenyl radicals initiate polymerisation, while the relatively stable triphenylmethyl radicals participate only in the chain termination by macroradicals to give a terminal bond. As has already been noted, the terminal bonds are fairly labile thermally and their homolytic cleavage results in re-initiation of polymerisation. It was found that up to a degree of conversion of ~2%, the polymerisation rate of MMA[148,175] and MA[176] increases (as in the presence of HPE); subsequently, in the transient region up to degrees of conversion of 5% – 15%, the rate markedly decreases; finally, gradual self-acceleration of the reaction starts. The dependence of the MM on the degree of conversion for polymer samples is linear up to 50% degree of conversion.

The MMD follows a specific pattern of variation during polymerisation, namely, the products formed at degrees of con-

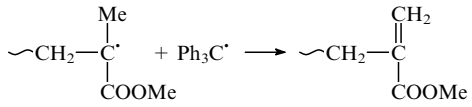
version ranging from 1% to 7% exhibit a unimodal MMD and are oligomeric products. As the degree of conversion increases, the MMD curves become bimodal: a second mode arises, which shifts to higher MM as polymerisation advances, and its area continuously increases. The position of the oligomeric mode does not change; however, its area gradually decreases. When the degree of conversion is high (nearly limiting), the oligomeric mode completely disappears, and the MMD of the resulting PMMA and poly(methyl acrylate) becomes again unimodal. A similar pattern of variation of the MMD is observed for 'pseudo-living' polymerisation of MMA involving trityl radicals.[148–150] Evidently, the mechanism of formation of PMMA in the presence of PAT is underlain by the same processes as in the initiation by AIBN with HPE [148–150] (see the previous Section).

An interesting feature of MMA polymerisation in the presence of PAT has been identified.[148,175] Starting with some degree of conversion (40% – 50%), the MMD mode stops moving to higher molecular masses, *i.e.*, the contribution of the 'pseudo-living' polymerisation to the formation of the polymer markedly decreases. In the opinion of the researchers cited, this may be due to the fact that the trityl radical is capable of initiating polymerisation of the acrylate, giving rise to a conventional 'dead' polymer, this process being more active at high degrees of conversion. In addition, accumulation of the 'dead' polymer in the system can be due to side reactions, resulting in deactivation of the labile bond in the macroiniferter, namely, isomerisation of the triphenylmethyl radical followed by its addition to the macroradical, which occurs in parallel with the formation of the labile bond [219]



(34)

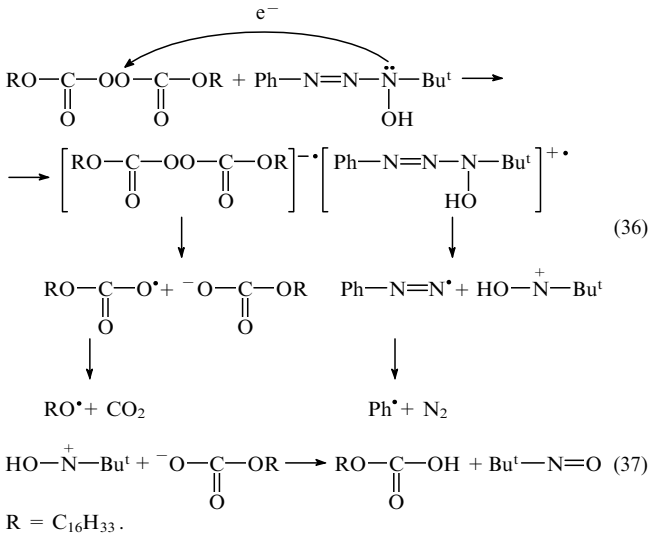
and disproportionation of these radicals [219]



(35)

As noted above, decomposition of the symmetric molecules of thio iniferters involves either the S – S bond or both the S – S and C – S bonds [see reactions (32) and (33)]. The former route yields symmetric S-centred radicals, which can initiate polymerisation without AIBN or peroxide. We have already discussed data on the use of DXS as a controlling additive in the copolymerisation of vinyl monomers.[158,159] The stable S-centred radical arising according to reactions (32) and (33) under the indicated conditions acts as both an initiator and a chain propagation controller and can be attributed to the class of iniferters under consideration because the labile bond in the terminal group of the copolymer is the C – S bond.

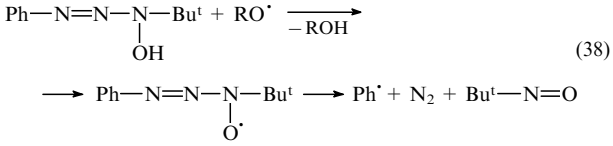
Original binary initiators and chain propagation controllers based on oxytriazenes and oxidants (metal oxides, organic and inorganic peroxides and hydroperoxides) have been proposed.[179–182] It was found by EPR spectroscopy that, owing to the simultaneous generation of reactive phenyl radicals (chain propagation initiators) and nitroso compounds, which can react with chain-propagating radicals to give nitroxides (which control the chain propagation), these systems are able, on the one hand, to initiate radical polymerisation, and, on the other hand, to act as process controllers.



(36) (37)

The possibility of realisation of a similar single-electron transfer mechanism in the reaction of acyl peroxides with substituted amines has been demonstrated previously.[220]

In addition, it cannot be ruled out that secondary reactions take place between triazene and the alkoxide radicals derived from the peroxide, which results in triazene decomposition.



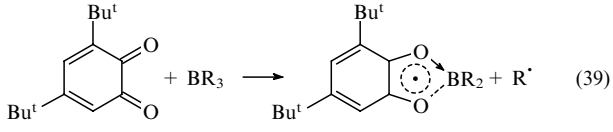
(38)

The presence of nitroxides in the polymerisate was detected by EPR using the spin trap technique [a triplet with the splitting constant at nitrogen a_N = 15.6 Oe corresponding to the adduct of the nitroso compound with the poly(methyl methacrylate) radical].

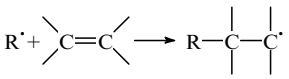
Polymerisation of MMA in the presence of oxytriazene, like that in the presence of MNP,[163,166–168] proceeds under relatively mild temperature conditions (50 – 60 °C) and exhibits features peculiar to 'pseudo-living' polymerisation, namely, the absence of gel effect in the polymerisation up to high degrees of conversion, linear increase in the MM following an increase in the degree of conversion, relatively low polydispersity, *etc.*[179–182] Thus, these systems can be regarded as a sort of binary iniferter.

Yet another example of unusual initiators and controllers of polymer chain propagation is provided by compositions based on sterically hindered quinones and OEC. Thus it has been found [177,178] that 3,5-di-*tert*-butylquinone, used traditionally as the inhibitor of radical processes, when combined with trialkylborane, is able not only to initiate effectively radical polymerisation of various monomers but also to control the propagation of the polymeric chain according to the 'pseudo-living' mechanism. It was found by EPR spectroscopy and by kinetic measurements that the rate of MMA polymerisation is comparable in this case with the rate of polymerisation of acrylic monomers in the presence of traditional radical initiators, AIBN and acyl peroxides, and in some cases, even exceeds it.

Analysis of the data obtained shows that several processes occur in the system. One process is the reaction of quinone, for example, with TIBB, which gives rise to radicals carrying the polymerisation.

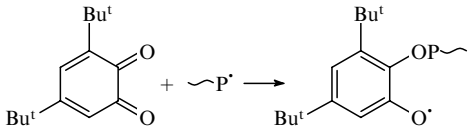


(39)

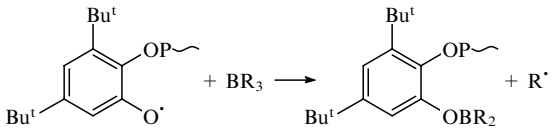


(40)

The occurrence of reaction (39) has also been assumed in other studies [221, 222] (this assumption was made taking account of the results of EPR investigations of the reaction of quinones with alkyl derivatives of Group III elements, in particular, gallium). In addition, the chain-propagating radicals can react with quinones to give oxygen-centred radicals of the phenoxyl type, which react with TIBB to generate new alkyl radicals,[223] able to initiate polymerisation.



(41)



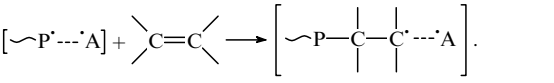
(42)

P is the chain-propagating (polymeric) radical.

The dependence of MM of poly(methyl methacrylate) synthesised in the presence of the 3,5-di-*tert*-butylquinone – TIBB system on the degree of conversion is linear over a broad range of MM values, from 17 000 to 200 000. As the degree of conversion increases, the polymer MMD mode moves continuously to higher molecular masses. This type of dependence of the polymer MM on the degree of conversion is characteristic of 'pseudo-living' chain propagation, including that in the presence of iniferters. It can be seen from Eqn (39) that the reaction of the components of the 3,5-di-*tert*-butylquinone – TIBB binary initiator furnishes the reactive alkyl radical R$^{\bullet}$, capable of initiating polymerisation, and a stable radical (A$^{\bullet}$), which can be coordinated to the chain-propagating radical to afford a labile bond.

$$\sim P^{\bullet} + {}^{\bullet}A \rightleftharpoons [\sim P^{\bullet}\text{---}{}^{\bullet}A]. \quad (43)$$

The polymer chain grows according to a stepwise pattern as a result of consecutive steps of cleavage of the terminal labile bond [$\sim$P---A] and consecutive addition of some number of monomer units to give a new labile bond according to the scheme



(44)

Thus, quinones combined with OEC act as a sort of low-temperature binary iniferters. In this case, the reactive radical (R$^{\bullet}$) which initiates polymerisation and the stable radical (A$^{\bullet}$) which controls the chain propagation are generated directly in the reaction system upon the reaction of the components of a binary initiator with each other [see Eqns (39) – (43)].

Similar regularities are also characteristic of some other quinones and OEC derived from Group III — V elements.[224]

Original initiators-chain propagation controllers based on sterically hindered trialkylboranes and oxidants have been proposed by Chung *et al.*[225] These investigators were the first to use stable boron-containing radicals produced upon oxidation of 1-octyl-9-borabicyclononane to control the chain propagation in the polymerisation of MMA. The use of this additive brings about the features typical of 'pseudo-living' radical polymerisation. It is of fundamental importance that, unlike most known systems, with this system the process occurs at room temperature which allows one to eliminate the undesirable thermal constituent of the process, which markedly deteriorates the MMD of the polymer.

4. Radical polymerisation in the 'living' chain regime in the presence of organoelement compounds

The use of OEC as chain propagation controllers in the 'pseudo-living' radical polymerisation of vinyl monomers opens up prospects for modelling 'pseudo-living' processes using individual features of the metal or non-metal atom in OEC.

Processes in which organic compounds of transition metal halides are used to control the growth of a polymer chain have been studied to date.[76, 119, 226 – 228]

It is known [229] that transition metal halides with the formula $X^n - Y_m - L_x$ (X is a transition metal, n is the valence of the metal, Y is chloride or bromide, L is an organic ligand, most often, a Lewis base) containing metal in a lower oxidation state react with alkyl halides (RX) at $\sim$100 °C to give the alkyl radicals R$^{\bullet}$ capable of initiating polymerisation. Simultaneously, oxidation of the transition metal takes place according to the reversible Kharasch reaction.[229]

$$R - X + X^n - Y_m - L_x \rightleftharpoons R^{\bullet} + X^{n+1} - Y_m - L_x, \quad (45)$$

$$R^{\bullet} + xM \longrightarrow R - M_x^{\bullet}, \quad (46)$$

M is monomer.

When this reaction was induced in the medium of a vinyl monomer, stepwise growth of the polymer chain was observed, *i.e.*, a 'pseudo-living' chain process took place.

Currently, a broad range of OEC (copper, iron, palladium and other compounds) are used as controlling additives; the organic ligands most often contained in these systems are 2,2′-bipyridine,[230, 231] 4,4′-di(non-5-yl)-2,2′-bipyridine,[232 – 236] triphenylphosphine,[226 – 228, 237] *etc*. The alkyl halides normally used for this purpose include alkyl(or aryl) bromides and dialkyl(or diaryl)- alkylaryl bromides.[226, 230, 232, 233, 235, 236]

For a series of vinyl monomers, namely, St,[226, 228, 232 – 235] MA,[233, 234] MMA,[226, 232, 234, 237 – 239] AN [230] and so on, the ATRP process has been accomplished [see redox reaction (45)]. The rate of this process is rather high; therefore, all the polymer chains are initiated almost simultaneously; this allows the manufacture of polymers with a polydispersity close to unity (1.05 – 1.30).[227, 228, 230, 232 – 239] Unlike the controlling additives on the basis of stable radicals considered above, the ATRP agents are not incorporated in the polymer chain and, hence, they can be regarded as analogues of catalysts.

In addition to transition metal compounds (for example, as in ATRP), other OEC are also employed to induce 'pseudo-living' radical polymerisation. As early as in the 1970s, Academician G A Razuvaev and co-workers [240, 241] synthesised block copolymers of MMA with AN using radical initiation by organo-mercury and -tin compounds. It was established by emission spectroscopy that PMMA contained mercury in the terminal groups, and subsequently these macromolecules can act as peculiar macroinitiators. The molecular mass of the secondary polymer is twice as high as the MM of the initial one, which confirms indirectly the possibility of a 'pseudo-living' chain mechanism.

IV. Characteristic features of homo- and co-polymerisation of vinyl monomers in the presence of organoelement compounds derived from Group V elements

The coordinatively unsaturated OEC containing Group II and, especially, Group III elements participate directly in the chain propagation step. The addition of compounds derived from Group IV and V elements also influences the elementary steps in polymerisation. These compounds have vacant *d* orbitals, which stipulates their electron density acceptor properties.

Tin and germanium tetrachlorides can influence significantly co-polymerisation of MAA esters with MMA.[51, 52] The introduction of 1 mol.% of these compounds to a polymerisate gives rise to alternating copolymers. Conversely, the addition of tetrabutyltin

barely influences either polymerisation rate or the MM of polymers. Apparently, this is due to the fact that vacant *d* orbitals of the tin atom are removed from the nucleus and, therefore, the electron-acceptor capacity of these orbitals is too low to activate the chain-propagating radical. Electron-donating alkyl radicals do not promote the coordinating capacity of OEC either. Data on the copolymerisation of MMA with MAA in the presence of tetrabutyltin additives confirm the conclusion that the activities of monomers and growing macroradicals virtually do not change.

Meanwhile, the controlling effect of Group IV element halides on the copolymerisation of acrylates, described by Smirnova and coworkers,[51, 52] can be explained by the fact that inorganic Lewis acids are more prone to form intermolecular complexes than organic compounds of the same elements.

A specific position is occupied by OEC containing Group V elements because they contain both a lone electron pair in the *p* orbital suitable for a nucleophilic attack and vacant *d* orbitals, which can give rise to electron-withdrawing properties.

It has been shown [242, 243] that the addition of alkyl derivatives of bismuth and antimony influences directly the kinetic parameters of polymerisation of vinyl monomers. Thus the rate of BA and VA polymerisation increases by more than an order of magnitude in the presence of catalytic amounts of triisobutylbismuth. The addition of triethylantimony markedly accelerates not only bulk polymerisation of acrylates but also solution polymerisation in ethyl acetate, which is a polar solvent and can be regarded as a hydrogenated analogue of MMA in terms of its electronic structure; like the monomer, it contains an ester group able to be coordinated to electron density acceptors. Organic compounds of bismuth and antimony, like those of Group III elements, do not exert any substantial catalytic effect on the decomposition of an initiator such as AIBN either in inert hydrocarbons or in the presence of vinyl monomers.[53]

Thus, the data presented above indicate unambiguously that acceleration of polymerisation of acrylic monomers in the presence of OEC containing Group V elements is due to the direct participation of these additives in the chain propagation stage.

It should be noted that catalytic amounts of OEC accelerate chain propagation in the polymerisation of VA and BA much more efficiently than in the polymerisation of MMA, which is in good agreement with the results of investigations into the influence of Group III element compounds on the polymerisation of acrylates.

The phenyl derivatives of Group V elements stable against oxidation by atmospheric oxygen also activate somewhat the process of MMA polymerisation. The accelerating effect of these derivatives decreases in the series $Ph_3Bi > Ph_3Sb > Ph_3As$, which is in line with the variation of nucleophilic properties of these compounds.

It is clear that the influence of organic derivatives of Group V elements on the polymerisation of acrylic monomers is directly related to the presence of the lone electron pair in the *p* orbital. This conclusion is supported by the fact that introduction of pentaphenylantimony in the polymerisate barely changes the polymerisation rate and the polymer MM.[242, 243]

Apparently, during its growth, a macroradical reacts with the metal atom in the OEC to give a four-coordinate radical complex

$$\sim P^{\bullet} + \ddot{E}R_3 \longrightarrow [\sim P^{\bullet}\text{---}\dot{E}R_3], \qquad (47)$$

where $\sim P^{\bullet}$ is the growing macroradical; E is a Group V element (antimony, bismuth); R = Et, Ph, Bu^i.

It is known [56] that, owing to the lone electron pair in the *p* orbital and free *d* orbitals, Group V elements are capable of expanding their electron shells. It has been shown by EPR [56] that compounds of trivalent Group V elements can react with free oxygen- and carbon-centred radicals; as this takes place, the coordination number increases to four and the corresponding intermediates are formed [reaction (47)].

The $[\sim P\text{---}ER_3]$ bond thus formed between the growing macroradical and a Group V element is labile and can be cleaved either yielding the initial compounds (OEC and the chain-propagating radical, which can continue polymerisation) or with the 'ejection' of a radical from the organoelement compound (S_R2 substitution).

$$\left[\sim P^{\bullet}\text{---}\dot{E}R_3\right] \longrightarrow \sim P^{\bullet} + \ddot{E}R_3 \quad \text{or} \quad \sim P\ddot{E}R_2 + R^{\bullet} \qquad (48)$$

Thus, one of the variants for the participation of OEC in the chain transfer stage and in the control of MM is realised.

It cannot be ruled out that in the presence of coordinatively unsaturated OEC, chain propagation takes place *via* insertion of the monomer at the labile $[\sim P^{\bullet}\text{---}\dot{E}R_3]$ bond to give a new coordinated macroradical.

$$\left[\sim P^{\bullet}\text{---}\dot{E}R_3\right] + CH_2{=}\underset{\displaystyle X}{\underset{|}{CH}} \longrightarrow \left[\sim P^{\bullet}\text{----}\dot{E}R_3 \;\; CH_2{=}\underset{\displaystyle X}{\underset{|}{CH}}\right] \longrightarrow \left[\sim P{-}CH_2{-}\underset{\displaystyle X}{\underset{|}{\dot{C}H}}\text{---}\dot{E}R_3\right] \qquad (49)$$

Thus, OEC is coordinated to the growing macroradical and thus participates directly in chain propagation and prevents bimolecular chain termination upon recombination of growing macroradicals. This type of process can be considered as a variant of 'pseudo-living' polymerisation.

It has been noted above that an increase in the rate of complex-radical polymerisation in the presence of metal halides can be explained by assuming the cyclic mechanism of chain propagation.[5] Similarly to OEC containing Group III elements, the alkyl derivatives of antimony and bismuth have a more pronounced influence on the chain propagation in the polymerisation of VA and BA than in the polymerisation of MMA.[242, 243] Since the distributions of electron density in the molecules of alkyl acrylates and methacrylates (for example, in MMA and BA) differ insignificantly,[79] it can be suggested that steric factors make the crucial contribution to the change in the kinetic parameters of polymerisation (in particular, the rate constants for chain propagation). The absence of substituents at the central carbon atom in the butyl acrylate radical makes the reaction centre more readily accessible for the coordination to OEC and subsequent chain propagation than in the case of MMA (tertiary radical).

The mechanism of chain propagation proposed above is also supported by the absence of inhibitory effect upon joint introduction of hydroquinone and triethylantimony in the polymerisate.[53] The organoelement additive enters into the coordination interaction with the growing macroradical and thus 'blocks' the reaction centre and prevents its interaction with the inhibitor. Consequently, the rate of polymerisation and the MM of polymers virtually do not change in the presence of hydroquinone and triethylantimony.

The character of influence of benzoquinone (a more effective inhibitor of radical polymerisation) on the kinetics of the processes studied is determined by the quinone concentration in the monomer mixture.[53] When the ratio [benzoquinone] : [triethylantimony] < 1, the rate of polymerisation virtually does not change. Conversely, with an excess of the quinone, polymerisation is retarded.

This pattern of variation indicates, apparently, that at least two independent processes take place. One process is fast reaction of triethylantimony with benzoquinone in which quinone is reduced to hydroquinone.[244, 245] As noted above, hydroquinone influences only slightly the kinetics of polymerisation of acrylic monomers in the presence of organic compounds of Group V elements. In addition, when [benzoquinone] : [triethylantimony] > 1, the excess benzoquinone reacts with the growing macroradical to give stable phenoxyl radicals; as a consequence, polymerisation also slows down. The substantial decrease in the molecular mass of PMMA upon introduction of the quinone

confirms the assumption that it participates in the chain termination step.[243]

Organoelement compounds containing Group V elements not only influence the rate of polymerisation of vinyl monomers but also control the MM of polymers, the effect being more pronounced than that induced by the addition of trialkylboranes.[53]

The addition of triethylantimony in amounts comparable with the concentration of the initiator markedly decreases the MM of poly(butyl acrylate) both for bulk polymerisation and for solution polymerisation in ethyl acetate.[243] The molecular mass of the polymer decreases with an increase in the OEC concentration: on introduction of 0.8 mol.% of triethylantimony, it decreases by more than an order of magnitude. The rate constant for the chain transfer to triethylantimony amounts to 0.118, which markedly exceeds the corresponding value for the chain transfer to the monomer (0.003).

The rate constants for the chain transfer to triisobutylbismuth in the polymerisation of MMA and VA calculated from experimental data are equal to 0.011 and 0.71, respectively.[242, 243] The values for the chain transfer to antimony and bismuth alkyl derivatives considerably exceed the corresponding parameters for TIBB (1×10^{-2} and 2.2×10^{-2} for MMA and VA, respectively).[20, 53] The very high rate constants for chain transfer in the polymerisation of BA and VA can be due to the occurrence of two processes involving the macroradical and OEC. One process, namely, free-radical substitution of the growing polymeric radical for the alkyl radical in organo-antimony and -bismuth compounds, occurs by a scheme similar to that presented above for trialkylboranes [see reactions (4) and (5)]. The rate constant for the substitution of oxygen-centred radicals for the alkyl radicals in triethylantimony is $\sim 10^5$ litre mol^{-1} s^{-1} (see Refs 246 and 247).

The second process, which also contributes to the control of the polymer MM, is abstraction of a hydrogen atom from the alkyl group of the OEC by the growing macroradical [similarly to Eqn (6)]. The occurrence of this reaction was proved unambiguously by EPR using the spin trap technique in a study of the influence of minor additives of methyl acrylate and other acrylic monomers on the control of the PMMA molecular mass during polymerisation involving organoelement initiators.[113]

It was found that, like trialkylboranes, organic compounds of antimony and bismuth also influence the composition of copolymers. Thus in the case of the MMA – MAA pair of monomers, the addition of triethylantimony in amounts commensurable with the concentration of the initiator induces transition from the copolymer enriched in one component ($r_{MAA} = 1.40$, $r_{MMA} = 0.08$) to strict alternation of units in the copolymer.[243] The appearance of alternation of units can be explained by an increase in the rate of cross propagation as a result of the formation of a cyclic reaction complex involving the monomer, the growing macroradical and the OEC. It is noteworthy that, as in the case of TIBB, the flat section in the composition curve corresponds to an MAA content in the copolymer, equal to 0.66 mol.%. This indicates that MAA is involved in the chain propagation step as a dimer.[243] Triethylantimony also influences somewhat the regularities of copolymerisation of MAA with the electron-donor St monomer:[53] the introduction of triethylantimony substantially increases the rate of copolymerisation; however, neither the composition of the copolymers, nor the relative activities of the monomers change noticeably.

The difference from the copolymerisation of the MAA – MMA pair of monomers is caused by the different in kind structures of MMA (electron density acceptor) and St (electron density donor), and the corresponding macroradicals.

Thus, OEC containing Group V elements participate directly in the elementary steps of polymerisation of vinyl monomers and control efficiently polymerisation kinetics and the MM and composition of copolymers prepared both in the bulk and in solution.

V. Conclusion

The effective methods for controlling the reactivity of macroradicals developed to date permit the preparation of homo- and copolymers uniform in composition and molecular mass. The control is attained *via* active influence on the elementary processes of polymerisation including the chain propagation step. The introduction of very small amounts of active additives makes it possible to achieve substantial and, what is more important, targeted change in the reactivity of the macroradicals and to control systematically the polymer chain propagation. It is of prime importance that some OEC, spin traps, iniferters and other controllers of chain propagation considered above are active when present in amounts comparable with the concentration of the initiator. Hence, in the future, they could be used in the industrial synthesis of polymers.

The analysis of published data given above demonstrates, in our opinion, considerable achievements in the development of controlled radical polymerisation — a new and promising line of research in the synthetic chemistry of polymers.

The review was supported by the Russian Foundation for Basic Research (Project No. 99-03-33346).

VII.	Control of intramolecular dynamics and an elementary chemical event	462
VIII.	The prospects of femtochemistry	466

Abstract. The review is devoted to a new field of chemistry — femtochemistry. New, in principle, possibilities of investigation and control of chemical reactions by means of ultrashort coherent light pulses are considered. The general concepts are illustrated by numerous examples of femtochemical studies of the dynamics and kinetics of elementary chemical reactions in the gas and condensed phases. The prospects of femtochemistry are discussed.
The bibliography includes 172 references.

I. Introduction

How does an elementary chemical reaction occur? What are intermediate configurations of a reacting system? How can the route and the rate of a chemical reaction be controlled? Chemists have asked themselves these questions throughout the history of the development of chemistry. However, the profundity of both the questions and the answers depends on the level of understanding of elementary processes and on the experimental capabilities.

Until quite recently, in all experiments dealing with elementary reactions the time evolution of either reactants or reaction products has been recorded. However, on the path from reactants to products, the molecular system passes through various structures (states) which can no longer be considered as reactants but cannot yet be regarded as products. From the experimenter's viewpoint, the range of interatomic distances corresponding to these structures is a 'black box' because the experiment does not provide any information about these structures or their change. Chemists call this range of interatomic distances the transition state,[1] and the time evolution of atom configurations in this 'black box' is called transition state dynamics. The passage of a reacting molecular system through the transition state represents an elementary step of a chemical reaction. The reaction path is usually characterised by the dependence of the potential energy on interatomic distances.

Theorists try to reconstruct the transition state dynamics from the results of investigations of the kinetics of reactants and products. However, it turned out that this often cannot be done unambiguously; experimental data are needed. The problem lies in the fact that the residence time of a molecular system in the 'black box' is very short, ~ 100 fs (1 fs = 10^{-15} s). Therefore, special laser equipment is required to detect the events taking place over this 100-fs period.

The appearance of a new tool — light pulses with durations of 10 – 100 fs — provided the possibility of detecting tiny changes, about 0.1 Å, in the distances between atoms in a molecular system; this triggered a new line of research in chemical physics, namely, femtochemistry. This field of investigations makes it possible to answer the questions posed above at a new, in principle, level; to verify some fundamental assumptions which we use; to distinguish the regions where they are no longer valid; and to discover new ways of controlling a chemical transformation. In 1999, an American scientist A Zewail was awarded the Nobel Prize for studies in the field of femtochemistry. Although femtochemistry is 'young' (its age can be estimated as 12 years), several reviews have been published (see, for example, publications [2–6]). In this review, we attempt to examine, from different standpoints, the rapidly developing approaches and concepts as well as new problems arising in this field.

II. Characteristic features of femtosecond pulses

Before discussing the problems of femtochemistry, let us consider characteristic features of ultrashort light pulses and new experimental capacities brought about by these features.

In a system of coordinates the z axis of which coincides with the direction of propagation of a laser pulse, the components of the electric field strength $E(t) = [E_x(t),E_y(t),E_z(t)]$ of a femtosecond light pulse for a specified point in space can be written in the form

$$\begin{aligned} E_x(t) &= E_{x0}\mathrm{f}(t)\cos[\omega_0 t + \delta_x + \alpha(t)], \\ E_y(t) &= E_{y0}\mathrm{f}(t)\cos[\omega_0 t + \delta_y + \alpha(t)], \\ E_z(t) &= 0. \end{aligned} \qquad (1)$$

In these equations, E_{x0} and E_{y0} are the maximum values of the x and y components of the field strength, respectively, f(t) is the

time dependence of the envelope of the pulse, t is the current time, ω_0 is the carrier light frequency related to the carrier wavelength λ_0 in the following way:

$$\lambda_0 = \frac{2\pi c}{\omega_0},$$

δ_x and δ_y are the phase constants and $\alpha(t)$ is the function describing the frequency modulation over the pulse duration. The polarisation of light in the pulse is characterised by the ratio E_{x0}/E_{y0} and by the δ_x and δ_y values. The pulse envelope $f(t) \propto \sqrt{I(t)}$, where $I(t)$ is the time dependence of light intensity in the pulse, can have different forms. However, irrespective of this, it is determined by pulse duration (τ).

Most often, Gaussian pulses with the envelope

$$f(t) = \exp\left(-\frac{t^2 2\ln 2}{\tau^2}\right), \tag{2}$$

and the frequency modulation

$$\alpha(t) = \frac{1}{2}\gamma t^2, \tag{3}$$

where γ is the temporal chirp (the parameter determining the rate of phase modulation) are considered. When $t = \pm\tau/2$, the light intensity in the pulse is equal to half its maximum.

Thus, parameters characterising a femtosecond pulse include pulse duration τ, field amplitude, carrier frequency and the function $\alpha(t)$ (expressed in most cases in terms of the temporal chirp γ).

It is known that a field can also be specified by spectral characteristics

$$\mathscr{E}_j(\omega) = \int_{-\infty}^{+\infty} E_j(t)\exp(i\omega t)\mathrm{d}t, \tag{4}$$

where $j = x, y$. Usually, the functions $f(t)$ and $\exp[i\alpha(t)]$ vary much more slowly than $\exp(i\omega_0 t)$; therefore, it can be written that

$$\mathscr{E}_j(\omega) = \frac{1}{2}\exp(-i\delta_j)F_j(\omega-\omega_0), \tag{5}$$

where

$$F_j(\omega-\omega_0) = E_{j0}\int_{-\infty}^{+\infty} f(t)\exp\{i[(\omega-\omega_0)t-\alpha(t)]\}\mathrm{d}t. \tag{6}$$

The function $F_j(\omega-\omega_0)$ is complex-valued and can be represented in the form

$$F_j(\omega-\omega_0) = |F_j(\omega-\omega_0)|\exp[i\varphi(\omega-\omega_0)], \tag{7}$$

where

$$|F_j(\omega-\omega_0)| \propto \sqrt{S(\omega)},$$

$S(\omega)$ is the the pulse power spectrum measured experimentally. The spectral phase $\varphi(\omega-\omega_0)$ is related to the functions $f(t)$ and $\alpha(t)$ in a complex manner. For Gaussian pulses, these functions are determined by relations (2) and (3), respectively. Therefore,

$$\varphi(\omega-\omega_0) = \frac{1}{2}\beta(\omega-\omega_0)^2,$$
$$\beta = \frac{4\gamma\tau^4}{16(\ln 2)^2 + \gamma^2\tau^4}. \tag{8}$$

The β parameter is called spectral chirp.

An important spectral characteristic of a femtosecond pulse is the width of its spectrum at the half-height of the amplitude ($\Delta\omega$). The spectral width is determined by the uncertainty relation

$$\tau\Delta\omega = \text{const}. \tag{9}$$

The value of const depends on the shape of the pulse and the chirp envelope. For a Gaussian pulse with $\gamma = 0$ (this pulse is usually referred to as transform-limited), const = 2.773. In the case of chirped pulses (*i.e.*, those with $\gamma \neq 0$), the constant can acquire arbitrarily large values depending on the chirp value.

Now we shall list the main experimental capacities resulting from the properties of femtosecond pulses.

First, due to the short pulse duration, evolution of processes can be studied with a temporal resolution even higher than the duration of the pulse itself. When the velocity of an atom is 10^5 cm s^{-1} and $\tau = 10^{-14}$ s, changes in the internuclear distances of about 0.1 Å can be detected. This means that not only the formation of products but also the time evolution of the nuclear configuration can be monitored with high accuracy in real time within the time scale of vibrational motion.

Second, since the spectral width of femtosecond pulses is rather large, several quantum states with different energies can be excited simultaneously. For example, a transform-limited pulse with $\tau = 10^{-14}$ s has the spectral width $\Delta\omega = 1100$ cm^{-1}. This light pulse can excite simultaneously several vibrational quantum states.

Third, a coherent light pulse can be obtained. In combination with the aforesaid, this means that coherent excitation of several vibrational or rotational states is possible. This new type of an excited state is called a non-stationary quantum state or a coherent nuclear wave packet.†

A specific feature of these states is that several eigen energy states with definite relative phases of atomic motion in a molecule can be subjected simultaneously to coherent excitation. The scheme of non-stationary and stationary quantum states of a molecule is shown in Fig. 1.

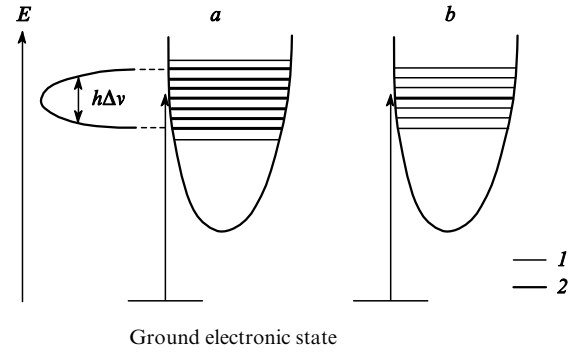

Figure 1. Non-stationary (*a*) and stationary (*b*) vibrational quantum states of a molecule. The horizontal lines mark unoccupied (*1*) and occupied (*2*) stationary vibrational states.

Fourth, due to high intensity (peak power) of femtosecond pulses with the pulse energy being relatively low, multiphoton absorption processes giving rise to highly excited molecular systems can be easily accomplished and numerous methods of non-linear spectroscopy can be used without heating the sample. Under the action of such pulses on a gas or a solid, light pulses with a broad spectral range (supercontinuum) and X-ray and electron pulses are generated. It should also be noted that light field intensities (10^{10} V cm^{-1}) exceeding even the intensities of intramolecular fields can be attained rather easily.

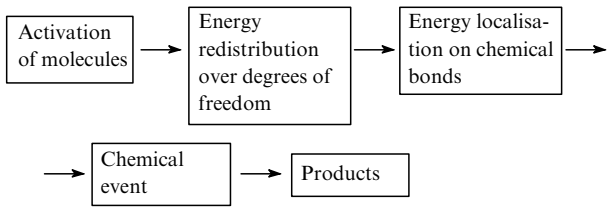
Thus, the use of femtosecond light pulses makes it possible to attain high temporal resolution, to create coherent non-stationary quantum states, to produce highly excited molecules, to act upon the potential energy surface (PES) and to generate ultrashort light, electron and X-ray pulses.

† The notion of wave packet was introduced in 1926 by E Schrödinger; however, it has virtually not been used in chemistry.

III. The main objectives of femtochemistry

How does the study of reactions within the femtosecond time scale pertain to practical chemistry? Indeed, the duration of an elementary reaction in practical chemistry is much longer than 100 fs. This is due to the fact that an elementary reaction includes both a fast chemical event and the preceding slower intra- and intermolecular energy exchange processes.

For an unimolecular chemical event to occur, the following processes should take place:



Activated molecules should possess a sufficiently high energy, which can be acquired either upon collisions, or due to a chemical reaction, or upon absorption of photons. Usually, this energy is redistributed very rapidly (in about 0.1 – 1 ps) over different vibrational degrees of freedom of the molecule. Then a fluctuation should occur, after which a certain energy is concentrated in the required site of the molecule, for example, in the form of vibrations of atoms of the bond to be cleaved. Only after this, does the chemical event take place. The time scale of the chemical event itself is 10 – 100 fs.

The specific features of new instrumentation noted above determine the following lines of research in femtochemistry: study of the dynamics of intramolecular processes and the transition state in a chemical transformation; study of the kinetics of ultrafast chemical reactions; control of the intramolecular dynamics and of the path of an elementary chemical reaction.

Now we shall briefly explain what is the purpose of each of these lines of investigation.

The goal of the first line is to obtain more detailed and substantiated views on the nuclear dynamics in a molecular system (either reacting or not). This refers both to the dynamics of intramolecular processes (coherent motion of nuclei, energy redistribution or localisation, *etc*.) and time evolution of the configurations of the molecular system on passing from reactants to products. In this connection, the possibility of creating a coherent wave packet (rotational, vibrational or electronic) in the molecular system is of fundamental importance. The most significant for chemistry is the vibrational wave packet in which several vibrational states undergo simultaneously coherent excitation. In this case, it can be said that intramolecular dynamics of nuclei is the time evolution of the vibration-rotational wave packets. A significant feature of this description is that phase characteristics of the nuclear motion are taken into account. However, it is known that after some time, dephasing takes place; as a consequence, the nuclear dynamics becomes incoherent and the regular nuclear motion switches to stochastic motion.

The purpose of the second line is to gain information on the kinetics of ultrafast reactions. Within the framework of this line of research, investigators are interested in the time evolution of the reactant or product concentration rather than in the phase characteristics of the nuclear motion. The features of femtosecond pulses most significant for this line of research include short duration, which allows implementation of techniques with high temporal resolution (using these techniques, one can study ultrafast reactions), and high intensity (this allows excitation of molecules with visible light to high energies).

The third line of research in femtochemistry is the most 'ambitious'. In this case, all the above-mentioned features of femtosecond pulses are significant. The possibility of creating femtosecond pulses opens new, in principle, opportunities for controlling intramolecular processes and the path of elementary chemical reactions. The idea of this control is based on the fact that, by using femtosecond pulses, one can switch the reacting system to a transition state with a definite initial wave function and then control the time evolution of this state. Due to the coherence of the light pulse, the initial state of the system can be created as a well-defined coherent wave packet. By changing the carrier frequency and the amplitude and phase characteristics of a femtosecond light pulse, it is possible to create in the initial (zero) instant of time different nuclear wave packets, the dynamics of which can be substantially different. The high temporal resolution allows researchers to 'monitor' the evolution of the transition state in order to act upon the system PES by one more femtosecond light pulse at the required point in time.

IV. Experimental methods of femtochemistry

Typical experimental methods of femtochemistry are based on the use of two femtosecond pulses according to the 'pump – probe' pattern (Fig. 2). The first pulse (λ_1) creates a wave packet in the electronically excited state. After some period of time, a second pulse (λ_2) probes the changes that have taken place. After the probe pulse, the molecular system passes into a different electronic state [either upper (Fig. 2 *a*) or lower (Fig. 2 *b*) in energy] and, owing to this transition, the response of the system to the action of the pump and probe pulses as a function of the time delay between them is recorded. The 'pump – probe' pattern makes it possible to detect both the dynamics of the motion of atoms (wavelength λ_2) and the kinetics of product formation (wavelength λ_2').

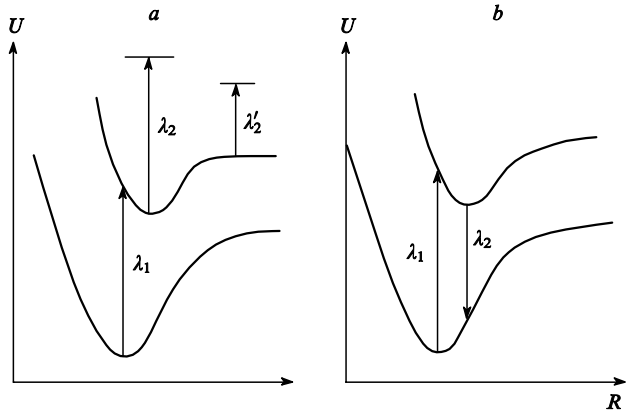


Figure 2. Simplest patterns of the 'pump – probe' technique. U is potential energy, R is the distance between the nuclei, λ_1 is the wavelength at the centre of the pump pulse spectrum, λ_2 is the wavelength at the centre of the spectrum of the pulse probing the transition state dynamics; λ_2' is the wavelength at the centre of the spectrum of the pulse probing the reaction products.

A typical scheme of the setup is shown in Fig. 3. A laser (as a rule, a dye or titanium-sapphire laser) usually pumped by a continuous-wave argon or solid-state laser generates consecutive femtosecond light pulses. The energy of these pulses is increased in a laser amplifier. The amplified pulse passes through a compensator of the envelope velocity dispersion (not shown in the Figure) and is then split into two components. One component is used as the pump pulse and the other, as the probe pulse. Both pulses pass through facilities which allow one to change the pulse parameters (carrier frequency, chirp, duration). The variable time delay between the pump and probe pulses is ensured by an optical delay line in which the optical path length of one of the pulses can vary. The pump and probe pulses are focussed on the specimen. The response to the two pulses as a function of the delay between them is recorded using a detector. The characteristics recorded as the response can include photoinduced absorption,[7–9] fluorescence,[10–12] stimulated radaiation,[13] miltiphoton ionisation[14]

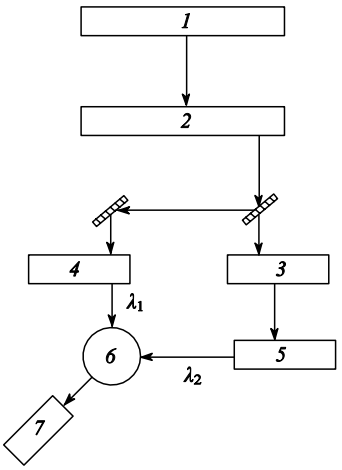

Figure 3. Experimental setup used for the 'pump – probe' experiments. (*1*) generator of femtosecond pulses; (*2*) optical amplifier of the pulse energy; (*3*, *4*) devices for changing the parameters of femtosecond light pulses, (*5*) optical line of the time delay between the pump and probe pulses; (*6*) reaction zone, (*7*) device for recording the response of the molecular system to the action of two pulses.

(often recorded using time-of-flight mass spectrometry techniques [15, 16]), rotation of the polarisation plane, [17] *etc*.

It is worth noting that the high intensity of femtosecond pulses permits utilisation of any non-linear spectroscopy technique developed to date in which several pulses are used.[18, 19] A special group of methods includes those in which the second pulse is focussed onto a target in order to generate ultrashort supercontinuum,[20, 21] electron [22–25] or X-ray [26, 27] pulses, which then serve as the probe pulses.

Supercontinuum pulses are used most effectively to study solutions. Primary processes in solutions result in broad absorption spectra of reactants, intermediate states and products. These spectra overlap, which markedly hampers interpretation of experimental data obtained at a particular wavelength. Regarding the time evolution of the intermediate states, more information is provided by an approach according to which time evolution of a broad spectrum of photoinduced absorption is recorded. This requires an ultrashort pulse which emits light over a broad spectral range. A supercontinuum the spectrum of which covers the whole visible region can serve as the source of such a pulse in femtochemistry. The methods that make use of this approach are documented.[20, 21]

Ultrashort pulses of electrons and X-rays are also used as probe pulses. In this case, diffraction of electrons or X-rays after reflection from the specimen under study is detected. By recording the diffraction pattern of electrons or X-rays at various points in time after the action of the pump light pulse, one can gain information on the structure of intermediates and the dynamics of structural changes. The methods based on electron diffraction are applicable only to gas media, while those based on X-ray diffraction are suitable also for condensed media. For example, electron diffraction has been used to determine the structure of an intermediate species.[22] The diffraction of X-rays has been used as yet only to detect the dynamics of structural changes in the absence of a chemical reaction. Thus time evolution of the arrangement of cadmium atoms in films of organic compounds heated by femtosecond light pulses has been studied.[26] There are publications in which absorption of the probe X-ray pulse is used to investigate photochemical reactions. For example, a study by Raksi *et al*.[27] deals with photodissociation of SF_6 molecules.

V. Dynamics of intramolecular processes and of transition states in a chemical transformation

It has been noted above that, due to the great spectral width, a coherent femtosecond light pulse excites a non-stationary quantum state, *viz*., a coherent wave packet (rotational, vibrational or electronic). The dynamics of nuclear motion shows itself in the time evolution of this packet. High temporal resolution permits real-time detection of the dynamics of wave packets.

A great number of theoretical studies devoted to the dynamics of coherent nuclear wave packets both in di- and polyatomic systems have been published.[28–36] Let us consider some properties of vibrational wave packets in relation to diatomic molecules in the absence of a chemical transformation.

Usually wave packets of this type are formed in some electronically excited state $|1\rangle$, to which dipole radiation transitions from the ground electronic state $|0\rangle$ are allowed. For simplicity, we assume that the pump pulse has a Gaussian shape, carrier frequency ω_0, duration τ and temporal chirp γ. Let us also assume that the crucial contribution to the wave packet is made by the ground vibrational state (the state with the vibrational quantum number $\upsilon = 0$) of the ground electronic state. Then at the instant of termination of the action of the light pulse ($\tau_f \approx \tau$), the vibrational wave packet $\Psi_1(R, \tau_f)$ (R is the distance between the nuclei) in the electronically excited state $|1\rangle$ has the form

$$\Psi_1(R, \tau_f) = \sum_{\upsilon} \varphi_{1\upsilon}(R) C_\upsilon(\tau_f, \tau, \gamma). \tag{10}$$

Here $\varphi_{1u}(R)$ are the vibrational wave functions of the molecule in the electronic state $|1\rangle$ corresponding to the vibrational quantum number υ and the vibration energy $\varepsilon_{1\upsilon}$ measured in relation to the minimum of the electronic potential curve of the state $|1\rangle$, while the complex coefficients are

$$C_\upsilon(\tau_f, \tau, \gamma) \approx S_{00,1\upsilon} \exp\left\{-i\frac{\varepsilon_{1\upsilon}\tau_f}{\hbar} - i\frac{\beta(\tau,\gamma)[\varepsilon_{1\upsilon} - (\omega_0 - T_{e1})]^2}{2\hbar^2}\right\} \times \times \exp\left[-\frac{\varepsilon_{1\upsilon} - (\omega_0 - T_{e1})^2}{2\Gamma^2(\tau,\gamma)}\right], \tag{11}$$

where $S_{00,1u}$ are the overlap integrals of the wave function of the ground vibrational state of the $|0\rangle$ electronic term and the wave functions $\varphi_{1\upsilon}(R)$, T_{e1} is the distance between the bottom of the ground state and the first excited state, the spectral chirp $\beta(\tau, \gamma)$ is defined by the formula (8), and

$$\Gamma^2(\tau,\gamma) = \gamma^2\frac{\tau^2}{4\ln 2} + \frac{4\ln 2}{\tau^2}. \tag{12}$$

The evolution of the wave packet $\Psi_1(R, \tau_f)$ that has formed by the instant τ_f at $t > \tau_f$ obeys the temporal Schrödinger equation for a free molecule and, hence, the corresponding non-stationary wave function has the form

$$\Psi_1(R, t) = \sum_{\upsilon} \varphi_{1\upsilon}(R) C_\upsilon(\tau_f, \tau, \gamma) \exp\left[-i\frac{(t-\tau_f)\varepsilon_{1\upsilon}}{\hbar}\right]. \tag{13}$$

The probability of obtaining in measurements the value ε_υ for the vibrational energy of the molecule the state of which is described by the non-stationary wave function $\Psi_1(R, t)$ is equal to $|C_\upsilon(\tau_f, \tau, \gamma)|^2$ and does not depend on time t. A significant feature of the wave packet is the fact that the probability density for finding a molecule with the distance R between the nuclei

$$|\Psi_1(R,t)|^2 = \sum_{\upsilon}|C_\upsilon|^2\varphi_{1\upsilon}^2(R) + \sum_{\upsilon>\upsilon'} 2|C_\upsilon| \times \tag{14}$$

$$\times \left\{\cos\left[\frac{(t-\tau_f)(\varepsilon_{1\upsilon} - \varepsilon_{1\upsilon'})}{\hbar} + \mathrm{Arg}(C_{\upsilon'}) - \mathrm{Arg}(C_\upsilon)\right]\right\} \times$$

$$\times \varphi_{1\upsilon}(R)\varphi_{1\upsilon'}(R)$$

(unlike the stationary states) depends on time t. This can be interpreted as movement of the wave packet along the PES.

The dynamics of wave packets in model anharmonic oscillators has been studied theoretically in detail.[28–36] It was found that it consists of two stages. The first stage is spreading of the packet with splitting into several sub-packets. Subsequently these sub-packets can be completely restored, owing to interference, to give the initial wave packet within time T/x, where T is the period of classical vibrations and x is the anharmonicity parameter. Similar results are obtained in numerical calculations for real systems, for example, for the I_2 molecule. Figure 4 shows the $|\Psi(R,t)^2|$ functions for the I_2 molecule in the electronically excited state $B0_u^+$ for three delay times calculated in relation to experimental data obtained by Sarkisov *et al.*[12] It can be seen that in the initial time instant, the vibrational wave packet is localised in space; then motion of the centre of gravity and spreading of the packet take place. The spreading is due to the fact that the phases of the Fourier components of the packet become less correlated with one another.

A vivid description of wave packet dynamics can be obtained by using representation of the quantum state of the system in terms of the Wigner distribution function in the phase space (see, for example, Ref. 37). The Wigner function for an anharmonic molecular oscillator is written as

$$W(R,P,t)=\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\exp\left(i\frac{Px}{\hbar}\right)\rho_1^{(\mathrm{vib})}(R+x,R-x,t)\mathrm{d}x, \quad (15)$$

where P is the momentum conjugate to the coordinate R, $\rho_1^{(\mathrm{vib})}(R+x,R-x,t)$ is the density matrix for the molecular oscillator in a coordinate representation (the definition for the notion of a density matrix can be found, for example, in Ref. 31); in particular, if the state of the molecular oscillator is described by the wave function $\Psi_1(R,t)$, then

$$\rho_1^{(\mathrm{vib})}(R+x,R-x,t)=\Psi_1(R+x,t)\Psi_1^*(R-x,t). \quad (16)$$

The Wigner distribution function is an analogue of the classical distribution function in the phase space. However, this analogy should not be understood literally because, due to quantum fluctuations, $W(R,P,t)$ is not a positively defined function. To get rid of the 'non-classical' behaviour of the Wigner distribution function for quasi-classical quantum states (for example, vibrational wave packets of diatomic molecules in typical femtosecond experiments), it is averaged over regions of the phase space (about $2\pi\hbar$). The function used most often is the following 'coarse-grained' distribution function (it is called sometimes the Husimi function):

$$W_{\mathrm{H}}(\bar{R},\bar{P},\sigma,t)=\frac{1}{\pi}\int_{-\infty}^{+\infty}\mathrm{d}R\int_{-\infty}^{+\infty}W(R,P,t)\times \quad (17)$$

$$\times\exp\left[-\frac{(\bar{R}-R)^2}{\sigma^2}-\frac{(\bar{P}-P)^2\sigma^2}{\hbar^2}\right]\mathrm{d}P,$$

where σ is a parameter expressed in units of length. The variables $\bar{R}$ and $\bar{P}$ can be regarded as the classical coordinate and the momentum of the molecular oscillator, respectively.

Lozovoy *et al.*[37] calculated, in relation to experiments described in other publications,[12,38] the Husimi distribution functions for the vibrational wave packets formed by the pump pulse in the $B0_u^+$ electronic state of the I_2 molecule. The results of calculations for two delay times show that at $\Delta t = 149$ fs, the packet is still localised, while at $\Delta t = 4944$ fs, it has split into four sub-packets. At longer times, interference takes place, resulting in the restoration of the initial wave packet. The physical pattern of the dynamics of the vibrational wave packet in a diatomic molecule in the absence of bond rupture can be described as follows. The packet is first spread, which is due to the 'disturbance' of the relative phases of various Fourier components of the wave packet. Then it is divided into sub-packets, the Fourier components of which have similar phases. These packets interfere either constructively or destructively; this may result in more localised wave packets. Thus, for diatomic molecules, the intramolecular dynamics can be represented as splitting and restoration of wave packets.

The dynamics of vibrational wave packets in the absence of chemical transformations of the diatomic iodine molecule in the electronically excited state $B0_u^+$ is manifested as time oscillation of the response in the 'pump–probe' experiment. This response is a dependence of the signal intensity (I) on the delay between the pump and probe pulses (Δt). Figure 5 shows the experimental data and the results of calculations of the response function in accordance with the theory developed by Sarkisov and co-workers.[39] This theory allows one to derive the response function of the 'pump–probe' experiment for diatomic molecules at various parameters of the pump and probe light pulses. The

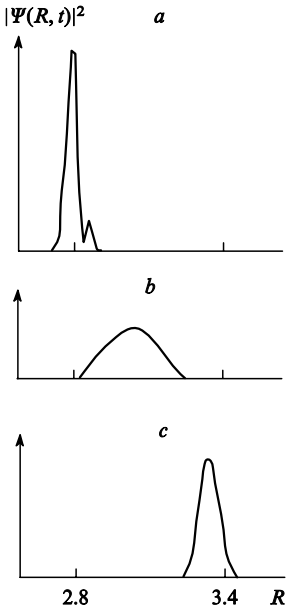

Figure 4. Dynamics of the vibrational wave packets in the bound electronic state $B0_u^+$ of the iodine molecule: distribution of the probability density $|\Psi(R,\mathrm{t})|^2$ of the occurrence of nuclei at distances R for time delays $\Delta t = 0$ (*a*), 30 (*b*), 60 fs (*c*).

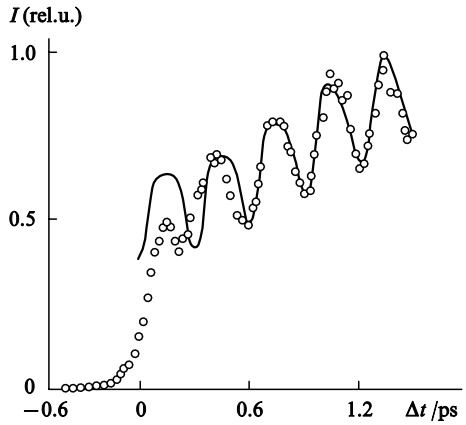

Figure 5. Superimposed oscillation signals in 'pump–probe' experiments for an iodine molecule in an electronically excited state.[12]
The dots show experimental data and the curve corresponds to calculations.

calculated response function for the detection of fluorescence is in good agreement with the experimental data without adjustable parameters. The deviation of the theoretical curve from the experimental points at short Δt values is due to overlap of these pulses (the theory used [39] does not imply this overlap.)

In terms of the classical theory, the vibrations of atoms in a diatomic molecule are represented as vibrations of two masses connected by a spring. Within the framework of the theory of stationary quantum states, the vibrations of nuclei are not considered at all. Only introduction of the notion of wave packets does provide a view on the vibrations from the quantum standpoint.

What are the dynamics of wave packets for polyatomic molecules? To answer this question, the dynamics of nuclear wave packets in a triatomic molecule (NO_2) has been studied.[40] In experimental studies, the author utilised the resonance variant of the stimulated scattering. The pump pulse had a circular polarisation; this made it possible to eliminate the influence of molecular rotation on the detected response. First, a coherent vibrational wave packet in an adiabatic electronically excited state was formed. The lifetime of this packet is determined by the interaction of the electronically excited and ground states. As a result of this interaction, the intramolecular non-adiabatic electron-vibrational dynamics switches from a regular to a stochastic mode. The experiments showed (and calculations confirmed) that this transition takes place over a period of 500 fs.

In the NO_2 molecule, the terms of the electronically excited and ground states undergo strong interaction; this provides grounds for regarding it as a model of a complex molecule. Therefore, it can be assumed that for polyatomic molecules, transition from a regular dynamic mode to the stochastic mode will take place in approximately the same time period (500 fs – 2 ps). Indeed, the wave packet dynamics manifested in the oscillations of the recorded signals has been observed for many complex molecules (see, for example, a number of studies [41–44]); in all cases, the time of oscillations did not exceed several picoseconds. As an example, we shall consider the results of a study [42] devoted to intramolecular vibrational dynamics of the azulene molecule during the internal conversion from the electronic state S_1 to the ground electronic state. In the experiments, both probe and pump pulses were shorter than 20 fs. Damped oscillations of the signal upon excitation of the molecule to the S_1 state with an excess of vibrational energy of >1300 cm^{-1} were observed. The damping time was 0.7 ps. Analysis showed that the main contribution to oscillations is made by only two (the corresponding frequencies are 160 and 200 cm^{-1}) of the 48 vibration modes. Thus, for large molecules, femtosecond pump pulses can generate vibrational wave packets consisting of a limited number of vibration modes. This example shows that the coherence of the atomic motion in a molecular system can also be retained on a picosecond scale.

Experimental methods have now been developed which provide the generation of rotational wave packets and recording of their dynamics not only in the excited but also in the ground electronic state.[17,45] The dynamics of the rotational wave packets observed experimentally for the NO_2 molecule in the ground electronic state is illustrated by Fig. 6. It can be seen that the signal reflecting the evolution of the rotational wave packet has the form of beats. Experiments were carried out using the method of non-resonance stimulated Raman light scattering. The pump and probe pulses are linearly polarised at an angle of 45° with respect to each other. The variation of the rotation angle of the plane of polarisation of the probe pulse as a function of Δt was detected. The rotational constants determined from this dependence coincide with the rotational constants determined by conventional microwave spectroscopy techniques.

Currently, approaches are being formed aimed at the formation and detection of vibrational wave packets in the ground electronic state. For example, as applied to diatomic molecules, methods for four-wave mixing of three pulses with a femtosecond

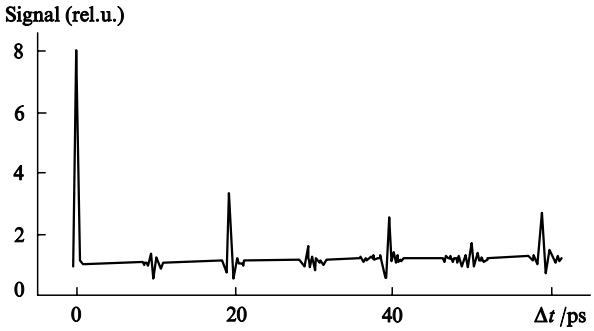

Figure 6. Experimentally observed dynamics of rotational wave packets for the NO_2 molecule in its ground electronic state.[17]

temporal resolution are being developed.[46–48] Methods for generation of vibrational wave packets in polyatomic molecules in the ground electronic state with excitation energies of either higher or lower than the dissociation threshold of these molecules have been proposed.[49,50]

Now we shall consider the intramolecular dynamics in the presence of a chemical transformation beginning also with a diatomic molecule. The most interesting example is pre-dissociation of the NaI molecule (Fig. 7). This system is characterised by avoided crossing of the covalent and ionic potential curves (Fig. 7 *a*). Both the dynamics of the transition state $[Na\cdots I]^{\#}$ and

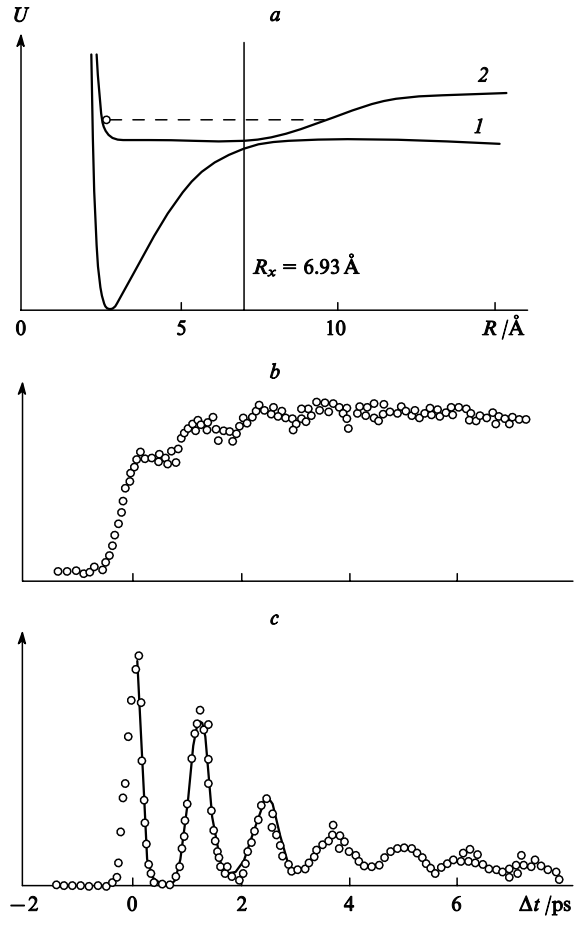

Figure 7. Dynamics of NaI dissociation.[51]
(*a*) potential energy curves for the ground (*1*) and excited (*2*) electronic states; (*b*) kinetics of accumulation of free Na atoms; (*c*) experimental monitoring of the $[Na\cdots I]^{\#}$ transition state.

the coherent kinetics of the formation of the pre-dissociation product, a sodium atom, were measured. The transition state dynamics gives an oscillating response with a decreasing amplitude. The decrease in the amplitude is related to 'skipping' of a part of the wave packet to a different electronic potential curve. Apparently, this is the first example of experimental real-time monitoring of the dynamics of intramolecular motion accompanied by non-adiabatic electron transitions. The product (sodium atom) is formed when the wave packet approaches the avoided crossing point. If we dealt with stationary states, the kinetics would be exponential with a rate constant equal to the vibration frequency multiplied by the probability of the non-adiabatic transition. However, in this case, the situation is different. When the wave packet is far from the avoided crossing region, the product yield does not increase. This type of kinetics is due to coherence; therefore, we call it coherent kinetics. By averaging the kinetics over all phases of wave packets, we shall obtain exponential kinetics.

It should be noted than the vibrationally coherent reactions induced by femtosecond pulses can take place in complex systems in various media. When these reactions occur, coherent wave packets can in some cases be observed experimentally in the products. Three reactions can be considered as examples, namely, decomposition of CH_2I_2 upon multiphoton absorption,[52] proton transfer in the 2-(2′-hydroxyphenyl)benzothiazole molecule [42] and the reaction responsible for the primary stage of vision.[53]

In the first reaction, the CH_2I_2 molecules were excited due to two-photon absorption on exposure to a femtosecond pulse with a carrier wavelength of 308 nm. Over a period of less than 100 fs, the carbene CH_2 and the iodine molecule in a non-stationary vibrationally excited state of the electronic state D' are formed.

In the case of proton transfer in the 2-(2′-hydroxyphenyl)benzothiazole molecule,[42] clear-cut damped oscillations of stimulated fluorescence were observed 60 fs after excitation with the probe pulse. The authors consider that the observed oscillations occur after the proton transfer has taken place. Analysis showed that only four of the 69 vibration modes (118, 254, 289 and 529 cm^{-1}) are involved in the formation of the vibrational wave packet, the predominant contribution to oscillations being made by only two vibration modes (118 and 254 cm^{-1}). The damping time for the contribution of the mode with a frequency of 118 cm^{-1} is 0.3 ps; that for each of other modes is $\sim$1 ps.

The third reaction is photoinduced isomerisation of the retinal chromophore in rhodopsin; more precisely, isomerisation of the excited 11-*cis*-retinal in the ground electronic state.[53] The 11-*cis*-retinal molecule was excited by a femtosecond pulse and the oscillating time dependence of the absorption of the product with a period of 550 fs was recorded. Two important experimental facts are worth mentioning: (i) the reaction occurs over a period of 200 fs; (ii) the reaction product was formed in a non-stationary vibrationally excited state of the ground electronic state. The researchers cited [53] give the affirmative answer to the question 'Does the vibrational coherence play an important role in the primary stage of vision?' They consider that avoided crossing of PES takes place and the wave packet can 'skip' from one PES to another and attribute the effective quantum yield of the reaction (0.67) to the reaction time (200 fs). The probability of this skip depends on the wave packet velocity in the avoided crossing region. If the velocity of the wave packet motion is decreased, the quantum yield of photoisomerisation should diminish. To confirm this hypothesis, femtosecond experiments on photoisomerisation of isorhodopsin were carried out. It was found that isorhodopsin isomerisation affords the same product, bathorhodopsin. It was suggested that the initial velocity of wave packet motion after excitation is lower in the case of isorhodopsin than in the case of rhodopsin. This was confirmed in experiments: the reaction proceeds more slowly (over 600 fs) and has a lower quantum yield (0.22). Therefore, the investigators concluded that the quantum yield is determined by the reaction dynamics rather than by the vibrational relaxation processes, as had been considered previously.

There are several publications in which the coherent wave packets have been observed when investigating elementary reactions within the femtosecond and sub-picosecond time scales. For example, vibrational coherence was observed in the photodissociation of OCS in the gas phase,[54] photodissociation of $Mn_2(CO)_9$ [55] and $Cr(CO)_6$,[41] intramolecular proton transfer,[56] femtosecond processes in proteins [57] and electron transfer.[58–62] For example, in a study of the hexamethylbenzene complex with tetracyanoethylene (TCE), oscillations were detected both in absorption and in fluorescence.[59, 60, 62] In a study of donor–acceptor interactions, Rubtsov and Yoschihara [61] have used various electron donors (carbazole, 1-chloronaphthalene, *N*-methylaniline) and acceptors (TCE, chloranil, fluoranil). It was shown that for each particular acceptor, irrespective of the nature of the donor, the same oscillation frequency in the fluorescence signal is observed: 155 cm^{-1} for TCE (oscillation period 215 fs), 178 cm^{-1} for chloranil (oscillation period 187 fs) and 212 cm^{-1} for fluoranil (oscillation period 157 fs). Hence, the oscillations are due to the formation of the vibrational wave packet associated with the excitation of a particular electron acceptor in the donor–acceptor complex.

It should be noted that the use of laser spectroscopy with ultrahigh temporal resolution often makes it possible to gain information on not only the product formation and the reactant decay but also on the transition state dynamics without observing the vibrational coherence. These studies also made a substantial contribution to the development of the views on the transition state dynamics. First of all, this refers to the study of electron transfer processes in molecular systems with intervalent transitions in organometallic compounds,[63, 64] charge recombination in photoexcited donor–acceptor complexes without covalent bonds,[59–70] charge separation and recombination in donor–acceptor supramolecules with covalent bonds.[70–75]

Studies of electron transfer in non-covalent donor–acceptor complexes and intervalent transitions in metal complexes provided important information on the dynamics of relaxation of their dipole environment.[61–68] These studies showed that, in addition to orientational relaxation, an important role is played by the libration motion of the medium dipoles.[60, 63, 64] In the same publications, it is noted that the single-mode approximation (when one average frequency of intramolecular vibrations is taken) is insufficient for describing the internal re-organisation of the system.

A situation typical of covalently bonded supramolecules is that an optical transition from the ground state gives rise to a locally excited state, which passes subsequently into a charge transfer state. The covalently bonded donor–acceptor supramolecules 'mimic' the charge separation process in a photosynthetic centre.[71, 72] Charge separation can take place both on the pico- and on the femtosecond time scale. This has been demonstrated [75] in relation to charge separation in the tetra-*meso*-substituted ferrocenylporphyrin molecules. The researchers studied the relaxation dynamics in various tetra-*meso*-substituted ferrocenylporphyrins, Fc_4PH_2, $ZnFc_4P$, $Fc_4PH_4^{2+}$ and $TCE:Fc_4PH_2$ (Fc is ferrocene, P is porphyrin), by the 'pump–probe' method. A supercontinuum was used as the probe pulse. The differential absorption in the 380–600 nm spectral range was recorded. Under the action of a femtosecond pulse with a wavelength of 610 nm, the $Q^1(\pi^*-\pi)$ state of the electron acceptor (porphyrin molecule) was excited, the ferrocene molecule serving as the electron donor. The formation of the charge transfer state $P^- - Fc^+$ from the locally excited $Q(\pi^*-\pi)$ state takes place over a period of $\sim$200–210 fs in the case of Fc_4PH_2 and $ZnFc_4P$. However, in the case of $Fc_4PH_4^{2+}$ and $TCE:Fc_4PH_2$, transition to the charge transfer state requires at least 10 ps. The different time scales of transition are, apparently, due to different conformation flexibilities of the porphyrin ring. Note that the transition to the charge transfer state occurs faster than the relaxation of solvent

molecules. A higher rate of electron transfer compared to the rate of relaxation of solvent molecules is also observed for complexes containing no covalent bonds.[62, 65] To interpret these facts, it is necessary to use new approaches to the standard views on electron transfer.

Other examples of investigation into transition state dynamics without observing the coherent wave packets can be found in a number of publications devoted to elucidation of the problem whether a reaction follows a stepwise or a concerted mechanism. Stepwise reactions differ from concerted ones in that the potential curves along the reaction coordinate have an intermediate minimum between the minima corresponding to reactants and products. In some cases, the reaction mechanism can be established rather easily. For example, photodecomposition reactions of acetone,[76] fluoroethane [77] and cyclic ketones [78] occur by stepwise mechanisms. This is proved (by experiment) by the fact that the primary and secondary bond ruptures occur at different time instants. The decomposition of CH_2I_2 upon multiphoton excitation [52] follows a concerted mechanism, which is confirmed by the short reaction time (< 50 fs) and by the product being formed in a non-stationary coherent state. However, it is often difficult to elucidate the reaction mechanism; this requires methods with a very high temporal resolution. Examples of reactions that follow stepwise and concerted mechanisms are listed in Table 1.

Table 1. Examples of reactions occurring by stepwise and concerted mechanisms.

Reaction	λ_1 /nm	Mechanism	t /fs	Ref.
$Fe(CO)_5 + 2\,h\nu \rightarrow$ $\rightarrow FeCO + 4\,CO$	400	concerted	~ 100	79
$Fe(CO)_5 + h\nu \rightarrow$ $\rightarrow Fe(CO)_4^* + CO$, $Fe(CO)_4 \rightarrow Fe(CO)_3 + CO$	267	stepwise	~ 100 ~ 3000	80
cyclo-$C_4H_8 \rightarrow 2\,C_2H_4$ (in the ground electronic state)	–	the same	~ 700	81
Cyclohexene $\rightarrow$ $\rightarrow$ ethylene + butadiene (in the ground electronic state)	–	concerted, stepwise	~ 200	82
Two-proton transfer in 2,2′-bipyridine-3,3′-diol	300 – 400	the same	~ 50 $\sim 10\,000$	83, 84

The first example is related to the photochemistry of metal carbonyls, which are widely used as photocatalysts and for the production of high-purity metallic films on various surfaces. Photodecomposition of these compounds has been studied using femtosecond spectroscopy techniques. For example, the ultrafast dynamics of photofragmentation of $Mn_2(CO)_{10}$, namely, rupture of the metal – metal and metal – ligand bonds occurring over hundreds of femtoseconds, has been studied.[85] The dynamics of $M(CO)_6$ dissociation (M = Cr, W, Mo) in solutions has been investigated [86] using femtosecond IR spectroscopy. It was found that the primary reaction in the UV photolysis is ejection of one CO group, which takes place over a period of less than 240 fs. Let us analyse decomposition of $Fe(CO)_5$ in the gas phase in more detail. Two groups of researchers [79, 80] have considered an important point, namely, whether the molecule loses one or several CO ligands after photoexcitation. The viewpoints of the researchers cited are appreciably different.

In experiments described in one of these publications,[79] the 'pump – probe' procedure was used. The pump pulse had a carrier wavelength of 400 nm. Upon the absorption of two photons, a transition state with an excitation energy of 50 000 cm^{-1} was formed. The probe pulse had a carrier wavelength of 800 or 400 nm. Using a time-of-flight mass spectrometer, the ions of both the starting compound and all the fragments of $Fe(CO)_n^+$ decomposition ($n = 0 - 5$) were detected. The experiments showed that the decay times of all the $Fe(CO)_n^+$ cations ($n = 2 - 4$) were nearly equal and amounted to ~ 100 fs. (Time characteristics of the growth of signals of the cations were not detected.) The maxima of signals of these cations are shifted in time relative to the maximum of the $Fe(CO)_5^+$ signal by 20 ± 5 fs for $Fe(CO)_4$, by 30 ± 5 fs for $Fe(CO)_3$ and by 60 ± 15 fs for $Fe(CO)_2$. Only for FeCO and Fe, were the kinetic characteristics of the growth of signals observed, the formation kinetics of iron atoms being correlated with the kinetics of the decay of FeCO. This means that dissociation of FeCO is a subsequent reaction which occurs with a characteristic time of 230 fs. The following model was proposed to interpret the experimental data. The excitation is followed by structural rearrangement of the transition state during the first 20 ± 5 fs; consequently, the distance between the centers of gravity of $Fe(CO)_4$ and CO increases relative to the equilibrium distance. With this transition state geometry, after absorption of the photons from the probe pulse, the parent molecule is converted into the corresponding ion, which decomposes to give the detectable $Fe(CO)_4^+$ ion and CO. Within 30 ± 5 fs after the pump pulse, a new configuration of the transition state appears (apparently, two CO ligands are separated from the Fe atom by distances greater than the equilibrium distance). The probe pulse induces the transformation of the parent molecule into the corresponding ion, which decomposes to give the detectable $Fe(CO)_3^+$ ion and two CO molecules. The origin of the detectable $Fe(CO)_2^+$ and $FeCO^+$ cations is explained in approximately the same way. Within the framework of this model, the observable ions are 'fingerprints' of the time evolution of the transition state. Thus, upon absorption of two photons with a wavelength of 400 nm, the reagent loses four CO ligands in ~ 100 fs. Since this value corresponds to the time scale of the period of the Fe – CO bond vibrations (the typical range is 80 – 100 fs), the researchers concluded that the reaction

$$Fe(CO)_5 + 2\,h\nu \longrightarrow FeCO + 4\,CO$$

occurs by a concerted mechanism.

The same reaction was studied by similar methods in another study.[80] Five consecutive processes with time constants of 21, 15, 30, 47 and 3300 fs were detected after the pump pulse. However, the four faster processes were attributed to intermediate intramolecular processes taking place in the excited $Fe(CO)_5$ molecule and in the primary product $Fe(CO)_4$ formed in an electronically excited state. In the opinion of the researchers cited, the second step of CO elimination, *i.e.*, transition of $Fe(CO)_4$ to $Fe(CO)_3$, occurs in the ground electronic state over a longer period (3.3 ps). They discussed the possibility of a concerted reaction mechanism and concluded that it does not take place.

The conclusions made in the two studies discussed above are contradictory. However, it should be noted that Trushin *et al.*[80] performed excitation of the $Fe(CO)_5$ molecule by one-photon absorption at a wavelength of ~ 267 nm, while in the study by Banares *et al.*,[79] this was done by two-photon excitation at ~ 400 nm. Therefore, in the latter case, the $Fe(CO)_5$ molecule could have a much greater excitation energy and, perhaps, different parameters of the initial vibrational wave packet. In addition, both groups of scientists did not control the structure of the pump pulse, although it is known, for example, that the chirp of the pump pulse can result in an increase in the product yield in the channel corresponding to the concerted mechanism. Thus, the question of the mechanism of this reaction remains open.

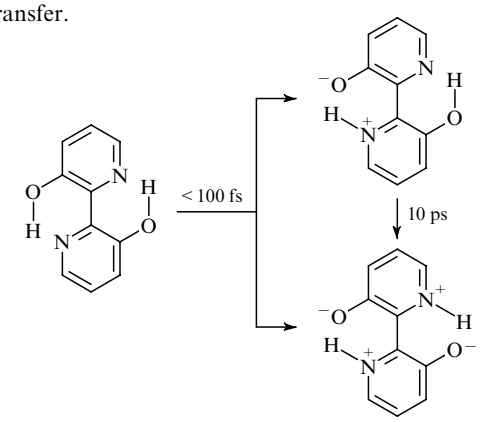
The second example is opening of the cyclobutane ring giving rise to two ethylene molecules.[81] Two mechanisms of this reaction are discussed in the literature — concerted (described by the Woodward – Hoffman rule) and stepwise (a biradical two-step mechanism). By investigating the kinetics of the decay of biradicals, the authors [81] arrived at the conclusion that the reaction follows the stepwise biradical mechanism. They believe that a

small potential well (4 kcal mol^{-1}) corresponding to the intermediate species, biradicals, is present near the top of the barrier.

The third example is represented by decomposition of cyclohexene and other cyclic compounds.[82] Experimental data and trajectory calculations showed that the reactions follow two mechanisms, a concerted and a stepwise biradical mechanism. In the researchers' opinion, the contributions of the two types of mechanisms to the overall reaction rate are dictated by the asymmetry of the molecular structure, localisation of the activated complex and the height of the potential barrier.

The problem of the search for an experimental criterion which would be indicative of a concerted reaction mechanism has been discussed.[82,87] It is generally accepted that several bonds are modified simultaneously in a concerted reaction — some of them are cleaved and some new bonds are formed. However, the notion of simultaneity for the experimenter has not been defined. The authors of the publications considered believe that a well-posed criterion should be related to the time scale of the movement along the reaction coordinate. This means that only the real-time dynamics of intermediate structures can substantiate the concept of concertness. It should be emphasised that the notion of concerted reactions has usually been related only to the structure of PES. In femtochemistry, realisation of either concerted or stepwise mechanism can also depend on the way of production of the wave packet, in particular, on the degree of its coherence.

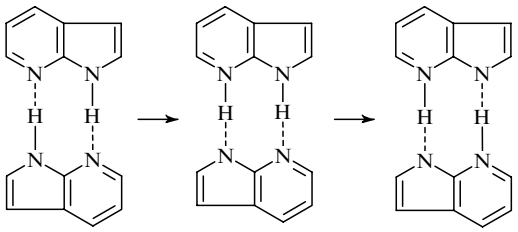
The last-mentioned example refers to the studies of intramolecular two-proton transitions in electronically excited states. Two-proton transfer in the 2,2′-bipyridine-3,3′-diol molecule has been studied.[83,84] It was found that this transfer can follow two mechanisms, namely, a one-step concerted mechanism and a two-step mechanism comprising two successive steps of one-proton transfer.



The concerted reaction and the first step in the stepwise process occur in less than 100 fs, while the last step requires ~10 ps.

One of the studies cited [84] is devoted to the dependence on the excitation energy of the ratio of the reaction yields obtained from the different channels. It was shown that an increase in the vibrational energy in the electronically excited state S_1 results in a higher ratio of the yields of mono- and diketo tautomeric products. The predominance of the concerted mechanism at low excitation energies was attributed to the fact that there exists a potential barrier for the first step, which affords the monoketo tautomer. Due to presence of an electrophilic substituent in these molecules, the one-proton transfer takes place.[88] This was demonstrated using tautomerisation of 6-methoxycarbonyl-2,2′-bipyridine-3,3′-diol as an example. The one-proton transfer in this molecule takes < 150 fs.

Yet another example is provided by the proton transfer processes in 7-azaindole dimers. They can be regarded as model processes mimicking tautomerisation in DNA pairs. Time evolution during the intramolecular tautomerisation of 7-azaindole dimers containing two N—H bonds has been investigated.[89] The molecular structures in which the transfer of one or two protons takes place are shown below



On exposure to a femtosecond pulse at 305–310 nm, the dimers formed in a molecular beam passed to an electronically excited state. Ionisation of various structures under the action of the probe pulse (wavelength 605 nm) took place at different points in time after the pump pulse. The result of ionisation was recorded by a time-of-flight mass spectrometer. The femtosecond temporal resolution made it possible to follow the motion of protons in each intermediate and to determine the characteristic times of this motion in the absence of a solvent. It was found that the first step of proton transfer occurs in several hundreds of femtoseconds, while the second step, which yields tautomer, is much slower, it proceeds over a period of several picosends. When the hydrogen atoms are replaced by deuterium atoms, the time scales of tautomerisation reactions change substantially. The mechanism of these processes has been discussed,[89] in particular, the role of quantum tunnelling in it. Nevertheless, the question of whether the two-proton transfer follows a concerted or a stepwise mechanism has been brought up in subsequent studies.[90–92] In these publications, the possibility of existence of active and inactive dimers with respect to tautomerisaton reactions and the role of solvation effects are discussed. It was shown [91] that clustering of water does not induce the formation of reaction-inactive dimers; the researchers concluded that the two-proton transfer follows a stepwise mechanism. However, Catalan *et al.*[92] believe that this transfer in 7-azaindole dimers occurs by a concerted mechanism. The conclusions made in this study provoked scientific discussion. Remarks concerning the publication cited [92] can be found in a study by Folmer *et al.*[93] The authors investigated this reaction using the 'Coulomb explosion' technique and concluded that it follows a stepwise mechanism.

VI. The kinetics of ultrafast chemical reactions

Study of the kinetics of a process includes monitoring of the time evolution of the concentration of a reactant or a product. This means that the populations of quantum levels rather than the dynamics of wave packets should be detected (we are not interested in the phase caracteristics of the nuclear motion). The features of femtosecond pulses significant for this line of femtochemistry include high temporal resolution and high intensity. Using these pulses with multiphoton absorption, it is possible to produce and to study molecules in high electronic states the lifetimes of which are very short.

Currently, vigorous studies dealing with the chemistry of highly excited molecules are being carried out. It is obvious that the rates and the ratios of channels of these reactions depend substantially on intramolecular processes such as conversion from highly excited electronic states, S_n, energy redistribution over vibrational modes and vibrational relaxation caused by intermolecular energy transfer to the solvent.

In a study of electron relaxation, it has been shown [94,95] that excitation of high electronic states in, for example, coumarin 481, oxazine 1 and sulforhodamine, is accompanied by internal conversion processes ($S_n \rightarrow S_1$), which occur in 180–280 fs. This conclusion is based [94] on the results of the following experiments. Coumarin 481 molecules in cyclohexane were excited by a pulse (duration 100 fs, wavelength 267 nm) to some electronic state S_n, the energy level of which is 12 000 cm^{-1} higher than the energy level S_1. From measurement of the kinetics of fluorescence (the up-conversion) related to the $S_1 \rightarrow S_0$ transition, the researchers reached a conclusion about the time characteristics of the $S_n \rightarrow S_1$

internal conversion. By investigating intramolecular processes for various porphyrins, it was found that the lifetime of the porphyrin molecule as the free base (H_2P) in the S_3 state is shorter than 40 fs, while that in the S_2 state is 90 fs. These and other data attest that the time scale of these processes is < 300 fs.

In some publications (see, for example, Refs 96–100), it is concluded that intramolecular energy redistribution occurs much faster, namely, in tens of femtoseconds. A somewhat different opinion was expressed by Hasche *et al.*,[100] who consider that redistribution of vibrational energy is faster (30–200 fs) for approximately iso-energetic vibrational levels and slower (200–1000 fs) for vibrational levels with appreciably different frequencies. Much longer times are required for relaxation of vibrational energy, *i.e.*, for the transfer of vibrational energy to the molecules of the environment. The time scale of these processes is about tens of picoseconds.[94, 101]

Let us consider examples of kinetic measurements for reactions of the following classes: bond rupture in electronically excited molecules, elimination of electronically excited molecules, decomposition of vibrationally excited molecules in the ground electronic state, photoisomerisation, bimolecular reactions in van der Waals complexes, bimolecular association reactions (*i.e.,* reactions in which the reactants are free and no chemical transformations take place upon collision; however, for definite distances between the reactants, photon absorption can take place; this induces the formation of a bond).

Examples of unimolecular reactions proceeding within femto- and sub-picosecond time scales are presented in Table 2. Below we discuss these reactions in more detail.

Table 2. Characteristic times (τ) of some ultrafast unimolecular reactions.

Reaction number	Reaction	t /fs	Ref.
Bond rupture in electronically excited molecules			
1	$(ICN)^e \rightarrow I + CN$	200	102
2	$(CH_3I)^e \rightarrow CH_3 + I$ (see [a])	100–200	103
3	$(CD_3I)^e \rightarrow CD_3 + I$ (see [a])		
4	$(C_2F_4I_2)^e \rightarrow (C_2F_4I)^* + I^*$ (see [b])	200	77
5	$(C_2F_4I_2)^e \rightarrow (C_2F_4I)^* + I$		
Elimination from electronically excited molecules			
6	$(CH_2I_2)^e \rightarrow CH_2 + I_2(D')$ (see [a])	< 100	52
7	$(NH_3)^e \rightarrow NH(c^1) + H_2$ (see [c])	< 50	104
Isomerisation of electronically excited molecules			
8	Isomerisation of spironaphthooxazine, multistep process	3000	21, 105, 106
Tautomerisation of electronically excited molecules			
9	$A^e \rightarrow T^e$	60	107
10	$T^e \rightarrow$ decay (A^e is the ketone form of methyl salicylate, T^e is the enol form of methyl salicylate)	> 1000	107
Decomposition of vibrationally excited radicals in the ground electronic state			
11	$(C_2F_4I)^* \rightarrow C_2F_4 + I$ (see [c])	25 000	77
12	$(CH_3CO)^* \rightarrow CH_3 + CO$	500	76
13	$[CH_2(CH_2)_{n-2}C{=}O]^* \rightarrow CH_2(CH_2)_{n-2} + CO$ (n = 4, 5, 6, 10)	100	78

Note. The superscript '*e*' designates electronically excited species, and '*' marks vibrationally excited species. Excitation energy/eV: [a] 8; [b] 4.7; [c] 10.

Dissociation of ICN from an electronically excited state (see Table 2, reaction *1*) takes place on the repulsive term. The kinetics of formation of the CN product has been measured experimentally.[102] The time of bond rupture was determined by comparing experimental data (obtained with ultrahigh temporal resolution) with the results of calculations in terms of the diatomic approximation.

After decomposition of the $(CH_3I)^e$ and $(CD_3I)^e$ molecules (see Table 2, reactions *2* and *3*) (each molecule gained an excitation energy of 8 eV due to two-photon absorption) from Rydberg states, the time evolution of processes was recorded for 100–200 fs.[103] An appreciable isotope effect was observed.

The electronically excited $(C_2F_4I_2)^e$ molecule is formed after exposure of $C_2F_4I_2$ to a femtosecond light pulse with a wavelength of 277 nm. Decomposition of the electronically excited molecule takes place along two channels over a period of 200 fs giving rise to the vibrationally excited $(C_2F_4I)^*$ radical in the ground electronic state and a iodine atom. One channel provides an electronically excited iodine atom, and the other channel, a non-excited iodine atom (see Table 2, reactions *4* and *5*, respectively).

Both mechanisms of decomposition of $(C_2F_4I_2)^e$ and the mechanism of decomposition of the $(C_2F_4I)^*$ radicals formed in the ground electronic state have been studied.[77] The results of this study are discussed in more detail below, when considering the processes with participation of vibrationally excited radicals in the ground electronic state.

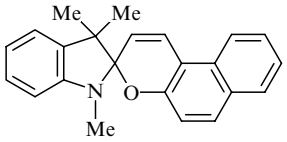
Elimination reactions of highly excited molecules occur due to multiphoton absorption. Femtosecond pulses have a high on-peak power; therefore, multiphoton processes readily take place. An example is reaction *6* (see Table 2), namely, gas-phase decomposition of a CH_2I_2 molecule excited by multiphoton absorption, induced by absorption of two photons with a wavelength of 310 nm (excitation energy 8 eV).[52] One product of this reaction is molecular iodine, which exists in a non-stationary quantum state; reaction time < 100 fs. Note that for low excitation energies, rupture of the C–I bond to give an iodine atom is the main reaction channel.

Yet another example is decomposition of ammonia induced by five-photon absorption ($\lambda = 615$ nm).[104] If the excitation energy of the ammonia molecule is 10 eV, decomposition by reaction *7* takes place (see Table 2); if it amounts to ~ 8 eV, the following reaction proceeds:

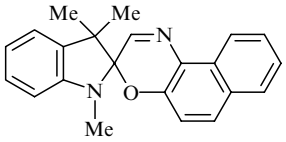
$$NH_3 \longrightarrow NH_2 + H.$$

These examples illustrate the potential of methods with the use of femtosecond pulses for the development of the chemistry of electronically excited molecules.

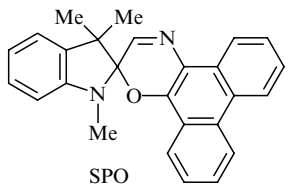
A large number of publications are devoted to photoisomerisation induced by femtosecond pulses (see, for example, papers [9, 21, 105–117]). In particular, many studies deal with isomerisation of electronically excited molecules of various photochromic compounds in solutions. On exposure to light, photochromic compounds can undergo reversible intramolecular transformations accompanied by a change in the absorption spectrum. This property of photochromic compounds can be used for generation of various optico-electronic devices. In particular, the possibility of using them for three-dimensional optical memory is discussed.[115, 116] Let us consider photoisomerisation of unsubstituted indoline spiro compounds, namely, spironaphthopyran (SNP), spironaphthooxazine (SNPO) and spirophenanthrooxazine (SPO).



SNP

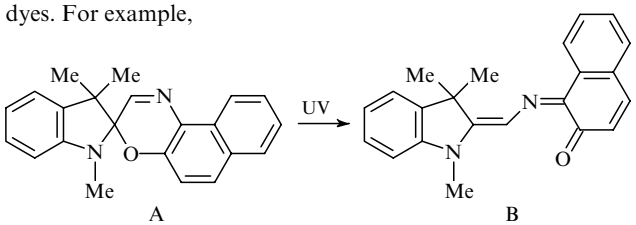


SNPO



SPO

Photoisomerisation is transition of form A into form B, which has a planar structure similar to the structure of merocyanine dyes. For example,



A B

Femtosecond pulses with durations of 170–400 fs have been used.[112–114] It was found that isomerisation proceeds *via* singlet states and is completed within a picosecond time scale.

The mechanism of these reactions has been studied in more detail in several publications.[21, 105, 106] The pump pulse centred at a wavelength of 308 nm had a duration of 70 fs. Probing was performed using a supercontinuum in the spectral range of 420–590 nm. For each of the three compounds, the dynamics of the photoinduced absorption spectra was recorded with a high temporal resolution for different time intervals after the action of the pump pulse. Figure 8 illustrates the dynamics of the photoinduced absorption spectra recorded experimentally for spirophenanthrooxazine. It was found that the reaction mechanism does not change when the position of the aromatic rings changes. On the basis of experimental data and quantum-chemical calculations, a photoisomerisation mechanism including the following processes was proposed:

(0) $A(S_0) + h\nu \longrightarrow A(S_2)$,

(1) $A(S_2) \longrightarrow A(S_1)$,

(2) $A(S_1) \longrightarrow X^*$,

(3) $X^* \longrightarrow B$.

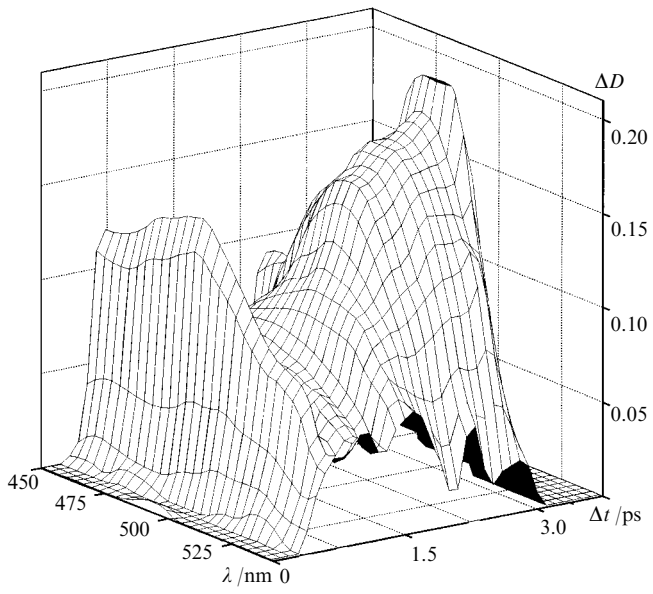


Figure 8. Dynamics of the photoinduced absorption spectra for SPO.[106] ΔD is the optical density change.

Here $A(S_i)$ ($i = 1, 2$) is molecule A in the singlet electronic state S_i; X is an intermediate species, which is characterised by rupture of the bond between spiro carbon and oxygen. It is worth noting that the experimental approach developed in a series of publications[21, 104] made it possible to observe the time evolution of the $S_2 \rightarrow S_1$ transition, vibrational relaxation in the S_1 electronic state, the formation of the intermediate species X*, which is the *cis*-cisoid isomer in the electronically excited state, and the formation of X and of the reaction products — forms B of the corresponding spiro compounds. The last-mentioned reaction includes the following steps: non-adiabatic $X^* \rightarrow X$ transition and the transition of X into species B. However, it was impossible to separate these steps in time, due to the superposition of the absorption spectra for species X and B. Therefore, both steps are written as a single reaction, which appears to be limited by the rotation of the molecule about bonds of the opened ring. The results of experimental studies for SNPO are shown in Fig. 9. Absorption of a light quantum brings the molecule to the S_2 excited state. This is followed by transition to the vibrational levels of the S_1 electronic state. This transition shows itself as accumulation of molecules $A(S_1)$; this is detected by a change in the absorption spectra observed for delays of up to 110 fs (Fig. 9 *a*). The next stage is transition of molecule $A(S_1)$ into the state X* (this intermediate state was observed by low-temperature phosphorescence[109]), which is characterised by rupture of the bond between the spiro carbon atom and the oxygen atom. The species X* is detected on the basis of absorption spectra in the spectral range of 420–450 nm; the variation of the concentration of X* is illustrated by Fig. 9 *b*. The next step is non-adiabatic transition of the system from the excited state X* to the ground electronic state X. The molecule acquires the possibility of rotating around the

Δt /fs: (*a*) −110 (*1*), 0 (*2*), 73 (*3*), 185 (*4*); (*b*) 665 (*1*), 739 (*2*), 812 (*3*), 886 (*4*), 960 (*5*), 1034 (*6*); (*c*) 960 (*1*), 3600 (*2*), stationary absorption spectrum of the reaction product (*3*).

bonds of the opened ring. Figure 9 *c* shows the variation of the absorption spectra associated with this process. The absorption spectrum for a delay of 3.6 ps shown in the same figure is similar to the known steady-state absorption spectrum of form B.

The calculation of the dynamics of this reaction is as yet too complicated; therefore, the experimental data were processed within the framework of the kinetic scheme presented above. This processing made it possible to describe quantitatively the three-step mechanism of photoisomerisation of the compounds under consideration in terms of the rate constants k_i (i = 1, 2, 3). The following values were obtained (fs):

Compound	k_1^{-1}	k_2^{-1}	k_3^{-1}
SNP	100	250	1800
SNPO	80	230	1000
SPO	100	300	2000

It can be seen that the rate constants found for the three compounds are virtually equal. Only the k_3 value, which, as noted above, is determined by the rate of rotation around the C–C and C–N bonds, does differ substantially in the case of SNPO. This is apparently due to the fact that rotation around the C–C bonds occurs more easily than rotation around the C–N bonds.[118]

Of substantial interest for researchers are tautomerisation reactions in which intramolecular proton transfer takes place. These reactions are involved in many chemical and biological systems; in some systems, these processes are photochromic, although no pronounced structural changes take place.

Tautomerisation has been studied in the vapour phase,[119] in supersonic molecular beams [89] and in solutions.[83, 84, 90–92, 120, 121] Herek *et al.*[119] investigated the methyl salicylate system in which a proton migrates from one oxygen atom to the other. This process is accompanied by the change of the structure from the ketone form (before the transfer) to the enol form (after the transfer). The authors consider that the proton transfer takes place over a period of 60 fs. At longer times (picosecond time scale), non-radiative decay of the resulting structure takes place, caused by intramolecular energy relaxation or dissociation. In the studies mentioned above [83, 84, 89, 90–92] dealing with one- and two-proton transfer reactions in bipyridinediols and 7-azaindole dimers, it was found that the transfer of two protons can occur both as a synchronous process and as two consecutive steps. Each step includes the transfer of one proton, the first proton migrating much faster than the second one. Neuwahl *et al.*[120] studied the same processes but employed other experimental methods. This work confirmed the results of a previous study;[83] according to these estimates, primary processes of one- and two-proton transfer in bipyridinediols occur over periods of < 50 fs.

The researchers cited above consider that the proton transfer takes place in electronically excited states. A different point of view is expressed by Takeda *et al.*,[121] who studied intramolecular proton transfer in 2-(2′,4′-dinitrophenyl)pyridine; they assumed that no intermediate or final products in excited states are formed. Only three different intermediate photoinduced absorption spectra were observed in the experiments. To interpret experimental data, they proposed a model which is often used to describe photochromic reactions. Under the action of excitation, the molecule passes into the singlet excited state S_1 (the $S_1 \rightarrow S_n$ transition was observed experimentally); relaxation of the excited state gives rise to an intermediate product in its ground electronic state, and subsequently, the final product is formed. According to author's estimate, the intramolecular proton transfer requires 320–500 fs. This is several times longer than the duration of proton transfer in other systems.[122, 123] In our opinion, the absence of excited intermediate species is unlikely. The assumption of the researchers cited [121] is based on the fact that they did not observe any luminescence. However, we have considered above a model of photoisomerisation of spiro compounds in which photoinduced absorption by the intermediate electronically excited product without luminescence was recorded.

Most of unimolecular reactions with photoactivation proceed in accordance with statistical laws. This is due to the fact that intramolecular redistribution of energy occurs in 0.1–1 ps, *i.e.*, over a period much shorter than the characteristic time of decomposition of the molecule. For a reaction not to obey the statistical laws, decomposition must be faster than the intramolecular redistribution of the vibrational energy. This requires a very fast excitation of the molecule to high energies. This process has been realised.[68] The molecule passed into an electronically excited state upon the action of a femtosecond pulse. Fast decomposition of the electronically excited molecule gave rise to vibrationally excited radicals in the ground electronic state. The degree to which the vibrational excitation surpasses the potential barrier to radical decomposition in the ground electronic state depends on the height of the barrier and on the wavelength of the pump light pulse. By adjusting the wavelength of the pump light pulse and by choosing an appropriate molecular system, one can obtain radicals with either slight or substantial vibrational excitation exceeding the potential barrier. The above-mentioned decomposition of vibrationally excited $(C_2F_4I)^*$ radicals generated in reactions *4* and *5* can be considered as an example of the former situation. The vibrationally excited radical decomposes along two pathways to give C_2F_4 together with excited or non-excited iodine atoms

$$(C_2F_4I)^* \longrightarrow C_2F_4 + I, \qquad \text{(reaction } 14\text{)}$$

$$(C_2F_4I)^* \longrightarrow C_2F_4 + I^*. \qquad \text{(reaction } 15\text{)}$$

The reaction was studied in a supersonic molecular beam using a time-of-flight mass spectrometer (multiphoton ionisation was induced by a second femtosecond pulse with a wavelength of 304 nm). The kinetics of product formation, the velocity distribution of I and I* atoms and the anisotropy of product dispersion in reactions *4*, *5* (see Table 2) and *14*, *15* were measured. The yields of I and I* atoms were 0.7 and 0.3, respectively. The average proportion of the translational energy was 59% for reaction *4* and 67% for reaction *5*. With allowance for the energy conservation law, the distribution of internal energy in the intermediate $(C_2F_4I)^*$ radical was determined. This distribution proved to be broad and to have two maxima located at 12 and 17 kcal mol^{-1}.

The vibrationally excited radical decomposes over a period of 25 ps. The measurements showed that only 30% of the excited radicals formed in reaction *4* decompose by channels *14* and *15*. On the basis of this result and of the distribution of internal energy in the radical, the potential barrier to reaction *14* was estimated to be $\sim$15 kcal mol^{-1}. Preliminary calculations resorting to the statistical theory indicate that decomposition by pathway *14* takes place within a picosecond time scale, which is in line with experimental results (although analysis of the velocity distribution of I and I* atoms showed that some molecules decompose faster than it follows from calculations).

Yet another example is decomposition of highly vibrationally excited $(RCO)^*$ radicals in the ground electronic state.[76] On exposure to a femtosecond pulse, electronically excited acetone molecules R^1COR^2 (R^1 = Me, R^2 = Et) are formed. Decomposition of electronically excited molecules (excitation energy 186 kcal mol^{-1}) takes place over a period of $\sim$100 fs. This affords vibrationally excited $(R^1CO)^*$ and $(R^2CO)^*$ radicals in the ground electronic state. Decomposition of the acetyl radical requires 500 fs (that of the propionyl radical lasts 750 fs) for an excitation energy of $\sim$65 kcal mol^{-1}. This time of decomposition is much shorter than the time calculated in terms of the Rice–Ramsperger–Kassel–Marcus (RRKM) statistical theory. This low rate of radical decomposition has been attributed [76] to the fact that upon photoexcitation, only a minor part of vibrational energy (less than the equilibrium energy) is evolved on the reaction coordinate, namely, the C–C bond.

The next example refers to the research into highly vibrationally excited radicals of the $[CH_2(CH_2)_{n-2}C=O]^*$ type in their ground electronic state.[78] The number of carbon atoms n in these

radicals was 4, 5, 6 and 10. These radicals were formed upon photodissociation (which took 100 fs) of the corresponding cyclic ketones. Decomposition of the vibrationally excited radicals does not obey statistical laws. This is proved by two facts. First, the reactions occur over a period of ~ 100 fs, which is several orders of magnitude shorter than the values calculated in terms of the statistical theory. Second, the reaction time barely depends on the number of carbon atoms in the radical and hence, on the number of vibrational degrees of freedom.

Thus, using femtosecond procedures, it is possible to generate vibrationally excited radicals with various, including non-statistical, distributions of intramolecular energy and to study decomposition of these radicals. An approach to the investigation of intramolecular processes at high vibrational energies and new ways of conducting reactions to circumvent the statistical laws have been considered.[76]

A complicated experimental problem of femtochemistry is fixing the zero point of time. Therefore, the question of the possibility of investigation of bimolecular reactions in van der Waals complexes has long remained open. The following approach has been proposed.[85] A weakly bonded van der Waals complex (VDWC) incorporating a molecule of one reactant is assembled in a supersonic molecular beam. Under the action of a femtosecond pulse, the second reactant is formed in the VDWC. In this case, the instant of action of the light pulse which generates the reacting system can be taken to be zero. Some examples of bimolecular reactions studied by femtosecond spectroscopy techniques are listed in Table 3.

Table 3. Examples of bimolecular reactions in VDWC.

Reaction number	Reaction	VDWC	t /fs	Ref.
Exchange reaction				
16	$H + CO_2 \rightarrow OH + CO$	$IH\cdots CO_2$	1000	124
Reactions with electron transfer				
17	$PhH + I_2 \rightarrow PhHI + I$	$PhH\cdots I_2$	1000	125
18	$PhH + I_2 \rightarrow PhHI + I^*$	$PhH\cdots I_2$	200	
Photoassociation reaction				
19	$Hg + Hg + h\nu \rightarrow Hg_2$	–	–	126

The first example is bimolecular reaction *16* in the $IH\cdots CO_2$ VDWC. On exposure to the light pulse, the I–H bond is cleaved. This point in time is taken to be zero. The hydrogen atom starts to move and then reacts with CO_2 to give the OH radical. If the structure of the complex is known, it becomes possible to study the bimolecular reaction that takes place with a specified rate and a specified impact parameter. In this particular case, it was shown [124] that reaction *16* proceeds *via* the step of formation of a long-lived complex over several picoseconds. A similar technique has been utilised to study [127] the bimolecular reaction

$$Br + I_2 \longrightarrow BrI + I.$$

The second example includes charge transfer reactions *17* and *18*. These reactions have been studied using various electron donors (D), for example, $D = C_6H_6$,[125] C_2H_5S.[128] A common feature of these reactions is a correlation between the ionic and covalent terms. In these reactions, the weakly bonded D···I complex consists of electron-donor molecules D and iodine. The complex was irradiated by a femtosecond pulse; as a consequence, the molecular system passed to a transition state in the ionic part of the potential curve (Fig. 10). This means that an electron has passed from the donor to the acceptor. The system moves along the term, enters the area of Coulomb attraction and approaches the avoided crossing point at which two channels of product

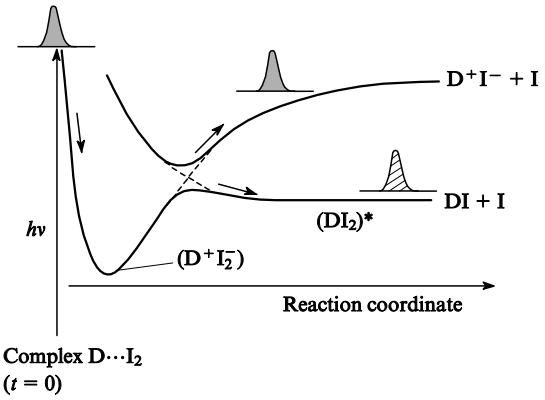

Figure 10. Chart of the potential energy change along the coordinate of the reaction $D\cdots I_2 \rightarrow DI + I$ (or $D^+I^- + I$).
After absorption of light by a weakly bound complex, the nuclei start to move towards the pseudo-crossing point of the ionic and covalent terms; after the pseudo-crossing point has been passed, two reaction channels appear.

formation appear. In the studies under consideration, the iodine atom was detected and its velocity was measured by time-of-flight mass spectrometry. As a rule, the formation of iodine atoms with two different velocities corresponding to the two channels was observed (for example, if benzene is used as the electron donor, these velocities are 400 and 1000 m s^{-1}). The channel yielding the excited iodine atom (the faster iodine atoms) is implemented over a period of 200 fs, while the channel giving rise to the non-excited iodine atom is performed in 1000 fs.

The third example is bimolecular photoassociation *19* in which an excited Hg_2 molecule is produced from two mercury atoms under the action of a femtosecond pulse. The potential curve for the Hg_2 molecule is repulsive. The femtosecond pulse allows the system to switch from the repulsive state to the binding state. The resonance character of this transition is determined by the pulse wavelength and the distance (the impact parameter) separating the mercury atoms in the ground electronic state. Thus, by varying the pulse wavelength, the mercury atoms participating in the reaction can be selected according to their impact parameters. The dynamics of the excited molecules thus formed can be studied by time-resolved fluorescence methods.

In the examples discussed above, the molecular systems were considered to be isolated. However, if the chemical reaction occurs in solution, the solvent has a substantial influence on it. After excitation of the molecular system by a femtosecond pulse, two types of fast dynamic processes can take place, namely, intramolecular processes (redistribution of electronic and vibrational energy) and intermolecular processes (vibrational relaxation and solvation of excited molecules). Information concerning these processes is gained most often from the shifts of time-resolved absorption, fluorescence and stimulated emission spectra for times of less than several picoseconds.[129–131] It was found that in many cases, the dynamics of solvation includes two steps, a faster step with a duration of < 200 fs and a slower step occurring within the picosecond time scale. The fast step is often attributed to intramolecular processes, while the slow step is ascribed to intermolecular relaxation, the formation and destruction of hydrogen bonds, *etc*.

The interaction of the solvent with the dissolved substance has a substantial influence on not only intermolecular but also intramolecular processes in the latter. Thus in a study of the dynamics of formation and rupture of a hydrogen bond and its influence on the rate of relaxation of the *trans*-retinal molecule in the S_3 and S_2 electronic states in a butan-1-ol–cyclohexane mixture,[132] it was found that the lifetime of the molecule in the S_3 state in pure cyclohexane is 30 fs, while that in the S_2 state is 0.7 ps; upon the

addition of butanol, these periods increase by factors of ~ 7 and ~ 2.5, respectively. The increase in the lifetime of the molecule in the S_2 state resulted in higher quantum yields of fluorescence and isomerisation. In another publication,[131] bithiophene, tertiophene and quaterthiophene oligomers have been studied in solution and photoinduced absorption and fluorescence spectra have been detected. For time periods of < 1 ps after excitation, spectral shifts were observed; they were interpreted as relaxation processes, resulting in an equilibrium between the excited oligomers and their solvation shells.

Femtosecond vibrational spectroscopy can serve as an efficient tool for the study of solvation mechanisms. For example, coumarin 102 has been studied (using C_2Cl_4 and $CHCl_3$ as solvents).[133] The carbonyl group of coumarin dyes was found to be linked to a solvent molecule by a hydrogen bond; the researchers showed how the presence of this bond is manifested in the dynamics. In the experiment, coumarin 102 was transferred to the electronically excited S_1 state by the action of a 100-fs light pulse with a frequency of 1500 to 1750 cm^{-1}, and the evolution of the absorption vibrational spectrum in the ground and in excited states and in polar ($CHCl_3$) and non-polar (C_2Cl_4) solvents was detected with a temporal resolution of 200 fs. In the spectrum of a coumarin solution in a non-polar solvent, the absorption band of the C=O bond was located at 1735 cm^{-1}, which is a characteristic frequency for a free carbonyl group. For the electronically excited state, a decrease in the dipole moment of the transition was observed; however, no significant shift of the C=O vibration band was found. In the case of a coumarin solution in a polar solvent, the absorption frequency of the C=O vibrations is markedly displaced, namely, to 1700 cm^{-1} for the coumarin molecule in its ground electronic state. This shift is attributed to the presence of a hydrogen bond between the $CHCl_3$ molecule and the C=O group of coumarin in its ground electronic state. For the electronically excited state, the frequency of the C=O mode shifts to 1740 cm^{-1}, *i.e.*, it is close to that in a non-polar solvent. This points to the absence of a hydrogen bond in the electronically excited state.

In the examples considered above, we virtually did not mention studies dealing with femtosecond processes in proteins. Detailed information concerning these processes has been reported.[53, 57, 134–138]

VII. Control of intramolecular dynamics and an elementary chemical event

Chemical reactions are controlled at the macroscopic level by changing reaction conditions — pressure, temperature and other parameters. Attempts at controlling an elementary reaction by changing the character of the interaction of light with reactants have been undertaken long ago.[139]

The development of femtosecond pulses, which permit one to change the transition state dynamics, opens new, in principle, opportunities of controlling an elementary chemical reaction and, hence, the product yield. Let us consider various approaches which can be helpful in developing this line of research.

