I. Introduction	1
II. Versions of catalytic pyrolysis	2
III. Pyrolysis with supported catalysts	2
IV. Conclusion	15

Abstract. The preparation of single-walled, double-walled and thin multi-walled nanotubes by hydrocarbon pyrolysis or carbon monoxide catalytic decomposition is considered. The versions of methods, reagents and catalysts are described systematically. The kinetics and mechanisms of processes are characterised. Trends in the development of methods for nanotube synthesis are shown: the increasing role of pyrolytic methods as compared with the graphite sublimation. The advantages of thin multi-walled nanotubes over single-walled ones are noted. Some unsolved problems are formulated. The bibliography includes 485 references.

I. Introduction

Carbon nanotubes (CNTs) and nanofibres (CNFs) belong to materials that attract the keenest attention of scientists and technologists all over the world (*e.g.*, see Refs 1–10).

In recent summarising publications,^{11–16} the methods of preparation of these materials are divided into two main groups, where the first group includes the graphite sublimation followed by desublimation and the second group comprises hydrocarbon pyrolysis and decomposition of carbon oxides (monoxide and suboxides). The other methods such as electrolysis, chemical reduction of certain organic derivatives with alkali and alkaline-earth metals, chlorination of metal carbides or thermal exfoliation play far less important roles.

Two current trends in the development of synthetic methods and the application of carbon nanotubes and nanofibres are observed. One of them reflects the increasing interest in pyrolytic methods of CNT or CNF preparation, while the second concerns revision of the role and significance of single-walled CNTs (SWCNTs).

Indeed, pyrolytic methods do not require such high temperatures as sublimation, are amenable to scaleup and easier to control, provide means for the effective organisation of continuous processes and are more diversified and versatile. As regards the number of versions, these methods far surpass the electro-arc and laser-oven sublimation of graphite. A potential advantage of certain pyrolytic methods is that in addition to CNTs they allow one to produce hydrogen free of CO, which is very important for

the development of hydrogen energetics¹⁷ and chemical syntheses.¹⁸

Initially, the potential of pyrolytic methods was believed to be restricted to the synthesis of multi-walled CNTs (MWCNTs); however, it is already clear that this is wrong and these methods can be applied for the SWCNT production. Dai *et al.*¹⁹ (1996),[†] were the first to demonstrate the possibility of the SWCNT synthesis by the catalytic pyrolysis of hydrocarbons, while the conditions for the synthesis of high-quality SWCNTs were found as early as in 1998.^{23,24}

The second trend reflects the fact that the opinion that SWCNTs have higher properties than MWCNTs has been shaken. Indeed, double-walled CNTs (DWCNTs) were the first to be appreciated as promising industrial materials.^{25,26} Particularly, DWCNTs were shown to surpass SWCNTs in mechanical properties.²⁷ In addition, DWCNTs exhibit the higher thermal stability, thermal and electric conductivity as compared with SWCNTs.²⁸ SWCNTs start coalescing at ~1200 °C, whereas DWCNTs coalesce above 2000 °C. DWCNT-based nanopaper exhibits higher characteristics than a paper made of SWCNTs.²⁹

The inevitable topological defects typical of all CNTs have a weaker effect on the DWCNT properties as compared with SWCNTs. Covalent addition of chemical groups to the surface drastically changes the electronic properties of SWCNTs and in certain cases makes their functionalisation (and, hence, their solubilisation and the possibility of using aqueous colloid solutions of SWCNT for purification, production of composites, *etc.*) extremely unwanted. In the DWCNT case, the groups are added to the external wall and have virtually no effect on the electronic properties of the internal wall.

Next, a concept of ‘thin MWCNTs’ (from here on; denoted as t-MWCNTs) has been formulated. These tubes gradually came to occupy a special place among other filamentous carbon nanomaterials. Tubes with diameters not exceeding 10 nm are classified as t-MWCNTs,^{30–34} although certain authors place the upper limit of diameters at 5 nm. Tubes that contain from 2 to 8–10 walls fall into this category.

Incidentally, the first industrial production of CNTs organised by ‘Hyperion Catalysis’ (USA) in the mid-1980s was based on the hydrocarbon pyrolysis and allowed the production of t-MWCNTs with diameters of 8–10 nm. Later, other countries have also organised the pilot production of CNTs and CNFs by pyrolysis. In 2004, a pilot-line production of carbon nanotubes

[†] The first syntheses of MWCNTs from hydrocarbons were carried out several years earlier,^{20,21} while their synthesis from CO was carried out more than 100 years ago, in the end of the XIXth century.²²

was organised in Tambov based on the works from the D I Mendeleev University of Chemical Technology of Russia.

Certain versions of pyrolytic methods of the CNT synthesis resemble those of chemical vapour deposition (CVD) which are widely used in the production of coatings of pyrolytic graphite, diamond and diamond-like carbon and are characterised by certain versatility. Indeed, they have their drawbacks, particularly, those associated with the necessity of strict control over the synthetic conditions aimed at the production of pure and uniform CNTs.

Several reviews were devoted to the pyrolytic methods (*e.g.*, see the recently published reviews^{35–42}); a survey that summarises studies on the plasma-enhanced pyrolysis has appeared.¹⁶ However, the majority of these reviews did not dwell into the synthesis of thin CNTs (one exception is a paper³⁷ entirely devoted to SWCNTs) and did not include the most of recent data. The present review summarises studies devoted to the synthesis of thin CNTs, which were carried out in the past 4–5 years. The attention is focused on bimetallic catalysts. For the first time, an attempt is undertaken to generalise the data on the kinetics of CNT formation. Certain potentials of pyrolytic techniques are demonstrated by the example of MWCNT synthesis.

II. Versions of catalytic pyrolysis

Pyrolysis is the transformation of organic substances on heating, which can proceed *via* many routes to ultimately yield elemental carbon. The process is carried out under different conditions, namely, the temperature of the process may vary from nearly ambient to above 1000 °C, while the pressure may be both below and above the atmospheric pressure. Solid (polyethylene, *etc.*) and liquid (supercritical toluene) substances and also aqueous and non-aqueous solutions undergo the pyrolysis to evolve carbon. Pyrolysis of gases and vapours is very close to the CVD processes (although it may differ from such processes⁴³), while the pyrolysis of aqueous solutions resembles the hydrothermal synthesis.

The CNT synthesis under hydrothermal conditions involves the introduction of organic precursors (polyethylene, ethylene glycol, *etc.*) and metal catalysts^{44,45} into the system. The process is carried out at 700–800 °C and a pressure of 60–100 MPa. It was employed for the production of only MWCNTs with the number of walls from 5 to 100 and more. The inner diameter of such MWCNT was 20–1300 nm.

MWCNTs were also synthesised by the pyrolysis of a ferrocene solution in toluene under supercritical conditions at 600 °C and a pressure of ~12.4 MPa (MWCNTs or CNFs were obtained).^{46,47} Resistive heating of the Si substrate covered with a thin Fe film up to 500–1000 °C in certain organic solvents (methanol, ethanol) also yielded CNTs.⁴⁸ Pyrolysis of organic substances in a gel matrix can be carried out at surprisingly low temperatures (300 °C).⁴⁹ The catalytic pyrolysis of liquid hydrocarbons under the conditions of supersonically induced cavitation stands somewhat apart from the above methods. This synthesis was first carried out to produce CNTs in 1999 as the pyrolysis of *o*-dichlorobenzene in the presence of ZnCl₂. Its new version was described recently.^{50,51}

The methods of catalytic pyrolysis of gases are divided into the following two groups according to the way of catalyst loading:

- pyrolysis with a supported catalyst;
- pyrolysis with a ‘volatile’ catalyst.

Based on this, two groups of processes performed under different condition are distinguished. In both cases, to minimise the non-catalytic decomposition of gaseous monoatomic and heteroatomic hydrocarbons, their pyrolysis is recommended to be carried out at a reduced total pressure in the system and a low partial pressure of the main reagent.

SWCNTs can also be prepared by the pyrolysis without a catalyst.^{52,53}

III. Pyrolysis with supported catalysts

1. Versions and specific features of processes

Pyrolysis on a supported catalyst has several versions and offers the widest opportunities. The pyrolysis with powder catalysts and the pyrolysis on smooth (flat) or relief (patterned) substrates can be assigned to its major versions.

The general possibilities may include the production of long CNTs, CNTs of a given diameter, CNTs of definite shapes, doped CNTs, CNTs with the diameter- and length-varying compositions and CNT-containing composites.

On smooth or patterned substrates, it is possible to prepare CNTs oriented in a definite way or various structures formed by CNTs, where oriented CNTs or their structures can occupy relatively wide areas.

The simplest and most frequently applied method is the pyrolysis with powder catalysts. The overwhelming majority of CNT syntheses were carried out in set-ups that represented a heated horizontal reactor in the central zone of which a combustion boat with a weighed portion of the catalyst was placed. The starting hydrocarbons were fed into the reactor. Upon the end of the process, the boat contents were taken out and the CNTs formed were washed from the catalyst remainders with acids and other reagents.

The large-scale pyrolysis with powder catalysts was performed in reactors of the following three types: reactors with stirred (mobile), suspended, and filter beds.⁵⁴ Horizontal vibroreactors used in the synthesis of carbon nanofibres pertain to the first-type reactors.^{55,56} Rotating tube reactors^{38,57} and screw-conveyer type reactors were also used. Suspended-bed reactors include vertical reactors⁵⁸ and reactors with fluidised beds.¹¹ The latter are most popular. They are intended to be used in the preparation of SWCNTs in the CoMoCAT (formed from the words Co – Mo-catalyst) processes^{43,59,60} and also in the pyrolysis of C₂H₂,⁶¹ C₂H₄–H₂ mixtures⁶² and CH₄.⁶³

Long (several mm or cm) CNTs and their bundles were prepared.^{64–74} Such tubes can be used later in the CNT ‘cloning’ (the growth of SWCNTs with identical geometry and structure),⁷⁵ for example, in a cycle shown in Fig. 1. For this purpose, an array of open-end SWCNTs was synthesised, then, the catalyst particles were deposited on their ends and the pyrolysis was repeated. The scheme of ‘cloning’ may be more complicated. Thus the catalyst particles were attached to shortened and functionalised SWCNTs in solution, which was followed by the deposition of tubes onto the substrate. The process resembles the epitaxial growth of single crystals.⁷⁵

Carbon nanotubes of equal lengths are used most often for growing arrays of identically oriented tubes (‘forest’) on smooth substrates. The use of calibrated catalyst particles allows one to synthesise CNTs of definite diameters. In this way, SWCNTs with diameters of 1.45 ± 0.50 nm (Refs 76 and 77) and 1.3 ± 0.4 nm

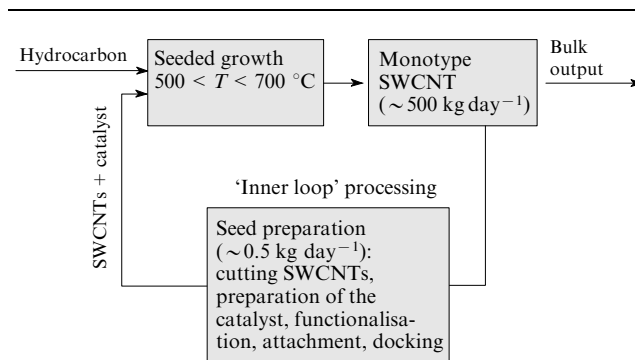

Figure 1. Block diagram of commercial production of SWCNTs of a definite diameter and desired morphology (chirality); [http://www.hydrogen.energy.gov/pdfs/review05/stp_37_smallley.pdf].

(Ref. 78) and also t-MWCNTs with diameters of 4–6 nm were prepared.⁷⁹ The use of the MSM-41 molecular sieves made it possible to control the SWCNT diameter within 0.5–0.8 nm with an accuracy of 0.05 nm.^{80–82} By varying the concentrations of added thiophene in the CH₄ pyrolysis it is possible to control the SWCNT diameter within 0.88–1.18 nm.⁸³ The chemical treatment of zeolites allowed varying the diameter of the void in their crystal structure thus changing the size of catalyst particles incorporated into this void and the diameter of resulting t-MWCNTs.⁸⁴ When MWCNTs are synthesised on flat substrates with deposited catalysts, it is possible to regulate the diameter of tubes and their density on the substrate by varying the intensity of the catalytic film pretreatment in the NH₃ plasma.⁸⁵ Morphology and diameters of CNTs can be changed as a result of changes in the catalyst composition, for instance, by the addition of Co to the Ni/Al₂O₃ catalyst.⁸⁶

Pyrolyses on flat and patterned substrates have their peculiarities, making possible the preparation of oriented CNTs and CNT structures. The oriented CNT packing is possible in the cases of pyrolysis in electric field (the majority of papers describe the MWCNT preparation)^{2, 87–96} and magnetic-field orientation of catalyst particles,⁹⁷ as well as in a directed gas stream^{66, 69–71, 98–100} and at a definite position of the substrate with respect to the gravity vector.¹⁰¹

The growth of oriented CNT was observed² in electric fields with the strength of $\sim 1 \text{ V } \mu\text{m}^{-1}$. Somewhat weaker fields ($0.4 \text{ V } \mu\text{m}^{-1}$) were used in the formation of SWCNT bridges as long as 25 μm between the electrodes.⁹¹ The induced dipole moment was $\sim 10^6 \text{ D}$ for $\sim 1 \mu\text{m}$ -long CNTs in a field of $1 \text{ V } \mu\text{m}^{-1}$.

The most perfect packing of CNTs on a substrate in electric field requires the optimisation of the electrode shape and the elimination of van der Waals interactions between the tubes. Periodic changes in the electrode position and in the direction of the constant electric field during the CNT growth allow one to change the CNT morphology, *viz.*, form bended and zigzag tubes.^{102–104} For CNTs to continue their growth upon a change in the electrode position, the carbon capping that passivates the catalyst particles should be etched away.

A method of SWCNT orientation (aligning), which involved the deposition of Al₂O₃ islets, has been developed.^{93, 105} In this process, the tubes grow perpendicular to the boundary due to the appearance of a space charge. The deposition of a local thin SiO₂ coating on the catalyst film allowed CNTs aligned along the silicon substrate to be grown.¹⁰⁶

Orientation under the effect of the gas flow made it possible to form networks of crossed SWCNTs (in a two-step process)^{66, 69} as well as more complex structures based on 1-cm long tubes.⁷⁰ The best results were achieved at rapid heating of the substrate. Here, a 'kite' mechanism was assumed to operate, *i.e.*, the temperatures of the substrate and the gas increased at different rates, which gave rise to upward convection flows. It is these flows that lift up the ends of growing SWCNTs from the substrate.⁷¹

CNT deposition on silicon, quartz or sapphire single-crystal substrates can also be accompanied by the CNT orientation, which resembled the epitaxial orientation. The growth of oriented SWCNTs coordinated with the surface orientation of silicon single crystals was first observed by Su *et al.*¹⁰⁷ (later, analogous studies were performed with sapphire^{108–112}). It was shown that when ferritin clusters were used as the catalyst and sapphire served as the substrate, the formed SWCNT deposits were ordered on the A and R faces of sapphire and disordered on its M and C faces. Such behaviour was attributed to the different packing of Al atoms on different faces. Sapphire is widely employed as the substrate material in microelectronics; hence, the further development of studies in this direction can lead to the appearance of a new integral circuit technology.

The oriented deposition of CNTs also occurs along atomic steps of vicinal faces of α -Al₂O₃.^{108, 113} The directed growth of

SWCNTs was also observed on the Y-cut of a quartz single crystal.¹¹⁴

As compared with the CNT deposition on flat or powder substrates, the method of growing of arrays of oriented CNTs in Al₂O₃ matrices with cylindrical pores arranged perpendicularly to the external surface was used less often. The vast majority of studies that employed this method were aimed at the MWCNT preparation.^{115–118} Mesoporous silicates were used for the same purposes.^{119, 120} On the other hand, the use of AlPO₄ single crystals,^{121–126} molecular sieves MSM-41 (Refs 80–82 and 127–129) and ordered films of mesoporous SiO₂ (Ref. 130) made it possible to prepare SWCNTs. Zeolites (see Section III.5) and porous silicon served as the matrices in the SWCNT growth. In Al₂O₃ matrices with crossed pores, branched CNTs were synthesised.¹³¹

The method of preparation of a CNT 'forest' described by Dai² is more popular. Catalyst particles of the given size and density were deposited onto inert substrates thus providing the tube growth in only one direction. This allowed SWCNTs to be grown on different substrates in the pyrolysis of ethanol,^{131–135} methane,¹³⁶ ethylene⁶⁷ and mixtures of different gases.

The use of photolithography, methods of substrate profiling or other methods in the deposition of patterns of catalyst particles on substrates made it possible to grow 'columns', 'towers', 'rods', 'tubes' and other CNT structures aligned perpendicularly to the surface. The growth of individual SWCNTs on the patterns formed by photolithographic or microprinting techniques is very promising.^{12, 23, 130, 136}

The preparation of structures of the 'power-line' type, namely, submicron Si or SiO₂ columns with CNT-connected vertices was a remarkable achievement.^{2, 12, 136–141} To synthesise such structures, catalyst particles were preliminarily deposited on column vertices. The formation of 'wires' was explained by swaying of the growing CNTs.

Patterned growth of CNTs on 100 (Refs 142–144) and 150 mm Si wafers [<http://www.elecdesign.com/Articles/Index.Cfm?AD=1&ArticleID=2462>] was documented.

The pyrolytic method of CNT preparation can be employed in the formation of two- and three-dimensional structures.^{145–147} A procedure of preparation of 'pellets' from CNTs aligned in parallel and transplantation them onto any substrate chosen has been developed (Fig. 2).¹⁴⁸

The catalytic pyrolysis allows, in principle, a process similar to the chemical deposition with infiltration to be carried out. Particularly, attempts were undertaken to prepare carbon–carbon composites built of carbon fibres and CNTs.¹⁴⁹

Figure 2. Sequence of operations in the preparation and packing of 'pellets' with CNTs (nanopelleting processes).

(1) Etching trenches, (2) filling trenches with the catalyst, (3) CNT growth, (4) spin casting⁴² an epoxy polymer, (5) planarising and polishing the outer layer to create isolated pellets with uniform-length CNTs, (6) withdrawal of pellets, (7) transplantation of pellets onto a new substrate, (8) etching in the O₂ plasma to remove the polymer.

In the pyrolytic synthesis, the yield of particular CNT types (SWCNTs or DWCNTs) can reach 90%–95% (e.g., see Ref. 150). However, the realisation of the above-described ‘cloning’ of tubes would be the most remarkable achievement.⁷⁵

Tube doping (with nitrogen, boron, *etc.*) was employed, as a rule, only in the production of MWCNTs or carbon nanofibres,^{151, 152} although examples are known where SWCNTs^{52, 153, 154} and even DWCNTs¹⁵⁵ were doped with nitrogen.

The synthesis of CNTs with a composition varying along their lengths or diameters was achieved by changing the growth conditions, particularly, the starting gas composition. Thus CNTs covered with one or several concentric coatings with different compositions were grown.

Pyrolytic methods for the preparation of composites of a ceramic matrix filled with CNTs were actively developed in France.^{156–166} The CNT synthesis was carried out on solid oxide solutions or spinels. In the course of their reduction, solid solutions and compounds based on Al_2O_3 or MgO with formulas of $\text{Mg}_{1-x}\text{M}_x\text{O}$ ($\text{M} = \text{Co}, \text{Ni}$) or $\text{Mg}_{1-x}\text{M}_x\text{Al}_2\text{O}_4$ ($\text{M} = \text{Fe}, \text{Co}, \text{Ni}; x \ll 1$) evolved Fe, Co or Ni nanoparticles which served as the catalysts of the CNT growth. Mixtures of SWCNTs with t-MWCNTs,^{167, 168} SWCNTs with DWCNTs,^{169, 170} DWCNTs,^{159, 160, 171} and also DWCNTs with triple-walled CNTs¹⁷² were prepared from the $\text{CH}_4\text{--H}_2$ gas mixture with appropriately chosen concentrations of Fe, Co or Ni (x values). Oxides CaO , Cr_2O_3 , La_2O_3 , *etc.* can also serve as the matrices.

The catalytic pyrolysis of the $\text{CH}_4\text{--H}_2$ mixture also allowed the formation of a composite film containing MgO and SWCNTs.¹⁷³ A composite containing long CNTs, Fe and ZrC was prepared by the pyrolysis of hydrocarbons on a Zr–Fe film.¹⁷⁴ A composite of SWCNTs and nanocrystalline Al was obtained.¹⁷⁵

Actually, any process of hydrocarbon pyrolysis or CO decomposition on powder catalysts can be modified to produce composites.

2. Methods of enhancement of pyrolytic processes

Several methods of enhancement of catalytic pyrolysis were described, namely, thermal, plasma, hot-filament, and laser enhancement.

There are two versions of thermal enhancement, *viz.*, heating of the substrate (either directly or through the reactor walls) and heating of gaseous hydrocarbons by their partial combustion. In the second version, which is used very rarely, the substrate covered with catalyst is placed into a certain zone of flame. Heating of the substrate was used more often. As a rule, the heating is performed through the reactor walls; however, resistive heating of the substrate was described (the use of Joule heat) in which the reactor walls remain cold^{176, 177} and also heating of the substrate using high-frequency current.^{178, 179} To decrease the temperature of the process¹⁸⁰ and the velocity of the gas flow,¹⁸¹ reduced pressure was used. Thus the pyrolysis of pure C_2H_4 at a pressure of 100 Pa made it possible to build SWCNT and t-MWCNT bridges between the electrodes of nitrided Ta.¹⁸²

The pyrolysis activated by different types of gas discharges, namely, arc, microwave, corona, glow, high-frequency (with frequency from several kHz to several and even tens MHz) was also carried out at reduced pressure.⁴¹ Two types of these processes are distinguished, *viz.*, in which the substrate is placed either immediately into the flame discharge zone or outside of it and it is the gases that are subjected to activation, while the substrate has a relatively low temperature. An example of the use of a plasma source at a distance from the substrate was described.¹⁸³ The elimination of the direct action of microwave plasma on the substrate favours the increase in the CNT growth rate.¹⁸⁴

The plasma enhancement allows one to carry out syntheses at low temperatures of the substrate. Thus MWCNTs were prepared from CH_4 with addition of small amounts of O_2 under the action

of high-frequency plasma at the substrate temperature of 350 °C¹⁸⁵ and also from a $\text{CH}_4\text{--H}_2$ mixture under the action of inductively coupled plasma at the substrate temperature of 200 °C.¹⁸⁶ This can be associated with the fact that charged species formed in plasma can change the mechanism of chemical reactions.

Presumably, the advantages of plasma enhancement over thermal enhancement are that the former allows the effective decomposition of starting hydrocarbons and a strict control over the concentration of reactive species; the drawbacks include the somewhat higher disordering of the product structure.¹⁸⁷

Plasma enhancement was used most often in the MWCNT synthesis.^{16, 41, 188–190} At the same time, the formation of SWCNTs and t-MWCNTs was reported. The microwave discharge plasma was used most extensively. Thus on a Fe catalyst, SWCNTs and DWCNTs with the packing density of $\sim 10^{12}\text{--}10^{13}\text{ cm}^{-2}$ were formed from a $\text{C}_2\text{H}_2\text{--NH}_3$ mixture,¹⁹¹ t-MWCNTs with diameters of 3–20 nm were prepared from a $\text{CH}_4\text{--CO}_2$ mixture,¹⁹² SWCNTs or t-MWCNTs were obtained from a $\text{CH}_4\text{--H}_2$ mixture [http://www.nsti.org/Nanotech2005/Showabstract.html?absno=273] and MWCNTs were formed from a $\text{CH}_4\text{--NH}_3\text{--H}_2$ mixture.¹⁹³ The MWCNT diameter was regulated by varying the size of catalyst particles on the substrate. This could be achieved, for example, by changing the thickness of the deposited metal-catalyst film.^{189, 194–197} A method of preparation of a SWCNT ‘forest’ under the action of point-arc microwave¹⁹⁸ or ‘diffusion’^{199–201} plasmas was described.

An interesting feature of SWCNTs formed in the CH_4 pyrolysis activated by high-frequency discharge is the domination of tubes with semiconductor characteristics.^{183, 202}

For the first time, in the plasma generated at the electron cyclotron resonance, SWCNTs or DWCNTs were grown directly on silicon substrates, which were not preoxidised.²⁰³

The hot-filament activated pyrolysis, *i.e.*, activated by an incandescent tungsten wire heated with Joule heat up to ~ 2000 °C, is a purely laboratory method. This process is easily organised (Fig. 3). Such activation can be accompanied by the formation of plasma, provided a certain potential difference is applied between the cathode and the tungsten wire, which allows SWCNTs to be grown. The tubes were deposited onto low-melting substrates.^{79, 204–206}

Figure 3. Illustration of CNT preparation in hot-filament activated pyrolysis.

(1) Gas mixture inlet, (2) hot tungsten spiral wire, (3) catalyst, (4) cathode, (5) substrate, (6) substrate heater.

Three types of laser activation are known. In the first method, a directed laser beam locally heats one or another substrate area (SWCNTs were obtained this way).^{207, 208} In the second method, by employing an appropriate frequency of laser radiation, one can selectively activate gases subjected to the pyrolysis or decomposition. Finally, laser beams can be used for heating of diathermic gases by adding to them substances capable of selective absorption of laser radiation.²⁰⁹

A specific feature of pyrolytic processes is that the CNT growth is accompanied by incorporation of only active metal particles²¹⁰ into CNT hollows, whereas the inert substrate (*e.g.*, oxide, see Section III.5) remains outside the tubes. This is the result of the effect of catalysts on the formation of tubes.

3. Starting compounds

The set of starting compounds used in the production of SWCNTs and t-MWCNTs is much more limited as compared with the production of MWCNTs or CNFs. Among hydrocarbons, methane is the most suitable for this purpose (Refs 23, 24, 27, 28, 83, 87, 92, 101, 105, 107, 114, 136, 141, 173, 185, 211–254). This hydrocarbon is thermally more stable as compared with others; this is why its catalytic pyrolysis produces smaller amounts of amorphous carbon impurities. Dilution with hydrogen, which is the main gaseous product of pyrolysis, inhibits the non-catalytic pyrolysis of methane even at relatively high temperatures.^{74, 106, 142, 143, 156–172, 186, 189, 199–201, 233, 246, 255–262} In the plasma-enhanced CVD, the dilution with hydrogen is of vital importance; here, mixtures containing as little as 2 vol.% – 6 vol.% CH₄ (*e.g.*, see Ref. 197) are often used. Dilution with inert gases also has a positive effect. The introduction of small amounts of C₂H₄ into the CH₄–H₂ mixture is a common practice.^{88, 94, 109}

In addition to methane, unsaturated hydrocarbons, particularly, ethylene (Refs 67, 75, 176, 180, 182, 219, 240, 262–270), acetylene (Refs 61, 79, 84, 89, 182, 209, 215, 271–299) and propylene,³⁰⁰ were pyrolysed to form SWCNTs, DWCNTs and t-MWCNTs. Mixtures of unsaturated hydrocarbons with methane^{31, 64, 301–304} and benzene^{227, 305} were also used.

As regards the CNT yield and purity, cyclic hydrocarbons, particularly, cyclohexane, naphthalene and anthracene, do not surpass methane.³⁰⁵ This is also true for benzene.

Mixtures C₂H₂–NH₃ proved to be efficient in the synthesis of CNFs,^{41, 306} MWCNTs,^{41, 188, 283, 307, 308} t-MWCNTs^{195, 196} and SWCNTs¹⁹¹ in plasma. The role of NH₃ in the MWCNT preparation consists of the maintenance of the active surface state of catalytic particles due to the removal of amorphous carbon,³⁰⁹ which accounts for the appearance of HCN in the gas^{308, 310} or the increase in the concentration of hydrogen atoms.¹⁹³ The synthesised CNTs contained up to 10 at.% of nitrogen.¹⁸⁸

The difference between the pyrolysis of C₂H₂ and the pyrolysis of other hydrocarbons is that the former process is highly exothermic. The catalytic synthesis of a CNT ‘forest’ was carried out using C₂H₂ molecular beams.²⁹⁴ In the initial stages, before the thickness of the layer of products reached 50 µm, SWCNTs with diameters of ~1 nm were preferentially formed, which was followed by the growth of SWCNTs with larger diameters and DWCNTs.

In the last 3–4 years, keen attention was paid to the use of ethanol as the starting compound in the CNT synthesis. It was assumed that OH radicals remove amorphous carbon admixtures to yield much purer SWCNTs as compared with cases where other reagents were used. This line of research was actively explored by Japanese scientists of the Maruyama group.^{132, 134, 135, 177, 311–320} Analogous syntheses were carried out by other scientific groups.^{66, 72, 75, 78, 178, 179, 321–327} Low partial vapour pressures (0.7–1.4 kPa or 5–10 Torr) and a temperature of 800 °C were commonly used. Ethanol pyrolysis on a Fe–Co/SiO₂ catalyst selectively produced DWCNTs.³²⁶

The introduction of OH radicals into the gas phase can also be accomplished by the addition of O₂ (Refs 185 and 187) or H₂O vapours.⁶⁷ Presumably, the higher yields and formation rates of MWCNTs in the CH₄ pyrolysis on the oxide catalysts that were not subjected to preliminary reduction as compared with reduced catalysts were also attributed to the effect of H₂O vapours evolved in the oxide reduction during the pyrolysis.²⁴⁴

Single-walled CNTs were prepared from vapours of methanol³²³ and mixtures CH₃OH + H₂ and CH₃OH + Ar.⁷¹

The rate of MWCNT formation from methanol was substantially lower as compared with ethanol.³²⁸ A synthesis of SWCNTs was carried out from methanol and propan-2-ol in a set-up with a hot filament.³²⁹ Low SWCNT yields were obtained from camphor³³⁰ and its analogues, namely, camphorquinone, norcamphor, norbornane, fenchone. These experiments did not reveal any beneficial effect of oxygen on the yield and quality of tubes.³³¹

A matrix synthesis of SWCNTs was carried out using tripropylamine.^{121, 125, 332} A mixture of SWCNTs and MWCNTs was isolated after the acetonitrile pyrolysis.³³³ The synthesis of CNTs (with a fraction of t-MWCNTs) from associated gas was described.^{236, 334}

In recent years, the CNT synthesis by the thermal decomposition of carbon monoxide was actively developed (Refs 19, 43, 59, 60, 68, 80–82, 127–129, 263, 335–349). The equilibrium of CO decomposition is such that the solid product yield decreases with an increase in the temperature. This makes the choice of conditions that suppress the formation of amorphous carbon much easier. An increase in the pressure substantially increased the yield of SWCNTs and made them more uniform in the diameter.¹²⁸ The addition of H₂ was observed to have a positive effect on the rate of CNT formation^{69, 71, 335, 342} and, in the case of Co/MgO catalysts, the tube diameter was observed to decrease with the decrease in the Co concentration.³⁴² This method allowed one to prepare both ordinary^{339–341} and long SWCNTs.³⁴⁴

A large-scale production of SWCNTs *via* the catalytic decomposition of CO was proposed based on the aforementioned CoMoCAT process (Fig. 4). The reaction is carried out at 700–950 °C and a pressure of ~0.5 MPa (5 atm). Stable operation of the set-up requires a low degree of CO decomposition in the reaction zone; this is why the set-up provides the CO recycling after the recovery of CO₂ formed. It was shown that the lower the temperature of the process the smaller the average diameter of SWCNTs formed, *i.e.*, the diameter approached 0.8 nm at 750 °C, 1.0 nm at 850 °C and 1.2 nm at 950 °C. The catalyst selectivity with respect to SWCNTs (the SWCNT fraction in the total CNT mass) was 80%–90%. The fraction of semiconductor CNTs in the total amount of tubes was 57%.

4. Catalysts

Among individual metals, Fe, Co and Ni exhibit the highest catalytic activity in the pyrolytic synthesis of CNTs. It is a wide opinion that the characteristics of metal–carbon systems are of the prime importance for the catalytic activity of metals in the pyrolysis.

In a review,⁴¹ the catalysts used in the preparation of various filamentous carbon nanoparticles on substrates were tabulated and the original literature references (more than 60) were cited; however, only three of references are devoted to the synthesis of SWCNTs. This is why the present survey shows a new list of catalysts as applied to the synthesis of SWCNTs, DWCNTs and t-MWCNTs.

The preparation of SWCNTs, DWCNTs and t-MWCNTs involves most often the use of bimetallic catalysts, *i.e.*, active metals.³⁵⁰ They exhibit enhanced activity, selectivity and thermal stability and are less susceptible to poisoning. Such catalysts allow the diameter and purity of CNTs obtained to be controlled within certain limits.

The major metal catalysts, namely, Fe, Co or Ni, are often supplemented with molybdenum compounds (Tables 1 and 2). Molybdenum as such, its oxides and certain other compounds also exhibit catalytic properties in the pyrolysis of hydrocarbons and the decomposition of CO; however, in the CNT synthesis, their

effect is either weak or they impair the morphology of the solid products of the pyrolysis. In place of CNTs, non-tubular CNFs or wide-diameter CNTs are often formed. At the same time, the use of Mo as a promoting additive favours the decrease in the CNT diameter, the increase in the total yield of solid products and the decrease in the amount of admixed CNFs. Particularly, it is assumed that the addition of Mo to the Co/MgO system gives rise to small Co clusters that are formed due to the decomposition of CoMoO₄ and provide sites for the CNT growth.²⁸⁸

Table 1 shows examples of the use of binary powder catalysts Co–Mo on different substrates in the heat-activated pyrolytic synthesis of SWCNTs, DWCNTs, t-MWCNTs and CNFs. The data in Table 1 may be supplemented by the results on disproportionation of undiluted CO on the Co–Mo/SiO catalyst.³³⁶ It was shown that this catalyst changes its chemical composition in the course of CNT formation. As reported in numerous publications, binary powder catalysts based on Co–Mo make it possible to synthesise SWCNTs from various carbon-containing precursors.

Table 1. Composition and application conditions of binary powder catalysts Co–Mo/support (A) in the heat-activated CNT synthesis.

A	Co : Mo : A /mol (Co : Mo)	Process conditions			Products	Ref.
		starting compounds	<i>T</i> /°C	<i>p</i> /atm

^a Mass ratio. ^b Ratio Fe:Co:Mg or Fe:Ni:Mg. ^c Content of MgAl_2O_4 /mol. ^d Good results were also obtained for the Fe–Co–Ni/ Al_2O_3 catalyst. ^e The MgO content was about 97 mass %; Si and SiO_2 supports were also used.

sors. Moreover, after certain changes in the conditions, even DWCNTs, t-MWCNTs and CNFs can be isolated. In the pyrolysis of CH_4 – H_2 mixtures, the highest yield was achieved for the molecular ratio $\text{Co}:\text{Mo} = 1:3$.^{34,357}

In addition to studies cited in Table 2, the use of the Fe–Mo/ MgO catalyst in the synthesis of DWCNTs from CH_4 – H_2 deserves mention.³⁵⁸

As follows from Tables 1 and 2, the lowest temperature of the SWCNT synthesis is 680 $^{\circ}\text{C}$ [e.g., from CH_4 with a catalyst based on Fe and Mo oxides deposited on Al_2O_3 at the mass ratio $\text{Fe}:\text{Mo} = 5:1$ (Ref. 220)];[†] however, such tubes are conventionally obtained at temperatures not lower than 800 $^{\circ}\text{C}$.

The pyrolytic synthesis of CNTs employs Fe–Co, Fe–Ni and Co–Ni catalysts on different substrates (Table 3). In addition to

[†] Iron oxides are inactive under these conditions but can be activated by pre-reduction with a He– H_2 (10%) mixture.

catalysts shown in Table 3, Fe–Co/ MgO (preparation of DWCNTs in the CH_4 pyrolysis),²⁴⁵ Fe–Co/Zeol (SWCNTs, C_2H_2)²⁷⁸ and Fe–Co/ SiO_2 (DWCNTs, $\text{C}_2\text{H}_5\text{OH}$)³²⁶ were described. The use of the Ni–Mo composition was also mentioned.³⁶¹

Besides Mo, the additions of platinum metals, e.g., Ru,²¹³ Pt^{71,317} and also compounds of tungsten,^{280,345} vanadium,³⁵³ chromium²⁸⁰ and manganese²⁸⁰ was used in the preparation of bimetallic catalysts based on Fe, Co or Ni. It was shown that the Co–Mo catalyst is more efficient than Co–Pt³¹⁷ and the Co–Ni catalyst is more efficient than Co–V, Co–Cr and Co–Mn.²⁸⁰

A series of iron-based catalysts with different additives were tested,³⁵⁹ namely, Fe–Cr/ Al_2O_3 , Fe–Ni/ Al_2O_3 , Fe–Ru/ Al_2O_3 , Fe–Cr/ Cr_2O_3 , Fe–Co–Ni/ Cr_2O_3 , Fe–Co–Ni/ MgO and Fe–Co–Ni/ MgAl_2O_4 .

In addition to binary powder catalysts based on Fe, Co or Ni, more complex catalysts and supported binary catalysts were also

Table 4. Composition and application conditions of multilayer catalysts sputtered on flat and patterned substrates in the heat-activated pyrolysis (the sequence of layers begins with the external layer).

^a Thickness of the layer on the substrate was 1–2 nm. ^b Particles measuring 10 ± 1 nm were deposited. ^c A promoting catalyst deposited as a powder was also used. ^d In this work,³⁶⁹ the deposition was carried out onto Si tips. ^e Substrates of Al₂O₃ and MgO were also tested. ^f The substrate was hydrophilised in the O₂ plasma.

used (Table 4). The synthesis of CNTs from CO on Co–Mo films deposited on quartz³⁴⁴ and also by plasma-enhanced pyrolysis on the Al₂O₃ (thickness 0.7 nm)–Fe (0.5 nm)–Al₂O₃ (5.0 nm) film sputtered on silicon^{198, 348} was described.

The studies by a group of Japanese scientists on the pyrolysis of hydrocarbons on sputtered Fe catalysts deserve mention.^{366–368} In particular, they have shown that the CNT diameter can be regulated by varying the thickness of the sputtered catalyst film.

In certain cases, the catalysts were applied onto substrates by the methods simpler than sputtering, *viz.*, by dipping in solutions or suspensions, chemical vapour deposition, *etc.* Table 5 shows the examples of CNT syntheses on such catalysts.

A two-step mechanism was proposed³⁷¹ to explain the effect of bimetallic catalysts in the formation of SWCNTs. The role of the second metal, *e.g.*, Mo, may consist of the promotion of the formation of an intermediate CNT precursor. This promoter can be spatially separated from the main metal on which CNTs are formed. For instance, a ‘conditioning’ catalyst or ‘pre-catalyst’ placed immediately in the gas stream fed into the pyrolysis reactor was observed to substantially increase the CNT yield.^{28, 29, 249, 372} It was found that the ‘pre-catalyst’ favours the formation of small amounts of C₆H₆ from CH₄.

5. Catalyst supports and substrates

In powder catalyst composition, an inert support separates the active metal particles preventing their aggregation. In the preliminary stages of the preparation of compositions, due to the formation of solid solutions, the support favours more uniform distribution of catalyst precursors. This is why attention is focused on the choice of supports and the selection of the composition. A combinatory method for the selection of the composition of catalysts for the synthesis of MWCNTs,^{373, 374} t-MWCNTs³⁷⁴ and SWCNTs^{375, 376} was described.

Based on a large number of examples, the relationship between the diameters of a CNT formed and a catalyst particle was studied and these diameters were shown to be similar.^{79, 277, 322} For instance, it was assumed that the size of metal particles should be limited to 3 nm.³¹⁹ At the same time, it was shown that SWCNTs with diameters of 1.45 ± 0.50 nm grow on uniform Ni particles with diameters of 4.7 ± 1.4 nm,^{76, 77} tubes with diameters

of 1.3 ± 0.4 nm grow on Fe particles with diameters of 1.7 ± 0.6 nm^{78, 377} and CNTs with diameters of 1–2 nm grow of Fe particles with diameters of ~ 5 –14 nm.²⁶⁰ The experimental results have not yet been brought in complete agreement with one another. It was shown³⁷⁶ that the ratio of diameters of a catalyst particle and a SWCNT approached 1.6; however, in the MWCNT preparation (diameter 27–57 nm), a considerably smaller ratio of diameters, namely, 1.2–1.4, was observed.³⁷⁸

Testing of various powder catalyst supports has shown that MgO surpasses SiO₂, ZrO₂, Al₂O₃, CaO, *etc.* in the stability and the SWCNT yields reached.²²⁷ For powder MgO with mesopores of a certain size ($d = 12$ –16 nm), the specific surface area (S_{sp}) of the powder is related to the SWCNT purity, as evidenced by the changes in the intensities of G- and D-modes in the Raman spectra of tubes (Fig. 5). At the same time, no unambiguous relationship between S_{sp} of the support and CNT characteristics was revealed, *viz.*, on a SiO₂ support with the pore diameter of 7.2 nm, no

**Figure 5.** Effect of the specific surface area of MgO powder prepared by different methods on (1) the average size of powder pores and (2) the ratio of intensities of G and D modes in the Raman spectra of SWCNTs synthesised.

Points correspond to experimental data.

CaO	4.8	38	"	—
ZrO ₂	102	22	"	—
Al ₂ O ₃	155	15	present	2.3

^a RBM is the radial breathing mode that characterises the presence of SWCNTs.

SWCNTs or t-MWCNTs were formed at all even if S_{sp} of the support was as large as 446 m² g^{−1} (Table 6).

The increase in the active metal content in the catalyst entailed the increase in the deposit yield (Fig. 6)¹⁵⁶ but impaired the CNT quality, as follows from the S_{sp} of the carbon product (Fig. 7).¹⁵⁶

For sputtered catalysts, the chemical composition of the substrate surfaces affects the CNT formation. Thus on hydrogenated silicon substrates, the formation of tube nuclei occurred easier than on oxidised substrates or those treated with tetramethylammonium hydroxide.²⁰⁵ A buffer layer (Al₂O₃, TiO₂, etc.) between the substrate (Si) and the active metal (Fe) is not less significant, because it can determine the chemical composition of the catalyst.^{379,380} For example, under similar conditions, iron deposited on an Al₂O₃ layer exists as FeO and can catalyse the formation of SWCNTs, DWCNTs and t-MWCNTs, whereas in an iron layer deposited on TiN and TiO₂ layers, iron is present in the metal form and causes the growth of thick MWCNTs with more than 20 layers.^{379,380}

To prepare t-MWCNTs with diameters of less than 10 nm on metal electrodes, it was recommended to sputter a silicon interlayer between the metal electrode and the catalyst particles.³⁸¹

By changing the composition and thickness of sputtered layers, one can regulate the CNT density on the substrate.³⁸² The results of a systematic study²³⁷ point to the strong effect of the substrate on the morphology and quality of CNTs formed (Table 7).

The different effects of substrates on the CNT growth were attributed^{237,383} to the different roughness of their surfaces. The surface roughness affects the S_{sp} value, the density of defects and, as a consequence, the size of catalyst particles. Rough supports should be preferred. In the case of powder catalysts, the important

Plasma SiO ₂	1.0	—	5.6–25.9
Si/Si	0.99	—	6.1–22.4

role was assigned²³⁸ to the interaction of the metal with the support.

For the plasma-enhanced catalytic pyrolysis of hydrocarbons, the substrate can become the source of radicals, *i.e.*, take part in chemical reactions and also be sputtered with the transfer of the substrate material to the CNF surface.⁴¹

To obtain SWCNTs with small diameters (0.4–0.5 nm), AlPO₄-5 molecular sieves were used.³⁸⁴ The pore size in the Co-substituted molecular sieves MSM-41 and, therefore, the SWCNT diameter could be regulated by varying the composition of liquid matrices in the sieve preparation.⁸¹

An unordinary substrate, namely, uniform SiO₂ microspheres with diameters from 300 to 700 nm was used in the synthesis of SWCNTs.²⁵¹ After the application of Fe particles on these spheres (the spheres were impregnated with a FeCl₃ solution), the CH₄ pyrolysis at 900 °C produced SWCNTs that formed ‘nanoclaws’ patterns on the spheres.

6. Methods of synthesis of catalysts

In the preparation of catalysts for the synthesis of SWCNTs, DWCNTs and t-MWCNTs, it is necessary to produce active-phase particles with sizes not exceeding 3–5 nm.^{76–79, 319, 377, 385} The methods of preparation of such catalysts are less abundant as compared with those used in the synthesis of ordinary MWCNTs and CNFs. The co-deposition of hydroxides, impregnation of fine-grain or mesoporous supports with metal salt solutions followed by the salt decomposition and the reduction of metals with hydrogen, and also the reduction of metallates, the method of ‘wet combustion’ and the sol–gel process were used in the catalyst preparation. Ion exchange processes were employed much more rarely.^{272, 386}

In particular, the co-deposition was used in the synthesis of catalysts deposited on MgO²²⁸ and Al₂O₃.³³⁴

Metal salt solutions were utilised in the impregnation of zeolites^{84, 177, 178, 267, 271, 272, 311, 316, 353, 360} (including the thermally stable Ti-containing zeolite TS-1),²⁸⁰ molecular sieve MSM-41,^{80, 127, 128, 387} MgO,^{227, 228, 231, 256, 288, 323, 354} silica gel,^{59, 60, 63, 264, 337, 343} Al₂O₃ powder and foam (Refs 19, 23, 24, 30, 223, 232, 263, 264, 353), Mg₂(OH)₂CO₃ (Ref. 333) and powders of different compositions.²²⁷ Catalysts were prepared by the hydrolysis of tetraethylorthosilicate in the presence of Al₂O₃ nanoparticles followed by impregnation.²¹³ An aerogel of Al₂O₃ impregnated with Fe and Mo salts proved its worth in the production of SWCNTs from carbon monoxide.³⁴⁰ Impregnation is conventionally carried out under conditions of ultrasonic activation. Salt melts can also be used for the impregnation.⁶³ The impregnation is carried out together with thermal decomposition and reduction of metals.

The reduction of solid solutions M_xMg_{1-x}Al₂O₄ (M = Fe, Fe–Co, Fe–Ni),^{158, 159, 169, 358} Fe_xMg_{1-x}O (Refs 159, 388, 389) and Co_xMg_{1-x}O,^{159, 168, 216, 390} Fe_xAl_{2-x}O₃ (Refs 159, 162, 255, 391 and 392) and also solid solutions of Co in MSM-41,^{80, 81, 127, 128, 388, 393–395} compounds FeLaO₃ (Ref. 396) and NiLa₂O₄ (Refs 397 and 398) was carried out. A linear correlation between the diameter of Fe particles formed in the reduction of Fe_{0.3}Al_{1.7}O₃ and the specific surface of the catalyst was revealed.³⁹¹ The reduction of solid solutions can also occur immediately in the course of pyrolysis.³⁹⁹

The method of ‘wet combustion’ consists of the preparation of a homogeneous aqueous solution of metal nitrates and an organic reducing agent, its rapid heating (an open vessel with the solution is placed into a heated furnace), evaporation of water and spontaneous ignition of the residue.⁴⁰⁰ Thus the reaction of Fe and Mg nitrates with citric acid yielded a highly efficient catalyst for the synthesis of t-MWCNTs, namely, Fe–Mo/MgO (Mo salts were also added to the starting mixture).³¹ The syntheses of a Co/MgO catalyst that involved the use of urea²¹⁶ and citric acid^{342, 401} were described. This method was also used in the synthesis of the following catalysts: Ni/MgO,^{402–404} Co–Mo/MgO (with the use of citric acid),³⁵² Fe–Mo/Al₂O₃ [with the use of poly(ethylene glycol) (PEG)],³⁵⁶ Fe–Mo/MgO²⁴¹ and Fe–Co/MgO (with the use of urea).^{169, 170}

The CNT quality and yields on catalysts prepared in such a way were largely determined by the treatment of the combustion product. In the presence of excess of a reducing agent, the catalyst contained carbon black admixtures, which were removed by annealing in air. In the Co/MgO synthesis, the annealing of the reaction products of Co and Mg nitrates with an organic reducing agent resulted in the formation of a solid solution Co_xMg_{1-x}O, which was difficult to reduce in the H₂ or CO medium (especially for low Co contents) and which proved inefficient in the synthesis of MWCNTs from CO.³⁴² A much more efficient catalyst was synthesised in the preliminary reduction of the uncalcined primary product in H₂. However, it is Co_xMg_{1-x}O from which Co particles necessary for the SWCNT production were formed.²⁸⁸

Active bimetallic catalysts based on alumogel were prepared by the sol–gel method.^{215, 233, 340, 355}

The catalysts were applied on flat or patterned substrates by sputtering (*e.g.*, magnetron), aerosol deposition, the ‘drop’ method, spin-coating of liquid compositions followed by thermal treatment (drying, calcination, reduction), pneumatic spraying of solutions or suspensions,²⁵⁸ microprinting. A method of dipping of the substrate into a solution followed by its withdrawal at a certain rate^{133, 318} (*e.g.*, at 4 cm min^{−1}) was also employed. This method is also suitable for the deposition of catalysts on fibres or wires.

The ‘drop’ method is very simple;⁷⁴ however, it can be applied only in laboratory syntheses. Spinning is more efficient and was used, *e.g.*, in the large-scale production of cantilevers with CNTs³⁶⁹ and in the growth of large CNT arrays.¹⁴² Particles of Al₂O₃ (Ref. 142) and polysiloxane solutions are sometimes added to the composition to be deposited.²⁶⁰ This method allows one to prepare size-uniform Fe₂O₃ particles that are used in the synthesis of SWCNTs with diameters around 1 nm.⁴⁰⁵

A unique version of the spinning method was used.²²⁸ A homogenised ethanolic solution of Mg and Fe nitrates and PEG was spread over the substrate, which rotated at 3500 rpm. After evaporation of ethanol, the substrate was placed into a furnace heated to 600 °C.

In the evaporation method, a block co-polymer is often added to the starting solution.¹⁷³ Dilute (0.01 mass %) ethanolic solutions of metal nitrates are commonly used.^{133, 134} Thus a solution of Fe(NO₃)₃·9 H₂O in propan-2-ol was utilised.²⁶⁸ Immersion of the substrate for a certain time into an aqueous FeCl₃ solution with preliminarily added NH₂OH·HCl was described.³⁰³

Nanosize catalyst particles can be prepared by the thermal decomposition of salts. Such particles are stored in organic solvents and deposited by spin-coating.²⁸⁶ Monodispersed particles Fe–Mo with diameters of 3–14 nm were formed in the thermal decomposition of carbonyls of these metals in a medium of long-chain carboxylic acids or amines.³⁷⁰ Iron particles of different diameters were synthesised by the thermal decomposition of Fe(CO)₅ solutions in dioctyl ether in the presence of oleic, lauric or caprylic acids.²¹⁹ Nickel formate, which forms uniform nickel particles upon decomposition, is a good precursor of Ni catalysts.^{222, 406} A catalyst based on Fe particles was prepared by the plasma treatment of Fe(C₇H₁₅COO)₃ deposited on the substrate by spin-coating.⁴⁰⁷ The methods based on the thermal decomposition of compounds containing metal clusters deserve special mention, *e.g.*, [H_xPMo₁₂O₄₀][−][H₄Mo₇₂Fe₃₀·(CH₃COO)₁₅O₂₅₄(H₂O)₉₈]·60 H₂O (contains 84 Mo atoms and 30 Fe atoms), Na₂[{Mo^{VI}(Mo^{VI})₅]₁₂{Mo^VFe^{III}}(CH₃COO)₂₀·O₂₅₈(H₂O)₈₄]·150 H₂O (78 Mo + 24 Fe), [(Mo^{VI})Mo^V·O₂₁(H₂O)₆]₁₂[Fe^{III}(H₂O)₂]₃₀]·150 H₂O (72 Mo + 30 Fe) and their analogues [http://www.hydrogen.energy.gov/pdfs/review05/stp_35_liu.pdf].

A procedure that involves the co-deposition of salts of two metals in the course of slow evaporation followed by thermal decomposition was used.²⁵⁵

The inverse micelle method^{304, 408–410} is usually combined with the deposition of a colloid solution by dipping, spinning or pneumatic spraying.

Very small (1–2 nm) individual catalyst particles of the same size may be supported with the use of ferritin, apoferritin^{2, 114, 226, 411–413} and ferritin-like proteins⁴¹⁴ or dendrimers.³⁰²

When annealed in an inert medium, thin metal films sputtered over flat substrates are transformed into islets or nanosize particles. The sputtering was performed using a magnetron,^{194, 195} by electron- or ion-beam evaporation²⁸² and the laser ablation of the target.³¹⁷ Usually, the thickness of the deposited film did not exceed several atomic monolayers, for example, corresponded to 5 × 10¹⁵ atoms per cm² (Ref. 92). According to a publication,¹⁴⁰ the sputtering and annealing of a Co-catalyst film with a thickness of 0.5–1.0 nm resulted in the formation of cobalt particles measuring 3–7 nm that favoured the growth of a dense ‘forest’ of SWCNTs. The results obtained in the plasma-enhanced pyrolysis of a mixture of NH₃ and C₂H₂ (Ref. 415) are quite demon-

Figure 8. Dependence of (1) the average diameter of islets formed in film annealing and (2) the average diameter of filiform carbon particles grown on islets on the initial thickness of the sputtered Fe film (D_{Fe}) (according to Wang *et al.*⁴¹⁶)

strative (Fig. 8, Ref. 416). The pyrolysis products synthesised under similar conditions differed not only in the diameter but also in the morphology, namely, SWCNTs, DWCNTs, t-MWCNTs, MWCNTs and, finally, CNFs were obtained.

In the preparation of MWCNTs, it was found that on a catalyst islet, several (up to 7–8) tubes could be grown with diameters much smaller (2–3-fold) than the islet diameter.⁴¹⁷ Moreover, the smaller the diameter of the islet the smaller number of tubes can grow; this is why the elucidated feature does not always hold for t-MWCNTs.

A procedure that allows the determination of the optimum thickness of a layered film in few experiments has been developed.³⁶² Combinatory methods were proposed for the determination and optimisation of the deposition conditions.^{319, 418, 419} Thermodynamic conditions for the transition of films (5-, 10- and 20-nm thick) into particles were considered.¹⁸⁹ According to thermodynamic calculations, in the case of Ni, the radius of a particle formed exceeded the thickness of the deposited film by a factor of 1.5.⁴²⁰

The deposition can be performed through masks to promote the growth of CNTs on definite areas on the substrate and their organisation into one or another type of structures (*e.g.*, see Refs 2, 136 and 291). Ordered arrays of SiO₂ microspheres can serve as a sort of masks in the preparation of individual SWCNTs or their bundles.³⁴¹ Polymeric spheres with diameters from 1 to 125 μm can also be used.^{421, 422}

Organometallic polymers deposited on the substrate as thin films can serve as the precursors of catalysts. Particularly, a polyferrocenylsilane block copolymer was used in the synthesis of SWCNTs.⁴²³

The synthesis of CNTs on catalysts deposited by the microprinting technique is of special interest (Fig. 9). In microprinting, polymethylsiloxane stamps are commonly used.^{87, 137, 372} This method is relatively simple and versatile; it allows one to prepare a considerable number of copies on relatively wide (more than 1 cm^2) areas with the resolution varying from below 100 nm to above 1 μm . The catalyst deposition involves the use of 'ink', *i.e.*, alcohol (ethanol, isopropyl alcohol) solutions of metal nitrates, *e.g.*, Fe(NO₃)₃·9H₂O containing Al₂O₃ or SiO₂ particles and MoO₂Cl₂ or MoO₂(acac)₂ additives.^{87, 137, 372} (The details can be found in numerous publications, *e.g.*, Refs 23, 99, 130, 138, 230, 257, 275, 273, 375, 424 and 425.) By changing the concentration of the applied solution and the pyrolysis temperature, it is possible to regulate the CNT diameter.²⁷⁵ A gel catalyst was used in the synthesis of t-MWCNTs.⁴²⁶

The deposition of Fe nanoparticles of the same size (1.7 ± 0.6 nm) on the substrate surface with the accuracy of their positioning of ± 5 nm was described.³⁷⁷ An organometallic com-

Figure 9. Sequence of steps in the production of stamps, microprinting and CNT growth.

pound mixed with the resist served as the catalyst precursor. The diameter of SWCNTs formed was 1.3 ± 0.4 nm.

The positional packing of SWCNTs on a substrate can sometimes be carried out by an unexpected method. For instance, it was found that lithographically deposited islets of Pb(Zr_{0.5}Ti_{0.5})O₃ are capable of sorbing the Fe–Mo catalyst particles and initiating the local growth of tubes.²²⁵ In this case, the stronger sorption of catalyst particles could be associated with the porous structure of islets. In the pyrolytic synthesis of CNTs on quartz or oxidised silicon surfaces, the localisation of tubes involves the creation of active sites by mechanically damaging the substrate (scratching).⁴²⁷

Studies devoted to the initial stages of CNT growth in the hot-filament activated pyrolysis demonstrated⁴²⁸ the important role of the catalyst pre-treatment stage in the preparation of finer particles.

MWCNTs can be used as the substrate.⁴¹³

7. Mechanism and kinetics

The catalytic growth of CNTs proceeds by the following three macroscopic mechanisms: base growth, tip growth and branched growth mechanisms.

In the base growth mechanism, a catalyst particle remains on the substrate. In the tip growth mechanism, the particle is detached from the substrate and removed from it as the CNT grows and the tube tip moves away from the substrate or the catalyst support. The branched growth can be a version of either base or tip growth mechanisms and is typical of MWCNT growth. In the first case, the catalyst particle is split to form a dendrite structure;⁴²⁹ in the second case, octopus-like structures are formed. Sometimes, branched MWCNTs grow from a single catalyst particle.⁴³⁰ The base and tip growth scenarios can occur simultaneously to form products with different morphology.^{29, 431} In many experiments, catalyst particles were observed to change their shape and size in the course of the process or to be in continuous or impulsive motion.

The base growth mechanism is typical of the preparation of SWCNTs, where the scheme of transformation of carbon or carbon-containing substances is described by a sequence vapour–liquid–solid.⁴³²

The rate of this process depends on several factors (seven factors have been proposed²⁹⁶), among which two most important factors can be outlined. First, the rate is determined by several reactions that occur both on the catalyst surface and in the gas phase. Precisely this factor was used for explaining the effect of the aforementioned ‘pre-catalyst’ (conditioning catalyst) on the formation rate and yield of SWCNTs.²⁴⁹ An equally bright example of the effect of gas-phase reactions on the overall process of CNT formation is the experimental fact that the length of a thin-film catalyst sample can affect the rate of the process.²⁷⁰ Thus, on a Mo–Fe/Al₂O₃ sample with the film dimensions of 1 × 1 cm, no CNTs were formed from CH₄, whereas the growth of a CNT ‘forest’ was observed on a sample of 1 × 15 cm. Moreover, the process strongly depends on the gas flow rate and the position of the substrate in the path of gases in the reaction zone.

Second, the rate is determined by the size of catalyst particles. In addition, it is important that the changes in the conditions of the process can cause changes in the CNT morphology.

On the surfaces of formed CNTs, secondary processes can occur. Thus the tubes can become thicker due to the deposition of amorphous carbon, polyaromatic compounds or graphitised particles on their walls; moreover, the increase in the temperature and the duration of the process results in the active growth of such deposits and substantially increases the CNT diameter.

This is why the catalytic pyrolysis differs substantially from the processes of chemical vapour deposition, although these processes are often confused in the literature. The optimum conditions for the CNT synthesis are developed in those cases where the temperature is sufficiently high for the rapid growth of tubes but too low for the formation amorphous carbon and other undesired forms.

The pyrolysis proceeds at different conditions on a powder catalyst, on a substrate with the catalyst deposit (the formation of ‘forest’) and on porous membranes of the Al₂O₃ type. Thus on a substrate, the secondary processes can be suppressed by building a ‘shelter’ over the catalyst particles.²⁷⁰

Table 8 shows the experimentally measured rates of the linear growth of CNTs under different conditions. As follows from these data, the rates vary in a very wide range, viz., from 0.2 to

660 $\mu\text{m min}^{-1}$ [for the MWCNT growth, the rate was found to vary in the ranges of 60–600 $\mu\text{m min}^{-1}$ (Ref. 436) and 0.4–50 $\mu\text{m min}^{-1}$ (Ref. 298)]. This entailed no changes in the kinetics of formation of SWCNTs and MWCNTs. It is noteworthy that some studies^{67,437} described the synthesis of high-quality SWCNTs that grew at a very high rate. The authors of those studies have explained this fact by the effect of small amounts of H₂O vapour that favour the prolongation of the catalyst service life. Still higher growth rates of SWCNTs with diameters of 4–6 nm (480 $\mu\text{m min}^{-1}$) were observed in the decomposition of CO at 880 °C.^{68,349} Ultralong SWCNTs were grown at a rate of 660 $\mu\text{m min}^{-1}$.⁷² Ultimately, at 700 °C the record-breaking rate of the MWCNT growth from C₂H₂, namely, 6000 $\mu\text{m min}^{-1}$ was reached (although in the 1st second).²⁹²

It should be noted that very high rates of MWCNT growth (60–600 $\mu\text{m min}^{-1}$) were observed at rather low pressures.⁴³⁶ The interpretation of these results requires their refinement.

So far, it is difficult to explain the wide deviations in the linear rates of tube growth found in different studies and relate the linear growth rates to the catalyst efficiency (a relative amount of CNTs formed before complete poisoning of the catalyst).

As seen in Fig. 10, the rate of CNT growth in the plasma-enhanced pyrolysis is associated with their diameter, the latter being determined by the thickness of the deposited metal-catalyst

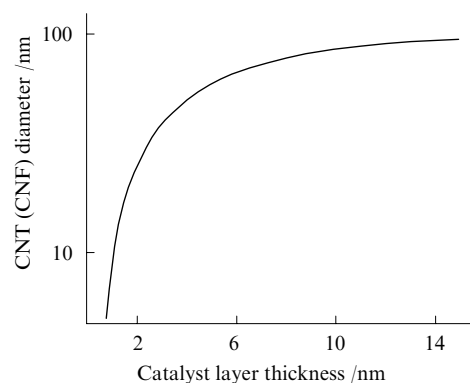

Figure 10. Effect of the average outer diameter of CNTs and CNFs on the thickness of sputtered Fe, Co or Ni films during the plasma pyrolysis.

Table 8. Linear growth rate of CNTs.

film.¹⁹⁵ In the C₂H₂–NH₃ mixture, the growth rate of nanofibres depended on the set-up design (the distance between the plasma source and the substrate) and on the reactant ratio (Fig. 11).⁴¹

The temperature of the SWCNT growth also depends on the diameter of catalyst particles. Thus, for Fe particles measuring 10–30 nm, tubes were formed at 900–950 °C, whereas for the 5-nm particles, the tubes started to form at 780 °C.¹⁹⁵

Only few papers show the classical kinetic parameters of processes involved in the pyrolysis of organic substances to yield CNTs. Thus the activation energy (E_a) was assessed as 71–73 kJ mol⁻¹ (Ref. 438) for the methane pyrolysis on a Ni/La₂O₃ catalyst to yield CNFs and as 95–98 kJ mol⁻¹ (Ref. 244) for the same process on a Co–Mo/Al₂O₃ catalyst to form MWCNTs with diameters of 10–30 nm. At the same time, E_a of the formation of a pyrolytic carbon deposit on a Fe catalyst at 500–600 °C was much higher being equal to 150 kJ mol⁻¹ (Refs 439 and 440). It was noted that the latter value is close to the E_a of the Fe₃C formation equal to 158 kJ mol⁻¹.

The formation of SWCNTs in the CH₄ pyrolysis on different catalysts at 900 °C has two periods, namely, a short period of a fast mass increase and a long period of a relatively slow mass gain.³⁰¹ The catalyst Fe–Mo/Al₂O₃–SiO₂, which was prepared by gelation of a SiO₂ sol in the presence of Al₂O₃ nanoparticles followed by impregnation of the calcined gel with Fe and Mo salts (the molar ratio of 1.00:0.17), proved to be the best for this reaction. Among all catalysts studied, this one has the largest specific surface area (S_{sp} = 196 m² g⁻¹) and the greatest pore volume (0.79 ml g⁻¹).

The results obtained by Choi *et al.*³⁰² were processed by Vinciguerra *et al.*⁴⁴¹ They described the reaction rate in terms of the extrusion-diffusion model and derived an empiric equation that adequately describes the experimental data but contains no standard kinetic parameters.

Our calculations based on experimental data obtained²⁵⁵ have shown that the reaction order in CH₄ changed from 1.24 to 1.77 being in average 1.45. It seems that the deviation of the reaction order from unity is associated with the increase in the contribution of non-catalytic decomposition of CH₄ with the increase in its partial pressure. The formal reaction order of the pyrolysis to yield CNFs was also shown⁴³⁸ to depend on the temperature and to increase from 1.05 at 600 °C to 1.3 at 700 °C. According to the results of another study,⁴³⁹ the order of this reaction is equal to 1.

A threshold value of CH₄ partial pressure (0.4 atm at 850 °C) above which the rate of the catalytic pyrolysis to yield SWCNTs becomes independent of the partial pressure was observed.²³³

Presumably, such behaviour is associated with the transition of the process into the region where the rate is limited by the surface or volume diffusion. It cannot be ruled out that the thermodynamic restrictions may also affect the reaction rate.

The kinetics of catalytic pyrolysis of CH₄ and C₂H₂ was also discussed by Nagy *et al.*²⁴³

Pulsed hydrocarbon feeding is one of the ways for the improvement of CNT purity and yield in the catalytic pyrolysis.^{235, 368} However, this can also decrease the average rate of the process; hence, this method requires optimisation.

Somewhat different mechanisms are typical of the acetylene pyrolysis. The use of an interesting method of ‘marks’ allowed the kinetic parameters of the MWCNT growth to be determined in the pyrolysis of C₂H₂ on Fe islets.²⁹⁷ It was shown that after a short interruption of the pyrolysis process due to the C₂H₂ feeding cutoff (by replacing it by Ar) followed by the resumption of the process on the grown tubes (‘forest’), clear boundaries (marks) were left which could characterise the growth rate if one took into account the duration of individual growth stages. The position of ‘marks’ and the length of grown segments were determined using a scanning electron or optical microscope. As a result, it was found that the activation energy of the process was 159 ± 5 kJ mol⁻¹ in the temperature range of 873–953 K (the partial pressure used in the calculation of the E_a value was not shown²⁹⁷) and the reaction order in C₂H₂ was unity for the C₂H₂ partial pressure of 2–10 kPa and a temperature of 953 K. The linear rate of CNT growth reached 20 μm min⁻¹. The E_a value of the MWCNT growth from C₂H₂ on a Fe catalyst at 800–1100 °C was 125 kJ mol⁻¹.⁴⁴²

The obtained E_a values made it possible to abandon the earlier assumptions that the process is limited by the carbon diffusion in a liquid or quasiliquid catalyst particle (a solution of carbon in a metal),⁴⁴³ because E_a of this process should be substantially lower than the found values. It was assumed that a surface reaction at the gas–catalyst interface is the limiting stage of this process. At the same time, the experimentally observed involvement of the liquid phase in this process cannot be denied.^{444, 445}

Yet another, optical method was used for measuring the growth rate of the MWCNT ‘forest’ in the C₂H₂ pyrolysis.^{298, 446} A multilayer film Mo(0.2 nm)–Fe(1 nm)–Al(10 nm) on Si served as the catalyst, the gas mixture contained 0.25% C₂H₂, 16.62% H₂ and 83.13% Ar. It was shown that with the increase in the temperature from 535 to 900 °C, thinner CNTs were formed, *viz.*, 6–10-walled CNTs were mainly formed at 575 °C, DWCNTs predominated at 725 °C and the fraction of SWCNTs increased at higher temperatures. The highest growth rate (~12 μm min⁻¹) was observed at 700–730 °C; the effective E_a of this process in the low-temperature region was ~2 eV (~190 kJ mol⁻¹). Under isothermal conditions, the pyrolysis occurred with deceleration. With the increase in the C₂H₂ concentration, this deceleration was more pronounced and the CNT growth stopped at a smaller ultimate length of tubes (the ‘forest’ height).

A simplified mechanism of C₂H₂ pyrolysis on a Fe catalyst involves the C₂H₂ dissociation on the Fe surface, the dissolution of carbon in the near-surface disordered ‘fused’ Fe layer and the diffusion of C atoms in this layer to the CNT formation site (with the diffusion coefficient that at 1000 K exceeds the diffusion coefficient in solid Fe by 3 orders of magnitude). CNTs grow until the near-surface carbon-containing layer is distributed throughout the surface of Fe particles. The equations that adequately describe the experimental results were derived.

Yet another method, laser diffraction was proposed⁴⁴⁷ for measuring the kinetic parameters of the CNT ‘forest’ growth. The results obtained⁴⁴⁷ point to the exponential increase in the CNT length in time. According to the field emission characteristics,⁴⁴⁸ the growth rate of MWCNTs in the electric field measured at a low pressure (less than 10⁻² mbar) was in the range of 60–600 μm min⁻¹. With the increase in the C₂H₂ partial pressure, the MWCNT growth rate increased.⁴⁴⁸

The addition of H_2 reduced the amount of amorphous carbon, favoured the decrease in the MWCNT diameter and increased the linear growth rate 1.85-fold.²⁷⁶

The growth rate of the CNT 'forest' from a mixture of C_2H_2 and NH_3 (the volume ratio 1:3, temperature 700 °C, total pressure ~ 0.2 kPa, or ~ 2 Torr) on a Ni catalyst increased in the initial plasma-enhanced stages, reached its maximum ($6.5\text{--}8.5\ \mu\text{m min}^{-1}$) and began to decrease upon reaching the CNT length of $\sim 2\ \mu\text{m}$.⁴⁴⁹ Such kinetics of the process is associated with the mechanism of the CNT growth that involves the surface diffusion. Presumably, the process decelerates when the tube length exceeds the diffusion path.

The formation of the MWCNT 'forest' in the plasma-enhanced process can proceed at the substrate temperature of 120 °C.^{283,450} The E_a value at 120–527 °C turned out to be very low ($22\ \text{kJ mol}^{-1}$) as compared with the value typical of the heat-activated process ($116.4\ \text{kJ mol}^{-1}$).⁴⁵¹ This means that the process is limited by the surface diffusion of carbon over Ni particles. This mechanism can operate on Fe, Ni and Co catalysts in the pyrolysis of not only C_2H_2 , but also CH_4 .⁴⁵² It should be noted that a comparatively low E_a value ($37\ \text{kJ mol}^{-1}$) was also found for the SWCNT formation at 1050–1200 °C under conditions of the laser-oven sublimation, which was associated with the following mechanism: vapour–liquid–solid.⁴⁵³

The MWCNT formation was observed *in situ* using transmission electron microscopy,^{292,293} which allowed the researchers to propose a realistic growth model. The tubes grow on individual faces of a Ni particle and with the highest rate on its (100) face. Catalyst particles rotate or are fused and recrystallised; hence, the growth direction can change.

The kinetics of ethylene pyrolysis was less thoroughly studied than that for methane; however, it is known that the rate of this reaction can be very high.^{67,437} The catalyst efficiency (the amount of CNTs formed per catalyst mass unit before its complete poisoning) in a process described by Japanese authors was $500\ \text{g g}^{-1}$, which exceeded the catalyst efficiency in the HiPco process (thermal decomposition of CO in the presence of volatile Fe carbonyl as a catalyst precursor) by two orders of magnitude. At the same time, the product contained less than 0.013% Fe.

The increase in the pyrolysis temperature narrows the region of C_2H_4 partial pressures at which SWCNTs are formed (Fig. 12).¹⁸⁰

The relative rate of the ethanol reaction with metal clusters depends on the metal nature and the cluster size (Fig. 13).

Many studies^{454–474} were devoted to the simulation of CNT formation; however, most of them dealt with high-temperature methods, namely, the graphite sublimation in an electric arc and in

Figure 12. Effect of the pyrolysis conditions on the morphology of CNTs formed.¹⁸⁰

(I) A region in which no SWCNTs could be obtained, (II) a region of SWCNT formation. (Reproduced with permission of the American Chemical Society.)

laser radiation. Particularly, a process in which mobile Ni atoms located on the tip of a growing CNT play the active role was considered.⁴⁵⁴ Later,⁴⁵⁶ a basically different mechanism of the effect of Ni atoms was substantiated and an attempt was undertaken to resolve the contradictions between these mechanisms.

A relationship between the Fe cluster size, the CNT diameter and the number of CNT walls was demonstrated.^{455,463} The processes of heat and mass transfer were considered as applied to the tip mechanism of CNT growth.⁴⁶⁹

The theoretical analysis of the catalytic pyrolysis of CH_4 mixed with H_2 arrived at the assumption that this method of SWCNT synthesis is a very difficult task.⁴⁷⁴ As follows from the experimental data mentioned above, this conclusion should be corrected. Nonetheless, a model that takes into account not only the chemical stages of the process but its hydrodynamics and the heat transfer has been developed.⁴⁷⁵ The authors of this model cited numerous publications and estimated the kinetic parameters for 47 gas-phase reactions, 19 reactions on powder Co catalysts and 15 surface reactions resulting in amorphous carbon, which may be useful for further calculations.

A thermodynamic model of the formation of MWCNTs with diameters of 5–35 nm in the C_2H_2 pyrolysis (this reaction releases a great amount of heat) assumes the presence of gradients of temperature and carbon concentration on a catalyst particle.⁴⁷⁰ It was shown that the growth rate should be inversely proportional to the CNT diameter (d). This corresponds to experimental results,⁴³⁴ although it was shown earlier⁴⁷⁶ that for CNFs the rate is inversely proportional to $d^{0.5}$.

The formation of a liquid external layer on a catalyst particle and its effect on the SWCNT formation was discussed.⁴⁷⁷ The SWCNT growth proceeds until the catalyst particle, which represents an eutectic metal–carbon mixture, remains liquid and stops when the catalyst becomes solid.

Presumably,⁴⁷⁸ the key stage in the CNT synthesis is the formation of tube nuclei. In this case, the SWCNT growth is possible only on liquid catalyst particles.

The choice of the catalyst affects its specific efficiency. Thus under equal conditions, the alumogel-supported catalyst exhibited the selective efficiency with respect to SWCNTs at least 5-times higher ($6\ \text{g g}^{-1}$) than a catalyst of the same composition prepared by impregnation of Al_2O_3 .²¹⁵ The efficiency of ordinary

catalysts in the SWCNT formation was ~ 40 mass % (or 0.40 g g^{-1}).²¹³ The catalyst efficiency in the CoMoCAT process was $\sim 0.25 \text{ g g}^{-1}$. The Fe–Mo/MgO catalyst exhibited the highest efficiency in the synthesis of t-MWCNTs (3000 mass %, or 30 g g^{-1}).²⁸

It was noted⁴³⁴ that the increase in the pyrolysis temperature accelerates the growth of MWCNTs in their length, and their average diameter increases. The hydrocarbon partial pressure affects both the pyrolysis rate and the morphology of CNTs prepared. The MWCNT diameter changes with variations in the total pressure in the system.⁴⁷⁹ The length and the diameter of growing SWCNTs can be controlled by changing the duration of the process or by adding a promoter.⁸³ The effect of the temperature and the hydrocarbon partial pressure on the CNT morphology was also studied by the other researchers.⁴⁸⁰ By the example of the $\text{C}_2\text{H}_2\text{--NH}_3$ mixture, it was shown that the decrease in the pressure favours the transition from bamboo-like nanofibres to cylindrical MWCNTs.⁴⁸¹

The catalytic decomposition of carbon oxide decelerates in time,³⁴⁰ and the product yield is proportional to $t^{0.5}$. The rate of MWCNT formation from the CO--H_2 mixture and the tube quality depended on the medium in which the catalyst based on the sputtered Fe–Co–Ni alloy was pre-treated.³⁶⁴ Thus catalysts pre-treated in vacuum demonstrated poorer properties than the catalysts treated in Ar or N_2 . After heating in these gases, the linear rate of MWCNT growth at 580°C was about $0.4 \mu\text{m min}^{-1}$, whereas after heating in vacuum the growth rate was ten times lower.

According to calculations,³⁴⁶ in the CO decomposition, SWCNTs can grow by the adsorption of molecules on the open ends of tubes; catalysts favour the formation of nanotube nuclei.³⁴⁶

IV. Conclusion

While this review was in the stage of preparation for publication, several new publications have appeared that deserve mention. These are the materials of the 7th International Conference on Scientific Application of Nanotubes,⁴⁸² two Russian books^{483, 484} and a monograph⁴⁸⁵ in English.

The 7th International Conference on Scientific Application of Nanotubes in which only one participant from Russia took part confirmed in a certain sense the trend mentioned in the beginning of this review. Thus analysing the posters presented in the Session devoted to the CNT synthesis, Professor A Windle (Cambridge University) noted that the majority of the 76 reports presented were devoted to the catalytic pyrolysis. Moreover, the majority of reports dealt with supported catalysts and heat-activated processes. Among metal catalysts, attention was focused on Fe, followed by Co and Mo; the main substrates were SiO_2 and Al_2O_3 , while the starting compounds included $\text{C}_2\text{H}_5\text{OH}$, CH_4 , C_2H_4 and CO (shown in the order of decreasing citation frequency). The latter factor was apparently associated with the domination of scientists from Japan who focus their attention on the ethanol pyrolysis.

Windle has formulated the following ‘five questions of science to answer:

1. Does surface of metal particle catalyse: (a) decomposition of hydrocarbon, (b) decomposition of further metal precursor?
2. What is metallurgy of nano particles? (a) Melting point, surface melting, internal pressure, (b) carbon solubility (as function of radius), (c) phase diagram with carbon (modelling + experiment).
3. Does a region of metal particles have to remain free of a graphene coating? If it doesn't, is that a killer?
4. What determines rate of growth? (a) Diffusion rate in metal (surface), (b) supply of carbon to particle, (c) shape changes due to flow of small (not necessarily molten) particles, (d) interface modifiers such as sulphur, (e) do we have a reliable E_a yet?

5. What determines type and size of nanotube? (a) Metal particle diameter and/or composition, (b) temperature, (c) feed-stock, (d) what is the difference in growth mechanism between (say) a double wall tube and an 8ish layer multi-wall tube of similar diameter?’

Two Russian books are written from absolutely different standpoints and contain complementary information, *viz.*, the monograph⁴⁸³ is largely devoted to the quantum chemistry of carbon nanotubes, a subject absent in the textbook.⁴⁸⁴ At the same time, the classification of nanotubes, their properties, synthesis and applications are described more comprehensively in the textbook⁴⁸⁴ with substantial attention paid to pyrolytic methods.

The textbook⁴⁸⁴ mentions the following most important challenges (some of them are beyond the frames of the present review):

- elucidation and mathematical description of the mechanism of formation of CNTs with different morphology and structure under different conditions;
- determination of the functional relationship between the kinetics of CNT formation and their morphology and structure;
- the search for the methods for regulation and control over the CNT morphology and structure during their syntheses;
- elaboration of methods for deep and selective as well as local functionalisation of CNTs;
- elucidation of mechanisms of the behaviour of CNTs with different morphology and structure in colloid solutions;
- determination of the influence of CNTs and modified CNTs on organisms.

According to the aforementioned book,⁴⁸⁴ the most important unsolved technological problems include the following directions:

- development of a process for efficient industrial production of CNTs with the same morphology and structure;
- development of a process for CNT isolation (grading) with respect to morphology, structure and size, that allows scaleup;
- elaboration of methods for preparation of stable dispersions of individual CNTs in aqueous and organic media;
- the search for the methods of introduction of individual CNTs into polymeric, ceramic, and metal matrices and preparation of CNT composites;
- development of methods for the production of macro-materials from CNTs, especially, macrofibres and nanopaper with the oriented packing of individual tubes;
- development of methods of commercial production of functional devices with CNTs, namely, electron emitters, transistors, sensors, actuators, *etc.*

The third book,⁴⁸⁵ which has an intriguing title, is destined, according to its summary and contents, for a learned reader and embraces both the main information on the subject, the latest achievements and potential application fields.

In the conclusion, I would like to express my gratitude to I V Anoshkin for making it possible for me to get acquaintance with the materials of the 7th International Conference on Scientific Application of Nanotubes, to Nguyen Tran Hung for his help in the preparation of this review and also to all colleagues who have sent me copies of their papers.

Progress in the studies of oxidation of dihydropyridines and their analogues

A I Matern, V N Charushin, O N Chupakhin

Contents

I. Introduction	23
II. Hydride transfer mechanisms in oxidation of dihydropyridines	24
III. Three-dimensional structures of dihydropyridines and stereospecificity of hydride transfer	32
IV. Molecular devices based on dihydropyridines	35

Abstract. Published data on oxidation of dihydropyridines and on the mechanisms and the role of hydride shifts in bioorganic chemistry, enantioselective synthesis and supramolecular chemistry are generalised. The bibliography includes 218 references.

I. Introduction

Almost two hundred years ago, the German chemist Schorlemmer defined organic chemistry as the chemistry of hydrocarbons and their derivatives, from which it follows that the nature of C–H bonds and the conditions of their formation and cleavage are important subjects of chemical investigation.