1. Non-statistical unimolecular reactions. The approach using non-statistical unimolecular reactions is based on the generation of vibrationally excited molecules with such an intramolecular distribution of vibrational energy that the unimolecular reaction proceeds to give desired products. The attempts to perform selective reactions in this way have been made for one-photon[140] and infrared multiphoton excitation.[141] However, it was found that unimolecular reactions induced by photoactivation took place in line with statistical laws, according to which the rate constants for these reactions do not depend on intramolecular energy distribution but are dictated by the total vibrational energy. This was due to the fact that intramolecular energy redistribution occurs faster (within 0.1–1 ps) than decomposition of the molecule. In order to control the decomposition route and to obtain desired products, it is necessary to localise the excitation energy in a particular fragment of the molecule; this should be done during the reaction.

This method of control can be realised using femtosecond pulses. Under the action of these pulses, the molecules are excited very rapidly; due to multiphoton absorption, the excitation energy can be so high that decomposition occurs faster than the intramolecular energy redistribution; the initial intramolecular distribution of the excitation energy can be changed by varying the amplitude and phase characteristics of the femtosecond light pulse.

The reactions considered above can serve as examples of processes in which femtosecond pulses are used to study non-statistical decomposition of vibrationally excited radicals. The first example is decomposition of the highly vibrationally excited $(R^1CO)^*$ and $(R^2CO)^*$ radicals (R^1 = Me, R^1 = Et) in their ground electronic state.[76] These radicals are formed upon decomposition of ketone molecules R^1COR^2 induced by a femtosecond pulse and taking 50–100 fs. When the vibrational excitation energy is ~ 65 kcal·mol^{-1}, rupture of the C–C bond in the acetyl radical takes place in 500 fs. This decomposition period is ten times as long as that calculated in terms of the RRKM statistical theory. According to the researchers' viewpoint, upon decomposition of the parent ketone molecule, the vibrational energy in the resulting $(R^1CO)^*$ and $(R^2CO)^*$ radicals is distributed non-uniformly; more precisely, only a minor portion of this energy has evolved onto the reaction coordinate along the C–C bond. During 500 fs, the vibrational energy does not have time to be redistributed; therefore, this coordinate receives less vibrational energy than expected in accordance with the statistical law.

The second example is stepwise decomposition of cyclic ketones with various numbers of carbon atoms (n = 4, 5, 6 and 10). After excitation of the molecules of cyclic ketones by a femtosecond pulse, the first C–C bond is cleaved to give radicals of the $[CH_2(CH_2)_{n-2}C=O]^*$ type in their ground electronic state. This cleavage requires ~ 50 fs. The species thus formed contains a store of non-statistically distributed vibrational energy, which is much greater than the energy needed to split off the carbon oxide. It was shows[78] that the rates of decomposition calculated by the statistical theory are two to four orders of magnitude lower than the measured rates. It was also noted that the measured decomposition rates virtually do not depend on the number of atoms in the decomposing species, whereas calculations in terms of statistical theory predict a decrease in the rate of decomposition by orders of magnitude following the change in the number of carbon atoms from 4 to 10. These results can be interpreted only by assuming that biradicals formed in the ground electronic state have a substantial energy of vibrational excitation in the reaction coordinate sufficient for their subsequent decomposition. Since decomposition proceeds faster than the energy redistribution over various vibrational modes, initially, there is much more energy in the reaction coordinate than would be there after statistical redistribution of the vibrational energy.

Hence, if decomposition can follow two channels, then, using femtosecond pulses, it is possible to create molecules in which the vibrational energy located on the reaction coordinate of one channel exceeds the threshold value, while that on the reaction coordinate of the other channel is lower than the threshold value. Thus, by varying the fraction of the vibrational energy on one or another reaction coordinate, one can direct the reaction along one channel.

2. Dynamics of wave packets. The known methods for laser separation of isotopes proposed by Letokhov[141] are based on small isotope shifts in the spectra of atoms and molecules. To implement these methods, monochromatic laser sources with tuned wavelength are required. An experiment dealing with the laser separation of bromine isotopes using femtosecond pulses has been described.[142]

The new approach to the separation of isotopes makes use of specific features of the wave packet dynamics. If wave packets for the isotopes of bromine molecules ($^{79}Br_2$ and $^{81}Br_2$) are created,

the wave packet dynamics in the two isotopic molecules will be different. During short periods of time, the differences related to the dissimilar vibration frequencies are insignificant. However, the time evolution of wave packets goes through periodic destructions and revivals.[37] Therefore, the deviations of the wave packet dynamics are accumulated in the isotopic molecules, and at times of the order of tens of nanoseconds, they would be sufficient for choosing the instant for acting upon the molecule of only one isotope by another femtosecond pulse. Averbukh *et al.*[142] employed a 100-fs pulse tunable in the region of 550 – 590 nm for the formation of wave packets. The second femtosecond pulse having the same duration and a wavelength of 340 nm was used for ionisation. The delay between the pulses was varied up to 50 ps. Ionised molecules were detected using a time-of-flight mass spectrometer. An isotope ratio of ~250% was attained.

3. Action on the PES. Femtosecond pulses can be used to control the dynamics of the transition state by changing the PES at the required time instant. Let us consider a simple example. Suppose that there are two crossing terms with different types of symmetry; a wave packet moves along one of the terms, without 'feeling' the other term, and forms products C and D. At the instant the wave packet approaches the crossing point of the terms, a femtosecond pulse acts upon the PES. The pulse would induce splitting of the terms. As a consequence, the wave packet continues moving but along the other potential term; this may give products A and B. This approach to the control of the reaction has been proposed and implemented in experiments on photodissociation of OClO.[143] The reaction proceeds by two channels

$$\mathrm{OClO} + h\nu \begin{cases} \rightarrow \mathrm{O} + \mathrm{ClO} \\ \rightarrow \mathrm{Cl} + \mathrm{O_2} \end{cases}$$

For low intensities of the pump pulse, both products are formed in a ratio corresponding to known published data. However, as the intensity of the pump pulse increases, the rate along the channel resulting in molecular oxygen starts to increase non-linearly, while the rate along the channel yielding ClO decreases. The time delay between the pump and probe pulses in these experiments was 40 ps. In the authors' opinion, these changes are due to distortions of the potential energy surface. The following model is possible: the pulse induces the formation of the electronically excited state $^2A_2$ ($^2A_2 \leftarrow X\,^2B_1$). This is followed by internal conversion to the $^2A_1$ electronic state, from which dissociation of OClO takes place to give ClO. Transition to the $^2B_2$ state is hindered; therefore, the amount of molecular oxygen formed is small. Upon an increase in the intensity of the pump pulse, the PES is distorted and transition to the $^2B_2$ state occurs much more easily; therefore, the fraction of the molecular oxygen increases. The yield of molecular oxygen increases following an increase in the pump pulse intensity (I) in proportion to I^4. In the study cited, the $\mathrm{ClO} : \mathrm{O_2}$ ratio varied by a factor of 12 and the intensity of the excitation field reached a value of 1.5×10^{12} W cm^{-2}.

It should be noted that intensities of 10^{18} W cm^{-2} can be attained in a field of focussed femtosecond pulses; therefore, the light field strength can reach 10^{10} V cm^{-1}. Thus, we can deal with fields exceeding the intraatomic fields (10^9 V cm^{-1} for the hydrogen atom). Under the action of so strong fields, distortion of PES can take place for a short period. The use of strong fields for the target-directed distortion of PES would apparently be an object of the future studies.

4. Dynamics of non-adiabatic transitions. A scheme for controlling the molecular evolution with the use of non-adiabatic transitions up and down in energy was first proposed by Tanor and Rice.[144] The scheme assumes the possibility of acting at a required instant upon the wave packet, generated by a pump pulse, by another pulse in order to bring the system to a different state. This approach is illustrated by Fig. 11, which shows the variation of the potential energy along the reaction coordinate for two electronic terms. Let us consider the molecule ABC. If there is

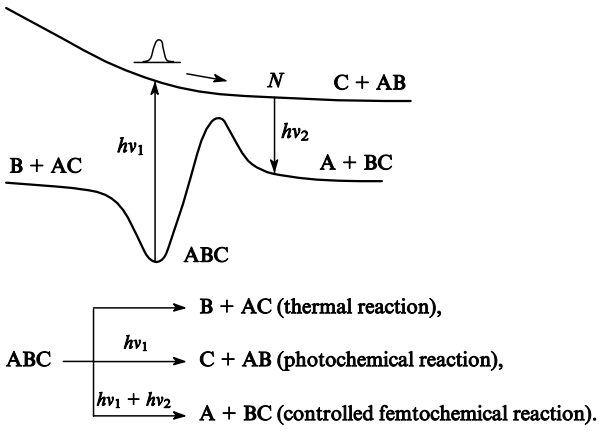

Figure 11. Scheme for the control of the reaction using non-adiabatic transitions performed at definite time instants.

a high potential barrier on the right, only B and AC can be formed as the reaction products in the case of thermal activation. Upon photoactivation by stationary light, the reaction yields C and AB. Irradiation with a femtosecond pulse gives a wave packet, which moves along the direction marked by the arrow. In femtochemistry, the wave packet dynamics is controlled in the real-time mode. By acting on the molecular system by a femtosecond pulse at the instant the wave packet reaches point N (to shift it down in energy to the right slope of the potential barrier), the reaction can be directed at the selective formation of only products A and BC. It should be emphasised that in terms of the model considered, these products cannot be obtained using other activation methods. The formation of iodine molecules in different electronically excited states[145] and the formation of Na^+ or Na^{2+} ions induced by a pair of femtosecond pulses with different time delays between the pulses[146] can be regarded as experimental illustrations of this approach. However, no convincing examples of the experimental use of this type of control can be found in the literature yet.

5. Orientation dynamics — control of the geometry of reactant approach. The efficiency of a reaction both in the gas and in the condensed phases is known to depend substantially on the mutual orientation of the colliding partners. In the gas phase, a specified orientation of one reactant with respect to the other is usually attained in crossed molecular beams on application of uniform or non-uniform electric fields. In recent years, attempts to use electromagnetic field pulses for creation of molecules with a predominant direction of the dipole moment have been made more and more often. Femtosecond pulses are used for the formation of coherent rotational wave packets in the ground electronic state.[17, 147, 148] In this case, the orientation varies with time while repeating the previous orientations rather than remaining static, as in the case where conventional techniques are used. The control of the geometry of reactant approach can be clearly demonstrated in relation to bimolecular reactions in VDWC. An example is provided by bimolecular reaction *16* in the $\mathrm{IH}\cdots\mathrm{CO_2}$ van der Waals complex (see Table 3) considered above. Under the action of the first femtosecond pulse, the I—H bond is cleaved, and the hydrogen atom starts moving towards CO_2. At a certain instant, the second femtosecond pulse creates a coherent rotational packet in the CO_2 molecule. By changing the time delay between the first and second pulses, one can control flying of the hydrogen atom towards CO_2 molecules having different orientations, *i.e.*, study the dependence of the product yield on the geometry of reactant approach. Naturally, there can be any other molecule in place of CO_2.

6. Coherent dynamics. The approaches being developed most successfully are those in which phase characteristics of the laser pulses are used. Several theoretical approaches have been elaborated; they envisage the use of phase characteristics of the exciting

light for controlling the yield of products in an elementary reaction. Shapiro and Brumer [149] proposed a scheme similar to the scheme of the interference of light which had passed along two channels and had arrived at the initial point with different phases. Similarly, two wave packets characterised by the wave functions ψ_1 and ψ_2 can follow different paths. If they come to the same final state, the probability of occurrence in this state is proportional to the total wave function squared. Hence, the amplitudes of the two wave functions should be summed up before squaring. The probability of the occurrence of the system in a particular state depends on the cross term which includes the phases of different wave functions. This approach has been implemented experimentally, for example, by Zhu *et al.*[150] A beam of DI molecules was excited by two laser beams, by one photon ($\lambda = 118$ nm) from the first beam and three photons ($\lambda = 354$ nm) from the second beam. The phase correlation between these beams was varied by passage of both light beams through a transparent gas medium: the refractive indices at different wavelengths are different; therefore, by varying the pressure inside the gas cell, one can control the phase. The excited DI molecules decay along two channels, $DI^+ + e^-$ and $D + I(^2P_{1/2})$. As expected, the relative yield is a sinusoidal function of the difference between the phases.

For creating a nuclear wave packet with definite phase and amplitude characteristics, the use of chirped femtosecond pulses has been proposed;[151] this would markedly simplify the control schemes for elementary chemical processes. First, under the influence of these pulses, multiphoton processes of light absorption occur more easily. Second, a femtosecond pulse is spectrally broad and it becomes possible to generate vibrational and rotational wave packets with different initial phases of the Fourier components by changing the phase characteristics of the pulse. Third, two wave packets with the wave functions ψ_1 and ψ_2 can be produced. The probability that the system occurs in a particular state depends on the cross term, which includes phases of different wave functions.

The influence of the chirp on the intramolecular dynamics and on photophysical and photochemical processes involving diatomic molecules is illustrated by examples presented in Table 4. It can be seen that the quantum yields in the processes considered above depend on the chirp of the pump pulse. When the pump pulse intensity is high (strong fields), the quantum yield of fluorescence of dyes in solution depends on the sign of the chirp (see the last example in Table 4).

Let us illustrate the variation in the vibrational dynamics for the iodine molecule in the electronically excited state as a function of the chirp sign.[37] For this purpose, we shall consider the results of calculations of the wave packet dynamics in the Wigner representation of the quantum state of the system, *via* the 'coarse-grained' Wigner distribution function in the phase space using relation (15). These calculations utilised the results of experiments performed under conditions where all the parameters including the magnitude of β remained invariant, only the sign of the chirp being changed. The dependence of the Husimi function W_H on the classical coordinate and the momentum (characterised by the change in the degree of blackening) for different times elapsed after absorption of the pump pulse is illustrated in Fig. 12. The density maps corresponding to wave packets formed by the pump pulse with $\beta = -2000$ fs^2 are shown at the left; those for the pulse with $\beta = 2000$ fs^2 are on the right. It can be seen that the wave packets formed by the pulse with a negative chirp retain localisation for much longer periods. This means that the intramolecular dynamics of atoms can be influenced by controlling phase characteristics of the pulses. By changing synchronisation of the atomic motion in the transition state and by varying phase characteristics of the pump pulse, one can control the transition state dynamics, *i.e.*, the product yields in an elementary chemical reaction.

Table 4. Examples of influence of the chirp on some physicochemical processes.

Process	Result	Ref.
$Na_2 + n\,h\nu \rightarrow Na^+ + e$ $Na_2 + n\,h\nu \rightarrow Na_2^+ + e$	the quantum yield of the ions depends on the chirp	152
$NaI + h\nu_1 \rightarrow NaI$ $(NaI)^* \rightarrow Na + I$ $(NaI)^* + h\nu_2 \rightarrow Na^* + I$	the Na*/Na ratio depends on the chirp	153
The vibrational dynamics of I_2 in the electronically excited state	the vibrational dynamics depends on the chirp	37, 154
The rotational dynamics of D_2 and N_2 in the ground electronic state	the rotational dynamics depends on the chirp	17, 147
Fluorescence of LD690 dye molecules	the fluorescence quantum yield depends on the chirp	155

In recent years, experimental works have been published, which demonstrated that the phase characteristics of the pulse can influence appreciably the channels of product yields in photodissociation of polyatomic molecules.

Multiphoton photodissociation of CH_2I_2 has been studied.[156] The normal channel for the photodissociation of this molecule is the formation of iodine atoms in the electronically excited and ground states and the CH_2I radical. However, it is known that in the case of one-photon absorption in the vacuum ultraviolet region (> 9 eV), one more channel exists ($\sim$1%), which affords molecular iodine in the $D'^3\Pi_g$ state and, to a small extent, in the electronically excited *f* states. In the study cited, the dependence of the multiphoton photodissociation of CH_2I_2 on the sign and the magnitude of the linear chirp was measured. Pulses with a carrier wavelength of 624 nm and with a duration of 47 fs were used in the experiments. Excitation was performed both by pulses centred at 624 nm and by pulses obtained by doubling the frequency, *i.e.*, centred at 312 nm. The value of the spectral chirp β was varied from -2000 to 2400 fs^2. The well-known fluorescence of the molecular iodine at 342 nm is a consequence of multiphoton absorption of light with a wavelength of 624 nm. The maximum yield of molecular iodine in the electronically excited state D' was observed at $\beta = -500$ fs^2, while the minimum yield was found at $\beta = -2400$ fs^2. The yield of molecular iodine varied by a factor of 2.9. The dependence of the product yield on the chirp value was also observed when the CH_2I_2 molecule was excited by pulses with a wavelength of 312 nm. However, the variation of the yield of molecular iodine in the excited state followed the opposite pattern: the highest yield was observed at $\beta = -2400$, whereas the lowest yield was observed at $\beta = -500$ fs^2. The chirp follows a quadratic dependence on the pulse duration. The absence of symmetry in the dependence of the product yields on the chirp relative to the zero chirp indicates that the observed variations of the yields are related to the phase characteristics of the pump pulse rather than to the pulse duration.

The second example is multiphoton photodissociation of ammonia. One-photon excitation with an energy higher than $\sim$6 eV is known to induce decomposition of ammonia to give the NH_2 radical in the ground state X^2B_1 and the hydrogen atom (the first channel).

Excitation of an ammonia molecule to 9.4 eV gives rise to the second channel, reaction *7* (see Table 2).[157]

Multiphoton photodissociation of ammonia under the action of femtosecond pulses centred at 615 nm (2 eV) has been studied.[104] The duration of the transform-limited pulse was 50 fs. To have an energy of excitation of the molecule higher than 9.4 eV, five photons should be absorbed. Since the excitation energy equal to 10 eV is still insufficient for ionisation, the molecule decomposes according to the two above-noted channels. The NH radical formed in photodissociation *7* occurs in the

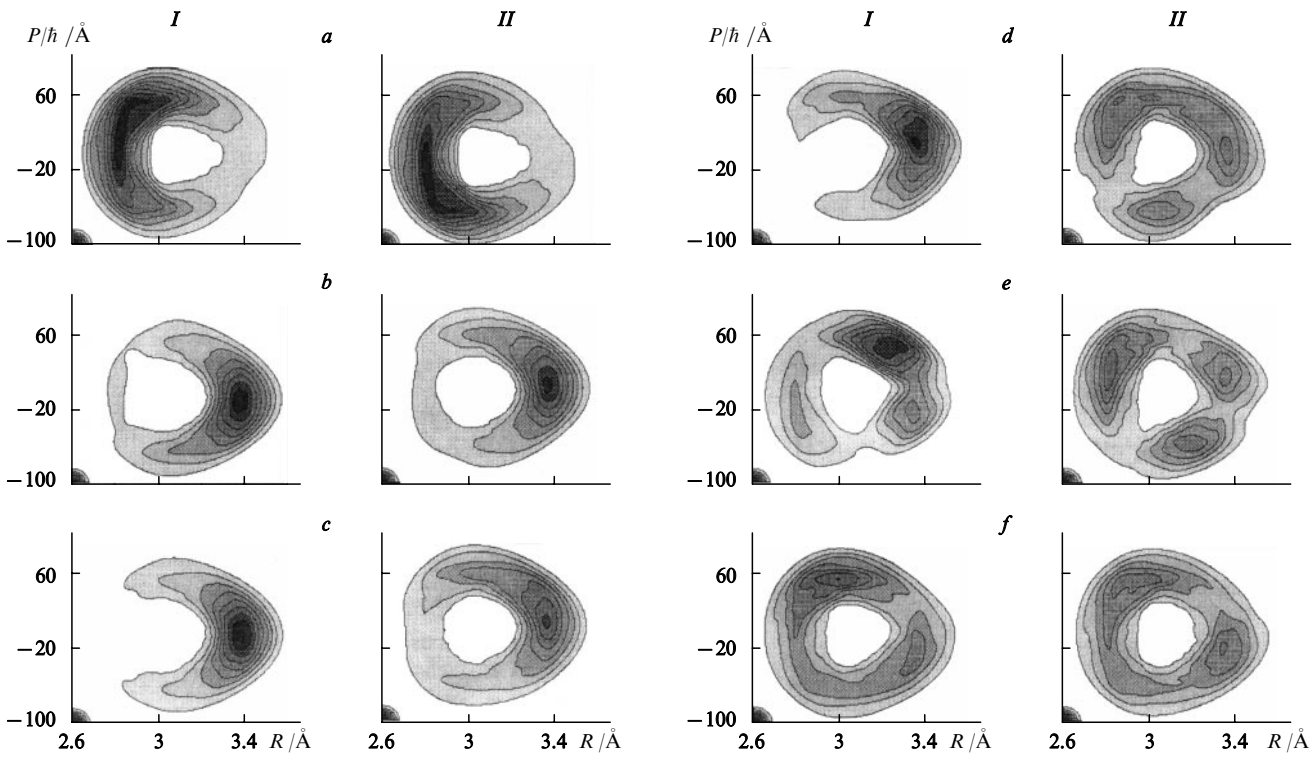

Figure 12. Dependence of the Husimi function on the classical coordinate (abscissa) and the momentum (ordinate) at different times (t) after absorption of the pump pulse for $\beta = -2000$ fs^2 (I), 2000 fs^2 (II).[37]
t /fs: (*a*) 0, (*b*) 150, (*c*) 750, (*d*) 1950, (*e*) 3150, (*f*) 4960.

electronically excited state $c^1\Pi$, from which fluorescence related to the $c^1\Pi \rightarrow a^1\Delta$ transition is observed at 324 nm.[157] Thus, the quantum yield of the ammonia decomposition according to the second channel can be judged by fluorescence intensity, which is proportional to the concentration of the NH($c^1\Pi$) radical. In the study cited, the variation of the integral fluorescence (F) in the spectral region of 300–340 nm was recorded as a function of the intensity of pump pulses (I). It was shown that experimental data are described adequately by the equation

$$F = A(\beta)(I)^5,$$

where $A(\beta)$ is the coefficient depending on the spectral chirp. This relation was used to determine the coefficient $A(\beta)$, expressed in relative units and reflecting the influence of the chirp on the photodissociation of ammonia by the second channel. Figure 13 presents the $A(\beta)$ dependences normalised to the $A(\beta = 0)$ values. The fluorescence intensity is proportional to the number of NH($c^1\Pi$) radicals formed; therefore, the plot in Fig. 13 reflects the dependence of the quantum yield of these radicals in relative units on the value of the spectral chirp. The ratio of the maximum quantum yield to the minimum quantum yield equals 12. It should also be noted that the variation of the quantum yield is non-symmetric with respect to the zero chirp; this implies that the observed changes are mainly related to the phase characteristics of the femtosecond pulse rather than to the pulse duration.

Taking these two reactions as examples, it was demonstrated that the product yields can be controlled using phase characteristics of the pump pulses. However, it has already been noted that the characteristic times of coherence of nuclear wave packets are normally 100–1000 fs. Hence, the reactions of excited molecules should occur over even shorter periods of time; this requires relatively high excitation energies (in the examples considered above, the excitation energies were 10–12 eV). The PES parameters for these energies are unknown; therefore, there arises the problem of determining and analysing these parameters for complex molecular systems for which quantum-chemical calcu-

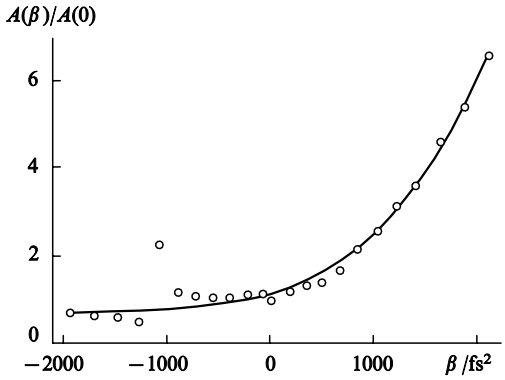

Figure 13. Yield of the product NH($c^1\Pi$) *vs.* the value of the spectral chirp.

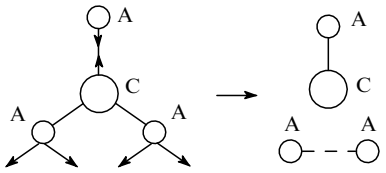
lations are difficult to perform. In this connection, some researchers are developing a different approach. Thus it has been found [158] that a scheme with the use of a feedback with the product yields can be implemented within the framework of optimal control theory; this method permits determination of pulse shape and spectral content. This scheme maximises the yield of a definite product. Experiments of this type have been carried out;[159] the researchers performed automated optimisation of the control of the reaction channels using photodissociation of the $LFe(CO)_2Cl$ molecule (L is cyclopentane) as an example. This molecule contains different bonds between the metal and the ligands (Fe–CO, Fe–Cl and Fe–L). On exposure to femtosecond pulses, products are formed *via* two channels; one channel implies rupture of only one Fe–CO bond, while according to the other channel, all the ligands, except Cl, are detached. Both products are detected by means of a mass spectrometer. The measured ratio of the product weights is fed to a computer and is processed in terms of a definite

algorithm. An instruction is devised according to which the phase characteristics of a femtosecond pulse change in such a way as to ensure a higher ratio of product weights. The minimum ratio is 1.2, and the maximum ratio is 4.9. In the opinion of the authors, the global minimum has not yet been found. Therefore, it is expected that this range of ratios can be markedly extended.

The effects caused by the chirp are related to the characteristics of the PES and to the wave packet dynamics. The change in the chirp of the pump pulse results in different distributions of the initial phases of the steady states (the superposition of which makes the wave packet); this influences the dynamics of the atomic motion in the transition state. The qualitative scheme for the control of the product yields by phase characteristics of the femtosecond pulse is shown below in relation to a planar tetraatomic molecule CA_3:



The standard photodissociation channel for molecules of this type involves rupture of the C–A bond where the vibrational energy is evolved on the stretching vibration, which determines the reaction coordinate. Let as assume that the wave packet consists of antisymmetric and bending vibrations, which determine the reaction coordinate by a concerted mechanism. If the motion of A atoms is so synchronised that two bonds are synchronously stretched and their bending vibrations, occurring in parallel with stretching, participate in the formation of the new A–A bond, the concerted mechanism would be realised more efficiently. It appears that synchronisation of the motion of atoms can be used to make a fairly large class of reactions follow a concerted mechanism.

Examples of control of reactions proceeding in condensed media upon one-photon absorption have been considered above. Studies [83, 84] of one- and two-proton transfer in the 2,2′-bipyridine-3,3′-diol molecule induced by femtosecond pulses in solutions was considered in Section V. Since these processes take place over periods of $< 50-100$ fs, it is reasonable to assume that the two-proton transfer follows a concerted mechanism. Then, by changing the chirp of the pump pulse, one can change the ratio of the channels of one- and two-proton transfer. Petrukhin and coworkers [160, 161] studied one- and two-proton transfer in 2,2′-bipyridine-3,3′-diol induced by femtosecond pulses in a hexane solution. The pumping was performed by pulses centred at a wavelength of 308 nm, while probing was accomplished by a supercontinuum pulse in the spectral range of 400–620 nm. The time evolutions of the photoinduced absorption spectra in the 400–470 nm range and of the photoinduced 'brightening' in the 470–620 nm range were monitored in experiments. It was found that photoinduced 'brightening' at a wavelength of 500 nm was due to stimulated emission from the excited diketo tautomer under the action of the probe pulse, while the photoinduced absorption at $\sim$450 nm is due to the $S_n \rightarrow S_1$ transitions in both the monoketo and diketo tautomers. It was found that the time evolution of brightening and absorption depends on the chirp of the pump pulse. In the opinion of the researchers, this is indicative of the fact that the ratio of the channels of one- and two-proton transfer is determined by both the sign and the magnitude of the chirp of the pump pulse. Hence, the reaction can also be controlled in the condensed phase.

VIII. The prospects of femtochemistry

In our opinion, the research in femtochemistry will develop vigorously in the near future according to four main lines.

The first line is the control of chemical reactions. We believe that the control of chemical reactions and physical processes aimed at obtaining desired products will be among the most promising fields of development of femtochemistry. In the majority of studies which have been considered in this review, pulses with durations of several tens of femtoseconds have been employed. Only a few studies operating with femtosecond pulses shorter than 10 fs are available. Obviously, chemical laboratories would be gradually equipped with lasers able to generate pulses with ever decreasing durations. This means that the coherent chemistry will cover more and more objects; it will become possible to use coherent wave packets even for those systems in which stochastisation occurs very rapidly. First, due to the shortening of a pulse, its spectral width increases; hence, the number of steady states included in the nuclear wave packet formed and the set of the initial phase distributions will increase. This markedly extends the range of variation of the amplitude and phase characteristics of the femtosecond pulse and thus enhances the capacity of controlling the dynamics of the molecular system in the transition state. Second, for very short pulse durations, localisation of the nuclear wave packet can reach even 0.005 Å. This makes it possible to increase the accuracy of controlling the orientation dynamics and non-adiabatic transitions. In other words, shortening of femtosecond pulses would provide the possibility of extending the number of molecular systems suitable for realisation of coherent reactions and of increasing substantially the selectivity. It is by virtue of femtosecond pulses that new schemes of controlling the processes such as photoionisation, fluorescence and light absorption would be implemented experimentally and substantiated theoretically in the near future. It appears that these schemes would include several femtosecond pulses (with different chirps) and time delays between them. Schemes of this type have already been proposed (see, for example, studies [162, 163]). We expect that the development of the above-considered approaches to the control of chemical reactions would result in the near future in the development of selective environmentally clean chemical technologies. Apparently, these technologies would be economically rational only for the preparation of expensive materials in small quantities. The approaches in question will become especially promising for the control of functional properties of nanostructures.

The shortening of the duration of pump pulses down to values at which the 'energy span' (ΔE) will be comparable with the bond energy (for a pulse duration of 1 fs, the ΔE value is $\sim$40 kcal mol^{-1}) will result in the development of new schemes for the control of chemical reactions. With sufficiently short pulses, it will be possible to generate electron wave packets in which several electronic quantum states are excited simultaneously. One can hope that schemes for controlling the electron motion in these packets would be designed.

The second line is the wave packet dynamics in the ground electronic state. Most of the examples considered in this review, especially for coherent chemistry, referred to reactions in which the reactant was in the electronically excited state. This is due to the fact that it is much more difficult to form vibrational packets in the ground electronic state than in an electronically excited state. As noted above, experimental methods are being currently developed [46–50] for the formation of coherent vibrational wave packets with excitation energies both higher and lower than the dissociation threshold. In this connection, two factors are significant: the decrease in the duration of femtosecond pulses and development of multi-pulse methods. The setting of shorter pulses in the practice of chemical experiment would substantially improve the possibilities of formation of coherent vibrational wave packets in the ground electronic state. Indeed, in this case, it is easier to use several femtosecond pulses to generate the required wave packets due to downward non-adiabatic transitions. The possibility of creating vibrational wave packets in the ground electronic state would appear as a result of multiphoton absorption of infrared femtosecond pulses. The increase in the probability of this

absorption is due to the fact that it would be possible to form a wave packet on the basis of high-frequency symmetrical vibration modes; consequently, the multiquantum factor for absorption would markedly decrease. We believe that the number of investigations into the coherent dynamics of the transition state for reactions in the ground electronic state will essentially increase in the near future.

The third line is the time evolution of the structural changes with femtosecond temporal resolution. Femtosecond pulses with a duration of 10^{-14} s allow the detection of shifts equal to 0.1 Å; however, conversion of the response function into the distance between the atoms is rather easy for diatomic molecular systems but very difficult for polyatomic molecular systems. In other words, the values measured in spectroscopic experiments cannot be transformed in the general case into the coordinates of moving atoms. An alternative variant is to develop methods that allow determination of the structures of intermediate species with a femtosecond temporal resolution.

By irradiating a target with a powerful femtosecond pulse, one can generate electron or X-ray pulses; measurement of electron or X-ray diffraction provides information on the time evolution of the positions of nuclei. Electron diffraction occurs only in the gas phase; X-ray diffraction can also be studied in condensed media. At present, these approaches are used in procedures with picosecond and sub-picosecond temporal resolution.

Time-resolved ultrafast electron diffraction has been used to study photodissociation of CF_2I_2 on irradiation with light pulses ($\lambda = 307$ nm).[22] It was found that abstraction of two iodine atoms is completed within ~ 4 ps; the structure of the resulting CF_2 radical was determined. The radical is formed in the ground electronic state with the following interatomic distances: C–F 1.30 (±0.02) Å, F···F 2.06 (±0.06) Å.

No convincing examples of using time-resolved X-ray diffraction have been reported yet. Therefore, study of the dynamics of positions of the cadmium atoms in a film containing 83 layers of cadmium atoms after heating the film by a femtosecond light pulse[26] can be referred to as an example. In this study, the dependence of the intensity of the diffraction signal on the delay between the heating light pulse and the probe X-ray pulse was measured. The experimental results obtained bear information on the time evolution of the shift of cadmium atoms from the corresponding layers with a sub-picosecond temporal resolution.

Evidently, spectroscopic measurements in dynamic investigations would be gradually replaced by measurements of this type.

The fourth line of research is femtochemistry with spatial resolution. Femtosecond spectroscopy has provided methods that allow investigations to be performed with high temporal resolution. Using scanning tunnelling microscopy, surface images (including those containing single adsorbed species) with angstrom spatial resolution were obtained for the first time; the energy distribution of surface electrons and the migrations of surface atoms have been measured; new nano-scale surface structures have been assembled. New spectroscopic techniques were developed which allow measurement of the vibrational spectra of single adsorbed species using a scanning tunnelling microscope, detection of single paramagnetic centres on the surface of oxidised metals, study of photoisomerisation of individual molecules, *etc.*[164–166] However, the number of problems the solution of which requires methods with high temporal and spatial resolution constantly increases. In recent years, several approaches to the development of these methods have been used.

The first approach is aimed at creating the possibility of performing detection by light pulses with high spatial resolution. However, the light pulses in the conventional optics are subject to a diffraction limit, which makes impossible a spatial resolution of less than $\sim\lambda/2$. In several recent years, so-called 'near-field optics' which permits a substantial improvement of the spatial resolution has been developed. The simplest implementation of the near-field optics is to replace the set of lenses by pointed optical light guide with the hole diameter d at the tip smaller than the wavelength. The near field decays rapidly with an increase in the distance from the light guide. Therefore, the specimen is mounted at distances less than d. Within the framework of this approach, it is possible to perform femtochemical investigations with a spatial resolution of tens of nanometers. The schemes used for the excitation of molecules have been reported.[167, 168]

Another approach is based on combination of femtosecond pulses with photoelectron spectroscopy. Light pulses generate electrons, which can be detected with high spatial resolution. This approach has been realised by Secatskii *et al.*[169] The researchers used very sharp silicone pins at the end of which femtosecond pulses were focused. These pulses induced two-photon emission of electrons, which was detected by a microscope. It was demonstrated that femtosecond two-photon laser photoelectron microscopy can ensure a spatial resolution of up to 3 nm.

An approach representing an attempt to combine femtosecond pulses with scanning tunnelling microscopy has been reported.[170, 171] Illumination of the tunnel gap with femtosecond pulses was combined with detection of components of the tunnelling current, which follow a non-linear dependence on the intensity of light pulses. In the opinion of the authors, this route could provide both high spatial and high temporal resolutions.

It has been noted[172] that modern chemistry cannot be conceived without coherence and high spatial and temporal resolutions. It is these points that appear to become important factors in the development of chemistry.

Abstract. Ultrafast nonradiative transitions between electronic levels of aromatic and dye molecules, competing with fast photochemical reactions (*e.g.*, electron or proton transfer, photoisomerisation, *etc.*), are considered. The results of determination of the rate constants for nonradiative transitions between higher excited singlet and triplet states using different methods are summarised. The experimental data are interpreted in terms of the exchange-resonance theory of nonradiative transitions. The bibliography includes 189 references.

I. Introduction

In his lecture at the XIX Mendeleev Congress academician A L Buchachenko noted that the development of experimental techniques that use short laser pulses has widened the horizons of chemistry. Fresh ideas thus introduced into chemistry have been embodied into femtochemistry.[1] The subject of femtochemical studies is ultrafast reactions, such as proton or electron transfer in acid – base (donor – acceptor) pairs, *cis* – *trans*-isomerisation with detection of the *twist*-conformation, photogeneration and relaxation of electron-hole pairs in semiconductors, elementary stages in photosynthesis, molecular decomposition, *etc.*[2, 3] Topicality of research into ultrafast processes is emphasised by the fact that the 1999 Nobel Prize in chemistry was awarded to A H Zewail, one of the originators of femtochemistry.

Single-photon excitation of a complex organic molecule to a higher excited singlet state (HESS) S_n ($n > 1$) is followed by transient relaxation processes. These processes, as well as transformations of excess electronic energy thus supplied to the molecule, are of considerable interest in studying the mechanisms of photochemical reactions in the vapour phase and in solutions. Most of the photochemical reactions of organic compounds in solutions are known to proceed involving the first excited singlet (S_1) and triplet (T_1) states. Both of them usually have rather long, on the molecular scale, lifetimes (from several nanoseconds for the S_1 states to hundreds of microseconds in liquids and tens of seconds in solid solutions for the T_1 states). However, the characteristic times of many fast photochemical reactions (electron and proton transfer, isomerisation, *etc.*) are much shorter. This suggests the involvement of other, upper excited states of the molecules (whose lifetimes are much shorter compared to those of the S_1 and T_1 states) in these reactions. Some of the fast reactions are considered in this review as examples. It should be noted that the possibility of estimating the HESS lifetimes has appeared only in the last decades. Nevertheless, a large body of experimental data obtained by direct and indirect methods has been accumulated to date. Therefore, it is of interest to analyse them, to assess their reliability and to consider possible mechanisms of excitation relaxation.

S I Vavilov was the first to obtain experimental data which allowed estimation of the rates of nonradiative transitions between the HESS of complex organic molecules (dyes) in solutions. He had shown experimentally[4, 5] that the quantum yields of dye fluorescence in solutions are independent of the wavelength of exciting radiation. In other words, light emission (fluorescence) always occurs from the first excited (fluorescent) S_1 level irrespective of the level to which the molecule was excited after absorption of a light quantum (the Vavilov law).

Attempts to observe emission from the HESS of complex molecules under standard conditions have failed for long. This means that emission from these levels (with rate constants of the order of $10^7 - 10^8$ s^{-1}) is accompanied by a competing fast nonradiative process (with a rate constant of at least 10^{12} s^{-1}). This interpretation is also supported by the fact that the fluorescence spectrum of a complex molecule in solution is independent of the wavelength of exciting light.

After establishment of the triplet nature of the metastable phosphorescent state of aromatic molecules[6, 7] the Vavilov law was supplemented by Kasha's rule,[8] according to which emission of light from complex molecules always occurs from the lowest excited level of a given spin multiplicity. The Vavilov law and Kasha's rule can be illustrated by a diagram of singlet (S_n) and triplet (T_n) vibronic energy levels of complex organic molecules (Fig. 1). Fulfilment of the Vavilov law and Kasha's rule means that the rate constants for nonradiative transitions (k_{nr}) from the S_n and T_n ($n \geqslant 2$) levels to the S_1 and T_1 levels, respectively, are

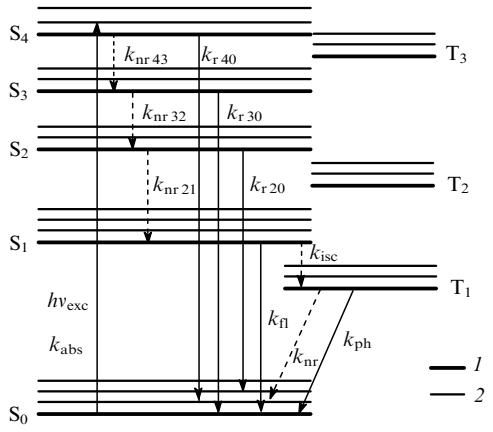

Figure 1. An energy level diagram illustrating transitions between vibronic levels of organic molecules.
Here and in Figs 2, 5–7 and 9 thick (*1*) and thin (*2*) lines denote electronic and vibronic energy levels, respectively. Notations of singlet energy levels: S_0 is the ground-state level and S_1, S_2, S_3 and S_4 are the first (fluorescent), second, third and fourth excited energy levels, respectively. Notations of triplet energy levels: T_1, T_2 and T_3 are the lowest (phosphorescent), second and third excited levels, respectively. Solid and dashed vertical lines respectively denote radiative and nonradiative transitions. Notations of rate constants: k_{r30} is the rate constant for the $S_3 \rightarrow S_0$ radiative transition (the radiative rate constant), $k_{r10} \equiv k_{fl}$ is the usual fluorescence rate constant, k_{nr32} is the rate constant for the $S_3 \rightarrow S_2$ nonradiative transition (internal conversion), k_{isc} is the rate constant for intersystem crossing (spin-forbidden $S_1 \rightarrow T_1$ nonradiative transition), k_{ph} is the phosphorescence rate constant, k_{nr} is the rate constant for nonradiative transition from the lowest triplet to the ground singlet state and k_{abs} is the absorption rate constant.

three for more orders of magnitude higher than the corresponding rate constants for radiative transitions (radiative rate constants, k_r) and intersystem crossing rate constants. However, this estimate says nothing about the rate constants for particular nonradiative transitions, *e.g.*, $S_n \rightarrow S_{n-1}$, $S_{n-1} \rightarrow S_{n-2}$, *etc*. However, knowledge of these rate constants is of interest for both research into fundamental problems of luminescence, photochemistry and photobiology and estimation of limiting energy characteristics of, *e.g.*, dye lasers and Q switches.

Recently, some experimental methods have been developed that allowed the obtaining of quantitative information on the rates of nonradiative transitions between higher excited energy levels of molecules. These are as follows:

1. Measurements of fluorescence spectra and yields from upper excited levels by direct single-quantum excitation of corresponding energy levels.

2. Measurements of $S_n \rightarrow S_0$ luminescence spectra and yields using a stepwise two-photon excitation technique, $S_0 + hv_1 \rightarrow S_1 + hv_2 \rightarrow S_n$ ($n > 1$).

3. Measurements of the fluorescence spectra from higher excited singlet levels populated *via* triplet–triplet annihilation.

4. HESS lifetime estimation from the results of (i) experiments on 'hole burning' in absorption spectra at low temperatures, (ii) linewidth measurements in fluorescence excitation spectra in supersonic jets or (iii) bandwidth measurements in structured emission spectra from higher excited levels.

5. Direct HESS lifetime measurements using picosecond or femtosecond spectroscopy.

6. Estimation of the rates of ultrafast nonradiative transitions involving triplet states.

Before presenting the results of particular experimental studies on the rates of nonradiative transitions we will briefly outline elements of modern quantum-mechanical theories of nonradiative transitions in complex organic molecules. According to formal theory of nonradiative transitions,[9–11] excitation of a molecule leads to its transition to a non-stationary excited state. Owing to short duration of the excitation pulse and high density of final vibronic states inherent in polyatomic molecules, nonradiative deactivation of the initial non-stationary state occurs exponentially. The rate constant for such a process, k_{nr}, is calculated using first-order, time-dependent perturbation theory. This process corresponds to the 'statistical limit' case.[12]

If the adiabatic approximation holds, the wave function of the system, $\Psi_{ma}(\mathbf{r}, \mathbf{Q})$, can be written as the product of electron wave function, $\varphi_{ma}(\mathbf{r}, \mathbf{Q})$, and vibrational wave function, $\chi_a(\mathbf{Q})$,

$$\Psi_{ma}(\mathbf{r}, \mathbf{Q}) = \varphi_m(\mathbf{r}, \mathbf{Q})\chi_a(\mathbf{Q}),$$

where $\mathbf{r}(r_1, r_2, r_3,...)$ are the electron coordinates, $\mathbf{Q}(Q_1, Q_2, Q_3,...)$ are the coordinates of atomic nuclei and the indices m and a denote the energy level and vibrational state, respectively.

Usually, the operator of nonadiabaticity, $V_{ma,nb}$ (m and n denote the energy levels and a and b denote the corresponding vibrational states), is considered as a perturbation inducing the nonradiative transition. Approximate expression for the matrix element of transition between the excited electronic state n and the state m with a lower energy has the form:

$$V_{ma,nb} \approx$$
$$\approx -\sum_i \frac{h^2}{M_i} \int \chi_{ma}(\mathbf{Q}) \left\langle \varphi_m(\mathbf{r}, \mathbf{Q}) \left| \frac{\partial}{\partial Q_1} \right| \varphi_n(\mathbf{r}, \mathbf{Q}) \right\rangle \frac{\partial}{\partial Q_1} \chi_{nb}(\mathbf{Q}) \mathrm{d}\mathbf{Q} +$$
$$+ \frac{1}{2} \sum_i \frac{h^2}{M_i} \int \chi_{ma}(\mathbf{Q}) \left\langle \varphi_m(\mathbf{r}, \mathbf{Q}) \left| \frac{\partial^2}{\partial Q_1^2} \right| \varphi_n(\mathbf{r}, \mathbf{Q}) \right\rangle \chi_{nb}(\mathbf{Q}) \mathrm{d}\mathbf{Q},$$

where M_i is the mass of the nucleus of ith atom. Neglecting the term containing the second derivatives of electron wave functions and simplifying this expression,[13] we get

$$V_{ma,nb} \approx \left\langle \varphi_m(\mathbf{r}, \mathbf{Q}) \left| \frac{\partial}{\partial Q_i} \right| \varphi_n(\mathbf{r}, \mathbf{Q}) \right\rangle = \frac{\langle \varphi_m(\mathbf{r}, \mathbf{Q}) | \partial U / \partial Q_i | \varphi_n(\mathbf{r}, \mathbf{Q}) \rangle}{E_m(\mathbf{r}, \mathbf{Q}) - E_n(\mathbf{r}, \mathbf{Q})},$$

where $U(\mathbf{r},\mathbf{Q})$ is the Coulomb energy of the interaction between electrons and nuclei and $E(\mathbf{r},\mathbf{Q})$ is the adiabatic potential for the excited state.

The total rate of a nonradiative transition between the states n and m can be written as the sum of partial transition probabilities

$$k_{r\,nm} = \frac{2\pi}{h} \sum_{a,b} |V_{ma,nb}|^2 p(nb) \delta(E_{ma} - E_{nb}).$$

Here, $p(nb)$ is the population of the initial vibronic state, δ is the Dirac delta function and E_{ma} and E_{nb} are the energies of the vibronic states ma and nb, respectively.

The aforesaid represents a framework of the general theory of nonradiative transitions. In the text below, we will consider the exchange-resonance theory of nonradiative transitions in ions and complex molecules developed by Sveshnikova, the author of this review and Bodunov.[14–16] According to this theory, all vibrations of a molecule under study are divided into two types, namely, promoting-accepting vibrations and accepting ones.

The first type of vibrations comprises high-frequency, strongly anharmonic vibrations responsible for the vibrational absorption spectrum of the molecule in both fundamental and overtone regions. These vibrations are usually almost inactive in vibronic molecular spectra since corresponding Franck–Condon integrals are close to zero.

The second type of vibrations comprises those responsible for the vibronic spectrum of the molecule due to nonzero Franck–Condon integrals. Often, these vibrations appear to be totally symmetric and are therefore inactive in the vibrational absorption spectrum of the molecule. For instance, the totally symmetric vibrations of aromatic molecules associated with changes in the C–C distances belong to accepting vibrations.

Bodunov[15] used the operator of nonadiabaticity as a perturbation inducing the nonradiative transition. He divided molecular

vibrations into two above-mentioned types and showed that the expression for the rate constant for the nonradiative transition between two electronic levels, k_{nr}, can be written using the overlap integral of the normalised vibronic emission spectrum of a molecule due to transition between the corresponding levels, $f(E)$, and the vibrational absorption spectrum of the same molecule, $\sigma(E)$

$$k_{nr} \approx \left|\overline{\langle\varphi_m|\frac{\partial U}{\partial Q_k}|\varphi_n\rangle}\right|^2 \int f(E)\sigma(E)E^{-(s+1)}\mathrm{d}E.$$

Here, the horizontal line denotes averaging over the first type of vibrations; $s = 3$ for dipole and $s = 5$ for quadrupole radiation. This formula is similar to the Förster–Dexter formulae for the nonradiative energy transfer between energy donor and acceptor, except that the transfer occurs intramolecularly to decrease the electron energy and to increase the vibrational energy. Validity of the exchange-resonance theory of nonradiative transitions was experimentally proved taking lanthanide ions in solutions,[14,17] transition-metal complexes[17,18] and (with some limitations) complex aromatic molecules[17–19] as examples. It should be noted that this theory was developed assuming a weak coupling between the energy levels involved in the transition, though this is not necessarily true in the case of HESS.

In this review, we will analyse the results of experimental studies from the standpoint of the exchange-resonance theory of nonradiative transitions, since this theory predicts that k_{nr} is proportional to k_r. Unfortunately, the rate constants for radiative transitions between higher excited singlet states are unknown for most of the molecules studied; nevertheless, in some instances such correlations can be found.

Recently, a number of reviews concerning fast photophysical and photochemical processes in complex organic molecules have been published (see, *e.g.*, excellent reviews[20,21]). However, the authors of these studies placed the emphasis on the vibrational energy redistribution after excitation of the molecules, whereas the problem of electronic relaxation was only briefly outlined. On the other hand, a large body of information on electronic relaxation reported in numerous studies allows some generalisation of the results obtained.

II. Single-photon excited fluorescence from higher excited S_n levels to the ground-state level

Beer and Longuet-Higgins[22] were the first who reported a strongly supported example of violation of the Vaviov law and Kasha's rule. They studied fluorescence of an azulene solution under conditions of single-quantum excitation and provided convincing proofs of the fact that the fluorescence observed after excitation of the solution into the second or shorter-wavelength absorption bands is due to transition from the second excited to the ground-state level ($S_2 \rightarrow S_0$). Azulene fluorescence was observed in the near UV spectral region (at about 28 000 cm^{-1}), though the long-wavelength absorption band of this compound lies near 14 000 cm^{-1}. These experimental observations were confirmed in more recent studies of azulene and a large number of its derivatives.[23–25] The quantum yields of $S_2 \rightarrow S_0$ fluorescence of a number of azulene derivatives were found to be as high as several percent while the S_2 state lifetimes were as long as 1.4 ns. The results obtained in these studies were briefly outlined in a monograph.[26]

Much weaker was the $S_2 \rightarrow S_1$ fluorescence of azulene observed in the region from 14 000 to 9500 cm^{-1} (710–1050 nm).[27–30] Thorough measurements allowed[31] the determination of the quantum yield ratio of the $S_2 \rightarrow S_0$ and $S_2 \rightarrow S_1$ fluorescence ($q_{fl\,20}$ and $q_{fl\,21}$, respectively)

$$\frac{q_{fl\,20}}{q_{fl\,21}} = 450 \pm 100.$$

This value characterises the ratio of the rate constants for radiative transitions from the S_2 level to the ground-state and first excited levels. From the standpoint of the exchange-resonance theory of nonradiative transitions[14] the low probability of $S_2 \rightarrow S_1$ internal conversion is due to not only the wide energy gap between these levels and minor changes in the molecular configuration in the S_1 state compared to those for the molecular configuration in the S_2 state, but also forbiddenness of the radiative transition between these levels.

Hirata and Lim[32] studied fluorescence of azulene and perdeuterated azulene vapours and, in particular, its dependence on the excess vibrational energy in the S_2 state. They suggested that a direct internal conversion from the second excited singlet state to the ground state can occur in the azulene molecule bypassing the S_1 state. Unfortunately, this assumption was not strengthened by convincing proofs, so that the arguments adduced by the authors had little force.

$S_2 \leftarrow S_0$-Fluorescence excitation spectra of azulene cooled in a supersonic jet have been studied.[33] It was found that the fluorescence excitation spectrum of the $S_2 \leftarrow S_0$ transition exhibits a fine vibrational structure. The fluorescence excitation spectra for transitions from the ground-state level to the S_3 and S_4 levels were found to be substantially broadened due to fast conversion from these levels to the S_2 state.

Direct measurements of fluorescence decay times from the S_2 state of 2-haloazulene and 1,3-dihaloazulene molecules in solution have been carried out.[34] It was shown that intersystem crossing to the triplet manifold with the rate constant $k_{isc}(S_2 \rightsquigarrow T_n)$ can occur in the molecules of compounds studied in addition to the $S_2 \rightsquigarrow S_1$ internal conversion and $S_2 \rightarrow S_0$ and $S_2 \rightarrow S_1$ transitions.

Table 1 lists the fluorescence quantum yields, energy level positions [$E(S_2)$], energy gaps (ΔE), rate constants for radiative and nonradiative transitions between different energy levels as well as the second excited singlet state lifetimes, $\tau(S_2)$, for azulene and a number of its derivatives.[31–51] For comparison, mention may be made that the $S_1 \rightarrow S_0$ fluorescence of azulene in solution ($\sim$14 000 cm^{-1}) is characterised by very low quantum yield ($\sim 10^{-4}$–10^{-6}) (see Refs 24 and 35) and a decay time, $\tau(S_1)$, estimated at 1.9 (see Ref. 36) or 1 ps (see Ref. 37).

The dynamics of isolated azulene molecules in the S_1 state has been studied in detail by femtosecond-resolved mass spectrometry in molecular beams.[38] The dephasing time of azulene was found to be shorter than 100 fs. With an excess vibrational energy of $\sim$2000 cm^{-1}, the $S_1 \rightarrow S_0$ internal conversion time in azulene vapours was estimated at 900±100 fs. It was concluded that, despite the wide energy gap ($\sim$14 000 cm^{-1}), such a high internal conversion rate can be rationalised by considering the conical intersection of the potential energy surfaces (PES) of the S_1 and S_0 states near the PES minimum of the S_1 state, as was suggested earlier.[22,39]

Luminescence studies[40] of azulene derivatives allowed the determination of the order in which light emission appears. At low temperatures, an increase in the energy of the S_1 level and narrowing of the $\Delta E(S_2-S_1)$ gap lead to the appearance of the $S_1 \rightarrow S_0$ fluorescence. At room temperature, the $S_2 \rightarrow S_0$ fluorescence remains the dominant process. At higher temperatures, the usual $S_1 \rightarrow S_0$ fluorescence prevails. A feature of azulene derivatives is the low-temperature $T_1 \rightarrow S_0$ phosphorescence.

Interesting results were obtained in studies of the fluorescence of 1,3,5,7-tetra-*tert*-butylindacene (TTBI), a representative of nonalternant antiaromatic hydrocarbons.[41] Similarly to azulene, TTBI has a low intensity transition in the near IR region [$E(S_1)$ = 9300 cm^{-1}] and has an intense, allowed transition in the visible spectral region [$E(S_2)$ = 18 300 cm^{-1}]. The authors of this study[41] succeeded in observing the $S_2 \rightarrow S_0$ fluorescence of a TTBI solution in cyclohexane (see Table 1). A salient feature of this compound is violation of the cascade character of internal conversion, so that the $S_2 \rightsquigarrow S_0$ nonradiative transition appears to be more probable than the $S_2 \rightsquigarrow S_1$ transition. In accordance with the proposed exchange-resonance mechanism of nonradiative transitions,[15] this violation can be suggested to be due to substantial increase in the probability of the $S_2 \rightarrow S_0$ radiative

Table 1. Characteristics of transitions from the second singlet level for a number of organic molecules.

Compound	Solvent	$E(S_2)$ /cm^{-1}	$\Delta E(S_2-S_1)$ /cm^{-1}	$q_{fl\,20}$	$k_{r\,20}$ /s^{-1}	$\tau(S_2)$ /ps	$10^{-8}\,k_{nr\,21}$ /s^{-1}	Ref.

transition compared to that of the $S_2 \rightarrow S_1$ transition and to the larger value of the Franck–Condon factor for the former transition. According to quantum-mechanical calculations,[41] the geometric parameters of the TTBI molecule in the S_2 and S_1 states are close, but they differ appreciably from those for the S_0 state.

Fluorescent properties of solutions of another representative of antiaromatic compounds, 1,3,5-tri-*tert*-butylpentalene, have been studied theoretically and experimentally.[42] Emission observed in the region near 27 000 cm^{-1} with a quantum yield of 2×10^{-3} after excitation by light with $\lambda = 313$ nm was assigned to the $S_3 \rightarrow S_0$ transition. The interpretation of the results obtained in this study appeared to be the subject of a discussion.[4,44] The role of conical intersection of the PES of the S_1 and S_0 states in quenching of usual fluorescence was pointed out.[44]

A study of fluorescence from the second excited singlet level of [18]-annulene (18A), a representative of alternant hydrocarbons, and its monofluoro derivative (F18A) in 3-methylpentane matrix at 4 K has been reported.[45] Symmetric (D_{6h}) molecular skeleton of 18A comprises 18 carbon atoms while the S_1 and S_2 states of the molecule are in the regions of 12 500 and 21 400 cm^{-1}, respectively. Both 18A and F18A were found to be $S_2 \rightarrow S_0$ fluorescent with rather high yields, the latter being also $S_1 \rightarrow S_0$ fluorescent (in this case, the fluorescence yield was 100 times lower). Nickel and Hertzberg[46] studied fluorescence of biphenylene (an antiaromatic hydrocarbon) in 3-methylpentane solution at 130 K. They found that the fluorescence yield from the second excited level is more than two orders of magnitude lower than that of the $S_1 \rightarrow S_0$ fluorescence, namely, $q_{fl}(S_1 \rightarrow S_0) = 2.3\times10^{-4}$.

Thioketones represent another class of compounds characterised by rather high fluorescence yields for transitions of their molecules from the second excited singlet state.[47–50] Huber and Mahaney were the first who reported the emission from the S_2 level of aromatic thioketone molecules taking xanthione as an example.[47] Shortly, their paper was followed by a series of related studies carried out using a large number of alkyarylthioketones.[48–50] For thioketone molecules, the orbital forbidden $S_1(n,\pi^*) \leftarrow S_0$ transition is near 15 000 cm^{-1} (the molar extinction coefficient at the absorption band maximum, ε_{max}, is 20 mol^{-1} litre cm^{-1}), while the allowed $S_2(\pi,\pi^*) \leftarrow S_0$ transition is near 23 500 cm^{-1} ($\varepsilon_{max} = 16\,000$ mol^{-1} litre cm^{-1}).[49,51]

The $S_2 \rightarrow S_0$ fluorescence bands are observed in the violet spectral region ($\sim$22 500 cm^{-1}) while those of the long-wavelength $S_1 \leftarrow S_0$ transition are observed in the near IR spectral region ($\sim$15 000 cm^{-1}). It should also be noted that no $S_1 \rightarrow S_0$ fluorescence was found. On the other hand, $T_1 \rightarrow S_0$ phosphorescence is observed even at room temperature, with a quantum yield (in frozen solution) can be as high as 10%.

Fluorescence from the second excited state of xanthione and related molecules is strongly quenched upon addition of saturated and aromatic hydrocarbons, which is indicative of a photochemical reaction between the thioketones and hydrocarbons.[50–54] The highest $S_2 \rightarrow S_0$ fluorescence yields were obtained in solutions of perfluoroalkanes (*e.g.*, $q_{fl\,20} = 0.014$ for xanthione at room temperature, see Table 1). The dipole $S_2 \rightarrow S_1$ radiative transition in the xanthione molecule is forbidden.[49] This substantially decreases the probabilities of nonradiative transitions in accordance with the proposed exchange-resonance mechanism of these transitions.[15]

A solution of 4-*H*-1-benzopyran-4-thione (BPT) in perfluoro-1,3-dimethylcyclohexane has been studied in detail.[55–57] It was shown that the phosphorescence quantum yield is independent of the frequency of exciting light up to 36 300 cm^{-1} (the $S_0 \rightarrow S_4$ transition). This fact contradicts the conclusion drawn previously[58,59] that the phosphorescence yield decreases by 30% upon excitation into the $S_0 \rightarrow S_1$ band as compared to direct excitation to the T_1 state. On the other hand, a 25% decrease in the $S_2 \rightarrow S_0$ fluorescence yield under excitation into the $S_0 \rightarrow S_4$ band was found. This was associated with changes in the rate of internal conversion from the S_2 state;[57] is it also implied that excitation to upper states leads to an increase in the vibrational energy of the molecule. Intersystem crossing from the HESS to the triplet manifold (namely, to higher excited triplet levels) due to the strong spin-orbit coupling, followed by fast internal conversion to the T_1 state also seems not to be improbable in thioketones.

Maciejewski *et al.*[60] proposed a method for determination of quantum yields of intramolecular nonradiative transitions, $q_{nr}(S_m \rightarrow S_{m-i})$ ($i = 1, 2, \ldots, m$), between different energy levels of complex organic molecules. The method was evaluated taking three aromatic thioketones dissolved in a perfluorinated hydrocarbon and directly excited to the S_3 state as examples. To determine the $q_{nr}(S_m \rightarrow S_{m-i})$ values, the relative fluorescence quantum yields $q_r(S_{m-1})$, $q_r(S_{m-2})$, ... $q_r(S_1)$ from all lower lying energy levels should be known. The authors of this study used the phosphorescence yield of thioketones, $q_r(T_1)$, instead of the usual fluorescence yield, $q_r(S_1)$, assuming that the T_1 state is populated exclusively *via* the S_1 state and thioketones exhibit no S_1 fluorescence. (The latter statement is incorrect since it is known[55,57] that for BPT the S_1 fluorescence intensity is $\sim$0.01 of the phosphorescence intensity at room temperature.) The relative quantum yields of nonradiative transitions between different excited singlet levels can also be estimated by comparing the absorption and fluorescence excitation spectra from different lower-lying energy levels. The internal conversion and emission quantum yields (q_{nr} and q_r, respectively) for the three thioketones are listed in Table 2.

The starting point of the study[60] was to rationalise marked violations of the cascade mechanism of internal conversion observed even for molecules with rather wide energy gaps (this

Table 2. Characteristics of nonradiative and radiative transitions in thioketones dissolved in perfluoro-1,3-dimethylcyclohexane, obtained at room temperature.[60]

Note. The data taken from Ref. 57 are given in parentheses.

particularly refers to quantum yields of the $S_3 \rightsquigarrow S_0$ and $S_2 \rightsquigarrow S_0$ nonradiative transitions, see Table 2). The authors cited suggested that these violations can be accounted for either by large differences between the electronic matrix elements appearing in the expression for the rate constant of nonradiative transition or by conical intersection of the PES when moving over the hypersurface of the S_3 state towards a distorted local minimum. In interpretation proposed in the study,[16] the above-mentioned matrix elements represent the rate constants for radiative transitions between corresponding energy levels. Conical intersection of the PES provides a direct transition to the ground state.

Difficulties in measuring q_{nr} should be pointed out. First, this is a strong overlap of the bands corresponding to population of different HESS in the absorption spectrum, especially if the intensities of neighbouring bands differ substantially, as is the case of the $S_3 \rightsquigarrow S_0$ and $S_2 \rightsquigarrow S_0$ transitions in thioketones. Because of this, information on violation of cascade mechanism of nonradiative transitions between excited levels in particular molecules including thioketones should be considered very carefully. For instance, Nickel[61] thoroughly studied nonradiative transitions in BPT and came to conclusion that there is no good reason to assume direct internal conversion from the S_2 and S_3 states of thioketone molecules to the ground state.† Fast appearance of an impurity (a photochemical reaction product) in the thioketone solution has also been reported.[56]

The method proposed by Maciejewski *et al.*[60] allows the obtaining of complete information on the nonradiative transitions between all energy levels only if direct single-quantum excitation of a HESS will give rise to fluorescence from all lower-lying levels. However, this is possible (and only for the S_2 state!) for a limited number of molecules (thioketones, several porphyrins, *etc.*). If direct single-quantum excitation gives rise only to S_1 fluorescence, one can only point to deviations from the Vavilov law and Kasha's rule which were repeatedly checked using many molecules.

Bright $S_2(\pi,\pi^*) \rightarrow S_0$ fluorescence of 1,8-(1′,8′)-naphthalylnaphthalene solutions, characterised by $q_{fl} = 0.18$ and $t = 3$ ns was observed,[62] despite the narrow gap between S_2 and S_1 levels [$\Delta E(S_2-S_1) = 5000$ cm^{-1}]. However, such a high quantum yield of fluorescence due to transition from the S_2 level in combination with the narrow energy gap seems to be unrealistic. Presumably, in this case there was a contribution of impurity or product of a photochemical reaction. Similarly to thioketones and azulene, no $S_1(n,\pi^*) \rightarrow S_0$ usual fluorescence was observed, only phosphorescence was found in this case.

† Private communication.

Direct single-quantum excitation of porphin derivatives also gives rise to the $S_2 \rightarrow S_0$ (or $S_3 \rightarrow S_0$) fluorescence. This fluorescence ($\sim$23 000 cm^{-1}) was first studied by Gouterman *et al.*[63] The fluorescence spectrum was found to be a mirror image of intense Soret absorption band. More detailed studies of this fluorescence have shown[64,65] that the highest quantum yield ($q_{fl\,20} = 1.2 \times 10^{-3}$) is observed for Zn-tetrabenzoporphyrin solutions. For metal-free tetrabenzoporphyrin, the absolute quantum yield of 'blue' fluorescence is nearly an order of magnitude lower (1.8×10^{-4}). It was also found that tetrabenzoporphyrin complexes with metals with partly filled *d*-shell exhibit no 'blue' fluorescence detectable under conditions of single-quantum excitation.

In a study[66] of Co(II) and Ni(II) complexes with crown ethers and phthalocyanine derivatives it was shown that the $S_2 \rightarrow S_1$ internal conversion time is shorter than 500 fs. Effect of complexation of *meso*-tetraphenylporphyrins (TPP) with trivalent Y, Lu and Th on the 'blue' fluorescence has been studied.[67] All the complexes under study, *viz.*, YTPP(acac), LuTPP(acac) and ThTPP(acac), exhibit fluorescence from the S_2 level with nearly equal quantum yields (0.001). In contrast to this, the quantum yield of usual fluorescence of these complexes decreases substantially in the above-mentioned order, which indicates that intersystem crossing has no effect on quenching of the S_2 level of porphyrins. No fluorescence from the second singlet level was found for free base TPP.[67,68] In spite of nearly equal energy gaps $\Delta E(S_2-S_1)$ for metal complexes with octaethylporphyrins (OEP) and TPP, such OEP as H_2OEP, AlClOEP and ZnOEP exhibit no $S_2 \rightarrow S_0$ fluorescence.[68] $S_2 \rightarrow S_0$-Fluorescence of tetra-*para*-tolylporphyrin complexes with Sm(III), Eu(III), Gd(III), Tb(III), Yb(III) and Lu(III) in ethanol has been studied.[69] Weak quenching (by factors of $\sim$1.5 to 3.0) of fluorescence of paramagnetic complexes with Gd(III), Sm(III) and Tb(III) as well as strong quenching of fluorescence for the complexes with Eu(III) and Yb(III) was explained by the appearance of charge-transfer states lying between the S_1 and S_2 levels on the energy scale. [Among lanthanide ions, Eu(III) and Yb(III) are known to possess the highest electron affinities.]

Due to the short lifetime of the S_2 state, 'blue' fluorescence of porphyrins is strongly polarised even in solutions of low viscosity (in contrast to usual $S_1 \rightarrow S_0$ fluorescence of organic compounds).[60] This feature was used[70] to separate out the $S_2 \rightarrow S_0$ fluorescence. Frequency modulation was performed using polarisers while signal measurements were carried out with an amplifier with synchronous detection. This experimental procedure allows one to separate out the desired fluorescence against the background of the impurity usual fluorescence, since the impurities emit natural light and their signal is not modulated. The quantum yield of S_2 fluorescence of Zn-ethioporphyrin under conditions of single-quantum excitation was 7.5×10^{-5}. An up-conversion study of the S_2 fluorescence decay and S_1 fluorescence rise of Zn(TPP) complexes in ethanol has been reported.[71] It was shown that the decay of the S_2 fluorescence at 430 nm and the rise of the S_1 fluorescence near 600 nm are characterised by the same time constant of 2.3 ps. A more complex picture is observed for the spectral region between these bands, which indicates a contribution of 'hot' luminescence.

$S_2 \rightarrow S_0$-Fluorescence studies of dye molecules under conditions of single-quantum excitation have been carried out taking Brilliant Green[72] and Malachite Green[73,74] dyes as examples.

Lipsky *et al.*[75–77] studied single-quantum induced fluorescence of aromatic molecules from the second and upper levels. Alkylbenzenes were excited with a Hg resonance line at $\lambda = 184.9$ nm (the vacuum UV spectral region). Very weak $S_2 \rightarrow S_0$ (or $S_3 \rightarrow S_0$) fluorescence bands appeared on the short-wavelength wing of the usual fluorescence spectra. To single them out, quenchers of usual fluorescence (CCl_4, CCl_3H, cyclo-C_7F_{14}) were added to the solutions. In contrast to usual fluorescence,

almost no quenching of the S_2 and S_3 fluorescence occurs due to the short lifetimes of these states. Presumably, impurity emission that precludes the observation of fluorescence from HESS of the molecules under study is also quenched simultaneously. Selected characteristics of nonradiative transitions in these molecules are listed in Table 3. High rates of internal conversion and small differences between them in solutions and as vapours, indicative of intramolecular process, are noteworthy.

Carotenoids play an important role in many processes occurring in living organisms. In particular, they serve as pigment protectors in cells of green plants and purple bacteria against their destruction by singlet oxygen. A systematic study of fluorescence of β-carotenes and their analogues, linear polyenes, has been carried out.[78] It was found that the energy gap $\Delta E(S_1-S_0)$ becomes narrower and the yield of usual fluorescence decreases as the polyene chain length increases. The fluorescence yield decreases from 7×10^{-3} for the polyene with five conjugated bonds down to 4×10^{-6} for β-carotene (solutions in hexane at room temperature). Among the compounds under study, the longest molecular chains were those of decapreno-β-carotene and dodecapreno-β-carotene with 15 and 19 double bonds, respectively. These compounds exhibited only S_2 fluorescence with the quantum yield $q_{fl\,20}\approx5\times10^{-5}$. The S_2 state lifetime, $\tau(S_2)$, estimated from q_{fl20} was ~100 fs. Therefore, despite the decrease in the usual fluorescence yield with lengthening of the molecular chain, fluorescence from the second excited level of these molecules remains nearly constant.

Weak $S_2\rightarrow S_0$ fluorescence was observed in an anthracene crystal directly excited by a resonance Hg line at $\lambda=254$ nm.[79] The ratio of fluorescence yields from the S_2 and S_1 states was estimated at $\sim5\times10^{-6}$ and $\tau(S_2)$ was roughly estimated at $\approx10^{-13}$ s.

However, measurements of fluorescence spectra and quantum yields of fluorescence due to transitions from the second and upper excited singlet states under conditions of direct single-quantum excitation are impossible for most of fluorescent complex organic compounds. This is due to the low fluorescence quantum yields, superimposition of impurity luminescence in solvents and in insufficiently purified substances under study and to the Rayleigh and Raman scattering.

In conclusion, mention may be made of an interesting example of fluorescence from a triplet rather than singlet higher excited state.[80] Irradiation of 9,10-dibromoanthracene and 9-bromoanthracene solutions in undegassed hexane by a high-power Xe lamp resulted in weak fluorescence near 840 nm for the former and near 865 nm for the latter compound. This phenomenon was suggested to be due to the $T_2\rightarrow T_1$ radiative transition. Fluorescence was excited in the regions of conventional absorption spectra of these compounds. The T_2 levels were populated *via* $S_1\rightarrow T_2$ intersystem crossing. The T_2 levels of the molecules under study are near the corresponding S_1 levels on the energy scale and the energy gaps, $\Delta(T_2-T_1)$, are $\simeq12\,000$ cm^{-1}. The $T_2\rightarrow T_1$ fluorescence quantum yield was estimated at 8×10^{-7} and the T_2 state lifetime, $\tau(T_2)$, was estimated at $\simeq10^{-11}$ s.[80]

III. Fluorescence due to transitions from higher excited S_n levels under conditions of stepwise excitation of molecules

The appearance of pulsed laser excitation sources allowed studies of ultrafast relaxation processes from HESS using the stepwise excitation technique. Essentially, the method is as follows. Excitation of a molecule by the first quantum leads to population of the first (fluorescent) excited singlet state S_1. Being in the thermalised S_1 state, the molecule absorbs the second quantum, thus populating an upper excited singlet state (Fig. 2)

$$S_0+h\nu_1\rightarrow S_1+h\nu_2\rightarrow S_n\ (n\geqslant2).$$

This excitation technique allows easy observation of fluorescence spectra corresponding to $S_n\rightarrow S_0$ transitions ($n\geqslant2$) with quantum yields of the order of $10^{-6}-10^{-7}$. It appears to be

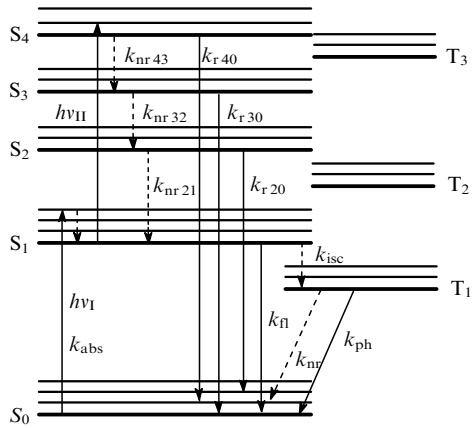

Figure 2. An energy level diagram illustrating nonradiative transitions between higher excited singlet states under conditions of two-quantum stepwise excitation and fluorescence due to transitions from the HESS to the ground state of the molecule;
$h\nu_I$ and $h\nu_{II}$ are the first and second excitation quanta, respectively.

particularly convenient when using tunable lasers generating nanosecond pulses and operating at repetition rates from 5 to 50 Hz. The method has the advantage that stepwise excitation has no effect on the fluorescent impurity molecules in the compound under study and in the solvent, whose absorption spectra are observed in the region of $S_n \leftarrow S_0$ ($n \geqslant 2$) transitions. In addition, the spectrum under study is not overlapped with the Raman spectrum since the latter is shifted up to 3000 cm^{-1} with respect to the former. To simplify the interpretation of the results obtained, nanosecond pulses were used with moderate radiation flux levels. (In this case, the use of picosecond and femtosecond laser pulses is less appropriate since it is accompanied by an increase in the contribution of two-photon excitation which affects also the impurity molecules). The best combination of molecular properties for performing stepwise excitation studies includes sufficiently high fluorescence yields, S_1 state lifetimes of the order of several nanoseconds and rather large absorption cross-sections for the $S_n \leftarrow S_1$ transitions.[81]

The first studies on fluorescence spectra corresponding to transitions from higher excited states to the ground state obtained by stepwise excitation technique date back to the late 1960s and early 1970s.[82–86] In particular, Terenin *et al.*[82] observed blue fluorescence of a chlorophyll solution excited by a high power ruby laser. Violet fluorescence of an aluminum phthalocyanine chloride solution was studied under similar conditions.[83] It was also found that the action of high-power radiation of a ruby laser on a solution of cyanine dye in methanol leads to the appearance of blue fluorescence with its intensity proportional to the squared exciting radiation intensity.[84] These results were subjected to criticism.[87,88] Blue fluorescence was suggested to be due to photochemical decomposition products of the dye. However, blue fluorescence was also observed in a CW excitation study of cryptocyanine.[89] The authors of this study found that the blue and red fluorescence excitation spectra match each other and the UV absorption spectrum in the UV spectral region. The quantum yield of the blue fluorescence was 10^{-4}.[89]

The potentialities of the stepwise excitation technique for studying fluorescence from higher excited states of complex molecules have been demonstrated in a series of studies by Lin, Topp *et al.*[90–95] They used a dye laser with an output of 0.1 to 0.5 mJ per ~ 5 ns pulse, pumped by a nitrogen laser operated at a repetition rate of up to 50 Hz. Fluorescence due to transitions from higher excited singlet states was detected using a monochromator and a photomultiplier with synchronous detection (the signal was averaged over 100–300 pulses). To eliminate scattered visible fluorescence, a light filter was placed in front of the monochromator. The advantages of consecutive stepwise excitation over simultaneous excitation by picosecond pulses with the same energy at the same wavelength were demonstrated taking rubrene as an example.

Stepwise excitation experiments can be performed even using a high-power CW laser. For instance, the $S_3 \rightarrow S_0$ fluorescence spectrum of tetracene (a solution in methylcyclohexane) was measured using an Ar laser with an output of 0.8 W at 233 K by focusing the laser light on a flow-through cell.[96] This is the first observation of fluorescence accompanying the transition from HESS of aromatic hydrocarbon molecules under conditions of stepwise excitation.

In studies of $S_n \rightarrow S_0$ fluorescence spectra of rhodamine B and rhodamine 6G (solutions in ethanol) at 300 K Lin and Topp[91] observed three prominent bands in the region 250–400 nm for each compound, at 275, 320 and 382 nm for rhodamine B and at 270, 310 and 377 nm for rhodamine 6G. The shapes of these band systems were found to be nearly mirror images of the three-band systems corresponding to electronic transitions in the absorption spectra of the dyes. The fluorescence band of rhodamine 6G at 377 nm matches that measured in the earlier[85,86] and more recent[97] studies. Polarisation spectrum measurements confirmed the presence of three electronic transitions in the observed fluorescence spectrum. It should be noted that positions of the fluorescence bands of the rhodamines at 382 and 377 nm remain virtually unchanged upon variation of the second quantum frequency from 22 000 to 18 000 cm^{-1}.

Stepwise excitation technique was used to study a large number of aromatic hydrocarbon molecules characterised by several electronic transitions in this spectral region.[92–95] It was shown that electronic relaxation of higher excited singlet states of organic molecules occurs until vibrational equilibration is established after the excitation event. Studies of $S_n \rightarrow S_0$ transitions in the 3,4,9,10-dibenzopyrene molecule revealed the appearance of a fine vibrational structure in the spectral region adjacent to the effective excitation frequency [$\nu_{ef} = \nu_{0-0}(S_1) + \nu_2$] after excitation by the second quantum (540–610 nm). It was found that this fine structure depends on the frequency of the second excitation quantum. The spacing between the observed bands (1460 ± 60 cm^{-1}) is close to that of the principal progression in the $S_1 \rightarrow S_0$ fluorescence spectrum (1440 ± 50 cm^{-1}). Topp and Lin[93] suggested that the observed vibrational structure of the spectrum is caused by the anti-Stokes Raman scattering; however, they did not rule out that a phenomenon similar to the Personov effect[98,99] is observed in this case.

Distinctions between the structures of the spectra measured near the excitation level have been found for centrosymmetric molecules and those without a centre of symmetry.[94] Under conditions of two-step excitation, selection rules forbid transitions of centrosymmetric molecules in those states from which radiative transitions to the S_0 ground state are allowed. Indeed, judging from the sum of the $S_1 \leftarrow S_0$ transition frequency and the second absorbed quantum frequency, in this case the fluorescence spectrum begins 'some distance' from its conventional position.

Stepwise excitation studies of a large number of fluorescent dyes and aromatic molecules in solutions at room temperature and at 77 K have been carried out.[100–106] It was found that intramolecular nonradiative transitions from higher excited singlet levels in dyes and most complex aromatic compounds in solutions occur in a cascade manner, *i.e.*, consecutively involving all the lower-lying electronic levels. This conclusion was drawn based on comparison of the shape of fluorescence spectra of organic molecules excited by the second quantum with varied frequency in states with different energies. The $S_n \rightarrow S_0$ ($n \geqslant 2$) fluorescence spectra of Magdale Red dye (a solution in ethanol) at 77 K are shown in Fig. 3 while those of 1,2-benzanthracene (a solution in ethanol) at 293 K are presented in Fig. 4. The spectra shown in Figs 3 and 4 exhibit prominent bands that are mirror images of corresponding $S_n \leftarrow S_0$ absorption bands. In addition, the intensity ratio of the $S_n \rightarrow S_0$ and $S_{n-k} \rightarrow S_0$ bands ($k < n$) remains constant as the energy of the second quantum varies.

The ratio of the areas under the bands corresponding to different $S_n \rightarrow S_0$ transitions characterises the relative quantum yield of a given fluorescence transition. Given the absolute quantum yield of a particular intramolecular transition, it is possible to determine the absolute quantum yields for other transitions. The corresponding radiative rate constant can be found from the area under that absorption band which is the mirror image of the fluorescence band of the given transition. Then, one can estimate the S_n state lifetimes

$$\tau(S_n) = \tau_r(S_n \leftarrow S_0)\, q_{fl}(S_n \rightarrow S_0).$$

Here, $\tau_r(S_n \leftarrow S_0)$ is the inverse of the rate constant for the $S_n \rightarrow S_0$ radiative transition and $q_{fl}(S_n \rightarrow S_0)$ is the fluorescence quantum yield. The fluorescence quantum yields and decay times thus obtained are listed in Table 4.

The results of analysis of the spectra presented in Figs 3 and 4 and those reported elsewhere[97,100–106] are sufficient to allow the following conclusions.

First, stepwise excitation of a molecule to an S_n ($n \geqslant 2$) state leads to the appearance of the spectral bands corresponding to the $S_n \rightarrow S_0$, $S_{n-1} \rightarrow S_0$, $S_{n-2} \rightarrow S_0$, *etc.* transitions in the fluorescence spectrum of the molecule.

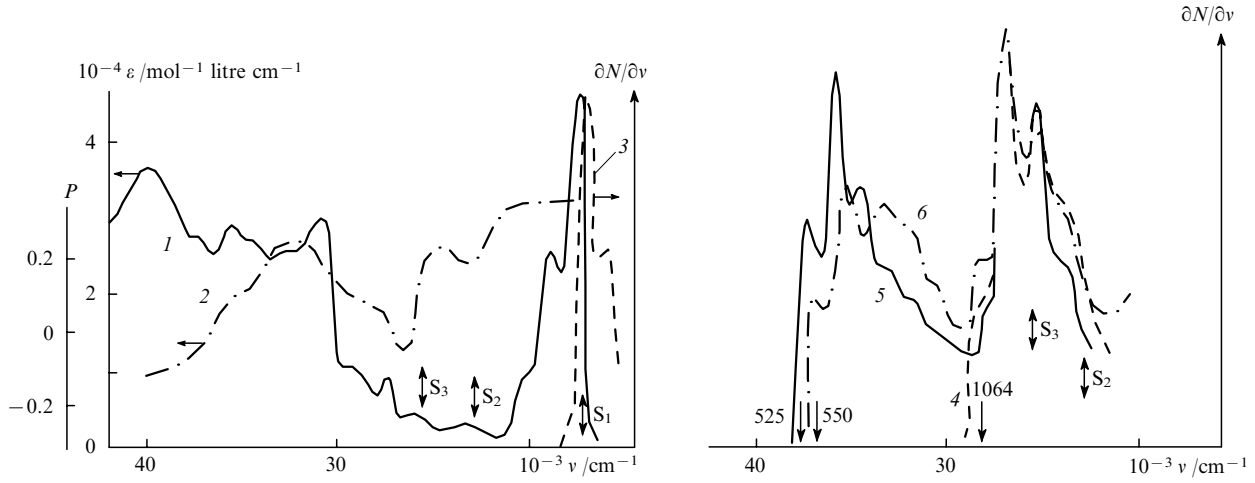

Figure 3. Magdale Red spectra (a solution in ethanol).
The $S_n \leftarrow S_0$ absorption spectrum at 77 K (*1*); polarisation spectrum of $S_1 \rightarrow S_0$ fluorescence excitation as function of excitation frequency at 293 K (a solution in glycerol) (*2*), see also a separate *P* scale; $S_1 \rightarrow S_0$ fluorescence spectrum at 77 K (*3*) and $S_n \rightarrow S_0$ ($n \geqslant 2$) fluorescence spectra (*4–6*) obtained under conditions of stepwise excitation from the S_1 state at λ_{exc} = 1064, 550 and 525 nm, respectively. Double vertical arrows denote the energy levels of S_n electronic states on the frequency scale. Single arrows denote the energy levels achieved under conditions of stepwise excitation. *N* is the number of absorbed quanta.

Second, for most of molecules (except for those characterised by strongly different equilibrium nuclear configurations in the S_1 and S_0 states) each band in the $S_n \leftarrow S_0$ absorption spectrum has a nearly mirror image in the $S_n \rightarrow S_0$ fluorescence spectrum.

Third, if excitation of a molecule by the second quantum leads to population of an upper S_k ($k > n$) state and if the S_n levels are populated by $S_k \rightsquigarrow S_{k-1} \rightsquigarrow S_n$ electronic relaxation, the shape of fluorescence spectra and, in particular, the shape of particular bands corresponding to $S_n \rightarrow S_0$ transitions and the band intensity ratios are in most cases independent of the energy of the second quantum.

Fourth, distortion of the fluorescence spectra from higher excited states is observed only if the total energy of the $S_1 \rightarrow S_0$ transition and the second excitation quantum is larger than the ionization energy of the molecule under study in solution (see Figs 3 and 4).

To obtain additional experimental verification of the assumption of cascade character of intramolecular electronic relaxation, the absolute quantum yields ($q_{fl\,n0}$) of $S_n \rightarrow S_0$ fluorescence were measured at different energies of the second excitation quantum. By the quantum yield of fluorescence due to intramolecular transitions from higher excited electronic states under conditions of stepwise excitation is meant the ratio of the number of the quanta emitted in the form of $S_n \rightarrow S_0$ fluorescence to the number of molecules excited to the S_n state. Determination of $q_{fl\,n0}$ requires knowledge of the number of absorbed (the $S_n \leftarrow S_1$ transition) and emitted ($S_n \rightarrow S_0$ transition) quanta. The former parameter is complicated to calculate. Previously,[97, 100–106] it was estimated

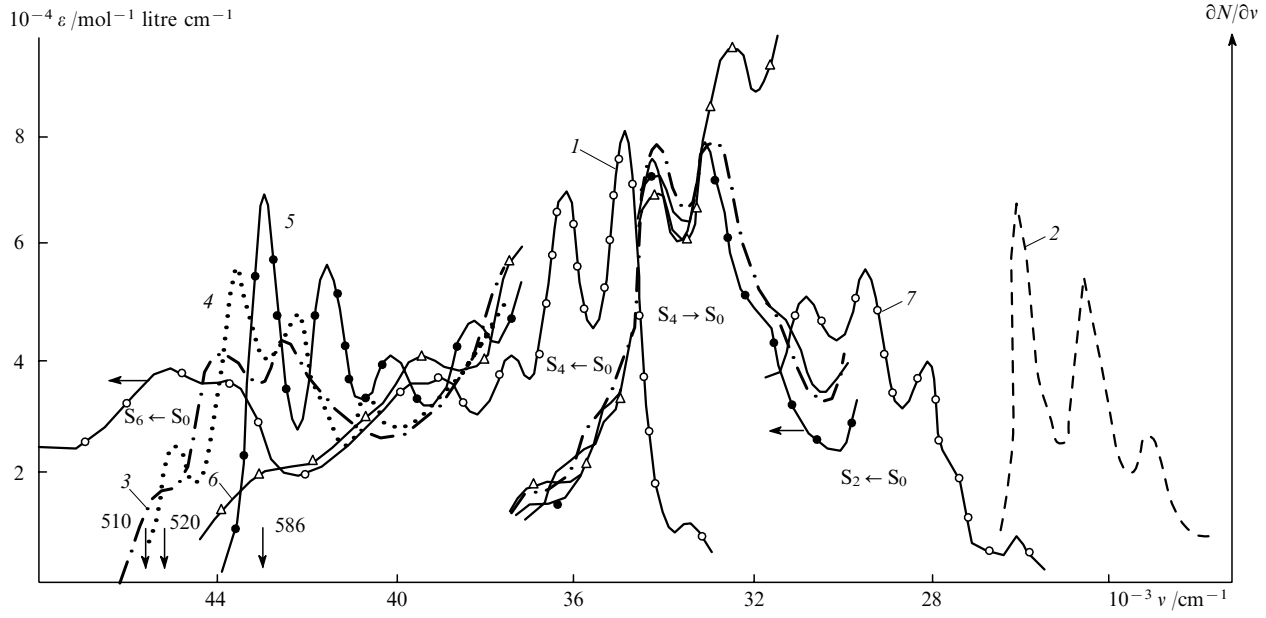

Figure 4. Spectra of 1,2-benzanthracene (a solution in ethanol) at 293 K.[72]
The $S_n \leftarrow S_0$ absorption (*1*) and $S_1 \rightarrow S_0$ fluorescence (*2*) spectra. The $S_n \rightarrow S_0$ ($n \geqslant 2$) fluorescence spectra obtained under conditions of stepwise excitation from the S_1 state at λ_{exc} = 510, 520, 586 and 340 nm, respectively (*3–6*); enlarged representation of the $S_n \leftarrow S_0$ absorption spectrum (*7*) (8 times along the ordinate axis). The spectral width of the instrumental response function was 200 cm^{-1}.

from changes in the intensity of transmitted laser radiation with the frequency ν_2 upon turning on a laser with the frequency ν_1 and from the amplitude of additional opto-acoustical signal which appeared upon simultaneous illumination of the object under study by two laser pulses.[107]

The fluorescence quantum yield was also estimated [108] from the following relationship

$$q_{\mathrm{fl}\,n0} = \frac{I_{\mathrm{fl}\,n0}}{I_{\mathrm{fl}\,10}\sigma_{1n}I_{\mathrm{ex}\,2}\tau_{\mathrm{r}1}},$$

where $I_{\mathrm{fl}\,n0}$ and $I_{\mathrm{fl}\,10}$ are the integrated intensities of the S_n and S_1 fluorescence, respectively; σ_{1n} is the absorption cross-section for the $S_n \leftarrow S_1$ transition, $I_{\mathrm{ex}\,2}$ is the power density of exciting radiation with the frequency ν_2 and $\tau_{\mathrm{r}1}$ is the radiative lifetime of the S_1 state.

Table 5 lists the results obtained for α-naphthylphenyloxazole, pyrene and 1,2-benzanthracene. As can be seen, the $q_{\mathrm{fl}\,n0}$ values are independent of energy of the second quantum within the experimental error. This is a strong argument in favour of the cascade mechanism of electronic relaxation of HESS.

Let us analyse the spectra of fluorescence accompanying transitions from the HESS of most of the molecules studied, obtained under conditions of stepwise excitation. The following picture is observed in the region adjacent to the frequency corresponding to the sum of the energies of the S_1 state and the second excitation quantum. The $S_n \rightarrow S_0$ fluorescence spectra (S_n is the state directly populated by absorption of the second quantum) exhibit a more pronounced vibrational structure compared to the $S_n \leftarrow S_0$ absorption spectra of the same molecules obtained under the same conditions and to the fluorescence

[a] Given are the $q_{\mathrm{fl}\,20}\times10^6$ values ($\nu_{\max} \approx 33\,200$ cm^{-1}) for α-naphthyloxazole and $q_{\mathrm{fl}\,40}\times10^6$ values ($\nu_{\max} \approx 34\,500$ cm^{-1}) for pyrene and 1,2-benzanthracene; [b] given are the $q_{\mathrm{fl}\,30}\times10^6$ values ($\nu_{\max} \approx 39\,300$ cm^{-1}) for α-naphthyloxazole and $q_{\mathrm{fl}\,50}\times10^6$ values ($\nu_{\max} \approx 41\,500$ cm^{-1}) for pyrene.

spectra from the HESS populated *via* relaxation from higher excited levels (see Figs 3 and 4).

Positions of all the fluorescence bands observed depend on the frequency of the second quantum. On the other hand, neither the structure nor the relative intensities of the fluorescence bands corresponding to transitions from the lower-lying HESS populated *via* relaxation remain unchanged (see curves *4–6* in Fig. 3 and curves *4* and *5* in Fig. 4).

If the frequency of the second excitation quantum varies within $\Delta\nu_2 < 1500$ cm^{-1}, the entire spectral region in question (it will be remembered that this is a region of the fluorescence spectrum) is shifted simultaneously with the position of the level to be populated. An increase in $\Delta\nu_2$ leads to substantial redistribution of vibronic band intensities. Further increase in the frequency ν_2 (by several thousands of cm^{-1}) causes the appearance of spectral bands corresponding to emission of nearly the same intensity; however, the new bands exhibit no pronounced vibrational structure.

The appearance of structured $S_n \rightarrow S_0$ fluorescence spectra can probably be rationalised by the effect of selective excitation of molecules with a particular configuration into a broad $S_n \leftarrow S_0$ absorption band by spectrally narrow (~ 0.5 cm^{-1}) radiation with the frequency ν_2. Due to ultrashort lifetimes of the S_n states (10 – 100 fs) of those molecules which exhibit structured spectra, inhomogeneous line broadening in the $S_n \leftarrow S_1$ absorption spectrum can be considered as manifestation of specific molecular conformations due to low-frequency, out-of-plane vibrations of the aromatic rings.

This explanation is also supported by the fact that Brilliant Green and Zn-tetrabenzoporphyrin exhibit no structured spectra upon excitation of the relatively long-lived ($\sim 1-3$ ps) S_2 state. On the other hand, stepwise excitation of Brilliant Green by the second quantum ($\lambda_2 = 500-620$ nm) and population of the S_5 level ($\tau_5 \leqslant 24$ fs) leads to the appearance of a structured spectrum. This is consistent with the assumption that the structured spectra are observed upon transitions from electronically and vibrationally unrelaxed states, while the excited states with the picosecond lifetimes undergo at least partial vibrational relaxation.

It was assumed [97, 103] that the effect in question (the appearance of structured spectra) is to some extent similar to the Personov effect, *i.e.*, the appearance of the $S_1 \rightarrow S_0$ fluorescence spectra with well-resolved fine structure under the action of selective laser excitation of organic molecules in solid solutions at 4 K (see Refs 98 and 109).

There are some distinctions between these effects. First, a structured spectrum appears in the case where one electronic transition ($S_n \leftarrow S_1$) is selectively excited while another transition ($S_n \rightarrow S_0$) is used for the detection of structured emission. Conventional Personov effect is not observed in this situation since the two transitions are uncorrelated. Second, structured spectra are observed in liquid solutions without cooling them down to the liquid helium temperature (though liquid solutions can be considered as solid ones during a time of the order of tens of femtoseconds). Third, corresponding vibronic levels are noticeably broadened (up to hundreds of cm^{-1}) due to the short lifetimes of the excited states, whereas in the case of the Personov effect the linewidths are equal to hundredth and thousandth fractions of cm^{-1}. Finally, structured spectra appeared under conditions of stepwise excitation are observed only for those molecules for which the 0 – 0 band of the $S_1 \rightarrow S_0$ transition is only slightly inhomogeneously broadened.

The appearance of a structured fluorescence spectrum under conditions of stepwise excitation was explained in another manner.[110] The authors of this study assumed that the observed fluorescence is due to anti-Stokes resonant vibronic Raman scattering (ARVRS). An energy level diagram illustrating the proposed [110] formation mechanism of structured emission spectrum is shown in Fig. 5. ARVRS occurs if excitation of a molecule to the S_1 state after absorption of the first quantum is followed by absorption of the second excitation quantum with the frequency ν_2. As a result, transition of the molecule to a vibrational electronic ground-state level is accompanied by scattering of a quantum corresponding to the frequency $\nu_2 + \nu_{0-0}(S_1-S_0) - \Sigma n_i \nu_i$. Later, the authors of other studies [108, 111, 112] supported this explanation and pointed to the similarity of the observed spectrum and the usual fluorescence spectrum shifted towards the high-frequency region.

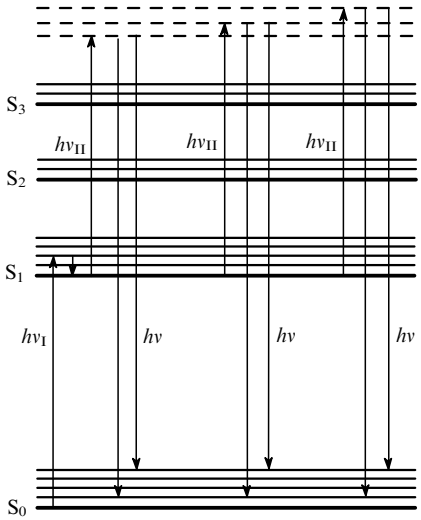

Figure 5. An energy level diagram illustrating the ARVRS mechanism. Dashed lines denote virtual energy levels involved in the Raman scattering. Vertical lines corresponding to ARVRS are denoted as $h\nu$.

Nevertheless, we dissent from the proposed [110] explanation for the experimental observations. Let us adduce some arguments in favour of the interpretation of structured emission appearing under conditions of stepwise excitation of organic molecules as fluorescence.

If an excited level is populated *via* relaxation from upper levels rather than by direct excitation, the integrated intensity of the structured spectrum is nearly the same as the emission intensity in the same spectral region.[97]

The bands in the structured spectrum are much broader than those in the $S_1 \rightarrow S_0$ fluorescence spectrum. On the other hand, the ARVRS mechanism requires that the width of the short-wavelength band in the structured spectrum obtained under conditions of stepwise excitation and the width of the 0 – 0 band in the $S_1 \rightarrow S_0$ fluorescence spectrum be equal.

If a molecule in the S_1 state is excited by a second quantum and if the energy of this quantum is sufficiently high for the molecule to undergo photoionisation, the fluorescence yield from higher excited states should decrease dramatically. It is just the situation that is observed in the experiments. For instance, in the case of rhodamine B the fluorescence yield from HESS decreases by more than an order of magnitude as the frequency ν_2 is varied from 19 000 cm^{-1} to $\nu_2 > 32\,000$ cm^{-1}. Assuming that structured emission is due to ARVRS, there is no grounds for such a large decrease in the emission intensity, since the process involves only virtual high-lying states.

Nonradiative energy transfer from a higher excited state of 1,2-benzanthracene, which was stepwise excited to the region of structured spectrum, to benzene and xylene molecules has been observed.[112] This transition was interpreted as ARVRS. However, the authors of this study noted that nonradiative energy transfer from the virtual levels involved in ARVRS is rather strange.

The problem of 'hot' fluorescence bands in emission spectra due to transitions from HESS has been considered.[113] If a molecule excited to an upper singlet state by the second quantum relaxes to a lower-lying HESS, a substantial excess vibrational energy is stored in the latter state. Hence, it is logical to expect the appearance of 'hot' fluorescence bands in the emission spectrum from this state. If the HESS lifetimes are shorter than the time of vibrational energy redistribution within a complex molecule, the intensities of 'hot' fluorescence bands are determined by the population probability of the states in question *via* internal conversion from upper electronic states and by the rate of the initial stage of energy exchange between the optically active and inactive vibrations. At first glance, the intensities of 'hot' bands in

the emission spectrum must be strongly dependent on the excess vibrational energy in the emitting S_n ($n > 1$) state and, hence, on the energy of the second quantum. However, as can be seen in Fig. 4, the $S_4 \rightarrow S_0$ fluorescence bandshape of 1,2-benzanthracene depends only slightly on the second-quantum energy when it is varied from 17 100 to 28 200 cm^{-1} (for the S_4 state, this corresponds to an excess vibrational energy lying between 8400 and 19 500 cm^{-1}). Considering a 'hot' fluorescence band lying 1400 cm^{-1} above the 0–0 band of the $S_4 \rightarrow S_0$ transition, Lyubimtsev [113] has come to the conclusion that cascade relaxation passes through an optically active vibrational state (1400 cm^{-1}) with a unit probability.

IV. Lifetimes of higher excited S_n states estimated from fluorescence quantum yields and absorption integrals

Determination of a HESS lifetime requires knowledge of the ratio of absolute quantum yield of $S_n \rightarrow S_0$ fluorescence to the number of absorbed second quanta and the radiative rate constant for the same transition. The latter parameter can be estimated using the absorption integral for the band corresponding to the $S_n \leftarrow S_0$ transition.[114, 115]

$$\tau_n = \frac{q_{\mathrm{fl}\,n0}}{k_{\mathrm{r}\,n0}}.$$

A number of studies concerning this subject have been reported.[97, 100, 106] It was found that the HESS lifetimes of organic molecules in solutions vary from several picoseconds for the S_2 states of certain molecules to 10–20 fs for the S_n states, $n = 3–6$. The τ_n values of the order of tens of femtoseconds mean that the electronic relaxation rates of these states are higher than the intramolecular vibrational relaxation rates which were estimated at hundreds of femtoseconds.[19, 116, 117] Elsaesser and Kaiser [20] proposed to distinguish between two types of vibrational excitation relaxation, *viz*., fast relaxation for the energy redistribution between isoenergetic vibrational states and slow relaxation corresponding to the relaxation to lower-lying energy levels. Transfer of excess vibrational energy from the molecule under study to the environment (solvent molecules) proceeds at lower rates and is characterised by the times of the order of several tens of picoseconds.[19, 116] Therefore, the cascade relaxation of the HESS of organic molecules (except for the S_2 state of a certain molecules) can be considered as occurring with conservation of the energy supplied to the molecules. Variation of the excess vibrational energy was found to have a slight effect on the band position and shape in the $S_n \rightarrow S_0$ fluorescence spectra, though in some cases this energy was varied by 10 000 cm^{-1} and more.

Electronic relaxation times of the HESS of aromatic and dye molecules are nearly equal to the period of optically active vibrations ($\nu = 1200–1600$ cm^{-1}) or even shorter.

To verify such interesting results, attempts have been undertaken at estimating the HESS lifetimes using other methods. For instance, the τ_v values were found from the line broadening in the structured spectra appearing upon selective excitation by the second quantum of the HESS lying near the initially excited state.[97, 104] The spectral widths of vibronic bands (the first vibronic band) in such spectra were compared with the spectral width of the 0–0 band in the usual fluorescence spectrum. In those cases where the 0–0 bands were only slightly inhomogeneously broadened (pyrene, 1,2-benzanthracene, phenanthrene, $T = 77$ K), the structured spectra were additionally broadened. Assuming that the broadening of the upper (S_n) and lower (S_1, S_0) levels is uncorrelated, the broadening $\Delta\nu'_{n0}$ due to the short lifetime of the S_n state (*i.e*., the homogeneous width) was estimated using the formula

$$\Delta\nu'_{n0} = \sqrt{[\Delta\nu_{n0}(S_n - S_0)]^2 - [\Delta\nu_{10}(S_1 - S_0)]^2},$$

where $\Delta\nu_{v0}$ and $\Delta\nu_{10}$ are the halfwidths of the corresponding bands.

The broadening calculated using this formula (300 cm^{-1} for the S_6 states of pyrene and 1,2-benzanthracene) corresponds to the lifetime of these states, $\tau_6 = 18$ fs.

These τ_6 values are in reasonable agreement with the estimates obtained for pyrene ($\tau_6 = 15–30$ fs) and 1,2-benzanthracene ($\tau_6 = 18$ fs) from the absolute quantum yields of fluorescence.

The rate constants for nonradiative transitions between the HESS are calculated using the absolute quantum yields of the $S_n \rightarrow S_0$ fluorescence and the radiative rate constants estimated from the band integral in the $S_n \leftarrow S_0$ absorption spectrum. It should be noted that the results of calculations of the absorption band integral refer to the molecule which is in the S_0 state and has its equilibrium configuration. However, the molecule excited from the S_1 state to a HESS after absorption of the second quantum retains the configuration of the former state. If the equilibrium molecular configurations in the S_1 and S_0 states differ only slightly, these estimates of τ_v are justified. However, in some cases (*e.g*., *p*-terphenyl or 2,5-diphenyloxazole) the molecular configuration in the excited (S_1) state is substantially different from the ground-state (S_0) configuration. This manifests itself in different patterns of their absorption and usual fluorescence spectra. According to X-ray diffraction data, the ground-state structure of the *p*-terphenyl molecule is nonplanar.[118] On the other hand, quantum-chemical calculations [119] showed that in the case of fluorescence emission this molecule has a nearly planar configuration. Clearly, the oscillator strengths of electronic transitions and the corresponding energy levels can vary over a wide range upon changes in the molecule geometry (Fig. 6).

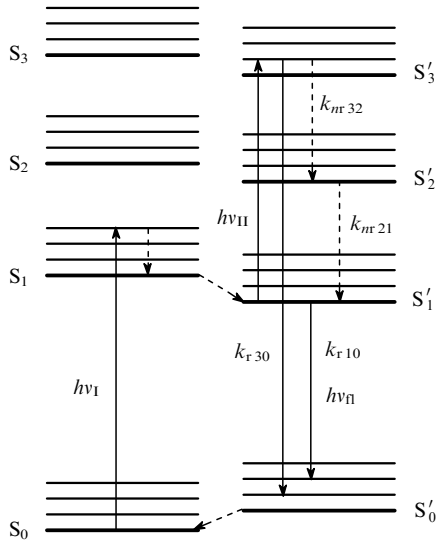

Figure 6. An energy level diagram illustrating two-quantum stepwise excitation of a molecule in the case of variations of the molecular configuration or solvate environment during the lifetime of the fluorescent (S_1) state. The energy levels belonging to the triplet manifold are not shown.

V. Delayed fluorescence from higher excited S_n states due to triplet–triplet annihilation

As has been shown experimentally,[120] annihilation of two molecules being in the lowest triplet state (the so-called triplet–triplet annihilation) can lead to generation of both the first and upper excited singlet (and triplet) states of the molecules:

$$T_1 + T_1 \rightarrow S_n + S_0, \; n \geqslant 1.$$

This process leads to the appearance of not only the usual $S_1 \rightarrow S_0$ fluorescence, but also the $S_n \rightarrow S_0$ ($n > 2$) delayed fluorescence due to triplet–triplet annihilation. This feature was used to detect the phenomenon in question. The first successful experiments were carried out taking 1,2-benzanthracene and fluoranthene dissolved in paraffin oil as examples. A schematical energy level diagram of the interacting molecules is shown in Fig. 7.

Triplet–triplet annihilation studies of a number of aromatic compounds, *e.g.*, naphthalene (S_2), phenanthrene (S_3), triphenylene (S_3), 1,2-benzanthracene (S_3), pyrene (S_2), chrysene (S_3), fluoranthene (S_4) and *N*-methylcarbazole (S_4, S_2?), anthraquinone (S_3, S_4), xanthone (S_3) have been carried out.[121–124] (The singlet state generated after triplet–triplet annihilation is given in parentheses.)

Triplet–triplet annihilation induced fluorescence from the HESS is observed using a phosphoroscope. This allows effective suppression of the stray exciting light, though the usual fluorescence light [it is nearly four orders of magnitude more intense than the $S_n \rightarrow S_0$ ($n \geqslant 1$) fluorescence] remains. In contrast to the stepwise excitation method, triplet–triplet annihilation technique does not allow variation of the energy of the second quantum over a wide range. However, in the former case it is difficult to observe the region near the short-wavelength limit of the usual fluorescence in the fluorescence spectra from HESS, since this spectral region is, as a rule, used for excitation of the molecule under study to the S_1 state by the first quantum. As a result, the stray light precludes measurements of the weak $S_n \rightarrow S_0$ ($n \geqslant 1$) fluorescence spectrum. Triplet–triplet annihilation techniques provides much better conditions for the observation of this spectral region (Fig. 8).

Delayed fluorescence spectra of 1,2-benzanthracene, fluoranthene, pyrene and chrysene solutions in methylcyclohexane at 193 K were obtained by triplet–triplet annihilation technique and corrected for the quantum spectral sensitivity of the experimental setup.[121] All the above-mentioned compounds exhibit clearly seen

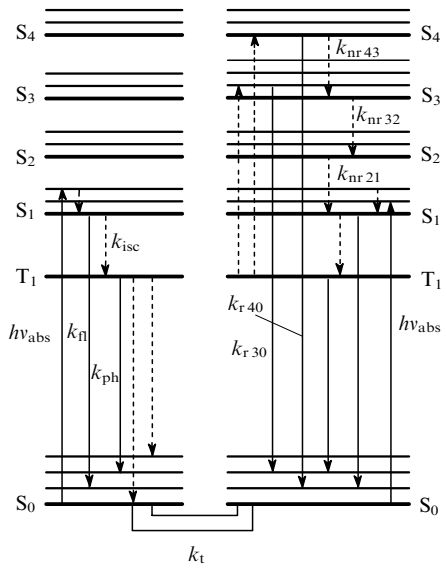

Figure 7. Schematic representation of energy level diagram for nonradiative transitions between higher excited singlet states of a molecule (fluorescence corresponding to transitions from the HESS to the ground state due to triplet–triplet annihilation). Vertical solid and dashed lines denote radiative and intramolecular nonradiative transitions, respectively. The system of dashed lines linked by upward-looking brackets (see the bottom of the diagram) corresponds to the interaction between two triplet molecules accompanied by energy transfer from one to the other molecule and excitation of the latter to a higher excited singlet state (k_t). The energy level diagram for the system of higher excited triplet states of the molecules and the scheme illustrating their triplet–triplet annihilation induced excitation are not shown.

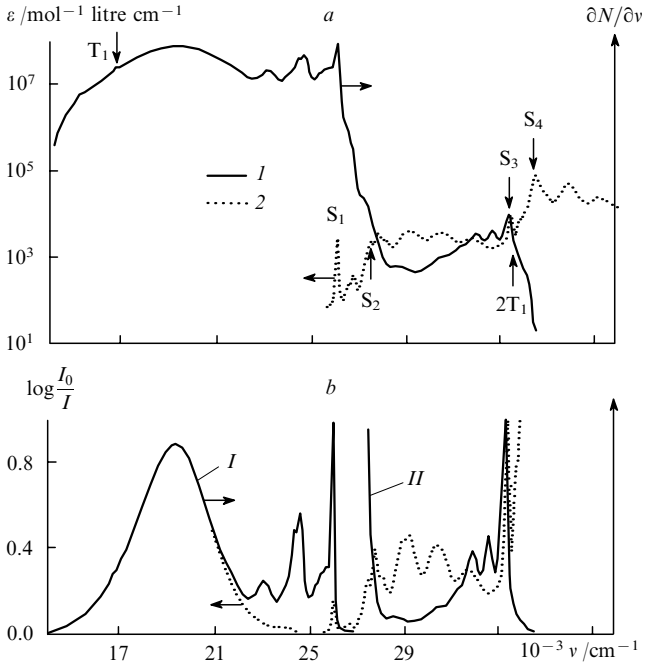

Figure 8. Spectrum of delayed fluorescence due to triplet–triplet annihilation (*1*) and absorption (*2*) spectrum of 1,2-benzanthracene (a 5×10^{-5} mol litre^{-1} solution in methylcyclohexane) measured at $\lambda_{exc} = 365–366$ nm ($T = 193$ K) (I_0 is the initial intensity).
The 'as-measured' (*I*) and expanded (9150 times along the ordinate axis, *II*) representation of the spectra.[121]

$S_n \rightarrow S_0$ fluorescence spectra. In some instances, the $S_n \rightarrow S_0$ fluorescence band appears to be a mirror image of the $S_n \leftarrow S_0$ absorption band, as in the stepwise excitation studies.

$S_n \rightarrow S_0$-Fluorescence spectra of *N*-methylcarbazole (NMC) dissolved in heptane and toluene (Tol) have been studied.[123] Triplet–triplet annihilation was found to induce both fluorescence from HESS of the NMC molecules and sensitised fluorescence of toluene, which is due to the nonradiative energy transfer from the HESS of *N*-methylcarbazole to the toluene molecule. This process can be schematically described as follows:

$$T_1(\text{NMC}) + T_1(\text{NMC}) \rightarrow S_n(\text{NMC}) + S_0(\text{NMC}),$$

$$S_n(\text{NMC}) \rightarrow S_0(\text{NMC}) + h\nu_{fl},$$

$$S_n(\text{NMC}) + S_0(\text{Tol}) \rightarrow S_0(\text{NMC}) + S_1(\text{Tol}),$$

$$S_1(\text{Tol}) \rightarrow S_0(\text{Tol}) + h\nu_{sens\ fl}.$$

Triplet–triplet annihilation of Cd-tetrabenzoporphyrin molecules also induces delayed fluorescence from the S_2 state.[125] In this case, the triplet state was sensitised by triplet–triplet energy transfer from Pd-tetraphenylporphyrin molecules which exhibit only weak S_2 fluorescence [$q_{fl}(S_2 \rightarrow S_0) < 10^{-5}$].

Hetero-triplet–triplet annihilation of azulene and fluoranthene solution in isopentane leads to the appearance of fluorescence from the second excited singlet level of azulene.[126, 127] These studies allowed the determination of the lifetime of the lowest triplet state for azulene (48 μs) and the quantum yields of intersystem crossing for this molecule, $q(S_1 \rightarrow T_1) = 4 \times 10^{-6}$ and $q(S_2 \rightarrow T_1) = 4 \times 10^{-2}$. The rate constants for intersystem crossing, corrected for the lifetimes of azulene molecule in the S_1 and S_2 states (see Table 1), were found to be $k(S_1 \rightsquigarrow T_1) = 2 \times 10^6$ s^{-1} and $k(S_2 \rightsquigarrow T_1) = 2.8 \times 10^7$ s^{-1}. Delayed $S_2 \rightarrow S_0$ fluorescence of 4,6,8-trimethylazulene due to homo-triplet–triplet annihilation was observed[128] at 27 680 cm^{-1} using sensitisation of triplet states by adding phenazine to the solution (the T_1 energy is 15 630 cm^{-1}). Hetero-triplet–triplet annihilation of anthracene and xanthone molecules was used[129] to study fluorescence from the S_6 ($^1B_{3u}^+$) level of anthracene, perdeuterated anthracene and

9,10-dimethylanthracene in their solutions in 1,1,2-trichlorotrifluoroethane. The intensity ratio of the $S_6 \rightarrow S_0$ fluorescence to the $S_1 \rightarrow S_0$ usual fluorescence was found to be $\sim 10^{-6}$. Triplet–triplet annihilation of biphenylene (an antiaromatic compound) sensitised with *N*-methylcarbazole in an isopentane–cyclopentane mixture at 178 K allowed the detection [130] of very weak $S_2 \rightarrow S_0$ fluorescence of this compound, which was not previously observed using direct excitation techniques (see Section II). This indicates a rather high sensitivity of the triplet–triplet annihilation method.

A method was proposed for increasing the intensity ratio of the fluorescence from the HESS and usual fluorescence.[123] It involves the addition of quenchers of the S_1 state to the solution under study. The potentialities of this method were demonstrated taking delayed fluorescence due to triplet–triplet annihilation of pyrene in the presence of efficient quenchers (diethylaniline and triethylamine) as an example. (The additives should be efficient quenchers of the lowest excited singlet state rather than the triplet state and be transparent to delayed $S_n \rightarrow S_0$ fluorescence due to triplet–triplet annihilation. They should also not enter into photochemical reactions with the compound under study.) This experimental technique was used in precise measurements of the $S_2 \rightarrow S_0$ fluorescence spectrum of pyrene.[123]

Interesting results were obtained [56] in studies of annihilation delayed fluorescence of 4*H*-1-benzopyran-4-thione (BPT) in perfluoro-1,3-dimethylcyclohexane. The experimentally determined probability of generation of the S_2 state by triplet–triplet annihilation was found to be 0.03. This is much lower than the statistical coefficient for the creation of a singlet state by triplet–triplet annihilation (0.25), obtained assuming that the quintet state is inaccessible from 'energy' considerations. The authors of this study mentioned that the probability obtained (0.03) is of the same order of magnitude as the known parameters for anthracene (0.08) and phenanthrene (0.02). The observed generation of the S_2 state of BPT by triplet–triplet annihilation was interpreted [56] as a special case of Förster's (exchange-resonance) energy transfer mechanism.‡ However, the lack of data on the $T_1 \rightarrow S_n$ absorption spectra of BPT precludes calculations of S_2 generation. Note that exchange-resonance mechanism of energy transfer between T_1 states should be common to processes of generation of both S_n and T_n states and that in the case of similar intensities of the spin-allowed and spin-forbidden transitions in the BPT molecule the $T_1 \rightarrow S_n$ spectra are indistinguishable from the $T_1 \rightarrow T_n$ ones.

The HESS lifetimes were estimated from the broadening of the 0–0 vibronic bands in the absorption spectra compared to the 0–0 band of the long-wavelength transition. Another method used for estimating the τ_v values involved the determination of (i) the quantum yield ratios of $S_n \rightarrow S_0$ fluorescence and delayed $S_1 \rightarrow S_0$ fluorescence under the same conditions and (ii) the rate constants for radiative $S_n \rightarrow S_0$ transitions from the absorption integrals for the corresponding $S_n \leftarrow S_0$ transitions. The estimates obtained are listed in Table 6.

Triplet–triplet annihilation technique has a drawback consisting in uncertainty in the identification of the annihilation-generated HESS, since the excitation probability distribution of these states is determined by the overlap integral of the $T_1 \rightarrow S_0$ emission and $S_n \leftarrow T_1$ absorption spectra normalised to a unit band area. Unfortunately, if the phosphorescence spectra are, as a rule, known, almost no information on the $S_n \leftarrow T_1$ absorption spectra is available. In the case of triplet–triplet annihilation, intersystem crossing becomes allowed in the $S_n \leftarrow T_1$ transitions; however, the effect of the Franck–Condon factors persists.[131]

Katoh and Kotani [132] studied fluorescence from the HESS of an anthracene crystal upon fusion of two singlet (S_1) excitons. They also investigated [133] $S_n \rightarrow S_0$ fluorescence of an anthracene crystal using a two-step laser excitation technique.

‡ Eisenberger *et al.*[56] pointed out that triplet–triplet annihilation of aromatic hydrocarbon molecules follows the exchange-resonance energy transfer mechanism. They used a much higher rate constant for the $T_1 \rightarrow S_0$ transition in BPT.

VI. Lifetimes of higher excited S_n states of molecules estimated from homogeneous broadening of absorption spectra

The method of estimation of the HESS lifetimes from the data on homogeneous line broadening in absorption spectra is based on the uncertainty relation, which relates the lifetime of an excited electronic or vibronic state of a molecule under study to the homogeneous broadening of the corresponding energy level

$$\tau_n = \frac{1}{2\pi c \Delta\nu_{1/2}},$$

where, τ_n is the lifetime of the energy level (in seconds), c is the velocity of light (in cm s^{-1}) and $\Delta\nu_{1/2}$ is the halfwidth of the energy level (in cm^{-1}). At first glance, τ_n values can be simply determined using this formula after measuring any absorption or emission line corresponding to the transition between the ground and excited states. Indeed, since the ground-state lifetime is infinitely long, this state contributes negligibly to the homogeneous broadening of the spectrum. However, there is also inhomogeneous broadening, which much exceeds the homogeneous broadening in the case of solutions, and the broadening due to phase relaxation.[134]

Subsequently several experimental methods for elimination or strong suppression of inhomogeneous broadening were developed.[135–142] These are as follows:

— low-temperature measurements of absorption and luminescence spectra of crystals;

— measurements of impurity spectra from crystals in those cases where the impurity molecule under study can be easily incorporated into the unit cell of the matrix crystal (*e.g.*, a naphthalene molecule in durene crystal);

— spectral line narrowing in Shpolskii matrices;

— obtaining of narrow fluorescence spectra using the Personov effect upon excitation to the region of the 0–0 electronic transition by monochromatic radiation;

— 'hole burning' in absorption spectra using photochemical reactions or another mode-selective technique for removal of 'inhomogeneously broadened' molecules with specified electronic energy;

— obtaining of extremely narrow absorption or fluorescence spectra in free supersonic jets.

Narrowing of spectral lines broadened due to phase relaxation is achieved by cooling the samples under study. Therefore, the above-mentioned experimental methods are, as a rule, applicable at temperatures close to the liquid helium temperature. Ignoring phase relaxation requires preliminary measurements and analysis of the temperature dependence of linewidths.

Hochstrasser and Marzzacco[134] studied the $T_n \leftarrow S_0$ and $S_n \leftarrow S_0$ absorption spectra of a number of aromatic compounds in the crystalline phase at 4.2 K. Presumably, they were the first who considered substantial broadening of vibronic bands in the absorption spectra upon excitation to the second and upper electronic states. For instance, marked broadening of vibronic lines was found in the spectra of pyrazine and its derivatives, phenazine, 9,10-diazaphenanthrene, naphthalene and its halogen derivatives in the region of the $T_2 \leftarrow S_0$ transition. According to Kasha's rule, excitation of a molecule to the second triplet state should be followed by fast internal conversion to the lowest triplet state. A similar broadening was observed in the singlet–singlet absorption spectra of naphthalene and quinoxaline molecules incorporated into durene crystals, of naphthalene and quinoxaline vapours and of naphthaldehyde. These spectra exhibited narrow $S_1 \leftarrow S_0$ absorption lines which were substantially broadened on approaching the lines corresponding to the $S_2 \leftarrow S_0$ transition.

Studies of vibronic absorption linewidths of different singlet–singlet transitions of anthracene, coronene and 1,2-benzperylene in Shpolskii matrices revealed[135] noticeable narrowing of the $S_n \leftarrow S_0$ ($n \geqslant 1$) lines with a decrease in the temperature from 300 to 77 K. Further reduction of temperature down to 4.2 K was found to have little effect on the linewidths. Narrowing of the $S_1 \leftarrow S_0$ line was followed down to 4.2 K. The linewidths for a number of compounds are listed in Table 7. However, the $S_1 \leftarrow S_0$ linewidths were found to be strongly overestimated since the S_1 state lifetimes of the molecules under study estimated from these linewidths are nearly three orders of magnitude shorter than the

measured lifetimes. Analysis of the results obtained in the above-mentioned studies [136–139] shows that these linewidths much exceed the natural linewidths even in the Shpolskii matrices; determination of the natural linewidths requires the Personov holes [98, 99] to be 'burnt' in the absorption lines.

The linewidths of transitions to upper excited singlet states also seem to be overestimated.

A series of studies on free porphyrin base dissolved in the Shpolskii matrices has been reported.[136–139] The homogeneous linewidths were determined using a photochemical hole burning technique based on the tautomeric transformations involving inner hydrogen atoms of the porphyrin molecule.[64, 136] Samples were irradiated by a tunable single-mode laser with a frequency jitter of $\sim$10 MHz. The contribution of phase relaxation was determined from the temperature dependences of the 0–0 linewidths in the range from 1.5 to 4.2 K. The homogeneous width of the 0–0 line for the $S_1 \leftarrow S_0$ transition was found to be $\sim$9 MHz (0.0003 cm^{-1}) at 1.5 K,[137] which corresponded to the experimentally observed $S_1 \leftarrow S_0$ fluorescence decay time of free porphyrin base in n-octane at 4.2 K (17 ns). This indicates that the hole burning technique does allow measurements of homogeneous line broadening, thus providing a means for determination of the lifetimes of the excited states of organic molecules.

The lifetimes of vibronic levels for the S_1 state of free porphyrin base in n-octane at 4.2 K (Table 8) were determined using the same procedure.[139] The homogeneous holewidth of the 0–0 band was found to be $\sim$9 MHz, whereas those of the vibronic bands for the same transition were varied from 5 to 150 GHz (0.1–7 cm^{-1}). Both hole burning and measurements of vibronic bandwidths in the spectra corresponding to transitions to upper electronic excited levels were performed using a tunable pulsed laser with a bandwidth of $\sim$1 cm^{-1}.

The lifetimes of several vibrational levels of the S_1 state of free porphyrin base at 4.2 K vary from 1 to 30 ps (Table 8). Totally symmetrical modes in the frequency range from 150 to 1160 cm^{-1} are characterised by substantial variations of the lifetimes. For the modes with frequencies lying between 1340 and $\sim$1580 cm^{-1}, the lifetimes of vibrational levels were estimated at 1.0 to 1.6 ps irrespective of the vibrational mode symmetry. This is in reasonable agreement with the results of measurements of the lifetimes of vibrational levels of organic molecules obtained by other experimental methods.[116, 117] Note that the rates of vibrational relaxation of most of higher excited states are much lower than those of electronic relaxation (see Tables 2–5).

The S_3 state lifetimes of a tetrabenzoporphyrin derivative [a solution in THF–Et_2O (1 : 1) mixture] determined from hole burning experiments at 4.2 K and estimated from the $S_3 \rightarrow S_0$ fluorescence quantum yield have been compared.[140] As in the preceding case, holes were burnt using photochemically induced tautomeric transformation involving inner hydrogen atoms of porphyrin molecule. The hole halfwidth was found to be 10 cm^{-1} for the $S_3 \leftarrow S_0$ transition (λ_{max} = 434 nm), which corresponded to the S_3 level lifetime, τ_3, of 0.53 ps. The lifetime of the same state estimated from the $S_3 \rightarrow S_0$ fluorescence quantum yield and the ratio of the radiative rate constants for the $S_3 \rightarrow S_0$ and $S_1 \rightarrow S_0$ transitions (these were determined from the absorption spectrum) was 1.2 ps. The discrepancy between the two τ_3 values is not too large; however, it seems to be greater than the experimental error. Position of the S_2 level of the tetrabenzoporphyrin derivative has also been determined.[140] The corresponding band in the absorption spectrum is overlapped with vibronic bands of the $S_1 \leftarrow S_0$ transition. However, hole burning measurements allowed the observation of the 0–0 band of the $S_2 \leftarrow S_0$ transition at 606 nm and estimation of the S_2 state lifetime at 0.38 ps. The lifetime of the vibronic sublevel of the S_1 state with an energy of 1108 cm^{-1} was also determined: the hole halfwidth was found to be 0.18 nm, which corresponded to a vibronic level lifetime of 1.1 ps.

Hole burning technique was used for studying internal conversion in Zn-tetraphenylporphyrin molecules incorporated into polymeric matrices at 4 K.[141] The homogeneous broadening in the Soret band was close to that found in the preceding case [140] (see Table 7). Supersonic jet measurements have led to similar results.[142, 143]

The HESS lifetimes were estimated by the photophysical (optical) hole burning method.[144] Previously,[145] this experimental technique was used in a study on the temperature dependence of phase relaxation of the S_1 state of Zn-porphyrin molecule. To burn holes in the $S_2 \leftarrow S_0$ absorption band of phenanthrene (a solution in isopentene–2-methylpentane mixture at 4.2 K), molecules were excited to a triplet state by irradiating samples by the light of a pulsed dye laser with frequency doubling. Absorption was measured using a high-resolution double monochromator. A phosphoroscope was constructed to provide alternate illumination of a sample placed in a cryostat by the laser light and by the transmitted light of a Xe lamp. The homogeneous halfwidth of hole burnt was found to be 67 cm^{-1}, which corresponded to the $S_2(0)$ state lifetime of phenanthrene, τ_2, of 0.079 ps. The lifetime of the S_2 vibronic state (400 cm^{-1}), also determined by both resonance and off-resonance hole burning techniques, was found to be nearly the same. On the other hand, homogeneous linewidth measurements of isolated phenanthrene molecules in a supersonic jet have led to a value of 0.5 ps for $\tau_2(0)$.[146] The reason for such a large difference between the estimates of the lifetimes of the second excited state of phenanthrene molecules is still to be clarified. Indeed, since fast internal conversion occurs intramolecularly, one would expect similar rates of internal conversion for the molecule in the condensed phase and in the vapour phase. Unfortunately, comparable information on the rate constants for internal conversion from higher excited states in the condensed phase and in supersonic jets for the same molecules is scarce.

Nickel and Wick [147] studied the vibrational structure of the S_0-S_2 absorption band of coronene in poly(methyl methacrylate) at 1.8 K by the photophysical hole burning technique. The lifetime of the vibronic S_2 states, estimated from the homogeneous width of resonance transitions, was found to be somewhat shorter than 2 ps. This is in reasonable agreement with the results obtained by different authors [148, 149] who observed fluorescence from the S_2 state of coronene under conditions of direct single-quantum excitation and with the results of measurements of the homogeneous width of fluorescence excitation lines in the Shpolskii matrices and in a supersonic jet. Such a relatively long lifetime of the S_2 state [with the energy gap $\Delta E(S_2-S_1) \simeq 5000$ cm^{-1}] seems to be due to high molecular symmetry and forbiddenness of the $S_2(^1B_{1u}) \rightarrow S_1(^1B_{2u})$ radiative transitions. Unlike phenanthrene, the homogeneous linewidth of coronene is nearly the same both in a supersonic jet and in the low-temperature matrix.

A large body of information on the linewidths in the molecular spectra (including those of porphyrins) obtained in supersonic jet studies has been reported.[142, 143, 146]

Table 8. Lifetimes of vibrational levels of the S_1 state of free base porphyrin molecules (a solution in n-octane) at 4.2 K.[139]

ν /cm^{-1}	Mode symmetry	Homogeneous width /GHz	τ /ps

VII. Lifetimes of higher excited S_n states estimated from picosecond and femtosecond spectroscopy data

In the last decade, direct measurements of the HESS lifetimes of organic molecules were reported. To measure the decay of very weak emission from these states with femtosecond resolution is a complicated problem. Conventional experimental techniques involve consecutive stepwise excitation by two picosecond or femtosecond light pulses with a small pulse delay. The second pulse is used for measuring the kinetics of either the induced absorption spectrum or the absorption spectrum reconstruction for the lower-lying state (laser photolysis with picosecond or femtosecond resolution). Excitation by the second pulse also allows photoionisation of a molecule followed by mass-spectrometric or another type of detection of the cation formed or electron detached. Recently, a large number of studies concerning measurements of ultrafast luminescence decay kinetics by luminescence up-conversion, *i.e.*, 'mixing' of weak luminescence with an optically delayed femtosecond pulse in a nonlinear crystal, were reported.

When comparing different methods for studying the dynamics of internal conversion from HESS, preference should be given to those which allow the observation of fluorescence kinetics due to transition from these states. Studies of molecular absorption spectra induced by laser pulses are complicated by three factors, *viz.*, transition-state absorption, ground-state 'bleaching' and stimulated emission from the excited state. The results of second-pulse induced photoionisation studies are also ambiguous.

A stepwise photoionisation study of the lifetime of the S_2 state (35 900 cm^{-1}) of naphthalene in a supersonic jet has been reported.[150] However, only the upper bound of the lifetime of this state (10^{-11} s) was estimated due to instrumental limitations on the pulse duration (6 ps). Quenching of the S_2 fluorescence of Zn(TPP) in acetonitrile due to the addition of dichloromethane has been studied by an up-conversion technique.[151] The lifetime $\tau(S_2)$ of ZnTPP was found to be 3.5 (in acetonitrile) and 0.75 ps (in dichloromethane). Since the S_2 state lifetime is very short, the concentration dependence of fluorescence quenching can be described using the Perrin model:

$$\ln\frac{I_0}{I} = VN_A[CH_2Cl_2],$$

where I_0 is the radiation intensity without a quencher, I is the radiation intensity, $V = (4/3)\pi R^3$ is the action range of the quencher ($R = 15$ Å) and N_A is the Avogadro constant. It was found [151] that quenching of fluorescence from the S_1 state of Zn(TPP) with dichloromethane is inefficient. The authors suggested that quenching of the S_2 fluorescence is due to electron transfer.

Internal conversion in complexes of Zn-porphyrin (ZnP) derivatives and free porphyrin base (H_2P) dissolved in benzene has been studied by femtosecond fluorescence spectroscopy.[152] For ZnP, two fast components of the $S_2(B) \rightarrow S_0$ fluorescence decay were associated with the $S_2 \rightarrow S_1$ internal conversion with a time constant of 150 fs (spectral changes in the region of the $S_2 \rightarrow S_0$ transition) and with vibrational relaxation to the $S_1(Q)$ state with a time constant of 600 fs (spectral changes in the region of the $S_1 \rightarrow S_0$ transition). Free porphyrin base exhibits ultrafast relaxation of the $S_3(B)$ state ($\tau < 40$ fs), fast relaxation of the $S_2(Q_y)$ state with a time constant of 90 fs and a slower vibrational relaxation of the $S_1(Q_x)$ state. A fluorescence up-conversion study of fluorescence decay from the $S_3(^1B_b)$ state of tetracene in solution using 280 fs pulses was carried out.[153] The decay time, τ, of the ($S_3 \rightarrow S_0$) fluorescence of tetracene in the UV region was estimated to be $\sim$120 fs. Usual fluorescence from the $S_1(^1L_a)$ level was found to arise with the same rate constant.

Decay kinetics of the S_2 and S_1 states of Malachite Green dye in different solvents (methanol, water, ethylene glycol and water–glycerol mixture) has been studied by femtosecond fluorescence up-conversion spectroscopy (pulse separation $\Delta t = 90$ fs).[154] The decay times in an aqueous solution were estimated at 0.27 ps for $\tau(S_2)$ and at 0.54 ps for $\tau(S_1)$. If the molecule is excited to the second singlet state, the rise of the S_1 fluorescence and the decay of the S_2 fluorescence occur with the same rate constant.

Femtosecond time-resolved photoelectron spectroscopy ($\Delta t < 200$ fs, $\lambda = 252$ nm) was used for studying ultrafast internal conversion in 1,3,5-hexatriene, which is one of the simplest representatives of polyenes.[155] The S_1 state lifetimes were estimated at 730 and 270 fs for *cis*- and *trans*-hexatriene, respectively. The authors of this study suggested that relaxation process occurs as a cascade, *viz.*, $S_2 \rightsquigarrow S_1 \rightsquigarrow S_0$. The estimate of the S_2 state lifetime, $\tau(S_2) \leqslant 50$ fs, is consistent with that obtained earlier [156] from the homogeneous width of the $S_2 \leftarrow S_0$ absorption line at 250 nm in supersonic jets. The S_2 state decay times were estimated at 50 fs for *trans*-hexatriene and at 20 fs for *cis*-hexatriene. This is close to the S_2 state lifetime of *trans*-hexatriene vapours (40 fs) obtained from the data on resonant Raman scattering.[157]

Femtosecond up-conversion studies of the effect of molecular structure and solvent on the S_2 state lifetimes of carotenoids have been reported.[158, 159] They revealed violation of Kasha's rule [8] and Ermolaev–Sveshnikova's rule [160, 161] (the sum of the fluorescence and triplet-state generation quantum yields equals unity for solutions of fluorescent compounds) in the case of linear polyenes including carotenoids. It was pointed also out that the main emission of molecules with C_{2h} symmetry originates from the S_2 level (the $S_2 \rightarrow S_1$ radiative transition is forbidden). If the molecular symmetry is broken, the S_1 emission becomes stronger. The τ_2 values for the three compounds studied lie between 100 and 200 fs. More recently, in studies of neurosporene (a linear carotenoid) it has been shown [162] that excitation to the S_2 state with an excess vibrational energy of $\sim$3000 cm^{-1} leads to the appearance of a time-dependent $S_2 \rightarrow S_0$ fluorescence spectrum. This was explained by the vibrational energy redistribution in the S_2 state from the Franck–Condon active modes to other (dark) modes with a time constant of 35–40 fs, followed by the $S_2 \rightarrow S_1$ internal conversion occurring in 250 fs.

The effect of hydrogen bond formation/dissociation on the relaxation rate of the S_3 and S_2 states of *trans*-retinal molecules (a solution in butan-1-ol–cyclohexane mixture) on the subpicosecond time scale has been first studied recently.[163] The $S_3[B_u^+(\pi,\pi^*)]$ and $S_2[A_g^-(\pi,\pi^*]$ state lifetimes of the molecules under study in neat butan-1-ol (200 fs and 1.8 ps, respectively) were found to be much longer than the corresponding lifetimes in neat cyclohexane (30 fs and 0.7 ps, respectively). In the S_2 state, all the *trans*-retinal molecules are hydrogen-bonded. The increase in the fluorescence and the isomerisation quantum yields and the decrease in the triplet quantum yield upon hydrogen bond formation were explained by the prolonged lifetime of the S_2 state of *trans*-retinal. The authors cited were the first to study the formation and cleavage of a hydrogen bond in a subpicosecond time.

Hirata *et al.*[164, 165] studied the dependence of the rate constant for the $S_2 \rightarrow S_1$ internal conversion on the energy gap width in the molecules of (i) diphenylacetylene and its derivatives and (ii) *trans*-α,ω-diphenylpolyenes with different chain length (solutions in n-hexane and THF were used in both cases). The S_2 state lifetimes of diphenylpolyenes with the molecular chains of length from 3 to 8 monomer units and the energy gaps of width from 1600 to 4800 cm^{-1} varied insignificantly (500 ± 100 fs) and increased only slightly with the decrease in the temperature. The rate constant for the $S_1 \rightarrow S_0$ nonradiative transition increased by three orders of magnitude for the same diphenylpolyenes.

A femtosecond laser flash photolysis study on fast photo-induced reactions of *trans*-azobenzene excited to the S_2 state (in solutions at 303 K, $\sim$200 fs resolution) has been reported.[166] Analysis of the induced absorption decay curve measured in the region 370–450 nm revealed its two-exponential structure and

allowed determination of the time constants which appeared to be different for different solvents. The time constant for the fast exponent, τ_1, was found to be 0.9 ps for hexane, cyclohexane and hexadecane and 1.2 ps for acetonitrile. That for the slow exponent, τ_2, was found to be 13 ps for the hydrocarbons and 16 ps for acetonitrile. The authors suggested that the decay of the fast exponent is due to deactivation of the $S_2(\pi,\pi^*)$ state. The appearance of the slow exponent was explained by the presence of an intermediate excited singlet state lying between the S_2 and S_1 states on the energy scale, corresponding to the *twist*-conformer of the excited *trans*-azobenzene molecule. The dynamics of the S_2 and S_1 states of *trans*-4-n-butyl-4′-methoxyazabenzene in hexane has been studied [167] by a similar experimental technique with the same resolution. The time constants were estimated at $\approx$250 fs for $\tau(S_2)$ and at 2.3 ps for $\tau(S_1)$.

Femtosecond time-resolved photoelectron spectroscopy was used for measuring the S_n state lifetimes of pyrazine molecules in a supersonic jet.[168] In particular, the lifetime of the S_2 state, $\tau(S_2)$, was estimated at 20 fs. A supersonic jet study of the S_2 state of benzene – ammonia complexes has been reported.[169] The S_2 state lifetime was estimated at $\sim$100 fs.

Fluorescence of coumarin 481 in cyclohexane at 293 K, which appeared after excitation by 100 fs pulses at λ = 267 nm has been studied in detail.[170] The molecules were excited to an S_n state lying 12 000 cm^{-1} higher than the S_1 state and then the dynamics of the rise of the $S_1 \rightarrow S_0$ fluorescence was observed using up-conversion technique. The time constant of the rise of the fluorescence in the region 419 – 475 nm was found to be 280 to 220 fs. This time was interpreted as that required for completion of the $S_n \rightarrow S_1$ internal conversion. It was also suggested that intramolecular redistribution of vibrational energy in the S_1 and S_0 states occurs with strongly different rates.[170]

However, there is also another concept of the redistribution of excess vibrational energy in the ground and first excited states after optical excitation.[20] The authors came to conclusion that vibrational excitation is redistributed in the S_0 and S_1 states of dye molecules with the same rate constant. Based on analysis of their original studies and published data, they also suggested that in most cases redistribution of excess vibrational energy involves two stages. The first stage is fast, with a time constant τ_1 estimated at 30 to 200 fs, while the second stage is slow, with a time constant τ_2 estimated at 200 to 1000 fs. It was assumed that the fast stage is due to the interaction of isoenergetic vibrational levels, whereas the slow stage is due to coupling of levels with different energies. Yet another assumption is that the time required to 'cool' a vibrationally 'overheated' molecule *via* transfer of excess energy to the environment (solvent molecules) should be much longer (from 15 to 40 ps for different solvents).

The dynamics of IR 125 dye in ethylene glycol solution was studied by pump-probe experiments.[171, 172] The pump pulse duration was 30 fs (λ = 425 nm) while the probe pulse width was 20 fs (λ = 850 nm). It was found that a dye molecule excited to an S_n ($n > 1$) state by a pulse at λ = 425 nm arrives at the S_1 state within 50 fs; however, the time constant of S_1 population (accumulation of molecules at the minimum of the PES of this state) is much larger ($\sim$1 ps).

A number of papers concerning nonradiative transitions between higher excited electronic levels of the molecules comprised of ten or smaller number of atoms was reported. In particular, the S_2 state lifetimes of acetone and its deuterated analogue in the vapour phase were studied using femtosecond photoionisation (λ_{exc} = 194 nm, λ_{ion} = 295 nm).[173] It was found that $\tau(S_2)$ = 13.5 ps for acetone-d_6 and 4.7 ps for acetone-h_6. In this case, the S_1 state lifetimes of both molecules ($<$ 150 fs) are shorter than the corresponding S_2 state lifetimes. This is similar to azulene and β-carotenes.

VIII. Ultrafast nonradiative transitions involving triplet states

A salient feature of aromatic and dye molecules is the possibility of ultrafast nonradiative transitions involving triplet states. Naturally, the question arises of the rates of such transitions.

Liu and Edman [174] studied photoisomerisation reactions of various alkenes sensitised by anthracene and its derivatives. All the reaction pathways were known to pass through triplet states. The authors assumed that the photoreactions can proceed only *via* excited molecules of anthracene and its derivatives. Since the lowest triplet levels of anthracenes lie much below those of alkenes, it was suggested that the reactions under study proceed due to energy transfer from the second triplet level (T_2) of the anthracenes and that the T_2 level is populated *via* intersystem crossing from the S_1 state. [The T_2 level of the sensitiser molecules lies somewhat lower than their first excited singlet level, $E(T_2)$ = 25 000 – 26 000 cm^{-1}]. Among all the alkene reactions studied, the highest quantum yield (0.042) was found for *cis – trans* isomerisation of piperylene in benzene (0.2 M) at 293 K sensitised by 9,10-dibromoanthracene. Assuming that the rate constant for triplet – triplet energy transfer from the T_2 level is equal to the diffusion rate constant, the T_2 state lifetime of 9,10-dibromoanthracene was estimated at 1.3×10^{-10} s.[175]

An alternative explanation for the results obtained by Liu and Gale [175] has been put forward in a paper [176] concerning fluorescence quenching of haloanthracenes by naphthalene and phenanthrene. Taking into account a correlation between the rate constants for quenching and the spin-orbit coupling constants of anthracene derivatives, the authors concluded that a spin-forbidden, singlet – triplet energy transfer occurs in this case. Similarly to the earlier results,[175] the most pronounced effect was observed for 9,10-dibromoanthracene. It was also assumed [176] that this process should also lead to population of triplet states of the energy acceptor and can induce alkene isomerisation.

Only a few observations of the fluorescence due to triplet – triplet transitions have been reported. For instance, $T_2 - T_1$ fluorescence was detected upon excitation of certain anthracene derivatives dissolved in methylcyclohexane to the S_1 state.[80, 177] Fluorescence spectra were measured in air at room temperature. The 0 – 0 bands in the $T_2 - T_1$ fluorescence spectra of these compounds lie in the region from 840 to 960 nm (12 000 – 10 400 cm^{-1}) and are nearly mirror images of the long-wavelength $T_n \leftarrow T_1$ absorption bands. The $T_2 \rightarrow T_1$ fluorescence quantum yields were estimated at 10^{-6} for 9,10-dibromoanthracene [$\tau(T_2) = 2 \times 10^{-12}$ s] and at 5×10^{-8} for the unsubstituted anthracene [$\tau(T_2) = 10^{-13}$ s]. These values are in poor agreement with indirect estimates of the T_2 state lifetime of anthracene, obtained from the results of photochemical sensitisation studies.[178]

Keller [179] was the first to report on the reverse intersystem crossing from higher excited triplet states of aromatic molecules to the excited singlet levels. At 77 K, aromatic molecules in a glassy matrix were excited by UV irradiation to populate the lowest triplet state. Then the molecules were excited by visible light into the $T_n \leftarrow T_1$ absorption bands and their UV fluorescence accompanying the $S_1 \rightarrow S_0$ transition (Fig. 9) was observed. The fluorescence intensity was proportional to the intensity of visible light and the fluorescence lifetime was identical to the lifetime of the lowest triplet T_1 state. The quantum yield of the triplet – singlet intersystem crossing process (the ratio of the number of $T_n \rightarrow S_1$ transitions to the number of photons absorbed by the T_1 state) is small, namely, 5×10^{-7} for naphthalene, 2×10^{-6} for quinoline and 10^{-6} for fluorene. Kobayashi *et al.*[180] also observed the $S_1 \rightarrow S_0$ fluorescence of anthracene and its 9-methyl and 9-phenyl derivatives due to reverse intersystem crossing. The quantum yield of the $T_n \rightarrow S_1$ intersystem crossing was estimated at 5×10^{-6} for anthracene and at 8×10^{-5} for 9-phenylanthracene. More recently [181] some arguments were adduced in favour of assumption that the S_1 state of 9,10-dibromoanthracene molecule is

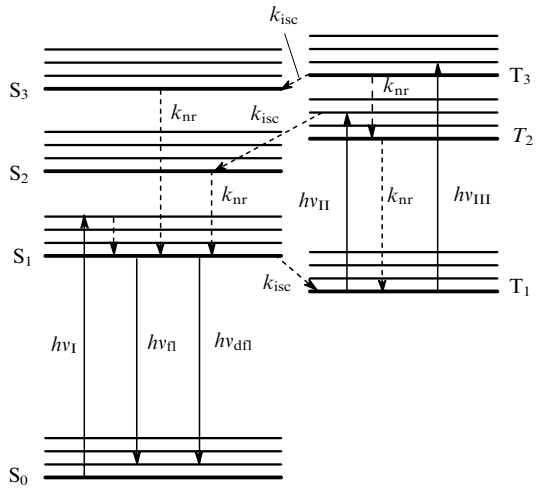

Figure 9. An energy level diagram illustrating the appearance of delayed fluorescence (ν_{dfl}) after excitation of a molecule to a higher excited triplet state and intersystem crossing from this state to the singlet manifold.

populated *via* absorption of a light quantum by the T_1 state and is also due to the $S_m \leftarrow T_1$ transition. Population of the fluorescent state of perylene vapours *via* excitation of the lowest triplet state by consecutive irradiation by two laser pulses has been reported.[182]

A version of Keller's technique [179] which uses stepwise excitation by nanosecond laser pulses has been proposed in studies of xanthene dyes (eosin, erythrosin and Rose Bengal) in polymeric matrices.[183, 184] The authors simultaneously observed both the delayed fluorescence induced by the second delayed pulse and the decrease in the optical density of the triplet–triplet absorption, which was rationalised by the occurrence of the $T_n \rightarrow S_m$ reverse intersystem crossing. Thus, a competition of nonradiative intersystem crossing with internal conversion over the triplet manifold is implied. This is quite probable since the molecules studied contain heavy Br or I atoms. However, too high quantum yields of the process [183, 184] are suspicious because the spin-forbidden transition competes with the spin-allowed process of internal conversion over the triplet manifold.

Similar approach was used in studies of the $S_1 \rightarrow S_0$ fluorescence of Rose Bengal in aqueous solutions (a phosphate buffer, pH 7.0).[185] Fluorescence appeared after stepwise excitation of the dye molecules from the lowest triplet state to excited triplet states, followed by reverse intersystem crossing to the singlet manifold and emission. An intense absorption band at $\lambda_{max} = 1063$ nm was detected by near-infrared laser flash photolysis measurements and assigned to the $T_2 \leftarrow T_1$ transition.[185] It was found that excitation of the dye by the second harmonic of a Nd laser ($\lambda = 532$ nm, $t_{pulse} = 134$ ps) to the S_1 state leads to population of the T_1 triplet state with a probability of 0.98 and to fluorescence emission with a quantum yield of 0.02. The second pulse of the fundamental frequency of the Nd laser excited the solution with a delay of 34 ns to populate the T_2 state since the fundamental frequency of neodymium penetrates the long-wavelength triplet–triplet absorption band.

Population of the T_3 state was achieved by irradiating the solution by the second pulse ($\lambda = 632$ nm) with the same delay. Then, the dependence of the intensity of two-step, laser-induced delayed fluorescence on the intensity of laser pulses was measured and analysis using a simplified kinetic scheme was performed. As a result, the quantum yield of the $T_2 \rightarrow S_1$ reverse intersystem crossing, $q(T_2,S_1)$, was estimated at 0.014 and the T_2 state lifetime, $\tau(T_2)$, was found to be 5.8 ps.[185] No $S_1 \rightarrow S_0$ fluorescence was observed upon two-step laser-induced excitation at $\lambda_2 = 632$ nm *via* the T_1 state. Therefore, only the upper bound of the reverse intersystem crossing yield from the T_3 state, $q(T_3 \rightarrow S_n)$, was estimated at 0.06. These results strongly disagree with those obtained in earlier studies,[183, 184], according to which $q(T_3 \rightarrow S_n) = 0.74$. Previously,[183] this value was estimated from the decrease in the T_1 state population of the dye after irradiation by the second pulse at $\lambda_2 = 632$ nm.

Table 9. Quantum yields of reverse intersystem crossing for excited triplet levels of Rose Bengal dye molecule.[185]

Energy level	E /cm^{-1}	$\Delta E(T_n \rightarrow S_n)$ /cm^{-1}	$\Delta E(T_n \rightarrow T_{n-1})$ /cm^{-1}	$q(T_n \rightarrow S_n)$
T_2	23 550	4030	9435	0.014
T_3	31 130	2820	7580	< 0.06
T_4	32 500	640	1370	0.8

Previously (see, *e.g.*, Refs 186 and 187), it was assumed that the reverse intersystem crossing occurs mainly from the T_2 level. However, the results of measurements of the quantum yield $q(T_n \rightarrow S_n)$ for Rose Bengal rule out this assumption. Table 9 lists the quantum yields of reverse intersystem crossing, positions of triplet levels and the energy gaps between them and the nearest lower-energy triplet and singlet levels of the Rose Bengal molecule. As can be seen, the quantum yields of reverse intersystem crossing are satisfactorily described by the 'energy gap law'; however, it should be remembered that internal conversion over the triplet manifold leads to the energy gap narrowing with increase in the level number. This casts some doubts on the too high yield of reverse intersystem crossing from the T_4 level, though the strength of the spin-orbit coupling between particular triplet and singlet states plays a significant role in this case.[185]

It was found that the addition of LiBr in combination with stepwise excitation to HESS leads to an increase in the quantum yield of triplet rhodamine generation in solution.[188]

IX. Conclusion

The results obtained using different methods of determination of the rate constants for ultrafast nonradiative transitions, considered in this review are, with rare exception, in reasonable agreement with one another. Those obtained by recently developed but rather widely used direct picosecond and femtosecond methods for measuring the fluorescence decay have for the most part confirmed indirect estimates based on the fluorescence yields from HESS under conditions of single-quantum or two-quantum excitation to corresponding levels and found from the homogeneous absorption linewidths. It was established that in most cases the HESS lifetimes of organic and dye molecules are of the order of tens of femtoseconds. The only exception is the second excited singlet state (S_2), the lifetime of which for a number of molecules is much longer, so that it can be considered as a specific state similar to the fluorescent state (S_1). More complex is the problem of theoretical interpretation of experimental results. Correspondence between the observed rate constants and predictions of modern theories of nonradiative transitions is fragmentary. In some instances even the 'physical' or 'chemical' mechanism responsible for the nonradiative transition remains unclear. Undoubtedly, the development of femtosecond measuring devices will provide the possibility of obtaining new information on transitions between HESS. For instance, only in the very recent past has it been possible to observe non-exponential fluorescence decay due to transitions from the HESS, which is interpreted as superimposed 'hot' fluorescence.

'Physical' ultrafast nonradiative transitions can occur by tunneling and as conical intersections of the PES of excited states. Comprehensive theory of nonradiative transitions, based on calculations of possible fast processes due to such conical intersections in complex molecules is now at an early stage. The state-of-the-art in multidimensional theory of nonadiabatic transitions

in the case of conical intersections of the PES has been recently considered in a special issue of the *Chemical Physics* journal.[189]

The author expresses his gratitude to Dr. B Nickel for submitting materials and valuable discussions and to Prof. V A Benderskii for valuable critical comments. This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 00-03-32208) and the Ministry of Industry, Science and Technology of the Russian Federation.

IV.	Site-specific RNA-cleaving reagents	499

Abstract. Data on chemical compounds capable of cleaving ribonucleic acids under physiological conditions are systematised and generalised. The possibilities of the design of site-specific RNA-cleaving reagents are considered. The bibliography includes 245 references.

I. Introduction

Reagents capable of performing efficient and specific cleavage of nucleic acids (NA) are required in molecular-biological investigations, used for the development of genetic-engineering techniques and employed in genetic engineering and gene therapy. Selective NA-specific cleaving reagents can be used for the preparation of biologically active gene-targeting compounds capable of suppressing or modulating expression of particular genetic programs. The design of such compounds offers possibilities of influencing the origin of pathological states.[1–4] This line of investigation can revolutionise the strategy of treatment of virtually all diseases.

The construction of NA-cleaving reagents for all the above-mentioned applications is a complicated problem because cleavage should proceed under nearly physiological conditions. Preparations used as therapeutic drugs should act strictly selectively on particular sequences in the compositions of certain types of nucleic acids. Side processes must be excluded, and the efficiency of the reaction with the target nucleic acid should be high to suppress functioning of the latter as completely as possible.

Since the design of gene-targeting chemical reagents is a topical problem, this line of investigation has been developed intensively in recent years. Presently, the following types of compounds are primarily used for DNA cleavage.

1. Compounds containing variable-valence metal complexes as reactive groups. The latter catalyse oxidation processes resulting in nucleoside degradation.[5–7]

2. Enediynes capable, under certain conditions, of generating biradical species, which react with both DNA chains and cause their cleavage.[8]

3. Alkylating reagents whose reactions weaken the glycoside bond in modified nucleosides resulting in their degradation.[9,10]

Recently, reagents cleaving DNA according to a photooxidation mechanism[11,12] as well as reagents based on natural and synthetic metal-independent antibiotics (varacin, lissoclinotoxin, *etc*.) generating hydroxyl radicals[13] have gained wide acceptance. Mechanisms of DNA hydrolysis, which occurs through interactions of radicals with various nucleic-acid elements, were considered in detail in reviews.[5,14,15]

Unlike DNA, RNA are substantially more stable to oxidative cleavage[16] (in particular, under the action of metal-dependent antibiotics, such as bleomycin,[17,18] and enediyne antibiotics, such as neocarzinostatin, esperamycin, *etc*.[19]) due to higher stability of the glycoside bond in ribonucleotides compared to that in deoxyribonucleotides. At the same time, hydrolytic cleavage of RNA proceeds much more readily.

Recently, considerable study has been given to the mechanisms of RNA cleavage with various compounds and to the design of catalysts for directed RNA cleavage. Data accumulated in this field and the construction of the first chemical RNA-cleaving agents exhibiting higher specificity compared to that of natural enzymes call for generalisation and analysis of the results of the investigations.

A very interesting line of investigation aimed at designing RNA-targeting agents involves the construction of ribozymes, *viz*., catalysts based on RNA or DNA. Different classes of ribosimes, procedures for their construction and the mechanisms of RNA cleavage under the action of these catalysts were considered in detail in reviews.[20–24]

The results of studies in the field of construction of artificial catalysts whose active groups catalysing hydrolysis of phosphodiester bonds are involved in conjugates with oligonucleotides, peptides and intercalates have not been systematised. The present review is intended to close this gap and is devoted to the main classes of compounds capable of catalysing RNA depolymerisation under physiological conditions and to their use in the preparation of 'synthetic ribonucleases' for directed cleavage of particular sequences of ribonucleic acids.

II. General problems of the design of site-specific RNA-cleaving reagents

Compounds capable of performing selective site-specific RNA cleavage must, like enzymes, contain two domains, *viz*., an RNA-binding domain, which can form a specific complex with particular RNA regions (target regions), and an RNA-hydrolysing domain performing hydrolysis of phosphodiester bonds adjacent to the binding sites or located in their vicinity (Fig. 1). Some

peptides forming complexes with particular nucleotide sequences or elements of the three-dimensional RNA structure as well as low-molecular-weight organic compounds, such as intercalators,[25] polycations [26] and aminoglycosides,[27] can provide selectivity of RNA binding. Selected aspects of interactions of low-molecular-weight ligands with nucleic acids have been considered previously.[28–30] Oligonucleotides and their analogues are the most promising affine structures for directed action on RNA. A complementary oligonucleotide can be directed at any nucleotide sequence of interest. An additional advantage of these reagents is the fact that all these compounds can be synthesised with the use of a universal technology. Nucleotide sequences consisting of 15–20 units are unique even in genomes with complex organisation, this length of complementary oligonucleotides being sufficient to provide recognition and efficient binding with an RNA target under physiological conditions. Recently, a series of oligonucleotide analogues, which are resistant to cell enzymes and can form more stable complexes with nucleic acids than those of natural oligonucleotides, have been designed.[31–36]

Natural RNA-hydrolysing compounds, *viz*., enzymes and antibiotics, can be used as RNA-cleaving groups. Thus compounds, which can perform selective RNA cleavage in the vicinity of sequences involved in binding of conjugates, were synthesised based on oligodeoxyribonucleotides and natural enzymes, *viz*., ribonucleases A, S [37,38] and H.[39,40] However, enzymes contain their own RNA(DNA)-binding affine structures along with catalytic centres, which is necessarily reflected in the specificity of such conjugates and in the effects caused by these conjugates in biological systems. Due to this fact as well as to the complexity of the synthesis of these conjugates, enzymes and natural antibiotics show little promise as reactive groups.

RNA-hydrolysing fragments or reactive groups whose properties have little effect on the recognition of nucleic acid by a conjugate are agents of choice.

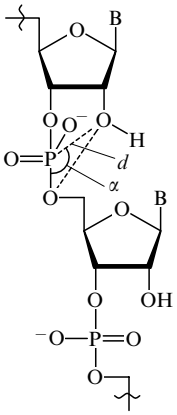
III. Catalysts of RNA cleavage

The presence of 2′-hydroxyl groups in RNA makes possible hydrolytic cleavage of these biopolymers according to the mechanism of intramolecular transesterification. RNA cleavage by this mechanism is widespread in nature, for example, in reactions catalysed by ribonucleases and ribozymes. It is reasonable to employ processes occurring in active centres of ribonucleases and ribozymes in the construction of RNA-cleaving chemical reagents.

It should be taken into account that high efficiency of natural enzymes results from functioning of complex active centres that arise in the course of evolution, while reactive groups forming a catalytic centre taken alone are generally weak catalysts of the corresponding processes. In the construction of artificial catalysts for the action on biopolymers, it is very important to provide the necessary spatial arrangement of all participants of the catalytic process by using the corresponding linkers.

1. Mechanism of hydrolytic cleavage of ribonucleic acids

Many enzymes and ribozymes cleave ribonucleic acids according to the mechanism of intramolecular transesterification through the nucleophilic attack of the oxygen atom of the 2′-hydroxyl group at the phosphorus atom. This reaction can proceed by two stereochemical mechanisms. One mechanism is realised when the angle α (Fig. 2) is close to 180° and the distance d between the



B, heterocyclic base residue.

Figure 2. Principal parameters responsible for the reactivity of phosphodiester bonds in RNA;
d is the 2′-O–P distance (Å) and α is the 5′-O–P–3′-O angle.

reacting groups < 3 Å (the linear mechanism), whereas another mechanism takes place when the angle α is close to 90° (the related mechanism). In the former case, the AE mechanism (an analogue of the S_N2 mechanism) is realised. The latter mechansim requires an additional stage, *viz*., migration of the leaving group from the equatorial to apical position (pseudorotation).[41] Pseudorotation was postulated for hydrolysis of a number of model compounds.[42–44] It was assumed that 3′→ 2′-isomerization in ribonucleotides also involves pseudorotation.[45] However, hydrolysis proceeded according to the linear mechanism in all cases for which the mechanism of catalytic RNA cleavage under the action of ribozymes or enzymes was established. Possible mechanisms of hydrolytic RNA cleavage under various conditions were considered in detail in a number of reviews and original studies.[45–47] The structural parameters of the regions of some RNA in which spontaneous hydrolysis is highly probable were analysed.[48] The dimensionless parameter F varying from 0 to 1 (for notations of α and d, see Fig. 2) was used as an integral value characterising stability of phosphodiester bonds in RNA sequences.

$$F = \frac{\alpha - 45}{180 - 45} \cdot \frac{(3\text{Å})^3}{d^3}.$$

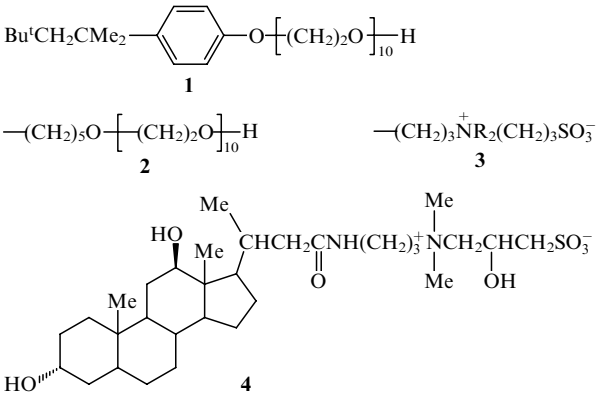
It appeared that the parameter F characterising the mutual spatial arrangement of the oxygen atom of the 2′-hydroxyl group, the phosphorus atom and the oxygen atom at the 5′-terminus of

the leaving nucleoside correlates well with stability of the internucleotide bonds. The structural elements with $F = 0.5-0.8$ correspond to sites of spontaneous hydrolysis, whereas stable regions are characterised by the parameter F of 0.1–0.15. Hydrolytically labile sites with low values of the parameter F are rare exceptions. Generally, heterocyclic bases in these sites form either noncanonical GA pairs or CpA(UpA) sequences in single-stranded regions in which short-lived structures (which are able to undergo cleavage according to the linear mechanism, but which are not detected by NMR spectroscopy and X-ray diffraction analysis) can, apparently, arise.

Low values of the parameter F are also typical of double-stranded RNA regions in which the phosphodiester bonds are characterised by high stability.

It should be noted that experimental data on the high hydrolytic lability of some sequences in RNA are available. However, no explanation for these data was offered. Thus, cleavage of the phosphodiester bonds in the CpA(UpA) sequences in single-stranded RNA occurs most readily, which is not clearly understood.[49] These sequences in short single-stranded oligoribonucleotides undergo cleavage in the presence of various proteins (T7 RNA polymerase, T4 polynucleotide kinase, lysozyme or trypsin) and some polymers, such as polyethylene glycol, dextran or polyvinyl pyrrolidone.[50–52] The efficiency of cleavage depends on the length of the oligonucleotide and on the nature of the flanking nucleotides. Thus, the ratio between the rates of hydrolysis of the bonds in the UA sequence for GUAC, GUAU and CGUA is 1 : 6 : 16, whereas the corresponding ratio for GUAA, CGUAA and UCGUAA is 1 : 4 : 6. The change of the nucleotide residue X at the 3′-terminus in the XUAA tetranucleotide has virtually no effect on the rate of hydrolysis, whereas the efficiency of GUAX cleavage decreases in the series X = G > A > U > C by a factor of three.[53]

It was also demonstrated that the UpA and CpA sequences in the loop regions of RNA are cleaved in the presence of nonionic [Triton X-100 (**1**) or Genapol X-100 (**2**)] or zwitterionic [zwittergent 3–10 (**3**) or an amide derivative of cholic acid (**4**)] detergents at concentrations corresponding to the critical concentrations of micelle formation.[54] Efficiency of hydrolysis is independent of the micelle size. The maximum rate of hydrolysis is achieved in the case of the loop consisting of five nucleotide units.[50] Anionic detergents, such as sodium dodecyl sulfate or deoxycholic acid, suppress cleavage.

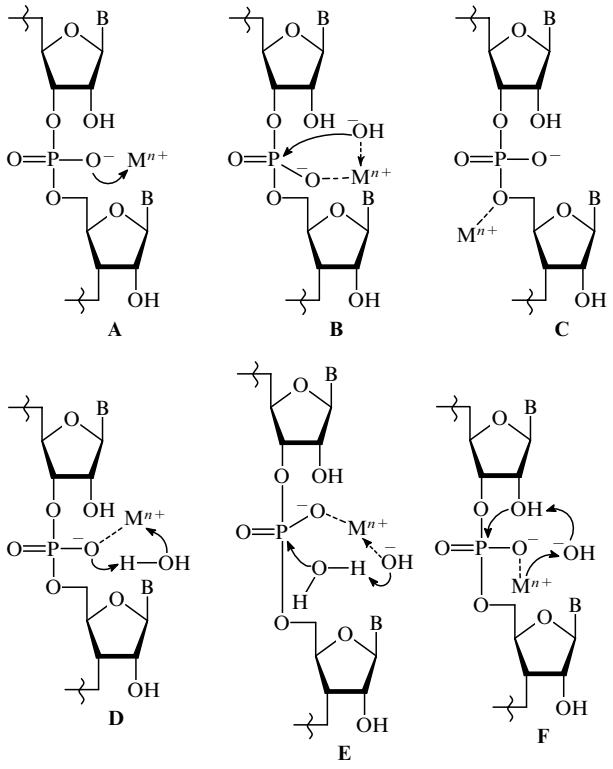


It can be suggested that the compounds **1**–**4** influence RNA in such a way that in some of its regions, *viz*., in the pyrimidine–purine sequences, the oxygen atom of the 2′-hydroxyl group of ribose and the internucleotide phosphate are brought into proximity and the angle α is increased, the resulting geometry being most favourable for spontaneous cleavage of the phosphodiester bonds. However, the mechanism of this reaction as well as the reasons for high lability of the CpA and UpA fragments still remain to be elucidated.

2. Hydrolysis of ribonucleic acids involving metal ions and metal complexes

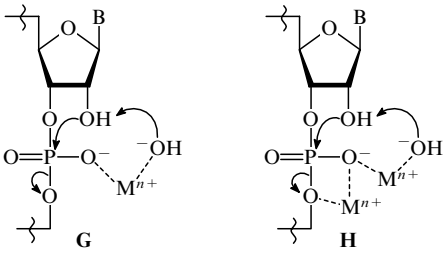
Presently, abundant data on hydrolysis of ribonucleic acids involving various metal ions are available. Destruction of ribonucleic acids under the action of the Zn^{2+}, Ni^{2+}, Ca^{2+}, Co^{2+}, Cu^{2+}, Mg^{2+}, Mn^{2+}, Pb^{2+}, Al^{3+} and Ln^{3+} ions and ions of other lanthanides has received the most study. Some of these ions can cause RNA cleavage under physiological conditions.

Metal ions are involved in active centres of many enzymes hydrolysing phosphodiester bonds, such as phosphomono-,[55] phosphodi-[56,57] and phosphotriesterases.[58] In some cases, these ions serve as cofactors necessary for functioning of ribozymes taking part in chemical catalysis of cleavage of phosphodiester bonds.[59] Below are considered the schemes of cleavage of phosphodiester bonds in RNA with the participation of metal ions. Metal ions can be involved in catalytic processes as Lewis acids by reacting directly with the oxygen atom of the phosphate group (**A**),[60] with a nucleophile (for example, with the hydroxide anion) (**B**)[61] or with the oxygen atom of the leaving group (**C**). In addition, metal ions can be indirectly involved in catalysis. Thus, these ions can either coordinate a water molecule and act as intramolecular general acid catalysts (**D**) or coordinate the hydroxide anion and act as intramolecular general base catalysts (**E** or **F**).[62,63]



Apparently, hydrolytic RNA cleavage with different metal ions can proceed by one or another mechanism or according to a combination of them. Two main models of the participation of metal ions in hydrolysis of phosphodiester bonds were proposed. According to the model **G**, the metal ion and the hydroxide anion coordinated to this ion are involved in the catalytic reaction.[64–68] The model **H** is based on the mechanism accepted for such natural enzymes as alkaline phosphatase and DNA polymerase I[57,69] and assumes the participation of two metal ions one of which coordinates the hydroxyl group and the second ion activates the oxygen atom of the leaving group. Most of the results obtained in studies of RNA hydrolysis catalysed by metal ions can be interpreted based on both the models **G** and **H**.[70] X-Ray diffraction data for some ribozymes provide evidence in favour of the reaction mechanism involving one metal ion.[64,71] However, information on substantial acceleration of RNA hydrolysis

under the action of the $Mg^{2+}-Pb^{2+}$ (see Ref. 72), $Nd^{3+}-Pb^{2+}$ (see Refs 73 and 74), $La^{3+}-Fe^{3+}$ and $La^{3+}-Sn^{4+}$ pairs [75] can be interpreted only within the framework of the model **H**.



G **H**

Using the ApA dinucleotide as an example, it was demonstrated that the phosphodiester bond can be hydrolysed under the action of both the hydroxy complex of La^{3+} (see Ref. 76) and the binuclear hydroxy complex $[La_2(OH)]_5^{+}$.[77] The rate of hydrolysis was increased by four orders of magnitude on going from the mono- to the binuclear complex.[78] It can be suggested that hydrolysis can proceed involving either one or two metal ions depending on the reaction conditions. Within the frameworks of all mechanisms proposed, metal ions, which are stronger Lewis acids and have a larger coordination sphere, should be more efficient catalysts of hydrolytic cleavage. In this connection, considerable study should be given to cleavage of phosphodiester bonds under the action of the Ce^{4+} (see Ref. 79) and Zr^{4+} ions.[80, 81]

The rate of hydrolysis of phosphodiester bonds in RNA catalysed by metal ions depends on the nature of the flanking nucleosides. Thus, hydrolysis of the phosphodiester bond in ApA in a solution of the Tm^{3+} salt (0.01 mol litre^{-1}) proceeded 4.8–5.1 times faster than that in UpU.[82] In studies of hydrolysis of six different nucleotide pairs (UpG, CpC, GpA, ApU, UpA and ApA) in solutions of the Lu^{3+} salt (0.01 mol litre^{-1}), the reaction rate for the UpG dinucleotide, which underwent hydrolysis most rapidly, was found to be 2.2 times higher than that for ApA, which is the most stable under these conditions.[82] The presence of the 3′-terminal phosphate group leads to substantial acceleration of hydrolysis of the internucleotide phosphate bond in dinucleotides due, apparently, to more efficient cation binding. Thus, hydrolysis of the phosphodiester bond in ApAp in the presence of Zn^{2+} ions proceeded more rapidly than that in ApA. At the same time, the presence of the 2′-terminal phosphate group or the 2′,3′-cyclophosphate group exerts only a slight effect on the rate of hydrolysis.[83] Analogous results were obtained in other studies as well.[84, 85] It was shown that the 3′-terminal phosphate group in oligodeoxynucleotides containing a ribonucleotide unit, *viz.*, Up(Tp)$_n$Tp or Up(Tp)$_n$T ($n = 0-4$ or 7), at the 5′-terminus accelerates hydrolysis even if it is spaced at seven nucleotide units.[86] Apparently, the observed 5–20-fold acceleration of hydrolysis of poly(U) compared to UpU under the action of the Mg^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+} or Zn^{2+} ions is attributable to the polyelectrolyte effect of the total negative charge of poly(U).[87]

The ability of metal ions to catalyse hydrolysis varies over a wide range depending on the nature of the substrate. Thus, the activity of metal ions in the hydrolysis of ApA decreases in the series Tm = Lu > Y > Nd = Eu = Sm > Ce = Sc = Gd = Tb > Pr = Dy > Ho = Er > Yb > La.[76] At the same time, the activity of metal ions in hydrolysis of 3′,5′-cycloadenosinemonophosphate (which is one of the intermediate hydrolysis products of ApA) under analogous conditions decreases in the series Ce $\gg$ Pr > Nd = La > Y = Sm = Dy > other lanthanides.[88]

Evidently, the differences in the rate of hydrolysis in the dunucleotide pairs as well as in more complex substantces arise from the different complex-forming ability of various fragments of nucleic acids. Problems of complex formation of metal ions with nucleic acids were considered in detail in a review. [89]

Hydrolysis of RNA in the presence of various metal ions is widely used for revealing the cation-binding sites in nucleic acids.[90–94] The magnesium, lead and lanthanide ions can catalyse selective cleavage of phosphodiester bonds in the regions of some specific elements of the three-dimensional RNA structure.[95–99] The sensitivity of these reactions to the orientation of the ligands was used in studies of the RNA structure in solution and for comparison of the three-dimensional structures of mutant tRNA and 5SRNA.[100, 101] It was demonstrated [102] that sequences of ribonucleic acids in complexes with oligodeoxynucleotides do not undergo hydrolysis in the presence of Eu^{3+} or La^{3+} complexes, apparently, because the conformational flexibility of RNA, which is necessary for efficient ion binding and for transesterification, is limited upon formation of the duplex. In imperfect complexes, loop single-stranded regions are cleaved more rapidly.[103] The effects of the nucleotide sequence and the size of the loop region on the efficiency of RNA hydrolysis in the presence of the Pb^{2+} and Zn^{2+} ions as well as in the presence of their complexes were examined in detail.[104] The efficiency of hydrolytic cleavage was demonstrated to be increased as the size of the loop increases and as the hydrolysed phosphodiester bond moves away from the stalk fragment. The results obtained confirmed once again the necessity of conformational flexibility of the ribosephosphate fragment subjected to hydrolysis.

Due to the ability of complexes of lanthanides,[105, 106] copper,[107] zinc and some other metals [108] to catalyse hydrolysis of phosphodiester bonds, they can be considered as potential hydrolytically active groups in the synthesis of conjugates with organic compounds and oligonucleotides. The lanthanide ions, which are strong Lewis acids [109] and have a flexible coordination sphere,[110] are believed to be the most promising catalysts. The construction of highly stable metal complexes, which are simultaneously characterised by the high acidity of the central atom, presents a contradictory problem. However, a number of metal complexes (for example, compounds **5**–**8**) possessing high stability with retention of high activity in hydrolysis were prepared.[85, 106, 111, 112] It was demonstrated that catalytic RNA cleavage can proceed in the presence of zinc(II) [85] and lanthanum(III) [106] complexes. The rate of RNA hydrolysis in the presence of different metal complexes depends on pH. This suggests that, as in the case of free metal ions, hydrolysis of phosphodiester bonds occurs, apparently, with the participation of two molecules of the metal complex. In this case, one molecule acts as a Lewis acid, whereas the second molecule coordinates the hydroxide anion and acts as a base.[113, 114]

3. Reagents modelling active centres of metal-dependent enzymes catalysing phosphoester-bond cleavage

Hydrolytic centres of metal-dependent enzymes, which are involved in hydrolysis of phosphoester bonds in various sub-

strates, often contain two complex-forming domains consisting of the amino acid residues His, Asp(Asn), Glu, Arg and Lys (in different combinations) and one of hydroxyl-containing amino acids, *viz*., Ser or Tyr. The distances between the metal ions (Ca^{2+}, Zn^{2+}, Mn^{2+}, Mg^{2+} and Fe^{3+}) in the active centres are in the range of 3–5 Å. In addition, the hydrolytic centres may contain one or several such amino acids as Glu, Arg, Lys, His or Ser. The functional groups of these amino acids are not directly bound to the metal ions and act as additional base, acid or nucleophilic catalysts (see reviews [115–118]). Active centres of some enzymes contain one (staphylococcus nuclease [119] and nuclease Sm from *Serratia marcescens* [120]) or more than two metal ions (nuclease P1).[121] Below are considered the principal structural elements of the active centres of natural metal-dependent enzymes, which hydrolyse phosphoester bonds in various substrates and contain from one to three metal ions, *viz*., staphylococcus nuclease (**9**), phosphorylase C from *Bacillus cereus* (**10**) and purpuric acid phosphatase (**11**).

Owing to success achieved in the synthesis of stable metal complexes and progress made in the determination of the structures of active centres and elucidation of the mechanisms of action of enzymes, which hydrolyse phosphoester bonds in various substrates, a broad range of synthetic catalysts, which serve as functional and structural models of natural enzymes, have been synthesised in recent years.[122–124]

Binuclear metal complexes based on the Zn^{2+} (see Refs 125–127), Cu^{2+} (see Refs 128–130), Co^{3+} (see Refs 131 and 132) and La^{3+} ions [133, 134] were prepared. The efficiency of hydrolysis in the presence of binuclear metal complexes appeared to be much higher than that in the case of their mononuclear analogues. This is particularly essential for the Zn ions, which are weak Lewis acids and whose mononuclear complexes do not catalyse hydrolysis.[129, 135] Compounds **12**–**16** proved to be the most efficient catalysts among all polynuclear metal complexes modelling active centres of natural enzymes. In particular, hydrolysis of the phosphoester bond in the model substrate in the presence of the complex **12**, which is a structural and functional model of D-fructose 1,6-bis(phosphate-1) phosphatase, proceeded 10^3 times more rapidly than that in the presence of similar cobalt complexes.[132] Analogous results were obtained for the copper complex **13**. In the presence of the latter the rates of hydrolysis of phosphoester bonds in various compounds are increased by a factor of $(1-2.7) \times 10^4$.[129] It should be noted that in the case of hydrolysis of natural substrates in the presence of polynuclear metal complexes, metal ions can interact not only with phosphate residues, but also with heterocyclic bases as a result of which these compounds acquire particular substrate specificity. Thus, the relative rates of cleavage upon hydrolysis of ribonucleoside-2′,3′-cyclophosphates of adenosine, guanine, uridine and cytosine in the presence of the binuclear copper complex **15** are 1.5, 8.5, 4.3 and 1, respectively, whereas the relative rates in the presence of the complex **16** are 31.1, 1, 2.9 and 5.1, respectively.[130] The ratio between the rates of hydrolytic cleavage of the GpG dinucleotide, which is most readily hydrolysed, and the most stable ApA dinucleotide in the presence of the trinuclear zinc complex **14** was 163 : 1.[136]

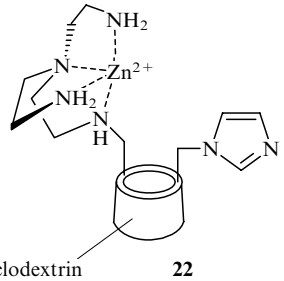
21

R = $(CH_2)_2OEt$

Modelling of the active centres of such enzymes requires a more rigid mutual spatial arrangement of the reactive groups compared to that in compounds containing only metal ions with flexible and bulky coordination spheres. In most cases, the compounds **17**–**22** proved to be only insignificantly more efficient than the basis metal complexes.



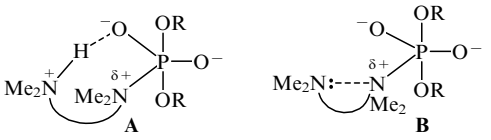
Cyclodextrin **22**

Probably, this is attributable to the unfavourable spatial arrangement of the reactive centres. The efficiency of cleavage is increased by a factor of 10^3–10^4 when the mutual arrangement of all participants of the catalytic process is optimum.[141, 142] Models of the active centres of natural enzymes based on metal complexes containing additional functional groups, which are not involved in complex formation, were discussed in detail in a review.[143]

4. Hydrolysis of ribonucleic acids with amino compounds and cationic peptides

Hydrolysis of RNA is catalysed by various amino compounds.[144] In the studies of hydrolysis of bis(4-nitrophenyl) and bis(2,4-dinitrophenyl) phosphates with diamines of the general formula $Me_2N(CH_2)_nNMe_2$ (**23a**–**c**) [n = 1 (**a**), 2 (**b**) or 3 (**c**)], two possible mechanisms of cleavage of the phosphodiester bonds were proposed. One of these mechanisms (**A**) is realised in the case of hydrolysis involving diamines as the corresponding monocations. The second mechanism (**B**) assumes the participation of neutral diamines. Thus hydrolysis in the presence of the diamines **23a**–**c** as monocations was accelerated by a factor of 870, 74 and 190, respectively, compared to hydrolysis in the presence of trimethylamine. In addition, the isotope effect, which was expected for

general acid catalysis, was observed when H_2O was replaced by D_2O ($k_H : k_D = 1.6$ for the diamine **23a**). The diamines **23a–c** in the neutral form exhibit substantially higher catalytic activity (1400–2040 times higher than that of trimethylamine), the isotope effect being absent. Apparently, in the latter case, the positive charge that arises in the course of the nucleophilic attack at the phosphorus atom (the transition state **B**) is electrostatically stabilised by the free electron pair of the second nitrogen atom.[145]

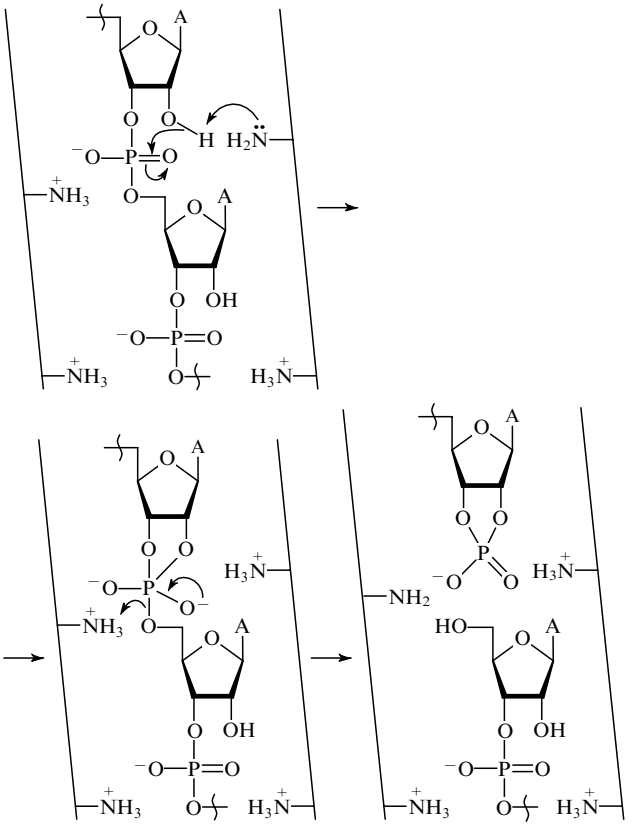


A **B**

R = 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$.

Hydrolysis of poly(A), poly(C) and poly(U) in solutions of polyamines (1–2 mol litre^{-1}), such as ethylenediamine, triethylenetetramine, *etc.*, was investigated.[146] It appeared that ethylenediamine possesses the highest catalytic activity, the efficiency of hydrolysis (50 °C, 2 days) in a solution of ethylenediamine (1 mol litre^{-1}) being decreased in the series poly(A) > poly(U) > poly(C) (33%, 28% and 16%, respectively). Under these conditions, poly(G) was not hydrolysed.[147]

Apparently, the weak hydrolytic activity of bleomycin (metal-dependent antibiotic) in the absence of metal ions is explained by the presence of aliphatic amino groups.[148] Regular peptides containing arginine and(or) lysine can accelerate hydrolysis of the phosphodiester bonds in ApAp and poly(A).[149–151] The regular peptides poly(Leu-Lys-Lys-Leu) and poly(Leu-Lys) capable of forming α-helices and β-folds, respectively, exhibit the highest activity in hydrolysis. In their complexes with RNA, the ratio $Lys^+ : PO_4^- = 2 : 1$ was achieved. Distortion of the polypeptide structure by introducing proline (Pro-Leu-Lys-Leu-Lys) or with the use of the D,L-isomers (D,L-Leu-D,L-Lys) leads to a sharp decrease in the catalytic activity of peptides. It should be noted that hydrolysis is not accelerated in the presence of poly(His), poly(Arg-Glu-Glu) and a number of other regular peptides containing various functional groups. No activity was also observed for the Ac-Leu-Lys-NHEt dipeptides. Apparently, the fact that the distances between the phosphate residues in the ribonucleotide (6.2 Å) coincide with the distances between the positive charges in poly(Leu-Lys-Lys-Leu) (6 Å) and poly(Leu-Lys) (6.9 Å) plays a decisive role in the manifestation of the catalytic activity exhibited by the above-mentioned peptides in RNA hydrolysis (Fig. 3).[152, 153]



A, heterocyclic base residue.

Figure 3. The assumed mechanism of hydrolytic RNA cleavage under the action of polycharged peptides.

On the whole, both polyamines and regular peptides ehxibit low hydrolytic activity. Thus, the degree of depolymerisation of ApAp under the action of the most active regular peptide, *viz.*, poly(Leu-Lys), at 50 °C (pH 8.0) was 85% after 7 days.[150] After 2 days, the degree of depolymerisation of poly(A), poly(U) and poly(C) under the action of the most active polyamines at 50 °C (pH 8.0) varied from 16% to 69%.[147]

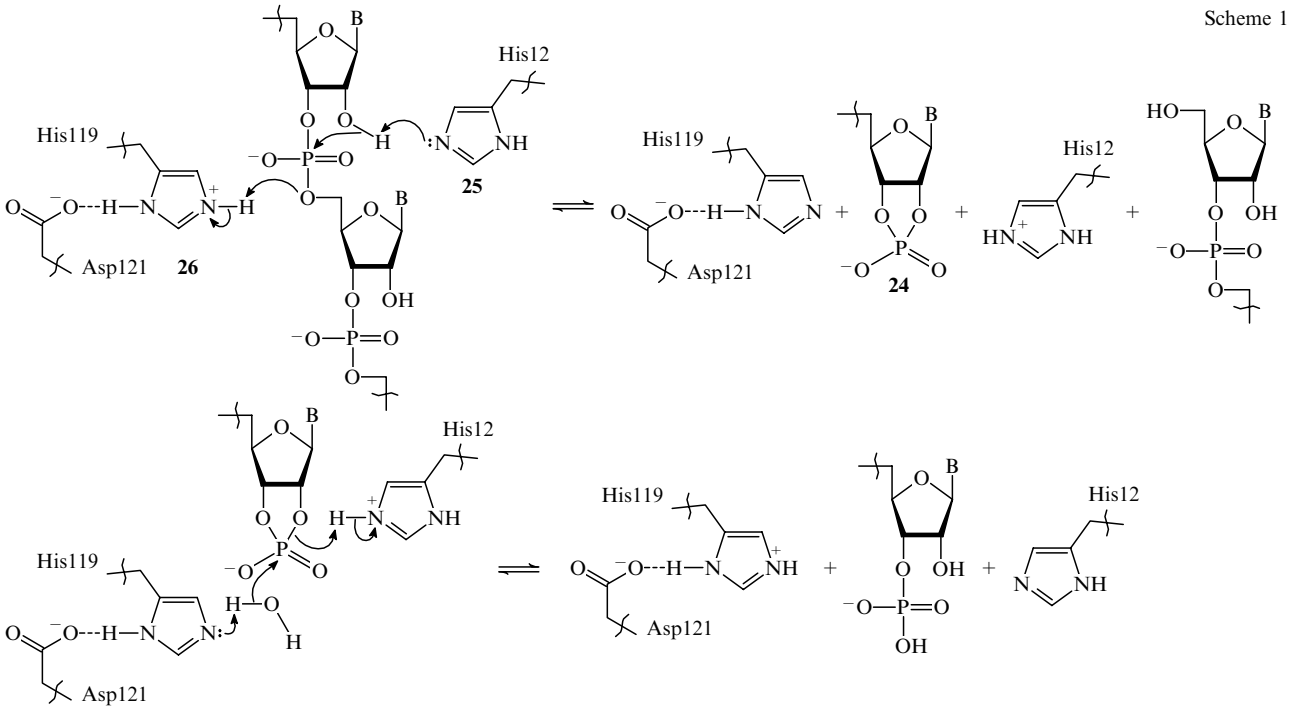
5. Reagents modelling active centres of metal-independent ribonucleases

Of metal-independent ribonucleases, ribonucleases A and T1 have received the most study. Both enzymes were found to cleave phosphodiester bonds in RNA according to the mechanism of intramolecular transesterification under conditions of acid–base catalysis. The scheme of the 'classical' two-step mechanism of acid–base catalytic hydrolysis of phosphodiester bonds in ribonucleic acids under the action of RNase A involves transesterification to form cyclic phosphodiester **24** followed by its hydrolysis. The abstraction of the proton from the 2′-hydroxyl group of the ribose residue under the action of the base **25** and the transfer of the proton from the fragment **26** to the oxygen atom of the leaving group are the key stages of this mechanism (Scheme 1).[154, 155] The details of interactions of the amino acid residues in the active centre both with each other and with the substrate have consistently been refined.[156–159]

Breslow and coworkers[160] proved that the active centres of ribonulceases can, in principle, be modelled by small molecules. The authors found that RNA hydrolysis was catalysed by a neutral concentrated (1–2 mol litre^{-1}) imidazole buffer and then synthesised a conjugate of cyclodextrin with molecules containing imidazole fragments. This conjugate catalysed hydrolysis of a model substrate, *viz.*, *tert*-butylcatechol 1,2-cyclophosphate.[161]

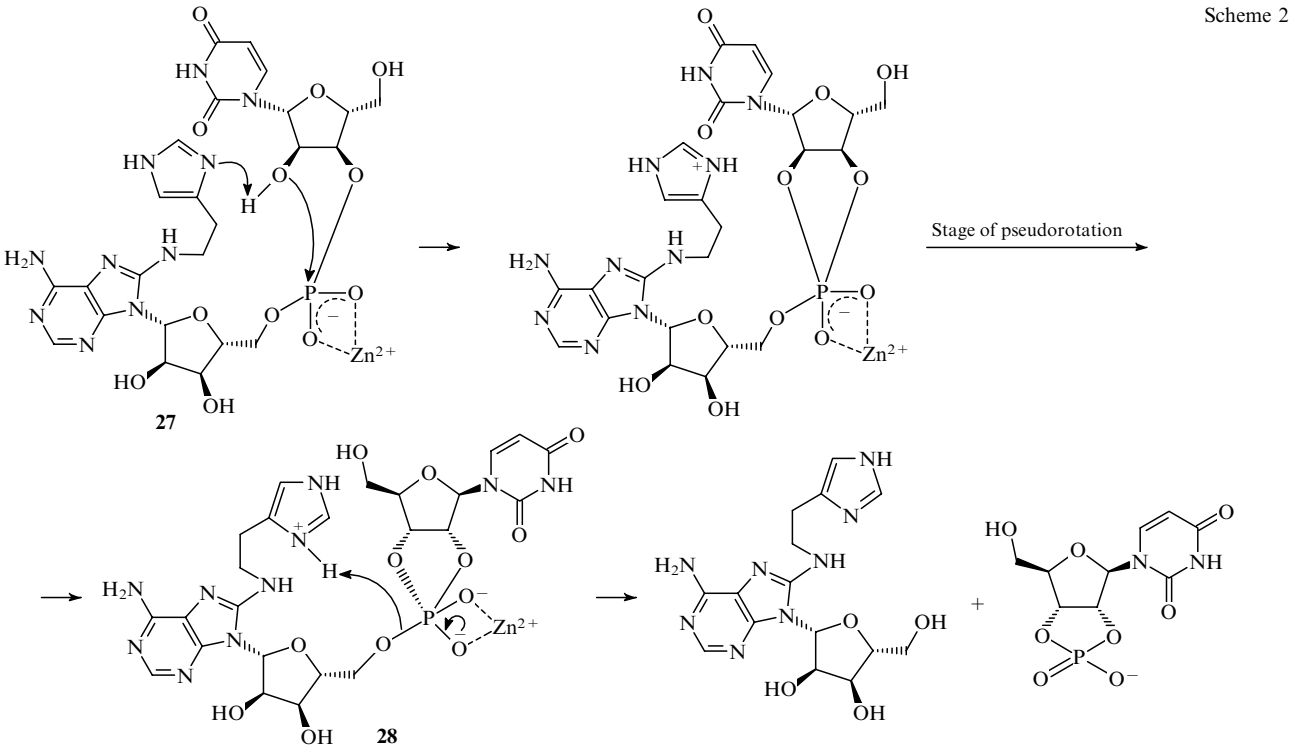
Hydrolysis of RNA with imidazole conjugates or an imidazole buffer proceeded most efficiently at pH 7, which corresponds, as in the case of ribonuclease A, to the mechanism of general acid–base catalysis, *i.e.*, one protonated and one nonprotonated imidazole fragment were involved in hydrolysis. Breslow examined three possible bisimidazole conjugates of cyclodextrin and found that only one of them, which is characterised by the spatial arrangement of the imidazole rings most favourable for the cleavage of the phosphodiester bond, exhibited catalytic activity in hydrolysis of the model phosphodiester.[162] Some conjugates of cyclodextrin containing various combinations of the imidazole and amino groups, cyclic and acyclic ethers and metal complexes also possess phosphoesterase activity with respect to model substrates.[163–166] Prakash *et al.*[167] proposed a structure modelling ribonuclease A in which the same imidazole fragment acts as a base and a proton donor. The model proved to be suitable in the presence of zinc ions, which stabilise the transition state and cause an increase in the electrophilicity of the phosphorus atom (structure **27**, Scheme 2). The authors believed[167] that hydrolytic cleavage of the phosphodiester bond in the diribonucleotide proceeds according to the related transfer mechanism (Section III.1). It was assumed that the leaving group in the structure **27** is located rather close to the 2′-hydroxyl group. The proton transfer from the 2′-hydroxyl group of the substrate to the

Scheme 1



B, heterocyclic base residue.

Scheme 2



imidazole fragment and the stage of pseudorotation are followed by the cleavage of the phosphodiester bond involving a proton of the same imidazole fragment (intermediate **28**). This mechanism requires an additional stage of pseudorotation; however, the process can involve the same histamine fragment as proton donor and proton acceptor.

More recently, hydrolytic RNA cleavage under the action of imidazole and its conjugates with cationic and intercalating compounds has been studied in detail.[168, 169] It was demonstrated that these compounds can be used as structural probes in studies of the secondary structures of RNA and RNA–deoxyoligonucleotide complexes in solutions.[168, 169]

Hydrolysis with both an imidazole buffer and imidazole conjugates proceeds predominantly in single-stranded regions of RNA. Apparently, this is associated with the lower conformational flexibility of nucleotides in double-stranded regions and the less favourable spatial arrangement of the 2′-hydroxyl group with respect to the phosphorus atom of the internucleotide phosphate group. It should be noted that the rate of hydrolysis with an imidazole buffer is independent of the nucleotide sequence in the region subjected to cleavage (Fig. 4), whereas imidazole conjugates have a pronounced tendency for cleavage at the pyrimidine – purine regions.[168]

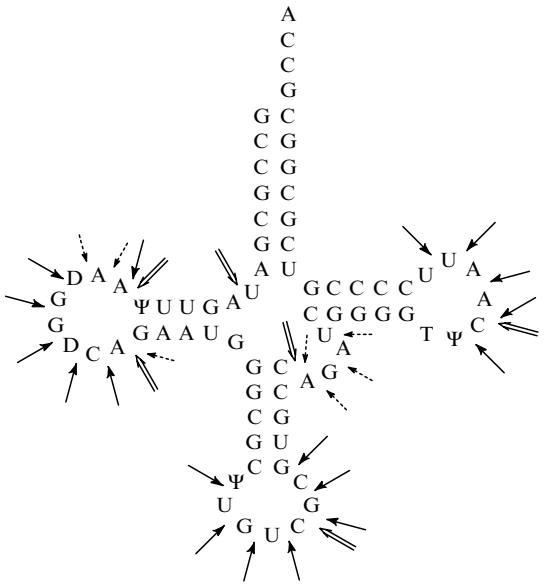


Figure 4. Structure and major cleavage sites of $tRNA^{Asp}$.
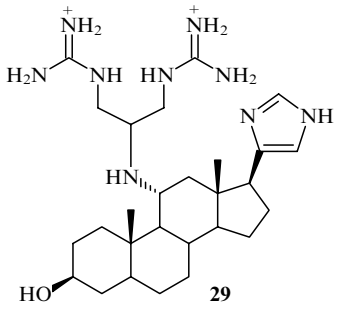
The most probable and less probable sites of cleavage under the action of an imidazole buffer are indicated by single and dashed arrows; the sites of cleavage under the action of imidazole conjugates are indicated by doubled arrows.

Modelling of the active centre of staphylococcus nuclease (nuclease S) is also of interest. The structure and the mechanism of action of nuclease S were established based on X-ray diffraction data, results of kinetic studies and data on substitutions of amino acids in the active centre of the enzyme.[170–172]

It is assumed that due to coordination by the guanidinium groups, the phosphate ion adopts the conformation favourable for hydrolysis with nuclease S. Simultaneously, the five-coordinate intermediate state of the phosphorus atom is stabilised. Although being a metal-dependent enzyme, nuclease S, like other compounds containing guanidinium groups, can be bound to the phosphate anions[173,174] and accelerate hydrolysis of the phosphodiester bonds in the absence of metal ions.[175] Hydrolysis of phosphodiester bonds under the action of compounds containing the guanidinium fragments is accelerated in the presence of external or internal nucleophiles.[176,177] Yet another type of hydrolytic centre combining elements of the active centre of RNase A (general base catalysis with imidazole) and nuclease S (coordination of the phosphate anion and stabilisation of the five-coordinate state of the phosphorus atom) was proposed by Oost and Kalesse.[178] The compounds synthesised contained the imidazole fragment and one or two guanidinium groups bound to a steroid core through spacers of different lengths. Most of the compounds synthesised exhibited low hydrolytic activity with respect to the model substrate, *viz*., 2′-hydroxypropyl 4-nitrophenyl phosphate. The efficiency of hydrolysis depended on both the number of guanidinium groups (two groups were better than one group) and their positions with respect to the steroid rings as well as on the length of the linker. The most efficient construction, *viz*., **29**, also exhibited a low hydrolytic activity with respect to UpU ($k = 2.4 \times 10^{-4}$ h^{-1}, 60 °C, pH 7.5). At the same time, simpler compounds containing only guanidinium groups [1,3-bis(guanidinium)propane] or simultaneously guanidinium and imidazole fragments {1,3-bis(guanidinium)-2[2-(1*H*-imidazol-4-yl)ethylamino]propane} appeared to be hydrolytically inactive.



29

Therefore, functional models of the active centres of natural ribonucleases can be, apparently, obtained by constructing molecules which contain basic and acidic catalytic centres adopting particular orientations.

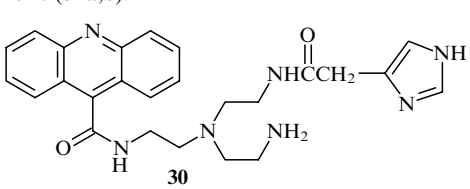
Most often, synthetic ribonucleases contain imidazole residues (an analogue of His12 in RNase A) or the carboxylate anion (an analogue of Glu58 in RNase T1) as a base and the protonated imidazole fragment as a proton donor (analogously to His119 and His92, respectively). Apparently, efficiency of catalysis can be improved by introducing positively charged groups (amino or guanidinium) into the catalytic centre to achieve a particular orientation of the phosphate ion with respect to the catalytic centres and to stabilise the five-coordinate intermediate state of the phosphorus atom. Probably, the introduction of the nucleophilic group (for example, the hydroxyl group simulating the 2′-hydroxyl group of ribose) into the reactive centre will allow one to construct catalysts hydrolysing phosphodiester bonds in DNA.[179]

IV. Site-specific RNA-cleaving reagents

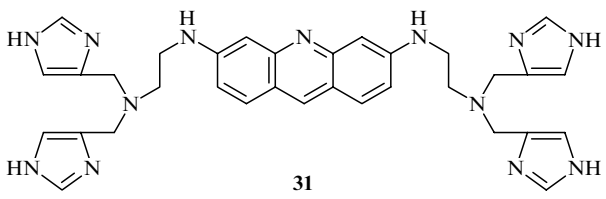
Site-specific RNA cleavage can be performed with the use of reagents containing groups which form complexes with particular nucleotide sequences or elements of the three-dimensional RNA structure. The most evident method for solving this problem is the use of oligonucleotides complementary to the predetermined primary sequences of the RNA target. In addition, a number of low-molecular-weight ligands possessing affinity for particular spatial structural elements of RNA are available.

1. Conjugates based on polycyclic compounds

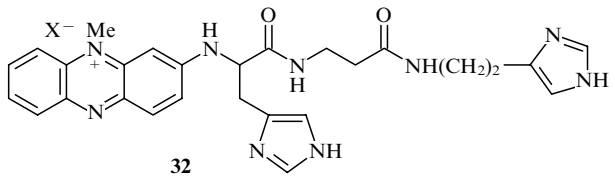
Catalytically active groups can be added to polyaromatic compounds capable of intercalating into double-stranded regions of nucleic acids *via* flexible linkers. Synthetic constructions containing polycyclic intercalating compounds and metal complexes are widely used for DNA cleavage.[180,181] Efforts were made to prepare compounds which can hydrolyse RNA, by adding various combinations of guanidinium, amino and carboxyl groups to intercalating compounds. Some most active representatives of such conjugates were synthesised based on acridine (**30** and **31**),[182–184] phenazine (**32**),[185] isoalloxazine (**33**)[186] and anthraquinone (**34a**,**b**).[187]



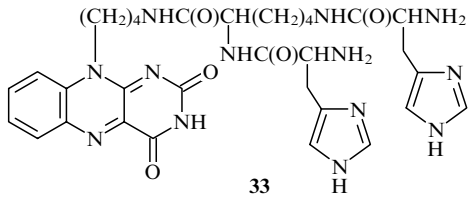
30



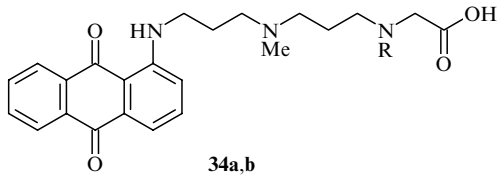
31



32



33



34a,**b**

R = H (**a**), CH_2CO_2H (**b**).

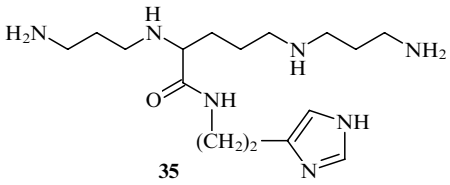
The substrates (tRNA, mRNA and synthetic oligonucleotides) employed did not enable one to perform a reliable comparison of the catalytic activity of the conjugates **30**–**34**. Generally, the catalytic activity is determined based on the disappearance of the initial nucleotide-containing substance without analysis of the hydrolysis products. This procedure does not allow one to reveal relationships between the structures of synthetic ribonucleases and their catalytic activity. We synthesised a series of compounds, which differ by both the structure of the linkers and the combination of reactive groups in the catalytic centre.[186] The phenazine conjugates whose RNA-hydrolysing centres contained two imidazole fragments, which were separated from the intercalator by the linker consisting of 8–14 C—C or C—N bonds, possessed the highest activity. The compounds containing the imidazolyl fragment and the carboxyl group exhibited somewhat lower activity.

The conjugates **30**–**32** and **34a** exhibited pronounced specificity with respect to cleavage of the CpA and UpA sequences in single-stranded RNA regions.[185,186] The exceptions are the isoalloxazine conjugate **33** (see Ref. 186) and the anthraquinone conjugate **34b** (see Ref. 187) containing two carboxyl groups. Hydrolysis of $tRNA^{Phe}$ in the presence of the anthraquinone derivative **34a** containing one carboxyl group proceeded predominantly at the CpA regions. However, when one more carboxyl group was introduced into the RNA-hydrolysing centre (the compound **34b**), the phosphodiester bonds in the GpA and GpG sequences were predominantly subjected to hydrolysis, and GpC was hydrolyzed to a lesser degree.

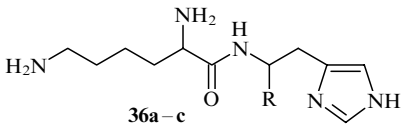
The low activity of most of the conjugates based on polycyclic compounds is attributable to the fact that these conjugates are inserted between RNA turns thus stabilising its double-stranded structure. In this case, the catalytic groups are located in the RNA region most resistant to hydrolysis. The use of long linkers makes possible localisation of the catalytic groups in the region of more labile single-stranded RNA fragments, which, in turn, provides higher efficiency of hydrolysis.[187]

2. Conjugates based on polycations

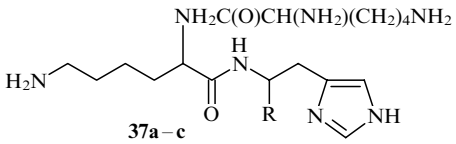
Unlike conjugates based on polycyclic compounds, which tend to be bound to double-stranded fragments of nucleic acids, conjugates based on cationic compounds are bound to RNA through Coulomb interactions, thus providing their homogeneous distribution over all sterically accessible phosphodiester bonds of the RNA target. Conjugates **35**–**39** based on synthetic and natural polyamines containing the imidazole and 1,4-diaminobutane fragments as the RNA-hydrolysing groups were described.[188–192]



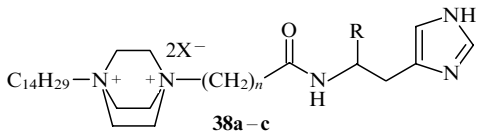
35



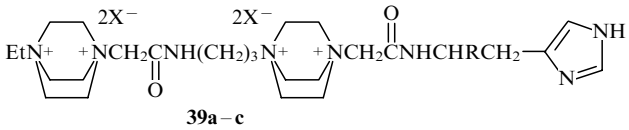
36a–**c**



37a–**c**



38a–**c**



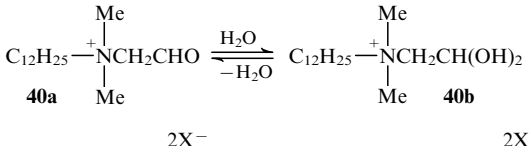
39a–**c**

35–**39**: R = H (**a**), CO_2H (**b**), CO_2Me (**c**).

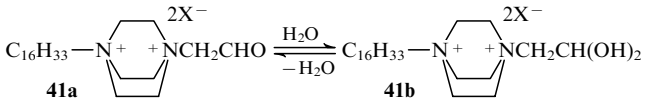
As mentioned above, 1,4-diaminobutane and imidazole at concentrations of 1–2 mol litre^{-1} promote RNA hydrolysis. Synthetic ribonucleases **35**–**39** based on conjugates of imidazole with polyamines efficiently catalyse hydrolysis at substantially lower concentrations (10^{-3}–10^{-5} mol litre^{-1}), which is indicative of the synergistic action of the individual elements of these constructions. A sharp decreases in the efficiency of catalysis on going from imidazole conjugates to *N*-methylimidazole conjugates [188] and the manifestation of an isotope effect ($k_H/k_D = 2.28$) upon hydrolysis of dinucleosidemonophosphate CpA in water and D_2O (see Ref. 169) indicate that acid–base catalysis occurs at the limiting reaction stage. The catalytic activity of the compounds **35**–**39** was investigated in experiments with synthetic oligonucleotides, various tRNA and fragments of virus RNA. The conjugates **35**–**39** were demonstrated to provide high rates of cleavage of the phosphodiester bonds in the 5′-Py-A motifs in single-stranded RNA regions.[188–190] It should be noted that no preferential binding of the conjugates to phosphates of the above-mentioned motifs compared to other internucleotide phosphates was assumed. The conjugates studied contained different RNA-binding fragments, while the RNA targets had different structures. Hence, high instability of pyrimidine–purine sequences in RNA can be explained only by their characteristic features. The conjugates **35**–**39**, which are able to perform efficient and specific depolymerisation of RNA under mild conditions, can be considered as an alternative for RNase A in studies of the secondary structure of RNA.[168,188]

Menger and coworkers [193,194] proposed to carry out hydrolytic cleavage of phosphodiester bonds in RNA with the use of compounds **40b** and **41b**, which, unlike the conjugates **35**–**39**, are nucleophilic catalysts. Due to the electronegative substituent in the β position, the aldehyde groups in the compounds **40a** and **41a** are hydrogenated in weakly alkaline and neutral solutions to give the highly nucleophilic catalysts **40b** and **41b**. Owing to the

positive charge of the nitrogen-containing fragment, the nucleophilic group is localised in the vicinity of the phosphodiester bond. The authors believed that the presence of the alkyl substituent leads to the enhancement of the efficiency of hydrolysis due to micellar catalysis (by analogy with the micellar analogues of serine proteases proposed previously [195]). The catalysts **40** and **41** accelerated hydrolysis of the model compound, *viz*., of bis-(4-nitrophenyl) phosphate, by a factor of 1800 and 750, respectively, compared to the rate of hydrolysis in the absence of catalysts. It should be noted that micellar catalysis led to acceleration by only a factor of 210.[193, 194] Since examples of cleavage of natural RNA substrates in the presence of catalysts of this type are lacking in the literature, the efficiency of these catalysts cannot be compared with that of compounds functioning based on the general acid – base catalysis.

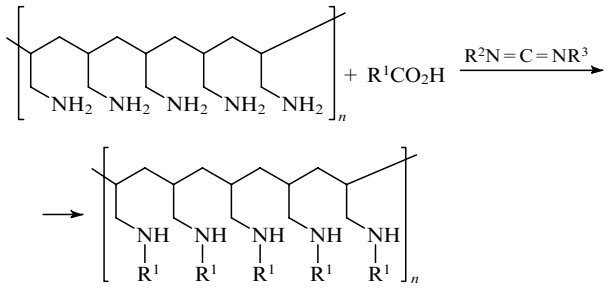


40a **40b**



41a **41b**

Catalysts for cleavage of phosphodiester bonds based on polyamines were constructed using methods of combinatorial chemistry.[196] A mixture of several carboxylic acids was activated by water-soluble carbodiimide in the presence of polyallylamine with a molecular weight of 30 000 – 40 000. The ratio between the components was chosen so that the total degree of acylation of the amino groups of the polymer was 5% – 45%. A large library of water-soluble polymers with a statistical arrangement of functional groups was obtained by varying both the ratio between the carboxylic acids in the reaction mixture and the degree of modification of the initial polyamine.



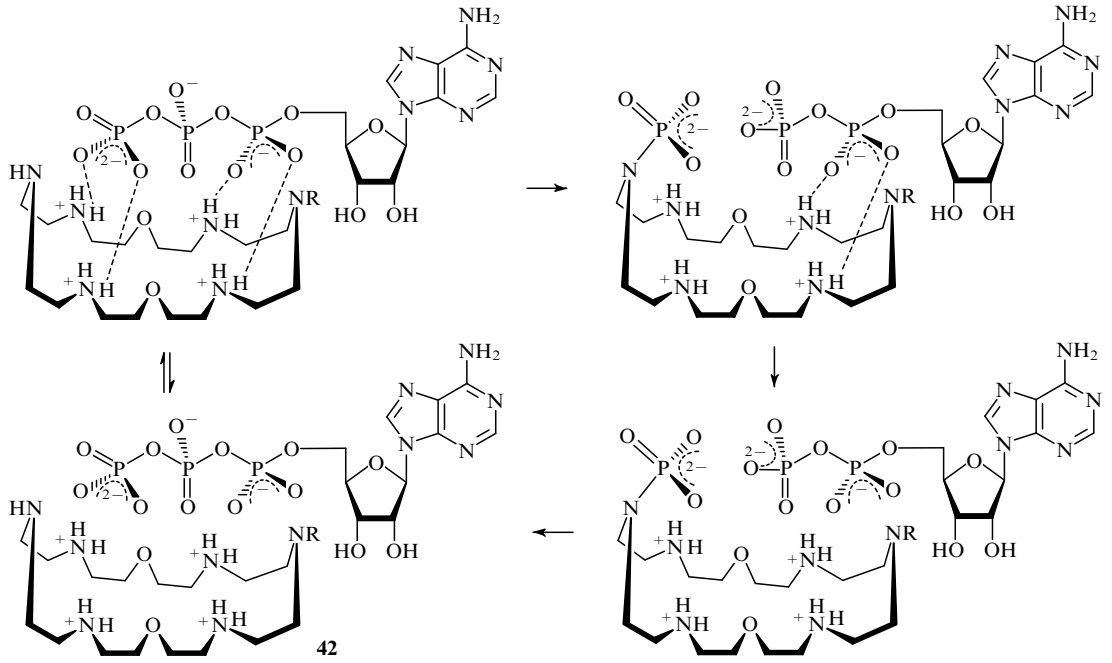
R^1 = HO_2C, 4-HOC_6H_4,  ,  , $(CH_2)_2NHCNH_2$,

$HOCH_2$, $HS(CH_2)_2$, C_7H_{15}; R^2 = Et, R^3 = $(CH_2)_3NMe_2$.

The catalytic activity of the compounds synthesised was determined from the degree of hydrolysis of bis(4-nitrophenyl) phosphate in the presence of metal ions (Mg^{2+}, Zn^{2+} or Fe^{3+}). This approach made it possible to reveal a series of polymers accelerating hydrolysis by a factor of 20 000 – 30 000. Polyamine containing 7.5% of caprylic-acid residues, 15% of imidazolylacetic-acid residues and 10% of 4-hydroxybenzoic-acid residues in the presence of iron ions proved to be most active (k_{cat}/k = 31 400).[197] The drawback of this approach is the lack of information on the structures of catalytically active sites. At the same time, methods of combinatorial chemistry make possible the rapid determination of functional groups necessary for particular catalytic processes to proceed efficiently.

Synthetic constructions based on macrocyclic polyamines are of particular interest. In these compounds, the catalytic and affine centres merge together. The efficiency of binding of macrocycles with RNA can be additionally enhanced by addition of the former to polyaromatic compounds.[198] The cleavage of the phosphodiester bond in adenosine-5′-triphosphate catalysed by macrocyclic polyamine **42** is presented in Scheme 3. Compounds of the type **42** did not exhibit hydrolytic activity with respect to nucleic

Scheme 3



42

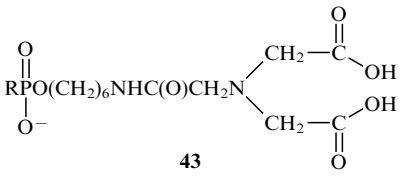
R =  .

acids.[199] However, the construction of synthetic catalysts based on molecules whose functional groups have a limited degree of freedom shows considerable promise.

3. Conjugates based on oligonucleotides

In the construction of oligonucleotide conjugates, virtually all types of the above-described catalytic groups were used (see reviews [200–204]). These groups were introduced into the midpoint of the oligonucleotide address (Fig. 5 *a*) or were added to the terminal fragments of the nucleotides (Fig. 5 *b*). The first mode of construction of conjugates seems to be attractive because subsequent RNA cleavage under the action of these conjugates leads to a substantial decrease in stability of the complexes of the conjugate with the substrate, which should be favourable for hydrolysis under the catalytic conditions. At the same time, the catalytic group in the complex of RNA with such a conjugate is located in the region of the duplex structure characterised by high stability.[102] When located at the terminus of the oligonucleotide, the catalytic group in the resulting complex is oriented toward the more labile single-stranded structure. However, the stability of the complex after RNA cleavage remains virtually unchanged. Therefore, exchange of the conjugate between depolymerised RNA and intact RNA is hindered, which should retard efficient functioning of the catalysts.

Conjugates containing catalytic groups attached to the 5′-terminal phosphate group differ substantially in efficiency of RNA depolymerisation. For the Lu^{3+} complex, which was prepared *in situ* based on oligo-DNA containing the iminodiacetic-acid residue (**43**) at the 5′-terminus, the degree of polymerisation was 17%



43

R, oligonucleotide residue.

(37 °C, 8 h). In the case of conjugates based on macrocyclic Eu^{3+} complexes **44a**,**b**, the degree of depolymerisation was 30% (37 °C, 18 h) and 80% – 90% (37 °C, 16 h), respectively.[206] The introduction of the same metal complexes at position 5 of thymidine located at the midpoint of the oligonucleotide address gave rise to inactive [205] or weakly active [206] conjugates. The catalytic activity of oligonucleotide conjugates **45** containing copper complexes at position 5 of thymidine also appeared to be low. Thus the degree of cleavage upon incubation of RNA with such conjugates at 45 °C for 72 h was at most 18% – 25%.[207]

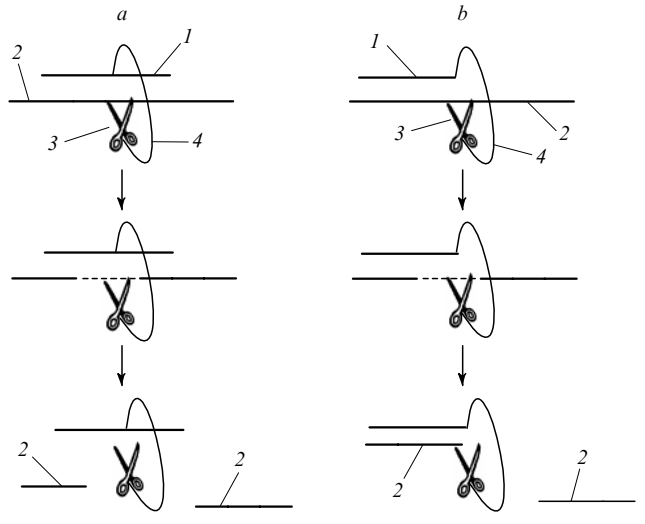

Figure 5. Main approaches to the construction of superspecific synthetic ribonucleases based on oligonucleotide conjugates;
(*a*) introduction of catalytic groups at the midpoint of the oligonucleotide address, (*b*) the addition to the terminal fragment; (*1*) is an oligonucleotide, (*2*) is an RNA target, (*3*) is a catalytic group, (*4*) is a linker.

High efficiency of cleavage is achieved when hydrolytic groups are located in the region of loop structures of the RNA target (Fig. 6 *a*). As mentioned above, phosphodiester bonds in loop regions of nucleic acids are characterised by high sensitivity with respect to cleavage under the action of reagents of different nature.[72, 103, 104, 208, 209] The efficiency of RNA cleavage with conjugates forming loop structures with RNA was as high as 92%, whereas that in analogous reactions involving conjugates forming perfect complexes was at most 7%.[205]

In the case of addition of a metal complex at the 5′-terminal phosphate group of the oligonucleotide address, hydrolysis of phosphodiester bonds occurs at a distance from one to seven nucleotide units depending on the type of the linker.[204, 210] In the case of formation of an artificial loop in the vicinity of the 5′-terminus, the cleavage is virtually quantitatively reoriented from the single-stranded region to the loop, the total degree of hydrolysis being increased.[205] It was demonstrated that synthetic ribonucleases based on 12-unit 2′-modified oligoribonucleotides, which were constructed on the above-described principle, can execute up to 40 events of RNA cleavage in the course of incubation at 37 °C during 64 h (at a reagent concentration of 1×10^{-3} mol litre^{-1}) in the presence of a 50-fold excess of RNA.[211]

Yet another way of increasing the flexibility of the sugar-phosphate core in the target RNA region is based on the replacement of one nucleotide unit in the oligonucleotide address by a non-nucleotide insertion.[212]

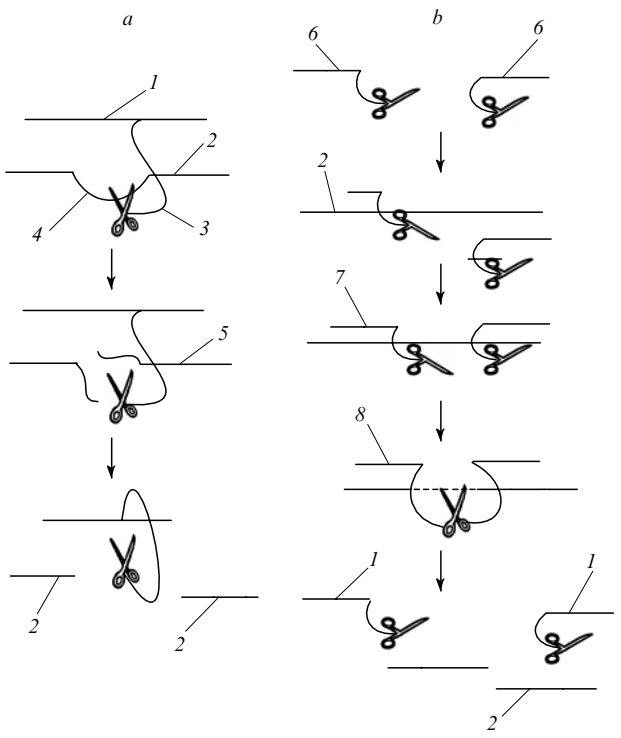

Figure 6. Principles of construction of synthetic ribonucleases based on conjugates containing noncomplementary regions (*a*) and based on module conjugates (*b*);

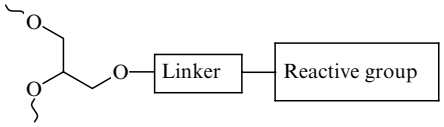
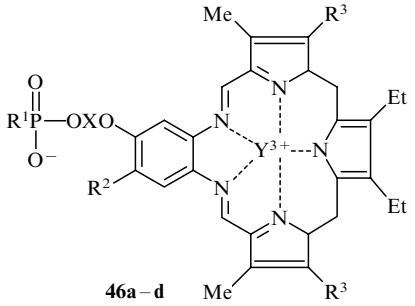
R = H, Me.