Actually, many processes associated with the formation of new chemical bonds involve the attack of various reagents, such as electrophiles, nucleophiles, radicals, carbenes and other active species, on the C–H fragment. Radical reagents cause C(sp³)–H bond homolysis, carbenes are inserted into C(sp³ or sp²)–H bonds, whereas the attack of electrophilic or nucleophilic species, which generally occurs on the carbon atoms of C(sp²)–H, ends in the transformation of the substrate molecule into σ^H adducts containing the C(sp³) fragment (a geminal unit). It should be noted that the hydrogen atom elimination is preceded by the formation of σ^H adducts and the latter process radically changes the C–H bond character.

Electrophilic aromatic substitution of hydrogen is a typical example of this transformation. This is a well-developed approach to structural modifications of arenes, which has come into common use as an industrial method for the synthesis of various aromatic compounds.

D is an electron-donating group and E is an electrophile.

Electrophilic aromatic substitution reactions are based on the ease of C(sp³)–H bond cleavage in cationic arene onium σ^H complexes **A** with restoration of aromaticity of the system, which is the driving force for the process.

The nucleophilic attack on aromatic carbon atoms gives rise to anionic σ^H adducts **B**. For many years, the difficulties associated with elimination of the hydride ion from these adducts have limited the development of studies on nucleophilic aromatic substitution of hydrogen (S_N^H). However, investigations performed in the last decades substantially extended knowledge of the synthetic potential of this important approach, which is nowadays used in both oxidative and elimination (*ipso* substitution) modifications.^{1–20}

W is an electron-withdrawing group and Nu is a nucleophile.

Since the publication of the first review on S_N^H reactions in 1976,⁹ extensive data on amination, arylation, alkylation, cyana-tion, hetarylation and other analogous reactions, which enable the direct introduction of fragments of various nucleophiles into activated aromatic compounds of carbo- or heterocyclic series, have been accumulated in the literature. The conditions of the formation of anionic σ^H adducts (as the first step of S_N^H reactions)^{1–3, 10–19} and the characteristic features of their spatial structures, dissociation and isomerisation were revealed. The asymmetric induction in the new bond formation in nucleophiles containing the unsubstituted carbon atom was examined for a series of azinium salts.²⁰

Received 25 May 2006

Uspekhi Khimii 76 (1) 27–45 (2007); translated by T N Safonova

The mechanism of abstraction of 'hydride-labile hydrogen' [†] (the second step of S_N^H reactions) from dihydropyridines is of fundamental importance for organic and bioorganic chemistry and has been the subject of numerous studies and discussions for almost three decades.^{21–28} The importance of knowledge of this mechanism is not only of theoretical interest. The characteristic features of transformations of dihydropyridines and the hydride transfer mechanism are at the basis of important processes in living nature involving nicotinamide adenine dinucleotides and their phosphates (NADH ⇌ NAD, NADPH ⇌ NADP), which are the main components of metabolism and cell energy supply.^{21–23, 28–32}

The mechanism of hydride-labile hydrogen transfer has come under discussion almost immediately after the publication of pioneering studies on oxidation of compounds containing such hydrogen atoms. Kosower²¹ explained an increased attention to this problem by the fact that the choice between the electron transfer and hydride ion transfer is critical to establishing the oxidation mechanism of pyridine nucleotides. Two fundamentally different mechanisms are considered: the one-step (concerted) and stepwise (redox, single-electron transfer, SET) mechanisms. In the latter case, the electron and hydrogen transfer or the two-electron–proton transfer are distinguished. Biochemists have long considered NADH as a source and a component in the electron transport chain, while organic chemists engaged in studies of model chemical compounds are actively debating the nature of hydride transfer.

In the last two decades, the main approaches to investigation of hydride-labile hydrogen transfer and to the choice of NADH models were developed. 1,4-Dihydropyridine derivatives, such as dihydronicotinamides **1**, Hantzsch esters **2** and *N*-methylacridane (10-methyl-9,10-dihydroacridine, AcrH₂, **3**), are most often used as models because these compounds are structurally similar to pyridine-dependent dehydrogenases and their spatial structures and electronic properties can be varied over a wide range, thus influencing the hydride ion mobility.

[†] The term 'hydride-labile hydrogen' is used to designate H[−] that can be eliminated as either a proton and two electrons or a hydrogen atom and an electron, and the hydride shift is used in reference to the transfer of these species.

R = Alk, Ar.

Nowadays, authoritative research groups concerned with the problem of hydride shift in such compounds work in different countries. A considerable contribution to the development of knowledge of the mechanism and characteristic features of oxidation of dihydropyridines was made by the research teams headed by Kosower and Chipman in USA, Stradyn and Duburs in Latvia, Bruice and Moiroux in France, Colter in Canada, Ohno and Fukuzumi in Japan, Cheng and Zhu in China, Hilgeroth in Germany, Beletskaya and Pozharskii in Russia, *etc.* For example, the group headed by Prof. Ohno investigated the characteristic features and stereoselectivity of reduction of various unsaturated systems by dihydronicotinamides, and the results of these studies were published in hundreds of articles. The group headed by Prof. Fukuzumi, who is a recognised expert in the field of investigation of single-electron transfer processes in chemistry and biology and one of the editors of the five-volume encyclopedia *Electron Transfer in Chemistry* published in 2001, has a comparable number of publications on hydride migrations in dihydro derivatives of pyridine and acridine.

The review of the literature demonstrates that the oxidation mechanism of dihydropyridines and the use of these compounds as a 'redox arm' (electron carriers) have attracted considerable interest in the last 5–10 years. This is confirmed by an increase in the number of investigations on the design of qualitatively new materials and processes based on these compounds. The extensive development of biotechnology, nanotechnology and materials sciences and the progress in the field of coordination and supramolecular chemistry facilitated investigations of the hydride shift mechanism. The acquired knowledge of the pathways of redox transformations of nicotinamide adenine dinucleotides was useful in the preparation of antioxidants, free-radical process inhibitors and corrosion inhibitors, in the enantioselective synthesis and asymmetric cleavage, in medicine and biochemistry, in the design of enzyme reactors, bioelectrochemical systems, organic conductors, molecular devices, *etc.*

The present review covers the main directions and trends of the development of knowledge of the hydride transfer mechanism in the series of dihydropyridines and their analogues discussed in the literature in the last two decades. This period of studies of hydride transfer reactions is characterised by development of new methods for initiation and catalysis of oxidation processes, the extension of the range of physicochemical methods and the combined application of various analytical methods.

II. Hydride transfer mechanisms in oxidation of dihydropyridines

1. Study of the properties of dihydropyridines by theoretical and kinetic methods

A combination of kinetic and calculation methods for studying oxidation of dihydropyridines is a main line of investigation of the hydride transfer mechanism. The development of the single-electron concept in organic chemistry,^{32,33} the progress in investigation of redox processes^{34–36} and the elaboration of the theory of single-electron transfer [‡] (Marcus theory)^{36–39} gave impetus to studies, in which experimental results were compared with the calculated energies of hydride transfer reactions and steps of this process.^{40–42}

[‡] This theory relates the driving force for redox reactions, *i.e.*, the energy differences of the reagents and reactions products, to their rates.

Nowadays, various methods are available for quantitative and qualitative estimation of the 'hydride activity' of dihydropyridines taking into account the energy, magnetic, chemical and structural criteria.^{1,6,23} For example, a comparison of the energy profiles of the hydride and hydrogen transfer reactions and of the proton and two-electron transfer led to different conclusions about the possible mechanisms of the process.^{43–46} It was noted that in the single-electron transfer mechanism, the electron and proton transfer occurs between different reaction centres, which is energetically unfavourable. The solvent effect and reorganisation of the solvent in transition states for both the one-step and stepwise oxidation mechanisms were discussed. A comparison of the calculated and experimental data demonstrated that enzymatic reactions are characterised by the one-step hydride transfer, whereas the proton and two-electron transfer occurs in solutions of model compounds. Analogous conclusions were drawn after calculations by the Marcus equation, which relates the reaction rate constants to the standard free energy changes, for the hydride transfer between NADH and NAD analogues.⁴⁷

The Gibbs free energy changes and the Brønsted and Hammett coefficients were calculated for oxidation of 1-aryl-1,4-dihydronicotinamides **1a–e** by 5-nitroisoquinolinium (**4**), tropylium (**5**) and xanthylium (**6**) cations.⁴⁸ It appeared that the one-step hydride transfer is most probable for isoquinolinium cation **4**, whereas the initial electron transfer (the single-electron transfer mechanism) is more probable for the tropylium and xanthylium cations.

X = OMe (**a**), Me (**b**), H (**c**), Cl (**d**), Br (**e**).

Analysis of the kinetic data, including the isotope effects, and calculations of the activation parameters of oxidation of 1,4-dihydropyridines (Hantzsch esters) and benzylidenemalononitriles suggested the one-step hydride transfer mechanism for these processes.⁴⁹ Based on the estimation of the influence of the structural factors of substituents on the hydride mobility and the direct detection of radical species, it was concluded that the hydrogen abstraction in reduction of radicals and radical ions by a series of 4-substituted 1,4-dihydropyridines occurs by the single-electron transfer mechanism.⁵⁰

Lu *et al.*⁵¹ believed that considerable differences between the expected and real kinetic isotope effects, the difference between the energy profiles of the one-step and stepwise hydride transfer reactions and the detection of intermediates in the reaction of 10-methyl-9,10-dihydroacridine (**3**) with the 1-benzyl-3-cyanoquinolinium ion (see below) do not rule out the possibility of hydride tunnelling.

Based on the energy profiles of the hydride transfer from 1-benzyl-1,4-dihydronicotinamide (BNAH, **1f**) to *p*-benzoquinone derivatives calculated thermodynamically, the stepwise mechanism of electron and proton abstraction according to the electron–proton–electron (EPE) scheme was assumed.^{52,53} It was noted that the Gibbs free energy changes for the single-electron transfer between dihydro adducts and electron acceptors correlate well with the rate constants and the primary kinetic isotope effects.

For the reactions of quinones (Q) with dihydropyridines PyH₂ (including 1-benzyl-1,4-dihydronicotinamide), the Gibbs free energy changes (ΔG°) for different steps of the mobile hydrogen

transfer (Scheme 1), such as the transfer of the first (et) and second (et') electrons and the proton, hydrogen and hydride abstraction, were calculated⁵⁴ according to Eqns (1)–(5), respectively.

$$\frac{\Delta G_{\text{et}}^\circ}{F} = E^\circ(\text{PyH}^{+\bullet}/\text{PyH}_2) - E^\circ(\text{Q}/\text{Q}^-), \quad (1)$$

$$\frac{\Delta G_{\text{et}'}^\circ}{F} = E^\circ(\text{PyH}^{+\bullet}/\text{PyH}^{\bullet}) - E^\circ(\text{QH}^\bullet/\text{QH}^-), \quad (2)$$

$$\Delta G_{\text{H}^+}^\circ = 2.3 RT[\text{p}K_a(\text{PyH}^{+\bullet}/\text{PyH}^{\bullet}) - \text{p}K_a(\text{QH}^\bullet/\text{QH}^-)], \quad (3)$$

$$\Delta G_{\text{H}^\bullet}^\circ = \Delta G_{\text{et}}^\circ + \Delta G_{\text{H}^+}^\circ, \quad (4)$$

$$\Delta G_{\text{H}^-}^\circ = \Delta G_{\text{et}}^\circ + \Delta G_{\text{H}^+}^\circ + \Delta G_{\text{et}'}^\circ, \quad (5)$$

where F is the Faraday constant and E° is the redox potential.

As a result, it was established that the energy barriers of the one-step hydride transfer for dihydronicotinamide are higher than those for the stepwise transfer. A comparison of the calculated and experimental primary kinetic isotope effects and the influence of the magnesium(II) concentration on the hydride transfer rate and the redox potentials of the reactants led to the conclusion that the reaction proceeds by the single-electron transfer mechanism:

The question about the possibility of homolytic and heterolytic C–H bond cleavage in oxidation of the main NADH models, *viz.*, compounds **1a–g**, **2a,b** and **3**, by perchlorate of the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine radical cation (TMPA^{•+}) was considered by Chinese researchers⁵⁵ with the use of thermodynamic calculations and data from cyclic voltammetry and calorimetric measurements.^{55,56}

R = 4-XC₆H₄ [X = OMe (**a**), Me (**b**), H (**c**), Cl (**d**), Br (**e**), F₃C (**g**)], PhCH₂ (**f**)

The heterolytic and homolytic C–H bond dissociation energies in an organic solvent (acetonitrile) are 64.2–81.1 and 67.9–73.7 kcal mol^{−1} (for neutral forms of NADH models) and 4.1–9.7 and 31.4–43.5 kcal mol^{−1} (for radical cations), respectively. The energy differences of the heterolytic C–H bond cleavage for BNAH and AcrH₂ are respectively smaller (by 3.62 kcal mol^{−1}) and larger (by 7.4 kcal mol^{−1}) than the corresponding energy of the homolytic process, whereas the analogous values for compound **2a** are similar (69.3 and 69.4 kcal mol^{−1}).

Consequently, the hydride transfer in dihydropyridines **1** should occur more readily than the hydrogen abstraction. An opposite situation is observed for dihydroacridine **3**, whereas both situations are equally probable for Hantzsch esters **2**. The data for the radical cations (for all 10 models, the homolytic C–H bond dissociation energies are 23.3–34.4 kcal mol^{−1} higher than the corresponding energies of heterolytic dissociation) are indicative of the single-electron transfer mechanism and provide evidence that the proton and electron transfer in the final oxidation step is more probable than the hydrogen abstraction.

Analogously, the probability of homolytic and heterolytic cleavage of the neutral and radical cationic forms of NADH in water (Scheme 2) was estimated for the first time:⁵⁶

R is adenosine diphosphoribosyl.

The following dissociation energies (kcal mol^{−1}) were obtained:

	NADH ^{•+}	NADH
ΔH_{het}	5.1	53.6
ΔH_{hom}	36.3	79.3

Therefore, the proton transfer from the NADH^{•+} radical cation in aqueous solutions should occur more readily than the hydrogen abstraction, *i.e.*, the EPE sequence is most probable of all possible mechanisms in living systems.

In a series of studies concerned with the hydride transfer mechanism, the possibility of the formation of a charge transfer complex and its position in the reaction coordinate were examined.^{57,58} The existence of charge transfer complexes was proved by calculations of changes in the activation enthalpy for the reactions of substituted dihydroacridines with *p*-benzoquinone derivatives and tetracyanoethylene.²⁶ The reaction rate was found to depend on the temperature. It was also demonstrated that the nature of the solvent influences the reaction enthalpy change. Calculations of the equilibrium constants of the electron and proton transfer steps demonstrated that deprotonation of radical cations is the rate-determining step.

The stepwise hydride transfer mechanism was suggested based on the results of calculations of the free energy changes of elementary reactions involved in the one-step and multistep mechanisms of reduction of metal cations and quinones by NADH models combined with measurements of the kinetic isotope effects.^{59–61}

Based on the results of theoretical studies performed for various models of nicotinamide adenine dinucleotides, it is impossible to unambiguously decide whether the hydride-labile hydrogen transfer occurs by the one-step or stepwise mechanism. It should be taken into account that most of calculations were carried out for models in the gas phase without consideration of

the solvent effect. However, these calculations can be used for comparing the reactivities of dihydropyridine derivatives.

The influence of such factors as the primary and secondary isotope effects, acid–base catalysis, the nature of the solvent, the steric and electronic effects of substituents in the substrate, the presence of metal complexes or ions and photoinitiation on the hydride transfer rate was examined.^{24,62–66} The experimental data can be interpreted in favour of both the one-step hydride transfer and the multistep (single-electron transfer) mechanism.

Measurements of the isotope effects, *viz.*, the kinetic effects (primary and secondary) and the label distribution in the reaction products, provide information on the rate-determining step of the C–H bond cleavage and give evidence for the existence of intermediates. The maximum primary kinetic isotope effect K_H/K_D , which is associated with the concerted hydride transfer and was calculated for the C–H bonds, is ~ 7 . The usual secondary kinetic isotope effects characterising the change in hybridisation of the carbon atom ($sp^3 \rightarrow sp^2$) in the transition state are $K_H/K_D \sim 1$.^{26,43,44,54}

A detailed study of the hydride transfer mechanism was carried out for deuterium- (D) and tritium- (T) labelled *N*-benzyl-dihydronicotinamides and their quaternary salts.⁶⁷ The course of the reactions was monitored based on the changes in radioactivity of the starting reactants and final reaction products. The secondary tritium isotope effects for the hydrogen transfer were anomalous, whereas the primary deuterium isotope effect was identical to the expected value. The typical secondary tritium isotope effects corresponding to the hydride transfer should be equal to ~ 1.2 and ~ 0.83 upon the change in hybridisation from sp^3 to sp^2 and from sp^2 to sp^3 , respectively. Anomalies of the secondary effects of the isotope are attributed to the larger contribution of the inductive isotope effect to stability of the radical cation generated as a result of electron transfer. In this case, the equilibrium constant of the single-electron step increases, which is responsible for the appearance of an anomaly. Due to symmetry of the reactants and the reaction products, the free-energy profile should also be symmetrical. Hence, the only mechanism consistent with the symmetry of the reaction involves the successive electron–proton–electron transfer (EPE). For BNAH, this sequence can be represented as follows:

The presence of isotope effects in the hydride transfer does not provide an unambiguous answer to the question as to the form in which hydrogen is abstracted (proton, the hydrogen atom or the hydride ion) in the rate-determining step. Studies of the secondary isotope effects, in particular, the tritium isotope effects, can provide information on the changes in the transition state. However, Colter *et al.*⁶⁸ were doubtful about this expectation. The authors studied *N*-methylacridane (**3**), which gives rather stable radical species due to annulation of the pyridine ring to the benzene rings, as the NADH model. Oxidation of the latter affords the acridinium cation.

A is benzoquinone, tetracyanoquinodimethane, chloranil or tetracyanoethylene.

The authors⁶⁸ considered two reaction mechanisms: the one-step hydride transfer and the electron and hydrogen transfer. No explanation was provided for the anomalous isotope effects, and it was only hypothesised that tunnelling can occur. Large primary isotope effects and the fact that they are in agreement with the isotope label distribution in the products are most likely indicative of the stepwise rather than the concerted mechanism. It should be emphasised that the measured isotope effects should be interpreted with care considering the results of detailed investigation of the reaction mixtures, the possibility of side reactions and concerted and equilibrium processes. All these data can have a substantial effect on the conclusions. For example, in one of the most-cited studies, Steffens and Chipman⁶⁹ observed the abnormally high primary isotope effects in reactions of different dihydropyridines with trifluoroacetophenone. The label distribution in the products differs from that determined by the reaction kinetics. Based on this fact, the authors suggested the existence of radical ionic intermediates in the hydride transfer. However, more recently Chipman refuted the earlier conclusions by reporting⁷⁰ that the disagreement between the isotope effects is due to the reversible formation of covalent adduct **7**, which does not lie in the redox reaction coordinate.

Unusual condensation of the reaction products of *N*-(α,α -dichlorobenzyl)pyridinium chloride with the chloride ion or pyridines was documented.⁷¹ Presumably, the proton in 4-substituted 1,4-dihydropyridines is transferred from the geminal unit of the dihydropyridine ring to the benzyl dichloromethylene group which is accompanied by the replacement of the chlorine atom to form the corresponding pyridinium cations. Experiments with the use of deuteropyridine confirmed the fact that the redox process involves the transfer of hydrogen (or deuterium) as the cation rather than as the hydride ion or the hydrogen atom.

In the study of oxidation of 3-substituted 1-benzyl-1,4-dihydropyridines **1f** and **8a–c** by copper ions, ferricyanide or *N*-methylacridinium iodide, the influence of substituents at position 3 of the heterocyclic moiety on the reaction rate was estimated.⁷²

1f, 8a–c

X = C(O)NH₂ (**1f**), C(S)NH₂ (**8a**), CO₂Me (**8b**), Ac (**8c**).

The authors have reached an unexpected (in our opinion) conclusion that oxidation by organic cations is accompanied by the one-step hydride transfer, whereas the reactions with inorganic cations occur by the stepwise single-electron transfer mechanism.

The study of the kinetics and mechanism of oxidation of 10-methyl-9,10-dihydroacridine (**3**) by chromium(VI, V or IV) compounds demonstrated²⁵ that oxidation of AcrH₂ to AcrH⁺ by chromate ions in a water–acetonitrile mixture occurs by the single-electron transfer mechanism and is inhibited by oxygen. The first step involves the formation of the AcrH₂^{•+} radical cation followed by ionisation to the neutral radical and, finally, the electron transfer to form AcrH⁺ (Scheme 3).

Scheme 3

Dihydropyridine–electron acceptor systems, in which the H[−] transfer occurs in the presence of metal ions, were extensively studied. These systems are more complex but they are most similar to biochemical processes catalysed by pyridine-dependent dehydrogenases. It is known⁶⁶ that zinc ions accelerate the hydrogen transfer between the coenzyme and the substrate. Reduction of methyl benzoyl formate with an analogue of 1-benzyl-1,4-dihydronicotinamide in the presence of magnesium ions is accompanied by the anomalous kinetic and product isotope effects due to the ability of the metal ion to stabilise the transition state in which the electron is transferred from the dihydro compound to the acceptor.⁷³ The magnesium ion can either enhance the ability of dihydropyridines to donate an electron to α -keto esters, trifluoroacetophenone, diketones and other electron acceptors^{74,75} or decrease this ability, as was exemplified by the reaction of BNAH with thiopivalophenone.⁷³

An attempt was made to explain the role of the metal ion in the electron transfer.⁷⁶ It was assumed that magnesium in the intermediate complex is coordinated by the dihydropyridine molecule and the acceptor (the parallel planes indicate the spatial orientations of the reagents).

As a result of this coordination, the positive charge is accumulated on the C(4) atom of the pyridine ring [the downfield shift of the signal for the H(4) proton in the ^1H NMR spectrum], which is favourable for the proton rather than hydride abstraction. This assumption was confirmed in the study,⁵⁴ where the authors observed that the single-electron oxidation potentials of dihydropyridines are changed in the presence of Mg^{2+} ions on the average by 0.2 V, whereas the oxidation potential of *N*-methylacridane in the presence of Mg^{2+} remains unchanged because acridane does not form complexes with metal.

A number of studies were concerned with oxidation of dihydroacridines by metal ions or their complexes. High reactivity of phenoxide radical complexes of alkali metals (Na and K) was documented.⁷⁷ The primary kinetic isotope effects provide evidence for the electron and proton transfer mechanism. The cobalt complex of tetraphenylporphyrin and decamethylferrocene catalyse the electron transfer from acridane to *p*-benzoquinones.⁷⁸ It was demonstrated⁷⁹ that the hydride transfer from 10-methyl-9,10-dihydroacridine (**3**) to 3,6-diphenyl-1,2,4,5-tetrazine (Ph_2Tz) occurs only in the presence of scandium(III) ions, which promote the electron transfer due to the formation of the Ph_2Tz –metal complex.

The mechanism of stepwise oxidation accompanied by the hydrogen abstraction or elimination of the substituent in 9-alkyl-10-methyl-9,10-dihydroacridines catalysed by monomeric or dimeric cobalt complexes in the presence of perchloric acid was suggested in the publication.⁸⁰ Acceleration of single-electron oxidation of acridane and 1-benzyl-1,4-dihydronicotinamide (**1f**) in the presence of ruthenium(IV) complexes was documented.⁶¹

Due to the observed differences in the influence of metal ions on the rate of the hydrogen or hydride transfer and the uncertainty of the nature of the bond between the metal and the hydride donor (with both the starting compound and the transition state), no reliable conclusions can be drawn regarding the mechanism of these complex reactions. Apparently, the systems under study should be simplified by separately elucidating the nature of interactions of the metal cation with dihydro compounds, hydride acceptors and radical ionic intermediates and estimating the possibilities of stabilisation of these species, removal from the solvation cage, *etc.*

2. Electrochemical simulation

Nicotinamide cofactors are involved in the electron and proton transport, due to which studies of the redox properties of these compounds with the use various model compounds have attracted attention of chemists and biologists.^{21, 22, 24, 27} Measurements of the oxidation potentials of NADH at different electrodes, the determination of the conditions of its electrochemical regeneration, biocatalysis and electrocatalytic oxidation of NADH were described in the studies.^{81–86} It is commonly accepted²³ that due

to the specific features of electrode reactions in solution and the specificity of the electric layer at the electrode–solution interface, the hydride transfer involving dihydropyridines under electrochemical conditions is a very approximate model of real electrochemical reactions in organisms. However, the electrochemical method enables not only the measurements of individual electrochemical characteristics of substances but also the detection of short-lived particles, the electroorganic synthesis, mediated catalysis and transformations of NADH, NAD and their models. In the last decade, the number of publications (see, for example, Refs 85–89) in the field of bioelectrochemistry concerned with regeneration of nicotinamide derivatives, the construction and immobilisation of new electrode systems and the design of electrochemical enzyme reactors has steadily increased, providing evidence that this direction of investigation holds promise.

The electrochemical behaviour of the oxidised and reduced forms of the nicotinamide cofactor was investigated.⁸⁴ Mediated electrocatalysis and electrode modifications were found^{88, 89} to substantially decrease the overvoltage, facilitate oxidation of NADH and enable an increase in the yield of NAD. Organic compounds, which are involved in redox two-electron transfer reactions and simultaneously act as proton donors/acceptors (for example, *ortho*- and *para*-substituted quinones, phenylenediamines, aminophenols), readily oxidise NADPH. NADH-Dependent enzymes existing in contact with an electrode provide high efficiency of bioelectrocatalytic oxidation of NADPH, which was observed, for example, in experiments with the use of diaphorase combined with various quinones, flavins or viologens. The structure–activity relationships of artificial analogues of NADP^+ and the possibility of their immobilisation were investigated.⁹⁰ The possibility of their use instead of natural NADP^+ was examined.⁹¹

The influence of the structure of dihydropyridines (Hantzsch esters) on their reactivity was studied.⁹² The authors mentioned the drawbacks of electrochemical simulation of oxidation of dihydropyridines, which ignores the influence of the nature and structure of the oxidant partner and of the solvent. Based on a comparison of the enzymatic and electrochemical oxidation of dihydropyridines, it is impossible to make an unambiguous choice between the fundamentally different mechanisms of this process involving the hydride and hydrogen transfer.⁹³ It appeared that 3,5-bifunctional 1,4-dihydropyridine derivatives are irreversibly oxidised at a rotating platinum electrode to the corresponding pyridines with consumption of two electrons and two protons, where the proton abstraction is not the rate-determining step.⁹⁴ However, the authors of the publication⁹⁵ observed the potential-determining influence of the deprotonation step of the radical cation generated after the electron transfer from the dihydropyridine molecule.

Many studies were concerned with electrochemical oxidation of 9-substituted 9,10-dihydroacridines **9** combined with chemical and spectroscopic methods. Oxidation of these compounds by a divalent copper salt revealed⁹⁶ that 2 mol of Cu^{2+} are consumed per mole of acridane. It was also found that electrochemical oxidation of acridanes, like other dihydroazines,^{97, 98} occurs by the EPE mechanism analogous to that presented in Scheme 3.

R = Me, Ph, NPhMe.

The results of the study⁹⁶ were confirmed by more recent investigations^{99–101} of oxidation of various 9,10-dihydroacridines. The data from cyclic voltammetry, controlled potential electrolysis and chemical syntheses demonstrated that 9,9-disubstituted 9,10-dihydroacridines **10** are oxidised to radical mono-

cations (reversible single-electron transfer), and, after the proton abstraction, the resulting radicals undergo dimerisation to readily oxidisable 2,2'-bi(acridane) systems.¹⁰⁰

R¹ = Me; R² = H, Me; R¹ = H, R² = Ph.

By contrast, oxidation of 9*H*-acridanes **9** occurs by the EPE mechanism to give the acridinium cation, a peak assigned to reduction of protons being observed in the cyclic voltammogram, which is an additional argument for the proposed oxidation scheme.

A series of 9-alkylacridanes **9** (AcrHR) were studied by cyclic voltammetry.¹⁰² The reversible formation of radical cations and radicals in the case of oxidation of acridanes and reduction of conjugated cations, respectively, was observed by varying the potential scan rate. The EPE mechanism was confirmed for electrochemical and chemical oxidation (by a trivalent iron salt).

R = Alk.

This example demonstrates that deprotonation of the radical cation is the rate-determining step. A substituent in the geminal unit of acridane favours an increase in the oxidation potential compared to the unsubstituted compound (AcrH₂). This increase is insignificant in the case of alkyl electron-donating substituents and is more substantial in the case of electron-withdrawing substituents.

Earlier, the EPE oxidation mechanism has been observed for 1-benzyl-1,4-dihydronicotinamide derivatives containing different substituents in the benzene ring.⁵⁴ Electron-donating substituents at position 9 of the acridinium cation favour an increase in the negative potentials of single-electron reduction and the formation of neutral radicals in the reaction pathway of electrochemical oxidation of the corresponding acridane.²⁶ Electron-withdrawing substituents in the C(sp³)-H fragment of dihydro compounds substantially decrease their tendency to undergo hydride abstraction and increase the electron affinity of the conjugated azinium cations.¹⁰³ For example, the introduction of the cyano group at position 9 of acridane leads to oxidation of the dihydro compound not only by the EPE mechanism but also by the EEP mechanism. Moreover, under certain conditions, hydrogen can be abstracted from dihydro derivatives as a proton.^{104, 105} For example, oxidation of 9-cyanoacridane **11** in the presence of sodium nitrite used

as a base is accompanied by the proton abstraction followed by the two-electron transfer (the PEE mechanism).¹⁰⁶

Electrochemical oxidation of unsubstituted *N*-methylacridane (**3**) to the *N*-methylacridinium cation in the presence of pyridinium bases also occurs by the single-electron transfer mechanism (EPE).¹⁰¹ The deprotonation rate constants of the AcrH₂^{•+} radical cation were determined depending on the strength of the base with the use of spectrophotometric and electrochemical methods, and the constants p*K*_a were calculated.

Therefore, electrochemical simulation of oxidation of dihydroazines enables the detection of short-lived intermediates in the hydride transfer, *viz.*, radical ions and radicals. The existence of these types of intermediates was confirmed by different physicochemical methods.

3. Detection of radical products

The radical forms of nicotinamide cofactors (NAD[•]) can be involved in enzyme-catalysed oxidation and reduction reactions. The pyridyl radicals are generated by the addition of one electron to the pyridinium ion or the hydrogen abstraction from dihydropyridine, for example, under irradiation. These radicals are generated also from pyridinium charge-transfer complexes in photochemical reactions, dihydropyridines being able to act as electron donors in charge-transfer complexes. The pyridyl radicals can undergo dimerisation to form unusual π complexes (π -mers).

Single-electron processes in hydride transfer reactions can be directly observed by ESR spectroscopy, which, like electrochemical methods, enables the detection of intermediate radical and radical ionic species.

The generation of radicals in chemical oxidation of different dihydro adducts of the pyridine series was confirmed by the formation of dimeric products^{107–109} and with the use of radical traps [diphenylpicrylhydrazyl, 2,4,6-tri(*tert*-butyl)phenol, nitroxides, *etc.*].^{21, 110} Direct reduction of stable radicals and radical cations by 1,4-dihydropyridines made it possible to observe radical derivatives of pyridines by ESR spectroscopy.⁴⁸ The free radical products were detected by UV irradiation of a ternary mixture consisting of bromobenzene, aromatic imine and 1-benzyl-1,4-dihydronicotinamide in acetonitrile.¹¹¹ Radicals and radical cations were found also in the study of photoinduced oxidation of 1,4- and 1,2-dihydropyrimidines with quinones.¹¹²

The direct detection of pyridyl radicals presents difficulties because of their high reactivity toward oxidising agents. Nevertheless, it has been possible to detect radicals generated in oxidation of BNAH with quinones and acids with the use of the ESR method by varying the reaction conditions and the structures of dihydro adducts and using special techniques for observing fast processes.^{113–116} The thiobenzophenone radical anion was detected by freezing a solution of dihydropyridine and thiobenzophenone in THF, the radical anion being then transformed into the free radical and anion, whereas dihydropyridine is oxidised to the pyridinium cation through the successive electron-proton-electron transfer.¹¹⁷

Radicals generated in reduction of the 4-acetyl-1-benzyl-*N,N*-diisopropylnicotinamide (ABNA) and 1-benzyl-4-phenylnicotinamide (PhBNA) cations in the presence of trivalent scandium cations, which form complexes with the corresponding pyridines, were detected by ESR spectroscopy.¹¹⁸

Benzannulation of the pyridine ring and the introduction of an electron-withdrawing substituent into the geminal unit stabilise the radical intermediates generated in oxidation of dihydro compounds. The generation of the stable 9-cyanoacridinyl radical in oxidation of acridane **11** by atmospheric oxygen in the presence of cyanide ions and potassium *tert*-butoxide used as bases was documented.¹⁰⁴ The acridine radical stable for several hours was prepared by oxidation of 9-cyano-10-methyl-9,10-dihydroacridine (**11**) in the presence of nitrite ions under an inert atmosphere in an electrochemical cell, which was placed in a resonator of an ESR spectrometer.¹⁰⁶ This radical can undergo reversible dimerisation in the temperature range from -30 to 20 °C.¹¹⁹

Chemical oxidation of acridane **11** in DMF by *p*-benzoquinone and atmospheric oxygen in the presence of lithium nitrite also enabled the detection of the cyanoacrydinyl radical by ESR. Such spectra were recorded in the case of reduction of the *N*-methylacridinium cation with the cyanide ion and of the 9-cyano-*N*-methylacridinium cation with sodium borohydride,¹²⁰ which confirms the possibility of the single-electron transfer from these compounds.^{121, 122}

The radical ionic and radical products generated in the photo-initiated reaction of 10-methyl-9-phenyl-9,10-dihydroacridine with *p*-xylene were directly detected by Ohkubo and Fukuzumi.¹²³

Photoinduced alkylation of the acridinium cation with 1-benzyl-4-*tert*-butyl-1,4-dihydronicotinamide was investigated.¹²⁴ Not only the detection of radical species, but also elimination of the *tert*-butyl radical from the radical cationic analogue of NADH due to the influence of the steric factors on the properties of dihydro compounds and intermediates of their oxidation are of interest.

R = Me, *n*-C₁₀H₂₁.

In more recent studies (see, for example, Ref. 125), the acridinium cation was used as a catalyst for photoinduced selective oxidation of aromatic compounds, which occurs through the formation of radical products.

The radical cations of 9-substituted *N*-methylacridanes **9** were observed with the use of the stopped-flow rapid-mixing ESR technique.¹⁰²

Direct evidence for the formation of the 1-benzyl-1,4-dihydronicotinamide radical cation in oxidation of this compound with the iron(III) and rubidium(III) bipyridyl complexes was obtained.^{53, 126, 127}

The results of measurements of the deprotonation rate of the 1-benzyl-1,4-dihydropyridine radical cation and the observed kinetic isotope effect are indicative of the single-electron transfer mechanism.

The predominant reaction pathway through the formation of radical intermediates was described for photocatalytic oxidation of Hantzsch esters in the presence of the platinum terpyridyl complex.¹²⁸

Useful information on the mechanism of processes involving radicals can be obtained by ESR spectroscopy combined with other instrumental methods for monitoring chemical reactions. However, in spite of numerous facts of the detection of radical ionic species in oxidation of dihydroazines and published results of investigation of the properties of pyridinyl radicals, it is still doubtful that ESR spectroscopy provides an unambiguous answer to the question whether the observed radical species lie on the reaction coordinate.

4. Mass spectrometric fragmentation

Ionisation of substrates can be studied by electron-impact mass spectrometry and correlated with the mechanisms of chemical reactions of various nature. In addition, mass spectrometry provides information on the relationship between the molecular structure and the reactivity.^{129, 130}

Stability of tetrahydropyrazines with annulated five- and six-membered heterocycles was studied by mass spectrometry.¹³¹ Criteria were proposed for the mass-spectrometric estimation of stability. The validity of estimates of stability of annulated tetrahydropyrazines based on the proposed mass-spectrometric criterion (the ratio of the peaks of the molecular ion or the radical cation and the 1,4-diazinium ion) was confirmed by chemical experiments. Stability of tetrahydropyrazines was demonstrated to depend on the nature and orientation of the heterocycle as well as on the nature and size of the substituent.

In the study,¹³² the results of measurements of stability to electron impact and the tendency of dihydroazines to undergo aromatisation were correlated for the first time with the experimental data on chemical oxidation of these compounds. Aromatisation of these compounds is characterised by the formation of conjugated cations from dihydroazines due to elimination of both the substituent and hydride-labile hydrogen.

The intensity ratio of the peaks of radical cations generated upon electron impact to the peaks corresponding to the hydrogen abstraction or elimination of a substituent from molecular ions was used as the mass-spectrometric criterion for the pathways of aromatisation of dihydroazines. It should be noted that the single-electron redox mechanism implies the formation of a radical cation identical to the molecular ion (M^+) generated upon electron impact. This indicates that aromatisation of dihydro compounds under electron impact correspond to chemical transformations under the action of dehydrogenating agents. However, it should be remembered that chemical oxidation in solution can differ substantially from the process in the gas phase.

In studies of aromatisation of dihydropyridine derivatives containing electron-donating or electron-withdrawing substituents in the geminal unit (Table 1), a rather good correlation between the products of chemical oxidation and the results of mass-spectrometric experiments was obtained. This can be attributed (with a certain degree of approximation) to the formation of a radical cation as the primary intermediate of the chemical oxidation reaction.^{24–27, 102–104}

Table 1. Data from mass-spectrometric fragmentation of dihydroazines.¹³²

Compound	Characteristic peaks, m/z (intensity, %)			Fragment elimination of which is the most probable in aromatisation
	M^+	$[\text{M}-\text{H}]^+$	$[\text{M}-\text{R}]^+$	
11	220 (49)	219 (77)	194 (31)	$-\text{H}^+$
13	163 (39)	162 (26)	137 (100)	$-\text{CN}^+$
14	170 (41)	169 (69)	144 (36)	$-\text{H}^+$
15	170 (99)	169 (99)	144 (100)	$-\text{H}^+$, $-\text{CN}^+$
16	220 (36)	219 (34)	194 (100)	$-\text{CN}^+$
17	293 (39)	292 (4)	194 (100)	$\text{CH}(\text{COMe})_2^+$
18	278 (12)	—	194 (100)	$-\text{C}_5\text{H}_8\text{N}^+$
19a	209 (43)	208 (6)	194 (100)	$-\text{CH}_3^+$
19b	223 (7)	—	194 (100)	$-\text{C}_2\text{H}_5^+$
19c	271 (100)	270 (39)	194 (14)	$-\text{H}^+$

Since the reactions occur in the gas phase at high temperature and radical cations are generated under drastic conditions, the mass spectra give only an approximate model of chemical experiments. Nevertheless, the results of studies demonstrated that mass spectrometry can provide useful information for estimating the influence of the electronic effects of substituents, the steric factors and hetero- and benzannulation on stability of NADH models and the possible pathways of aromatisation.

5. Modelling of biochemical reactions

In recent years, investigations of the hydride transfer mechanism with the use of various models approximating chemical systems to biochemical systems have increased in number. These studies were concerned primarily with catalysis of redox reactions by metal ions and complexes, photoinitiation of processes and the use of mediators and intermediates.^{30–32, 133, 134} Quantum-chemical methods are widely used for calculations of the energies of the hydride transfer processes involving enzymes.^{40, 135–137}

Japanese chemists¹³⁸ studied oxidation of NADH by a system that models the respiratory chain and demonstrated that the ATP synthesis is accompanied by electron transfer. The fact of electron transfer from NADH to the flavin analogue and then to a hemin complex and oxygen was established by spectroscopic studies. Analogous model reactions were performed.^{84, 139, 140}

A study of the structure–activity relationships for artificial analogues of NADP⁺ and examination of the possibility of immobilising these derivatives⁹⁰ revealed the conditions for the use of these compounds instead of natural compounds.⁹¹ The influence of DNA on oxidation of BNAH by photoinduced oxygen¹⁴¹ and acridinium cations and on reduction of the quinolinium cation by a ruthenium bipyridyl complex was investigated.¹⁴² The photoinduced electron transfer from the donor [Ru(bipy)₃²⁺] to the quinolinium cation (QuH⁺) is efficiently accelerated by DNA, as is evidenced by the shift of the single-electron reduction potential of the QuH⁺ cation to positive values due to intercalation of QuH⁺ with DNA molecules. The QuH[•] radical generated upon the electron transfer can be stabilised through π – π intercalation with two bases of the DNA chain. The electronic spectrum of this system was recorded by laser flash photolysis (in the absence of DNA, absorption was not observed). The opposite situation is observed when DNA is involved in the hydride transfer from BNAH to the AcrH⁺ cation. In the presence of DNA, oxidation of dihydro compounds is inhibited, which is attributed to the intercalation of the bulky AcrH⁺ ion with bases from the DNA chain.¹⁴³

The isotope effects and their dependence on the temperature for proton transfer reactions involving transhydrogenases were described.¹⁴⁴ Various compact chemical coenzyme reactors were designed based on nicotinamide compounds.^{145, 146} An enzyme reactor for enantioselective reduction of pyruvate to L-lactate in high yield can be mentioned as an example.¹⁴⁷

Arguments in favour of the EPE mechanism of reduction of lipophilic quinones with NADH models were presented by Zlatovic *et al.*¹⁴⁸ The dynamics of the photoinduced electron transfer during oxidation of 1-benzyl-1,4-dihydropyridine by the DNA-intercalated acridinium, quinolinium and phenanthridinium cations in the presence of a ruthenium bipyridyl complex was investigated.¹⁴⁹ The shift of the reduction potentials of cations intercalated into DNA to more positive values and acceleration of the reaction in the presence of metal complexes additionally support the stepwise hydride transfer mechanism. However, the possibility of the single-electron mechanism of reduction of flavins by NADH was not denied.¹⁵⁰ In the study cited, the formation of a charge-transfer complex was detected by stopped-flow electron spectroscopy.

Presumably,¹⁵¹ insignificant kinetic isotope effects observed in the case of reduction of D-xylose by dihydronicotinamide attest to the one-step hydride transfer mechanism. However, thermodynamic analysis of reduction of quinones by NADPH¹⁵² provided evidence for the stepwise EPE mechanism of hydride-labile hydrogen abstraction.

Photobacterial catalysis of the single-electron transfer from NADPH to ferredoxin or flavodoxin was examined.¹⁵³ Kinetic studies by the stopped-flow technique confirmed the stepwise mechanism of reduction of flavodoxin by enzymes. The equilibrium in the NADPH–flavin system was described in the study,¹⁵⁴ where intermediates of the hydride transfer were observed by spectroscopic and electrochemical methods.

The stereoselectivity of reduction of NO-containing cytochromes by dihydropyridines can be considered as evidence for the direct hydride transfer.¹⁵⁵ However, intermediates of hydride transfer were detected in the analogous NADH–cytochrome system,¹⁵⁶ and the oxidation rate was demonstrated to depend on the substituents.

Based on the characteristic features of the reactions involving dihydropyridines in model or real biological systems and understanding of the mechanism of hydride transfer reactions and ways of controlling these reactions, many of the known compounds were recommended as biomimetics and bioprotectors, inhibitors of bacterial processes, neuroprotectors and neuromodulators, radioprotectors, antidiabetic and anti-dermatitis drugs, *etc.* (Refs 157–163).

Therefore, a combination of chemical, electrochemical and enzyme models holds promise for investigation of the hydride transfer reactions.

III. Three-dimensional structures of dihydropyridines and stereospecificity of hydride transfer

In studies of processes that model NADH–NAD transformations, it is necessary to take into account that the dihydropyridine–pyridinium cation system undergoes a substantial rearrangement because hybridisation of the geminal carbon atom changes from sp³ to sp². In this case, not only the aromaticity, chemical, magnetic, electrochemical, physical and energy characteristics of the molecule but also its spatial structure are changed. It is known that biological activity of compounds is related to their structures. Enzymes, for which a dihydronicotinamide derivative is a cofactor, are sensitive to the stereoconfiguration of the substrates involved in the interaction, *i.e.*, the spatial structure of the latter is responsible for stereospecificity of biochemical processes.^{29–31}

The development of X-ray spectroscopy enabled the direct examination of the structures of dihydropyridines and estimation of the influence of various substituents on the conformation of NADH analogues.

The presence of sp^3 -hybridised carbon atoms in dihydropyridines leads to a distortion of the planarity characteristic of aromatic pyridinium salts. X-Ray diffraction data for 3,5-di(methoxycarbonyl)-1-methyl-4-phenyl-1,4-dihydropyridine demonstrated that the strain causes bending of the plane of the pyridine ring along the N–C(4) axis (Fig. 1)¹⁶⁴ and a certain degree of shielding of hydride-labile hydrogen in the geminal unit.^{165, 166}

Figure 1. Three-dimensional structure of 3,5-di(methoxycarbonyl)-1-methyl-4-phenyl-1,4-dihydropyridine.¹⁶⁴

Shielding of the geminal hydrogen atom by bulky substituents decreases the ‘hydride activity’ of dihydro derivatives, with the result that steric hindrances prevail over the electronic effects.¹⁶⁷ It would be interesting to estimate the $C(sp^3)–H$ bond length and energy in the geminal unit in a series of related compounds. It is the steric factors that are apparently responsible for elimination of substituents, which is sometimes observed in the case of oxidation of dihydropyridines.^{54, 102, 132}

For 9-substituted 10-methyl-9,10-dihydroacridines, the pyridine ring is also strongly puckered along the N–C(9) axis, which is characterised by the average dihedral angle of 150° .^{168–171} The ease of dissociation of recombination products of acridinyl radicals is attributed to the strained structures of heterocyclic systems,¹⁷² which was exemplified by acridine dimer **20** (Fig. 2).^{119, 169}

The spatial structures of dihydroacridine radical cations generated in oxidation of 9,10-dihydroacridines by an iron(III) salt were discussed.¹⁰² Radical cations of 9-substituted *N*-methylacridanes **9** were detected with the use of the stopped-flow rapid-mixing ESR technique. The hyperfine splitting constants were calculated by comparing the observed ESR spectra with the results of computer simulation using molecular orbital calculations. The calculations demonstrated that the acridane system adopts a boat conformation with the substituent R in an axial position and the hydrogen atom at C(9) in an equatorial position. It was hypoth-

Figure 2. Three-dimensional structure of *N*-methylacridine dimer **20**.

esised that the steric demands are responsible for the reactivity of the radical cations.

In our opinion, the calculations demonstrating the nonequivalence of the axial and equatorial hydrogen atoms in unsubstituted dihydroacridine are of considerable interest. It is quite probable that the steric effects are not the only factors responsible for differentiation of the geminal hydrogen atoms. Thermodynamic instability of systems that lost aromaticity is also increased by the charge effects, which act together with the structural factors. Presumably, this facilitates stereospecificity of reduction of various substrates by unsubstituted dihydropyridines, which exist in the activated transition state initiated by the single-electron transfer. After the proton abstraction, the sterically hindered active pyridinium radical cation is transformed into the neutral radical structurally similar to the cation, and the secondary electron transfer gives rise to the thermodynamically more favourable planar molecule of the aromatic pyridinium cation or its analogue.¹⁷³

The characteristic feature of the processes in organisms is that only particular stereoisomers are involved in the reactions, resulting in the formation of stereochemically pure products.^{30, 174} The stereospecificity is responsible for the fact that only one of enantiomers exhibits biological properties and this lies at the basis of the active principle of many pharmaceuticals. In enzymatic processes in living organisms, the protein chain acts as the chiral recognising fragment. Reduction processes involving NADH are stereoselective. The formation of one of stereoisomers is associated with the fact that enzymes (dehydrogenases) distinguish the enantiotopic hydrogen atoms at the C(4) atom in the 1,4-dihydropyridine ring. The stereospecificity of the transfer of hydride-labile hydrogen was experimentally proved by studying oxidation of deuterium-labelled ethanol. Actually, after oxidation of (*R*)-1-D-ethanol, deuterium was found in the reduced form of NADD at the C(4) atom having the *R* configuration, whereas deuterium completely goes to acetaldehyde in the case of oxidation of (*S*)-1-D-ethanol.³⁰

To model natural processes, chiral substituents are deliberately introduced into synthetic dihydropyridines. In the case of formation of reactive chiral complexes, the mutual arrangement of the reactants is determined only by the structural factors. The resulting energy difference of diastereomeric transition states provides an enantiomeric excess of one of the adducts. In recent years, the regiospecific NAD–NADH conversion has been extensively studied because NADH is a necessary component of various bioorganic processes accompanied by the formation of chiral organic compounds.

As an example, let us mention stereoselective reduction of ketones, which was performed by Ohno and co-workers¹⁷⁵ with the use of specially prepared model compounds **21**. The process is characterised by high enantioselectivity.

X = H, Me, OMe, Cl, Br.

The chiral recognition is provided by steric interactions along with the electronic effects of the substituents. The stereoselectivity of oxidation of NADH by *p*-quinone derivatives controlled by the electronic effect of the carbonyl group was documented.⁶³ The structural effects of the substituents at position 4 are responsible also for the reactivity of 1,4-dihydropyridines in reactions with stable radicals.⁵⁰

Quantum-chemical calculations of the potential energy surface for isomers of 2-methyl-4(*R* or *S*)-methyl-1,4-dihydropyridines in the gas phase and in solution were performed by the extended Hartree–Fock method with the 6-311 basis set.¹⁷⁶ The stereoselectivity of reduction with NADH analogues was demonstrated to be controlled by the steric and electronic properties of substituents at position 4 as well as by the solvent polarity.

Enantioselective reactions often proceed through the formation of active prochiral radical species. Numerous examples of such reactions were cited in the review.¹⁷⁷ This is indicative of the single-electron nature of reduction processes based on dihydropyridine derivatives.

Chiral NADH models providing stereoselectivity of the hydride transfer were designed based on benzo[*b*]-1,6-naphthyrindines.¹⁷⁸ A system consisting of dihydronicotinamide and a zinc complex was used for reduction of flavin.¹⁷⁹

X is a chiral linking group.

The involvement of bipyridyl complexes of ruthenium and other metals in regioselective reduction of substrates by NADH models was documented.^{180, 181}

Data on stereospecificity of the hydride transfer in NAD-dependent synthases in the antibiotic synthesis were published in the literature.¹⁸² The conformational exchange of the carbothioamide group in the hydride transfer between transhydrogenase and the thionicotinamide analogue of NADH was documented.¹⁸³ The factors influencing the stereoselectivity of the hydride transfer between the NADH model and the NO-bound cytochrome P450,¹⁵⁵ keto esters¹⁸⁴ and dehydrogenases were reported.¹⁸⁵

A series of studies on the synthesis and the use of chiral NADH models were performed by French researchers. Detailed NMR studies of asymmetric reduction of methyl benzoylformate by dihydropyridines **22**–**24** were carried out.¹⁸⁶

New chiral NADH models were designed based on hydrogenated quinoline.^{187–189} It appeared that electron-donating groups in the benzene ring of quinoline enhance its ability to eliminate the hydride ion, thus providing a high degree of reduction of methyl benzoylformate with quinoline in the presence of magnesium ions. The enantioselectivity of reduction is determined by the concentration of metal ions. The best results (*ee* 45%) were obtained for dihydroquinoline **25**.¹⁸⁷

Models favourable for an increase in the stereoselectivity of the hydride transfer were synthesised based on benzo[*b*]-1,6-naphthyrindine **26**, its analogue **27**¹⁷⁸ and pyridinium salts **28**.¹⁹⁰

R = Me, Buⁿ, Ph; (a) (1) R₂CuLi, (2) (Cl₃CCO)₂O, (3) MeONa.

The optically active model NAD compound based on quinoline was reduced by chiral dihydropyridine¹⁹¹ to form a mixture of the corresponding 1,2- and 1,4-dihydroquinolines. The orientation of the carbonyl group in quinoline is responsible for regio- and enantioselectivity of the reaction products. Thus, the *S* isomer forms predominantly the chiral 1,4-adduct with *ee* 96%.

Regioselective reduction of 1-benzylnicotinamide triflate in the presence of a ruthenium bipyridyl complex was documented.¹⁹² Many bridged NADH analogues¹⁴⁷ and 1-benzyl-3-(*p*-toluenesulfonyl)-1,4-dihydropyridine derivatives¹⁹³ have high enantioselective reducing ability.

Due to ability of NADH and their synthetic models to be involved in enantioselective reactions along with their tendency to perform the single-electron transfer, dihydropyridines and their analogues are unique compounds, because the optical activity is not generally retained upon the formation of radicals.

IV. Molecular devices based on dihydropyridines

Supramolecular chemistry deals with structures containing non-bonded interactions, such as hydrogen bonds, electrostatic effects, hydrophobic forces, *etc.* These interactions are responsible for fast and reversible changes of biological molecular structures, such as nucleic acids, proteins and enzymes.¹⁹⁴ In the design of supramolecular devices, studies of hydride transfer processes in chemical models of NADH, investigation of the fine mechanism of these reactions and elucidation of the structure–property relationship are of considerable interest.

For example, it was found that macrocycles containing the 1,4-dihydropyridine fragments substantially accelerate the hydrogen transfer. In the studies,^{195, 196} crown ether of dihydropyridine **29** was used as the hydride ion donor. The rate of the reaction of ether **29** with acceptors is 2700 times higher than that of the reactions of classical Hantzsch esters or 1-methyl-1,4-dihydropyridine.

Efficient reduction of the pyridinium fragments within supramolecular compounds of type **30** through the hydrogen transfer from dihydropyridines in the peripheral positions was documented.¹⁹⁷

X = C(O)NHBuⁿ.

Such first-order intracomplex reactions are inhibited by cations capable of complex formation.¹⁹⁴ As mentioned above, the influence of metal ions or complexes on the hydrogen transfer is a characteristic feature of oxidation of dihydropyridines.

It was suggested to use 4-(*m*-nitrophenyl)dihydropyridine **31** for the design of new photoinduced intramolecular electron-transfer systems.¹⁹⁸

R = Alk.

Molecular magnetism is, in essence, a supramolecular phenomenon, because it is associated with the collective properties of the system components that contain unpaired electrons, and depends on the relative arrangement of these compounds in organised ensembles and crystal structures. A search for high-spin components of the organic (free radicals, carbenes or charge-transfer salts), organometallic (metal complexes) or inorganic (coordination metal centres) nature is presently an important problem.^{199–202} This is why the radical ionic salts based on dihydropyridine derivatives have attracted interest. The synthesis and the mechanism of formation of radical anionic salts in the reactions of unsubstituted acridane, *N*-methylacridane or 1-propyl-1,4-dihydropyridine with π -electron acceptors (tetracyanoquinodimethane, dicyanodichloro-*p*-benzoquinone, tetra-cyanoethylene, *etc.*) were described.²⁰³

We synthesised analogous compounds by oxidation of 9-cyano-10-methyl-9,10-dihydroacridine (**11**) to the corresponding radical anionic and dianionic salts with the cyanoacridinium cation. These salts have a very narrow electrochemical gap, *i.e.*, a small difference between the reversible oxidation and reduction potentials. These systems hold promise for the design of molecular switches, conductors, semiconductors, visible light converters into the electric energy (solar elements) and, on the contrary, nonlinear optical materials, *etc.*

Hydrogen bonding, π - π -stacking interactions or Coulombic interactions can be employed for recognition of amino acids, nucleotides and heterocycles through complementary binding. It was mentioned¹⁴² that such interactions have an effect on the electron and hydride transfer involving DNA in redox reactions of DNA intercalates with NAD and NADH models.

Coulombic interactions and structural factors can be efficiently used for the recognition of systems containing the charged pyridine rings. Supramolecular charge-transfer complexes formed by cyclobis(paraquat-*p*-phenylene) as a model of a molecular receptor and different neuromediators (for example, by dopamine in compound **32**) were studied.²⁰⁴ Analogous structures were described in the publications.^{205–207}

N-Methylacridinium derivatives, which are acceptors of anionic and neutral nucleophiles, can be involved in macrocyclic bis-intercalates (for example, compound **33**) capable of interacting with nucleosides, nucleotides and planar anionic substrates.^{208, 209}

Along with homogeneous processes of molecular recognition in solution, heterogeneous recognition on the surface or in the bulk of organised ordered phases and solid materials is also known. Examples of these reactions are the formation of solid inclusion compounds, *viz.*, clathrates, with the use of zeolites or other natural sorbents, as well as intercalation in the formation of hollow clays and the design of hybrid organic–inorganic structures by sol–gel methods.¹⁹⁴ A polysiloxane-immobilised NADH model compound was prepared.²¹⁰ This compound provides easy reduction of olefins as well as isolation of the reaction products and recycling of the reducing agent. This environmentally safe process for olefin reduction by immobilised dihydropyridine in a two-phase system is an example of green chemistry (Scheme 4). Catalytic transformations of natural compounds under mild conditions, which are accompanied by the conversion of the reagents, are among such processes.²¹¹

Scheme 4

Redox processes involved in NAD–NADH transformations can be performed in molecular devices which convert molecular recognition events into electronic signals. Quinones and the 1,1'-dimethyl-4,4'-bipyridinium dication were examined as such compounds.²⁰⁷

Pyridinium cations **34** linked by a long chain of conjugated C=C bonds are fragments of so-called molecular wires.¹⁹⁴ In such oligomers, pyridinium cations are used as electron acceptors capable of forming stable radicals.

The design of supramolecular ensembles based on the 10-carboxymethyl-9-mesitylacridinium ion and the fullerene cluster with titanium(IV) oxide or tin(IV) oxide for light energy conversion was documented.^{212, 213} Systems consisting of donor–acceptor metal complexes, dihydropyridine-based hydride donors and

acceptors and acridinium cations have been designed and found use as photocatalysts.²¹⁴

Macrocyclic NADH models containing two or four nicotinamide fragments were prepared.²¹⁵ In the presence of magnesium ion as a catalyst, these macrocyclic dihydropyridines selectively reduce ethyl benzoylformate. Macrocyclic NAD (compound **35**) and NADH models (compound **36**), which can form host–guest complexes were synthesised based on the pyridinium cation and dihydropyridine.^{216, 217}

The above data demonstrate that investigations of the hydrogen transfer mechanism $\text{NAD} \rightleftharpoons \text{NADH}$ with the use of model compounds provide a deeper insight into processes in living nature and give possibilities for designing different-purpose devices, receptors and new materials.

* * *

A review of studies on oxidation of dihydropyridines and their analogues leads to the conclusion that, in spite of a continuing discussion regarding the one-step or stepwise mechanism of hydride transfer, evidence in favour of the latter mechanism prevails in the modern literature. It should be noted that the successive electron–proton–electron transfer (EPE mechanism) was accepted by chemists as the most probable pathway of hydride transfer involving coenzymes.

The Nobel laureate Albert Szent-Györgyi stated that electrons drive life. In living systems, electrons move to higher energy levels due to sunlight absorption by the substance and then electrons portionwise release an excess energy. It should be emphasised that electrons perform this cycle one-by-one by being excited and passing through cytochromes, because the central metal atom in cytochrome can undergo only single-electron transformations.²¹⁸

In recent years, studies on the fine mechanism of the $\text{C}(\text{sp}^3)\text{--H}$ bond cleavage in dihydroazines have received new impetus due to the design of new pharmaceuticals and technical materials, enzyme reactors, bioelectrochemical systems and molecular devices (switches, antennas, sensors, etc.) based on these compounds and the use of partially hydrogenated heteroarenes as reagents for stereoselective reduction of various unsaturated systems.

Abstract. It is shown that catalytic carbonylation of various compounds using iron carbonyl complexes is based on two types of reactions [redox disproportionation of iron carbonyl induced by Lewis bases and oxidative addition of Brønsted and Lewis acids to (hydrido)carbonylferrate anions] comprising single-electron initiation steps and subsequent radical chain reactions. The role of iron carbonyl radical anions as catalysts for carbonylation processes with controlled reduction potential of the medium is noted. Characteristic features of the radical chemistry of iron and other transition metal carbonyls is analysed. The bibliography includes 262 references.

I. Introduction

The chemistry of transition element carbonyls has been developed for more than a century since the initial discovery in 1890 of complexes of transition metals with CO ligands, first, nickel tetracarbonyl¹ and then iron pentacarbonyl.^{2,3} The discovery of the Fischer–Tropsch process for hydrocarbon synthesis from synthesis gas (CO + H₂)^{4–7} and hydroformylation of organic compounds made a major impact on the development of this field of chemistry.⁸ Metal carbonyls are used as catalysts in all these processes. The development of homogeneous catalytic systems for the Reppe synthesis and the replacement of synthesis gas by water gas (CO + H₂O)⁹ may be regarded as the major achievements of these studies. As far as carbon monoxide is a key component of the CO + H₂ and CO + H₂O gas mixtures, the mechanism of catalysis by transition element-based catalysts should be governed by the chemistry of metal carbonyls. Owing to the structural and chemical similarities between a metal surface with adsorbed CO molecules and carbonyl metal complexes, the latter can be

regarded as simple models of catalytic processes, because studies of heterogeneous transformations are often extremely labour-consuming (see for example Refs 5–7, 10 and 11).

It is quite possible that in the nearest future the humankind will solve the energy problem by using renewable sources of energy instead of oil and gas; however there is no substitute for hydrocarbons in the industrial organic synthesis. The problem of alternative sources of raw materials for petrochemical industry will inevitably arise as the world oil supply gradually diminishes.^{5,6,12} Hydrocarbons and other organic products obtained from CO may be such an alternative. In spite of some successful examples of application of CO conversion processes, in most cases they cannot compete with the petrochemical ones for economic reasons. The main problem is lack of inexpensive and selective catalysts for operation under mild conditions. The search for such catalysts requires a detailed investigation of the reactions of various coordination compounds with CO. The iron carbonyl complexes are regarded as the most promising ones, as they are readily available, stable and highly catalytically active in a variety of transformations.

In the early 1930s, Hieber and co-workers started to study the properties of iron carbonyls, particularly their reactions with Lewis bases (cited from^{13,14}). They have shown that the two-electron redox disproportionation is the predominant pathway of these reactions. This process results in the formation of Fe²⁺ salts with carbonyl-ferrate dianions (CFA) and (or) with their protonated analogues, hydridocarbonyl-ferrate monoanions (HCFA).

$n = 1, m = 5; n = 2, m = 9; n = 3, m = 12; p = 1, q = 5; p = 2, q = 9; p = 3, q = 12; p = 4, q = 14; 2 \leq k \leq 6; \text{L}$ is a nucleophilic ligand (a neutral Lewis base).

Besides, these reactions may yield the products of substitution of nucleophilic ligands for the CO groups. Rearrangements of the metal core accompanied by the change in the number of metal

atoms in a cluster also may take place in these reactions. Numerous iron carbonyl complexes containing various functional groups have been obtained nowadays.^{15, 16}

Studies of the mechanisms of transformations of iron carbonyls are crucial for elucidation of their catalytic activity. The mechanisms are usually described by schemes that include 16-electron coordinatively unsaturated species. Thus, the following sequence of reactions was suggested for substitution processes:^{2, 5, 14–16}

$n = 1, m = 5; n = 2, m = 9; n = 3, m = 12$; L is a nucleophilic ligand.

The catalytic scheme of water–gas shift reaction (Scheme 1) suggested by Pettit and co-workers^{17, 18} is another example of transformations catalysed by iron carbonyl complexes. The same scheme with only minor variations was also used by the same authors for the description of the mechanism of Reppe synthesis. The most general and complete version of this scheme has been published by King *et al.*^{19, 20} The nucleophilic addition of a base to a carbonyl ligand takes place at the first stage of the catalytic cycle, which is followed by decarboxylation and the formation of hydridocarbonylferrate anion. The Scheme contains two redox reactions.

Scheme 1

The substitution of nucleophilic ligands for the CO groups during the activation of iron carbonyls by trimethylamine oxide proceeds in a similar way (Scheme 2).^{21–24}

Scheme 2

The three abovementioned schemes are unified by a common paradigm, which has been formed over more than a century, concerning the major role of 16-electron intermediate species in the transformations of metal carbonyls. The paradigm is formulated as the Tolman rule,²⁵ which states that the predominant pathway of these reactions consists of consecutive formation of 18-, 16- and 18-electron complexes ($18e \rightarrow 16e \rightarrow 18e$).

The formation of 16-electron coordinatively unsaturated species, for example $\text{Fe}(\text{CO})_4$, is postulated on the basis of their detection by IR spectroscopy in the gas phase^{26, 27} and in noble gas matrices at 4–20 K.^{28–31} However, only recently, was the existence of $\text{Fe}(\text{CO})_4$ in a solution registered by femtosecond IR spectroscopy during UV photolysis of iron pentacarbonyl. The lifetime of such species is 660 ps (6.6×10^{-10} s).^{32, 33} Obviously, special experimental conditions of flash photolysis and the so short lifetime of iron tetracarbonyl cast doubt upon its participation in the processes in the liquid phase.

II. Iron carbonyl radical anions

Alongside with neutral and charged iron carbonyl complexes containing an even number of electrons, iron derivatives with an odd number of electrons may also exist. We are talking about iron carbonyl radical anions (ICRA) $[\text{Fe}_n(\text{CO})_m]^{-\cdot}$ ($n = 1, m = 5$; $n = 3, m = 12$) and $[\text{Fe}_n(\text{CO})_{m-1}]^{-\cdot}$ ($n = 1, m = 5$; $n = 2, m = 9$; $n = 3, m = 12$; $n = 4, m = 14$), which may be generated by various methods.

Electrochemical single-electron reduction of iron carbonyls in various solvents leading to the formation of ICRA has been studied by polarography using dropping mercury electrodes^{34–39} and by cyclic voltammetry using platinum,^{37–41} gold^{42, 43} and glassy-carbon electrode.³⁹

Iron carbonyl radical anions were also obtained by chemical methods: either by reactions of iron carbonyls with strong reducing agents such as alkali metals or sodium benzophenone ketyl,^{44–46} or by oxidation of carbonylferrate anions by, for example, ferrocenium or silver salts.^{46, 47} Iron carbonyl radical anions are formed also during UV or ⁶⁰Co γ -irradiation of the corresponding iron carbonyls or CFA.^{43, 45, 48–52}

The formation of $[\text{Fe}(\text{CO})_4]^{-\cdot}$ in noble gas matrices at low temperatures has been observed in the same experiments in which the 16-electron $\text{Fe}(\text{CO})_4$ species have been registered.^{31, 53, 54} In order to suppress the formation of mono- and polynuclear iron carbonyl radical anions, a stabilising agent, namely, 0.02% of CCl_4 , has been added to the system (the mechanism of stabilisation is discussed in Section VII).³¹ The $[\text{Fe}(\text{CO})_4]^{-\cdot}$ radical anion in Ne or Ar matrices has C_{3v} symmetry and its IR spectrum exhibits a CO absorption band at 1859.7 cm^{-1} (in Ne) or at 1853.5 cm^{-1} (in Ar).^{31, 48, 53, 54}

Only the signals of terminal CO groups [$\nu_{\text{CO}} = 2057 \text{ (vw)},^\dagger$ 2017 (w), 1984 (vw), 1966 (m), 1922 cm^{-1} (w, sh)]^{55, 56} are present in the IR spectra of $[\text{Fe}_3(\text{CO})_{11}]^{-\cdot}$ in THF, while in a solution in aqueous THF in the presence of NaOH, the spectrum changes [$\nu_{\text{CO}} = 2057 \text{ (vw)}, 2019 \text{ (vw, sh)}, 1982 \text{ (vw)}, 1969 \text{ (m)}, 1960 \text{ (m, sh)}, 1933 \text{ (w)}, 1916 \text{ cm}^{-1}$ (w, sh)].⁵⁷

The ESR spectra of iron carbonyl radical anions in different solvents at various temperatures were studied in a number of papers.^{38, 44–46, 49, 58, 59} The ESR spectral parameters of ICRA and their hydrido analogues (g -factor and hyperfine splitting constants a on the ¹H, ¹³C and ⁵⁷Fe nuclei) are given in Table 1.

The iron carbonyl radical anions in which one or several CO groups are replaced by phosphine or phosphite ligands are also known.^{37, 44, 45, 60, 61}

Low-temperature ESR-spectroscopic studies of ICRA in crystalline matrices and solid solutions have been performed.^{47, 50–52, 62, 63}

The most stable iron carbonyl radical anion, $[\text{Fe}_3(\text{CO})_{11}]^{-\cdot}$, has been isolated as bis(triphenylphosphine)iminium (PPN^+) and $[\text{PPh}_4]^+$ salts and characterised by elemental and X-ray diffraction analysis. The X-ray study has shown that the anion consists of a triangular core of iron atoms with one semibridging and ten terminal CO ligands.^{55, 56}

The photoelectron spectra of the $[\text{Fe}(\text{CO})_4]^{-\cdot}$ radical anion have been reported,^{64–66} and its reactivity towards various compounds in the gas phase was studied by mass spectroscopy and ion cyclotron resonance.^{67–70} Besides, clusterisation of ICRA in the

[†] The following notation is used for the band intensities in the IR spectra: v. is very, w. is weak, s is strong, m. is medium; sh (shoulder) is a signal superimposed as a shoulder on another signal.

Table 1. ESR data of some ICRA and its hydride analogues.

Note. MeTHF is 2-methyltetrahydrofuran.

reactions of [Fe(CO)₄]^{−•} with iron pentacarbonyl in the gas phase were studied^{71–73} and IR spectra of the clusters formed were obtained.⁷⁴

Thus, on the one hand, we have got 16-electron intermediate complexes, formed during iron carbonyl transformations, which are short-lived and ghostly ‘as the Cheshire cat smile’ (the comparison was made by Poliakoff, one of the founders of this field of chemistry). On the other hand, the relatively stable ICRA resulting from single-electron reduction of iron carbonyls, are regarded at best as by-products of processes involving iron carbonyls.

III. Reactions of iron carbonyls with Lewis bases. Activating complex formation

During investigation of the reactions of iron carbonyls with various Lewis bases in anionic or neutral form, it was found that radical anions are easily generated in an ESR spectrometer cavity even at early stages of reactions at low conversions of the initial complexes.^{75–79} Nevertheless, the concentrations of the ICRA were relatively high (10^{−5}–10^{−2} mol litre^{−1}).

Naturally, these data may be interpreted as evidence in favour of single-electron reduction of iron carbonyls similar to the electrochemical reduction or to the action of strong reducing agents such as the sodium mirror and sodium benzophenone ketyl. However, the Lewis bases used (supposed electron donors) may hardly be regarded as reducing agents, because their oxidation potentials are too high (for example, these values for Cl[−] and HO[−] in acetonitrile are equal to +2.24 and +0.92 V, respectively⁸⁰). These processes have to be interpreted as anomalous reactions proceeding ‘against the potential’, which are similar to the reactions between *p*-quinones and bases studied by Pedersen.⁸¹

The concept of the ‘activating complex formation’ was suggested by Abakumov^{82,83} to explain the mechanisms of this type of reactions. As applied to iron carbonyls, this concept may be formulated as follows: if a donor L[−] (a Lewis base in its anionic form) is unable to reduce directly an acceptor C (an iron carbonyl) but forms a complex CL[−], which becomes a reducing agent with respect to the initial iron carbonyl molecule, then a single-electron process becomes possible (Scheme 3).

The Lewis bases used are, most often, quite simple molecules (or ions) containing localised σ-bonds without a π-electronic conjugated system. Elimination of an electron from such a compound results in a significant change in the atomic charge of

Scheme 3

the ‘key’ atom. This process is energetically unfavourable. On the contrary, the CL[−] complex formed acquires donor properties and electron elimination stabilises the complex due to delocalisation.

The activating complex formation for the reactions of iron carbonyls with Lewis bases consists of the addition of the base to the carbonyl group.

The structure of such adducts is well known (see, for example, the review⁸⁴). The kinetics of formation of hydroxycarbonyl (L = OH) and methoxycarbonyl (L = OMe) iron complexes in solution has been studied.^{85–87} The thermodynamic and kinetic aspects of the formation of such derivatives in the gas phase are described in papers.^{67,88–92}

In some cases it is possible to isolate an adduct of an iron carbonyl with Lewis base. This fact was used to confirm the second redox step in Scheme 3. Thus, the salt (PPN)[Fe(CO)₄.C(O)OMe] has been isolated.^{86,93} No ESR signals have been observed for this salt in solution, as for the initial iron pentacarbonyl. The reaction of the salt with iron pentacarbonyl directly in the cavity of an ESR spectrometer reveals that fast reduction of the iron carbonyl yielding ICRA takes place even at temperatures below −80 °C. The type of ESR spectrum and the character of its gradual change are similar to those for the reaction of Fe(CO)₅ with sodium methoxide.⁷⁷ Therefore, the reaction of iron carbonyl with anionic Lewis bases may be represented as follows:

n = 1, *m* = 5; *n* = 2, *m* = 9; *n* = 3, *m* = 12.

This scheme of formation of radical anions is general and does not depend on the type of iron carbonyl or Lewis bases. A great number of anionic Lewis bases in the form of sodium derivatives NaL [$\text{L} = \text{OR}, \text{SR}, \text{NR}_2, \text{CR}_2\text{NO}_2$ ($\text{R} = \text{H}, \text{Alk}, \text{Ph}$)], alkali metal and complex cation salts M^+L^- (M is an alkali metal, PPN, NR_4 ; $\text{L} = \text{H}, \text{F}, \text{Cl}, \text{Br}, \text{I}, \text{CN}, \text{SCN}, \text{N}_3, \text{MeCO}_2, \text{CF}_3\text{CO}_2, \text{MeSO}_3, \text{NO}_2$) as well as sodium salts of dianions $\text{S}^{2-}, \text{CO}_3^{2-}, \text{SO}_4^{2-}$ have been studied in the reactions with $\text{Fe}(\text{CO})_5$, $\text{Fe}_2(\text{CO})_9$ and $\text{Fe}_3(\text{CO})_{12}$.^{76–79} Tetrahydrofuran, 2-methyltetrahydrofuran, diethyl ether, monoglyme, dioxane, methylene chloride, methanol, ethanol and THF–water (10:1 by volume) were used as solvents.⁷⁸

Redox disproportionation of iron carbonyls induced by neutral Lewis bases is much more difficult. Particularly, the interaction of $\text{Fe}(\text{CO})_5$ with neutral bases ($\text{ROH}, \text{RSH}, \text{R}_2\text{NH}$) yields a set of radicals, which is virtually identical to that formed in the reactions of anionic forms; however the process is considerably slower and takes place only at high temperature.⁷⁷ The rate of ICRA generation may be lower due to both a smaller equilibrium constant of the first step of activating complex formation [reaction (3)] and the additional energy expenditure for the generation and separation of charges during the second, redox stage of the process [reaction (4)].

$n = 1, m = 5; n = 2, m = 9; n = 3, m = 12$.

Besides the abovementioned reactions, the reactions of iron carbonyls with standard solvents and reagents, such as pyridine, DMF, DMSO, *o*-phenanthroline⁷⁷ and trimethylamine oxide⁷⁹ were studied by ESR. All these neutral Lewis bases possess electron-donating properties.

A study on the rates of reactions between Lewis bases and $\text{Fe}(\text{CO})_5$, $\text{Fe}_2(\text{CO})_9$ and $\text{Fe}_3(\text{CO})_{12}$ has shown that the rate is the lowest for $\text{Fe}(\text{CO})_5$ and the highest for $\text{Fe}_3(\text{CO})_{12}$. The difference is a result of the higher reduction potential ($E_{1/2\text{red}}$) for $\text{Fe}_3(\text{CO})_{12}$ (which is in the range from -0.32 to -0.44 V)^{38, 39} in comparison with that for $\text{Fe}(\text{CO})_5$ ($E_{1/2\text{red}} = -1.77$ V).³⁹ The electron transfer step [reactions (2) and (4)] proceeds much easier for $\text{Fe}_3(\text{CO})_{12}$ for this reason. Probably, the heterogeneity of the $\text{Fe}_2(\text{CO})_9\text{--L}$ (or L^-) system does not affect the process rate in this particular case. The electron transfer from the activated complex formed to the neighbouring iron carbonyl molecule [reactions (2) and (4)] proceeds on the surface of a crystal and is accompanied by charge delocalisation over the crystal, thus reducing the energy required for the process and compensating the diffusion limitations.

Thus, the scheme comprising a complex formation stage followed by the transfer of one electron from the activated complex to another substrate molecule may be regarded as general for the disproportionation reactions of iron carbonyls with Lewis bases.

However, for a long time there has been no answer to the main question: 'Do the radicals take part in the reaction or are they just by-products?' In order to solve this problem, kinetic studies of the reactions of iron carbonyls with various Lewis bases have been performed. The following conclusions may be drawn from the obtained data:

1. The initial stage of the interaction of iron carbonyls with Lewis bases is a reversible bimolecular reaction having the first order with respect to each of the components,^{84, 86, 87, 94} which consists of activating complex formation [reaction (1)]. The subsequent processes are multistep.^{86, 95}

2. A scheme of transformations including (according to the Tolman rule²⁵) the formation of 16-electron coordinatively unsaturated species of the $\text{Fe}(\text{CO})_4$ type underlay all kinetic calculations.

3. Methods that determine only the parameters of the initial reactants and final reaction products were used in kinetic studies of the multistep processes. (The complexes with the bases formed at the first step of the reaction were an exception.) The absence of the kinetic data on the intermediate catalytically active species makes such schemes look like a 'black box' (*i.e.*, the change of the input parameters results in the change in the output parameters, but there is no way to find out what is going on inside the box).

The radical chain mechanism of the process was first proved by studying the kinetics of accumulation and loss of the intermediate radical species, namely, iron carbonyl radical anions.⁹⁶ A well studied reaction of iron dodecacarbonyl with tetraethylammonium ethanethiolate in THF was used as a model. For this reaction, the structures of intermediate radical species^{77, 97} and final products are known.⁹⁸ The reaction was carried out directly in the cavity of an ESR spectrometer in a flow system using the stopped flow method. It was shown⁹⁶ that the experimental results on the kinetics of accumulation and loss of intermediate radical anions **3** and **4** correspond well to the calculated ones. These calculations were based on the suggested mechanism of two-step redox formation of ICRA [reactions (1) and (2)].

The iron in complexes with Lewis bases formed in reactions (2) and (4) are in the formal oxidation states (+1) and (−1), respectively.[‡] These complexes initiate two chains of transformations caused by substitution reactions in the coordination sphere of the radicals. Whereas $\text{Fe}(-1)$ radicals are intrinsically stable and easily detectable, the registration of $\text{Fe}(+1)$ radicals is much more challenging, because such complexes (the iron configuration is d^7) are usually extremely unstable. In the case of hard Lewis bases (L), the coordination sphere of the carbonyl complex is destabilised with elimination of CO ligands and oxidation of the iron atom to Fe^{2+} . This gives inorganic compounds of the FeL_2 type (L is an anion) or salts of the $[\text{FeL}_k]^{2+}$ cation (L is a neutral base).^{13, 14} Stabilisation of the coordination sphere of an iron carbonyl complex becomes possible in the case of soft Lewis base L (or in the case of transition of hard base into a soft one, *e.g.*, NO_2^- into NO^{76}) or when the η -bonding of ligand L with the metal core increases during the reaction. Sometimes such iron(+1) radicals may be detected by ESR either directly or as spin adducts.^{76, 99}

The radical complexes $[\text{Fe}(\text{CO})_{5-n}\text{L}_n]^{+ \cdot}$ ($n = 1, 2$), in which one or two CO groups are replaced by phosphine or phosphite ligands are most stable.^{100–103} The complex $[\text{Fe}(\text{CO})_3(\text{PPh}_3)_2] \cdot [\text{PF}_6] \cdot 0.5 \text{CH}_2\text{Cl}_2$ has been isolated¹⁰⁰ and characterised by X-ray crystallography.¹⁰⁴

The reactions of iron carbonyls with sodium hydrosulfide and thiolates, which may be regarded as soft Lewis bases, are suitable for the detection of radical complexes of $\text{Fe}(+1)$. These bi- and trinuclear radical anions of the $[\text{Fe}_2(\text{CO})_6(\text{SR})_2]^{- \cdot}$ and $[\text{Fe}_3(\text{CO})_9(\text{SR})_2]^{- \cdot}$ types formed in the reaction with $\text{Fe}(\text{CO})_5$ may be detected.^{77, 97} The number of metal atoms may change as a result of exchange of the CO ligands with the starting iron carbonyl or the L^- ion. These processes take place in the coordination sphere of the initially formed $\text{Fe}(+1)$ complexes [reaction (2)].^{77, 105}

[‡] Strictly speaking, the oxidation stages should be noted as $+(1/n)$ and $-(1/n)$, where n is the number of iron atoms in the corresponding species. One should keep this in mind when regarding the designations used in this review.