The ability of these oligonucleotide conjugates to cleave RNA under catalytic conditions was exemplified by conjugates **46a** containing macrocyclic Dy^{3+} complexes.[213]



R^1 is the oligonucleotide residue; R^2 = H, OMe; R^3 = $(CH_2)_3OH$, Et; X = $(CH_2)_3$, $(CH_2)_6$, $(CH_2)_6NHCOCH_2$; Y = Dy (**a**), La (**b**), Lu (**c**), Eu (**d**).

A promising approach to the construction of RNA-cleaving oligonucleotide conjugates involves the design of module (binary) reagents (see Fig. 6 *b*). The approach is based on separation of the catalytic centre into two fragments and the synthesis of conjugates of these fragments with oligonucleotides complementary to the adjacent regions of the RNA target. The catalytic centre arises only in the case of formation of a proper ternary complex in which two inactive structures are recombined to form a catalytically active centre. This centre can be formed either by individual reactive groups involved in natural ribonucleases (for example, two imidazole fragments) or by poorly reactive metal complexes forming more reactive binuclear catalytic centres. Undoubtedly, this approach imposes much more rigid limitations on both the structural parameters of the fragments of the reactive centre and the geometry of the conjugates as a whole. However, this approach has a number of important advantages, *viz*., it makes possible the improvement in specificity of the reaction with the target sequence and allows one to exclude side reactions of the conjugates with non-target biopolymers.

The most efficient conjugates of **46a–d** contain complexes of rare-earth metals (La^{3+}, Lu^{3+}, Eu^{3+} or Dy^{3+}) as catalytic groups. Dissociation of these ions from the metal complexes can lead to nonspecific cleavage of other biopolymers resulting in their high toxicity in biological systems. Recently, binuclear zinc complexes have been proposed for solution of this problem. Under physiological conditions, zinc ions by themselves cannot efficiently catalyse depolymerisation of biopolymers, whereas the efficiency of their binuclear complexes is rather high.[214]

Reagents based on oligonucleotide conjugates with catalytic groups, which do not contain metal ions, seem to be more promising because they allow one to exclude completely any cofactors. In combination with high specificity of the oligonucleotide address, the above fact may enable one to prepare compounds capable of performing efficient cleavage of the target RNA sequences leaving other biopolymers intact. However, some groups (amino and carboxyl groups, heterocyclic fragments) exhibit substantially lower catalytic activity than metal ions and metal complexes. High efficiency of hydrolysis in the presence of organic compounds is achieved only in the case of the optimum spatial arrangement of all groups involved in the catalytic process. Oligonucleotide derivatives containing ethylene-[215] or propylenediamine[216] at the 5′-terminus are the simplest RNA-cleaving conjugates, which do not contain metal ions. Cleavage of $tRNA^{Phe}$ under the action of a 19-unit oligonucleotide conjugate containing the diamine residue was reported.[217] The efficiency of this reaction was 10% after incubation at 50 °C for 4 h. Similar efficiency was observed upon cleavage of a 30-unit model oligoribonulceotide under the action of an analogous conjugate.[218] In both cases, the 5′-CpA sequences in the region of the reagent localisation were subjected to hydrolysis. The introduction of oligoamines through a non-nucleotide insertion at the midpoint of the conjugate leads to a decrease in efficiency of hydrolysis under analogous conditions to 3%.[219] At the same time, the degree of hydrolysis performed at 40 °C for 4 h with the use of a 10-unit oligopeptidylnucleotide containing diethylenetriamine at the 5′-terminus instead of the 19-unit oligodeoxyribonucleotide was 30%, and hydrolysis was quantitative after 24 h.[220] The target used in the latter study differed from that employed in the study [217] by the single substitution G → C as a result of which the CpApCpA fragment was present in the region of location of the hydrolytic group. Both bonds in CpA were subjected to hydrolysis, but to a different degree.

In the absence of metal ions, conjugates containing fragments, which bear the 1,4-diaminobutyl, *N*-propylimidazolium or histamine residues at the 3′-terminal phosphates of oligonucleotides, do not exhibit catalytic activity in hydrolysis of the model oligoribonucleotide. The histamine-containing compound exhibited weak activity upon introduction of zinc ions into the reaction mixture.[221] In a latter study, the polyuridyl sequence was used as the target.

The synthesis of oligonucleotide conjugates containing the $(Leu\text{-}Arg)_nGlyNH_2$ oligopeptides (n = 2–4) at the 5′-terminal

phosphate was reported.[222, 223] Incubation of a model 14-unit oligoribonucleotide with the complementary six-unit oligodeoxyribonucleotide whose oligopeptide fragment consists of alternating Leu-Arg pairs led to cleavage of the RNA target. In the case of the conjugate containing three Leu-Arg pairs, prolonged incubation (48 h, 37 °C) resulted in insignificant cleavage (~5%) of the target at the CpU site in the vicinity of the localisation site of the oligopeptide. In experiments with conjugates bearing two or four Leu-Arg pairs, the efficiency of cleavage under these conditions reached 30% and 70%, respectively. In the latter case, two GpA sequences and, to a lesser extent, UpU located in the double-stranded region of the complex were the major cleavage sites. In the case of incubation of *E. coli* $tRNA^{Phe}$ with conjugates based on the pTCAATC oligonucleotide, which is complementary to two sequences in the anticodon and TΨC loops, the phosphodiester bonds in the region of the D loop, in the TΨC loop and, to a lesser extent, in the anticodon region of this tRNA were cleaved. Cleavage of the phosphodiester bonds in the non-target region of the D loop was related to the possible spatial proximity to the TΨC loop possessing the partial binding site of the reagent.[222, 223] Unlike the model 14-unit oligoribonucleotide, the site of tRNA subjected to hydrolysis under the action of the reagent ($n = 3$ or 4) was independent of the length of the peptide residue, although the degree of hydrolysis of the target was also substantially decreased on going from $n = 4$ to $n = 3$. The maximum efficiency of hydrolysis was 80% ($n = 4$, 48 h, 20 °C).

We prepared oligonucleotide conjugates containing the bisimidazolium fragments at the 5′- or 3′-terminal phosphate.[224] The activity of the conjugates was tested using yeast phenylalanine tRNA as well as pre- and mini-exons of mRNA from *Leishmania amazonensis*. In the case of $tRNA^{Phe}$, the C(61)A(62) and C(63)A(64) sequences located in the vicinity of the hydrolytically active groups were subjected to cleavage, in all cases the highest efficiency of cleavage being observed at the CpA bond separated from the binding site of the reagent by three nucleotide units. The reagent containing the catalytic group at the 3′-terminal phosphate appeared to be somewhat more active than its 5′-analogue. After incubation at 37 °C for 8 h, the total efficiency of tRNA cleavage at three sites reached 60%.[225] In the case of the mini-exon of mRNA from *Leishmania amazonensis*, the efficiency of hydrolysis for the 17-unit oligonucleotide containing the bisimidazolium fragment at the 3′-terminus was 100% after 5 h. Cleavage proceeded primarily at the CpA sequences (80%) in the region of the expected localisation of the reactive groups. Similar results were obtained for oligonucleotide conjugates whose 5′-terminal phosphates bear synthetic fragments containing the imidazole fragment and the aliphatic amino group.[226] An increase in the length of the spacer, which links the bisimidazole fragments with the oligonucleotide address, as well as the introduction of reactive groups through a non-complementary nucleotide residue led to substantial enhancement of the efficiency of hydrolysis. Incubation of $tRNA^{Phe}$ with such conjugates at 37 °C for 3–5 h resulted in quantitative RNA cleavage (Fig. 7). Hydrolysis was completely inhibited in the presence of an oligonucleotide complementary to the cleavage sites (indicated by arrows, the oligonucleotide A, see Fig. 7).[227] Dendrimeric oligonucleotide conjugates containing from 2 to 24 imidazole residues were proposed.[228] This approach seems to be attractive for the synthesis of libraries of oligonucleotide conjugates containing not only imidazole fragments, but also other functional groups typical of the active centres of natural enzymes.

Methods of combinatorial chemistry can be used not only for the construction of reactive groups, but also for the choice of the RNA region most favourable for hydrolysis. The synthesis of a library of 8-unit 2′-*O*-modified oligoribonucleotides with random sequences was reported.[229] Each oligonucleotide contains the Eu^{3+} complex **44** at the 5′-terminus. Four hydrolysis sites were found after incubation of this library with 39-unit RNA (1 mmol litre^{-1} of the conjugates, 50 nmol litre^{-1} of RNA, 37 °C) for even 2 h. This result was unexpected because the

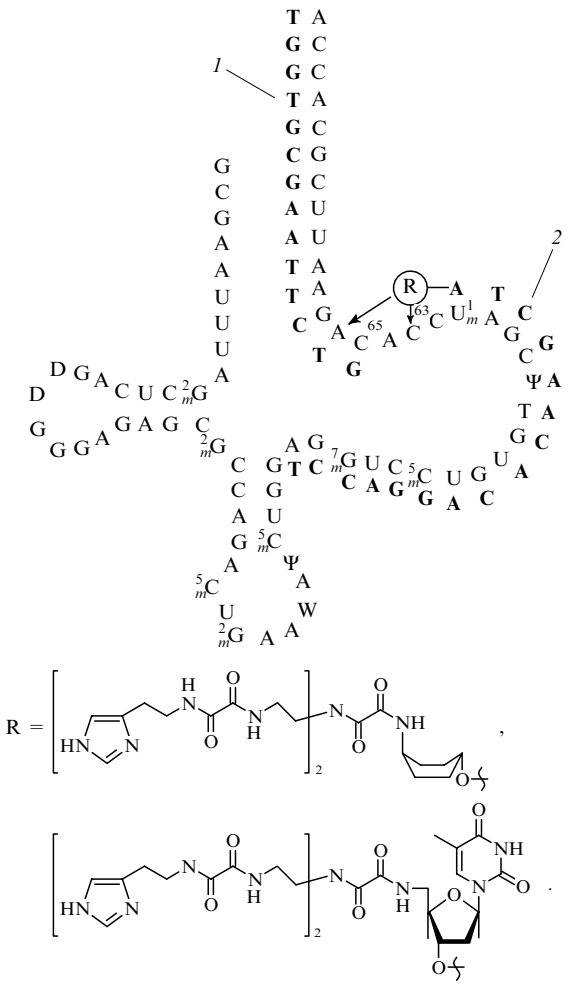


Figure 7. Metal-independent catalytic groups R used in the construction of synthetic ribonucleases based on oligonucleotide conjugates.
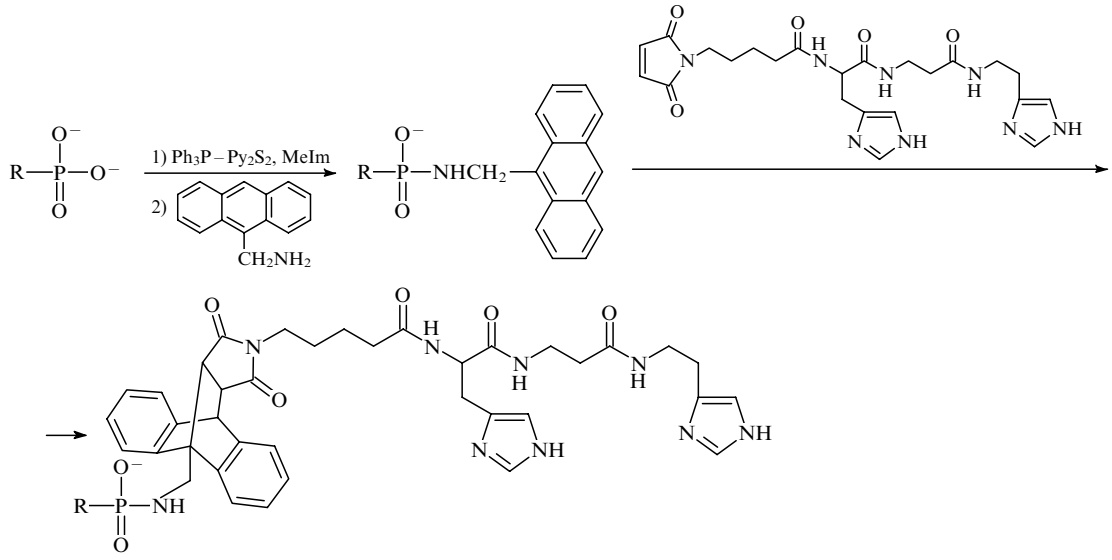
Sites of $tRNA^{Phe}$ cleavage with bisimidazole oligonucleotide conjugates are indicated by arrows; (*1*) oligonucleotide A, (*2*) oligonucleotide B.

concentration of each particular conjugate in the reaction mixture was no higher than 15 pmol litre^{-1}.

Two radically different approaches to the synthesis of oligonucleotide conjugates with various ligands, *viz*., the introduction of ligands in one of the stages of the oligonucleotide synthesis and the post-synthetic modification of the oligonucleotide, are of considerable current use.[230] Several alternative procedures for performing both strategies are available. The first approach most often involves the automated synthesis of oligonucleotides based on amidophosphites of protected nucleosides and ligands. Monomeric blocks containing fragments of various metal complexes[231–235] and imidazole-containing constructions[236–240] were proposed for the preparation of synthetic ribonucleases based on oligonucleotide conjugates. The successive synthesis of the oligonucleotide and catalytic fragments of the conjugate at the same solid-phase carrier is a promising variation of this approach.[221, 241] However, this approach is unavailable for the majority of potential consumers of these conjugates because of the necessity of synthesising unique amidophosphites in each particular case and the problems associated with the choice of protective groups and procedures for their removal in the case of the successive synthesis of oligonucleotide conjugates. On the contrary, the synthesis of oligonucleotides containing functional groups along with 5′- or 3′-terminal phosphates and amino, hydroxyl and carboxyl groups was well developed by many biochemical companies due to which the post-synthetic modification of oligonucleotides shows considerable promise. Variations

Scheme 4



R is deoxyoligonucleotide; MeIm is methylimidazole.

of the functionalisation of the above-mentioned groups were considered in the studies.[230, 242] The latter approach was widely used in the synthesis of ribonucleases containing metal complexes,[103, 205, 210, 211, 229] polyamines[215, 219] or imidazole derivatives.[226] The soft procedure for activation of the terminal phosphate group[243] makes possible the preparation of oligonucleotide conjugates with molecules bearing aliphatic amino groups without protection of the imidazole[224, 225, 244] or guanidinium[222, 223] fragments. Beloglazova *et al.*[245] proposed an ingenious approach to the preparation of oligonucleotide conjugates with molecules containing virtually any functional groups necessary for the design of highly efficient catalytic centres. The authors attached the catalytic centre to the terminal phosphate group of deoxyoligonucleotide by a Diels–Alder reaction between the anthracene fragment and the double bond of a maleimide group (Scheme 4).

* * *

Intensive studies on the construction of synthetic catalysts for the specific cleavage of ribonucleic acids have resulted in the preparation of promising compounds belonging to a new family of structural probes for investigation of RNA conformations and for the design of conjugates of antisense oligonucleotides. Low-molecular-weight synthetic catalysts capable of cleaving RNA with an efficiency and selectivity close to those typical of natural ribonulceases are as yet unavailable. However in many cases, this efficiency is not necessary. In particular, in spite of low efficiency, synthetic ribonucleases as structural probes have advantages over natural enzymes. For example, when binding with RNA, ribonuclease A, which is an enzyme catalysing hydrolysis predominantly of pyrimidine–purine sites in single-stranded regions, changes the RNA structure and even leads to untwisting of double-stranded regions, which limits the possibilities of its use in structural studies. Small synthetic molecules do not destroy the structures of nucleic acids and cleave the latter only within single-stranded regions existing in the native molecule, which allows one to obtain information on the biologically active RNA structure.

Studies both aimed at examining processes occurring in the active centres of enzymes and directed towards modelling of these processes in small chemical nucleases are being continued. It is hoped that synthetic nucleases, which may be highly competitive with natural biocatalysts and even outperform them in efficiency, will be prepared in the coming years. Such compounds can help in designing a new generation of highly efficient antiviral and anticancer drugs.

Abstract. The published data on the main methods for the preparation of polymeric supports containing nucleic acids (NA) or their fragments (oligonucleotides) are reviewed with special emphasis on chemical immobilisation. Some physical and physicochemical immobilisation techniques, including those based on the use of enzymes and avidin – biotin interactions and preparation of NA-containing supports by direct oligonucleotide synthesis on these supports are considered. A special section is devoted to the application of NA-containing sorbents for the isolation of individual NA and proteins as well as in hybridisation analysis including those utilising DNA chips and DNA biosensors. The bibliography includes 391 references.

I. Introduction

Polymeric supports containing nucleic acids (NA) and their fragments have long attracted the attention of specialists in different fields of biochemistry, gene engineering and molecular biology. In the past decade, such supports have successfully been used in hybridisation analysis for research purposes as well as in medicine for the diagnostics of infectious, cancer, genetic and other diseases. NA-Containing matrices are efficient tools for isolation of individual NA and NA-dependent enzymes. The synthesis of affinity sorbents is based on the following principle: the ligands (in our case, NA, oligonucleotides or polynucleotides) are immobilised on a polymeric support (a matrix) through a linker or a spacer, or without them. With the advent of automated synthetic techniques, oligonucleotides have become commercially readily available, which makes them especially attractive as ligands. Native NA are also immobilised as ligands for the solution of some practical tasks.

All presently known methods for immobilisation of oligonucleotides and NA can be conventionally divided into chemical methods, which involve covalent binding of NA to the support, and other methods, which include all the procedures demanding special equipment or technology (*e.g.*, synthesisers, irradiation, *etc.*) in addition to the support, NA and chemicals.

This review is devoted to the description of the main methods for the preparation of NA-containing sorbents, their properties and applications. It should be noted that these methods can be used for immobilisation of not only oligo(poly)nucleotides, but also their analogues and peptide-nucleic acids (PNA) in which the sugar-phosphate backbone is replaced by the peptide chain. A separate section is devoted to the use of NA-containing matrices for the isolation of individual NA and proteins as well as in hybridisation analysis (including DNA chips and DNA biosensors).

II. Solid supports and linkers

1. Supports

Before we pass to the consideration of various procedures for immobilisation of NA, we shall dwell briefly on the requirements placed upon polymeric supports to be used in the design of 'ideal' affinity matrices. These include:

(1) insolubility (to avoid the loss of the ligand attached and contamination of the isolated compound with the dissolved support);

(2) accessibility of the immobilised ligand for the formation of complexes with specific biomolecules;

(3) zero adsorption capacity (to prevent non-specific interactions);

(4) high reactivity essential for chemical modification of the support surface;

(5) chemical stability under conditions employed for the attachment of ligands as well as sorption and desorption of the products and regeneration of the matrix;

(6) high resistance to microbes and enzymes;

(7) hydrophilicity (to reduce non-specific sorption due to hydrophobic interactions);

(8) commercial availability.

The requirements for the nature, shape, composition and mechanical strength of the solid support vary depending on the experimental task. The most popular supports can be divided into two groups, *viz.*, natural and synthetic ones (Table 1). High-

Table 1. Commercially available carriers.

Carrier	Commercial name	Manufacturer
Natural supports		
Agarose	Sepharose, Superose	Pharmacia, LKB

pressure affinity chromatography demands hard materials, whereas in column chromatography performed at normal pressure hardness is not a critical factor. The relatively small specific surface area in non-porous supports can largely be compensated by the reduced size (down to the micron level) of the support particles with the preservation of their satisfactory hydrodynamic characteristics. Porous supports are suited to affinity chromatography where the size of the analysed molecules is much smaller than that of the matrix pores. In the majority of cases, sorbents represent spherical granules with the size of 40 to 150 μm, whereas silica gel-based sorbents for high-performance affinity chromatography have a particle size of about 10 μm.

Modern studies often utilise membranes as supports. They are usually manufactured from various polymeric materials, such as cellulose, polyamide (nylon), polyacrylonitrile, polysulfone, polypropylene, polyesters, polyethylene, *etc*. Cellulose, nylon and poly(ethylene terephthalate) are the most popular supports, since they allow easy incorporation of various functional groups. Cover glasses and polystyrene immunological assay plates are widely used in hybridisation analysis.

Some supports incorporating various functional groups (Table 2) accessible for immobilisation of ligands are commercially available; however, they demand additional modification prior to application because they partly lose their activities upon storage. Therefore, we shall consider some synthetic procedures leading to such sorbents along with the principal known methods for the preparation of affinity sorbents containing NA or their fragments.

2. Linkers and spacers

Oligonucleotides and NA can be immobilised directly on the surface of the solid support; however, this can result in steric hindrance to subsequent reactions with biomolecules, especially in the case of planar supports, such as membranes and slides. To prevent this, immobilisation is carried out with the use of linkers or spacers which hold the ligand at some distance away from the surface and thus make it more accessible for further interactions.

In the absence of linkers, immobilisation can be carried out by virtually all physical methods (*e.g.*, UV irradiation, sorption on the surface by drying) or by direct synthesis of oligonucleotides on glass [1] or on aminated polypropylene.[2] However, immobilisation is usually performed after incorporation of spacers into the oligonucleotide and/or on the surface of the support.[3–40] The larger is the distance between the immobilised ligands and the surface, the more accessible they are for the reaction with the dissolved molecules. Most often, the role of linkers is played by linear aliphatic chains containing different numbers of hexamethylenediamine, 6-aminocaproic acid or ethylene glycol units. In addition to the length, an important role is played by the nature of the linker, which may govern the extent of non-specific sorption. This can be overcome through the use of linker chains consisting of hydrophilic molecules, *e.g.*, 1,3-diaminopropan-2-ol or amino acid residues. Hydrophilic linkers of any length can be designed from phosphoroamidites of various diols [8] or by stepwise addition of 1,3-diaminopropan-2-ol and bromoacetic acid.[9,10] The linkers are usually attached to the support by the same methods as ligands. Silica gel and glass are premodified by (3-aminopropyl)-triethoxysilane (**1**),[11–13] (3-glycidyloxypropyl)trimethoxysilane (**2**),[3,4,13–15] [*N*-(2-aminoethyl)-3-aminopropyl]trimethoxysilane (**3**), (diethylenetriaminopropyl)trimethoxysilane (**4**)[16] or other trialkoxysilanes.[17–21] The number of immobilisation sites can be increased by an order of magnitude using branched linkers, such as dendrimers (**5**).[22]

Oligonucleotides with linkers (3–11 units) attached to their 5′- (see Refs 7, 23–28) or 3′-terminal [15,29] phosphates, to the apurinisation sites,[30] to the amino group of 5-methyldeoxycytidine,[31,32] to C(5) of deoxyuridine [33–36] or to C(8) of deoxyadeno-

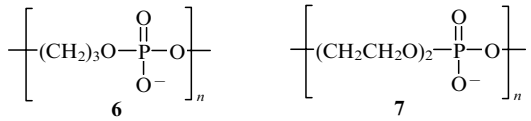
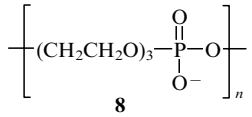
sine [37] are immobilised on commercially available supports (see Table 2) bearing relatively short linkers (2–11 units).

There is no general agreement as regards the dependence of hybridisation properties of immobilised oligonucleotides on the linker's length. It was noted [6, 16] that the hybridisation abilities of immobilised oligonucleotides are enhanced with increase in the linker's length. It is also suggested [8, 38, 39] that efficient hybridisation requires the optimum length of the spacer to be selected. The use of linkers (**6**–**8**) containing different numbers of repeating units has also been documented.[8]



6 **7**



8

The maximum efficiency of hybridisation is achieved for $n = 8-10$ with all three types of units. This suggests that the yields of hybridisation products depend not only on the length of the linker, but also on its structure (in this case, probably, on the number of negative charges). The maximum increase in the yields of hybridisation products (150-fold in comparison with the yields in the absence of the spacer) was observed with the linkers **7** and **8** for $n = 8$. With a further increase in the number of units, the hybridisation ability diminishes, and for $n = 25-30$ the yields of the hybridisation products are virtually the same as in the absence of the linker.

However, it was shown [40] that the length of the linker between the polyacrylamide support and an oligonucleotide does not influence the stability of a duplex formed. This is consistent with the results of the above-cited studies and those devoted to the sequencing of DNA by hybridisation on oligonucleotide microchips.[41–47] Presumably, the optimum length of the linker depends on many factors, such as the nature of the support, the ligand and the linker itself, and should be chosen experimentally for each particular task. It is noteworthy that immobilisation on granulated supports can be made using short linkers or no linkers at all, whereas films and slides demand longer linkers.

In order to increase the distance between the surface and an oligonucleotide to be immobilised, the latter sometimes is elongated by introducing additional chains consisting of thymidine units [*e.g.*, oligo$(dT)_{1-400}$][17, 19, 48, 49] or non-essential oligonucleotide sequences (*cf.* **9**).[7, 18]

III. Chemical methods for the immobilisation of nucleic acids

Immobilisation of NA by covalent binding to polymeric supports is achieved by the reaction of available or incorporated functional groups of the oligonucleotide with reactive groups of the support. In this review, the chemical methods used for the formation of a covalent bond between the ligand and the polymer are divided into two large groups, *viz.*,

(1) immobilisation of functionalised and/or activated NA on nucleophilic supports, and

(2) immobilisation of NA on supports containing electrophilic groups.

It should be noted that the functional groups of the natural nucleic acids (hydroxy groups of ribose, phosphoric acid residues and heterocyclic bases [50]) possess nucleophilic properties and react with the electrophilic groups of the polymer. These reactions usually yield numerous binding sites of the ligands to the supports, which results in the loss of the full-value interactions of immobilised NA with biomolecules. To prevent this, NA are modified by introduction of additional functional groups which are more reactive than the corresponding functional groups of the natural NA.

1. Immobilisation of functionalised and activated nucleic acids on nucleophilic supports

Immobilisation of NA and their fragments on solid supports containing surface nucleophilic groups (*e.g.*, hydroxy, thiol or amino groups) can be achieved by preliminary activation of the functional groups of the ligand (Fig. 1).

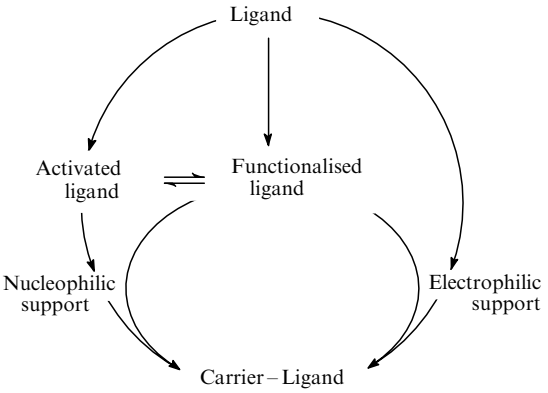


Figure 1. Chemical methods for the immobilisation of ligands.

The introduction of functional groups into poly- and oligonucleotides has been the subject of several reviews.[51–53] Most often, the post-synthetic introduction of additional functional groups involves terminal phosphate groups using reagents which affect other functional groups of NA to a much lesser extent. Carbodiimides, arenesulfonyl chlorides, 2,4,6-trimethylbenzoyl chloride, *etc.*, are commonly used for this purpose.[54–58] The reactive oligonucleotide derivatives formed are unstable and used for the introduction of additional functional groups into oligonucleotides or for direct immobilisation on solid supports immediately following preparation.

a. Activation of nucleic acids by carbodiimides

The addition of NA using carbodiimides **10a**–**c** has been one of the earliest approaches to the preparation of affinity sorbents and has continued to be a very popular procedure.[50–64] This method is based on the ability of carbodiimides to activate either the carboxy groups of polymers or the terminal phosphate group of NA. Carbodiimide-activated oligonucleotides react readily with amino or thiol groups of solid supports. Reactions with hydroxyl-containing supports proceed less effectively.

The carbodiimide method is used for the immobilisation of mono-, oligo-, polydeoxyribonucleotides and DNA in both organic solvents using dicyclohexylcarbodiimide (**10a**)[50–62] and aqueous media using water-soluble carbodiimides, *e.g.*, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (**10b**)[13, 18, 24, 25, 65, 66] or 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluenesulfonate (**10c**).[25, 67]

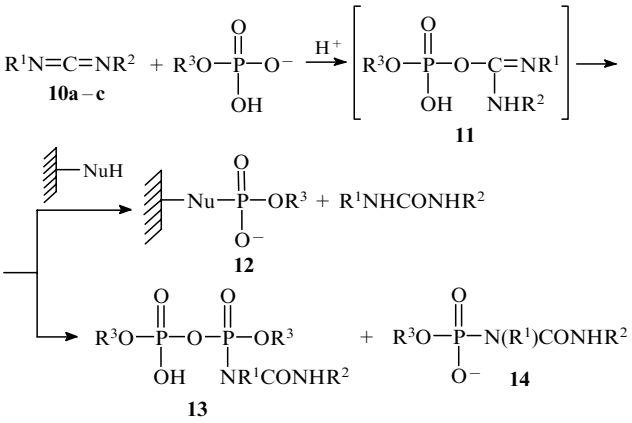
$R^1N{=}C{=}NR^2$

10a–c

$R^1 = R^2$ = cyclo-C_6H_{11} (**a**); R^1 = Et, $R^2 = Me_2N(CH_2)_3$ (**b**);

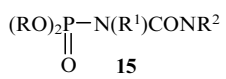
R^1 = cyclo-C_6H_{11}, R^2 =  $[SO_3C_6H_4Me\text{-}4]^-$ (**c**).

The mechanism of activation of phosphate groups of oligonucleotides by carbodiimides has been studied in detail and some side reactions have been revealed.[68–73] Protonation of carbodiimides and the formation of intermediate unstable reactive *O*-phosphorylisourea derivatives **11** is the limiting step of this reaction.[74] This stage is also inhibited by strongly basic nucleophilic groups of the support. Besides, protonated nucleophilic groups do not react with compounds **11**. As a consequence, the yield of the final product **12** decreases if polymers with strongly basic groups are used. The substituted *O*-phosphorylisoureas **11** can also be transformed into side products, *e.g.*, be hydrolysed with the liberation of the original phosphate group and urea or undergo consecutive conversions leading to pyrophosphates, polyphosphates and *O*-phosphorylisourea derivatives.[75] The latter, in turn, produce non-reactive *N*-pyrophosphorylurea derivatives **13**[75,76] or *N*-phosphorylurea derivatives **14**.[66,77–79]

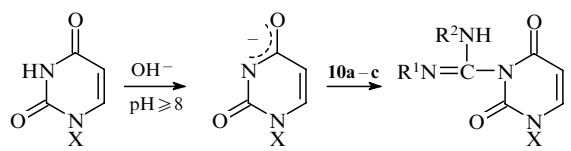


R^3, oligonucleotide residue; NuH = NH, SH, OH.

In the activation of oligonucleotides by carbodiimides resulting in compounds **11**–**14**, modification of internucleotide phosphate groups[76,79] and heterocyclic bases[69,80] is observed. In the case of oligodeoxyribonucleotides, the reaction with the internucleotide phosphate groups results in the urea derivatives **15**,[76] whereas the reaction with oligoribonucleotides leads to the isomerisation and cleavage of the internucleotide bonds.[51,81]



The activation of the terminal phosphate group of the nucleotide by carbodiimide in alkaline media (pH $\geqslant$ 8) can be accompanied by nucleophilic addition of the anion formed from the heterocyclic base to the double bond of the carbodiimide. This reaction affects the bases containing a CONH group, *i.e.*, the N(3) atom in the uracil and thymine residues and the N(1) atom in the guanine residues.[69]



X, oligonucleotide residue.

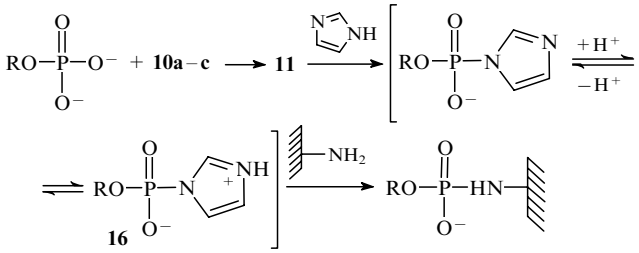
The rate of the limiting stage can be accelerated, the yield of the target product **12** in the immobilisation of the oligonucleotide derivatives **11** can be increased and the modification of the internucleotide phosphodiester groups and heterocyclic bases by carbodiimides can be overcome if the reaction is carried out in weakly acidic media (pH 4.25–5.0).[80] In this case, the carbodiimide-activated terminal phosphate group of an oligonucleotide reacts predominantly with the amino, thiol or hydroxy groups on the surface of the support.

The selectivity and efficiency of oligonucleotide immobilisation increases slightly after functionalisation of their 5′-phosphate groups by linkers containing a terminal carboxy group,[18,82] which reacts with the amino groups of the support after its activation by carbodiimide.

An alternative approach consists in the activation of the carboxy groups of the polymer by carbodiimides (see Section III.2). In this case, immobilisation of nucleotides and oligonucleotides on supports involves the amino groups of the heterocyclic bases or linkers attached to the 3′- (see Refs 66, 83) or 5′- (see Refs 25, 84) terminal phosphates of the oligonucleotides.

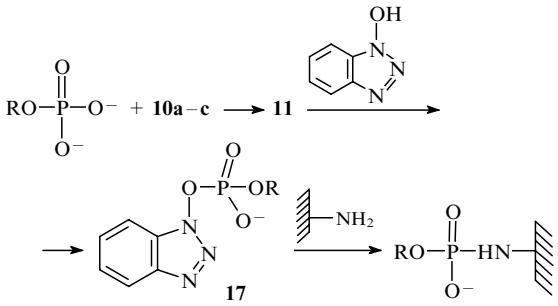
Immobilisation of NA and oligonucleotides by the carbodiimide method is carried out on virtually all available solid supports, *e.g.*, cellulose, Sepharose,[59–63,72,85] Sephacryl,[23,65,67] Sephadex,[23,73,85] SiO_2-based supports[12,18,64,65,86,87] and various membranes.[66,82,83,88] In addition to conventional supports, magnetic carriers (*e.g.*, polystyrene-coated magnetite particles)[25] and latex microspheres (polystyrene beads able to form colloidal suspensions)[24] are used. The resulting matrices are used in hybridisation analysis[12,13,18,23,25,66,67] and in affinity chromatography.[63,89]

The efficiency of immobilisation of oligonucleotides on polymeric supports can be increased by performing activation by carbodiimides in the presence of nucleophilic catalysts, *e.g.*, imidazole, triazole or tetrazole, which generate the corresponding phosphoramidates;[24,25,65,73,88] the latter manifest high reactivities towards nucleophiles after protonation of the azole units. Phosphorimidazolidates **16** are commonly used.[88,90,91]



R, oligonucleotide residue.

The addition of compounds containing hydroxy groups with higher acidities, *e.g.*, *N*-hydroxysuccinimide or *N*-hydroxybenzotriazole, to the reaction mixture instead of nucleophilic catalysts results in the formation of the activated NA esters **17**.[73,92]

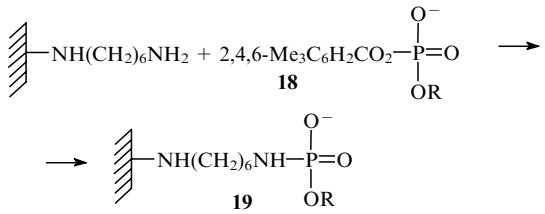


R, oligonucleotide residue.

The main advantage of the last two approaches is the lack of side reactions, since the derivatives **16** and **17** are more stable than the *O*-phosphorylisoureas **11**. The compounds **16** and **17** react with the amino groups of the support more efficiently, which increases the yield on immobilisation.

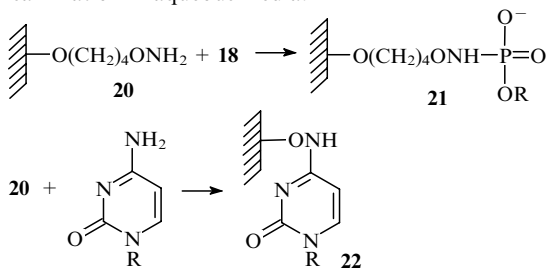
b. Activation of nucleic acids by 2,4,6-trimethylbenzoyl chloride

High reactivity of the title reagent with respect to the terminal and internucleotide phosphate groups ensures rapid formation of the corresponding mixed anhydrides. In aqueous media, only the mixed anhydride **18** formed upon reaction with the terminal phosphate persists.[93,94] This is used for the immobilisation of deoxyribonucleic acids on polymers containing nucleophilic amino groups. In aqueous media, immobilisation is due to the formation of a phosphoramide bond between the terminal 5′-phosphate group of the oligonucleotide and the primary amino group of the polymer (the product **19**).[57,95]



R, oligonucleotide residue.

In the study by Shumyantseva and Khomutov,[96] the activated oligonucleotide **18** was immobilised on aminooxybutylcellulose **20**. The resulting affinity sorbent **21** is stable only at pH 7.0 due to the high lability of the alkoxyamide bond. In addition, binding of oligonucleotides to the polymer **20** occurred involving the amino groups of cytidine to give the product **22**, most probably due to transamination in aqueous media.[56,94]

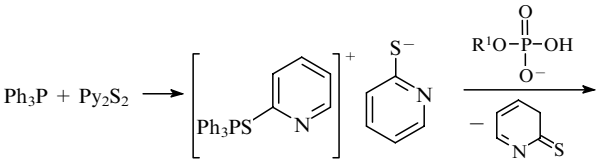


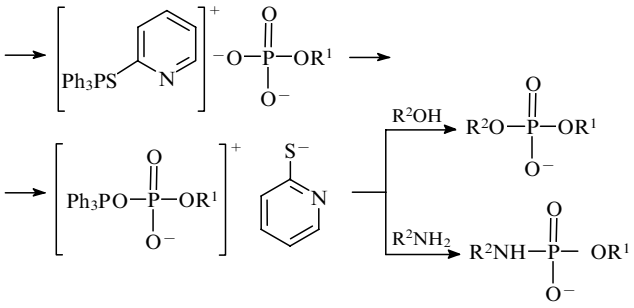
R, oligonucleotide residue.

This method has not gained wide acceptance despite the fact that TMP, AMP, CMP, d(pT)$_3$, d(pA)$_3$ and other oligonucleotides[57,95,96] were immobilised on polysaccharide supports in fairly good yields (0.05–0.15 mmol of the nucleotide per 1 g of the support). The significant disadvantages of this method are the lengthy immobilisation step (> 3 days) and side reactions (*e.g.*, the formation of pyrophosphates of oligonucleotides, reactions involving internucleotide phosphates and the heterocyclic bases of oligonucleotides). This method is inappropriate for the immobilisation of ribooligonucleotides and RNA, since mixed anhydrides favour the formation of cyclophosphates in the activation step, subsequent isomerisation and cleavage of the internucleotide bonds.[93]

c. Activation of the terminal phosphates of oligonucleotides by the triphenylphosphine–dipyridyl disulfide redox couple

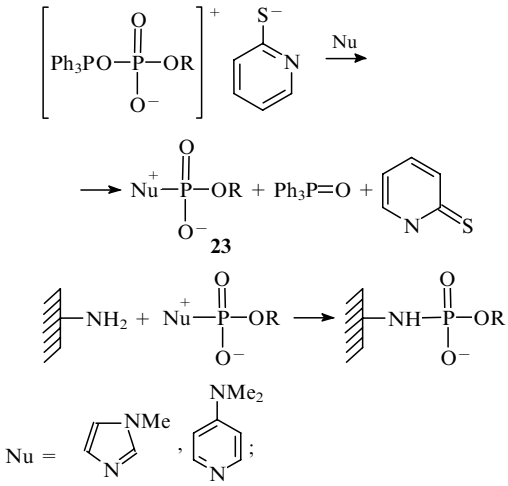
The triphenylphosphine–dipyridyl disulfide redox couple ($Ph_3P-Py_2S_2$) was first recommended for use as a condensation reagent for peptide and oligonucleotide syntheses by Mukaiyama *et al.*[97,98] The following reaction scheme was proposed:[98]





R^1, nucleotide or oligonucleotide residue; R^2 = Alk, Ar.

However, the reaction of an oligonucleotide with highly basic amino groups in the presence of the Ph_3P-PyS_2 couple occurs at a slow rate and with low yields, which places certain restrictions on its practical application. A detailed study of this system by Zarytova *et al.*[99–102] revealed that the $Ph_3P-Py_2S_2$ couple selectively activates the terminal phosphate group of an oligonucleotide in the presence of nucleophilic catalysts with the formation of the zwitterionic oligonucleotide derivatives **23**.



R, nucleotide or oligonucleotide residue.

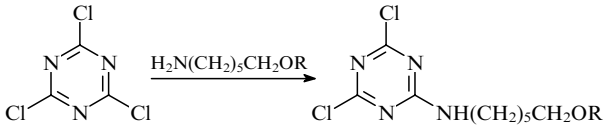
It should be emphasised that heterocyclic bases and internucleotide phosphate groups are not involved in the activation, which precludes the formation of side products. Therefore, this approach can be used for the activation of both deoxyoligonucleotides and their analogues and, which is especially important, of ribooligonucleotides without migration of the C(3)–C(5′) internucleotide bond.

The activated derivatives **23** react rapidly and virtually quantitatively with primary amines to yield oligonucleotide phosphoramides.[100] The activated oligonucleotide **23** can easily be immobilised provided the primary amino group is localised on its surface.[101,102] The immobilisation is completed within 2 h in aqueous alkaline media or in organic solvents. Up to 97% of the starting oligonucleotide material binds to the support, which enables one to control and vary the capacities of affinity sorbents. Any material can be used as a support, but silica gel[103–105] and polymethacrylate gels[101,106] are especially widely used. The matrices with immobilised oligonucleotides were used for affinity chromatography of NA-dependent proteins,[101,106] nucleic acids and their analogues.[102–105] The $Ph_3P-Py_2S_2$ couple can be recommended for the immobilisation of ribooligonucleotides and RNA, since in contrast with the known condensation reagents (*e.g.*, carbodiimides, arenesulfonyl chlorides, azoles, 2,4,6-trimethylbenzoyl chloride), it does not react with internucleotide phosphates and nucleophilic centres of heterocycles and no corresponding side products are formed.

d. Activation of nucleic acids by bifunctional reagents

Activation and subsequent immobilisation of NA and their fragments can be achieved through the use of bifunctional reagents. The reactions with bisoxiranes, disuccinimidyl carbonate, carbonyldiimidazole and glutaraldehyde will be considered in detail in Section III.2.

The bifunctional reagents also include 2,4,6-trichloro-1,3,5-triazine (**24**), which reacts with the primary amino group of a spacer introduced into the oligonucleotide in the course of its synthesis.[27]



24 **25**

R, oligonucleotide residue

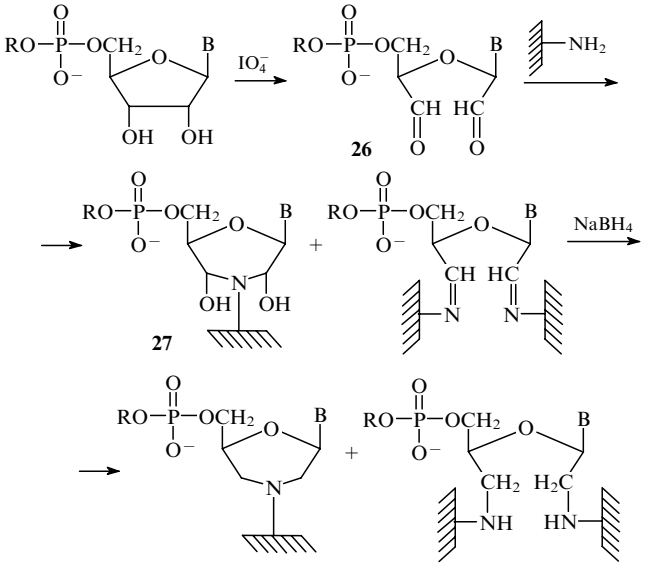
The triazine derivatives of oligonucleotides **25** are stable for at least one week at 4 °C and can be immobilised on any supports containing amino (see Refs 6, 27) or thiol groups.[6] The resulting sorbents are characterised by low non-specific sorption of proteins and NA and are stable under hybridisation conditions.[27, 107]

e. Reductive amination with nucleic acids and oligonucleotides containing aldehyde groups

Reductive amination is based on the well-known reaction of aldehydes and ketones with primary amines resulting in the formation of Schiff's bases. The reduction of Schiff's bases by sodium borohydride affords stable secondary amines.

$$R^1NH_2 + O{=}CHR^2 \rightleftharpoons R^1N{=}CHR^2 \xrightarrow{NaBH_4} R^1NHCH_2R^2$$

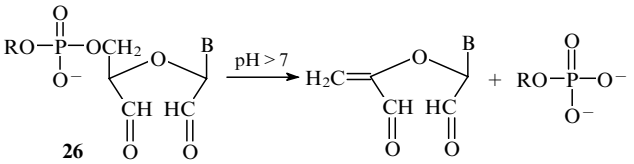
Immobilisation based on this method requires that NA or oligonucleotides contained aldehyde groups. This requirement is easy to meet in the case of ribooligonucleotides, RNA and deoxyoligonucleotides carrying a 3′-terminal ribose moiety. The *cis*-diol group of the terminal ribose is selectively oxidised by sodium periodate. The aldehyde groups formed (compound **26**) react with supports containing surface amino [108–111] and hydrazide [112–114] groups.



R, ribooligonucleotide, RNA or deoxyoligonucleotide;
B, heterocyclic base.

In this reaction, the dialdehyde can react both with one amino group of the support (to give the morpholine derivative **27** [50, 52]) and with two amino groups leading to bisadducts. Since the derivatives of the type **27** are stable only at pH > 9 and phosphate undergoes β-elimination at pH < 8, they should be reduced with sodium borohydride or cyanoborohydride immediately after preparation.

A decrease in the yield of the immobilisation products can also be due to the cleavage of the 5′-C—O bond in the periodate oxidation product **26** in alkaline media (β-elimination) resulting in the splitting of the modified nucleoside from the 3′-end of RNA.[50]



26

Immobilisation on supports containing hydrazide groups occurs with higher yields, since hydrazones do not require treatment with reductants, being more stable than azomethines.[29] It should be noted, however, that the binding of an oligonucleotide to the support through the aliphatic amino group formed upon reduction is stronger [29] than that formed through the hydrazone group.

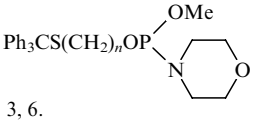
Reductive amination was used for efficient immobilisation of all ribonucleoside mono-, di- and triphosphates [114–118] on cellulose and agarose (Sepharose) modified by amino or hydrazide groups. The sorbents formed were used in affinity chromatography of proteins, such as myosins [118] and the elongation factors Tu and Ts.[110] Reductive amination is the main technique in immobilisation of ribonucleotides. Polyribonucleotides [poly(A) and poly(U)] following oxidation of the *cis*-glycol groups were attached to polysaccharide supports.[111, 115, 119] Among numerous studies aimed at immobilisation of RNA by this method,[112, 116, 119–121] special mention should be made of those studies [115, 117, 122, 123] in which ribosomal RNA were covalently attached to hydrazide-agarose and used for the isolation and purification of ribosomal proteins. tRNAs immobilised on polysaccharide templates [111, 115, 124] were used for the purification of aminoacyl-tRNA synthases.[125–128]

Recent developments in oligonucleotide synthesis have stimulated studies aimed at the synthesis of oligodeoxyribonucleotides containing a terminal ribonucleoside unit. Its 3′-*cis*-glycol group is oxidised and used for immobilisation of oligodeoxynucleotides on solid supports.[29, 64, 129, 130] The affinity matrices thus prepared are widely used in hybridisation analysis and sequencing of DNA.[42, 43, 45, 131–133]

Immobilisation of NA and their fragments by reductive amination can also be achieved by the introduction of the aldehyde groups into the supports. One can synthesise polymers of virtually any type containing reactive aldehyde groups. The methods of their synthesis will be discussed in Section III.2.i.

f. Immobilisation of nucleic acids containing thiol groups

The introduction of chemically reactive thiol groups into NA and their fragments [53] allows specific immobilisation of such ligands by conventional methods, *e.g.*, on supports containing epoxy groups (Section III.2.b) or active halogen atoms (Section III.2.e).[134] Special procedures can also be used for this purpose. Thiol groups can be introduced in the last step of the phosphoramidite oligonucleotide synthesis, *e.g.*, using commercial phosphorylating reagents, such as phosphoramidites of *S*-protected thio alcohols.[49, 134, 135]

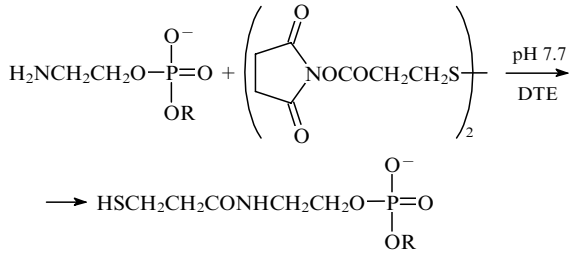


n = 3, 6.

The removal of all protective groups (including the trityl group) by silver nitrate leads to an oligonucleotide containing a

5′-terminal thiol group.[49, 135] Thiol groups can either be introduced into the 3′-end of an oligonucleotide in the initial stage of the synthesis,[16, 136] or incorporated into the isolated oligonucleotide by an enzymic reaction, *viz*., using ATP containing a γ-thiol group.[137]

An alternative approach consists in preliminary incorporation of an easily modifiable aliphatic amino group into the terminal 5′-phosphate group of an oligonucleotide.[90] The reaction of the spacer amino group of the deblocked oligonucleotide with 3,3′-dithiobis-*N*-(propionyloxy)succinimide in the presence of a disulfide bond reductant, *e.g*., dithioerythritol (DTE), dithiothreitol (DTT), cysteine or mercaptoethanol, affords an oligonucleotide containing a thiol group.



R, oligonucleotide residue; DTE, dithioerythritol.

Oligonucleotides containing thiol groups (SH-oligonucleotides) can be selectively immobilised on solid supports containing thiol groups, *i.e*., through the formation of a disulfide bond. Prior to immobilisation, the thiol groups of oligonucleotides can be activated by 2,2′-dipyridyl disulfide.[6]

If the supports and oligonucleotides contain non-activated thiol groups, the formation of the disulfide bond between NA and the matrix occurs under the action of oxidants (I_2 or H_2O_2).[49] Polysaccharides, glass (CPG),[90] magnetite particles coated with a silicon-containing polymer (Biomag),[49] polyacrylamide (Trisacryl, Sephacryl)[28] and polymethacrylate[6] are widely used as supports. Owing to the ease of the formation and the cleavage of the disulfide bonds by oxidising and reducing agents, thiol matrices are often used for reversible immobilisation of oligonucleotides containing thiol groups.

Immobilisation of purified SH-oligonucleotides proceeds rapidly and specifically. The resulting matrices manifest high stability and purity in hybridisation analysis[28, 49, 90] and in the purification of DNA-dependent proteins.[137] It should be noted, however, that the susceptibility of the thiol groups to oxidation creates storage problems. In the course of time, intermolecular disulfide bonds and side products can be formed. Immobilisation of SH-oligonucleotides on activated or functionalised supports will be considered below (Section III.2.f).

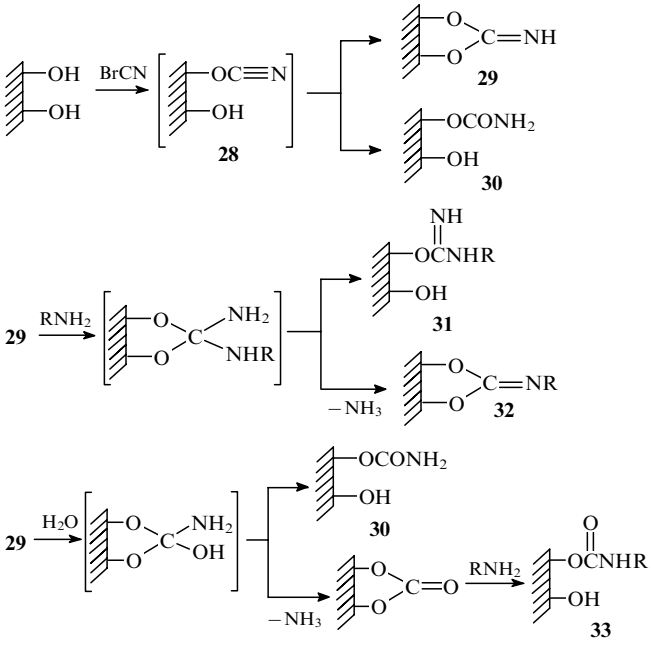
2. Immobilisation of nucleic acids on electrophilic supports

Native non-modified NA and their fragments are immobilised on functionalised and activated supports. Such supports can also be used for immobilisation of NA containing primary aliphatic amino or thiol groups introduced either in the course of or following the synthesis. The methods for the incorporation of the functional groups on the surface of supports able to react with the corresponding groups of the ligand will be discussed below.

a. Activation of supports by cyanogen bromide

A method of the activation of supports containing hydroxy groups by cyanogen halides was first proposed in 1967 for immobilisation of proteins and peptides.[138] The activation is usually carried out by cyanogen bromide at pH 10–11.[139–141] The reactive cyanate **28** formed upon activation reacts with the free hydroxy group of the support to give the reactive cyclic imidocarbonate **29** and the inactive carbamate **30**.[142, 143] A significant contribution to the development of this method was made by Cuatrecasas[144] who has selected the conditions for the immobilisation of various ligands including NA.[145]

In the early 1970's, this method became a routine procedure for the immobilisation of NA.[84, 139, 140, 146–150] The attachment of NA occurs at the amino groups of heterocyclic bases of a polynucleotide. In this way, polyuridylic[147, 149] and polyadenylic[139] acids and RNA[84, 141, 150] have been immobilised. After immobilisation of NA, the remaining reactive groups of the support are blocked by treatment with 1 M 2-aminoethanol.



It was shown that the isourea derivatives **31** were the main products formed in the immobilisation of a single-stranded DNA (0.2 mol litre^{-1} of 2-morpholinoethanesulfonic acid, pH 8.0) in formamide[139, 145]; the *N*-substituted imidocarbonates **32** and carbamates **33** are formed in lesser amounts.

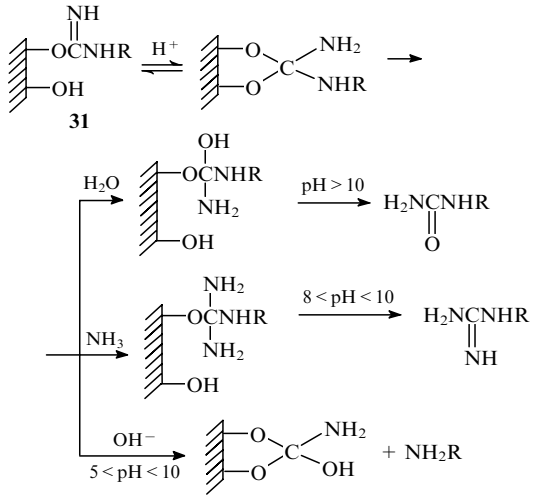
This method is most commonly used for the immobilisation of single-stranded DNA[139, 140, 146, 151, 152] and RNA.[84, 139, 141, 150] It was possible to prepare polymeric supports of high capacity and specificity despite possible reaction of the amino groups of heterocycles with activated supports. However, the affinity properties of the sorbents containing short oligonucleotides are weak, since the NH_2 groups of the heterocyclic bases involved in the covalent binding to the polymer cannot take part in the complex formation.

Immobilisation of poly- and oligonucleotides on cyanogen bromide-activated supports is much more selective when the linkers containing aliphatic primary amino groups are attached to either the 5′- or the 3′-end of the oligonucleotide chain[54–58, 153] or the internucleotide phosphate group.[154] However, in this case, too, partial immobilisation of the ligand occurs through heterocyclic bases.[155]

Nucleoside mono-, di- and triphosphates, such as AMP,[156, 157] ADP,[158, 159] ATP,[160] UMP,[58, 161] GTP[58] and dCp_4 (see Ref. 162), were immobilised on cyanogen bromide-activated Sepharose (all the nucleotides contained linkers with primary aliphatic amino groups incorporated into the phosphate groups or the heterocyclic bases). These sorbents were used for the purification of ribonucleotide reductase of phage T4,[160] the cap-binding protein[163] and deoxynucleotide kinase of *Lactobacillus*.[162]

The disadvantages of this method are as follows. First, immobilisation of the ligand must be carried out immediately after the activation of the support because of the low stability of the reactive groups formed upon treatment with cyanogen bromide. Second, cyanogen bromide is a toxic substance. Third, the basic isourea groups of the support **31** (pK_a = 9.5) formed by the reaction with the primary amine appear to be positively charged at physiological pH values, which confers undesirable anion-exchanging properties on such affinity sorbents. Moreover, this reaction yields numerous side products, while the binding sites of

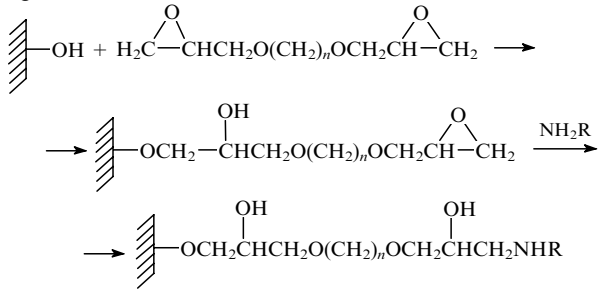
nucleotides cannot be determined with certainty. On storage, the ligand is gradually split off from the polymeric support.[113, 146, 164] It was shown [153] that affinity matrices prepared by immobilisation of oligothymidylates containing 5′-terminal amino groups on cyanogen bromide-activated cellulose retain their stabilities in aqueous media during one week at 22 °C and for only 24 h at 42 °C. Most probably, this is due to the instability of the *N*-substituted isourea derivatives **31**.[143]



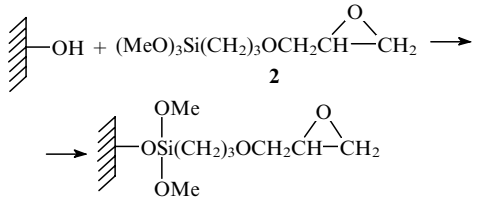
However, despite these drawbacks this method is widely employed for the immobilisation of DNA, RNA and synthetic oligonucleotides [165–170] aiming at the preparation of affinity matrices which are further used for the isolation and purification of DNA-dependent proteins.

b. Activation of supports by oxiranes

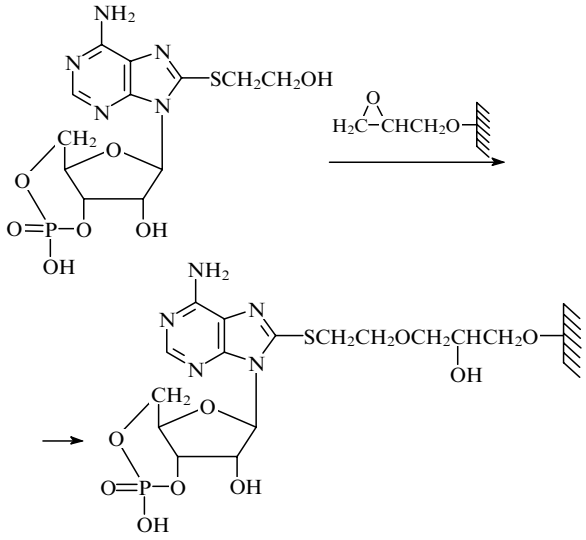
Bifunctional oxiranes were first recommended for the incorporation of reactive groups into polymeric supports and the stabilisation of gels by cross-linking.[171] The hydroxy groups of supports are usually activated by the diglycidyl ether of 1,4-butanediol at pH > 7.0.[37, 172, 173] This treatment affords a polymer containing reactive epoxy groups, which react with the nucleophilic groups of the ligands.



Epichlorohydrin is also used for the preparation of supports containing epoxy groups.[78, 107, 114] At present, epoxy groups are often incorporated on silica gel [3, 174] and glass [15, 175] using trimethoxysilanes **2** rather than polysaccharides.



As a rule, immobilisation of ligands containing amino, hydroxy or other nucleophilic groups on the supports containing epoxy groups occurs smoothly at pH 9–13 (8–20 h, 20–25 °C). The unconsumed epoxy groups are blocked by treatment with 2-aminoethanolamine (1 mol litre^{-1}). This method was used for the covalent binding of polynucleotides and some DNAs.[37, 172, 173, 176] The efficiency of binding of polynucleotides changed in the series: poly(dT) > poly(dC) = poly(dA) > poly(dG).[172] As nucleotides usually contain many functional groups, the exact binding site for polynucleotides is difficult to establish and therefore this is not always specified.[172, 173] For example, it is believed [37] that the immobilisation of the C(8)-hydroxyethylthio derivative of cyclo-AMP on a polymeric support containing epoxy groups is achieved by its binding through the terminal hydroxy group of the linker.

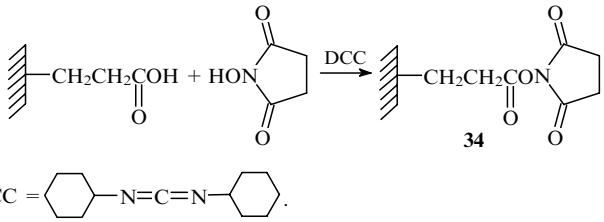


It was shown that the immobilisation of oligodeoxyribonucleotides in concentrated (2.7 mol litre^{-1}) potassium phosphate occurs predominantly through purine bases.[177] Despite its obvious advantages over other methods, this method has only one disadvantage, *viz*., the uncertainty of the binding site of nucleic acids. The use of an extended bisoxirane reagent ensures the introduction of a long uncharged hydrophilic arm between the ligand and the polymer surface, which is especially convenient for chromatography of large biomolecules. The affinity sorbents prepared on such supports are rather stable, since the ligand is attached through an ether bond, and the immobilisation is not accompanied by non-specific sorption of biopolymers.[15, 171] Immobilisation of biologically active ligands on mechanically stable silica gels containing epoxy groups allows preparation of matrices for high-performance affinity chromatography. It should be remembered, however, that some supports are unstable in alkaline media where such immobilisation takes place.

c. Supports containing *N*-hydroxysuccinimide groups

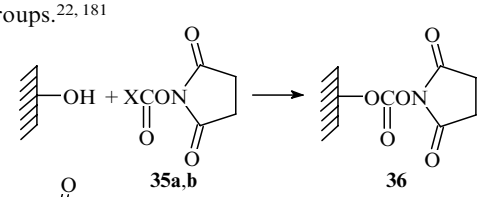
The idea to use *N*-hydroxysuccinimide esters as reactive groups for the formation of amide bonds with the primary amino groups of ligands was first formulated and realised in studies devoted to peptide synthesis.[178, 179] High solubility of *N*-hydroxysuccinimide in water and organic solvents makes it a convenient reagent for the activation of various polymeric surfaces.

The supports containing esterified *N*-hydroxysuccinimide **34** are obtained by treating the polymers containing terminal carboxy groups with *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide (DCC) in dry solvents.[26, 180]



Bifunctional reagents, *e.g*., *N*,*N*′-disuccinimidyl carbonate (**35a**) or *N*-succinimidyloxycarbonyl chloride (**35b**), are used for

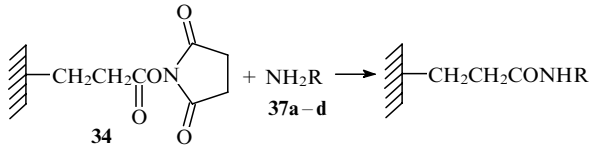
the activation of supports containing hydroxy or amino groups.[22, 181]



35a,**b** **36**

X =  NO (**a**), Cl (**b**).

The *N*-hydroxysuccinimide esters **34** and **36** react rapidly with oligonucleotides containing aminoalkyl groups at the 5′-terminal phosphate (**37a**–**d**) or in the heterocyclic bases in buffer solutions (pH 7.5–9.0) resulting in the formation of stable amide bonds.



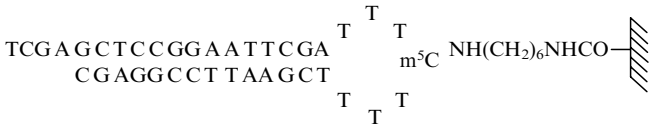
34 **37a**–**d**

R = $(CH_2)_6NH(pT)_{29}$ (**a**), $(CH_2)_2SS(CH_2)_2NH(pN)_{29}$ (**b**), $(CH_2)_{12}O(pCTT)_7$ (**c**), $(CH_2)_2O(pT)_{18}$ (**d**).

It was shown [65] that immobilisation of a 29-membered oligonucleotide occurs predominantly through the amino group of 6-aminohexyl linker attached as 5′-phosphoramidates (**37a**). Immobilisation through the cystaminyl linker (**37b**) is less efficient, while binding through the amino group of the heterocyclic bases proceeds to a smaller degree. Unfortunately, the capacity of the affinity sorbents thus obtained does not exceed 1 nmol g^{-1} at best, apparently, due to rapid hydrolysis of the activated ester **34**. The efficiency of immobilisation is higher in non-aqueous media where competitive hydrolysis is reduced to a minimum.

Hydrolysis of the reactive surface groups of the support **34** yields carboxy groups which confer ion-exchange properties on the affinity sorbent, while unconsumed groups of the activated support **36** are gradually hydrolysed to regenerate the starting groups.

An interesting approach to the immobilisation of double-stranded fragments of DNA on *N*-hydroxysuccinimide-activated Sepharose has been proposed.[31, 182] A 39-membered oligonucleotide was synthesised with a hairpin and a 1,6-diaminohexane unit was introduced into a heterocyclic base of the hairpin loop. The incorporated amino group was used for the attachment of the oligonucleotide to the polymer. Any double-stranded DNA fragments containing the corresponding sticky ends can be bound then to the immobilised oligonucleotide using DNA-ligase.



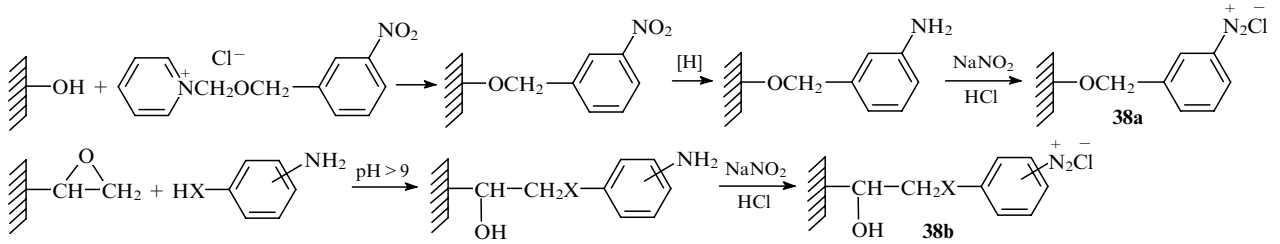
Supports with immobilised poly- and oligonucleotides were used in hybridisation analysis [21, 22, 183] and affinity chromatography.[7, 26] Thus the amino-containing oligonucleotide $(CTT)_7$ **37c** was immobilised on Sepharose and this sorbent was used for the isolation of plasmid pXL2563 containing GAA sites due to triplex formation.[7] Column chromatography on silica gel containing immobilised 5′-aminoethyloctadecathymidylate (**37d**) was successfully used for the separation of a mixture of adenylates A_{12}–A_{18}.[26]

d. Diazotised supports

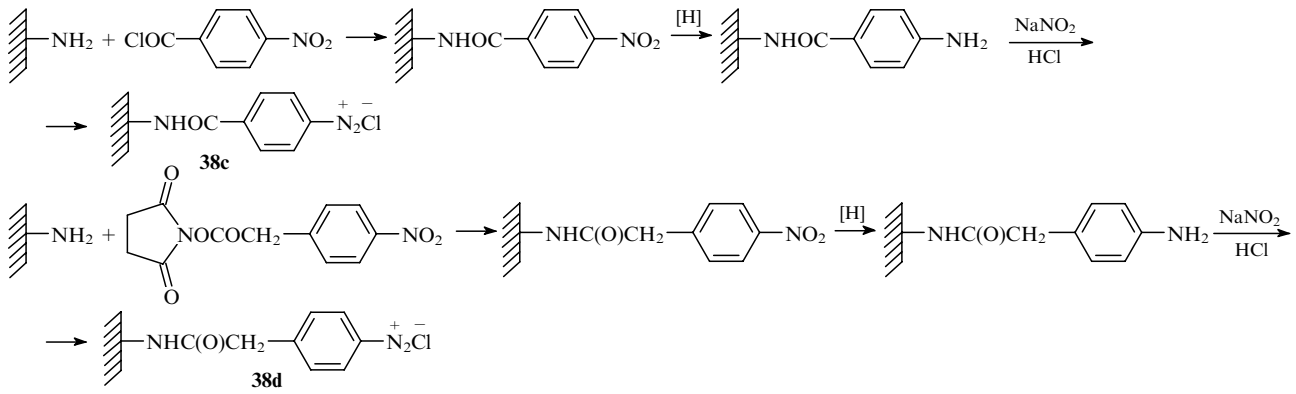
The azo coupling reaction has long attracted the attention of investigators engaged in immobilisation of nucleotides, since the introduction of aromatic amino groups into the support can be performed under mild conditions. Different approaches to the synthesis of polymers containing aromatic amino groups are shown in Scheme 1.[144, 184–186] Such supports are usually prepared by the reduction of the corresponding aromatic nitro compounds.[187] Diazotisation of aromatic amino groups is carried out with sodium nitrite in acidic media.

Immobilisation of native nucleic acids on diazotised supports, such as compounds **38a**–**d** (see Scheme 1), involves exclusively heterocyclic bases.[25, 67, 184] The introduction of spacer groups into oligonucleotides, *e.g.*, the introduction of phenol residues into 5′-phosphate groups, results in the predominant (up to 87%) immobilisation at this particular group.[188]

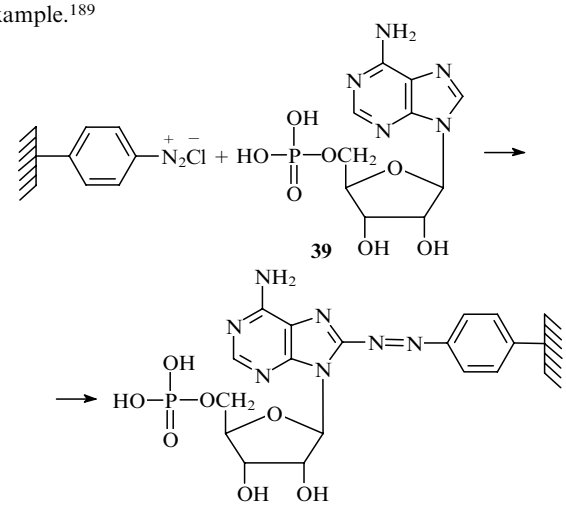
Scheme 1



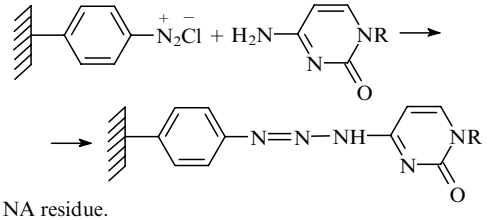
X = NH, S.



The azo coupling reaction consists in electrophilic substitution where the diazonium ion plays the role of an attacking agent. This reaction can be visually monitored by following colouration of the support. Immobilisation of 5′-AMP (**39**) at the C(8) atom of the heterocyclic base on agarose containing diazo groups is an example.[189]



Azo coupling can be accompanied by the reaction of diazonium salts with the amino groups of heterocyclic bases, which affords a diazoamino compound.[190]



R, NA residue.

In addition to reactions of diazonium salts with heterocyclic bases of nucleic acids, side reactions with water (to give phenols) and aromatic amino groups which are always present on the surface of such supports can also take place. If azo couping occurs at a slow rate, the formation of phenol and the cross-linking of the polymeric support can predominate.[185]

Aromatic diazo compounds are rather unstable, they decompose at elevated temperatures and upon illumination. Therefore, diazotised supports are used immediately after their synthesis. They can also be treated with $NaBF_4$ or $NaPF_6$ to give more stable tetrafluoroborates or hexafluorophosphates.[185]

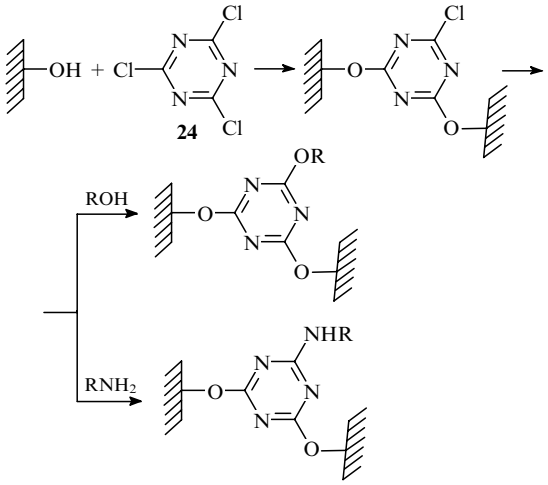
Denatured DNA and RNA immobilised by this method were used mostly in hybridisation analysis.[184, 185, 191] Good results were obtained with the use of supports **38b** (see Scheme 1) containing diazophenylsulfide groups.[140] Immobilised cyclic DNA was used as a template in an asymmetric polymerase reaction.[192]

The efficiency of immobilisation on diazotised supports is differently estimated by different authors, *viz*., from 795 μg of the nucleotide per 1 g of the support [146] to trace amounts.[25] Affinity sorbents prepared by azo coupling are usually unstable. Up to 50% of immobilised DNA is lost within the first 2–3 days at 45 °C irrespective of the nature of the matrix.[146] Low non-specific sorption of biopolymers on diazotised supports is their main advantage.

Cellulose or paper filters containing diazo groups are most commonly used for immobilisation of DNA; however, Sephacryl proved to be the best polymer for such immobilisation.[67] Magnetic particles were also tested, however, with little effect.[25]

e. Supports containing active halogen atoms

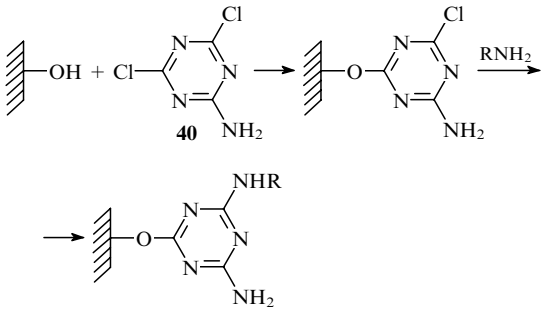
Activation of oligonucleotides by 2,4,6-trichloro-1,3,5-triazine (**24**) was considered in Section III.1.d. In this section, we shall consider the preparation of supports activated by 2,4,6-trichloro-1,3,5-triazine and their use for the immobilisation of ligands. The reactions of polynucleotides and NA with non-modified polysaccharides (cellulose and dextran) in the presence of 2,4,6-trichloro-1,3,5-triazine (**24**) [107] which permit consecutive substitution of chlorine atoms will also be discussed.



R, NA or oligonucleotide residue.

When the activation is carried out in an alkaline medium, two chlorine atoms react with the hydroxy groups of the supports resulting in the binding of triazine to the polymers. The third chlorine atom remains intact and can be substituted by the amino or hydroxy groups of the ligand to be attached.[193, 194] It was shown that immobilisation of DNA using 2,4,6-trichloro-1,3,5-triazine involves predominantly the amino groups of the heterocyclic bases.[107] As a result, the multipoint binding of DNA and oligonucleotides to the polymer makes the ligand less accessible for the interaction with the complementary polynucleotides in solution. Immobilisation of oligonucleotides bearing an amino group-containing linker at the 5′-end occurs selectively through the introduced amino group.[107, 194] However, even in this case the yields of the addition products are rather low due to the low accessibility of the chlorine atom in the triazine-containing support.

In order to increase the efficiency and selectivity of the method, it was suggested to activate the supports by 2-amino-4,6-dichloro-1,3,5-triazine (**40**).[142, 193]



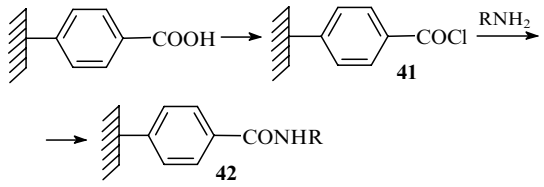
R, oligonucleotide residue.

The presence of an amino group in the triazine **40** decreases the reactivity of one of the chlorine atoms with respect to nucleophilic attack and thus prevents cross-linking of the polymer. The remaining chlorine atom reacts exclusively with strong nucleophiles, *e.g*., with the aliphatic amino group of the spacer introduced into an oligonucleotide.[193]

Triazine-activated polymers are fairly stable at elevated temperatures and can be stored for several weeks at 4 °C. The use of matrices with immobilised DNA or poly(U) made it possible to isolate both proteins and the complementary chains of NA.[193] However, application of this method is restricted by the high toxicity of trichlorotriazine.

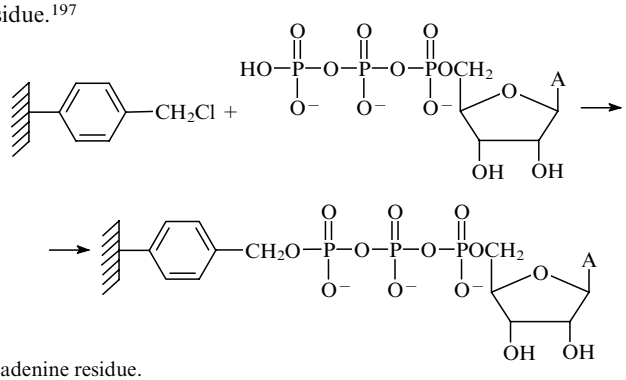
The carboxy groups of polyethylene terephthalate films can easily be converted into acid halide groups upon treatment with PCl_3, PCl_5, $POCl_3$, $SOCl_2$ or $(COCl)_2$ in the presence of DMF.

The polymers **41** containing acid halide groups react with the nucleophilic groups of the ligands. Immobilisation carried out under anhydrous conditions involves predominantly primary amino groups of the spacer incorporated into the 5′-terminal phosphate groups of oligonucleotides.[195] The stability of the sorbents **42** is provided by the stability of the amide bond formed. The films containing immobilised oligonucleotides obtained by this method were successfully used in hybridisation analysis.[196]



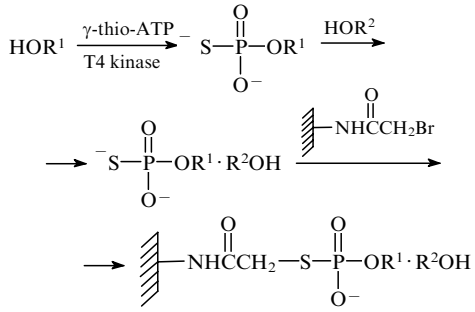
R, NA or oligonucleotide residue.

A chloromethylated styrene–divinylbenzene copolymer can also be used for the immobilisation of ligands. This approach was used for the attachment of 5′-ATP through the triphosphate residue.[197]



A, adenine residue.

Halogenoacetyl agarose has become especially popular among commercially available supports containing active halogen atoms (see Table 2). This sorbent is resistant to hydrolysis; therefore, the immobilisation procedure can be carried out in aqueous buffers. The best results were obtained in the case of immobilisation of oligonucleotides containing thiol groups. To prevent attachment at heterocyclic bases, the SH-containing oligonucleotide obtained with the use of T4 kinase and γ-thiol-ATP was hybridised with the complementary chain.[137] The duplex formed was attached to bromoacetyl agarose. The immobilisation occurred exclusively at the 5′-terminal thiolphosphate group of the oligonucleotide. If required, the complementary chain could be removed.

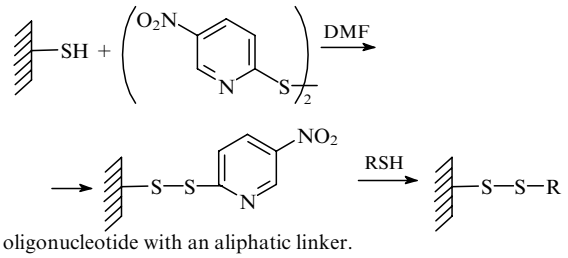


R^1,R^2, complementary oligonucleotide residues.

f. Activated supports for the immobilisation of SH-containing oligonucleotides

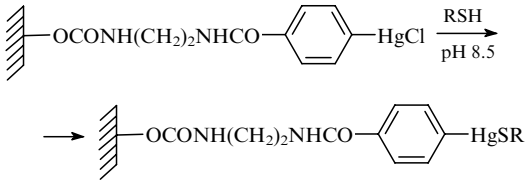
Immobilisation of NA and their fragments containing thiol groups on supports containing epoxy groups or active halogen atoms[134] has been described in Sections III.2.b and III.2.e, respectively. SH-containing ligands can also be immobilised using other methods.

Oligonucleotides containing thiol groups can selectively be immobilised on solid supports containing thiol groups owing to the formation of disulfide bonds. The supports are pretreated with *p*-chloromercuribenzoate, di(3-ethoxycarbonyl-4-nitrophenyl) disulfide, 2,2′-dipyridyl disulfide or 2,2′-dithiobis(5-nitropyridine).[90, 144]



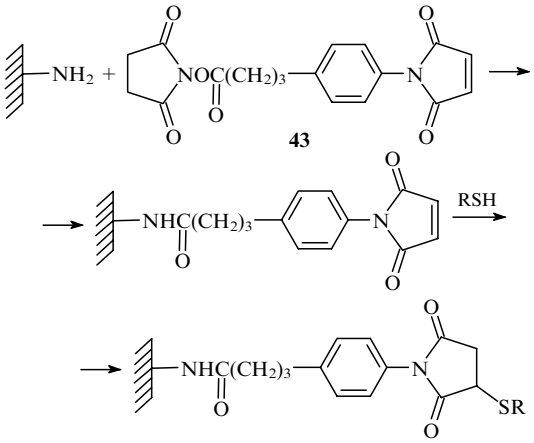
R, oligonucleotide with an aliphatic linker.

High thiophilicity of mercury ions allows the attachment of SH-containing oligonucleotides to modified polymers (*e.g.*, to agarose) containing HgCl groups.[90]

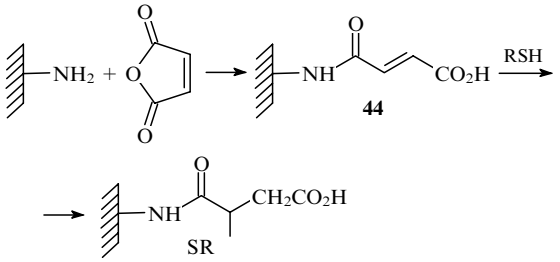


R, oligonucleotide with an aliphatic linker.

The reaction of the thiol groups with the maleimide residues present on the polymer surface is yet another approach to the immobilisation of SH-containing oligonucleotides. Maleimide can be incorporated into virtually all materials containing primary amino groups using succinimidyl 4-(maleimidophenyl)butyrate (**43**) or maleic anhydride.[11, 16, 136]



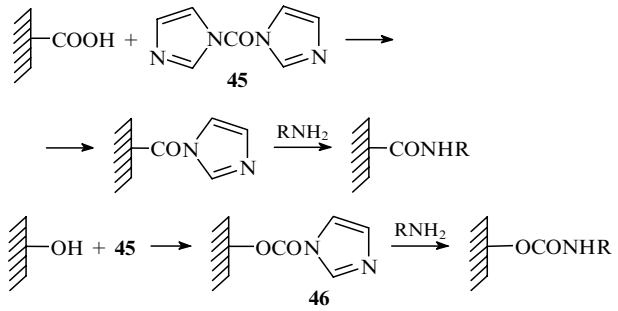
The nucleophilic addition of SH-containing oligonucleotides to the double bonds of the support **44** in a buffer solution occurs rapidly (2 h at 4 °C) resulting in the formation of a stable bond between the support and an oligonucleotide.



R, oligonucleotide residue.

g. Activation of supports by carbonyldiimidazole

Hydroxy and carboxy groups of supports can easily be activated by *N*,*N*′-carbonyldiimidazole (**45**). This reagent earlier proposed for peptide synthesis [198] is now successfully used for the immobilisation of ligands containing primary amino groups.[199, 200]



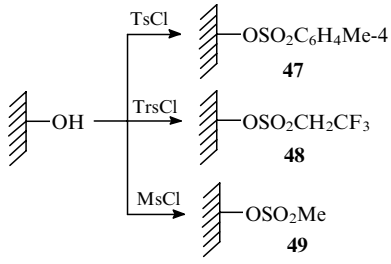
R, oligonucleotide residue.

The activation of polymers is performed in non-aqueous media; the optimum conditions for the immobilisation of ligands must be selected for each particular case. The high efficiency of the ligand attachment in dry solvents is due to the lack of competitive hydrolysis. Affinity matrices prepared by this method are rather stable, since the amide bond formed between the support and the ligand is very strong. The support **46** is stable in dry solvents for several years. The half-life time of the hydrolysis of imidazolyl carbamate **46** is several hours. Thus activated agarose loses completely its activity in aqueous buffers only after 30 h at pH 8.5–9.0.[200] Following elimination of CO_2 and imidazole, the support **46** is converted into the original hydroxyl-containing carrier devoid of charged groups, which excludes the manifestation of ion-exchange properties of the support and non-specific sorption of biomolecules. It is noteworthy that the half-lifetime of the hydrolysis of cyanogen bromide- or hydroxysuccinimide-activated supports is several minutes.

However, despite the advantages of the above-described imidazole-containing supports the immobilisation of, *e.g.*, 6-aminohexylphosphoryl-dCTP and 5′-aminoalkyloligonucleotides, occurs with low yields.[3, 201] This method has not found wide application for the immobilisation of NA and its fragments.

h. Activation of supports by sulfonyl chlorides

Organic sulfonyl chlorides, such as *p*-toluenesulfonyl chloride (TsCl), 2,2,2-trifluoroethanesulfonyl chloride (TrsCl) and methanesulfonyl chloride (MsCl), are potent acylating agents, which convert hydroxy groups of a carrier into reactive sulfonates to afford the supports **47**–**49**.[202–204]



TsCl = $ClSO_2C_6H_4Me$-4, TrsCl = $ClSO_2CH_2CF_3$, MsCl = $ClSO_2Me$.

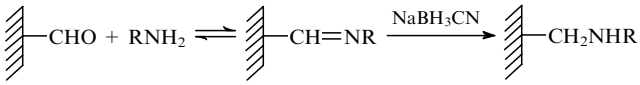
Immobilisation of oligonucleotides on the supports **48** [205] and **49** [29] occurs exclusively through the amino group of a spacer attached to the 5′- or 3′-end of the oligonucleotide. In the absence of aminospacers, immobilisation through heterocyclic bases and terminal phosphate groups of oligonucleotides proceeds with lower yields. Immobilisation on the support **49** occurs with low yields,[29] whereas polymers **48** are used for the preparation of affinity sorbents with high capacities; these are used for purification of DNA-dependent proteins.[205] The sulfonate residues are good leaving groups and the reactivities of the activated supports depend on the nature of the sulfonate and decrease in the following order: Trs > Ts > Ms. Thus, the support **49** is the most stable and the least reactive. The supports **47**–**49** are stable in non-aqueous media and can be stored for several weeks at 4 °C in aqueous HCl (1 mmol litre^{-1}) without any loss in their activities. Immobilisation of NA containing thiol or primary amino groups on sulfonyl chloride-activated supports occurs as the nucleophilic substitution of the sulfonate residue with the formation of a stable bond between the nucleophile and the carbon atom of the original support. The attachment of the ligand can be carried out in both aqueous and organic media. Immobilisation on the more reactive polymers **48** is more efficient at neutral pH values at 4 °C, whereas that on the carriers **47** is better performed at pH 9–11.[204]

i. Supports containing aldehyde groups (reductive amination)

Immobilisation of NA and their fragments by reductive amination can be carried out using two approaches. The first of them consists in the introduction of the aldehyde groups into NA and their subsequent immobilisation on supports containing hydrazide or primary aliphatic amino groups (see Section III.1.e). The second approach includes the incorporation of aldehyde groups into supports and their subsequent application for the immobilisation of NA through the amino groups of heterocyclic bases or through introduced spacer groups. The latter version is considered in this section.

Aldehyde groups can be introduced into supports by different methods. Polysaccharide supports containing diol groups are oxidised by sodium periodate to give the modified polymer **50** with high content of the aldehyde groups. The supports devoid of hydroxy groups are modified by glutaraldehyde (**51**), glycidol (**52**), an oligomer containing aldehyde groups (**53**) or compounds which are further oxidised by periodate. Some examples of preparation of polymers of virtually any type containing aldehyde groups are shown in Scheme 2.

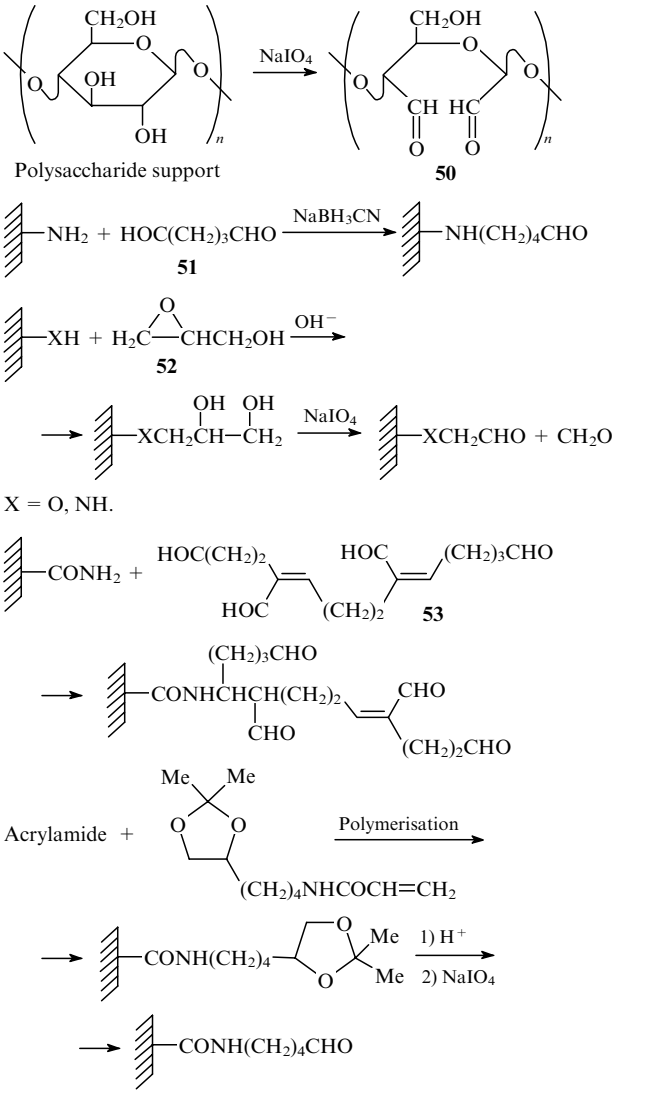
The aldehyde groups of the polymer react readily with ligands containing primary amino groups to give Schiff's bases. The latter are further reduced by $NaBH_4$, $NaBH_3CN$ or the pyridine–borane complex ($Py \cdot BH_3$). Unlike sodium borohydride, the last two reagents rapidly reduce the Schiff's bases, but not the aldehyde groups.[29, 206] It should also be noted that $NaBH_4$ is decomposed in acidic media, whereas $NaBH_3CN$ functions effectively at pH 4–10. It was recommended to replace highly toxic $NaBH_3CN$ by the $Py \cdot BH_3$ complex.[29]



Oligonucleotides with incorporated aminospacers are immobilised in good yields on supports containing aldehyde groups to form strong bonds.[11, 12, 29, 30] However, this is accompanied by the addition of oligonucleotides through the amino groups of the heterocyclic bases. Especially strong non-specific immobilisation was observed in the case of supports activated by glutaraldehyde (**51**).[29]

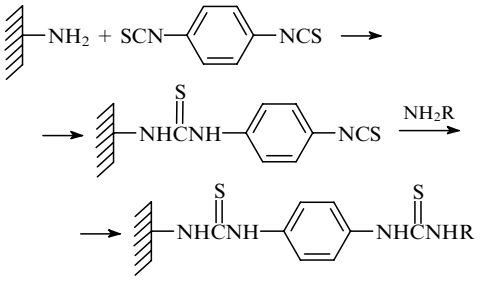
The glutaraldehyde **51** is used to prepare affinity sorbents with a high content of NA. This reagent brings about cross-linking of the polysaccharides with nucleotides and NA (DNA, RNA [207], NAD [208]) through primary amino groups of the modified carriers (aminoethylcellulose,[207] aminohexylsepharose [208]) and the heterocyclic bases. High concentrations of the ligand on the carrier results from additional intramolecular cross-linking of the ligand, which is often a drawback, especially in affinity chromatography.

Scheme 2



j. Supports bearing isothiocyanate groups

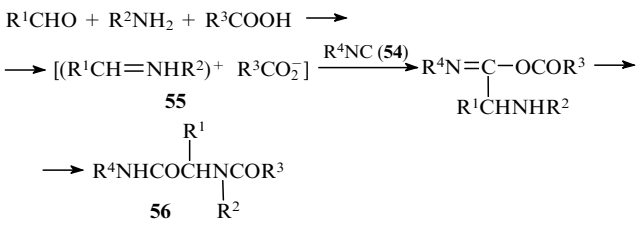
The isothiocyanate group is yet another functional group which rapidly reacts with aliphatic primary amino groups to give stable thiourea derivatives. 1,4-Phenylene diisocyanate can be used for the activation of virtually all polymers containing primary amino groups.[17, 19, 22] Immobilisation of oligonucleotides on isothiocyanate-containing supports occurs with good yields[17, 19] and is not accompanied by immobilisation of non-modified oligonucleotides.[19, 22] The remaining isothiocyanate groups of the activated carrier undergo gradual hydrolysis to amino groups, which imparts ion-exchange properties to the affinity matrices.



3-Isothiocyanatopropyltriethoxysilane [209] or 1-(3-trimethoxysilylpropyl)-3-(4-isothiocyanatophenyl)thiourea [19] can be used for the modification of glass surfaces. This one-step procedure is used for the preparation of glasses bearing reactive isothiocyanate groups.

k. The four-component condensation

The Ugi reaction is a multicomponent condensation leading to *N*-alkylamides under mild conditions [171, 210–212] and involves α-addition of electrophilic compounds containing C=N bonds to isocyanides **54**. The immonium salt **55** formed in the reaction of a carboxylic acid with an amine and an aldehyde or a ketone is added to isocyanide. Intramolecular acylation affords the final product **56**.

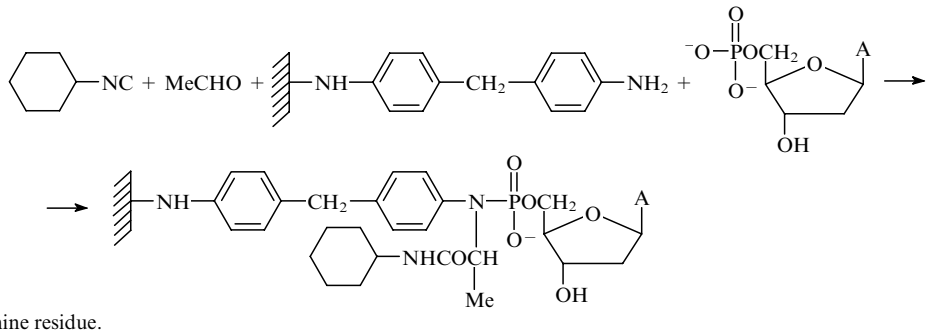


The three soluble reactants may be varied depending on the nature of the functional groups (isocyanide,[201] carboxy, aldehyde or amino groups [212]) present on the support surface.

The reaction of 5′-AMP with Sepharose modified by 4,4′-diaminodiphenylmethane in the presence of cyclohexyl isocyanide and acetaldehyde is an example of the Ugi reaction employed for the preparation of modified supports.[171, 212, 213] In this case, the role of an anion of the immonium salt **55** is played by the phosphoric acid residue of 5′-AMP and not by the carboxy group (Scheme 3).

The best results (39 mg g^{-1}) were obtained in the immobilisation of RNA on Sepharose containing amino groups.[212] However, this method has not found wide application due to the side reactions between the functional groups of the nucleotides and the components of this complex system.

Scheme 3



A, adenine residue.

IV. Immobilisation of nucleic acids in the course of solid-phase synthesis

The development of automated methods for oligonucleotide synthesis offered new opportunities for the preparation of affinity matrices bearing covalently bound oligonucleotides. The carriers on which oligonucleotides are synthesised can be used as affinity sorbents. This obviates the necessity of removal of the nucleotide material from the carrier and its further immobilisation on the support. However, one essential step, *viz*., purification of the newly synthesised oligonucleotide and the estimation of the quality of the immobilised material, is lost.

The last step in any solid-phase oligonucleotide synthesis includes the removal of protective groups from the heterocyclic bases and splitting of the nucleotide material from the support by treatment with concentrated ammonia. Elimination of the nucleotide material under deblocking conditions can be excluded if oligodeoxythymidylates [214] devoid of protective groups are synthesised or if supports are used containing primary aliphatic amino [8, 22, 215] or hydroxy [1, 216–218] anchor groups or the hydroxy groups of preliminarily attached nucleosides.[31, 219] Oligonucleotide synthesis on such supports results in the formation of an ether bond resistant to ammonia. Monomers containing non-conventional protective groups of heterocyclic bases are also used in the synthesis of affinity sorbents; their removal requires milder conditions,[220] which do not cause the destruction of the ester bond between the support and the nucleotide residue.

In addition to macroporous glass [8, 31, 214, 216, 217, 220] and glass slides,[22] polyacrylmorpholide,[31] polypropylene,[215] silica gel [31] and Teflon copolymers [216] are used as supports for oligonucleotide synthesis. The affinity matrices based on them manifest good hybridisation properties [8, 215, 217] and can be used for the isolation of mRNA [214] and DNA-specific proteins.[216]

The advantages and disadvantages of different supports in the synthesis of oligonucleotide libraries (combinatorial synthesis) have been reviewed in detail.[218] TentaGel (polyoxyethylene-coated polystyrene beads, Rapp Polymere GmbH) and Merck-Gel [partially hydrolysed poly(vinyl acetate), Merck KgaA] were recognised as the best granulated carriers. Their capacities with respect to the first fragment (nucleoside) are 120 and 700 μmol g^{-1}, respectively (*cf.* 30–50 μmol g^{-1} for conventional supports); the elongation of the oligonucleotide chain occurs also with high yields.

At present, new procedures and equipment for oligonucleotide synthesis on films and glass slides used as DNA chips and DNA sensors are being developed (see Section VII.2.b).

V. Miscellaneous methods of immobilisation of nucleic acids

Physical and physicochemical methods have been used for the immobilisation of NA earlier than other methods. Adsorption, UV irradiation and mechanical incorporation into different gels are especially popular nowadays.

Adsorption of DNA on cellulose is a very simple and rather widespread procedure which consists in freeze-drying [221–223] or conventional drying [222, 224] of cellulose impregnated with solutions of NA. The DNA-cellulose thus prepared is successfully used for purification of DNA-dependent proteins. However, such DNA-cellulose is not always suitable for hybridisation of NA because of instability of the nucleotide material at elevated temperatures and its easy desorption in buffers of low ionic strength. Nevertheless, non-covalent sorption of DNA fragments on nitrocellulose filters is a very popular procedure for the preparation of samples for hybridisation analysis [225] despite its obvious disadvantages, such as the loss of the nucleotide material during multistage hybridisation assays, fragility of cellulose after vacuum treatment, *etc*.

The development of polymerase chain reaction (PCR) and the advent of new methods of hybridisation assay brought forth the need for rapid immobilisation of NA fragments on the surface of microplates. Adsorption of oligonucleotides on such surfaces is carried out in the presence of high salt concentrations (NaCl, tetramethylammonium chloride) and/or cationic detergents (cetyltrimethylammonium bromide, dimethyloctylamine hydrochloride).[88, 226–229] Presumably, in this case immobilisation occurs exclusively by virtue of hydrophobic interactions between the oligonucleotides and the support surface.[88] It was noted [22] that adsorption is selective as regards surfaces which possess hydrophilic properties.[226] Although the mechanism of such immobilisation is not completely understood, the samples prepared by this method are widely used in hybridisation assays.[88, 227, 228]

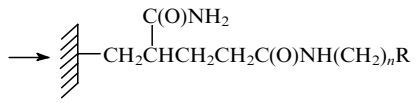
Yet another procedure consists in the application of polyelectrolyte films onto glass surfaces and the sorption of DNA or polynucleotides occurs owing to ion-exchange interactions.[230, 231]

Nucleic acids and their fragments can be immobilised on different supports upon irradiation with UV light.[155, 222, 223, 232–235] Side reactions occurring in the ligands are not significant and do not prevent the application of these systems in affinity chromatography of proteins and enzymes.[222, 232, 234] The use of specially prepared photosensitive supports, *e.g*., cellulose [236] or microporous Nylon 6 [237] containing aryl azide residues, increases significantly the maximum capacity and efficiency of photoimmobilisation of NA. The sensitivity of hybridisation assays with these matrices is 2- to 4-fold higher than that obtained with matrices prepared by conventional sorption on nitrocellulose. This may be ascribed to mild immobilisation conditions which do not affect the structure of NA.

Nucleic acids or their fragments can be immobilised on polyacrylamide,[238, 239] agar [240] or on glass slides bearing the acrylamide groups,[20, 241] which allows the preparation of sorbents with high content of the nucleotide material. The advantage of this method is that the immobilisation can be carried out on virtually any surface.[241, 242]

To ensure higher selectivity of immobilisation, copolymerisation is carried out with oligonucleotides functionalised with groups containing multiple bonds (*e.g*., pyrrolyl,[242] allyl [20] or acrylamide [241]).

$$NH_2C(O)CH{=}CH_2 + CH_2{=}CHC(O)NH(CH_2)_nR \xrightarrow{\text{Polymerisation}}$$



R, oligonucleotide residue.

VI. Immobilisation of nucleic acids using enzymes and avidin–biotin interactions

Recently, streptavidin- or avidin-containing sorbents have gained wide acceptance for the attachment of biotin-modified DNA or oligonucleotides. In these matrices, immobilisation of oligonucleotides is achieved due to the formation of a stable avidin–biotin complex ($K_d \approx 10^{-15}$ mol litre^{-1}) rather than a covalent bond. Such sorbents are easily and rapidly prepared by mechanical mixing of a streptavidin carrier and a biotin-modified oligonucleotide and used for the isolation of proteins and enzymes,[35, 36, 243–246] DNA sequencing [34, 247] and hybridisation assays.[248, 249] However, these sorbents possess a number of disadvantages, such as non-specific sorption of proteins which is more pronounced in the case of avidin-containing matrices,[250, 251] than in the case of streptavidin supports.[252] The remaining avidin residues are blocked by bovine serum albumin or methyl mannoside;[253] buffers of high ionic strength are used for chromatography.

Short and homogeneous oligonucleotides are more accessible and can be immobilised more easily than long NA fragments. The sorbents containing oligo(dT) [especially oligo$(dT)_{25}$-Dynabeads] and oligo(dA) have now become especially popular.[254–256] Immo-

bilisation of large fragments of NA on these or any other supports containing short oligonucleotides (10–20 nucleotide residues) can be carried out enzymically using ligase, by attaching specially synthesised or isolated long fragments of NA,[24, 257] or using DNA-polymerase, by completing the mRNA [258, 259] or the DNA template [260] which forms complexes with the short oligonucleotide on the polymer.

VII. The use of matrices containing nucleic acids

1. Affinity chromatography

The solution of the key problems of molecular biology and biochemistry related to the structure and interactions between biopolymers demands the use of special techniques allowing the isolation of individual biopolymers from complex multicomponent mixtures. Thus proteins, enzymes, NA, oligonucleotides and their analogues are necessary in a pure state for the studies of their structures as well as for protein-NA, DNA-DNA and RNA-DNA recognitions. These biomolecules can be isolated by affinity chromatography on sorbents containing immobilised NA or oligonucleotides. This method is based on the ability of ligands immobilised on insoluble supports to form highly specific complexes with macromolecules, which dissociate under definite conditions (*e.g.*, either upon change in the ionic strength or pH of the eluent or upon increase in temperature).

a. Isolation of individual nucleic acids and their fragments

The principle of affinity chromatography of NA was first applied to the isolation of oligo- and polynucleotides having homogeneous sequences. The possibility of fractionation of oligonucleotides on supports containing immobilised polynucleotides has been noted in the early papers.[60, 61, 261] A series of papers devoted to affinity chromatography of poly(A)-mRNA,[214, 254, 262, 263] NA or oligonucleotides containing homogeneous sequences were published in the late 1980's–early 1990's owing to the development of methods of synthesis of oligonucleotides and the accessibility of novel carriers.[26, 264] However, this method was not successful for the isolation of individual oligonucleotides or longer sequences devoid of homogeneous inserts. Present-day studies widely employ commercial supports carrying immobilised homogeneous oligonucleotides, most commonly, oligo(T) supports. The use of durable materials, such as silica gel, glass and some methacrylate-based copolymers as supports allows high-performance affinity chromatography and complete separation of oligonucleotides differing in length by one base.[105]

Affinity chromatography of heterogeneous oligonucleotides and NA has become possible following development of efficient methods for immobilisation of heterogeneous oligonucleotides on insoluble supports. Matrices containing relatively short (10–15-mers) immobilised oligonucleotide fragments complementary to a region of an oligonucleotide to be purified have been used for the isolation of extended (more than 30-mers) synthetic oligonucleotides which can hardly be purified by conventional chromatographic methods.[102, 104] This approach was applied for the isolation of a synthetic 34-membered oligonucleotide representing a deoxy copy of an RNA fragment of the Russian tick-borne encephalitis virus on LiChrosorb-NH_2 bearing an immobilised 17-membered oligonucleotide complementary to the 5′-end of the 34-membered fragment (Fig. 2).[102]

Apart from synthetic oligonucleotides, individual NA and DNA fragments obtained upon scission of DNA with restriction enzymes can be isolated by affinity chromatography from complex mixtures (see Fig. 2).[102, 104] This approach was used to obtain highly enriched $tRNA^{Phe}$ from human placenta [103] utilising two successive affinity chromatography steps on matrices containing immobilised oligonucleotides complementary to the CCA-end of tRNA (the first step) and to a site in the anti-codon loop of $tRNA^{Phe}$ (the second step).

Both single- and double-stranded NA can be isolated from cell extracts on sorbents carrying immobilised specific oligonucleotides. In the latter case, oligonucleotides should be able to form triplexes with definite regions of NA, as can be exemplified by purification of the DNA plasmids pTS2 (Ref. 265) and pXL2563 (Ref. 7) from cell extracts.

b. Separation of diastereomeric mixtures of non-ionic oligonucleotide analogues

Considerable interest in oligonucleotide analogues containing modified internucleotide phosphate groups, *viz.*, methylphosphonates and phosphotriesters, can be explained by their physicochemical and biological properties, *e.g.*, resistance to nucleases, sorption on cell membranes, penetration inside the cell and ability to form complexes with the complementary regions of NA. Since these analogues contain an asymmetric internucleotide phosphorus atom, they represent mixtures consisting of a large number of diastereomers which differ in the stabilities of the complementary complexes formed. Individual diastereomers are necessary for detailed investigations of physicochemical properties and biological behaviour of oligonucleotide analogues in cellular systems.

For the first time, chromatographic separation of diastereomers of nonathymidilyluridine octaethyl ester into fractions was carried out on a column with poly(A) cyanogen bromide-activated Sepharose.[266] However, individual diastereomers of non-ionic analogues of oligonucleotides could be obtained only by high-performance affinity chromatography.