In this situation, $\text{Fe}(\text{CO})_5$ acts as a peculiar spin trap stabilising the radical $\text{Fe}(\text{I})$ complex by delocalisation of the unpaired electron over the iron carbonyl fragment. The subsequent oxidation, which happens during either disproportionation or catalysis, and substitution by electron transfer (ETC mechanism, see Section VI), yields the final diamagnetic products. The sequences of the reactions (6) represent the case where no transitions of the L^- ligand in the metal coordination sphere take place. The delocalisation of the unpaired electron on the ligand makes possible the reorganisation (reduction, oxycarbonyl bond formation, *etc.*) of this ligand followed by coordination of the modified ligands. The formation of bi- and polynuclear iron complexes with unusually coordinated modified ligands is well known.^{106, 107}

As it was mentioned before, the reactions of iron carbonyls with Lewis bases generate unstable (with exception of radical anion **4**, see Table 1) electron-rich ICRA $[\text{Fe}_n(\text{CO})_m]^-$. These ICRA are formed during single-electron redox disproportionation [reactions (2), (4)]. The ICRA are transformed into more stable electron-deficient species $[\text{Fe}_n(\text{CO})_{m-1}]^{2-}$ by decarbonylation. According to the Sedgwick's rule of closed 18-electron configuration, the transition from 19- to 17-electron complexes takes place during this process:⁸

Usually, the formation of ICRA **2–5** is observed in any combination of the starting iron carbonyl and the base.^{76–79} Differences are only in the succession of their generation and consumption at various stages of the process. For example, in the reactions of $\text{Fe}(\text{CO})_5$ with the bases, the radical anions are generated in the sequence **1**, **2**, **4** and **3**, **5**. The mononuclear radical anion **1** was detected at the initial stages of the reaction of $\text{Fe}(\text{CO})_5$ with strong bases, such as NaOMe and NaOEt , in 2-methyltetrahydrofuran at -100°C .⁷⁸ In similar reactions of $\text{Fe}_3(\text{CO})_{12}$ the radical anions **3**, **4** are produced first and the radicals **2**, **5** are formed later. Species **2** is generated initially in the heterogeneous system containing $\text{Fe}_2(\text{CO})_9$; radical anions **3–5** emerge at later stages. Similar succession of ICRA generation was observed during the reduction of iron carbonyls over a sodium mirror.⁴⁶ The equilibrium between ICRA **2–5** with the trinuclear radical anion **3** as the major component was observed at room temperature when the reaction was performed in a closed system, *e.g.*, in a sealed ampoule. Higher temperature shifts the equilibrium towards the species containing more metal atoms. At the same time the ESR signals of species **2–5** appear and become dominant during the generation of penta- and hexanuclear $[\text{Fe}_5\text{C}(\text{CO})_{14}]^{2-}$ and $[\text{Fe}_6\text{C}(\text{CO})_{16}]^{2-}$ radical anions in the temperature range from -30°C to 50°C .⁷⁷

The coordination sphere of iron carbonyl radical anions **1–5** is quite labile and capable of fast ligand and electron exchange. This enables interconversions of radical ion clusters

Donor compounds, particularly the solvent molecules (Solv), may take part in these processes¹⁰⁴

The reactions (8)–(11) represent a sort of radical-ion ‘oligomerisation’ of iron pentacarbonyl in solution. The same reaction may take place in the gas phase.^{72–74} The reverse process, namely, a catalytic conversion of $\text{Fe}_3(\text{CO})_{12}$ into $\text{Fe}(\text{CO})_5$ by electron transfer, has been described.¹⁰⁸

Being labile electron-deficient species, ICRA **1**, **2**, **3** and **5** tend to fill their electronic shells. Therefore, in the reactions of iron carbonyls with Lewis bases they convert into carbonylferrate dianions $[\text{Fe}_n(\text{CO})_{m-1}]^{2-}$, containing 18, 34, 48 and 60 cluster valence electrons for $n = 1, 2, 3$ and 4 respectively. The unstable intermediate complexes of $\text{Fe}(\text{I})$ mentioned above may act as reducing agents for iron carbonyl radical anions.⁷⁷

Thus, in general, the reactions of iron carbonyls with Lewis acids proceed as two-electron disproportionations and afford traditional products of these transformations, the CFA salts.^{13, 14}

IV. Reactions of (hydrido)carbonylferrate anions with Brønsted and Lewis acids

The (hydrido)carbonylferrate anion–Brønsted (or Lewis) acid system is the antipode of the previously discussed iron carbonyl–Lewis base system. It is very important to note that most of the carbonylation processes are catalysed by one of these systems.^{19, 20, 84, 109, 110} Besides, the interaction of CFA and HCFA with Brønsted and Lewis acids may take place in non-catalytic processes as well, namely, in stoichiometric reactions giving aldehydes, ketones, carboxylic acids, esters and amides,¹¹¹ α -diketones,¹¹² and in the reduction of α, β -unsaturated carbonyl compounds.^{113, 114} The iron carbonyl radical species were detected in early investigations of these reactions, but not identified, and this explains the interest in these processes.^{113, 115} For example, the radicals are formed during the direct reduction of an alkyl halide (Lewis acid) by HCFA.^{116, 117}

The formation of a 16-electron intermediate species of the $\text{Fe}(\text{CO})_4$ type is traditionally suggested in this reaction, as in Schemes 1 and 2. The existence of this species in solution has been discussed in the Introduction. Besides, the direct reduction of RHal is also thermodynamically unlikely and possible only in the case of aromatic iodides with the smallest negative reduction potentials.^{109, 118} Intensive generation of ICRA **2–5** in the reactions of CFA and HCFA with Lewis and Brønsted acids has been observed by ESR spectroscopy.⁵⁹ These radical anions are identical to those formed in the reactions of iron carbonyls with Lewis bases. The hypothesis of ‘activating complex formation’, used previously to explain the mechanism of the reactions of iron carbonyls with Lewis bases (see Section 3), has been used to explain this fact too. The only difference between these two cases is that CFA or HCFA play a donor role (B^-), while their complexes (BA) with the acid (A^+) are acceptors. If the donor (CFA or HCFA) cannot directly reduce an acceptor (an acid), but the formation of their complex is still possible, then this complex may take part in a single-electron transfer, which thus becomes achievable (Scheme 4).

Scheme 4

[§]In fact, the electron shells of ICRA **1–5** contain 17, 33, 47, 49 and 59 cluster valence electrons respectively. The 18-electron closed shell configuration rule is conventionally accepted for clarity and in order to compare the complexes with different numbers of metal atoms.

According to Scheme 4, the activating complex formation stage corresponds to the well known processes: either the protonation of CFA or HCFA

$n = 1, m = 5; n = 2, m = 9; n = 3, m = 12; n = 4, m = 14;$

or the oxidative addition of alkyl and acyl halides to them^{15, 93, 109, 111, 113, 119–124}

$\text{R} = \text{H}; \text{R}' = \text{Alk}, \text{AlkC}(\text{O}); \text{R} = \text{R}' = \text{Alk}, \text{Ar}, \text{AlkC}(\text{O}), \text{ArC}(\text{O});$
 $\text{X} = \text{Cl}, \text{Br}, 4\text{-MeC}_6\text{H}_4\text{SO}_2 (\text{Ts}).$

The reactions (14) and (15) are given for well studied mononuclear iron complexes, which are most active in the redox transformations affecting the metal coordination centres.[¶]

The electron transfer itself happens at the next step during the reduction of the formed neutral complex $\text{R}'\text{RFe}(\text{CO})_4$

A similar electron transfer stage for protonated complexes CFA looks as follows:

The pure starting compounds without any traces of the oxidation products are required in order to confirm that the electron transfer occurs during this stage of the reaction. This was achieved, for example, by vacuum distillation of complex $\text{H}_2\text{Fe}(\text{CO})_4$ [$\text{R} = \text{R}' = \text{H}$ in reaction (16) or $n = 1, m = 5$ in reaction (17)] directly into an ampoule located in the cavity of an ESR spectrometer.⁵⁹ No ESR signals were observed in a solution of $\text{H}_2\text{Fe}(\text{CO})_4$ in 2-methyltetrahydrofuran at temperatures below -60°C . A similar situation has been found in the case of a solution of $(\text{PPN})[\text{HFe}(\text{CO})_4]$ in MeTHF over a wide range of temperatures up to room temperature. At the same time, the reaction of $\text{H}_2\text{Fe}(\text{CO})_4$ with $(\text{PPN})[\text{HFe}(\text{CO})_4]$ in this solvent results in the appearance of ICRA signals at as low as -100°C . It was shown,⁵⁹ that 17-electron radical $[\text{HFe}(\text{CO})_4]^\cdot$ and 19-electron radical anion $[\text{H}_2\text{Fe}(\text{CO})_4]^{-\cdot}$, formed at the electron-transfer stage of the reaction, are unstable under these conditions and are quickly converted into $[\text{Fe}_2(\text{CO})_8]^{-\cdot}$ by reactions (18) and (19), respectively.

Radical anions **3–5, 11** containing greater numbers of metal atoms arise in reactions (21) and (9)–(11).

The transformations of $\text{RR}'\text{Fe}(\text{CO})_4$ complexes ($\text{R} = \text{H}, \text{R}' = \text{Alk}, \text{Ac}$) should be particularly noted. These are the key compounds in many processes involving $[\text{HFe}(\text{CO})_4]^-$ (Ref. 106). In this case, reaction (16) is as follows:

The unstable 19-electron complex $[\text{R}'\text{HFe}(\text{CO})_4]^{-\cdot}$ formed initially is transformed into the more stable 17-electron species by elimination of $\text{R}'\text{H}$ or CO [reaction (23)]. In the latter case, the $[\text{R}'\text{HFe}(\text{CO})_3]^{-\cdot}$ radical anions are formed. They were detected in the reactions of acyl halides $\text{R}'\text{X}$ ($\text{R}' = \text{Ac}, \text{Bz}$) with $[\text{HFe}(\text{CO})_4]^-$ (Ref. 59).

It is remarkable that the $[\text{R}'\text{Fe}(\text{CO})_4]^-$ and $[\text{HFe}(\text{CO})_4]^-$ anions do not react with each other. For instance, propionaldehyde is not formed in the reaction between $[\text{EtC}(\text{O})\text{Fe}(\text{CO})_4]^-$ and $[\text{HFe}(\text{CO})_4]^-$; however it is formed in 57% yield when the acetic acid, which partially protonates the $[\text{HFe}(\text{CO})_4]^-$, is added to the reaction mixture.¹²⁵ This confirms that the process proceeds according to pathway (22). The yield of the target compound, which is approximately half of the theoretical one, points out to the partial protonation of $[\text{HFe}(\text{CO})_4]^-$ and its consumption according to reactions (16) (for $\text{R} = \text{R}' = \text{H}$) and (18)–(20).

As it was noted before, on the one hand, ICRA are relatively stable species (during the reaction their steady-state concentrations may be fairly high). On the other hand, these ICRA are coordinatively unsaturated electron-deficient systems with labile coordination sphere capable of fast ligand and electron exchange. An important consequence of these two characteristics is the ability of ICRA to add Brønsted or Lewis acids. These reactions are the key stages in a number of reduction and carbonylation processes of various compounds. Initially, the radical anion reacts with an electron acceptor (the corresponding acid):

and then, similarly to reaction (18), species **2** are formed.

The subsequent transformations of the ICRA are of the radical chain type and are accompanied by the increase in the number of metal atoms in the radical complex:

Radical anions **3** and **5** are reduced to corresponding CFA by reactions (26) and (27) at the final stages of the interaction of (hydrido)carbonylferrate anions with Brønsted and Lewis acids. The reduction potentials of these CFA make the processes thermodynamically favourable.^{42, 126}

¶ Tri- and tetranuclear CFA can be alkylated and acylated at the carbonyl group resulting in the formation of the $[\text{Fe}_n(\text{CO})_{m-2}(\text{COR})]^-$ ($\text{R} = \text{Me}, \text{Ac}; n = 3, m = 12; n = 4, m = 14$) complexes, which mainly tend to undergo transformations of the carbonyl ligand.¹⁵

$n = 3, m = 12$ (3); $n = 4, m = 14$ (5); $p = 1, q = 5$ (1); $p = 2, q = 9$ (2).

The final products of the reaction are diamagnetic compounds, mainly the modified organic ligands and polynuclear CFA and HCFA.

Thus, the reactions of (hydrido)carbonylferrate anions with the Brønsted and Lewis acids, like the reactions of iron carbonyls with Lewis bases, may be described as radical chain processes which include the preliminary activating complex formation and the redox initiation stage.

V. Reactions of iron carbonyls with carbonylferrate anions

It is believed that the nucleophilic displacement of the CO groups in the reactions of diamagnetic iron carbonyls and carbonylferrate anions results in the formation of CFA with an increased number of metal atoms. Thus, the reaction of $\text{Fe}(\text{CO})_5$ with $[\text{Fe}(\text{CO})_4]^{2-}$ yields $[\text{Fe}_2(\text{CO})_8]^{2-}$ [reaction (28)].^{42, 43, 113, 127–129}

The $[\text{Fe}_3(\text{CO})_{11}]^{2-}$ anion is formed from $\text{Fe}(\text{CO})_5$ and $[\text{Fe}_2(\text{CO})_8]^{2-}$ (Ref. 127)

while the reaction of $[\text{Fe}_3(\text{CO})_{12}]$ with $[\text{Fe}(\text{CO})_4]^{2-}$ results in the formation of $[\text{Fe}_4(\text{CO})_{13}]^{2-}$ (Ref. 130):

It was shown⁷⁷ that the $[\text{Fe}(\text{CO})_4]^{2-}$ and $[\text{Fe}_2(\text{CO})_8]^{2-}$ anions easily react with $\text{Fe}(\text{CO})_5$ and $\text{Fe}_3(\text{CO})_{12}$, ICRA 2–5 being formed at the initial steps of the reaction. At the same time, the reactions of tri- and tetranuclear CFA salts, $[\text{Fe}_3(\text{CO})_{11}]^{2-}$ or $[\text{Fe}_4(\text{CO})_{13}]^{2-}$, with $\text{Fe}_3(\text{CO})_{12}$ give first mainly heavier radical anions 3–5. It should be noted that the reaction of $(\text{PPN})_2[\text{Fe}_3(\text{CO})_{11}]$ with $\text{Fe}_3(\text{CO})_{12}$ is the preparative method for the synthesis of the stable radical anion salt, $(\text{PPN})[\text{Fe}_3(\text{CO})_{11}]^{\cdot-}$ (Ref. 131). These data show that in the reactions of carbonylferrate anions with iron carbonyls, single-electron transfer takes place at low degrees of conversion.

for $p = 1, q = 5$ and $p = 2, q = 9$: $n = 1, m = 5$; $n = 2, m = 9$; $n = 3, m = 12$; for $p = 3, q = 12$ and $p = 4, q = 14$: $n = 3, m = 12$.

Such process may be regarded as direct single-electron reduction of iron carbonyls,[†] which is quite natural, taking into account the high reduction potentials of CFA (Fig. 1).⁴²

The two-electron reduction potential ($E_{\text{red}} = -1.77\text{ V}$)³⁹ for $\text{Fe}(\text{CO})_5$ is shown in Fig. 1. This potential, probably, corresponds to the reduction of iron pentacarbonyl in very fast reactions of types (7) (for $n = 1, m = 5$) and (8) followed by the reduction of $[\text{Fe}_2(\text{CO})_8]^{\cdot-}$ to the corresponding anion. In the electrochemical terms, this corresponds to the two-electron reduction with an intermediate chemical stage (ECE). The value $E_{1/2\text{red}} = -2.67\text{ V}$

[†] This scheme of the direct reduction may be regarded as a variant of the redox disproportionation with the preliminary activating complex formation stage, if the ‘additional’ lone pair of CFA is considered as a donor ligand.

Figure 1. The scale of the redox potentials of the following pairs: $[\text{Fe}(\text{CO})_4]^{2-}/[\text{Fe}(\text{CO})_4]^{\cdot-}$ (1), $[\text{Fe}_2(\text{CO})_8]^{2-}/[\text{Fe}_2(\text{CO})_8]^{\cdot-}$ (2), $[\text{Fe}_3(\text{CO})_{11}]^{2-}/[\text{Fe}_3(\text{CO})_{11}]^{\cdot-}$ (3) and $[\text{Fe}_4(\text{CO})_{13}]^{2-}/[\text{Fe}_4(\text{CO})_{13}]^{\cdot-}$ (4) in THF.⁴²

has been reported⁴³ for the reduction potential of $\text{Fe}(\text{CO})_5$, which is probably related to the supporting electrolyte used, Bu_4NBF_4 ($E_{1/2\text{red}} = -2.75\text{ V}$)¹³².

Whereas the interaction of trinuclear $[\text{Fe}_3(\text{CO})_{11}]^{2-}$ and $\text{Fe}_3(\text{CO})_{12}$ complexes ($E_{1/2\text{red}}$ from -0.32 to -0.44 V ^{38, 39}) in an open system results in the formation of trinuclear ICRA 3 and 4, the reaction of tetracarbonylferrate anion with iron pentacarbonyl proceeds as a radical chain reaction. The reaction gives $[\text{Fe}_2(\text{CO})_8]^{2-}$ when the concentrations of the starting compounds are equimolar [see reaction (28)].

With excess iron pentacarbonyl, the process continues further to give trinuclear CFA incapable any more of reducing the starting iron pentacarbonyl at ambient temperature at the final stage of the reaction.

The radical chain process with single-electron redox steps ends in the formation of diamagnetic complexes. In a closed system, when CO is not removed from the reaction vessel, the iron carbonyl radical anions 2–5 are in equilibrium [reactions (9)–(13)].

A series of papers^{127, 131, 133–137} dealing with the reactions of CFA with other metal carbonyls and the reactions of anionic carbonyl compounds of various metals with iron carbonyls should be noted. The electron transfer between such complexes and the formation of ICRA at the intermediate stages of the process have been discussed.^{127, 134, 135, 137} The charge transfer in the $\text{A}_2[\text{Fe}_2(\text{CO})_8]$ salts, where A are *N*-methylated pyridine derivatives, PPN, Ph_4P or the organometallic cation $[\text{CpFe}(\text{C}_6\text{H}_6)]^+$ (Cp is cyclopentadienyl), has been described.¹³⁸ The electron transfer in this system results in the formation of radical anion 2, which undergoes subsequent conversions.

The structures of $[\text{Li}_2(\text{THF})_6\text{Fe}_2(\text{CO})_8]$ and $[\text{Li}_2(\text{THF})_4\text{Fe}_2(\text{CO})_8]_n$ complexes in which the iron carbonyl fragment contains two bridging CO ligands with coordinated $\text{Li}(\text{THF})_3$ and $\text{Li}(\text{THF})_2$ groups have been determined by X-ray

crystallography.¹³⁹ A similar structure of the $\text{Fe}_2(\text{CO})_8$ fragment was suggested for the $[\text{Fe}_2(\text{CO})_8]^{-\bullet}$ radical anion.^{7,63} On the contrary, the structure of the corresponding carbonylferrate anion $[\text{Fe}_2(\text{CO})_8]^{2-}$ does not contain any bridging groups, two $\text{Fe}(\text{CO})_4$ fragments being linked only by the Fe–Fe bond.^{133, 138, 140, 141} It should be noted that the lithium salt with the $[\text{Fe}(\text{CO})_4]^{2-}$ anion is unknown in a pure state. As the reduction potential of Li^+ ($E_{1/2\text{red}}$ from -1.42 to -1.82 V)^{142, 143} is less negative than the redox potential of the $[\text{Fe}(\text{CO})_4]^{2-}/[\text{Fe}(\text{CO})_4]^{-\bullet}$ pair (see Fig. 1), the reduction of Li^+ occurs. In the case of $[\text{Li}_2(\text{THF})_6\text{Fe}_2(\text{CO})_8]$ and $[\text{Li}_2(\text{THF})_4\text{Fe}_2(\text{CO})_8]_n$ complexes, when the redox potential of the $[\text{Fe}_2(\text{CO})_8]^{2-}/[\text{Fe}_2(\text{CO})_8]^{-\bullet}$ pair (see Fig. 1) falls in the $E_{1/2\text{red}}$ region of lithium, charge transfer from CFA to Li^+ may take place followed by the rigid fixation of the cation in a contact ion pair. The presence of two different types of lithium atoms in the structure of the polymeric complex also supports this suggestion.

Thus the carbonylferrate anions are quite strong reducing agents, able to take part in the direct single-electron reduction of various substrates, including iron carbonyls. The iron carbonyl radical anions are formed in these processes and the radicals undergo further conversions by a radical chain mechanism.

VI. Nucleophilic substitution and catalytic conversions of iron carbonyls induced by electron transfer

A series of papers on the nucleophilic substitution of CO by phosphine, phosphite and isocyanate ligands in iron carbonyl complexes under the conditions of preliminary chemical or electrochemical reduction of the initial complex to the corresponding radical anion was published in the early 1980s. The trinuclear iron carbonyl complex $\text{Fe}_3(\text{CO})_{12}$ (Refs 60, 144–146) and complexes of the $\text{Fe}_3(\mu_3\text{-E})_2\text{L}(\text{CO})_8$ type, where $\text{L} = \text{CO}$; $\text{E} = \text{NAr}$, PPh , S , Se ;^{147–151} E_2 is 2,3-diazanorbornene;¹⁵² $\text{L} = \text{C}_3\text{H}_2\text{S}_2$, $\text{E} = \text{S}$ ^{153, 154} were the main objects of these studies. The replacement of CO in iron pentacarbonyl by phosphine and phosphite ligands, initiated by sodium benzophenone ketyl, has been described.¹⁵⁵ It appeared that these processes correspond to the known substitution reactions or to the catalytic conversions induced by electron transfer:^{156–158}

MCO is iron carbonyl complex,

$\text{L} = \text{PR}_3, \text{P}(\text{OR})_3, \text{NCR}$ ($\text{R} = \text{Alk}, \text{Ar}$).

If the standard electrochemical potentials of reactions (29) and (32) obey the inequality $E_2^\circ > E_1^\circ$, then the electron-induced nucleophilic substitution, EINS, takes place.^{140, 155} If $E_1^\circ > E_2^\circ$, then a catalysed reaction called electron-transfer chain catalysis (ETC) takes place.^{146, 157, 158} The catalytic cycle is shown in Scheme 5.

Reactions (29)–(33) and Scheme 5 represent the simplest case of an ETC process without taking into account the interconversions of the intermediate 19-electron ($\text{MCO}^{-\bullet}$ and $\text{ML}^{-\bullet}$) and 17-electron ($\text{M}^{-\bullet}$) radical anions. After the electron addition in reaction (29) the reorganisation of the radical anions accompanied by the change in the number of iron atoms in the metal core and rearrangement of the coordination sphere are possible [see, for

Scheme 5

example, reactions (6), (8)–(10) in Section III and also the papers^{108, 159}].

In spite of the fact that no data on the ETC processes involving intermediate 17-electron radical cations are known for iron carbonyls, similar reactions for the carbonyls of Group VI metals were described in the literature.¹⁶⁰ As applied to the iron carbonyls, these transformations may be described as follows (Scheme 6):

Scheme 6

MCO is iron carbonyl complex,

$\text{L} = \text{PR}_3, \text{P}(\text{OR})_3$ ($\text{R} = \text{Alk}, \text{Ar}$).

If $E_1^\circ > E_2^\circ$, then electron-induced nucleophilic substitution takes place. For instance, the nucleophilic substitution of the CO group in the $[\text{Fe}(\text{CO})_3(\text{PPh}_3)_2]^{+\bullet}$ radical cation yielding the $[\text{Fe}(\text{CO})_2 \cdot (\text{PPh}_3)_2(\text{L}-\text{L})]^{+\bullet}$ complex, where $\text{L}-\text{L}$ are 1,2-diketones, *o*-chloranil, 1,2-naphthoquinone, belongs to this type of reaction.^{102, 161} If $E_2^\circ > E_1^\circ$, the catalytic ETC process occurs. Only one example of ETC process in which the addition of the nucleophilic anion (EtS^-) is followed by rearrangement of the metal skeleton is known for 17-electron $\text{Fe}(\text{I})$ carbonyl complexes.⁹⁶

Thus, in the ETC processes involving complex iron carbonyl radical ions, ligand exchange takes place in the coordination sphere of a complex with incomplete 17-electron configuration. This is a radical chain process; however its final products are diamagnetic.

VII. Iron carbonyls as reducing agents

It was shown in Section III that disproportionation reactions of iron carbonyls with Lewis bases include a stage of activating complex formation followed by single-electron transfer from the carbonyl complex activated by the electron donor to another molecule of the starting carbonyl. This gives complexes of iron in the oxidation state (+1) and radical anions containing iron in the oxidation state (−1) [see reactions (1)–(4)]. If the reaction mixture contains a third component (Q), more easily reducible than the starting iron carbonyl, then the reduction of only this component is possible.

L is a Lewis base.

The situation represented by reactions (37) and (38) occurs when the reduction potentials of the compound Q are higher than those of iron pentacarbonyl [$E_{1/2\text{red}} = -1.77$ V in THF vs. the saturated calomel electrode (SCE)],³⁹ as, for example in the case of the nitroso compound Bu^tNO [$E_{1/2\text{red}} = -1.36$ V (MeCN, SCE)];¹⁶² haloalkanes, viz., CCl₄ [$E_{1/2\text{red}} = -0.78$ V (dioxane, SCE)]¹⁶³ and CHCl₃ [$E_{1/2\text{red}} = -1.68$ V (dioxane, SCE)],¹⁶³ as well as sulfur [$E_{1/2\text{red}} = -1.077$ V in DMF vs. the Fe/Fe⁺ couple (Fe is ferrocene)]¹⁶⁴.

A study of the reaction of Fe(CO)₅ with 2-methyl-2-nitrosopropane (Bu^tNO) in THF or toluene in the absence of electron donors has shown that at 20 °C, the induction period of the reaction is rather long (~20 min).⁷⁶ The fast accumulation of the Fe(CO)₃NO[•] [Fe(1⁺)] and Bu^tNO^{•-}, which are subsequently converted into the stable radicals (OC)₃(NO)FeN[•](O)Bu^t and Bu₂NO[•], takes place after this period.

The intermediate nitrosyl anion NO^{•-} initiates the already discussed scheme of redox disproportionation of Fe(CO)₅ under the action of an anionic nucleophile.

After the end of the induction period, the process proceeds as a chain reaction, which is provided by the formation of Bu^tNO^{•-} in reaction (40) and its decomposition [reaction (39)]. In the case of excess Fe(CO)₅ relative to Bu^tNO, after complete decomposition of nitroso compound, the resulting Bu₂NO[•] [$E_{1/2\text{red}} = -1.63$ V (MeCN, SCE)]¹⁶⁵ is reduced to the hydroxylamine anion according to a scheme similar to reaction (38).

The Fe(CO)₅–Lewis base system (L = DMF, HMPA, tertiary amines, etc.) is widely used as an initiator for radical addition, telomerisation of olefins with haloalkanes and the reduction of polychloro-substituted compounds.^{166–171} Haloalkanes (mainly, polyhaloalkanes) are quite reactive in these processes, because they are reduced more easily than iron pentacarbonyl. The scheme of the process initiation may be represented by reactions (37), (38), where L is DMF or HMPA, and Q is an easily reduced haloalkane RX. The resulting RX^{•-} radical anion decomposes to give the R[•] radical, which subsequently participates in the radical process, and a halide ion X⁻. The latter reacts with Fe(CO)₅, as a Lewis base, as described above, thus enhancing the initiation of subsequent transformations. The intermediate species of the single electron redox process, namely, the Fe⁺ carbonyl complexes, for example Cl(OC)₄FeN[•](O)Bu^t, and alkyl radicals, were identified by spin-trap methods.^{99, 169–171} In the presence of olefins, diamagnetic Fe²⁺ complexes and the products of addition of haloalkanes to the double C=C bond are the final products of telomerisation. Without olefins the reaction of Fe(CO)₅ with polyhalomethanes CCl₃X (X = Cl, Br) in the presence of DMF yields hexachloroethane, which is also evidence for the radical Cl₃C[•] generation.^{172, 173} In the presence of hydrogen donors (alcohols, mercaptans, organosilicon hydrides), the hydrogen atom adds to the RCCl₂[•] radical formed upon decomposition of RCCl₃. Thus, readily available compounds containing a trichloromethyl group are reduced to dichloro derivatives.¹⁶⁹

A study¹⁷⁴ of the reaction of Fe(CO)₅ with sulfur (S₈) in THF at 20 °C has demonstrated that after the induction period (> 10 min), the ESR spectra exhibit a broadened signal for S₃^{•-} with $g = 2.031$ (according to the literature, $g = 2.032$ ¹⁷⁵ and 2.033 ¹⁷⁶). However, no ICRA are detected. The stable radical anion S₃^{•-}, together with S_n²⁻ ($n < 8$), is formed from S₈^{•-} through a relatively complicated disproportionation.^{164, 177, 178} The polysulfide dianions S_n²⁻, being Lewis bases, initiate the redox process according to reactions (38) and (39), where Q = S₈. The identification of the Fe⁺ radical carbonyl complexes in this system is difficult, because their signals overlap with the broad signal of S₃^{•-}. However, the formation of diamagnetic complexes of the S₂Fe₂(CO)₆, S₂Fe₃(CO)₉ and SFe₃(CO)₁₀ type^{179–181} points to the fact that their precursors are the Fe⁺ radical ion complexes, which are involved in the transformations similar to reaction (6).

If an unsaturated compound is introduced in the reaction of an iron carbonyl with S₈, the S_n^{•-} radical anions appearing in the system will add to the double bond, forming cyclic polysulfides, various organic sulfur derivatives and their iron carbonyl complexes.^{181, 182} This process may be used for the low-temperature vulcanisation of resins. It was also reported that Fe(CO)₅ in the presence of sulfur is an effective catalyst of lignite and bituminous coal liquefaction under hydrogen^{183, 184} or water gas (CO + H₂O)¹⁸⁵ gasifications.

Thus, in the reactions with Lewis bases in the presence of compounds reduced more easily than iron pentacarbonyl, Fe(CO)₅ forms an activated complex with a Lewis base and acts as a single-electron reducing agent. The resulting Fe⁺ radical carbonyl derivatives are then oxidised either to Fe²⁺, or to diamagnetic carbonyl complexes of the L₂Fe₂(CO)₆, L₂Fe₃(CO)₉ and LFe₃(CO)₁₀ type, where L is a nucleophilic ligand. Another reaction pathway is determined by the Q^{•-} radical anion formed upon the reduction.

VIII. Catalytic processes involving iron carbonyl radical anions

The catalytic transformations of iron carbonyls in the processes of carbonylation of various compounds are usually described by a scheme constructed according to the Tolman rule for determination of the major reaction pathway *via* complexes with even numbers of electrons in the outer shell (18e → 16e → 18e). However, all attempts to prove this mechanism failed. In fact, catalytic processes of carbonylation with iron carbonyl complexes include reactions of two types: the redox disproportionation of iron carbonyls induced by Lewis bases (see Section III) and the oxidative addition of Brønsted and Lewis acids to the (hydrido)-carbonylferrate anions (see Section IV).^{19, 20, 84, 109, 110} In both cases, ICRA 2–5 are formed. These ICRA are fairly stable and their steady-state concentrations during the reaction may be high (10⁻⁵–10⁻² mol litre⁻¹). At the same time, ICRA 2, 3 and 5 are coordinatively unsaturated electron-deficient systems with a labile coordination sphere, capable of fast ligand and electron exchange. Usually reactions involving these ICRA follow a radical chain mechanism (see Sections III and IV); therefore these species are, most likely, catalysts of carbonylation. The catalytic activity of ICRA was demonstrated for the first time in the reductive carbonylation of nitro and nitroso compounds⁷⁶ and was confirmed later^{56, 57} with [Fe₃(CO)₁₁]^{•-} as a model compound.^{56, 57} Radical anion nitrene complexes were found by ESR method in the reactions of Bu^tNO₂ and Bu^tNO with participation of the ICRA (Scheme 7).

Scheme 7 depicts the case where only one molecule of nitro compound is present in the coordination sphere of an iron carbonyl cluster. This molecule is reduced consecutively to nitroso derivative and then to the nitrene complex. If the process is carried out in the catalytic mode with a controlled negative reduction potential of the medium, the intermediate nitrene complexes are carbonylated to give isocyanates and the starting ICRA. The iron

oxidation state (−1) in the catalytic species remains unchanged in this process. The addition of the second molecule of the nitro compound yields intermediate radical species containing ligands with nitro groups reduced to different extent.⁷⁶

If the reaction is carried out with a stoichiometric component ratio, the reduction of nitrogen-containing ligands may end after the formation of nitrene structures. In the absence of an adequate reduction potential of the medium and with additional supply of carbon monoxide, the nitrogen-containing ligands in intermediate complexes are reduced at the expense of oxidation of Fe(−1) into Fe(+1). Further on, the radical anions lose the unpaired electron to be transformed into well known diamagnetic complexes with d⁷ electron configuration of the iron atom, for example, into Fe₂(CO)₆(NR)₂, Fe₃(CO)₉(NR)₂, Fe₃(CO)₁₀NR, *etc.*^{186, 187} This results in withdrawal of the complex from the catalytic cycle, and the subsequent formation of isocyanates becomes impossible (Scheme 8).

In the presence of proton donors in the reaction mixture, the nitro compounds are reduced to amines.^{56, 188} The intermediate radical anion nitrene complexes may be stabilised by being

reduced to diamagnetic anions, [Fe₃(CO)₉NR]^{2−} and [HFe₃(CO)₉NR][−] (Ref. 56).

It is noteworthy that the catalytically active species are 17-electron radical anions; in the process of catalysis, they add a ligand, *e.g.*, CO, and are transformed into 19-electron species. The latter eliminate the product being thus converted into the original electron-deficient form. There is a possibility of the transformation of an electron-rich system into an electron-deficient one upon cluster core rearrangement due to breaking of the Fe–Fe or Fe–N bonds and upon localisation of the excessive electron on the ligand. In these cases, a new bond is formed between the coordinated ligands, for example, CO–NR, or their reduction, for example into the RNH ligand, takes place in the presence of proton donors. These transformations afford various diamagnetic complexes, which may be isolated upon the reaction of iron carbonyls with nitro compounds.^{186, 189}

Thus, the catalytic cycle of reductive carbonylation of nitro and nitroso compounds catalysed by ICRA includes transformations *via* complexes 17e → 19e → 17e, and the process itself has a radical chain character.

IX. Reactions with possible involvement of iron carbonyl complexes

The concept of the ‘activating complex formation’ discussed in Section III describes adequately a wide variety of redox processes in organic and organometallic chemistry,^{82, 83} for example, the reactions of ferrocenium salts with different nucleophilic reagents.¹⁹⁰

If the neutral complex C in Scheme 2 is replaced by the radical cation C^{•+}, we get Scheme 9. This may explain the halide-induced disproportionation of radical cations [Fe(CO)₃(PR₃)₂]^{•+} containing iron atom in the formal oxidation state 1+ into the complexes Fe(CO)₃(PR₃)₂ [Fe(0)] and Fe(CO)₂(PR₃)₂X₂ [Fe(II)], where X = Cl, Br, I.^{100, 101, 103}

Scheme 9

The ‘activating complex formation’ produces at the first stage the known^{100, 101} radical [Fe(CO)₃(PR₃)₂X][•] [reaction (41)]. This is followed by an electron transfer from this compound to the starting radical cation and the formation of the coordination sphere of Fe(+2) carbonyl complex [reactions (42) and (43)].

The mechanism of single-electron redox disproportionation of iron carbonyls induced by Lewis bases, resulting in the formation of ICRA, is quite common and may be applied to a wide variety of bases (see Section III). However, this mechanism has to be proved in every particular case. For instance, some authors^{23, 24} regard the N-oxide-induced ligand substitution in iron carbonyls as a special type of transformations caused by ‘oxygen atom transfer reagents’ (see Scheme 2 in Introduction). However, it was shown⁷⁹ that, in reality, such processes start with the formation of ICRA according either to reactions (1) and (2) (L[−] = OH[−]), if commercial Me₃NO · 2 H₂O available as [Me₃NOH]⁺OH[−] · H₂O is applied, or to reactions (3) and (4) (L = Me₃NO), if the preliminarily dehydrated amine oxide is used. This is followed by nucleophilic displacement of CO in the formed ICRA according

to reactions (29)–(33), which is a typical electron transfer induced catalysis (see Section VI).

The activation of nucleophilic substitution and CO exchange in $\text{Fe}(\text{CO})_5$ under the action of salts (such as CoHal_2 and NiHal_2)¹⁹¹ or transition metal complexes^{192,193} occurs in a similar way. These compounds are able to dissociate yielding negatively charged species, for example, halide ions X^- , which act as Lewis bases. They react with $\text{Fe}(\text{CO})_5$ to form complexes $[\text{Fe}(\text{CO})_4\text{C}(\text{O})\text{X}]^-$ [reaction (1)], which subsequently react with the starting $\text{Fe}(\text{CO})_5$ molecule according to equation (2), producing iron carbonyl radical anions.⁷⁸ It is important to note that in these compounds, the transition metal is in a low oxidation state and is unable to oxidise the emerging radical anions. The activation of such processes by potassium hydride¹⁹⁴ and by the complex hydride derivatives, R_3BH^- ($\text{R} = \text{H}, \text{Alk}, \text{AlkO}$) and AlH_4^- (Refs 194 and 195), which produce the $[\text{Fe}(\text{CO})_4\text{C}(\text{O})\text{H}]^-$ formyl iron complex^{196–199} proceeds by a similar way.

The kinetic data on one of the most important carbonylation processes, Reppe olefin hydroformylation in alkaline solutions containing $\text{Fe}(\text{CO})_5$,⁹ have been interpreted according to the traditional scheme based upon the Tolman rule. Several intermediate 16-electron species, the possible existence of which was not proved, are included in this scheme.

However, the very same data can be consistently interpreted by assuming the formation of ICRA in the iron carbonyl–Lewis base system and their radical chain transformations through complexes $17e \rightarrow 19e \rightarrow 17e$, which do exist in solution and are easily detectable by ESR spectroscopy. The key stage of the process is the addition of an olefin to the coordinatively unsaturated 17-electron radical anion in the presence of a proton donor. As a result, an alkyl-containing iron carbonyl radical is generated [reaction (44)].

$\text{R}, \text{R}' = \text{Alk}; n = 2, m = 9; n = 3, m = 12.$

The next stage is the addition of CO producing a 19-electron species and the transformation of the latter into the 17-electron radical upon carbonylation of the $\text{Fe}-\text{Alk}$ bond.

The subsequent reaction of radical **12** with $[\text{HFe}(\text{CO})_4]^-$ produces an aldehyde and radical anion with an increased number of iron atoms, similarly to the reactions of acyl derivative $[\text{RFe}(\text{CO})_4]^{\cdot-}$ [reactions (24) and (25)]. The hydridocarbonylferrate anion $[\text{HFe}(\text{CO})_4]^-$ is formed in this process as a result of redox disproportionation of $\text{Fe}(\text{CO})_5$ in the presence of a proton donor.^{19,20,109} In the presence of carbon monoxide, ICRA **2–5** interconvert^{76–78,96,108} according to reactions (8)–(11). This provides the regeneration of radical anions **2** and **3** and thus determines the catalytic character of the process.

Stoichiometric reduction of various unsaturated compounds (alkenes,²⁰⁰ 1,3-dienes,²⁰¹ α,β -unsaturated carbonyl compounds,^{113,114} enamines,²⁰² a number of nitrogen-containing heterocycles and anthracene²⁰³) by HCFA occurs in the absence of CO in a proton donor medium. During the reduction, ESR signals that may be assigned to ICRA **2–4** were detected. However, the formation of such species was usually attributed to side processes.¹¹³

An alkyl-containing complex is formed at the first step of the reduction.

$\text{R}, \text{R}' = \text{Alk}; n = 1, m = 5; n = 2, m = 9.$

The subsequent process is believed to proceed according to reactions (22) and (23) (see Section IV), *i.e.*, the scheme of single-electron redox disproportionation in the HCFA–Lewis acid system, resulting in the formation of ICRA and reduction products, is implemented. The iron carbonyl radical anions react with the starting compounds [see reactions (44), (24) and (25)]. As a result, the hydrocarbonylferrate anion is completely spent for the reduction of unsaturated compound.

The transformation schemes *via* the $17e \rightarrow 19e \rightarrow 17e$ complexes may be applied also to the explanation of other processes, which involve the iron carbonyl–Lewis base and HCFA–Lewis (or Brønsted) acid systems. However, the validity of using such schemes should be proved in each particular case.

X. Redox disproportionation of transition metal carbonyls

The redox disproportionation induced by Lewis bases is a typical reaction of transition metals carbonyls. As a result of this reaction, the reduction of carbonyls to carbonylmetallate or hydridocarbonylmetallate anions and their oxidation to positively charged complexes take place. The general features of the formation of stable complexes, namely, binary carbonyls containing only the metal atoms and carbonyl ligands, should be considered in the discussion of these processes, because the relationship between the stability and reactivity is important for the choice of potential carbonylation catalysts.

All complexes require the 18-electron configuration of the outer electron shell of a metal atom in order to achieve the thermodynamic stability (the Sidgwick rule). The number of CO ligands coordinated to the metal (not more than 6) is an important factor determining the stability of carbonyl complexes obtained in various processes. The size of the metal atom is another such factor. The larger is the metal atom and the smaller is the number of CO groups required for its coordination, the more pronounced is the tendency of the complex to form cluster structures. This fact is reflected in the concept of close packing of ligands on a metal core surface.²⁰⁴ For instance, the vanadium atom, which possesses a d^5 electron configuration, forms a stable 17-electron radical, $[\text{V}(\text{CO})_6]^{\cdot-}$, unable to dimerise. On treatment with a Lewis base (L), this radical easily disproportionates yielding the salt $[\text{VL}_n][\text{V}(\text{CO})_6]_2$ ($n = 3, 6$), in which the mononuclear anion $[\text{V}(\text{CO})_6]^-$ obtains the closed 18-electron configuration.²⁰⁵

A stable mononuclear carbonyl $\text{Ni}(\text{CO})_4$ with a closed 18-electron shell is known for nickel (electron configuration d^{10}). During the redox disproportionation induced by Lewis bases (L), it transforms into salts of polynuclear carbonyl-containing $\text{Ni}(-2)$ anions, $[\text{NiL}_n][\text{Ni}_p(\text{CO})_q]$ with $p \geq 5$ nickel atoms in the anion cluster, for example $[\text{Ni}_6(\text{CO})_{11}]^{2-}$, $[\text{Ni}_9(\text{CO})_{18}]^{2-}$ or $[\text{Ni}_{12}(\text{CO})_{21}]^{4-}$ (Refs 206–208). Platinum, which is located in the Periodic Table in the same group as nickel, but in Period 6, does not form a stable mononuclear carbonyl $\text{Pt}(\text{CO})_4$, but produces a polymeric cluster $[\text{Pt}(\text{CO})_2]_x$ instead.²⁰⁹ The same is true for carbonylplatinates, for example for $[\text{Pt}_3(\mu-\text{CO})_3(\text{CO})_3]_n^{2-}$ (Ref. 210).

Group VI metals, Cr, Mo and W, form very stable hexacarbonyls $\text{M}(\text{CO})_6$, which disproportionate only under the action of strong bases and under drastic conditions. For instance, the reactions of $\text{M}(\text{CO})_6$ with KOH produces $[\text{HM}_2(\text{CO})_{10}]^-$ binuclear anions,^{211,212} and the reactions of $\text{Cr}(\text{CO})_6$ with KOH in the presence of the cryptand **222** (4,7,13,16,21,24-hexaoxa-1,10-

diazabicyclo[8.8.8]hexacosane) result in the formation of the $[\text{HCr}(\text{CO})_5]^-$ anion.²¹³ Dianionic carbonylmetallates, $[\text{M}_2(\text{CO})_{10}]^{2-}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$), are also known for these metals.^{212, 214–216} When less basic nucleophiles are used, the redox disproportionation does not occur. The reactions stop after the formation of complexes at the CO group, for example $[\text{M}(\text{CO})_5\text{C}(\text{O})\text{L}]^-$ [$\text{M} = \text{Cr}$: $\text{L} = \text{N}_3, \text{H}, \text{NEt}_2$ (Ref. 214); $\text{M} = \text{W}$, $\text{L} = \text{OMe}$ (Ref. 217)]. The subsequent transformations are accompanied by replacement of the carbonyl group and yield either $[\text{M}(\text{CO})_5\text{L}]^-$ anions ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$; $\text{L} = \text{NCS}, \text{H}, \text{CN}, \text{Cl}, \text{Br}, \text{I}$) or neutral compounds $\text{M}(\text{CO})_5\text{L}$ ($\text{M} = \text{W}$: $\text{L} = \text{THF}, \text{NAlk}_3, \text{AlkCN}$).^{216, 218}

Group VII metals, $\text{Mn}, \text{Tc}^\ddagger$ and Re (with the electron configuration d^7), form stable binuclear carbonyls $\text{M}_2(\text{CO})_{10}$ with a closed 18-electron shell. Their redox disproportionation induced by Lewis bases (L) produces the $[\text{ML}_6][\text{M}(\text{CO})_5]_2$ salts ($\text{M} = \text{Mn}, \text{Re}$).^{219–221} The oxidation state of the metal in the pentacarbonylmetallate anions is -1 . In the case of manganese, the formation of complex salts $[\text{Mn}(\text{CO})_{6-n}\text{L}_n]^+[\text{Mn}(\text{CO})_5]^-$ [$n = 3$ or 6 ; L is pyridine (Py), amines, *etc.*] is possible.²²²

Stable binuclear $[\text{Co}_2(\text{CO})_8]$ and tetranuclear $[\text{Co}_4(\text{CO})_{12}]$ carbonyl complexes with 18-electron closed shells are typical of cobalt (the electron configuration d^9).^{223, 224} Their disproportionation induced by Lewis acids (L) generates the mononuclear $[\text{Co}(\text{CO})_4]^-$ anion.

The disproportionation of $\text{Co}_2(\text{CO})_8$ in the presence of pyridine may give also the trinuclear $[\text{Co}_3(\text{CO})_{10}]^-$ anion. Depending on the conditions, the counter-ions are represented by Co^+ and Co^{2+} complexes, such as $[\text{Co}(\text{CO})_4\text{Py}]^+$, $[\text{Co}(\text{CO})_4\text{Py}_3]^+$, $[\text{CoPy}_3]^{2+}$ and $[\text{CoPy}_4]^{2+}$ (Ref. 224).

The cobalt group metals, Rh and Ir , also form dimeric carbonyls $\text{M}_2(\text{CO})_8$; however these carbonyls are unstable and are converted into tetranuclear complexes, $\text{M}_4(\text{CO})_{12}$.^{209, 225} The clusters $\text{M}_6(\text{CO})_{16}$ are also known for rhodium and iridium.^{209, 225} The reduction of the carbonyls of these metals results in the formation of the mononuclear anion $[\text{M}(\text{CO})_4]^-$; however, the anionic Rh and Ir carbonylmetallate complexes usually exist as polynuclear clusters $[\text{M}_p(\text{CO})_q]^{n-}$ with the number of metal atoms $p \geq 5$ and the charge n ranging from -1 to -4 , for example, $[\text{M}_5(\text{CO})_{16}]^-$, $[\text{M}_6(\text{CO})_{16}]^{2-}$, $[\text{Ir}_{12}(\text{CO})_{26}]^{2-}$, $[\text{Rh}_{22}(\text{CO})_{37}]^{4-}$ and $[\text{Rh}_{26}(\text{CO})_{32}]^{2-}$ (Refs 204, 209, 225 and 226).

Iron (the electron configuration d^8) forms stable 18-electron carbonyls, $\text{Fe}(\text{CO})_5$, $\text{Fe}_2(\text{CO})_9$ and $\text{Fe}_3(\text{CO})_{12}$, and also a carbidocarbonyl cluster $\text{Fe}_5\text{C}(\text{CO})_{15}$. The redox disproportionation of iron carbonyls produces the salts of carbonylferrate or hydrocarbonylferrate anions with the number of iron atoms from 1 to 4 (see Introduction). Carbidocarbonyl anionic clusters $[\text{Fe}_5\text{C}(\text{CO})_{14}]^{2-}$ and $[\text{Fe}_6\text{C}(\text{CO})_{16}]^{2-}$ are formed in the reactions of iron carbonyls at temperatures around 150°C .^{204, 227} These clusters contain the largest number of iron atoms. The redox transformations of these compounds produce complexes with fewer number of iron atoms.⁷⁸

The iron group metals, Ru and Os , have a larger atom size and produce stable trinuclear carbonyls $\text{M}_3(\text{CO})_{12}$, while mononuclear pentacarbonyls of these atoms $\text{M}(\text{CO})_5$ are unstable. The redox disproportionation of $\text{Ru}_3(\text{CO})_{12}$ under the action of KOH produces the $[\text{HRu}_3(\text{CO})_{11}]^-$ and $[\text{Ru}_6(\text{CO})_{18}]^{2-}$ anionic complexes,²²⁸ and its pyrolysis gives the $\text{Ru}_6\text{C}(\text{CO})_{17}$ cluster.²⁰⁹ The thermal destruction of $\text{Os}_3(\text{CO})_{12}$ yields new polynuclear

carbonyls, $\text{Os}_5(\text{CO})_{16}$, $\text{Os}_6(\text{CO})_{18}$, $\text{Os}_7(\text{CO})_{21}$ and $\text{Os}_8(\text{CO})_{23}$.²⁰⁹ The polynuclear anionic clusters of Ru and Os , for instance $[\text{Ru}_{10}\text{C}_2(\text{CO})_{24}]^{2-}$ and $[\text{Os}_{10}\text{C}(\text{CO})_{24}]^{2-}$, are also known (Refs 204, 228 and 229).

Generally, the anionic carbonyl clusters of platinum group metals are able to combine into polynuclear clusters with larger number of metal atoms, up to several dozens or even hundreds. The resulting clusters have a metal core like a crystal lattice with a 'coat' of CO ligands at the surface. This seriously hinders the determination of their structure, because during the X-ray study of such clusters the localisation of carbonyl ligands and determination of their number is problematic due to high absorption of X-rays and strong scattering by metal atoms.²⁰⁴ Besides, the '18-electron configuration rule', which is valid for mono- and polynuclear complexes of transition metals, does not work for large clusters. The stable forms of these structures are described in terms of the concept of cluster valence electrons (CVE) and cluster core electrons (CCE), which are directly involved in the metal–metal bonding.²⁰⁴

Thus, the disproportionation of Group V–VII metals and Fe or Co , which belong to Group VIII of Period 4 of the Periodic Table, produces either stable mononuclear carbonyl complexes or clusters of few metal atoms. Polynuclear cluster structures are more typical of carbonyls of platinum Group VIII metals of Periods 5 and 6.

The reducing ability of metal carbonyls is an important factor, affecting the rate of the redox disproportionation induced by Lewis bases. This ability is determined by the single-electron reduction potential (E_{red}°). There are some difficulties in measuring E_{red}° , caused by chemical transformations of carbonyl complexes during electrolysis. The initially formed electron-rich radical anion of a metal carbonyl tends to transform into an electron-deficient one (transition $19e \rightarrow 17e$) by elimination of CO or by breaking of the metal–metal bond. More energetically favourable radical anion is formed in the former case. The unpaired electron of this radical anion is located in the highest occupied molecular orbital, which is lower than the lowest unoccupied molecular orbital bearing the unpaired electron of the initial 19-electron radical anion. The breaking of the metal–metal bond may be accompanied either by a decrease in the number of metal atoms in the complex or by rearrangement of the cluster core. For example, the initial 19-electron radical anions $[\text{Mn}_2(\text{CO})_{10}]^{\cdot -}$ and $[\text{Co}_2(\text{CO})_8]^{\cdot -}$ decompose quickly into 18-electron anions $[\text{Mn}(\text{CO})_5]^-$ and $[\text{Co}(\text{CO})_4]^-$ and 17-electron radicals $[\text{Mn}(\text{CO})_5]^\cdot$ and $[\text{Co}(\text{CO})_4]^\cdot$ respectively.^{134, 222, 224, 230, 231} The latter are then easily reduced to the corresponding anions, because their reduction potentials are less negative.²³² As a result, the two-electron reduction of the starting metal carbonyl takes place; in this process, the electrochemical stages are accompanied by a chemical reaction (ECE mechanism).²³³

The two-electron reduction in the ECE-reactions is also typical of $\text{Fe}(\text{CO})_5$ (see Section V, Fig. 1 and its caption) and for Group VI metal carbonyls $\text{M}(\text{CO})_6$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) [reactions (45)–(48)]. In these cases, as in the previous example, the reduction potential of the formation of binuclear complexes at the second electrochemical stage (48) is less negative than the potential of stage (45).^{43, 234}

[†] The chemistry of the carbonyl complexes of radioactive technetium is barely known. Only the reduction of $\text{Tc}_2(\text{CO})_{10}$ to $[\text{Tc}(\text{CO})_5]^-$ is described.²¹⁹

Another interpretation of this process with the same final product, instead of stages (47), (48), includes further reduction of $[\text{M}(\text{CO})_5]^{-\bullet}$ to $[\text{M}(\text{CO})_5]^{2-}$ and either the reaction of the latter with the starting complex $\text{M}(\text{CO})_6$ ($\text{M} = \text{Cr}$)⁴³ or its dimerisation, resulting in the formation of $[\text{M}_2(\text{CO})_{10}]^{2-}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$).⁴⁰ However, irrespective of the possible reaction pathway, the two-electron potential of the ECE process may be regarded, with some restrictions, as the potential of single-electron reduction of the metal carbonyl. The ECE process includes fast chemical transformations and the diffusion-controlled first stage [reaction (45)] with the most negative reduction potential.

In some cases, when relatively stable radical anions, *e.g.* $[\text{Fe}_3(\text{CO})_{12}]^{-\bullet}$, are formed, it is possible to determine two consecutive single-electron reduction potentials (Table 2).^{37–39}

Table 2. Reduction potentials of metal carbonyls.

Starting complex	Product	Potential /V (method) ^a	Number of electrons ^b	Ref.

^aThe determination method is either the cyclic voltammetry (C) or polarography (P). ^bThe number of electrons, which determines the character (one- or two-electron) of the reduction potential, is indicated. The question mark means that the authors doubt the reliability of the value.

The reduction potentials listed in Table 2 were measured by different methods and under different conditions. These potentials describe the ECE processes, which are irreversible in some cases, but on the basis of these data, some qualitative conclusions about the ability of a carbonyl complex to undergo Lewis base-induced redox disproportionation may yet be drawn. The complexes $\text{M}(\text{CO})_6$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$), possessing the most negative reduction potentials, are difficult to disproportionate. Therefore, the processes in which metal carbonyls reduce, for example, organic compounds are typical of the carbonyls of these metals. These complexes are used as the initiators of radical addition reactions, the olefin telomerisation with haloalkanes and the

reduction of polychlorinated compounds.^{166–171, 238} Their transformations in the presence of Lewis bases may be described by reactions (49)–(54) similarly to reactions (37), (38) and (1), (2), (5) for $\text{Fe}(\text{CO})_5$.

$\text{M} = \text{Cr}, \text{Mo}, \text{W}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$; L is a Lewis base.

The radicals $\text{M}(\text{CO})_5\text{Cl}^{\bullet}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$), detected by the spin trap method, may be regarded as a proof for the suggested scheme.^{99, 166, 168, 169, 171, 238} Other metal carbonyls possessing low reduction potentials such as $\text{Re}_2(\text{CO})_{10}$, $\text{Mn}_2(\text{CO})_{10}$, $\text{Ni}(\text{CO})_4$, are also used as the initiators of similar reactions.^{166–171, 238, 239} In the case of binuclear complexes $\text{Re}_2(\text{CO})_{10}$, $\text{Mn}_2(\text{CO})_{10}$ and $\text{Co}_2(\text{CO})_8$, the initiation may proceed as a result of photolytic generation of monomeric radicals $[\text{M}(\text{CO})_5]^{\bullet}$ ($\text{M} = \text{Re}, \text{Mn}$) and $[\text{Co}(\text{CO})_4]^{\bullet}$, respectively.

The metal carbonyls possessing high reduction potentials, *e.g.*, $\text{V}(\text{CO})_6$, $\text{Co}_2(\text{CO})_8$ and $\text{Fe}_3(\text{CO})_{12}$, disproportionate easily. It is reasonable to suggest that this process proceeds according to a scheme similar to that proposed for iron carbonyls [see Section III, reactions (1)–(4)]:

The formation of the adducts $[\text{M}_n(\text{CO})_{m-1}\text{C}(\text{O})\text{L}]^{0/-}$ (see §) in the reactions of metal carbonyls with Lewis bases in the neutral (L^0) or anionic (L^{-}) form [reaction (55)] is well known and has been discussed in a review.⁸⁴ The higher is the reduction potential of the complex, the easier is the redox disproportionation according to equation (56). The detection of carbonyl radical anions in these processes is difficult due to their low stability, although they are known for most metal carbonyls. For instance, the $[\text{Ni}(\text{CO})_3]^{-\bullet}$ (Ref. 240), $[\text{Ni}_2(\text{CO})_7]^{-\bullet}$ (Ref. 241) and $[\text{M}(\text{CO})_5]^{-\bullet}$ ($\text{M} = \text{Cr},^{43, 241} \text{Mo}, \text{W}^{242}$) radical anions and the $[\text{M}(\text{CO})_5]^{\bullet}$ ($\text{M} = \text{Mn}, \text{Re}$)^{243–245} and $[\text{Co}(\text{CO})_4]^{\bullet}$ (Ref. 232) radicals formed upon decomposition of the $[\text{M}_2(\text{CO})_{10}]^{2-}$ and $[\text{Co}_2(\text{CO})_8]^{-\bullet}$ radical anions respectively, have been studied.

The $[\text{Ru}_3(\text{CO})_{12}]^{-\bullet}$ radical anion was detected in the reaction of $\text{Ru}_3(\text{CO})_{12}$ with anionic forms of bases: HO^{-} , MeO^{-} , EtO^{-} , EtS^{-} , Et_2N^{-} , H^{-} and Cl^{-} (Ref. 78). Taking into account the fact that the first stage of this reaction yields the $[\text{Ru}_3(\text{CO})_{11}\text{C}(\text{O})\text{L}]^{-}$ anion,⁸⁷ the scheme of single-electron redox disproportionation may be represented by reactions (57) and (58).

The CO group of the $[\text{Ru}_3(\text{CO})_{12}]^{-\bullet}$ radical anion may be substituted by another ligand (ETC process), similarly to the substitutions in iron carbonyl radical anions [see Scheme 5 and reactions (30), (31) and (33)], as occurs, for example, in the electrochemical generation of this species in the reactions of $\text{Ru}_3(\text{CO})_{12}$ with PPh_3 .²³⁶ The only difference is in the method of generation of the radical anion. This scheme describes well the

§ The superscript after the slash indicates the alternative charge.

nature of the catalytic action of various Lewis bases in the substitution of CO by phosphine ligands, which was studied in a series of papers.^{246–250} The catalytic activity of the $\text{Ru}_3(\text{CO})_{12}-\text{Et}_4\text{NCl}$ system in the reductive carbonylation of nitro compounds²⁵¹ may also be related to the generation of the radical anion $[\text{Ru}_3(\text{CO})_{12}]^{\cdot-}$, which is a total analogue of ICRA, which are the catalysts of these processes (see Section VIII).

An important feature of the $\text{Ru}_3(\text{CO})_{12}$ complex should be noted: the main products of its reactions with such Lewis bases as halide ions are trinuclear complexes with halide ligands, and the yield of the (hydrido)carbonylruthenate anions is negligible.^{246, 248, 249} Probably, this is caused by the fact that the rearrangement of the radical product $[\text{Ru}_3(\text{CO})_{11}\text{C}(\text{O})\text{L}]^{\cdot}$ is accompanied by ETC process and, similarly to $\text{Fe}_3(\text{CO})_{12}$ [see reactions (34)–(36)], may be represented by the following equations:

Taking into account reaction (57), in the overall process, a significant part of reactants is converted into the final product $[\text{Ru}_3(\text{CO})_{11}\text{L}]^-$. The role of the single-electron transfer (58) in this process is reduced to the initial generation of the $[\text{Ru}_3(\text{CO})_{11}\text{C}(\text{O})\text{L}]^{\cdot}$ radical. Reactions (59) and (60) describe the formation of a possible product, $[\text{Ru}_3(\text{CO})_{11}\text{L}]^-$. Other products, $[\text{Ru}_3(\mu_2\text{-L})(\text{CO})_{10}]^-$ ($\text{L} = \text{Cl}, \text{Br}, \text{I}$) and $[\text{Ru}_3(\mu_3\text{-L})(\text{CO})_9]^-$ ($\text{L} = \text{I}$),²⁴⁸ are produced upon the subsequent transformation of the ligand L in the coordination sphere of the radical $[\text{Ru}_3(\text{CO})_{11}\text{L}]^{\cdot}$ followed by reduction.

The more negative is the reduction potential of a metal carbonyl, the less important are the processes of its redox disproportionation induced by Lewis bases. For instance, for the $\text{M}(\text{CO})_6$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$),^{214, 217} the formation of the carbonyl group adducts $[\text{M}(\text{CO})_5\text{C}(\text{O})\text{L}]^-$ and their transformation into $[\text{M}(\text{CO})_5\text{L}]^-$ may be represented by reactions (57)–(60). In these reactions, thermodynamically the most unfavourable redox stage (58) is the first stage of the process initiation.

Whereas for metal carbonyls with the most negative reduction potentials the transformations of M^+ complexes formed at the redox disproportionation step of process (58) are typical, in the case of complexes with higher reduction potentials, the transformations of the $\text{M}(0)$ derivatives become more significant. The reaction of $\text{Co}_2(\text{CO})_8$ with ligands L ($\text{L} = \text{AsPh}_3, \text{PBu}_3, \text{PPh}_3, ^{13}\text{CO}$) is an example of such transformation. The initiation of the reaction of the starting metal carbonyl by a base first produces the $[\text{Co}_2(\text{CO})_8]^{\cdot-}$ radical anion [reactions (55) and (56)]; its further transformations proceed as follows:²³¹

Substituted cobalt carbonyls $\text{Co}_2(\text{CO})_7\text{L}$ ($\text{L} = \text{AsPh}_3$), $\text{Co}_2(\text{CO})_6\text{L}_2$ ($\text{L} = \text{AsPh}_3, \text{PBu}_3$) and the ionic complex $[\text{Co}(\text{CO})_3\text{L}_2][\text{Co}(\text{CO})_4]$ ($\text{L} = \text{PBu}_3, \text{PPh}_3$) are the final products of the radical chain process. Similar radical chain substitution of CO by various basic ligands during photochemical disproportionation of $\text{Mn}_2(\text{CO})_{10}$ has been described.²³⁰

Thus, the reactions of metal carbonyls with Lewis bases may be represented by a single scheme of redox disproportionation. This scheme includes the stage of activating complex formation (55) followed by single-electron transfer from a carbonyl complex

activated by an electron donor to another metal carbonyl molecule. The radical and radical ion complexes formed at stage (56) may undergo two types of transformations: (i) further disproportionation yielding stable cationic metal complexes containing Lewis bases in the coordination sphere and (hydrido)carbonylmethylate anions; (ii) radical chain ETC processes, resulting in the formation of diamagnetic derivatives of metal carbonyl complexes with initial oxidation state of the metal $\text{M}(0)$.

XI. Conclusion

Two types of redox reactions underlie catalytic carbonylation of various compounds by iron carbonyls. The first type is the redox disproportionation of iron carbonyl induced by Lewis bases (see Section III), while the second type is the oxidative addition of the Brønsted or Lewis acids to carbonylferrate and hydridocarbonylferrate anions (see Section IV). The reactions of both types include single-electron stages of redox initiation and subsequent radical chain transformations of iron carbonyl complexes. The resulting iron carbonyl radical anions are coordinatively unsaturated electron-deficient systems with labile coordination sphere, capable of the fast ligand and electron exchange. These particular properties allow one to suggest that ICRA are the catalytically active species in carbonylation processes (see Section VIII). It is very important to note that a catalytic cycle with radical anions as catalysts is based on the transformations which include consecutive formation of the odd-electron complexes ($17e \rightarrow 19e \rightarrow 17e$), the whole process having a radical chain character. This scheme uncontradictorily describes from a unified standpoint the two-electron redox processes of iron carbonyls and explains the formation of all known reaction products. Besides, this scheme is able to interpret the main chemical transformations of other metals carbonyls, to suggest new promising catalytic systems for carbonylation and to propose the optimal conditions for homogeneous catalysis (the heterogeneous catalysis is beyond the scope of the present review).

Mononuclear complexes and small clusters are effective homogeneous catalysts of various processes with CO participation. It is advisable to use either carbonyl complexes of the Period 4 transition metals, which do not form big clusters, or to use complexes with bulky substituents, which prevents the clusterisation of the platinum-group metals, such as, for example, the Wilkinson catalyst $[\text{RhCl}(\text{PPh}_3)_3]$ or the complex $\text{RhH}(\text{CO}).(\text{PPh}_3)_3$. These platinum group metal-based catalysts may be effectively applied in the small-scale organic synthesis of expensive chemicals,²⁵² but they are not cost-effective in the large-scale industrial processes. Moreover, in the course of the process the ligands in the metal coordination sphere may be replaced by molecules of the main process participants (in our case, CO). This results in the change in the catalytic system properties. The metal carbonyl-based complexes are suitable catalysts as they contain the ligands taking part in the catalysis. In this respect, the commercially available carbonyl complexes of Group VIII metals, namely, Fe, Co and Ni, are the most promising as catalysts. The cobalt carbonyl complexes are industrially important and used in hydroformylation.^{6, 12} Numerous studies of Fe and Ni carbonyl complexes have revealed their reduced catalytic activity in comparison with that of the platinum-group metal carbonyls in, for example, hydroformylation and water gas conversion^{6, 17} and in the reductive carbonylation of nitro compounds.²⁵³ A possible reason for such reduced activity may be the traditional approach towards the catalytic processes with participation of metal carbonyls, according to which they are carried out under the conditions similar to those of their synthesis (high pressure and temperature). Assuming that in the case of Fe and Ni, the metal carbonyl radical anions are the catalytically active species in carbonylation, it is possible to suggest that the optimal conditions for their catalytic activity will be controlled reduction potential of the medium and also relatively low temperature and a nearly

atmospheric CO pressure. This results in a new approach to catalytic carbonylation processes, namely, the idea to carry out the process under conditions favourable for chain propagation reactions rather than under the traditional conditions involving high pressures and temperatures. The traditional conditions increase the role of chain termination reactions and decrease the catalytic activity of metal carbonyl radical anions.

The reduction potential of the reaction medium is an important condition for the formation of Fe and Ni carbonyl complexes from their inorganic salts. For instance, the following compounds were obtained at room temperature and atmospheric CO pressure: $\text{Na}_2\text{Fe}(\text{CO})_4$ from FeCl_3 and $[\text{Na}^+(\text{C}_{10}\text{H}_8)^-]^-$;²⁵⁴ $[\text{HFe}(\text{CO})_4]^-$ from FeCl_3 and NaBH_4 upon acetic acid treatment;²⁵⁵ $\text{Ni}(\text{CO})_4$ from $\text{Ni}(\text{acac})_2$ (acac is acetylacetonate) upon reduction with Bu_2AlH , Bu^nLi or Pr^nMgBr ;²⁵⁶ $\text{Ni}(\text{CO})_2(\text{bipy})$ (bipy is bipyridyl) upon electrochemical reduction of $[\text{Ni}(\text{bipy})]^{2+}$ (Ref. 257). It should also be noted that the catalytic synthesis of ammonia from N_2 and H_2 (using the coal-supported $\text{K}_2\text{Fe}(\text{CO})_8$ – metallic sodium system²⁵⁸ as a catalyst), quite similar to carbonylation, also proceeds in reductive media.

It is necessary to note the second important aspect of the catalytic processes, namely, that they follow a radical chain mechanism proceeding through the $17e \rightarrow 19e \rightarrow 17e$ complexes. Similar radical reaction schemes were discussed in the late 1970s,^{259,260} but this idea has not been generalised and was regarded as a specific case. The traditional approach, which describes the process in usual terms of the Tolman rule about 16-electron intermediates, has prevailed. However, the latest studies attest more and more often to the radical chain mechanism as the major one for such catalytic processes. For example, the electrochemical studies of very well known complexes, the Wilkinson catalyst and $\text{RhH}(\text{CO})(\text{PPh}_3)_3$, have revealed that they easily form radical cations ($E_{1/2\text{ox}} = +0.035 \text{ V}$, Ref. 261, and $E_{1/2\text{ox}} = -0.48 \text{ V}$, Ref. 262, respectively). This means that, according to the Nernst equation, the radical cation concentration in a catalytic process may reach tens of percent even when the electrochemical potential of the reaction medium is close to neutral. The role of such active species must be taken into account.

Thus, the features of the radical chemistry of iron carbonyls discussed in the present review provide new opportunities in the search for effective catalysts for metal carbonyl-based carbonylation processes and in carrying out these processes as radical chain ones with odd-electron (17 and 19) intermediates and under the controlled electrochemical potential of the reaction media.

Abstract. Experimental probe methods for investigation of the free volume in polymers (positron annihilation lifetime spectroscopy, ^{129}Xe NMR spectroscopy and inverse gas chromatography) and relevant theoretical approaches (computer simulation) are considered. Various definitions of the free volume and related terms are given. The physical principles that underlie particular probe methods as well as the scope and limitations of each method are discussed. A systematic comparison of the size of free-volume elements in polymers determined by different methods is carried out. The bibliography includes 175 references.

I. Introduction

The notion of the free volume is of paramount importance for physical chemistry of polymers. Being initially formulated for liquid state,¹ it was extended to amorphous polymers that are either above or below the glass transition temperature (T_g).^{2–5} The free volume in polymers determines their viscosity, relaxation and mechanical properties (deformation), thermal expansion, as well as the rates of interdiffusion of polymers and diffusion of low-molecular-mass species (gases and vapours) in polymers. Considering the free volume in polymers, one should keep in mind that this is not only an abstract physical parameter (although it can of course be described quantitatively), but also a real physical object characterised by an average size and shape of the ‘hole’ (a free-volume element, FVE), FVE size distribution, topology and connectivity (closed or open internal porosity). The FVE in glassy polymers are treated as ‘frozen’ in the polymer matrix. For rubbers, where the free volume has a fluctuation nature like in liquids, both the size of randomly formed FVE and the rate of their diffusion in the polymer matrix are essential.

The early phenomenological models treated the free volume as an abstract notion not related to the chemical structure and geometry of constituting polymeric chains. At temperatures

above T_g , one can distinguish, in the free volume, the ‘hole’ component characterised by zero energy expenditure for redistribution (*i.e.*, motion) of FVE and the interstitial component that becomes accessible to transport owing to energy fluctuations greater than kT . At temperatures below T_g , yet another component of the free volume appears corresponding to the nonequilibrium thermodynamic state of glassy polymers.^{4,5}

Elaboration of additive incremental (group contribution) methods for inclusion of the effect of the chemical structure of polymers on their properties became an important step towards establishment of relations between the free volume and physical properties of polymers. These methods were developed to correctly estimate the occupied volume in the polymer, which makes it possible to calculate the macroscopic free volume using the van der Waals atomic radii and particular concepts of chain packing in polymer.^{6–8} Here, the calculated free volume is considered as the property of solely the polymer; however, only a fractional free volume ‘sensed’ by different molecular probes can be estimated.⁹ This group of methods is useful for constructing correlations between the free volume and various characteristics of polymers (*e.g.*, gas diffusion and permeability coefficients), but their analysis is beyond the scope of the present review because our goal is to consider methods for investigation (first of all, experimental) of the free volume on the microscopic (molecular) level.

In connection with the development of methods of computer simulation of polymers, the fractional free volume and related notions had to be redefined more rigorously.^{10,11} These methods treat polymeric chains as consisting of rigid atomic spheres with the corresponding van der Waals radii. The occupied volume (V_{oc}) is the total volume of the polymeric chains in the region under study. The unoccupied volume (voids) is defined as the volume including all points lying outside the van der Waals atomic spheres that form the polymer. Thus, the specific volume (V_{sp}) of the polymer can be represented by the sum of the occupied and void volume. Because free volume calculations are most often carried out in connection with analysis of gas diffusion, a very important notion ‘accessible volume’ (V_{ac}) was introduced. The accessible volume is the volume including the points that can be occupied by the centres of mass of penetrant molecules without overlap between the van der Waals volumes of the penetrant molecules and the atoms of the polymeric chains. Hence, it follows that the accessible volume is the property of the polymer–gas system, *i.e.*, V_{ac} in a given polymer will be considerably different for, *e.g.*, He and Xe atoms. It should be noted that the void volume is the

Received 7 February 2006

Uspekhi Khimii 76 (1) 66–87 (2007); translated by A M Raevskiy

property of each polymer. The accessible volume forms clusters in the interior of the polymer, the cluster size and geometry being significantly different for different penetrants.

Experimental investigations of the free volume in polymers are often carried out using probe methods. Common features of these techniques consist of introducing certain molecules (probes) into the polymer and monitoring their behaviour. The results of observations allow conclusions about the structure of the free volume to be drawn. These methods use probes of different nature and size and provide differently detailed information. For instance, in ^{129}Xe NMR spectroscopy the only probe (^{129}Xe atom) 'explores' the free volume in different polymers. In studies of polymers by positron annihilation lifetime spectroscopy (PALS), an electron-positron pair (positronium atom) serves as a probe. In inverse gas chromatography (IGC), the role of probes is played by series of structurally similar compounds.

The present review concerns the principles, fields of possible applications and results obtained by different probe methods of investigation of the free volume. The chemical formulae and names of the polymers mentioned in the text are listed in the Appendix.

II. Positron annihilation lifetime spectroscopy

Positron annihilation lifetime spectroscopy allows one to obtain information on the size, size distribution and concentration of free volume elements as well as on the effect of temperature, pressure, mechanical deformations and phase compositions of polymers on the free volume.^{12–15} This method makes it possible to follow changes in the free volume occurring in the course of physical ageing of polymers, as a result of sorption and swelling and during cross-linking. Parameters of positron annihilation lifetime spectra strongly depend on the polymer structure but only slightly depend on the molecular mass,¹⁶ which facilitates comparison of different polymers. In addition, these parameters are fairly reproducible in studies of different polymer samples and, as showed investigations carried out in different research laboratories, in the experiments with reference samples.¹⁷

The PALS method is based on measuring the positron lifetimes in matter. In polymers, positrons can exist in both free (e^+) and bound states, the latter being represented by H-like positronium atom, *i.e.*, an electron–positron pair (Ps or e^-e^+). The singlet state of this species, *p*-Ps, has antiparallel spins and a short lifetime (0.125 ns in vacuum), whereas the triplet state, *o*-Ps, with parallel spins has a much longer lifetime (142 ns in vacuum). It is believed that long-lived species, *o*-Ps, appear in the regions with reduced electron density (*i.e.*, in the FVE).^{18–20} Due to overlap between the wave functions of *o*-Ps and electrons of atomic groups that form the FVE walls, the *o*-Ps lifetimes become much shorter compared to annihilation in vacuum, lying usually in the range from 1.5 to 4.0 ns. The observed lifetimes depend on the FVE size, namely, the larger the FVE the longer the positron lifetime in the polymer. The lifetime spectrum is a set of experimental characteristic times τ_i (ns) and corresponding statistical weights or intensities I_i (%). It is assumed that the intensity of the positronium component depends on the concentration of FVE, although it can also be affected by other factors.

Usually, ^{22}Na isotope with a half-life time of 2.6 years serves as a source of positrons. Particles formed are characterised by energies distributed between zero and 0.540 MeV with a maximum at ~ 0.2 MeV and a mean free path of ~ 1 mm in conventional polymers. In matter, positrons are rapidly (within ~ 10 ps) thermalised and all subsequent processes involve particles with thermal energies.

An experimental setup for measuring positron annihilation lifetimes (see Fig. 1) consists of a source of positrons placed between two samples of the polymer under study (a plate, a stack of films or a powder). The lifetimes are measured using an electronic system (time–amplitude converter). The circuit measures the time interval between two events, namely, the appearance

Figure 1. Scheme of a setup for measuring positron annihilation lifetime spectra.

of primary γ -quanta from the source and the appearance of quanta that accompany positron annihilation. Once detected a total of 10^5 – 10^7 events by a photomultiplier, an experimental positron lifetime distribution curve $y(t)$ is plotted, which shows the number of events y as function of the time elapsed t (Fig. 2).

Figure 2. Typical experimental positron annihilation lifetime distributions of various polyimides.²¹

The primary experimental dependences $y(t)$ can be interpreted in the framework of analysis based on a discrete or continuous model. In the former case, the $y(t)$ curve is represented by the sum of several exponents

$$I_i \lambda_i \exp(-\lambda_i t), \quad (1)$$

where I_i is the intensity (in %) and $\lambda_i = 1/\tau_i$ (in ns^{-1}) is the annihilation rate. The number of exponents n is set in such a manner that the deviation from the experimental $y(t)$ curve be minimum. Traditionally, it is assumed that $n = 3$, although for many polymers studied recently one has $n > 3$. The first two spectral components τ_1 and τ_2 (times ~ 0.1 – 0.2 and ~ 0.3 – 0.5 ns, respectively) are due to annihilation of *p*-Ps and the free e^+ , being not related to probing of the free volume in polymers. At the same time, the 'long-lived' components τ_i ($i = 3$ or 4) are due to annihilation of *o*-Ps located within the FVE. It is analysis of these spectral components that forms the basis for the use of PALS as probe method. Discrete analysis of primary data is performed using different programmes, *e.g.*, PATFIT.²² Continuous data analysis using the CONTIN^{23,24} or MELT²⁵ programmes gives the probability density function of positron annihilation characterised by a given lifetime in the polymer.

Figure 3. Correlation between positronium lifetime and average FVE radius in polymers according to the Tao–Eldrup relationship.

Here, the number of components in the lifetime spectrum is chosen by the programme automatically.

A semiempirical expression relating the lifetime of *o*-Ps (τ_3) to the average radius (R_3) of a spherical FVE in a polymer (the Tao–Eldrup relationship)^{19,20} has the form

$$\tau_3 = \frac{1}{2} \left[1 - \left(\frac{R_3}{R_0} \right) + \frac{1}{2\pi} \sin \left(\frac{2\pi R_3}{R_0} \right) \right]^{-1}, \quad (2)$$

where $R_0 = R_3 + \Delta R$ (the fitting parameter $\Delta R = 1.66$ Å was determined from analysis of the data for media with the known ‘hole’ size including zeolites). The FVE radii increase almost linearly as τ_3 increases (see Fig. 3).

A similar relationship is used in the case of several lifetimes of *o*-Ps. Assuming spherical geometry and a known radius, the FVE volume (v_f) or the volume distribution are found

$$v_f = \frac{4\pi}{3} R_3^3.$$

The assumption of spherical geometry of FVE in polymers seems to be somewhat incorrect (see Section VI). Cylindrical and ellipsoidal FVE were also considered and the corresponding relations for calculating the FVE volumes from the known *o*-Ps lifetimes are available in the literature.^{26–29} However, most probing studies of free volume in polymers were carried out using the Tao–Eldrup relationship.

Variations of the free volume in polymers can be illustrated by the data listed in Table 1. Here, the polymers are arranged in almost the same order as the gas permeability and radius R_3 increase. The barrier materials (*e.g.*, Vectra copolyester) are characterised by the smallest size of FVE. As the gas permeability increases, the lifetimes of *o*-Ps and the FVE size increase. It was established (see, *e.g.*, Ref. 33) that the conventional glassy polymers have a monomodal size distribution of FVE (*i.e.*, the *o*-Ps lifetime spectrum includes one time τ_3) and the lifetime distribution can be represented by Gaussian peaks when analysing the data using the CONTIN programme. However, statistical processing of spectra reveals bimodal lifetime and FVE size distributions that appear starting with particular free volume and gas permeability values (Fig. 4). For instance, the long-lived components in the lifetime spectra of PVTMS and certain relatively high-permeability polyimides³⁶ have a ‘shoulder’ or superposition of two Gaussian peaks, whereas two *o*-Ps lifetimes appear, namely, τ_3 and τ_4 (see Fig. 4) for polymers with even greater permeabilities. When treated with the CONTIN programme, maxima in the curves coincide with the lifetimes obtained by discrete processing of the primary data. Bimodal (or even polymodal) FVE size distributions were found in numerous studies of highly permeable polymers.^{37–42} Note that the average FVE size and the size distribution determined from PALS data are consistent with the data obtained by other probe methods and with the results of

molecular dynamics (MD) simulation of the free volume in polymers (see Sections IV and VI).

Free volume elements of even larger sizes were found in polymeric sorbents and organic clusters. In particular, PALS data showed that hypercross-linked polystyrene sorbents contain cavities with a radius of 14 Å and their content is ~20% of the total number of FVE in the material.^{43,44} A cluster prepared by the reaction of terephthalic acid with chromium nitrate, hydrogen fluoride and water has pores ~3 nm in diameter and a specific surface area of 5900 m² g⁻¹ (Ref. 45). This is much larger than the maximum specific surface area in zeolites. Even larger cubic cavities (volume is ~8000 Å³) were identified in the crystal lattice of a phthalocyanine macrocycle.⁴⁶ Similar cavities probably form an open system of pores, which is important, in particular, for separation processes in membranes.

Thus, the PALS technique provides a microscopic description of the free volume in terms of the average FVE radii and corresponding volumes v_f . To relate these parameters to macro-

scopic characteristics of polymers, one should know the average FVE concentrations N (cm^{-3}) and then estimate the fractional free volume (FFV) as the product $v_f N$. This can be done using various approaches.

According to the simplest early models,^{32, 47, 48} the intensity I_3 was assumed to be proportional to N . Then, if we know the coefficient of proportionality, A , from independent data, the concentration N is given by

$$N = AI_3,$$

and therefore one gets

$$\text{FFV} = AI_3 v_f.$$

However, a more correct treatment showed that the intensity I_3 also depends on the probability of o -Ps formation, trapping rate of o -Ps by FVE and on the 'decay' of positronium under the action of polar groups (e.g., C=O groups in imidazole rings of polyimides).³⁵ Because of this, the simple model mentioned above is no longer used. A number of more reliable methods of determination of the parameter N were developed.

1. The temperature dependences of τ_3 and FVE volume are very similar to the classical dilatometric curves for polymers, i.e., the temperature dependences of the specific volume that determine the volumetric expansion coefficients of polymers. However, there is a significant quantitative difference between these dependences. Namely, the thermal expansion coefficients of a polymer (i.e., its specific volume) below and above T_g (α_g , α_r) are of the order of 10^{-4} K^{-1} , whereas the thermal expansion coefficients of the free volume (α_{hg} , α_{hr}) are an order of magnitude larger. A natural explanation for this fact is as follows: the α_g and α_r values characterise the thermal expansion of both the FVE and the more dense matrix (walls surrounding the FVE). By comparing the temperature dependences of the specific volume V_{sp} and τ_3 (or v_f) one can choose N values suitable for both dependences, i.e., one can determine the parameter N .^{49–52} Recently, this approach was systematically used for estimating the concentration N in various amorphous polymers.^{49, 53, 54} It was shown that in most cases the concentrations N depend only slightly on the chemical structure of polymers and their values lie in the range $(2–8) \times 10^{20} \text{ cm}^{-3}$ at $T = T_g$ and show a relatively weak temperature dependence.

2. The N values can also be determined from PALS data obtained in studies of gas sorption by polymers. The time τ_3 is shortened upon gas sorption. This can be interpreted as a result of selective sorption by FVE of different sizes. Because the amount of gas molecules sorbed by polymers in the course of sorption experiments under different conditions is known, Kirrheim and co-workers⁵⁵ postulated different types of FVE size distributions and estimated the N values that are consistent with the dependences $\tau_3(p)$ and $I_3(p)$, where p is the pressure. However, the N values for polycarbonate and tetramethylpolycarbonate lie in the range $(2–4) \times 10^{21} \text{ cm}^{-3}$ and seem to be overestimated. Indeed, they correspond to the situation where the fractional free volume in these polymers is from 30% to 100%. Here, the polymer volume per FVE should be 200 \AA^3 , which corresponds to a cube with a nearly 6 \AA -edge. With allowance for the average FVE diameter this means that the neighbouring FVE should nearly contact one another, thus indicating an open porosity, which does not occur in these polymers. An attempt to estimate the parameter N from the results of sorption experiments gave a more realistic value of $4 \times 10^{20} \text{ cm}^{-3}$ for three polycarbonates.⁵⁶

3. Yet another method of estimation of the N value is based on detailed analysis of the kinetics of formation and annihilation of o -Ps in polymers.^{57, 58} According to this approach, only a fraction of positrons that form o -Ps contributes to the long-lived component of the PAL spectrum. Therefore, the intensities I_3 and I_4 should depend not only on N , but also on the probability of trapping of o -Ps by FVE. The trapping rate is given by equation

$$v_i^t = 4\pi D_{Ps} R_i N_i \quad (i = 3, 4), \quad (3)$$

where D_{Ps} is the diffusion coefficient of non-localised o -Ps and N_i is the concentration of a particular type of traps (FVE) of radius R_i .

To determine N_i , one should know the coefficient D_{Ps} from independent data. The D_{Ps} estimates available in the literature³¹ lie in the range $(0.5–15) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$. Probably, the value $D_{Ps} = 1.3 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ obtained for polyimides⁴⁹ is the most reliable, because it is consistent with the N values determined from the temperature dependence of τ_i below and above T_g . Of course, one should also know how the coefficient D_{Ps} varies for different polymers. Analysis of the D -vs.- d^2 dependences (D is the diffusion coefficient of molecules with the gas-kinetic diameter d lying between 2.5 and 4 \AA) for different polymers showed that extrapolation to the o -Ps size ($\sim 1 \text{ \AA}$) gives the diffusion coefficients that fall in a relatively narrow range of one decimal order of magnitude.

The concentration N in partially crystalline polymers can be estimated from the densities of polymers of different crystallinity.⁵⁹ Assuming that the specific volume of the crystalline phase equals the occupied volume, one can determine the fraction of the specific volume of the amorphous phase h . Then N is given by

$$N = \frac{h}{v_h}, \quad (4)$$

where v_h is the average FVE volume found from PALS data.

At last, the N values for polymeric sorbents and some high-permeability open-pore polymers can be estimated from joint analysis of the annihilation parameters and pore size distribution obtained according to Brunauer–Emmet–Teller.⁴³

An indirect estimate of N can be obtained using the average size of FVE in polymers. The average volume of the polymer matrix per FVE in a polymer should be much larger than the FVE volume. Assuming that the specific volume of the polymer is about $1 \text{ cm}^3 \text{ g}^{-1}$ and N is nearly $\sim 10^{20} \text{ g}^{-1}$ (or $\sim 10^{20} \text{ cm}^{-3}$), one gets the volume per FVE $v = 10^4–10^3 \text{ \AA}^3$. This corresponds to a cube with a $20–10 \text{ \AA}$ -edge. The average diameter of FVE in polymers is $\sim 5–13 \text{ \AA}$; therefore, one can conclude that the average distance (k) between neighbouring FVE is 5 to 10 \AA . At much smaller k values, the regularities of gas transport in polymers will be similar to those in porous media, which contradicts the majority of experimental data. At $N > 10^{21} \text{ cm}^{-3}$, the parameter k should take negative values. Note also that the k values determined are in good agreement with the diffusion jump lengths of gas molecules in polymers estimated using the Meares model.⁶⁰ The values of N obtained by different methods for different polymers are listed in Table 2.

Table 2. FVE concentrations in different polymers according to PALS data.

Polymer	$10^{-20} N / \text{cm}^{-3}$	Ref.
PE	6–8	59
Polyolefins	5	61
EVA	6, 7	62
Rubbers	2–6	52

	4	56
PVTMS, PTMSP, AF2400, AF1600, PTMSS, etc.	6–15	35, 49
Poly(ether imides)	4–8	49

Thus, the PALS technique allowed one to obtain a fundamental result, namely, the FVE concentration in all polymers lies in a narrow range from 10^{20} to 10^{21} cm^{-3} .

1. Free volume in thin films and on the surface of solids

Traditionally, the PALS method is used in studies of the free volume inside a polymer matrix. However, there is a variety of objects [free thin polymer films (membranes), coatings on the surface of various materials, *etc.*] for which the surface rather than bulk properties of polymers are important. Glass transition temperature,^{63,64} density,^{65,66} chain mobility and some other characteristics⁶⁷ of polymers measured for the bulk phase (polymer matrix) and at interfaces can be significantly different.

Positrons used in traditional version of the PALS technique have an average energy of 200 keV and a braking distance of ~ 1 mm. The latter value is several orders of magnitude larger than the characteristic thickness of surface layers; therefore, the positron lifetimes in PALS experiments contain information on the free volume in the matrix. Studies of the free volume in near-surface layers require that the positron beam energy be much lower than 200 keV (positrons should not penetrate into the interior of the sample and annihilate in the near-surface layers). The development of monochromatic low-energy positron beam techniques⁶⁸ with much lower controllable positron energies (0.2–20 keV) made it possible to probe the free volume in thin polymer layers (of the order of a few nanometres) and to plot the corresponding free volume profiles.

The surface layers at polymer–vacuum interfaces have been best studied,^{69,70} whereas investigations at the polymer–polymer interface are less detailed.⁷¹ As the positron energy decreases, the *o*-Ps lifetimes (τ_3) in different glassy polymers [an epoxide copolymer, polystyrene, poly(methyl methacrylate)] increase compared to the lifetimes measured in conventional PALS experiments where the depth of position penetration is larger.^{69,70,72,73} Taking into account the Tao–Eldrup relationship, this suggests an increase in the size of FVE in the near-surface layers. Using the density profile, it was shown⁷¹ that there is a variable-density layer 30–40 Å thick near the interface where the size of FVE does increase. The FVE size distribution is broadened near the polymer–vacuum interface.⁷⁰ An unexpected result was obtained for polystyrene, namely, a bimodal positron lifetime distribution with τ_4 values lying in the interval from 8 to 14 ns was revealed,^{71,72} which corresponds to FVE size from 5.7 to 6.2 Å and exceeds considerably the size of FVE in polystyrene matrix. However, it cannot be ruled out that we deal with an artifact due to superposition with positron annihilation in vacuum characterised by much longer Ps lifetimes.

Yet another observation has no reasonable explanation so far. In addition to a very thin near-surface layer (a few tens of ångström thick) characterised by densification with an increase in the distance from the interface, there is a much thicker (a few micrometres) layer the density of which decreases as the distance from the interface increases. This is indicated by changes in the densities of glassy polymers and in the coefficients of gas diffusion therein.^{65,66} Probably, harmonisation of these data requires further studies.

2. Effect of chemical structure on the free volume in polymers

Analysis of the results of numerous PALS studies showed that the free volume in polymers is highly sensitive to the chemical structure of the monomer unit. That is why the gas permeability and gas diffusion coefficients of polymeric materials depend on their structure (Table 3).

An efficient method of increasing the free volume of a polymer consists of introducing bulky substituents [first of all, Si(CH₃)₃ groups] into the main chain (see the data for two metathesis-derived polynorbornenes in Table 3). The introduction of other substituents (*e.g.*, a methyl group) into aromatic nuclei of the main chain also causes a systematic increase in the positron lifetime and FVE size (in Table 3, this can be followed using the data for polyimides and polycarbonates).

Table 3. Effect of polymer structure on lifetimes τ_3 and FVE radii.

Tetramethylpolycarbonate	2.4	3.2	33

3. Effect of temperature

The temperature dependences of Ps lifetimes were mentioned above in connection with the estimation of FVE concentration in polymers. Numerous studies (see, *e.g.*, Refs 33, 47, 52–54, 77, 78) showed a linear increase in τ_3 in the glassy-state region followed by a kink near T_g and subsequent linear increase in τ_3 (with a greater slope) in a highly elastic state with an increase in temperature. This is illustrated in Fig. 5. Most polymers are characterised by thermal expansion coefficients of FVE of $1 \times 10^{-3} \text{ K}^{-1}$ below the glass transition temperature and $(2-10) \times 10^{-3} \text{ K}^{-1}$ above T_g (see Refs 52, 53 and 77).

Figure 5. Temperature dependence of positronium lifetime τ_3 in polycarbonate.⁷⁸

Interestingly, some polymers present exceptions. For instance, a study of PTMSP (polymer with the largest FVE and record high gas permeability) showed that the times τ_3 and τ_4 are independent of temperature.³⁹ Probably, for this polymer the effect of temperature on small-scale motions of atomic groups in the FVE walls (these motions should govern the temperature dependences of τ_3 in conventional glassy polymers) is less pronounced due to abnormally large FVE size. Substantiation of this hypothesis requires additional measurements of the $\tau_i(T)$ dependences for other polymers with large free volumes.

4. Effect of pressure

The nanostructure of the free volume (average FVE radius and FVE size distribution) in polymeric materials can be significantly changed by applying high pressure. These changes are well ‘sensed’ by the PALS technique. In particular, the average FVE

radius in polyepoxide decreases from 2.5 to 0.73 Å and the FVE size distribution becomes narrower as the pressure increases from 0 to 14 kbar.⁷⁹ The effect of high pressure on the polymer also manifests itself as an aftereffect, namely, the lifetimes τ_3 and corresponding FVE size decrease after decompression.^{48, 80, 81}

5. Mechanical effects

The PALS method is also suitable for probing changes in the free volume (cavity size and concentration) due to deformation of polymers. However, because orientation of polymeric films can be accompanied by crystallisation and the changes in the supra-molecular structure and in FVE geometry, interpretation of experimental data can be ambiguous. If deformation of amorphous polymers (*e.g.*, polycarbonate⁷⁸) at room temperature causes no crystallisation at small relative elongations (less than 2%, *i.e.*, in the region of quasielastic deformation), the time τ_3 linearly increases with the relative elongation thus indicating an increase in FVE. At the same time biaxial orientation of poly(ethylene terephthalate), poly(ethylene naphthenate) and their copolymers at temperatures above T_g causes only minor changes in τ_3 and I_3 and significant changes in the gas permeability and diffusion coefficients. This points to predominance of sample morphology (lengthening of ‘diffusion paths’).⁸² Much greater changes in the annihilation parameters were observed at larger relative elongations Δl upon deformation of partially crystalline polymers (taking polyethylene as an example).⁸³ As Δl increases, the positron lifetime, τ , corresponding to the fractional free volume in the amorphous phase initially decreases and then (at large Δl) remains unchanged. It was assumed that the changes in τ characterise a change in the shape of FVE from nearly spherical in undeformed sample to ellipsoidal in oriented polymer. Other examples of PAL studies of mechanical effects in polymers can be found in the review.¹⁵

One of the first PAL studies of the phenomena accompanying deformation of polymers was reported by Askadskii *et al.*⁸⁴ Unfortunately, the authors studied a polyimide based on pyromellitic dianhydride and 4,4'-diaminodiphenyl oxide, which is also known as Kapton polyimide. This and numerous subsequent studies (see, *e.g.*, Refs 31, 85 and 86) revealed that the PAL spectrum of this polymer shows only one relatively short-lived component (lifetime 0.3–0.4 ns) instead of three components. It is noteworthy that this feature allows Kapton polyimide to be used as a component of the source of positrons, because Kapton films do not change the positron lifetimes in the sample under study. Apparently, this is due to the fact that at high concentration of dicarboximide rings in this polymer the positronium production is efficiently inhibited through trapping of positrons by the ring carbonyl groups. As a result, annihilation mainly involves free positrons and occurs in relatively close-packed polymer domains rather than FVE. Again, the absence of the long-lived component ($I_3 = 0$) shows that the parameter I_3 cannot serve as a measure of FVE concentration, because it depends on the positronium yield. Otherwise, Kapton should be characterised by zero free volume, whereas the gas diffusion coefficients for the polymer are similar to those found for other polymers (*e.g.*, $D_{O_2} = 0.29 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ according to Ref. 87). Also note that the absence of the τ_3 component can be due to a decrease in the FVE concentration owing to an increase in the concentration of cross-links, as shown for oligo(ester acrylates).⁸⁸

III. ^{129}Xe NMR spectroscopy

Chemical shifts in the ^{129}Xe NMR spectra are highly sensitive to the free volume in the medium where gaseous xenon is sorbed. Qualitatively, the larger the FVE size the smaller the ^{129}Xe chemical shift relative to the chemical shift characteristic of the gas phase. In this respect, polymers differ insignificantly from other condensed media, namely, large chemical shifts are observed in, *e.g.*, the media with high refractive indices. In this connection we can say that the xenon atom placed inside the FVE is in a local

low-refraction medium and characterised by a smaller chemical shift.⁸⁹

Note that the ^{129}Xe chemical shift is sensitive to structural and morphological features of partially crystalline and cross-linked polymers, polymer blends and block copolymers; it also changes near the glass transition temperature.^{90–97}

According to Fraissard and co-workers^{98, 99} who studied the sorption of xenon in various zeolites, the chemical shift in the NMR spectrum of a ^{129}Xe atom sorbed in nanoporous medium in the absence of paramagnetic species or admixtures producing a strong local electric field (*e.g.*, cations) can be written as follows:

$$\delta_{\Sigma} = \delta_0 + \delta + \delta_{\text{Xe/Xe}} \rho, \quad (5)$$

where δ_0 is a constant, δ is the chemical shift due to collisions with the FVE walls, $\delta_{\text{Xe/Xe}}$ is the chemical shift due to collisions with other xenon atoms in the gas phase and ρ is the density of the gas phase. Therefore, after extrapolation to zero pressure of gaseous xenon the difference

$$\delta = \delta_{\Sigma} - \delta_0$$

should characterise only the collisions with the walls within the FVE. Based on analysis of the data for zeolites, an empirical relation for the experimentally measured chemical shift was proposed⁹⁸

$$\delta = \frac{499.1}{2.054 + \lambda}, \quad (6)$$

where λ (in Å) is the mean free path of a xenon atom within the FVE. Note in advance that this method is only applicable to studies of those FVE the size of which exceeds that of the xenon atom. Assuming different FVE geometries, from the λ value one can estimate the diameter of either a spherical cavity (D_{sp}) or a cylindrical FVE (D_c) with a large length-to-diameter ratio,

$$\lambda = \frac{D_{\text{sp}}}{2} - 2.2, \quad (7)$$

$$\lambda = D_c - 4.4. \quad (8)$$

The free terms in relations (7) and (8) are the radius and diameter of the xenon atom, respectively. This approach is based on the possibility of determining the size of the lattice cell from X-ray diffraction data for zeolites¹⁰⁰ and availability of various characteristics of xenon. By extending relationships (6)–(8) to other nanoporous systems (in particular, polymers) it is possible to estimate their FVE sizes. However, it should be noted that there are some difficulties related to, *e.g.*, a large scatter of numerical characteristics of the size of xenon atom determined by different methods (see details below).

The FVE size was determined from the results of ^{129}Xe chemical shift measurements of xenon sorbed in different polymers. NMR measurements were carried out at low pressures or extrapolation to low pressures was used. ^{129}Xe NMR data obtained assuming spherical and cylindrical FVE geometries are listed in Table 4. For comparison, we also present the results obtained by other probe methods for different polymers. Analysis of these data allows one to draw some general conclusions.

First of all, the ^{129}Xe chemical shift can be considered as a characteristic property of the polymer, as indicated by coincidence of the chemical shifts for the polymers studied by different authors (*e.g.*, for PE and PS).

Polymers studied to date can be divided into two groups. Polymers with relatively small free volume and low gas permeability are characterised by the chemical shifts (δ) in the region δ 200–214. This corresponds to the FVE radii lying between 2.5 and 2.9 Å, being in good agreement with the PALS data (see Table 4). Significantly smaller δ values are observed for high-permeability perfluorinated polymers.¹⁰¹ Because small δ values correspond to larger FVE radii, this was interpreted as substantiation of the higher permeability of such polymers. However,

Table 4. Radii of spherical (R_{sp}) and cylindrical (R_c) FVE (Å) determined by different methods.

PEMA	203	0.40	2.60	2.40	97	3.0	3.9	109		

other factors affecting the chemical shift can exist. This is indicated by the δ values measured for PTMSP (polymer with the largest free volume and record high gas permeability).^{89,104} Typical of perfluorinated polymers are relatively low refractive indices n_D equal to ~ 1.3 , which corresponds to the molecular refraction

$$R_m = \frac{n_D^2 - 1}{n_D^2 + 2} = 0.187,$$

whereas conventional polymers (*e.g.*, PS, PC, PEMA) are characterised by n_D value lying between 1.5 and 1.7 (molecular refraction is ~ 0.3 – 0.4).¹¹⁰ One can assume that the ^{129}Xe nuclei arrive at regions with lower refraction upon collisions with the FVE walls in perfluorinated polymers, *i.e.*, the lower polarisabilities of chemical bonds in these materials cause less pronounced perturbations of ^{129}Xe nuclei.⁸⁹ The aforesaid suggests that the FVE radii calculated from relations (6)–(8) and listed in Table 4 seem to be somewhat overestimated. This does not contradict the PALS and IGC data that are also shown in Table 4. Only PTMSP presents an exception, namely, the FVE size estimates for this polymer not only do contradict the data for other polymers, but are also inconsistent with the PALS data. Probably, errors in estimation of the FVE size from expressions (7) and (8) are due to the complex geometry of the free volume in PTMSP.¹¹¹

The second problem is related to uncertainty in the size of the xenon atom, which is used for estimation of FVE. Different methods of determination of the atomic diameter (d) of xenon (from viscosity of gas, second virial coefficient, intermolecular interaction potentials, liquid and crystal densities) give the values in the range from 3.2 to 4.6 Å (values obtained before 1990 were summarised in Ref. 112). Traditionally, it is accepted that d equals 4.4 Å (this value was obtained using the van der Waals radii corrected by Pauling and reported by Breck¹⁰⁰). However, Breck also reported a smaller value (3.96 Å) calculated using the Lennard-Jones potential of intermolecular interactions. The data listed in Table 5 illustrate the effect of d value on the theoretical radius of spherical FVE for two polymers with large free volume. Clearly, agreement with the data obtained by other probe methods is more or less depending on the d value chosen. However, a broad FVE size distribution found from MD simulation suggests that the FVE radii mentioned above fall in the range of possible values.

The results of experiments on encapsulation of ^{129}Xe atoms in C_{60} fullerene and measurement of ^{129}Xe NMR spectrum¹¹³ offered some prospects for refinement of the ^{129}Xe NMR data (see above). On the one hand, the synthesis of inclusion compound

$\text{Xe}@\text{C}_{60}$ is quite unexpected, because the diameter of xenon atom (4.4 Å) exceeds that of the fullerene cavity. This could be evidence of smaller $d(\text{Xe})$ value. On the other hand, the measured ^{129}Xe chemical shift in this compound is δ 179.24, which gives an estimate of 5 to 6 Å for the inner diameter of the C_{60} cavity. Probably, in this case estimation from expressions (6)–(8) is not substantiated, because we can assume that the xenon atom encapsulated in C_{60} cavity will simultaneously interact with a few (probably, all) fullerene carbon atoms and this will cause large chemical shifts, thus making the Fraissard model inapplicable.¹¹⁴ However, this result indicates the necessity of taking into account the interactions between xenon atom and FVE walls in polymers.

IV. Inverse gas chromatography

Inverse gas chromatography (IGC) is used to study the thermodynamics of sorption of gases and vapours in polymers and to determine their physicochemical parameters.^{115,116} To this end, a polymer is applied on the surface of a solid porous substrate and the sorbate is introduced in the carrier gas flow. Under particular

conditions, by measuring the retention times t_r one can calculate various thermodynamic parameters of the polymer–gas system.

From the known t_r values, it is possible to calculate the net retention volume V_n of a sorbate

$$V_n = (t_r - t_a)J_n^m F_c \frac{273}{T}, \quad (9)$$

where t_a is the retention time of the ‘non-sorbable’ component (e.g., air), which takes into account the dead volume of the chromatograph; J_n^m is the correction for pressure drop in the column; F_c is the rate of the carrier gas; and T is the temperature (in K) at which the experiment is carried out.

A correct application of IGC technique in studies of bulk sorption in polymers implies no diffusion control of the chromatographic experiments; namely, the characteristic times of diffusion into the bulk of the supported polymer should be shorter than the ‘effective’ times of contacts of a sorbate with the polymer phase. Experimentally, this can be achieved using lower rates of the carrier gas, by applying thinner polymer films or by carrying out measurements at higher temperatures.

The main thermodynamic characteristic of bulk sorption (in contrast to adsorption on polymer surface) is the specific retention volume V_g defined as follows:

$$V_g = \frac{V_n}{\omega_L}, \quad (10)$$

where ω_L is the mass of the polymer in the column. With this parameter known, one can calculate¹¹⁷ the solubility factors (S) at infinite dilution

$$S = V_g \frac{\rho}{p_0} \exp \left[(2B_{11} - V_1)J_n^m \frac{p_0}{RT} \right], \quad (11)$$

where ρ is the density of the polymer at temperature T ; p_0 is the standard pressure (1 atm); the exponential term, which includes the second virial coefficient B_{11} and the molar volume of the sorbate V_1 , takes into account the non-ideal state of vapours; R is the universal gas constant.

Yet another important thermodynamic characteristic determined using V_g is the activity coefficient $(a_1/w_1)_\infty$ at infinite dilution

$$\ln \left(\frac{a_1}{w_1} \right)_\infty = \ln \left(\frac{273R}{V_g p_1^0 M_1} \right) - \frac{p_1^0}{RT} (B_{11} - V_1), \quad (12)$$

where M_1 is the molecular mass of the sorbate and p_1^0 is the vapour pressure of the sorbate at temperature T .

The partial molar enthalpy of mixing, ΔH_m , characterises the sorbate–polymer interaction and can be calculated from the temperature dependence of the activity coefficient.

$$\Delta H_m = R \frac{\partial \ln(a_1/w_1)_\infty}{\partial (1/T)}. \quad (13)$$

It can also be estimated from the temperature dependence of the solubility coefficient

$$S = S_0 \exp \left(-\frac{\Delta H_s}{RT} \right), \quad (14)$$

because the enthalpy of sorption can be represented by the sum

$$\Delta H_s = \Delta H_c + \Delta H_m, \quad (15)$$

where ΔH_c is the enthalpy of condensation, which is tabulated for different sorbates.¹¹⁸

Studies of several glassy polymers [polysulfone,¹¹⁹ poly(vinyl-trimethylsilane),¹²⁰ poly(phenylene oxide)¹⁰⁵ and amorphous Teflons AF^{102, 121}] showed that the ΔH_m values strongly depend on the size of the sorbate molecule. The ΔH_m values of n -alkanes

C₃–C₁₂ initially decrease as the molecular masses of these hydrocarbons increase, pass through minima at particular sizes of the sorbate molecules (these sizes are different for different polymers) and then increase again. It was assumed¹²² that the critical size of the sorbate molecule, which corresponds to the minimum and the highest exothermicity of mixing, is also related to the average size of FVE. This hypothesis is substantiated by establishment of correlations between the minimum ΔH_m values and the diffusion coefficients and gas permeabilities of glassy polymers. Probably, this behaviour is due to the ability of FVE to uptake molecules with sizes smaller than the FVE size. Sorption within FVE requires no energy expenditure to overcome the intermolecular interaction forces; therefore, the observed ΔH_m values are negative. The smaller the size difference between the sorbate molecule and FVE size the softer the restrictions imposed on the internal degrees of freedom of the sorbed molecule; as a result, the entropy of mixing ΔS_m , which correlates with ΔH_m , also passes through a minimum.¹²² Thus, the IGC technique permits estimation of the FVE size. The IGC data can be compared with the results obtained using other methods of investigation of the free volume.

The effect of the critical volume V_c used as a measure of the molecular size of sorbates (n -alkanes) on the ΔH_m of particular polymers is illustrated in Fig. 6a. The ΔH_m values pass through minima the coordinates of which ($V_{c, \min}$) are in qualitative correlation with the gas permeability and diffusion coefficient of a given polymer, namely, polymers with larger $V_{c, \min}$ values are characterised by higher diffusion coefficients and gas permeabilities and *vice versa*.

Figure 6b presents the FVE size distributions plotted from PALS data. The ordinate axis denotes the probability density

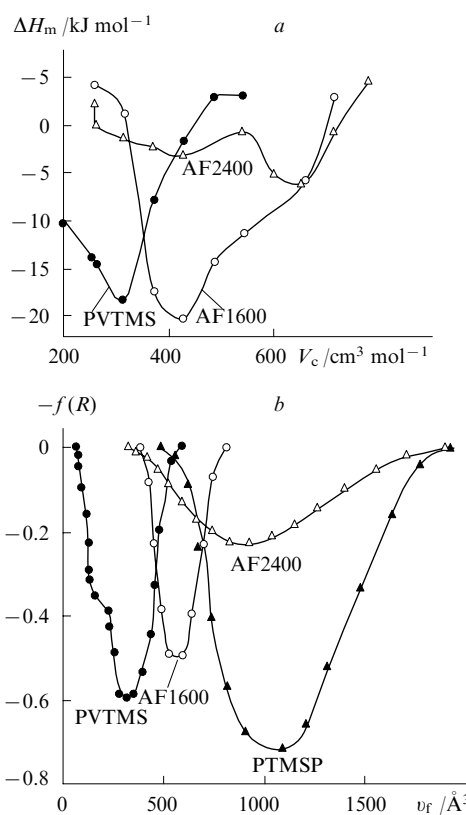

Figure 6. FVE size distribution in glassy polymers.¹²¹

function $f(R)$ determined using the CONTIN program. The radii of FVE were calculated for spherical geometry using the Tao–Eldrup relationship and then the v_f were found. For clear visual comparison with the dependence on V_c (Fig. 6a), it is appropriate to recalculate the necessary parameters per mole of a particular compound, *i.e.*

$$v_f' = v_f N_A \text{ (cm}^3 \text{ mol}^{-1}\text{)},$$

where N_A is the Avogadro constant. A comparison of the plots shown in Fig. 6a and Fig. 6b shows a clear analogy between the FVE size distributions obtained by two independent methods. Consider this result in more detail.

1. The relative positions of the curves in Fig. 6a and Fig. 6b are very similar. Both methods assign the smallest FVE size to PVTMS and the largest one to AF2400. Minima in the $\Delta H_m(V_c)$ curves for AF1600 and PVTMS correspond to alkanes C_6 and C_7 , respectively, whereas for AF2400 the minima correspond to bulkier sorbates C_{10} and C_{11} (minima at V_c and v_f' equal to $\sim 600 \text{ cm}^3 \text{ mol}^{-1}$).

2. According to PALS data, polymer AF1600 has a much narrower FVE size distribution compared to AF2400. Probably, the narrower this size distribution the stricter the size segregation of the molecules sorbed in FVE. This conclusion is also consistent with the IGC data, namely, the minimum in the ΔH_m curve is much broader for AF2400 than for AF1600.

Quantitative determination of the FVE size from IGC data requires substantiated choice of the probe size (probes are the *n*-alkanes sorbed in polymers). To this end, different parameters can be used, *e.g.*, the van der Waals volume V_w ,¹²³ the molar volume in the liquid phase V_b (at the corresponding boiling temperature T_b)¹²⁴ and the critical volume V_c .¹²⁵ Although these quantities are significantly different from one another (see Table 6), they show the same trend of changes among the polymer–sorbate systems studied. A comparison with other probe methods (PALS, ¹²⁹Xe NMR spectroscopy) and with the results of MD simulation¹¹¹ showed that the best agreement is achieved using V_b or even V_c as a measure of FVE. This is probably due to the fact that linear *n*-alkane molecules should adopt a folded conformation in order to be arranged within (postulated) spherical FVE; because of this, a rather large excluded volume should be added to the intrinsic (van der Waals) volume of the probe.

Some features and limitations of the IGC technique should be pointed. First of all, the FVE size determined using this method is found from the temperature dependence of ΔH_m , *i.e.*, the IGC method provides a temperature-averaged value. Though, with allowance for the thermal expansion coefficient of FVE (about 10^{-3} K^{-1} for glassy polymers according to PALS data) these

differences seem to be insignificant for the temperature intervals (nearly 100 degrees) corresponding to operating conditions. Another problem is related to a limited set of compounds suitable for free volume determination by IGC. The dependences of ΔH_m on the sorbate size in rubbers do not pass through minima due to another mechanism of dissolution and mixing. Additionally, the diffusion coefficients of many glassy polymers are insufficiently high so that the experiments are carried out with diffusion limitations. The results obtained show that the IGC technique is applicable to free-volume studies of polymers characterised by oxygen permeabilities $P_{O_2} > 20$ Barrer at room temperature. However, the number of such polymers is rather large. Polymers with lower permeabilities can be investigated at elevated temperatures.

V. Miscellaneous methods

Many processes involving low-molecular-mass compounds dissolved in polymers are controlled by mobilities of these compounds. The rate of translational (or rotational) mobility strongly depends on the molecule (probe)-to-FVE size ratio in a given polymer. Therefore, by following the mobility of probes of different size in different polymers one can obtain information on the free volume.

1. The photochromic probe technique

The technique is based on a hypothesis,¹²⁷ according to which the implementation of monomolecular chemical reactions (in particular, photoisomerisation) in glassy matrices requires a minimum (critical) FFV in the immediate vicinity of the dissolved probe molecule. This method involves measurements of the degree of *cis*–*trans*-photoisomerisation of a probe in a glassy polymer and in a dilute solution in a model non-viscous solvent where the free volume imposes no restrictions on the isomerisation. Having determined the ratio of these parameters as a function of the probe size (more exactly, as a function of the volume necessary for isomerisation to occur), one can estimate the average size of FVE. Victor and Torkelson¹²⁸ studied the free volume in glassy polystyrene using various stilbene and azobenzene derivatives with the van der Waals volumes in the range of 127–571 Å³ as probes. The implementation of photoisomerisation requires an additional volume for the rearrangement of the molecule that undergoes isomerisation in the excited state. This volume can be estimated from geometric considerations. It was found that more than 90% of the FFV in PS exceeds 120–130 Å³, no FVE with size $> 400 \text{ Å}^3$ are present, and the maximum in the FVE size distribution curve is at $\sim 270 \text{ Å}^3$. Assuming, as in other cases, spherical symmetry of FVE, one gets a FVE radius of $\sim 4 \text{ Å}$, which is somewhat larger than the values obtained using other probe methods (2.4–3.8 Å, see Table 4).

Data on changes in the free volume during physical ageing of glassy polymers obtained by this method worth mentioning. Larger FVE are the first to disappear in the ageing of poly(methyl methacrylate) and PS.¹²⁹ At the same time, an ageing study of polycarbonate characterised by a broader FVE size distribution showed that both large and small free-volume elements disappear simultaneously.¹³⁰

2. The spin probe technique

This was one of the first methods used for estimating the free volume in polymers. It is based on the concept that the mobility (rotational frequency ν_{cor}) of spin probes, namely, stable nitroxyl radicals, first of all 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO), is sensitive to the dynamic or structural features of the polymers in which the probes are dissolved.¹³¹ The probe rotational frequency ν_{cor} can be estimated from EPR spectral parameters. Depending on the ν_{cor} values, slow ($0.2 \times 10^9 < \nu_{\text{cor}} < 10^7 \text{ s}^{-1}$) and fast ($\nu_{\text{cor}} > 0.5 \times 10^9 \text{ s}^{-1}$) motions of probes in polymers are distinguished. At room temperature, the rotational frequencies of probes in rubbers decrease as

Table 6. Molecular volumes (Å³ per molecule) and FVE radii (Å) corresponding to minima in ΔH_m -vs.- v_f plots.¹²⁶

Polymer ^a	$\frac{V_w}{R}$	$\frac{V_b}{R}$	$\frac{V_c}{R}$
PVTMS (C_6)	$\frac{113}{3.0}$	$\frac{235}{3.8}$	$\frac{611}{5.3}$
AF1600 (C_7)	$\frac{130}{3.1}$	$\frac{269}{4.0}$	$\frac{708}{5.5}$
PDSNb (C_8)	$\frac{147}{3.3}$	$\frac{316}{4.2}$	$\frac{807}{15.8}$
AF2400 (C_{11})	$\frac{198}{3.6}$	$\frac{436}{4.7}$	$\frac{1096}{6.4}$

Note. The molecular volumes are given in the numerator and the FVE radii are given in the denominator.

^a *n*-Alkane corresponding to minimum ΔH_m value is given in parentheses.

the glass transition temperature increases. Initially, it was accepted that the FVE size in glassy polymers is less than the probe size and therefore only slow motions should occur, as is the case of, *e.g.*, polystyrene. However, it was unexpectedly found that TEMPO radicals execute fast motions while larger spin probes execute slow motions in PVTMS.¹³² Thus, estimation of the FVE size in PVTMS, which possesses rather high permeability, showed that it exceeds the size of the TEMPO molecule (more exactly, it is larger than the volume necessary for rotation of the TEMPO molecule by an angle of 1 radian). Later, similar relations were established by different probe methods for a number of polymers with relatively large FVE sizes.¹³³

However, it was shown^{134, 135} that the model for rotation used in the interpretation of the EPR spectra of the spin probes is simplified and the character of the motion and librations of spin probes in glassy polymers and low-molecular-mass glasses is more complex. Nevertheless, even assuming that the parameter v_{cor} does not reflect the actual dynamics of spin probe motions in FVE, it can be considered as an indicator of the probe-to-FVE size ratio in polymers, which shows the relative differences in the FVE values in different polymers.

3. The electrochromic probe technique

The electrochromic effect, *i.e.*, a change in colour under the action of an electric field, is due to the effect of the electric field on the light-absorption of organic compounds. Orientation of light-absorbing molecules in an electric field changes their extinction coefficients. This can be used for estimating the molecular mobility or the free volume in polymers.¹³⁶ To this end, the light-absorbing molecules acting as probes are dissolved in polymers. Experiments involve detection of changes in the extinction coefficients upon switching the electric field on and then off when random reorientation of the dissolved probe molecules occurs. To make the effect more pronounced, the probe molecules should have large dipole moments, *e.g.*, azo dyes with the van der Waals volumes lying in the range of 770–2900 Å³.¹³⁷ Note that so large probe sizes correspond to hypothetical FVE sizes that are absent in real polymers. In addition, molecules with large dipole moments can strongly interact with polar groups in the polymer structure. Therefore, the electrochromic probe technique is not a ‘non-perturbative’ one, *i.e.*, the FVE size thus determined should sense distortions produced by the introduction of the probe molecules. Nevertheless, the results obtained by this method were useful in the early stages of investigations of the free volume in polymers.

To estimate the average FVE size, one has to analyse the kinetic curves of changes in the optical density upon orientation of dipoles by the electric field and after switching this field off. Experiments are carried out with probes of different sizes. The FVE size is determined using the Cohen–Turnbull model.^{2, 3}

Studies of glassy polymers (PS, PVTMS and PTMSP)^{138, 139} using the electrochromic probe technique gave a ‘correct’ order of changes in the free volume in these polymers, *i.e.*, its increase with an increase in the gas permeabilities and diffusion coefficients. Interestingly, the temperature dependence of the average FVE size in PTMSP was found to be an order of magnitude weaker than in PS; this was confirmed by PALS data.³⁹

The average FVE size in PS was found to be in good agreement with that obtained by the photochromic probe technique.¹²⁸ However, studies by both methods were carried out using very large probes; therefore, it cannot be ruled out that the FVE sizes are overestimated. For instance, the value $v_f = 3290$ Å³ found for PTMSP corresponds to a spherical cavity with the radius of 9 Å. This exceeds considerably the value obtained from PALS data for this polymer (according to results of MD simulation, the presence of so large cavities seems not to be improbable, see Section VI). Based on the aforesaid, data of free-volume studies carried out using large probes should be analysed with special care. Additionally, when comparing different polymers taking into account the

matrix-perturbing effects, it is more correct to consider the probe mobility as a semiquantitative characteristic of the free volume.

4. The conformation probe technique

To probe the free volume in polymers, it was proposed to use organic compounds that can exist as two conformers with different IR spectra.^{140–142} The FVE size can be estimated from the shift of the conformational equilibrium for such probes introduced into glassy polymers. If no conformational transitions occur at a certain temperature (conformational equilibrium is ‘frozen’), the FVE size is less than the critical probe size necessary for its isomerisation. At certain temperature, the ratio of the conformers changes, which means that the FVE size at this temperature is comparable with the probe size. The experimentally used conformation probes were dichloroethane, 1,2-bromofluoroethane, 1,1,2,2-tetrabromoethane and some other compounds. Free-volume studies were carried out for polystyrene, poly(vinyl chloride), poly(methyl methacrylate) and some other glassy polymers. For each probe, the characteristic IR bands corresponding to *trans*- or *gauche*-conformations were chosen. At low temperatures, the optical density ratio $D_{\text{gauche}}/D_{\text{trans}}$ is independent of temperature, then an inflection is observed at certain T_f value after which this ratio (in the $1/T$ coordinates) linearly decreases with temperature. Because the volume necessary for isomerisation of a given probe is known, one can estimate the FVE size at T_f . As the probe size increases, the T_f increases. This makes it possible to estimate the temperature dependence of the limiting FVE size ($V^\#$) necessary for the conformational transition (isomerisation) of the probe in the polymer under study. An example of this dependence for poly(methyl methacrylate) is presented in Table 7. The results obtained are comparable with the PALS data.¹⁴³

Table 7. Temperature dependence of FVE size in PMMA from the conformation probe technique data.¹⁴³

Probe	T_f /K	$V^\#$ /Å ³
1-Bromo-2-fluoroethane	190 ± 20	13.0
1,2-Dichloroethane	195 ± 10	29.5
1,1,2,2-Tetrabromoethane	239 ± 9	56.6
1,2-Di(<i>p</i> -bromophenyl)ethane	326 ± 18	108.2

Experiments with the same probe in different polymers showed that for polymers with high permeabilities the conformational mobility of the probe unfreezes at much lower temperatures than for polymers with low permeabilities. For instance, $T_f = 326$ K for PMMA and 163 K for PTMSP with 1,2-di(*p*-bromophenyl)ethane as probe. Unfreezing of conformation transitions of a smaller probe (1,1,2,2-tetrabromoethane) in PTMSP occurs at even lower temperatures ($T_f < 90$ K).

However, this method is of limited use for studying the free volume in polymers due to the overlap of the spectral bands of the probe and polymer, scarcity of probes and problems associated with the introduction of the probe into the polymer from a common solvent.

On the whole, the methods considered in this Section cannot compete in reliability and informativity with the PALS technique. However, some of them played an important role in the early stage of development of studies on the free volume in polymers and still remain suitable for obtaining additional useful information.

VI. Simulation of the free volume by molecular dynamics

So far, we considered experimental methods of investigation of the free volume. Recently, methods of computer simulation of the nanostructure of polymers aimed at predicting many properties of

polymeric materials [in particular, the diffusion (D) and gas solubility (S) coefficients] have become increasingly important. When solving such problems, the construction of a correct model for the free volume in the polymer under study is prerequisite for obtaining accurate results. The results of computer simulation are analysed using relevant data obtained by probe techniques for substantiation of the reliability of calculations. At the same time, MD simulation provides valuable information that cannot be obtained by the probe methods (see below).

The free volume in polymers can be simulated by, *e.g.*, the Monte Carlo method,^{8, 144–148} molecular mechanics,^{8, 149, 150} theory of transition state and related approaches.^{8, 151, 152} MD simulation appeared to be the most efficient method and a large number of polymers were studied by this method in recent years. In this Section we will consider the results of MD simulation of the free volume in amorphous polymers.

In MD simulation of amorphous polymers, the free volume is described using a cubic box filled with polymer chains. The results of analysis of the free volume and theoretical parameters including D and S can depend on the size of the cubic box, which is undesirable. Calculations with small boxes (cube edge is shorter than 20 Å) take a shorter time. Starting with a certain size (cube edge of about 40–50 Å) this correlation is no longer valid, but the results become more reliable. Usually, the model boxes contain 2000 to 10 000 atoms in the polymer chain.¹⁵³ All atoms in the polymer chains are represented by spheres of preset diameters and masses. The interactions of covalently bonded atoms are described with allowance for the bond lengths, bond angles and torsion angles. Non-covalent intermolecular interactions are described using commonly accepted (most often, the Lennard-Jones and Coulomb) potentials. The chemical structure of the polymer studied is determined in different approximations. The ‘United Atoms’ method ignores all hydrogen atoms and treats all quasi-spherical atomic groups (*e.g.*, CH₂, CH₃) as individual species in order to reduce the computing time. More reliable results can be obtained using the ‘All-Atom Strategy’.¹¹

The sum of all atom–atom interactions expressed as the potential energy model of the packing is called the force field. A correctly determined force field is the key for successful MD simulation of the nanostructure of the system. The force field should reproduce the equilibrium structure, thermodynamic and dynamic properties of the polymer under study and govern the accuracy of prediction of all parameters of the system. One of the most popular force field types is known as the COMPASS (Condensed-phase Optimized Molecular Potentials for Atomistic Simulation Studies)¹⁵⁴ force field (for details, see Ref. 8).

Theodorou and Suter^{155, 156} proposed an efficient box-filling procedure, which allows the length of the polymer chain to be chosen in such a manner that the packing be completely amorphous. The polymer chains are generated using the so-called periodic boundary conditions. Namely, as a propagating virtual chain reaches a cube face and starts to ‘penetrate’ it, a similar propagating chain is automatically introduced on the opposite face. The box is filled until a preset, experimentally determined density of the polymer is reached. Therefore, the polymer density serves as an ‘input parameter’ for calculations. This can cause some difficulties, because the densities of glassy polymers depend on the sample prehistory, amount of residual solvent, *etc.* Since the number of possible types of packing within the cubic box is infinitely large, a packing containing domains with too low or too high local density can be formed in the initial stage. Obtaining a more realistic packing requires an additional stage of the process, namely, the relaxation stage. Various procedures are used to accelerate relaxation. In particular, molecules of ‘plasticiser’ (*e.g.*, methanol) can be introduced into the box and then removed upon relaxation. Detailed consideration of the polymer structure models can be found in, *e.g.*, Refs 8, 111, 153, 157 and 158.

Computer simulation opens new, additional prospects for investigation of the free volume in polymers, most of which are inaccessible in principle to probe methods:

- visualisation of the free volume;
- analysis of connectivity of free-volume elements (cluster size, closed or open porosity);
- construction of FVE size distribution;
- studies of mobility (dynamics) of the free volume elements in polymers.

Consider as an example model nanostructures of the free volume^{111, 157} in a polymer with moderate permeability, poly(*p*-trimethylsilylstyrene) (P_{O_2} = 56 Barrer¹⁵⁹) and in two polymers with high permeabilities and large FVE (according to PALS and IGC data), namely, poly(trimethylsilylpropyne) and amorphous Teflon AF2400 (P_{O_2} = 7700 and 1140 Barrer, respectively^{41, 160}). The force field was calculated using the COMPASS programme,¹⁵⁴ which includes interactions of all atoms in the monomer unit in explicit form and optimizes the bond lengths, bond angles, dihedral angles and the Coulomb and van der Waals potentials. Calculations involve optimisation of the force field in order to correctly reproduce the physical properties of the polymer in the block. The *cis:trans* ratio in PTMSP, which contains double bonds in the main chain, was set to 1 : 1 assuming random distribution of *cis* and *trans* units over the chain. In this approximation all dihedral angles were determined based on the Boltzmann distribution obtained using the torsion potentials included in the COMPASS force field for particular bonds with allowance for local non-bonding interactions.

It is convenient to carry out visualisation by slicing the cubic boxes generated. In boxes with 4–5 nm edges, the neighbouring layers are separated by a distance of about 0.3 nm (Fig. 7). In Fig. 7a, the white background denotes the free volume; the free volume elements in PTMSP represent compact aggregates the size of which is comparable with the slice-to-slice separation. For instance, the visible FVE in slice c_4 is not seen in the neighbouring slices c_3 and d_1 . This means that the FVE size is comparable with the slice-to-slice separation of ~0.3 nm. The visible ‘diameter’ of FVE in this slice is also similar to this value. Thus, our simplest analysis shows that the shape of the free volume elements in PTMSP is nearly spherical or ellipsoidal with similar lengths of semiaxes. PTMSP has another shape of the free volume elements (Fig. 7b). Here, the characteristic size of FVE is much larger and the same FVE can be seen in many slice sequences in the cubic box. This can be considered as a proof of the assumptions of quasi-open porosity in this polymer, which were based on some indirect observations.^{161, 162} A broad FVE size distribution was also obtained in another study¹⁵² where it was found that larger FVE tend to form channels.

According to MD simulation data, the other polymer with high permeability, *viz.*, amorphous Teflon AF2400, has yet another type of the nanostructure of the free volume elements. The results of MD simulation of the packing in this polymer showed¹¹¹ that the FVE size here is also rather large, but the FVE no longer pierce the whole cubic box, as in the case of PTMSP. Elongated FVE rarely extend to more than one or two slices. Thus, the structure of the AF2400 polymer is rather characterised by the closed porosity.

It is interesting to follow how these microscopic properties are reflected in the macroscopic behaviour of membrane materials, in particular their gas permeabilities and diffusion coefficients (Table 8). Since

$$P = DS,$$

the changes in P in series of penetrants are governed by the kinetic (D) or thermodynamic (S) factors. For all polymers their D values decrease, although at different rates, as the size or molecular mass of penetrant increase. On the contrary, the solubility coefficients S , which characterise the ability of transition to condensed state,

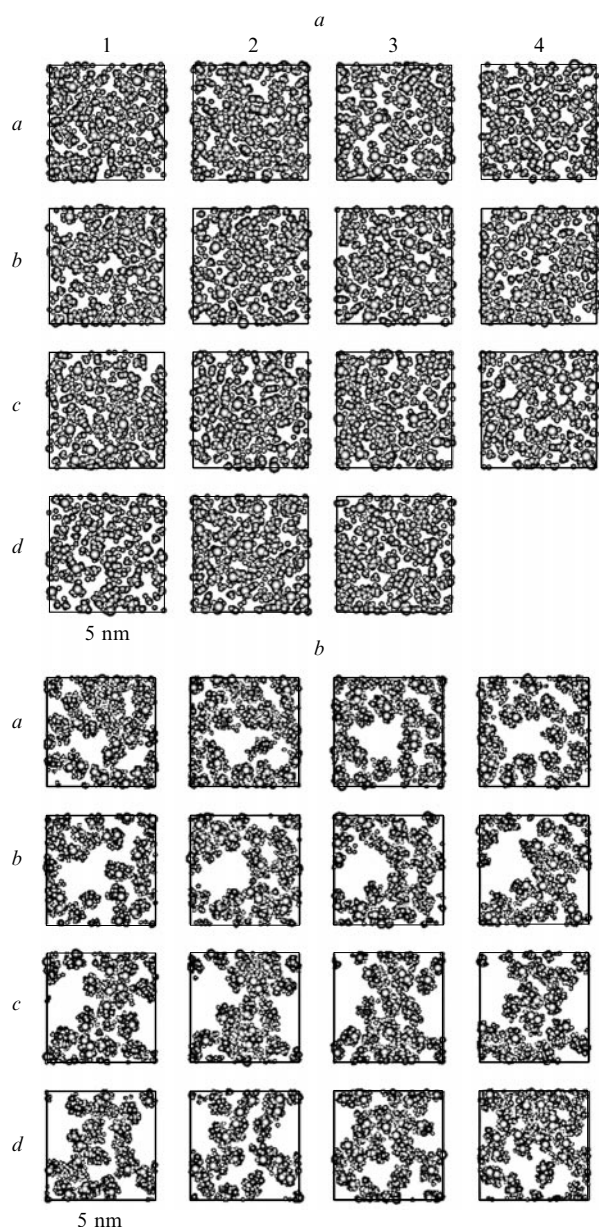

Figure 7. Model representation of the free volume in PTMSS (a) and PTMSP (b).¹⁵⁷

Cube edge is about 5 nm, slice-to-slice separation is nearly 0.3 nm; slices are shown as follows: $a_1 \dots a_4$, $b_1 \dots b_4$, $c_1 \dots c_4$, $d_1 \dots d_3(d_4)$.

Table 8. Permeability and diffusion coefficients of hydrocarbons in AF2400 and PTMSP.

Gas	P /Barrer		$10^7 D$ /cm ² s ⁻¹	
	AF2400 ⁴¹	PTMSP ¹⁶³	AF2400 ⁴¹	PTMSP ¹⁶³
CH ₄	435	15 000	—	240
C ₂ H ₆	252	31 000	3.6	110
C ₃ H ₈	97	38 000	0.42	98
C ₄ H ₁₀	—	78 000 ^a	0.24	—

^a Data taken from Ref. 162.

increase in this case. In polymers the with open porosity characterised by low barriers to diffusion the parameter P is more

strongly affected by the solubility coefficient S . It is this behaviour that is typical of PTMSP, which has a relatively weak dependence of D on the size of the penetrant. Contrary to this, polymer AF2400 behaves as a conventional glassy polymer and demonstrates a rather strong dependence of D on the size of the penetrant; therefore, here the P values decrease on going from CH₄ to C₃H₈. Thus, the connectivity of the free volume elements has a crucial effect on the selectivity of glassy membrane materials.

Using MD simulation, it is possible to determine the FVE size distribution. The corresponding procedure involves filling of the box with probes of different size and calculations of the volume where the rigid spheres of the probes and polymer atoms do not overlap. However, because the free volume in polymers has a complex geometry (irregular shape; for details, see, *e.g.*, Refs 164–167), the results obtained can depend on how the notion ‘FVE’ used in analysis of the computer model is defined. Hofmann *et al.*^{111, 157, 168} put forward two definitions of the FVE in polymers; these are illustrated in Fig. 8. One limiting case (V_{connect} approximation) corresponds to a topological situation where a given FVE contains all points having at least one neighbour with no overlap of the rigid spheres of the probe and atoms of the polymer chain. This approach makes it possible to identify cavities that can be large and have irregular shape. In the other limiting case (R_{max} approximation), the FVE contains only the points located at the shortest distance to the atoms of the polymer chain surrounding the FVE. This approach allows partition of large FVE having irregular or extended shape into smaller ‘local’ regions, as shown in Fig. 8.

Figure 8. Schematic illustration of two approaches to visualisation of the free volume in glassy polymers.¹⁵⁷

The V_{connect} approximation characterises the ‘global’ FVE, while the R_{max} approximation characterises the ‘fractional’ FVE more similar to spherical.

Now consider how the shape of the FVE size distribution in polymers, obtained using these two approximations, are represented. PTMSP is characterised by a nearly Gaussian distribution with a maximum at $R = 2$ Å (Fig. 9), which is consistent with the results of qualitative analysis of the cubic box (see above and Fig. 7a). For this polymer, both approximations give similar FVE size distributions. Another pattern was obtained for the polymers with high permeabilities and large free volumes. As examples, Fig. 10 presents the FVE size distributions obtained for amorphous Teflon AF2400 in the R_{max} and V_{connect} approximations. In the former case, this is a broadened continuous FVE size distribution with radii of up to 13 Å. In the latter case, we have a clearly seen bimodal distribution consistent with the results of PALS data processing using the CONTIN programme (see Section II). Because the real structure of the free volume in polymers should be considered as superposition of these two limiting models, it seems that we get even better agreement between the predictions of MD simulations and experimental results obtained using probe methods.

Similar characters of the distributions obtained in the V_{connect} and R_{max} approximations were also established for PTMSP

Figure 9. Size distribution of free volume elements in PTMSS.¹⁵⁷ Rectangles denote the results obtained in the R_{\max} approximation. The curve corresponds to averaged data.

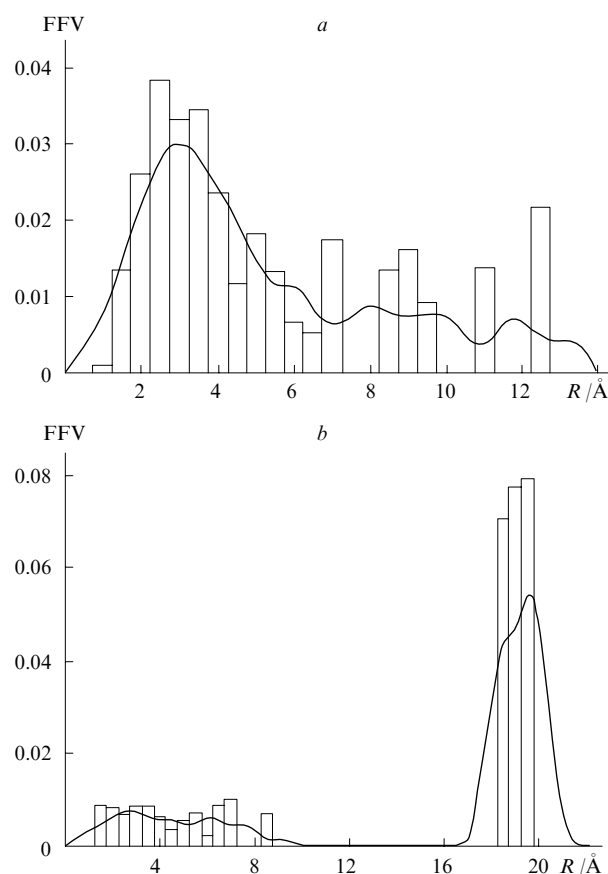

Figure 10. Size distribution of free volume elements in perfluorinated polymer AF2400.¹¹¹ Results obtained in the R_{\max} (a) and V_{connect} (b) approximations. Rectangles denote the corresponding theoretical results and the curves correspond to averaged data.

and other polymers with high permeabilities.¹¹¹ Bimodal distributions in the V_{connect} approximation were also obtained in simulation of polymers with smaller permeabilities (polyimides, see Fig. 11). However, a decrease in gas permeability (and free volume) of polyimides is followed by rapid transformation of the bimodal distribution to monomodal (Gaussian).¹⁶⁸

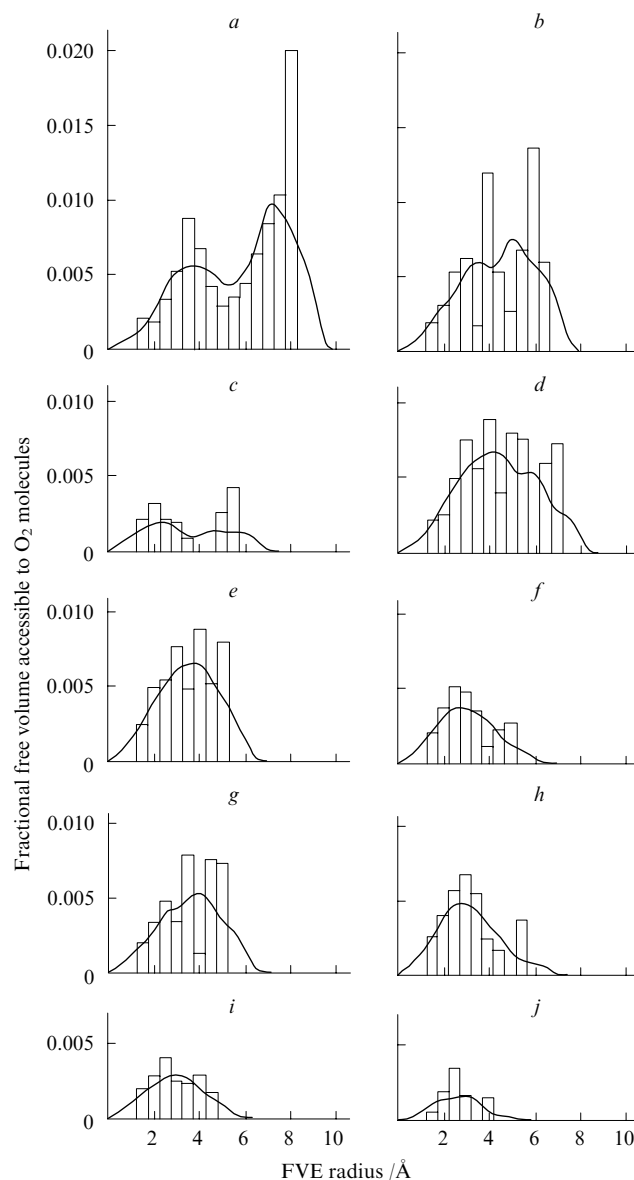

Figure 11. Size distribution of free volume elements in different polyimides.¹⁶⁸

Shown is the evolution of the size distribution upon a change in the polymer permeability P_{O_2} /Barrer: P13, $P_{O_2} = 124$ (a); P14, $P_{O_2} = 137$ (b); T6, $P_{O_2} = 69$ (c); B4, $P_{O_2} = 54$ (d); BAFF, $P_{O_2} = 13$ (e); MDX, $P_{O_2} = 11$ (f); PDA, $P_{O_2} = 5$ (g); ODX, $P_{O_2} = 4$ (h); DDS, $P_{O_2} = 3$ (i); and KAP, $P_{O_2} = 0.5$ (j).

The character of the FVE size distribution depends on the probe size. For instance, the use of oxygen molecules (van der Waals radius 1.73 Å) instead of *o*-Ps (Bohr radius 1.06 Å) as probes causes the distribution to be shifted to the left at larger radii; however, the overall distinctions between the two distributions are insignificant.¹¹¹

By substantially reducing the probe size, one can plot the 'total' FVE size distribution^{157,169} (Table 9), which includes even so small cavities that cannot participate in transport of the smallest molecules. For most glassy polymers extrapolation to zero probe size gives a FFV of about 0.3, but in some cases (e.g., PTMSP) it can be as high as 0.5 (Ref. 157). Taking atactic polypropylene as an example, Greenfield and Theodorou¹⁴⁴ showed that a decrease in the probe size causes a rapid increase in continuous free-volume clusters in the polymer, which overcome the percolation threshold. Indeed, an infinite cluster is

Table 9. FFV estimates obtained from MD simulation with probes of different sizes.¹⁵⁷

Polymer	Probe size /Å	FFV
PTMSS	1.1	0.02
	0.43	0.185
	0.18	0.331
	extrapolation to zero	~0.36
PTMSP	1.1	0.211
	0.43	0.369
	0.18	0.469
	extrapolation to zero	~0.50

formed at a virtual (unnatural) probe radius of 0.9 Å (*cf.* a range from 1.20 to 1.30 Å reported by different authors for the van der Waals radius of the He atom).

Correctness of the results of MD simulation of the free volume in polymers can be assessed not only by comparing them with the results obtained by experimental probe methods, but also by checking for consistence with the FVE size distributions in the same polymers treated using different computational approaches (see, *e.g.*, Refs 157 and 169). To date, MD simulations of the free volume in many glassy polymers (polyimides, polysulfones, polystyrenes, polyacetylenes, *etc.*) have been carried out.^{110, 148, 160, 163, 164} For most polymers, the FVE radii lie in the range 2–4 Å, which is consistent with the data obtained by two probe methods, PALS and ¹²⁹Xe NMR spectroscopy. However, for some polymers with high permeabilities MD simulation gives much larger FVE radii (up to 10–20 Å), which undoubtedly determines unusual transport properties of these compounds. Selected results of MD simulation of the free volume and experimental PALS data are listed in Table 10. Taking into account a large number of admissions made in both MD simulation and experimental free-volume studies, the degree of consistency obtained for most polymers can be considered reasonable.

In the aforesaid we considered the static free volume in polymers. However, MD methods are also suitable for studying the redistribution dynamics of FVE in polymers. For rubbers [*e.g.*, polydimethylsiloxane, poly(methyloctylsiloxane)^{172–174} and poly(dimethylsilamethylene)¹⁵⁸] the average lifetime of FVE in a certain domain within the box is a few picoseconds while the opening of channels connecting the neighbouring FVE seems to take even shorter time. Glassy polymers, *e.g.*, polyimides and poly(ether-ether-ketone)^{172, 175} are characterised by much longer average lifetimes, but reliable data on these times are unavailable as yet, because analysis of the events occurring on a few-nano-second time scale requires unreasonably high computational resources.

The time necessary for visualisation of FVE redistribution in glassy polymers is much longer than several nanoseconds.¹⁵⁸

Consider the dynamics of FVE redistribution in rubbers^{153, 158, 172} in more detail. Simulation of the free volume in poly(methyloctylsiloxane) rubber showed that the opening time of a channel between neighbouring FVE is of the order of nanoseconds, *i.e.*, is two orders of magnitude longer than the ‘settled’ lifetime of the penetrant molecule (H₂O). Channels being opened are rather broad; as a result, two neighbouring FVE coalesce. This provides an explanation for the well-known phenomenon of low-selectivity diffusion in rubbers; indeed, here size selection of the diffusing molecules in the opening channels is impossible. Microscopically, migration of FVE (or, which is the same, opening of channels) is a consequence of both segmental mobility and small-scale mobility of side groups (CH₃ and C₈H₁₇ for poly(dimethylsiloxane) and poly(methyloctylsiloxane),¹⁵³ respectively).

Table 10. FVE radii (Å) in polymers obtained from molecular dynamics simulation and by PALS.

Polymer	MD simulation			PALS			
	R_m	$R_{1/2}$	Ref.	R	R_3	R_4	Ref.

AF1600	3.1	1.6–5.2	111		2.5	4.9	111
						4.8	40

Note. R_m is the FVE radius at the distribution maximum; the width of the FVE size distribution is represented by the range of $R_{1/2}$ (radii at half-height) values; PALS data are represented by either a unique radius of spherical FVE (R) or two values (R_3 and R_4) if the size distribution is bimodal.

Similar conclusions were also drawn in studies of the dynamics of fluctuating FVE in another organosilicon rubber, poly(dimethylsilamethylene).¹⁵⁸ MD simulation of this polymer was carried out for the free volume ‘sensed’ by two penetrant molecules of different sizes, namely, methane and a spherical penetrant with diameter of 2.8 Å (similar to the size of H₂ molecule). The FVE concentrations accessible to methane molecule appeared to be much lower than those accessible to the smaller penetrant. In both cases the larger FVE were characterised by longer ‘settled’ lifetimes compared to the smaller FVE. The spatial FVE distribution significantly changed after a period of 10 ns (time interval between two successive ‘frames’ in MD simulation of the free-volume dynamics); the effective diffusion coefficients of FVE were of the order of 10^{-3} – 10^{-4} cm² s⁻¹. This provides an explanation for fast gas diffusion in rubbers.

VII. Conclusion

At present, the free volume in polymers is studied by experimental methods based on different physicochemical principles and measuring techniques. On the whole these techniques give mutually consistent results. Among them, analysis of positron annihilation lifetimes has been best developed and most often used. Despite some admissions associated with uncertainties in the hypothesis of spherical geometry of the FVE in polymers and some doubt concerned with bimodal FVE size distribution, this method gave a clear description of the free volume in hundreds of polymers. Also, it is at least equally important that the method makes it possible to study changes in the free volume upon chemical modification of polymers, sorption and plastification, upon change in temperature and under the action of pressure and deformations.

The results obtained showed that other probe methods are of much more limited use. However, their role should not be under-

estimated. Indeed, reasonable agreement between the FVE sizes determined by different methods increases the degree of confidence for the principle of probing the free volume in polymers. This made it possible to establish various correlations between the free volume and particular characteristics (*e.g.*, diffusion coefficients and gas permeabilities), which are suitable for quantitative predictions.

Recently, MD methods have become of particular importance for the description and prediction of free-volume parameters. The results obtained by the probe methods are still needed to confirm the results of simulation, but it seems likely that in the future the

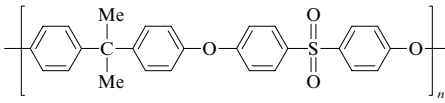

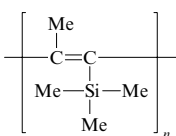

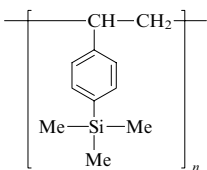

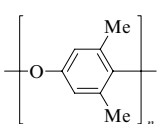

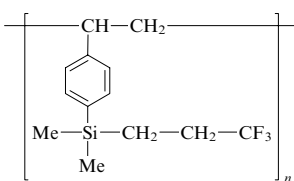

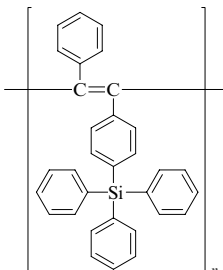

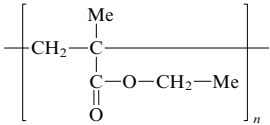

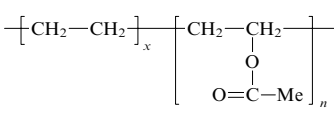

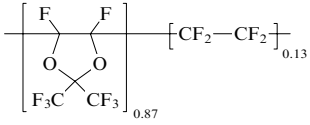

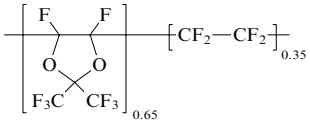

MD methods will become the main tool of studying the free volume in polymers. It is also of crucial importance that MD simulation provides not only local characteristics of the free volume (FVE size and FVE size distribution), but also information on its topology (closed or open porosity, percolation phenomena, *etc.*). This is inaccessible to probe methods. The aforesaid suggests that the results of studies on the properties of polymers (*e.g.*, membrane polymers) should be complemented with the data obtained by probe methods and by the results of MD simulation of the free volume in polymers.

VIII. Appendix

List of polymers.

Notation	Name	Formula
PVA	poly(vinyl acetate)	$\left[\begin{array}{c} \text{CH}_2 - \text{CH} \\ \\ \text{O} \\ \\ \text{C} = \text{O} \\ \\ \text{Me} \end{array} \right]_n$
PVTMS	poly(vinyltrimethylsilane)	$\left[\begin{array}{c} \text{CH}_2 - \text{CH} \\ \\ \text{Me} - \text{Si} - \text{Me} \\ \\ \text{Me} \end{array} \right]_n$
PVC	poly(vinyl chloride)	$\left[\begin{array}{c} \text{CH}_2 - \text{CH} \\ \\ \text{Cl} \end{array} \right]_n$
PDMS	poly(dimethylsiloxane)	$\left[\begin{array}{c} \text{Me} \\ \\ \text{Si} - \text{O} \\ \\ \text{Me} \end{array} \right]_n$
PDSNb	poly(disilylnorbornene)	$\left[\begin{array}{c} \text{Me} \quad \text{Me} \\ \diagdown \quad \diagup \\ \text{Si} \quad \text{Si} \\ \diagup \quad \diagdown \\ \text{Me} \quad \text{Me} \end{array} \right]_n$
PC	bisphenol-A polycarbonate	$\left[\begin{array}{c} \text{Me} \\ \\ \text{C} \\ \\ \text{Me} \end{array} \begin{array}{c} \text{O} \\ \\ \text{C} - \text{O} \end{array} \right]_n$
PMMA	poly(methyl methacrylate)	$\left[\begin{array}{c} \text{Me} \\ \\ \text{CH}_2 - \text{C} \\ \\ \text{C} - \text{O} - \text{Me} \\ \\ \text{O} \end{array} \right]_n$
PPrSiDPA	poly{1-phenyl-2-[<i>p</i> -(triisopropylsilyl)phenyl]acetylene}	$\left[\begin{array}{c} \text{C}_6\text{H}_5 \\ \\ \text{C} = \text{C} \\ \\ \text{C}_6\text{H}_4 \\ \\ \text{CH} - \text{Si} - \text{CH} \\ \quad \quad \\ \text{Me} \quad \text{CH} \quad \text{Me} \\ \quad \\ \text{Me} \quad \text{Me} \end{array} \right]_n$
PS	polystyrene	$\left[\begin{array}{c} \text{CH}_2 - \text{CH} \\ \\ \text{C}_6\text{H}_5 \end{array} \right]_n$

List of polymers (continued).

Notation	Name	Formula
PSP	polysulfone	
PTMSP	poly(trimethylsilylpropyne)	
PTMSS	poly(<i>p</i> -trimethylsilylstyrene)	
PTFE	poly(tetrafluoroethylene)	
PPO	poly(1,3-dimethyl-2,5-phenylene oxide)	
PFPDMSS	poly[<i>p</i> -(3,3,3-trifluoropropyl)dimethylsilyl]styrene	
PPHSiDPA	poly{1-phenyl-2-[<i>p</i> -(triphenylsilyl)phenyl]}acetylene	
PE	polyethylene	
PEMA	poly(ethyl methacrylate)	
LDPE	low-density polyethylene	
EVA	ethylene – vinyl acetate copolymer	
AF-2400	random copolymer of 2,2-bis(trifluoromethyl)-4,5-difluoro-1,3-dioxole (87 mol.%) and tetrafluoroethylene (13 mol.%)	
AF-1600	random copolymer of 2,2-bis(trifluoromethyl)-4,5-difluoro-1,3-dioxole (65 mol.%) and tetrafluoroethylene (35 mol.%)	

List of polymers (continued).

Notation	Name	Formula
6FDA-ODA	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 4,4'-diaminodiphenyl ether	
6FDA-BAAF	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 2,2-bis(4-aminophenyl)hexafluoropropane	
6FDA-P13	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane and 2,3,5,6-tetramethyl-p-phenylenediamine	
6FDA-P14	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 2,4,6-trimethyl-m-phenylenediamine	
6FDA-2	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 2,5-dimethyl-p-phenylenediamine	
6FDA-1	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and methyl-p-phenylenediamine	
6FDA-PDA	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and p-phenylenediamine	
6FDA-T6	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 4,4''-diamino-3,5,2',5',3'',5''-hexamethylterphenyl	
6FDA-B4	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 4,4'-diamino-3,5,3',5'-tetramethylbiphenyl	
6FDA-MDX	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 4,4'-diamino-3,5,3',5'-tetramethyldiphenylmethane	
DDS	polyimide based on 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride and 4,4'-diaminodiphenyl sulfone	
KAP	polyimide of pyromellitic dianhydride and 4,4'-diaminodiphenyl oxide	

List of polymers (continued).

Notation	Name	Formula
Hyflon AD80X	random copolymer of 2,2,4-trifluoro-5-trifluoromethoxy-1,3-dioxolane (80 mol.%) and tetrafluoroethylene (20 mol.%)	
Hyflon AD60X	random copolymer of 2,2,4-trifluoro-5-trifluoromethoxy-1,3-dioxolane (60 mol.%) and tetrafluoroethylene (40 mol.%)	
Vectra	copolyester of <i>p</i> -hydroxybenzoic acid and 6-hydroxy-2-naphthoic acid

Determination of biologically active phenols and polyphenols in various objects by chromatographic techniques

M V Kochetova, E N Semenistaya, O G Larionov, A A Revina

Contents

I. Introduction	79
II. General characteristics of biologically active phenols and polyphenols	79
III. Sample preparation	81
IV. Chromatographic determination of phenols and polyphenols in various objects	82

Abstract. Chromatographic techniques for determination of biologically active phenols and polyphenols are considered. Various methods for sample preparation and detection are compared. The advantages of high performance liquid chromatography with spectrophotometric detection for determination of antioxidants are demonstrated. Data on determination of biologically active phenols and polyphenols published in the period from 1995 to 2005 are analysed. The bibliography includes 270 references.

I. Introduction

During the last decade, the number of publications devoted to chromatographic studies of natural and synthetic biologically active compounds has sharply increased.^{1–8} The studies of the antioxidant activity of, in particular, phenol and polyphenol derivatives attract special attention of researchers. The environment deterioration and the increase in the number of stress situations decrease the defense forces in humans. This, in turn, increases the risk of pathological states (cardiovascular diseases, inflammatory processes, atherosclerosis, etc.). Studies of the active forms and the mechanisms of action *in vitro* and *in vivo* of natural and synthetic biologically active compounds is a topical problem related to preservation of human health.

Phenols and polyphenols possess a broad spectrum of biological activities: they exert antioxidant,^{9–11} antiinflammatory,¹² antitumour,¹³ capillary strengthening^{14,15} and hepatoprotector¹⁶ actions. They are able to form chelates with metals. These chelates can exhibit both antioxidant and prooxidant[†] activities.^{17–19} This accounts for the use of biologically active compounds in medicine, pharmacology, biochemistry and food industry. Despite the wide use of polyphenols as antioxidants, the mechanisms of their action *in vitro* and *in vivo* and the cases where these compounds behave as prooxidants²⁰ are still not entirely clear. This is due, on the one hand, to the existence of numerous natural derivatives of these compounds and the diversity of their oxidised forms and, on the

other hand, to the complexity of composition of the extracts from which these compounds are isolated and determined. Therefore, to analyse biologically active compounds, one needs information on their transformations during all stages of sample preparation.

This review considers the studies devoted to chromatographic methods for determination of biologically active phenols and polyphenols published over the last 10 years. The attention is focused on the most widely used procedures.

II. General characteristics of biologically active phenols and polyphenols

Phenol derivatives constitute a widely encountered and abundant class of natural products exhibiting biological activity. They are distinguished by the presence of free or bound OH group as a substituent in the benzene ring.

[†]Prooxidant activity of a compound usually implies an increase in the yield of active oxygen-centred radicals in the presence of this compound.

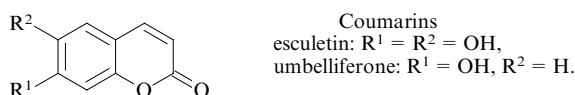

Aromatic compounds containing two or more non-fused aromatic rings

Flavonoids (arylbenzo[*b*]pyrans) and coumarins

kaempferol: $R^1 = R^2 = R^3 = R^4 = H$;
morin: $R^1 = OH$, $R^2 = R^3 = R^4 = H$;
quercetin: $R^1 = R^3 = R^4 = H$, $R^2 = OH$;
myricetin: $R^1 = R^4 = H$, $R^2 = R^3 = OH$;
quercetrin (quercetin rhamnoside): $R^1 = R^3 = H$, $R^2 = OH$,
 $R^4 = \alpha\text{-L-Rhap}$; rutin (quercetin rutinoside):
 $R^1 = R^3 = H$, $R^2 = OH$, $R^4 = \beta\text{-D-Glcp-(6}\leftarrow\text{1)}\text{-}\alpha\text{-L-Rhap}$.

Phenols are present almost in all plants either as glycosides or in the free state in amounts from 0.1% to 7%.²¹

Phenolic alcohols and their glycosides favour the increase in human performance capability and the organism resistance against adverse effects. Hydroxycinnamic acids (*p*-coumaric, caffeic, ferulic and sinapic acids) are present in many plants²² and fruits^{23,24} in various combinations, either in the free state or as glycosides or esters. Caffeic acid and its derivatives (chlorogenic acid and its isomers), which have antiinflammatory and choleric actions, are found in nature most often. Chlorogenic acid occurs in large amounts in coffee beans, bilberry, mountain tobacco, wild chamomile leaves, *etc.* Ferulic acid is a part of plant cell walls.²⁵ Caffeic, chlorogenic, ferulic and coumaric acids together have a hypouricemic effect, enhance the kidney function and stimulate the detoxifying function of the liver. Hydroxycinnamic acids are also present in echinacea, burdock root, hawthorn and rhubarb.

Ellagic acid is abundant in many fruits and vegetables, especially in raspberry, strawberry and pomegranates. Stilbenes are mainly contained in various kinds of wood (pine tree, gum-tree, *etc.*).

Catechins were found in many fruits²⁶ (apples, peaches, apricots, queen-apples and plums) and berries (cherry, strawberry, currant, raspberry, gooseberry and cowberry). Large amounts of catechins are present in tea-plant browses²⁷ (up to 20%–25% of the dry weight) and acacia catechu browses (which gave rise to the name of these compounds), in grapes (mainly in stones and peel),²⁸ and in cocoa beans.²⁹ Catechins show high biological activity; in the human body, they control the capillary permeability and increase the wall elasticity and also increase the bioavailability of ascorbic acid. Therefore, catechins are classified as substances having P-vitamin activity and are used in the therapy of diseases related to capillary dysfunction and edemas.³⁰

The cell vacuoles of many flowers and fruits contain pigments such as anthocyanidins and anthocyanins [as oligomeric and polymeric forms (proanthocyanidins) or complexes with metals, proteins and polysaccharides], which are responsible for their bright colour.^{31,32} Proanthocyanidins were found in most fruits³³ and vegetables³⁴ and in leaves of many plants. The main source of these compounds on an industrial scale are grape stones and peel and the cluster pine cork. In medicine, they are used to prevent the cardiovascular diseases and to reduce the cholesterol level in blood.³⁵ Studies of the antitumour activities of anthocyanidins are in progress.³⁶ The instability and structural diversity of anthocyanidins complicate their qualitative analysis.

Flavonols (dihydroflavonols) are mainly present in coniferous wood (pine tree, larch tree and cedar) and some leaf wood (eucalyptus, beech, cherry). Flavanones are encountered in citrus plants. Hesperetin and its glycoside, hesperidin, are contained in the orange, lemon and citron pulp; the glycoside naringin is responsible for the bitterish taste of grapefruit, and eriodictyol occurs in lemons.^{37,38}

Like flavones, flavonols are yellow pigments,³⁹ which are distributed in plants most widely (almost universally).⁴⁰ Compounds of this group encountered most frequently include kaempferol, quercetin, myricetin and their numerous derivatives. 3,5,4'-Trihydroxystilbene (*trans*-resveratrol) present in red wine is an interesting biologically active polyphenol, which has been the subject of a large number of studies in recent years. It was found⁴¹ that *trans*-resveratrol protects the membrane lipids from peroxidation; it quenches free radicals less effectively than flavonoids but it is more effective in chelating copper ions.

Coumarins are also widely distributed in nature.^{42–44} They are present in umbelliferous, leguminous and rue plants, being mainly concentrated in roots and fruits.⁴⁵ Owing to the availability and the ease of chemical modification, coumarins can be used for the development of medicinal drugs.⁴⁶ A meptazinol derivative based on coumarin is more easily uptaken in the body than the starting drug,⁴⁷ and the coumarin derivative with *trans*-

resveratrol is a more efficient vasodilator than *trans*-resveratrol itself.⁴⁸ Coumarins are used as anticoagulants;⁴⁹ they exhibit bactericidal,⁵⁰ fungicidal⁵¹ and antitumour⁵² activities.