The silica gel-based sorbent LiChrosorb bearing the octanucleotide pTGTTTGGC immobilised through the 5′-terminal phosphate group was used for the isolation of individual diastereomers of the heterogeneous octanucleotide GCCAAACA ethyl esters at a constant column temperature.[105] This allowed separa-

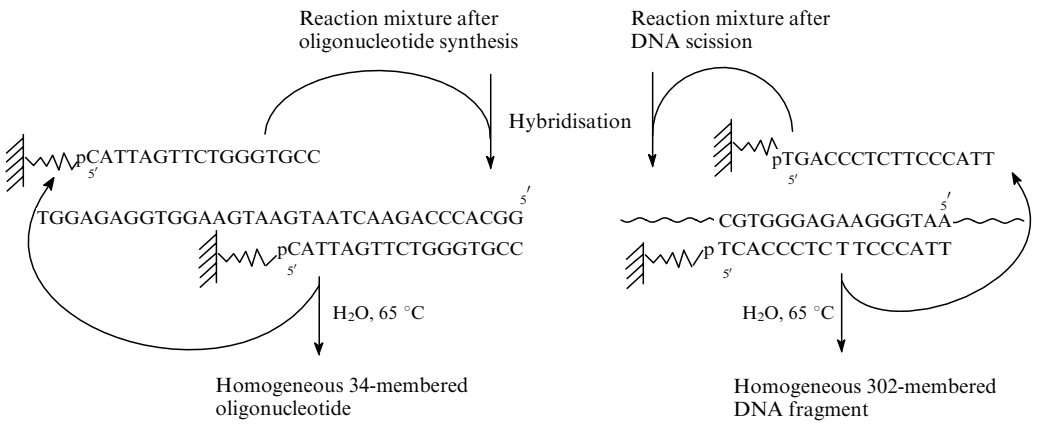


Figure 2. Affinity chromatography.

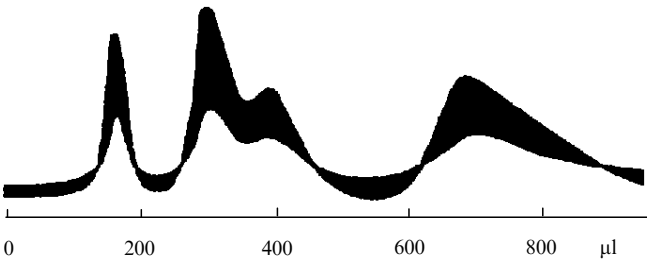

Figure 3. A chromatographic separation profile of a mixture of four diastereomers of the octanucleotide GpCpCpAp_{OEt}Ap_{OEt}ApCpA ethyl esters on an affinity sorbent (LiChrosorb) containing pTGTTTGGC immobilised through the 5′-terminal phosphate group.[105]

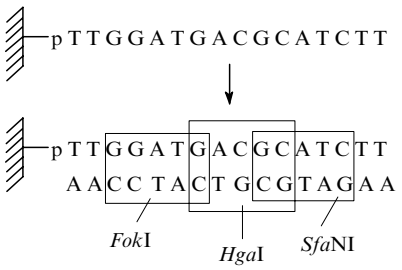
tion of stereoisomers of the octanucleotide GCCAAACA containing one, two or three phosphotriester groups (Fig. 3). The same affinity sorbent was successfully used to obtain individual diastereomers of the heptanucleoside methylphosphonate $Cp_{Me}Cp_{Me}Ap_{Me}$ $Ap_{Me}Ap_{Me}Cp_{Me}A$; the absolute configurations of these diastereomers have been established.[267]

c. Isolation of NA-dependent enzymes

At present, affinity chromatography on cellulose and Sepharose containing calf thymus DNA has become a routine procedure for obtaining pure preparations of NA-dependent proteins which are non-specific as regards the nucleotide sequence. Purification of site-specific proteins is carried out on sorbents with immobilised oligonucleotides having the corresponding recognition sites. Most of the proteins isolated represent transcription and replication protein factors (for a comprehensive description, see the reviews [181, 268, 269]). The list given in these reference can be supplemented by several other papers [36, 137, 270, 271] describing the methods for the preparation of affinity sorbents used for the purification of these proteins. Affinity chromatography was also used for the isolation of some receptors.[62, 168, 252]

Isolation of site-specific restrictases is of the greatest interest, since affinity matrices in this particular case should be resistant to enzymes to be isolated. The restriction endonucleases *Eco*RI [272] and *Sph*I [273] hydrolyse DNA only in the presence of Mg^{2+} ions, whereas in the absence of Mg^{2+} ions they bind to the site-bearing DNA. This property is used for their isolation. For the isolation of IIS-type restrictases (*Fok*I, *Hga*I, *Sfa*NI), which hydrolyse DNA at a site other than the recognition site, a duplex which incorporates the recognition sites for these enzymes but contains no sites necessary for DNA hydrolysis has been synthesised.[101] The structure of the duplex is given below (the corresponding recognition sites are enclosed in boxes). One of the oligonucleotides of the duplex was covalently linked to the methacrylate-based polymeric support.



Sorbents containing immobilised oligonucleotide duplexes, which, in turn, contain non-canonical base pairs, are used for the isolation of DNA repair enzymes responsible for mismatch correction. Thus thymine-DNA glycosylase [274, 275] was isolated on an affinity DNA sorbent containing a dG : U mismatch, however, in only trace amounts. Highly purified biologically active mismatch-specific DNA glycosylases (MutM and MutY) responsible for the removal of the oxidised form of guanine from DNA as well as for mismatch correction were isolated by affinity chromatography.[106] This study utilised a support (Toyopearl-AF) carrying an immobilised oligonucleotide duplex containing the non-canonical pairs $N8^{oxo}$-dC or rA-dG (where $N8^{oxo}$ is 8-oxonebularine, an analogue of the oxidised form of guanine).

Affinity chromatography on oligonucleotide-containing sorbents allows both the isolation of NA-dependent proteins and studies of their interactions with immobilised NA fragments.[106, 276]

2. Hybridisation assay

Molecular hybridisation of NA is based on the fundamental property of complementary chains of NA to form stable duplexes. This method allows rapid testing of mutated viral NA and viroids and is distinguished by high specificity, sensitivity and reproducibility. The main stages of the hybridisation analysis have been described in detail.[277–282]

The sensitivity of this method is determined by the choice of procedures for the detection of oligonucleotide probes carrying radioactive ([^{32}P]), fluorescent and other labels.

The selection of a support and the procedure for the immobilisation of NA or oligonucleotides is the key problem in any solid-phase hybridisation assay, which is determined by a specific goal in each particular case.

Dot-blot hybridisation includes immobilisation of a denatured portion of total NA to be tested on nitrocellulose.[283–289] Polystyrene immunological microwell plates are employed for the automation of serial tests of clinical samples.[290, 291] Immobilisation of NA targets or specific cloned fragments is carried out by physicochemical methods, *e.g.*, by sintering at 80 °C or by UV irradiation.

Blot-hybridisation in which a NA preparation is hydrolysed by restriction enzymes subjected to fractionation (*e.g.,* separation according to the molecular mass) by gel electrophoresis and further transferred to a support from the gel is a more efficient method of analysis. After immobilisation on the support, NA are hybridised with labelled probes (the so-called Southern blot DNA assay) [225] and Northern blot (RNA assay).[292] Currently, the Southern blot is used for the detection of PCR products and determination of the reaction specificity.[293–295] Nitrocellulose filters [225, 292, 296, 297] and nylon membranes [298, 299] (less frequently, *p*-azidobenzoylcellulose [236]) or dried gels following fractionation of NA fragments [300] are commonly used for the fixation of the nucleotide material. Sandwich blot is a promising approach to the analysis of NA in non-purified specimens containing proteins, polysaccharides and other components.[301] This method is based on the use of two different oligo- or polynucleotide fragments complementary to different sites of the NA to be assayed. One of these fragments is immobilised on a support, whereas the other is soluble and carries a reporter group (*e.g.*, a radiolabel, a biotin residue, *etc.*). After hybridisation and removal of admixtures and the excess of the second (labelled) probe, the NA that has formed a complementary complex with the nucleotide immobilised on the support is detected by the label bound. A vast number of solid supports and immobilisation procedures have been used for sandwich blot. Initially, nitrocellulose filters have been used,[302, 303] which were replaced by mechanically stronger nylon membranes [304] and more handy polypropylene and polystyrene immunological microwell plates.[32, 305–307] Hybridisation of NA with oligonucleotide probes immobilised on the surface of microgranulated supports is a way of acceleration of the hybridisation. Different versions of this approach using Sephacryl,[67] polyacrylamide,[28] nylon [27] and polystyrene beads [304, 308, 309] and magnetic microparticles [25, 219, 304, 310] have been described. The use of magnetic microparticles has an additional advantage, since they can easily be concentrated from suspensions, which significantly simplifies manipulations with samples.

'Reverse dot blot' [48] implies the introduction of a label into the NA or its fragment obtained by PCR. After hybridisation of a labelled NA with an oligonucleotide immobilised on a solid

support, the complementary hybrid formed is detected by virtue of the label bound to the support. Nylon [48, 66, 83, 311] and poly(ethylene terephthalate) [195, 312, 313] membranes, immunological microwell plates [314, 315] and glass [17, 316] have been used as supports for the reverse dot blot. The use of cover glasses in hybridisation assays is especially convenient, since glass is readily available, inexpensive and has a well-studied surface which is easy to modify and is suitable for fluorescent detection. Immobilisation of oligonucleotides is usually carried out by photochemical or various chemical methods.

3. DNA chips and DNA sensors

The development of effective methods for the immobilisation of oligonucleotides as well as array-based mapping methods have led to the design of microchips with immobilised oligonucleotide sets (arrays). Such DNA chips which represent slides (usually, glass slides) containing an immense variety of immobilised oligonucleotides (tens of thousands of DNA fragments) find ever growing application in molecular biology, medicine, biotechnology, *etc.*

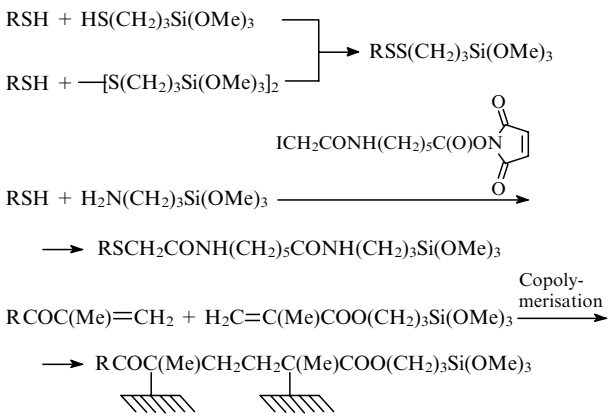
Initially, microchips were proposed for the sequencing of nucleic acids (the so-called SBH method, sequencing by hybridisation).[132, 317–319] It was assumed that the use of arrays with a complete set of immobilised octanucleotides ($65536 = 4^8$) would make it possible to determine the unknown sequences of nucleic acids by hybridisation assays. However, it was found that serious problems are inherent in the SBH method and not much success in this area has been achieved yet. These studies have shown, however, that microchips can find wide application in the analysis of gene expression and mutations as well as in the diagnostics of genetic, infectious and cancer diseases.[320–334]

There are two main approaches to the preparation of DNA microchips, *viz.*, the synthesis of oligonucleotides directly on surfaces [4, 5, 8, 175, 215, 217, 218, 321, 333–341] and immobilisation of presynthesised oligonucleotides on slides of glass or other materials.[17, 19, 22, 30, 131, 133, 248, 322, 323, 330–332, 342–344]

The former approach has been realised in such methods as combinatorial photolithography on glass slides or other supports using photoreactive protective groups.[321, 337–341] Irradiation of slides through a cover mask results in the removal of photoreactive protective groups from the oligonucleotide chains at the predetermined sites so that the next monomeric unit is coupled to the deblocked oligonucleotide chain. By shifting the mask and by iterating the irradiation and coupling procedures, one can obtain ultimately surfaces containing a large number of oligonucleotides of predetermined sequences at specified points. Despite its obvious economic expediency, direct synthesis of oligonucleotides on surfaces suffers from one serious disadvantage, since it does not provide 100% yields in coupling steps, which can result in errors in further analysis.

The latter approach to the manufacture of DNA microchips entails the use of isolated and purified oligonucleotides.

Thorough pre-washing and etching prior to immobilisation is a very important stage. These are necessary for the removal of admixtures (grease, dirt, dust, *etc.*) and for the generation of surface hydroxy groups.[345, 346] The washing procedure makes use of organic solvents (most commonly, methanol) or potent oxidants (*e.g.*, hydrogen peroxide). The activation of the glass surface is achieved by inorganic acids or alkalis (HF, HCl, HNO_3, H_2SO_4 or NaOH). This is followed by the introduction of functional groups on the slide surface for subsequent reactions using silanes of the general formula $(R^1O)_3Si(CH_2)_nR$,[2] where R^1 = Me or Et and R^2 is a functional group (see compounds **1**–**4** in Section III.2). The reactions considered in the foregoing sections are used for covalent attachment of oligonucleotides onto the surface of glass slides. Here we shall cite a paper [344] which describes a novel approach. Oligonucleotides or cDNA with linkers containing 5′-terminal SH or $CH_2=CH$ groups were preincubated with the corresponding trimethoxysilanes, after which the conjugates obtained were immobilised on non-modified glasses.



R, oligonucleotide or cDNA.

The nature and the lengths of the linkers binding the oligonucleotide to the surface are important characteristics for effective hybridisation. Steric accessibility of oligonucleotides for complementary interaction can be achieved through the use of long-chain linkers. The efficiency of hybridisation increases severalfold through the use of spacers of appropriate lengths [8, 38, 320, 331–333] (see Section III.2). The amount of the immobilised oligonucleotide referred to the unit of surface area (the surface capacity) is yet another important characteristic of DNA chips; this should not exceed a certain optimum value in order to avoid steric hindrances during subsequent hybridisation. The capacity is not very high (0.01–1.00 pmol mm^{-2}) [8, 15–17, 19, 20, 242, 333] but sufficient for successful assays. The optimum capacity of 0.25–0.35 pmol mm^{-2} for the immobilisation of polynucleotides (150–350 b.p.) has been recommended.[17]

Obviously, the sensitivity of a hybridisation assay increases with an increase in capacity. This is achieved using several approaches, *viz.*, by attachment of oligonucleotides to branched linkers (dendrimers) [22] and by formation of acrylamide,[20, 29, 30, 45, 347–349] agarose [183] or gelatine [350] layers on glass surfaces, which ensures 'three-dimensional' attachment of oligonucleotides. In this case, the capacities of oligonucleotides referred to the unit of surface area is much higher than in two-dimensional immobilisation and can amount to 30 pmol mm^{-2},[45] while steric accessibility of oligomers for subsequent hybridisation is preserved.

In early studies, radiolabelled probes were used for the detection of signals in hybridisation assays. However, other labels incorporated into oligonucleotide probes, such as biotin, digoxigenin, chemiluminophores, fluorescent and enzymic labels, also gained wide acceptance.[302, 308, 351]

Physical methods of detection have come into use owing to the recent progress in DNA chip technology. The DNA sensors (biosensors), like other biosensors, provide rapid and direct detection both with labels and without them. The use of biosensors allows kinetic studies of hybridisation processes. The topology of immobilised oligonucleotides in films applied onto the surfaces of slides and fine details of molecular interactions at the film-solution interface are also investigated.[337–341, 352–356] Thus the effects of the shape, length and composition of the double helix formed on the efficiency of hybridisation have been studied.[4, 357, 358]

DNA sensors can utilise piezoelectric technologies for measuring the changes in the oscillation frequencies of crystals bearing immobilised oligonucleotides during the sorption of the complementary DNA chain,[359–362] surface plasmon resonance technology (in this case, the refractive index of the metal surface changes upon binding of the soluble ligand to the ligand immobilised on the metal film),[363–366] scanning microscopy [352, 367] and X-ray photoelectron spectroscopy (XPS).[353] Electrochemical detection makes use of electrodes bearing immobilised oligonucleotides which change their electrical characteristics in the course of hybridisation.[365, 368–370] Optical sensors able to detect changes

in the optical properties (*e.g.*, refractive index, interference, *etc.*) of films are also widely used for the detection of hybridisation of DNA chains on the surfaces containing immobilised oligonucleotides.[230, 371 – 373]

These methods ensure high sensitivity, *i.e.*, the detection of nano- and picogram quantities of compounds.

The design of DNA chips and DNA sensors is an explosively developing field of science and biotechnology. Advances in this area will be a breakthrough in the diagnostics of genetic, cancer and infectious diseases as well as in medicine and pharmacology.

4. Enzymic synthesis on NA templates

Immobilised synthetic oligonucleotides and NA as templates or primers for enzymic synthesis of oligo- and polynucleotides can repeatedly be used for the synthesis of complementary oligonucleotide chains, which simplifies the separation of the final product from the templates. The latter circumstance is especially important, since along with the template or the primer the reaction mixture contains the enzyme and a large excess of nucleoside triphosphates (NTP) used as substrates for NA biosynthesis.

DNA polymerases of bacteriophage T7,[34, 374] polymerase I of *E.coli*, the Klenow fragment [85, 257, 260, 375, 376] and Taq polymerase [377 – 380] are used in solid-phase enzymic synthesis of DNA or DNA fragments. cDNAs synthesised on oligo(dT)-bearing supports (*e.g.*, cellulose,[258, 259, 381] latex [382 – 384] or magnetic particles [374]) by transcription of the corresponding poly(A) – mRNAs in the presence of RNA-dependent DNA polymerase (reverse transcriptase) are most often used as templates. Some authors recommend to immobilise plasmids [34] or bacteriophages [192, 376] containing incorporated exogeneous DNAs (including cDNAs) [192] and utilise them as templates for subsequent enzymic synthesis on supports. Using primers complementary to the 3′-terminal region of the immobilised template, one can obtain full complementary DNA.[85, 192, 257, 380] Enzymic template synthesis permits one to introduce various functional groups and labels into DNAs and their fragments [257, 375] using primers, dNTP or terminating dideoxyribonucleoside triphosphates (ddNTP) carrying the corresponding functional groups. The addition of one or all the four ddNTP with different labels to the reaction mixture along with four dNTP makes it possible to obtain series of labelled products and to determine the oligonucleotide sequence of the immobilised DNA.[34, 378, 379]

The chemical synthesis of oligoribonucleotides and RNA is more complicated than that of oligodeoxyribonucleotides, hence, the interest in enzymic methods is obvious. Biosynthesis of RNA is carried out using DNA-dependent RNA polymerases, *e.g.*, RNA polymerases of T7 [129, 385, 386] and *E.coli*.[381, 387, 388] Immobilised oligodeoxyribonucleotides [129, 385, 386, 388] and cDNA are used as templates for oligoribonucleotide and mRNA syntheses, respectively.[381, 387] The amount of the final products can be increased by means of PCR technology, while modern magnetic particles (Dynabeads) ensure easier separation of the products synthesised.

Enzymic synthesis on immobilised NA templates is used for the replication, transcription and sequencing of nucleic acids as well as for the introduction of functional groups and labels and the construction of genomic and cDNA libraries.

VIII. Conclusion

The work considered in this review demonstrates the immense diversity of methods for immobilisation of NA on solid supports. Immobilisation of NA on activated supports are especially widely used. In this case, native NA is immobilised non-specifically through many points. However, this results in the preparation of affinity matrices with higher capacities. The attachment of nucleotides and oligonucleotides containing additional reactive groups occurs much more selectively, *i.e.*, without affecting the heterocyclic bases and with the preservation of their abilities for affinity interactions.

Physical immobilisation methods are irreproducible and non-specific. The advantage of chemical approaches is the possibility to use the immobilisation methods corresponding to a specified experimental task. The stability of affinity sorbents under various conditions and the procedure used for the removal of the ligand from the support can be determined in advance provided that the nature of the bond between the ligand and the support is known.

Reactions of ligands containing amino or thiol groups with the reactive groups of the support have become especially widespread among other methods of immobilisation of NA and their fragments. The attachment of oligonucleotides containing amino groups to supports containing aldehyde groups is a common procedure. The method utilising the $Ph_3P-Py_2S_2$ couple as an activating reagent has proved to be efficient in the binding of oligonucleotides with terminal phosphate groups to granulated polymers. In the case of planar supports, *e.g.*, films and glasses, it is more expedient to use methods implying the activation of the functional groups of the support or utilise bifunctional cross-linking reagents, *e.g.*, 1,4-phenylene diisocyanate. It should be noted, however, that no universal immobilisation procedure exists and both the support and the immobilisation procedure should be chosen for each particular case.

NA-containing carriers have found wide acceptance for both research and applied purposes. A number of reviews devoted to this topic has been published in recent years.[326, 328, 347, 389 – 391] The supports with immobilised oligonucleotides are used as sorbents in affinity chromatography in order to obtain highly purified individual NA or their fragments. Affinity chromatography seems to be the only efficient procedure for the separation of diastereomeric mixtures of non-ionic oligonucleotide analogues. Affinity oligonucleotide-containing matrices have proved to be highly efficient for the isolation of nucleotide-dependent enzymes. Such supports are also used in solid-phase enzymic synthesis of DNA, RNA and their fragments.

Special mention should be made of NA-containing carriers for hybridisation assays, which underlie the diagnostics of many diseases. It is used for detecting mutations, viral and bacterial NA, *etc.* This method is gaining increasing popularity for genetic expertise in medical and forensic practice.

The trend which includes the design and application of DNA microchips is developing explosively in recent years. These tools have proved to be useful in various fields of biology and medicine. Their unique properties are based on the fact that a small area of glass slides contains a large amount of immobilised oligonucleotides, which allows a great number of assays to be conducted simultaneously.

The use of immobilised oligonucleotides as biosensors adds novel unique capabilities to the arsenal of modern analytic techniques. They permit one to obtain information more rapidly, simply and less expensively than in conventional hybridisation techniques. The novel devices, *viz.*, DNA biosensors, hold tremendous potential in many areas, *e.g.*, clinical analyses for forensic expertise, monitoring of the environment, food quality, *etc.*

Abstract. Two methods of detection of a single electron spin, namely, optical detection (1993) and tunnelling spectroscopy (1998) are described. Both methods are based on the spin chemistry laws. Physical principles and prospects of application of these methods are considered. The bibliography includes 34 references.

I. Introduction

Electron spin resonance (ESR) spectroscopy has found numerous applications in physics, chemistry, molecular biology and medicine. This method has two key functions. First, it is used as a physical tool in studies of the structure and dynamics of spin carriers (radicals, ions, complexes, high-spin molecules, *etc*.). The hyperfine (electron – nucleus) interaction constants as well as the magnitudes of dipole (electron – electron) splitting of the Zeeman energy levels and the parameters of spin – orbit interaction, which manifests itself as different values of *g*-factors, contain structural information. The width and shape of ESR spectral lines contain information on the rotational, translational and intramolecular spin carrier dynamics. This information can be extracted by means of the spin relaxation times τ_1 and τ_2 which are determined by the rate of energy relaxation of the Zeeman reservoir and the rate of phase relaxation (*i.e*., spin precession) respectively.

Second, ESR spectroscopy is an important analytical method which is used not only in fundamental areas of science (physics, chemistry and biology), but also in ecology, archaeology, medicine and history (*e.g*., in age determination using ESR[1,2]). Analytically, the key advantage of this method is its high sensitivity. The aim of this review is to analyse the evolution of this parameter and to outline some ways toward progress in reaching the limiting sensitivity, which allows detection of a single, individual paramagnetic species.

II. ESR sensitivity evolution

In his pioneering paper Zavoiskii reported a sensitivity of $\sim 10^{19}$ spins. In 1959, Semenov and Bubnov[3] improved the ESR sensitivity and reached a value of $\sim 10^{11}$ spins using high-frequency modulation and automatic frequency control. Since then this value appeared to be a 'nearly limiting' one for all commercial ESR spectrometers including modern instruments. Further improvement of sensitivity up to $\sim 10^7$ spins[4] appeared to be solely due to the development of high-resolution ESR spectroscopy (an 'elite' division of ESR spectroscopy) which operates with magnetic fields of ~ 50 kŒ. The sensitivity of 'routine' ESR spectroscopy is, as a rule, $\sim 10^{11}$.

Technically, this threshold is difficult to overcome since it is determined by the low sensitivity of detectors of microwave and radiofrequency radiation (it should be remembered that classical ESR spectroscopy is based on measurements of energy losses).

A great breakthrough in studies aimed at improving the ESR sensitivity is associated with the use of a combination of the microwave pumping of the spin system with optical detection of results. High photon energy allows them to be detected even in the photon-counting regime. This provides a colossal gain in sensitivity and starts the development of non-classical ESR spectroscopy, *viz*., the so-called optically detected magnetic resonance (ODMR).

The principle of ODMR is illustrated in Fig. 1. Let us assume that a triplet radical pair with the total spin $S = 1$ is generated by photolysis or radiolysis in solution or in a solid. In the magnetic field, only two spin states are mixed. These are the triplet state T_0 with the zero spin projection and the singlet state S, whereas the other two spin states (T_+ and T_-) with the spin projections $S_z = \pm 1$ are excluded from the triplet – singlet intersystem crossing of the pair. Fast intersystem crossing from the non-reactive state T_0 to the reactive state S followed by the formation of reaction products in the radical pair leads to depopulation of the levels T_0 and S. Microwave pumping at the ESR frequency ω corresponding to the difference between the Zeeman energies of

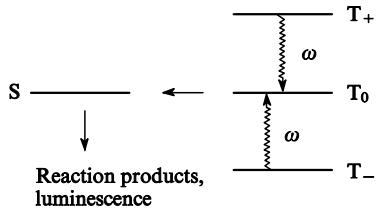

Figure 1. An energy level diagram illustrating the ODMR mechanism. Here and in Fig. 2 wavy arrows denote the microwave pumping of corresponding transitions.

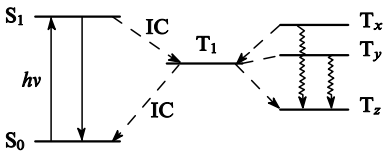

Figure 2. An energy level diagram illustrating transitions between different levels in the pentacene molecule.
Notations of energy levels: S_0 and S_1 are the ground-state singlet and excited singlet levels, respectively; T_1 is the lowest triplet state; T_x, T_y and T_z are the magnetic sublevels of the triplet state T_1. IC denotes intersystem crossing.

the states T_0-T_+ and T_0-T_- leads to an inversion drop and accumulation of electron spins on the level T_0, thus increasing the yield of reaction products. Clearly, the radical pair serves as a chemical microwave detector. If reaction products fluoresce, 'chemical reception' of microwaves can be optically detected, which is the case with ODMR. However, this is not the only reception technique since in the case of charged reaction products magnetic resonance can be detected using changes in conductivity. Generally, this technique is well known as Reaction Yield Detected Magnetic Resonance (RYDMR). Pioneering studies on RYDMR were reported by Frankevich.[5,6] Among different versions of the RYDMR method, ODMR is the most sensitive one.

The outstanding possibilities of the ODMR technique can be best illustrated by the results obtained by Molin *et al.*[7,8] taking detection of aromatic radical anions as an example. Generation of anion–cation radical pairs in the experiments on radiolysis of solutions of aromatic molecules is followed by their annihilation and creation of electronically excited luminescent molecules. The yield of such molecules is strongly dependent on the microwave pumping of ESR transitions in the radical pair. In this case the ODMR sensitivity is as high as several tens of spins. It should be noted that both pulsed and CW ODMR can be observed experimentally.

Having reached such a high sensitivity, it is logical to pose the next problem which can be formulated as detection of single-molecule ESR (or ESR of a single electron spin carrier).

III. Optical detection and magnetic resonance of single triplet molecules

Progress in photodetection technique and confocal optical microscopy has opened the possibility of visual observation and optical detection of single molecules.[9] Upon being illuminated, luminescent molecules (*e.g.*, rhodamine 6G, terrylenediimine, *etc.*) adsorbed on a surface, implanted (in low concentrations) in monomolecular layers or embedded in thin polymer films can be observed as molecular 'fireflies' using a microscope. Currently, this experimental technique has been intensely developed. It is widely used in, *e.g.*, molecular dynamics studies. Translational dynamics are studied by tracing the 'firefly' trajectory while information on rotational dynamics is obtained by measuring luminescence depolarisation. Other areas of application of the 'firefly' technique include measurements of the rates of energy transfer to neighbouring molecules, verification of the ergodic theorem, *etc.*[10,11]

Many optical chromophores used in the experiments on observation of single molecules occur in the long-lived triplet states. By placing such molecules in a permanent and a microwave magnetic field one can initiate paramagnetic resonance and detect it optically by means of observation of light emission from the molecular 'fireflies'. The possibility of using such a detection technique can be aptly illustrated taking the ODMR of single pentacene molecules in a *p*-terphenyl single crystal (the mole fraction of pentacene was $\sim 10^{-8}$) as an example. *A propos*, it is this system that was used in the first successful single-molecule ODMR experiments.[12,13]

An energy level diagram of pentacene spins, typical of almost all molecules, is shown in Fig. 2. After absorption of a quantum $h\nu$, the molecule goes from the ground state S_0 to the excited state S_1 which is then depopulated *via* fluorescence or molecular relaxation to the lowest triplet state T_1. The state T_1 is paramagnetic and triply spin degenerate. The dipole interaction between two spins leads to removal of degeneracy and the appearance of three energy levels (T_x, T_y and T_z).

The dipole electron–electron interaction is described by a tensor, the principal components of which, ε_x, ε_y and ε_z, are different with respect to different molecular axes. In ESR spectroscopy, they are usually expressed through the parameters D and E.

$$D = \frac{3}{2}\varepsilon_z,\ E = -\frac{1}{2}(\varepsilon_x - \varepsilon_y).$$

These parameters characterise the deviation of the symmetry of the dipole interaction (and, hence, spin distribution) from spherical and axial symmetry, respectively.

Dipole splitting also exists in the absence of a magnetic field. If a molecule is placed in an external magnetic field, one should take into account not only the dipole magnetic interaction, but also the Zeeman magnetic interaction, so that in the limiting case (in strong magnetic fields) the spin states T_x, T_y and T_z with the energies ε_x, ε_y and ε_z, respectively, are transformed into the corresponding canonical spin states T_+, T_0 and T_-.

Intersystem crossing from the state S_1 to the state T_1 is spin-forbidden and is thus induced by the intramolecular spin–orbit interaction, which partially removes this forbiddenness (due to exchange between the intrinsic angular momentum of an electron and its orbital angular momentum). Since the orbital angular momentum is anisotropic (*i.e.*, it takes different values with respect to different molecular axes), the spin–orbit interaction is also anisotropic. Because of this, the rate of inversion drop from the state S_1 also appears to be dependent on the symmetry of the molecule: the states T_x, T_y and T_z with the energies ε_x, ε_y and ε_z (and, correspondingly, the states T_+, T_0 and T_-) are populated at different rates.

For the same reason, the depopulation rates of these levels due to spin relaxation from the state T_1 to the ground state are also different. These differences in the population and depopulation rates of the three spin sublevels of the triplet T_1 are responsible for colossal differences in their steady-state populations. For instance, excitation of a pentacene molecule to the state S_1 followed by red $S_1 \rightarrow S_0$ fluorescence also causes population of the lowest triplet level T_1 with a probability of 0.5%. Among the triplet sublevels, the highest population rates ($1.5 \times 10^5\ s^{-1}$) are observed for the levels T_x and T_y; the depopulation rates of these levels (transition to the ground state S_0) are also high ($0.25 \times 10^5\ s^{-1}$).

For the level T_z, these rates are very low, so that in the steady-state regime only the levels T_x and T_y appear to be populated, whereas the level T_z remains nearly completely depopulated.

If microwave pumping is tuned to resonance with the energy difference between the spin levels T_x and T_z, their populations are

equalised. As a result, a proportion of pentacene molecules pass to the long-lived T_z level and are temporarily excluded from the 'community' of fluorescent molecules.

Clearly, a decrease in the fluorescence intensity of a single pentacene molecule is an indicator of magnetic resonance. Knowing the kinetic constants of photophysical and relaxation processes, one can estimate the magnitude of this effect: it reaches $\sim 20\%$ in the case of microwave pumping of the transition $T_x - T_z$.[13]

An ODMR spectrum of a single triplet pentacene molecule is shown in Fig. 3 *a*. In accord with theory, microwave pumping at the resonance frequencies of the $T_x - T_z$ and $T_y - T_z$ transitions (~ 1470 and ~ 1410 MHz, respectively) leads to noticeable (by more than 10%) decrease in the fluorescence intensity; the latter transition is less intense since the population of the level T_y is intermediate between those of the 'active' (T_x) and 'passive' (T_z) levels.

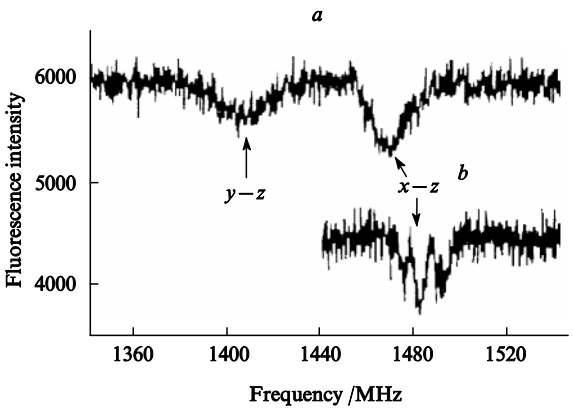

Figure 3. An ODMR spectrum of a single pentacene molecule implanted in a *p*-terphenyl crystal (*a*) and hyperfine structure of the ODMR spectrum of a pentacene molecule deuterated at all positions except for two positions at the carbon atoms lying on the central symmetry axis (*b*).

If the number of magnetic nuclei is small and the hyperfine splitting exceeds the linewidth, one can resolve the hyperfine structure in the spectrum of triplet ODMR. For instance, the ODMR spectrum of a pentacene molecule deuterated at all positions except for two protons at the carbon atoms lying on the central symmetry axis exhibits a clearly seen hyperfine structure originating from two magnetically equivalent protons (a triplet with the 1 : 2 : 1 intensity ratio) and corresponding to the $T_x \rightarrow T_z$ (Fig. 3 *b*) transition with an electron – proton interaction constant of ~ 10 MHz (~ 3.6 Gs).[13]

At first glance, observation of hyperfine structure seems to be a mysterious phenomenon. In a single-molecule experiment, nuclear configurations (a total of four for two protons of the partially deuterated pentacene) should be fixed during the time taken for one excitation – fluorescence cycle ($S_0 \rightarrow T_z \rightarrow S_0$), which is of the order of $10^{-5} - 10^{-6}$ s. The unpaired electron of the triplet molecule must experience only one nuclear configuration. However, the spectral shape suggests that it somehow 'sees' all the four pairs of spin configurations, namely, $\alpha_n\alpha_n$, $\alpha_n\beta_n$, $\beta_n\alpha_n$ and $\beta_n\beta_n$ (here, α_n and β_n denote the proton spins; the pairs $\alpha_n\beta_n$ and $\beta_n\alpha_n$ are equivalent and correspond to identical nuclear configurations).

The answer to this enigma is simple. In single-molecule ODMR experiments, the molecule experiences over 10^6 cascade excitation – fluorescence cycles during the typical measuring time (usually, about 10 min). Hence, the number of 'arrivals' at the ground state with a residence time of 100 μs during each cascade cycle is the same. Due to the dipole interaction of pentacene protons with the nuclei of neighbouring molecules and other nuclei of the indicator pentacene molecule, this time appears to be sufficient for reorientation of the spins of the pentacene protons (in spectroscopy, this is called spin diffusion or spectral diffusion). As a result, the pentacene protons have time to 'arrive' at all the four nuclear configurations during the ODMR measuring time and the final spectrum exhibits a triplet with the 1 : 2 : 1 intensity ratio (see Fig. 3 *b*).

It should be noted that reorientation of the proton spins (spectral diffusion) occurs only at those instants when the molecule is in the ground state. In the triplet state, strong electron – nuclear magnetic interaction fixes the proton spins and 'excludes' them from spectral diffusion (or, as spectroscopists say, excludes these protons from the dipole – dipole nuclear reservoir).

The hyperfine structure of the ODMR spectrum of ^{13}C nuclei of a pentacene molecule isotopically substituted at different positions is due to the same reasons.[14] However, it should be noted that all the ODMR spectra of single triplet molecules observed so far were measured for only one case, *viz*., a pentacene molecule implanted in a terphenyl crystal. Further progress of this experimental technique and extension of the areas of its application is closely related to advances of optical detection of single molecules in crystals and on the surface of solids.[15]

Magnetic resonance of single spin carriers has been intensively developed. Recently, Köhler[16] has reported an excellent review concerning the state-of-the-art and prospects of studies in the field, so that there is no need to dwell on this point.

Mention may be made of one important circumstance: it is spectral diffusion and change in the nuclear spin configurations at a single electron spin that cause a remarkable phenomenon, *viz*., a single spin Hahn echo.[17] It should be remembered that spin echo (Hahn echo) appears as a result of coherent behaviour of a spin ensemble; the observation of a single spin Hahn echo confirms the ergodic theorem, according to which averaging over the ensemble is equivalent to averaging over time.

IV. Single-molecule tunnelling spectroscopy

Recently published series of pioneering studies on tunnelling vibrational spectroscopy[18–20] has promoted the transformation of scanning tunnelling microscopy from a 'topographic' method for monitoring the atom-molecular relief of a surface into a new powerful method of chemical physics, which allows one not only to 'see' a desired single molecule, but also to identify it from 'fingerprints' (the vibronic spectrum) and even follow its chemical fate. The last-mentioned circumstance seems to be of great value owing to the possibility of observation of chemical transformations of a single molecule, which has appeared for the first time. So far classical chemistry has been concerned with molecular ensembles even in the best versions of molecular beam techniques. Modern coherent chemistry also deals with single wave packets (ensembles of coherent molecules) rather than single molecules.[21]

Physically, the idea a single-molecule, resonance tunnelling vibrational spectroscopy[18] is very simple. If a scanning tunnelling microscope operates in the field emission mode and the tip voltage exceeds the work function of electrons, the tunnelling electrons leaving the tip appear to be confined in the space between the tip and the adsorbed molecule 'sitting' on the surface under the tip. The electrons confined in this space can move between two potential barriers, *viz*., the tip and the surface. The residence time of an electron under the tip is of the order of $10^{-13} - 10^{-14}$ s (it is much longer than the mean free time), *i.e*., the space between the tip and the surface represents a specific nanoscale resonator in which standing waves (field emission resonances) appear at particular energies. Since the resonance energy depends on the tip potential, the tunnelling current as function of the bias voltage exhibits some clearly seen peaks corresponding to vibronic (resonance) energy levels of the specified adsorbed molecule which interacts with an the electron trapped in the resonator. This is a specific form of manifestation of a fundamental quantum effect called resonance bleaching of double potential barriers. Such barriers can be as 'wide and high' as it is wished, but if the

energy of the species corresponds to that of a quasi-stationary level, they appear to be penetrable.[22] The double potential barriers for which the energy of the tunnelling species can vary [23] (*e.g.*, thin layers of a dielectric containing impurity atoms or the tunnelling contacts containing adsorbed molecules) also appear to be penetrable.

In such systems, energy exchange between the tunnelling electrons and vibrational degrees of freedom of the impurity atoms or adsorbed molecules can occur, thus leading to excitation of oscillations (inelastic interaction). For those electrons whose energies correspond to those of vibronic levels of the resonator containing an adsorbed molecule, the vacuum gap between the surface and the tip becomes transparent; in this case, the tunnelling current is a maximum.

V. Tunnelling spectroscopy of a single electron spin

Tunnelling spectroscopy also allows detection of a single electron spin on the surface. This requires that the tunnelling electron be able to distinguish (discriminate) two spin states of the unpaired electron with $S_z = \pm 1/2$ (*e.g.*, the Zeeman energy levels of a paramagnetic species). There are two parameters suitable for performing such a discrimination, *viz.*, energy and spin. In typical magnetic fields $H \approx 3000$ Gs, the Zeeman energy of the unpaired electron is $\sim 10^{-5}$ eV, which is 4–5 orders of magnitude lower than the energies of the tunnelling electron and 3 orders of magnitude lower than the resolution of tunnelling spectroscopy (~ 0.01 eV). Clearly, it is impossible to use energy as a parameter for discriminating the Zeeman energy levels of the unpaired electron. This means that the other parameter, spin, should be used and that the detection principles of a single spin should be based on the spin chemistry laws.

Let us consider from this viewpoint the spin states and spin dynamics of two electron spins, the spin of a paramagnetic (probed) centre and that of a tunnelling (probing) electron. This two-spin system represents a spin analogue of the radical pair considered in the spin chemistry. It can be in two states, *viz.*, in a singlet state with the total spin $S = 0$ or in the triplet state with the total spin $S = 1$.

The energy splitting between these spin states equals the exchange energy J of two electrons in the nanoscale resonator. This means that all vibronic levels of the spin carrier situated under the tip should be split into doublets corresponding to the singlet and triplet spin states of the electron pair. The nanoscale resonator is 'transparent' to the tunnelling electrons of the electron pair irrespective of the state (singlet or triplet) of the pair at different energies (different tip potentials).

The interaction between two electrons (the tunnelling electron and the unpaired one) is identical to the interaction between radicals in a radical pair. For instance, recombination of a singlet radical pair, CH_3 and OH, involves the singlet channel only to give a singlet CH_3OH molecule, while their disproportionation involves the triplet channel (the reaction $CH_3 + OH \rightarrow {}^3CH_2 + H_2O$) to give the triplet carbene ${}^3CH_2$. Thus, formally, both channels are spin-allowed (*i.e.*, the total spins of the reagents and products in each channel conserve). However, the energy 'cost' of each channel is different, *viz.*, the former process proceeds barrierlessly (without activation energy), whereas the latter requires the overcoming of an energy barrier of ~ 6 kcal mol^{-1}.

Tunnelling spectroscopy of a single electron spin on the surface was theoretically substantiated and experimentally implemented by Dalidchik and Kovalevskii.[24] The spectrum of a O_2^- anion sitting on the TiO_2 surface (Fig. 4) exhibits a doublet splitting of each line, which is in complete agreement with theory. The splittings *1–2*, *2–3*, *1′–2′* and *2′–3′* equal 0.15 eV, which exactly corresponds to the vibrational quantum for the O–O bond in the anion (the frequency of the stretching vibrations O–O is 1180 cm^{-1}). Singlet–triplet splitting between the peaks, *i.e.*, the separations between the lines *1–1′*, *2–2′* and *3–3′*, is equal to the exchange energy of two electrons (the tunnelling

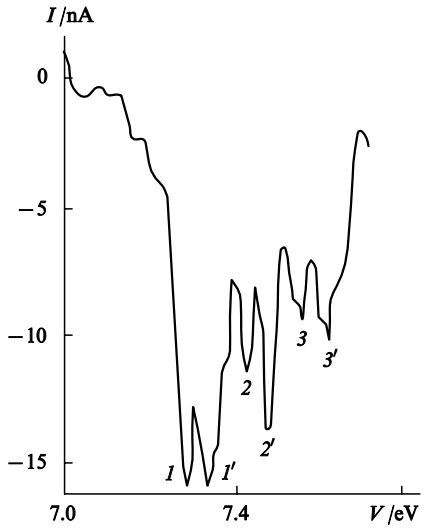

Figure 4. Tunnelling current I as function of the tip potential V (tunnelling spectrum) of a single radical anion O_2^- on the TiO_2 surface.

electron and the unpaired electron of the radical anion O_2^-) in the nanoscale resonator.

This experiment also allowed the exchange energy to be measured ($J = 0.07$ eV), which provided the possibility of estimating the size of the nanoscale resonator, R. Let us write the known relationship

$$J(R) = J_0 \exp(-\alpha R),$$

where J_0 is the exchange energy in a strongly coupled two-electron system (*e.g.*, H_2 molecule) and α is the characteristic parameter of the J decay as a function of R. Assuming that $J_0 \approx 4.5$ eV and $\alpha \approx 2$ Å^{-1}, we get $R \approx 2.1$ Å, which seems to be physically realistic for the nanoscale resonator.

VI. Tunneling spectroscopy of spin channels

As mentioned above, a single paramagnetic species can be detected using tunnelling spectroscopy due to the appearance of two resonance channels (a singlet and a triplet one) of the tunnelling current. These channels are separated by ~ 0.1 eV on the energy scale. Such a doublet splitting of vibronic levels was confirmed experimentally and discussed above (see Fig. 4). Equidistant doublet splitting of all lines in the tunnelling spectrum (on the plot of the dependence of the current I on the potential V) is an unambiguous indicator of the presence of a spin carrier (a radical or an ion) under the tip. However, direct attribution of each of the two spin channels to the singlet and triplet channel is impossible (we cannot determine to which channel the groups of lines *1*, *2* and *3* and *1′*, *2′* and *3′* in Fig. 4 belong). Based on general considerations and following Pauli, one can only suggest that the triplet level lies above the singlet one on the energy scale, *i.e.*, that the low-energy lines of the doublets correspond to the singlet channel, while their high-energy components correspond to the triplet channel. However, these considerations seem to be quite unreliable since no details of the interaction between the tunnelling electron and paramagnetic centre are currently known.

Microwave pumping is also unhelpful in distinguishing these channels since the singlet channel is ESR 'silent' while the response of the triplet channel (transitions between the states T_+, T_0 and T_-) does not produce any changes in the tunnelling current. Therefore, if microwave pumping causes no transitions between the states S and T, no transfer of the tunnelling electrons between the two channels occurs. On the other hand, yet another reason seems to be stronger: the lifetime of the electron pair in the nanoscale resonator is much shorter than the time taken for spin reorientation induced by microwave pumping. This means that

classical ESR of a single electron spin is impossible and other approaches should be used.

Imagine that the tip of a tunnelling microscope is made of a ferromagnetic material and emits spin-polarised electrons. (Such tips are widely used in topographic studies of the surface of ferromagnetic materials.[25]) If the voltage is chosen in such a way that the nanoscale resonator is 'tuned' in resonance with the singlet level, the potential barrier on the surface is transparent to the tunnelling electrons with the spins antiparallel to the spin of the paramagnetic centre. The singlet spin state of two electrons (the tunnelling electron and the unpaired one) in the nanoscale resonator is of course a combination of the spins of these electrons. Let the emitted (polarised) electrons leaving the paramagnetic tip have the spin β and the unpaired electron of the paramagnetic centre have either the spin α of β (here, the difference between the populations of the Zeeman energy levels of the electrons is neglected and the probabilities of the appearance of electrons with the spins α and β are taken to be equal). Then, the combinations αβ correspond to the singlet state of the electron pair, thus providing conditions for the tunnelling current to flow, while the combinations ββ correspond to the triplet state whose energy differs by a value of J. For the spin combinations ββ the potential barrier is impenetrable, so this contribution to the tunnelling current is locked.

Here, an important point which was first reported by Kozhushner *et al.*[26,27] should be taken into account. Due to exchange interaction between the electrons (more exactly, its nonsecular term $(1/2)J(S_+S_- + S_-S_+)$, where S_+ and S_- are the spin operators which increase and decrease the spin projection, respectively), the polarised electrons leaving the tip also polarise the spin of the unpaired electron in such a manner that its α spin it transformed into a β spin and the energy level α of the paramagnetic centre is depopulated. The system undergoes a transition from the singlet state to the triplet state and the resonance tunnelling current in the singlet channel no longer flows.

An energy level diagram illustrating the population of the Zeeman levels of both electrons in the system 'ferromagnetic tip – paramagnetic centre' is shown in Fig. 5. Initially (*a*), both energy levels corresponding to the single spin have nearly equal populations. If the tip potential differs from zero, the tunnelling current I_t proportional to $N_\beta P_\alpha$ (N_β is the population of the Zeeman energy level of the polarised tip electrons and P_α is the population of the upper Zeeman energy level α of the paramagnetic centre) flows in the system. The singlet current will flow only provided that the single spin of the paramagnetic centre will be oriented antiparallel to the spins of the tunnelling electrons, *i.e.*, in the combination βα.

It is known that

$$\frac{P_\alpha}{P_\beta} = \exp\left(-\frac{g\beta H}{kT}\right),$$

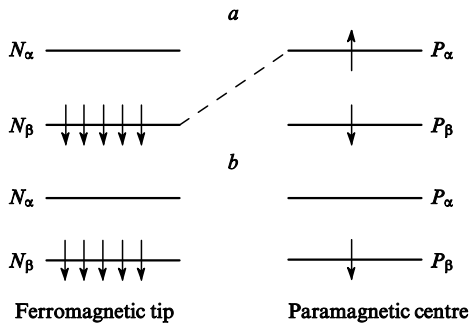

Figure 5. An energy level diagram illustrating population of the Zeeman levels in the system 'ferromagnetic tip – paramagnetic centre'. Initial state (*a*) and after passage of the tunnelling current (*b*).

where $g\beta H$ is the Zeeman splitting. Since $g\beta H \ll kT$, we get $P_\alpha \approx P_\beta$. Exchange interaction causes polarisation of the spin α of the paramagnetic centre (an analogue of the flip-flop transition in the nuclear Overhauser effect) and depopulation of the upper Zeeman energy level. As a result, only the spin combinations ββ remain in the system (Fig. 5*b*). The singlet resonance peak on the $I-V$ plot disappears and the tunnelling current (singlet channel) is locked.

The polarisation mechanism of the singlet tunnelling current lock has not been experimentally observed so far. However, should it be found, it could be possible to distinguish between the singlet and triplet channels of the resonance tunnelling current and to determine not only the magnitude, but also sign of the electron – electron exchange interaction in the nanoscale resonator. This opens new prospects for single-molecule tunnelling spectroscopy.

VII. Single electron spin relaxation

Observation of the lock effect of the singlet tunnelling channel requires that the spin of the paramagnetic species be completely polarised. This is possible only in the case of slow spin – lattice relaxation where the spin orientation of the species remains fixed between the acts of electron transport between the ferromagnetic tip and the surface. For characteristic spin relaxation times ($\tau_s \approx 10^{-8}$ s), this condition is met if the tunnelling currents are rather heavy, $I > 0.1$ nA s^{-1}. At weaker tunnelling currents, the species can have random spin orientations at the instances corresponding to the acts of interaction with the tunnelling electron; this means that both parallel and antiparallel orientations of the spins of the species and the electron are possible. During the measuring time of the tunnelling current (at specified voltage), the paramagnetic species sequentially interacts with numerous electrons leaving the tip (the number of electrons is $N = It$, where t is the measuring time). The probabilities of the singlet and triplet states of electron pairs are determined not only by the statistics of these states, but also by the kinetics of both spontaneous (relaxation) spin transitions and those induced by the polarised electron current.

In the case of ferromagnetic tip the lock rate of the singlet channel is given by the relation

$$\frac{\partial P}{\partial t} = -\left(I - \frac{1}{\tau_s}\right). \quad (1)$$

Here, P is the population of the singlet channel (*i.e.*, the population of the spin states αβ) and I is the tunnelling current of those electrons that had experienced exchange scattering by the paramagnetic centre. The first term in Eqn (1) includes the polarisation of the paramagnetic centre due to the polarised electron current (the pumping rate of the triplet channel and the depopulation rate of the singlet channel) while the second term includes the depolarisation (relaxation) rate of the triplet channel and the recovery rate of the singlet channel.

If $I > \tau_s^{-1}$ ($\partial P/\partial t < 0$), population of the triplet channel and depopulation of the singlet channel occur; the tunnelling current in the singlet channel is locked. At weak currents, where $I < \tau_s^{-1}$ ($\partial P/\partial t > 0$), the relaxation rate is higher than the population rate of the triplet channel. In this case, the weak tunnelling current cannot lock the singlet channel that remains open. In fact, the condition $I = \tau_s^{-1}$ determines the lock threshold of the tunnelling current. It allows measurements of the electron spin relaxation time of the single paramagnetic centre under conditions of tunnelling spectroscopy.

VIII. Can single-spin ESR be detected by tunnelling spectroscopy?

Novel spin spectroscopy methods, *viz.*, optical spectroscopy and tunnelling spectroscopy are based on spin combinations of two

electrons. In both cases, not only detection of single paramagnetic species, but also measurements of their spin relaxation parameters is possible. However, these methods use fundamentally different detection techniques. In the case of optical detection, the singlet channel manifests itself *via* fluorescence and, hence, some of its characteristics can be measured. The triplet channel is nondetectable; however, both the channels are strongly coupled *via* the spin–orbit and magnetic interactions, so that any changes in the triplet (nondetectable) channel affect some parameters of the singlet channel. In tunnelling spectroscopy, both these channels are detectable; however, no magnetic interaction between them occurs so that they are independent.

There is also a number of dynamic distinctions between the two above-mentioned detection techniques. In the case of optical detection, the residence time of a molecule in the triplet state is $\sim 10^{-5}$ s in each excitation–deactivation cycle. This time is much longer than that required for spin reorientation under the action of microwave pumping, $\tau_{mw} = (\gamma H)^{-1}$ (γ is the gyromagnetic ratio of an electron and H is the strength of the microwave field). Typically, $\tau_{mw} \approx 3.1 \times 10^{-7}$ s; this means that the triplet lifetime is long enough for both spin reorientation and change in the populations of the triplet levels under the action of the microwave magnetic field. In other words, the triplet state is an effective 'receiver' of external microwave radiation. In tunnelling spectroscopy, the residence time of the electron in the nanoscale resonator is very short. As mentioned above, it does not exceed 10^{-14} to 10^{-13} s. This means that the triplet states in the nanoscale resonator cannot act as effective 'receivers' of microwave radiation.

In tunnelling microscopy, single-spin magnetic resonance should be detected using non-classical approaches (*e.g.*, polarised tunnelling electrons).

In this case, the population kinetics of the spin states is similar to that considered above; however, transitions between two spin orientations of a paramagnetic species can now be stimulated not only by the tunnelling electrons, but also by microwave pumping.

This can be easily understood by considering Eqn (1) again. If resonance microwave pumping occurs (*i.e.*, the ESR conditions are met), this equation takes the form

$$\frac{\partial P}{\partial t} = -\left(I - \frac{1}{\tau_s} - \frac{1}{\tau_{mw}}\right). \qquad (2)$$

As can be seen, a new term appears, which is due to the spin relaxation induced by the microwave pumping. Spin relaxation induces additional transitions from the state ββ to the state αβ, thus additionally populating the singlet channel with a rate of τ_{mw}^{-1}. In other words, microwave pumping shifts the lock threshold of the singlet channel in such a manner that the old condition $I = \tau_{mw}^{-1}$ is replaced by a new one,

$$I = \frac{1}{\tau_s} + \frac{1}{\tau_{mw}}.$$

Since the values τ_s^{-1} and τ_{mw}^{-1} are commensurable under standard ESR conditions, the additional shift of the lock threshold of the tunnelling current in the singlet channel due to microwave pumping can be noticeable and even experimentally measurable. Moreover, experiments under conditions where $\tau_{mw}^{-1} \ll \tau_s$ can be readily set up (at $H \gg 1$ Œ). In this case, the shift of the lock threshold will be nearly completely determined by the microwave pumping. This offers considerable promise for single-spin ESR detectable from the tunnelling current. A complete theory of this phenomenon has been developed recently.[28]

IX. Excited states and single-molecule chemistry

In the aforesaid, we assumed conservation of the electron energy (it should be remembered that the Zeeman transition energies are negligible). Hence, the spin effects due to exchange interaction, relaxation and microwave pumping were associated solely with changes in the spin orientations of the paramagnetic species and tunnelling electrons. However, more complex effects can also occur, where the tunnelling electrons are responsible not only for the change in the spin orientation of the adsorbed species, but also for the excitation of internal (vibrational and/or electronic) degrees of freedom of the species. In the case of tunnelling between conductors in which all electron states below the Fermi level can be considered filled, such processes can proceed only at the voltages V exceeding the energy loss $\delta\varepsilon$ (usually, $\delta\varepsilon \gg tT$) and the dependence of I on the potential V exhibits the so-called threshold features (conductivity jumps), which appear at the voltage $eV = \delta\varepsilon$. Threshold features manifest themselves as maxima of the second derivatives of the tunnelling current with respect to the tip potential. They are observed in those cases where the tunnelling electrons excite the molecule 'sitting' under the microscope tip and induce its chemical transformations.

The possibility of observation of inelastic processes using tunnelling microscopy was predicted in 1985; however, experimental studies have been reported only recently.[29–31] For instance, it was found that molecules C_2H_2 and C_2D_2 adsorbed on the (001) surface of a copper single crystal dissociate to give C_2H and C_2D, respectively. This occurs at potentials of 2.8 V for C_2H_2 and 3.9 V for C_2D_2.[31] The C_2H and C_2D radicals thus formed undergo further dissociation to give C_2 at potentials of 2.1 and 2.7 V, respectively. In this case, large isotope effects are due to differences between the vibrational excitation cross-sections of different isotopomers rather than to isotopism of the C–H and C–D bonds. The excitation cross-section is determined by the probability of energy transfer (an inelastic process) from the 'light' tunnelling electron to the 'heavy' molecule; its magnitude is proportional to a small parameter $(a_0/R)^{2\Delta v} \leqslant 10^{-2\Delta v}$ (a_0 is the amplitude of zero-point vibrations of the molecule or constituent atoms, R is the characteristic atomic size and Δv is the change in the vibrational quantum number upon excitation). This formula readily demonstrates large isotope effect for the excitation cross-section.

Dehydrogenation was also observed for single ethylene molecules adsorbed on the Ni(110) surface (finally, ethylene loses two protons to give C_2H_2) and for benzene, pyridine and their isotopomers adsorbed on the Cu(001) surface.[31] Moreover, diffusion displacements and rotational motions of single molecules induced by the tunnelling electrons can also be observed along with their chemical transformations.

No observations of threshold features in the experiments on the excitation of adsorbed species by tunnelling electrons using a scanning tunnelling microscope (STM) have been reported so far. These features are assumed to be 'large-scale' since in this case we are concerned with electron–electron energy exchange. Of particular interest is consideration of a physically adsorbed oxygen molecule. The ground state of the molecule (a triplet $X^3\Sigma_g^-$) is separated from the nearest excited singlet state ($a^1\Delta_g$) by about 1 eV on the energy scale. The reactivity and relaxation of singlet dioxygen adsorbed on various surfaces were studied in detail by Ryskin [32] and Krylov and Shub.[33] Using different 'macroscopic', kinetic and spectroscopic methods, they first determined the relaxation times of singlet dioxygen. It was found that this parameter depends strongly on the surface characteristics and its magnitude can vary over a wide range. Optimum experimental conditions for observation of threshold features of the $X^3\Sigma_g \rightarrow a^1\Delta_g$ transitions of an oxygen molecule 'sitting' under the tip using a STM should be chosen so that the rates of stimulated and spontaneous (relaxation) transitions be comparable. This allows detection of new changes in the tunnelling current by varying the tunnelling current (*i.e.*, by changing the populations of two electronic states of the oxygen molecule). This situation is quite similar to that described above for the single spin ('self-regulation' and lock of the tunnelling current).

X. Single-molecule spin chemistry

In STM experiments, the operating current densities can be as high as 10^8 A cm^{-2}. It is for this reason that is possible to transform the equilibrium conditions into nonequilibrium ones and cause creation of nonequilibrium distributions over vibrational and electron energy levels of the single molecules 'sitting' under the tip.[34] (It should be remembered that in the case of single-molecule experiments we are dealing with ensembles of elementary events, *i.e.*, a manifold of independent interaction acts of a species with individual tunnelling electrons.) Heating leads to acceleration of chemical transformations such as desorption, dissociation, transfer of the adsorbed species from the tip to the surface, *etc*. Experiments with ferromagnetic tips allow the observation of versatile single-molecule spin chemistry effects. The simplest case is deposition of a paramagnetic species from the ferromagnetic tip on the surface containing a paramagnetic centre. It is easy to understand that at sufficiently heavy tunnelling currents (both species are polarised) recombination is forbidden. At weak currents (the spin of the species adsorbed on the surface has no definite orientation), recombination is allowed.

XI. Conclusion

Thus, classical scanning tunnelling microscopy gave impetus to the emergence and development of two new, important and promising methods, *viz*., single-molecule tunnelling spectroscopy and single-molecule chemistry.

The emergence of these methods signifies a new stage of the development of modern chemistry, which offers considerable prospects for surface sciences, catalysis, *etc*. In particular, the use of single-molecule spectroscopy and single-molecule chemistry in combination with photochemistry and femtochemistry presents new, inestimable possibilities for manipulating the molecules. In the framework of single-molecule spectroscopy and single-molecule chemistry classical spin chemistry also undergoes transformation into 'single-molecule' spin chemistry. This offers unique possibilities for spin channel detection, single electron spin manipulation and detection of ESR of a single paramagnetic centre (including triplet molecules, carbenes and ions) from the tunnelling current.

Electrochemical reactions of alkenes induced by anodic oxidation and their applications in organic synthesis

Yu N Ogibin, G I Nikishin

Contents

I.	Introduction	543
II.	Reactions induced by direct anodic oxidation	543
III.	Reactions induced by indirect anodic oxidation	558
IV.	Conclusion	573

Abstract. The main achievements and trends in the use of anodic oxidation and electrochemical reactions of alkenes in organic synthesis are analysed, systematised and generalised. The large potential and advantages of electrochemical methods of synthesis of organic compounds are demonstrated. These methods allow transformation of alkenes into functional derivatives the preparation of which by conventional chemical methods is either difficult or impossible. Primary attention is paid to the influence of the structures of substrates and electrolysis conditions on the regio- and stereoselectivities of the reactions. The bibliography includes 305 references.

I. Introduction

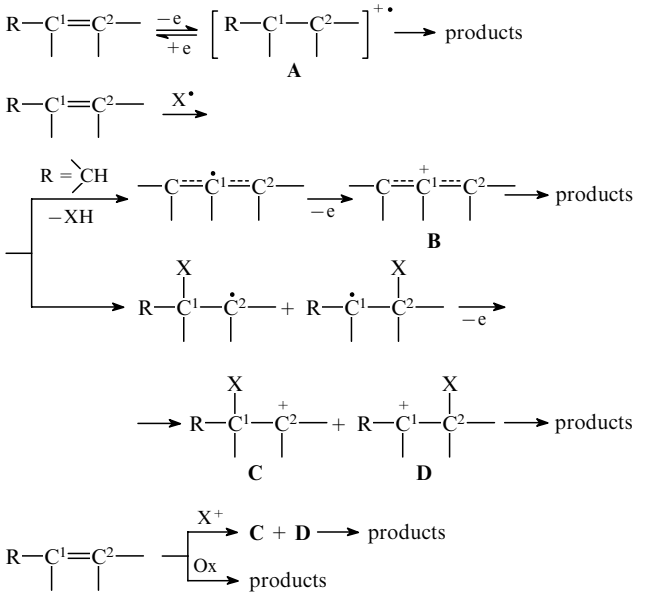
Anodic oxidation and electrochemical reactions of unsaturated organic compounds represent a vigorously developing line of research in organic electrochemistry. These reactions allow transformation of alkenes into functionally substituted compounds the synthesis of which by chemical methods is either impossible or difficult from the experimental standpoint. In many cases, electrochemical reactions are more advantageous from the environmental standpoint than chemical reactions.

This review describes systematically the published data on the reactions of alkenes taking place at the anode and in electrolyte solutions and on the use of these reactions in organic synthesis. More than 200 studies on electrooxidation of alkenes have now been published (most of them, during the last 15 years). There are several reviews [1–18] and monographs [19–23] containing data on the anodic processes involving unsaturated compounds. However, the information on electrooxidation of alkenes presented in these sources is not systematised in any way and does not reflect adequately the knowledge accumulated to date. The present review is meant to fill these gaps, to shed light upon the new trends in the development of alkene reactions induced by anodic oxidation, and to demonstrate the use of these reactions in organic synthesis taking electrooxidation of unsubstituted and functionally substituted alkenes and cycloalkenes, substituted dienes, and some other types of alkenes as examples. The review covers publications of the last two decades and also some earlier studies that have not been reflected adequately in the above-mentioned reviews and monographs.

An alkene can be directly involved in an electrochemical process upon transfer of an electron from its higher occupied molecular orbital at the anode (direct route). Alkenes can also participate in the electrochemical process *via* the reaction with electrogenerated organic or inorganic radicals ($X^{\bullet}$), ions (X^{+}), or oxidants (Ox), which can be formed from the corresponding precursors at potentials lower than the potential of alkene oxidation (indirect route).[24–26] The role of precursors can be played by the solvent, organic or inorganic anions and mediators (Scheme 1).

In accordance with the possibility of electrochemical transformations of alkenes into final products by both direct and indirect routes, the reactions considered in the review are classified into two groups.

Scheme 1



II. Reactions induced by direct anodic oxidation

The efficiency of direct anodic oxidation depends, most of all, on the rate of electron transfer from the alkenes adsorbed on the anode and is determined by their oxidation potentials. The oxidation potentials of the alkenes considered in this Section are listed in Table 1.[27–39]

1-Acetoxy-2-methylcyclopentene	1.18	$LiClO_4$	MeCN	Pt	39

Note. Hereinafter, the oxidation potentials are given in the unified scale *versus* a silver halide electrode at 25 °C; the potentials determined *versus* saturated calomel and standard hydrogen reference electrodes were decreased by 0.30 and 0.54 V, respectively.

The high oxidation potentials of alkenes with a terminal double bond hamper their direct anodic oxidation. The replacement of hydrogen atoms at double bonds by alkyl or other electron-donating groups decreases the oxidation potential and thus facilitates this process. To reach the anodic potentials at which alkenes undergo effective direct oxidation, tetrafluoroborates are used as supporting electrolytes and acetonitrile, 2,2,2-trifluoroethanol, trifluoroacetic acid or fluorosulfonic acid are used as solvents. Oxidation of activated alkenes, for example, styrenes and enol ethers (or esters), is normally carried out in methanol and ethanol, which are the best solvents for most of the electrochemical processes considered in this review. In undivided cells, these protic solvents suppress side cathodic reactions of alkenes due to easy discharge of protons. Owing to their versatile solvent capacity, they permit the use of high concentrations of the electrolyte and the organic substrate.

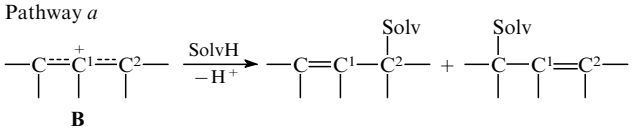
The transformation route of radical cations **A** (see Scheme 1) depends on their reactivity with respect to other compounds present in the reaction mixture. In most cases, radical cations behave as proton donors or electrophiles and react with nucleophiles or bases. They can also be oxidised or be involved in radical dimerisation, recombination, disproportionation and addition processes. The most typical reactions of the radical cations electrogenerated from alkenes are considered below (Sections II.1 – II.8).

1. Allylic substitution in alkenes

The allylic substitution in activated alkenes occurs *via* direct anodic oxidation, and allylic substitution in non-activated or weakly activated alkenes can occur *via* either direct or indirect anodic oxidation, or involve both types of reaction. For representing the full picture of allylic substitution, the direct and indirect routes of anodic oxidation are considered together in Section II. In both cases, cationic intermediates **B**, **C** and **D** are generated at initial stages (see Scheme 1); they enter into solvolysis (Scheme 2, pathway *a*) and deprotonation reactions (Scheme 2, pathways *b*, *c*).[30]

Scheme 2

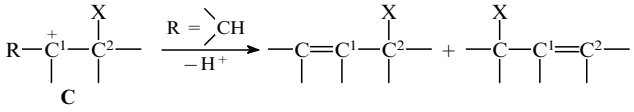
Pathway *a*



B

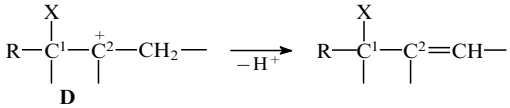
SolvH is protic solvent.

Pathway *b*



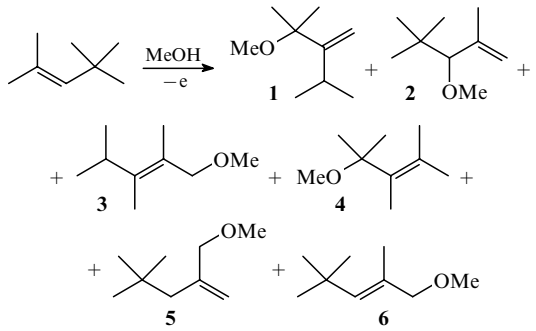
C

Pathway *c*

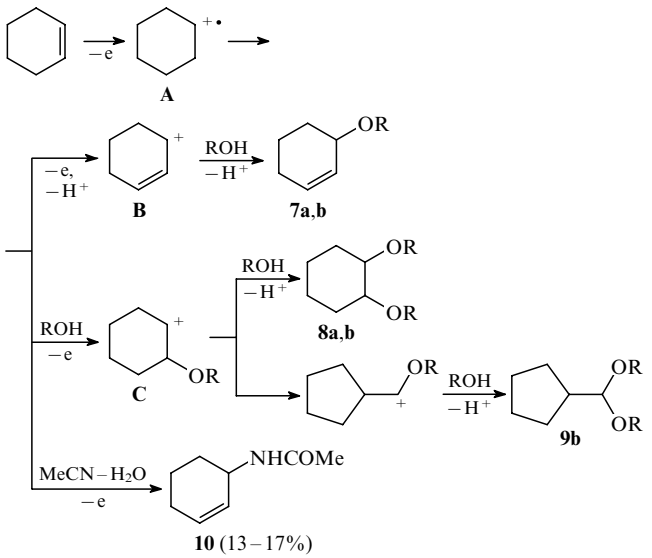


D

Allylic substitution in alkenes has been studied in relation to diisobutene,[40 – 42] cyclohexene,[30, 43 – 48] 1-, 3- and 4-methylcyclohexenes,[30] α- and β-pinenes,[30] allylbenzene,[36, 49] 4-allylanisole and some other allylarenes.[50] The efficiency and the direction of the direct anodic oxidation in undivided cells at a controlled anode potential or in the direct-current mode depends substantially on the nature of the anode material, supporting electrolyte and the solvent. This effect is attributed to different susceptibilities of electrolytes, alkenes and solvents for chemo- and electrosorption on the anode surface. Allylic substitution in non-activated alkenes — diisobutylene and cyclohexene — is most efficient in methanol with tetraalkylammonium toluene-*p*-sulfonate as the supporting electrolyte and with graphite or lead dioxide supported on graphite as the anode material. Diisobutylene is converted into a complex mixture of products mainly consisting of isomeric methoxyoctenes **1** – **6**.[41]

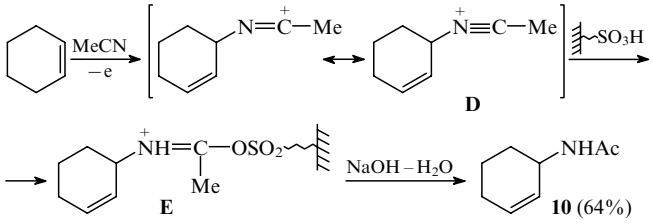


The electrolysis of cyclohexene in acetic acid gave 3-acetoxycyclohexene (**7a**) as the major product; that in methanol yielded 3-methoxycyclohexene (**7b**). In both cases, 1,2-disubstituted cyclohexanes **8a**,**b** are also formed. The composition of reaction products depends on the solvent nucleophilicity: when the electrolysis is carried out in acetic acid, radical cations **A** are converted predominantly into cations **B** and then into the product **7a**, whereas in more nucleophilic methanol, they mainly react with the solvent to give intermediates **C** and then the products **8b** and **9b**.[30] In wet acetonitrile, 3-acetamidocyclohexene (**10**) is formed.[30,43,45]



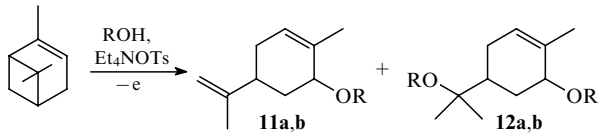
R	Yield (%)		
	7	**8**	**9**
Ac (**a**)	55	1.1	2.6
Me (**b**)	24	2.5	23

To increase the selectivity of electrochemical acetamidation of hydrocarbons, in particular, cyclohexene, the use of an ion exchange resin with sulfonate groups has been proposed.[48] In the presence of an ion exchange resin, the reactive nitrilium ions **D** formed in acetonitrile solutions are transformed into stable imidoyl sufonates **E** attached to the polymeric support. With this approach, the yield of the reaction products markedly increases and the isolation of products is substantially facilitated.



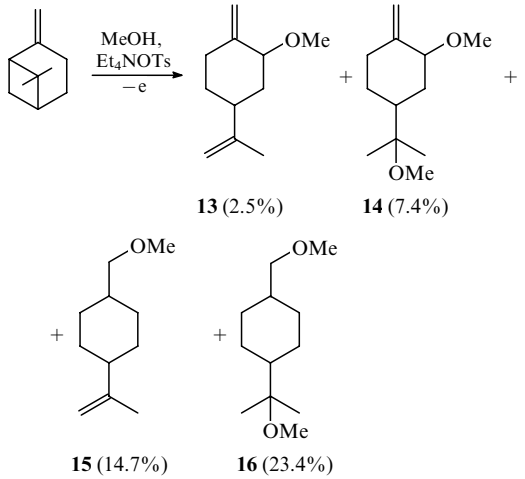
It is worth noting that acetoxylation of 1-, 3- and 4-methylcyclohexenes, oct-1-ene and oct-2-ene, gives the same products both in the electrochemical[30] and standard versions.[50–52] This is evidence in favour of participation of carbenium ions in electrochemical acetoxylation. However, the *cis*- to *trans*-isomer ratios obtained in the electrochemical and chemical acetoxylations are different; the electrochemical process yields mainly *cis*-isomers.

Electrochemical allylic acetoxylation and methoxylation of α-pinene, unlike those of methylcyclohexenes, give predominantly *trans*-isomers of substituted cyclohexenes **11a**,**b** and **12a**,**b**.[30]

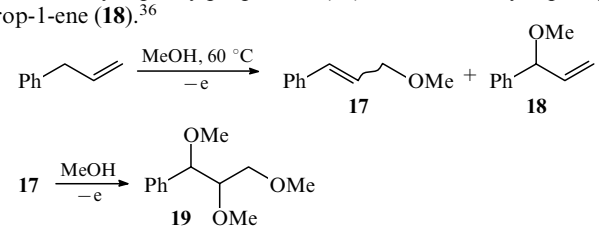


R	Yield (%) (*trans* : *cis* ratio)	
	11	**12**
Ac (**a**)	24 (2.2 : 1)	12 (2.9 : 1)
Me (**b**)	22 (6.2 : 1)	41 (2.6 : 1)

Under similar conditions, allylic methoxylation of β-pinene gives rise to a mixture of mono- and dimethoxy derivatives **13**–**16**.[30]



Electrooxidation of allylbenzene in methanol results initially in 3-methoxy-1-phenylprop-1-ene (**17**) and 3-methoxy-3-phenylprop-1-ene (**18**).[36]



Under conditions of electrolysis, compound **17** is converted almost entirely into 1,2,3-trimethoxypropylbenzene (**19**) because of its lower oxidation potential compared to those of **18** or allylbenzene (1.42, 1.95 and 1.89 V, respectively, see Table 1). The degree of conversion and the yields of electrolysis products depend on the supporting electrolyte used (Table 2).

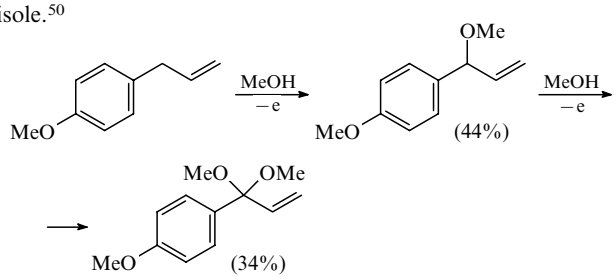
In the presence of acidic electrolytes (TsOH, H_2SO_4), 3-methoxy-3-phenylprop-1-ene (**18**) undergoes fast isomerisation into 3-methoxy-1-phenylprop-1-ene (**17**); as a consequence, the product of allylbenzene trimethoxylation, namely, the compound **19**, is produced predominantly. The major products formed in the presence of basic electrolytes are the allylic methoxylation products **17** and **18**. When neutral salts are used as electrolytes (Bu_4NBF, TsONa), the products of allylic methoxylation and trimethoxylation of allylbenzene are formed in comparable amounts.

Table 2. Effect of the supporting electrolyte on the degree of conversion and the yield of products of allylbenzene electrolysis.[36]

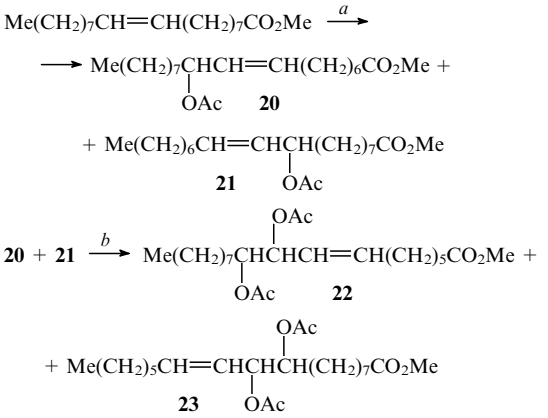
Electrolyte	Conversion (%)	Yield (%)		
		17	**18**	**19**
MeOLi	58	8	59	4
MeONa	24	4	54	9
Bu_4NBF_4	26	5	36	43
TsONa	63	4	32	25
TsOH	62	4	–	55
H_2SO_4	82	2	–	44

Note. Electrolysis under amperostatic conditions in an undivided cell (ACU), Pt anode, Cu cathode, 220 mA cm^{-2}, 6.8 F mol^{-1}, MeOH, 60 °C. Here and below, F is the quantity of electricity equal to one Faraday.

In an initial stage of electrolysis in methanol with a graphite anode and with sodium methoxide as the supporting electrolyte, 4-allylanisole is methoxylated similarly to allylbenzene at the benzylic carbon atom; however, during the subsequent, more extensive electrooxidation, it is converted into 1,1-dimethoxyallylanisole.[50]



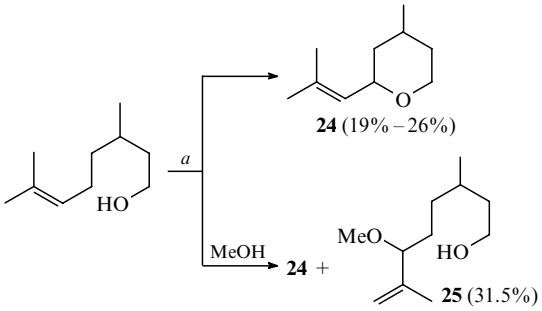
In the anodic oxidation of methyl oleate, allylic substitution also takes place. This yields predominantly unsaturated monoacetates **20** and **21** (yield of up to 60%); further electrooxidation affords unsaturated diacetates **22** and **23** (upon subsequent allylic substitution). The highest yield of the diacetates (85%) was attained when the anode current density was 8 mA cm^{-2} and the consumption of electricity was ~4 F mol^{-1} (see Ref. 53).



(*a*) ACU, Pt anode, 1.3 F mol^{-1}, AcOH, $LiClO_4$;
(*b*) ACU, > 1.3 F mol^{-1}.

Apart from unsaturated mono- and diacetates **20**–**23**, small amounts of the corresponding saturated mono- and diacetates are also formed.

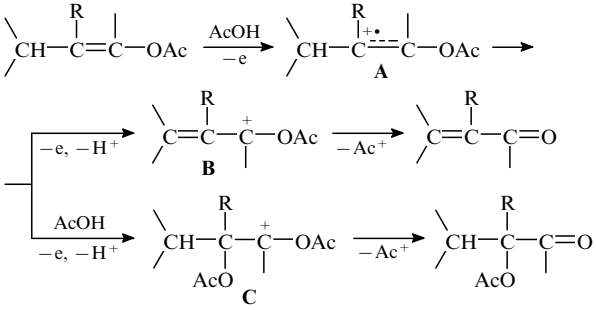
Allylic substitution can follow an intramolecular pathway provided that the electrogenerated cation of type **B** (see Schemes 1 and 2) contains an internal nucleophile. An example of this reaction is anodic oxidation of citronellol in acetonitrile or propylene carbonate giving rise to 2-(2-methylprop-1-enyl)-4-methyltetrahydropyran (**24**), a valuable fragrance compound known as rosenoxid.[54, 55] The use of methanol instead of acetonitrile changes the electrochemical behaviour of citronellol: the yield of the product **24** decreases to 7%, while 3,7-dimethyl-6-methoxyoct-7-en-1-ol (**25**) becomes the major product of electrolysis.



(*a*) ACU, C anode, 40 mA cm^{-2}, 2 F mol^{-1}, MeCN or propylene carbonate, Et_4NOTs.

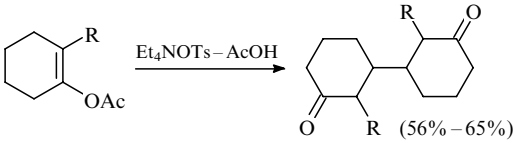
2. Transformation of enol acetates into enols and α-acetoxy ketones

During the electrolysis of enol acetate in acetic acid, radical cations **A**, generated in the first stage, undergo electrooxidation, deprotonation, and solvolysis to give α-acetoxy-substituted allylic cations **B** and α,β-diacetoxy-substituted carbenium ions **C**. Elimination of acetyl cations from these intermediates results in enones and α-acetoxy ketones.[39, 56]



The nature of the supporting electrolyte exerts a crucial influence on the composition of the electrolysis products. Indeed, when a solution of Et_4NOTs in AcOH or in MeOH is used as the electrolyte, amperostatic electrolysis of enol acetates in a divided cell (ACD) with a carbon anode, as a rule, results predominantly (in some cases, solely) in enones;[39] when the anodic oxidation is carried out in potassium acetate or triethylamine, α-acetoxy ketones are produced (Table 3).

It is noteworthy that in an undivided cell, enol acetates are converted almost entirely into 1,6-diketones as a result of cathodic dimerisation of the enones formed. For example, enol acetates derived from cyclohexanones are transformed into bis(3,3′-dioxo)cyclohexyls.[57]



R = H, Me.

In the presence of catalytic amounts (0.4 mol % – 1.0 mol %) of metal salts (iron and copper sulfates, cobalt acetate), the cathodic dimerisation is completely suppressed and cycloalk-2-enones become the major product of electrolysis, as in a divided cell (yield 80% – 86%).[57]

Electrochemical transformation of enol acetates into enones served as the basis for the development of a general method for the synthesis of 2-mono- and 2,3-disubstituted cyclopent-2-enones.[56, 57]

Table 3. Composition of products of anodic oxidation of enol acetates in AcOH.[39, 56, 58]

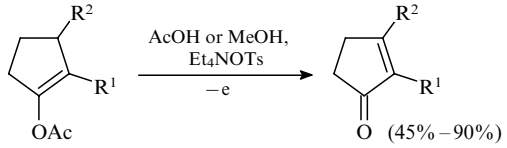
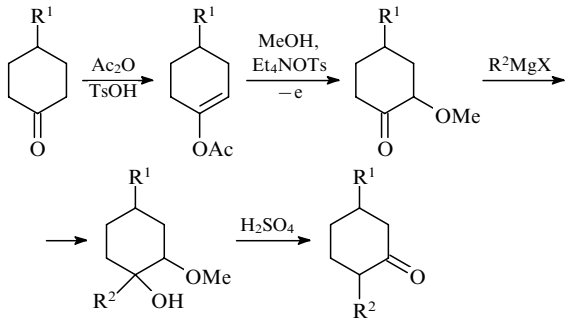
Note. Electrolysis under amperostatic conditions in a divided cell (ACD), carbon anode; [a] electrolysis was carried out in methanol.



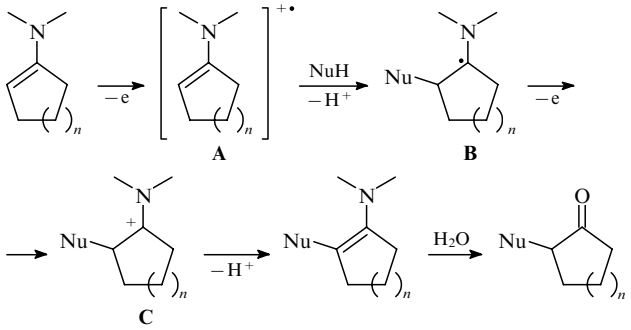
Methoxylation of enol acetates, which occurs similarly to acetoxylation, is used to accomplish 1,2-shift of the carbonyl group in ketones. An example of such transformation for substituted cyclohexanones is given below.[58]



3. Reactions of enamines

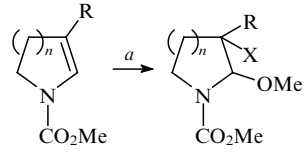
Electrooxidation of enamines affords radical cations **A**, which then add a nucleophile to give radical intermediates **B**. Electrooxidation of these species followed by deprotonation of cationic intermediates **C** gives rise to enamines containing a nucleophilic substituent in the β-position. Hydrolysis of the enamines furnishes the corresponding α-substituted ketones.[59, 60]

This electrochemical process was implemented for cyclopentanone ($n = 1$) and cyclohexanone ($n = 2$) enamines. Methanol and the anions derived from acetylacetone, ethyl acetoacetate and diethyl malonate were used as nucleophiles, and a methanolic solution of sodium methoxide was used as the electrolyte.[59, 60]



$n = 1, 2$.

N-Methoxycarbonyl-substituted enamines **26a–d** are converted into halomethoxylation products **27a–d** upon electrolysis in methanol in ammonium bromide or iodide as the supporting electrolyte.



26a–d **27a–d**

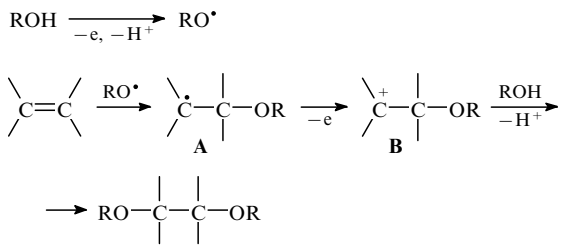
4. Dimethoxylation and diacetoxylation of alkenes

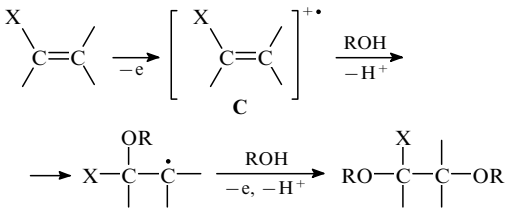
The scheme of electrochemical dimethoxylation and diacetoxylation of non-activated alkenes includes the formation of radical intermediate **A**, its electrooxidation and the reaction of the carbenium ion **B** with MeOH or AcOH.



R = Me, Ac.

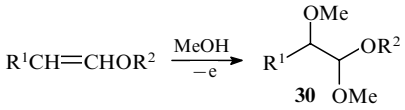
Electrochemical dimethoxylation of alkenes, for example, of conjugated arylalkenes and enol ethers (or esters) occurs with high selectivity and results in the formation of products in high yields. The most interesting examples are listed in Table 4.

Electrochemical dimethoxylation of weakly activated double bonds in arylalkenes (styrene, 2-phenylpropene and so on) takes place as an irreversible two-electron process (one two-electron oxidation wave is observed).[26,75] Highly activated double bonds in vinylanisole, 4-propenylanisole, α,α′-dimethoxystilbene and so on are dimethoxylated in two steps (two single-electron waves are observed), the first being reversible and the second being irreversible.[24,25,75,76]

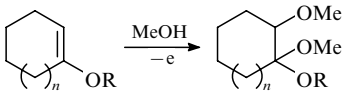


X = Ar, Bn, AlkO; R = Me, Ac.

The transfer of the first electron from the substrate molecule adsorbed on the anode, which occurs on the anode, is the rate-limiting step of this reaction. In the radical cations **C** thus formed, the highest spin density and the positive charge density are located on the β-carbon atom.[75] The process selectivity is markedly affected by the arylalkene concentration both in the solution and on the anode surface, by the current density at the anode, the anode material and the nature of the electrolyte anion.[26,40,75,77] The rate of oxidation of *trans*-alkenes is about an order of magnitude higher than that for the *cis*-isomers.[78] The yield of dimethoxylation products increases with a decrease in the substrate concentration in the solution and on the anode surface and with an increase in the current density up to values close to limiting ones; the yield sharply increases when a platinum, lead dioxide, or magnetite anode is used instead of the graphite anode[75] and sodium toluene-*p*-sulfonate is used as the electrolyte.[77] Unlike $NaClO_4$, sodium toluene-*p*-sulfonate exhibits desorption-replacing properties with respect to arylalkenes and other organic substrates; as a consequence, the substrate concentration on the anode surface during the electrolysis with TsONa is 50 times lower than that in the presence of $NaClO_4$. The same effect, although less pronounced, can be traced for tetrabutylammonium tetrafluoroborate. The highest yields (substance yield 60% – 80% and current yield 66% – 71%) of the products of dimethoxylation of arylalkenes are attained with a Pt anode, Bu_4NOTs or Bu_4NBF_4 as the supporting electrolyte and when the substrate concentration is close to 1 mol $litre^{-1}$ (see Ref. 64). Under similar conditions of electrolysis in the presence of potassium hydroxide as the electrolyte, enol ethers are converted predominantly into acetals and ketals of α-methoxy-substituted aldehydes and ketones. For example, alkyl vinyl ethers give rise to α-methoxyaldehyde acetals **30**, 1-alkoxycycloalkenes are converted into α-methoxycycloalkanone ketals **31**,[39,59,72,79] while bicyclic enol ethers yield dimethoxy-substituted oxabicycloalkanes **32**.[73,74]

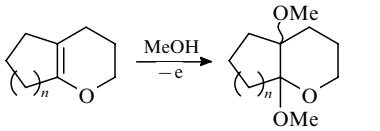


R^1	R^2	Yield of **30** (%)
H	Me	60
H	Et	68
H	Bu^n	75
n-C_6H_{13}	Me	60



31 (45% – 60%)

n = 0, 1; R = Me, Et.



32 (64% – 68%)

n = 2, 8.

The selectivity of dimethoxylation of arylalkenes and enol ethers is substantially affected by the competing electrooxidative dimerisation and oligomerisation reactions, which will be considered in Section II.5. These side reactions are effectively suppressed by tris(4-bromophenyl)amine. In the presence of this compound, the yield of the reaction product in the dimethoxylation of propenylbenzene increases to 93%.[80]

Electrochemical diacetoxylation of alkenes at the double bond is usually accompanied by allyllic substitution; this diminishes the synthetic value of this process.

This reaction carried out in acetic acid with potassium or sodium acetate as the supporting electrolyte occurs with moderate selectivity but only for alkenes the structure of which rules out the possibility of allylic substitution, for example, stilbenes, 1,1-diphenylethylene,[81] indene and 1-alkylindenes.[82–85] In these cases, the yields of diacetoxylation products do not exceed 40%. An example is provided by 1-alkylindenes, which are converted into 1-alkyl-2,3-diacetoxyindans in 55% – 75% yields; small amounts of 2-acetoxy-1-alkyl-3-hydroxyindans (yields 6% – 20%) are formed simultaneously.[84] A mechanism for the anodic acetoxylation of indenes involving the intermediate for-

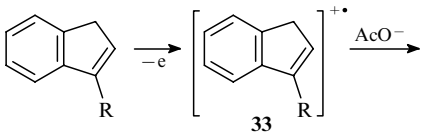
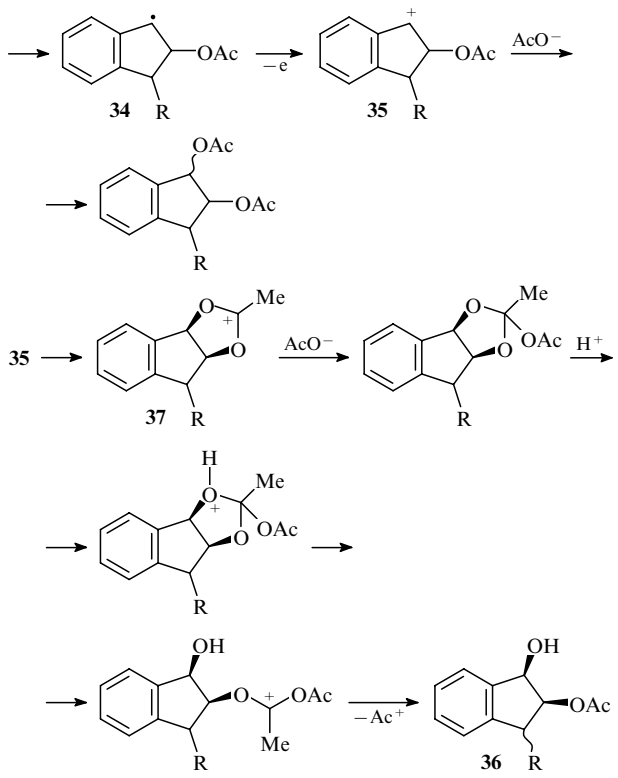
mation of radical cation **33**, radical **34** and carbenium ion **35** has been proposed.[85] The side products, namely, acetoxy-3-hydroxy-derivatives **36**, are produced from cation **37**, which results from an intramolecular attack of the OAc group on the electron-deficient centre of the carbenium ion **35**.



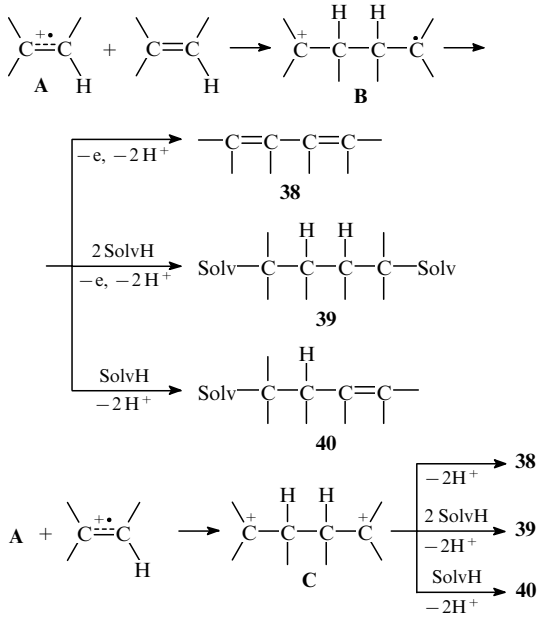
33



R = H, Me, Et, Pr^n, Pr^i, Bu^n, Bu^t.

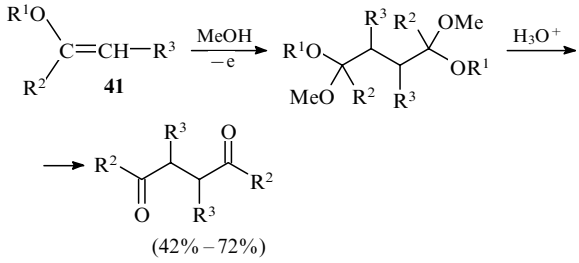
5. Dimerisation of alkenes

The electrochemical transformation of alkenes into dimerised products of type **38**–**40** takes place *via* several consecutive steps. Radical cations **A** generated in the first step undergo recombination and add to the initial alkene molecules. The radical-cation and dication intermediates **B** and **C** undergo solvolysis, electrooxidation and deprotonation giving rise to unsubstituted and substituted (saturated and unsaturated) dimeric compounds.



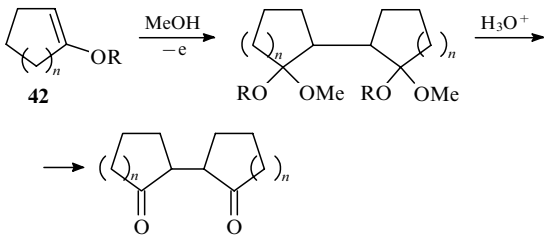
SolvH is a protic solvent.

The optimal conditions for these reactions are as follows: the initial concentration of alkene >1 mol litre^{-1}, methanol as the solvent, $NaClO_4$ as the supporting electrolyte, and a graphite anode.[33, 35, 38, 72] Under these conditions, the aliphatic and alicyclic vinyl ethers **41**, **42** are converted into ketals of 1,4-dicarbonyl compounds, which are hydrolysed to give the corresponding diketones; 5,6-dihydro-4-pyran (**43**) is converted into dimethoxy derivative **44**.[38, 72]



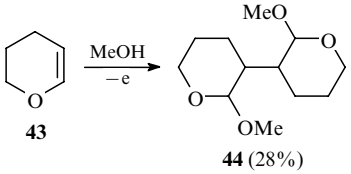
(42%–72%)

R^1 = Me, Et; R^2 = H, Et, Ph; R^3 = H, Me, Bu^n.



(48%–61%)

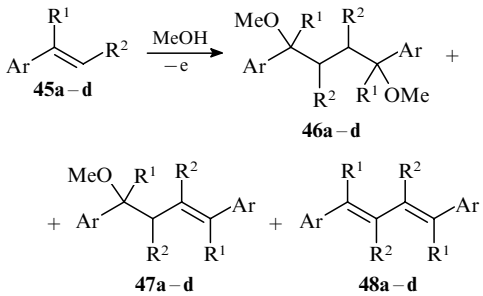
R = Me, Et; *n* = 2, 4.



44 (28%)

Dimerisation of vinyl ethers **41**–**43** is accompanied by side addition of methanol to the double bond, which is catalysed by the protons resulting from anodic oxidation of the solvent and solvolysis of electrogenerated radical cations. To suppress this reaction, electrolysis of vinyl ethers is usually carried out in the presence of bases, for example, pyridine or 2,6-lutidine.[38]

Unlike vinyl ethers, arylalkenes are unable to add methanol under conditions of electrooxidative dimerisation; therefore, the reaction can be carried out without a base. The composition, the structure and the yield of dimerisation products of arylalkenes depend on the type of substitution at the double bond, the nature of the supporting electrolyte and the anode potential.[33, 34] Thus electrolysis of arylalkenes **45a**,**c** in the presence of sodium perchlorate yields 1,4-dimethoxy-1,4-diarylbutanes **46a**,**c** as the only or major products, while in the presence of sodium camphorsulfonate, 1,4-diaryl-1-methoxybut-1-ene **47a** and 1,4-diarylbuta-1,3-diene **48a** are formed (Table 5). Electrolysis of 2-phenylpropene (**45b**) with the $NaClO_4$ electrolyte at an anode potential of 1.6–1.7 V yields dimer **48b**; at lower potentials (1.1–1.2 V), a mixture of dimers **46b**, **47b** and **48b** in 4.2 : 2.5 : 1 ratio is formed. In the case of 4-methoxystyrene (**45c**), an increase in the potential from 0.8 to 1.2–1.3 V increases the yield of the dimer **46c** from



Ar = Ph, 4-$MeOC_6H_4$; R^1 = H, Me; R^2 = H; R^1–R^2 = $(CH_2)_3$.

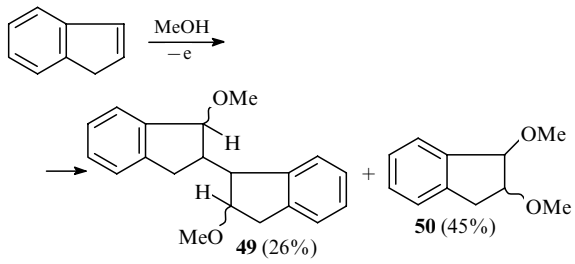
Table 5. Electrooxidative dimerisation of arylalkenes **45** in methanol.[33, 34]

Compound **45**	Ar	R^1	R^2	Electrolyte	Potential /V	Reaction product (yield) (%)
a	Ph	H	H	$NaClO_4$–MeONa (10 : 1)	1.1	**46a** (64)
	Ph	H	H	Sodium camphorsulfonate	1.6–1.7	**47a** (28) + **48a** (36)
b	Ph	Me	H	$NaClO_4$–MeONa (10 : 1)	1.6–1.7	**48b** (67)
	Ph	Me	H	$NaClO_4$–MeONa (10 : 1)	1.1–1.2	**46b** (42) + **47b** (17) + **48b** (10)
c	4-$MeOC_6H_4$	H	H	$NaClO_4$, MeOH, CH_2Cl_2	1.2–1.3	**46c** (79)
	4-$MeOC_6H_4$	H	H	$NaClO_4$, MeOH, CH_2Cl_2	0.8	**46c** (66)
d	Ph	$(CH_2)_4$		$NaClO_4$, MeOH, CH_2Cl_2	0.9	**46d** (3.4)

Note. Electrolysis was carried out under potentiostatic conditions in an undivided cell (PCU) with a graphite anode; the current yield was determined relative to the isolated products; the initial concentration of the substrate was 5.8–6.0 mol litre^{-1}.

66% to 79%. Alkenes with a greater extent of substitution at the double bonds, for example, 1-phenylcyclohexene **45d** give the corresponding dimer **46d** in a yield of only 3.4%.

Apart from dimer **49**, the electrooxidative dimerisation of indene gives dimethoxylation product **50**.[33, 34]

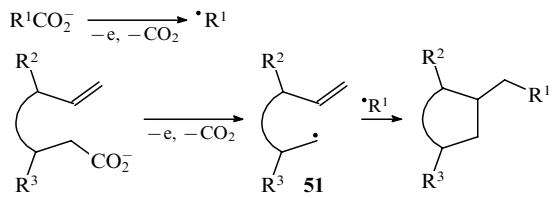


6. Intramolecular electrooxidative cyclisation

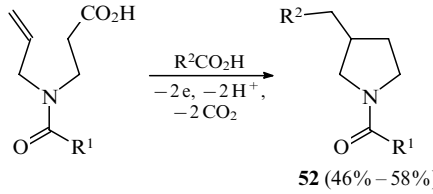
Intramolecular electrooxidative cyclisation is possible for alkenes the molecules of which contain, in addition to the C=C bond, a group capable of electrooxidative transformation into a radical-cation or a radical centre and the chain separating them consists of three to five atoms. The radical cations and radical intermediates electrogenerated from alkenes of this type, for example, from unsaturated carboxylic acids, unsaturated ethers and carbamates, activated α-stannyl or α-silyl groups, aryl(hetaryl)alkenes and non-conjugated α-alkoxy- and α-acetoxydienes, are converted into cyclic products upon intramolecular addition at the double bond followed by solvolysis or other secondary reactions. These processes are considered in more detail below, in Sections II.6.a–e.

a. Cyclisation of unsaturated carboxylic acids

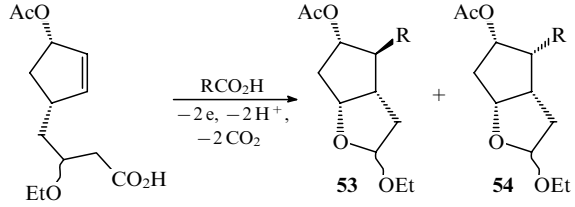
In the cyclisation of unsaturated carboxylic acids, the reaction products result from intramolecular cyclisation of alkenyl radicals **51** generated by the anodic oxidation of the anions of unsaturated acids under conditions of the Kolbe reaction.



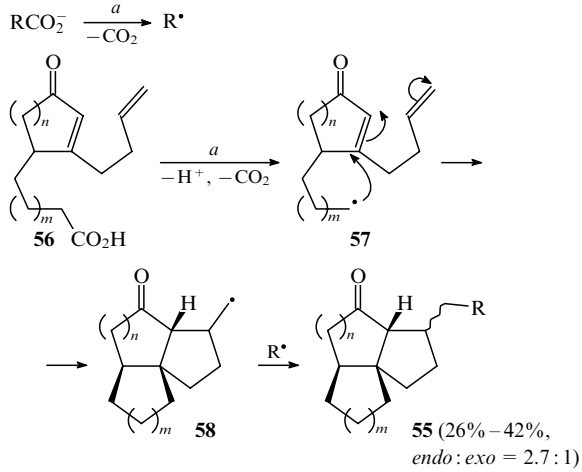
The recent comprehensive reviews devoted to this known reaction [1–4, 86] describe, along with other aspects, the results of application of anodic oxidation to the generation of radicals from carboxylic acids and investigation of the electrochemical cyclisation of unsaturated acids. Further progress along this line [87–90] resulted in the elaboration of new methods for the synthesis of natural and related cyclic products, for example, pyrrolidines **52**,[88, 89] precursors of prostaglandins **53** and **54**[90] and angular triquinanes **55**.[91]



R^1 = H, Me; R^2 = Me, n-C_5H_{11}, $(CH_2)_4CO_2Me$.



R	Yield (%)	
	53	**54**
Me	50	18
n-C_8H_{17}	40	14
$(CH_2)_2CO_2Me$	42	14
$CH_2SiMe_2CH_2$	30	8
Me_3SiCH_2	29	10
n-$C_5H_{11}COCH_2CH(SiMe_3)$	4–5	–



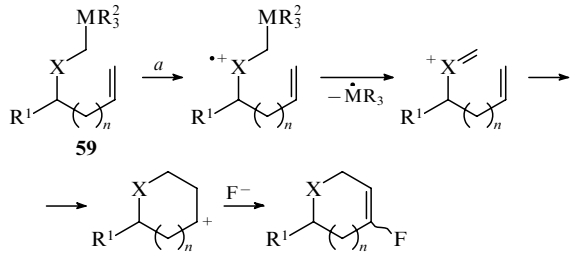
R = Me, n-C_5H_{11}, $(CH_2)_2CO_2Me$; n = 1–3, m = 1, 2; (*a*) ACU, Pt anode, steel cathode, 25 mA cm^{-2}, 1.2 F mol^{-1}, MeOH, 4 equiv. of RCO_2H neutralised by KOH to 5%, 40–45 °C.

The formation of the compounds **55** from acids **56** takes place *via* regio- and stereoselective radical tandem cyclisation initiated by anodic oxidation and giving rise to three new C–C bonds. Two

bonds are formed at the stage of cyclisation of radical **57**, and the third one, upon recombination of tricyclic radical **58** with the R$^{\bullet}$ radical generated from the saturated acid, which is used as the second reactant. This distinguishes electrochemical cyclisation from tandem cyclisations initiated by chemical methods: in this case, C–H or C–I bonds are formed at the final stage.[92–94] An advantage of the electrochemical tandem cyclisation is that it does not use organotin reagents, normally employed in the chemical version, and the combination of the initial unsaturated and saturated acids makes it possible to change the side chain of the product **55**.

b. Cyclisation of unsaturated ethers and carbamates activated by α-stannyl and α-silyl groups

Silyl, stannyl or thioaryl groups in the α-position markedly decrease the oxidative potentials of ethers or carbamates **59**; this facilitates the electrochemical transformation in oxonium (X = O) or *N*-acyliminium (X = NCO_2Me) ions.[95–101] Intramolecular cyclisation of substrates **59** yields products containing an endocyclic fluorine atom, indicating a cationic mechanism of the reaction (in the case of a radical mechanism, an exocyclic product would be formed at $n = 1$). The supporting electrolyte, namely, tetrabutylammonium tetrafluoroborate or hexafluorophosphate, serves as the source of the fluorine anion at the final stage of the process.[98]

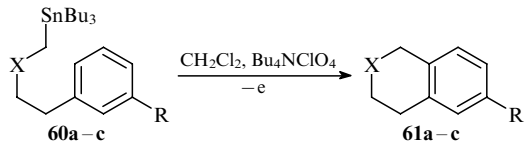


(50%–98%, *cis* : *trans* = 1.2 : 3)

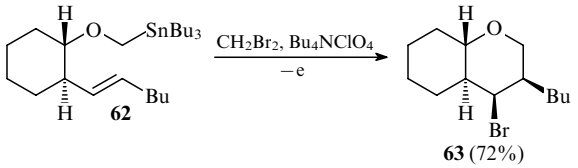
M = Sn, Si; R^1 = H, Me; R^2 = Alk; X = O, NCO_2Me; n = 1, 2; (*a*) ACU, graphite anode, CH_2Cl_2, Bu_4NBF_4.

Trialkylstannyl groups exert a more pronounced activating effect than trialkylsilyl groups; as a consequence, cyclic products are formed in higher yields from stannyl derivatives.

This method has been used to convert α-stannyl-substituted arylaliphatic ethers **60a–c** into isochroman (**61a**), 6-fluoroisochroman (**61b**) and *N*-methoxycarbonyl-1,2,3,4-tetrahydroisoquinoline (**61c**). The transformation of *trans*-1-(tributylstannylmethoxy)-2-(hex-1-enyl)cyclohexane (**62**) gave rise to *trans*-3-butyl-4-bromo-1-oxadecalin (**63**).[99, 101]

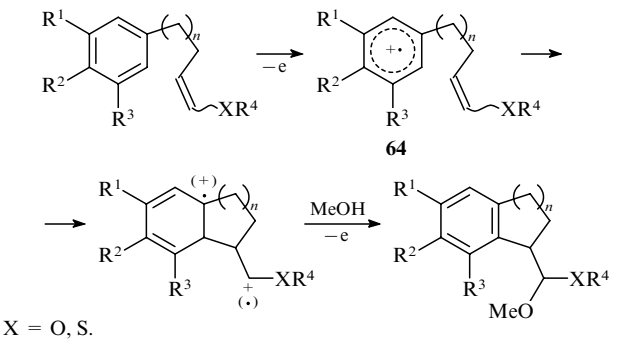


X = O: R = H (**a**, 55%), F (**b**, 80%); X = NCO_2Me, R = H (**c**, 54%).