The relationship between the antioxidant activity and the chemical structure of polyphenols has not been ultimately elucidated as yet. Chromatographic methods can be used to study the relationship between the structures and some properties of phenols.⁵³ This is done by modelling the retention in various versions of chromatography^{54–56} and by numerical methods.⁵⁷ It has been established⁵⁸ that the antioxidant activity of polyphenols increases in the following cases:

(i) in the presence of a 2,3-double bond of the heterocyclic ring, as this seems to allow electron delocalisation between rings A and B [see the structure of (+)-catechin] and, hence, stabilisation of the aryloxy radical formed;

(ii) in the presence of hydroxy groups in positions 2 and 4 of ring B, because this apparently also contributes to radical stabilisation;

(iii) on passing from polyphenol glycosides to aglycons, because carbohydrate residues in glycosides markedly decrease the antioxidant activity;

(iv) in the presence of a free phenolic hydroxy group.

It is known^{59–65} that vegetables, fruits, red wine, chocolate, and other foodstuffs rich in polyphenols, when eaten on a regular basis, decrease substantially the risk of cardiovascular diseases.

Depending on the type and concentration of the initiator of free radicals, polyphenols can behave as either antioxidants or prooxidants.^{66–69} The understanding and interpretation of the dual behaviour of polyphenols is complicated by the fact that despite the large body of data on high biological activity accumulated in recent years, the questions concerning the mechanism of their action and existence in the active forms *in vitro* and *in vivo* are still open. Therefore, development of procedures for determination of phenols and polyphenols in various objects by various analytical techniques, including chromatographic ones, is a topical task.

III. Sample preparation

An important problem that researchers are often faced with when investigating complex mixtures is the need to isolate the analytes from natural sources and thoroughly purify the extracts prior to the analysis.

The strategy of determination of biologically active compounds in plants depends on the nature and structure of the compound under study, the object of analysis (sample) and goals of analysis and cannot be completely unified. The following main stages of the investigation can be distinguished: extraction of the compounds from the sample, purification of the extract from accompanying compounds, separation and identification.

1. Extraction of compounds from natural sources

As a rule, biologically active compounds come from plant sources. Therefore, the primary task of a research is to extract the target compounds from the raw material as fully as possible, better in the native form. Usually, this is done by liquid or supercritical fluid extraction, in some cases, by high-pressure steam extraction. The extraction methods that permit preliminary purification of the extract from accompanying compounds are preferred.

The plant material is crushed and defatted by treatment with light petroleum, hexane or chloroform. If it is necessary to isolate a particular compound or a group of compounds from a complex sample, successive extractions with solvents in the order of increasing polarity is carried out (hexane, diethyl ether, ethyl acetate, butanol, water–ethanol mixtures).⁷⁰ In simple cases, one-stage extraction with methanol^{71,72} or dichloromethane is performed.⁷³ Pinelo *et al.*⁷⁴ used ethanol for complete extraction of biologically active phenols from the almond shell and pine sawdust, while polyphenols were selectively extracted with methanol. In another study,⁷⁵ phenols were extracted from lablab

stems, flowers and fruit coat with 90% methanol and from leaves, with 90% ethanol. Preliminary separation of the flavonoids in plant extracts is carried out using preparative thin layer chromatography or preparative reversed phase chromatography.⁷⁶ The isolation of polyphenols from plant material is performed most often using 80% ethanol. The purity of the resulting fractions is checked by thin layer chromatography.^{77–79}

Anthocyanins and anthocyanidins are extracted and separated in an acidic medium in order to avoid the destruction of non-acylated derivatives. In addition, the most stable resonance form of anthocyanins, flavylium cation, is formed at pH < 2. The extraction of anthocyanins from the ghost plant (*Graptopetalum paraguayense*) leaves with water and water–ethanol mixtures at different temperatures has been studied.⁸⁰ The highest antioxidant activity was found for a 50% ethanolic extract (extraction for 3 h at 75 °C). A mixture of water, acetonitrile and formic acid (1:1:0.1)⁸¹ or trifluoroacetic acid (1:1:0.5)⁸² was used to extract anthocyanins from liliaceous plant petals. Extraction with water⁸³ or methanol⁸⁴ with addition of an acid is also possible; however, the extraction time in this case is 12–16 h. Water–methanol–organic acid mixtures are more efficient. These extractants were used to isolate anthocyanidins of ornamental plants.^{85–87} The extraction efficiency increases when an ultrasonic bath or a magnetic stirrer is used.

Sample preparation of procyanidins has some specific features. These compounds readily form complexes with metals, polysaccharides and proteins, which hampers their extraction using solid sorbents. The extraction of procyanidins from the seed coats or fruit pulp is complicated by the fact that procyanidins are oxidised during fruit ripening. This yields procyanidin–polysaccharide complexes and the solubility of procyanidins thus decreases.⁸⁸

Rohr *et al.*⁸⁹ proposed a procedure for quantitative determination of procyanidins (three dimers and a trimer of epicatechin) in hawthorn leaves and flowers by reversed phase high performance liquid chromatography. The most complete extraction of procyanidin oligomers (yield 99%) was achieved using 70% aqueous acetone. However, during acetone evaporation, polymerisation and precipitation of the target compounds may take place. Extraction with 70% aqueous methanol has been reported.^{90,91} Methanol was used to obtain extracts from olive tree, hawthorn and oregano leaves.⁹² The extraction of procyanidins from the cat's claw (*Uncaria tomentosa*) bark by refluxing with water has been reported.⁹³ Flavonoid glycosides and anthocyanidins can be destroyed by acid hydrolysis carried out at ~90 °C for several hours. The effect of the addition of an acid during extraction on the antioxidant activity of plant extracts has been studied.⁹⁴ The activity was found to increase in the vast majority of cases.

The higher the pressure, the higher the efficiency in liquid extraction. Papagiannopoulos *et al.*⁹⁵ identified 41 polyphenols in an aqueous acetone extract of algaroba obtained in this way. By varying temperature and pressure, biologically active phenols have been selectively extracted with water from rosemary⁹⁶ and other plants.⁹⁷ By combined use of solid-phase extraction and high performance liquid chromatography, an automated procedure for determination of procyanidins in malt was developed.⁹⁸

Using supercritical fluid extraction technique, one can substantially increase the yield of labile compounds from biological matrices. As a rule, supercritical carbon dioxide is used. Since the polarity of CO₂ is relatively low, a polar modifying agent is often added. The effects of temperature, pressure and polar additives on the extraction kinetics and antioxidant properties of the ginger oil have been studied.⁹⁹ The efficiency of supercritical fluid extraction of phenols from the olive tree leaves with supercritical CO₂ has increased after the addition of methanol.¹⁰⁰ Thermodynamic modelling of quercetin solubility in supercritical CO₂ in the presence of ethanol has been carried out.¹⁰¹ A scheme for broad-scale supercritical fluid extraction of the rosemary oil followed by liquid chromatography–mass spectrometry analysis of the obtained fractions has been proposed.¹⁰² The use of supercritical

CO₂ for the fractionation of plant extracts has been reported.¹⁰³ New extraction techniques such as supercritical fluid extraction and automated tunnelling solid-phase microextraction has been described.¹⁰⁴ The extent of extraction of polyphenols from grape stones with liquid–liquid, solid-phase and supercritical fluid extraction have been compared.¹⁰⁵ The highest yield was achieved by the last-mentioned technique, possibly, due to the fact that the sample was located in a carbon dioxide atmosphere and was protected from light. This minimised decomposition of unstable compounds such as catechins.

A comparison of the efficiency of extraction from natural sources by liquid–liquid, solid-phase and supercritical fluid extraction techniques and by high-pressure extraction using various solvents has been reported.¹⁰⁶

Usual objects of analysis, *i.e.*, plants, berries, fruits and vegetables, contain diverse phenols and polyphenols. However, substantial portions of these compounds are often lost during extraction, isolation and purification. Therefore, correct choice of the sample preparation method is a key issue in the qualitative and quantitative analysis of complex multicomponent mixtures.^{107, 108}

2. Methods for extract purification and preconcentration

A number of techniques for the extraction and purification of phenols from complex mixtures have been reported,^{109, 110} specifically, supercritical fluid extraction, semipreparative high performance liquid chromatography, high-speed counter-current liquid chromatography and superheated solvent extraction. Liquid–liquid and solid-phase extractions are used most widely for purification and preconcentration of polyphenols.^{111–120}

For correct quantitation of phenol derivatives, it is necessary to take into account their possible transformations. This is especially important for analysis of food and beverages. During their production, phenols present in the raw materials undergo various transformations.

The influence of different wine manufacture processes on the composition of phenols and the antioxidant properties of the red wine Spatburgurder (Pinot Noir) and Cabernet Franc have been studied.¹²¹ The processes included the grape peel fermentation, mash heating and a combination of these processes. The highest concentrations of anthocyanins, flavan-3-ols, flavonols and stilbenes were found in the red wine prepared by process combination. Lower concentrations of biologically active compounds were present in the wine prepared by mash heating; the wine produced by peel fermentation contained the lowest amount of anthocyanins. The process of fermentation during production of wine from blackberry and cherry berries caused ~25% decrease in the content of the total polyphenol fraction.¹²²

Table 1. Eluents used for fractionation and separation of extracts.

Phenols	Thin layer, preparative and column chromatography
Procyanidins	MeOH, acetone–water, ethyl acetate–HOAc–H ₂ O
Anthocyanins	Bu ⁿ OH–HOAc–H ₂ O (4:5:1); Bu ⁿ OH–2 N HCl (1:1), 1% HCl, HOAc–HCl–H ₂ O (15:3:82)
Anthocyanidins	HOAc–HCl–H ₂ O (30:3:10); HCO ₂ H–HCl–H ₂ O (5:2:3)
Phenolic acids	Bu ⁿ OH–HOAc–H ₂ O (4:5:1); EtAc–HOAc–H ₂ O (3:1:1); EtOH–H ₂ O–NH ₄ OH (16:3:1); toluene–HOAc–H ₂ O (40:10:5)

Note. The following mixture are used as eluents in high performance liquid chromatography: organic solvent (methanol, acetonitrile, ethanol)–water–acid (HCl, acetic, trifluoroacetic, formic, phosphoric) or organic solvent–acid.

In the extraction of phenols from grapefruit and orange juices¹²³ and dry leaves of green tea,¹²⁴ high yields were attained by repeated liquid–liquid extraction with aqueous methanol and acidified methanol. However, solid-phase extraction¹²⁵ ensures higher yield of phenols and polyphenols from various samples than liquid–liquid extraction. The main eluents for fractionation and separation of extracts are presented in Table 1.

IV. Chromatographic determination of phenols and polyphenols in various objects

1. Determination in plant materials

Determination of phenols in objects with a large number of components (complex mixtures) is performed most often by chromatography and capillary electrophoresis. Due to the thermal and chemical lability of most compounds to be determined, thin layer chromatography, its high performance version, capillary electrophoresis and high performance liquid chromatography are used. Thin layer and flash chromatography were the first methods used to separate many biologically active compounds of the plant origin. These methods are distinguished by low cost and simplicity. High-performance and two-dimensional thin layer chromatography can be used for analysis of complex natural sources of phenols.

Plant extracts do not require thorough purification by thin layer chromatography. Examples of such analyses are qualitative and quantitative determination of flavonoids in the passion flower (*Passiflora coerulea*)¹²⁶ and beech extracts.¹²⁷ Flavonoids were detected by exposure to UV light,¹²⁸ while procyanidins and anthocyanins were visualised by spraying with a 5% solution of vanillin in an ethanol–HCl (4:1) mixture.¹²⁹ Aglycons and glycosides were detected in the UV light and then visualised by spraying with a solution of H₂SO₄ and heating.¹³⁰ Scanning densitometry was used to analyse plant pigments.¹³¹ Simultaneous separation and detection of compounds with antioxidant properties was carried out on plates with 1,1-diphenylpicrylhydrazide¹³² and silver nanoparticles¹³³ applied thereon as indicators.

Gas chromatography is of limited utility for the analysis of natural biologically active compounds due to the necessity of derivatisation of phenols into methyl or trimethylsilyl derivatives. Nevertheless, such analysis is practised. Gas chromatography with mass spectrometric detection was used to determine phenolic acids in a coriander extract,¹³⁴ the main flavonoids and their glycosides in the willow wood¹³⁵ and phenols in the wormwood oil.¹³⁶ Fiamegos *et al.*¹³⁷ have developed a procedure for simultaneous extraction and derivatisation of flavonoids and phenolic acids for their determination in plant extracts by gas chromatography with mass spectrometric detection.

High performance liquid chromatography is used most often for determination of phenols. This is due to the following advantages of the method: high selectivity of the sorbents, sensitivity and selectivity of the diode array, ultraviolet, fluorescence and mass spectrometric detectors and mild conditions of analysis under which the analytes are not decomposed. High performance liquid chromatography on reversed phase columns with binary solvent systems and diode array detector is used both for routine analyses and to study plant extracts with complex composition. The detection limit of flavonoids can be reduced by using electrochemical or fluorescence¹³⁸ detectors. Examples of solvent systems and columns for this type of chromatography of plant extracts are summarised in Table 2.

Chromatography with amperometric detection is used to estimate the antioxidant activities of foodstuffs, beverages and drugs.^{149, 150} Most natural biologically active phenols can be oxidised on an electrode; therefore, the amperometric detector is convenient for their determination. This allows one to establish the presence of unknown compounds in complex natural sources of phenols, whereas classical chemical methods¹⁵¹ are only

Table 2. Results of analyses of the extracts of some flavonoids in plant samples by high performance liquid chromatography.

Sample	Identified compounds	Extractant	Column	Mobile phase	Detection	Ref.
Red clover	11 flavonoids	ethanol, methanol; acid hydrolysis	HP ODS Hypersil	H ₂ O/AcOH – MeOH	UV-MS	139
Passion flower (<i>Passiflora incarnata</i>)	10 flavonoids	'dry' extract	LiChrospher RP-18	H ₂ O – THF – MeCN – Pr ⁱ OH	UV-MS	140
Cistus (<i>Cistus ladanifer</i>)	8 flavonoids	chloroform, methanol	LiChrosorb RP-18	0.1 M NH ₄ OAc in H ₂ O – THF – MeCN – Pr ⁱ OH	UV-MS	141
Goatweed herb (<i>Hypericum perforatum</i> , St John's wort)	16 phenolic compounds	methanol	TP 544 RP-18	H ₂ O/H ₃ PO ₄ – MeCN – MeOH	UV-MS	142
Oregano, caraway, fennel	flavonoids, methoxyflavonoids	methanol – water (62.5%)	Phenomenex RP C ₁₈	H ₂ O/HCO ₂ H – MeOH	UV, MS-MS	143
Siberian larch and Gmelin larch bark	21 flavonoids	ethyl acetate	TLC: silica gel, HPLC: Separon C ₁₈	H ₂ O/AcOH – MeCN	UV, IR, NMR	144
Gnidia (<i>Gnidia socotrana</i>) herb	flavone and coumarin derivatives	ethanol, heptane, ethyl acetate, n-butanol	RP 18	MeOH; H ₂ O/AcOH – MeCN	UV, UV-MS	145
Cyclopia	8 flavonoids, two isomers separated	methanol	Phenomenex Synergy MAX-RP C ₁₂	H ₂ O/AcOH – MeCN – THF	electrochemical detector	146
Veronica (<i>Veronica thymoides</i>)	acylated flavonoids and glycosides	methanol, light petroleum	polyamide column for flash chromatography, TLC: silica gel	MeOH – CHCl ₃ , MeOH – H ₂ O	fluorescence detector	147
Brazilian pine tree	6 flavonoids	methanol – water, hexane	Phenomenex Synergy C18	MeOH – CHCl ₃ /HCO ₂ H	DAD, MS	148

Notes. The following designations are used: UV-MS a combination of UV and mass spectrometric detectors, MS-MS is tandem mass spectrometry, TLC is thin layer chromatography, DAD is diode array detector.

suitable for estimating the overall antioxidant activity of the sample or the activity of a known compound.

The difficulties arising in the determination of phenols by chromatographic methods are mainly related (apart from the necessity of preliminary purification of the extracts before the introduction into the column) to the lack of standards due to the great diversity of natural forms of these compounds. Therefore, the so-called fingerprint method is used in some cases for analysis of complex plant extracts.^{152, 153} These fingerprints are specific for each plant species and can be used to identify the source of a plant raw material. Secondary metabolites, including phenolic acids and flavonoids, are used as chemical markers in the fingerprints.¹⁵⁴ The plants species are differentiated based on the variation of the composition and content of these compounds.¹⁵⁵ A combination of the fingerprint method and chromatographic analysis of biological fluids is used to identify fake drugs.¹⁵⁶

A number of methods have been described for quantitative and qualitative determination of proanthocyanidins and their derivatives,¹⁵⁷ chromatography and spectrometry being used most often.

The spectrometric methods are based on reactions giving chromophores (the Folin–Ciocalteu reagent, the use of HCl–BuOH, vanillin, and so on). However, these methods do not provide information on the amounts and structures of oligomers with different degrees of polymerisation. Spectrophotometry is used to determine the total amount of procyanidins in complex samples,⁹³ however lately it has been replaced by mass spectrometry. Gel chromatography,¹⁵⁸ thin layer and column chromatography are used to isolate anthocyanin and procyanidin fractions and to separate them according to the degree of polymer-

isation.^{92–94} A mixture of individual procyanidins (from monomers to trimers) can be separated by reversed phase high performance liquid chromatography.^{99, 159} The method proposed by Svedstrom *et al.*⁹¹ made it possible to separate epicatechin oligomers (from monomers to hexamers) present in the extract of hawthorn leaves and to isolate previously unknown trimers and pentamers using a polyamide column and an acetonitrile-based eluent.

Capillary electrophoresis is gaining increasing acceptance for determination of pharmacologically important compounds in plants.^{160–162} *trans*-Resveratrol was determined using a borate buffer (pH 8–11), as borates form complexes with the hydroxy groups of flavonoids, thus facilitating the separation.¹⁶³ The buckthorn flavonoids were separated in the presence of a modifying agent, dimethyl- β -cyclodextrin.¹⁶⁴ Anthocyanins have been separated by capillary electrophoresis in an acidic medium.¹⁶⁵

Neutral molecules can be separated in an electric field by micellar electrokinetic capillary chromatography. By varying the concentration of the micelle-forming agent (most often, sodium dodecyl sulfate), the system selectivity can be changed. Various modifying agents are used: methanol for determination of flavonoids, phenolic acids and aldehydes,¹⁶⁶ butan-1-ol for flavonoids and iridoids¹⁶⁷ and acetonitrile for coumarins.¹⁶⁸ Drawbacks of the method include lower sensitivity and reproducibility compared to high performance liquid chromatography.

2. Determination in foodstuffs and beverages

Most often, phenols are detected by spectrophotometry using a number of wavelengths: 230, 280, 360, 503 nm, *etc.* In some studies dealing with particular groups of flavonoids, only one

wavelength was used, namely 280 nm for catechins^{169–173} and 520 nm for anthocyanins.^{174–178} Other studies made use of wavelengths of 280, 306 and 360 nm for phenol detection.^{179–184} Since many phenols have several absorption maxima, they are often determined using simultaneous scanning at several wavelengths called diode array detection.^{185–190} High performance liquid chromatography with diode array detection is often used to determine phenols present in foodstuffs and beverages. The key advantage of this method is the low detection limits. For example, the detection limit for catechins in the green tea extract was reported to be 0.05 mg ml⁻¹ (with detection at 205 nm).¹⁹¹ Examples of using the diode array detection in the determination of phenols and polyphenols in fruit and vegetable extracts and in

beverages by high performance liquid chromatography are summarised in Table 3.

Determination of phenols in foodstuffs and beverages is often carried out by reversed phase chromatography on modified silica gels, because reversed phase columns ensure high separation selectivity and better reproducibility of the results and have longer service life. Some types of modified silica gels used most often in the analysis of phenols in various objects are summarised in Table 4.

To increase the sensitivity and selectivity of determination of phenolic acids and aldehydes, simultaneous diode array and fluorescence detection is used. In order to ensure the highest sensitivity of the analysis, a fluorescence detector should be time

Table 3. Results of determination of phenol and polyphenol antioxidants in fruits, vegetables and beverages by high performance liquid chromatography.

Object	Identified compounds	Detector	Quantifiable concentrations	Ref.
Apples, grapes, beans	(+)-catechin, (-)-epicatechin, 3 catechin derivatives	DAD	0.1–3.9 mg per kg — —	192
Grapefruit juice	naringin	DAD 280 nm	2.5 mg litre ⁻¹	193
Grape berries	<i>trans</i> -resveratrol, rutin, quercetin, quercitrin	DAD 306 nm	4.5–10.1 mg per 100 g — 0.16–0.45 mg per 100 g —	194
Bulgarian wine, 11 brands	quercetin, myricetin, morin, kaempferol	DAD 360 nm	the highest total content of flavonols in the brand Melnic: 12.2–16.9 mg litre ⁻¹	195
Green and black tea	16 phenols including (-)-epigallocatechin	DAD 205 nm	2.84 mg g ⁻¹ (black tea) (23.46–36.53) mg g ⁻¹ (green tea)	196–199
Juices and beverages	21 phenols including: quercetin (-)-quininic acid	DAD 215 nm	0.03 mg litre ⁻¹ 12.5 mg litre ⁻¹	200

Table 4. Characteristics of some reversed phase columns used in analysis of phenol derivatives in various objects by high performance liquid chromatography.

Object	Column			Elution time and mode	Identified compounds	Ref.
	sorbent type	sorbent grain diameter /μm	column size /mm			
Juices (apple and multifruit)	Shim-Pack VP-ODS	5	250 × 4.6	80 min, gradient	31 phenols	201
Cranberry	XDR C ₁₈	5	150 × 4.6	47 min, gradient	13 phenols	202
Apples, pears	Nucleosil 120 C ₁₈	5	250 × 4.6	25 min, gradient	5 phenols	203
Green and black tea, 8 brands	PartiSphere 5 C ₁₈	3	110 × 4.6	27 min, gradient	15 phenols	191
Chocolate, 11 brands	Hypersil ODS	5	250 × 4.6	30 min, isocratic	9 phenols	173
Grapefruit, orange	μ-Bondapak C ₁₈	5	250 × 4.6	20 min, isocratic	3 phenols	204
White wine, 11 brands	Alltima	3	100 × 4.6	20 min, isocratic	4 phenols	205
Grape berries	Hypersil ODS	5	150 × 4.6	25 min, gradient	4 phenols	206

Onion, soy	Hypersil 120	3	125 × 4.6	30 min, gradient	5 phenols	208
Green tea	YMC-Pack ODS-AQ	5	150 × 4.6	50 min, isocratic	6 phenols	209
Orange juice	Luna	3	150 × 2.0	15 min, gradient	10 flavonoids	181
Lemon peel	Nova Pak C ₁₈	5	150 × 4.6	60 min, gradient	7 flavonoids	210
Wine ^a	Spherisorb ODS 2	3	250 × 4.6	55 min, gradient	17 phenols	211
Orange and grapefruit juice concentrates	Alltech C ₁₈	5	250 × 4.6	30 min, isocratic	3 flavonoid glycosides	123
French wine ^b	Nucleosil 100 C ₁₈	5	250 × 4.0	75 min, gradient	1 phenol	212
Linseed	Spherisorb S-ODS	5	250 × 4.0	50 min, isocratic	6 phenols	213
Lentil, beans	Nucleosil 120 C ₁₈	5	250 × 4.6	20 min, gradient	5 phenols	214

^a The wine brand was not specified. ^b Red and white wine, 5 brands each.

programmed for the optimal excitation and fluorescence wavelengths for the group of phenols with similar spectral characteristics. The use of statistic multivariate methods is of interest for composing an optimal program for detection of a complex sample.¹⁸⁸ After optimisation of all individual parameters of the analysis, the detection limit for *trans*-resveratrol using fluorescence detector was 0.003 mg litre⁻¹, and using diode array detector, this value was an order of magnitude higher, 0.02 mg litre⁻¹ (Ref. 187).

The sensitivities of various versions of detection in the determination of flavonoids in orange juice by high performance liquid chromatography have been compared.²¹⁵ The detection limits and the concentrations of some flavonoids found in orange juice are presented in Table 5. It can be seen that all detection methods ensured high reproducibility and allowed quantitative determination of low levels of flavonoids.

Table 5. Detection limits and results of quantitative determination of flavonoids in orange juice by high performance liquid chromatography with different detectors.¹⁸⁶

Compound	Detector		
	UV	mass spectrometer	electro-chemical
Detection limits (μg in 1 ml) for some flavonoids			
Quercetin	0.15	0.2	0.3
Narirutin	0.2	0.1	1.0
Eriocitrin	0.2	0.08	0.5
Hesperidin	0.3	0.1	0.5
Naringin	0.25	0.15	1.0
Content (mg per 100 g) of flavonoids detected in juice			
Quercetin	1.34 ± 0.15	0.90 ± 0.03	1.18 ± 0.11
Narirutin	5.10 ± 0.17	5.4 ± 0.2	5.0 ± 0.6
Eriocitrin	1.0 ± 0.2	0.9 ± 0.3	—
Hesperidin	73 ± 7	78.9 ± 0.4	79.3 ± 0.5
Naringin	2.6 ± 0.3	0.14 ± 0.0	—

The compounds to be determined may have a broad range of polarity; therefore, their analysis requires either a gradient elution mode or several mobile phases with isocratic elution. Thus the isocratic mode was used to determine anthocyanins, flavan-3-ols, flavonols and phenolic acids in three brands of Bulgarian wine and gradient elution was employed to determine stilbenes in the same brands of wine.¹²² In some cases, virtually no sample preparation was required. For analysis of *trans*-resveratrol isomers in red wine, the sample was directly applied (without the sample preparation stage) on a chromatographic column and the fractions containing each of the target stilbenes were isolated by reversed phase high performance liquid chromatography.²¹⁶ Then these fractions were analysed by the gas chromatography–mass spectrometry technique.[‡]

A popular method for detection of phenols is coulometric detection. Unlike amperometric analysis, in this case the analyte is completely oxidised. The coulometric detector has been used for qualitative and quantitative determination of phenols in vegetable oils.¹⁹⁵ The advantages of this detector are the simple design and the possibility of simultaneous determination of eluates with different oxidation potentials. This detector ensures a lower detection limit and a higher selectivity than the UV detector when used for quantitative determination of biologically active

phenols in plant extracts. However, it suffers from a number of drawbacks, namely, contamination of the electrode by oxidation products and, as a consequence, a change in the electrode characteristics, dependence of the signal on the eluent flow rate and limited applicability in the gradient elution mode.²¹⁸ It has been found²¹⁹ that phenolic acids and tocopherol show the maximum coulometric detector response at low potentials (100–450 mV), while flavonoids show the maximum responses in two ranges: 0–300 and 600–900 mV.

In the studies of complex natural objects by any chromatographic method, identification of the components is an important stage. This task is solved by comparing the retention times, spectroscopic data and/or retention indices of the analytes with the same parameters of standard (reference) compounds. In analysis of natural objects, the most informative data can be obtained by combined use of all characteristics.²²⁰ The phenol derivatives determined by high performance liquid chromatography are identified by comparison of spectroscopic characteristics (mass spectra)²²¹ and retention indices^{222, 223} with the respective characteristics of the standard compounds. In the absence of standard compounds,²²⁴ the impurities in dihydroquercetin can be identified by combined consideration of the retention indices and spectral ratios at different wavelengths. It is possible to use retention indices in micellar electrokinetic chromatography.²²⁵

In recent years, high performance liquid chromatography with mass spectrometric detection^{226–230} or combinations of diode array and mass spectrometric detection with various ionisation sources^{231–234} have been used most often to identify phenols present in plant raw materials and foodstuffs. The latter technique is especially valuable in the study of acylated flavonoid glycosides present in plants, vegetables or fruits in small amounts.

Using high performance liquid chromatography with mass spectrometric detection and with chemical ionisation under atmospheric pressure, extracts of about 40 fruit and vegetable species have been characterised qualitatively and quantitatively.²³⁵ Seven flavonoids were isolated and identified. For example, apples contained up to 2 mg of quercetin per 100 g of the sample weight and parsley contained up to 185 mg of apigenin per 100 g of the sample weight.

Studies of flavonoids in many spice plants carried out by high performance liquid chromatography with electrospray ionisation mass spectrometry detection have shown¹⁴³ the possibility of determining molecular masses of aglycons and glycosides.

Capillary electrophoresis starts to be actively used to determine phenols in juices, tea, vegetable oils, wines and berries.^{236–241} Advantages of this method include the possibility of introducing the sample into a capillary in a dilute form under pressure,²⁴² i.e., the sample preparation stage is avoided, and performing the experiments over a broader pH range^{243, 244} than in the case of high performance liquid chromatography.

A review²⁴⁵ cites an interesting example of using capillary electrophoresis for the separation of six diastereomeric flavanone-7-*O*-glycosides. The separation was carried out at pH 10 in a phosphate buffer with addition of chiral compounds, viz., cyclodextrins and their derivatives, to the supporting electrolyte. Under chosen conditions, lemon juice was analysed and the mixture of four flavanone-7-*O*-glycosides present was separated into isomers.

Currently, capillary electrophoresis is used as a technique supplementary to high performance liquid chromatography for the separation and determination of phenols.

3. Determination in biological fluids

Biological fluids (blood, urine) are analysed for the presence of antioxidants and to estimate the bioavailability of these compounds (after consuming various kinds of food), study their metabolism and influence on the human health. In virtually all studies of this type, high performance liquid chromatography and capillary electrophoresis techniques are used. The applications of

‡ The original procedure for the analysis of hydrophobic samples including direct injection of plant or animal fats into a column has been reported.²¹⁷ The procedure is applicable to determination of biologically active compounds in plant oils.

capillary electrophoresis, in particular, that with mass spectrometric detection, for analysis of antioxidants, metabolites and toxins have been surveyed.²⁴⁵ In the present review, we will consider the use of high performance liquid chromatography in more detail.

The extraction of flavonoids from biological fluids is rather simple. A sample is centrifuged to remove proteins and other polymeric components and is subjected to solid-phase extraction with elution by methanol, ethanol and ethyl acetate. If necessary, enzymatic or acid hydrolysis is carried out. Sample preparation methods for blood samples have been compared.²⁴⁶ The addition of anticoagulants does not influence noticeably the accuracy of analysis, 1% ascorbic acid mixed with orthophosphoric acid (10 $\mu\text{l ml}^{-1}$) being the best stabiliser. The samples should be stored at -20°C .

Isoflavones were the first flavonoids to be determined quantitatively in human urine. Routine methods for analysis of human blood and urine for the presence of daidzein and equol (120 ng ml^{-1})²⁴⁷ using reversed phase high performance liquid chromatography with UV detection have been developed. The high performance liquid chromatography technique with electrochemical detector is more sensitive, permitting determination of daidzein, genistein and equol at a level of 1–2 ng ml^{-1} (Ref. 248). By gas chromatography–mass spectrometry, isofla-

vone metabolites were identified in blood serum and rat internal tissues at a minimum content of 10–20 pg mg^{-1} (Ref. 249). A fast method for determination of isoflavone in urine by immunofluorometric assay was proposed by Uehara *et al.*²⁵⁰ The method is sensitive (0.1 ng ml^{-1}) and reproducible (the root-mean-square deviation is 2%–10% between the series of analyses); however, like gas chromatography with the same detection method, this method is expensive and labour-consuming.

The total amount of quercetin and its metabolites in biological samples is determined using liquid chromatography with mass spectrometric detection^{251–254} and some other methods, for example, versions of high performance liquid chromatography with mass spectrometric,²⁵² UV,^{255,256} affinity chromatographic,²⁵⁷ fluorescence and electrochemical^{258,259} detection. Gas chromatography with mass spectrometric detection has been proposed for determining quercetin and its conjugates in human urine and blood plasma in concentrations of down to 10 pg ml^{-1} (Ref. 260). The characteristics of some methods for determination of quercetin and other biologically active phenols are given in Table 6.

Thus, nowadays, reversed phase high performance liquid chromatography combined with various detection techniques (most often, diode array and mass spectrometric detection) is

Table 6. Characteristics of some methods for determination of biologically active phenols in various samples.

Sample	Identified compounds	Extractant	Hydrolysis	Method ^a	Detection limit / ng ml^{-1}	Ref.
Blood, human blood serum and plasma, rat urine	(+)-catechin, quercetin, <i>trans</i> -resveratrol	ethyl acetate	see ^b	GC-MS	0.01	261
Human blood and urine	quercetin and its glycosides	aqueous methanol	HCl–methanol, 5 h (blood), 8 h (urine)	HPLC, fluorescence detector	—	262
Rat blood plasma	quercetin	preliminary purification on a C_{18} column, extraction with a toluene– CH_2Cl_2 mixture	ascorbic acid + β -glucuronidase	HPLC, electrochemical detector	0.63	263
Rat urine and blood	flavonoids, phenylalkanoic acids	water, methanol, fractionation (SPE C_{18})	HCl–methanol, 45 min	RP HPLC-UV (C_8 , C_{18})	—	264
Human blood plasma	naringin, naringenin	ethanol, fractionation (Sep-Pak, C_{18} , 80% methanol)	—	RP HPLC-UV (C_{18})	2	265
Human blood plasma	catechin, epicatechin, 3 derivatives	ethyl acetate	HCl–methanol, 30 min	RP HPLC-UV (C_{18})	—	266
Human urine	apigenin, acacetin	addition of 2 M NaOAc + 10% ascorbic acid	β -glucuronidase + arylsulfatase, 60 min	RP HPLC-UV with column switching (C_8 , C_{18})	10–70	267
Human blood plasma	naringenin, hesperetin	SPE on a C_{18} cartridge	β -glucuronidase + arylsulfatase, 18 h	HPLC-UV, C_8	10	268
Rat blood, urine, tissues	a mixture of 8 catechins	methanol–ethyl acetate–sodium dithionite (2 : 1 : 3)	β -glucuronidase + arylsulfatase, 45 min	RP HPLC (C_{18}), electrochemical detector	5	269
Human blood serum	6 phenolic acids and aldehydes	formic acid–acetone–water (4 : 140 : 56)	—	HPLC-MS (C_{18})	8	270

Notes. The following designations are used: GC-MS is gas chromatography–mass spectrometry, RP HPLC-UV is reversed phase high performance liquid chromatography with UV detection, SPE is solid-phase extraction, HPLC-UV is high performance liquid chromatography with UV detection, HPLC-MS is high performance liquid chromatography with mass spectrometric detection.

^a The hydrocarbon sorbent is indicated in parentheses. ^b Prior to the analysis, the sample was modified with bis(trimethylsilyl)trifluoroacetamide.

one of the most efficient methods for separation and identification of biologically active phenols and polyphenols in various objects.

The mechanism of electronic excitation in the bacterial bioluminescent reaction

E V Nemtseva, N S Kudryasheva

Contents

I. Introduction	91
II. General characteristics of the bioluminescent reaction of bacteria	92
III. Formation of the emitter in the bioluminescent reaction	93
IV. Excitation of secondary emitters of bacterial bioluminescence	96
V. Conclusion	99

Abstract. The current state of the problem of formation of the electron-excited product in the chemiluminescent reaction that underlies the bacterial luminescence is analysed. Various schemes of chemical transformations capable of producing a bacterial bioluminescence emitter are presented. The problem of excitation of secondary emitters is considered; two possible mechanisms of their excitation are analysed. The bibliography includes 76 references.

I. Introduction

The bioluminescence, *i.e.* glowing of living organisms, is based on chemiluminescent reactions catalysed by biological catalysts, *i.e.*, enzymes that are called luciferases.^{1,2} Luminescence is inherent in more than 700 animal species, the best studied of which are bacteria, fireflies, marine coelenterates (jelly-fishes, hydranths, *etc.*), fishes, and so on.¹ Among the luminescent organisms, only bacteria emit light continuously. Being developed on organic remainders formed, they make a substantial contribution to the ocean glow. It is believed that by luminous bacteria attract more advanced species (for example, fish or shrimp) and thus they can populate their organs as symbiotes or parasites.¹ However, the signal function of bioluminescence may be secondary. Many researchers suggest an important metabolic role of light-producing systems,³ in particular, the relationship between the bioluminescent reactions and the antioxidant system of the organisms is considered.^{4–6} Presumably, bioluminescence is due to the hereditary change in the mechanisms that protect cells specially releasing reactive oxygen species for particular purposes from self-destruction.⁷ In addition, it has been suggested that luciferases and their substrates perform only metabolic functions in the cells, while emission of a light quantum is a ‘random’ process.^{4–6} According to a hypothesis, the bioluminescent reaction serves for hydrogen peroxide deactivation by the cells under

conditions of intensive energy metabolism.⁸ The excess energy is emitted as a light quantum; otherwise, its dissipation as heat or side chemical reactions would threaten the cell viability.

The substrates of bioluminescent reactions (traditionally called luciferins) present in various organisms differ in chemical structure and belong to different classes of organic compounds.^{1,9} The amino acid composition and structure of luciferases are also different even for related species of luminescent bacteria.¹⁰ Currently, about 30 bioluminescent reactions, *i.e.*, about 30 luciferin – luciferase combinations, are known.

Unlike most chemiluminescent processes in the inanimate nature, the luminescence of living organisms has a high intensity. This is due, first, to high rates of enzymatic chemiluminescent reactions, and second, to high quantum yields of the luminescence of the reaction products, *viz.*, emitters. Despite the fact that emitter molecules of various bioluminescent organisms belong to different classes of chemical compounds, they bear similarity in the electronic structure: they belong to the same spectral luminescent group in the classification of molecules according to spectral luminescence properties.¹¹ The molecules of this group are characterised by high quantum yields of $\pi\pi^*$ fluorescence and high efficiency of intramolecular relaxation of energy from upper excited states.

In addition, certain contribution to the high bioluminescence yields (the number of quanta per reaction event) is made by the protein environment of the bioluminescence emitters, which protects them from energy transfer and transformation processes competing with light emission. In this case, the protein can act as a matrix that ensures rigid fixation of the fluorophore. In some bioluminescent reactions, the yields of bioluminescence are close to unity.^{2,9}

High efficiency of formation of the light quantum distinguishes bioluminescence from another type of biological glow, namely, weak and ultraweak chemiluminescence, which always accompanies the vital activity of an organism. In the case of ultraweak luminescence of animal tissues, photons are usually formed as by-products of free radical autoxidation of unsaturated fatty acids.¹² In addition, bioluminescence usually performs a definite biological function (*e.g.*, attracts a partner or deters beasts from prey) and in this sense, the light quantum is physiologically the main reaction product.

A common feature of all biological light emitting reactions is that molecular oxygen is always a reaction component.

The luminescence of bacteria has been attracting the attention of researchers for four decades; in some aspects, this is one of the best studied bioluminescent processes.^{2,13} This, however, does not refer to the chemical mechanism of formation of the electron-

excited product in the bioluminescent reaction; this question still remains open and arouses the interest of chemists and physicists who study chemiluminescence. Throughout the history of investigations of bacterial luminescence, a dozen of possible routes for the excitation of chemiluminescence in the bacterial luciferase-catalysed reaction have been proposed. This review gives comparative analysis of the main excitation mechanisms in the bioluminescent reaction of bacteria.

II. General characteristics of the bioluminescent reaction of bacteria

It has been found long ago¹³ that the chemical grounds of bacterial luminescence include the enzymatic oxidation of the reduced flavin mononucleotide [(FMN)H₂, **1**] to flavin mononucleotide (FMN, **2**) and oxidation of long-chain aldehyde **3** to myristic acid (**4**) with atmospheric oxygen.

The overall reaction can be written as follows:

The bacterial luciferase is a heterodimer with a molecular mass of ~80 kDa. The components of the bioluminescent reaction can also react without an enzyme but the efficiency of chemiluminescence in this process is 10 orders of magnitude lower.² From this standpoint, bacterial luciferase is considered to be the most catalytically active known enzyme.

The heat of this reaction is 110 kcal mol⁻¹; this comprises the heats of oxidation of (FMN)H₂ (40 kcal mol⁻¹) and the aldehyde (70 kcal mol⁻¹).⁷ The overall heat of the reaction is greater than the energy of the bioluminescence quantum equal to ~60 kcal mol⁻¹. However, it can be seen that the oxidation energy of only (FMN)H₂ does not suffice for the observed light quantum emission.

It is noteworthy that none of the starting reactants of the discussed reaction can exist in a bacterial cell in the free state, in particular, (FMN)H₂ (**1**) is rapidly autoxidised, while aldehyde **3** is a poison and is not produced by organisms. Therefore, bacteria have special enzyme systems that facilitate the reduction of FMN (**2**) and carboxylic acid **4** only for the purpose of bioluminescence. The reduction of FMN in bacteria is believed to be catalysed by NADH:FMN-oxidoreductase (NADH is the reduced form of nicotinamide adenine dinucleotide):

The question of the transfer mechanism of the reduced flavin mononucleotide between the oxidoreductase and bacterial luciferase still remains open.

There is indirect evidence for both the independent operation of these enzymes¹⁴ and the formation of a strong complex between them.^{15,16} This problem has been studied in detail.¹⁶⁻¹⁸

Luciferases from various sources have different specificities with respect to the second substrate (aldehyde). The affinity of the aldehyde for luciferase is due to the hydrophobic interactions between the aliphatic fragment of the aldehyde and the hydrophobic groups of the enzyme. Therefore, as the length of the carbon chain in the aldehyde increases, the aldehyde becomes more strongly bound to luciferase.^{1,13} In addition, the length of the aliphatic chain determines the position of the aldehyde carbonyl group involved in the chemical rearrangements in the luciferase active site. Perhaps, this is why aldehydes with chains shorter than the octanal chain are not involved in the luminescent reaction. Tetradecanal (**3**) is considered to be the natural substrate of bacterial luciferase,¹⁹ because the enzymatic system that reduces a carboxylic acid for the purpose of bioluminescence is specific exactly toward myristic acid (**4**).²⁰

The general scheme of reactant transformation in the reaction catalysed by bacterial luciferase was proposed more than forty years ago²¹ and confirmed by subsequent investigations. According to this scheme, the reaction proceeds *via* three intermediate complexes (intermediates) formed by flavin derivatives with luciferase (Scheme 1). Complex I contains reduced flavin, (FMN)H₂, complex II, flavin hydroperoxide and complex IIA, flavin peroxyhemiacetal (the numbers **1**, **2**, and **5**–**7** refer to the proper substrates rather than to their complexes). The existence of intermediates I and II was proved by NMR spectroscopy.²² The formation of intermediate IIA has not been proven experimentally as yet, but is recognised as a necessary step of the reaction.⁹ It was shown by NMR spectroscopy that the major chemical transformations during the reaction affect the C(4a) atom of the FMN isoalloxazine fragment.²² The results of these studies made it possible to compose the sequence of chemical transformations of the reduced flavin mononucleotide in the active site of bacterial luciferase (see Scheme 1) (this and subsequent schemes show only the part of flavin that is involved in transformations).

Here and below, RibP = CH₂(CHOH)₃CH₂OP(O)(OH)₂.

There is still no unified opinion concerning the mechanism of transformation of intermediate IIA [5-hydroxyflavin mononucleotide 4*a*-peroxyhemiacetal (**6**) bonded to luciferase] into the excited emitter. This step, designated by the interrogation mark in Scheme 1, may comprise several steps. The problem of identification of the structure of the emitting chromophore (emitter) has not been completely solved either. It has been accepted by most researchers that luciferase-bound 4*a*-hydroxy-5-hydroxyflavin mononucleotide (**7**) acts as the bacterial bioluminescence emitter. We will call this complex intermediate III. The photoluminescence spectrum of compound **7** (in the bound state) is similar to the emission spectrum recorded during the bioluminescent reaction. The problem of formation of the emitter is considered in more detail in Section III.

The key steps of the bacterial bioluminescent reaction are as follows.^{12, 23}

1. Formation of intermediates I, II and IIA [the energy range of the possible excited states of intermediates is approximately 260–390 kJ mol⁻¹ (21 700–32 700 cm⁻¹)].
2. Elementary excitation event in which the intermediate IIA is converted into emitter P* (intermediate III).
3. Light emission step P* → P + *hν*.

The optical properties of the reactants deserve attention. The spectrum of bacterial bioluminescence is a nearly symmetrical Gaussian distribution over the frequency scale with a peak at a wavelength of ~490 nm. The position of the peak does not depend on the acidity or temperature of the reaction mixture. The bioluminescence yield in this reaction ranged from 0.1 to 0.3 under optimal conditions, depending on the luciferase and aldehyde types.² According to NMR studies,²² the reduced flavin, (FMN)H₂ (**1**), is bound to luciferase as the (FMN)H⁻ anion. The absorption spectra of intermediates I, II, IIA and III differ little from one another and have a peak at 380 nm characteristic of all hydroflavins.^{2, 21} Among these intermediates, noticeable fluorescence (with a peak at ~490 nm) is observed only for luciferase-bound hydroxyflavin **7**.

The emitter of bacterial bioluminescence **7** refers to group V of the classification of molecules in terms of their spectral luminescence properties.¹¹ This group includes all aromatic heterocyclic compounds characterised by high quantum yields of fluorescence. The energy levels of the electron-excited states of the molecules of this group, taking into account the orbital nature and multiplicity, can be represented as follows:

These molecules have upper excited states of the $n\pi^*$ type and undergo effective conversion of the excitation into the fluorescent $S_{\pi\pi^*}$ state from the $T_{\pi\pi^*}$ and $S_{n\pi^*}$ states.²⁴

As noted above, an interesting fact is that the emitters of bioluminescent reactions of other organisms (for example, glow-worms and jelly-fishes) also belong to group V of the spectral-luminescent classification, although the chemical structures of the emitters differ from that of the bacterial emitter.

Thus, the bioluminescent reaction of bacteria is an efficient chemiluminescent process which passes, like most known liquid-phase chemiluminescent reactions, through the formation and decomposition of organic peroxides. However, this reaction is still an exception, because no other efficient chemiluminescent processes involving hydroperoxides (such as derivative **5**) have been found as yet.⁹

III. Formation of the emitter in the bioluminescent reaction

Kurfurst and Hastings²⁵ identified and characterised the emitting intermediate of reaction (1). While monitoring both the variation of the absorption and bioluminescence intensity during the reaction of intermediate II [luciferase complex with 4*a*-hydroperoxy-5-hydroxyflavin mononucleotide (**5**)] with decanal, the researchers detected the formation of two forms of enzyme-bound flavin. The greater part of bound flavin was FMN (**2**) responsible for characteristic absorption peaks at 370 and 440 nm and a fluorescence maximum at 530 nm. The second form of the enzyme complex with flavin exhibited an absorption maximum at 360 nm and a fluorescence maximum at 490 nm and was identified as the intermediate responsible for bioluminescence. Based on the spectral-luminescent characteristics, the researchers postulated that the fluorophore of this intermediate has the structure of 4*a*-hydroxyflavin **7**. It was found that the emitting intermediate has a relatively short lifetime (7 min at 9 °C) and its fluorophore is readily oxidised to FMN (**2**) by dissolved oxygen (the activation energy for this process equals 83 kJ mol⁻¹).²⁶ The ultimate identification of 4*a*-hydroxyflavin **7** as an emitting fluorophore (*i.e.*, emitter) is hampered by the fact that this compound has not yet been synthesised in a stable form, which is required to describe comprehensively its spectral-luminescent properties. The studied stable analogues of this compound, even those having suitable absorption spectra, exhibit very weak luminescence and provide much lower yields in chemiluminescent reactions (10⁻⁴–10⁻⁷).^{27, 28} Only recently was a paper published describing a model derivative of flavin with acceptable luminescent characteristics.²⁹ The authors studied binding to bacterial luciferase and fluorescence quantum yields for 5-decyl-4*a*-hydroxyflavin mononucleotide (**7a**). It was found that this compound having weak fluorescence in the free state provided a fluorescence quantum yield of 0.08 (this makes about 50% of the yield of bacterial bioluminescence) and a maximum intensity at 440 nm when bound to bacterial luciferase. In the opinion of the researchers cited, this fact confirms the identity of 4*a*-hydroxyflavin **7** and the natural bacterial bioluminescence emitter.

R = n-C₁₀H₂₁.

Of the multitude of mechanisms of excitation of the bacterial bioluminescence emitter proposed to date, six main mechanisms discussed below are most interesting from our standpoint.

The first mechanism was proposed rather long ago by Eberhard and Hastings.³⁰ Having postulated the key steps of reaction (1), they suggested that flavin peroxyhemiacetal **6** incorporated in intermediate IIA undergoes the Baeyer–Villiger rearrangement to give directly carboxylic acid **4** and excited hydroxyflavin **7**.

6 (R = n-C₁₃H₂₇)

An objection to this hypothesis is the fact that in chemical reactions, the Baeyer–Villiger rearrangement does not give electron-excited products.³¹

Subsequently, Kosower proposed another route to the bioluminescence emitter.³² It is worth noting that this mechanism is the first attempt to rationalise the excitation process based on analysis of elementary physicochemical processes. According to this hypothesis (Scheme 2), the excited state results from dissociative electron transfer from the flavin semiquinone radical **8a**. The peroxide radical anion $\text{RCH}(\text{O}_2)\text{O}^{\cdot-}$ formed after the superoxide attack abstracts a hydrogen atom from the luciferase SH group; this is followed by cleavage of the C–H bond in aldehyde to give protonated flavin mononucleotide **8b** in the excited state, which acts as the emitter.

Three critical remarks are pertinent as regards the above mechanism. First, this hypothesis is considered doubtful because it implies the occurrence of free radical steps in this reaction, which have not yet been detected by EPR.³³ (However, this may be due to limitations of the method.) Second, this mechanism implies involvement of the enzyme mercapto group in the process. Indeed, it has now been found³⁴ that the active site of the bacterial luciferase contains a cysteine residue Cys106, which could theoretically provide the SH group for the reaction with the peroxy radical anion $\text{RCH}(\text{O}_2)\text{O}^{\cdot-}$. However, the subsequent studies showed that this amino acid residue is not involved in the bioluminescent process, because its replacement by serine, alanine or valine does not result in the loss of bioluminescent activity of the enzyme.³⁵ It was found that the SH group of the Cys106 residue influences the aldehyde binding and the stability of intermediate IIA.³⁶ Third, an analogue of reduced flavin has been synthesised that cannot form the *N*(1)-protonated form [1-deaza-(FMN) H_2] but is nevertheless involved in the bacterial luciferase-catalysed reaction with emission of a light quantum.³⁷

The mechanism proposed by Kosower can be criticised regarding several points; however, its main value is that the

excitation of molecules during bioluminescence was related for the first time to dissociative electron transfer, *viz.*, one of the key probable mechanisms of chemiluminescence.

After the discovery³⁸ of chemically initiated electron exchange luminescence (CIEEL) as a mechanism of chemiluminescent reactions, Mager and Addink attempted³⁹ to adopt this mechanism to bacterial bioluminescence. The CIEEL process typical of the chemiluminescence of some peroxides implies the following steps: (i) the reaction of peroxide with an electron donor and the formation of a radical ion pair, (ii) the transformation of the radical anion into the carboxyl radical and the reverse electron transfer to give the excited fluorophore. According to the Mager and Addink concept,³⁹ the formation of flavin peroxyhemiacetal **6** within intermediate IIA is followed by intramolecular single-electron rearrangement to give hydroxyflavin radical cation **A**. This rearrangement includes the transfer of an electron from the *N*(5) atom of flavin to the antibonding orbital of the peroxide fragment and the subsequent localisation of this electron on an oxygen atom accompanied by simultaneous homolytic cleavage of the peroxide bond.

Presumably, radical cation **A** is a key intermediate in the reverse electron transfer giving rise to either excited hydroxyflavin **7** or excited carboxylic acid **4**. The existence of 4*a*-hydroxyflavin

Scheme 2

HSE is luciferase.

radical cations structurally related to radical **A** has been shown using electrochemistry and radiolysis of model systems.⁴⁰ The efficiency of this reaction is controlled, first of all, by the single-electron transfer rate. On this basis, numerous attempts to verify this hypothesis using modified flavins with different redox properties have been undertaken. Eckstein *et al.*⁴¹ generalised the results of these studies. The kinetic parameters of bioluminescence for the reaction with FMN analogues having different substituents at C(8) were measured. An inverse correlation has been found between the rate constant for the first-order reaction and the single-electron redox potential of FMN analogues. In the researchers' opinion, this means that in the rate-limiting step the flavin moiety of the complex loses the negative charge. This result is consistent with the intramolecular CIEEL mechanism for the bacterial luciferase-catalysed reaction. The Baeyer–Villiger type rearrangement of the intermediates implies an inverse dependence of the rate on the redox potential of flavins. Nevertheless, McCapra criticised⁴² the study by Eckstein *et al.*⁴¹ He noted that the obtained dependences were due to the shift of the equilibrium between flavin derivatives **6** and **7**; it was concluded that no evidence for preference of the CIEEL mechanism for the bacterial luciferase reaction is currently available.

Yet another line of research in the studies of the mechanism of bacterial bioluminescence has been pursued by Raushel and Baldwin.⁴³ They were the first to propose⁴³ the 'dioxirane' mechanism of the bioluminescent reaction catalysed by bacterial luciferase. According to their hypothesis, instead of elimination of the α -proton from the carbonyl carbon of the aldehyde (initiating the Baeyer–Villiger rearrangement), the formation of flavin peroxyhemiacetal **6** is followed by an attack by the aldehyde oxygen atom on the peroxide bond, resulting in its cleavage to give 4*a*-hydroxyflavin **7** and dioxirane **9**.

The formation of dioxirane is the key point of this hypothesis. There are two possible ways of dioxirane decomposition. First, dioxiranes can undergo homolytic cleavage of the peroxide bond to give radical anion **10**, which rearranges to give carboxylic acid (in either singlet or triplet excited state). This pathway bears direct analogy with decomposition of dioxetanes. Hydroxyflavin **7** is this type of a fluorophore, which can accept the electron excitation

energy from both triplet and singlet states of the dioxirane decomposition product. Second, the excited fluorophore can be formed *via* CIEEL in which dioxirane accepts an electron from fluorophore thus forming a radical ion pair. The subsequent transformation of the dioxirane radical anion into the carboxyl radical and the reverse electron transfer give the electron-excited fluorophore. Both the first and second route of dioxirane decomposition release sufficient energy for occupation of the excited states capable of emitting a photon upon deactivation, even in the blue region.

The Raushel and Baldwin's research group have studied the isotope effect of deuterated aldehyde on the rate of the bioluminescent reaction under various conditions.⁴⁴ This gave a relatively low but reliable k_H/k_D value in the range of 1.5–1.9, which is consistent with the theoretical calculations of the same researchers carried out with the assumption of intermediate formation of dioxiranes.

However, there are some serious objections to the formation of dioxiranes in the bacterial luciferase reaction, in particular, those stated by McCapra.⁹ First, no cases of dioxirane formation from an aldehyde are known to date.⁴⁵ Usually, the loss of a proton by an aldehyde results directly in carboxylic acid. Second, dioxiranes are highly reactive molecules,⁴⁵ and their formation would result in oxidation (injury) of the enzyme in the active site.

A distinctive feature of the next mechanism proposed by Kudryasheva *et al.*⁴⁶ is the occurrence of only intramolecular rearrangements during the formation of the excited structure of the bioluminescent emitter upon transition from structure **6** to **7**. The possibility of occupation of the upper excited states as the primary states of the bioluminescent emitter through the intramolecular electron transfer from the deprotonated ketoimide group to the peroxyhemiacetal fragment of intermediate **IIA** has been substantiated.⁴⁶

For flavins **5–7**, the $T_{n\pi^*}$ states are not the lowest excited states. The authors suggested that it is in this excited state (structure **B**) that flavin is formed in the bioluminescent reaction. According to this hypothesis, the formation of the excited carbonyl group is followed by intramolecular transfer of energy to the fluorescence state, $T_{n\pi^*} \rightarrow S_{n\pi^*}$, which is allowed as a transition between the levels of different orbital nature and multiplicity (the El-Sayed rule⁴⁷). The prohibition as regards multiplicity is eliminated due to spin–orbit coupling. This fact has been explained previously in a study by Plotnikov,²⁴ who calculated the rate constants for intramolecular transitions in this type of molecules; the resulting values were high, being equal to 10^{10} – 10^{11} s⁻¹. The importance of spin–orbit couplings in the physicochemical processes has been emphasised by Minaev *et al.*^{48–50} The efficiency of intramolecular transitions between the levels of different multiplicity was proved for many complex heteroaromatic compounds. Indeed, for a series of aromatic compounds including flavins, photoexcitation is known to be typically accompanied by reverse intersystem crossing from the

upper excited triplet states to the excited singlet states followed by fluorescence during transition to the ground state.⁵¹

The above-described relaxation process of the excitation in the bioluminescence emitter is associated with rearrangements of the electronic structure of the emitter molecule. The excitation located on the carbonyl group ($n\pi^*$ excitation) is delocalised throughout the molecule ($\pi\pi^*$ excitation). The process ends by the radiative transition $S_{\pi\pi^*} \rightarrow S_0$. It was noted²⁴ that the upper triplet states of these structures have too short lifetimes (10^{-10} – 10^{-11} s) to be detected by EPR. It is noteworthy that this course of bioluminescent reaction also predicts an inverse dependence of the rate constant for the first-order reaction on the single-electron oxidation potential of FMN analogues, which was mentioned above in the discussion of the CIEEL mechanism.³⁹ The data obtained using the FMN derivative in which oxygen at the C(2) atom was replaced by sulfur (2-thio-1,5-dihydroflavin mononucleotide) as the substrate of the bioluminescent reaction are also in line with this hypothesis.⁵² This is accompanied by a shift of the bioluminescence spectrum toward longer wavelengths (to 535 nm).

The fluorescence spectroscopy techniques have been used to carry out a number of studies aimed at detection of upper excited states of the bacterial bioluminescence emitter.^{53–55} In particular, the energy transfer to exogenous molecules introduced in the bioluminescent reaction has been attempted.^{53,54} Fluorescent aromatic molecules with energies of the first singlet excited state in the range of 22 000–32 000 cm^{-1} (i.e., higher than the analogous energy of the emitter molecule) have been used as the exogenous molecules (potential acceptors of excitation energy). Note that the absorption spectra of the chosen molecules did not overlap with the bioluminescence spectrum. During the bioluminescent reaction in the presence of these compounds, their sensitised luminescence was observed as low-intensity bands in the short-wavelength region of the spectrum. This result was attributed to non-radiative energy transfer from the upper electron-excited states of the emitter to the levels of these exogenous molecules, probably, by the exchange-resonance (collision) mechanism. Since the sensitised luminescence was detected only for compounds with an energy of the fluorescent state of not more than 26 000 cm^{-1} , this energy was taken as the characteristics of the upper electron-excited state of the bacterial bioluminescence emitter.⁵⁴ A study of the fluorescence anisotropy decay of the acceptor molecules in the presence of bacterial luciferase proved the possibility of hydrophobic binding of acceptor molecules to luciferase, and, hence, these molecules can approach the emitter to distances appropriate for energy transfer by the exchange mechanism.⁵⁵

The last mechanism of bacterial bioluminescence to be mentioned was proposed by McCapra.⁹ He considered the following advantages of this mechanism over all other mechanisms: (i) this mechanism is consistent with the isotope effect data⁴⁴ and with experimental results obtained by variation of substituents;⁴¹ (ii) this mechanism has a chemiluminescent analogy, namely, the reaction of peroxy esters with fluorescent compounds. McCapra postulated that the formation of intermediate IIA in the bacterial luciferase reaction is followed by the addition of hydrogen peroxide and second aldehyde molecule to the peroxyhemiacetal fragment of the complex.⁹

B is a base.

The resulting adduct **11** decomposes to hydroxyflavin and peroxy ester. The next step involves decomposition of the ester in the presence of fluorescent compound (hydroxyflavin) to give the excited molecules of the latter. This reaction route is confirmed by the detected enhancement of bioluminescence upon the addition of hydrogen peroxide.⁵⁶ The spontaneous formation of H_2O_2 adduct with two aldehyde molecules is also a proven fact.⁵⁶ The McCapra scheme proposed for bacterial bioluminescence is rather original and substantiated; however, as the author himself admits, this does not explain the key step, viz., the formation of the emitter, because the mechanism of chemiluminescence of peroxy esters has not been ultimately established as yet.

Thus, the question of the excitation mechanism of the molecules in the reaction catalysed by bacterial luciferase is still debated. The proposed schemes are diverse and cover almost all mechanisms currently applied to liquid-phase chemiluminescent reactions. However, as some researchers remark, none of the proposed reaction mechanisms is consistent with the whole set of experimental data accumulated throughout a five-decade history of the studies of bioluminescence.

IV. Excitation of secondary emitters of bacterial bioluminescence

1. Characteristics of the fluorescent proteins, secondary emitters of luminescent bacteria

The fact that bacterial luminescence is based on reaction (1) was established by 1965. However, the difference between the spectral characteristics of bioluminescence of the bacteria themselves (bioluminescence *in vivo*) and luminescence in the reactions of the reagents isolated from them (bioluminescence *in vitro*) has remained uninterpreted for many years. The position of the spectral peaks of bioluminescent reactions depends on the luciferase type but is confined within the range of 487–505 nm. Meanwhile, the bioluminescence maxima of living bacteria differ much more appreciably. Indeed, some bright strains of luminescent bacteria of the *Photobacterium* genus emit light with a maximum at 475 nm,¹³ while the bioluminescence of the Y1-strain of *Vibrio fischeri* discovered in the mid-1970s has a maximum at 545 nm.⁵⁷ It has now been proven that the reason for the change in the spectral composition of the above-mentioned bacterial emission is the presence of specific fluorescent proteins functioning as bioluminescence emitters, i.e., in these cases, indirect or sensitised chemiluminescence takes place.

The fluorescent proteins of luminescent bacteria are protein complexes with low-molecular fluorophores capable of fluorescing in the visible spectral region. A fluorescent protein was isolated from the bacteria *Photobacterium*; this protein was called the lumazine protein (LumP), as its fluorophore is represented by 6,7-dimethyl-8-(1-D-ribityl)lumazine (**12a**).⁵⁸ The yellow green strain of *V. fischeri* was found to contain^{59,60} the so-called yellow fluorescent protein (YFP) with a similar mass and, as has been found later,^{61,62} with a primary structure also similar to that of LumP. The YFP fluorophore is represented by FMN (**2**) or riboflavin (**12b**).⁶³

The key characteristics of these fluorescent proteins are given in Table 1.

To avoid confusion, we will designate the protein parts of LumP and YFP, which remain after removal of the fluorophore (this is called apoprotein), by LumP_A and YFP_A, respectively. The proteins LumP_A and YFP_A are notable by the fact that, unlike most other proteins, they do not quench the fluorescence of flavin bound to them.⁶⁴ On binding to LumP_A and YFP_A, the fluorescence maxima of their natural fluorophores shift to opposite directions (see Table 1): a hypsochromic shift is observed for lumazine **12a** and a bathochromic shift is observed for flavin **2**. However, both these facts indicate a high polarity of the micro-environment of the above fluorophores in the binding site of the protein (since it is known that with a decrease in the solvent polarity, the peak of flavin fluorescence shifts to shorter wavelengths and the peak of lumazine luminescence shifts to longer wavelengths).^{2, 64}

It was found that in the presence of micromolar concentrations of LumP or YFP, the following effects can be observed depending on the type of luciferase, the length of the aldehyde carbon chain and the source of the fluorescent protein: (i) a shift of the emission peak (hypsochromic in the presence of LumP or bathochromic in the presence of YFP); (ii) an increase in the emission intensity (up to a threefold in the presence of LumP and up to tenfold in the presence of YFP).² The mechanisms that underlie these effects are considered in more detail below.

Since the effect of fluorescent proteins on the characteristics of the bacterial bioluminescent reaction starts to be observed at low effective concentrations, they probably (or even obviously) form complexes with the reaction intermediates. It was shown by fluorescent spectroscopy and chromatography that LumP and YFP form 1 : 1 complexes with intermediates II and III (but not with free luciferase).^{65, 66} The lack of interaction with luciferase looks reasonable, because otherwise, the addition of the fluorescent protein would prevent the substrates of the bioluminescent reaction (mainly reduced flavin **1**) from accessing the active site of this enzyme. The binding constant of intermediate III with the YFP determined by fluorescent titration is equal to $7 \times 10^{-7} \text{ mol litre}^{-1}$ (0 °C), which is comparable with the effective concentration at which the effect of this protein on the bioluminescent reaction starts to be observed.⁶⁶

A study of the kinetics of bioluminescent reactions involving LumP and YFP has shown that an important role in the formation of protein complexes is played by aliphatic components (aldehydes, carboxylic acids, alcohols).⁶⁷ In the absence of aliphatic components, no reaction was detected between the proteins.

2. The mechanism of the change in the spectral composition of bioluminescence by fluorescent proteins

Comparison of the changed patterns of the bioluminescence spectra with the fluorescence spectra of LumP and YFP on photoexcitation indicates unambiguously that these proteins are involved in the light emission event resulting from the reaction. The problem of the excitation mechanism of the fluorescent proteins upon their introduction into reaction (1) is still debated. A non-radiative inductive resonance energy transfer (IRET) from the primary emitter due to weak dipole–dipole interaction could be the simplest and most attractive mechanism responsible for the excitation of secondary emitters. The rate constant for this transition k_{ET} is determined by the Förster equation:

$$k_{\text{ET}} = A Q_D k^2 \tau^{-1} R^{-6} J,$$

Table 1. Comparative characteristics of fluorescent proteins of luminescent bacteria.

Characteristics	Values for proteins ^a	
	LumP	YFP ^b
Molecular mass /kDa	21	24
Fluorophore	Lumazine derivative 12a	FMN
Binding constant of the fluorophore with the protein /mol litre ⁻¹	1.6×10^{-8} (20 °C, pH 7)	1×10^{-8} (4 °C, pH 7)
Long-wavelength absorption maximum of the fluorophore in the free/bound state /nm	406/417	445/470
Molar extinction coefficient of the fluorophore in the free/bound state /litre mol ⁻¹ cm ⁻¹	10 300 (406 nm)/10 300 (414 nm)	12 500 (445 nm)/12 500 (460 nm)
Fluorescence spectral maximum of the fluorophore in the free/bound state /nm	490/475 (water)	525/538 (water)
Fluorescence quantum yield of the fluorophore in the free/bound state	0.45 (water, 22 °C)/0.58 (water, 20 °C)	0.26 (water, 22 °C)/—
Lifetime of the fluorescent state of the fluorophore in the free/bound state /ns	8.9 (20 °C)/1.7 (2 °C)	4.7 (20 °C)/5.5 (2 °C)
Rotational correlation time ^c of the fluorophore in the free/bound state /ns	0.15 (2 °C)/20 (0 °C)	0.2 (0 °C)/20 (0 °C)
Overlap integral of the absorption spectrum of the fluorescent protein with the bioluminescence spectrum /cm ³ litre mol ⁻¹	2×10^{-15}	1.54×10^{-14}

^a The conditions of determination of the parameters are given in parentheses. ^b Characteristics are given for the best studied YFP form with FMN (**2**) as the fluorophore. ^c The rotational correlation time is the characteristic time of the exponential decay of the fluorescence anisotropy of the molecule upon pulse excitation.

where A is a constant, Q_D is the quantum yield of the donor fluorescence, k^2 is the orientation factor, τ is the lifetime of the fluorescent state of the donor in the absence of the acceptor, R is the distance between the energy donor and acceptor, J is the overlap integral of the absorption spectrum of the acceptor and the emission spectrum of the donor. The acceptor properties are characterised by three quantities in this formula: the distance R , the orientation factor k^2 and overlap integral J . The values of the first two can be such that they would favour a high rate of the IRET from hydroxyflavin **7** to fluorescent proteins: the proven existence of complexes formed by intermediate III with LumP and YFP can ensure a proximate arrangement and a favourable orientation of the fluorophores. The last factor, *viz.*, the overlap integral of the spectra, is high for YFP and low for LumP (see Table 1).

It is the small overlap integral of the absorption spectrum of LumP with the bioluminescence spectrum that draws objections against effective accepting of energy by this protein according to the inductive resonance mechanism. In addition, the fluorescence maximum of hydroxyflavin **7** is at 495 nm, while the maximum of the absorption spectrum of LumP is at ~ 420 nm, and the hypothetical energy transfer should be followed by an increase in the emitted quantum energy, which is not observed in the photoluminescence of dyes in solutions. A great contribution to the investigation of this problem was made by Lee's research group.^{2,67–71} Initially, Lee and co-workers attributed⁶⁹ the effect of the lumazine protein to the existence of a high-energy precursor of the bacterial bioluminescence emitter with an excited state energy of $\sim 25\,000\text{ cm}^{-1}$. They assumed that this precursor transmits the electron excitation energy to either hydroxyflavin or the lumazine protein. However, subsequently, Lee refuted the high-energy precursor concept and attributed^{2,64} the efficiency of IRET to a special orientation of the donor and the acceptor with a small overlap integral of the spectra. Fluorescence spectroscopy studies^{64,68} revealed the existence of a short-time component in the fluorescence anisotropy decay of intermediates II and III complexed with LumP (on excitation to the flavin absorption band at 370 nm). This fast decay of the anisotropy was attributed to the occurrence of the IRET from flavin, incorporated in the intermediates, to lumazine **12a**. The results were adequately described by a model in which the rate constant for the IRET varied from 4×10^8 to 10^9 s^{-1} (depending on the luciferase type and LumP source).^{65,68} Since the rate constant for the radiative transition of the primary emitter containing fluorophore **7** is 10^8 s^{-1} , it was concluded that the change of the spectral characteristics in the bioluminescent reaction in the presence of LumP can occur *via* the IRET. Lee's calculations⁶⁴ showed that a fixed distance of 1.5 nm and a favourable mutual orientation of flavin **7** and the lumazine fluorophore **12a** can make up for the small overlap integral of the spectra and account for the observed high efficiency of the 'anti-Stokes' migration of the excitation energy to LumP. Note that the spectral properties of the intermediate III – LumP donor–acceptor pair, namely, the close arrangement of the emission spectral peaks of the donor and the acceptor (490 and 475 nm, respectively), do not allow one to study the energy transfer by classical fluorescence spectroscopy methods. Usually, the energy transfer rate is determined from the change in the quantum yield of the donor in the presence of the acceptor (upon excitation to the donor absorption band).

Study of the energy transfer processes in the bioluminescent emitter – YFP system is easier than that for the LumP-containing system due to the large bathochromic shift between the emission peaks of the presumptive energy donor and acceptor. Hence, the emission bands of the donor and the acceptor can be effectively separated and the energy transfer rate can be measured more precisely from the change in the lifetime of the fluorescent state of the donor. This study has been carried out.⁶⁷ The rate constant for the IRET to the YFP ($4 \times 10^9\text{ s}^{-1}$) was found from the change in the rate constant for the fluorescence decay of intermediate III. Thus, it was found that the IRET rate for the YFP system is about

ten times as high as that for the LumP system.⁶⁰ The overlap integrals of the absorption spectrum with the bioluminescence spectra of LumP and YFP differ by a factor of 7.7. The authors⁶⁷ consider this to confirm the assumption that the secondary emitters are excited through weak dipole–dipole interaction according to the Förster (inductive resonance) mechanism.

The bioluminescence spectra in the presence of YFP consist of two bands: a strong yellow-green band with a peak at 540 nm and a weak blue band with a peak at 490 nm. For more detailed determination of the mechanism of formation of this spectrum, Eckstein *et al.*⁷² studied the kinetics of reaction (1) in the presence of YFP. They found a complex and, what is more important, different patterns of variation of the time decay rates for the 'blue' and 'yellow-green' bioluminescence components. In the researchers' opinion, this indicates that the classical non-radiative energy transfer alone cannot account for the effect of YFP on the bacterial luciferase-catalysed reaction. A scheme was proposed according to which YFP forms a complex with intermediate IIA, thus decreasing its lifetime. This complex decomposes to give excited YFP, while the 'blue' component of the bioluminescence is emitted only by non-bonded intermediate III.

This mechanism resembles the intermolecular activated chemiluminescence where the fluorophore catalyses decomposition of the peroxide through charge or electron transfer, thus passing to the excited state. The mathematical model constructed according to the proposed scheme described adequately the experimental data obtained for the kinetics of two bioluminescence components (for low YFP concentrations). As has already been noted, subsequent studies showed that, upon photoexcitation, the IRET from intermediate III to YFP in the complex is a very efficient process.⁶⁷ Its rate is more than an order of magnitude greater than the rate of the radiative transition for hydroxyflavin **7** in intermediate III. Therefore, this excitation pattern for the yellow-green bioluminescence in a system involving YFP should not be underestimated.

3. Change in the bioluminescence intensity in the presence of fluorescent proteins

As noted above, both natural bacterial fluorescent proteins (LumP and YFP) increase the bioluminescence intensity of reaction (1). However, these effects were found to be due to different mechanisms.

The addition of LumP to the bioluminescent reaction was found to increase the bioluminescence yield. The reason for this increase (trivial, in the opinion of some researchers^{2,67}) is as follows: the quantum yield of LumP fluorescence (0.58) is almost twice as high as that of luciferase-bound hydroxyflavin **7** (0.28–0.33). Therefore, the emission event is more efficient with LumP. We would like to note that this explanation is reasonable if the rate of energy transfer to LumP actually exceeds the rate of the intrinsic radiative transition in hydroxyflavin **7** by a large factor (4–10), as it was estimated in the works cited.^{65,68} Unfortunately, the spectroscopic properties of the intermediate III – LumP system preclude precise measurement of the energy transfer rate; hence, the explanation for the high efficiency of this transfer casts doubts due to the small overlap integral of the spectra.

The fluorescence quantum yields of YFP and hydroxyflavin **7** differ slightly; therefore, despite the known⁶⁷ high rate constant for the energy transfer in the YFP system, no increase in the total

number of the emitted quanta takes place in the reaction involving this secondary emitter.

The emission intensity of the bioluminescent reaction in the presence of YFP is controlled in a somewhat different way. It was found⁷³ that in the presence of this protein the rate of reaction (1) substantially increases. A unique feature of this system is that this effect is enhanced with a decrease in temperature. The highest efficiency of YFP defined as the ratio of the emission intensity at 540 nm (I_{540}) to the intensity at 490 nm (I_{490}) is observed at 4 °C. Some researchers argue⁷³ that this system is perhaps the only enzyme system having a negative temperature coefficient. The loss of YFP activity with the temperature rise cannot be attributed to dissociation of flavin and YFP_A alone (for example, on heating of the reaction mixture from 4 to 15 °C in the presence of 4×10^{-6} mol litre⁻¹ of YFP, only 15% of YFP molecules dissociate, while the I_{540}/I_{490} value decreases threefold). A change in the conformation of this protein on heating could be an additional factor contributing to YFP inactivation with the temperature rise, but this phenomenon has not found experimental proof or disproof. It is also of interest that not only the optimal reaction temperature but also the optimal length of the aldehyde carbon chain change in the presence of YFP.⁷⁴ The highest efficiency of YFP is attained in the reaction involving octanal, whereas in the absence of YFP, the highest intensity was observed for aliphatic aldehydes containing no less than 12 carbon atoms. This was attributed to the fact that the longest lifetime of intermediate IIA in reaction (1) is observed with octanal (compared with reactions involving other aldehydes). As a consequence, YFP has more opportunities to react with this intermediate and to 'switch' the reaction to the pathway leading to excitation of the 'yellow-green' chromophore.⁷⁴

The biological role of the secondary emitters of luminescent bacteria is not entirely clear. Most assumptions concerning this issue imply that the main function of bioluminescence is signalling. From this standpoint, the involvement of LumP in the light emission provides at least a gain in the luminescence intensity (due to the increase in the bioluminescence yield). And YFP allows bacteria to glow over a broad temperature range (from 5 to 25 °C). It is also assumed that the high luminescence intensity of 'yellow-green' bacteria at 4 °C (*i.e.*, at a temperature where their metabolic processes are retarded) makes them attractive symbionts for fishes or other organisms.⁷³

If the hypothesis of 'non-thermal energy discharge' in a bioluminescent process is taken as the basis,⁸ the possibility of changing the energy of the 'discharged' quantum in the presence of secondary emitters can be considered as an important adaptation feature of bacteria under conditions of variable amounts of energy entering the cell (for example, in the presence of different amounts of hydrogen peroxide).

To conclude this Section, we would like to note that any proposed scheme of the bioluminescent reaction should be consistent with the above-described effects produced by fluorescent proteins. This is especially true for the lumazine protein, as it gives rise to a hypsochromic shift of the bioluminescence spectrum. Of the six schemes presented in the previous Section, the last four schemes imply occupation of the electron-excited states of the secondary emitter, which can be represented by LumP. If the reaction follows the CIEEL mechanism, this may give excited carboxylic acid, which then functions as the energy donor for fluorescent molecules. Similarly, dioxirane decomposition can involve LumP and result in the excitation of the lumazine chromophore. According to the scheme proposed by Kudryashova *et al.*,⁴⁶ LumP is capable of accepting energy from highly excited levels of the hydroxyflavin intermediate. The reaction proposed by McCapra may also involve another fluorophore (apart from hydroxyflavin) in the step of peroxy ester decomposition followed by excitation of this fluorophore.

Thus, although the secondary emitters of bacterial bioluminescence (the lumazine and yellow fluorescent proteins) induce different changes in the spectral characteristics of the biolumines-

cent reaction, they still resemble each other in their properties: their proteins have similar structures and interact efficiently with the bioluminescent reaction intermediates, thus creating conditions for the excitation of the secondary fluorophore. The highly effective change in the spectra and bioluminescence intensity upon the addition of fluorescent proteins is due, first of all, to the formation of protein complexes. Therefore, their fluorophores occur in the vicinity of the luciferase active site, almost at the centre of events, and can be involved in some chemical steps of the process and the physical transfer of the excitation energy. To date, it can be stated that neither 'physical' nor 'chemical' way of excitation of secondary emitters can alone explain the whole set of effects of fluorescent proteins on the bacterial bioluminescence parameters. It is noteworthy that the uncertainty in the mechanism of energy transfer to secondary emitters is partly due to the uncertainty of the mechanism of the proper reaction catalysed by bacterial luciferase. Subsequent studies of the pathways leading to the primary emitter of bacterial bioluminescence would apparently make corrections in the proposed schemes of excitation of fluorescent proteins. Conversely, investigation of the interactions of the secondary bioluminescence emitters with the components of the main chemical process can, in the future, shed light on the mechanism of the bioluminescent reaction.

V. Conclusion

Bioluminescence is a unique natural phenomenon and an exceptionally convenient tool that can be used in various fields of human activities ranging from environmental monitoring and clinical analysis to investigations of gene expression and regulation.^{3,75} The transformation of the chemical reaction energy into light with a high quantum efficiency in bioluminescent reactions has always attracted the interest of scientists. By now, the sequences of formation of chemical intermediates have been established and the spectral and kinetic characteristics of bioluminescent reactions involving enzymes (luciferases) have been described. Genetic engineering works aimed at modification of luciferase are in progress.⁷⁶ However, since bioluminescence is traditionally a subject studied by biologists (physiologists, microbiologists and biochemists), the formation of excitation is the most debated issue. Solving this problem requires the use of results obtained in structural, luminescence and chemiluminescence studies based on analysis of elementary physicochemical processes. Thus classification of molecules in terms of their spectral luminescent properties developed in the 1970–1980s shows that the emitters of all bioluminescent organisms belong to the group of molecules characterised by high $\pi\pi^*$ -fluorescence quantum yields. The belonging of bioluminescence emitters to this group of compounds determines (together with enzymatic catalysis) the high bioluminescence intensity. In our opinion, study of the intramolecular energy transfer, the use of the theory of intermolecular migration of the excitation energy developed for solutions of fluorescent dyes and data for chemiluminescent oxidation reactions would allow researchers to achieve considerable insight in the processes giving electron-excited states of molecules upon bioluminescence.

This review was prepared with financial support of the Ministry of Education and Science of the Russian Federation and the American Civilian Research and Development Foundation (the Programme 'Fundamental Research and Higher Education', Grants RUX0-002-KR-06 and Y1-B-02-13), the Federal Central Science and Engineering Programme 'Studies and Projects along the Priority Lines of Science and Engineering' for the 2002–2006 (the Programme 'Scientific Research Carried out by Young Scientists', Grant 2006-RI-19.0/001/454), the Russian Academy of Sciences (the Programme 'Molecular Cell Biology', Grant 'Molecular Mechanisms of Formation of the Emitter in Bioluminescent Reactions of Various Organisms', 2005–2007) and the Krasnoyarsk Regional Science Foundation (Grant 15G120).

VII. Conclusion	129

Abstract. Characteristic features of the crystal structures of mercury oxohalides, chalcahalides and related compounds are surveyed. The structures of these compounds are described using both the traditional way and a modern approach based on the identification of stable building blocks coupled with the analysis of their packing. The crystallographic and crystal chemical data for the title compounds are given. The bibliography includes 123 references.

I. Introduction

Crystal chemistry of mercury compounds is unique being principally different from that of lighter neighbours of mercury in Group 12 of the Periodic system, *viz.*, Zn and Cd. In contrast to zinc and cadmium, the Hg^{2+} ions are capable of forming two linear shortened strong bonds that are prone to further association, in addition to ordinary tetrahedral bonds. The complexity and multiplicity of crystal chemistry of mercury compounds is also manifested in the co-existence of various combinations of ionic and covalent bonds in a mercury compound with various anions Y (N, O, S, Se or Te) and X (F, Cl, Br or I). Yet another characteristic feature consists of the frequently occurring short covalent bonds between mercury atoms giving rise to cluster-like polyatomic fragments, such as $[\text{Hg}_2]^{2+}$ dumbbells or $[\text{Hg}_3]^{4+}$ triangles (with the Hg–Hg bond lengths of 2.5–2.7 Å). There are a number of structures where mercury atoms form covalent bonds with other crystal chemically similar cations (*e.g.*, Ag, Pb and Cu) to generate, for instance, $[\text{Ag}_3\text{Hg}]^{3+}$ or $[\text{Ag}_2\text{Hg}_2]^{4+}$ tetrahedra, *etc.* The mercury atoms in these cluster fragments occur in an oxidation state lower than +2. It is interesting to note that the

$[\text{Hg}_2]^{2+}$ dumbbells tend to linear coordination to Y atoms to yield covalently bound $\text{Y} - [\text{Hg}_2]^{2+} - \text{Y}$ moieties, which can further be involved as building blocks in diverse assemblies (including extended ones), in addition to the $\text{Y} - \text{Hg}^{2+} - \text{Y}$ group. A similar behaviour is also typical of the $[\text{Hg}_3]^{4+}$ triangular clusters.

The results of structural investigations into inorganic compounds containing mercury atoms either in the bivalent (Hg^{2+}) or a 'low-valence' (*i.e.*, $[\text{Hg}_2]^{2+}$, *etc.*) states gathered to date reveal a variety of covalently bound chains, layers and frameworks as building blocks to form the general structural motifs. These compounds also contain additional isolated or extended atomic groups, which compensate for the charges and fill in the voids of the structure presumably favouring the formation of specific motifs in some cases (owing to the so-called 'template' synthesis mechanism).

A special interest in the crystal chemistry of mercury compounds is partially explained by the fact that this environmentally important element is highly mobile in the earth's crust, waters and atmosphere. Presently, about 100 mercury-based and mercury-containing minerals are known. Among them, mercury amalgams, sulfo salts, oxo compounds (predominantly oxohalides) and sulfohalides can be distinguished as the most representative groups. Furthermore, about 30 minerals (mainly halides, oxohalides and oxochromates) contain low-valence mercury as $[\text{Hg}_2]^{2+}$ or $[\text{Hg}_3]^{4+}$ cluster fragments.

Several aspects of the crystal chemistry of mercuric inorganic compounds with Y and X anions have been elucidated for the first time by Karin Aurivillius.¹ The linear $\text{Y} - \text{Hg} - \text{Y}$ fragment [with a YHgY bond angle of $\sim 180^\circ$ and short Hg–Y bond lengths: $(\text{Hg} - \text{O})_{\text{av}}$ of 2.04 Å and $(\text{Hg} - \text{S})_{\text{av}}$ of 2.34 Å] was recognised as the main building block in the crystal structures known at that time. It was also noted that two major types of assemblies based on these fragments are possible: the fragments can occur as isolated ions or molecules (such as linear $\text{X} - \text{Hg} - \text{X}$ molecules in the crystal structures of mercuric halides or complex cation $[\text{OHg}_3\text{Cl}_3]^+$ in the structure of Hg_3OCl_4); or they can join into infinite chains characterised by a certain sequence of the HgYHg angles between the neighbouring $\text{Y} - \text{Hg} - \text{Y}$ fragments. Aurivillius introduced¹ a classification of such chains including three distinct types: helical chains that can be either right-handed (+) or left-handed (–) (in particular, they occur in the hexagonal modification of HgO), zigzag chains '+ –' (occur in the orthorhombic modification of HgO) and crankshaft chains '+ + – –' (occur in $\text{Hg}_5\text{O}_4\text{Br}_2$). The exact geometry of a chain is determined by the HgYHg angle, which in turn depends on the nature of the Y

Uspekhi Khimii 76 (2) 115–146 (2007); translated by Ya V Zubavichus

anion (for instance, different forms of crankshaft chains '+ + - -' are realised in oxo- and sulfoxo compounds, such as $\text{Hg}_5\text{O}_4\text{Br}_2$ and $\text{Hg}_3\text{S}_2\text{Cl}_2$). These chains can assemble into various planar or puckered ribbons, layers or frameworks.

Bivalent, low-valence and mixed-valence mercury compounds (nitrates, molybdates, tungstates, vanadates, arsenates and so on containing the Hg^{2+} , $[\text{Hg}_2]^{2+}$ or $[\text{Hg}_3]^{4+}$ cations) have been the subject of investigations by many research groups, including the ones headed by Brodersen, Jeitschko, Beck, Keller, Mayer, *etc.* The group headed by Voroshilov has contributed a lot into the structural studies of mercuric ternary chalcogenides. Over the recent years, about fifty mercury inorganic compounds in different oxidation states have been synthesised and characterised by Weil and co-workers. Over the recent years in Russia, the crystal chemical analysis of factors affecting the structure formation for these compounds has been in the focus of research interest of a group headed by Borisov.

Various aspects of crystal chemistry of naturally occurring and synthetic compounds containing low-oxidation-state mercury [including mixed-valence compounds, compounds with polyatomic groups $[\text{Hg}_n]^{n+}$ ($n > 2$), low-valence mercury compounds with organic ligands and mercury-containing transition metal clusters] have been surveyed in two reviews^{2,3} and a monograph.⁴

The structures of inorganic mercury compounds are of significant interest from the viewpoint of the crystal formation process encompassing all changes in the interactions between atoms upon their incorporation into a crystalline phase imposed by the regular packing, symmetry and long-range ordering requirements. A number of characteristic representatives of those compounds have been analysed using an original software package KAP-PLATS⁷ within a concept considering the crystalline state to be a result of ordering of atoms or rigid atomic fragments produced by families of parallel equi-distant (crystallographic) planes.^{5,6} Such an approach has been extended to a wider range of mercury compounds in a recent review by Borisov *et al.*⁸

The present review is concerned with specific features of the crystal structure of mercury oxo- and chalcogenides and closely related compounds, which are determined to a large extent by crystal chemical preferences of the mercury atoms, in particular, their tendency to form strong covalent bonds yielding stable atomic fragments, the so-called 'rigid' atomic groups. The structures of compounds are described both in the traditional way and using a modern approach based on the recognition of such stable 'building blocks' coupled with the analysis of their packings.

II. Mercury chalcogenides

1. Preparation, properties and occurrence in nature

Within the Hg-S binary system, there are at least three sulfides corresponding to the composition HgS .⁹ Two stoichiometric modifications, *viz.*, low-temperature α modification, cinnabarite, and high-temperature β modification, metacinnabarite, are widely known. The third phase that becomes stable at even higher temperature mentioned for the first time in the mid 1960s¹⁰ as non-stoichiometric γ - HgS has been later referred to as hypercinnabarite.

Mercuric sulfide occurs in nature predominantly as crimson cinnabarite (cinnabar, vermilion), whereas velvet black metacinnabarite is very scarce.⁹ There has been some evidence¹⁰ of natural occurrence of non-stoichiometric hypercinnabarite with iron impurities as well. Mercury selenide and telluride occur as rare minerals,¹¹ *viz.*, purple black tiemannite HgSe and dark grey coloradoite HgTe .

Ternary mercury chalcogenides (with a 3:2:2 composition) $\text{Hg}_3\text{Y}_2\text{X}_2$ ($\text{Y} = \text{S, Se, Te; X} = \text{Cl, Br, I}$) have been known for a long time. Recently, they start to attract a great interest from researchers due to their potential application in advanced technologies. These compounds manifest photoconductivity, large refraction indices and large specific angle-of-polarisation rotation in the visible light range. In particular, cubic mercury chalcogenides simultaneously demonstrate the optical activity and linear electrooptic effect, which makes them promising optical and gyrotropic materials in optoelectronics.

Comprehensive investigations into the crystal structures of ternary mercury chalcogenides started in the early 1960s. For instance, the crystal structures of $\text{Hg}_3\text{S}_2\text{Cl}_2$, $\text{Hg}_3\text{Se}_2\text{Cl}_2$, $\text{Hg}_3\text{Te}_2\text{Cl}_2$ and $\text{Hg}_3\text{Te}_2\text{Br}_2$ belonging to one of 9 rare cubic space symmetry groups, $I2_13$, which contain non-intersecting three-fold symmetry axes, were reported.^{12,13} Polymorphism is very typical of these compounds. Puff *et al.*¹⁴ elucidated polymorphism in a number of mercury sulfochlorides and sulfobromides. According to their results, the low-temperature cubic α - $\text{Hg}_3\text{S}_2\text{Cl}_2$ modification can be crystallised from a stoichiometric mixture of HgS and HgCl_2 at 300 °C. The high-temperature cubic β - $\text{Hg}_3\text{S}_2\text{Cl}_2$ modification is formed at 400 °C. The low-temperature α - $\text{Hg}_3\text{S}_2\text{Cl}_2$ modification can reversibly transform into β - $\text{Hg}_3\text{S}_2\text{Cl}_2$ under hydrothermal conditions at 300 ± 0.5 °C. The orthorhombic γ - $\text{Hg}_3\text{S}_2\text{Cl}_2$ phase can be produced at ~ 750 °C and is probably metastable over the entire temperature range studied.

The orthorhombic low-temperature modification of mercury sulfobromide, α - $\text{Hg}_3\text{S}_2\text{Br}_2$, can be synthesised from HgS and HgBr_2 at 200 °C, the high-temperature (also orthorhombic) phase β - $\text{Hg}_3\text{S}_2\text{Br}_2$ is formed from the same reactants at ~ 420 °C. The metastable γ - $\text{Hg}_3\text{S}_2\text{Br}_2$ phase was prepared *via* the interaction of a HgBr_2 solution with an excess of KBr and sodium thiosulfate at 80 °C. No single crystal of this modification has been grown, but the authors claimed that it was isomorphous to the tetragonal phase of mixed mercury sulfobromiodide $\text{Hg}_3\text{S}_2\text{Br}_{0.5}\text{I}_{0.5}$.¹⁴

Single crystals of mercury sulfofluoride $\text{Hg}_3\text{S}_2\text{F}_2$ were grown by heating of a mixture of HgS and dipyrindinium tetrafluoromercurate up to 260 °C in vacuum according to the reaction

This compound was isomorphous to cubic α - $\text{Hg}_3\text{S}_2\text{Cl}_2$; isomorphous mercury selenofluoride $\text{Hg}_3\text{Se}_2\text{F}_2$ can be prepared in a similar way.¹⁵

Earlier, an oxidative method for the synthesis of these compounds has been suggested,¹⁶ which implied heating of the respective reaction mixtures in sealed evacuated ampoules at a temperature of the onset of exothermic effects:

Among all possible combinations, only $\text{Hg}_3\text{Te}_2\text{F}_2$ could not be prepared in pure form by this method, owing to the fact that heating of mixtures of Hg_2F_2 and Te in a temperature range of 180–350 °C always yielded liquid mercury. The oxidative synthesis of mercury seleno- and tellurohalides was successfully realised. The preparation of cubic mercury $\text{Hg}_3\text{S}_2\text{I}_2$ sulfoiodide was also reported.¹⁷

Systematic investigations into the ternary mercury chalcogenides are performed by a group of Ukrainian researchers starting from the early 1980s.^{18–23} The preparation, physical and crystallographic characterisation of cubic α - $\text{Hg}_3\text{S}_2\text{Cl}_2$, $\text{Hg}_3\text{Se}_2\text{Cl}_2$, $\text{Hg}_3\text{Te}_2\text{Cl}_2$, $\text{Hg}_3\text{Te}_2\text{Br}_2$ and $\text{Hg}_3\text{S}_2\text{I}_2$ were reported.¹⁹ The phase equilibria in the HgS-HgTe-HgCl_2 ternary system were elucidated.²² The existence of a single ternary compound, $\text{Hg}_3\text{S}_2\text{Cl}_2$, in the HgS-HgCl_2 system was confirmed, which occurs as three polymorph modifications, *viz.*, low-temperature α modification with a cubic structure, high-temperature cubic β modification with the double lattice parameter and metastable γ modification. It turned out that the structure of the γ phase belonged to the so-called order-disorder type. In addition to the ternary compound $\text{Hg}_3\text{Te}_2\text{Cl}_2$, another compound with a composition Hg_3TeCl_4 was found in the HgTe-HgCl_2 system.

A study of the HgS-HgBr_2 system revealed²³ two modifications of mercury sulfobromide $\text{Hg}_3\text{S}_2\text{Br}_2$, *viz.*, low- (α) and high-temperature (β) ones. According to single-crystal X-ray diffraction data, both compounds belong to the monoclinic system. No confirmation of the existence of a metastable phase γ - $\text{Hg}_3\text{S}_2\text{Br}_2$

was found. Two ternary mercury tellurobromides, *viz.*, cubic $\text{Hg}_3\text{Te}_2\text{Br}_2$ and Hg_3TeBr_4 isomorphous to their chloro analogue, Hg_3TeCl_4 , were found in the $\text{HgTe}-\text{HgBr}_2$ system. Within the $\text{HgTe}-\text{HgI}_2$ system, only one ternary compound Hg_3TeI_2 was identified.

Voroshilov and Slivka¹⁸ have observed for the first time the formation of ternary compounds $\text{Hg}_3\text{S}_2\text{I}_2$ (at 658 K) with an orthorhombic lattice and $\text{Hg}_3\text{Se}_2\text{I}_2$ (at 693 K), in the $\text{HgS}-\text{HgI}_2$ and $\text{HgSe}-\text{HgI}_2$ systems, respectively. Syntheses of $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$ by heating stoichiometric mixtures of the respective mercury chalcogenides and iodine in sealed evacuated ampoules at 260 °C for 2–3 days were reported.²⁴

Based on the analysis of equilibrium diagrams for the $\text{HgY}-\text{HgX}_2$ system, Voroshilov and Slivka¹⁸ concluded that the reactivity of mercuric chalcogenides towards mercuric halides increases on going from sulfur to tellurium (an increase in the ionic character of bonding) and from iodine to chlorine (an increase in the covalency of bonding).

In nature, mercuric sulfosalides occur as typical but rare exogenous minerals within the oxidation zone of mercury deposits, which are often characterised by a variable composition, depending on the number and type of halogen atoms incorporated into the crystal structure. These include the following minerals: corderoite $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$,²⁵ lavrentievite $\text{Hg}_3\text{S}_2(\text{Cl},\text{Br})_2$ and arzakite $\text{Hg}_3\text{S}_2(\text{Br},\text{Cl})_2$,^{26,27} grechishchevite $\text{Hg}_3\text{S}_2(\text{Br},\text{Cl},\text{I})_2$,²⁸ radtkiteite $\text{Hg}_3\text{S}_2\text{ClI}$ ²⁹ and kenshuaitite $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$.³⁰

The data given above indicate that both naturally occurring and synthetic mercury chalcogenides are of interest in terms of their polymorphism and possible isomorphous replacements of the halogen atoms in the crystal structures.

2. The crystal structures of ternary mercury chalcogenides

The rare mineral metacinnabarite ($\beta\text{-HgS}$) crystallises in the sphalerite structural type (the $\text{Hg}-\text{S}$ bond length is 2.54 Å).³¹

The more common trigonal modification, $\alpha\text{-HgS}$ (cinnabar),³¹ possesses a unique structure with no close analogues among monosulfides, since it involves chains combined into helices with the mercury atoms surrounded by two closest S atoms at 2.368 Å, two more S atoms at 3.10 Å and two even more distant S atoms at 3.30 Å. The $\text{S}-\text{Hg}-\text{S}$ and $\text{Hg}-\text{S}-\text{Hg}$ bond angles are 173° and 105°, respectively (Fig. 1). Similar to $\beta\text{-HgS}$, HgSe (tiemannite) and HgTe (coloradoite) crystallise in the sphalerite structural type ($\text{Hg}-\text{Se}$ 2.615, 2.634 Å, $\text{Hg}-\text{Te}$ 2.797 Å, the YHgY angle of 109.47°). Upon compression to 1.5–2 GPa, the crystal structures of HgSe and HgTe are transformed into that of $\alpha\text{-HgS}$.³²

a. 3:2:2 Mercury chalcogenides

The crystal structure of synthetic $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$ (natural mineral corderoite²⁵) was determined by means of single-crystal X-ray diffraction.^{33,34} An analysis of the interatomic distances and angles taking into account the tendency of mercury atoms towards

Figure 2. The crystal structure of $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$ (corderoite).

the formation of infinite chains¹ $(-\text{S}-\text{Hg}-\text{S}-)_{\infty}$ identified a $[\text{Hg}_3\text{S}_2]_{\infty}^{2n+}$ framework in the structure, which can be described in two ways. From the one side, the infinite nearly planar $(-\text{S}-\text{Hg}-\text{S}-)_{\infty}$ chains of the ‘+ + –’ type (Table 1, Fig. 2) can be considered as major building block of the structure. The chains go through the unit cell near the $z = \pm 1/4$ planes and include 8 out of 12 mercury atoms and all 8 sulfur atoms of a unit cell. The remaining mercury atoms combine the chains *via* the $\text{S}-\text{Hg}-\text{S}$ bridges into a $[\text{Hg}_3\text{Y}_2]_{\infty}^{2n+}$ spatial framework with the halogen atoms localised in its cavities.³³ The cubic symmetry (space group $I2_13$) provides the equivalency of all three chain orientations.

The same authors³³ suggested an alternative method for the description of the $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$ structure based on the identification of the trigonal pyramidal SHg_3 groups. The sulfur atoms located on the spatial diagonal of the cubic cell, *i.e.*, on the three-fold axis, coordinate three mercury atoms with $\text{Hg}-\text{S}$ bond lengths of 2.42 Å. These three mercury atoms compose regular triangles with an edge of 3.543 Å. The distance from the centre of such a triangle to the sulfur atoms in the pyramid apex is 1.30 Å. The SHg_3 groups are combined into a common framework by sharing mercury vertices. Large cavities present in the framework are occupied by the chlorine atoms. Very long $\text{Hg}-\text{Cl}$ bond lengths (2.87 Å) are indicative of the ionic character of bonding.

Frueh and Gray³⁴ described this structure in a more traditional way: each Hg atom is octahedrally coordinated by two S and four Cl atoms. Strongly distorted $[\text{HgY}_2\text{X}_4]$ octahedra are interlinked by face sharing.

Structural data on the isostructural compounds of the $\alpha\text{-Hg}_3\text{Y}_2\text{X}_2$ family ($\text{Y} = \text{S}, \text{Se}$ and Te ; $\text{X} = \text{F}, \text{Cl}, \text{Br}$ and I)¹² that crystallise in the enantiomorphous space group $I2_13$ with four formula units per unit cells are given in Table 1.

In order to rationalise the interatomic interactions in $\text{Hg}_3\text{S}_2\text{Cl}_2$, $\text{Hg}_3\text{S}_2\text{F}_2$, $\text{Hg}_3\text{Se}_2\text{Cl}_2$, $\text{Hg}_3\text{Te}_2\text{Cl}_2$ and $\text{Hg}_3\text{Te}_2\text{Br}_2$, a crystal chemical analysis of their structures has been accomplished.¹⁸ The authors note that the interactions between the mercury and chalcogen atoms are predominantly covalent. The $\text{Hg}-\text{Y}-\text{Hg}$ bond angles imply a significant contribution of the chalcogen p electrons to the chemical bond (the coordination is trigonal prismatic). Meanwhile, the $\text{Y}-\text{Hg}-\text{Y}$ angles close to 180° are characteristic of six-coordinated mercury atoms in distorted $[\text{HgY}_2\text{X}_4]$ octahedra. The packing density of the structure calculated based on mean specific volumes of the atoms involved estimated from their effective radii is 65%–71%, which

indicates that the structure is organised similar to a dense packing typical of many chalcogenides and halides.

In the crystal structure of β -Hg₃S₂Cl₂, virtually linear –S–Hg–S– groups forming closed isolated [Hg₁₂S₈] cubes with the S atoms in their vertices (Table 1, Fig. 3) can be identified.²² The Cl atoms are located both in the centres of the cubes and between them. According to an analysis of the interatomic distances and bond angles, the sulfur atoms are coordinated (similar to those in α -Hg₃S₂Cl₂) by three mercury atoms to form strong covalently bound trigonal pyramidal SHg₃ groups, which can be considered as basic building blocks of the structure. Closed isolated [Hg₁₂S₈] cubes are composed of eight SHg₃ groups. It is interesting to note that in both of these cubic structures (*i.e.*, α - and β -Hg₃S₂Cl₂), each sulfur atom is located on the spatial diagonal of the cubic lattice, *i.e.*, on the three-fold axis, in the intersection point of three virtually perpendicular linear –S–Hg–S– groups. Such isolated cubes occur also in other classes of compounds, in particular, they are similar to the [Si₈O₁₂] cubes found⁴⁵ in octasilsesquioxanes (and can be actually regarded as their antitypes).

The crystal structure of the γ modification of Hg₃S₂Cl₂ was solved³⁵ as belonging to the order–disorder type. It is composed of different polytypes with the prevalence of blocks with the *A2/m* or *F2/m* symmetries. The crystal structure includes layers built up of the SHg₃ groups interlinked by sharing mercury vertices to

Figure 3. A fragment of the crystal structure of β -Hg₃S₂Cl₂.

Figure 4. $[\text{Hg}_3\text{S}_2]_{\infty}^{2+}$ pucker layers with closed $[\text{S}_4\text{Hg}_4]$ rings in the crystal structure of $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$.

form $[\text{Hg}_3\text{S}_2]_{\infty}^{2+}$ polycations. Within the layers, the Hg–S and Hg–Cl bonds are covalent and ionic, respectively (Table 1, Fig. 4). A comparison of the polycationic motifs in $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$ and $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$ reveals that in the case of $\alpha\text{-Hg}_3\text{S}_2\text{Cl}_2$, these groups are characterised by the $3m$ symmetry and the covalent Hg–S bonds form a spatial framework. In the γ modification, the SHg_3 groups appear distorted and the network of the covalent Hg–S bonds extends only in two dimensions. Each pair of neighbouring layers is bridged by a system of the Hg–S bonds. However, the whole structure is joined only by significantly weaker Hg...Cl contacts. This explains the perfect cleavage of the $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$ crystals parallel to the (100) plane.

Two polymorph modifications of $\text{Hg}_3\text{S}_2\text{Br}_2$, viz., α and β , were prepared and characterised.²³ In the case of the α phase, nearly undistorted SHg_3 groups act as the basic structural unit. Similar to the situation observed in $\beta\text{-Hg}_3\text{S}_2\text{Cl}_2$, eight such groups linked by the mercury atoms compose isolated closed $[\text{Hg}_{12}\text{S}_8]$ cubes with the S atoms in their vertices, which can be regarded as main building blocks of the structure. The Br atoms are located both in the centres of the cubes and between them.

The monoclinic modification $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$ (Ref. 23) is isostructural to $\text{Hg}_3\text{Se}_2\text{Br}_2$.³⁶ X-Ray diffraction patterns of $\text{Hg}_3\text{Se}_2\text{Br}_2$, $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$ and $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$ are very similar.²³ The crystal structure of $\gamma\text{-Hg}_3\text{S}_2\text{Br}_2$ remains unknown.

The crystal structures of isomorphous $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$ have been reported.²⁴ The mercury atoms therein are covalently bound to two chalcogen atoms with the mean Hg–Y bond lengths of 2.411 Å and 2.512 Å for Y = S and Se, respectively. The Y–Hg–Y bond angles lie in the range of 160.8–163.9° and 161.48–171.78° for $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$, respectively. The mercury and chalcogen atoms form Hg–Y chains with the mean Hg–Y–Hg angles of 99.3° and 96.9° for $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$, respectively. The Hg–Y chains go along the *a* axis parallel to each other and are interlinked by the mercury atoms to form step-like ribbons (Fig. 5). Since the tricoordinated chalcogen atoms in the YHg_3 groups are characterised by the oxidation state –2, these one-dimensional polycations can be formulated as $[\text{Hg}_3\text{Y}_2]_{\infty}^{2+}$. The Hg–I interatomic distances exceeding 3 Å clearly indicate the ionic character of bonding. The iodide ions are located both inside the covalently bound ribbons and between them. Therefore, the structures of $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$ reveal a new type of the mutual disposition of the trigonal YHg_3 groups for compounds of the $\text{Hg}_3\text{Y}_2\text{X}_2$ family (Y = S, Se or Te; X = Cl, Br or I).

Minets *et al.*³⁶ reported on the synthesis and structural studies of selenohalides $\text{Hg}_3\text{Se}_2\text{Br}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$. The former compound is isostructural to $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$. Each mercury atom is covalently

Figure 5. $[\text{Hg}_3\text{Y}_2]_{\infty}^{2+}$ step-like polycationic ribbons composed of the closed $[\text{S}_4\text{Hg}_4]$ rings going along the [100] direction in the crystal structure of $\text{Hg}_3\text{S}_2\text{I}_2$.

bound to two selenium atoms, whereas each selenium atom is connected with three mercury atoms to form the SeHg_3 groups (see Table 1). These groups are linked by sharing Hg vertices into $[\text{Hg}_{12}\text{Se}_8]_{\infty}$ pucker layers. The majority of the Hg–Se bonds (5/6) are involved into closed $[\text{Hg}_4\text{Se}_4]$ rings oriented in two different ways and the remaining bonds combine the rings into layers *via* the Hg–Se–Hg bridges. The Br atoms are localised inside the $[\text{Hg}_{12}\text{Se}_8]_{\infty}$ layers and between them. Similar pucker layers are observed in the crystal structure of $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$.³⁵

The authors³⁶ assign the structure of $\text{Hg}_3\text{Se}_2\text{I}_2$ to the same type as $\alpha\text{-Hg}_3\text{S}_2\text{Br}_2$, *i.e.*, the structure containing isolated closed $[\text{Hg}_{12}\text{Se}_8]$ cubes with the Se atoms in their vertices. The I atoms are located both in the centres of the cubes and between them. It is of note that this conclusion contradicts the results reported by Beck and Hedderick.²⁴

The crystal structure of $\text{Hg}_3\text{Te}_2\text{I}_2$ has been studied by several authors.^{36,37} Its unit cell contains three types of Hg atoms in the sites with point symmetries 1, $\bar{1}$ and 2. The coordination polyhedron of the Hg atoms in the inversion centres can be described as a distorted octahedron with four relatively long Hg–I bonds (3.425–3.499 Å) and two short Hg–Te bonds (2.648 Å, the TeHgTe angle is 180°). Meanwhile, the Hg atoms residing on the 2-fold axes are surrounded by two Te atoms with the Hg–Te bond lengths of 2.678 Å and two I atoms at longer distances [$(\text{Hg}–\text{I})_{\text{av}}$ of 3.093 Å, the TeHgTe and IHgI angles are 157.80° and 100.99°, respectively]. Therefore, this type of crystallographically independent mercury atoms is characterised by the tetrahedrally distorted ‘butterfly’ coordination. The shortest Hg...Hg distance is 3.782 Å. According to a crystal chemical analysis, a complex framework of the Hg–Te bonds is realised in the $\text{Hg}_3\text{Te}_2\text{I}_2$ structure. It is built up of the $[\text{Te}_8\text{Hg}_{12}]$ fragments, which are in turn a combination of two $[\text{Te}_4\text{Hg}_4]$ rings related to each other by the two-fold symmetry axis parallel to the ring plane linked by a Te–Hg–Te bond. These fragments are assembled into a crankshaft ribbon, which differs from the $[\text{Y}_4\text{Hg}_6]_{\infty}$ ribbon in that only a half of the rings therein are closed and open rings form bonds with the neighbouring translationally equivalent chains. This gives rise to a framework with non-uniformly distributed bonds: 2/3 of the Hg–Te bonds form identically oriented closed $[\text{Te}_4\text{Hg}_4]$ rings, whereas 1/3 of the bonds link these rings by the Hg–Te–Hg bridges (Fig. 6). The eight-membered $[\text{Te}_4\text{Hg}_4]$ rings in the crystal structure of $\text{Hg}_3\text{Te}_2\text{I}_2$ have no shared edges with neighbouring rings, which is typical of other ribbon and layered Hg–Y motifs; this constitutes the principal distinction of this structural type from the structures of other known chalcogenides. All four Te–Hg–Te bonds formed by a ring are bridging, they link the ring with four neighbouring ones at different levels.

Figure 6. A complicated framework of the Hg–Te bonds in the crystal structure of $\text{Hg}_3\text{Te}_2\text{I}_2$.

Voroshilov and Minets³⁹ described the crystal structure of $\text{Hg}_3\text{Te}_2\text{BrI}$, which belongs to the structural type of $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$ ($\text{Hg}_3\text{Se}_2\text{Br}_2$). Due to the presence of two different halogens, the morphotropic transition $\text{Hg}_3\text{Se}_2\text{Br}_2 \rightarrow \text{Hg}_3\text{Te}_2\text{BrI}$ is accompanied by lowering of the structure symmetry (space group $C2/m \rightarrow C2$) with the approximate retention of the unit cell parameters due to the regular iodide substitution for a half of the bromide ions.

Mercury sulfosalides rarely occur in nature. Only a few minerals within the ternary $\text{Hg}_3\text{S}_2\text{Cl}_2\text{--Hg}_3\text{S}_2\text{Br}_2\text{--Hg}_3\text{S}_2\text{I}_2$ system are known, all of them have structures closely related to each other. One of them (corderoite) has been discussed above in the beginning of Section II.2.a.

Crystals of a synthetic mercury chalcogenide that represents the analogue of naturally occurring mineral grechishchevite²⁸ have been structurally elucidated by means of X-ray diffraction.⁴⁰ In agreement with the refined stoichiometry $\text{Hg}_3\text{S}_2\text{Br}_{1.0}\text{Cl}_{0.5}\text{I}_{0.5}$, each mercury atom is connected with two sulfur atoms. As in other structures of mercury chalcogenides with a common formula $\text{Hg}_3\text{Y}_2\text{X}_2$, covalently bound S--Hg--S and SHg_3 groups assembled into a general motif can be readily identified in the crystal structure. A significant deviation of some of the SHgS angles (141.8° and 140.9°) from the linearity typical of bivalent mercury compounds¹ is of note. The halogen atoms are located between the zigzag chains. The eight-membered $[\text{Hg}_4\text{S}_4]$ rings composed of the SHg_3 groups are assembled into infinite crankshaft ribbons going along the $[001]$ direction. As has been mentioned above, similar polycationic motifs were found²⁴ in $\text{Hg}_3\text{S}_2\text{I}_2$ and $\text{Hg}_3\text{Se}_2\text{I}_2$. In these structures, all ribbons are translationally equivalent, whereas they are related to each other by the inversion centre and 2_1 -axis in $\text{Hg}_3\text{S}_2\text{Br}_{1.0}\text{Cl}_{0.5}\text{I}_{0.5}$. This difference is sufficient to classify the structure of the grechishchevite analogue as a new structural type (Fig. 7).

Naturally occurring mercury sulfosalide $\text{Hg}_3\text{S}_2\text{ClI}$ was characterised as a new mineral radtkite in 1991.²⁹ A few years later, its synthetic analogue $\text{Hg}_3\text{S}_2\text{Cl}_{1.00}\text{I}_{1.00}$ was prepared and its crystal structure was determined.⁴¹ As in the case of $\text{Hg}_3\text{S}_2\text{Br}_{1.0}\text{Cl}_{0.5}\text{I}_{0.5}$,⁴⁰ the SHgS groups deviate significantly from the linearity (see Table 1). The SHg_3 groups form $[\text{Hg}_{12}\text{S}_8]_\infty$ puckered layers similar to those found in the crystal structures of $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$,³⁵ $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$ ²³ and $\text{Hg}_3\text{Se}_2\text{Br}_2$.³⁶ The orientation of the layers strictly corresponds to the planes of perfect cleavage of the crystals.

Figure 7. Crankshaft ribbons composed of closed $[\text{S}_4\text{Hg}_4]$ rings going along the $[001]$ direction in the crystal structure of the synthetic analogue of grechishchevite $\text{Hg}_3\text{S}_2\text{Br}_{1.0}\text{Cl}_{0.5}\text{I}_{0.5}$.

A series of isostructural minerals $\text{Hg}_3\text{S}_2\text{Cl}_m\text{Br}_n$ ($m+n=2$; $m>n$, lavrentievite and $m<n$, arzarkite)^{26,27} have not been studied by means of X-ray crystallography due to the lack of suitable single crystals. Attempted syntheses of these minerals afforded new mercury chalcogenides corresponding to compositions $\text{Hg}_3\text{S}_2\text{Cl}_{1.5}\text{Br}_{0.5}$ (I), $\text{Hg}_3\text{S}_2\text{Cl}_{1.54}\text{Br}_{0.46}$ (II)⁴² and $\text{Hg}_3\text{S}_2\text{Br}_{1.5}\text{Cl}_{0.5}$ (III, IV),⁴³ which have been successfully characterised by single-crystal X-ray diffraction (see Table 1).

Compound I is isostructural to synthetic $\gamma\text{-Hg}_3\text{S}_2\text{Cl}_2$, $\beta\text{-Hg}_3\text{S}_2\text{Br}_2$, $\text{Hg}_3\text{Se}_2\text{Br}_2$ and $\text{Hg}_3\text{S}_2\text{ClI}$ (a synthetic analogue of radtkite). A part of the halogen sites in the structure are statistically occupied by Cl and Br.

Compound II is isostructural to $\beta\text{-Hg}_3\text{S}_2\text{Cl}_2$ except for some increase in the lattice parameter a due to the incorporation of larger bromine atoms. The monoclinic modification III is isostructural to the synthetic compound $\alpha\text{-Hg}_3\text{S}_2\text{Br}_2$, and the cubic modification IV is isostructural to $\beta\text{-Hg}_3\text{S}_2\text{Cl}_2$. In the latter structure, 64 Br atoms are located in the nodes of a sublattice with a sublattice constant $a/4$, and eight $[\text{Hg}_{12}\text{S}_8]$ groups are arranged in a way similar to that found in $\beta\text{-W}$: they are located in the nodes and in the centre of the unit cell; additionally, each face of the unit cell accommodates these two groups.

b. 3 : 1 : 4 Mercury chalcogenides

Two isomorphous compounds Hg_3TeCl_4 and Hg_3TeBr_4 were found in the HgTe--HgCl_2 (see Ref. 22) and HgTe--HgBr_2 (Ref. 23) systems (see Table 1). Both Hg_3TeX_4 compounds ($\text{X} = \text{Cl}$ or Br) have layered structures with puckered layers stacked nearly parallel to the crystallographic xz plane, which agrees with the fact that the crystals manifest perfect cleavage along the (010) plane. Double layers oriented perpendicular to the y axis contain the halogen, tellurium and mercury atoms along with the TeHg_3 pseudotrigonal pyramids analogous to the SHg_3 groups observed in the $\text{Hg}_3\text{Y}_2\text{X}_2$ chalcogenides described above. The isolated TeHg_3 groups are arranged in such a way that two mercury atoms are located in the same layer as the tellurium atom, whereas the third Hg atom is located in the neighbouring layer (Fig. 8) thus making a covalent contribution into the predominantly ionic bonding between the atoms within a double layer. Owing to the stoichiometry change, the TeHg_3 groups are slightly more distorted than the YHg_3 groups in $\text{Hg}_3\text{Y}_2\text{X}_2$ ($\text{Y} = \text{S}, \text{Se}$ or

Figure 8. A projection of the crystal structure of Hg_3TeCl_4 onto the (100) plane.

Te; $X = \text{Cl, Br or I}$); the spread in the HgYHg bond angles increases from 3° (in $\text{Hg}_3\text{S}_2\text{Cl}_2$) to 7° (in Hg_3TeCl_4).

In a study of the HgTe-HgI_2 system, a new compound Hg_3TeI_4 has been found and an attempt at determining its structure from powder X-ray diffraction data has been undertaken.⁴⁴ According to the results obtained, the compound possesses a structure similar to that of sphalerite (ZnS) with a statistical distribution of atoms over the available sites, which can be described as a cubic close packing of the anions with the mercury cations statistically occupying its tetrahedral cavities (see Table 1). The authors also suggested that Hg_3TeI_4 in the ordered form can contain fragments of the red modification of HgI_2 bridged by chains composed of the HgX_4 tetrahedra ($X = \text{Te or I}$) in a way similar to that observed in the crystal structure of SiS_2 .

3. Preparation and crystal structures of quaternary mercury chalcogenides

a. Synthesis and crystal structures of MHgYX compounds

($M = \text{Cu or Ag}$; $Y = \text{S or Se}$; $X = \text{Cl, Br or I}$)

Silver and copper halides are well known cationic conductors. With this regard, the crystal structures of compounds of the MHgYX family ($M = \text{Cu or Ag}$; $Y = \text{S or Se}$; $X = \text{Cl, Br or I}$) have been in the focus of intense investigations. Main methods for their preparation can be classified into two types: (a) solid-state reactions of appropriate stoichiometric amounts of the binary precursors MX and HgY in sealed evacuated ampoules upon heating to a specific temperature for a certain time; (b) hydrothermal reactions of the starting binary components MX and HgY in concentrated or dilute solutions with HCl , HBr or HI as solvents in sealed evacuated ampoules at a certain temperature.

The major crystallographic and crystal chemical parameters of the MHgYX compounds are summarised in Table 2.

The quaternary sulfosalides CuHgSCl and CuHgSBr are isostructural. According to the X-ray diffraction study of their orthorhombic single crystals,⁴⁶ both crystal structures include planar crankshaft $-\text{S}-\text{Hg}-\text{S}-$ chains assembled into a spatial framework with pairs of strongly distorted $[\text{CuS}_2\text{X}_2]$ tetrahedra sharing an $X-X$ edge (Fig. 9). The coordination polyhedron of the mercury atoms is supplemented to a distorted octahedron with the halogen atoms. The coordination polyhedron of the copper atoms can be regarded as a strongly distorted $[\text{CuS}_2\text{X}_2]$ tetrahedron, where the copper atom occupies a position shifted from the centre of the tetrahedron (see Table 2). The sulfobromide CuHgSBr undergoes a phase transition at 323 K transforming into another orthorhombic phase with the halved parameter b . The crystal structures of CuHgSBr (at 358 K) and $\beta\text{-AgHgSI}$

Figure 9. A projection of the crystal structure of CuHgSCl onto the (001) plane.

(Ref. 50) become virtually identical after the y and z axes in the former crystal structure are interchanged.

The crystal structure of CuHgSI has been determined independently by two research groups using the Rietveld refinement of a powder X-ray diffraction pattern⁴⁸ and single-crystal X-ray diffraction.⁴⁷ As major structural units therein, the $-\text{I}-\text{Cu}-\text{I}-$ and $-\text{S}-\text{Hg}-\text{S}-$ zigzag chains going along the c axis can be identified (Fig. 10). The copper atoms are tetrahedrally coordinated by the S and I atoms, whereas the Hg atoms are linearly coordinated (see Table 2). The structure of CuHgSI is similar to those of CuHgSCl and CuHgSBr , except for the fact that the shape of the $-\text{S}-\text{Hg}-\text{S}-$ chains is distorted in the two latter structures.

As a part of an investigation into the CuCl-HgSe system, a new compound CuHgSeCl has been synthesised and character-

^a M = Cu, Ag, Sn, Pb; Y = S, Se; X = Cl, Br, I; ^b the position is occupied by the Cu and Hg atoms in a 0.53 : 0.47 ratio; ^c the Cl–Cl distance is 3.738 Å; ^d $\beta = 102.68^\circ$; the HgSn angles are $95.7–113.9^\circ$.

ised.⁴⁹ Its structure represents a framework assembled from the $-\text{Se}-\text{Hg}-\text{Se}-$ chains running along the $[100]$ direction. Two chains related to each other by a translation along c are bridged by distorted $[\text{CuSe}_2\text{Cl}_2]$ tetrahedra involving two Se atoms from different chains and two Cl atoms. The copper atoms in these tetrahedra are strongly shifted from the centres. Pairs of these tetrahedra combined by sharing a $\text{Cl}-\text{Cl}$ edge assemble the $-\text{Se}-\text{Hg}-\text{Se}-$ chains lying in the xy plane into a framework. The geometry of the $-\text{Se}-\text{Hg}-\text{Se}-$ chains in CuHgSeCl differs from that of the $-\text{S}-\text{Hg}-\text{S}-$ chains in MHgSX ($\text{M} = \text{Cu}$ or Ag ; $\text{X} = \text{Cl}, \text{Br}$ or I).⁵⁸ The $-\text{Se}-\text{Hg}-\text{Se}-$ chains are similar to the chains present in the structures of HgO , $\text{Hg}(\text{OHg})_4\text{Br}$ and $\text{Hg}_2\text{O}_2\text{NaI}$ described as zigzag chains (the ‘+ – + –’ type) by Aurivillius,¹ whereas the chains in CuHgSeCl are of the ‘+ + – –’ type (*i.e.*, crankshaft chains) according to the same classification.

The preparation methods and crystal structures of isostructural chalcogenides CuHgSeBr , AgHgSBr and $\beta\text{-AgHgSI}$ have been reported by Beck *et al.*⁵⁰ The structures are built up of puckered layers composed of crankshaft chains with the covalent $\text{Hg}-\text{Y}$ bonds. These chains are assembled into a framework by pairs of strongly distorted $\text{M}[\text{Y}_2\text{X}_2]$ tetrahedra with shared $\text{X}-\text{X}$ edges (Table 2, Fig. 11).

Figure 11. Puckered layers constituted by the $\text{Hg}-\text{S}$ and $\text{Ag}-\text{S}$ bonds in the crystal structure of $\beta\text{-AgHgSI}$.

A new phase, $\alpha\text{-AgHgSI}$, has been synthesised recently.⁵¹ Its structure is based on a distorted hexagonal close packing of the sulfur and iodine atoms. One fourth of the tetrahedral cavities of the packing is occupied by the silver atoms, whereas a half of the octahedral sites is occupied by the mercury atoms. The mercury atoms, like those in other mercuric compounds, are connected to two sulfur atoms. The $-\text{S}-\text{Hg}-\text{S}-$ chains (of the ‘+ – + –’ type) oriented along the $[100]$ direction are assembled into a framework by pairs of distorted $[\text{AgS}_2\text{I}_2]$ tetrahedra with shared $\text{I}-\text{I}$ edges (Fig. 12). Each tetrahedron includes two S atoms from different chains and two I atoms. The low-temperature modification $\beta\text{-AgHgSI}$ is transformed into high-temperature $\alpha\text{-AgHgSI}$ at 273°C .

We conclude this section by considering two compounds that do not formally fall into the MHgYX family, although they also correspond to a 1 : 1 cation-to-anion ratio. The crystal structures of $\text{CuHg}_2\text{S}_2\text{I}$ (Ref. 47) and Ag_2HgSI_2 (Ref. 52) are similar. Each mercury atom is linearly coordinated to two sulfur atoms (see Table 2). In these structures, the planar (in the yz plane) zigzag $-\text{S}-\text{Hg}-\text{S}-$ chains go along the c axis (Fig. 13). The coordination polyhedron of the Hg atoms is supplemented by the I atoms to a distorted octahedron. In the crystal structure of

Figure 12. A fragment of the crystal structure of $\alpha\text{-AgHgSI}$.

Figure 13. The crystal structure of $\text{CuHg}_2\text{S}_2\text{I}$.

$\text{CuHg}_2\text{S}_2\text{I}$, one of the cationic sites is statistically occupied by mercury and copper in a 0.47 : 0.53 ratio. The Hg/Cu cation is characterised by a distorted tetrahedral coordination environment composed of three S and one I atoms. The $[(\text{Hg},\text{Cu})\text{S}_3\text{I}]$ tetrahedra assemble the $-\text{S}-\text{Hg}-\text{S}-$ chains into a framework by vertex-sharing. In the crystal structure of $\text{AgHg}_2\text{S}_2\text{I}$, the silver atoms are surrounded by three I and one S atoms forming distorted tetrahedra. These tetrahedra assemble the $-\text{S}-\text{Hg}-\text{S}-$ chains into a framework by sharing their S vertices.

b. Quaternary mercury chalcogenides with a cation-to-anion ratio of 3 : 4

Blachnik *et al.*⁵³ reported on the synthesis of $\text{Hg}_2\text{SnS}_2\text{Br}_2$ by a solid-state reaction of HgS and SnBr_2 . In the crystal structure of this compound, helical $-\text{S}-\text{Hg}-\text{S}-$ chains, which are nearly square in the cross-section, oriented parallel to $[010]$ are packed into a tetragonal structure giving rise to voids accommodating the Sn_2Br_4 fragments (Fig. 14). The Hg atoms are characterised by a distorted octahedral coordination (two S plus four Br atoms, see Table 2).

In a study of quaternary compounds within the $\text{HgS}-\text{PbI}_2$ system involving elements of Groups 12, 14, 16 and 17,⁵⁴ a new sulfoiodide $\text{Hg}_2\text{PbS}_2\text{I}_2$ has been synthesised (see Table 2). In its crystal structure, the Hg atoms form two covalent bonds with the S atoms, and four longer $\text{Hg}-\text{I}$ bonds supplement its coordination environment to distorted octahedral one. The coordination polyhedron of the Pb atoms can be described as a monoclapped trigonal prism composed of four S and three I atoms. The sulfur atoms are tetrahedrally coordinated by two Hg and two Pb atoms. The 3D structure is built up of planar $[\text{Hg}_4\text{S}_4]$ rings stacked in columns along the $[001]$ direction. The columns are linked by the

Figure 14. Helical axes $-S-Hg-S-$ going along the $[010]$ direction in the crystal structure of $Hg_2SnS_2Br_2$.

Pb atoms coordinated to four S atoms from four $[Hg_4S_4]$ rings of two neighbouring columns into a spatial framework; the iodine atoms occupy its cavities (Fig. 15).

As has been noted by Blachnik *et al.*,⁵⁴ $Hg_2PbS_2I_2$ can be considered as a cinnabarite (α - HgS) (see Fig. 1) derivative built up of helical $-S-Hg-S-$ chains.¹ The replacement of an S^{2-} ion in cinnabarite with two I^- ions gives rise to the $Hg_3S_2I_2$ structure,²⁴ where the chains are joined by the Hg bridges. The coordination number of the sulfur atoms increases to three. The sulfoiodide $Hg_2PbS_2I_2$ can be regarded as a $Hg_3S_2I_2$ derivative that is obtained by the Pb^{2+} substitution for one third of the Hg^{2+} ions, this modification is accompanied by a change of the sulfur coordination to the tetrahedral one (2 Pb plus 2 Hg).

Figure 15. Columns of the $[Hg_4S_4]$ rings linked by the Pb atoms in the crystal structure of $HgPbS_2I_2$. The Pb–I bonds supplementing the coordination environment of the lead atoms to a monocapped trigonal prism are shown as dashed lines.

c. Naturally occurring quaternary mercury chalcogenides

Presently, there are only three known rare minerals falling into the class of quaternary mercury chalcogenides, *viz.*, perroudite, capgaronnite and iltisite. Perroudite and capgaronnite contain three halogens (Cl, Br and I) at once; among naturally occurring ternary mercury sulfosalts, all three halogens are present simultaneously only in grechishchevite.²⁸

In the structure of perroudite $Hg_5Ag_4S_5(Cl,Br,I)_4$, the mercury atoms are covalently bound to two sulfur atoms to form specific crankshaft chains parallel to b .⁵⁵ The coordination environment of the mercury atoms is supplemented by the halogen X atoms to the distorted octahedral one; the halogen sites are occupied by the Cl, Br and I ions statistically. The silver atoms of the first type are tetrahedrally coordinated by three S and one X atoms ($Ag-S$ 2.46–2.78 Å, $Ag-X$ 2.99 Å), whereas those of the second type are tetrahedrally coordinated by three X and one S atoms ($Ag-S$ 2.66 Å, $Ag-X$ 2.59–3.03 Å). The $S-Hg-S$ chains are assembled into a framework by the $[Ag(S,X)_4]$ tetrahedra (Fig. 16). An accurate refinement of the crystal structure indicated the complete mutual isomorphous substitution of the halogen atoms, Cl substitution for a part of the sulfur atoms and Ag substitution for a part of the mercury atoms. The mineral was finally formulated as $Hg_{4.6}Ag_{4.4}S_{4.6}Cl_{2.0}Br_{0.8}I_{1.6}$.

Figure 16. A projection of the crystal structure of perroudite $Hg_5Ag_4S_5X_4$ ($X = Cl, Br$ or I) onto the (001) plane.

The mineral capgaronnite corresponds to the stoichiometry $HgAgS(Cl,Br,I)$. In contrast to the framework structure of perroudite considered above, in the crystal structure of capgaronnite, the zigzag $-S-Hg-S-$ chains (of the ‘+ – + –’ type) are assembled into layers parallel to the (010) plane by pairs of edge-sharing $[AgS_2X_2]$ tetrahedra (Fig. 17).⁵⁶ The mercury atoms inside the chains are linearly coordinated by two S atoms, and four X atoms supplement their coordination to the octahedral one. The Ag atoms are tetrahedrally coordinated by two S and two X atoms.

Figure 17. A projection of the crystal structure of capgaronnite HgAgSX ($\text{X} = \text{Cl}, \text{Br}$ or I) onto the (100) plane.

A hexagonal polymorph of the orthorhombic capgaronnite, *viz.*, iltsite $\text{HgAgS}(\text{Cl}, \text{Br})$, has been reported by Sarp *et al.*,⁵⁷ although its crystal structure has not been determined so far.

The major crystallographic and crystal chemical parameters of quaternary mercury chalcogenides are summarised in Table 2.

III. Mercuric oxohalides

Two binary mercury oxides are well known, *viz.*, yellow orthorhombic (natural mineral montroidite) and red hexagonal phases.

According to investigations into the pressure-induced polymorphism in HgO ,⁵⁹ a black polycrystalline powder with the tetragonal symmetry (the Laue class is $4/mmm$) is formed at 35 GPa. The authors assume that the $-\text{Hg}-\text{O}-\text{Hg}-\text{O}-$ chains are preserved in the new structure, *i.e.*, no dramatic structural rearrangement occurs.

A new triclinic phase of mercuric oxide has been reported by Benjamin.⁶⁰ It is spontaneously formed as a thin film on the surface of pure mercury under the action of oxygen under humidity. Meanwhile, stirring of mercury in ozonated oxygen affords a mixture of the orthorhombic and triclinic HgO modifications. According to X-ray diffraction data, the film represents the triclinic HgO modification with the double parameters of the orthorhombic unit cell. The structure contains zigzag $-\text{Hg}-\text{O}-\text{Hg}-\text{O}-$ chains with the bond lengths and angles typical of the HgO structures. Nevertheless, the $\text{Hg}-\text{Hg}$ distance between the neighbouring chains is ~ 2.64 Å, which is rather typical of compounds of monovalent mercury. Therefore, Benjamin suggested this compound to be a mixed-valence one.

Mercury forms various oxo salts. In particular, a series of mercuric oxochlorides $n\text{HgO} \cdot \text{HgCl}_2$ ($n = 0.5, 2, 3, 4$) and an oxobromide $\text{Hg}(\text{OHg})_4\text{Br}_2$ are known.

There are only a few quaternary mercury oxohalides. The heating of a mixture of PbO , PbBr_2 , HgBr_2 and H_2O in a 3 : 1 : 2 : 1 ratio in a sealed evacuated ampoule at 280 °C yields⁶¹ $\text{HgPb}_2\text{O}(\text{OH})\text{Br}_3$. Within the $\text{PbO}-\text{HgCl}_2$ system, single crystal of $\text{HgPb}_2\text{O}_2\text{Cl}_2$ has been synthesised by heating a mixture of PbO and HgCl_2 (in a 2 : 1 ratio) in a sealed evacuated ampoule at 275–300 °C.⁶² As a part of investigations into Hg-containing high-temperature superconductors, the first barium mercury oxochloride $\text{BaHg}_2\text{O}_2\text{Cl}_2$ has been synthesised by heating a mixture of BaO_2 and Hg_2Cl_2 in a sealed ampoule at 360 °C for three days.⁶³ The first strontium mercury oxochloride $\text{SrHg}_2\text{O}_2\text{Cl}_2$ has been prepared as reddish brown powder by the solid-state reaction of strontium peroxide SrO_2 with calomel Hg_2Cl_2 .⁶⁴

The crystal structure of the orthorhombic HgO modification reveals infinite planar zigzag $-\text{O}-\text{Hg}-\text{O}-\text{Hg}-$ chains (of the

$+ - + -$ type)¹ lying in the *ac* plane parallel to *a* ($\text{Hg}-\text{O}$ 2.039–2.067 Å, the OHgO and HgOHg angles are 179.5° and 107.3°, respectively). A comparison of the crystal structures of HgO and the hexagonal modification of mercury sulfide (cinnabarite) reveals similar principles of their structural organisation. The planar zigzag $-\text{O}-\text{Hg}-\text{O}-\text{Hg}-$ chains in oxide correspond to the infinite helical $-\text{S}-\text{Hg}-\text{S}-\text{Hg}-$ chains oriented parallel to *c* in sulfide. In both cases, the $\text{X}-\text{Hg}-\text{X}$ bond angles do not deviate substantially from 180°. A decrease in the $\text{Hg}-\text{X}-\text{Hg}$ bond angle on going from oxygen (109°) to sulfur (105°) fully reproduces the respective trend observed in other structures.

The crystal structure of hexagonal red mercury oxide is built up of infinite helical $(-\text{O}-\text{Hg}-\text{O}-)_\infty$ chains going parallel to the *c* axis. The $\text{Hg}-\text{O}$ bond lengths (2.03 Å) and $\text{Hg}-\text{O}-\text{Hg}$ (108°) and $\text{O}-\text{Hg}-\text{O}$ (176°) bond angles inside the chains are nearly the same as in the planar zigzag chains of the orthorhombic modification.⁵⁹ Four O atoms at 2.79–2.90 Å supplement the coordination polyhedron of the Hg ions to a strongly distorted octahedron. Inside the chains, the $\text{Hg}-\text{O}$ bond in the hexagonal modification is of the same type as in the orthorhombic modification but the interchain bonds are significantly weaker (the $\text{Hg} \cdots \text{O}$ distances are 2.79 and 2.90 Å, the $\text{Hg} \cdots \text{Hg}$ distances are 3.30, 3.58 and 3.72 Å, the $\text{O} \cdots \text{O}$ distances are 3.41–4.06 Å).

1. The crystal structures of ternary mercuric oxohalides

The basic crystallographic and crystal chemical parameters of mercury oxohalides are listed in Table 3.

The structure of Hg_3OCl_4 ($n = 0.5$) includes the Cl^- anions and pyramidal $[\text{OHg}_3\text{Cl}_3]^+$ cations (Ref. 65). The O atoms are located on the body diagonals of the cubic unit cell (that is on the three-fold axes) coordinating three mercury atoms. The oxygen atoms are shifted by 0.30 Å from the centres of regular triangles composed of the mercury atoms. Furthermore, each mercury atom is connected to a chlorine atom (2.302 Å) in a way that three linear $\text{Cl}-\text{Hg}-\text{O}$ groups intersect at the central oxygen atom. Therefore, the triangle composed of mercury atoms is located inside the regular triangle of the chlorine atoms; their edges are virtually parallel. The remaining chlorine atoms are situated at significantly larger distances from the mercury atoms. Each $[\text{OHg}_3\text{Cl}_3]^+$ pyramidal cation is surrounded by three Cl^- anions and *vice versa* each Cl^- anion is surrounded by three $[\text{OHg}_3\text{Cl}_3]^+$ cations. The bonds inside the pyramidal cation are covalent, as evidenced by the respective $\text{Hg}-\text{O}$ and $\text{Hg}-\text{Cl}$ bond lengths (see Table 3). The $\text{Hg}-\text{O}-\text{Hg}$ bond angle (118°) is also indicative of the covalent bonding between the oxygen and mercury atoms.

A similar nearly planar $[\text{O}(\text{HgI})_2(\text{HgOH})]^+$ cation occurs⁷¹ in two isostructural compounds $[\text{O}(\text{HgI})_2(\text{HgOH})]\text{ClO}_4$ and $[\text{O}(\text{HgI})_2(\text{HgOH})]\text{BF}_4$ ($\text{Hg}-\text{O}$ 1.99–2.12 Å, HgOHg 115.4–128.1°; $\text{Hg}-\text{OH}$ 1.98 Å, $\text{Hg}-\text{I}$ 2.57 Å, OHgI 175.0–177.2°, OHgOH 175.9°).

In the structure of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$ ($n = 2$), two crystallographically independent mercury atoms are characterised by different coordination environments: the first type Hg atoms are linearly coordinated by two O atoms ($\text{Hg}-\text{O}$ 2.07 Å), whereas the second type Hg atoms are coordinated by three O atoms ($\text{Hg}-\text{O}$ 2.17, 2.32 and 2.33 Å).⁶⁶ Nearly planar HgO_3 triangles are combined by edge- and vertex-sharing into puckered layers lying in the *ac* plane. The layers are further assembled into a framework by the linearly coordinated Hg atoms. The chlorine atoms occupy cavities of the framework (Fig. 18). Examples of non-linear coordination types involving a third O atom (T-shaped, *etc.*), which are less typical of Hg^{2+} cations, can be found elsewhere.³

There is another modification of this compound, $\beta\text{-Hg}_3\text{O}_2\text{Cl}_2$, which can be alternatively formulated as $\text{Hg}_6\text{O}_4\text{Cl}_4$.⁶⁷ Its structure is more complex than that of the α phase, which is evidenced by a four times larger unit cell volume. A unit cell of the β -phase

Figure 18. A projection of the crystal structure of α - $\text{Hg}_3\text{O}_2\text{Cl}_2$ onto the (010) plane.

contains six crystallographically independent mercury atoms. One of them is linearly coordinated by two oxygen atoms ($\text{Hg}-\text{O}$ 2.068 and 2.099 Å, the OHgO angle is 175.1°), four types of the Hg atoms are coordinated (similarly to the structure of α - $\text{Hg}_3\text{O}_2\text{Cl}_2$) by three O atoms in the 2+1 manner ($\text{Hg}-\text{O}$ 2.028–2.184 and 2.436–2.781 Å, the OHgO angles are 154.9 – 171.4°). The last type of the Hg atoms forms close contacts with two O atoms ($\text{Hg}-\text{O}$ 2.100 and 2.586 Å) and binds covalently a Cl atom ($\text{Hg}-\text{Cl}$ 2.364 Å, the OHgCl angle is 158.9°). The structure is built up of infinite Hg–O chains (of the ‘+ + – –’ type).¹ Four these symmetry-related chains cross a unit cell nearly parallel to the [001] direction, a repeating unit of a chain forms two O–Hg–O bonds with the nearest chain, *i.e.*, individual chains are assembled into pairs forming 12-membered $(\text{Hg}-\text{O})_6$ rings. Taking into account slightly longer contacts, these double chains are joined by pairs into extended ribbons. The sixth type of the Hg atoms is connected to a chain oxygen atom and a Cl atom to form a finite –Hg–Cl side chain. As a result, extended double ribbons with the general formula $[\text{Hg}_2(\text{OHg})_4\text{Cl}^{3+}]_n$ act as the primary building blocks of the structure. The ribbons are further assembled by the Hg atoms into a complicated framework with the remaining Cl atoms occupying its cavities. The Hg–Cl bonds with these Cl atoms are essentially ionic, according to their lengths. The authors of this study proposed to write the crystal chemical formula of this compound as $[\text{Hg}_2(\text{OHg})_4\text{Cl}]\text{Cl}_3$. It is of note that the structure of this phase was determined independently by another research group⁶⁸ and they described its structure as a motif of condensed cationic oxo-centred tetrahedra (see Section IV.1).

The presence of extended virtually planar –O–Hg–O– chains containing two of three crystallographically independent types of the Hg atoms and all O atoms constitutes the main structural feature of mercury oxobromide $\text{Hg}(\text{OHg})_4\text{Br}_2$ ($n = 4$).⁶⁹ They can be classified as crankshaft chains of the ‘+ + – –’ type ($\text{Hg}-\text{O}$ 2.05 and 2.09 Å, the OHgO angles are 175° and 163° , whereas the HgOHg angles are 113°). The remaining Hg atoms bridging the chains into a framework are located between the planes of the chains; these Hg atoms are tetrahedrally coordinated by the oxygen atoms ($\text{Hg}-\text{O}$ 2.24 Å, the OHgO angles are 86 – 133°). Cavities of the framework accommodate the Br atoms (Fig. 19). The crystal structure of naturally occurring mercury oxochloride $\text{Hg}_5\text{O}_4\text{Cl}_2$, or $\text{Hg}(\text{OHg})_4\text{Cl}_2$ (pinchite), as determined by Hawthorne *et al.*,⁷⁰ appeared fully analogous to that of $\text{Hg}(\text{OHg})_4\text{Br}_2$.

Figure 19. A projection of the crystal structure of $\text{Hg}(\text{OHg})_4\text{Br}_2$ onto the (100) plane.

The Cl atoms play different roles in the structures of the mercury oxochlorides. Above, in α - $\text{Hg}_3\text{O}_2\text{Cl}_2$ and $\text{Hg}_5\text{O}_4\text{Cl}_2$, all bonds between the Cl atoms and the respective frameworks ($[\text{Hg}_3\text{O}_2^{2+}]_n$ and $[\text{Hg}_5\text{O}_4^{2+}]_n$, respectively) are ionic. In β - $\text{Hg}_3\text{O}_2\text{Cl}_2$ and Hg_3OCl_4 , a fraction of the Cl atoms (25% and 75%, respectively) form covalent bonds with the mercury atoms giving rise to the $[\text{Hg}_6\text{O}_4\text{Cl}^{3+}]_n$ ribbons in the former case and isolated $[\text{OHg}_3\text{Cl}_3]^+$ cations in the latter one. The –O–Hg–O– fragments with terminal covalently bound Cl atoms present in the structure of β - $\text{Hg}_3\text{O}_2\text{Cl}_2$ loose them upon heating and the compound converts into $\text{Hg}_5\text{O}_4\text{Cl}_2$ with the liberation of HgCl_2 . The similarity between the crystal structures of β - $\text{Hg}_3\text{O}_2\text{Cl}_2$ and α - $\text{Hg}_3\text{O}_2\text{Cl}_2$ is not obvious. The presence of planar HgO_3 groups is their common structural feature. The β - $\text{Hg}_3\text{O}_2\text{Cl}_2$ phase is more stable at 25°C . Upon heating in air at 200°C for 70 h, both modifications convert into $\text{Hg}_5\text{O}_4\text{Cl}_2$; its structure is similar to that of β - $\text{Hg}_3\text{O}_2\text{Cl}_2$. The α - $\text{Hg}_3\text{O}_2\text{Cl}_2$ phase can be transformed into the β -modification by annealing in vacuum at 200°C for a week. A subsequent heating at 230°C for three days affords a mixture of $\text{Hg}_5\text{O}_4\text{Cl}_2$ and HgCl_2 , as evidenced by powder X-ray diffraction data. Therefore, β - $\text{Hg}_3\text{O}_2\text{Cl}_2$ remains stable at about 200°C , whereas $\text{Hg}_5\text{O}_4\text{Cl}_2$ becomes more stable at 230°C . In overall, solid oxohalides undergo the following reactions upon heating in vacuum in the above temperature range:⁶⁷

2. The crystal structures of quaternary mercuric oxohalides

In the crystal structure of $\text{HgPb}_2\text{O}(\text{OH})\text{Br}_3$, it is a complex fragment $[\text{Hg}_2\text{Pb}_4\text{O}_2(\text{OH})_2]^{6+}$ with the so-called heterocubane skeleton that acts as the principal building block.⁶¹ The central empty tetrahedron therein is constituted by the lead cations; four exterior tetrahedra sharing faces with the central one contain interstitial oxygen atoms in their centres, whereas their exterior vertices are occupied by two mercury and two hydrogen atoms. The mercury atoms in the structure are linearly coordinated by O and Br at 2.07 Å and 2.42 Å, respectively (the OHgBr angle is 166.7°). The coordination polyhedron of the mercury atoms is supplemented to a distorted trigonal bipyramid with three Br atoms at larger distances. The $[\text{Hg}_2\text{Pb}_4\text{O}_2(\text{OH})_2]^{6+}$ moieties are assembled into a framework by sharing Br vertices of the mercury polyhedra (Fig. 20).

Mercury lead oxochloride $\text{HgPb}_2\text{O}_2\text{Cl}_2$ is characterised by a significantly different structure.⁶² In this case, the $[\text{OHgPb}_3]$ tetrahedra and the linear –O–Hg–O– groups can be considered as basic structural units. The $[\text{OHgPb}_3]$ tetrahedra are

Figure 20. A projection of the crystal structure of $\text{HgPb}_2\text{O}(\text{OH})\text{Br}_3$ onto the (001) plane. The $[\text{Hg}_2\text{Pb}_4\text{O}_2(\text{OH})_2]^{6+}$ groups are localised in the nodes of the unit cell and in the centres of its faces (the H atoms are omitted for clarity).

assembled into puckered $[\text{HgPb}_2\text{O}_2^{2+}]_{\infty}$ layers in the ab plane by sharing vertices and edges. The Cl^- anions are located between the layers (Fig. 21).

The crystal structure of $\text{BaHg}_2\text{O}_2\text{Cl}_2$ has been solved from powder X-ray diffraction data.⁶³ The Hg atoms in the structure form two covalent bonds with the O atoms with bond lengths of 2.03–2.09 and 2.382 Å. The coordination environment of the Hg atoms is supplemented to a distorted octahedron by four Cl atoms (see Table 3). The coordination polyhedron of the Ba atoms can be described as a monocapped trigonal prism composed of four O (Ba–O 2.72 Å) and three Cl atoms. The structure is built up of planar Hg_4O_4 rings stacked into columns along the [001] direction.

Figure 21. The crystal structure of $\text{HgPb}_2\text{O}_2\text{Cl}_2$.

These columns are assembled into a framework *via* the Ba atoms coordinated by four O atoms from four Hg_4O_4 rings belonging to two neighbouring columns; cavities of the framework accommodate the Cl atoms. Oxochloride $\text{BaHg}_2\text{O}_2\text{Cl}_2$ is isostructural to sulfiodide $\text{Hg}_2\text{PbS}_2\text{I}_2$ (see Fig. 15), its structure contains columns of isolated Hg_4S_4 squares.

The crystal structure of $\text{SrHg}_2\text{O}_2\text{Cl}_2$ has been determined using powder X-ray diffraction owing to the lack of suitable single crystals.⁶⁴ Two crystallographically independent types of mercury atoms present in the structure are characterised by different coordination environments. The first type Hg atoms are linearly coordinated by two O atoms ($\text{Hg}-\text{O}_{\text{av}}$ 2.07 Å), whereas the second type Hg atoms have the so-called T-shaped HgO_3 coordination.^{3,4} Two HgO_3 groups form four-membered rings, which are further assembled into extended $[\text{Hg}_2\text{O}_2]_{\infty}$ puckered layers oriented perpendicular to the [101] direction with the linear $-\text{O}-\text{Hg}-\text{O}-$ bridges. The $[\text{Hg}_2\text{O}_2]_{\infty}$ layers are joined together into a framework (Fig. 22) by the Sr^{2+} cations, which are characterised by irregular coordination polyhedra composed of three oxygen and five chlorine atoms. Thus the structure of $\text{SrHg}_2\text{O}_2\text{Cl}_2$ can be classified as a new structural type. The crystallographic and crystal chemical parameters of quaternary mercuric oxohalides are summarised in Table 3.

Figure 22. A projection of the crystal structure of $\text{SrHg}_2\text{O}_2\text{Cl}_2$ onto the (010) plane.

IV. Stable atomic groups (building blocks) in mercury compounds

1. Oxo-centred complexes in mercury compounds

In addition to the traditional crystal chemical approach to the structure description based on the coordination polyhedra of cations, an alternative method relying on the identification of anion-centred $[\text{M}_4\text{Y}]$ tetrahedra ($\text{M} = \text{Hg}, \text{Cu}, \text{Pb}$ or Ln ; $\text{Y} = \text{O}$ or N) in the structures came in use starting from 1968.⁷² More details on this concept can be found elsewhere.^{73–77}

The $[\text{Hg}_4\text{O}]$ tetrahedra that are stable in terms of their shape and size are capable of forming finite groups, chains, ribbons, layers and spatial frameworks in the crystal structures of mercury oxo compounds.⁷⁸ The Hg–O bond lengths in the oxo-centred tetrahedra lie in the range of 1.90–2.78 Å. The upper limit significantly exceeds the sum of the ionic radii of Hg and O, which implies that no chemical bonding is realised in such cases. It is worth noting that the spread in the Hg–O bond lengths in mercury oxo compounds is much larger than that in the M–O bond lengths for the $[\text{M}_4\text{O}]$ tetrahedra ($\text{M} = \text{Cu}, \text{Pb}$ or Ln).⁷⁵ This is explained by the ability of Hg atoms to form strong covalent bonds with only one or two oxygen atoms, which gives rise to a

shift of the O^{2-} anion from the centre of the Hg-tetrahedron to one or two of its vertices.

As has been demonstrated by theoretical calculations, not only Hg—O covalent bonds are of importance in the $[Hg_4O]$ tetrahedra, but the interactions between the mercury atoms as well, despite relatively large Hg—Hg interatomic distances (~ 3.5 Å).⁷⁹ This fact additionally justifies the consideration of these groups in crystal structures. The relative spread in the Hg...Hg distances in the oxo-centred tetrahedra is smaller than that in the Hg—O bond lengths. Therefore, the interatomic interactions in the $[Hg_4O]$ groups (or in the $[Hg_4O_5]$ groups formed by the addition of external covalent Hg—O bonds to the oxo-centred tetrahedron) cannot be represented as a mere sum of the pairwise Hg—O contacts. It is a more complex system of many-body interactions also involving the Hg...Hg bonding.⁷⁹

The oxo-centred $[Hg_4O]$ tetrahedra can form topologically complicated assemblies by sharing vertices and edges. Their examples can be found elsewhere.⁷⁸ The Hg:O* ratio (where O* is the so-called free oxygen, *i.e.*, oxygen atoms not involved into stable groups, such as AsO_4 or CrO_4 acid anions, *etc.*) is the main parameter governing the type of the structures. Below, a series of such crystal structures are considered, where all oxygen atoms are 'free' and the remaining anions are represented by halogens.⁸⁰ These compounds contain mercury in different oxidation states. The crystallographic and crystal chemical parameters of some of these compounds are given in Tables 3 and 4.

The structure of the mineral poyarkovite⁸¹ Hg_3OCl , or $[Hg_2]_3O_2Cl_2$, is determined both by the covalent Hg—Hg bonds in the binuclear Hg_2 fragments and the Hg—O bonds giving rise to the bond angles of 87.9 – 121.6° at the central oxygen atom.⁷⁸ Taking into account the geometry of the covalent bonds, a $[Hg_6O_2]$ moiety composed of two edge-sharing oxo-centred mercury tetrahedra can be identified in the structure. The convex polyhedron, which is a joint coordination polyhedron of two

central oxygen atoms of the two tetrahedra, has been considered earlier for the structures of rare-earth metal fluorides and denoted as *r*-octahedron, *i.e.*, rhombically distorted octahedron.⁹⁰ It can be considered as a fragment of a cubic close packing, which means that its long edge and diagonal have lengths of $a_r\sqrt{2}$ and $a_r\sqrt{3}$, respectively (where a_r is the length of its short edge).

In order to confirm the reasonability of the consideration of this moiety, quantum chemical calculations on $[Hg_4O_5]^{2-}$ and $[Hg_6O_8]^{4-}$ have been accomplished using the ZORA method⁹² as implemented in the software code ADF-2002.02.⁹¹ In addition to the internal oxygen atoms in the moiety, the covalent bonds formed by the Hg atoms with the 'external' O atoms were taken into account. According to the results obtained,⁹³ the $[Hg_6O_8]^{4-}$ fragment is substantially more preferable in terms of energy as compared to the isolated oxo-centred tetrahedron $[Hg_4O_5]^{2-}$.

This implies that these energetically favourable fragments would spontaneously form during the crystallisation provided that appropriate conditions are realised (the required Hg/O stoichiometry, the availability of suitable charge-compensating components, *etc.*). The crystal structure formation is completed by the packing of such hinged joint moieties and remaining components in an ordered way. Indeed, many structures of mercury oxohalides support this concept.

^a Some discrepancies in the listed geometry parameters as compared to those reported in Tables 3, 4 and 6 are due to the use of different software codes for their calculation (based on the same structural data);

^b 1.23 Å is the O—H distance in the [OM₃H] tetrahedron.

Table 5 lists possible types of building blocks based on the $[\text{OHg}_4]$ tetrahedra and $[\text{Hg}_6\text{O}_2]$ *r*-octahedra realised in the crystal structures of some natural and synthetic mercury oxohalides.

The dimensions of the *r*-octahedra determine the unit cell parameters and, to a some extent, its symmetry. Most frequently, they are packed in a herringbone manner. Herringbone layers of the *r*-octahedra represent stable structural units, which occur in various structures.

Two independent *r*-octahedra can be identified in the structure of poyarkovite $[\text{Hg}_3\text{O}_2\text{Cl}_2]$. A crystallographic inversion centre resides in the centre of one of them. The second *r*-octahedron has no symmetry elements, although its geometry is close to that of the first one. All cation vertices of an *r*-octahedron covalently link them with the neighbouring *r*-octahedra *via* the Hg—Hg bonds. If the $[\text{Hg}_2]^{2+}$ dumbbell is taken as the cation, the ideal poyarkovite stoichiometry 3 : 2 : 2 is resulted. It is important to note that the unit cell parameters of the poyarkovite structure are determined by the size and orientation of the cationic *r*-octahedra coupled with the lengths of the Hg—Hg bonds that join the *r*-octahedra together (these are the so-called contact links). The poyarkovite structure is composed of two types of layers made up of the *r*-octahedra oriented parallel to the *yz* plane.

The structure of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$ analysed earlier in Section III.1 can be regarded as a result of the Hg^{2+} 'isomorphous' substitution for the $[\text{Hg}_2]^{2+}$ dumbbells in the poyarkovite structure; this is accompanied by a reduction in the length of the contact link between the *r*-octahedra to zero, *i.e.*, the octahedra are directly linked by sharing Hg vertices. In a unit cell of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$, there are two symmetry-related *r*-octahedra. Furthermore, there are two types of the mutual orientations of the neighbouring *r*-octahedra: the neighbouring *r*-octahedra are translationally equivalent along the *x* axis, which means that the translation *a* is equal to their long diagonal. In other directions, translationally equivalent *r*-octahedra alternate with the *r*-octahedra transformed by a 2_1 screw axis or a *c* gliding reflection plane. As a result, the unit cell parameters *b* and *c* are nearly identical being equal to the vector sum of two short edges of the *r*-octahedra.

The structure of mixed-valence Hg_2OI takes^{83,84} a position intermediate between those of poyarkovite and $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$. In these structures, only two Hg-vertices of the *r*-octahedra are replaced with the $[\text{Hg}_2]^{2+}$ dumbbells. The layer of vertex-sharing *r*-octahedra analogous to that in the structure of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$ is located in the *yz* plane, which gives rise to nearly identical *b* and *c* in these two structures. Two vertices of an *r*-octahedron (at the ends of the long diagonal) are occupied by the $[\text{Hg}_2]^{2+}$ dumbbells extended along the *a* axis. The vector sum of the parameter *a* with the long diagonal of the *r*-octahedron is $a/2 = 8.8$ Å, which is close to the parameter *b* of the poyarkovite structure. The residual free volume is filled with bulky I^- anions.

In the structure of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$, the translation parameters of the orthogonal two-dimensional lattice of the herringbone layer are 6.8657 and 6.8759 Å, whereas its thickness is ~ 6 Å. The structure of Hg_2OI can be represented as two herringbone layers parallel to *x*, which are linked by the Hg—Hg dumbbells (~ 2.5 Å) also oriented along the *x* axis, rather than by shared Hg vertices. Thus the *a* parameter of the Hg_2OI structure corresponds to the doubled *a* of the $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$ structure (6.310 Å) plus two Hg—Hg bond lengths: 17.603 Å $\approx 2 \times 6.310 + 2 \times 2.50$ Å.

The symmetry centre of an *r*-octahedron often coincides with the crystallographic inversion centre of the structure, which implies that the 'rigid' moiety partially determines the structure symmetry in addition to the unit cell dimensions. In particular, a single $[\text{Hg}_4\text{O}]$ tetrahedron with no inversion centre can possess a dipole moment. Meanwhile, a pair of the inversion-related tetrahedra mutually compensate for their dipole moments in the minimum volume, which gives rise to the stabilisation of such a structural fragment.

In contrast to the $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$ structure, a $[\text{Hg}_{10}\text{O}_4]$ moiety with an inversion centre localised in the middle of an edge shared by two *r*-octahedra acts as the basic building block in the

β -modification of $\text{Hg}_3\text{O}_2\text{Cl}_2$ due to the condensation of a part of the *r*-octahedra. Dimensions of this moiety determine the unit cell parameters *b* and *c*: the double *r*-octahedra centred at $1/2, 1/2, 1/2$ form a layer in the *yz* plane, the packing of the moieties in the layer is determined by the symmetry (*a c* plane and a 2_1 axis). This layer is stacked along *a* on another layer constituted by two types of the *r*-octahedra formed around oxygen atoms of two other types with the inversion centres at $00, 1/2$ and $0, 1/2, 1/2$. The condensation of the two *r*-octahedra changes the Hg : O stoichiometry, a ratio of Hg : O = 5 : 4 is expected provided that each vertex of the double *r*-octahedron is shared with the neighbouring ones. In order to compensate for the stoichiometry violation, two Hg atoms from the $[\text{Hg}_{10}\text{O}_4]$ fragment become terminal; this is accompanied by the introduction of a Cl^- anion at a distance of 2.36 Å (the sum of ionic radii of Hg and Cl is 2.50 Å!) into their coordination environments in place of oxygen. Taking into account that all other vertices of the *r*-octahedra in the structure are bridging, this configuration restores the 3 : 2 Hg : O stoichiometry.

The ratio of mercury cations to oxygen anions (taking into account dumbbell groups) in the structure of mixed-valence hanawaltite $[\text{Hg}_2]_3\text{HgO}_3\text{Cl}_2$ is 4 : 3, *i.e.*, it includes a larger amount of cations than $\text{Hg}_3\text{O}_2\text{Cl}_2$. As a result, isolated $[\text{Hg}_4\text{O}]$ tetrahedra are present in the structure in addition to the *r*-octahedra. The *r*-octahedra are grouped nearby the inversion centres $1/2, 1/2, 1/2$ filling the space between the mirror planes that accommodate the isolated $[\text{Hg}_4\text{O}]$ tetrahedra. The unit cell parameter *c* is determined by the length of the long diagonal of the *r*-octahedron. The only Hg^{2+} atom resides in an inversion centre and is characterised by the strictly linear O—Hg—O coordination.

Despite a relatively small number of cations in the structure of pinchite $\text{Hg}_5\text{O}_4\text{Cl}_2$, all oxygen atoms therein are tetrahedrally surrounded by the cations. There are two types of the *r*-octahedra with partially overlapping volumes; their centres are located at an inversion centre $1/4, 1/4, 1/4$ (the packing of this type of polyhedra determines the structure in the *ab* plane) and at a two-fold axis parallel to *x*, respectively.

In overall, the pinchite structure can be represented as an assembly of four symmetry-related columns composed of the *r*-octahedra extended along the *b* axis. The bonding between the columns is realised by sharing Hg vertices. Within the columns, the bonding is stronger: each *r*-octahedron shares a common $[\text{Hg}_4\text{O}]$ tetrahedron with a neighbouring one. Therefore, this represents a new pattern of bonding between structural units, *viz.*, partial volume-sharing in addition to known types, such as vertex-, edge- and face-sharing.

The structure of mixed-valence oxobromide $\text{Hg}_8\text{O}_4\text{Br}_3$ reveals a complex combination of structural elements observed in pinchite and poyarkovite. All four basic oxygen atoms are involved in *r*-octahedra but only one of the *r*-octahedra (composed of the mercury atoms forming dimeric $[\text{Hg}_2]$ groups) is located at an inversion centre ($1/2, 00$). This type of the *r*-octahedra form a layer in the *xy* plane (layer 1), which is similar in terms of its structure to layers present in poyarkovite. Two other types of the *r*-octahedra with partly overlapping volumes (similar to those found in the pinchite structure) occupy larger volume filling the space between the layers composed of the first type *r*-octahedra separated by *c*/2 (layer 2). Pairs of overlapping *r*-octahedra are linked by sharing Hg^{2+} vertices in such a way that one of the typical coordination types is realised for all mercury atoms. The unit cell parameter *b* is equal to the long diagonal of the *r*-octahedron (like *b* parameter of pinchite, *c* parameter of hanawaltite and *b* parameter of $\alpha\text{-Hg}_3\text{O}_2\text{Cl}_2$).