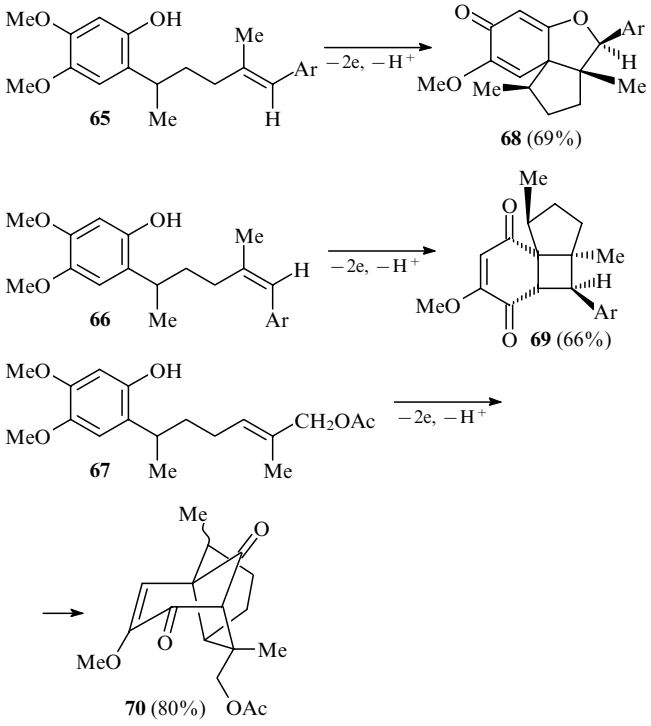
c. Cyclisation of aryl and hetarylalkenes

Intramolecular cyclisation of aryl- and hetarylalkenes is a result of transformations of radical cations **64** electrogenerated from these substrates. This cyclisation is one of the most useful reactions induced by direct anodic oxidation.[102–118]



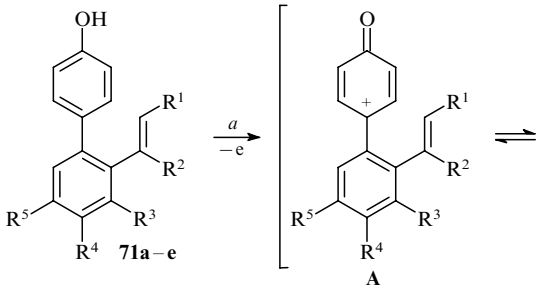
X = O, S.

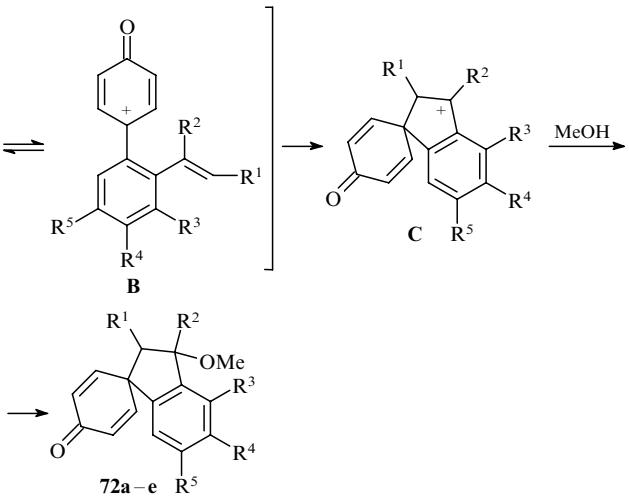
The structure of the bi- and polycyclic compounds thus obtained depends on the nature and the stereochemistry of substituents at the double bond. For example, cyclisation of substrates **65–67** having related structures but differing in the nature and the positions of substituents at the double bond affords absolutely different tricyclic compounds **68–70**, precursors of natural products.[102–111]



Mild experimental conditions and high product yields are important advantages of this method for the preparation of this type of polycyclic polyfunctionalised compound.

4-Hydroxy-2′-alkenylbiphenyls **71a–e** have been used as examples to study the influence of the structure of the initial substrates, electrolysis conditions and some other factors on the cyclisation. Presumably,[112, 113] the initial step represents generation of cationic intermediates **A** and **B** induced by anodic oxidation; this is followed by their cyclisation and the reaction of cations **C** with methanol giving rise to compounds **72a–e**.[112, 113]

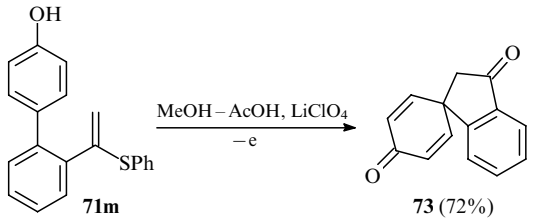




(*a*) ACD, platinum wire or glass carbon anode, 1.6–2.0 F mol^{-1}, MeOH or MeOH–AcOH (CH_2Cl_2, MeCN), $LiClO_4$, 0–20 °C.

Compound **71**	R^1	R^2	R^3	R^4	R^5	The yield of compounds **72** (%)	Ref.
a	H	H	H	H	H	16	112, 113
b	H	Me	H	H	H	85	112, 113
c	H	Ph	H	H	H	65	112, 113
d	Me	H	H	H	H	35	112, 113
e	$(CH_2)_3$		H	H	H	69	112, 113
f	H	H	Me	H	H	70	114
g	H	H	H	H	OMe	47	115
h	H	Me	H	H	OMe	84	115
i	H	Me	H	OMe	H	80	115
j	H	H	H	OMe	OMe	70	115
k	H	Me	H	OMe	OMe	92	115
l	H	Me	H	OCH_2O		70	115

The cyclisation of 4-(2′-alkenylphenyl)phenols **71b**,**c**,**e**, containing α-substituents in the alkenyl group, occurs with high yields (65%–85%). In the case of the compounds **71** in which R^2 = H the yields are much lower. The compound **71m**, containing a phenylthio group at the double bond, is converted into diketone **73**.

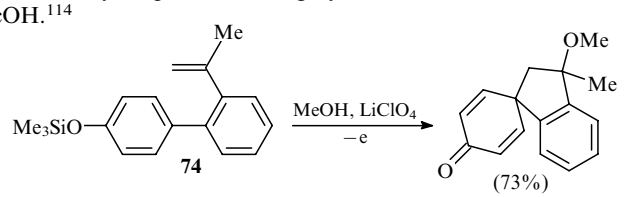


The yields of reaction products also depend on the solvent, current density, anode material and addition of mild acids, for example, acetic acid. The highest yields are attained when the reaction is carried out in a mixture of acetonitrile with methanol (4 : 1) containing 5–10 equiv. of AcOH, using lithium perchlorate as the supporting electrolyte and a current density of 0.84 mA cm^{-2} on a platinum electrode.[113]

The increase in the yields of the compounds **72** following the replacement of hydrogen at the α-carbon atom in the olefinic group by a methyl group is presumably [115] due to the fact that in this case, the cationic intermediate exists preferably in conformation **A**, in which the double bond is close to the reaction centre. For the substrates **71** in which R^2 = H, conformation **B** is preferred. A similar effect is exerted by the methyl group in the *ortho*-position to the alkenyl substituent. For example, the transformation of 4-hydroxy-2′-vinyl-3′-methylbiphenyl (**71f**) gives the cyclisation product — spirodienone **72f** — in 70% yield.[114]

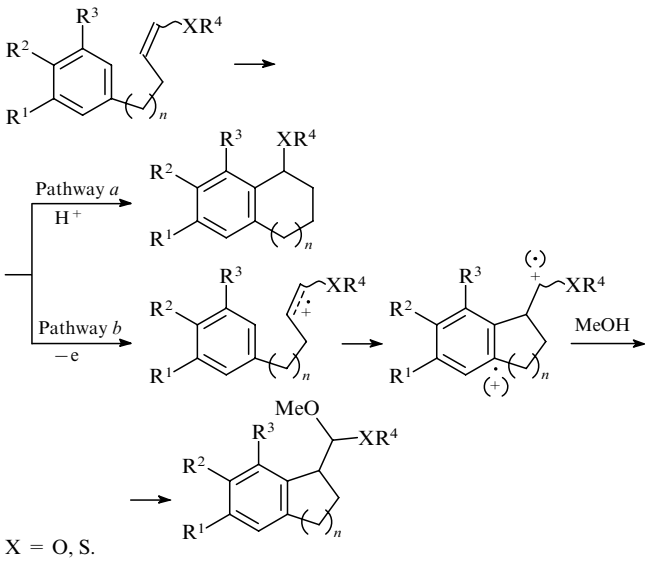
Cyclisation of 4-hydroxyarylalkenes with R^2 = H containing methoxy groups in the *para*-position or both in the *para*- and *meta*-positions relative to the vinyl group (the compounds **71g**,**j**) is more efficient. Similar *meta*-methoxy-derivatives do not cyclise. Cyclisation of *para*- and *meta*-methoxy-substituted **71h**,**i**,**k**,**e** in which R^2 = Me gives products in high yields.[115]

The trimethylsilyl ethers of 4-hydroxyarylalkenes, for example, compound **74**, unlike the corresponding phenols, are converted into cyclic products in high yields even in the absence of AcOH.[114]



Silyl ethers can cyclise in the presence of bases. Thus, depending on the nature of the functional groups present in the substrate, this process can be carried out both in a neutral medium and in the presence of acids or bases.

Within the framework of investigation of cyclisation, anodic oxidation of aryl- and hetarylalkenes with electron-enriched double bonds has been vigorously developing in recent years.[116–118] The interest in these reactions is determined by the possibility of performing the cyclisation of arylalkenes with a regioselectivity (pathway *b*) differing from that observed in the case of the Friedel–Crafts cyclisation (pathway *a*). The cyclisation process during the anodic oxidation is based on the inversion of polarity of enol ethers. This reaction makes it possible to prepare cyclic products of various structures from the same initial substrate, depending on the method used to initiate cyclisation.

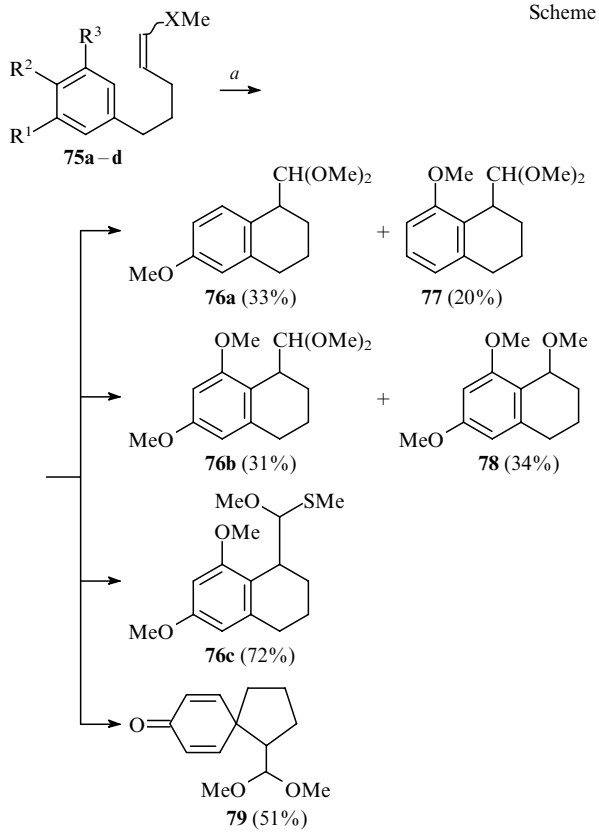


X = O, S.

Thus by anodic oxidation of enol ethers and enol thioethers **75a**–**c**, cyclisation products, namely, substituted tetralins **76a**–**c**, **77**, and **78** have been prepared in high yields. Under the same conditions, the enol ether **75d** is converted into spiro derivative **79** (Scheme 3).[116, 118]

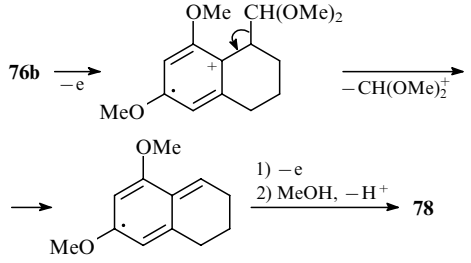
It should be noted that cyclisation of the enol ether **75a** to give the tetralins **76a** and **77** is accompanied by the formation of 1,6- and 1,8-dimethoxytetralins, resulting from further electrooxidation. The tetralin **76b**, formed from the enol ether **75b**, is converted into 1,6,8-trimethoxytetralin **78**.[118]

Scheme 3

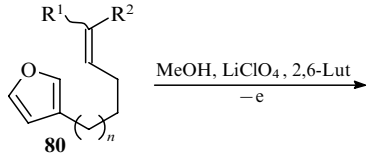


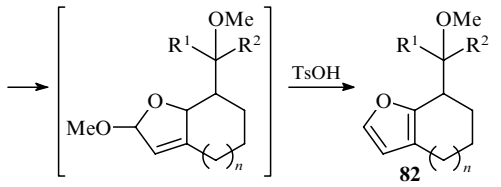
75: R^1 = OMe, R^2 = R^3 = H, X = O (**a**); R^1 = R^3 = OMe, R^2 = H, X = O (**b**), S (**c**); R^1 = R^3 = H, R^2 = OMe, X = O (**d**); (*a*) ACD, glass carbon anode, 1.6–2.0 F mol^{-1}, MeOH–CH_2Cl_2 (1 : 4), $LiClO_4$, 5 equiv. of 2,6-lutidine (2,6-Lut), ~20 °C.

These side reactions do not take place if electrolysis is carried out with a controlled potential (1.1 V). Unlike cyclisation of the enol ethers **75a**,**b**, cyclisation of the enol thioether **75c** under similar conditions occurs without further oxidation of the reaction product **76c**.

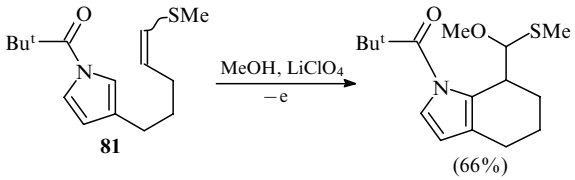


The cyclisation of furyl- (**80**) and pyrrolyl-substituted alkenes **81** containing electron-enriched double bonds induced by anodic oxidation has opened a new way for assembling bicyclic structures incorporating five-membered heterocycles.[116,117] A compound of type **82** can be used in the synthesis of furan-containing bi- and polycyclic natural products.[119–126]



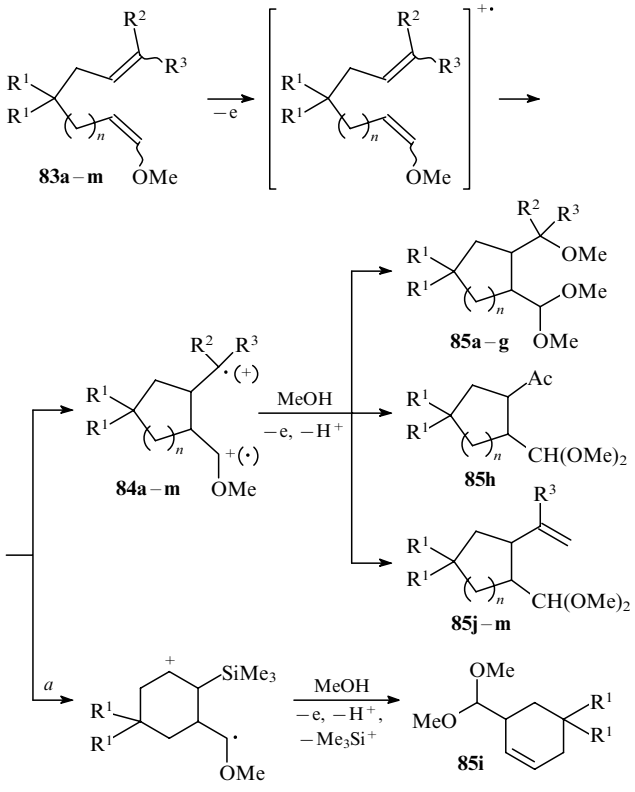


R^1 = SMe, OMe, Ph, Me, CH_2SiMe_3; R^2 = H, Me, n = 1, 2.



d. Cyclisation of non-conjugated 1-alkoxy-dienes

Cyclisation of non-conjugated 1-alkoxy-dienes has not yet been adequately studied. This electrochemical process, which has much in common with cyclisation of aryl- and hetarylalkenes, has found application for the synthesis of carbocyclic compounds. The value of this method is dictated by the possibility of reverting the polarity of the β-carbon atom in the initial 1-alkoxy-dienes **83a**–**m** from nucleophilic to electrophilic due to the fact that an initial stage of the process is transformation of the substrates into radical cations **84a**–**m**.[127–134] The electrolysis conditions and the yields of the reaction products **85a**–**m** are listed in Table 6.



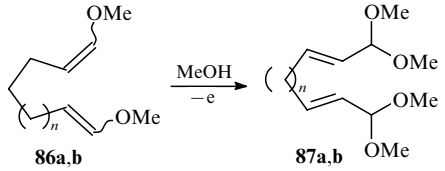
(*a*) R^1 = Me, R^2 = $SiMe_3$, R^3 = H.

The 1-methoxy-dienes **83** (n = 1–3), which contain substituents R^2 and R^3 activating the double bond, ensure the most selective formation of cyclic compounds (see Table 6).[127–134] Cyclisation of 1-methoxy-dienes **86a**,**b** does not proceed under similar conditions: these compounds are converted into unsaturated dialdehyde diacetals **87a**,**b**.

Table 6. Anodic oxidation of 1-methoxy dienes **83a**–**m**.

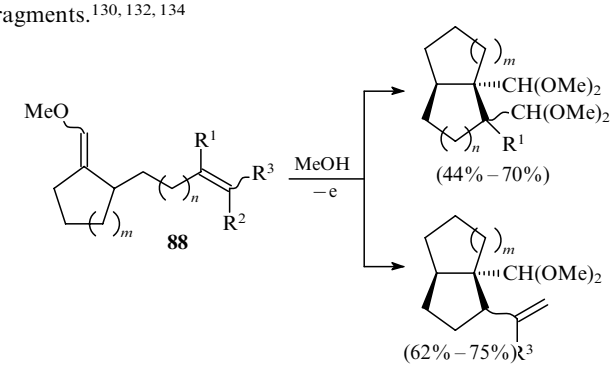
Compound **83**	n	R^1	R^2	R^3	Reaction product	Yield (%)	Ref.
a	1	Me	OMe	H	**85a**	68	128
b	1	H	OMe	H	**85b**	70	128
c	2	H	OMe	H	**85c**	65	128
d	3	H	OMe	H	**85d**	50	128
e	1	H	Ph	H	**85e** [a]	65–73	127, 128
f	2	H	Ph	H	**85f**	65	128
g	1	H	Me	Me	**85g**	60	128
h	1	Me	OMe	Me	**85h**	62	132
i	1	Me	$SiMe_3$	H	**85i**	29	129
j	1	Me	CH_2SiMe_3	H	**85j** [a]	84	132
k	1	Me	CH_2SiMe_3	Me	**85k**	89	128
m	2	H	CH_2SiMe_3	H	**85m**	59	128

Note. Conditions of electrolysis: ACU, Pt or wire glass carbon anode, 15 mA cm^{-2}, 2 F mol^{-1}, methanol–THF (1 : 1) or MeOH–CH_2Cl_2 (1 : 4), $LiClO_4$, 2,6-Lut. [a] A mixture of *trans*- and *cis*-isomers.



n = 4 (**a**), 12 (**b**).

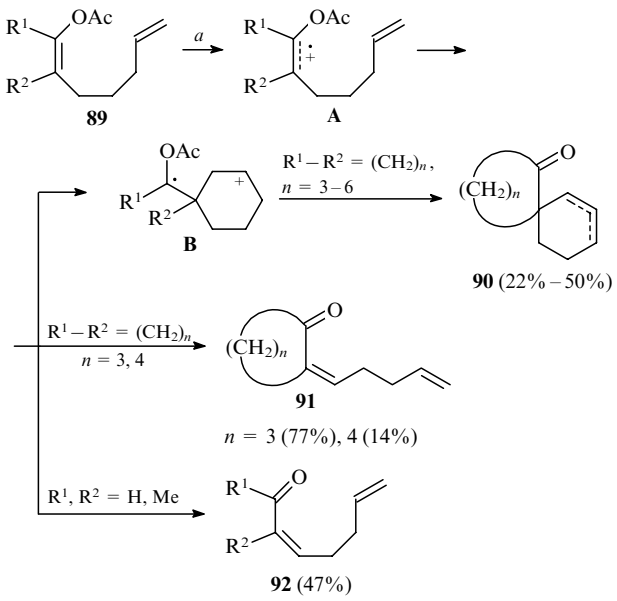
The principle of electrochemical cyclisation of linear 1-methoxy-dienes has been extended successfully to compounds **88**, containing cyclopentane (m = 1) and cyclohexane (m = 2) fragments.[130, 132, 134]



R^1, R^2 = H, Me; R^3 = OMe, $SiMe_3$; m, n = 1, 2.

e. Cyclisation of non-conjugated 1-acetoxy-dienes

Cyclisation of non-conjugated 1-acetoxy-dienes **89** has many common features with the transformation of enol acetates into enones and α-acetoxy ketones (see Section II.2). A fundamental distinction between these electrochemical processes is that radical cations **A** electrogenerated from the 1-acetoxy-dienes **89** can react with a second C=C bond acting as an internal nucleophile. The intramolecular electrophilic attack on the double bond by the cationic centre of the radical cation gives rise to cyclic radical cation **B**. The subsequent deprotonation and electrooxidation of intermediate **B** are accompanied by elimination of the acetyl cation, resulting in the formation of cyclisation product **90** and competitive formation of conjugated enones **91** or **92**.[135]

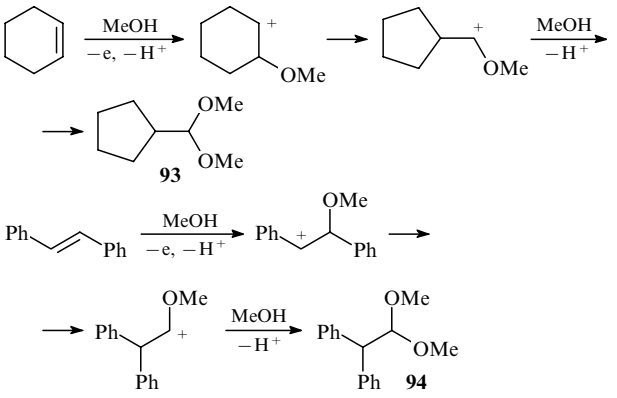


(*a*) ACU, graphite electrodes, 4–10 F mol^{-1}, AcOH, Et_4NOTs (1 mol $litre^{-1}$), ~20 °C.

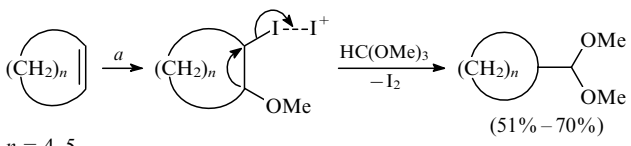
Cyclisation of radical cations **A** by a radical mechanism does not occur under these conditions.

7. Transformations of alkenes with skeletal rearrangement

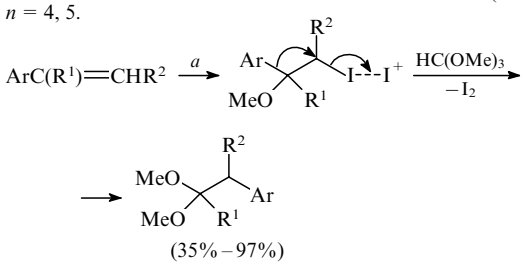
The transformations of alkenes with skeletal reconstruction take place as a result of rearrangement of carbenium ions, which are intermediates in the anodic oxidation of alkenes. For example, cyclohexene is converted into cyclopentanecarbaldehyde dimethyl acetal (**93**),[136] while *trans*-stilbene yields diphenylacetaldehyde dimethyl acetal (**94**).[67]



Since carbenium ions react competitively with MeOH, the dimethyl acetals **93** and **94** are formed as mixtures with 1,2-dimethoxycyclohexane and 1,2-dimethoxy-1,2-diphenylethane. When anodic oxidation of cyclohexene, *trans*-stilbene and related alkenes is carried out in trimethyl orthoformate in the presence of iodine, this side process is suppressed and acetals are produced as the only electrolysis products.[136] The promotory effect of iodine is related presumably [136] to the formation of iodonium salts, which efficiently assist the rearrangement.



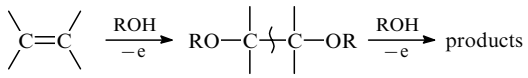
n = 4, 5.



Ar = Ph, 4-MeC_6H_4, 4-$MeO_2CC_6H_4$, 4-ClC_6H_4; R^1 = H, Me; R^2 = H, Me, Ph, CH_2OMe; (*a*) ACU, graphite anode, 0.1 mA cm^{-2}, 3–17 F mol^{-1}, $HC(OMe)_3$, $LiClO_4 \cdot 3H_2O$, 0.25–1.2 equiv. I_2, 20–100 °C.

8. Cleavage of the double bond in alkenes

Electrochemical cleavage of the double bond in alkenes takes place in an aqueous or alcoholic solution. This is a two-stage process consisting of vicinal dioxygenation of the alkene double bond at the initial stage and cleavage of the C–C σ-bond in the resulting species at the subsequent stage.

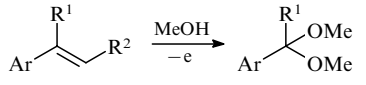


ROH is water or alcohol.

For conjugated arylalkenes, aryl(areno)cycloalkenes and enol acetates, the two stages can proceed successively as a one-pot reaction because the same electrolytes are effective for both processes. The attempts to cleave the double bond in enol ethers in the same way failed (see Section II.8.b).

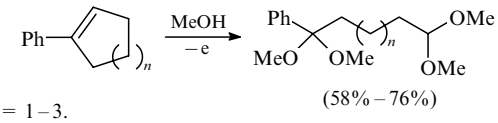
a. Direct cleavage of the C=C bond in arylalkenes, aryl(areno)cycloalkenes and enol acetates

Stepwise investigation of styrene electrooxidation in methanol in an undivided cell showed that the initial and the subsequent stages of this process are affected in different ways by the nature of the electrolyte, anode material and temperature. The highest selectivity (76%–80%) of the first stage (degree of substrate conversion 90%–93%) is attained in potassium fluoride or tetrabutylammonium tetrafluoroborate as the supporting electrolyte with a platinum anode, while for the second stage a selectivity of 70%–83% (degree of conversion 85%–98%) is observed in the presence of sodium toluene-*p*-sulfonate and tetrabutylammonium tetrafluoroborate with a graphite anode.[64, 65] Operation of the overall process under conditions favourable for the second stage permits preparation of the target products in higher yields. Under these conditions, conjugated arylalkenes were converted into benzaldehyde acetals and arylketone ketals (the consumption of electricity is 4–8 F per mole of alkene).[64, 137–139]



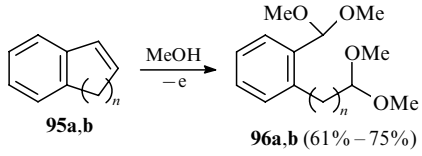
Ar = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$; R^1 = H, Me, Ph; R^2 = H, Me, Et.

1-Phenylcycloalkenes give acetal and ketal derivatives of ω-benzoylalkanals.[64, 140]



n = 1–3.

Indene (**95a**) and 1,2-dihydonaphthalene (**95b**) form the bis(acetals) **96a**,**b**.[64, 140]

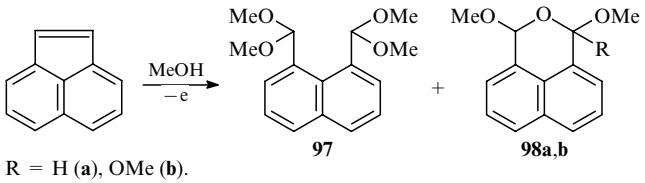


95a,**b**

96a,**b** (61%–75%)

n = 1 (**a**), 2 (**b**).

Acyclic (**97**) and cyclic (**98a**,**b**) acetals of naphthalene-1,8-dicarboxaldehyde were prepared from acenaphthene.[70] The **97** to **98a**,**b** ratio depends substantially on the electrolyte used: in the presence of potassium fluoride, these products are formed in 30% and 34% yields, respectively; in the presence of tetrabutylammonium tetrafluoroborate, the ratio is ~1 : 25 (overall yield 57%).



97 **98a**,**b**

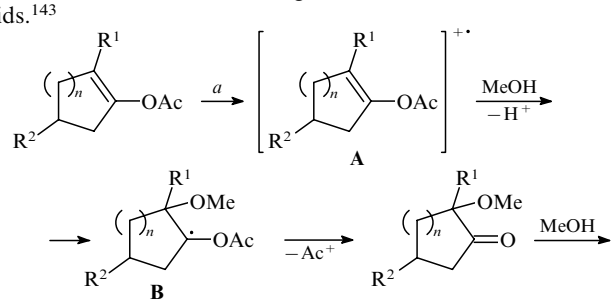
R = H (**a**), OMe (**b**).

The process selectivity sharply decreases when the initial alkene concentration is higher than 1.0 mol $litre^{-1}$ because of the increase in the relative amount of the alkene involved in the side dimerisation, oligomerisation and polymerisation reactions (see Section II.5). The decrease in the alkene concentration in the reaction mixture by using its gradual addition to the electrolyte during electrolysis makes it possible to increase the product yield to 15%–20%.[65]

The predominant formation of the cyclic acetals **98** from acenaphthene is, apparently, caused by the fact that, during the electrolysis in the presence of Bu_4NBF_4, the space near the anode surface gets acidified by the electrogenerated HBF_4, which catalyses the transformation of the acetals **97** into **98a**,**b**.

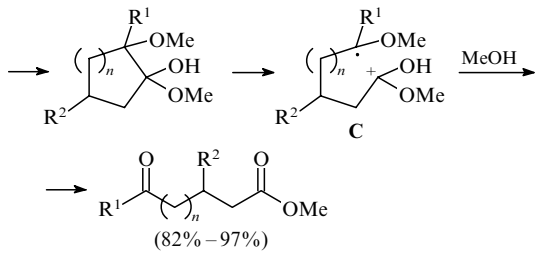
The rupture of the C–C bond in glycols formed upon the electrooxidation of the double bond in conjugated arylalkenes in aqueous and water-organic media proceeds at a substantially higher rate than that in their alkyl ethers. In this case, the process cannot be stopped at the stage of formation of glycols due to the fast rupture of the C–C bond in the HO–C–C–OH fragment. Direct anodic oxidation of propenylbenzene, anethole and isosafrole has been studied in most detail.[138–142] Anisaldehyde was prepared from anethole in high substance yield (81%–85%) but a low current yield (~20%).[141, 142] The cleavage of double bond in isosafrole has not resulted in the synthesis of 3,4-methylenedioxybenzaldehyde (piperonal) in a yield higher than 34%.

Electrochemical rupture of the C=C bond in enol acetates proceeds *via* consecutive transformation into radical-cation and radical intermediates **A** and **B**, α-methoxy ketones, their semiketals, and radical cations **C** and gives rise to esters of oxoalkanoic acids.[143]



A

B

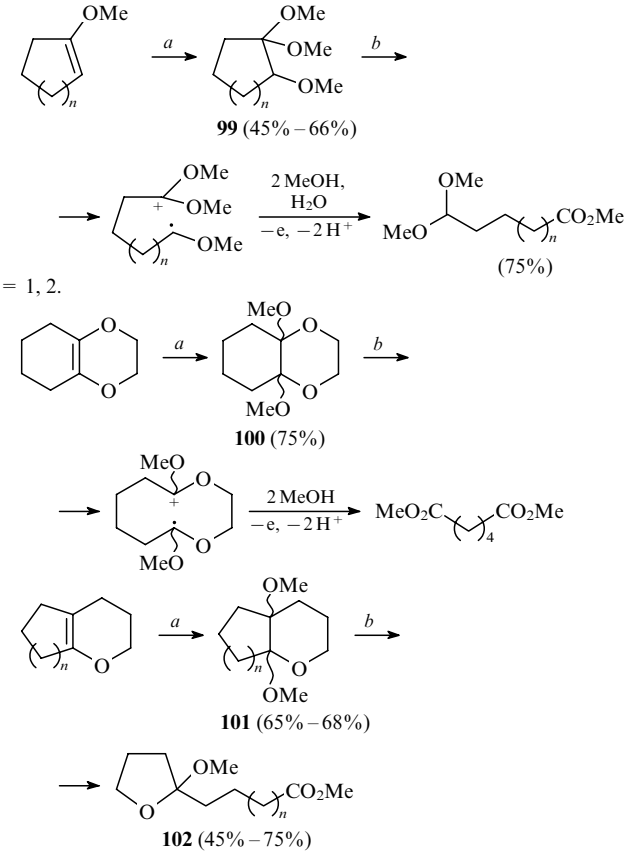


n = 1, 2; R^1, R^2 = H, Me, Pr^i; (*a*) ACU, Pt anode, 4 F mol^{-1}, MeOH – AcOH (10 : 1), $LiClO_4$, 2 – 8 °C.

Starting from (+)-menthone enol acetate, methyl (+)-3,7-dimethyl-6-oxooctanoate was prepared by this method in 74% yield.[143]

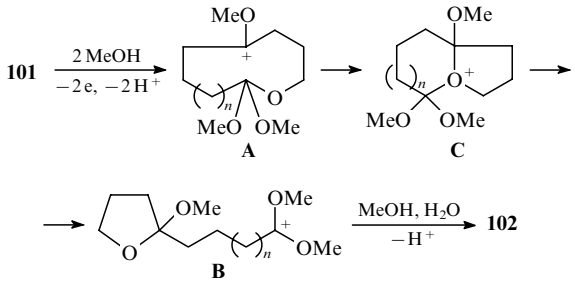
b. Direct cleavage of the double bond in cyclic enol ethers

It has been noted above that cleavage of the double bond in enol ethers cannot be carried out as a one-pot reaction with the same selectivity as for conjugated arylalkenes, aryl- and benzocycloalkenes. This is due to the fact that the electrochemical vicinal dialkoxylation of enol ethers proceeds with a satisfactory selectivity only with basic electrolytes, which are inefficient at the stage of electrooxidative cleavage of dialkoxylation products. Therefore, the process is carried out as two separate electrochemical stages with isolation of the products of dialkoxylation of enol ethers **99** – **101** after the first stage.[59, 144 – 146]



n = 2, 8; (*a*) ACU, Pt anode, 3.5 – 6.2 F mol^{-1}, MeOH, MeONa or KOH, – 5 – 20 °C; (*b*) ACU, graphite anode, 6 – 8 F mol^{-1}, MeOH, Et_4NOTs or Bu_4NBF_4, 20 °C.

The electrochemical processes at the second stage result in ring opening in the dialkoxylation products **99** – **101**. In the case of the compounds **101**, the reaction is accompanied by their electrooxidative rearrangement into methyl ω-(2-methoxytetrahydrofuryl)alkanoates **102**. The rearrangement takes place due to isomerisation of intermediates **A** into carbocations **B** *via* oxonium ions **C**. The subsequent alcoholysis of cations **B** results in the reaction product **102**.[145, 146]



III. Reactions induced by indirect anodic oxidation

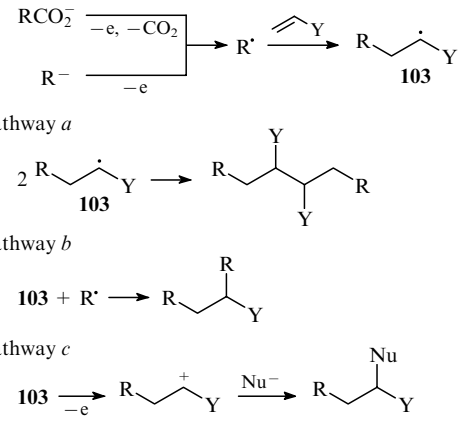
In the reactions induced by indirect anodic oxidation, unlike reactions induced by direct anodic oxidation, no direct electron transfer from the alkene molecule takes place at the anode. In this case, alkenes are involved in the electrochemical process through interaction with electrogenerated inorganic or organic radicals, ions or reagents (see Scheme 1). These intermediates arise from their precursors at potentials lower than the potentials of alkene oxidation. The process of alkene transformation into products takes place partly or entirely in the bulk solution rather than on the anode surface and is markedly facilitated and accelerated. This strategy allows one to perform electrochemical transformations of alkenes impossible in the case of direct anodic oxidation and thus extends the scope of applicability of anodic processes in organic synthesis.

The most typical precursors for the generation of oxidants and reagents in the alkene transformations induced by indirect anodic oxidation are anions of organic and inorganic acids, variable-valence metal compounds and triarylamines.

1. The reactions of alkenes with radicals electrogenerated from carboxylate anions and 1,3-dicarbonyl and related compounds

In the anodic oxidation of carboxylate, acetoacetate, malonate and cyanoacetate anions, carbon-centred radicals are generated;[1 – 4, 86] in the presence of alkenes, they add to the double bond. The resulting radical adducts **103** are converted along two routes: they either undergo pairwise or cross recombination (Scheme 4, pathways *a*, *b*) or are oxidised to give carbocations (pathway *c*). Subsequently the carbocations react with internal or external nucleophiles.[1 – 4]

Scheme 4

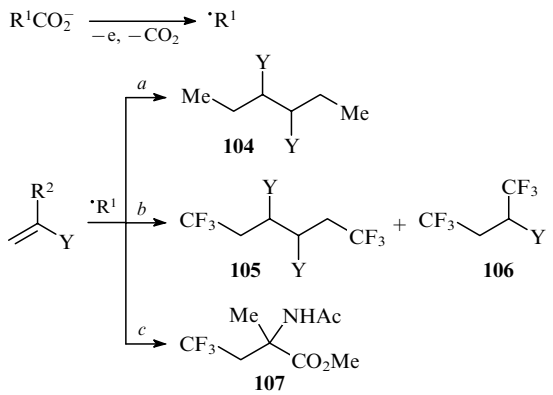


a. Reactions of alkenes with alkanoic acids

The reactions of alkenes with radicals generated from saturated acids and 1,3-dicarbonyl and related compounds have been generalised in a review,[5, 6] which covers the data published up to 1981. In this review, we consider later publications.

The main difference between alkene reactions with radicals generated by the anodic oxidation of alkanoic acids and their reactions with similar radicals generated by chemical methods is that the electrochemical method makes it possible to vary the radical concentration on the electrode surface over a broad range by varying the current density and thus to control the process. An increase in the current density favours recombination of radicals, while a decrease facilitates the oxidation of radicals. The electrochemical and chemical processes also differ in the way in which electron-withdrawing substituents Y in the alkene molecule influence the reaction route. The formyl, acetyl and alkoxycarbonyl groups direct the electrochemical reaction exceptionally to pathway *a* [147] and the chemical reaction, to pathway *a* or *b*. The alkenes $CH_2=CHY$ with electron-donating substituents Y, such as alkyl, aryl, vinyl and alkoxyl groups are converted along each of the three pathways: *a*, *b* and *c* (see Scheme 4).[5,6]

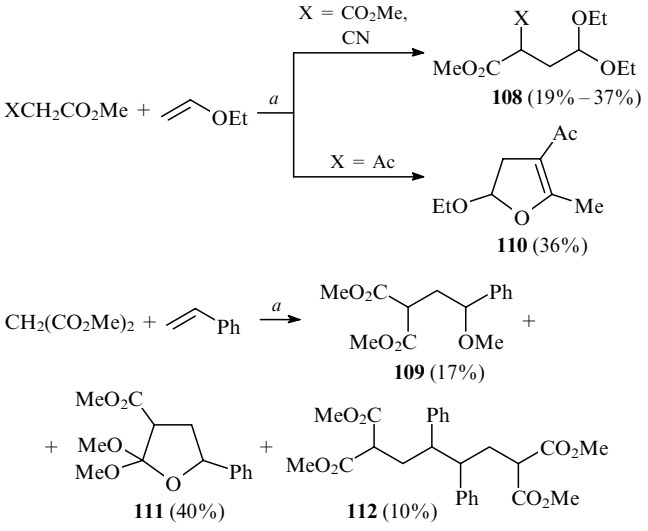
The electrochemical reactions under consideration have been studied in relation to the methylation [147] and trifluoromethylation [148–162] of acrylates,[147–159] methacrolein, vinyl ketones,[147] acrylo- and fumaronitrile,[149,160] esters of fumaric, maleic [151,152] and but-3-enoic acids,[150] alkenes,[148,149,153,154] vinyl acetate,[151,152] isopropenyl acetate, allyl chloride,[153,154] but-3-en-1-ol [161] and undec-10-enoic acid.[162] These reactions are normally carried out in an aqueous solution of a mixture of acetonitrile with partially (to 10%) neutralised acetic or trifluoroacetic acid in a cell with platinum electrodes at an anodic current density of 50–100 mA cm^{-2} and with passage of 1.1–1.5 F of electricity per mole of the acid.[147,159] Methylation and trifluoromethylation of methacrolein, vinyl ketones and acrylates results under these conditions in pairwise and cross coupling of the arising radicals to give 2:2 (**104**, **105**) and 2:1 (**106**) adducts in 40%–80% yields.[147–149,156,157] The decrease in the anodic current density to 1 mA cm^{-2} and a decrease in the temperature from 20 to 0–5 °C directs the reaction of trifluoroacetic acid with methyl methacrylate almost entirely along pathway *c* giving rise to methyl 2-acetamido-2-methyl-4,4,4-trifluorobutanoate (**107**). The compound **107** is formed upon oxidation of the initial radical adducts and the reaction of the resulting carbocations with the solvent (MeCN).[156] This change in the direction of the process is due to the fact that electrooxidation of radical adducts occurs much faster than their dimerisation.[159]



Y = CHO, Ac, CO_2H, CO_2Me, CN; (*a*) R^1 = Me, R^2 = H, 50 mA cm^{-2}; (*b*) R^1 = CF_3, R^2 = H, 50–100 üA·cü$^{-2}$; (*c*) R^1 = CF_3, R^2 = Me, Y = CO_2Me, 1 mA cm^{-2}, 0–5 °C.

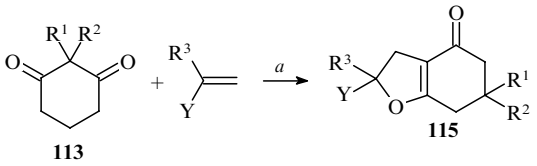
b. Reactions of alkenes with 1,3-dicarbonyl and related compounds

Radical adducts formed by ethyl acetoacetate, diethyl malonate or malononitrile with vinyl ethyl ether or styrene are oxidised at the anode to cationic intermediates, which react with external or internal nucleophiles being thus converted into linear (**108**, **109**) and/or cyclic products (**110**, **111**). The adducts formed with styrene also give dimers **112**.[163]



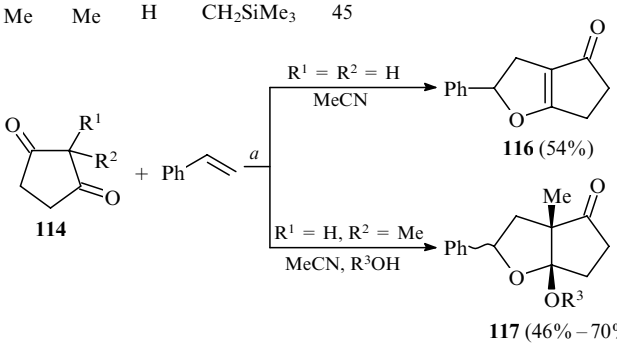
(*a*) ACU, 14 mA cm^{-2}, 1.5 F mol^{-1}, EtOH or MeOH, EtONa or MeONa.

Joint electrolysis of cycloalkane-1,3-diones **113**, **114** with alkenes affords the products of formal [3+2]-cycloaddition, dihydrofuran (**115**, **116**) and tetrahydrofuran (**117**) derivatives.[164–167]



(*a*) ACU, 14 mA cm^{-2}, 1.5 F mol^{-1}, MeCN.

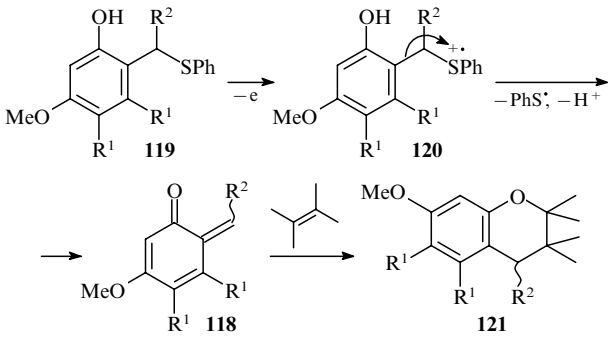
R^1	R^2	R^3	Y	Yield of **115** (%)
H	H	H	Ph	85
H	H	Me	$CH=CH_2$	62
H	H	H	OEt	57
Me	Me	H	Ph	97
Me	Me	H	CH_2SiMe_3	45



R^3 = H, Me; (*a*) ACU, 14 mA cm^{-2}, 1.5 F mol^{-1}.

2. Reactions with electrochemically generated *o*-quinonemethides

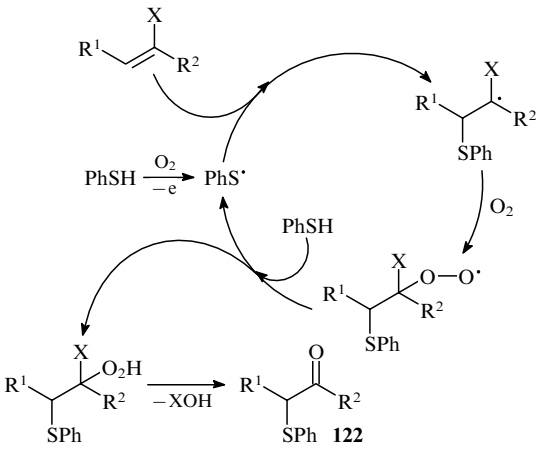
o-Quinonemethides **118** are generated upon the anodic oxidation of *o*-[1-(phenylthio)alkyl]phenols **119** in nitroethane followed by fragmentation of the radical cations **120** thus formed with elimination of the phenylthiol radicals. In the presence of alkenes, which are active acceptors of *o*-quinonemethides, cycloaddition to give chromans **121** takes place.[168,169]



R^1 = H, OMe; R^2 = H, Alk.

3. Arylthiocarbonylation

Electrochemically initiated arylthiocarbonylation is typical of alkenyl sulfides and alkenylsilanes. In this reaction, they are converted into α-phenylthio ketones **122**.[170–172]

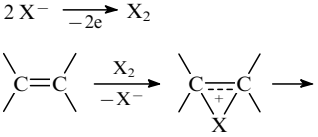


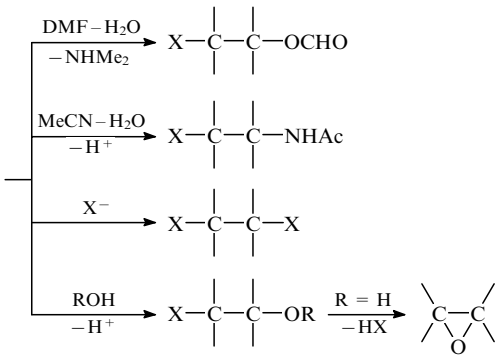
X = SPh, $SiMe_3$; R^1, R^2 = H, Alk.

The reaction is carried out in an undivided cell (at ~20 °C) in acetic acid with Et_4NOTs as the supporting electrolyte in the presence of 2–4 equiv. of benzenethiol with passage of 20 mA current for 1-min periods at 30-min intervals (0.16–1.19 F mol^{-1}) and with bubbling oxygen.

4. Halogenation, halooxygenation, haloacetamidation, epoxidation and other related reactions

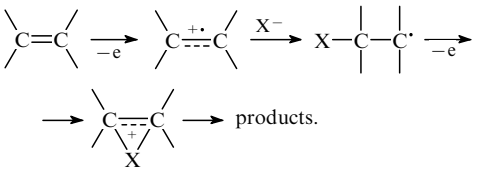
Anodic oxidation initiates halogenation, halooxygenation and related reactions in aqueous MeCN or DMF or in water-alcoholic media, in the presence of chloride, bromide or iodide anions. The halide anions are readily oxidised due to the low oxidation potentials (0.8, 0.4 and 0.2 V *vs.* Ag/Ag^+, respectively), being converted into molecular chlorine, bromine and iodine; these reagents are responsible for alkene halogenation, halooxygenation and haloacetamidation [173–184] and, under certain conditions of electrolysis, epoxidation [184–193] and other related reactions (for example, azidoalkoxylation,[194] oxyselenenation, acetamidoselenenation,[195–198] acetamidosufenation,[199] intramolecular arylthio- and arylseleno-esterification and lactonisation,[200–203] and nitroacetamidation [203,204]).





X = Cl, Br, I.

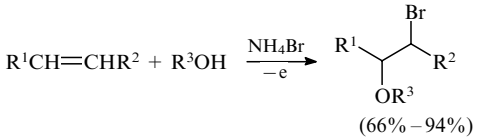
In the case of alkenes activated by electron-donating substituents, competitive formation of these products *via* radical cations is also possible.



Due to the high discharge potential of fluoride anions (2.5 V), fluorination, fluorooxygenation and fluoroacetamidation of alkenes occurs exclusively with participation of radical cations.[205–207]

The composition of oxidation products in the presence of hydrogen halide salts depends considerably on the substrate type, the nature of the solvent and electrolysis conditions (Table 7, 8). A highly selective transformation of alkenes into halohydrins and epoxides takes place in water and aqueous acetonitrile or dimethylformamide with participation of bromides; sodium and tetraalkylammonium bromides as well as readily regenerable poly(4-vinylpyridine) hydrobromide are the most effective among them.[192] The selectivity of epoxidation is greatly affected by the medium pH and the anode current density. In a solution of sodium bromide in aqueous acetonitrile, the reaction medium becomes alkaline at the final stage of electrolysis in an undivided cell; this induces the transformation of the bromohydrin formed into the epoxide. Oxidation of an alkene under similar conditions with a small amount of an acid added (normally, sulfuric and hydrochloric acid) permits bromohydrin to be produced in a nearly quantitative yield. In the case of α-arylalkenes (for example, isosafrole), glycols are formed under these conditions due to hydrolysis of α-bromo-β-hydroxyalkylarenes.[184] The selectivity of transformation of alkenes into bromohydrins and epoxides sharply decreases for an anode current density of > 20 mA cm^{-2} and an anode potential of > 1.5 V. For alkenes reactive towards halogen molecules, the optimal values are 1–2 mA cm^{-2} and 0.8 V.[179,180]

Alkene bromoalkoxylation is highly selective in anhydrous alcohols at an anode current density of 100–200 mA cm^{-2} under conditions that ensure complete cathodic reduction of the dihalides formed in a competing reaction to give the initial alkene (graphite anode, nickel cathode, 30 °C, 5.6 F mol^{-1} of electricity) (see Table 8).[182]



R^1 = Alk, Ar; R^2 = H, Alk; R^3 = Me, Et, Pr^i, Bu^t.

Table 7. Influence of electrolysis conditions on the composition of products of anodic oxidation of acyclic alkenes in the presence of halogen-containing mediators (20–45 °C).

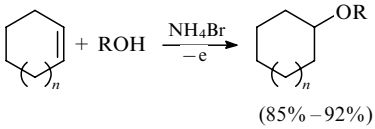
When the quantity of electricity increases to 10–14 F mol^{-1} and the nickel cathode is replaced by a brass one, or by a nickel cathode coated with powdered Raney nickel, not only dibromide but also the bromo ether formed is reduced. The reaction yields ethers and thus it can formally be regarded as a very facile and effective method for the addition of alcohols to alkenes.[63, 208]



(85%–92%)

n = 1, 2, 7; R = Me, Et, CH_2CH_2OMe.

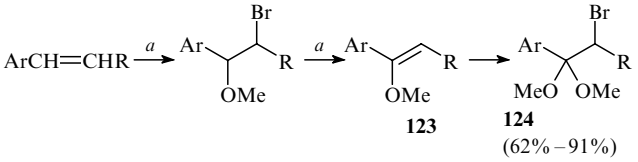
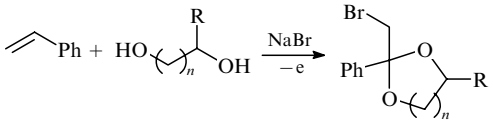
[a] Substance yield (in parentheses, current yield); [b] α-halocycloalkanone dimethyl ketals. [c] α-halocycloalkanones. [d] α-azido ketone ketal.

In more profound electrooxidation of arylalkenes in the sodium bromide electrolyte, the bromo ethers formed are dehydrobrominated and the resulting enol ethers **123** are converted into α-bromoalkyl aryl ketone dimethyl ketals **124** under the action of methanol and bromine.[63, 209]



R = H, Alk; (*a*) ACU, Pt anode, brass cathode, 220 mA cm^{-2}, 9 F mol^{-1}, MeOH, NaBr, 60 °C.

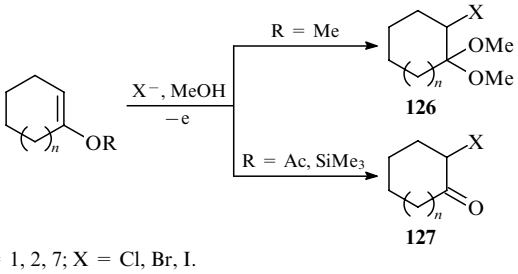
Electrolysis of styrene in ethylene-, 1,3-propylene- or 1,3-butylene glycol gives rise to cyclic ketals of bromomethyl phenyl ketones **125**.[63]



125 (66%–80%)

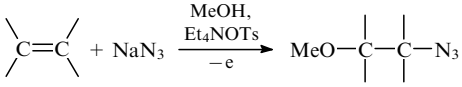
n = 1, 2; R = H, Me.

Anodic oxidation of enol ethers in the presence of ammonium bromide yields ketals of α-halo ketones **126**. When lithium, sodium, or potassium bromide is used, the yield of the ketals decreases by 20%–30%. α-Halo ketones **127** are formed in 55%–97% yields from enol acetates and trimethylsilyl ethers under similar conditions (see Table 8).[180]



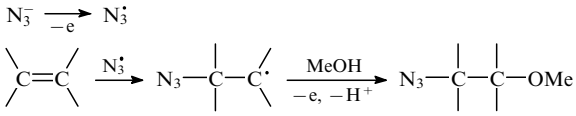
n = 1, 2, 7; X = Cl, Br, I.

Other reactions induced by anodic oxidation proceed similarly to electrochemical halooxygenation and haloacetamidation of alkenes. For example, azidomethoxylation of alkenes is documented.[194]

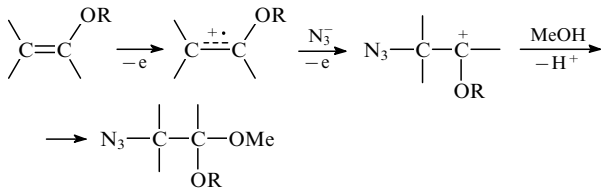


Two mechanisms have been proposed for this reaction, namely, pathway *a* for non-activated alkenes and pathway *b* for activated alkenes.[194]

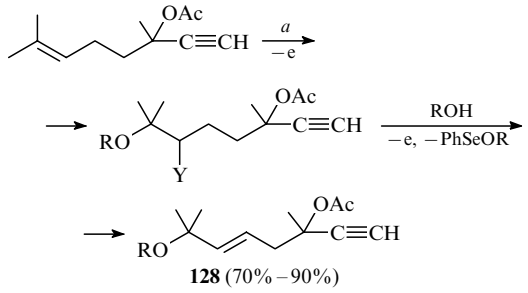
Pathway *a*



Pathway *b*



Alkene oxyselenenation – deselenenation results in allyl ethers such as **128**.[195, 196]

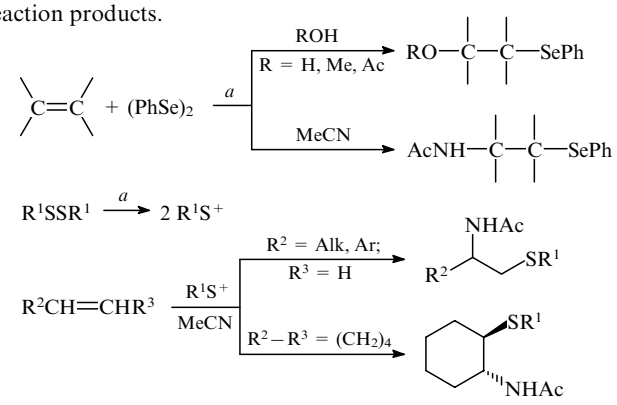


128 (70% – 90%)

R = H, Me; Y = SePh, Se(O)Ph; (*a*) ACU, Pt anode, 10 – 20 mA cm^{-2}, ROH or MeCN – H_2O, 0.1 equiv. $(PhSe)_2$, 1.5 equiv. $MgSO_4$, 60 – 70 °C.

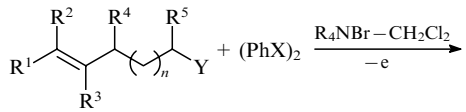
Electrolysis of alkenes in the presence of diselenides and disulfides is accompanied by hydroxy-, alkoxy- and acetamidoselenenation [196 – 198] and acetamidosulfenation.[199]

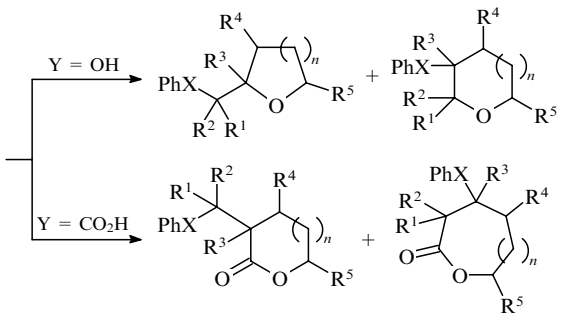
Hydroxy-, alkoxy- and acetamidoselenenation reactions are initiated by electrogenerated halogenonium ions. Under the action of these species, diphenyl diselenide and diphenyl sulfide are converted into phenylselenenyl and phenylsulfenyl halides. These electrophilic intermediates add to alkenes, and the resulting adducts react with external or internal nucleophiles to give reaction products.



(*a*) ACU, Pt anode, 6.7 – 13 mA cm^{-2}, MeOH, AcOH, MeCN – H_2O, $Et_4NX - H_2SO_4$ (X = Cl, Br, I).

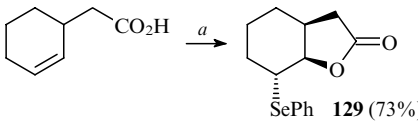
Unsaturated alcohols and acids undergo intramolecular arylthio and arylseleno esterification and lactonisation during electrolysis in the presence of disulfides and diselenides.[200 – 203] The reaction mechanism is similar to the mechanism of electrochemical alkoxyselenenation and acetamidosulfenation.





R^1, R^2, R^3, R^4, R^5 = H, Me; $R^1 - R^2$ ùöù $R^1 - R^3 = (CH_2)_m$ (m = 2, 3); n = 0, 1, 2; Y = OH, CO_2H; X = S, Se.

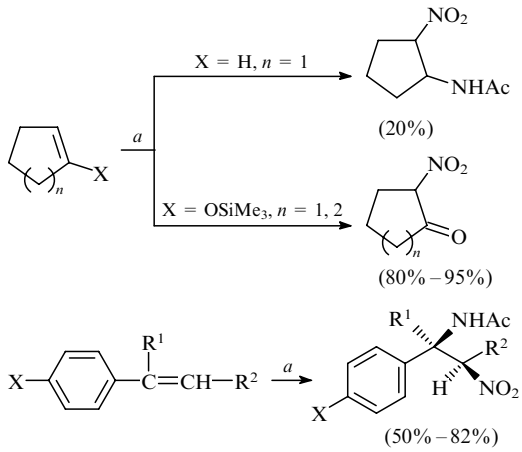
Electrochemical intramolecular phenylthio and phenylseleno esterification and lactonisation of unsaturated alcohols and carboxylic acids proceed with high selectivity (50% – 86%) only in the case where five- and six-membered rings are formed. If the substrate double bond is endocyclic as, for example, in cyclohexen-3-ylacetic acid, stereospecific *trans*-addition of phenylsulfenyl and phenylselenenyl halides takes place to give *cis*-fused bicyclic system **129**.[201, 202]



129 (73%)

(*a*) ACU, graphite anode, Cu cathode, 400 mA cm^{-2}, 6 F mol^{-1}, MeOH, 0.5 equiv. $(PhSe)_2$, NH_4Br, 15 – 20 °C.

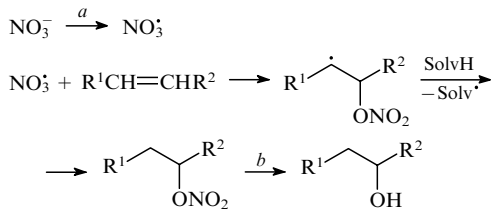
Nitronium tetrafluoroborate resulting from anodic oxidation of N_2O_4 in MeCN adds to alkenes to give nitroacetamidation products.[203, 204]



X = H, Br; R^1 = H, Me; R^2 = H, Me, Ph; (*a*) $NO_2^+ BF_4^-$ (0.25 mol litre^{-1} in MeCN), – 70 °C.

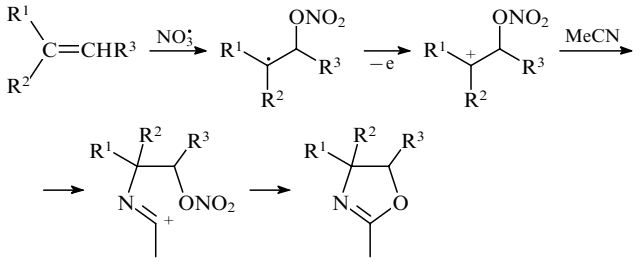
5. *o*-Nitration and diacylation

Electrochemical *o*-nitration and diacylation involve the nitrate radical NO_3 generated by the anodic oxidation of the nitrate anions.[210] In the presence of terminal alkenes and cycloalkenes, the nitrate radicals add to them, and the resulting radical adducts are converted into alkyl nitrates upon detachment of hydrogen atoms from the solvent. The resulting alkyl nitrates are transformed into the corresponding alcohols without isolation.[211]



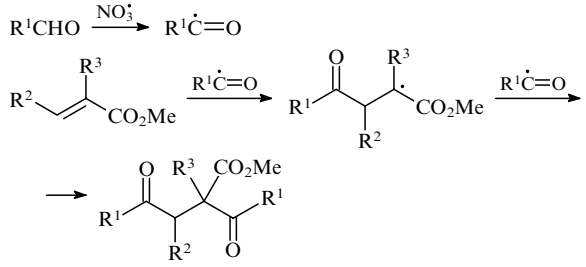
R^1 = Alk, R^2 = H; R^1-R^2 = $(CH_2)_m$ (m = 4, 6); (*a*) ACU, Pt anode, 50 mA cm^{-2}, 8 F mol^{-1}, $MeCN-H_2O-Et_2O$ (10 : 2 : 1), $LiNO_3$, 10 °C; (*b*) NaSH.

Under similar conditions of electrolysis, 1,1-di- and 1,1,2-trisubstituted alkenes furnish oxazoline derivatives.[211]



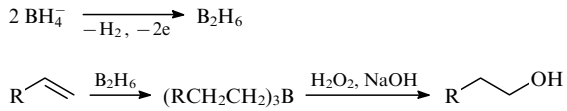
R^1 = Me, Et, n-C_9H_{19}; R^2 = Me, Et; R^3 = H, Me.

In the case where the reaction mixture contains, apart from nitrate (usually, lithium, ammonium, sodium, or potassium nitrate) and alkene, an aldehyde in a concentration sufficient for trapping nitrate radicals, diacylation of the alkene takes place.[212]



6. Hydroboration

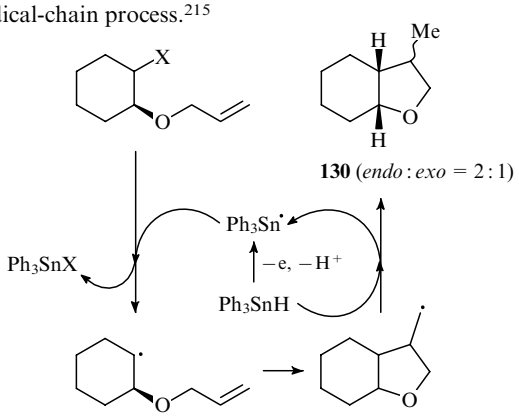
Electrochemical hydroboration of alkenes includes two stages, namely, electrogeneration of diborane from borohydride anions and addition of the diborane formed *in situ* to alkenes to give trialkylboranes; treatment of these products with hydrogen hydroperoxide in an alkaline medium results in alkanols.[213,214]



Hydroboration is carried out with the sodium iodide electrolyte under galvanostatic conditions in an undivided cell with a platinum anode and a steel cathode by passing 2 F of electricity per mole of alkene. The reaction is regio- and stereoselective and gives products in high yields. This procedure has been used to prepare primary alkanols from unsaturated and hydroxy- and acetoxy-substituted terminal alkenes (yields 64%–81%), cycloalkanols from cycloalkenes (70%–72%), (−)-*cis*-myrtanol from (−)-β-pinene (82%), *exo*-borneol from norbornene (72%), *etc*. The method is promising for organic synthesis. The electrogenerated diborane can also reduce carboxylic acids to the corresponding alcohols.[214]

7. Electrochemical cyclisation assisted by tin hydrides

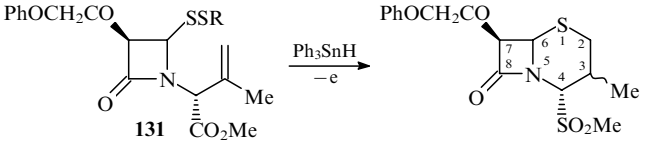
The electrochemical cyclisation assisted by tin hydrides is illustrated by transformation of 2-halocyclohexyl allyl ethers into octahydro-3-methylbenzofuran **130** (yield 65%). Tin hydrides act in this reaction as precursors of tin-centred radicals and as hydrogen atom donors, while the electric current initiates this radical-chain process.[215]



130 (*endo* : *exo* = 2 : 1)

X = Br, I; (*a*) ACD, Pt electrodes, 10 mA cm^{-2}, 0.2–0.5 F mol^{-1}, THF, Bu_4NBF_4, 1.2 equiv. Ph_3SnH, ~20 °C.

Similarly, octahydro-3-methylidenebenzofuran was prepared from 2-halocyclohexyl propargyl ethers (65%–69%), β-lactam derivative **131** was converted into dihydrocephalosporin **132**.



131

132 (80%, 3α : 3β = 1 : 2)

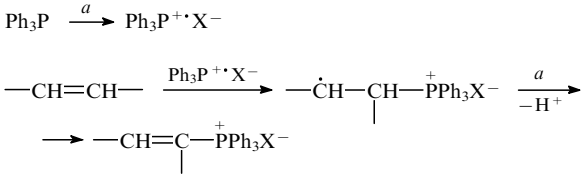
R is 2-benzothiazolyl.

These reactions can also be carried out in undivided cells. However, complete conversion of the substrate in an undivided cell required a four times greater quantity of electricity.

An advantage of the electrochemical method over the chemical methods in which azoisobutyronitrile, benzoyl peroxide, trialkylboranes, *etc*., serve as initiators[216,217] is higher stereoselectivity.

8. Phosphorylation

Indirect electrochemical phosphorylation of alkenes and cycloalkenes occurs upon the electrophilic addition of triphenylphosphinium radical cations generated by anodic oxidation of triphenylphosphine followed by electrooxidative deprotonation of the adduct thus formed. The reaction yields 1-alkenyl- and 1-cycloalkenyl-substituted triphenylphosphonium salts.[18,218–220]



X = ClO_4, BF_4; (*a*) X^-, ACU, graphite anode, Fe cathode, 1.07 mA cm^{-2}, 2 F mol^{-1}, CH_2Cl_2, 0.2 equiv. Ph_3P, 0.5 equiv. 2,6-LutHClO$_4^-$ or 1.33 equiv. K_2CO_3, N_2 atmosphere, ~20 °C.

This reaction has been used to prepare phosphonium salts from ethylene, C_5-C_8 cycloalkenes, norbornene, substituted styrenes, vinyl and allylsilanes, α,β-unsaturated compounds, *etc*. (Table 9).[218–225] When vinyl- and allylsilanes are used, desilylation of the adducts formed initially takes place, and phosphorylated alkenes are formed as the reaction products.[220–222]

Table 9. Electrochemical triphenylphosphorylation of alkenes.

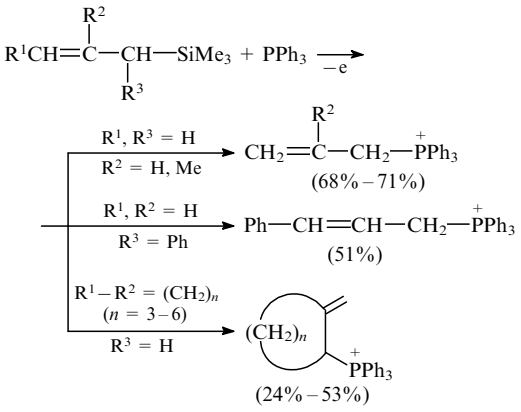
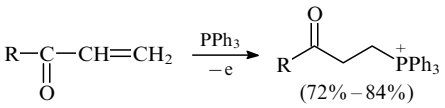
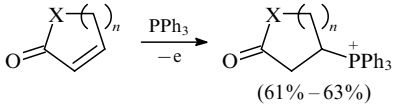
Note. Method A: ACU, graphite anode, stainless-steel cathode, 1.07 mA cm^{-2}, 2 F mol^{-1}, CH_2Cl_2, 0.2–1 equiv. of Ph_3P, 0.5 equiv. of 2,6-$LutHClO_4$ or 2,6-$LutHBF_4$, ~20 °C; method B: ACU, glass carbon anode, Pb cathode, 1.1 mA cm^{-2}, 1.8 F mol^{-1}, CH_2Cl_2, 2 equiv. of Ph_3P, 0.5 equiv. of 2,6-$LutHClO_4$ or 2,6-$LutHBF_4$, K_2CO_3, ~20 °C; method C: ACU, glass carbon anode, Pb cathode, 1 mA cm^{-2}, 2 F mol^{-1}, MeCN, 1–3 equiv. of Ph_3P, 0.5 equiv. of $LiBF_4$, N_2 atmosphere, ~20 °C.



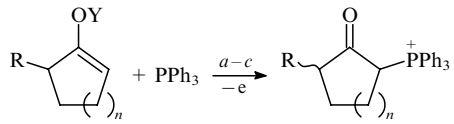
Electrochemical reactions of triphenylphosphine with vinyl ketones, acrolein, cycloalk-2-enones, ethyl acrylate, acrylamide [220, 223] and cycloalkenol ethers [220, 224] give rise to phosphorylated ketones.



R = H, Me, Et, EtO.



X = CH_2O, n = 1, 2.



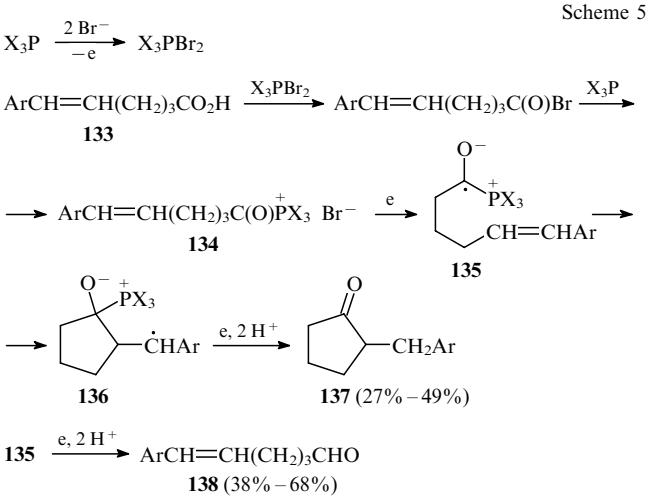
R = H, Me; n = 1–3; (*a*) Y = Ac (47%–96%); (*b*) Y = $P(O)(OEt)_2$ (23%–51%); (*c*) Y = $SiMe_3$ (11%).

Electrochemical phosphorylation of carboxy-substituted alkenes **133** by phosphines with Bu_4NBr as the supporting electrolyte results in acylphosphonium salts **134**, which are readily reduced at the cathode under the conditions of diaphragmless electrolysis to give intermediates **135**. These undergo radical cyclisation, electroreduction and protonation and are thus converted first into cyclic intermediates **136** with separated anionic, cationic and radical centres and then into cyclopentanones **137**. The reaction is carried out in an undivided cell (graphite electrodes, 2.4 mA cm^{-2}, 4 F mol^{-1}, CH_2Cl_2, 3 equiv. of X_3P (X = Ph, Bu^n), 1 equiv. of Bu^n_4NBr, 2 equiv. of $MeSO_3H$). Together with cyclopentanones **137**, aryl-substituted alkenals **138** are produced (Scheme 5).[225]

This electrochemical reaction is an example of successful use in organic synthesis of paired electrolysis in which the processes occurring at both the cathode and the anode are involved in the assembling of the final product.

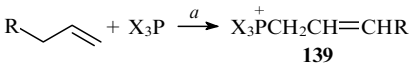
By phosphorylation of alk-1-enes with the phosphines X_3P in the presence of thiols RSH (R = Pr^n, Bu^n) under conditions of electrolysis differing substantially from those used in the studies cited above,[218–225] alk-2-enylphosphonium salts **139** have been

Scheme 5



X = Ph, Bu^n; Ar = 4-YC_6H_4, Y = H, Me, MeO, Cl, Br.

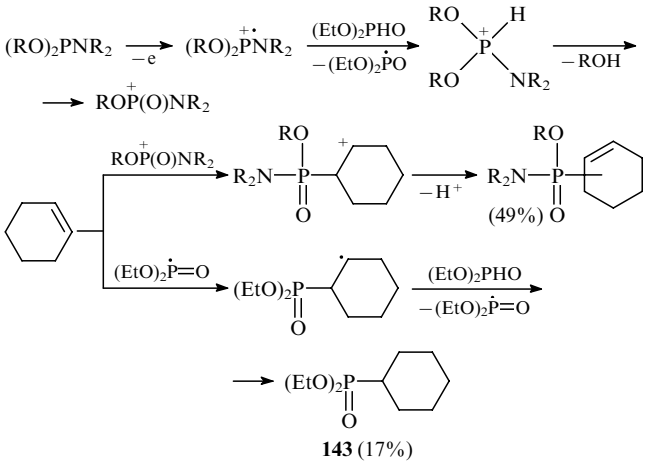
prepared (yields 46%–85%). The products of alkene thioalkylation are formed as side products.[226]



R = n-C_5H_{11}, n-C_6H_{13}; X = Mes, Bu^n; (*a*) ACD, Pt anode, Ni cathode, 4 mA cm^{-2}, 2.2–4.8 F mol^{-1}, MeCN, 0.05 equiv. X_3P, 0.75 equiv. RSH, 0.5 equiv. $NaClO_4$, 0.6 equiv. Na_3PO_4.

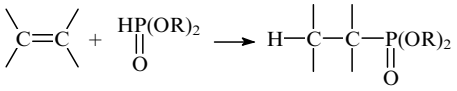
The processes of regiospecific phosphorylation of alkenes presented in Table 9 take place only with triphenylphosphine. If it is replaced by trialkylphosphines, trialkyl phosphites, dialkyl trimethylsilyl phosphites or phosphorous amides, the reactions yield mixtures of phosphorylation products with different positions of the C=C bond in the alkenyl or cycloalkenyl fragment. For example, electrolysis of Et_3P, Pr^n_3P or Bu^n_3P in the presence of cycloalkenes gives rise to regioisomeric cycloalkenyl phosphonium salts with the double bond in positions 1, 2 or 3.[227] This difference between the behaviours of triphenylphosphine and other phosphines in this reaction is related, in the researchers' opinion, to higher thermodynamic stability of alk-1- and cycloalk-1-enyltriphenylphosphonium salts compared to the corresponding trialkylphosphonium salts caused by the effective stabilisation of the positive charge with participation of the π-systems of the phenyl groups. Phosphorylation of hex-1-ene and cyclohexene with trialkyl and dialkyl trimethylsilyl phosphites gives rise to three types of isomeric products, while the reactions involving phosphorous mono- and diamides, yield two types of isomers.[228,229] Phosphorous amides are more basic than alkyl phosphites; thus, they can bind more efficiently the protons generated during the electrolysis, and the prototropic isomerisation of the intermediates is suppressed (Scheme 6).[229]

The yields of alk(cycloalk)-2-enylphosphonates of type **140**, **141** are 2–4 times as high as the yields of other regioisomers. In some cases, they are formed as the only products.[228,229] In the presence of diethyl phosphite or *O*,*O*-dibutyl phosphorothioite as a mediator which changes the nature of the phosphorus-containing active intermediates, the regiodirectivity of phosphorylation of alkenes by phosphorous mono- and diamides changes towards the predominant formation of alk(cycloalk)-1-enyl-substituted phosphonamidates of type **142**. For example, cyclohexenyl phosphonamidates **141** and **142** (1:2 ratio) were prepared in the presence of diethyl phosphite, together with the side product diethyl cyclohexylphosphonate (**143**).[229]



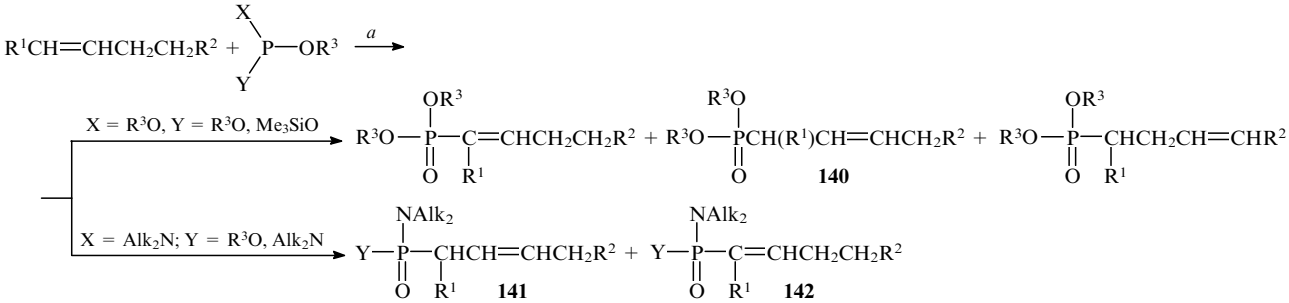
9. Hydrophosphonylation and hydrothiophosphonylation

Indirect electrochemical hydrophosphonylation of alkenes with dialkyl phosphites takes place in the presence of trialkylphosphines, trialkyl and dialkyl trimethylsilyl phosphites [Bu^n_3P, $(Pr^iO)_3P$, $(EtO)_2POSiMe_3$].[230]



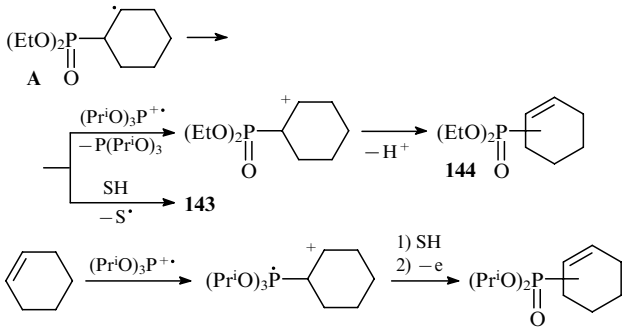
The promotory effect of these compounds is based on electric generation of the radical cations $X_3P^{+\bullet}$ at potentials at which dialkyl phosphites and alkenes are electrochemically inactive (0.8–1.6 V). The products of hydrophosphonylation are formed upon the detachment of hydrogen atoms from dialkyl phosphites by the $X_3P^{+\bullet}$ radical cations and subsequent addition of the generated $(RO)_2P(O)^{\bullet}$ radicals to alkenes. A chain transfer takes place in the reaction between the radical adducts and dialkyl phosphites.[230] The products of hydrophosphonylation of alkenes, for example, cyclohexene,[230] are formed selectively only with the assistance by trialkylphosphines.

Scheme 6

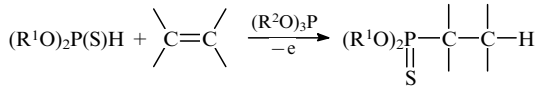


R^1, R^2 = H, Bu^n; R^1-R^2 = $(CH_2)_2$; R^3 = Alk; (*a*) ACD, Pt anode, 0.1–8 mA cm^{-2}, 1.1–1.7 F mol^{-1}, MeCN, 5–6 equiv. of alkene, 0.25 equiv. $NaClO_4$, 8 equiv. Na_3PO_4.

Trialkyl and dialkyl trimethylsilyl phosphite-initiated reactions give rise to saturated and unsaturated phosphonates derived from the mediator and the dialkyl phosphite. The triisopropyl phosphite-assisted reaction of cyclohexene with diethyl phosphite yields eight products including diethyl and diisopropyl cyclohexyl-, cyclohex-1-enyl-, cyclohex-2-enyl- and cyclohex-3-enylphosphonates. Presumably,[230] this is due to active oxidation of the intermediate radical adducts **A** by the radical cations generated from triisopropyl phosphite and to addition of the latter species to cyclohexene.

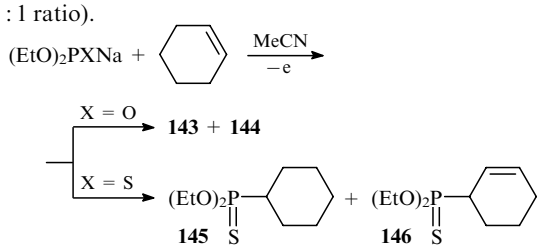


Similarly, the radical cations electrogenerated from trialkyl phosphites initiate hydrothiophosphonylation of alkenes with *O*,*O*-dialkyl phosphorothioites.[231,232]



R^1 = Et, Pr^i, Bu; R^2 = Alk.

Joint electrolysis of alkenes with dialkyl phosphites or *O*,*O*-dialkyl phosphorothioites or with their sodium or lithium salts affords mixtures of alkene hydrophosphonylation (hydrothiophosphonylation) products and the products of substitution of the diethoxyphosphoryl or -thiophosphoryl group for the allylic hydrogen atom.[231–235] Thus the reaction of cyclohexene with sodium diethyl phosphite yields diethyl cyclohexyl- and cyclohexenylphosphonates **143** and **144** (overall yield 52%, 2 : 1 ratio).[232,233] A similar reaction with sodium *O*,*O*-diethyl phosphorothioite gives compounds **145** and **146** in a total yield of 87% (11 : 1 ratio).



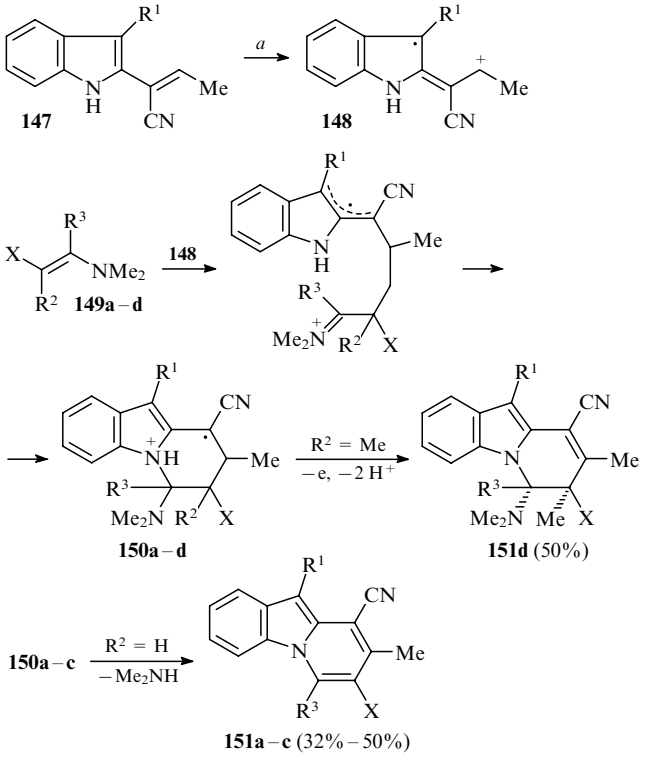
X = O, S.

In the reactions of alkenes with dialkyl phosphorothioites, the formation of phosphorylation products is completely suppressed when a 1 : 1 acetonitrile – THF mixture is used as the solvent.[232]

10. Radical-cation [4 + 2]-cycloaddition of styrenes and enamines to vinylindoles and -pyrroles induced by anodic oxidation

The radical-cation [4 + 2]-cycloaddition reactions have been vigorously studied during the last two decades. Owing to the very low activation barriers, they proceed tens or hundreds times as fast as the ordinary Diels – Alder reactions; hence, they can be performed under milder conditions. The radical-cation [2 + 4]-cycloaddition is highly regio- and chemoselective. Moreover, they can be carried out for dienophiles with electron-donating substituents at the double bond, which do not enter into conventional Diels – Alder reaction. There are strong grounds for believing that they will find extensive application in organic synthesis.[236]

The [4 + 2]-cycloaddition of enamines to 2-vinylindoles or -pyrroles acting as dienes induced by anodic oxidation[237–240] proceeds efficiently only in the case where the difference between the oxidation potentials of dienophiles and dienes does not exceed 500 mV.[241] To avoid polymerisation, there should not be hydrogen atoms at the 3-position of the pyrrole or indole ring. The radical-cation cycloaddition of enamines to 2-vinylindoles **147** includes generation of radical cations **148** at the anode, their addition to enamines **149a–d** and subsequent cyclisation, electrooxidation and deprotonation of the radical-cation cycloadducts **150a–d** to give cycloaddition products **151a–d**.[239,240] The structure and the yield of the reaction product depend most of all on the structure of the initial substrates. Electrolysis of 2-vinylindoles **147** together with methyl β-(*N*,*N*-dimethylamino)acrylate (**149a**) or substituted β-(*N*,*N*-dimethylamino)acrylonitriles **149b–d** affords compounds of the pyrido[1,2-*a*]indole series (**151a–d**), which are of interest as building blocks in the synthesis of indole alkaloids.[237,239]



(*a*) PCU, graphite anode, 0.49 – 0.67 V, CH_2Cl_2 – MeCN (1 : 1) or MeCN, 0.1 equiv. $LiClO_4$.

Compounds **149–151**	R^1	R^2	R^3	X	Yield of **151** (%)

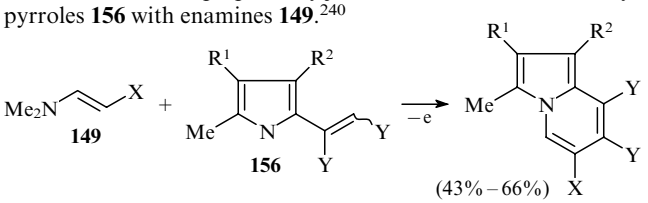
153 → **155** (52% – 53%)

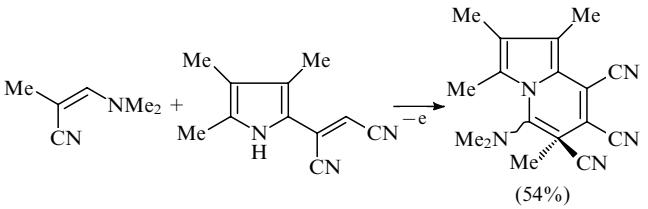
(*a*) PCU, graphite anode, 0.49 – 0.67 V, CH_2Cl_2 – MeCN (1 : 1) or MeCN, 0.1 equiv. $LiClO_4$.

Polysubstituted indolizines, difficult to synthesise by other methods, have been prepared by joint electrooxidation of 2-vinylpyrroles **156** with enamines **149**.[240]

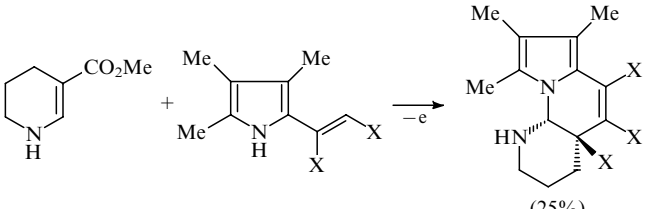


149 + **156** → (43% – 66%)

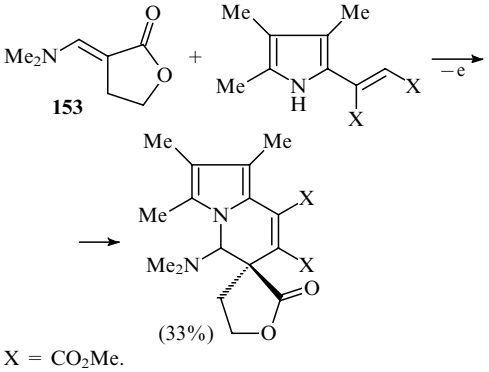
X = CO_2Me, CN, NO_2; Y = CO_2Me, CN; R^1, R^2 = Me, CO_2Me.



(54%)



(25%)



153 → (33%)

X = CO_2Me.

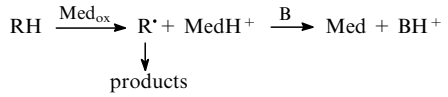
The tentative asynchronous mechanism of the radical-cation cycloaddition[241, 242] allows the formation of the final product as a mixture of *cis*- and *trans*-isomers because rotation around the C – C bond in the initial radical-cation adduct is possible. The formation of only *trans*-isomers indicates that cyclisation occurs much faster than the rotation around the C – C bond. Stabilisation of the radical intermediates by radical-stabilising substituents such as nitrile or alkoxycarboxyl group is favourable for the reaction.[238, 239]

11. Reactions of alkenes induced by electrooxidation of variable-valence metal compounds

Compounds of variable-valence metals (manganese, copper, palladium, ruthenium, nickel, cobalt, cerium, and thallium) act in electrochemical processes as mediators (Med) and participate in the electron transfer at the anode and in the reaction of the oxidised form of the mediator (Med_{ox}) with the substrate (RH). The reaction between RH and Med_{ox} can follow two pathways, one giving rise to a radical cation (pathway *a*) and one giving rise to a radical (pathway *b*).

Pathway *a*

Pathway *b*



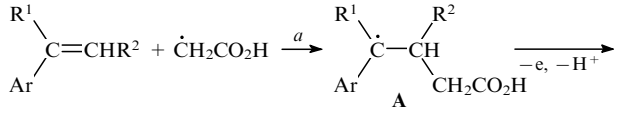
B is proton acceptor.

In many cases, compounds and complexes of variable-valence metals are used in these processes as binary mediator systems in combination with other mediators including organic compounds (CH acids, benzoquinone or triarylamines).

a. Reactions induced by electrooxidation of manganese compounds

Despite the fact that the addition of carboxylic acids, aldehydes, ketones and amines to alkenes initiated by manganese triacetate or oxidative systems based on it have been comprehensively studied,[243, 244] their extensive use is held up, most of all, by the need to introduce relatively large amounts of initiators and by problems associated with their regeneration. In the last decade, a strategy has been developed according to which this type of electrochemical reaction is carried out in the presence of a catalytic amount (0.03 – 0.2 equiv.) of $Mn(OAc)_2$, acting as a mediator and the source of electrogenerated manganese triacetate. Examples of the addition of CH acids to alkenes initiated by $Mn(OAc)_2$-based oxidative systems are listed in Table 10.

Using the $Mn(OAc)_2$–$Cu(OAc)_2$ mediator system, γ-lactones have been obtained in acceptable yields from acetic acid and styrenes,[246, 250] and alk-2-enyl- and cycloalk-2-enyl-substituted cyanoacetic esters were synthesised from ethyl cyanoacetate, alkenes and cycloalkenes.[246, 247] In these reactions the carboxymethyl and (ethoxycarbonyl)cyanomethyl radicals together with their adducts with alkenes are formed as intermediates; the former species result from single-electron oxidation of acetic acid and ethyl cyanoacetate by electrogenerated $Mn(OAc)_3$ and the latter arise upon the addition of the primary radicals to alkenes. These secondary intermediates (**A** and **B**) are further oxidised by regenerable Cu(II) ions, which react with radical adducts **A** and **B** by different mechanisms, namely, single-electron transfer for **A** and oxidative β-deprotonation for **B**.[246, 247]



A

Table 10. Electrochemical addition of CH acids to alkenes initiated by manganese diacetate-based oxidative systems.

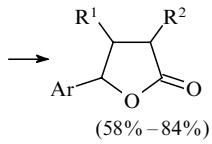
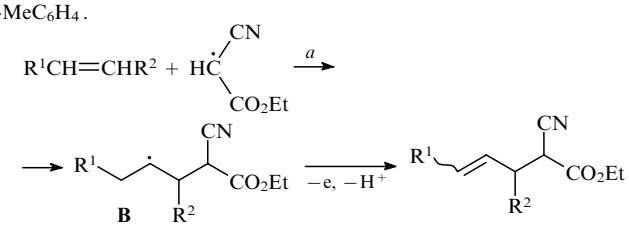
Note. Method A: ACD, graphite anode, 20–30 mA cm^{-2}, 2 F mol^{-1}, AcOH–AcOEt (13:3), 0.03–0.25 equiv. of AcONa, $Mn(OAc)_2 \cdot 4H_2O$, 60–70 °C; method B: ACD, graphite anode, 0.2–0.5 mA cm^{-2}, 2 F mol^{-1}, 0.1 equiv. of AcOH, Bu_4NBF_4, $Mn(OAc)_2 \cdot 4H_2O$, 60 °C. [a] Succinimido.



(58%–84%)

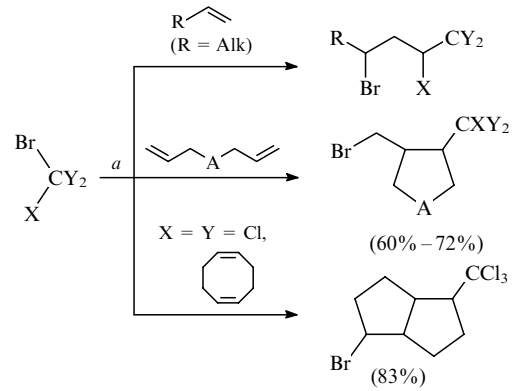
R^1 = H, Me; R^2 = H, Ph, CO_2Et, CH_2OH; Ar = Ph, 4-ClC_6H_4, 4-MeC_6H_4.



(44%–58%)

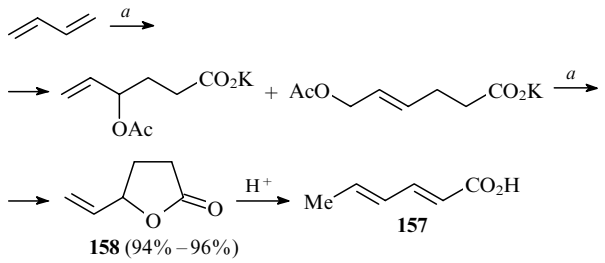
R^1 = $Me(CH_2)_n$ (n = 2, 4, 6), R^2 = H; R^1-R^2 = $(CH_2)_n$ (n = 2–5, 9); (*a*) ACD, graphite anode, 10 mA cm^{-2}, 2 F mol^{-1}, AcOH–Ac_2O (2:1), AcONa, 0.065 equiv. $Mn(OAc)_2 \cdot 4H_2O$, 0.025 equiv. $Cu(OAc)_2 \cdot H_2O$, 95–97 °C.

The binary mediator system, $Mn(OAc)_2$–$NCCH_2CO_2Et$, proved to be a good initiator of free-radical chain addition of polyhalomethanes[251] (bromomalonic esters and methyl bromoacetate) to alkenes.[251,252]



X = Y = Br, Cl; X = Br, Y = F; A = O, NAc; (*a*) ACU, graphite anode, 0.06–0.6 F mol^{-1}, AcOH, AcOK, 0.05 equiv. $Mn(OAc)_2$, 0.1 equiv. $NCCH_2CO_2Me$, 40 °C.

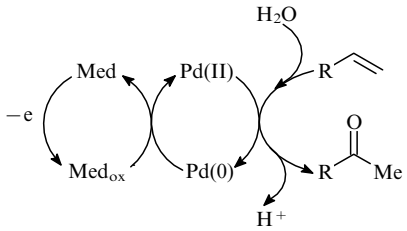
Certain progress has taken shape in the field of practical implementation of indirect electrooxidation with manganese diacetate as a mediator. For instance, electrosynthesis of a precursor of sorbic acid (**157**), namely, γ-vinyl-γ-butyrolactone (**158**), from butadiene and acetic acid, which allows preparation of kilograms of this compound, has been developed.[253]



(*a*) ACU, AcOH – Ac_2O (1 : 1), AcONa, 0.1 equiv. $Mn(OAc)_2 \cdot 4H_2O$, 0.037 equiv. $Cu(OAc)_2 \cdot H_2O$, 95 – 125 °C.

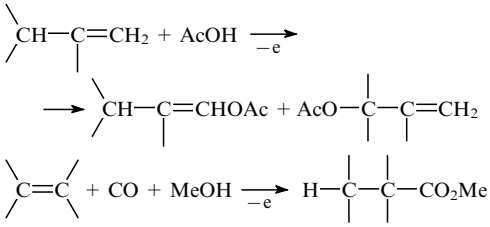
b. Reactions induced by electrooxidation of palladium, ruthenium, osmium and silver compounds

The chemical prototypes of these reactions such as the Wacker process of oxidation of α-alkenes to methyl ketones,[254–256] ethylene to vinyl acetate,[257] hydroalkoxycarbonylation[258–260] and epoxidation of alkenes,[261] suffer from a number of drawbacks including the low rate of oxidation of alkenes with internal double bonds, the explosive risk from the gaseous mixtures of alkenes with oxygen, fast corrosion of the equipment induced by corrosive reaction media, *etc*. Numerous publications have been devoted to the search for new procedures for performing the above-listed reactions.[262–277] Methods of indirect anodic oxidation of alkenes using redox systems consisting of $Pd(OAc)_2$ and an organic mediator (hydroquinone, benzoquinone, their analogues or triarylamines) have been developed to date.[263–269] The mediator acts as an electrogenerated oxidant with respect to Pd(0), which results from the reaction of alkene with Pd(II).



Med is hydroquinone or $(4\text{-}BrC_6H_4)_3N$; Med_{Ox} is benzoquinone or $(4\text{-}BrC_6H_4)_3N^{+\cdot}$.

This procedure has been used to perform electrooxidative transformation of alkenes into ketones[263–266] or into vinyl or allyl acetates.[267,269] Electrooxidation of alkenes in alcohols in the presence of CO yields esters of alkanoic acids (Table 11).[268]



Ruthenium and silver polypyridyl complexes, the ruthenium heteropolyanion $[SiRu(H_2O)W_{11}O_{39}]^{5-}$ and potassium osmate have also shown themselves as effective mediators in indirect anodic oxidation of alkenes. Thus the complex $[Ag(bipy)_2]^+$ (bipy is 2,2′-bipyridine) catalyses epoxidation of alkenes.[270]

Table 11. Indirect anodic oxidation of alkenes with mediator systems containing catalytic amounts (0.01 – 0.1 equiv.) of $Pd(OAc)_2$ or $PdCl_2$.

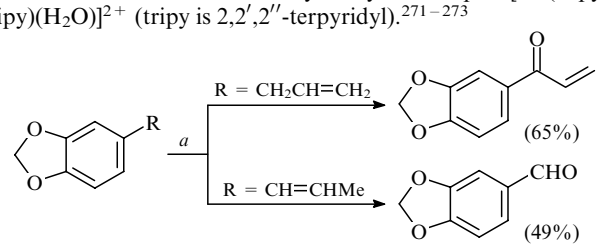
H	H	Bu^n	– (30)
H	Me	CO_2Bu^i	87 (21)
n-C_5H_{11}	H	CO_2Me	80 (20)
MeO_2CCH_2	H	CO_2Me	90 (20)

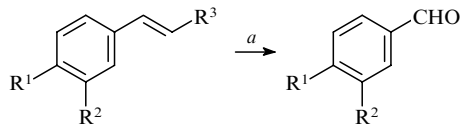
L = bipy; (*a*) ACU, Pt or graphite anode, MeCN – H_2O (19 : 1), $LiClO_4$, 0.0125 – 0.05 equiv. AgOAc, 0.025 – 0.1 equiv. L.

Oxidation of allylic and benzylic C – H bonds and rupture of double bonds in alkenes are catalysed by the complex $[Ru(tripy)(bipy)(H_2O)]^{2+}$ (tripy is 2,2′,2″-terpyridyl).[271 – 273]



(*a*) PCD, Pt anode, 0.8 V, 3.9 F mol^{-1}, $Bu^tOH - H_2O$ (1 : 1), 0.065 equiv. $[Ru(tripy)(bipy)(H_2O)]^{2+}$, pH 6.8 (phosphate buffer), 30 °C.

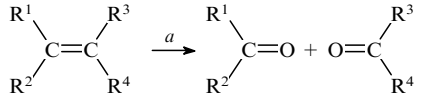
Rupture of double bonds in alkenes also takes place in the presence of $SiRu(H_2O) \cdot W_{11}O_{39}^{5-} - NaIO_3$ [274] and $K_2OsO_2(OH)_4 - HIO_4$ [275] mediator systems.



R^1	R^2	R^3	The yield of aldehyde (%)
H	H	Ph	79
MeO	H	Me	59
MeO	H	4-$MeOC_6H_4$	38
OCH_2O		Me	70

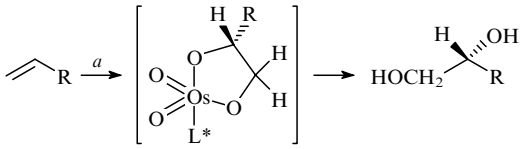
(*a*) ACD, PbO_2 anode, 8 mA cm^{-2}, 3.5 – 5.5 F mol^{-1}, $CH_2Cl_2 - H_2O$, 0.0034 – 0.006 equiv. $SiRu(H_2O)W_{11}O_{39}^{5-}$, 2 equiv. $NaIO_3$, 50 °C.

The $K_2OsO_2(OH)_4 - [K_3Fe(CN)_6]$ system catalyses alkene dihydroxylation and the subsequent cleavage of diols giving rise to ketones (total yields 62% – 91%).[276, 277]



R^1, R^3 = H, Me, Ph; R^2 = H, Me; R^4 = Ph, $(CH_2)_2OCOPh$, 3,4-$(OCH_2O)C_6H_3$; (*a*) ACU, PbO_2 anode, Pt cathode, 5.6 mA cm^{-2}, 5 F mol^{-1}, MeCN – H_2O (10 : 3), Et_4NOTs, 0.04 equiv. $K_2OsO_2(OH)_4$, 0.5 equiv. HIO_4.

The electrochemical asymmetric dihydroxylation of alkenes in the presence of the $K_2OsO_2(OH)_4 - [K_3Fe(CN)_6]$ system and the Sharpless ligand is markedly superior to the corresponding chemical process in enantioselectivity and in yields of target products.[278] The main advantage of the electrochemical variant is that it implies the use of catalytic amounts of the osmate (0.002 equiv.) and the electrically regenerable oxidant, $[K_3Fe(CN)_6]$ (0.1 equiv.). In the classical version, at least a stoichiometric amount of the oxidant is required. The electrochemical dihydroxylation of styrene, 2-methyl-1-phenylpropene, *trans*-stilbene and 1,2-dihydronaphthalene results in the corresponding chiral diols; the degree of conversion is 90% – 97% and the enantiomeric yield is 90% – 100%.[276, 277]



L* is the Sharpless ligand.

R	The yield of diol (%)	Configuration (*ee*)

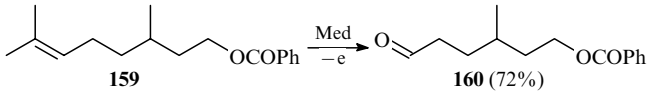
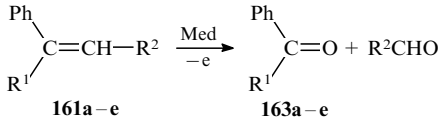
12. Indirect electrochemical rupture of double bonds in alkenes

Indirect electrochemical rupture of double bonds in alkenes takes place with assistance of mediators and mediator systems such as manganese sulfate,[279] methanesulfonate and cerium sulfate,[280, 281] triarylamines,[80] $RuSi(H_2O)W_{11}O_{39}^{5-} - NaIO_3$,[274] $K_2OsO_2(OH)_4 - HIO_4$,[275] PhSSPh – NaBr [80] and $CuCl_2 - O_2$.[282] Two procedures have been developed: a single-stage procedure in which the electric generation of the oxidised form of the mediator (Med_{ox}) and the substrate oxidation by this species take place simultaneously in an electrolytic cell and a two-stage procedure in which the electric generation of Med_{ox} takes place in the cell, while the alkene oxidation by Med_{ox} occurs in a separate reaction vessel. These methods have been used to cleave the double bonds in 3,7-dimethyloct-6-enyl benzoate (**159**) in order to prepare 4-methyl-6-benzoyloxyhexanal (**160**);[275] and in styrenes (**161a – d**),[276, 280, 282] *trans*-stilbene (**161e**),[274, 275] anethole (**162a**)[275] and isosafrole (**162b**)[80, 271, 275, 276, 279] in order to prepare aromatic carbonyl compounds (**163a – d** and **164a,b**). The conditions of synthesis and the product yields are summarised in Table 12.

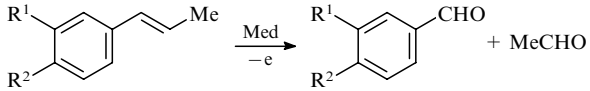


159 **160** (72%)



161a – e **163a – e**

$R^1 = R^2 = H$ (**a**); R^1 = Me, R^2 = H (**b**); R^1 = Ph, R^2 = H (**c**); R^1 = H, R^2 = Me (**d**); R^1 = H, R^2 = Ph (**e**).



162a,b **164a,b**

R^1 = H, R^2 = MeO (**a**); $R^1 - R^2 = OCH_2O$ (**b**).

Electrooxidative cleavage of the double bonds in alkenes solves the same problems as chemical methods such as ozonolysis,[283 – 289] oxidation with chromic [290, 291] or cerium reagents,[292]

Table 12. Indirect electrooxidative cleavage of the C=C bond in alkenes.

[c] $PhCH(OMe)_2$. [d] PhCHO.

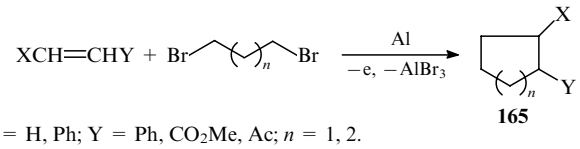
the RuO_4–MeCHO–O_2 system,[293] *etc.*[294,295] The drawbacks peculiar to chemical methods have been largely overcome in the electrochemical method for the cleavage of double bonds in alkenes.

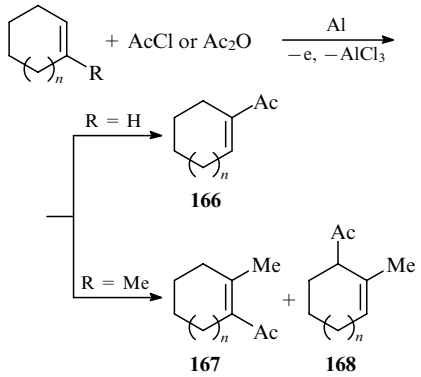
13. Reactions involving sacrificial metallic anodes

Electrochemical alkylation or acylation of alkenes with organic halides and acyl halides giving rise to C–C bonds is carried out using sacrificial metallic (usually, aluminium, zinc and magnesium) anodes. Their role is to suppress the formation of halogen molecules and thus to prevent halogenation of alkenes. The electrochemical formation of a C–C bond is an alternative to the reaction including deprotonation of organic CH acids induced by metals, organometallic compounds or strong bases and subsequent alkylation with the organic halide. In this case, the C–C bond formation is usually accompanied by side reactions, namely, O-alkylation, dialkylation or condensation of the substrate. In the processes with sacrificial anodes, the C–C bond is formed more selectively. For example, the reactions of activated alkenes with organic 1,1-, 1,3- and 1,4-dihalides,[296] non-activated alkenes with acylating reagents,[297,298] and cyclisation of unsaturated bromoacetals [299] afford compounds **165**–**169** in high yields.



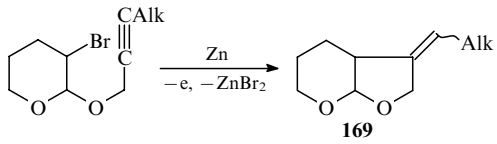
165

X = H, Ph; Y = Ph, CO_2Me, Ac; n = 1, 2.



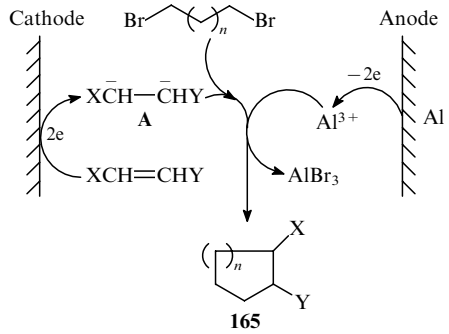
166 **167** **168**

R = H, Me; n = 1, 2.



169

Besides preventing the generation of molecular bromine, a sacrificial aluminium anode participates (through Al^{3+} ions) in stabilisation of the type **A** dianions generated by cathodic reduction of the activated alkene.