In the mineral terlinguaite $[\text{Hg}_3]\text{HgO}_2\text{Cl}_2$, the $[\text{Hg}_3]^{4+}$ triangular clusters and $[\text{Hg}_6\text{O}_2]$ *r*-octahedra (taking into account the covalent Hg–O interactions) act as basic structure-forming units. The structure is built up by their packing together with the Cl^- anions. A unit cell includes one type of the *r*-octahedra centred at the inversion centre in the origin (000). In agreement with the space group $C2/c$, they are arranged in a way that all equatorial Hg-vertices are bridging and all axial vertices are terminal, which provides the required stoichiometry $\text{Hg} : \text{O} = 4 : 2$. The first type of the mercury atoms are characterised by the linear O–Hg–O coordination; the second type of the Hg atoms reside in the plane composed of two oxygen atoms and two mercury atoms of the third type; the latter are characterised by a non-typical $2\text{O} + 2\text{Hg} + \text{Cl}$ coordination. These structural peculiarities are due to the presence of the $[\text{Hg}_3]^{4+}$ cluster fragment, which includes two mercury atoms of different types.

In Hg-deficient structures, a part of vertices of the *r*-octahedra can be occupied by other cations (Sr, Pb), which results in only insignificant geometry changes ($\text{SrHg}_2\text{O}_2\text{Cl}_2$, $\text{HgPb}_2\text{O}_2\text{Cl}_2$, see Table 5). The approach based on the identification of ‘rigid’ atomic groups in crystal structures becomes increasingly more popular.^{99–102} In particular, very similar atomic arrangements were found in gold $[\text{Au}_6\text{O}_2]$ (Ref. 103) and mixed gold–rhodium $[\text{Rh}_2\text{Au}_4\text{O}_2]$ (Ref. 104) clusters. These fragments manifest a high stability due to the formation of Au–Au (3.008 Å) and Au–Rh (3.00 Å) bonds.

In the structure of $\text{SrHg}_2\text{O}_2\text{Cl}_2$, a cationic *r*-octahedron with an inversion centre and two strontium atoms occupying two its vertices can be identified. The $[\text{Sr}_2\text{Hg}_4\text{O}_2]$ *r*-octahedra are assembled by isolated $[\text{Sr}_2\text{Hg}_2\text{O}]$ tetrahedra into a three-dimensional motif, like that in the hanawaltite structure. The formation of stable atomic groups explains many structural features of these compounds, in particular, irregular coordination polyhedra of some atoms, as noted by Harrison *et al.*⁶⁴

In the above compounds, the charge-compensating halogen atoms play an insignificant structure-forming role, since rigid polyatomic moieties ($[\text{Hg}_4\text{O}]$ tetrahedra and $[\text{Hg}_6\text{O}_2]$ *r*-octahedra) by far exceed them in terms of both mass and size. In this class of compounds, they play a secondary role merely filling available space.

In the majority of structures analysed above, *r*-octahedra possess only inversion centres, their short edges, long edges and long diagonals are 3.40–4.00 Å, 5.30–5.40 Å and 6.10–6.30 Å, respectively. Each Hg vertex of the polyhedra is involved into covalent bonding with external oxygen atoms belonging to neighbouring *r*-octahedra in addition to one or two internal oxygen atoms. Therefore, these groups can be regarded as isolated ones only formally similar to, for instance, SiO_4 tetrahedra in framework silicates. It is the mutual packing of these polyhedra that governs the crystal structure. Although Hg vertices of *r*-octahedra are also involved into external covalent bonding, in particular, with neighbouring *r*-octahedra, the spread in the respective bonding angle is significantly larger than for the internal bonds. It is worth noting that up-to-date methods for the quantitative simulation of chemical bonding fully support the emergence of intuitively apparent cation–cation bonds in these groups.^{79, 105}

2. Stable structural units in mercury compounds with the AO_4 tetrahedral anions (A = Cr, P, As or V)

A number of crystal structures of naturally occurring and synthetic mercury sulfo- and oxochromates reveal even more complex fragmentation patterns. The crystal structures of mercury compounds with the AO_4 tetrahedral anions (A = Cr, P, As or V) include, in addition to the Hg–S and Hg–O covalent bonds formed by the mercury atoms, covalent A–O bonds within the $[\text{AO}_4]$ tetrahedral complexes, which are also incorporated into the structure as ‘rigid’ moieties.¹⁰⁶ The crystallographic and crystal chemical parameters of these compounds are summarised in

Table 6, whereas the types of cationic and anionic ‘rigid’ atomic fragments are listed in Table 7.

With an increase in the effective size of the anionic fragments, their role in the structure formation becomes more important. The $[\text{AO}_4]$ tetrahedra can combine into inversion centre-related pairs in such a way that two triangular faces looking toward each other form an octahedral cavity of oxygen atoms. For example, such pairs are present in the structures of edoylerite and deanesmithite (see Table 7); the distances between the centres of the tetrahedra in these structures are 4.10 and 4.30 Å, respectively. The cationic part of the edoylerite structure is represented by zigzag chains composed of the $[\text{Hg}_4\text{S}_4]$ rings that separate the anionic fragments from each other. The centres of gravity of these rings coincide with the crystallographic inversion centres. In the deanesmithite structure, a three-dimensional framework of Hg–Hg and Hg–S covalent bonds constitutes the cationic part.

The crystal structures of mercury chromates (HgCrO_4 , $\text{Hg}_3\text{O}_2\text{CrO}_4$ and $\text{HgPb}_2\text{O}_2\text{CrO}_4$) contain various configurations of the $[\text{CrO}_4]$ tetrahedra retaining the same type of contacts *via* the octahedral cavity of oxygen atoms. Edge-sharing oxo-centred tetrahedra, which can be identified as $[\text{Hg}_6\text{O}_2]$ and $[\text{Hg}_2\text{Pb}_4\text{O}_2]$ *r*-octahedra and $[\text{HgPb}_2\text{O}]$ triangles (in $\text{HgPb}_2\text{O}_2\text{CrO}_4$), act as the cationic parts of these structures. Similar structural units occur in the crystal structure of $[\text{Hg}_3]\text{HgO}_2(\text{PO}_4)_2$ (see Table 5), where centrosymmetrical $[\text{Hg}_6\text{O}_2]$ *r*-octahedra are assembled into a framework by shared vertices and the $[\text{Hg}_3]^{4+}$ cluster cation; the $[\text{PO}_4]^{3-}$ tetrahedra together with the centrosymmetric empty oxygen octahedra separating them from each other form zigzag columns, which run through the cationic framework parallel to the *z* axis.

In the crystal structure of mineral wattersite $[\text{Hg}_2^{2+}]_2\text{Hg}^{2+}\text{O}_2\text{CrO}_4$, a more complex moiety acts as the basic unit, which in the ideal shape is known as stella quadrangula.¹¹¹ The central core of this unit comprises an empty $[\text{Hg}_4]$ tetrahedron (Hg...Hg 3.30–3.72 Å) capped with two $[\text{Hg}_4\text{O}]$ and two $[\text{CrHg}_3\text{O}]$ tetrahedra at each face; the rotation axis 2 of this group coincides with the crystallographic two-fold axis. Along the *z* axis, the groups are sharing Hg vertices (these Hg atoms reside in the inversion centres so that the Hg–Hg distance is $c/2 = 3.30$ Å); in other directions, these groups are bridged by the $[\text{Hg}_2]^{2+}$ dumbbells. Zigzag columns formed by the $[\text{CrO}_4]$ tetrahedra alternating with the centrosymmetrical empty oxygen octahedra are strongly elongated (the Cr–Cr distance is 5.407 Å), which implies that they play only a secondary role in the structure formation as compared to the cationic moiety. In the wattersite structure, the $[\text{Hg}_6\text{O}_2]$ cationic group can be represented in terms of both composition and geometry as a distorted *r*-octahedron in which one of the long Hg–Hg edges is shortened to ~ 3.5 Å. Taking into account two additional relatively close oxygen atoms of the $[\text{CrO}_4]$ tetrahedra along with the chromium atoms themselves, this group can be considered as an intermediate case between an *r*-octahedron and a more symmetric stella quadrangula.

The crystal structure of $\text{HgPb}_2\text{O}(\text{OH})\text{Br}_3$ reveals a similar fragment referred to as ‘heterocubane skeleton’ (see Table 5), which is similar to the aforementioned group in terms of both symmetry and dimensions.⁶¹ The central empty tetrahedron is formed by four Pb cations, four adjacent (face-sharing) tetrahedra contain interstitial oxygen anions, two mercury and two hydrogen atoms act as external vertices. This example as well as the structure of $\text{HgPb}_2\text{O}_2\text{CrO}_4$ described above demonstrate similar crystal chemistry of Pb^{2+} and Hg^{2+} cations in compounds of the approximate compositions.¹¹² Notwithstanding, there are substantial differences between them: the mercury atoms preferably form linear O–Hg–O fragments and thus tend to occupy equatorial positions of the *r*-octahedra, whereas the lead atoms tend to form three covalent bonds with the oxygen atoms and can occupy both equatorial and apical positions.

Quite different atomic groups occur in the HgCrO_4 structure (see Tables 6, 7): these include two $[\text{CrHg}_2\text{O}]$ triangles sharing a

^a Hg/Ag means that the respective sites are occupied statistically.

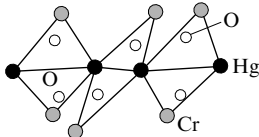

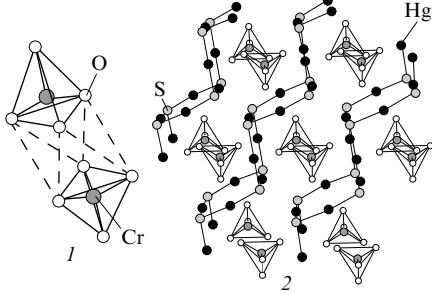

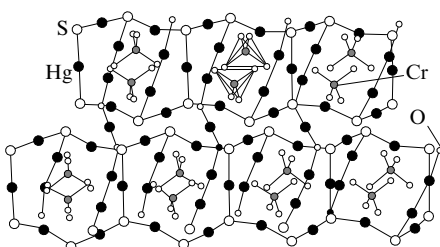

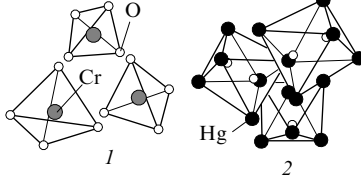

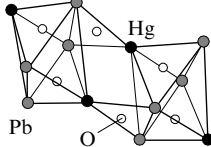

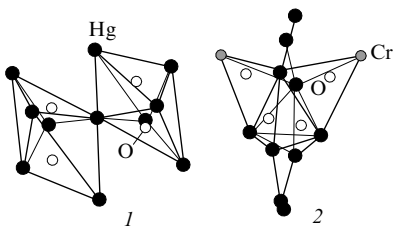

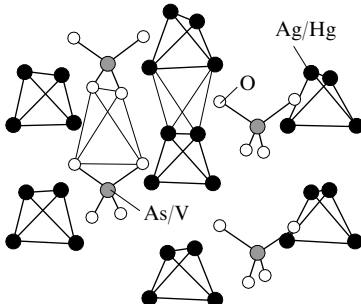

common Hg—Hg edge (~ 3.5 Å) (an inversion centre is located in the middle of this bond) forming a nearly planar rhombus.

A non-typical combination of cationic and anionic fragments occurs in the crystal structure of AgHg₂PO₄ (see Table 6).¹⁰⁹ Its cationic part is represented by an [Ag₂Hg₄] *r*-octahedron composed of two [Ag₂Hg₂] tetrahedra sharing an Ag—Ag edge with the crystallographic inversion centre in the middle. In contrast to the structures described above, the tetrahedra are substantially smaller since they contain no interstitial oxygen atoms. A pair of the [PO₄] tetrahedra separated by an empty oxygen octahedron constitutes the anionic fragment of the structure. The centres of the complex cations and anions are packed into a pseudocubic *I*-centred cell with the following parameters: $\mathbf{a}' = \frac{1}{2}\mathbf{a} + \frac{1}{2}\mathbf{b}$

(6.32 Å); $\mathbf{b}' = -\frac{1}{2}\mathbf{a} + \frac{1}{2}\mathbf{b}$ (6.32 Å); $\mathbf{c}' = \mathbf{c}$ (6.152 Å); $\alpha' = \beta' = \gamma' = 94.12^\circ$.

The recently solved tetragonal crystal structure of tillmannsite [Ag₃Hg][(V,As)O₄] (see Tables 6, 7)¹¹⁰ also includes an 'empty' [Ag₃Hg] cationic tetrahedron with three Ag and one Hg atoms statistically distributed over four vertices. The [(V,As)O₄]³⁻ tetrahedra alternating with empty oxygen tetrahedra and combined with them by shared edges form a ribbon going along the *z* axis, and the centres of both tetrahedra types have the $\bar{4}$ point symmetry. Two other sites with the 4 symmetry are located in the centres of the aforementioned cationic tetrahedron and another adjacent, also 'empty', [Ag₃Hg] tetrahedron sharing cation—cation edges with the former one. The latter tetrahedron is

tetragonally distorted along the z axis [the Ag(Hg)–Ag(Hg) side edges are 3.316 Å]. As in the AgHg₂PO₄ structure, the two adjacent edge-sharing cationic tetrahedra can be considered as a deformed ‘empty’ r -octahedron. The overall crystal structure is built up of ribbons of such r -octahedra packed in the xy projection together with the ribbons of anionic tetrahedra in a herringbone manner. The positions of (Ag,Hg) and (V,As) cations themselves form a pseudocubic F -centred sublattice with a volume constituting 2/5 of the unit cell volume with the following parameters: $a' = 3/5a + 1/5b = 4.90$ Å; $b' = -1/5a + 3/5b = 4.90$ Å; $c' = c = 4.648$ Å; $\alpha' = \beta' = \gamma' = 90^\circ$.

A series of compounds with the [Ag,Hg]₄ clusters have been synthesised within the Ag–Hg–E–O system ($E = V^{5+}$, As^{5+}) (see Table 6). In the tetragonal structure of [Ag₃Hg]VO₄, the tetrahedral cluster is formed by the statistical distribution of the Ag and Hg atoms in a 3 : 1 ratio over the available positions. Meanwhile, the tetragonal clusters corresponding to the [Ag₂Hg₂] stoichiometry also with the statistical distribution of Ag and Hg with a mean metal–metal distance of 2.72 Å are present in tetragonal [Ag₂Hg₂]₃(VO₄)₄ and trigonal [Ag₂Hg₂]₂HgO₂·(AsO₄)₂. Assuming the [Ag,Hg]₄ moieties and the VO₄ or AsO₄ tetrahedra to be pseudospherical ‘building blocks’, the structures of [Ag₃Hg]VO₄ and [Ag₂Hg₂]₂HgO₂(AsO₄)₂ can be described as a cubic close packing with the (ABC) stacking sequence and a mixed-layer packing with the ABACACAB stacking sequence, respectively, where A is the layer formed by VO₄ or AsO₄, B and C are the layers formed by the [Ag₂Hg₂] clusters. The crystal structure of [Ag₂Hg₂]₃(VO₄)₄ cannot be described in a similar way. It is interesting that another compound synthesised in this system, AgHgVO₄, which has a monoclinic structure, contains no cluster groups; the cations therein are characterised by usual coordination types: Ag and V are tetrahedrally coordinated by oxygen, the Hg coordination is a distorted octahedron.¹⁰⁰

Therefore, it might be concluded that the crystal structures considered above represent the net result of two major structure-forming factors: the ‘chemical’ one, which induces the formation of stable atomic fragments that can undergo only minor changes after their formation and the crystallographic one, which promotes their dense packing into highly symmetric extended assemblies by fixing centres of these groups or single atoms at specific families of crystallographic planes.

V. The modular principle in the structure formation of mercury oxo- and chalcogenides

The presence of linear Y–Hg–Y groups ($Y = O, S, Se$ or Te) is commonly accepted as a specific structural feature of mercury oxo- and chalcogenides. Additionally, trigonal pyramidal [YHg₃] groups, in which the Y atom is connected to three mercury atoms forming variable Hg–Y–Hg bond angles in a range from 110° to 90° frequently occur in the crystal structures of ternary chalcogenides with the 3 : 2 : 2 stoichiometry, *i.e.*, Hg₃Y₂X₂ ($Y = S$ or Se , Te ; $X = Cl, Br$ or I). These groups can be assembled into various one-, two- or three-dimensional motifs.¹ Typically, large monovalent halogens ($X = Cl, Br$ or I) in these structures merely fill the space between chains, ribbons or frameworks formed by these stereochemically active structural elements and compensate for their positive charge. A more thorough analysis shows¹¹³ that the halogen atoms tend to form a pseudocubic primitive sublattice with a periodicity constant of 4.4–5.4 Å, depending on the nature of X.

The original software package KAP-PLATS⁷ can be efficiently applied to objectively evaluate the role played by all types of atoms in the crystal structure formation and identify common structural features of these compounds. As a starting postulate, this approach assumes that the atoms most important for the structure formation are characterised by most densely occupied atomic planes within the range of interplane distances d_{hkl} of the order of shortest interatomic distances. Furthermore, an analysis of the distribution of special positions, *i.e.*, of the location of

different types of atoms with respect to space group symmetry elements, is of importance. This is due to the fact that any special position represents a locus of intersection of both symmetry elements and closely packed atomic layers and thus they serve as natural boundaries in dividing a structure into fragments.

1. The role of halogen atoms in the structures of ternary mercury chalcogenides Hg₃Y₂X₂ ($Y = S, Se$ or Te ; $X = Cl, Br$ or I)

In the crystal structure of α -Hg₃S₂Cl₂ (corderoite) (see Table 1), a single basis Cl atom occupies a special position 8(a) on a three-fold axis. These atoms form a primitive cubic sublattice with a translation vector $a' = a/2 = 4.47$ Å. Deviations of the Cl atoms from expected ideal positions of the sublattice nodes do not exceed 0.15 Å. The sulfur atoms are located in the centres of cubes of the Cl sublattice, their deviations from the geometric centres being ~ 0.3 Å. The mercury atoms centre three of six faces intersecting in a vertex deviating from the centres by ~ 0.5 Å. Therefore, the chlorine atoms (as well as other atoms) can shift along the three-fold axis and appear most rigidly ordered in the lattice since they are located in the intersection of the (200), (020) and (002) planes and planes derived from them, such as (222).

A similar situation is observed in the structure of β -Hg₃S₂Cl₂ (see Table 1); its unit cell comprises 64 cubic Cl sublattices ($a' = a/4 = 4.48$ Å). The Cl atoms are dominantly localised in special positions and are most rigidly ordered by systems of the {004}, {044} and {444} planes, which intersect in nodes of the sublattice. The sulfur atoms localised in the centres of the Cl sublattices are ordered nearly as rigidly, whereas the mercury atoms deviate substantially from the centres of faces of the Cl sublattice.

In the monoclinic structure of β -Hg₃S₂Br₂ (see Table 1), all Br atoms are located on the mirror reflection planes, which determine one of the lattice parameters of the Br sublattice as $b/2$. Two other lattice parameters are $a/4$ and $c/2$, since the intersection points of the (400), (020) and (002) crystallographic planes most densely occupied by the Br ions form a pseudocubic primitive sublattice with exactly these translation vectors: $a' = 4.42$, $b' = 4.69$ and $c' = 4.72$ Å. The S atoms localised in the centres of cubes of the Br sublattice are ordered by the same systems of crystallographic planes but are phase-shifted by 180°. The ordering of the S atoms is again less rigid than that of the Br atoms due to the fact that the sulfur atoms occupy general positions in the structure. The disposition of the Hg atoms is even less ordered.

In the crystal structure of the α -modification of this compound (α -Hg₃S₂Br₂) (see Table 1), a unit cell is constructed from the Br sublattices in a different manner as compared to the β -phase, thus the sublattice of nodes occupied by Br is formed by the intersection locus of the (401), (020) and (002) crystallographic planes, which cut a pseudocubic sublattice with $a' = a/4 = d_{401} = 4.50$, $b' = b/2 = 4.64$ and $c' = d_{002} = 4.62$ Å (Fig. 23 a). The sulfur atoms are arranged nearly as regularly as the bromine atoms, whereas the mercury atoms are distinctly shifted from the centres of faces of the Br cubes.

The unit cell of Hg₃Te₂I₂ (see Table 1) is constructed of the iodine sublattices in an even more complicated manner. It is formed by the intersection of families of the (202), (020) and (202) crystallographic planes. They cut a parallelepiped with edges of 5.47, 4.85 and 5.45 Å and angles close to 90° (Fig. 23 b).

Therefore, the structures of Hg₃Y₂X₂ compounds ($Y = S, Se, Te$) despite their formal diversity are constructed, to the first approximation, from ‘cubic’ modules with the halogen atoms in the vertices, chalcogen atoms in the centres and the mercury atoms in the centres of three faces intersecting in a common vertex. Such a cubic module is further attached to a common motif by bonds going out from the centres of three faces towards the centres of neighbouring modules. Each of them can be connected by sharing a face in four possible orientations differing from each other by the rotation around the Y–Hg–Y bond by 90°. Using this algorithm, various puckered ribbon, layered and spatial frameworks can be assembled from them (Table 8). The dimensions of a

module determine the unit cell dimensions and partially the general symmetry of the structure, although the prevailing contribution is made by the specific pattern of the covalent bonding distribution.¹¹³

Signatures of the modular structure preserved to a greater or lesser extent can be observed in the crystal structures of a number of mercury oxohalides and more complex compounds.

2. The role of halogen atoms in the structures of mercury oxohalides

In the crystal structure of the orthorhombic mineral pinchite Hg₅O₄Cl₂ (see Table 3), the halogen atoms form a planar network with the translation periods of the Cl sublattices of 4.13 and 4.34 Å. This network is centred by the mercury atoms. In addition to these eight centring mercury atoms, a unit cell contains 12

mercury atoms, which constitute together with the oxygen atoms a second layer, where two distorted tetragonal networks of oxygen atoms sandwich a hexagonal network composed of the mercury atoms. The commensurability of the (Hg₄Cl₄) and (Hg₆O₈) networks is provided by a change in the geometry of the latter, which gives rise to a non-typical flattened tetrahedral oxygen coordination of the mercury atoms within the hexagonal network. Meanwhile, the Hg atoms of the tetragonal network are characterised by the linear O–Hg–O coordination supplemented to an octahedral one by a square of the Cl atoms.

The halogen atoms play a key role in the structure formation of some low-valence mercury halides. In particular, in the crystal structure of the cubic mineral kuznetsovite [Hg₃]AsO₄Cl (see Table 4), the Cl atoms occupy special positions on a three-fold axis (xxx , $x \approx 0.23$). A point on the three-fold axis with a coordinate $x = 0.25$ corresponds to the intersection of families of the (200), (020) and (002) crystallographic planes (with phases of 180° for all planes), which cut a unit cell into eight cubes with an edge $a' = a/2 = 4.19$ Å. A half of nodes of this sublattice are occupied by the Cl atoms according to the chessboard pattern; the centres of the sublattices are alternately filled with the [Hg₃]⁴⁺ triangles and [AsO₄]^{3–} tetrahedra. In the crystal structure of cubic eglestonite [Hg₂]₃O₂HCl₃ (see Table 4), which is characterised by a lattice parameter nearly doubled as compared to that of kuznetsovite, the cubic sublattice ($a' = a/4 = 4.01$ Å) is formed by the intersection of families of the (400), (040) and (004) crystallographic planes, which gives rise to 64 sublattice nodes per unit cell. Among them, 48 nodes are occupied by the Cl atoms and 16 nodes remain vacant. The centres of the sublattices virtually coincide with the centres of the [Hg₂]²⁺ dumbbells (again 48 centres out of 64 sublattices are occupied). Two latter examples demonstrate that in the absence of large S^{2–} anions, space-filling structural units larger than the oxygen atoms, such as [Hg₃]⁴⁺, [AsO₄]^{3–} or [Hg₂]²⁺ moieties are required to preserve the cubic sublattice of halogen atoms. In both cases, the sublattice has vacant nodes, which gives rise to its slight contraction with respect to the sublattice with no vacancies.¹¹³

3. General trends in the structure formation and an analysis of the structure-forming factors in the crystal structures of mercury oxo- and chalcogenides

The crystal structures of mercury oxo- and chalcogenides fully confirm general regulation of the structure formation formulated by Borisov *et al.*^{5,6,114} Rigid multiatomic fragments, *e.g.*, [M₄O], [M₆O₂], [M₁₀O₄], [AO₄], *etc.*, are most probably generated in a reaction medium even prior to the initiation of crystallisation. The forces driving the transition of a substance into the crystalline state are substantially weaker than the interatomic interactions within these fragments, thus they remain nearly unchanged upon the nucleation and crystal growth. The dimensions and shape of the rigid multiatomic fragments determine the unit cell parameters and partially the space symmetry group, since the sym-

metry element intrinsic to these groups often convert into the symmetry elements of the whole crystal structure.

In some complicated cases, the software package KAPPLATS⁷ helps a lot in the analysis of structure-forming factors. Among the crystallographic planes it separates those are closely populated by atoms or gravity centres of rigid multiatomic moieties.^{115, 116} The crystal structure is then interpreted as a result of the spatial ordering of these atoms and centres of moieties by a set of basis crystallographic planes.⁶ The stability of the crystal structure is increased if these planes are related to each other by symmetry operations (even provided that these operations are slightly violated^{6, 114}).

As has been shown by Borisov *et al.*,¹¹⁶ the relative space-filling density for isolated Hg atoms is significantly lower than that for centres of rigid fragments, which implies that the effect of the ordering of isolated mercury atoms is weakly pronounced and the overall structure is predominantly determined by the ordering of centres of rigid atomic fragments.

The spatial segregation of Hg cations with different oxidation states over different layers¹¹⁶ facilitates solid-state mercury disproportionation reactions, since the pre-existing layers with bivalent mercury are retained thus stabilising the structure-forming motif, whereas the low-valence mercury (*i.e.*, Hg in the $[\text{Hg}_3]^{4+}$ and $[\text{Hg}_2]^{2+}$ clusters) partly leave the structure. It has to be noted that naturally occurring compounds with 'cluster' mercury, *e.g.*, $[\text{Hg}_2]^{2+}$ or $[\text{Hg}_3]^{4+}$ moieties, are characterised by a cation-to-anion ratio distinctly different from that of more common rock-forming minerals. In particular, in known mercury minerals, this ratio is close to unity, whereas it is about 1.5 in poyarkovite. The minerals growing in an anion-deficient medium are obliged to saturate the valence bonds by forming Hg...Hg contacts, which gives rise to cluster fragments. Due to the deficit, anions can act as a core for the formation of polyatomic groups, which probably exist in a mother liquor even prior to the initiation of crystallisation.

Since the total sequence of solid-state transformations happening to a mercury mineral upon its transition into an oxygen-rich medium and giving rise to the complete mercury oxidation, which is actually realised in nature, cannot be elucidated, the relevant information can be retrieved from an analysis of methods for the synthesis of compounds containing the $[\text{Hg}_3]^{4+}$ and $[\text{Hg}_2]^{2+}$ clusters and their stepwise oxidation as realised under laboratory conditions. Typically, the synthesis is accomplished starting from Hg^{2+} oxides and other components in sealed evacuated ampoules at a temperature $> 400^\circ\text{C}$ or under hydrothermal conditions at a sufficiently high temperature. It would be reasonable to assume that minerals with the $[\text{Hg}_3]^{4+}$ and $[\text{Hg}_2]^{2+}$ clusters are formed in nature under similar conditions. When the minerals are transferred to the earth's surface, the mercury disproportionation processes are initiated:

In a laboratory, the disproportionation of 'cluster' mercury to Hg^{2+} and Hg^0 is typically carried out in an open system, since mercury vapour is liberated. The process proceeds at a high rate at $200\text{--}450^\circ\text{C}$, however presumably, this process proceeds at a lower temperature and thus at a lower rate under natural conditions. A pair of closely related compounds, $[\text{Hg}_2]\text{As}_2\text{O}_6$ and HgAs_2O_6 , offer a very illustrative example of this process.¹¹⁷ These compounds include identical layers of interlinked AsO_6 octahedra; layers formed by the Hg cations are also similar provided that the centres of the $[\text{Hg}_2]^{2+}$ dumbbells are taken as cations in the former case. Therefore, the reaction

can be interpreted as a progressive withdrawal of a half of the mercury atoms from the cationic layers of the $[\text{Hg}_2]\text{As}_2\text{O}_6$ structure, which gives rise to the replacement of the $[\text{Hg}_2]^{2+}$ dumbbells with single Hg^{2+} cations. This transformation is

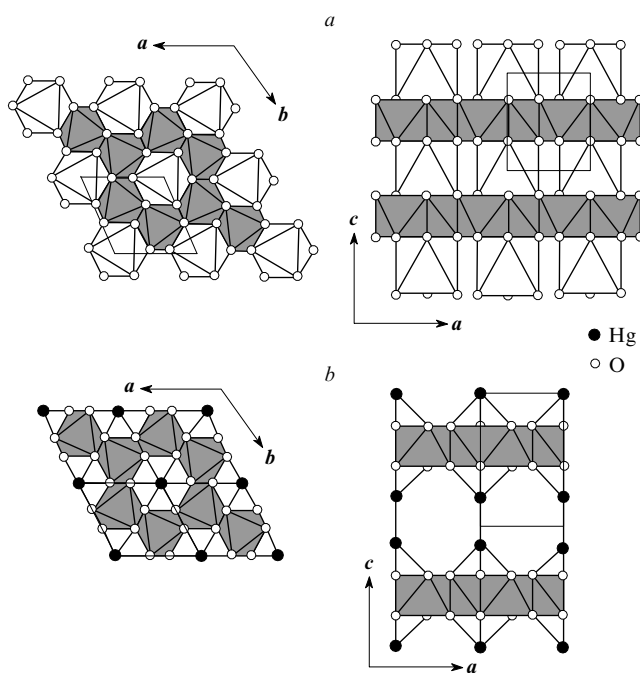

Figure 24. Projections of the crystal structures of HgAs_2O_6 (a) and $[\text{Hg}_2]\text{As}_2\text{O}_6$ (b) drawn to a common scale.

Plain octahedra denote HgO_6 , grey octahedra denote AsO_6 ; the As atoms are not shown for clarity, the Hg atoms are shown only in Fig. b. Although the projections onto the *ab* plane are identical, those onto the *ac* plane differ by a length of the Hg–Hg dumbbell (2.5 \AA) along the *c* axis.

accompanied only by a decrease in the *c* parameter of the hexagonal lattice (Fig. 24).

The conversion of a part of mercury atoms from cluster moieties into the bivalent state with the simultaneous withdrawal of free mercury metal from the structure is well possible, especially in the surface regions of crystals owing to the fact that many crystal structures reveal large voids and channels (in particular, channels with a diameter as large as $\sim 13.6\text{ \AA}$ are present in the structure of the mineral szymanskiite¹¹⁸). This process can serve as a source of mercury in natural waters and atmosphere.¹¹⁹

The segregation of different types of mercury over different layers observed in the structures of some minerals¹¹⁶ can be a consequence of processes directed towards most stable forms, which slowly proceed under natural conditions. Solid-state transformations changing the overall composition but retaining the structure of large fragments occur most easily exactly in layered compounds. The mechanism of the 'layer-by-layer' transformation was suggested by Hawthorne *et al.*⁷⁰ within a discussion of the crystal structures of monoclinic terlinguaite and orthorhombic pinchite, which are tightly associated in nature.

The important role in the crystal structure formation played by large anions (Cl, Br and I) has already been noted above as a part of discussion concerning mercury chalcogenides (see Tables 1 and 8). Mercury and chalcogen atoms are bound by strong covalent bonds and thus are incorporated into the structure as extended atomic groups with constrained variations in the bond lengths and angles. In contrast, quite bulky and large halide anions are not involved into strictly oriented chemical bonding and thus are free to form a more ordered sublattice.¹¹³

The phenomenon of ordering of various atomic groups by independent systems of crystallographic planes has earlier been observed for other classes of compounds, including rare-earth metal sulfides.¹²⁰ Normally, the subdivision into groups is performed according to the spectrum of shortest cation–cation, anion–anion and cation–anion interatomic distances. Within

this approach, the effective size of an atom or atomic group rather than only their chemical nature are of importance.⁶

Therefore, the crystal structure formation in mercury compounds can be formally subdivided into two steps.⁶ As the first step, larger 'building blocks' are ordered by basis families of planes (which are the coordinate planes constituting the translation sublattice of these large blocks). As the second step, which proceeds simultaneously, smaller building blocks and single atoms are ordered by basis planes of independent sublattices within a range of shorter interplane distances d_{hkl} . Some atoms of large building blocks are also involved in the second step. The crystal formation means that an initial set of independent sublattices possible for all combinations of atoms and 'rigid' atomic groups converts into a common lattice (least common multiple) with a unit cell composed of an integer number of sublattices and the ordering families of planes become crystallographic planes, which requires the respective indices to be integers.

VI. Crystal chemical features of the MHgYX compounds (M = Cu or Ag; Y = S or Se; X = Cl, Br or I)

1. An analysis of the anion packing

According to several groups of authors,^{46–52} the two-layer hexagonal close packing is realised in the crystal structures of MHgYX (M = Cu or Ag; Y = S or Se; X = Cl, Br or I). On the other hand, the anion packing therein is rather close to body-centred cubic packing, at least for some representatives of this class of compounds, according to our results.¹¹³

A comprehensive analysis of all closely packed anionic planes for typical structures of MHgYX^{46–52} as well as of Ag₂HgSI₂ (Ref. 52) and CuHg₂S₂I,⁴⁷ which are characterised by similar stoichiometries, was performed using the software package KAP-PLATS⁷ to establish the character of their anionic packings. It was demonstrated that idealised hexagonal close packing (hcp) and body-centred cubic packing (bcc) differ from each other only in the stacking sequence of dense hexagonal layers³⁶ and some distortions of the layers themselves, which complicates the straightforward assignment of real structures to one of the two packing types.⁵⁸

For all the structures, the degree of anion ordering significantly (by 15%–20%) exceeds that of cation ordering for the same range of interplane distances d_{hkl} essential for the crystal packing formation. This is surprising taking into account the respective results for the structures of heavy metal fluorides, oxides and sulfides,^{114,120} where cations are more ordered.

In the series of the compounds considered, the anion packing varies from ideal hcp (*e.g.*, in CuHgSI)^{47,48} to ideal bcc (*e.g.*, in Ag₂HgSI₂).⁵² This result requires additional elucidation for the cases of large differences in the sizes of the Y^{2–} and X[–] anions ($r = 1.84$ Å and 2.20 Å for S^{2–} and I[–], respectively). According to an analysis of the arrangement of all atoms in these structures,⁵⁸ the relatively small radii of an S^{2–} anion is compensated for by the fact that all direct S–S contacts, which could have distorted the packing (due to a large difference as compared to typical lengths of the I–I or I–S contacts) involve cations, which results in either linear S–Hg–S or bent S–M–S fragments, and the S...S contact appears comparable in length with the S–I and I–I distances (in the former case, S...S ~ 4.7 Å). Therefore, the mercury atoms, due to the covalent Hg–S and, to a lesser extent, M–S interactions, actually occupy positions with a coordination number of 2, which are non-typical from the classical viewpoint, thus acting as an auxiliary spacer to the S–S contact, which apparently increases its length to that of the I–I contact of the anion packing. The resultant commensurability of the strongest covalent S–Hg–S bond and the van der Waals contact between the large I[–] anions enables the regularity of a stable collective packing involving anions with different sizes.

Within this concept, the reason for a less ordered arrangement of cations becomes evident: it is controlled by the covalent interactions between cations and anions and between cations, which is a more powerful factor than mere ordering. As has been mentioned in Section IV.4, weak attractive Hg...Hg interactions in the oxo-centred [Hg₄O] tetrahedra exist at a Hg–Hg distance of ~ 3.5 Å.⁷⁹ Thus it would be reasonable to consider the crystal structures in more detail taking into account both well known Hg–Y interactions and possible Hg...Hg and Hg...M interactions.

2. The structure-forming role of the [(Hg,M)₄Y] tetrahedra

According to structural studies on quaternary chalcogenides MHgYX (M = Ag or Cu; Y = S or Se; X = Cl, Br or I) and closely related Ag₂HgSI₂ and CuHg₂S₂I, the S^{2–} anions in these compounds are characterised by the stable tetrahedral surrounding by cations (in contrast to the umbrella-like environment typical of mercury chalcogenides). A similar environment of the sulfur anions is observed in the structures of Hg₂PbS₂I₂ (Ref. 54), perroudite Hg_{4.6}Ag_{4.4}S_{4.6}(Cl,Br,I)_{4.8} (Ref. 55) and capgaronnite HgAgS(Cl,Br,I),⁵⁶ where the [M₂Hg₂S] tetrahedra similar to the oxo-centred [Hg₄O] tetrahedra present in mercury oxosalts can be identified. These tetrahedra can be considered as Y-centred; it would be reasonable to assume that it is the sp³-hybridised orbitals of the chalcogen atoms that are involved into the bonding with the cations, since sulfur and selenium are similar to oxygen in terms of the valence electron structures.⁵⁸

Experimental data summarised in Table 9 indicate that the cationic tetrahedra surrounding the S^{2–} anions (only one example is available for Se^{2–}) are sufficiently stable in terms of the geometry parameters.

Tetrahedron edge	Length / Å
Hg–Hg	3.56–3.60
Cu–Cu	4.08–4.14
Hg–Cu	3.48–3.90
Hg–Ag	3.63–4.08
Ag–Ag	4.56–4.83

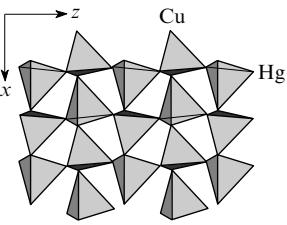

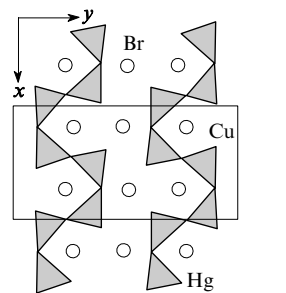

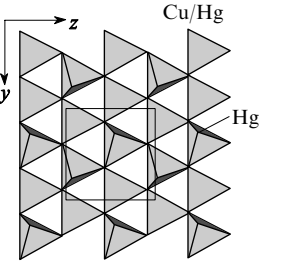

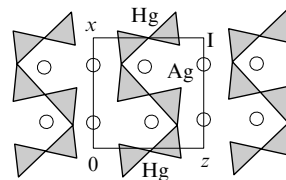

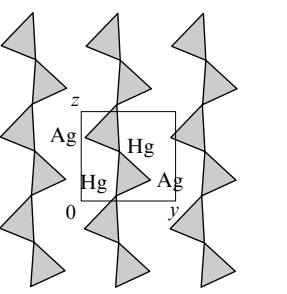

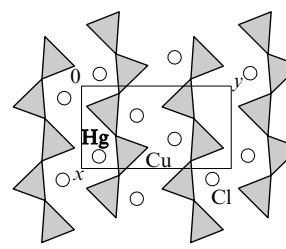

Noting the small variations in the cation–anion distances (see Table 2), the [(M,Hg)₄Y] tetrahedra can be considered as 'rigid' atomic moieties (building blocks), which are incorporated into a crystal structure as a whole. This is due to both well known Hg–S and Hg–Hg covalent interactions and less elucidated M–S, M–Hg and M–M bonding.

In the crystal structure of CuHgSI, a chain of the [Cu₂Hg₂S] tetrahedra going along the 2₁ axis parallel to the *z* axis acts as the 'load-bearing' structural unit, which includes the strongest inter-atomic interactions, *i.e.*, Hg–S and Hg...Hg. A unit cell includes two such chains, *viz.*, in the origin and in the centre of the *xy* projection. The chains are assembled into a common framework by sharing Cu vertices, the I atoms coordinated (like the S atoms) by four cations (2 Hg + 2 Cu) fill the interchain cavities.

In the structure of CuHg₂S₂I, the [(Cu,Hg)₄S] tetrahedra are assembled into a layer in the *yz* plane by sharing (Hg,Cu) vertices. The layers are further assembled into a framework by sharing Hg vertices. As outlined in Table 9, some edges of the [(Cu,Hg)₄S] tetrahedra are shorter than 3.8 Å, which assumes attractive interactions.

In both CuHg₂S₂I and Ag₂HgSI₂, mercury and sulfur are present in a 1 : 1 ratio. Although the anion packings in the two structures are similar (positions of the S and I ions are interchanged), the covalent skeleton in Ag₂HgSI₂ involves only isolated chains composed of the [Ag₂Hg₂S] tetrahedra going along the *z* axis together with a virtually linear rows of the Hg atoms with Hg–Hg ≈ *c*/2 = 3.55 Å. In a projection onto the *xy* plane, the chains of the [Ag₂Hg₂S] tetrahedra go through the origin and the centre of the unit cell composing an approximate hexagonal packing of these isolated one-dimensional fragments in this cross-section.

Table 9. Frameworks of the $[(M,Hg)_4Y]$ tetrahedra in the structures of some quaternary mercury chalcogenides.

^a For the Hg–Y, Cu–Y and Ag–Y distances, see Table 2; ^b Hg/Cu means that the respective site is statistically occupied by Hg and Cu (see Fig. 13);

^c data for crystallographically independent $[(M,Hg)_4Y]$ tetrahedra are given.

In the crystal structures of CuHgSBr (295 K),⁴⁶ the vertex-sharing $[Cu_2Hg_2S]$ tetrahedra form puckered layers lying in the xz plane. The mercury atoms in these structures are arranged into zigzag rows [in contrast to the linear Hg–Hg columns that determine the respective unit cell parameters in the above structures (the double Hg–Hg distance is ~ 7 Å)]. Two Hg–Hg–Hg fragments intersect at an angle close to 90° and thus $a \approx 7\sqrt{2} = 9.84$ Å. A unit cell accommodates two layers related to each other by a glide-reflection plane associated with a shift by $b/2 = 9.17$ Å. Meanwhile, unit cells of similarly organised β -AgHgSI and CuHgSBr (358 K) accommodate only one such layer. These structures feature a short translation (~ 4 Å) normal to the mirror reflection plane.

In the structure of CuHgSeCl, the Se^{2-} anions are also characterised by the tetrahedral environment (2 Cu and 2 Hg, see Table 9). The structure is based on chains of the $[Cu_2Hg_2Se]$ tetrahedra formed around linear rows of the Hg^{2+} cations with the doubled Hg–Hg distance of $a = 6.94$ Å. The chains are assembled into a layer in the xz plane by sharing Cu vertices. Due to the short translation c (4.25 Å), the Cl atoms lie in the same plane as the Cu atoms, thus the layers formed by the $[Cu_2Hg_2Se]$ tetrahedra are separated from each other by layers of the Cl^- anions. In the structure of α -AgHgSI,⁵¹ symmetry factors do not prevent the formation of a framework of vertex-sharing $[Ag_2Hg_2S]$ tetrahedra; cavities of the framework are occupied by the large iodine atoms.

3. Crystal structure-forming factors for the MHgYX structures

Summarising structural data outlined above, we conclude that it is the Hg–Y covalent interactions and Hg \cdots Hg bonding contacts that act as the prevailing structure-forming factors in the crystals of quaternary mercury chalcogenides.⁵⁸ Linear or zigzag $\cdots Hg\cdots Hg\cdots Hg\cdots$ chains (with Hg–Hg distances of ~ 3.5 Å) determine one of the unit cell dimensions. Other unit cell dimensions are dictated by the necessity to combine the $[(M,Hg)_4Y]$ tetrahedra by vertex-sharing. The commensurability of the Hg \cdots Hg, X \cdots X and X \cdots Y contacts enables the close packing of anions and a rather high symmetry of the resultant crystal structure. The stability of a structure towards isomorphous substitution of components can be regarded as an additional argument in favour of its robustness. In particular, the isomorphous substitution $HgS \rightleftharpoons AgX$ over a wide concentration range with the preservation of the crystal structure type (minerals perroudite⁵⁵ and capgaronnite⁵⁶) has been reported. Structural investigations into the synthetic analogues of minerals greischchevite, lavrentievite, arzakite, radtkite (corresponding to the $Hg_3Y_2X_2$ stoichiometry) confirm the ability of the anion packings to remain unchanged over significant variations in the halogen composition within the $Hg_3S_2Cl_2$ – $Hg_3S_2Br_2$ – $Hg_3S_2I_2$ system.^{40–43} The halogen atoms always occupy positions in the nodes of a primitive cubic sublattice centred by the S^{2-} anions. The introduction of monovalent atoms, *i.e.*, Cu and Ag, relieves this limitation making the X and Y anions more equivalent.

Within the approach adopted (based on the identification of stable 'building blocks') it would be interesting to compare the structures of two natural HgS modifications, *viz.*, trigonal α -HgS (cinnabar or cinnabarite) and cubic β -HgS (metacinnabarite). These structures are traditionally considered as distinctly different. Our approach to the crystal chemical analysis aimed at the identification of densely packed crystallographic planes⁷ (separately for cations and anions) established that the cationic matrices are identical in both phases. It can be represented as the three-layer cubic close packing (with the stacking sequence ABC).¹²¹ In the cubic phase, both anions and cations are packed according to this pattern and thus the overall structure can be considered as a three-dimensional motif of [S₄Hg] or, alternatively, [Hg₄S] tetrahedra. Meanwhile, the anion packing is significantly different in the trigonal phase. The S²⁻ anions are shifted from the initial cationic tetrahedron through a common face to a neighbouring cationic octahedron while the bonds with two Hg atoms are preserved and remain the strongest in the new location. *F*-centred cubic and rhombohedral cells are equivalent provided that $c_R/a_R = 2.45$.¹²² For the cinnabar structure, this ratio is 2.29, which means that the rhombohedron of Hg atoms somewhat deviates from cube: $a'_R = 5.74$ Å; $\alpha'_R = 92.5^\circ$ (Fig. 25).

Figure 25. A relation between the rhombohedral and *F*-centred cubic cells in the cinnabarite (α -HgS) structure. Only mercury atoms involved into a lattice close to the *F*-centred cubic one are shown.

The stability of the cationic framework both in α - and β -HgS is confirmed by its preservation upon the Al substitution for 1/4 of the Hg cations, as evidenced by the crystal structure of Hg₃AlF₆O₂H (space group $R\bar{3}m$, $a = 7.262$ Å, $c = 10.441$ Å, $Z = 3$).¹²³ In contrast to the framework realised in α -HgS, the *F*-centred cubic sublattice of cations is deformed in the opposite direction, *i.e.*, the cube is elongated along the three-fold axis: $a'_R = 5.449$ Å, $\alpha'_R = 83.57^\circ$. This pseudocubic cationic sublattice corresponds to a hexagonal one with $a_R = a/2 = 3.631$ and $c_R = c = 10.441$ Å. In this case, the $c_R/a_R = 2.88$, which by far exceeds the ideal value of 2.45 (Fig. 26). We note that the F atoms in this structure occupy cationic tetrahedra, whereas the O atoms composing the linear O—Hg—O fragments are characterised by a less regular coordination environment.

The fact that the coordination of an S atom to only two Hg atoms is preferred can be a reason for the 'dissolution' of cinnabar in specific natural processes, which gives rise to the replacement of two remote Hg atoms in the coordination environment of the sulfur atoms with two Cu, Ag, Pb, *etc.* atoms. The incorporation of these cations is accompanied by the introduction of charge-compensating anions, *viz.*, Cl, Br or I, which results in the formation of structures considered above corresponding to the MHgXY stoichiometry with HgS:MX = 1:1.

Figure 26. The cationic *F*-centred sublattice in the crystal structure of Hg₃AlF₆O₂H.

In the case of more mercury-excessive compounds (here, we focus on the Hg:Y:X = 3:2:2 stoichiometry, since it is best represented by structurally studied compounds), the crystal structures emerge under the action of two factors: covalent bonding between the Hg and S atoms giving rise to isolated, ribbon, layer or framework assemblies and arrangement of the halogen atoms into a packing close to a primitive cubic one.^{8,113} As has already been stated above, the 'cubic' unit in these structures provides the commensurability of the geometric parameters of this two components resulting in the stability of the packing motifs even against substantial variations in the halogen composition. The freedom in the rotation of the blocks upon their assembling produces [HgS]_n moieties with diverse topologies, which explains rich polymorphism intrinsic to these class of compounds.

VII. Conclusion

The crystal chemical analysis of natural and synthetic inorganic mercury compounds with anions abundant in nature (O, S, Se, Te, F, Cl, Br, I, CrO₄, PO₄ and AsO₄) also containing auxiliary cations similar to mercury in terms of structural preferences (*i.e.*, Cu, Ag and Pb) demonstrate a huge diversity of their crystal structures. As has been established, some atomic groups with strong covalent Hg—O, Hg—Y (Y = S, Se or Te) and A—O (A = Cr, P or As) bonds are not substantially deformed in the course of the crystallisation. These include oxo-centred [Hg₄O] tetrahedra (which also involve weaker attractive Hg...Hg interactions), S- and Se-centred [(M,Hg)₄Y] tetrahedra, [Hg₆O₂] *r*-octahedra, *etc.* The centres of these 'rigid' groups upon their incorporation into a crystal structure undergo ordering by systems of parallel (crystallographic) planes to form sublattices and the true translation lattice.

In the crystal structures of compounds with the 3:2:2 stoichiometry, the monovalent anions are more strictly ordered than the cations. This is explained by the fact that large weakly bound anions adapt much easier to the sublattice requirements than the covalently bound Hg—Y component of the structure.

Specific features of the assembly of these covalently bound groups and their ability to change the configuration without substantial redistribution of the bonding topology facilitate polymorph transitions and other structural transformations therein. This observation can shed light upon complex associations between naturally occurring mercury-containing minerals. A deep understanding of the mechanisms underlying structural transitions in associations of these minerals is of great environmental significance.

Abstract. Methods of synthesis of highly dispersed inorganic materials based on the use of ultrasonic treatment are considered. Particular attention is paid to current trends in sonochemistry, namely, ultrasonic hydrothermal treatment and high-temperature ultrasonic processing of liquid- and solid-phase systems. The bibliography includes 218 references.

I. Introduction

The synthesis of modern inorganic materials usually presents significant difficulties. Indeed, such systems are multicomponent and a number of successive stages of formation of intermediates should be carried out in order to obtain target products. The multistage character of the synthesis is responsible for inhomogeneity of chemical and phase compositions (this presents a severe problem in the formation of single phase multicomponent products) and the microstructure of materials. These problems are solved using a variety of chemical homogenisation techniques,^{1,2} which make it possible to obtain reaction mixtures in which the starting reactants are in highly dispersed reactive state. Good mixing of reactants provides the possibility of formation of numerous interfacial contacts and, as a consequence, the emergence of a developed reaction interface. The rate of formation of new phases near the developed reaction interface much exceeds the rate of interaction between reactants in conventional state. However, by no means all interfacial contacts formed in the course of homogenisation become reaction interfaces during the synthesis. This is first of all due to the compaction of reactant

particles, breakdown of the contacts formed in the course of mechanical mixing of reactants and demixing of reaction mixtures owing to different chemical nature of the reactants.

Solving a number of problems in the synthesis of inorganic materials requires the use of novel methods that allow one to change the character of the reaction zone or the reaction mechanism in a targeted manner and to additionally activate the reaction mixtures.³ Recently, synthetic methods based on utilisation of microwave radiation have been progressed rapidly.^{4–6} Microwave irradiation makes it possible to considerably accelerate such important physicochemical processes as dehydration, decomposition of salt and hydroxide precursors, synthesis of multicomponent composites and sintering of ceramics. This approach is promising due to high rate of heating and short delay of the process in contactless regime (no contact between the heater and the heated body) and to the possibility of selective heating of the components of reaction mixtures.⁷ Nevertheless, practice shows that prediction of the behaviour of a system under microwave irradiation is a very complicated task. The reason is that the electrophysical and thermophysical characteristics responsible for the absorbance of compounds strongly depend on temperature. Correct allowance for this factor is a practically insoluble problem. The situation becomes even more complicated for the systems in which chemical processes occur, because changes in the phase composition of such systems cause jumpwise and often uncontrollable changes in their electrophysical and thermophysical characteristics.

Yet another important problem in modern inorganic chemistry and inorganic materials science consists in the need of elaboration of methods for targeted synthesis of nanodisperse materials.⁸ Methods of preparation of nanopowders have been studied for a rather long time and many of them are successfully used not only in laboratory practice, but also in industry. The mechanisms of formation of free nanoparticles have been a subject of intensive research and some of them have found experimental substantiation. This made it possible to choose the strategies of the synthesis of nanopowders with preset physicochemical properties, however some problems are still to be solved.⁹ In particular, highly dispersed powders have an excess surface energy, which causes their aggregation. Additionally, enhanced reactivity of nanopowders compared to bulk crystals predetermines their instability to the action of various media and rapid degradation. These problems can be solved by introducing nanopowders into

inert matrices or by using low- and high-molecular-mass surfactants that form a shell on the surface of nanoparticles in the course of the synthesis and thus protect them from aggregation and degradation.^{10, 11}

A promising method for solving a number of problems mentioned above is sonication. Utilisation of ultrasonic vibrations in chemistry and materials science has long gone beyond research laboratories. Ultrasound is widely used in industry for intensification of many technological processes including degassing of metal melts, dispersion of liquids and solids, extraction, filtration and cleaning of various surfaces.^{12, 13} Considerable attention has been paid to applications of ultrasound in chemical synthesis including the synthesis of advanced inorganic materials. Progress of research in this field led to emergence of a new branch of chemical science, sonochemistry.[†]

A number of reviews and monographs devoted to various aspects of application of sonication in inorganic chemistry and materials science have been reported in the last decade.^{14–20} At present, chemically- and materials-science-attractive features of sonochemical synthesis have been well documented. The advent of promising sonochemical research avenues, *e.g.*, high-temperature synthesis of complex oxides²¹ and synthesis of highly dispersed oxide materials under concurrent hydrothermal and ultrasonic treatment²² should also be pointed out. In the course of preparation of the present review the authors tried to outline general ideas of the synthetic potential of the methods involving ultrasonic treatment, to consider the mechanisms of processes occurring under sonication and to systematise recent advances in sonochemical synthesis.

II. Methods of generation of acoustic vibrations

Acoustic vibrations are elastic (mechanical) longitudinal vibrations that propagate through a medium. The frequency spectrum of acoustic vibrations is usually divided into three regions, namely, infrasound (frequencies lower than 30 Hz), audible sound (frequency range from 30 Hz to 20 kHz) and ultrasound (frequencies higher than 20 kHz). This classification is to a great extent conditional, being based on human perception of acoustic vibrations.

From the standpoint of applications, ultrasonic vibrations are grouped into low-frequency vibrations (frequency range from 20 kHz to 1 MHz) and high-frequency (frequencies higher than 1 MHz) ones.²³ Low-frequency ultrasonic vibrations are mainly utilised in industry, chemistry and materials science (production of metals and alloys with specified microstructure, ultrasonic cutting and welding,²⁴ pressing,²⁵ synthesis of various compounds and materials,¹⁵ sample preparation in analytical chemistry,²⁶ *etc.*). High-frequency (diagnostic) ultrasound is used in non-destructive methods of analysis (ultrasonic defectoscopy and microscopy, studies of biological objects, *etc.*); in particular, it is widely used for contactless precision measurements of fluid parameters in flow systems.²⁶ The speed of propagation of an acoustic wave is determined by the properties of the medium through which the wave propagates; therefore, any changes in the liquid phase caused by, *e.g.*, the occurrence of a chemical reactions will change the speed of propagation of the wave and, as a consequence, change the time interval between the generation of an acoustic pulse and reception of the echo signal. Ultrasound diagnostic methods are used if a large number of contactless measuring devices are available (in, *e.g.*, petrochemical industry).^{27–29}

Generation of ultrasonic vibrations is based on transformation of electromagnetic oscillations to elastic mechanical vibra-

tions using specific devices. Electrical energy is converted to mechanical energy using the magnetostriction or piezoelectric effect.³⁰ These phenomena are due to the ability of certain materials to change their linear dimensions upon the action of alternating electric or magnetic field (piezoelectric effect and magnetostriction, respectively).

Magnetostrictive transducers characterised by ultrasound intensity of up to several tens of Watt per cm² (electroacoustic efficiency in liquid media exceeds 50%) at frequencies below 30 kHz are best for solving various problems in preparative chemistry and metallurgy. The maximum amplitude of acoustic vibrations is ~2 µm for ferrite transducers and more than 10 µm for metallic transducers.

Piezoelectric transducers are mainly used for generation of high-frequency (500 kHz–100 MHz) ultrasonic vibrations in defectoscopes, sonars and acoustoelectronic devices. The radiation intensity can be as high as 60 W cm⁻² and even reach the values 200–500 W cm⁻² at an efficiency of 60%–65% in, *e.g.*, pulsed mode of operation.¹³

In order to increase the acoustic wave intensity in a local spatial domain compared to its intensity at the surface of ultrasonic radiation source, the so-called concentrators are used.³¹ Rod-like concentrators (acoustic waveguides) are most widely used because of simple design and ease of replacement. A rod-like concentrator increases the amplitude of vibrations due to a decrease in its cross-section or density in accordance with the momentum conservation law. The gain coefficient of a waveguide (with respect to acoustic wave intensity) depends on the shape of the waveguide. The stepwise and conical concentrators have the simplest design while the highest gains are provided by exponential and catenoidal concentrators. The best materials for manufacturing of concentrators with maximum amplitude of the vibrational speed are titanium and its alloys. However, the maximum operating temperatures of these materials are at most 500–600 °C and therefore operation at higher temperatures requires the use of various steels with high acoustic characteristics (*e.g.*, steels with high content of silicon, manganese and chrome).

III. Action of ultrasound on liquid-phase systems

The basic phenomena accompanying propagation of an acoustic wave through a liquid are summarised in Fig. 1. Numerical data presented below (including the acoustic wave intensities) refer to the low-frequency ultrasonic region.

At a rather low intensity (usually, less than 0.1 W cm⁻²), the behaviour of the system can be quite correctly described using the classical wave equation. In this case no phenomena that could be

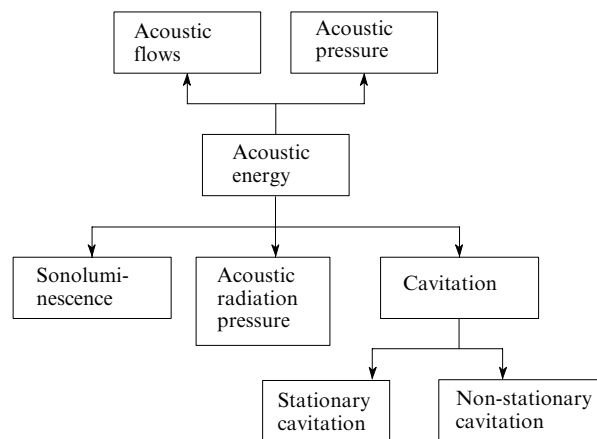

Figure 1. Physical phenomena accompanying the action of high-power acoustic radiation on liquids.

[†] In 1994, Elsevier B V (now a part of Reed – Elsevier Group) established a scientific journal *Ultrasonics Sonochemistry*. This fact substantiates that research in this field is in high demand.

useful for preparative chemistry and materials science are observed. As mentioned above, low-power ultrasound can only be used for solving particular diagnostic problems.

An increase in the acoustic energy flux density to $\sim 1 \text{ W cm}^{-2}$ and more causes the onset of some non-linear phenomena in the liquid. Among them, the most important is cavitation.^{14, 32–34}

The mechanism of the onset of cavitation can be described as follows.^{14, 35} Propagation of acoustic vibrations through a liquid causes the appearance of alternating rarefaction and compression zones in this liquid. A negative pressure is produced in the rarefaction zone. At high acoustic energy densities, it can exceed a critical value corresponding to discontinuity in the liquid and formation of cavitation bubbles in the bulk (Fig. 2, curve *AC* or *ABL*). The critical acoustic pressure for an ideal liquid should be equal to the difference between the atmospheric pressure and the pressure at which boiling of the liquid occurs at a given temperature (P_s). Actually, the critical pressure is much lower than this difference due to the presence of dissolved gases and mechanical impurities in the liquid. In this connection the formation of cavitation bubbles in a real system can be treated as a transition *AF* (see Fig. 2).

Figure 2. The phase diagram of water.¹⁴

Notations of points: *AF* is cavitation, *K* is critical point, *BKH* is binodal, *BK* is onset of boiling, *KH* is condensation of vapour, *CK* is spinodal, *P* is acoustic pressure, P_s is saturated vapour pressure, P_c is ultimate tensile stress.

At present, there are two main approaches to explanation of the mechanism of initiation of sonochemical reactions. One approach is usually called the 'hot spot' theory. It is widely used by researchers and is based on the following considerations.

During certain time interval the size of an emerged cavitation bubble and the external acoustic field execute almost in-phase oscillations. Then, due to a large difference between the hydrostatic pressure of the liquid and the pressure within the cavity of the cavitation bubble and to an abrupt increase in the acoustic pressure in the liquid in the compression zone of the ultrasonic wave the liquid moves towards the centre of the bubble and the bubble collapses (Fig. 3).³⁶ This is accompanied by concentration of energy similarly to the focussing of a converging shock wave. A high pressure developed in the central region of the collapsing bubble causes generation of a diverging spherical shock wave.³⁷ It is accepted that collapse of a cavitation bubble leads to the formation of a 'hot spot' at the centre, characterised by a local

Figure 3. Evolution of a cavitation bubble.³⁴ Generation (1), growth and oscillations (2), collapse (3).

temperature of about $5 \times 10^3 \text{ K}$ [up to $(2-3) \times 10^4 \text{ K}$]³⁸ and a pressure ranging from 500 to 1000 atm.³⁹ The rate of cooling of the 'hot spot' can be as high as 10^{10} K s^{-1} (Ref. 40). Note that these numerical values were obtained ignoring the effects of heat exchange, surface tension and viscosity of the medium on the parameters of collapse and no correction for non-ideal character of the gas was applied.^{41–44}

Thus, the key idea of the 'hot spot' theory is that ultrasonic cavitation causes concentration of acoustic energy within very small spatial domains in the medium. This leads to production of extremely high local energy densities (mainly in the form of heat), which thus initiates the sonochemical reactions.⁴⁵

The second approach to explanation for the mechanism of initiation of sonochemical processes involves analysis of electrical phenomena accompanying the evolution of cavitation bubbles. The approach has been best developed by Margulis,^{42, 46–50} who proposed a theory of local electrification of cavitation bubbles. The key ideas of this theory are as follows. The action of an acoustic energy flux causes partial removal of the electrical double layer near the liquid–cavitation bubble interface. As a result, an uncompensated electric charge appears on the surface of the cavitation bubble. Later on, oscillations of the size of cavitation bubbles under sonication lead to the loss of stable spherical shape and to formation of various microirregularities (branches and jogs) on the surface of cavitation bubbles. In the limiting case, deformation of cavitation bubbles leads to their fission and abstraction of fragment bubbles. Deformation of the bubble surface creates favourable conditions for the appearance of high local densities of uncompensated electric charge, which eventually leads to electrical breakdown. Electrical discharge is accompanied by excitation and splitting of the gas and liquid molecules in the cavitation bubble. Thus, the mechanism of sonochemical reactions is closely related to the processes occurring during electrical discharge in a vapour–gas medium in the cavity of the cavitation bubble.

It should be noted that the local electrification theory reasonably describes some experimental results that cannot be explained in the framework of the 'hot spot' theory,⁴² including the occurrence of sonochemical reactions at very low ultrasound intensities (about $10^{-3} \text{ W cm}^{-2}$) or at high ultrasound frequencies ($> 100 \text{ Hz}$) and an increase in the efficiency of suppression of sonochemical reactions using high-boiling additives, etc.

IV. Cavitation parameters

Cavitation can be characterised by three main parameters, namely, intensity, cavitation threshold and stationarity.⁵¹

The cavitation intensity means the volume-average intensity (power) of spherical shock waves generated in a liquid medium upon collapse of cavitation bubbles. The higher the power of the shock waves the higher the cavitation intensity.

The intensity of vibrations I (energy transferred per unit time through a unit surface area) can be estimated from the relation

$$I = \frac{1}{\tau} \int_0^{\tau} I(\zeta) d\zeta = \frac{P^2}{2\rho c_0} = \frac{\xi^2 \omega^2 \rho c_0}{2},$$

where τ is time, ζ is the integration constant, $P = \xi \omega \rho c_0$ is the amplitude of acoustic pressure, ρ is the density of the medium, c_0 is the velocity of sound, ξ is the amplitude of acoustic vibrations and $\omega = 2\pi f$ is the angular frequency of vibrations.

It should be noted that the specific power (intensity) of acoustic vibrations is usually expressed in W cm^{-2} (power per unit surface area of acoustic radiator) or in W cm^{-3} (power per unit volume of irradiated sample).⁵²

Clearly, the relation presented above is appropriate for determination of the acoustic energy flux density only if the wave propagates through a continuous isotropic medium with no scattering of acoustic power and the propagation of sound through the system treated causes no non-linear physicochemical effects (pre-cavitation regime).

Otherwise, one should use indirect methods of determination of the energy flux density.^{52, 53} The most widely used method is a calorimetric technique⁵⁴ based on the assumption that a large proportion of the acoustic energy absorbed by the system is released in the form of heat. The main advantage of the technique is simplicity of both practical implementation and corresponding calculations. The method involves measurements of the rate of an increase in the temperature of the medium to which the acoustic wave radiation is transferred followed by calculations of the specific acoustic power using the relation

$$I = \frac{C_p \Delta T v}{S \tau},$$

where C_p is the molar (mass) heat capacity of the medium, ΔT is the experimentally determined change in the temperature during the time interval τ , v is the mass of the substance being processed and S is the radiating surface area of the waveguide (or the volume of the system treated).

Using the definition of specific absorbed acoustic power, it is possible to estimate the efficiency (η_{ef}) of a sonochemical process

$$\eta_{\text{ef}} = \frac{m}{S I \tau},$$

where m is the amount of the substance (in moles) involved in the sonochemical reaction. The yield of a sonochemical process (η) can be defined⁵⁵ using the transferred power of the source of vibrations W instead of absorbed acoustic power

$$\eta = \frac{m}{W \tau}.$$

However, the calorimetric technique described above has a number of significant drawbacks.⁵⁶ First, this is an intense heat exchange between the metallic waveguide contacting the cavitating liquid. Second, the heat capacities of cavitating media may differ appreciably from the heat capacity of the liquid (one should also keep in mind that the properties of the cavitating liquid differ from those of the same liquid in its normal state). Third, large local temperature gradients can be produced in the liquid in the course of experiments.

An alternative method is the comparative calorimetric technique.⁵⁷ This approach involves initial irradiation of the liquid with ultrasound over a short period (τ) and measurements of the dependence of the temperature of the liquid on the duration of the treatment stage (curve A). After cooling, the liquid is heated again using a conventional technique (by, *i.e.*, an electrical resistive heater) and the dependence of the temperature of the liquid on time (curve B) is also measured. Then, by varying the

power of the heater the shape of curve B is changed in order to match curve A . Once matched, the output power of the heater is considered equal to the acoustic power absorbed by the liquid. The most favourable conditions for calorimetric measurements are as follows: a slight increase in temperature (0.1–0.4 °C), short-term operation of the source of ultrasound (5–15 s) and efficient mixing of the liquid.

The cavitation threshold is a minimum intensity of ultrasonic waves at which cavitation emerges. Cavitation is quantitatively characterised by the so-called critical cavitation number (χ_c) defined by the relation

$$\chi_c = \frac{P_0 - P_s}{P_c},$$

where P_0 is the external pressure. Interestingly, the χ_c value corresponding to the onset of cavitation usually differs from the value corresponding to its disappearance, *i.e.*, hysteresis occurs. The χ_c value depends on many parameters that characterise both the state of the liquid (content of dissolved gases, temperature, presence of impurities) and the acoustic field (frequency, pulse duration, *etc.*). For instance, the cavitation threshold increases as the concentration of gas dissolved in the liquid decreases, the frequency of acoustic vibrations increases, the pulse duration decreases and the flow turbulence enhances.

Depending on the lifetime of cavitation bubbles, cavitation is classified into two types,²³ stationary and non-stationary cavitation. Non-stationary cavitation bubbles are formed at an acoustic energy density of the order of 10 W cm^{-2} and exist during one or a few acoustic cycles. The bubble radius becomes at least twice as large as the initial radius and then the bubbles are rapidly collapsed in the liquid compression stage. Some bubbles disintegrate into smaller bubbles that in turn form cavitation centres. Non-stationary cavitation is characterised by high intensity because the vapour pressure in the bubble cavities is very low owing to short bubble lifetimes.

Stationary cavitation bubbles are characterised by relatively long lifetimes and high vapour pressure in cavities. They are formed at rather low ultrasound intensities ($1\text{--}3 \text{ W cm}^{-2}$).

It has been accepted for long that only non-stationary cavitation can induce sonochemical processes. However, recent calculations showed that the temperature and pressure produced in the collapsing stationary bubbles are only slightly lower than in the collapsing non-stationary bubbles. Additionally, the stable cavitation bubbles have much longer lifetimes and therefore a stronger effect on the course of the sonochemical reaction.¹⁴

The key parameters of acoustic cavitation (cavitation intensity and threshold) depend on various factors. The most important factors are listed below.

Ultrasound power and frequency. The ultrasound power necessary for carrying out a sonochemical reaction should be chosen taking into account the need of overcoming the power threshold associated with the onset of cavitation ($1\text{--}5 \text{ W cm}^{-2}$ for aqueous solutions) and the optimum power ($10\text{--}50 \text{ W cm}^{-2}$ for aqueous solutions), because further increase in acoustic power makes the process less efficient.²³ The limitation imposed on the second parameter is due to the formation of a cavitation cloud near the radiating surface at high ultrasound power, which precludes the development of cavitation in the bulk of the liquid.¹⁴

Sonochemical processes are usually carried out with 20–500 kHz ultrasound, because at lower frequencies the role of vapour cavitation increases appreciably, which reduces the overall cavitation intensity. At the same time at acoustic frequencies of 2–3 MHz the cavitation threshold substantially increases¹⁴ and the efficiency of the sonochemical processes decreases.

Physical properties of solvent. It is accepted⁴⁰ that an increase in the viscosity of the medium causes a substantial increase in the cavitation threshold and a decrease in cavitation intensity.

According to calculations⁵⁸ for acoustic vibrations at 23 kHz, an increase in the viscosity of the medium from 0.001 to 0.1 Pa s leads to more than twofold decrease in cavitation intensity. As the viscosity of the liquid phase increases to 1.0 Pa s, cavitation almost disappears.

Based on analysis of experimental data, the following relation between the viscosity of the liquid medium η and cohesion pressure p_{co} (characterises the hydraulic resistance of the liquid to the formation of cavitation bubbles) was proposed⁵⁹

$$\log\left(\frac{\eta}{\eta_0}\right) = -3.05p_{co},$$

where $\eta_0 = 0.13$ MPa s and the empirical constant -3.05 is expressed in atm^{-1} .

The cohesion pressure cannot be measured directly, but it can be expressed through the experimentally measured parameters, namely, the amplitude of acoustic pressure (p_{min}) and the intensity of ultrasonic waves corresponding to the onset of acoustic cavitation (I_{min}), i.e., the cavitation threshold⁶⁰

$$p_{co} = p_0 - p_{min} = p_0 - \sqrt{2I_{min}\rho v_{us}},$$

where p_0 is the hydrostatic pressure and v_{us} is the speed of ultrasonic waves in the liquid medium.

Not only the viscosity, but also the surface tension of the liquid phase has a strong effect on the cavitation intensity and threshold. Experiments⁶¹ showed that a decrease in the surface tension of the liquid from 0.072 to 0.040 N m⁻¹ causes a more than threefold acceleration of sonochemical reactions. The main reason for this effect is the decrease in the cavitation threshold.⁶¹

According to calculations,⁵⁸ the surface tension of the liquid sonicated at 23 kHz has no pronounced effect on the cavitation intensity. At the same time an increase in the surface tension of the liquid medium from 0.020 to 0.1 N m⁻¹ reduces the cavitation intensity by a factor of nearly 2.5 for sonication at high frequencies (2–3 MHz).

Thus, a correct choice of the medium is of crucial importance for carrying out sonochemical reactions, namely, the liquid media of low viscosity (weak intermolecular interaction) and surface tension are more appropriate for the onset of intense low-threshold acoustic cavitation.

Presence of dissolved gases and purity of reaction system. An abrupt drop of external pressure in a liquid causes liberation of gas dissolved in it. If an acoustic wave is in the rarefaction phase, the dissolved gases liberate in the form of small bubbles, which can act as nuclei of cavitation centres, and the cavitation threshold decreases appreciably.⁶² Additional cavitation nuclei are usually produced by bubbling an inert gas (nitrogen or argon) through the liquid.

Any microinhomogeneities or free surfaces present in the liquid medium also act as nuclei of cavitation bubbles; this considerably decreases the cavitation threshold.⁶³

Temperature. Experiments⁶² showed that raising the temperature favours a decrease in the cavitation threshold on the one hand and an increase in the rate of solvent evaporation and in the partial pressure of the solvent inside the bubble on the other hand. Because of this, a transition is possible from gas cavitation to vapour cavitation⁶⁴ characterised by an abrupt decrease in the efficiency of collapse of cavitation bubbles and in the intensity of acoustic cavitation. For instance, the oxidation of aqueous FeSO₄ solution under sonication is suppressed at 50 °C and sonolysis of water resulting in the formation of H₂O₂ is suppressed at 67 °C.⁶² Thus, the operating temperature for sonochemical processes in open systems should be much lower than the boiling point of the solvent.

External pressure. The cavitation threshold depends on the pressure developing in the rarefaction phase. This pressure exceeds the hydrostatic pressure of the liquid medium in absolute

value. An increase in external pressure reduces the difference between the acoustic pressure in the rarefaction phase and the hydrostatic pressure. At high external pressure, this difference can appear to be insignificant for formation of cavitation bubbles in the liquid medium. In this case the onset of cavitation requires a substantial decrease in the acoustic pressure in the rarefaction phase (increase in the amplitude of acoustic vibrations). Experimental studies¹⁴ showed that the optimum external pressure for sonochemical processes in open systems ranges from 0.1 to 0.5 MPa.

Thus, cavitation emerged upon sonication of liquid-containing systems enhances the efficiency of ultrasonic treatment due to concentration of acoustic energy in small spatial domains. Using this effect, one can solve a number of chemical, materials science and technological problems, e.g., fabrication of metal slabs with homogeneous microstructure,^{65–68} finely dispersed powders,⁶⁹ emulsions^{60,70} and aerosols.^{71–73} Additionally, sonication is successfully utilised for etching of surfaces,²³ regeneration of catalysts,⁷⁴ monitoring of precipitation,²³ etc.

Ultrasonic dispersion procedure is based on violation of symmetry of collapse of a cavitation bubble near the interface (e.g., liquid–solid interface, Fig. 4).¹⁵ As a result, intense local fluid microflows towards the phase boundary are produced; the speed of propagation of such flows reaches several tens of metres per second. Physicochemical consequences of this phenomenon can be followed taking ultrasonic treatment of various suspensions as examples.

It was experimentally established⁷⁵ that sonication of suspensions of inorganic oxide and sulfide materials in organic solvents causes a considerable increase in the surface area of target powders (20–30-fold increase after ~45 min at an initial specific surface area of 0.3–0.5 m² g⁻¹) due to collisional disintegration of particles. Chemical processes in the liquid–solid systems can also occur at higher rates under these conditions;⁷⁶ this particularly concerns molecular intercalation into layered inorganic materials. For instance, the intercalation rate of amines, metal-locenes, metallic sulfide clusters and some other compounds into ZrS₂, V₂O₅, TaS₂, MoS₂ and MoO₃ under sonication increases by more than two orders of magnitude compared to conventional intercalation rates. Ultrasonic treatment of suspensions under normal conditions can initiate reactions giving binary compounds from elements (Fig. 5).⁷⁷

A common feature of the fields of application of high-power ultrasound mentioned above is utilisation of mainly mechanical effects of sonication of liquids. At the same time there is a broad spectrum of pure chemical problems that can also be solved using acoustic treatment of the liquid phase.

Figure 4. Collapse of a cavitation bubble near interface.¹⁵ The direction of the liquid flow after collapse of the bubble is shown by arrows.

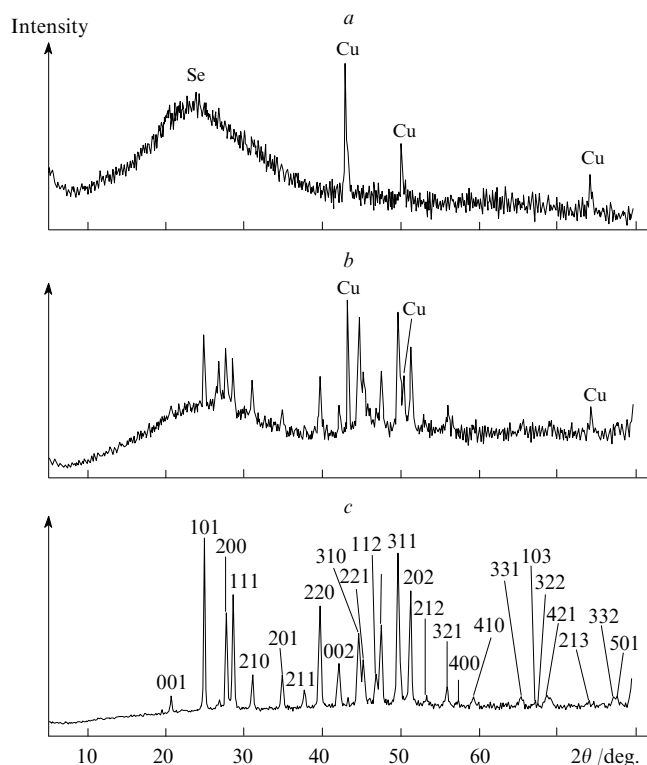

Figure 5. Powder X-ray diffraction data of the samples obtained upon irradiation of a suspension of Cu/Se mixture in methanol with ultrasound for 30 (a), 120 (b), and 480 min (c).⁷⁷ The X-ray diffraction pattern in Fig. c corresponds to single Cu₃Se₂ phase; the reflections were indexed according to [PDF 47-1745].

V. Sonochemical reactions in aqueous media

The chemistry of aqueous solutions under sonication has been studied in considerable detail.^{8, 14, 33, 78} In most cases sonochemical reactions in aqueous solutions are due to the fact that water vapour present in the cavity of a cavitation bubble at the instant of bubble collapse experiences the action of high temperature and high pressure; as a consequence, water molecules undergo the so-called sonolysis^{79, 80}

The rate of formation of HO[•] radicals in solutions in the absence of oxygen dissolved in water is ~25 μmol litre⁻¹ min⁻¹ and the rate of formation of hydrogen peroxide in air-saturated solutions is 0.6 mmol litre⁻¹ min⁻¹ (Ref. 81).

Sonication of water causes ionisation of water molecules at the instant of collapse of the cavitation bubble and emergence of hydrated electrons⁸²

The presence of solvated electrons in an aqueous solution strongly depends on the acidity of the medium.⁸³ For instance, in an acidic medium the solvated electrons participate in the formation of hydrogen atoms following the reaction

whereas another process occurs in a basic medium

Thus, sonication of aqueous solutions should initiate redox and radical reactions in them. For instance, sonication of an acidified aqueous solution of Mohr's salt in air causes oxidation of Fe(II) to Fe(III) as follows⁸⁴

The oxidation of iodide ions in aqueous KI solution occurs under similar conditions

Reactions (1)–(3) are considered as reference reactions in sonochemistry. They are used, in particular, for dosimetric purposes in the determination of specific acoustic power from the data of kinetic experiments, because it is clear that the rates of these redox reactions are related to the acoustic power absorbed by the solution.⁵³ In addition to the oxidation reactions of divalent iron and iodide anion, the decomposition reactions of various porphyrin derivatives, *e.g.*, 5,10,15,20-tetrakis(4-sulfophenyl)porphyrin (TPPS)⁸⁵ (Fig. 6), are also used as reference reactions.

Figure 6. Extent of decomposition of TPPS (1) and absorbances of Fe³⁺ (2) and I⁻ (3) solutions plotted vs. duration of ultrasonic treatment.⁸⁵ $R_{\text{TPPS}} = c_{\text{TPPS}}/c_{\text{TPPS}}^0$ is the ratio of the TPPS concentration after ultrasonic treatment to the initial TPPS concentration.