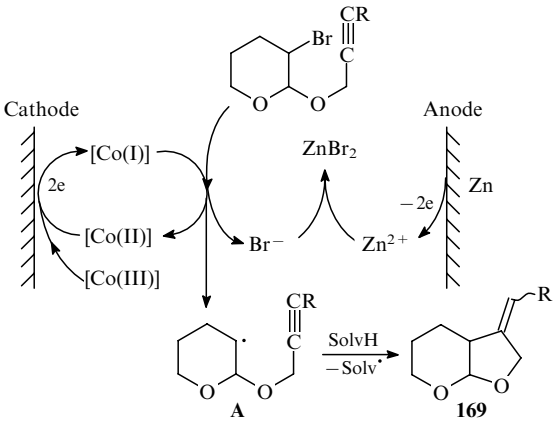


165

The substituted cycloalkanes **165** are formed in reasonable yields (30%–60%) only from activated alkenes, namely, esters of maleic, fumaric, cinnamic and acrylic acid and 4-phenylbut-3-en-2-one, upon reaction with 1,3- and 1,4-dihaloalkanes. The reaction proceeds with high stereoselectivity (isomer ratio *trans* : *cis* > 10 : 1). Cyclobutane derivatives are obtained by this method in very low yields, and only from 1,2-dichlorides. When 1,2-dibromides are used, electrochemical debromination takes place. In the reaction of dimethyl maleate with 1,3-dibromopropane, dimethyl 2-allylbutanedioate (yield 10%) and 1,2-cyclopentadicarboxylate (50%) are formed.[296]

In acylation of cycloalkenes with acetyl chloride, an aluminium anode not merely suppresses the generation of molecular chlorine but also catalyses the reaction, due to the influence of $AlCl_3$ formed during the electrochemical process. The electrochemical acylation occurs more selectively than the classical Friedel–Crafts reaction.[300–304] Joint electrolysis of equimolar amounts of acetyl chloride and cyclohexene or cycloheptene in an undivided cell at −10 to −5 °C (3 F mol^{-1}) results in complete conversion of cycloalkenes into 1-acetylcycloalkenes **166** (yields 60%–80%).[297,298] The transformation of 1-methyl-substituted cycloalkenes gives rise to two isomers, 1-acetyl-2-methylcycloalkenes **167** and 3-acetyl-2-methylcycloalkenes **168**, in a total yield of 65%–85%; the compounds **168** markedly predominate. Elec-

trochemical acetylation of acyclic alk-1-enes involves only the terminal carbon atom but the yields are relatively low (22% – 25%). The side products formed are α,β-dichlorides (1% – 10%), which become the only reaction products when a carbon or platinum anode is used.



The intramolecular electrochemical cyclisation of unsaturated bromoacetals to dioxabicycloalkanes **169** is an example in which the use of sacrificial metallic anodes is combined successfully with the catalysis of the cathodic single-electron reduction of organic halides with cobaloxime. The cathodic generation of Co(I) complexes, single-electron reduction of bromoacetal to radical **A** by these complexes, cyclisation of the radical and subsequent transformation into the final product (yields 70% – 77%) are the key steps of this process.

Electrochemical reactions of alkenes with sacrificial metallic anodes provide good results in many cases where the chemical analogues either do not occur at all or are hardly suitable due to the low yields of the target products. This also eliminates the necessity of performing a labour-consuming and, in some cases, unsafe step of the synthesis of organometallic compounds. By using high current densities (up to 1 A dm^{-2}), one can produce substantial amounts of reaction products.

IV. Conclusion

Although electrochemical reactions are a powerful tool for transforming and assembling organic molecules, they are still used in most cases only by specialists and have not become a routine method of chemical synthesis. We hope that this review would be useful not only as a source of specially selected information but also as a manual for the practical use of electrochemical reactions for solving problems of organic synthesis. From this standpoint, reactions carried out in an electrolytic cell not separated into electrode compartments, which are simple in experimental implementation and require much less electricity, are more advantageous. The review demonstrates the substantial progress achieved in recent years in the investigation of alkene reactions induced by anodic oxidation and in development, on this basis, of theoretical and procedural aspects of modern organic chemistry. First of all, this refers to indirect anodic oxidation of alkenes with assistance by inorganic and organic mediators and mediator systems. Study of electrochemical processes involving these systems made it possible not only to establish the regularities and propose mechanisms of transformation of alkenes into functionally substituted products but also to elaborate simple methods which ensure high degrees of alkene conversion with minimum electricity consumption to give compounds the synthesis of which by chemical methods is either impossible or difficult from the experimental standpoint. Substantial progress has also been achieved in the study of electrochemical cyclisation, [4 + 2]-cycloaddition, phosphorylation, rupture of double bonds, and reactions involving sacrificial anodes. Methods of electrochemical transformation of alkenes and other organic compounds under conditions of diaphragmless electrolysis (in which both anodically and cathodically induced processes are involved in the assembling of the final product) have been developed. Vivid examples of this type of transformation are cyclisation of carboxy-substituted arylalkenes to give 2-benzylcyclopentanones in the presence of a tertiary phosphine (Scheme 5) [225] and indirect electrochemical reduction of carboxylic acids to the corresponding alcohols with assistance by the same reagent.[305] In our opinion, the scope of application of organic electrosynthesis should be extended. This is largely due to the fact that electric current would remain one of the most available, inexpensive and facile oxidants and reductants.

IV. Electronic absorption spectra of porphyrins and metalloporphyrins 595

Abstract. The data of IR, ^{1}H NMR and electronic absorption spectroscopy of porphyrins and their precursors and derivatives are analysed, systematised and generalised. The bibliography includes 105 references.

I. Introduction

Problems of spectroscopy of porphyrins have been considered in detail in a number of papers and monographs (see, for example, Refs 1 – 8). However, the last 10 – 15 years have been marked by impressive progress in the synthetic chemistry of porphyrins resulting in the determination of the spectral characteristics of new heterocyclic compounds (porphyrins and their intermediates) with very complex structures. It should be noted that most studies dealt with the spectra of particular porphyrins and their precursors with the aim of establishing the structures of the newly synthesised compounds. However, the results of investigations by different spectral methods, which were performed under different conditions and using a limited number of compounds, cannot necessarily be compared.

In order for the relationship between the structure and the spectral properties of complex multicontour chromophores (among which are, undoubtedly, porphyrins) to be revealed, comprehensive investigation of a diversity of compounds whose structures vary from simple to complex must be carried out. Pyrrole intermediates are of obvious interest because they can be used to follow changes in the spectral characteristics as the macrocycle undergoes chemical modifications. In the present review, we analyse, systematise and generalise the recent data of IR, ^{1}H NMR and electronic absorption spectroscopy of porphyrins and their derivatives and precursors, *viz*., of mono-, di- and tetrapyrrole compounds.

II. IR spectra of porphyrins and their precursors and derivatives

IR spectroscopy enables one not only to identify compounds, but also to follow changes in various characteristics of individual chemical bonds and the molecule as a whole that occur upon chemical modifications. For example, information on the relative stabilities of corresponding chemical bonds in the molecules can be obtained by comparing the force constants of these bonds, which can be calculated from the spectral data. Since all force constants cannot necessarily be determined from the spectral data, qualitative conclusions about the relative stabilities of the bonds are often made based on the experimental vibration frequencies observed in IR spectra. These frequencies are functions of the atomic weights and the force constants of the bonds. A comparison of the frequencies of analogous vibrations for different compounds can be performed only in the case of the characteristic vibrations. The shifts of characteristic vibration frequencies are directly related to the changes in the electronic states of the bonds and the fragments within which the vibrations under consideration are localised.

Investigation of a large number of structurally similar molecules can be a help in refining the assignment of vibrations to particular fragments of the porphyrin ring.

1. Pyrroles

The assignment of virtually all bands in the IR spectrum of pyrrole (**1a**) was made[9,10] and this spectrum can be used in studies of pyrrole derivatives (Table 1). The NH stretching vibrations in the spectrum of solid pyrrole are observed in the region of $\sim$3500 cm^{-1}. In chloroform, this band is split into two components (at 3400 and 3497 cm^{-1}). The intensity of the band at 3497 cm^{-1} increases upon dilution. Therefore, the band at 3400 cm^{-1} corresponds to associated NH bonds, whereas the band at 3497 cm^{-1} is assigned to the free bonds. According to the results of calculations carried out for the isolated pyrrole molecule, the NH stretching vibration band in its spectrum is located at 3491 cm^{-1} (Table 2).

Two pronounced bands at 3100 and 3130 cm^{-1} are assigned to CH stretching vibrations of pyrrole. Calculations by the semiempirical PM3 method demonstrated[11] (see Table 2) that the more intense band (at 3100 cm^{-1}) corresponds to vibrations of the C(α)–H bonds, whereas the less intense band corresponds to vibrations of the C(β)–H bonds. The frequencies in the region of 1350 – 1600 cm^{-1} belong to skeletal vibrations of pyrrole. In the spectrum, these vibrations are observed as an intense band at 1350 cm^{-1} and a medium intensity band at 1530 cm^{-1}.

[a] According to the published data.[2]

Examinations[9–12] of the spectra of substituted pyrroles **1b**–**l** demonstrated that chemical modifications of the molecule lead to essential spectral changes. Thus, the spectrum of 2-ethoxycarbonyl-3,4,5-trimethylpyrrole (**1b**) shows CH deformation vibrations of the alkyl groups.

The skeletal vibration bands are shifted to the lower-frequency region and are more intense than the corresponding bands in the spectrum of unsubstituted pyrrole. Apparently, a rise in the intensities of these bands can be accounted for by the effect of the electron-withdrawing ester group.

This assumption is supported by the following fact. In the spectrum of 2-benzyloxycarbonyl-5-ethoxycarbonyl-4-ethyl-3-methylpyrrole (**1g**), the vibration bands of the pyrrole ring are shifted further to the low-frequency region with a simultaneous increase in their intensities. Of the molecules under consideration, the largest low-frequency shifts of skeletal vibrations are observed for the α-carboxypyrroles **1h**,**i**. Noteworthy are also the low-frequency shifts of NH vibrations of these pyrroles. The spectrum of 4-butyl-2-ethoxycarbonyl-3-methylpyrrole (**1l**) has an intense band at 3108 cm^{-1} corresponding to CH stretching vibrations of the pyrrole ring. Investigations demonstrated that this band corresponds to vibrations of the C(α)–H bond of pyrrole (the β positions are occupied by substituents). The spectral characteristics of the positional isomers **1h**,**i** and **1j**,**k** differ only slightly from each other. An increase in the size of the alkyl substituent (R) in 4-R-2-ethoxycarbonyl-3,5-dimethylpyrroles **1b**–**d** (R = Me, Et or Bu^n) is accompanied primarily by an increase in the intensity of the CH vibration bands of the alkyl groups. It should be noted that the C=O, C–O, C–OH and C–I vibrations are characteristic. The bands belonging to these vibrations are present in the spectra of all compounds of the series **1b**–**l** and allow one to

identify the pyrrole synthesised and to establish its structure and purity.

2. Dipyrrolylmethanes

The IR spectra of dipyrrolylmethanes **2a**–**x** were measured and examined.[12–14] The structures of these compounds have been previously investigated by calculation methods (the MM + molecular mechanics method and the semiempirical PM3 method). The calculated energy parameters and geometric characteristics corresponding to the energy minima are summarised in the studies.[15,16] The energy parameters of the dipyrrolylmethane molecule are substantially affected by the substituents at positions 5 and 5′, while the effects of the alkyl substituents at positions 3, 3′, 4 and 4′ are insignificant.

As mentioned above, the NH stretching vibrations of pyrrole are observed at 3495 cm^{-1}. On going to dipyrrolylmethane (**2x**), the NH vibration band is shifted to the low-frequency region by $\sim$40 cm^{-1}. Introduction of the phenyl substituent at the *meso*-position of dipyrrolylmethane (the compound **2w**) leads to a further short-wavelength shift (by 15 cm^{-1}) of this band (Table 3). Below are given the charge distributions on the atoms of the dipyrrolylmethane molecules, which show the influence of the electronic factors upon chemical modifications of the molecule.

Thus, the presence of electron-withdrawing substituents (for example, the carboxy group) at positions 5 and 5′ of dipyrrolylmethane leads to a decrease in the electron density on the nitrogen atoms (the compound **2b**), which is accompanied by lowering of the ν(NH) frequency by $\sim$40 cm^{-1} (Tables 3 and 4). The presence of the electron-donating methoxy groups in the *meso* substituents of the carboxy derivatives **2n**,**p**,**r** causes a high-frequency shift (by $\sim$15 cm^{-1}) of the NH vibration band compared to that in the spectrum of the carboxy derivative **2b**. The larger the electron density on the nitrogen atom, the higher the vibration frequency.

The intense band at 3100 cm^{-1} was assigned[12] to CH stretching vibrations of pyrrole [C(α)–H stretching vibrations]. The formation of the dipyrrole structure is accompanied by the high-frequency shift of this band by $\sim$20 cm^{-1} (see Table 3). The introduction of the aryl substituent at the *meso* position of dipyrrolylmethane has virtually no effect on CH vibrations of the pyrrole rings. The spectral characteristics of the positional isomers **2h**,**i** are very similar (see Table 4).

The intense band at 1350 cm^{-1} and the medium intensity band at 1530 cm^{-1} belong to skeletal vibrations of pyrrole. In the dipyrrolylmethane **2w**, the C–C vibration frequency of the pyrrole fragment is shifted to the low-frequency region by $\sim$5 cm^{-1}. Alkylation of the pyrrole rings and the replacement

[a] Stretching vibrations of the pyrrole fragment; [b] stretching vibrations of the methine bridge.

of one of the *meso*-hydrogen atoms by the aryl group are accompanied by an increase in this shift (see Tables 3 and 4). The presence of electron-withdrawing substituents at positions 5 and 5′ of dipyrrolylmethane leads to lowering of the ν(C–C) frequency of the pyrrole fragment compared to that in the spectrum of unsubstituted dipyrrolylmethane.

Calculations of the spectra of dipyrrolylmethanes demonstrated that the intense band in the region of 1340–1365 cm^{-1} corresponds to C–C vibrations of the methane bridge. The presence of the electron-withdrawing nitro groups in the aryl *meso*-substituents leads to a substantial increase in the intensity of this band.

On going from pyrroles to dipyrrolylmethanes, the C=O, C–O and C–OH vibrations remain characteristic and allow the identification of the dipyrrolylmethane synthesised. It can be seen from the data presented in Tables 1–4 that the IR spectra of pyrroles differ substantially from those of dipyrrolylmethanes. The involvement of pyrrole in the open conjugated system of hexamethyldipyrrolylmethene as well as in the cyclic octamethylporphyrinogen system [7] is accompanied by further complications of the spectra. However, the most pronounced effect is observed when pyrrole is involved in the conjugated porphyrin macrocycle.

3. Porphyrins

The effects caused by an increase of the molecular symmetry (for example, upon formation of metal complexes) or its lowering (for example, in the case of introduction of substituents in the macrocycle) are manifested in the IR spectra of porphyrins along with the changes in stretching vibration frequencies.

When studying these effects, it is useful to consider two series of compounds: (1) porphyrins containing the hydrogen atoms at the *meso* positions of the macrocycle and substituents at the β positions of the pyrrole fragments and (2) porphyrins containing substituents at the *meso* positions and the hydrogen atoms at the β positions of the pyrrole fragments.

The IR spectra of β-alkylated porphyrins **3a**–**w** in which two and four *meso*-hydrogen atoms are successively replaced by the alkyl (CH_3–C_6H_{13} or $C_{11}H_{23}$), phenyl or aryl (C_6H_4X, X = H, 4-OMe, 3-OMe, 2-OMe, 4-NO_2 or 3-NO_2) substituents were investigated.[14, 17–21]

The geometric and energy parameters of the porphyrin molecules corresponding to the energy minima are summarised in the studies.[22, 23] The experimental vibration frequencies of the porphyrins **3a**–**w** and those calculated by the PM3 method are given in Table 5. The *meso*-alkyl substituents in the porphyrins **3a**–**g** can adopt various conformations. However, calculations by the semiempirical PM3 method demonstrated [24] that the extended zigzag chain typical of n-alkanes in the crystalline state is a preferential conformation of the alkyl substituents. The cisoid and transoid relative arrangements of the alkyl substituents at positions 5 and 15 are equally probable. The corresponding conformers shown in Fig. 1 *a*,*b* have equal energies of steric strain (365 kJ mol^{-1}). The *meso*-phenyl or *meso*-aryl substituents in the porphyrins **3h**–**s** are located perpendicular to the plane of the porphyrin macrocycle (Fig. 1 *c*,*d*).[22]

The out-of-plane CH deformation vibrations of porphyrins are observed in the region of 830–850 cm^{-1}. Among these are the CH vibrations of the pyrrole rings and methine bridges of the macrocycle. The γ(CH) vibration frequency of the pyrrole fragments of porphyrins increases compared to the corresponsing frequency in the spectrum of pyrrole as the interactions between

[a] Stretching vibrations of the alkyl groups; [b] deformation vibrations of the alkyl groups; [c] out-of-plane deformation vibrations of the methine bridges.

the C(β)–C(β) bonds and the π-system of the macrocycle are weakened due to the introduction of alkyl or aryl substituents.

In the spectra of β-unsubstituted porphyrins (*meso*-tetraalkyl- and -tetraphenylporphyrins), an intense band in the region of 772–805 cm^{-1} corresponds to γ(CH) vibrations. This band is absent in the spectra of octamethyl-, octaethyl-, dodecaalkyl- and dodecaphenylporphyrins.[25–27] The γ(CH) vibration frequency depends substantially on the presence of substituents at the *meso* positions of the macrocycle. Thus, the bands at 772 and 780 cm^{-1} correspond to these vibrations in the spectra of porphyrin and *meso*-tetra(*iso*-butyl)porphyrin, respectively. This effect is more pronounced in the spectrum of tetraphenylporphyrin in which the γ(CH) vibration band is observed at 797 cm^{-1}.[25]

In the IR spectrum of 2,8,12,18-tetrabutyl-3,7,13,17-tetramethylporphyrin (**3t**), out-of-plane C(β)–H deformation vibration bands are absent, whereas an intense band at 835 cm^{-1} belongs to γ(CH) vibrations of the *meso*-hydrogen atoms (see Table 5). This band is absent in the spectra of the 5,15-dialkyl-10,20-diphenylporphyrins **3u**–**w**, whereas it is observed in the region of ~830–850 cm^{-1} in the spectra of the 5,15-dialkyl- and 5,15-diaryl-β-octaalkylporphyrins **3a**–**m**.

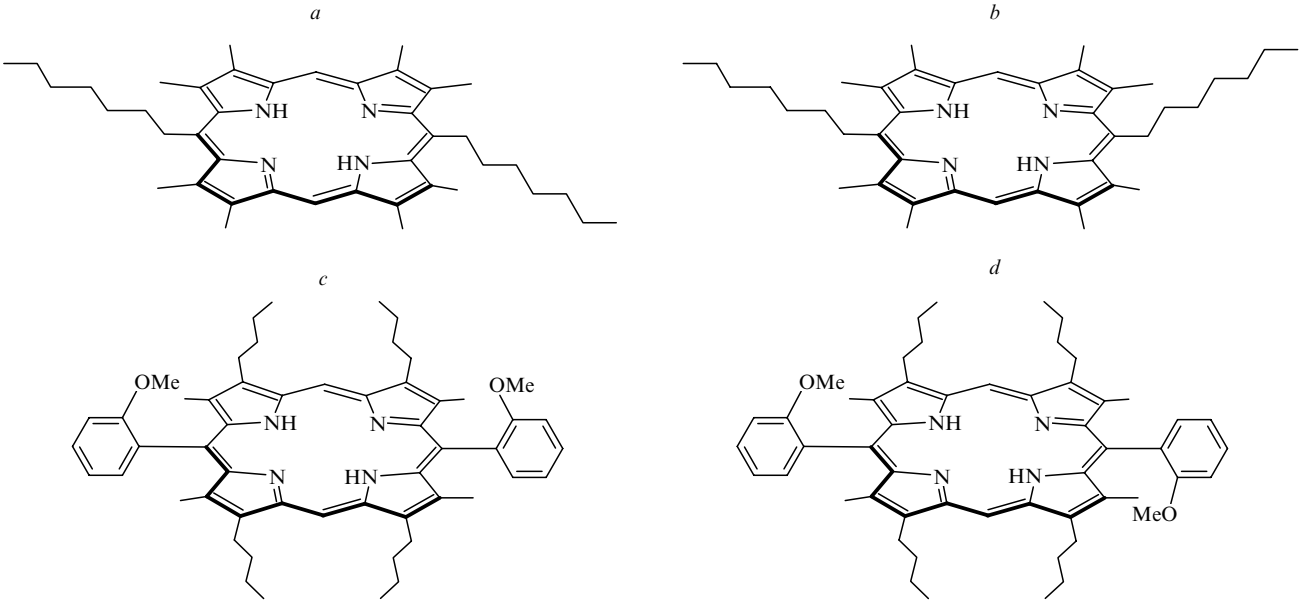

Figure 1. Cisoid (*a*) and transoid (*b*) conformers of 5,15-di-n-heptyl-2,3,7,8,12,13,17,18-octamethylporphyrin and the atropoisomers [α,α (*c*) and α,β (*d*)] of 2,8,12,18-tetrabutyl-5,15-di(2-methoxyphenyl)-3,7,13,17-tetramethylporphyrin.[22]

Since the out-of-plane deformation vibrations of the adjacent CH bonds of the phenyl fragments, which occur in phase, strongly interact with each other, the positions of the corresponding bands in the spectra depend on the number of the above-mentioned bonds. These bands are intense and can be used for the determination of the position of the substituent in the phenyl fragment (Table 6).

The spectra of the 5,15-diphenylporphyrins **3h**,**n** have an intense band at 745 cm^{-1} due to interactions between five adjacent CH bonds (for example, in monosubstituted benzene).[25] The spectra of the di(*meta*-R-phenyl)porphyrins **3j**,**m**,**p**,**s** have bands in the regions of 780–787 cm^{-1} (three adjacent CH bonds) and 870–896 cm^{-1} (one CH bond). The spectra of the di(*ortho*-R-phenyl)porphyrins **3k**,**q** have a band at ~750 cm^{-1} (four adjacent CH bonds), whereas the spectra of the di(*para*-R-phenyl)porphyrins **3i**,**l**,**o**,**r** have a band in the region of 840–848 cm^{-1} (two adjacent CH bonds) (see Table 6).

The identification of in-plane CH deformation vibrations presents a more complicated problem. The bands in the region of 964–1060 cm^{-1} are generally assigned[28] to δ(CH) vibrations of the pyrrole fragments of porphyrins. These bands are observed as two narrow closely spaced intense bands. The spectra of β-octaalkylporphyrins have no intense bands in this region. The medium intensity bands in the region of 1484–1500 cm^{-1} belong to δ(CH) vibrations of alkyl groups. Their positions remain virtually unchanged as the length of the alkyl substituent increases (see Table 5). The in-plane CH deformation vibrations of the phenyl fragments are observed in the region of 1000–1300 cm^{-1}.[25] In the spectra of *meso*-diphenyloctaalkylporphyrins, these vibrations are observed as medium intensity bands at 1170 and 1050 cm^{-1}, which are insignificantly shifted upon introduction of electron-withdrawing or electron-donating substituents into the benzene rings (see Table 6). The spectra of the positional isomers **3h**,**n** are similar. In the spectra of tetraphenylporphyrins, the *ν*(CH) vibrations of the phenyl substituents are observed at 3100 cm^{-1}. Therefore, it is conceivable that the band at 3000 cm^{-1} has a complex nature because the CH vibrations of both the porphyrin and benzene rings are observed in this region. The spectra of the β-alkylated porphyrins **3a**–**m**,**u**–**w** have bands in the region of 2940 cm^{-1}, which, apparently, belong to CH stretching vibrations of the alkyl groups.

The skeletal vibrations of the porphyrin ring are observed in the region of 1100–1250 cm^{-1}.[24, 26] The IR spectra of the β-octaalkylporphyrin **3t** and the 5,15-dialkyl-β-octamethylporphyrins **3a**–**g** have several medium intensity bands in this region. The assignment of the skeletal vibration bands in the spectra of *meso*-phenyl-substituted porphyrins is hampered by the fact that vibrations of the porphyrin ring overlap with those of the benzene fragments. The bands in the region of 1350–1600 cm^{-1} were assigned to *ν*(C–C) vibrations of the benzene rings.[26] In the spectrum of *meso*-tetraphenylporphyrin, these vibrations are manifested as three rather weak bands (at 1489, 1570 and 1590 cm^{-1}) whose intensities become higher as the frequency increases. It is known[29] that the ratio of the intensities of these bands in the spectra of functional benzene derivatives is determined by the presence or absence of conjugation between the phenyl fragments and functional groups. In the spectrum of *meso*-tetraphenylporphyrin, alternation of the intensities of the bands is analogous to that observed in the spectrum of biphenyl.

Chemical modifications of the phenyl substituents in *meso*-phenyl-substituted porphyrins exert a substantial effect on the skeletal vibrations of the macrocycle.[25, 26] Tetra(*ortho*- and *meta*-R-phenyl)porphyrins exist as two atropoisomers due to which the band at 1200 cm^{-1} is split. The spectra of tetra(*para*-R-phenyl)-porphyrins have one intense band at about 1100 cm^{-1}, which is shifted to the low-frequency region in parallel with the increase in the mass of the substituent. The spectra of the di(*ortho*- and *meta*-R-phenyl)porphyrins **3j**,**k**,**m**,**p**,**q**,**s** have a pronounced doublet at 1200 cm^{-1}, whereas the spectra of the *para*-derivatives **3i**,**l**,**o**,**r** show an intense band at 1100 cm^{-1} (for the nitro derivatives) or at 1180 cm^{-1} (for the methoxy derivatives).

Since the nitrogen atoms in porphyrins are more electronegative than those in pyrroles, the N–H bond length (90 pm) in porphyrins is 10% smaller than that in pyrrole. Because of this, the bands at 719 and 725 cm^{-1} (which are 160 cm^{-1} higher than those in the case of pyrrole) are assigned to out-of-plane γ(NH) deformation vibrations of the porphyrin molecule, while the bands at 970 and 980 cm^{-1} (which are 160 cm^{-1} lower than those in the case of pyrrole) are assigned to in-plane δ(NH) deformation vibrations.[26, 30] The validity of this assignment is additionally confirmed by the absence of the corresponding bands in the spectra of metalloporphyrins. In the spectra of the β-octaalkylporphyrins **3a**–**w**, the γ(NH) and δ(NH) vibrations are observed in the regions of 690–710 and 960–990 cm^{-1}, respectively (see Table 5).The positions of the bands change only slightly upon *meso*-substitution. No relationship between the effects of the substituents (OMe or NO_2) in the benzene rings of the porphyrins **3i**–**m**,**o**–**s** and the NH deformation vibration frequencies was revealed.

The NH stretching vibrations of porphyrins are characteristic and their identification presents no problems. The *ν*(NH) frequency of porphyrins is ~190 cm^{-1} lower than that of pyrrole because the electron density is transferred from the pyrrole fragments to the macrocyclic aromatic π system, the lowering of the *ν*(NH) vibration frequency being accompanied by stabilisation of the porphyrin anion. Further lowering of the stretching vibration frequency (by ~15 cm^{-1}) and stabilisation of the porphyrin anion (*i.e.*, an increase of the acid ionisation constant) occur as the aromaticity increases in the porphyrin–tetraazaporphyrin–phthalocyanine series (Table 7).

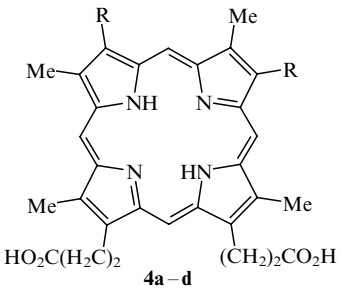
Deuteroporphyrin	–	25.30 ± 0.04

The ν(NH) frequency becomes higher on both deep alkylation and hydrogenation of porphyrins due to an increase of the electron density on the nitrogen atoms. The ν(NH) vibration band in the spectrum of the octaalkylporphyrin **3t** is shifted to the high-frequency region by ~ 30 cm^{-1} compared to that in the spectrum of porphyrin. This effect is further enhanced (by ~ 10 cm^{-1}) in the presence of the electron-donating alkyl substituents ($CH_3-C_6H_{13}$ or $C_{11}H_{23}$) at the *meso* positions of the macrocycle. At the same time, the introduction of aryl substituents at the *meso* positions leads to the low-frequency shift (by ~ 15 cm^{-1}) of the ν(NH) vibration bands compared to the analogous band observed in the spectrum of the porphyrin **3t** (see Table 5).

4. Metalloporphyrins

The molecular symmetry of metalloporphyrins is higher than that of porphyrins due to the replacement of two hydrogen atoms in the coordination centre of the porphyrin ligand by the metal atom and equalisation of the geometric parameters of the pyrrole fragments in metal complexes. Changes in the geometric parameters of the porphyrin molecule upon complex formation are clearly manifested in the IR spectra. Thus, the number of absorption bands decreases and their symmetry and resolution increase. These facts are associated with degeneration of the energies of particular types of vibrations as the molecular symmetry becomes higher.[2, 31–33]

In the spectra of metalloporphyrins, the following NH absorption bands disappear first: the NH stretching vibration bands in the region of 3345–3360 cm^{-1} and the NH deformation vibration bands in the regions of 720–740 and 960–980 cm^{-1}.[2, 7] In the spectra of mesoporphyrin **4a**, protoporphyrin **4b**, deuteroporphyrin **4c** and hematoporphyrin **4d**, the fingerprint region where the skeletal vibrations of the porphyrin molecule are located is most sensitive to the introduction of the metal atom.[34]



4a–d

R = Et (**a**), CH=CH$_2$ (**b**), H (**c**), CH(Me)OH (**d**).

The formation of metalloporphyrin from porphyrin leads to sharp changes in the intensities of the bands in the regions of 675–683 (I) and 705–711 cm^{-1} (II). A substantial decrease in the intensity of the band I is accompanied by an increase in the intensity of the band II. The positions of these bands depend only slightly on the nature of the metal atom. Other skeletal vibrations of the pyrrole rings of porphyrin are less sensitive to the introduction of the metal atom into the coordination centre of the molecule.

All absorption bands caused by vibrations of the peripheral substituents of porphyrin are weakly sensitive to the introduction of the metal atom. Thus, the intense band at 900 cm^{-1} observed in the spectrum of the protoporphyrin **4b** is retained on complex formation with divalent metals. On going to the porphyrin complex with Mn(III), the relative intensity of this band decreases, but its position remains unchanged. Analogous situations are observed for the complexes of the mesoporphyrin **4a** and the hematoporphyrin **4d**.[34] The presence of at least two free β positions in the pyrrole rings of porphyrin leads to substantial changes in the spectral pattern. Thus, the number of the bands in the region of 900–1000 cm^{-1} in the spectra of complexes of the deuteroporphyrin **4c** is smaller and their intensities are higher compared to those observed in the spectrum of the ligand.

The changes in the IR spectra of porphyrins on complex formation with divalent metals depend on the nature of the metal atom (Tables 8 and 9). However, the most substantial changes in the spectral characteristics of the porphyrin complexes are observed in the case of polyvalent metal ions. The formation of these complexes results in essential changes in the structure and symmetry of the metalloporphyrin molecule due to the displacement of the cation from the plane of the macrocycle.[7, 35]

In the case of *meso*-tetraphenylporphyrin complexes, the most essential changes associated with complex formation are observed in the region of the spectrum where the out-of-plane γ(CH) deformation vibrations of the pyrrole ring are manifested (~ 800 cm^{-1}).[25] The IR spectrum of *meso*-tetraphenylporphyrin has three bands in this region (at 783, 797 and 810 cm^{-1}), the intensities of the first and third bands being equal and low. The band at 797 cm^{-1} is the most intense one. In the spectrum of the corresponding metalloporphyrin, the band at 783 cm^{-1} disappears, the intensity of the band at 810 cm^{-1} decreases sharply and the latter is shifted to the high-frequency region due, apparently,

to the fact that complex formation leads to lowering of the electron density in the macrocycle.

The high-frequency shift of the band at 797 cm^{-1} is observed in the spectra of porphyrin complexes with polyvalent metal ions. In the case of Mo(V) and W(V), this band is observed at 805 cm^{-1}.[36] Apparently, the shift of the band at 797 cm^{-1} in the spectra of complexes with polyvalent ions is associated with the geometric characteristics of these complexes in which the metal ion deviates substantially from the plane of the molecule. The noncoplanar arrangement of the metal atom reduces the possibility of transfer of the σ- and π-electron density from the nitrogen atom to the metal atom as a result of which the complexes should be destabilised.

Complex formation causes substantial changes in the frequencies and intensities of the bands in the region of 964–1030 cm^{-1} where the in-plane δ(CH) deformation vibrations of the pyrrole fragments of the porphyrin molecule are manifested. It is worthy of note that the intensity of the band at 1003 cm^{-1} in the spectrum of *meso*-tetraphenylporphyrin rises sharply upon complex formation. Koifman[34] believed that this band is associated with two types of vibrations of the pyrrole fragments, *viz*., with in-plane δ(CH) deformation vibrations and ν[C(β)–C(β)] stretching vibrations. As mentioned above, the introduction of electron-withdrawing substituents into the pyrrole ring results in a more substantial change in the dipole moment of the molecule in the course of vibration. This leads to significant changes (generally, to a rise) in the intensities of the out-of-plane and in-plane CH deformation vibration bands. By analogy, the increase in the intensity of the band at 1003 cm^{-1} in the spectrum of *meso*-tetraphenylporphyrin can be related to the electron density redistribution in the molecule upon complex formation. Apparently, the δ(CH) vibrations make the major contribution to this absorption band.

Complex formation with *meso*-tetraaryl-substituted porphyrins as well as the change of the metal atom lead to substantial changes in the region of 690–758 cm^{-1} (see Table 9) in which two out-of-plane deformation vibration bands of the aryl groups are observed. The position of one band depends on the nature of the metal atom and changes from 690 to 708 cm^{-1}.[20,25] The second band belongs to the most intense bands manifested in the IR spectra of metal complexes and is observed in the region of 732–758 cm^{-1}. The frequencies and intensities of the ν(C–C) stretching vibration bands of the benzene rings are also changed substantially upon complex formation. Thus, two intense bands appear instead of three medium intensity bands in the region of 1430–1590 cm^{-1}. It was noted[37] that the changes in the electronic structure of the *p* and *d* shells of the metal atom as well as the changes in the geometric parameters of the coordination centre caused by complex formation have no effect on the position and intensity of the ν(C–C) band (1590 cm^{-1}) in the spectrum of *meso*-tetraphenylporphyrin. Hence, there is no clear correlation between the electronic structure of the coordination centre and the ν(C–C) vibration frequency. However, it can be stated that the C–H and C–C vibrations of the benzene rings depend on the change in the symmetry of the π system of the macrocycle due to complex formation.

The spectral characteristics of the complexes of 2,8,12,18-tetrabutyl-3,7,13,17-tetramethylporphyrin (**3t**) and its *meso*-di-(**3a**–**c**,**g**–**m**) and -tetrasubstituted derivatives (**3u**,**w**) with Zn, Cu and Ni[38] are given in Table 10. Complex formation leads to the disappearance of the NH vibration bands in the IR spectra and to a decrease in the number of the bands in the regions where C–C vibrations of the pyrrole and benzene rings are manifested. In the case of both protoporphyrin and deuteroporphyrin, the spectral characteristics are less affected by the introduction of the metal ion into the coordination centre of the porphyrin molecule. However, the changes are comparable with those observed on coordination of *meso*-tetraphenylporphyrin.

The region about ~1000 cm^{-1} in which the metal-sensitive bands are most pronounced is of particular interest. The spectra of all complexes have three bands at ~980, 955 and 910 cm^{-1}, the positions of the first and third bands being dependent on the nature of metal.[27,38] The high-frequency shifts of these bands increase in the series Zn < Cu < Ni. It should be noted that the above-mentioned sequence corresponds to the hypsochromic shifts of the absorption bands in the electronic absorption spectra of the complexes of **3a**–**c**,**g**–**m**,**t**,**u**,**w** (see Table 10).[39] The bands at 955 and 910 cm^{-1} in the IR spectrum of the copper complex of octaethylporphyrin belong to deformation vibrations of the alkyl groups, which is confirmed by the absence of these bands in the spectrum of the copper complex of porphyrin.[34] The band at 980 cm^{-1} may be assigned to deformation vibrations of the porphyrin ring. An analogous assignment was made for the copper complex of octaethylporphyrin.[25]

The CH vibration frequencies of the methine bridges in the *meso*-unsubstituted (**3t**) and the *meso*-disubstituted β-octaalkylporphyrins (**3a**–**s**) depend substantially on the nature of the metal ion.[27] These frequencies at 3110, 1220 and 835 cm^{-1} belong to stretching and deformation (in-plane and out-of-plane) CH vibrations, respectively. The positions of the absorption maxima of the CH deformation vibrations of the methine bridges in porphyrins are given in Table 10. The stronger the coordination of the metal atom and the higher its electronegativity, the larger the high-frequency shift. The in-plane deformation vibrations depend on

Table 10. Positions of absorption maxima in the IR (cm^{-1}) and electronic absorption (nm) spectra of the β-octaalkylporphyrin complexes **3a–c,g–m,t,u,w**.[38,39]

[a] In KBr pellets; [b] a solution in chloroform.

the nature of the metal atom more strongly than the out-of-plane vibrations. The regularity revealed for the δ(CH) and γ(CH) vibrations of the methine bridges agrees with the changes that occur at 1000 cm^{-1} in the IR spectra upon complex formation and is confirmed by the results of studies by electronic absorption spectroscopy.

Therefore, examination of the IR spectra demonstrated that the introduction of the metal ion into the porphyrin molecule affects substantially the macrocycle (particularly, its π-electron system) and causes changes in the frequencies and intensities of vibrations of most of the bonds and molecular fragments.

III. ^{1}H NMR spectra of porphyrins and their precursors

Studies performed in the last decades demonstrated that ^{1}H NMR spectra are very informative and adequately reflect the structural features of porphyrins.[40–59] The presence of the extended delocalised π-electron system of the porphyrin macrocycle gives rise to a strong ring current in the molecules placed in the magnetic field. The ring current causes anisotropic shielding of the protons located in the field of its action and (together with the diamagnetic component of paired σ-electrons) leads to a substantial shift of their signals in the ^{1}H NMR spectra. It can be stated that the ring current and aromaticity of porphyrins change in a similar way in response to the analogous changes in the molecular structure of the porphyrin and the medium, which is most clearly seen on comparison of the spectra of porphyrins and their precursors.

1. Pyrroles

The chemical shifts of protons depend on the electron density on the hydrogen atom, the ring current of the molecule, the π-electron charge on the atom bound to the proton under consideration and the steric effects resulting from interactions with the substituents or the heteroatoms involved in the ring. Generally, separation of these effects presents a considerable problem.

The introduction of substituents into the pyrrole molecule leads to essential spectral changes.[9,10,13] A comparison of the characteristics of pyrrole (**1a**) and 3,4-dimethylpyrrole (**1m**) (Table 11) demonstrated that the positions of the signals for the protons of the CH groups of the pyrrole rings remain unchanged. Apparently, the β-substitution in the pyrrole ring exerts only a slight effect on the π-electron system of the molecule. In the spectrum of 2,3,4-trimethylpyrrole (**1o**), the signals for α-H are shifted upfield by 1.06 ppm compared to those in the spectrum of unsubstituted pyrrole due, apparently, to the positive inductive effect of the methyl group. Correspondingly, the downfield shift of the signal for α-H (0.43 ppm) observed on going from 3,4-dimethylpyrrole (**1m**) to 2-ethoxycarbonyl-3-ethyl-4-methylpyrrole (**1q**) occurs due to the effect of the electron-withdrawing ester group.

The most essential changes associated with chemical modifications of the molecule are observed in the region of the signals for the protons of the β-methyl and NH groups (see Table 11). An increase in the number of methyl groups in the pyrrole ring on going from the compound **1m** to the compound **1o** causes upfield shifts of the signals for the protons of the alkyl substituents by 0.13 ppm. The introduction of the electron-withdrawing ester or formyl group into the molecule results in downfield shifts of these signals by ~0.2 ppm. Of all the structures under consideration,

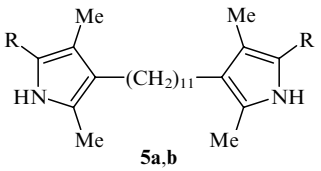
Note. Hereinafter, the ^{1}H NMR spectra were measured in $CDCl_3$; the chemical shifts (δ) are given in ppm. [a] Signals for the protons of the phenyl groups; [b] signals for β-H.

this chemical shift is maximum (~0.5 ppm) in the case of the carboxy derivatives.

The chemical shifts of the signals for the protons of the NH groups are changed more substantially. Methylation of the pyrrole ring (the compounds **1a** and **1o**) is accompanied by the upfield shifts of these signals by ~0.9 ppm (see Table 11). The signals for the protons of the NH groups are shifted downfield (up to 3.3 ppm) upon introduction of electron-withdrawing groups at the α positions of pyrroles.

The spectral characteristics (the intensities and multiplicities of the signals) agree well with the structures of the pyrroles synthesised. The signals for the protons of the ester (at δ 1.2–4.5) and carboxy (at δ 9.45–12.65) groups remain very characteristic and do not overlap with the signals of other proton-containing groups.

No substantial changes in the chemical shifts of the signals for the protons of the β-alkyl substituents and functional groups are observed on going from the compounds **1c**,**q** to β-bound pyrroles **5a**,**b**.



5a,**b**

R = CO_2Et (**a**), CHO (**b**).

In the ^{1}H NMR spectra of the compounds **5a**,**b**, the arrangement of the signals of the $(CH_2)_{11}$ methylene bridge linking the β positions of the pyrrole fragments is of interest.[60] The signals for the protons of two methylene groups directly bound to the pyrrole ring (see Table 11) are resolved from the signals for the protons of the remaining nine units of the bridge. The intensity distribution of the signals provides information on the relative number of equivalent protons (4 and 18, respectively). The signals for the protons of the NH groups in the spectrum of the compound **5b** are shifted upfield and are broadened compared to those observed in the spectrum of the pyrrole **1r**. Since the bispyrroles **5a**,**b** consist of two pyrrole rings separated from each other, the observed changes are, apparently, associated with the fact that solutions contain several conformers with different relative arrangements of the pyrrole nuclei. As a result, the positions of the NH groups in the bispyrrole molecule are nonequivalent (different shielding of the nuclei in different molecules or in different positions of a single molecule). On the contrary, the signals for the protons of the NH groups in the spectra of analogous dipyrrolylmethenes and biladienes are shifted downfield due to extension of the conjugated system and enhancement of the aromaticity of the pyrrole rings.[61]

2. Dipyrrolylmethanes

A comparison of the ^{1}H NMR spectra of the compounds **1b** and **2a** revealed no substantial changes in the region of the signals for the protons of the NH groups [12, 13] (Tables 11 and 12) due, apparently, to the absence of conjugation between the nearby π-electron systems of the pyrrole rings. On going from unsubstituted dipyrrolylmethane to the carboxy derivatives, the signals for the protons of the NH groups are shifted downfield (by ~0.5 ppm) due, presumably, to the electron-withdrawing effect of the carboxy groups. Methylation at the β positions of dipyrrolylmethane is accompanied by slight upfield shifts of the signals for the protons of the NH groups. The shifts successively increase on going from β-dialkyl-substituted dipyrrolylmethane to the β-tetraalkyl-substituted analogue and as the length of the alkyl substituent increases (the compounds **2a**,**c**,**d**), which is consistent with the positive inductive effect of the alkyl substituents.

The introduction of the phenyl substituent at the *meso* position of dipyrrolylmethane (the compound **2k**) leads to a slight downfield shift of the signal for the protons of the NH groups by 0.2 ppm compared to that in the spectrum of unsubstituted dipyrrolylmethane. A more substantial shift is observed in the spectrum of the structural isomer **2l**. Apparently, the above-considered changes can be attributed to the small negative inductive effect of the phenyl groups.

Chemical modifications at positions 5 and 5′ in the dipyrrolylmethane molecule (on going from the ethoxycarbonyl derivatives to the carboxy analogues) have virtually no effect on the positions of the signals for the β-alkyl protons. However, it should be noted

Table 12. Positions and multiplicities of the signals in the ^{1}H NMR spectra of dipyrrolylmethanes and their derivatives.[12–14]

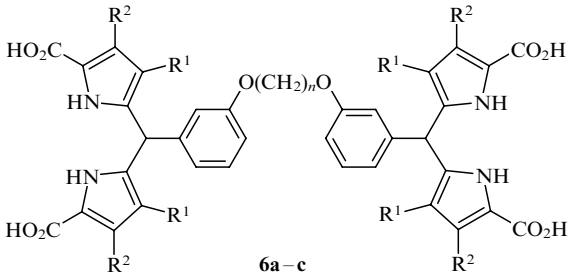
[a] According to the published data.[30]

that the introduction of the phenyl substituent at the *meso* position of the molecule is accompanied by the upfield shifts (by ~0.7 ppm) of the signals for the protons of the methyl substituents at positions 3 and 3′ (see Table 12) due to the shielding effect of the ring current of the phenyl substituent.

In the ^{1}H NMR spectra of the 5,5′-diesters **2a**,**c**,**d**,**f**,**k**,**l**, the signals for the *meso*-protons are observed as a pronounced singlet in the region δ 3.73–4.12. As expected, the signals are shifted downfield (by ~2 ppm) on going to the 5,5′-dicarboxy derivatives **2b**,**h**,**i**,**n**,**p**,**r**, (see Table 12). The electron-withdrawing effect of the carboxy group is identical in both the *meso*-unsubstituted and *meso*-aryl-substituted dipyrrolylmethanes. The introduction of the phenyl substituent at the *meso* position of porphyrin leads to an increase in the downfield shift (by ~0.5 ppm) in the case of both the ethoxycarbonyl and carboxy derivatives. Apparently, this fact can be explained by a small negative inductive effect of the substituent. The signals for the *meso*-protons and the protons of the phenyl fragments in the structural isomers **2k**,**l** are observed at δ ~4.0 and 6.6–6.9, respectively (see Table 12). In the ^{1}H NMR spectra, the signals for the protons of the unsubstituted *meso*-phenyl groups in the compounds **2h**–**l** are observed as a doublet of the *ortho*-protons and a multiplet of the *meta*- and *para*-protons. The *para*-substitution (the compounds **2n**,**t**) results in the appearance of a doublet for the *meta*-protons along with a doublet for the *ortho*-protons. In the spectra of the *meta*-substituted dipyrrolylmethanes **2p**,**v**, the signals for the *meta*- and *para*-protons again coalesce into a multiplet.

In the spectra of the linear tetrapyrrole compounds **6a**–**c**, the signals for the *meso*-protons are shifted downfield by ~1.5 ppm, whereas the positions of the signals for the protons of the β-alkyl and NH group change only slightly compared to those in the spectra of the monomeric analogue **2c**.



6a–**c**

R^1 = Me, R^2 = Et, n = 3 (**a**); R^1 = Et, R^2 = Me, n = 4 (**b**); R^1 = Me, R^2 = Et, n = 4 (**c**).

More substantial changes are observed in closed tetrapyrrole structures. It was found [61] that the signals for the protons of the β-alkyl and NH groups are shifted upfield by 0.65 and 0.28 ppm, respectively, on going from pyrrole to octamethylporphyrinogen due, apparently, to the positive inductive effect of the methyl groups at the β positions. The introduction of the methyl group at the α position of pyrrole also leads to the upfield shift of the signal for the β-alkyl protons.

3. Porphyrins

Conjugated macrocyclic structures are of most interest. The imposition of the external magnetic field on these molecules gives rise to ring currents, which make the major contribution to the observed chemical shifts. Theoretical analysis of the ^{1}H NMR spectra shows that the positions of the signals for the protons of porphyrins are determined primarily by the strength of ring π-electron currents (the macrocyclic current enclosing the molecule as a whole and local currents localised in the pyrrole nuclei). It should be noted that the macrocyclic current (Fig. 2) possesses the major 'bed' corresponding to the main 18-membered contour of conjugation and 'arms' formed by the semi-isolated C(β)–C(β) bonds in the pyrrolenine nuclei.

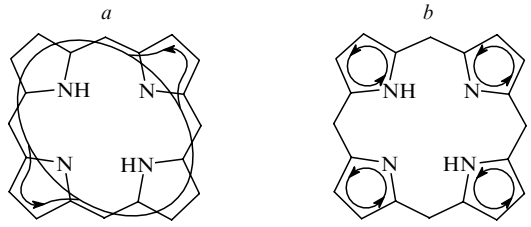


Figure 2. Schematic representation of the circuits of the ring π-electron currents in the porphyrin molecule; (*a*) the macrocyclic current, (*b*) local currents.[7, 25]

The protons at the β and *meso* positions are exocyclic with respect to the macrocyclic and local pyrrole currents and experience the deshielding influence of the latter. The signals for these protons are observed at low field (at δ from 9.7 to 11.2 for the *meso*-protons and at δ from 8.5 to 9.9 for the β-protons; see Table 13). The protons of the NH groups are exocyclic with respect to the local ring currents and endocyclic with respect to the macrocyclic current. Undoubtedly, the shielding effect of the latter prevails and the signals for the protons of the NH groups are observed at very high field (at δ from −1.4 to −4.4; see Table 13).

The β-hydrogen atoms of the pyrrole and pyrrolenine fragments are in principle nonequivalent. However, rapid (within the NMR time scale) transformations occur at room temperature and the signals for the β-protons are averaged. Two different peaks corresponding to resonance absorption of the energy by the protons of the β-CH groups of the pyrrole and pyrrolenine fragments can be observed at low temperature.[7, 62]

Table 13. Chemical shifts (ppm) of the β- and *meso*-protons and the protons of the NH groups in the ^{1}H NMR spectra of porphyrins.[7]

Porphyrin	δ(β-H)	δ(*meso*-H)	δ(NH)
Porphin	9.74	10.58	−3.76
Porphin [a]	9.92	11.22	−4.40
Octaethylporphin	–	10.18	−3.70
Ethioporphyrin-I	–	10.10	−3.67
Tetra-*iso*-butylporphyrin	9.41	–	−2.73
Tetra-n-pentylporphyrin	9.28	–	−2.75
Tetraphenylporphyrin	8.70	–	−2.81
Tetraphenylporphyrin [a]	8.45	–	−2.38
Tetra(2-methylphenyl)porphyrin	8.60	–	−2.66
Tetra(2-methoxyphenyl)porphyrin	8.65	–	−2.68
Tetra(2-bromophenyl)porphyrin	8.45	–	−2.63
Tetra(2-aminophenyl)porphyrin	8.82	–	−2.72
Tetra(3-methoxyphenyl)porphyrin	8.85	–	−2.85
Tetra(3-nitrophenyl)porphyrin	8.77	–	−2.96
Tetra(3-bromophenyl)porphyrin	8.82	–	−2.91
Tetra(3-hydroxyphenyl)porphyrin [a]	8.52	–	−2.45
Protoporphyrin	–	9.96	−4.08
Chlorin	–	9.65	−1.40
Deuteroporphyrin [a]	9.66	11.21	–

Note. In all tetrasubstituted porphyrins, the substituents are located in the *meso* positions. [a] The spectrum of a solution in CF_3CO_2H was measured.

On going from porphin to chlorin, the signals for the protons of the NH groups in the ^{1}H NMR spectra are shifted downfield, whereas the signals for the *meso*-protons are shifted upfield, *i.e.*, these signals are shifted toward each other, which is indicative of a decrease in the strength of the induced magnetic field produced by the macrocyclic ring current.[7, 62] In our opinion, two consequences of hydrogenation of one of the C(β)=C(β) bonds are responsible for these changes. First, due to hydrogenation of the C(β)=C(β) bond, the number of charge carriers providing the macrocyclic ring current is decreased by two electrons and, correspondingly, the strength of the macrocyclic ring current is diminished. Second, one of the 'arms' through which this current flows disappears, *i.e.*, the effective diameter of the ring conductor is reduced. As a result, the strength of the magnetic field induced by the macrocyclic ring current decreases.

On going from a solution of porphin (P) in deuteriochloroform to a solution in trifluoroacetic acid, the neutral form H_2P is converted into the doubly protonated form H_4P^{2+} in which the excess positive charge is located primarily on four nitrogen atoms. In this case, the electron density on the central hydrogen atoms is sharply reduced, which was confirmed by calculations for the neutral and protonated forms of porphin by the PM3 method.[63] In this connection, one would expect that the signals for the protons of the NH groups in the ^{1}H NMR spectrum will be shifted downfield upon protonation of porphin. However, the signals are shifted upfield by ~0.7 ppm (see Table 13). Simultaneously, the signals for the β- and *meso*-protons are shifted downfield. This character of the spectral changes indicates that protonation of porphin leads to a substantial increase in the strength of the magnetic field induced by the macrocyclic ring current.

Calculations [23] carried out by the PM3 method demonstrated that protonation of porphin is accompanied by a change in the geometric structure of the molecule. The C(α)–NH–C(α) fragments in the initial porphin are planar and the nitrogen atoms are sp^2-hybridised. In the protonated porphin, these fragments adopt a pyramidal structure (the nitrogen atoms have nearly sp^3 hybridisation) and the degree of involvement of the nitrogen atoms in conjugation with the α-carbon atoms is substantially reduced. This fact is confirmed by an increase in the C(α)–N bond length observed upon protonation of porphin. The above-mentioned rearrangements lead to a change in the contour of macrocyclic conjugation. In the case of protonated porphin, this conjugation is realised primarily along the outer contour of the molecule. Therefore, protonation causes an increase in the diameter of the conjugation ring resulting in upfield shifts of the signals for the internal protons and downfield shifts of the signals for the external protons.

In the case of β-alkyl substitution in porphin (on going to octaethylporphin and ethioporphyrin), the signals for the protons of the NH groups and the signals for the *meso*-protons are shifted downfield and upfield, respectively. Analogous, but more pronounced, changes are observed in the presence of a substituent in the *meso* position. It should be noted that the introduction of both electron-donating (*meso*-tetra-*iso*-butyl- and *meso*-tetra-n-pentylporphyrin) and electron-withdrawing (tetraphenylporphyrin and its derivatives) substituents gives the same results, *viz.*, the signals for β-protons and for the protons of the NH groups are shifted upfield and downfield, respectively. It seems likely that the introduction of substituents both at the β- and *meso* positions leads to reduction in the strength of the aromatic macrocyclic current regardless of the electronic nature of the substituent. The reasons for this phenomenon remain unclear.

The currents in the porphyrin molecule are substantially affected by complex formation.[7] The higher the degree of covalence of the N–H bond, the larger the decrease in the ring current due to the presence of the coordinated metal atom. Coordination to the medium-sized M^{2+} cations (M = Mg, Zn, Cd, Ni or Pd) is

accompanied by upfield shifts of the signals for the *meso*-protons (the ring current is reduced). In the spectra of the complexes in which the M^{2+} metal ion deviates from the plane due to its large radius and weak coordination interactions (M = Sn or Pb) or in the spectra of the complexes with the M^{3+} or M^{4+} ions in which the metal atom deviates from the plane of the macrocycle under the action of the extra ligands, the signals for the *meso*-protons are shifted downfield relative to those in the spectra of the porphyrin ligand. These shifts may be due to an increase in the ring current. However, this effect is insignificant and depends on the nature of the ions serving as the extra ligands.[7]

The following characteristic features should be noted in the ^{1}H NMR spectra of β-octaalkylporphyrins and their 5,15-diaryl-, 5,15-dialkyl- and 5,15-dialkyl-10,20-diaryl derivatives.[14, 19, 20, 24, 27] On going from 2,8,12,18-tetrabutyl-3,7,13,17-tetramethylporphyrin (**3t**) to 2,8,12,18-tetrabutyl-3,7,13,17-tetramethyl-5,15-diphenylporphyrin (**3h**), the most substantial changes are observed in the region of the signals for the protons of the β-methyl and NH groups (Table 14). The upfield shifts of the

[a] α,α-Atropoisomer; [b] α,β-atropoisomer; [c] signals for the protons of the *meso*-alkyl groups.

signals for the protons of the methyl groups (by 1.06 ppm) can be attributed to the shielding effect of the ring currents of the phenyl fragments. Apparently, the signals for the protons of the NH groups are substantially shifted downfield ($\sim$1.4 ppm) due to both the negative inductive effect of the phenyl fragments and a reduction in the strength of the macrocyclic ring current. The planar porphyrin macrocycle is deformed and its aromaticity is decreased due to steric strains caused by the phenyl groups. On going from the compound **3h** to the compound **3n**, the porphyrin macrocycle undergoes further deformation due to steric interactions between the butyl and phenyl substituents resulting in the downfield shifts (by 0.1 ppm) of the signals for the protons of the NH groups. The shielding effect of the ring currents of the phenyl fragments is manifested in the upfield shifts of the signals for the protons of the butyl substituents. These shifts are maximum (1 ppm) for the CH_2 groups directly bound to the macrocycle, whereas the positions of the signals of the terminal CH_3 groups remain virtually unchanged (0.02 ppm). The introduction of the substituents into the phenyl rings of 5,15-diphenylporphyrin (*o*,*m*,*p*-OMe or *m*,*p*-NO_2) exerts only a slight effect on the positions of the signals for the *meso* protons and for the protons of the NH groups (see Table 14).

In the ^{1}H NMR spectra of the 5,15-dialkyloctamethylporphyrins **3a**–**f**, the signals for the protons of the NH groups are shifted downfield compared to those in the spectrum of the porphyrin **3t**. Apparently, this is associated with the deformation of the molecule caused by the *meso*-substitution. The magnetic field of the π-electron ring current of the porphyrin, in turn, affects the positions of the signals for the protons of the alkyl *meso*-substituents. In this case, the spectra contain individual non-overlapping signals for the protons of the methylene and methyl fragments of the alkyl substituents. Thus, the spectrum of 5,15-dihexyl-2,3,7,8,12,13,17,18-octamethylporphyrin (**3f**) has the signal for the protons of the methylene group, which is directly bound to the macrocycle, as a triplet at δ 4.32, the signal of the adjacent methylene group as a quintet at δ 2.5 and the signals for the protons of the next two CH_2 groups as quintets at δ 2.16 and 1.64.[12] The signals of the last methylene group and the terminal methyl group are observed as a sextet at δ 1.09 and a triplet at δ 0.78.

The signals of the β-methyl groups in the spectra of the compounds **3a**–**f** are shifted downfield by $\sim$0.4–0.5 ppm compared to the corresponding signals in the spectra of 5,15-diarylporphyrins, which is attributed to elimination of the shielding effect exerted by the ring currents of the *meso*-aryl substituents.

Not only the signals for the *meso*-protons, but also the signals for the protons of the NH groups disappear in the ^{1}H NMR spectra on going from the *meso*-disubstituted porphyrins to the *meso*-tetrasubstituted compounds (**3u**–**w**). The reasons for this phenomenon remain unclear. Analogous changes are observed in the spectrum of tetraphenyl-substituted β-octamethylporphyrin.[27]

The signals for the β-methyl protons of *meso*-tetrasubstituted porphyrins are observed in the region (at δ $\sim$2.4) identical to that of 5,15-diarylporphyrins (see Table 14). It should be noted that the above-mentioned region is intermediate between the regions in which these signals are observed in the spectra of the octaalkylporphyrin **3t** (at δ 3.47) and its *meso*-tetraphenyl derivative (at δ 1.76),[25] which confirms the assumption that the magnetic anisotropy of the aryl *meso*-fragments exerts an effect on the protons of the β-substituents.

The chemical shifts of the protons of the phenyl fragments are observed in the region δ $\sim$7.7–8. The signals of the unsubstituted phenyl groups of the compounds **3h**,**n**,**u**,**v** are observed as a doublet for the *ortho*-protons and a multiplet for the *meta*- and *para*-protons. The chemical shifts of the protons of the substituted phenyl fragments vary depending on the nature of the substituent. Among the spectra of the porphyrins containing the electron-donating methoxy group in the *meso*-phenyl fragment, only the spectra of the *para*-substituted compounds **3i**,**o**,**w** have pronounced individual signals, *viz*., a doublet for the *ortho*-protons and a doublet for the *meta*-protons. In the spectra of the *meta*-methoxy-substituted compounds **3j**,**p**, the corresponding signals are observed as multiplets.

In the spectra of porphyrins containing the electron-withdrawing nitro group in the *meso*-phenyl fragment (both in the *meta*- and *para*-substituted compounds), the signals are observed as pronounced multiplets. The spectra of the *para*-nitro derivatives **3l**,**r** have a doublet for the *ortho*-protons and a doublet for the *meta*-protons. The signals of the *meta*-nitro derivatives **3m**,**s** are observed as a doublet for the *para*-protons, a triplet for the *meta*-protons and a singlet and a doublet for the nonequivalent *ortho*-protons (see Table 14).

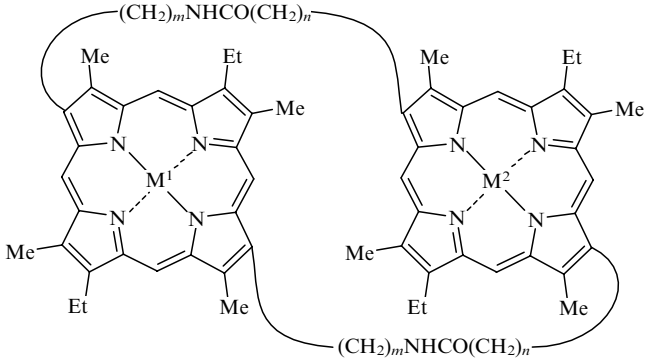
The *ortho*-methoxy-substituted porphyrin **3k** can exist as two atropoisomers (α,α and α,β), which differ by the orientation of the methoxy groups with respect to the porphyrin plane. The ^{1}H NMR spectra of these compounds are characterised by the presence of the signals for the phenyl protons as multiplets. The spectrum of the α,α-atropoisomer has two doublets for the *ortho*- and *meta*-protons and two triplets for the *meta*- and *para*-protons. The spectrum of the α,β-atropoisomer has a doublet for the *meta*-protons, a triplet for the *para*-protons and a multiplet for the *ortho*- and *meta*-protons (see Table 14).

4. Bisporphyrins

As mentioned above, the porphyrin fragments in cyclophane dimers are brought into proximity due to the bridging bonds located at the *meso* or β positions of the macrocycles. The lengths and rigidity of the bridges are responsible for the conformational flexibility of the dimer.

Interactions between the π-electron systems of the macrocycles are clearly manifested in the ^{1}H NMR spectra. The chemical shifts of the protons depend on the length of the bridge and the mutual orientation of the macrocycles.[64–86]

Dimeric porphyrins **7a**–**f** in which the porphyrin rings are linked through the β positions of the pyrrole rings by two amide bridges can exist as two isomers (*syn* and *anti*). The possibility of



7a–**n**

Compound **7**	M^1	M^2	*n*	*m*

formation of a particular isomer depends on the orientation of the porphyrin fragments at the instant the second amide bond is formed.[72, 73]

Figure 3 presents the ^{1}H NMR spectrum of the *anti*-isomer of the bisporphyrin **7c**, which has signals for four *meso*-protons (at δ 9.29, 8.84 and 8.78) and signals for the protons of the alkyl substituents (at δ 3.60, 3.64, 3.68 and 3.74). The signals for the protons of the NH groups are shifted upfield (δ −7.78 and −7.81) compared to those observed in the spectra of their monomeric analogues (δ −3.75). The amide bridges in the compound **7c** contain two methylene groups each. Two of these groups bound to the NH groups give a quadruplet (δ 5.8) and a doublet (δ 4.7), whereas two other groups bound to the porphyrin fragment of the dimer give signals at δ 4.1. The signals for the methylene protons of the ethyl groups are observed in the same region. The signals for the protons of the amide groups are observed as a doublet at δ 6.97. The chemical shifts of the protons of the alkyl substituents in the compound **7c** differ only slightly from those of the analogous protons in the monomeric analogue **8** (Table 15).

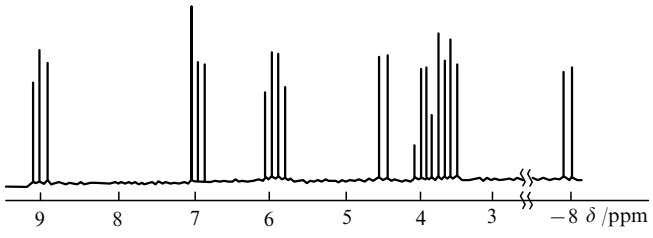

Figure 3. ^{1}H NMR spectrum of the bisporphyrin **7c** in $CDCl_3$.[73]

Three homologous dimers **9a**–**c** were investigated.[74] It was found that the porphyrin fragments approach each other by 100–120 pm as the number of the methylene groups in the bridges is decreased by one. The spectral properties are indicative of the 'face-to-face' orientation of the macrocycles.

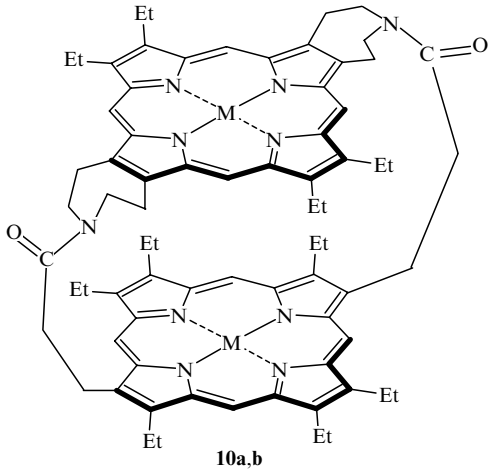
^{1}H NMR spectral studies revealed the existence of two conformers of dimer **10a**. In one of them, the porphyrin rings are located parallel to each other (*anti*). In another conformer, the porphyrin rings are bent with respect to each other (*syn*, 'half-open shell').[80] The conformers occur due to rigidity of the amide bonds and their appearance depends on the relative orientation of the carbonyl groups. The spectrum of a mixture of the conformers has four signals for the protons of the NH groups (at δ −8) and twelve signals for the *meso*-protons (at δ 7–10). Four signals (at δ 9) correspond to the *meso*-protons of the *anti* conformer and eight signals belong to the *meso*-protons of the *syn* conformer. The characteristic features of the crystal structure of the compound **10a** are responsible for the rather steady existence of both conformers in equal amounts. A decrease in the intensities of the signals for the protons in the spectrum of the *anti* conformer of the zinc complex of the dimer **10b** compared to the signals for the protons of the *syn* conformer indicates that the *anti* : *syn* ratio is 1 : 9. On protonation of the porphyrin **10a**, the amount of the *anti* conformer increases and the *anti* : *syn* ratio becomes equal to 1 : 6. No hypsochromic shift of the Soret band (see Section IV) is observed in the electronic absorption spectrum of the dimer **10a** compared to the spectrum of the monomeric analogue.

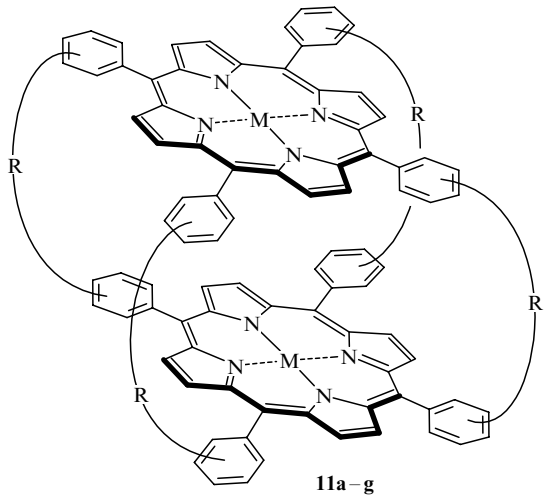


10a,**b**

M = 2H (**a**), Zn (**b**).

^{1}H NMR spectral studies established the characteristic structural features of cyclophane dimers **11a**–**d** in which the tetraphenylporphyrin fragments are linked through the *meta* or *ortho* positions of the phenyl substituents by four ether bridges.[77, 78]

The spectrum of the dimer **11a** differs from that of monomeric *meso*-tetra(3-butoxyphenyl)porphyrin in that the signals for the β-protons of the pyrrole rings are substantially split and the protons of the central CH_2 groups of the bridges give two signals. The signals for the protons of the OCH_2 and CH_2 groups are broadened. These characteristic features are retained on going from the neutral to protonated form of the dimer.



11a–g

R = *m*-O(CH$_2$)$_n$O-*m*, *n* = 4: M = H$_2$ (**a**), Zn (**b**); R = *o*-O(CH$_2$)$_n$O-*o*, *n* = 3: M = H$_2$ (**c**), Zn (**d**); R = *m*-CH$_2$NHCH$_2$-*m*, M = H$_2$ (**e**); R = *m*-CH$_2$NTsCH$_2$-*m*, M = H$_2$ (**f**); R = *m*-CH$_2$NTs-*m*, M = H$_2$ (**g**).

The cyclophane structure of the dimer imposes rigid limitations on the conformational flexibility of the O(CH$_2$)$_n$O chains. The fact that the protons of the bridging CH$_2$ groups give two signals is indicative of a skewed conformation of the ether bridges due to which the benzene rings of the adjacent macrocycles are inclined relative to each other. As a result, both fragments of tetraphenylporphyrin in the dimer adopt a nonplanar dome-shaped conformation. The resulting strain is partially relieved due to corrugation of the tetrapyrrole rings, *viz*., two opposite pyrrole fragments are bent upward, while two other fragments are bent downward. The inclination of the phenyl groups in combination with corrugation of the porphyrin macrocycle are responsible for the magnetic nonequivalence of the *ortho*-protons of the phenyl groups (external and internal) and the β-protons of the pyrrole rings. The external *ortho*-protons are located in proximity to the β-protons of the pyrrole rings directed upward, whereas the internal protons are located in proximity to the β-protons of the pyrrole rings bent downward. The distances between the pairs of the protons of the first type are smaller than those between the pairs of the protons of the second type due to which the deshielding effect of the ring currents of the macrocycle and the benzene ring in the first case is more pronounced (Table 16).

The corrugated dome-shaped conformation of the macrocycle is retained in the protonated form of the dimers. In the latter case, one pair of the protons of the NH groups is located in the centre of the macrocycle and is substantially shielded by the ring current, whereas the second pair of the protons is bent outward and the shielding effect of the ring current of the macrocycle exerted on the latter pair is weakened.

Corrugation of the porphyrin macrocycles in the protonated form of dimeric porphyrin leads to weakening of the macrocyclic ring current and strengthening of the local currents in the pyrrole fragments. For the external β-hydrogen atoms, the above-mentioned two effects compensate each other, whereas these effects with respect to the internal protons of the NH groups add up together resulting in substantial downfield shifts of the signals for these protons in the case of the dimeric porphyrin **11a** compared to its monomeric analogue (see Table 16).

The mutual effect of the macrocyclic ring currents of the adjacent porphyrin fragments leads to the nonequivalence of the protons of the NH groups in the dimer **11c**. Due to corrugation of the porphyrin rings, the distance from one pair of the protons of the NH groups to the adjacent tetrapyrrole fragment is 0.8 Å larger compared to that for the second pair.[78] This is a sufficient reason for the appearance of two signals for these protons in the ^{1}H NMR spectrum (see Table 16). The bridging groups in the dimer **11c**, unlike those in the dimer **11a**, are conformationally flexible. Judging from the fact that the positions of the signals of two OCH$_2$ groups are somewhat different (δ 4.25 and 4.11), two conformations of the bridge in solutions are rapidly (within the NMR time scale) transformed into one another. Apparently, the conformation with the unsymmetrical arrangement of the OCH$_2$ groups with respect to the tetraphenylporphyrin rings prevails.

In the ^{1}H NMR spectra of the cyclophane dimers **11e–g** in which the tetraphenylporphyrin fragments are linked through the *meta* positions of the phenyl groups by two- or three-membered bridges, the ring current exerts an even more pronounced shielding effect on the chemical shifts of the protons located below the plane of the adjacent porphyrin ring. The largest shifts are observed for the signals for the protons of the NH groups and for the *ortho*-protons of the phenyl groups because they are located between the porphyrin fragments.[79] The shifts of the signals for the β-protons of the pyrrole rings are much smaller because these protons are located at large distances from the shielding region.

Table 16. Positions and multiplicities of the signals in the ^{1}H NMR spectra of the cyclophane dimers of tetraphenylporphyrin **11a**,**c** and *meso*-tetra(3-butoxyphenyl)porphyrin.[77]

It can be seen that the mutual effect of the porphyrin fragments is strengthened as the lengths of the bridges in the compounds **11e** and **11g** decrease. Steric restrictions resulting from the presence of the bulky substituents in the bridges of the dimer **11f** lead to rotation of the macrocycles with respect to each other about the axis passing through the centres of both porphyrin rings (in the dimers **11f** and **11e**, the angle of rotation of the macrocycles with respect to each other is 26° and 13°, respectively). The molecule adopts an energetically more favourable conformation in which the porphyrin fragments, while remaining parallel to each other, are located at shorter distances and exert a more substantial shielding effect. This fact is confirmed by the ^{1}H NMR spectral data. As in the case of the dimers **11a**,**c**, the characteristic features of the cyclophane structures of the dimers **11f**,**g** are responsible for the magnetic nonequivalence of the *ortho*-protons of the benzene rings (internal and external) and the β-protons of the pyrrole rings.

In dimeric porphyrins **12a–d**, the aromatic bridge does not provide the 'face-to-face' orientation of the macrocycles.[81] This

Table 17. Positions and multiplicities of the signals in the ^{1}H NMR spectra of the dimeric porphyrins **12a**–**d** and 2,8,12,18-tetraethyl-3,7,13,17-tetramethyl-5-phenylporphyrin.[81]

Compound	δ(NH)	δ(Ar)	δ(*meso*-H)

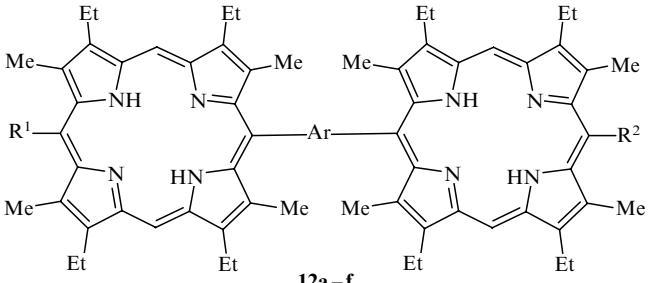
2,8,12,18-Tetraethyl-3,7,13,17-tetramethyl-5-phenylporphyrin	−2.39 s (2H)	8.00 d (2H), 8.24 t (2H), 8.75 t (1H)	9.79 s (1H), 10.21 s (2H)

fact is clearly manifested in the ^{1}H NMR spectra of the above-mentioned compounds (Table 17). The spectra of the unsymmetrical dimers **12c**,**d** are of most interest. The signals for the protons of the NH groups in these spectra are observed as singlets at δ −2 and −3, which is indicative of the nonequivalence of the π-electron systems of the porphyrin fragments of these dimers. Neither the spectra of the unsubstituted dimers **12e**,**f** nor the spectra of the symmetrical compounds **12a**,**b** show analogous splitting of the signals for the protons of the NH groups. The spectra of the dimers **12a**,**b** have one singlet each at δ −2.27 and −1.90, respectively. The high-field signal (at δ −3.0) was assigned to the *meso*-unsubstituted porphyrin fragment in the dimers **12c**,**d**, while the low-field signal (at δ −2.1 or −1.95) was assigned to the *meso*-substituted porphyrin fragment.[81] The chemical shifts of the protons in these compounds correspond to those in the linear *meso*-bound dimers of porphyrins whose spectra have signals for the protons of the aliphatic alkyl groups at δ 1.0–4.0, signals for the *meso*-H atoms at δ 9.8–11.0 and signals for the protons of the NH groups at δ −2.0 and −3.0. The signals for the protons of the phenyl fragments are observed at δ 7.95–8.95. These chemical shifts have different values in the spectra of the dimers **12a**,**c** and **12b**,**d** (see Table 17). The multiplicities and intensities of the signals correspond to the assumed structures of the compounds.

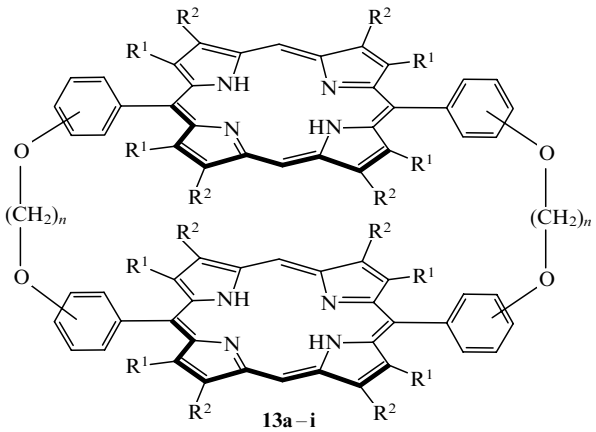


12a–**f**

$R^1 = R^2 =$  : Ar =  (**a**);  (**b**); R^1 = H, R^2 =  :

Ar =  (**c**),  (**d**); $R^1 = R^2$ = H: Ar =  (**e**);  (**f**).

Dimeric *meso*-diphenyl-β-octaalkylporphyrins **13a**–**i** containing the bridging $O(CH_2)_nO$ groups at different positions of the phenyl substituent were investigated.[82–86]



13a–**i**

R^1 = Me, R^2 = Bu: n = 2, *para* (**a**); n = 3, *para* (**b**); n = 4, *para* (**c**); R^1 = Me, R^2 = Et: n = 3, *meta* (**d**); n = 4, *meta* (**e**); R^1 = Et, R^2 = Me: n = 4, *meta* (**f**); R^1 = Me, R^2 = Bu: n = 2, *ortho* (**g**); n = 3, *ortho* (**h**); n = 4, *ortho* (**i**).

The cyclophane structures of these compounds were confirmed by the ^{1}H NMR spectral data (Table 18). The *meso*-protons and the protons of the β-CH_3 and NH groups give singlet signals. This indicates that the dimers adopt a symmetrical conformation in which the porphyrin macrocycles are located one above the other. However, it is conceivable that the singlet signals are observed due to the time-averaging of different (including unsymmetrical) conformations of the porphyrins.

In the spectra of the dimers under consideration, the signals for the protons of the NH groups are shifted upfield compared to those of the monomeric analogues **3i**–**k**, which is a manifestation of the mutual magnetic shielding of the ring currents of the aromatic macrocycles. Judging from the positions of the signals, the distance between the porphyrin fragments increases as the length of the bridging group increases (see Table 18). This distance is responsible also for the upfield shifts of the signals for the protons of the methylene groups in the spectra of the compounds **13a**,**b**,**d**,**g**,**h** (in which the number of the methylene units in the bridges n = 2 and 3) compared to the signals for the protons of the methoxy groups in the spectra of *meso*-di(methoxyphenyl)-substituted monomeric porphyrins. Starting from n = 4, these signals in the spectra of both the dimeric and monomeric compounds are observed virtually in the same region regardless of the positions of the bridging units in the benzene rings of the compounds **13c**,**e**,**i**.

The chemical shifts of the β-alkyl protons change only slightly on going from the monomers to the corresponding dimers. However, these shifts are substantially different for different structural isomers. Thus, the dimers **13e**,**f** differ by the arrangement of the methyl and ethyl groups at the β positions of the porphyrin fragments. In the porphyrin **13e**, the protons of the methyl groups experience the shielding effect of the ring currents of the phenyl substituents. In the case of the dimer **13f**, the shielding effect is exerted on the protons of the ethyl groups. The maximum shifts (1.08 ppm) are observed for the protons of the methylene groups directly bound to the macrocycle, while virtually no shifts (0.02 ppm) are observed for the signals for the protons of the CH_3 groups.

The signals for the protons of the bridging OCH_2 groups and the signals for the protons of the OCH_3 groups of the monomeric analogues are located nearly in the same region. The protons of the bridging CH_2 groups give signals at $\delta \sim 1.90$, which is characteristic of the protons of the corresponding substituents in the monomeric porphyrins.[12] Apparently, this is attributable to the fact that the peripheral substituents are not virtually enclosed by the ring current of the conformationally flexible dimers.

The signals for the protons of the phenyl groups in the spectra of the dimers **13a**–**c** are observed as a doublet for the *ortho*-

Table 18. Positions and multiplicities of the signals in the ^{1}H NMR spectra of the dimeric porphyrins **13a**–**i** and their monomeric analogues **3i**–**k**.[82–86]

[a] Signals for the protons of the methoxy group; [b] zinc complexes. Atropoisomers of the zinc complex of the dimer **13h**: [c] α,α,α,α; [d] α,β,α,α; [e] α,β,α,β.

protons (at $\delta \sim 7.8$) and a doublet for the *meta*-protons (at $\delta \sim 7.15$).

The dimers linked through the *meta* (**13d**–**f**) or *ortho* positions (**13h**,**i**) of the phenyl substituents exist as three atropoisomers, which differ by the orientations of the oxygen atoms of the ether bridges (Fig. 4). The compound **13g** containing short ether bridges ($n = 2$) does not form atropoisomers. The assignment of the signals to particular atropoisomers was made based on comparison of the chromatographic mobilities and polarities of the porphyrin molecules. From Table 19 it can be seen that the experimental data (R_f) agree with the calculated characteristics (the dipole moments of the molecules). The smaller the dipole moment of the molecule, the higher the chromatographic mobility of the atropoisomer.

The atropoisomerism of porphyrins is well studied.[89,90] For the phenyl fragments to be rotated, the macrocycle must be deformed to reduce steric interactions between the *ortho*-substituents and the protons of the NH or CH_2 groups. The addition of the side methyl groups would be expected to hinder rotation. However, the activation energy of thermal atropoisomerism is increased only slightly on going from *meso*-tetraphenylporphyrin to (*meso*-diphenyl)octamethylporphyrin. This phenomenon was

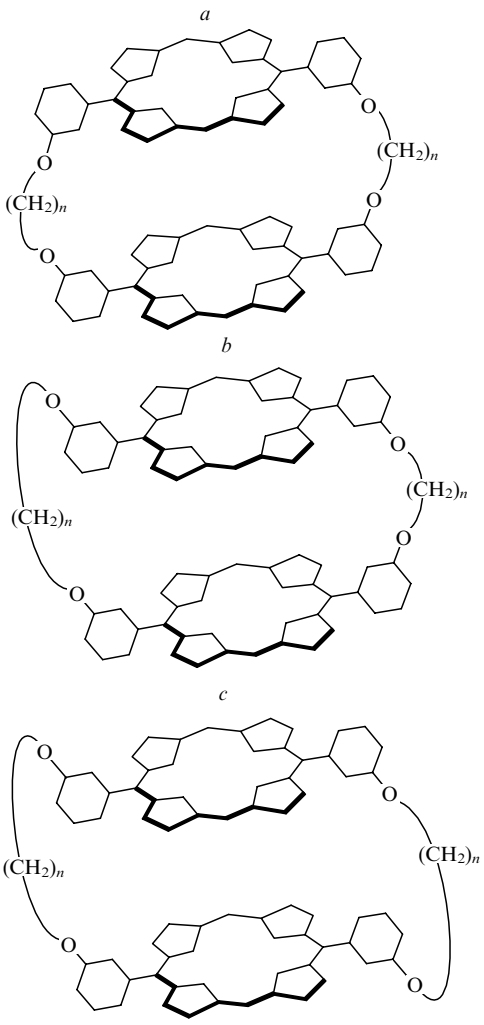

Figure 4. The α,α,α,α- (*a*), α,β,α,α- (*b*) and α,β,α,β-atropoisomers (*c*) of the dimers **12d**–**f**.[86]

accounted for by the flexibility of diphenylporphyrins.[89,90] The molecules of these compounds possess two free *meso* positions along which the ring is, apparently, folded. Therefore, steric restrictions arising from the introduction of additional β-methyl groups are compensated by flexibility of the diphenylporphyrin molecule.

Table 19. Dipole moments (μ) and chromatographic mobilities (R_f) on Silufol of the monomeric (**3h**–**m**) and dimeric (**13h**) porphyrins.[87,88]

Compound	Substituent in the benzene ring	Atropoisomer	μ /D (see [a])	R_f (see [b])
3h	H		0.107	0.60
3i	4-OMe		0.681	0.43
3j	3-OMe		0.674	0.45
3k	2-OMe	α,α	0.970	0.30
		α,β	0.100	0.65
3l	4-NO_2		0.424	0.50
3m	3-NO_2		0.026	0.75
13h	2-O$(CH_2)_4$O-2	α,α,α,α	0.075	0.61
		α,β,α,α	0.755	0.49
		α,β,α,β	1.398	0.31

[a] The dipole moments were calculated by the semiempirical CNDO and INDO methods. The conformations with the minimum energies were optimised by the block-diagonal Newton–Raphson method; [b] in the case of monomeric porphyrins, the spots were visualised with toluene; in the case of the atropoisomers of the dimeric porphyrin, the spots were visualised with a 1 : 4 pyridine–hexane mixture.

It was demonstrated [12] that, unlike the monomeric porphyrin **3k**, which readily underwent atropoisomerisation in boiling *o*-xylene (starting from one isomer, a mixture of the α,α and α,β isomers was formed in a ratio of 1 : 1), the phenyl fragments in the dimeric porphyrins cannot rotate and the atropoisomers of these compounds are stable. The ^{1}H NMR spectral data for the α,α,α,α, α,β,α,α and α,β,α,β isomers of the zinc complex of the dimer **13h** are given in Table 18. As in the case of the monomer **3k**, the spectra of the atropoisomers of the dimeric porphyrin **13h** differ only by splitting of the signals for the protons of the phenyl groups. The spectrum of the α,α,α,α atropoisomer, which is, apparently, characterised by the higher degree of equivalence of the protons, has a doublet for the *ortho*-protons and a triplet for the *para*-protons. The nonequivalent *meta*-protons give individual signals as a doublet and a triplet. The spectra of the α,β,α,α and α,β,α,β atropoisomers have a pronounced triplet for the *para*-protons and a doublet from a portion of the *meta*-protons. The signals for the other portion of the *meta*-protons and the signals for the *ortho*-protons coalesce into a multiplet.

IV. Electronic absorption spectra of porphyrins and metalloporphyrins

Electronic absorption spectra of porphyrins are very characteristic and contain four low-intensity absorption bands in the visible region and one very intense band in the violet region of the spectrum (the Soret band). The commonly accepted classification of these bands is as follows. The bands *I* and *III* in the visible region of the spectrum (Fig. 5 *a*) belong to quasi-forbidden electron transitions, whereas the bands *II* and *IV* are of electronic-vibrational origin, *i.e.*, are vibrational satellites of the bands *I* and *III*, respectively. Although possessing a number of common features, the spectra of porphyrins show substantial variations, which reflect the changes in the molecular structure and the effect of the solvent. According to the universally accepted concepts, light absorption is accompanied by excitation of the porphyrin molecule and the characteristic features of the absorption spectrum are determined by transitions of the π-electrons between two higher occupied and two lower unoccupied orbitals (the four-orbital Platt–Gouterman model [1]).

The intensity ratio of the absorption bands in the spectra of porphyrins depends on their structures in a peculiar fashion. The ethio type of the spectrum (see Fig. 5 *a*) with the intensity ratio *IV* > *III* > *II* > *I* is typical of *meso*-tetraphenylporphyrin, ethio-

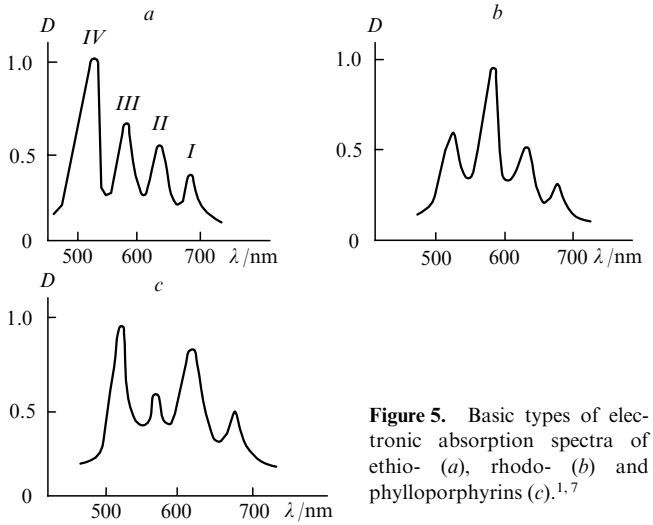

Figure 5. Basic types of electronic absorption spectra of ethio- (*a*), rhodo- (*b*) and phylloporphyrins (*c*).[1,7]

porphyrin and other symmetrically substituted porphyrins. For porphyrins characterised by the rhodo type of the spectra (Fig. 5 *b*), another sequence, *viz*., *III* > *IV* > *II* > *I*, is realised. Among the latter compounds are rhodoporphyrin and other porphyrins containing an electron-withdrawing substituent (COOH, NO_2, Cl, *etc*.) in the pyrrole fragment. Phylloporphyrin and other porphyrins containing one or two *meso*-substituents are characterised by the phyllo type of the spectrum (*IV* > *II* > *III* > *I*) (Fig. 5 *c*). Chlorin, tetrabenzoporphyrin and phthalocyanine give characteristic spectra of their own. In their spectra, the long-wavelength band *I* has the maximum intensity.

On going from porphyrin to metalloporphyrin, the symmetry of the planar macrocyclic fragment (of the π-electron cloud of the macrocycle) increases due to which the spectrum is simplified. The Soret band changes only slightly upon complex formation. The visible region of the spectra of metal complexes has two absorption bands, *viz*., the band *I* corresponding to the electron transition and the band *II* corresponding to the electronic-vibrational transition. The energy of the electron transition for the band *I* and its position in the spectrum (λ_1) can serve as reliable criteria for determining the strength and the type of the metal (M)—nitrogen chemical bond in metalloporphyrins. The band *I* is shifted hypsochromically as the strength of the M—N coordination bond in metalloporphyrins containing the planar MN_4 coordination unit increases.[91,92]

One of the most important features of metalloporphyrins is the deviation of the metal atom from the plane of the MN_4 coordination unit under the influence of the strongly coordinated molecular ligands or acido ligands. In most cases, the deviation of the metal atom from the plane is accompanied by a long-wavelength shift of the band *I*, whereas the movement of the metal atom toward the plane is accompanied by a short-wavelength shift.[7]

Therefore, electronic absorption spectroscopy is a powerful tool in studying the type and strength of the coordination bonds in metalloporphyrins, the degree of aromaticity of the macrocycle and its change upon chemical modification of the porphyrin.

1. Porphyrins

Electronic absorption spectra of porphyrins depend substantially on both the electronic and steric factors. Not only the positions and intensities of the absorption bands, but also their number can be changed. From this viewpoint, of special note is the introduction of four substituents at the *meso* positions of porphyrin. A rise in the aromaticity and an increase in the rigidity of the macrocycle lead to the complete disappearance of vibrational satellites and to a sharp increase in the intensities of the electron transition bands (Fig. 6). The band *I* in the electronic spectrum of tetraazoporphyrin is shifted to the short-wavelength region.[6]

On the whole, the introduction of substituents at the *meso* positions of the porphyrin macrocycle has a more substantial

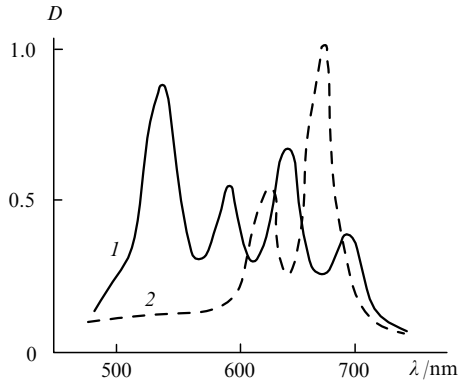

Figure 6. Electronic absorption spectra of porphyrin (*1*) and tetraazaporphyrin (*2*) in chloroform.[6,7]

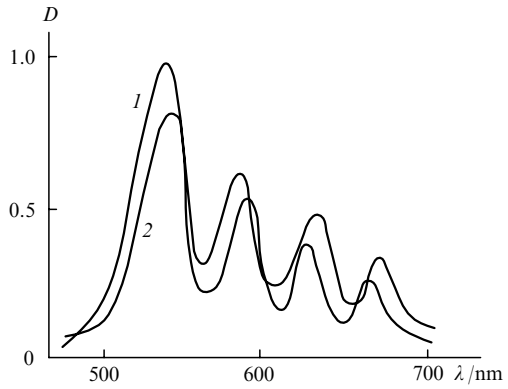

Figure 7. Electronic absorption spectra of *meso*-tetramethylporphyrin (*1*) and *meso*-tetraphenylporphyrin (*2*) in chloroform.[25]

effect on the absorption spectra than the introduction of substituents at the β positions. The *meso*-tetrasubstituted porphyrins are characterised by a distorted ethio type of spectra with rather large (25–40 nm) bathochromic shifts of the bands (Fig. 7, Table 20). It should be noted that small hypsochromic shifts of all absorption bands are observed on going from *meso*-tetramethylporphyrin to its homologues containing longer alkyl substituents.[38] Similar bathochromic shifts are observed in the electronic absorption bands on going from porphyrin to *meso*-tetraphenyl- or *meso*-tetramethylporphyrin (see Table 20). In these cases, the steric factor, apparently, prevails over the electronic effect.

The introduction of various substituents at the *para* positions of the phenyl rings of *meso*-tetraphenylporphyrin causes bathochromic shifts of the absorption bands in the visible region of the spectra. A comparison of the spectra of tetraphenylporphyrin and its *para*-substituted derivatives demonstrated that the intensities of the electron transition bands (*I* and *III*) rise as the electron-donating properties of the substituents increase. Simultaneously, the intensities of the vibrational bands (*II* and *IV*) are diminsihed.[93] The ethio type of the spectrum of tetraphenylporphyrin is distorted because the band *I* becomes more intense than the band *II*.

The presence of electron-donating substituents at the *meta* positions also leads to bathochromic shifts of the bands, the intensities of the vibrational bands being increased, while the intensities of the electron transition bands remaining virtually unchanged.[25] The spectra of *ortho*-substituted tetraphenylporphyrins are characterised by lower intensities of the electron transition bands compared to those observed in the electronic absorption spectrum of tetraphenylporphyrin. In some cases, this gives rise to the spectra of the phyllo type, for example, in the case of tetra(2-halogenophenyl)porphyrins and, particularly, in the case of tetra(2,6-dihalogenophenyl)porphyrins.

The absorption spectra are also dependent on the solvent. Thus, the bands in the electronic absorption spectra of substituted *meso*-tetraphenylporphyrins are shifted bathochromically and the intensities of the electron transition bands grow on going from nonpolar hexane to polar pyridine.[25]

It is known[39] that the introduction of methyl groups at the β positions of the porphyrin ring causes only slight bathochromic shifts of the absorption bands (5–10 nm). The effect of the *meso*-substitution on the spectral characteristics of β-alkylporphyrins and their complexes with some transition metals (Zn, Cu or Ni) was investigated.[14,17,38,39] 2,8,12,18-Tetrabutyl-3,7,13,17-tetramethylporphyrin (**3t**), which is similar in the electronic effect of the substituents to natural porphyrins, was used as the starting compound. Derivatives of the porphyrin **3t** containing aryl (**3h**–**m**) or alkyl (**3a**–**g**) substituents or aza bridges (**14m**) at positions 5 and 15 are structurally related to the most important

As can be seen from Fig. 8, the absorption spectra of these compounds, as well as of their zinc complexes, are similar. The spectral changes are quantitative rather than qualitative. This fact indicates that the corresponding electron transitions are of the same type and suggests that the introduction of two phenyl or alkyl substituents or the replacement of the carbon atoms at the *meso* positions by the nitrogen atoms exerts a rather small perturbing effect on the π-system of the porphyrins and their zinc complexes under study, and the π-system retains the approximate symmetry D_{2h} and D_{4h}, respectively.

It was demonstrated [17] that electron transitions in metalloporphyrins occur from the a_{1u} and a_{2u} orbitals to the e_{gx} and e_{gy} orbitals. The a_{1u} orbital has four nodal planes passing through the *meso* positions and the central nitrogen atoms. The a_{2u} orbital possesses zero electron density on the β-carbon atoms. Hence, perturbation of the π-system of metalloporphyrins at the β positions, for example, upon alkylation, destabilises the a_{1u} orbital, while the energy level of the a_{2u} orbital remains unchanged. On the contrary, perturbation at the *meso* positions and the nitrogen atoms has no effect on the a_{1u} orbital and affects the a_{2u} orbital. Two degenerate antibonding e_g orbitals differ in that one of the nodal planes of the e_{gx} orbital and one of the nodal planes of the e_{gy} orbital pass through different pairs of the nitrogen atoms (in porphyrins, NH – NH).

Figure 9 shows the changes in the energy levels of the a_{1u}, a_{2u} and e_g orbitals (taking into account their nodal properties) that occur on going from the zinc complexes of the octaalkylporphyrin **14g** to the zinc complex of the *meso*-diazaoctaalkylporphyrin **14j**. The energy levels of the higher occupied (b_1 and b_2) and lower

unoccupied (c_1 and c_2) orbitals of free porphyrins are also presented in Fig. 9.

The replacement of the carbon atoms at the *meso* positions by the nitrogen atoms results primarily in lowering of the energy levels of the a_{2u} and e_g orbitals compared to the levels of these orbitals in the compound **14g** and, as a consequence, in weakening of the configuration interactions between the excited one-electron states $a_{1u}e_{gx}$ and $a_{2u}e_{gx}$ and between $a_{1u}e_{gy}$ and $a_{2u}e_{gy}$. Correspondingly, the intensity of the absorption band *I* in the electronic absorption spectrum of the complex **14j** is higher than that present in the spectrum of the complex **14g**. An analogous effect is observed in the case of free porphyrins. Thus, the bands *I* and *II* in the spectrum of the *meso*-diazaoctaalkylporphyrin **14m** are more intense than those in the spectrum of the octaalkylporphyrin **3t**.

Weakening of the configuration interaction would be expected to cause hypsochromic shifts of the absorption bands in the visible region of the spectra of the aza derivatives **14j**,**m** and the bathochromic shift of the Soret band. However, experimental studies demonstrated that the replacement of the carbon atoms by the nitrogen atoms has the opposite effect. Apparently, the direction of the shift of the absorption bands on going from the porphyrins **3t** and **14g** to their aza analogues **14m** and **14j** is determined by a change in the energy of the corresponding one-electron transitions, *i.e.*, by stabilisation of the a_{2u} and e_g levels in the compound **14j** and the b_1 and c_2 levels in the ligand **14m**. On going from the above-mentioned porphyrins to their aza derivatives, the intensities of the electronic-vibrational bands *II* and *IV* of the porphyrin and the band *II* of the complex are sharply diminished (see Fig. 8, Table 21). These bands borrow the intensity from the adjacent allowed Soret band.[17] The smaller the difference between the energies of the interacting transitions, the higher the efficiency of this rearrangement of the intensities. The replacement of the carbon atoms by the nitrogen atoms is accompanied by a

hypsochromic shift of the Soret band resulting in the low intensities of the electronic-vibrational bands in the spectra of the compounds **14m** and **14j**.

A comparison of the electronic absorption spectra of the metal complexes of octaalkylporphyrin derivatives (M = Zn, Cu or Ni) demonstrated that the bands are shifted to the low-frequency region. These shifts increase in the series Zn < Cu < Ni, *i.e.*, as the strength of the metal–nitrogen coordination bond increases. An enhancement of the electronegativity of the metal atom leads to lowering of the electron density on the occupied π-orbitals of the porphyrin molecule, which is accompanied by hypsochromic shifts of the bands (particularly, of the band *I*).

An analogous regularity is also observed for the positions of the 'metal-sensitive' bands in the IR spectra of porphyrins.[11] The deformation vibration bands of the alkyl groups (at 955 and 910 cm^{-1}) and the stretching and deformation vibration bands of the *meso*-protons (at 3110, 1220 and 835 cm^{-1}) are shifted to the high-frequency region as the degree of coordination of the metal atom increases.

On going from the octaalkylporphyrin **3t** to the *meso*-diphenyloctaalkylporphyrin **3h**, the Soret band is shifted bathochromically (see Table 21). It was demonstrated [38] that the introduction of strong donor or acceptor substituents into the phenyl rings of the diphenyl-substituents porphyrins **3i**–**m** has virtually no effect on the absorption spectra. Apparently, all absorption bands are shifted bathochromically due to distortion of the planar structure of the porphyrin macrocycles due to the presence of the phenyl substituents. This suggestion is evidenced by the ^{1}H NMR spectral data.[12, 14] It is known that steric restrictions are responsible for analogous changes in the electronic absorption spectra of *ortho*-derivatives of tetraphenylporphyrin [81] and cyclophane dimeric porphyrin. [76] A comparison of the electronic absorption spectra of the structural isomers **3h** and **3n** showed that the replacement of the methyl groups at positions 3, 7, 13 and 17 of the porphyrin macrocycle by the butyl groups leads to a substantial increase in the bathochromic shift of the absorption bands resulting from additional deformation of the porphyrin molecule due to the mutual effect of the adjacent butyl and phenyl fragments.

The electronic absorption spectra of the *meso*-dialkyl-substituted octaalkylporphyrins **3a**–**g** belong to the ethio type. For the first four members of the series, the odd-even alternation of the positions of the bands *I* and *III* is observed (see Table 21).

The porphyrin rings in the *meso*-tetrasubstituted octaalkylporphyrins **3u**,**v** have distorted 'corrugated' structures giving rise to substantial bathochromic shifts and broadening of the bands in their electronic absorption spectra compared to those observed in the spectra of tetraphenylporphyrin and *meso*-disubstituted octaalkylporphyrins (see Table 21).

2. Bisporphyrins

The electronic absorption spectra of cyclophane dimeric porphyrins have the following distinguishing features as compared to the monomeric analogues:[76–86, 94–102]

(1) a relatively large hypsochromic shift and substantial broadening of the Soret band;

(2) one diffuse absorption band at the long-wavelength side of the Soret band;

(3) a small bathochromic shift in the visible region.

The shifts of the bands in the absorption spectrum are determined by two factors, *viz*., by essential interactions between two identical porphyrin fragments whose nature depends on the symmetry of the dimer (the factor of exciton interactions) and by the effect of the solvent, which reflects the different degree of solvation of the ground and excited states (the factor of solvation).

In the short-wavelength region, the effect of the first factor leads to the hypsochromic shift of the Soret band in the electronic absorption spectra of symmetrical porphyrins, while the second factor causes broadening of this band. The manifestation of the low-energy excited states is possible in the case of displacement or inclination of the porphyrin macrocycles due to which the Soret band has a shoulder at 450 nm. Small bathochromic shifts of the bands in the visible region are attributable to weakening of the effect of exciton interactions in the long-wavelength region of the spectrum.

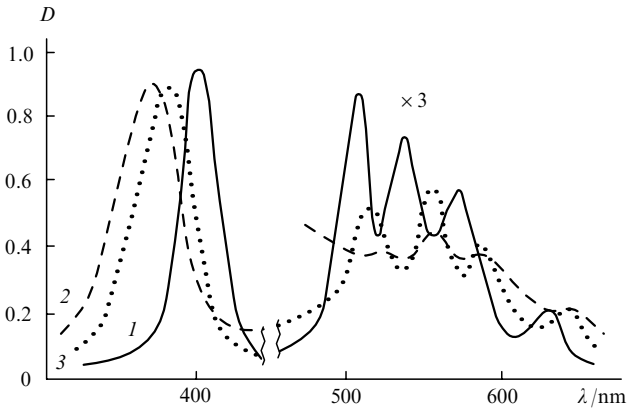

Figure 10. Electronic absorption spectra of the monomeric porphyrin **8** (*1*) and the dimeric porphyrins **7a** (*2*) and **7b** (*3*) in dichloromethane.[72]

The electronic absorption spectra of the monomeric porphyrin **8** and the β-bound dimers **7a**,**b**[72] are shown in Fig. 10.

The hypsochromic shift of the Soret band increases and the absorption bands in the visible region are shifted bathochromically and become more diffuse as the number of units in the bridge increases. The changes in the positions of the amide groups in the bridges also exert an effect on the electronic absorption spectra (Table 22).

In the electronic absorption spectra of the dimers **15a**–**d** and **16a**,**b** linked through the flexible hydrocarbon bridges and rigid aromatic fragments, respectively, the Soret band is shifted hypsochromically and the bands in the visible region are shifted bathochromically compared to those in the spectra of their monomeric analogues.[57, 70, 100] These shifts are determined by the strength of interactions between the porphyrin fragments, which depends not only on the distance between the macrocycles, but also on their mutual arrangement.

The hypsochromic shift of the Soret band in the electronic absorption spectrum of the compound **15c** containing two eight-atom bridges is 10 nm (Table 23). A decrease in the length of one bridge by two methylene units (the compound **15b**) leads to a

Table 22. Electronic absorption spectra of monomeric porphyrin (**8**) and the dimeric porphyrins **7a**–**n** in dichloromethane.[72, 73]

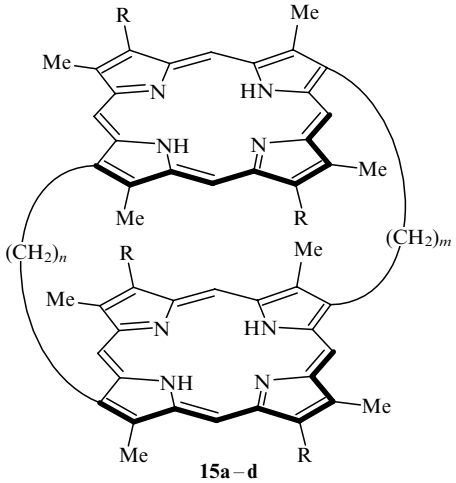
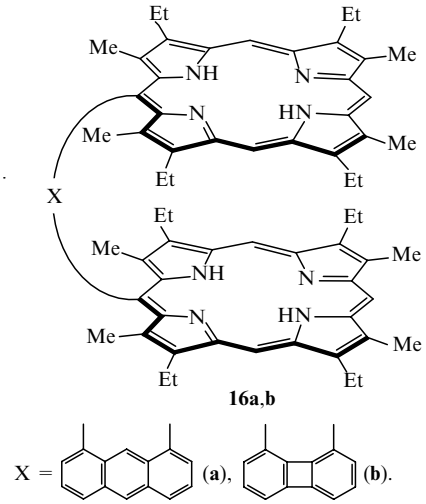
[a] The absorption maximum of the Soret band; the electronic absorption spectrum was measured in dichloromethane; [b] the emission spectrum was recorded in dichloromethane on irradiation in the Soret region; [c] the quantum yield of fluorescence of the dimeric complexes with respect to the corresponding monomeric complexes; [d] the Zn complex of the compound **8**; [e] the protonated form of the compound **8**.

decrease in this shift by 4 nm. Apparently, the interactions between the π-electron systems of the macrocycles are weakened and the effect of exciton interactions on the spectral properties is reduced due to inclination of the porphyrin macrocycles arising from the different length of the bridges. An analogous spectral behaviour was observed [94, 103, 104] in the case of dimers containing two flexible ester bridges.



15a–d

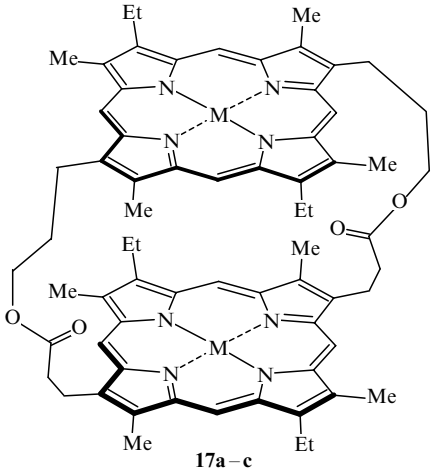
$m = n = 5$ (**a**), $m = 8$, $n = 6$ (**b**), $m = n = 8$ (**c**), $m = n = 10$ (**d**).



16a,b

X = (**a**), (**b**).

The Soret band in the electronic absorption spectra of the dimer **17a** and its zinc complex **17b** is broadened and is hypsochromically shifted relative to the Soret band in the spectra of the monomer **8** and its zinc complex. The distance between the macrocycles in the dimers increases and interactions between the porphyrin fragments are weakened upon protonation (Table 24).



17a–c

M = H_2 (**a**), Zn (**b**), H_4 (**c**).

The dimers adopting a 'face-to-face' conformation are characterised by fluorescence quenching due to interactions between the porphyrin fragments. In the case of the dimer **17a**, this quenching was ~50% of the corresponding value for the monomeric analogue.

In the absorption spectra of the dimers containing four bridges, no hypsochromic shift is observed in the short-wavelength region (Table 25). The spectrum of the dimer **18a** containing the ester bridges is characterised (Fig. 11) by noticeable broadening and the bathochromic shift of the band in the visible region of the spectrum, while the position of the Soret band

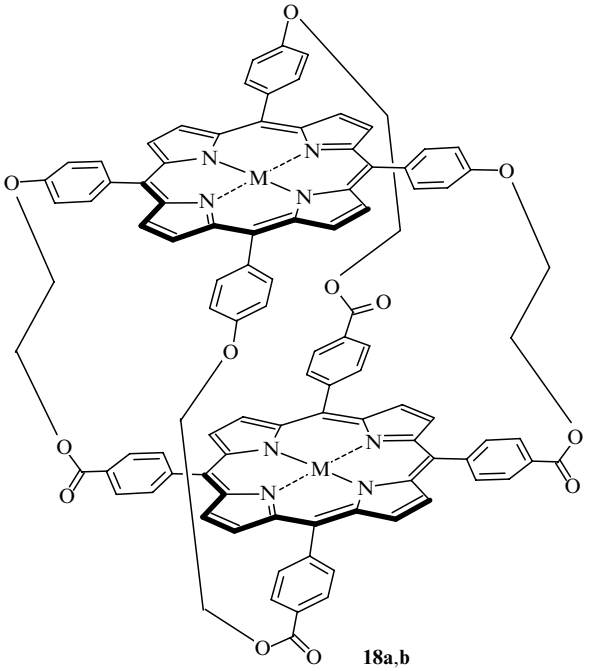
[a] The spectra were measured in chloroform.

remains unchanged.[70, 105] The absorption bands in the visible region of the spectrum of the dimer **11a** containing ether bonds are shifted bathochromically [77] by 25–40 nm and the Soret bands are shifted by 20–25 nm compared to those observed in the spectrum of the monomeric analogue (Fig. 12 *a*).



18a,**b**

M = H_2 (**a**), Zn (**b**).

This spectral behaviour of the dimer **11a** is attributed to extension of the conjugated π-electron system due to partial conjugation between the π-systems of the phenyl rings and the porphyrin macrocycles.[77] This effect is most clearly pronounced in the electronic absorption spectrum of a solution of the compound **11a** in CH_3CO_2H in which the dimer **11a** exists in the protonated form (Fig. 12 *b*).

Protonation leads to an essential increase of deformation of the macrocycle, while the dihedral angle between the mean porphyrin plane and the plane of the benzene π-systems decreases significantly. A decrease in the length of the bridge by one methylene group on going from the dimer **11a** to the dimer **11c** is accompanied by hypsochromic shifts of all bands by 7–21 nm (see Table 25). However, the bathochromic shift with respect to

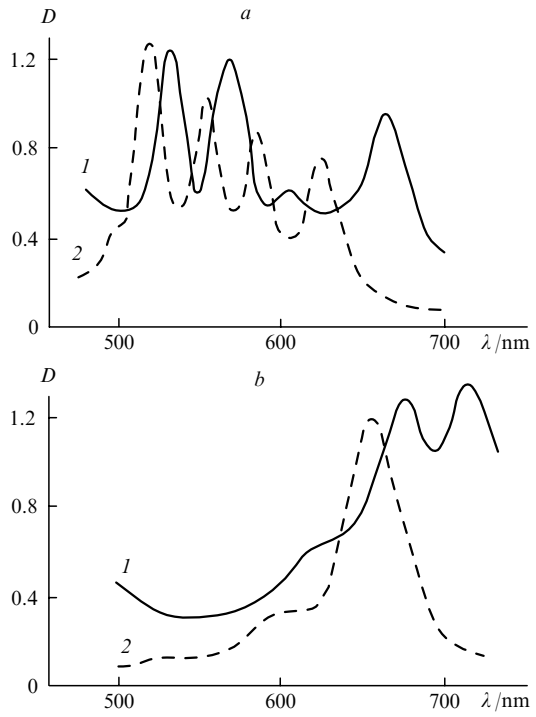


Figure 12. Electronic absorption spectra of the dimer **11a** (*1*) and tetra-*meso*-(*m*-butoxyphenyl)porphyrin (*2*) in pyridine (*a*) and acetic acid (*b*).[77]

the absorption bands in the spectrum of the monomeric analogue is retained.

In the electronic absorption spectra of the cyclophane dimers **11e**–**g**, the Soret band is shifted to the short-wavelength region by 4–5 nm and is broadened compared to the Soret band in the spectrum of the monomer (see Table 25).[79] Broadening is more pronounced in the case of the dimer **11f** in which the porphyrin fragments, while remaining parallel, are rotated with respect to each other (α_{max} = 26°). The spectral characteristics are changed due to interactions between the dipoles of the electronic transitions in two porphyrin fragments located at angles other than 0 or 180° with respect to each other. Bookser and Bruice [79] believed that the observed broadening and shifts of the bands indicate that solutions contain the dimers **11e**–**g** predominantly in a twist conformation. In this case, steric restrictions are less significant and the adjacent porphyrin rings are brought into proximity, which is also confirmed by the ^{1}H NMR spectral data.

The electronic absorption spectra (Fig. 13 *a*,*b*) of the dimeric *meso*-diphenyl-β-octaalkylporphyrins **13a**–**i** containing the $O(CH_2)_nO$ bridging groups were investigated.[82–85] The absorption bands of all dimeric porphyrins **13** are broadened and shifted hypsochromically by 5–20 nm compared to those in the spectrum of the monomeric porphyrin **3h** (Table 26). The short-wavelength shifts of the bands increase regularly as the length of the $O(CH_2)_nO$ bridge decreases and the adjacent porphyrin fragments approach each other. Considering this shift as a characteristic of the average distance between the porphyrin fragments in the dimer, it can be concluded that this distance decreases on going from the α,α,α,α to α,β,α,β atropoisomer (see Fig. 4). Calculations of the structures of the octamethyl analogues of the dimers by molecular mechanics demonstrated that the distance between the porphyrin fragments is no less than 3.6 Å.[87]

Consequently, exciton interactions between the porphyrin rings are responsible for the shifts of the absorption bands. Since the bands are shifted hypsochromically, the dimers have predominantly the 'face-to-face' orientation with the parallel arrangement of the interacting dipole moments of the electronic transitions. Each atropoisomer of the dimer exists as an equilibrium mixture of a large number of conformers. The structures of some of these

conformers were studied by molecular mechanics (the MM+ force field). The atomic coordinates and the components of the potential energy of the optimised structures are summarised in the study.[87] From Table 27 it follows that a change from one conformer to another is generally accompanied by insignificant changes in the energy of the molecule (at most 10 kJ mol^{-1}). In spite of the fact that it is presently impossible to carry out complete analysis of the potential energy surface of such complex molecules, the existence of various conformational isomers in the gaseous phase and solutions is beyond question.

The results of geometry optimisation of dimeric porphyrins by the MM+ method (Fig. 14) demonstrated [87,88] that the aromatic tetrapyrrole macrocycle is deformed very readily. None of 15 conformers contains the planar porphyrin fragment. Conformational rearrangements of the tetrapyrrole nucleus occur through changes of the dihedral angles C–C–C–C, C–C–C–N, *etc.*, while the bond lengths and bond angles remain constant.

Each conformer of the dimeric porphyrins **13a**–**i** has its own individual absorption spectrum. It is needless to say that these spectra are qualitatively similar to the spectra of the monomeric analogues. However, in a quantitative sense these differences may be significant. One would expect that the absorption bands of the conformers with the parallel and perpendicular arrangement of the porphyrin rings will be shifted hypsochromically and bathochromically, respectively, under the influence of the exciton factor. The experimental spectra represent superpositions of the spectra of all conformers present in solution due to which the absorption bands of dimeric compounds are broadened and their intensities are lower compared to those of monomeric porphyrin. At the same time, the corresponding absorption bands in the spectra of monomeric and dimeric porphyrins do not differ in oscillator strength (f), which was calculated according to the approximate equation

$$f = (4.6 \times 10^{-9})\, \varepsilon_{max} \Delta\nu_{1/2},$$

where ε_{max} is the absorption coefficient at the absorption maximum and $\Delta\nu_{1/2}$ is the half-width of the band.

The data in Table 26 show that the absorption bands in the spectra of the *para*-bound dimers **13a**–**c** are shifted bathochromically compared to those of their *meta*- (**13d**–**f**) and *ortho*-analogues (**13g**–**i**). This phenomenon may be attributed both to an increase in the proportion of conformers of the 'half-open shell' type and to a more substantial deformation of the porphyrin macrocycle in the *para*-bound dimers.

Table 27. Strain energies of the conformers of the *ortho*-, *meta*- and *para*-bound dimers **13a**,**d**,**h** (E/kJ mol^{-1}) and their components (kJ mol^{-1}): strain energies of bonds (E_1), bond angles (E_2), torsion angles (E_3), van der Waals interactions (E_4), stretching–bending (E_5) and Coulomb interactions (E_6).[87,88]

	12	683	21	437	99	71	2	53

[a] For notations of the conformers, see Fig. 14.

It should be noted that not only the positions of the absorption bands, but also the ratio of their intensities in the electronic absorption spectra of dimeric porphyrins are changed. In the case of *para*-bound dimers, the phyllo type of the spectrum, which is characteristic of monomeric β-octaalkyl-*meso*-diphenylporphyrins, is retained, while the spectra of the *ortho*- and *meta*-analogues belong to the ethio type (Fig. 15).

The differences in the electronic absorption spectra are reduced due to protonation of the porphyrin rings of the dimers **13a**–**i** in acetic acid and, correspondingly, to an increase of the distance between the likely charged fragments.

* * *

The data surveyed in the present review give convincing evidence that the combined use of modern spectroscopic methods enables one to obtain comprehensive information on the molecular

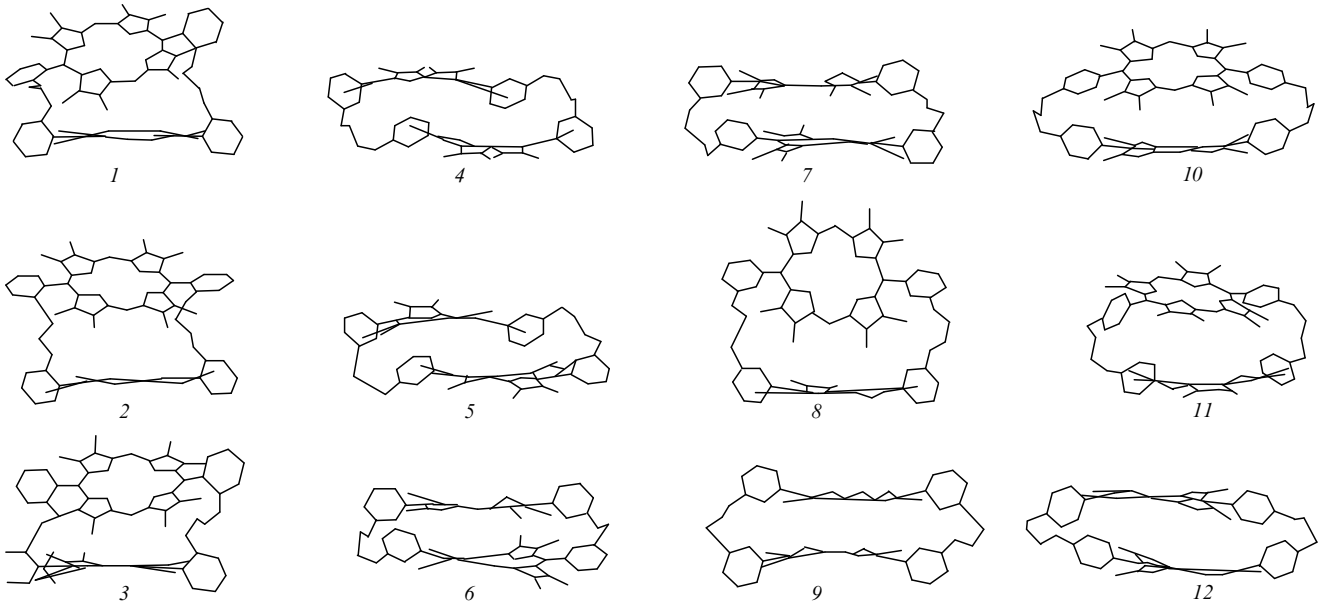

Figure 14. Conformers of the dimeric porphyrins **13h** (*1*–*3*), **13d** (*4*–*9*) and **13a** (*10*–*12*).[87,88]

structures of the newly synthesised compounds. The development of the spectroscopy of porphyrins provides the theoretical basis for the wider use of this unique class of tetrapyrrole macrocyclic compounds in technology, medicine and biology because the determination of the correlations between the structure and the spectral properties of the molecules can help in solving the problem of the construction of new materials with the desired properties.

Abstract. Published data on the properties of a novel nanomaterial *viz*., detonation synthesis ultradispersed diamonds (UDD), are summarised and systematised for the first time. Certain properties of UDD synthesised under different conditions are compared. Particular attention is drawn to substantiation of the cluster model of UDD and the fractal nature of their aggregates. The potential application fields of UDD are considered. Operating parameters of new materials are presented. The bibliography includes 110 references.

I. Introduction

Detonation synthesis ultradispersed diamonds (UDD or nanodiamonds) pertain a class of nanomaterials the fabrication, modification, and application of which attract the attention of scientists and engineers from different countries. This area of science and technology is at the boundary of solid-state physics and chemistry and thus becomes the world's most rapidly growing field as regards fundings provided for its development.

At present, a wide spectrum of nanoparticles is studied which differ in both their nature (metals, non-metals, chemical compounds) and the technologies for their production (gas-phase and plasmochemical syntheses, precipitation from colloidal solutions, thermal decomposition and reduction, mechanical synthesis, electrical-detonation and detonation syntheses) and the unique properties of particles and materials and articles manufactured on their basis. The latter aspect is of prime importance in view of the development of novel industrial technologies which include miniaturisation of facilities.

We believe that, among all types of nanomaterials, UDD represent the most interesting subject. Indeed, first of all, even a bulk diamond (*e.g*., natural diamond) exhibits a unique combination of chemical, physicochemical (particularly, thermophysical) and mechanical properties. Second, diamonds resulting from miniaturisation or, more precisely, prepared in a form of nanoparticles (mean size 4 – 6 nm) from a plasma upon detonation of powerful explosive mixtures (EM), acquire more pronounced anomalous properties.

Whereas ordinary (natural) diamonds are applied in practice, as a rule, as abrasives and cutting tools and substrates for microelectronics, the application sphere of UDD is much wider. By chemical, barochemical and thermal treatment of UDD one can impart to them different surface properties. In this connection, the attention of scientists is focused on detailed studies of characteristics and properties of diamonds and a search for new application fields.

In Russia, UDD are used as a composite material in electrochemical and chemical metal – diamond coatings, polymeric films and membranes; in different kinds of rubbers; as anti-friction and anti-wear additives to lubricants of different purposes; in finishing and super-finishing polishing compositions; in abrasives. Nanodiamonds serve in fabrication of magnetically soft and hard input media, anti-friction tribotechnological diamond-containing compositions based on thermoplastic materials (used in friction joints), abrasion-resistant structure materials based on ethylene thermoplastic co-polymers and in manufacture of radiation- and ozone-resistant rubbers. Moreover, they are most important components in the reprocessing of worn tire rubber. Studies are launched on sintering of UDD under high dynamic and static pressures (for manufacture of cutting tools, abrasives, substrates for microelectronics), on using them in medicine (as anti-cancer drugs and a component of such drugs, an effective gastroenteritis

V Yu Dolmatov Special Design Bureau (SDB) 'Tekhnolog' at the St. Petersburg State Technological Institute (Technical University), Sovetskii prosp. 33A, 193076 St. Petersburg, Russian Federation. Fax/Tel. (7-812) 100 38 98. E-mail: alsen@comset.net

Uspekhi Khimii **70** (7) 687 – 708 (2001); translated by T Ya Safonova

remedy, an immobiliser of biologically active substances, a super-effective sorbent for purification of blood and lymph, *etc*.).

In Russia, particularly, at SDB 'Tekhnolog' industrial technologies are developed for the detonation synthesis of UDD, which allow production of diamonds (as powders and suspensions) in amounts that run into tons.

In this review, for the first time, an attempt is undertaken to describe the properties of detonation synthesis diamonds in sufficient detail. All the available literature on UDD is analysed for the last 15 years including publications by the author.

Inasmuch as UDD are extremely complex materials and their characteristics are largely determined by the methods of preparation, chemical purification and surface modification, the properties of nanodiamonds reported in different studies can differ. The literature data reviewed do not exhaust the subject, because the approaches of different authors were different, the UDD samples used differed from one another and the studies were carried out under different conditions and often were sporadic.

II. Synthesis and morphology

Detonation-induced transformations of powerful explosives and their mixtures with the composition $C_aH_bN_cO_d$ with a negative oxygen balance (*i.e*., with the oxygen content lower than the stoichiometric value) in a non-oxidising medium yields a condensed carbon phase which involves ultradispersed diamonds.[1,2] The pressure and temperature in the detonation wave ($P-T$ parameters) correspond to the region of thermodynamic stability of diamonds ($P \geqslant 10$ GPa, $T \geqslant 3000$ K).[3,4] Such condensed carbon, which is commonly named a diamond blend (DB), can contain up to 75% UDD. Calculation and experimental methods have shown[5,6] that the primary UDD particles with diameter of $\sim$4 nm form fractal cluster structures (of 30–40-nm size) from which larger aggregates (of an order of magnitude of hundreds of nanometers) are formed. The clusters are built of a limited number of atoms (from several tens to several thousands) and, with regard to their properties, occupy an intermediate position between individual atoms and bulk solids.[7,8]

In the liquid-phase oxidation of condensed carbon, non-diamond structures gradually decompose, the most sophisticated method of chemical purification of DB being their treatment by dilute nitric acid at elevated temperature and pressure.[9,10]

According to the literature data,[11] purified UDD contain no intermediate amorphous phase. This is indicated by the shape of the (111) band in X-ray diffraction spectra and the results of electron microscopy. Depending on the conditions of the detonation synthesis, the mean size of UDD grains varies from 2 to 20 nm.

Diamond grains with sizes up to 100 nm are shown to exhibit highly defective block structures (1–3-nm blocks were observed in dark-field images).[12] With an increase in the grain size, the crystalline structure becomes more perfect. These results are confirmed in studies by high-resolution electron microscopy.[13]

It was found[14] that UDD are single-phase materials and contain no Lonsdalite, graphite and other admixtures. The size of subgrains (mosaic blocks) was found to be 4 nm by the method of diffractometry of co-ordination spheres,[15] no lattice microdistortions were revealed and the dislocation density determined from the value of subgrain size by the Williamson–Smallman relationship $N = 3/z^2$ was found to be equal to 1.8×10^{17} m^{-2}.

An X-ray diffraction pattern for UDD powders[16] also characterises UDD as a diamond phase containing no admixtures of Lonsdalite and graphite.

The coherent-scattering regions (CSR) were found to be of a mean size of 4.2 ± 0.2 nm and represent the proper UDD grains of diamond-lattice structure and an insignificant amount of aggregates of carbon atoms dispersed throughout the bulk which form no lattice and are mainly spaced at $\sim$0.15 nm from one another.[16] Along intergrain boundaries, carbon-atom aggregates are located for which the distribution in interatomic distances is close to Gaussian. The latter fact indicates that the structure of intergrain boundaries is amorphous.

Sizes of UDD crystals were estimated based on the so-called phonon confinement model.[17–19] It was shown that the nanocrystal size is 4.3 nm, which coincides with the results X-ray diffraction analysis of the same samples.[20]

In their usual state, UDD represent a powder of a specific surface area of 250–350 m^2 g^{-1} and a pore volume of 0.3–1.0 cm^3 g^{-1} (see Ref. 21). Heating of samples to 1273 K does not result in any decrease in the specific surface area. In a suspension, the size of UDD particles reaches 0.05×10^{-6} m; in a dried form, nanodiamonds represent a polydispersed powder. On heating above 873 K in an inert atmosphere, UDD particles begin to grow and acquire spherulitic shapes which measure up to $(150-200) \times 10^{-6}$ m and disintegrate at a load of 10–15 kg mm^{-2}. No polycrystals are formed in this case.

Due to the non-equilibrium conditions of their synthesis, UDD particles display a high density of defects, an active and well-developed surface (reaching 450 m^2 g^{-1}) and an excess enthalpy of formation.

III. Elemental composition and admixtures

Ultradispersed diamonds are characterised by the presence of a substantial amount of difficultly removable volatile and solid admixtures. The former include adsorbed gases (CO, CO_2, N_2), water and acids remaining after chemical purification (HNO_3, H_2SO_4). The latter group of admixtures involves non-diamond carbon, insoluble metal compounds (oxides, carbides) and salt admixtures. Powders of UDD can be considered as a certain diamond-containing composite material that consists of different carbon forms (80%–89%), nitrogen (2%–3%), hydrogen (0.5%–1.5%), oxygen (up to 10%), and an incombustible residue (0.5%–8.0%). Carbon represents a mixture of proper ultradispersed diamond (90%–97%) and non-diamond carbon (3%–10%). In detonation synthesis nanodiamonds, the impurity percentage is higher compared with other artificial diamonds (diamonds prepared by steady-state synthesis contain no less than 96% carbon); and, therefore, the effect of impurities on physical and chemical properties should be more pronounced for UDD compared with other diamonds.

Impurities present in UDD can be arbitrarily divided into the following groups:

(1) water-soluble ionised (free electrolytes);

(2) chemically bonded to the diamond surface and prone to hydrolysis and ionisation (salt forms of functional surface groups);

(3) water insoluble (mechanical impurities, non-dissociating salt and oxide forms of surface impurities);

(4) incorporated into the diamond lattice and encapsulated.

The impurities of the first and second groups are formed in the stage of chemical purification of UDD by acids.[9] Major water-soluble admixtures (first group) are removed by washing UDD with water. To make the removal more efficient, the suspensions are additionally treated by ion-exchange resins.

Surface functional groups (the second group of impurities) of the COOH, OH, SO_3H, NO_3 and NO_2 types can be considered as ionogenic with the diamond itself as the ion-exchange material.[22] In this case, treatment of UDD aqueous suspensions by ion-exchange resins, which involves demineralisation of surface groups, is also the most efficient.

Water-insoluble impurities (the third group) represent both individual microparticles of metals, oxides, carbides, salts (sulfates, silicates, carbonates) and surface compounds of salts and metal oxides incapable of dissociation. For their removal, *i.e*., transformation into soluble forms, UDD are treated by acids.

By using different methods of UDD purification, one can remove 40%–95% of the impurities of these three groups. All attempts to obtain individual UDD have failed. This is explained by the fact that the impurities of the fourth group are virtually

impossible to remove by chemical methods; moreover, the transition of third-group impurities into a soluble state is incomplete.

The main admixed elements are silicon, calcium, iron and sulfur; titanium, copper, chromium, and potassium are present virtually always in small amounts. Having an active and well-developed surface, nanodiamonds can sorb solution impurities. Hence, the presence of certain impurities, namely, silicon, potassium and, partially, iron can be attributed to the hardness of water employed in UDD purification.

Being among the major technological impurities in UDD, iron in concentrations of no less than 0.1 mass% – 0.5 mass% (which corresponds to the presence of insoluble iron compounds, preferentially on the surface) is difficult to remove.

Powders of UDD also contain substantial amounts of volatile admixtures ($\sim$10 mass%);[23] thermal treatment of UDD in vacuum (0.01 Pa) allows one to either remove the volatile impurities or substantially decrease their content. The optimum temperature of annealing is 673 K.

Ultradispersed diamonds studied in Ref. 21 were of the following composition: carbon, up to 88%; hydrogen, up to 1%; nitrogen, up to 2.5%, oxygen, up to 10%. The same ratio of elements remains after a thermal treatment up to 1273 K in either reductive (hydrogen) or neutral (argon) atmosphere. The carbon content in UDD samples passes through a maximum in a range of 973 – 1073 K, whereas hydrogen and nitrogen contents remain virtually unchanged. The maximum density of UDD was reached after heating in an argon atmosphere at 1073 K and amounted to 3.21×10^3 kg m^{-3}.

Scientists from the Russian Federation Nuclear Centre — All-Russian Research Institute of Technical Physics (RFNC-ARITP, Snezhinsk) have determined the contents of admixed elements in UDD samples manufactured at SDB 'Tekhnolog' and RFNC-ARITP (Table 1).

Table 1. Content (mass %) of admixed elements in UDD samples (AES data).

Admixture	UDD powder of UDD-STP brand [a]	Aqueous UDD suspension of UDD-TAH brand [a]	Typical UDD [b]
Fe	0.150	0.100	0.100

Incombustible residue	0.950	0.400	1.400

[a] Produced at SDB 'Technolog' in accordance to specification TU 05121441-275-95. [b] Produced at RFNC-ARRITP. [c] Undetected at a sensitivity of 5×10^{-4} mass %.

Due to the fact that the time of synthesis of UDD is very short, surface carbon atoms have no time to stabilise by closure of all the bonds in the newly formed diamond lattice. They form a bond or two bonds with other elements of explosive materials, *viz*., hydrogen, nitrogen and oxygen. Hence, it is of great importance to assess the changes in the relative contents of heteroatoms that stabilise surface carbon atoms on the interface as a function of chemical treatment conditions and the degree of oxidative decomposition of DB.[24] For this purpose, an original diamond blend is treated by oxidising systems based on nitric acid and also by organic solvents, hydrocarbons and alcohols in the temperature interval of 358 – 578 K. Table 2 shows the results of the analysis as arbitrary molecular formulas calculated per 100 carbon atoms. Generally, the relative content of heteroatoms varies in a wide interval: from 5 to 35 hydrogen atoms and from 4 to 32 oxygen atoms per 100 carbon atoms. The nitrogen content varies from 2 to 4 atoms per 100 carbon atoms and is independent of the treatment conditions.

Table 2. Elemental composition of DB.[24]

Treatment conditions	Arbitrary molecular formula	Number of heteroatoms per 100 carbon atoms
DB sample		
Original, $\alpha = 0$	$C_{100}H_{5.3}N_{2.84.1}$	12.2
Treated by hydrocarbons C_nH_{2n+2}	$C_{100}H_{13.8}N_{2.94.6}$	21.3
Treated by alcohols $C_nH_{2n+1}OH$	$C_{100}H_{15.5}N_{2.68.0}$	26.1
Oxidative decomposition, $\alpha = 26.3\%$	$C_{100}H_{25.4}N_{2.922.5}$	50.8
Oxidative decomposition, $\alpha = 31.8\%$	$C_{100}H_{34.9}N_{2.923.1}$	60.9
UDD sample		
Original, $\alpha = 55.0\%$	$C_{100}H_{11.2}N_{2.29.1}$	22.5
Oxidative decomposition, $\alpha = 64.9\%$	$C_{100}H_{19.3}N_{2.123.5}$	44.9
Oxidative decomposition, $\alpha = 74.4\%$	$C_{100}H_{18.7}N_{2.022.8}$	43.5
Oxidative decomposition, $\alpha = 75.6\%$	$C_{100}H_{23.7}N_{2.422.9}$	48.8

Note: α is the degree of oxidative decomposition determined from the expression

$$\alpha = \frac{[C_{ox}] - [C_{ox}]'}{[C_{ox}]},$$

where $[C_{ox}]$ and $[C_{ox}]'$ are the mass fractions of the oxidisable carbon in original DB and UDD and in treated (oxidised) samples, respectively.

Non-oxidative treatment of DB by organic solvents (hydrocarbons C_nH_{2n+2} and alcohols $C_nH_{2n+1}OH$) does not affect the carbon skeleton of particles, but causes changes in the composition of surface functional groups. In this process, the elemental composition of DB changes regularly: relative concentrations of hydrogen and oxygen increase owing to the addition of hydrocarbon- and hydroxyl-containing fragments. The total number of heteroatoms is doubled.

In the oxidative decomposition of DB, the spectrum of carbon-to-heteroatom ratio in the products may be wider. As the action of oxidants on DB is stronger (increase in temperature, acid concentration, *etc*.), carbon gradually transforms into carbon dioxide.

First of all, the most disordered amorphous part of carbon is oxidised, next comes the turn of micrographite structures. After practically complete removal of non-diamond carbon forms from DB, the resulting UDD represent a chemically inactive material difficultly susceptible to further oxidation. Nonetheless, the author has succeeded in decomposing partially the diamond substance by long-term etching. The etching degree was 45% of UDD mass or 75.6% of the mass of original DB. The dependence of DB composition on the degree of oxidative decomposition (Fig. 1) has a complicated shape.

The minimum contents of heteroatoms correspond to both the original DB and purified UDD, the maximum values (53.5 and 44.9 heteroatoms per 100 carbon atoms) are typical of partially oxidised DB ($\alpha = 26\% - 31\%$) and etched UDD

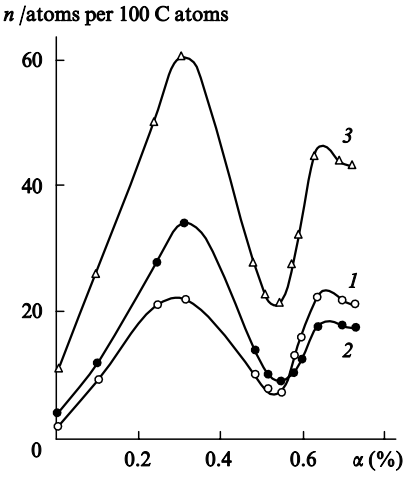

Figure 1. Elemental composition of DB as a function of the degree of oxidative decomposition (α).[24]
Relative content (n) of (*1*) oxygen, (*2*) hydrogen, (*3*) all heteroatoms.

(α = 65% – 75%), respectively. The concentrations of hydrogen and oxygen bonded to the surface vary in parallel. This makes it possible to assume that the chemical composition of surface functional groups is constantly reproduced.

For metastable structures, like partially oxidised DB and products of UDD etching, the recovery of surface-group composition results from active interactions with the reaction medium and the formation of a maximum number of heterobonds. The more stable forms, *viz*., the original DB and UDD, contain the smallest numbers of heteroatoms, which however is higher compared with that in the well-known diamond micropowders of steady-state synthesis ($C_{100}H_{1.1}O_{2.2}$) and soot ($C_{100}H_{5.1}O_{4.1}$).

From the chemical standpoint, the curves obtained allow the process of oxidative decomposition to be interpreted as two consecutive stages: (1) preferential etching of the carbon matrix at structural defects and along links between species, in the course of which the reaction surface increases and is enriched with oxidation intermediates; (2) etching of the loosened surface, gas formation and removal of surface oxidation products. A cyclic nature of these stages suggests that decomposition affects only structurally heterogeneous materials, whereas the oxidation selectively involves different structural forms.

Inasmuch as the concentrations of heteroatoms in DB and UDD are very high, a question arises of a possible location of these heteroatoms and the nature of their bonds with carbon. Calculations show that a 4-nm diamond particle consists of $\sim 12 \times 10^3$ carbon atoms, nearly 3×10^3 of which are located on the surface. For example, for UDD, we can write the following arbitrary molecular formulas: C_{75} for bulk and $C_{25}H_{11.2}N_{2.8}O_{9.1}$ for the surface atoms. Thus almost every carbon atom on the surface should be bonded to a heteroatom.

IV. Surface properties

The concentration of active hydrogen ([H_a]) on a UDD surface has been determined.[25] It is commonly agreed that a hydrogen atom bonded to an atom of any other element except carbon is active. For a carbon surface, the quantity [H_a] may serve as a measure of its enrichment by functional groups (hydroxy, carboxy, amine, sulfonic, *etc*.).

In the studies on the reaction of methylmagnesium iodide in anisole with functional surface groups of DB and UDD, three stages can arbitrarily be distinguished, *viz*., (1) the reaction with molecular impurities and the external surface (with functional groups most easily accessible), (2) the reaction with the surfaces of open pores and (3) the reaction with the surface becoming free upon mechanical destruction of UDD aggregates.

Depending on treatment conditions of DB and UDD, the density of protogenic groups in them varies from 0.34 to 2.52 μg-equiv m^{-2}, and the concentration of active hydrogen varies from 0.49 to 7.52 μg-equiv m^{-2}. The proportion of the mobile hydrogen on DB and UDD surfaces amounts to 4% – 22% of the total hydrogen content in the powders.

Surface and electrophysical properties of nanodiamonds of two different specimens (UDD-1 and UDD-2) differing in the content of incombustible residue ([I.r.]) have been studied (Table 3).[26]

Table 3. Characteristics of the nanodiamond powders studied.[26]

Parameter	UDD-1	UDD-2
[I.r.] (%)	0.75	1.16
χ /m^3 kg^{-1}	$-0.35 \cdot 10^{-8}$	0
S_{sp} /m^2 g^{-1}	167	162
C_{BET}	303	814
A /J g^{-1}	400	550
A' /J m^{-2}	2.4	3.4

Note. The parameters are specified in the text.

The amounts of incombustible residues in powders and their specific magnetic susceptibilities (χ) were measured following the procedures developed at the Bakul' Institute of Superhard Materials (Kiev, Ukraine). Adsorption and structural characteristics, *viz.,* the C_{BET} constant, the adsorption potential (A), the specific adsorption potential of UDD (A') and the specific surface area (S_{sp}) were determined by the BET method from isotherms of nitrogen low-temperature adsorption measured on an 'Akusorb-2100' instrument. For UDD samples from both specimens studied, the isotherms of the second kind are typical.

As can be seen from Table 3 the UDD-1 and UDD-2 samples have equal specific surfaces but differ somewhat in the degree of purity and especially in the adsorption potential (for UDD-2 this is 37% larger). According to the values of the C_{BET} constant found, the UDD-2 powder exhibits higher adsorption activity, which suggests that the use of the degree of purity for characterising UDD is ambiguous.

It is found[26] that the absorption band in the IR spectrum of UDD at 1640 cm^{-1} is associated with the deformation vibrations of water, both bound and free. A band at 1750 cm^{-1} corresponds to vibrations of the OH groups.

Drying of UDD powders at 393 K did not result in any noticeable qualitative changes in the spectra. This suggests that the UDD surface bears active functional groups which favour adsorption of water.

On the basis of absorption spectra of UDD powders, it was concluded that the amount of moisture in the form of bound water molecules on the surfaces of nanodiamonds is higher compared with common diamond micropowders obtained in steady-state synthesis. Carboxy and carbonyl groups were also identified. The contents of methyl and methylene groups in UDD powders were insignificant.[26]

An analysis of IR spectra revealed the presence of potassium and aluminium sulfates, chromates and their complex compounds involving silicon in incombustible residues of UDD. Most probably, all these compounds have appeared as a result of a contamination during chemical purification of UDD by chromic anhydride in sulfuric acid.[26]

The changes in the nature of a 'coat' of functional groups on the surface of nanodiamonds upon their treatment in different media, affects the susceptibility of UDD to cold pressing.[27] Table 4 shows the values of limiting pressures during the compaction and the densities of compacted UDD both non-modified and

Table 4. The effect of UDD pretreatment on the limiting compacting pressure (P_{lim}) and the density (ρ) of compacts.[27]

Parameter	Initial UDD	UDD modified by treatment with		
		H_2	CO_2	concentrated HNO_3
P_{lim} /kg cm^{-2}	800–900	300–400	1200	1200
ρ /g cm^{-3}	1.2	1.00–1.15	1.23–1.30	1.3–1.4

modified by treatment with concentrated nitric acid, hydrogen and carbon dioxide.

V. Phase composition, microstructure and surface texture

Depending on the synthesis conditions, the explosion condensed products contain either only a cubic phase of diamond or also Lonsdalite as an admixture (up to 30%).[21] The X-ray diffraction pattern of a UDD sample contains five reflections characterised by the following intensity distribution:

Reflection	(111)	(220)	(113)	(400)	(331)
Fraction (%):					
UDD sample	85.0	14.0	0.5	0.3	0.2
reference sample	44	22	18	4	12

It may be assumed that the predominance of the reflection from the (111) plane in the spectrum is associated with the spherical shapes of UDD particles.

Table 5 shows microstructure parameters of UDD specimens. Nanodiamonds formed during detonation of a trotyl–hexogen melt (60 : 40) [21] exhibit the highest microstresses of the second kind and, as a consequence, have most deformed lattices. It was found that the microstresses of UDD lattice do not change until the onset of graphitisation at 1473 K. Thus, a highly strained structure of UDD is thermally stable. Nonetheless, UDD synthesised by the aforementioned method should be expected to possess an enhanced reactivity.

Table 5. Microstructure of detonation synthesis nanodiamonds.

Coherent scattering region /nm	a/a_0 (%) [a]	Microstresses /GPa	a /nm	Ref.
4–6	1.0	10	0.3562 ± 0.0003	21
5–10	0.42–0.47	4.2–4.7	–	28
5–15	0.1	1.0	0.3572 ± 0.0004	29

Note. [a] Relative lattice distortion (a is the parameter of a real lattice, a_0 is the parameter of the diamond cubic lattice).

Peculiarities of the surface structure were studied for DB, partially oxidised DB and UDD,[30, 31] and the degree of oxidative decomposition was estimated (see footnote to Table 2).

The BET method was used for the determination of the specific surface area (S_{BET}) and the size distribution of pores from the adsorption isotherms of nitrogen. By gradually increasing the degree of oxidative decomposition (α) of DB by acids it was possible to obtain a series of specimens of partially oxidised DB containing different amounts of oxidised carbon, *viz*., from the initial DB (sample *1*) to UDD (sample *12*). Table 6 shows the texture parameters of the specimens.

The dependences of the specific surface area, the volume, and geometrical parameters of pores on the quantity α reach an extremum at $\alpha = 0.63$; at this point, S_{BET} and the volume of pores are a minimum, and C_{BET} is a maximum. At this stage of

Table 6. Parameters of DB and UDD textures.[30]

Sample	$[C_{ox}]$ (%)	α	S_{BET} /m^2 g^{-1}	V_p /cm^3 g^{-1}	C_{BET}	d_a /nm	d_d /nm
1	53.4	0	404	1.2451	108	9.1	8.8
2	44.4	0.17	409	1.0746	112	8.1	8.0
3	38.4	0.28	399	0.9931	107	7.7	7.9
4	36.3	0.32	314	0.7488	109	7.5	7.6
5	27.8	0.48	244	0.6621	133	8.6	6.8
6	27.6	0.49	209	0.5406	136	8.7	8.8
7	23.7	0.56	198	0.5236	155	9.1	9.1
8	19.5	0.63	195	0.5089	182	9.5	9.3
9	9.9	0.81	240	–	–	–	–
10	7.9	0.85	252	–	–	–	–
11	3.4	0.94	276	0.8241	135	9.8	9.6
12	1.2	0.98	290	0.8396	121	9.2	9.2

Note. Here, $[C_{ox}]$ denotes the mass fraction of oxidised carbon; V_p is the limiting volume of the sorption space at $P/P_s = 0.995$ (P is the partial pressure of nitrogen, P_s is the pressure at which the whole internal surface of pores is covered by a nitrogen monolayer); d_a is the size of an open pore; d_d is the critical neck size, *i.e*., the maximum pore size at which the atoms of an adsorbed gas can enter the adsorbent.

decomposition, a partially oxidised DB retains ~20% of non-diamond carbon. In the range of $\alpha = 0.63–0.98$, carbon particles are etched at the stressed and defective areas. Here, a new kind of surface with predominant relaxed diamond-type structures is formed. Thus, when passing from the original DB to UDD, the texture characteristics of the substances change non-monotonically. This distinguishes DB from other carbon phases (technological carbon, coals, carbon fibres) being associated, first of all, with the presence of two carbon phases, *viz*., diamond-type and non-diamond in DB, which differ in their chemical activities and oxidation mechanisms. Comparing the values of S_{BET}, C_{BET} and the volume of pores found for DB and UDD, on the one hand, and those obtained for intermediate oxidation products, on the other hand, we can conclude that the powders of detonation carbon represent organised space structures formed during multistep aggregation of original particles rather than a mechanical mixture of UDD and non-diamond carbon.

In the liquid-phase oxidation, chemical decomposition (etching) of secondary aggregates occurs, which entails regular changes in the surface area and in texture characteristics of the powders. Primary aggregates remain practically unchanged. These data taken altogether point to a structural self-organisation of detonation synthesis ultradispersed carbon.

As was discussed above, the properties of UDD surface strongly depend on the conditions of their chemical pretreatment, which in a number of cases plays a key role in the production of new composite diamond-containing materials with the required characteristics.

VI. Sorption properties and exchange capacity

The sorption properties of DB and UDD, which are extremely important characteristics for different application fields of UDD have been studied.[32]

Oxygen-containing groups present on nanodiamond surfaces [33] impart a charge to UDD aggregates in aqueous solutions; the value and sign of this charge depend on the concentration and the dissociation constant of these groups, the solution pH and the background-electrolyte concentration. Ions H^+ and OH^- are potential-determining. The dependence of the specific adsorption on the solution pH, which is observed for all powders under study, can be attributed to an increase in the degree of dissociation of surface groups with acidic properties.

In the gradual oxidation of the detonation-derived carbon, the specific adsorption changes non-monotonically and passes

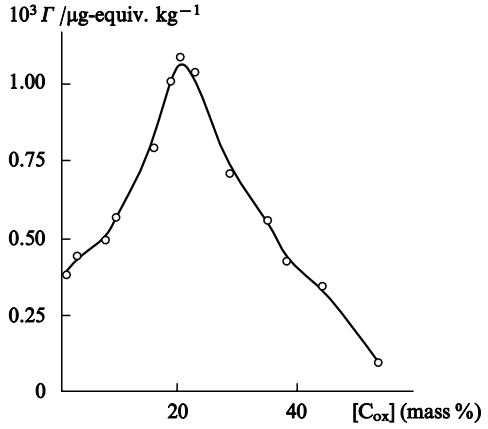

Figure 2. Specific adsorption (Γ) as a function of oxidisable carbon content in DB (pH 11).[32]

through a pronounced extremum (Fig. 2). A low specific adsorption value for the original DB is explained by the fact that this DB has been synthesised in a non-oxidative medium and thus involves a small amount of surface oxygen-containing groups.

When a DB is exposed to oxidants, two processes proceed simultaneously, *viz*., surface enrichement with oxygen-containing groups and etching of carbon. With an increase in the degree of oxidative decomposition, the surface is enriched with oxygen-containing groups, the specific adsorption would have been expected to reach a maximum and then remain constant. However, starting from 18% – 20% of residual oxidisable carbon, the specific adsorption decreases.

The presence of an extremum in the curve (see Fig. 2) reflects qualitative changes in the surface structure of DB upon treatment, namely, a transition from a graphite-like form to a diamond-like form.[31] In this transitional state, the material exhibits the best adsorption properties. The DB subjected to drastic oxidation retains only a stable diamond form. Under the conditions of mild oxidative etching, the boundary between diamond-like and non-diamond carbon shifts. The residual oxidisable carbon (the remaining 18% – 20%) actually represents a diamond-like phase, *i.e*., corresponds to the periphery of a diamond cluster.

For UDD samples listed in Table 1, the sorption capacity with respect to benzene and chloroform vapours was estimated at 292 – 294 K by a weighing method under steady-state conditions close to the isothermal ones. The results obtained are as follows.

1. The sorption capacity of a dry powder of UDD-STP (produced at SDB 'Tekhnolog') amounts to 9 mol kg^{-1} with respect to benzene vapour and 10.5 mol kg^{-1} with respect to chloroform vapour. The observation time was 15 days; 90% – 95% of adsorbate was absorbed in 2 days.

2. The sorption capacities of four fractions isolated from the suspension of UDD-TAH decrease monotonically from 8 mol kg^{-1} for the first fraction to 7 mol kg^{-1} for the fourth fraction with respect to benzene vapour and, correspondingly, from 8.5 to 7.5 mol kg^{-1} with respect to chloroform vapour. The observation time was 13.3 days; 95% – 100% of the adsorbate was adsorbed in 2 days (more quickly for chloroform).

3. For comparison, sorption capacities of certain UDD samples made at RFNC-ARITP were determined, which varied from 12 – 16 to 10 – 14 mol kg^{-1} for benzene vapour and from 14 – 19 to 12 – 17 mol kg^{-1} for chloroform vapour. A distinguishing feature of this type of UDD is that its sorption capacity gradually increases: 55% – 65% of adsorbate is adsorbed in 2 days. The adsorption capacities and rates virtually coincide for DB and diamonds isolated from it (*i.e*., the sorption capacity in fact is independent of the content of non-diamond carbon in the diamonds).

Inasmuch as the adsorption phenomenon forms the basis of many technological processes, the degrees of adsorption of heavy-metal ions on the UDD surface were estimated. For this purpose, an electrochemical technique of cathodic potentiodynamic pulses was applied.[34]

Table 7. Results on the adsorption activity studies of UDD-1 and UDD-2 powders with respect to heavy metal ions.[26]

M^{n+}	$[M^{n+}]$ in electrolyte /mol kg^{-1}	θ (%)	
		UDD-1	UDD-2
Fe^{2+}	0.1	18.0	26.5
Fe^{2+}	10	80.6	82.5
Ni^{2+}	0.1	16.0	33.0
Ni^{2+}	10	75.0	80.0
Cr^{6+}	0.1	12.0	40.0
Cr^{6+}	10	48.0	53.3

It was shown that the adsorption activities of UDD powders with respect to metal ions (iron, nickel, chromium) differ substantially (Table 7). In all experiments, the surface coverages (θ) of UDD-2 were higher. On the whole, the adsorption activity of nanodiamonds with respect to the ions under study decreases in the following order: $Fe^{2+} > Ni^{2+} > Cr^{6+}$ (Ref. 26). However, at low concentrations of metal ions (0.1 mol kg^{-1}), this sequence for UDD-2 is reversed: $Cr^{6+} > Ni^{2+} > Fe^{2+}$. With an increase in the ion concentrations from 0.1 to 10 mol kg^{-1}, the degree of surface coverage of diamond particles increases 3 – 4-fold and reaches 70% – 80%.

It was thus confirmed [26] that the adsorption activity of UDD surface depends substantially on the method of chemical purification of nanodiamonds of detonation synthesis.

Studies of surface properties of UDD isolated from DB under the action of nitric acid and atmospheric oxygen [35] and modified by different reagents [36, 37] showed UDD to possess pronounced cation-exchange properties, which manifest themselves in the exposure of nanodiamonds to aqueous solutions. It was also found that UDD represent sorbents of high activity with respect to gases.[23]

As was mentioned above, chemical purification of UDD enriches the diamond surface with oxygen-containing groups that determine its cation-exchange properties as a sorbent. The surface of UDD oxidised by atmospheric oxygen bears a greater amount of oxygen-containing groups of the acid type (*i.e*., protogenic) compared with the diamonds of liquid-phase oxidation. As a result, the former nanodiamonds possess better ion-exchange properties. Hence, UDD can serve as promising sorbents for ions of a basic nature.

On the other hand, the method for cooling of the products of detonation synthesis plays a significant role in the formation of the nanodiamond surface. Comparison [38] of nanodiamonds obtained from the same explosive compositions and with charges of the same geometry (*i.e*., fused and pressed in the same moulds) but with different cooling procedures and isolated from the synthesis products by the same methods has shown that their surfaces differ in the composition and the number of admixed functional groups including those groups that affect the ion-exchange properties. Particularly, the use of ice as a cooling agent (*i.e*., as an armour for the charge) is beneficial for the maximum protection of UDD from the subsequent graphitisation. This refers primarily to its finest crystals, which have the highest specific surface area and, hence, high sorption activity.

The sorption capacity of UDD obtained in different conditions or purified by different methods was studied with respect to cesium ions.[38] It was found that the sorption capacity of nanodiamonds synthesised under identical conditions but purified using different oxidants and different treatment conditions varied from 0.01 to 0.50 mol kg^{-1}. This suggests that this depends on the nature of the oxidant and the conditions (duration, temperature) of UDD isolation from synthesis products. Samples obtained from DB by ozone purification exhibited the highest sorption

abilities (0.4–0.5 mol kg^{-1}). The value found exceeds substantially those of known natural sorbents[39] (0.01–0.15 mol kg^{-1} with respect to cesium) and is commensurable with the sorption capacity of KU-8-2 resin (0.8 mol kg^{-1}), which is a widely used ion-exchange resin.

An analysis of IR spectra showed that the UDD samples contain different polar functional groups: OH, NH, C–O, C=O, C–H, C–N, C=N, C–O–O in different concentrations. Nanodiamonds of higher sorption capacities are characterised by higher intensities of absorption bands of oxygen-containing (C=O, in the region of 1700 cm^{-1}) and peroxide (C–O–O, 1800–1900 cm^{-1}) groups compared with other samples. Apparently, it is the presence of these groups that is responsible for the enhanced cation-exchange ability of the samples under discussion.

An IR spectrum of UDD synthesised in a gaseous cooling medium shows a wide absorption band in the region of 1600–1900 cm^{-1}, which points to a higher concentration of oxygen-containing groups which determine the cation exchange.

It was proposed to use UDD as a potential sorbent for cesium radionuclides.[38] Compared with conventional ion-exchange resins, ion-exchange materials based on nanodiamonds possess basically better new characteristics: substantially higher thermal stability (400 °C in air compared with 120–150 °C for KU-8-2 resin), resistance against aggressive media, mechanical strength, the absence of swelling and high sorbent density (3.1–3.3 g cm^{-3} against 0.7–0.8 g cm^{-3} for KU-8-2).

In the context of the commercial application of UDD for deposition of composite electroplates, it is of interest to study the behaviour of UDD hydrosols in the presence of different ions under the action of an external electrical field and without it.

Electrochemical studies of an aqueous suspension of UDD were carried out in the pH range of 3–10, at an ionic strength varying from 10^{-4} to 10^{-1} in a temperature interval from 20 to 70 °C.[40] A combination of macroelectrophoresis and potentiometric and conductometric titrations were applied. The experimental data were analysed within the framework of a model that takes into account the complex nature of UDD aggregation with the formation of primary and secondary structures.[6,41]

The dependence of the exchange capacity (G) for UDD on the pH of KCl solutions with concentrations (c) of 0.1 and 0.01 mol $litre^{-1}$ was examined by potentiometric titration. The titration curves for UDD powders and sedimentation-unstable hydrosols virtually coincide, which points to the similarity of the structures (or specific surface areas) of coagulated precipitates and dried powders. A threshold of fast coagulation of the hydrosols and loss of sedimentation stability corresponds to pH 5.5 in KCl solution with c = 0.01 mol $litre^{-1}$. With an increase in pH, the exchange capacity of UDD increases from 0.05×10^3 μg-equiv. kg^{-1} (pH 3) to $(0.4–0.6) \times 10^3$ μg-equiv. kg^{-1} (pH 10). In the pH range of 9–10, the exchange capacity of the hydrosol substantially increases, in contrast to that of the UDD powder. This reflects different dispersion of nanodiamond particles.

On the basis of the specific surface value of 322 m^2 g^{-1} found by the BET method for powder particles,[40] the surface charge density was calculated, which made it possible to roughly assess the potential of the UDD surface for both powders and hydrosols. Figure 3 shows the dependences of the surface, diffusion and electrokinetic potentials on the solution pH.

The pH-dependences of the surface (curve *1*) and diffusion (curve *2*) potentials have similar shapes. The electrokinetic potential (curve *3*) was estimated from the results of macroelectrophoresis by using a formula valid for particles with unipolar conduction.[42]

From comparison of the potentials (see Fig. 3), it follows that a substantial volume ascribed to the immobile part of the electrical double layer can be attributed not only to the presence of water layers with different structures near the nanodiamond surface, but also to the immobilisation of the dispersion medium inside the UDD aggregates. Such a conclusion is confirmed by the different

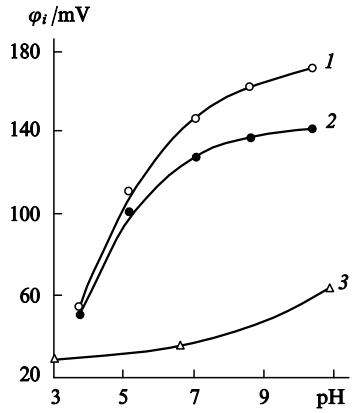

Figure 3. Dependences of (*1*) surface, (*2*) diffusion and (*3*) electrokinetic potentials (φ_i) on pH for UDD particles in a hydrosol in KCl solution (c = 0.01 mol $litre^{-1}$).[40]

shapes of the temperature dependences for electrokinetic and diffusion potentials.

At a low ionic strength (in a KCl solution with $c = 10^{-4}$ mol $litre^{-1}$), no apparent flocculation of primary aggregates occurs, and the destruction of the interfacial water layers, which proceeds at elevated temperatures, is accompanied by an increase in the electrophoretic mobility of UDD. In solutions of higher ionic strengths, the destruction of interfacial layers at elevated temperatures facilitates flocculation of primary aggregates. Water immobilised inside newly formed secondary aggregates does not necessarily take part in the motion; however, the exchanged ions retain their mobility. In this case, the electrophoretic mobility decreases and the diffusion potential remains unchanged. Indeed, the diffusion potential calculated for the isopolarisation mode from the data on the conductivity of UDD hydrosols, under an assumption of a constant size of hydrosol particles, does not decrease with an increase in the temperature (in contrast, a slight increase is observed).

Electrochemical studies of the surface allowed refinement of the structure of solid phase in UDD hysrosols. Using the values of the diffusion potentials found in potentiometric titration and the results of conductivity measurements at the isoconduction point (pH 6, KCl solution, c = 0.01 mol $litre^{-1}$), the sizes of non-conducting spherical UDD formations were determined and proved to coincide with the radii of primary aggregates (10–30 nm) estimated by electron microscopy.[6] This implies that primary aggregates are non-conducting, *i.e.*, have dense ion-impermeable structures.

Thus, UDD represent presumably a cation-exchange system with a variety of functional groups of different acidic strengths.[40] Hydrosols of UDD consist of dense primary aggregates which form ion-permeable secondary structures. Different shapes of the pH dependences for diffusion and electrokinetic potentials, as well as many other properties of UDD hydrosols as a function of pH, ionic strength and temperature are determined by the changes in their secondary structures.

VII. Chemical properties of ultradispersed diamonds

Studies of the chemical composition of DB and UDD were carried out by the methods of gas chromatography (CG), polarography, IR spectroscopy and X-ray photoelectron spectroscopy (XPS).[43] Table 8 shows the results of polarographic and GC studies of DB and UDD samples.

It follows from the data in Table 8 that the carbon of the UDD surface groups is oxidised to a higher degree and the hydrogen content is substantially lower compared with DB.

Table 8. Composition of desorbed gases and their activation energies.[43]

Sample	Composition of desorbed gases [a]		Activation energy of desorption [b] /kJ mol^{-1}
	gas	gas content /cm^3 g^{-1}	
DB [c]	CO_2	3.9	23.4
	N_2	0.7	22.5
	CH_4	4.03	47.6
	H_2	7.8	–
	CO	0.09	103.6
	NH_3	1.43	27.2
UDD [d]	CO_2	11.4	48.5
	N_2	0.83	23.0
	CH_4	1.7	28.4
	HCN	traces	–

Note. [a] Determination conditions: 673 K; desorption time, 2 h; pressure, 0.1 Pa. [b] At 573 – 773 K. [c] Elemental composition (%): C, 86.3; H, 0.4; N, 3.7; O, 9.6. [d] Elemental composition (%): C, 86.0; H, 0.1; N, 2.5; O, 11.4.

The IR spectroscopy data suggest the presence of the carbonyl, carboxy, hydroxy, methyl and nitrile groups on the surfaces of UDD and DB. Thermodesorpsion of large amounts of methane and hydrogen from a DB sample (Table 8) gives us grounds to assume that it has a different composition of surface groups. Apparently, this is associated with the following reactions involving carbon surface atoms with uncompensated bonds

$$\equiv R^1-Me + {}^{\bullet}CR^2R^3R^4 \longrightarrow R^1-CH_2-CR^2R^3R^4 + 0.5\,H_2\,, \quad (1)$$

$$\equiv R^1-Me + {}^{\bullet}CH_2R^2 \longrightarrow R^1=CHR^2 + CH_4\,. \quad (2)$$

If reactions (1) and (2) do occur, then the fraction of carbon atoms with uncompensated bonds (surface atoms) amounts to no less than 1.6 %. An estimation based on these data showed that the mean particle diameter is 45 nm (no more than 300 carbon atoms).

According to XPS results [21, 43], the C_{1s} band in the spectrum of DB represents a wide asymmetric peak (half-width, $\Delta E_{1/2}$ = 4.1 eV), which narrows after bombardment with argon ($\Delta E_{1/2}$ = 2.5 eV) and takes a shape typical of graphite and fine-grain coals. In this case, the surface charging is zero, which is typical of conducting substances. These results suggest that the bulk of the sample represents the graphite phase, whereas, in the surface layer (several tens of angstrom deep), the diamond carbon phase is located.

For UDD samples (see Table 8), a symmetrical C_{1s} peak ($\Delta E_{1/2}$ = 3.3 eV) is typical, and the surface charging is + 3.3 eV. After bombardment with argon, the shape of the carbon peak remains unchanged, and the surface charging reaches + 6.2 eV, $\Delta E_{1/2}$ = 2.9 eV. It was concluded that carbon in the surface layer (no less than 10-nm deep) of a sample is represented exclusively by the diamond phase.[43] The initial sample includes nitrogen and oxygen (O : C = 0.027, N : C = 0.020) as the admixtures. After bombardment with argon, the admixture content becomes lower than the threshold sensitivity of a spectrometer.

Thus, in DB particles the diamond-like carbon phase surrounds the graphite phase or, more precisely, a non-diamond carbon form. UDD particles consist entirely of a diamond-like carbon phase. Admixtures in the form of carbon compounds with oxygen and nitrogen are accumulated preferentially in the surface layer of a particle.

In accordance with a classification of functional derivatives of diamonds, UDD pertain to a group of 'colloidal diamonds' as regards the crystal sizes and the ratio of surface carbon atoms (C_s) to the total number of carbon atoms (C_{tot}) in a diamond crystal.[44]

For nanoparticles measuring 2 – 10 nm, the number of surface C atoms with respect to their total number in the core varies from 63% to 15%, *i.e.*, from 4 to 18 internal carbon layers are present. Hence, UDD properties should largely be determined by the chemical states of their surfaces, in contrast to coarse diamond crystals with $C_s/C_{tot} \to 0$. However, to date the chemical properties of UDD remain less understood as compared with diamonds of other types.

The functional 'coat' of UDD particles, the possibilities of their chemical modification in different gaseous media, and their behaviour at elevated temperatures have been studied.[27]

The UDD samples were produced at the Research Industrial Association (RIA) 'Altai' (Biisk) and purified by using oleum – nitric acid mixtures at 523 K. The isolated UDD were dark-grey powders with microcrystals of 3 – 8 nm, which, being placed in water, formed aggregates measuring up to 2×10^{-4} m. The elemental composition of these UDD (%) is given below.

C	H	O	N	Ash content
78.6 – 78.8	0.65 – 0.70	16.5 – 17.0	1.78 – 2.16	1.34 – 2.47

The high content of oxygen in UDD agrees with the C_s/C_{tot} ratio and the amount of possible functional oxygen-containing groups on the surfaces of diamond particles of such sizes.[44]

The first step of UDD modification included drying them in air and heating the fine fraction in a flow of nitrogen at 348 K in a flow-through system. In the second stage, UDD were heated at 673 – 973 K in a flow of a gas (N_2, CO_2, CH_4, H_2, air) passed at a rate of 5.6×10^{-7} m^3 s^{-1}.

The results obtained [27] allowed the authors to assess the effect of pretreatment of UDD on the temperature of oxidation initiation. After treatment with water oxidation starts at 673 K, whereas upon exposure to a $CH_4 + CO_2$ mixture, it begins at 773 K, *i.e.*, hydroxylated surfaces are oxidised more easily.

Studies on the behaviour of UDD in oxidising gas mixtures under isothermal heating showed that the oxidants may be arranged in the following series with respect to their activities: air $\gg CO_2 > H_2O$.

It was shown that all the temperature dependences of UDD oxidation rate clearly manifest two regions. In the low-temperature region (below 673 K), the change in the UDD mass depends little on the temperature, whereas in the high-temperature region oxidation sharply accelerates with an increase in temperature.

On the basis of the results obtained, the apparent activation energies of UDD oxidation were calculated (Table 9). This table also shows the temperatures of transition to high-temperature regions for different oxidation conditions.

As is seen from the data of Table 9, the activation energies in two regions differ by a factor of 3 – 6 for the same oxidant. Probably, this is associated with the fact that, in the low-temperature region, oxidation actively involves the 'coat' of functional groups present on the surface of UDD particles and their decom-

Table 9. Apparent activation energies (E_a) of UDD oxidation in low-temperature (I) and high-temperature (II) regions.

Oxidant	Temperature of I to II transition /K	E_a /kJ mol^{-1}	
		region I	region II
$O_2 + N_2$ (20% O_2)	673	24.7 ± 1.7	96.1 ± 4.2
$O_2 + N_2$ (10% O_2)	773	24.7 ± 1.7	96.1 ± 4.2
$O_2 + N_2$ (4% O_2)	773	25.5 ± 5.9	91.1 ± 13.0
CO_2	898	36.4 ± 7.1	120.4 ± 15.0
CO_2, K_2CO_3 (see [a])	838	18.8 ± 5.0	88.6 ± 5.0
H_2O	933	22.2 ± 13.4	152.2 ± 7.1
H_2O, K_2CO_3 (see [a])	703	20.5 ± 12.1	126.7 ± 10.0

Note. [a] Successive treatment.

position products, whereas in the high-temperature region only hydroxy groups take part in the reaction. In the presence of a catalyst (K_2CO_3), the activation energies of UDD oxidation are somewhat lower than that of the noncatalysed process. On the whole, the activation energies of UDD oxidation in the high temperature region are slightly lower compared with detonation diamonds synthesised from graphite and soot [45] and twice as low as those of kimberlite diamonds.[46]

The aforementioned results confirm the presence of a 'coat' of different functional groups on the surfaces of UDD particles and suggest that this 'coat' changes as a result of chemical modification and has a pronounced effect on physical and chemical properties of UDD, particularly, the resistance of the latter against oxidising gas mixtures, their compactibility (see Table 4), *etc*.

Furthermore, the results obtained allow us to conclude that UDD represent not simply diamond-like materials (*e.g*., see Ref. 4), but typical diamonds, the surface of which, as for the other diamond types, contains different functional groups that saturate free valences of carbon surface atoms. A unique specific feature of UDD is that, with respect to the C_s/C_{tot} ratio, they occupy an intermediate position in a series of functional derivatives of diamond cores, between low-molecular forms similar to adamantane functional derivatives and the polymeric forms representing diamond macro-crystals with specific functional 'coats'. It has been shown [44] that such a mesoregion corresponds to colloidal sizes of the particles. Therefore, bearing in mind that, due to the presence of a functional 'coat', an electrical double layer can surround UDD particles in solution, it is quite reasonable to call the latter particles colloidal diamonds.

VIII. Spectroscopy

Absorption spectra of UDD powders do not reveal any specific features in the optical range. A microscopic study have shown that UDD microparticles by themselves are colourless, so that the typical colour of the powder is, most probably, caused by diffuse scattering and reflection. The microparticles demonstrated no optical anisotropy.

The refractive index of UDD estimated by the immersion technique amounted to ~ 2.55 at the wavelength of 580 nm, which is substantially higher than that of natural diamonds and artificial diamonds of steady-state synthesis.

1. Infrared spectroscopy

The diamond lattice is known to possess over 50 defect centres active in the optical spectra. Most synthetic diamonds contain nitrogen as atomic dopant of substitution. With respect to shapes of the IR spectra, diamonds are divided into two types, *viz*., (I) with one-phonon absorption and (II) without absorption in the single-phonon spectrum range. The first group includes diamonds of the Ia type the one-phonon absorption of which is caused by three independent defective centres: A (1282, 1210, 1110, 480 cm^{-1}), B1 (1332, 1175, 1000, 775, 328 cm^{-1}) and B2 (1350–1380 cm^{-1}), and the diamonds of the Ib type the one-phonon absorption of which is caused by C centres. A well developed surface of UDD (up to 4.5×10^5 m^2 kg^{-1}) and high C_s/C_{tot} ratios that determine the high concentration of surface functional groups allow the method of IR spectroscopy to be used [27] with the aim of reliable identification of the nature of these functional groups.

For insufficiently purified UDD (produced by RIA 'Altai'), the spectra measured both before and after modification revealed absorption bands of carbonyl (1730–1790 cm^{-1}) and hydroxy groups (1640, 3400 cm^{-1}). A wide band with a maximum in the range of 1100–1140 cm^{-1} is probably related to the overall absorption of a number of admixed nitrogen centres of types A (two nitrogen atoms in neighbouring substitution cites), B1 (an accumulation of vacancies 'decorated' by nitrogen), B2 (laminar formations in the cube's plane) and C (isolated nitrogen atoms substituting carbon atoms in the lattice) and the vibrations of C–O–C fragments (NO_2 groups at primary and secondary carbon atoms, SO_2OH groups, OH groups in CO_2H and at ternary carbon atoms absorb in the same range, which complicates unambiguous interpretation).

Comparison of the spectra shows that the positions and intensities of the bands of the carbonyl-group absorption vary widely depending on the UDD modification conditions. Treatment in a nitrogen atmosphere at 937 K results in elimination of carbonyl and carboxy groups, which is indicated by reduced intensities of the corresponding bands. Independently of the modifying gas used, treatment at 673 K shifts the maximum at 1730 cm^{-1} to the region of 1780–1790 cm^{-1}, which indicates the formation of $-C(O)-O-C(O)-$ structures. Insignificant changes in the spectral patterns observed after treating UDD by different kinds of gases suggest that these gases affect insignificantly the composition of surface functional groups of these UDD samples under the conditions specified.

For UDD purified by the nitric-acid procedure (SDB 'Tekhnolog'), the IR spectrum slightly differs from previous spectra and contains characteristic bands at 3500 cm^{-1} (strong, wide), 1740 and 1640 cm^{-1} (both medium), 1260 and 1170 cm^{-1} (both strong and wide) and 610 cm^{-1} (wide, of medium intensity). These bands are well reproducible irrespective of the purification procedure used and, hence, can be assumed to be caused by UDD intrinsic absorption.

A band at 1260 cm^{-1} corresponds to one-phonon absorption of the diamond lattice. Presumably the width and intensity of this band are determined by distortion of the diamond lattice,[18] diamonds of the IIa type, which contain no admixtures, do not absorb in this region. The nature of the other bands in UDD IR spectrum is unclear. Evidently, they do not coincide with any known absorption centres in diamonds. It is possible that some of these bands are caused by adsorbed nitrogen and water.

Our results allowed also us to reveal additional bands dependent on the procedure used for the isolation of UDD. For instance, the spectrum of UDD treated by nitric acid shows bands at 2940, 1390, 1505, 650 cm^{-1}, which were absent in the spectrum of UDD treated by sulfuric acid (produced at RIA 'Altai'); in turn, the latter spectrum contained bands at 2800, 2205 and 670 cm^{-1}. Apparently, the latter bands are caused by the presence on UDD surfaces of conglomerates of functional groups either chemically bound or adsorbed in the course of treatment.

In contrast, due to a substantial amount of background impurities, IR spectra of non-purified DB appear to have a substantially uniform shape with prominent regions of enhanced absorption at 3300 and 1170 cm^{-1}. The presence and width of the latter correlate with the concentration of the diamond component in DB. The spectrum of diamond-free DB reveals none of these peculiarities. It cannot be ruled out that processing of a sufficient body of experimental data will allow development of a quantitative method for the estimation of the diamond concentration in DB.

On the whole, IR spectra of UDD and DB are a good source of information on their structures.

2. NMR and ESR spectra

^{13}C NMR spectra [21] of nanodiamonds involve four signals. A signal with δ 34.5 corresponds to the diamond carbon atoms; a broad signal in the region of δ 30 is due to the fact that carbon atoms are not structurally equivalent, first of all, due to the presence of defects and the Lonsdalite phase. Weakly pronounced peaks with δ 68 and 53 can be attributed either to the effect of partially oxidised structures or the presence of nitrogen atoms in the sample.

In the ^1H NMR spectrum,[21] three overlapping peaks were observed. A signal with δ 2.2 corresponds to the isolated C–OH groups, whereas a signal with δ 3.8 corresponds to bound C–OH groups. A signal with δ 6.7 most probably belongs to S–OH groups formed on the surface of a sample during its chemical

purification (in Ref. 21, oleum–nitric acid treatment of DB was applied).

In the ESR spectra, the UDD signal at 293 K is a singlet with a g-factor of 2.003 and a half-width $\Delta H_{1/2} = 6.3-8.3$ Œ.[21] The concentration of paramagnetic particles ranges from 2.7×10^{21} to 2.0×10^{22} kg^{-1}. The parameters of this signal are most close to the ESR signal of broken bonds on the diamond surface ($g = 2.0027$, $\Delta H_{1/2} = 5.5$ Œ).[47] A similar ESR spectrum was also observed for AV detonation diamonds.[48] It is of note that, despite a high concentration of nitrogen atoms in UDD ($\sim 1.6 \times 10^{24}$ kg^{-1}) no triplet signal associated with doped nitrogen atoms that substitute carbon in the diamond lattice was observed.

3. Raman spectra

Deconvoluted profiles reveal maxima at 1580 and 1620 cm^{-1}, which coincide well with the maxima of the density-of-states function of the sp^2-bound carbon atoms. This suggests that UDD involve an amorphous graphite phase.[20] A band with a maximum at 1530 cm^{-1} can be attributed to the sp^3-bound carbon atoms of that part of the structure which is susceptible to a severe distortion. Apparently, the appearance in the spectrum of a number of specific features of the phonon density of states for the sp^3-bound carbon atoms suggests that, in addition to an amorphous graphite phase, UDD involve an amorphous diamond carbon phase.

4. X-Ray diffraction spectra

X-Ray diffraction spectra [20] of UDD samples contain wide, symmetrical diffraction maxima at $2\theta = 43.9$, 75.3 and 91.5°, which can be adequately described by Lorentz profiles and correspond to the (111), (220) and (311) reflections of the diamond-like lattice with a parameter $a_0 = 0.3565 \pm 0.0005$ nm. The average size of UDD particles determined by using the Selyakov–Scherrer relationship from the half-widths of these lines for all diffraction maxima is equal to 4.5±0.5 nm.

In the region $2\theta = 17°$, an intense localised halo is detected; further, as θ decreases, an increase in the scattered radiation is observed. An intense scattering near the incident beam is typical of diffraction on disordered amorphous structures. Apparently, the observed halo cannot be caused by diffraction on macrostructures with a long-range order and should be associated with its scattering on structural units of a middle-range order. For UDD, not only spherical particles with sizes < 4 nm, but also ordered carbon chains and packages of planes can serve as such structural units. This makes it possible to explain the high intensity of the halo compared with the intensity of the basal (111) maximum. The size of these particles roughly estimated from the halo half-width (in accordance with the Selyakov–Scherrer formula, with assumption of a spherical shape) amounts to ~1.5 nm.

Apparently, it is these small (< 4 nm) ordered particles that represent the 'amorphous' diamond and graphite phases detected in the Raman spectra.

IX. Thermal analysis

Thermal analyses of UDD were carried out either in air or in an atmosphere of an inert gas.[21] On heating in air at a rate of 10 K min^{-1}, oxidation of UDD starts at 703 K,[49] whereas oxidation of diamonds of DSD (detonation synthetic diamond), DDG (detonation diamond with graphite nuclei) and SDB 1/0 (synthetic diamond micropowder) brands begins at 863, 843 and 923 K, respectively.[50] After heating in a neutral atmosphere below 1273 K, the mass loss is 3%–4%. Heating in a CO_2 atmosphere in the temperature range from 443 to 753 K increases the sample's mass by 5%, which can be attributed to CO_2 adsorption and displacement of lighter molecules. Heating in a hydrogen atmosphere is accompanied by HCN evolution.

A complex thermal analysis of UDD carried out in our studies showed that thermograms in air manifest three characteristic regions. At 373–383 K, the mass loss is 5%–7%. This process is endothermic and reversible. An analysis of gaseous products showed that 97%–98% of the gas evolved at this temperature represents nitrogen. Hence, it can be assumed that nitrogen captured from the atmosphere desorbs.

At 523 K, the decrease in the mass of a sample is accompanied by a positive thermal effect. At 753–773 K, an extesive mass loss occurs (up to 95%), which is accompanied by a substantial thermal effect up to 1023–1053 K. Thereafter, no changes take place, and the residual mass corresponds with a 10% accuracy to the ash content of the initial sample estimated according to a standard procedure. It can be assumed that in the interval from 773 to 1023 K carbon is intensively oxidised yielding an incombustible residue. It is noteworthy that oxidation is accompanied by an intense glow.

Wet UDD lose the main mass of water in the interval from 403 to 433 K. Thereafter, the parameters vary practically in the same way as for the predried samples.

Heating in an inert gas atmosphere (helium) at 383–393 K is also accompanied by desorption of nitrogen captured from the atmosphere. In the temperature range of 673–1173 K, a sample loses up to 10% of its mass and heat is liberated. Carbon dioxide and nitrogen are evolved (the molar ratio is 4:1) and the morphology of the material changes.

At 1153–1163 K, a slight positive thermal effect is observed; however, the mass of the sample remains unchanged. The process is accompanied by changes in the morphology and colour of the material. Note that according to the literature data [21] heating in an inert atmosphere entails a practically complete removal of surface groups (adsorbed and chemically bound) from diamond crystals.

X. Defects of the bulk structure

Bulk structural defects of UDD were studied [2] by the method of electron–positron annihilation for all the modes of diamond crystallisation discussed below.

Nanodiamonds were synthesised by detonation of trotyl–hexogen welded charges with 5 mass %–70 mass % of highly dispersed hexogen in water. To estimate the effect of the hexogen concentration and the type of bulk-structure defects and the degree of dispersion of UDD on the sintering process, not only the carbon/hydrogen ratio in the explosive mixture, but also the geometry of charges affecting the time of manifestation of high pressures and temperatures and quenching conditions were varied. After chemical purification, the crystalline structures of UDD were studied by the method of electron–positron annihilation of bulk structural defects. Moreover, a technique of low-temperature adsorption of nitrogen was used for estimating the specific surface area. For studying the sintering processes, UDD of the maximum density of bulk defects (the pycnometric density of 3.05–3.10 g cm^{-3}), the mean CSR size of 1.5–2.0 nm and the maximum degree of dispersion (the specific surface area of 420 m^2 g^{-1}) were chosen. UDD powders were sintered under a pressure of 4–12 GPa. Then, the microhardnesses of sinters and the crushing strengths of the polycrystalline grinding powders obtained were determined.

It was found that with an increase in the carbon temperature and its concentration in the detonation of carbon-containing explosives the distribution curve of vacancy clusters and pores passes through a maximum, after which their concentration begins to decrease. In the region of the maximum corresponding to 3900 K, both an increase in the concentration of vacancy clusters (*i.e.*, agglomerates of vacancies) and the highest concentration of micropores of radii of 1–2 nm in UDD are reached. The aggregates, which contain several vacancies and serve as nuclei for submicropores, represent the centres that capture positrons. The presence in UDD of positronium which has never been observed in diamonds suggests that it appears on the internal surfaces of submicropores formed from vacancy agglomerates.

The absence of submicropores and a low volume density of structural defects (pycnometric density of 3.3×10^3 kg m^{-3}) in

UDD crystallised from trotyl brings these diamonds closer to SDB 1/0 diamonds. This is indicated, for instance, by identical IR spectra of their powders.

XI. Electrophysical properties of ultradispersed diamonds

Diamonds are diamagnetics with a constant magnetic susceptibility ($\chi = -0.62 \times 10^{-8}$ m^3 kg^{-1}).[51] The magnetic susceptibility of UDD substantially differs from this value (see Table 3). The specific magnetic susceptibility of any powder material characterises quantitatively the magnetic properties of the powder as a whole, being the sum of specific magnetic susceptibilities (χ_i) of all components present in the powder with account of their compositions. Table 10 shows the values of magnetic susceptibilities for UDD admixtures.[52]

Table 10. Magnetic susceptibility of admixtures in UDD powder.[52]

Component	UDD	Micropowder of steady-state synthesis	$10^8\chi_i$ /m^3 kg^{-1} (see [a])
Diamond	+	+	−(0.1 – 0.5)
Metal	traces	+	$10^3 - 10^4$
Graphite	+	+	−(0.1 – 8.2)
Carbon materials	+	−	−(0.1 – 2.0)
Gelatine	−	+	−(0.5 – 0.9)

Note. [a] Tentative value.

According to the literature data,[21] the conductivities of UDD are minimal for samples heated at 573 K (resistivity of $\sim 10^{12}$ Ω m). Subsequent heating increases the conductivity (resistivity decreases to $6.0 \times 10^{10} - 2.0 \times 10^{11}$ Ω m). If the samples are heated in a carbon-dioxide atmosphere, then, at temperatures above 1173 K, the resistivity sharply decreases to 2.3×10^4 Ω m, which apparently manifests the beginning of graphitisation.

The permittivity (ε) of different UDD samples varies in a range from 1.7 to 2.7 (Ref. 21). The dissipation factor is $0.5 \times 10^{-3} - 1.0 \times 10^{-2}$.

Thus, UDD exhibit a number of properties that distinguish them from the known types of synthetic diamonds. Despite enhanced reactivity, the diamond-like carbon phase remains stable in neutral and reductive media up to 1273 K, as regards their physicochemical characteristics.

According to our results, at ~293 K the resistivity of a pressed UDD pellet is $10^6 - 10^7$ Ω m. After moistening the pellet, the resistivity sharply increases ($< 10^3$ Ω m for a sample with 5% of water). With further moistening, the resistivity remains unchanged and appears to be determined by the amount of absorbed water. It cannot be ruled out that these data can serve as a basis for the development of a method for determining the residual moisture in UDD.

Yet another important characteristic of the diamond surface is the electrokinetic potential (ζ potential). Taking into account the fact that its value depends substantially on the state of the nanodiamond surface, ζ potential values should be expected not to differ for different fractions of the same UDD and, more so, for UDD samples obtained by different methods of purification and surface modification.

Determination of ζ potential was carried out by electrophoresis based on an electrical current-induced directed transfer of particles of the dispersed medium with respect to the liquid phase.[53] The values of ζ potential were found for three fractions, *viz*., precipitated (I), intermediate (II) and suspended (III), which were obtained from UDD manufactured at RFNC-ARITP (Table 11).

Table 11. Basic physicochemical parameters of isolated UDD fractions.[53]

Parameter	Fraction I	Fraction II	Fraction III
Appearance	light-grey readily crumbling powder	grey powder	black thread-like quasi-crystal formations
Pycnometric density ($10^{-3}\rho$) /kg m^{-3}	3.3	3.2	3.1
[I.r] (mass %)	1.6	1.3	0.9
[C_{ox}] (mass %)	1.0	1.5	1.9
Viscosity [a] of UDD aqueous suspension /MPa s			
at [UDD] = 10 kg m^{-3}	1.04	1.07	1.12
at [UDD] = 60 kg m^{-3}	1.32	1.63	5.15
Electrokinetic potential /mV	+16	+32	+39

Note. Fractions are specified in the text. [a] At 293 K.

The value of ζ potential was also determined for UDD of UDD-TAH (produced at SDB 'Tekhnolog'). The samples were preliminarily purified by ion-exchange resins. For non-fractionated UDD (UDD-TAH), the value of the ζ potential of 32 – 34 mV was found (from three experiments) at 297 – 298 K (for a comparison, ζ potential of non-fractionated and non-dried UDD produced at RFNC-ARITP and similarly pretreated was ±25 – 26 mV).

For four isolated fractions of UDD (UDD-TAH), values of +55, +76, +25 and +33 mV, respectively, were obtained. The resistances (R) of the suspensions (not exceeding 2×10^{-5} Ω) differed only insignificantly after the measurements.

XII. Fractionation process and sedimentation stability

The fractionation process has been discussed in detail.[53] It was claimed that the traditional methods of fractionation of particles with respect to composition and size based on stirring of nanodiamonds in a chosen liquid and subsequent sedimentation under the action of gravity, cannot be applied to highly dispersed colloidal systems including UDD. In the best case, fine fractions are decanted and later form aggregates during drying. The use of organic liquids cannot be accepted due to the high sorption capacity of nanodiamonds (the author of the present work thinks differently).

UDD of different purity grades are shown to include a typical set of functional groups, which remain unchanged up to the destruction of the diamond structure. These are polar OH, NH, C=O, CH and C=N functional groups. It is these groups, especially, the carbonyl and hydroxy groups that determine the trend of UDD particles to form aggregates in aqueous solutions.

Centrifugation of a sedimentation-stable suspension for different periods allowed isolation of UDD fractions (see Table 11).[53] Analysis of IR spectra of the fractions isolated showed that practically the same functional groups were present in all the fractions; however, their concentration differed for different fractions.

UDD was considered as a complex composite material, which consists of individual fractions.[53] The latter differ from one another in the nature and composition of surface groups, as well as in the sizes of aggregates.

Ultrasonication of a dry UDD powder (UDD-STP, produced by Joint Stock Company 'Diamond Centre', St. Petersburg) in water allowed preparation of a stable suspension the dispersed composition of which remained unchanged for a month and

longer.[54] The average size of formed aggregates was 300 nm. An attempt to stabilise the suspension by using different surfactants failed. The UDD particles appear to be surrounded by surfactant molecules with hydrophobic tails directed towards the aqueous medium. Thus, additional hydrophobisation of UDD particles takes place, and the stability of the latter in water decreases.

It was found [55] that, with an increase in the ability of molecules of the medium to association (acetone < benzene < propan-2-ol < water), the degree of dispersion of UDD particles in suspensions also increases. Hence, the solvation of the accessible surface of diamond clusters is favoured not only by the polarity, but also by the tendency of substances to form π-complexes.

From the practical viewpoint, the most important goal is the preparation of stable UDD suspensions in non-polar organic solvents. Nanodiamond suspensions of such a kind will allow cluster compositions based on elastomers to be developed. A real way of solving this problem is to change the nature of the surface of UDD particles from hydrophilic to hydrophobic. For this purpose, a dry nanodiamond powder was added to a benzene solution of commercial co-polydimethyl siloxane and polyisoprene.[55] The adsorption of hydrophobic polymer chains on the surface of UDD clusters was assumed to be beneficial for stabilisation of the suspension. Indeed, the authors managed to enhance the degree of dispersion of UDD in an organic solvent. A method for modifying surfaces and optimising suspensions was developed;[54, 55] for this purpose, polyisoprene proved to be most suitable. Its use for the modification of the surfaces of UDD clusters gave a suspension in which particles measuring 300 nm predominated. This suspension retained its sedimentation stability for no less than 10 days.

XIII. The diamond – graphite structural phase transition

Systematic studies of the diamond – graphite structural phase transition were carried out for UDD clusters.[20] The phase transition occurs in the course of heating in an inert atmosphere in the temperature range of 720 – 1400 K. To detect the transition, the Raman spectroscopy and X-ray diffractometry were used.

The analysis of Raman spectra and X-ray diffraction patterns makes it possible to conclude that UDD represent a cluster material of a diamond crystalline structure with nanocrystals with a characteristic size of ~4.3 nm.

A narrow range of sizes of UDD nanoclusters, *viz*., 4 – 5 nm, was often reported.[17, 56, 57] Apparently, this is explained by the fact that for nanoclusters of small sizes diamond rather than graphite constitutes the thermodynamically stable form. This assumption is confirmed by the results of calculations.[58]

The fact that the lines in the Raman spectra of nanodiamonds coincide with the maxima of the function of phonon density of states in diamond and graphite suggests that UDD involve only small amounts of amorphous diamond and graphite. Inasmuch as nanodiamond clusters, like other ultra-dispersed materials, exist only in an aggregate form,[6] the amorphous phase apparently is located inside such aggregates on the surfaces of diamond cores. The presence of the amorphous phase was also confirmed by the results of X-ray diffractometry, which made it possible to assess the characteristic sizes of particles as ~1.5 nm.

The invariant position of a maximum at 1322 cm^{-1}, which is observed in the Raman spectra with an increase in the support temperature (T_{app}) up to 1000 K, points to the absence of any substantial changes in the structure of the diamond core at such annealing temperatures. This is confirmed by the data from X-ray diffractometry, which state that the graphite phase appears only at $T_{app} > 1200$ K.

The diamond – graphite structural phase transition in the annealing in an inert atmosphere starts from the cluster surfaces. As follows from the analysis of X-ray diffraction data, the graphite phase originates as a set of equidistant graphite nanoplates with a characteristic size < 4 nm and then at $T_{app} > 1200$ K the formation of this phase predominantly involves the diamond core.

The temperature of phase transition (T_{pt}) found correlates well with the results of electron microscopy,[59] according to which the core of a nanocrystalline diamond begins to decrease only as a temperature of 1300 K is reached. This process is accompanied by the transition of carbon into an onion-like structure. A peak at 1575 cm^{-1}, which appears in the Raman spectrum and is clearly pronounced at 1400 K, was interpreted [59] as the manifestation of the carbon onion-like structure. This fact confirms the correctness of the T_{pt} value determined.

It was noted [59] that the diamond – graphite phase transition starts in UDD at substantially lower temperatures compared with diamond single crystals for which $T_{pt} > 1900$ K (see Ref. 60). Such a decrease in a phase-transition temperature, *e.g*., a melting point, was observed earlier for metal clusters.[61]

In parallel with the formation of the graphite phase on the diamond core of a cluster, ordering of sp^2-bound carbon fragments present on original UDD occurs at $T_{app} > 720$ K. Such an sp^2-coordinated crystallisation, in the course of which a disordered (amorphous) phase of carbon located between diamond cores forms continuous graphite nets (patterns), takes place beyond the crystalline diamond core and reflects the changes in the amorphous sp^2-bound carbon. This crystallisation is indicated by an increase in the band intensity at 1350 and 1600 cm^{-1} in the Raman spectra and the appearance of a fine structure in the diffraction pattern in the region of low and medium angles at $T_{app} > 1300$ K.

XIV. A cluster model and the fractal nature of UDD aggregates

Being a structure of the classical type, a UDD particle consists of a relatively dense and ordered crystal-like core and a loose chemically labile shell. The diamond core determines the basic diamond-type properties of UDD, namely, their thermal and chemical stability, heat conduction and thermal diffusivity, low electrical conductivity, the X-ray diffraction pattern quasi-abrasiveness and quasi-hardness. The cluster shell is responsible for such properties of the substance as the sign and value of the UDD surface charge, the chemical composition of surface functional groups, absorption, adsorption, chemisorption and colloidal stability of UDD particles in liquid and other media. In contrast to 'classical' metal clusters the cores and ligand shells of which are built of chemically different elements, *viz.,* metal atoms and complexing ions, in UDD clusters both the cores and the stabilising shells are largely the carbon atoms. In this case, the diamond lattice of the core can gradate to a non-diamond periphery through a system of diamond-like polyhedral polycyclic structures and net patterns. The cluster boundary is stabilised by the products of interaction of periphery carbon atoms with the environment, *viz*., gaseous detonation products, oxidising mixtures and modifying reagents. Peripheral structures play a decisive role in aggregation of diamond clusters and their interaction with matrix substances of composite materials and coatings. The presence of two carbon components in UDD particles is confirmed by a number of experimental data (*e.g*., see Refs 62 and 63).

The structure of condensed detonation products is formed during both the main process, *viz*., in the chemical-reaction zone of the detonation wave, and in the discharge stage where the explosion products are scattered and undergo the action of reflected shock waves.[1, 4, 64] In the latter case, such secondary processes as graphitisation of diamonds and amorphisation of the crystal phase are highly probable. In addition to structural and phase transformations that affect the carbon core of the particles, chemical reactions of the condensed matter with gases take place in the detonation chamber. These interactions are highly diversified due to the wide temperature range and the impact loads that operate throughout the 'life-time' of the carbon condensate in the reactor.

Taking into account the fact that condensation of the diamond substance from detonation products proceeds in fractions of several tenths of a millisecond,[1,2,4] we assumed that, first of all, in the chemical-reaction zone, the primary products of explosive decomposition of the EM are not completely homogenised [64] and, secondly, segregation of condensed and molecular components of detonation products (DP) does not manage to proceed completely. Hence, condensed DP can retain certain 'chemical markers' of the diamond formation process, namely, molecular compounds and fragments of condensed structures, the composition and structure of which can indicate the mechanism of the EM free carbon condensation and reveal the intrinsic structure of a carbon particle.

The expected chemical markers can be divided into the following four groups:

— cage, bridged, alicyclic carbon compounds, which represent the fragments of diamond and diamond-like structures characterised by sp^3-hybridisation of the carbon atoms;

— derivatives of mono- and polycyclic aromatic compounds, which represent the fragments of graphite-like structures (sp^2-hybridisation of the carbon atoms);

— aliphatic (linear and branched) compounds, which represent the fragments of the maximally amorphous carbon-cluster periphery, as well as indications of the presence of carbyne structures;

— compounds that involve C – N and C – O bonds, representing the fragments of the surface layer of particles.

To detect and analyse these 'chemical markers', we experimentally studied the products of mild thermal and organolytic decomposition of UDD and DB.

Low-temperature (cold) extraction was carried out in a Soxhlet apparatus at a solid : liquid ratio of 1 : 10 and an extraction time of 10 – 12 h. Organolytic decomposition was accomplished under the conditions of the supercritical state of the solvent where the extractive power of the liquid is a minimum. This treatment was carried out in a steel autoclave of a volume of 0.4 litre at 573 – 673 K under a pressure > 5 MPa.

The extracts obtained were studied by the methods of low-temperature luminescence and IR spectroscopies, gas-liquid chromatography, chromato-mass spectrometry and ^{1}H NMR spectroscopy.

Different types of detonation charges including a sample which contained no diamonds (the so-called 'under-developed' charge) were subjected to cold extraction. Depending on the synthesis conditions, the DB contained variable amounts of extractable substances. These are largely bi- and polycyclic aromatic hydrocarbons with a single or several substituents in the rings. Thus compounds containing sp^2- and sp^3-hybridised carbon atoms were obtained among molecular products of low-temperature extraction of DB. However, it is evident that such compounds are formed most probably from ultradispersed graphite and turbostratic carbon rather than from diamond. Under cold extraction, the solid carbon matrix is not split, but its extractant-soluble molecular components are desorbed and washed out. Hence, it can be concluded that the compounds identified are the intermediates of a transition from primary products of EM detonation to a condensed carbon phase.

The following correlation is observed between the amount of extracted polyaromatic compounds, on the one hand, and the composition and perfectness of the diamond phase in the mixture (*i.e.*, the amount of various defects on the surface and in the bulk of diamond grains, the presence of lattice distortions dependent on both the detonation conditions and the configuration of the blasting chamber), on the other hand: the maximum yield of soluble substances ($\sim$ 5%) is reached for detonation carbon that contains no diamond.

A deeper extraction in combination with partial decomposition of the solid matter was carried out at 473 – 637 K and elevated pressure, *i.e.*, under conditions of supercritical states of organic solvents used. The supercritical liquefaction of carbon proceeds most completely in pyridine, which ranks among the most active solvents.

At present, we know the composition of simplest high-temperature (hot) extracts obtained by using the following relatively mild hydrocarbon solvents (Table 12): of normal structure (heptane and decane), aromatic (benzene and toluene) and alicyclic hydrocarbons (cyclohexane) and hydronaphthalenes (tetralin and decalin). These solvents are relatively stable under experimental conditions; their extraction ability increases in the following sequence: normal < aromatic < alicyclic hydrocarbons < hydronaphthalenes.

Table 12. Aromatic heterocyclic compounds in high-temperature extracts from UDD and DB isolated using different solvents.

	+	+	–	+
	–	–	+	+
	–	–	+	–
	+	–	–	–

Note. Sign '+' denotes the presence of a compound in the extract.

The extracts obtained differed in colour: from light yellow (normal hydrocarbons) to dark brown (hydronaphthalenes). Upon the treatment, the ratio of diamond to non-diamond phases changed, as well as the surface properties. Supercritical liquefaction allows solubilisation of up to 10 mass % of diamond-containing phase in 30 min. In this case, relatively weak and reactive chemical bonds are cleaved including elimination of the surface groups and most disordered near-surface carbon layers of clusters. Stable macroscopic structural units are retained as a solid carbon residue, microunits survive as individual molecules which pass into solution. Among the latter, polycyclic nitrogen-containing heretocycles (Table 12) with one and two nitrogen atoms in the ring and a number of rings up to four were detected.

Taking into account the laws of organic chemistry, the formation conditions of these compounds allow us to conclude that nitrogen is incorporated into the condensed carbon (including the diamond phase) as a result of primary reactions, most probably, due to polycondensation of nitrogen-containing monomers with carbon – nitrogen bonds. At first glance, this contradicts the ESR spectra for nanodiamonds [21] which demonstrated

no characteristic triplet signal related to admixed nitrogen atoms replacing carbon in the diamond lattice. However, this a comparison rather emphasises the difference between 'common' diffusional growth of a diamond crystal and the polycondensation mechanism of the formation of UDD during the detonation process. The former involves capture of admixed nitrogen atoms into the newly formed diamond lattice and distribution of such admixed atoms throughout the crystal bulk. In contrast, the formation of UDD first involves incorporation of nitrogen (more precisely, a nitrogen–carbon pair) into an aromatic ring (with a high binding energy in the ring, which is typical of aromatic structures), and then these rings are built into a compacting prototype structure of condensed carbon. In the latter case, the paramagnetic properties of nitrogen should differ from those of admixed nitrogen atoms.

The structure of the outer shell of a diamond cluster was also assessed on the basis of the results on thermodesorption. The studies were carried out on an LKB-2091 chromato-mass spectrometer (Sweden). Thermodesorption was carried out at 573 K in a flow of helium with collection of the products in a capillary cooled by liquid nitrogen. Then, thermodesorption products were vaporised and separated by chromatography on a capillary column with a weakly polar phase (SPB-5; column length, 60 m; diameter 3.2×10^{-4} m), at a helium flow (rate of 2.5×10^{-6} m^3 s^{-1}) in a mode of programmed temperature increase from 293 to 543 K (heating rate, 4 K min^{-1}).

The mass spectra were processed and the products were identified using a built-in computer RDR-2 using a mass spectra data base. Table 13 shows the composition of substances desorbed from the surface of the diamond-containing mixture and UDD.

Table 13. Products of thermodesorption (T = 253 K) from UDD and DB surfaces.

Naphthalene	+	+	–

Note. Three samples of each type were analysed. The signs '+', '++' and '+++' show that the compound was detected in thermodesorption products for one, two and three samples, correspondingly. [a] After hydrogen treatment.

Only hydrocarbons are desorbed from the DB surface: saturated C_8–C_{11}, unsaturated C_8–C_9, alicyclic and aromatic. The predominance of C_{10} alkanes and, probably, n-decane ($C_{10}H_{22}$) agrees with the result that detonation products contain carbyne, the structure of which is most thermodynamically favourable in the condensation of C_{10}–C_{12} carbon chains with the formation of cumulene bonds. The proportion of aromatic hydrocarbons including C_{10} alkylbenzenes among the substances desorbed from DB is comparatively small, although the presence of polycyclic aromatic nets in DB itself is unambiguously proved.[63] Hence, the degree of sp^2-type condensation of carbon is high enough; however, the polyaromatic nets have a very disordered, predominantly aliphatic coating, *viz*., a peculiar type of hydrocarbon 'fringe'. In the desoption products from the DB surface, hydrogen is present in an inactive C–H form, which agrees with the results of determination of active hydrogen on the surface of ultradispersed carbon.[31]

The composition of the desorption products from the UDD surface is more complex and diverse. In addition to hydrocarbons, oxygen- and nitrogen-containing compounds were identified, which are formed as a result of oxidation of the carbon surface. Benzene and C_7–C_{10} homologues are abundant and are second only to C_{10}-alkanes, n-decane prevailing among the latter. Of bridged alicyclic structures, camphene and terpene $C_{10}H_{16}$ are present. Such a composition of the desorption products suggests that the appearance of the diamond structures themselves at the interface is highly improbable. Stabilisation of the diamond structure in a UDD cluster occurs *via* various transition carbon structures. An exposure of UDD to a hydrogen flow at 673 K (UDD-H in Table 13) results in irreversible desorption of most of the C_8–C_{11} hydrocarbons; however, the decomposition of surface carbon structures with the formation of C_2–C_7 hydrocarbons goes on, *i.e*., the surface metastability is reproduced.

Below, certain characteristics of UDD cluster particles are summarised together with the methods of their estimation.

Characteristic	Method
Crystalline core with 4–6-nm diameter	X-ray diffractometry
The presence of peripheral condensed structures of the following types:	
— polyaromatic nets	selective oxidation, organolysis
— aromatic heterocycles	organolysis
Stabilising system of surface compounds:	organolysis, thermodesorption, hydrogenolysis
— aliphatic units	
— bridged structures	
— aromatic rings	
Surface functional groups:	IR spectroscopy,
— carboxyl	chemical analysis,
— carbonyl	potentiometry, polarography, thermodesorption, thermovacuum desorption
— ester	
— quinone	
— nitrile	

These so very diverse and different fragments are combined into a single particle and then into an ensemble of particles in accordance with the fractal rules by a non-continuous filling of a random volume by the mass of a substance.[65] Two- and three-dimensional classical models fail to describe these particles due to their very high C_s/C_{tot} ratio. The packing and arrangement of UDD crystals also cannot be described within the frameworks of the classical theory of filling. It is assumed[6] that the aggregates formed can have a fractal structure. The practical application of UDD requires these properties to be taken into account.

An original procedure has been developed for the direct determination of the fractal dimension of UDD aggregates in hydrosols.[41] The fractal dimension (D), which varied insignificantly in the range of 2.1–2.3, was studied as a function of the

pH, ionic strength and temperature. It was found that an increase in the temperature and ionic strength and a decrease in the pH favour flocculation accompanied by a decrease in the density and fractal dimension of UDD aggregates.

A two-stage mechanism for UDD aggregation was assumed. In the first stage, relatively compact primary aggregates are formed by a particle–cluster mechanism, which takes place in the oxidation of a non-diamond component of DB during its chemical purification. The second stage of cluster–cluster aggregation with the formation of a looser secondary structure is reversible and preferentially associated with the flocculation of primary aggregates.

It is by the structural heterogeneity of the interactions of clusters both with one another and with individual carbon-containing molecules (this is associated with the fact that different particles in powder systems are surrounded by different numbers of active 'neighbours'), as well as by highly irreversible conditions of UDD formation that the fact that the experimental values of UDD fractal dimension do not correspond to any definite type of aggregation (cluster–cluster, cluster–particles) can be explained.

XV. Comparison of properties of diamonds of different origins.

Table 14 (see Ref. 66) presents comparison of the properties of finely dispersed diamond powders of different origins synthesised by three different methods.

The chemical compositions of UDD synthesised by detonation of EM with a negative oxygen balance differ in the presence of substantial amounts of oxygen. Studies of electrophoretic properties of aqueous dispersions of UDD showed that the surface of particles acquires a considerable negative charge (−78.44 mV) caused apparently by ionogenic oxygen-containing groups.

Such a powder possesses high adsorption capacity. Being a characteristic of UDD, the adsorption potential exceeds that of SDB 1/0 powder by an order of magnitude, and the specific adsorption potential exceeds the corresponding value more than twice. On the other hand, with respect to magnetic and electrophysical characteristics UDD powders differ insignificantly from commercial diamond powders SDB 1/0 synthesised under steady-state conditions. Substantial differences are also observed in the values of the degree of surface hydrophilicity and electrophoretic charge: for UDD, they are two- and ten-fold higher, respectively.

Despite their fine degrees of dispersion, UDD have the same graphitisation threshold, although the initial temperature of oxidation in air is 50 K lower for UDD as compared with SDB 1/0 diamonds synthesised under steady-state conditions.

Diamonds obtained by a detonation impact on graphite and soot in an explosive mixture consist of two phases, cubic and hexagonal (Lonsdalite). UDD powders involve only a cubic modification.

XVI. Application fields of ultradispersed diamonds

1. Electrochemical and chemical co-deposition of ultradispersed diamonds with metals

Co-deposition of UDD with metals is applied in machine-building, ship-building, aircraft, electronic, radio-engineering, medical, and jewelry industries.[71–83]

Table 14. Characteristics of diamond powders of different nature.

Characteristic	SDB 1/0 [a]	Finely dispersed diamond [b]	UDD [c]

Metal–diamond composition coatings are characterised by the following common features: superior wear-resistance and microhardness, substantial corrosion stability, low porosity, a sharply reduced friction coefficient, substantial adhesion and cohesion, high throwing power of electrolytes.

The advantages that may be achieved by using UDD in electroplating processes are listed below.

1. The quality and competitive characteristics of manufactured articles are improved. The articles are characterised by

— better resistance to wear and high microhardness;

Coating UDD + M, where M	Resistance to wear increases by a factor of n, where n	Microhardness, $(10^3 h)$/kg mm^{-3}
Cr	2–12	1.4
Ni	5–8	0.68
Cu	9–10	0.154
Au	1.8–5.5	0.25
Ag	4–12	0.18
Sn	3	–
Al	10–13	1.5

— enhanced adhesion and a reduced friction coefficient;

— reduced porosity (the porosity decreases six- to eightfold for UDD coatings with Zn, sevenfold with Sn, sixfold with Au, eightfold with Ag, and a pore-free coating is formed with Cu);

— high insulating ability of anodic alumina films (a relative weight gain of such a film is higher by a factor of 2.0–3.5);

— corrosion stability (for UDD co-deposits with Cu, no mass loss in standard tests was observed; for co-deposits with Zn, the corrosion resistance increased two- to fourfold);

— a sharp increase in the throwing power of electrolytes (threefold for UDD with Cu, 1.5–2.0-fold for co-deposits with Zn);

— enhanced elasticity (for UDD–Cu deposits, by a factor of 2–4);

2. The service life of articles increases two- to tenfold.

3. The economy in materials, energy and labour are achieved (the coating thickness is recommended to decrease two- to threefold);

4. The effectiveness of an electroplating unit increases by 20%–50% due to a decrease in the coating thickness and (in a number of cases) an acceleration of film formation.

5. The environmental parameters of the electroplating process improve.

Addition of UDD to the electrolyte for nickel plating results in a four- to ninefold increase in the wear-resistance of nickel plates.

The UDD content in metal films varies from 0.1 mass % to 1.5 mass % for all metals and from 0.5 mass % to 40 mass % for anodic oxide films.

For a 1×10^{-6}-m thick metal layer, UDD consumption is ~ 1 carat (2×10^{-4} kg) per 1 m^2.

2. Ultradispersed diamonds in polymer compositions

Modified polymers are applied in the manufacture of aircraft, cars, tractors and ships, in medicine, chemical and petrochemical industries, production of seals, cut-off devices of various kinds, in protective and anti-friction film coatings.[79, 83–91]

a. Film coatings based on fluoroelastomers and polysiloxanes

A technology of cold vulcanisation and filling of fluoroelastomers with UDD particles allows one to obtain coatings with a number of advantages.

1. The permeability with respect to hydrocarbons and polar solvents decreases by a factor of 50, *viz*., from 1.389×10^{-7} to 0.0278×10^{-7} kg m^{-2} s^{-1}. Co-polymers with ethylene and with perfluoroalkyl vinyl ethers (protective coatings) exhibit the highest chemical resistance to acidic and alkaline salt media.

2. The coefficient of dry friction with metal decreases to 0.01.

3. The elasticity and strength parameters improve: the stretch modulus at 100% elongation and the conditional rupture strength increase more than tenfold (from 8.5 to 92 MPa and from 15.7 to 173 MPa, respectively). In this case, the elongation increases by a factor of 1.6 (from 280% to 480%), and the residual elongation decreases by a factor of 1.2 (from 108% to 81%).

4. The strength of adhesion contacts increases

(a) for active surfaces (St.3 steel, zinc, aluminium), by 200%–500% (from 1.7 to 5.1 kN m^{-1} for St.3 and from 0.5 to 3.3 kN m^{-1} for aluminium);

(b) for inactive surfaces (lead, copper), the strength of adhesion contact is 2.8–3.1 kN m^{-1};

(c) the coating developed has the following dielectric characteristics:

— at 4000 MHz, the dissipation factor is 2.58–2.71 depending on the film thickness;

— at 5000 MHz, the transmission and reflection factors may reach 15.0 and 12.4, respectively, depending on the film thickness;

— at 11 000 MHz, the transmission and reflection factors may reach 14.3 and 12.4, respectively, depending on the film thickness.

The coating retains its physical and mechanical properties and operation efficiency under a load up to 2×10^6 kg m^{-2}.

Film coatings based on UDD-modified polysiloxanes possess enhanced elasticity and strength characteristics: the modulus at 100% elongation increases by a factor of 3 (from 19 to 53 MPa); the rupture strength also triples both at 100% (from 52 to 154 MPa) and absolute (from 730% to 1970%) elongation; the tear strength increases by a factor of 1.4.

Fluorine-containing elastomers modified with UDD possess improved elasticity and strength characteristics and are resistant to thermal ageing; the modulus at 100% elongation increases by a factor of 1.6 (from 7.9 to 12.5 MPa), the resistance to rupture is 1.1-times higher (from 15.4 to 16.5 MPa), the rupture elongation increases by a factor of 1.35 (from 210% to 285%).

The resistance of UDD-modified fluoroelastomers to abrasive wear increases by a factor of 1.5–2.0, *i.e*., with respect to this parameter, they are similar to polyisoprene rubbers.

b. Rubbers

Under thermal ageing at 573 K, UDD-containing rubbers either virtually retain their physical and mechanical characteristics at a level of analogous characteristics of standard compositions (non-subjected to heating) or exceed this level. The use of UDD is beneficial for cross-linking in non-destructive changes in the course of thermal ageing.

Polyisoprene rubbers modified by UDD demonstrate enhanced elasticity and strength characteristics. Thus, for the SKI-3 isoprene rubber, the modulus at 300% elongation increases by a factor of 1.6 (from 7.7 to 12.3 MPa), the conditional tensile strength increases by a factor of 1.4 (from 20.5 to 28.2 MPa), and the tear strength increases from 139 to 148 kN m^{-1}. The maximum swelling degree of rubbers in toluene decreases by 45%. These rubbers have a higher degree of vulcanisation and increased strength characteristics (approximately 30% higher than that of standard rubbers based on SKI-3) and higher wear endurance.

The increase in elongation with an increase in the modulus observed for these rubbers contradicts the commonly accepted notions. This points to the changes in the supramolecular structure of the rubber, evidenced by a substantial cohesion increase (by a factor of 1.6: from 1.7 to 2.7 MPa).

Modification of the SKI-5 isoprene rubber by UDD particles results in a 1.6–1.8-fold increase in the controlled strength parameters (modulus at 300% elongation, rupture and tear strengths) with retention of elastic properties.

Oil-containing rubbers modified by UDD possess higher degrees of vulcanisation compared with those without UDD (the modulus at 300% elongation increases from 5.8 to 7.4 MPa, relative elongation decreases from 700% to 610%). Moreover, rubbers that contain UDD together with technological carbon have a tear strength 25%–35% higher then the reference samples.

With introduction of UDD into a standard rubber mixture SKMS-30 ARK based on a butadiene–styrene co-polymer with 30% styrene units, the cohesion strength increases by a factor of 1.5–2.0 (from 1.6 to 3.1 MPa) compared with reference samples.

Rubbers modified by UDD are distinguished by high degrees of vulcanisation, their strength characteristics being practically equal to those of reference rubber, and twice surpass them in tear strength (which increases from 71 to 135 kN m^{-1}). The modulus at 300% elongation increases by a factor of 1.44 (from 7.9 to 11.4 MPa).

Butadiene–nitrile V-14 rubbers modified by UDD exhibit improved operating characteristics: the friction coefficient decreases by a factor of 1.5, wear resistance is enhanced by a factor of 1.3, the elasticity increases by a factor of 1.7, frost resistance also improves (the glass transition temperature decreases by 8%–10%).

For RSS natural rubber (Malaysia) modified by UDD, the modulus at 300% elongation increases threefold (from 1.8 to 5.4 MPa), which is accompanied by a certain improvement in operational characteristics.

Epoxy glues based on UDD exhibit good adhesion and cohesion properties.

Nanodiamonds are applied in technologies for polymerisation from solutions and melts, chemical solidification, and in the techniques for electron-beam, flame, and electrostatic sputtering. Standard equipment is used for fabrication of UDD-containing compositions.

Polymeric compositions containing UDD display substantial advantages.

1. The quality and commercial characteristics of the production improve: the articles exhibit superior strengths, wear resistance, resistance to ageing and action of abrasives. The friction coefficient is low for polyfluoroelastomers (such as co-polymers of polyvinylidene fluoride with perfluorinated co-monomers, *e.g.*, perfluoropropene) and high for polyisoprenes (SKI-3 and SKI-5). The materials and coatings can be adapted to particular technologies and articles.

2. Cheap polymeric starting materials can be substituted for expensive ones.

3. Expensive and deficient components and materials may be saved.

Nanodiamond consumption amounts to 1–5 kg per 1000 kg rubber (polymer) and 1–5 kg per 1000 m^2 of a polymeric coating or a film.

3. Ultradispersed diamonds in lubricants, greases, and lubricating–cooling liquids.

Modified lubricant compositions are used in machinery, metal working, engine-building, ship-building, the aircraft industry and transport.[79, 83, 92–100]

Addition of nanodiamonds to oils allows one to obtain high-quality sedimentation-resistant and environmentally safe systems with superhard particles that measure $< 5 \times 10^{-7}$ m.

The merits of UDD additives to oil compositions are as follows:

1. The quality and competitive characteristics of articles improve: the service life of vehicles and equipment increases; the economy of fuel and lubricants is achieved, these additives can serve as an alternative to expensive oils and special lubricants.

2. The friction torture is reduced by 20%–40%.

3. The wear of friction surfaces decreases by 30%–40%.

4. Fast run in of friction gears is observed.

The consumption of nanodiamonds is 0.01–0.2 kg per 1000 kg of oil.

4. Ultradispersed diamonds in abrasive tools

Tools fabricated from nanodiamonds are used in abrasive, mining and metal working industries, in machinery, electronics, medicine and jewelry production.[83, 101–103]

Below, the quality indices [microhardness (h), electrical resistivity (R), heat-conductivity (γ) and permittivity (ε)] are shown for clinkers obtained from diamond powders subjected to high pressures and temperatures, both for UDD themselves and diamond-oxide compositions with vitreous oxides (diamond ceramics).

	$10^{-3}h$ /kg mm^{-2}	R /Ω m	γ /W m^{-1} K^{-1}	ε
Individual UDD	3.0–3.5	10^9–10^{12}	100–150	7–9
Diamond ceramics (UDD + MgO)	3–4	10^{10}–10^{12}	120–160	8–10

For individual UDD, the density of defect-free fragments is $(3.35–3.50) \times 10^3$ kg m^{-3}.