Reduction reactions, *e.g.*, reduction of Fe(III) upon sonication of weak acid or neutral aqueous solution of complex K₃[Fe(C₂O₄)₃] in air⁸⁶ can also proceed in aqueous solutions

Reduction of Ce(IV) to Ce(III) under ultrasonic treatment of acidified aqueous cerium(IV) sulfate solution proceeds analogously.⁸⁷

Particular attention should be paid to a series of studies of oscillation processes in ultrasonic field taking the Belousov–Zhabotinsky reaction as an example; the results obtained are summarised in a monograph.¹⁴ It was shown that the parameters of the self-oscillatory chemical process (frequency, intensity, duration of vibrations) strongly depend on the instant (within the period of oscillations of the concentration of reaction mixture components) at which the acoustic energy is transferred to the irradiated medium.

Radical processes occurring under high-power ultrasound in aqueous solutions saturated with an oxygen–nitrogen mixture have also been studied.^{88–90} It was established that molecular nitrogen undergoes a series of chemical transformations involving the formation of nitrate and nitrite ions at nearly the same rates (about 0.03 μmol litre⁻¹ W⁻¹).⁹⁰

As mentioned above, sonolysis of water in the course of ultrasonic treatment of aqueous and aqueous alcoholic solutions creates favourable conditions for redox reactions, which can be used for the synthesis of various compounds in highly dispersed state. In this connection it is convenient to consider direct and indirect sonochemical redox reactions. In the former case the chemical reaction is solely driven by hydrogen peroxide formed in the course of sonolysis while in the latter case the oxidising (or reducing) agent is added to the reaction mixture during the synthesis.

It should be noted that often the role of sonication during the synthesis of disperse powders from aqueous solutions is reduced to intensification of the mixing of the reaction medium, disaggregation of particles, renewal of their surfaces, fabrication of uniform heterogeneous mixtures of solids, *etc.* Thus, sonolysis of water has almost no effect on the physicochemical features of synthesis.

1. Reduction of metals from aqueous solutions

Metals characterised by large positive redox potentials corresponding to semireactions (gold, platinum, palladium) can be reduced by direct sonochemical reduction (no additional reducing agents) to give disperse elements. For instance, ultrasonic treatment of aqueous tetrachloroaurate solutions in argon atmosphere makes it possible to prepare colloidal solutions of 10-nm gold particles⁹¹ with very narrow size distribution. The addition of aliphatic alcohols to the reaction mixture significantly accelerates the formation of colloidal solution, the effect being even more pronounced with enhancement of the hydrophobic properties of the alcohol. Similar results were obtained⁹² in a study of the influence of aliphatic alcohols on the rate of reduction of platinum from H_2PtCl_6 . The effect seems to be due to the fact that the interaction of alcohols with primary radicals H^\bullet and HO^\bullet formed in the sonolysis of water results in more stable and long-lived secondary radicals, which then act as reducing agents. As the hydrophobic fragments of molecules increase, the concentration of alcohol at the cavitation bubble–solution interface increases. As a consequence, most primary radicals interact with the alcohol molecules, thus favouring an increase in the yield of the secondary radicals. Therefore, the highest rate of sonochemical reactions in aqueous solutions is expected in the presence of surfactants.

Indeed, the rate of sonochemical reduction of some metals in the absence of surfactants is very low. For instance, the reduction of hexachloroplatinum acid and formation of nanodisperse platinum particles with the size of 3 nm occurs only in the presence of anionic surfactants (sodium dodecyl sulfate, sodium dodecylbenzene sulfonate or polyethylene glycol sodium monostearate); moreover, the reaction rate remains almost unchanged if the surfactant concentration becomes higher than the critical micelle concentration ($0.1\text{--}5\text{ mmol litre}^{-1}$).⁹³

The effect of the surfactant concentration on the micro morphology of nanodisperse powders formed under sonochemical reduction conditions was studied.⁹⁴ With no surfactant, ultrasonic treatment of aqueous hydrogen tetrachloroaurate solution in the presence of poly-*N*-vinyl-2-pyrrolidone resulted in the formation of highly dispersed almost spherical gold particles (average size $\sim 7\text{ nm}$). The particles formed in the presence of $\text{NaO}_3\text{SC}_{12}\text{H}_{23}$ have different morphologies including spherical, needle-shaped, disk-like and triangular crystals (Fig. 7). As the $[\text{HAuCl}_4]:[\text{NaO}_3\text{SC}_{12}\text{H}_{23}]$ ratio decreased from 1 to 0.05 with an increase in the surfactant concentration, the average particle size reduced from 18 to 10 nm and almost all triangular particles disappeared (only disk-like or spherical gold particles formed at high surfactant concentrations).

A negative consequence of the presence of surfactants in solution consists in reduction of cavitation efficiency due to the decrease in the surface tension of the solution. Because of this, the efficiency of formation of primary radicals decreases.

Figure 7. Micrographs of nanodisperse gold particles prepared by ultrasonic treatment for 1 h at a $[\text{HAuCl}_4]:[\text{NaO}_3\text{SC}_{12}\text{H}_{23}]$ ratio of 1 (a), 0.2 (b), 0.1 (c), 0.05 (d).⁹⁴

A study⁹⁴ of the effect of the acoustic power on the micro-morphology and average size of gold particles showed that an increase in the acoustic power from 30 to 90 W causes the average particle size to decrease from 20 to 10 nm. Additionally, nearly perfect spherical particles formed under high-power treatment, whereas low-power sonication resulted in the formation of disk-like, prismatic and needle-shaped particles. The authors believe that an increase in the ultrasound power increases the reduction rate of gold ions and the nucleation rate of the new phase and, correspondingly, the average particle growth rate decreases. Hydrogen peroxide that is formed during sonolysis of water is not a unique reducing agent; other compounds can also play this role. The mechanism of sonication is most likely associated with initiation of redox reactions due to the appearance of reactive radicals in the aqueous solution. The synthesis⁹⁵ of nanodisperse copper particles of size 50–70 nm from copper(II) hydrazine carboxylate can also be treated as indirect sonochemical reduction.

The results obtained in a study⁹⁶ of sonochemical reduction of potassium dicyanoaurate(I) in the presence of ascorbic acid deserve particular attention. It was shown that strongly aggregated gold particles of irregular shape are formed in aqueous solution. At the same time, gold nanoparticles formed in polyethylene glycol (PEG-400) have a needle-shaped morphology (diameter $\sim 40\text{ nm}$ at an anisotropy coefficient of about 15). It was assumed that the mechanism of formation of needle-shaped particles is due to the fact that individual 3-nm gold particles formed in the redox reaction form chains owing to coordination by OH and C–O–C groups of the polymer solvent molecules. Then, these chains aggregate to form needle-shaped particles. This mechanism was confirmed by the results of a study of the effect of potassium dicyanoaurate(I) concentration on the micromorphology of particles formed. The size and anisotropy coefficients of aggregates formed upon sonochemical reduction of gold from solutions with higher salt concentrations considerably increased and the content of particles with dendritic morphology also increased.

At present, studies on the synthesis of inorganic composite materials based on simple metals using sonochemical reduction techniques are scarce. In particular, direct sonochemical reduction of HAuCl_4 , AgNO_3 and PdCl_2 was successfully used^{97–101} for preparation of nanocomposites based on SiO_2 xerogels and containing 4–7-nm nanoparticles of corresponding metals. The matrix (SiO_2) plays an important role in the formation of nanodisperse metal particles. First, the xerogel pore diameter determines the size of the metal particles and, second, the matrix precludes aggregation of individual particles. Nanodisperse ruthenium particles were synthesised in a similar fashion by sonochemical reduction of ruthenium trichloride in the presence of mesoporous silica SBA-15.¹⁰²

Sonochemical reduction of HAuCl_4 and H_2PtCl_6 was also employed to prepare conducting composite materials based on polypyrrole¹⁰³ and polyaniline.¹⁰⁴ It was shown that acoustic treatment makes it possible to significantly accelerate (by ~ 50 times) the formation of the composite and to increase the yield of the reaction product.

2. Sonochemically induced reduction of metal oxides and hydroxides from aqueous media

Iron, chromium and manganese cannot be obtained from aqueous solutions by sonochemical reduction (standard electrode potential of semireactions is negative or has a small positive value). However, sonication can be utilised for preparation of corresponding highly dispersed oxides. In particular, nanocrystalline Fe_3O_4 powder comprising needle-shaped particles (average size 14×48 nm) was obtained by ultrasonic treatment of $\text{Fe}(\text{OAc})_2$ solution under argon bubbling.¹⁰⁵ Good examples of typical publications in this field are provided in Refs 83, 106 and 107. In particular, highly dispersed (50–200 nm) powders of X-ray amorphous manganese and chromium oxides Mn_2O_3 and Cr_2O_3 were synthesised from potassium permanganate and ammonium bichromate, respectively.¹⁰⁷ The addition of ethanol to the reaction mixture considerably increased the rate of sonochemical synthesis due to the formation of secondary radicals (α -hydroxyethyl radical). A study of the effect of temperature of the solution treated on the sonochemical reaction showed that the yield of the reaction product increases (but not decreases) with the increase in temperature due to a decrease in the cavitation intensity. Probably, in this case the thermodynamic and kinetic factors predominate. Recently, various modifications of the sonochemical synthesis of manganese oxides from aqueous solutions have attracted considerable attention because these compounds are promising in the design of materials for d.c. sources.^{108–110}

As mentioned above, in some cases the mechanism of sonochemical synthesis does not involve the redox processes and the role of cavitation is reduced to various mechanical effects. The reaction products obtained under sonication can differ in phase composition and micromorphology from those synthesised under similar conditions without sonication. In particular, this was observed¹¹¹ in the course of preparation of nanodisperse α - $\text{Ni}(\text{OH})_2$ powder (particle size 20 nm) by precipitation from aqueous solutions of nickel salts under ultrasonic treatment. The reaction carried out under similar conditions with no sonication resulted in the β -modification of nickel hydroxide characterised by somewhat larger particle size (70 nm).

A number of highly dispersed simple metal oxides were prepared in a similar fashion by sonohydrolysis.⁸ In particular, nanodisperse ceria was synthesised^{112,113} from cerium ammonium nitrate, hexamethylenetetramine, and polyethylene glycol. The procedure resulted in relatively small particles (size 2–4 nm) with narrow size distribution. Additionally, it was shown that the micromorphology of powder obtained by precipitation from a solution containing cerium nitrate and azoformamide noticeably

changes upon addition of some bases. In particular, the addition of quaternary ammonium bases gave monodisperse CeO_2 powder with a particle size of 3.3 nm.

Recently, extensive literature on the synthesis of titania powders under sonication has been published.^{114–122} Interest in preparation of highly dispersed titania is first of all due to the fact that this compound is a promising photocatalyst, which finds application in cleaning of waste water from organic waste. Most often, the sonochemical synthesis of TiO_2 is carried out by hydrolysis of titanium tetraisopropoxide in ethanol–water mixture followed by thermal annealing of the product at relatively low temperatures (400–500 °C). In this case spherical dense or mesoporous monophase anatase particles (average size 100–500 nm) or a mixture of anatase with brookite are formed depending on the reaction conditions.^{117,119} In some cases preparation of spherical particles during the synthesis requires the addition of high-molecular-mass compounds, *e.g.*, polyethylene glycol¹¹⁵ or octadecylamine.¹¹⁸ It should be noted that synthesis of titania from titanium tetrachloride results in monophase rutile^{119,121} with needle-shaped or dendritic morphologies.

Acoustic treatment of rutile suspensions in sodium hydroxide solution¹²² leads to formation of nanotubes and needle-shaped particles of approximate composition $\text{H}_2\text{Ti}_3\text{O}_7 \cdot 0.5 \text{H}_2\text{O}$. No such structures are formed without sonication. The authors assumed that this is due to partial dissolution of TiO_2 upon sonication.

The photocatalytic activity of titania can be considerably enhanced by carrying out the photodegradation reaction under sonication (Fig. 8).¹²³ This effect is due to continuous renewal and activation of the surface of titania particles.

A study¹¹⁴ of the photocatalytic activity of titania powders synthesised by sonohydrolysis of titanium tetraisopropoxide in aqueous and aqueous-alcohol media showed that this procedure makes it possible to prepare photocatalysts whose catalytic activities are at least comparable with those of the samples of commercially available materials (comparison with the Degussa-P25 sample was made, see Fig. 9).

More complex compounds, in particular aluminates,¹²⁴ nickelates and manganites⁸ were synthesised using similar sonochemical procedures (addition of precipitating agent to aqueous metal salt solutions).

Figure 8. Absorption spectra of: aqueous KI solution irradiated with UV light (1) and ultrasound (2), aqueous KI solution with TiO_2 additive (3), pure aqueous KI solution (4) and aqueous KI solution with TiO_2 additive simultaneously irradiated with UV light and ultrasound (5).¹²³

3. Sonochemical synthesis of metal chalcogenides

Recently, extensive literature has been devoted to sonochemical synthesis of transition metal chalcogenides. This method was used for preparation of nanodisperse ZnS ,^{125–127} Sb_2S_3 ,^{128, 129} HgSe ,¹³⁰ HgS ,¹³¹ SnS_2 ,¹³² CdS ,^{133–137} CdSe ,^{133, 138} PbX ($\text{X} = \text{S}, \text{Se}, \text{Te}$),^{139–141} CuS ,^{96, 142} Cu_{2-x}Se , Cu_3Se_2 , CuSe ,^{143–145} $\text{Bi}_2\text{Se}_x\text{Te}_{3-x}$, Ag_2Se , Ag_2Te , Cu_5Se_4 , PbSe , Ni_3Se_4 ,¹⁴⁶ Ag_2Se , $\text{NiS}_{1-x}\text{Se}_x$,^{142, 147} MoS_2 ,¹⁴⁸ Ag_2S ,¹⁴⁹ $\text{RuS}_{1.7}$,¹⁵⁰ Bi_2S_3 ,¹⁵¹ HgTe ,¹⁵² MoTe_2 ,¹⁵³ and Bi_2Te_3 powders.¹⁵⁴

Here, salts are most widely used as the source of metal. First of all, these are acetates,^{125, 130, 139} nitrates and chlorides.¹³² The source of sulfur is provided by thioacetamide, thiourea, elemental sulfur or sodium thiosulfate. Selenides and tellurides are mainly synthesised from elemental selenium and tellurium as the sources of the non-metals; at the same time, the syntheses of selenides and tellurides using sodium selenite or tellurite were reported.^{138, 146}

The most often used solvents are water or aqueous-alcohol solutions;^{125, 134, 136} however, in some cases ethylenediamine^{145, 147, 149, 152, 155} or polyethylene glycol^{130, 140} is more appropriate. This concerns the reactions involving elemental sulfur (or selenium) as the source of the non-metal, because sonication of a suspension of a chalcogen in ethylenediamine induces the reaction

resulting in liberation of hydrogen sulfide.¹⁴⁹ Nanodisperse sulfides are formed as a result of the interaction of hydrogen sulfide with a metal salt or a metal complex.¹⁵⁶ By carrying out reactions in polyethylene glycol it is possible to substantially reduce the minimum acoustic power necessary for the sonochemical synthesis of chalcogenides.¹³⁰ In some cases polyethylene glycol also acts as a reducing agent.¹³⁰ Additionally, the synthesis of metal chalcogenides in the presence of polyethylene glycol or other polymers capable of playing the role of complex-forming agents (e.g., hydroxyethylcellulose¹³⁶) permits fabrication of submicron disperse particles with strip and dendritic morphologies. A similar procedure [sonochemical oxidation of iron(II) acetate in aqueous solution in β -cyclodextrin matrix] was used for preparation¹⁰⁵ of needle-shaped magnetite (Fe_3O_4) nanoparticles.

It should be noted that low-molecular-mass complex-forming agents affect the micromorphologies of the powders formed in the course of sonochemical synthesis. This concerns, in particular, sodium tartrate and sodium citrate.^{143, 151} However, the most interesting results were obtained using ethylenediaminetetraacetic acid (EDTA) as complex-forming agent. Namely, the reactions of formation of needle-shaped or strip-like nanodisperse Bi_2S_3 ,¹⁵¹

PbS ,¹⁴¹ and CdS ¹³⁶ particles in the presence of EDTA were substantially accelerated. The formation of highly anisotropic particles in the presence of EDTA was explained using a mechanism involving the formation of a very stable pentadentate complex between EDTA (Y^{4-}) and Cd^{2+} ion. Steric hindrances allow the interaction between Cd^{2+} and S^{2-} ions

to follow only one direction.¹⁶ Correspondingly, the chalcogenide particles grow in this direction (Fig. 10).

Figure 10. Micrograph of rod-like CdS crystals (~ 80 nm in diameter, ~ 1.3 μm long) formed under ultrasonic treatment in the presence of EDTA (a) and an electron diffraction pattern of an individual rod (b).¹⁶

When chalcogenides are synthesised in aqueous media, the compositions and structures of reaction products are strongly influenced by the pH value of the solution. Taking mercury sulfides as examples, it was shown that nanodisperse α -HgS powders can only be synthesised from solutions with pH 9–11.¹³¹ In more acidic media, coarse-grained precipitate is formed rapidly. If the medium pH is controlled by adding ammonia (triethanolamine), the powder formed is characterised by an average particle size of ~ 35 nm (10–15 nm, spherical particles). The smaller particle size in the case of triethanolamine was explained¹³¹ by the fact that this compound is an effective ligand that forms stable complexes with Hg^{2+} . The synthesis of nanodisperse β -HgS powder only proceeds at pH values from 3 to 5. Reactions in media of lower acidity result in coarse-grained β -HgS precipitate. Additionally, it was shown that the β -HgS particle size also depends on the treatment duration, namely, the average particle size changes from 13 to 20 nm as the duration of sonochemical synthesis increases from 0.5 to 1 h. This effect can be due to recrystallisation and growth of nanodisperse particles.

By and large, the micromorphologies of products of sonochemical synthesis are to a great extent determined by the reaction conditions. For instance, the synthesis of Sb_2S_3 gave both amor-

phous nanospheres and needle-shaped nanoparticles.¹²⁸ Star-like Sb_2S_3 particles were synthesised under somewhat different conditions.¹²⁹

The mechanism¹³⁹ of sonochemical formation of nanodisperse lead sulfide powders can probably be extended to other metal sulfides and selenides provided that the source of the non-metal is elemental sulfur or selenium. Sonication of such systems increases the rate of dissolution of the non-metal (conventionally, this is the limiting stage of the chalcogenide formation reactions) and, hence, the formation of E^{2-} ($\text{E} = \text{S}, \text{Se}, \text{Te}$) ions. Additionally, ultrasonic treatment precludes aggregation of chalcogenide particles.

VI. Sonochemical processes in non-aqueous media

As shown above, in the course of sonochemical reactions in aqueous media the cavity of a cavitation bubble is only filled with water vapours and dissolved gases, because usually the volatilities of other components of the aqueous solution are negligible. The mechanism of sonochemical processes in aqueous solutions involves the formation of mainly H^\bullet , HO^\bullet , and HO_2^\bullet radicals upon collapse of cavitation bubbles and subsequent interaction of these species with compounds in solution.

In the case of non-aqueous solutions the number of compounds capable of competing with the solvent in volatility considerably increases and includes, *e.g.*, various metal complexes. Large amounts of such compounds can be present in the gaseous phase within the cavitation bubble along with the solvent molecules. Collapse of the cavitation bubble causes their decomposition and formation of solid-phase products of sonolysis. Since each collapsing cavitation bubble can be treated as a specific microreactor, sonochemical decomposition products are characterised by very high degree of dispersion.

Sonolysis of non-aqueous solutions makes it possible to obtain simple (metals) and complex substances (*e.g.*, binary compounds including nitrides, carbides, oxides, sulfides, silicides, borides) and composites based on them.¹⁵ The compositions and structures of nanomaterials strongly depend on the characteristics of the reaction medium, namely, the type of solvent, chemical inertness of the solvent or its ability to interact with the substance treated; the presence of surfactants and/or high-molecular-mass compounds; the oxidative, reductive or inert character of the atmosphere in which ultrasonic treatment is carried out.

1. Synthesis of nanodisperse metals and alloys

Sonolysis of solutions of transition metal carbonyls [$\text{Fe}(\text{CO})_5$, $\text{Ni}(\text{CO})_4$, $\text{Co}(\text{CO})_3\text{NO}$, $\text{Mn}_2(\text{CO})_{10}$, $\text{Re}_2(\text{CO})_{10}$, $\text{Cr}(\text{CO})_6$, $\text{Mo}(\text{CO})_6$] in high-boiling alkanes leads to formation of nanosized clusters of amorphous metal particles.^{39, 157–161} In particular, high-power ultrasonic treatment of a solution of iron pentacarbonyl in decane under argon bubbling at 0 °C led to weak aggregation of amorphous particles of elemental iron of size at most 5–6 nm.³⁹ Subsequent heat treatment of the powder thus obtained in inert atmosphere at 350 °C resulted in partial crystallisation of iron.

Starting from a mixture of metal carbonyls, one can prepare nanodisperse alloys. For instance, sonication of a solution of iron and cobalt carbonyls in decane gave a highly dispersed Fe–Co alloy (particle size 6–10 nm).¹⁶² By varying the concentrations of the starting compounds it is possible to obtain a continuous series of iron–cobalt alloys from pure iron to pure cobalt.^{162, 163} Similar results were obtained in the synthesis of Co–Ni and Fe–Ni alloys.^{164, 165}

Not only elemental iron, but also carbonyl complexes of more complex structures are formed³⁹

It is impossible to obtain $\text{Fe}_3(\text{CO})_{12}$ by thermolysis of photolysis of $\text{Fe}(\text{CO})_5$ as well as by other methods. Therefore, the synthesis of compound $\text{Fe}_3(\text{CO})_{12}$ can be considered as specific sonochemical reaction.

Small metal and alloy particles formed in the sonochemical reaction undergo strong aggregation. The degree of dispersion of powders obtained can be considerably increased using surfactants and some other compounds. A method of synthesis of stable colloidal solutions of elemental iron and cobalt using high-power sonication was proposed.^{166–168} The technique is based on sonochemical decomposition of iron pentacarbonyl or cobalt carbonyl-nitrosyl in decane in the presence of stabilisers (poly-*N*-vinyl-2-pyrrolidone, oleic acid^{8, 15} or higher aliphatic alcohols).^{167, 168} As a result, a stable colloidal solution of nanosized paramagnetic iron particles (size range 8–10 nm) is formed (Fig. 11). A modified procedure was used for the synthesis of colloidal Fe_2O_3 solution stabilised with oleic acid.⁸

Figure 11. Micrograph of colloidal iron sample obtained under sonochemical irradiation and stabilised by oleic acid.¹⁵

It should be noted that nanodisperse metals can be sonochemically synthesised in non-aqueous media not only from carbonyls, but also from other volatile metal compounds. For instance, a colloidal solution of nickel particles (size 3.9–4.3 nm) in diethyl ether was prepared from nickel acetylacetonate in the presence of triphenylphosphine with diethyl aluminium hydride as reducing agent at –40 °C.¹⁶⁹ Colloidal particles can be separated and redispersed in another polar solvent, *e.g.*, pyridine. Colloidal particles are stabilised by the triphenylphosphine shell on the surface.

The use of transition metal β -diketonates instead of carbonyl and carbonyl-nitrosyl complexes is not very promising because of rather high metal–oxygen and oxygen–carbon bond energies. Therefore, sonolysis of solutions of transition metal β -diketonates (even carried out in high-boiling alkanes C_{12} – C_{17}) only results in partial decomposition of these compounds and formation of products with high content of organic residues.^{170, 171}

Catalysis is one of the largest fields of application of nanodisperse metals.¹⁷² The vast majority of metals used as heterogeneous catalysts represent supported catalysts. Here, compounds characterised by large specific surface area (usually, alumina or silica) act as substrates. A conventional method of synthesis of heterogeneous catalysts involves the soaking of a porous substrate with a corresponding metal salt solution followed by heat treatment in reductive atmosphere. Clearly, in this case metal particles

Figure 12. Micrograph of a sample prepared by sonolysis of iron pentacarbonyl in decalin in the presence of silica microspheres followed by hydrogen reduction.¹⁷⁴

are adsorbed not only on the surface, but also within the pores of the substrate, which significantly reduces the specific activity of the catalyst. In this connection the development of sonochemical methods for the synthesis of catalysts with uniformly distributed nanodisperse metal particles with narrow size distribution (Fig. 12) on the substrate surface seems to be quite promising.^{173, 174}

Sonolysis of iron pentacarbonyl in decane in the presence of silica gel results in nanodisperse powders of amorphous metallic iron (3–8 nm); the powder particles are uniformly distributed over the surface of silica particles.¹⁷⁵ The catalytic activity of the material thus obtained was studied taking the Fischer–Tropsch reaction as an example. A comparison of its catalytic activity with that of a catalyst prepared by the soaking technique showed that at the same loading the activity of the sonochemically prepared catalyst was nearly tenfold higher than the activity of the ‘soaked’ catalyst. The former catalyst exhibited a high activity at relatively low temperatures (< 250 °C), whereas the activity of the latter catalyst in this temperature range was very low (Fig. 13).

Figure 13. Catalytic activity of Fe/SiO₂ plotted vs. hydrogenation temperature of carbon monoxide.¹⁷⁵

N is the number of hydrogenated CO molecules per active site per second; catalysts were prepared by ultrasonic treatment (1) and by soaking (2).

2. Synthesis of binary compounds

Metal carbonyls can serve as precursors in the synthesis of binary metal compounds, *e.g.*, carbides and chalcogenides. Depending on the synthesis conditions and the character of subsequent treatment, a variety of products can be obtained.¹⁷⁶ Often, preparation of the end product involves high-temperature heat treatment of an intermediate. For instance, the sonochemical decomposition of molybdenum hexacarbonyl in hexadecane followed by heating of the product in CH₄–H₂ atmosphere resulted in a nanosized Mo₂C_{1.02} powder with particle size of 3–5 nm.¹⁶²

In order to synthesise metal chalcogenides, the corresponding carbonyl and elemental chalcogen are sonicated in a high-boiling non-polar solvent. In particular, ultrasonic treatment of a solution of molybdenum hexacarbonyl and sulfur in tetramethylbenzene under argon bubbling results in the formation of nanocrystalline MoS₂ (particle size ~15 nm) with unusual morphology (aggregates of porous spherical particles).¹⁴⁸ Molybdenum telluride MoTe₂ was synthesised¹⁵³ by sonicating tellurium and Mo(CO)₆ in decalin under argon bubbling for 4 h. The product obtained immediately after sonication was X-ray amorphous powder characterised by high degree of aggregation of particles of size 50–150 nm. The powder obtained at shorter duration of the synthesis had a different micromorphology and comprised plate-like particles of nearly the same size (50–150 nm). Subsequent thermal annealing of the products of sonochemical synthesis at 650 °C for 10 h gave a molybdenum telluride powder the particles of which were nanotubes of length 100–500 nm and 20–50 nm in diameter.

Nanosized amorphous cobalt ferrite (CoFe₂O₄) powder was obtained by sonochemical decomposition of iron carbonyl Fe(CO)₅ and cobalt carbonyl-nitrosyl Co(CO)₃NO in decalin at 0 °C under oxygen flow.¹⁷⁷ Nanosized amorphous nickel ferrite NiFe₂O₄ was prepared under similar conditions.¹⁷⁸ Subsequent annealing of the amorphous products at 450 °C led to partial crystallisation with retention of the nanosized state.

Composite materials can also be synthesised using the procedure described above. Considerable advances in this field were made by a research group headed by Prof. Gedanken. Most studies of researchers from this group were devoted to preparation of reactive catalytic materials.^{8, 15} In particular, a novel method of fabrication of molybdenum oxide–silica and molybdenum carbide–silica composites was reported.¹⁷⁹ These materials were synthesised by ultrasonic treatment of a suspension of silica microspheres and molybdenum hexacarbonyl in decane. Treatment in air gave amorphous powder of Mo₂O₅–SiO₂ composite, whereas ultrasonic treatment in argon atmosphere resulted in amorphous Mo₂C–SiO₂ composite.

Preparation of nanodisperse amorphous oxides, in particular, nickel and cobalt oxides can also be treated as specific methods of sonochemical synthesis. It is believed¹⁸⁰ that similar compounds can be synthesised only under sonochemical treatment, because one should attain unusually high cooling rates (up to 10¹⁰–10¹¹ K s⁻¹).

It should be noted that sonochemical reactions in non-aqueous media are far from being reduced to the transformations of metal carbonyls. Extensive literature is devoted to sonochemical transformations of organic (alkanes, halogenated hydrocarbons) and organometallic compounds; Diels–Alder synthesis, Friedel–Crafts reaction, *etc.* under sonication. It was shown that concurrent microwave and ultrasonic treatment is promising for acceleration of hydrazinolysis of esters.¹⁸¹ A scheme of a setup for combined microwave–ultrasonic treatment is shown in Fig. 14. A number of reviews concerned with various aspects of liquid-phase and heterophase sonochemistry of non-aqueous media are available.^{14, 23, 33, 182}

Thus, at present the most often used starting compounds for sonochemical synthesis of nanodisperse inorganic materials in non-aqueous media are transition metal carbonyl and carbonyl-

nitrosyl complexes. Possible methods of synthesis of such materials are shown in Fig. 15.

VII. Sonochemical processes under hydrothermal conditions

Initially, hydrothermal synthesis was used as efficient method of growth of single crystals of various inorganic compounds and for production of high-purity inorganic materials.^{183, 184} Later on, the method was shown to be promising for the synthesis of highly dispersed (including nanodisperse) inorganic materials. At present, hydrothermal method is widely used for preparation of both single crystals and highly dispersed powders of simple and complex oxides, chalcogenides, hydroxides, phosphates, zeolites, supramolecular and many other classes of compounds.¹⁸⁵

The promise for using concurrent hydrothermal and ultrasonic treatment for the synthesis of disperse powders has been documented.^{22, 186–188} The authors assumed that the main effects accompanying sonication of liquid-phase and heterogeneous liquid–solid systems under conventional conditions (cavitation, sonolysis and sonochemical redox reactions, intense local microflows of liquids and shock waves) should also be observed under hydrothermal conditions. At the same time the possibility of onset

of cavitation in aqueous solutions at temperatures above 100 °C required experimental substantiation. This was done in analysis of the level of acoustic noise in an aqueous medium measured by a broadband hydrophone.¹⁸⁶ It was established that the cavitation intensity at 250 °C is 70%–80% of the cavitation intensity at room temperature. Unfortunately, the temperature dependence of the cavitation intensity in the temperature range from 100 to 250 °C was not measured. Additionally, the influence of the physicochemical properties of liquid media at temperatures above 100 °C (viscosity, surface tension, saturated vapour pressure, etc.) on the cavitation parameters was also not studied.

It was also shown¹⁸⁶ that sonication of hydrothermal solutions initiates redox processes in them. The authors assumed that the oxidation of divalent cobalt salts and hydroxide to Co₃O₄ involves HO• radicals generated in aqueous solutions during sonolysis of water. It should be noted that nanodisperse Co₃O₄ particles formed under concurrent hydrothermal and ultrasonic treatment of a cobalt nitrate solution have a well-developed mesoporous structure (Fig. 16). Under conventional hydrothermal treatment of solutions, mesoporous metal oxide powders are formed at such concentrations at which the rates of nucleation processes (they dominate at low concentrations) and growth of crystallites (they dominate at high concentrations) are commensurable.¹⁸⁹ It was shown experimentally that the growth of crystallites predominates under hydrothermal treatment of solutions of cobalt(II) salts. At the same time sonication probably increases the rate of nucleation of the new phase, which leads to a shift of the hydrothermal synthesis towards the transient ‘nucleation–crystallite growth’ region characterised by the best conditions for the formation of mesoporous oxide powders.

Figure 16. Micrographs of Co₃O₄ samples synthesised by concurrent hydrothermal and ultrasonic treatment (a) and by conventional hydrothermal treatment (b).¹⁸⁶

A study¹⁹⁰ of the synthesis of mixed nickel–zinc ferrites showed that ultrasonic treatment under hydrothermal conditions causes a slight increase (by 10%–20%) in the size of nanodisperse product crystallites and the formation of powders with a narrower crystallite size distribution compared to the particle size distribution typical of conventional hydrothermal synthesis.

Sonication under hydrothermal synthesis also has a moderate effect on the micromorphology of titania and zirconia powders prepared by crystallisation of X-ray amorphous zirconyl and titanyl hydroxide gels.¹⁹⁰ At the same time the TiO₂ and ZrO₂ powders synthesised under concurrent hydrothermal and ultrasonic treatment are characterised by significantly different phase compositions compared to powders prepared under conventional hydrothermal conditions. For instance, hydrothermal treatment of amorphous zirconyl hydroxide gel for 3 h at 250 °C results in the formation of a mixture of two crystalline polymorphs of

zirconia, namely, a thermodynamically stable monoclinic modification ($\sim 12\%$) and a metastable tetragonal modification ($\sim 88\%$). Hydrothermal treatment of amorphous gel $\text{ZrO}_2 \cdot n\text{H}_2\text{O}$ under similar conditions with concurrent sonication leads to appreciable acceleration of crystallisation of the amorphous phase and to an increase in the content of thermodynamically stable monoclinic modification of zirconia (to $\sim 30\%$) in the reaction product.

Similar results were obtained in the synthesis of nanodisperse titania by high-temperature hydrolysis of aqueous $\text{H}_2\text{TiO}(\text{C}_2\text{O}_4)_2$ solution.¹⁹⁰ A conventional hydrothermal treatment of the solution gave a mixture of thermodynamically stable (rutile) and metastable (anatase) TiO_2 polymorphs, the content of rutile being at most 10%. Concurrent hydrothermal and ultrasonic treatment led to an increase in the content of rutile to 20%.

At the same time sonication in the course of hydrothermal synthesis of ZrO_2 and TiO_2 from zirconyl nitrate and X-ray amorphous $\text{TiO}_2 \cdot n\text{H}_2\text{O}$ gel, respectively, had almost no effect on the phase composition of reaction products.

Thus, sonication during the hydrothermal synthesis of oxide powders can be accompanied by (i) substantial acceleration of crystallisation of X-ray amorphous gels and formation of highly dispersed and nanodisperse powders, (ii) an increase in the content of thermodynamically stable phases in the products of synthesis provided that the oxide being synthesised exists as a number of polymorphs and (iii) initiation of redox reactions in aqueous solutions resulting in highly dispersed (including mesoporous) particles.

VIII. Solid-phase sonochemical processes

The mechanisms of liquid-phase sonochemical reactions are closely related to a number of non-linear effects emerging upon sonication of solutions and suspensions (first of all, cavitation). Clearly, cavitation cannot be the driving force of the processes occurring in the solids irradiated with high-power ultrasound. Therefore, the mechanism of the action of ultrasound on solids should be fundamentally different.

Consider the effect of acoustic vibrations on the real structure of solids. At present, such studies are only carried out for polycrystalline metals and alloys¹⁹¹ as well as for single crystals of ionic compounds (alkali metal halides) and $\text{A}^{\text{II}}\text{B}^{\text{VI}}$ and $\text{A}^{\text{III}}\text{B}^{\text{V}}$ semiconductor crystals.¹⁹² Main trends in the behaviour of these systems under alternating stresses are similar.

Sonication causes the following processes in solids to occur.

1. Dislocation motion and redistribution over the volume of the crystal, which is only possible upon attainment of a threshold amplitude of ultrasonic vibrations ($\xi_{\text{threshold}}$).^{193, 194} Translational motion of dislocations mainly follows one direction in spite of periodic changes in the sign of the stress, because the chain of point defects, small dislocation loops and dislocation dipoles formed behind the moving dislocation precludes the change in the direction of the dislocation motion. The speed of translational motion of dislocations in various crystals varies from 0.2 to $2.4 \mu\text{m min}^{-1}$ (Ref. 192). The action of ultrasound on crystals induces the appearance of stable dislocation patterns, thus having much in common with thermal annealing.^{195, 196}

2. Dislocation multiplication and an increase in the concentration of dislocations to a certain limiting value (saturation) occur at stresses corresponding to the dynamic yield stress σ_f^0 . Sonication causes an increase in the concentration of dislocations by several orders of magnitude to $10^8 - 10^{10} \text{ cm}^{-2}$ (Ref. 194). The dislocation distribution over the volume is highly non-uniform; dislocations are mainly concentrated near sources (at grain boundaries, cracks and other macroscopic structural defects).

3. Formation of point defects, which can occur at dislocation jogs or follow the mechanism of annihilation of dislocations of opposite sign.^{197, 198}

It should be noted that the concentration of structural defects in ultrasonically treated material is a non-linear function of both

the acoustic power and the treatment temperature. Here, a considerable (by more than an order of magnitude) increase in defectiveness of the crystal is observed in particular temperature and ultrasound power ranges,¹⁹¹ *i.e.*, there is well-defined synergism between acoustic and heat treatment. Clearly, such a change in the real structure of a solid should lead to considerable enhancement of the diffusion mobility of ions in the crystal structure and, correspondingly, to acceleration of certain solid-phase reactions.

The simplest types of solid-phase reactions are polymorphic transformations and phase decomposition. In the text below we summarise the results of studies on the effect of sonication on solid-phase austenite transformations in steels.

The effect of ultrasonic radiation on the kinetics of intermediate (beinite) transformation of 30XГCH2A steel was studied.¹⁹⁹ The ultrasonically treated samples showed a considerable increase in the content of beinite, *i.e.*, acoustic treatment favoured acceleration of the austenite transformation. Electron microscopy studies revealed that the dislocation density in the untreated samples was an order of magnitude lower (10^8 cm^{-2}) than in the samples exposed to ultrasonic irradiation (at least 10^9 cm^{-2}). The ultrasonically treated steel samples showed that dislocations are present both in the interior of grains and at grain boundaries. Additionally, the dislocation structure of austenite developed under sonication rapidly disappears upon short-term heat treatment of the steel samples. The authors¹⁹⁹ suggested the following mechanism of austenite transformations. The interaction of point defects that are formed abundantly under sonication with dislocations during high-temperature annealing is due to diffusion and subsequent annihilation of the defects. Acceleration of the beinite transformation under ultrasonic treatment results from enhancement of the mobility of carbon atoms, which in turn is a consequence of an increase in the density of lattice defects (dislocations and vacancies).

The effect of sonication on the reverse martensite transformation in iron/nickel (29% Ni) alloy pre-annealed from 950 °C was a subject of yet another study.²⁰⁰ It was established that the process slows down upon ultrasonic treatment. The authors²⁰⁰ pointed out that austenisation on heating causes the formation of concentration inhomogeneities, namely, regions with higher and lower concentration of nickel atoms. According to the phase diagram of the Fe–C system, the nickel-enriched martensite phase should transform into austenite at lower temperatures compared to the Ni-depleted phase. Continuous ultrasonic irradiation results in a high concentration of vacancies and, as a consequence, enhanced mobility of nickel atoms. Here, the formation of the nickel-enriched zones becomes less probable. As a result, the reverse martensite transformation is shifted towards the higher-temperature region.

Studies of the effect of acoustic activation on polymorphic transformations were carried out for a few oxides, in particular, PbO ²⁰¹ and zirconia.²⁰² For instance, it was shown²⁰¹ that ultrasonic treatment of $\beta\text{-PbO}$ initiates the $\beta\text{-PbO} \rightarrow \alpha\text{-PbO}$ phase transition even in the absence of additional heat treatment; the degree of transformation was about 5%. The efficiency of sonication in the course of phase transition appreciably increases as the temperature increases. At 400–475 °C, the $\alpha\text{-PbO}$ phase formed under sonication is partially oxidised to Pb_3O_4 . A kinetic study of the $\beta\text{-PbO} \rightarrow \alpha\text{-PbO}$ phase transition and oxidation of $\alpha\text{-PbO}$ to Pb_3O_4 at 425 °C showed that an increase in the duration of ultrasonic treatment of $\beta\text{-PbO}$ causes the overall extent of the transformation $\beta\text{-PbO} \rightarrow \alpha\text{-PbO} + \text{Pb}_3\text{O}_4$ to increase. Then, the rate of the phase transition decreases and the curve of the $\beta\text{-PbO}$ content reaches saturation stage. The maximum extent of transformation of $\beta\text{-PbO}$ under concurrent sonication and heat treatment is 0.85, which is in good agreement with the results obtained in studies of mechanochemical activation of the $\beta\text{-PbO} \rightarrow \alpha\text{-PbO}$ transition.²⁰³

Sonochemical initiation of the phase transformation ‘metastable polymorph \rightarrow stable polymorph’ of zirconia proceeds in a

similar fashion.²⁰² Under conventional heat treatment the tetragonal polymorph of zirconia remains stable on heating up to 600 °C, whereas under concurrent high-temperature and ultrasonic treatment the monoclinic modification is formed at 500 °C (the content of the latter is 18%).

More complex types of solid-phase reactions undoubtedly include processes in binary and multicomponent systems, because reactions in such systems occur at grain boundaries.

Enikolopov *et al.*²⁰⁴ were the first who studied the possibility for solid-phase chemical processes to occur under ultrasonic treatment in mixed (not pure metallic) systems. The following reactions were carried out under sonication:

(1) decomposition

(2) substitutions in metal–oxide systems (metallothermy)

(3) exchange in the citric acid–iron oxide system

(4) azo couplings in solid-phase synthesis of some azo dyes (Bismarck brown, pigment Red G) from stoichiometric mixtures including an aromatic amine and sodium nitrite.

It was shown that in all these systems ultrasonic treatment favours initiation of solid-phase reactions. For instance, irradiation of metal–metal oxide systems with ultrasound (vibrational amplitude 5 μm) initiated reactions that completed in 15–25 s depending on the system. An increase in the amplitude had no effect on the reaction rate. Sonication had similar action on the reactions of ammonium bichromate decomposition and interaction of iron(III) oxide with citric acid. In the latter case the maximum extent of transformation was only 50% and did not increase with an increase in the duration of ultrasonic treatment and in the acoustic power delivered, apparently, due to the formation of a dense layer of reaction product on the Fe_2O_3 surface. On the contrary, the synthesis of azo dyes appeared to be sensitive to the ultrasonic power, namely, the rate of the reaction increased on the average by 30%–40% upon an increase in the vibrational amplitude from 10 to 15 μm .

It was established that each system studied is characterised by a particular threshold amplitude of ultrasonic vibrations (no reaction initiation occurs at smaller amplitudes). Solid-phase sonochemical reactions require a rather high density of compaction of the starting powder.²⁰⁴ For instance, initiation of the decomposition of ammonium bichromate under sonication occurred only if the density of the starting pellet was at least 80% of the theoretical value. This is probably due to the need of creation of good acoustic interparticle contacts in powder (if no contacts are available, acoustic power substantially dissipates at interfaces and the efficiency of sonication considerably decreases).

It was assumed²⁰⁴ that the initiating action of ultrasound causes an appreciable reduction of diffusion limitations, which allows solid-phase reactions to proceed at rather high rates under relatively mild conditions. However, in this case the role of acoustic activation is likely reduced to initiation of the solid-phase reactions mentioned above. In particular, it is known that metallothermic processes and decomposition of ammonium bichromate release much heat. Ultrasonic deformations can cause local heating in powder systems; for instance, heat release occurs at interparticle contacts at the instant of reaction initiation. At high density of compacted samples, the energy released is almost not dissipated, being completely spent for heating of the surrounding particles and thus initiating further interaction. Then the reaction proceeds by a mechanism similar to high-temperature

self-propagating synthesis (in this case ultrasound acts as initiator of the reaction). This assumption is consistent with the fact that an increase in the amplitude of ultrasonic vibrations upon attainment of a threshold value does not accelerate the reaction, because after initiation the effect of sonication on the process becomes negligible compared to the effect of heating of the reaction mixture due to heat released.

Obviously, the data on the formation of complex organic compounds²⁰⁴ could not be interpreted in the framework of the diffusion formalism. In this case the reaction mixtures are multicomponent systems including not only ionic, but also molecular compounds, and the chemical reaction involves formation of numerous intermediate products.

The effect of sonication on high-temperature self-propagating synthesis of Ti_5Si_3 and TiSi_2 in the titanium–silicon system was studied.²⁰⁵ This is a multiphase system and therefore the reaction product can contain a variety of intermediates depending on the blend composition and synthesis conditions. Sonication causes changes in both the temperature profile of the combustion wave (heating zone is extended) and the rate of combustion. Ultrasonic treatment reduces the reaction rate and the maximum temperature of the synthesis. It was assumed that alternating stresses produced at contacts between the reactant particles induce local heating of the starting mixture. This can cause the formation of intermediate reaction products in the heating zone and thus change the reaction conditions; as a consequence, the amount of heat released will be smaller compared to the combustion of mixtures without sonication.

A study by Khanukaev and Khanukaeva²⁰⁶ was a logical continuation of an earlier investigation.²⁰⁴ The authors²⁰⁶ also studied a number of solid-phase processes occurring under ultrasonic treatment:

(1) decomposition of ammonium bichromate, chromate and sulfate;

(2) dehydration of copper(II) and magnesium sulfate crystal hydrates;

(3) decomposition of $\text{Mg}(\text{OH})_2$ and $\text{Fe}(\text{OH})_2$;

(4) synthesis of copper(I) phthalocyanine from *o*-phthalonitrile

The results obtained in both studies appeared to have much in common. The vast majority of the reactions studied were characterised by a threshold amplitude of ultrasonic vibrations ($\sim 5 \mu\text{m}$) and by a threshold density of compact samples (no reaction at lower densities). Acceleration of the reactions under ultrasonic treatment was associated with the overcoming of diffusion limitations.

New information was as follows. First, it was found that the amplitude of ultrasonic vibrations has a strong effect on the reaction kinetics in these systems. In particular, the mass loss rates during the decomposition of hydroxides, $\text{Mg}(\text{OH})_2$ and $\text{Fe}(\text{OH})_2$, appeared to be proportional to the squared amplitude of vibrations at the end face of the waveguide at the same treatment durations (*i.e.*, the reaction rates are proportional to the transferred acoustic power). Additionally, almost all reactions were characterised by rather long induction periods (3–8 min), which was associated with the need of accumulation of the energy necessary for initiation and keeping up the reactions in the reaction volume. The distribution of the reaction product over the sample volume has a cylindrical symmetry.

The threshold pattern of ultrasonically treated solid-phase reactions was explained as follows. First, effective mixing of reactants occurs under such conditions where the stress due to ultrasonic vibrations exceeds the corresponding yield points. The threshold amplitude was estimated at $\sim 5 \mu\text{m}$, which coincides with experimental data. Second, it is well known that initiation of any chemical reaction requires the overcoming of an energy barrier (threshold amplitude of ≥ 10 – $11 \mu\text{m}$).

According to a model proposed,²⁰⁶ the key factors responsible for acceleration of ultrasonically treated solid-phase reactions are renewal of the reactant surfaces and removal of the reaction product layer between the interacting particles rather than the overcoming of diffusion limitations by generation of structural defects.

We believe that both mechanisms of acoustic activation of solid-phase processes take place in real systems.

The fact that sonication of a solid-phase reaction mixture can accelerate the interaction between the mixture components due to elimination of diffusion limitations was first experimentally proved in studies^{207–209} on the kinetics and mechanism of ultrasonically treated high-temperature reaction

At 800 °C, the rate of magnesium ferrite formation under ultrasonic activation was noticeably higher (by 15%–20%) than the rates of the blank reactions (no activation). On the contrary, the rate of the solid-phase reaction carried out at 700 °C under ultrasonic activation decreased to some extent. At 900 °C, ultrasonic treatment of the samples had almost no effect on the rate of ferrite formation. The results obtained correlate with the characteristics of the defectiveness of the iron(III) oxide samples, which is formed upon ultrasonic treatment in the temperature range 700–900 °C.^{209,210} The character of changes in the defectiveness of $\alpha\text{-Fe}_2\text{O}_3$ directly affects the formation kinetics of MgFe_2O_4 , namely, if the sonicated Fe_2O_3 samples have less defect structures compared to the products of the blank reactions (700 °C), the formation of MgFe_2O_4 and the yield of the reaction product in the former case is lower than in the latter case. However, if the reaction is carried out at 800 °C, both the defectiveness of the Fe_2O_3 samples and the rate of MgFe_2O_4 formation from the ultrasonically treated samples are higher than those for the blank reactions. At 900 °C, the ultrasonically processed samples and the untreated ones are characterised by the same defectiveness and the formation of MgFe_2O_4 occurs at nearly the same rates.

Additionally, alternating stresses at 700–900 °C should obviously cause the same mechanical effect of renewal of the reactant surfaces. Thus, it is the diffusion mobility of ions that governs all changes in the reaction rates under ultrasonic treatment compared to the rates of the blank reactions.

These non-linear changes in the defectiveness of $\alpha\text{-Fe}_2\text{O}_3$ crystallites and in the rate of solid-phase reactions of $\alpha\text{-Fe}_2\text{O}_3$ were explained^{207–209} by the occurrence of the following concurrent processes in the system: generation of structural defects under sonication; thermal annealing of defects, which dominates at 900 °C; and annihilation of extensive defects in the acoustic field upon ultrasonic annealing.

The effective activation energies of the solid-phase reactions carried out under ultrasonic treatment and without it were determined from formal kinetic analysis of experimental data. It was found that in both cases the formation of MgFe_2O_4 is a diffusion-limited process. Analysis of the Arrhenius relation $\ln k = f(T^{-1})$ (k is the rate constant for the reaction in the framework of the kinetic model chosen) gave an apparent activation energy of 180 kJ mol⁻¹ for the samples formed in the blank reactions. The relationship between $\ln k$ and T^{-1} for the reaction conducted under combined heat and ultrasonic treatment is non-linear. The temperature range studied can be divided into two intervals, 700–800 °C and 800–900 °C, which are characterised by the apparent activation energies of 320 and 100 kJ mol⁻¹, respectively.

The efficiency of sonication performed to accelerate diffusion was also demonstrated taking the solid-phase reaction of iron(III) oxide with lithium carbonate as an example.²¹¹

An additional substantiation of interrelation between the mechanism of ultrasonic activation of solid-phase reactions and elimination of diffusion limitations is provided by the results of a study²¹² of ion exchange in acid tantalum and zirconium phos-

phates in the presence of caesium chloride under ultrasonic treatment.

It was shown that dehydration of mixtures of acid tantalum phosphate with caesium chloride upon sonication occurs at a higher temperature, being characterised by smaller mass loss. This effect is most pronounced for the decrease in the mass loss in the low-temperature region corresponding to the loss of weakly bound water. This is due to partial substitution of caesium ions for $(\text{H}_3\text{O}_2)^+$ ions in acid tantalum phosphate. The ultrasonically treated samples also show a smaller mass loss corresponding to solid-phase ion exchange accompanied by liberation of HCl. The major effect of sonication is achieved in the initial stages of treatment; additional processing of the samples in the reactor has a much weaker effect. Probably, this is due to the fact that solid-phase ion exchange between $(\text{H}_3\text{O}_2)^+$ and caesium ions is controlled by cation diffusion through the layer of reaction product. Therefore, initially (at zero degree of conversion and diffusion layer thickness) the reaction rate is rather high, being exponentially decreased with the development of the reaction.²¹³ The overall extent of ion exchange and dehydration reduces on the average by 15%–20% due to ultrasonic treatment.

Sonication has a similar effect on ion exchange between acid zirconium phosphate $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ and alkali metal chlorides. The ultrasonically treated samples were also characterised by the mass loss at higher temperatures compared to the untreated samples. This effect was observed for both dehydration (80–350 °C) and ion exchange ($T > 450$ °C). As in the preceding case, this is an indication of solid-phase ion exchange induced by ultrasonic vibrations.

A series of recent studies^{21,214–218} was devoted to detailed investigations of the effect of ultrasonic activation on high-temperature solid-phase synthesis of various ferrites including LiFe_5O_8 , ZnFe_2O_4 and NiFe_2O_4 (Fig. 17). Kinetic studies of the solid-phase reactions of iron(III) oxide with zinc oxide, nickel oxide and lithium α -orthoferrite and investigations of the evolution of the structure of the reactants during the synthesis of the final phases revealed similarity of the mechanisms of ultrasonic

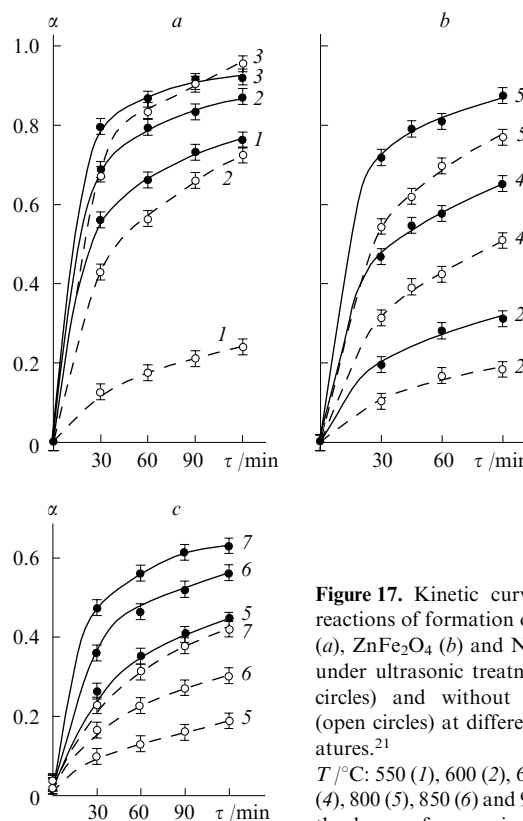

Figure 17. Kinetic curves of the reactions of formation of LiFe_5O_8 (a), ZnFe_2O_4 (b) and NiFe_2O_4 (c) under ultrasonic treatment (filled circles) and without sonication (open circles) at different temperatures.²¹ T / °C: 550 (1), 600 (2), 650 (3), 700 (4), 800 (5), 850 (6) and 900 (7); α is the degree of conversion.

activation of these reactions. With no sonication, the reaction products (LiFe_5O_8 , ZnFe_2O_4 , NiFe_2O_4) are formed only on the outer surface of iron(III) oxide particles representing dense aggregates of primary Fe_2O_3 crystallites. The microstructure of the starting Fe_2O_3 shows no significant changes [the size of the coherent scattering domains (CSD) in iron(III) oxide remains almost unchanged in the corresponding temperature ranges for all reaction mixtures] and small particles of reaction products rapidly aggregate into relatively large crystallites, as indicated by rapid increase in the CSD size in the initial stages of the reactions.

At the same time the reactions of ferrite formation under ultrasonic treatment are characterised by a decrease in the size of the primary iron(III) oxide crystallites and by prolonged retention of small size of the CSDs in lithium, zinc and nickel ferrites that are formed. This indicates non-uniformity of the reaction front, which penetrates into the bulk of Fe_2O_3 aggregates with the development of the reaction due to intensification of ion transfer through diffusion along Fe_2O_3 grain boundaries (Fig. 18).

IX. Conclusion

An undoubted advantage of ultrasonic treatment consists in the possibility of concurrent use of the technique and other methods of activation of reaction mixtures including conventional thermal activation procedures. Such 'combined' methods are characterised by manifestation (to some extent) of characteristic physical effects of sonication. Targeted use of ultrasonic treatment makes it possible to considerably enhance the possibilities of the available synthetic approaches and to synthesise novel inorganic materials in a targeted manner. The main effects accompanying the action of high-power ultrasound on liquid- and solid-phase systems are listed below.

Liquid-phase systems	Solid-phase systems
Processes accompanying sonication	
1. Cavitation. Local heating to ~ 5000 K, local increase in pressure to ~ 1000 atm, microflows of liquids with velocities of up to 100 m s^{-1} , intense local electric discharge.	1. Motions, generation and multiplication of dislocations (nearly 1 000-fold increase in concentration).
2. Considerable intensification of mass transfer.	2. Nearly tenfold increase in effective diffusion coefficients.
	3. Formation of interparticle contacts through mutual motions of particles.
Main physicochemical consequences of ultrasonic treatment	
1. Decomposition of volatile components of solutions.	1. Acceleration of solid-phase reactions.
2. Initiation and acceleration of redox reactions.	2. Reduction of reaction temperature
3. Disaggregation of particles.	
4. Formation of stable suspensions and emulsions.	
5. Degassing of solution.	
Main fields of application of high-power ultrasonic waves	
1. Organic and inorganic syntheses.	1. Activation of solid-phase reactions; synthesis at lower temperatures.
2. Preparation of nanodisperse materials based on amorphous and crystalline metals, simple and complex oxides, etc.	2. Targeted formation of the structure of solids.
3. Design of materials with preset morphologies of aggregates.	

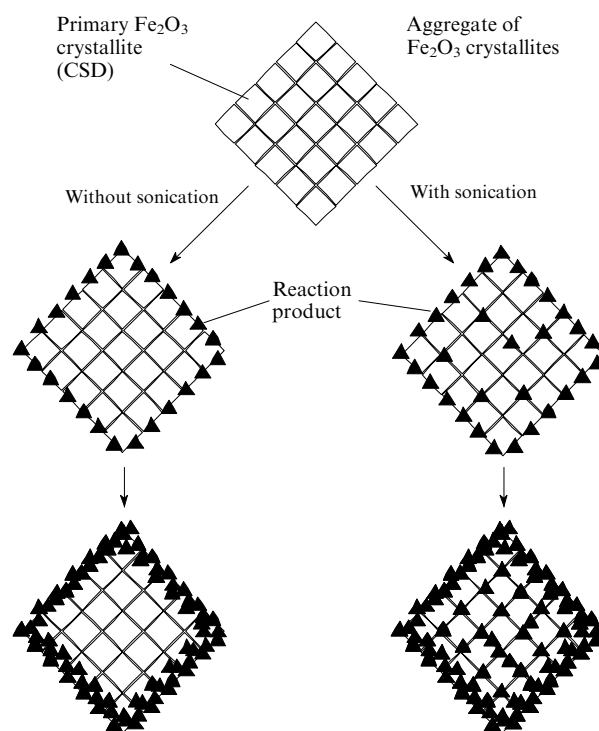

Figure 18. Mechanisms of reactions of ferrite formation under ultrasonic treatment and without it.²¹

Summing up, it should be emphasised that sonication techniques open new prospects for targeted synthesis of various inorganic materials. Sonochemical treatment allows one not only to considerably accelerate chemical transformations (first of all, in heterogeneous systems), but also often to prepare highly dispersed phases with controllable micromorphology.

This review has been written with the financial support from the Russian Foundation for Basic Research (Project Nos 06-03-33042 and 05-03-33036), the Foundation for Support of Domestic Science, the Chemistry and Materials Science Division of the Russian Academy of Sciences (in the framework of the Programme 'Development of Scientific Foundations of Advanced Chemical Technologies and Synthesis of Pilot Batches of Compounds and Materials') and the Presidium of the Russian Academy of Sciences (in the framework of the Programme 'Elaboration of Methods of Synthesis of Chemical Compounds and Design of Advanced Materials').

Abstract. The results of studies of the catalytic oxidation of organic compounds in the presence of molten transition metal salts and oxides are surveyed. The attention is focused on extensive oxidation of halogen-containing compounds. The bibliography includes 197 references.

I. Introduction

Molten salts, in particular, alkali, alkaline earth and rare earth metal halides, carbonates, sulfates, molybdates, tungstates and vanadates, are distinguished by thermal and radiation stability, low volatility, low viscosity, and high electrical and thermal conductivities over a broad temperature range. Owing to these properties, ionic melts are of interest as high-temperature electrolytes,^{1,2} energy storage devices and heat carriers,^{1–5} and as gas- and dust-trapping liquids.^{6–8} Molten electrolytes (metal oxides and salts) are used in coating of metal surfaces^{9,10} and in thermal and electrochemical storage cells and fuel cells.^{1,2,9,11–13} The present review considers the use of metal oxide and salt melts as catalysts of oxidation of some organic and inorganic compounds and as the media for these reactions.

In recent years, considerable attention has been devoted to the so-called ionic liquids, *i.e.*, salts formed by quaternised nitrogenous heterocycles (or amines) and Lewis acids, which are liquid under normal conditions. The application of these compounds as catalysts for skeletal isomerisation of alkanes and for metathesis, alkylation, disproportionation and oligomerisation of alkenes has been described.^{14–25} High catalytic activity of ionic liquids, which is attributable to their high polarity and high acidity, was noted. Thus they induce isomerisation of alkanes at 30–70 °C.

The salt melts considered in this review are also ionic liquids.[†] These high-temperature melts are used to carry out reactions that are thermodynamically allowed only at elevated temperatures (cracking, dehydrogenation). In addition, due to the high thermal conductivity, it is expedient to use molten salts in the processes accompanied by pronounced heat evolution or absorption, for example, pyrolysis, partial and extensive (complete) oxidation of organic compounds, coal gasification, and so on.

Molten catalysts (MC) have the following specific features which make them unique.

1. Unlike the conventional heterogeneous catalysts, MC exhibit high performance stability, because the ‘liquid–vapour (or gas) phase’ interface is constantly renovated during the catalysis.^{28–30}

2. High thermal conductivity of ionic melts provides easy solution to the heat supply or withdrawal problem in highly endo(or exo)thermic reactions. The risk of local overheating resulting in the destruction of active sites, which is typical of traditional catalysts, markedly decreases.

3. An important advantage of MC is the simplicity of their preparation. They are usually prepared by simultaneous or consecutive fusion of the components. There is no need to be concerned about optimisation of the surface texture and the surface area, the mechanical strength or the grain-size distribution of the catalyst, *etc.*

4. High electrical conductivity of ionic melts allows one to use electrochemical methods for the monitoring and control of MC composition during the process.

5. The reactions on MC proceed in the absence of water or aqueous solutions; this is very important as regards environment protection (no wash water).

However, molten catalysts are not free from drawbacks, first of all, this is their relatively high corrosion activity and the need to use special reactors.

Despite the fact that the first studies dealt with reactions of organic compounds catalysed by melts were published more than a hundred years ago,³¹ these catalysts have not yet found wide use in industry. Apart from the high corrosion activity of the melts, this is due to poor knowledge of their catalytic properties. Currently, melts are used on an industrial scale only for the synthesis of isoalkanes^{26,27,32–34} and for chlorination of hydro-

carbons^{3, 12, 35–41} and on a pilot scale for coal gasification.^{11, 12, 42–44}

The purpose of this review is to summarise the published data on the characteristic features of processes catalysed by melts.

II. Experimental techniques for the work with molten catalysts

The catalytic processes on molten metal salts and oxides are carried out using special equipment and procedures. Several versions of process implementation involving molten catalysts have been proposed. Most often, MC-catalysed reactions are carried out by bubbling vapour of the feedstock with or without a carrier gas through a melt bed.^{35, 43, 44} Bubble-type reactors are used for this purpose,^{45–47} and the contact time of the reaction mixture with the catalyst is controlled by changing the height of the melt bed.^{47, 48}

In the bubbling of a gas–vapour mixture through a melt, the contact area of the gas–liquid phases and, hence, the degree of feedstock conversion depends on the degree of dispersion of the gas flow. In an ideal case, a gas bubble has a diameter of less than 1 mm, *i.e.*, it is a microreactor with a great surface-to-volume ratio. Therefore, in these systems, the processes that tend to acquire an explosive character when carried out in usual reactors become easily controllable.⁴⁹

A study of thermal properties of a $\text{KPO}_3\text{--V}_2\text{O}_5$ melt has shown^{50, 51} that oxygen is evolved from the melt in discrete portions. This was attributed to the formation of oxygen microbubbles, which have no time to unite into large particles. The minimum volume of an evolved bubble was calculated to be $5 \times 10^{-5} \text{ cm}^3$. Each bubble acts as a microreactor on the walls of which free radicals are ‘quenched’ and, hence, chain reactions cannot switch to the explosive mode. Probably, this accounts for the possibility of safe extensive oxidation of phthalic anhydride and nitrobenzene production wastes on the $\text{K}_2\text{O--V}_2\text{O}_5$ melt,^{52, 53} whereas their combustion in an open flame is accompanied by explosion.

Gas-phase oxidation of *o*-xylene with oxygen bubbled through an eutectic (eut) melt $\text{K}_2\text{SO}_4\text{--V}_2\text{O}_5$ (39 mass %) and a melt $\text{K}_2\text{S}_2\text{O}_7\text{--V}_2\text{O}_5$ (14 mass %) has been reported.^{54, 55} The experimental data were processed, to determine the bubbling velocity (U), using the equation

$$U = \frac{H}{(H-h)(\pi R^2/Q)} = -\frac{1}{h\pi R^2} \frac{dQ}{d(1/H)},$$

where H is the effective height of the melt; h is height of the melt at a zero gas velocity; Q is the gas volume flow rate at the melt temperature; R is the radius of the reactor. The resulting velocity was used to determine the residence time of the mixture in the reaction zone.

In the 509–570 °C temperature range for $Q = 40 \text{ cm}^3 \text{ s}^{-1}$, the U value varied from 9 to 18 cm s^{-1} . At 500 °C, the conversion of *o*-xylene in a mixture with oxygen reached 35–42%. (Note that oxidation of *o*-xylene mixed with nitrogen under the same conditions results in a low conversion of the hydrocarbon, *viz.*, 2.5%–4.5%.) The residence time of the gas–vapour bubbles in the melt zone was $\sim 2 \text{ s}$. It is believed^{54, 55} that the higher reaction selectivity observed in the melt compared with a solid catalyst having the same composition is due to the isothermal mode of the process, resulting in a decrease in the yields of extensive oxidation products.

The kinetics of reactions on MC is usually studied using a tubular reactor with a melt layer applied onto its internal surface.⁵⁶ The residence time is controlled by varying the feed rate of the reaction mixture or the reactor length. The reactor can operate in either continuous or pulse mode.^{56, 57} Processing of the experimental results obtained with a pulse-type reactor has been described in detail.⁵⁸ For reactors operating in the displacement

mode, a dependence of the substrate conversion on time was derived using different forms of kinetic equations.

If it is necessary to increase the specific surface area of a molten catalyst, this is applied on a sorbent surface.^{59, 60} In this case, reactors traditional for heterogeneous catalysis are utilised. The use of supported MC often results in higher yields of the target products with respect to those obtained in the bubbling mode.

The combined reactor and regenerator in which the catalyst reduction and reoxidation stages occur separately appears to be the best version. The ammoxidation process of *m*-xylene using this reactor design has been reported.⁶¹ The reaction mixture enters the reactor at a high rate through a specially designed nozzle and sprays the melt. The reaction proceeds in a vessel filled with finely dispersed drops of the melt. The partially reduced melt flows into a tank from which it moves again into the reactor by means of a gas lift[‡] with simultaneous oxidation. The non-consumed hydrocarbons and ammonia are separated from the reaction products and recycled.

The necessity to separate the reactor zones in which the reaction occurs and the catalyst is regenerated is quite common. Thus the oxidative dehydrogenation of ethylbenzene and aliphatic alcohols on the $\text{K}_2\text{O--V}_2\text{O}_5$ melt proceeds more easily than the reaction of vanadium(IV) with oxygen (catalyst regeneration);^{46, 62} therefore, it is expedient to carry out the oxidation of vanadium(IV) with oxygen at higher temperatures ($> 640 \text{ °C}$) and to carry out the oxidation of organic compounds at 500 °C in another reactor zone.

The catalyst regeneration (saturation with oxygen in the case of oxidation) can be performed during gas lift transportation of the melt.⁶³ The melt is first saturated with oxygen and then excess oxygen is removed in the separation zone until a specified partial pressure is attained. To increase the selectivity of oxidation of organic compounds⁶⁴ and prevent the formation of explosive mixtures, it is necessary to eliminate the contact of the hydrocarbon feedstock and reaction products with oxygen. This allows one to carry out simultaneously two processes with opposite signs of thermal effect (an endothermic process in one zone and an exothermic process in the other zone) and thus to balance the heat flows. For example, such reactor has been used for the production of synthesis gas by oxidation of lower alkanes ($\text{C}_1\text{--C}_4$) in a flow of molten metal oxides.⁶⁵ The proper oxidation was carried out in one reactor zone, while in the other zone, the oxidation products were reformed. This endothermic process yielded synthesis gas virtually free from nitrogen. The partially reduced melt was routed into the regeneration zone for oxidation with atmospheric oxygen.

A special reactor has been developed for the processing of solid urban waste by fusion in a slag melt under conditions of air bubbling. In this reactor, solid waste particles of different sizes are captured by melt drops, get into the high-temperature region (1250 °C) and burn. This process for urban waste destruction has already been tested on an industrial scale.^{66–68}

Non-friable bulk materials are processed using tanks filled with a molten catalyst.^{69, 70} The possibility of using molten catalysts for extensive oxidation of organic polymers containing a metal cord with subsequent recovery of the metal from wastes formed in the manufacture and applications of various reinforced polymeric and rubber articles has been demonstrated.⁷¹

III. Characteristic features of reactions proceeding on melts

Owing to the high thermal conductivity of inorganic melts, the heat supply to the reactor in the case of endothermic reactions (hydrocarbon pyrolysis and cracking) and the heat withdrawal from the reaction zone in the case of oxidation (especially,

[‡] Gas lift is a device for lifting a liquid by the energy contained in the compressed gas that is mixed with this liquid.

extensive oxidation) of organic compounds are easier for the reactions with MC. This allows one to intensify the processes.

The by-products (tars and coke) formed during high-temperature reactions are either collected on the melt surface (and, hence, they can easily be removed mechanically from the reaction zone) or distributed throughout the bulk of the melt without the formation of a continuous crust^{30, 72} (this facilitates their removal by oxygen bubbling, *i.e.*, burning out³⁰). The addition of glass-forming metal oxides (boron oxide²⁹ or metal oxides that increase coke wettability⁷³) favours the uniform distribution of coke throughout the melt. High rate of oxidation of soot was attributed⁷⁴ to good wettability of soot in the presence of the V₂O₅ melt.

Since metal oxides and inorganic salts exist as melts over a broad temperature range and have a high thermal conductivity, the temperature in the reactor can be quickly changed and finely controlled, which is important for catalytic reactions carried out under non-steady-state conditions.⁷⁵ The perturbations introduced into a heterogeneous catalytic system (the changes in the reactant concentration, temperature and electrode potential) are controlled more easily when the reaction is carried out on the melts rather than on solid catalysts for which the surface structure is poorly reproducible.

High diffusion coefficients of oxygen in melts, in particular, 10^{-7} – 10^{-5} cm² s⁻¹ (Refs 75 and 76), determine high rate of structure relaxations and allow one to study fast steps of a heterogeneous catalytic process. Structural changes in a molten catalyst can be induced and detected by various methods, including electrochemical ones. In this case, the reaction products are simultaneously detected, which is important to gain information on the process mechanism.^{77, 78} This possibility was demonstrated for the first time in a study of SO₂ oxidation mechanism under non-steady-state conditions on a K₂S₂O₇–V₂O₅ melt.^{75, 76}

The relatively high oxidation temperatures of organic compounds on MC do not prevent investigation of the kinetic effects, namely, the isotope (KIE) and compensation effects. For example, for the oxidative dehydrogenation of *para*-substituted and deuterated ethylbenzene on the KVO₃–V₂O₅ eutectic melt, primary KIE and inverse secondary KIE were observed and the log *k* vs. σ_R^0 dependence was established.^{56, 79} It was concluded that oxidative dehydrogenation of ethylbenzene derivatives is a multi-step process. At a temperature of up to 550 °C, the oxidation involves sorbed oxygen and follows an associative (concerted) mechanism, which switches to the stepwise oxidation–reduction mechanism at higher temperatures. The first step is the reaction of V₂O₅ as the MC component with the aromatic system of the benzene ring. Presumably, the reaction is facilitated by the replacement of hydrogen atoms in the benzene ring by deuterium. This leads to an increase in the equilibrium concentration of the initially formed π -complex, which is then converted into styrene, and to an increase in the dehydrogenation rate (inverse secondary KIE). The replacement of hydrogen atoms at α -carbon in ethylbenzene by deuterium results in a twofold decrease in the rate constant for ethylbenzene dehydrogenation (or a 25% decrease per deuterium atom). This relatively high (in view of the fact that the rate constants were determined at 540–600 °C) primary KIE value indicates that the hydrogen atom is rather remote from the carbon atom in the transition state.

This assumption is supported by the dependence of the rate constants for oxidative dehydrogenation of *para*-substituted ethylbenzenes on the σ_R^0 Hammett constants of the substituents R.⁵⁶ The equation for this dependence at 600 °C has the form

$$\log k = -0.187 \pm 0.016 + (1.345 \pm 0.120) \sigma_R^0$$

($r = 0.9907$, $s = 0.0173$),

where r and s are correlation parameters.

The dependence of log *k* on σ_R^0 shows that in the transition state the substituent is involved in resonance interaction with the aromatic system. The polarity of the transition state is also

confirmed by high reaction constant ($\rho = 1.345$ at 600 °C), which suggests a radical mechanism of the process. On the basis of elemental and powder X-ray diffraction analyses of solidified catalyst samples taken before and after the reaction, it was concluded that the reaction follows a stepwise mechanism, which switches to a concerted mechanism at temperatures below 550 °C.⁸⁰

A study of the oxidation kinetics of ethanol on K–V–M oxide catalysts containing various metal oxides (about 300 compositions) over a broad temperature range (573–873 K, below and above the melting points of the systems) has revealed^{81, 82} a kinetic compensation effect, *i.e.*, parallel variation of the activation energies (E_a) and pre-exponential factors (A) in the Arrhenius equation. This effect is expressed by the relation

$$\log A = cE_a + d = E_a/2.3RT_s + \log k_s,$$

where c and d are constants, T_s and k_s are isokinetic parameters.

Different dependences of log A on E_a for oxidative dehydrogenation of ethanol to acetaldehyde, extensive oxidation of ethanol to CO₂ and dehydration of ethanol to ethylene indicate that these processes occur on different active sites of the catalyst.^{82, 83} The aggregation state of the oxide composition does not influence the pattern of isokinetic dependence.

IV. Relationship between the catalytic reactions proceeding on solid and molten catalysts

Molten catalysts can be used as models to search for new catalytic systems, to establish correlations between the catalyst composition and activity and to study the catalysed reaction mechanisms. The surface of melts has a more uniform composition than that of solid-phase catalysts, which have surface defects and structural and chemical inhomogeneities.^{51, 84, 85}

The features elucidated in the studies of properties and action of MC can be used when preparing solid catalysts. However, one should take into account the correspondence of the conditions of application of molten and solid catalysts, for example, coincidence of the temperature range. A large number of salt and oxide systems with melting points ranging from room temperature to 900 °C are available.⁸⁶ This makes it possible to select melt compositions with melting points below the temperatures used to carry out most of petroleum refining and petrochemistry processes such as pyrolysis and cracking of petroleum hydrocarbons, oxidation of alcohols and alkylaromatic hydrocarbons and production of monomers.

Analysis of the published data shows that the principles of selection of the chemical composition of molten and solid catalysts do not differ much. For example, the chemical composition (in particular, the content of vanadium with the oxidation state +4 in the KVO₃–V₂O₅ melt) was found to correlate with specific oxygen desorption from the melt and its catalytic activity with respect to ethanol oxidation.^{85, 87} It is noteworthy that the relationship between the nature of the transition metal oxide added to the K₃V₅O₁₄ melt and the catalyst activity in the oxidation of ethanol (Fig. 1) is similar to the relationship established⁸⁸ for solid catalysts.

In the oxide catalysts with a more complex chemical composition, the dependence of the catalytic activity on the composition is more complicated. Thus for the oxidation of ethanol, the curve for the activity of the K₃V₅O₁₄–MoO₃ melt vs. the content of MoO₃ has three maxima for MoO₃ concentrations of 13.3 mol %, 20.5 mol % and 34 mol % (*i.e.*, for molar ratios K₃V₅O₁₄:MoO₃ = 2:1, 1:1 and 1:2, respectively).^{85, 87} However, the curve for solid catalysts having a simpler composition, V₂O₅–MoO₃, has only one maximum at a MoO₃ content of about 30 mol %. The lack of other maxima on the catalytic activity curve can be attributed to the formation, on the surface of catalyst grains, of a compound with the same composition (irrespective of

Figure 1. Correlation between the catalytic activity of the $K_3V_5M_{0.33}O_{14}$ melts in the oxidation of ethanol at 500 °C and specific desorption of oxygen from these melts at 600 °C.

M: (1) Ni, (2) Ba, (3) Cr, (4) Co, (5) Al, (6) none, (7) Ti, (8) Zn, (9) Fe, (10) Fe (V : Fe = 7), (11) Pb, (12) Sn, (13) Sb, (14) Bi, (15) Ag, (16) W, (17) B, (18) Mo, (19) Mn, (20) Cu.

the amount of MoO_3), which is thermodynamically more stable under these conditions.

A clear correlation between the catalytic activity of melts based on vanadium oxides in oxidative dehydrogenation of ethylbenzene and the content of vanadium +4 in the melts has been noted.⁸⁰ The rate of transformation of ethylbenzene into styrene on $K_2O-V_2O_5-V_2O_4$ melts was found to decrease with a decrease in the V_2O_5 concentration. The extrapolation to a zero rate shows the lack of activity for a catalyst with the composition 6 mass % V_2O_4 , 69 mass % V_2O_5 and 25 mass % K_2O . In the phase diagram of the $K_2O-V_2O_5-V_2O_4$ system, this composition corresponds to the bronze $K_{(2+2x)}V_2O_{16}$ ($x = 0.35-0.45$)⁸⁹ the presence of which in solidified samples taken from the melt was proved by powder X-ray diffraction.⁸⁰ For solid-phase catalysts it was found⁹⁰ that the phase Ψ of the $K_2O-V_2O_5-V_2O_4$ system containing 3 mol % – 8 mol % V_2O_4 exhibits the lowest activity in the oxidation of *o*-xylene as compared with other formulations of the same system. In the oxidation of alcohols, the activity of the molten $K_2O-V_2O_5$ catalyst is governed by the $KV_4O_{(10.5-x)}$ concentration.^{81,85} The activity of the solid catalyst with the same composition in the oxidation of naphthalene was also higher than the activity of other potassium vanadates.⁹¹

The similarity of action of a catalytic system in the solid or molten states can be revealed by comparing the reaction rates at temperatures above and below the catalyst melting point. The results obtained are useful for solving the problem concerning the role of the chemical composition and the solid surface in the catalysis.

The kinetic parameters for catalytic reactions proceeding on melts and on the solid phase have been compared by many researchers (see, for example, Refs 75, 85, 92–94). In particular, the activation energies of some oxidation reactions at temperatures below and above the catalyst melting points were determined.^{75,85,92} Presumably, the invariable activation energy of the process on going through the melting point can serve as evidence for the predominant influence of the chemical composition of the

catalyst rather than the pattern of its surface on the reaction rate. However, the decrease in the activation energy upon melting observed in some cases is attributable to the fact that the process occurs not only on the surface but also in the bulk of the molten catalyst. For example, oxidation of SO_2 to SO_3 on the $K_2S_2O_7-V_2O_5$ melt proceeds both on the melt surface and in the bulk, depending on the conditions, which was established in a study of the thickness of an ‘operating’ catalyst film.^{76,92,95} This results in a more than twofold decrease in E_a for the reaction on melts compared with the reaction on the solid catalyst surface.⁶² The activation energy also increases upon partial crystallisation of the melt.⁷⁶ High solubility of sulfur dioxide in the $K_2S_2O_7-V_2O_5$ melt was also proved.^{75,76}

The decrease in the activation energy upon passing the catalyst melting point is not common to all the studied reactions. Thus the activation energy for elimination of HCl from alkyl chlorides is the same for catalysis by $ZnCl_2$ solid phase and melt,⁹³ which is explained by the fact that the process occurs only on the melt surface. Analogous data were obtained for oxidative dehydrogenation of ethylbenzene on the $KVO_3-V_2O_5$ catalyst applied onto alumina grains,⁹⁶ and also for benzene oxidation on vanadium oxide catalysts.⁹⁴

A similar dependence of the activation energy on the catalyst aggregation state was found in the oxidation of hydrogen chloride on $CuCl_2$ melt.^{38,97} On solidification of the molten catalyst, the activation energy of this reaction sharply increases.

Oxidation of naphthalene on the $K_2SO_4-V_2O_5$ melt has been investigated.⁹⁷ The activation energy for the reaction on the melt was found to be lower by 36 kJ mol^{−1} than that on the solid catalyst with the same composition. No data on the solubility of naphthalene in the melt of the given composition are available from the literature; however, according to calculations, molecules with sizes greater than the size of the benzene molecule (about 0.6 nm) are poorly soluble in such systems. For example, the solubility of naphthalene in potassium chloride melt was calculated to be 10^{-12} g·mol (cm³ Pa)^{−1} at 400 °C.⁹⁸ The solubility of CO_2 (the size of the molecule is ~0.3 nm) in the $Li_2CO_3-Na_2CO_3-K_2CO_3$ eutectic melt at 700 °C found experimentally equals 9.5×10^{-7} g·mol (cm³ Pa)^{−1} (Ref. 99). The enhanced solubility of CO_2 in alkali metal carbonate melts was attributed⁹⁹ to the formation of the dicarbonate ion:

In the oxidation of naphthalene on the potassium–vanadium–sulfate melt, the rates of naphthalene consumption and oxygen adsorption are proportional to the surface area of the melt and do not depend on its volume.⁹⁷ Therefore, the decrease in the E_a for naphthalene oxidation upon passing of the catalyst from the solid to the molten state can hardly be attributed to occurrence of the reaction in the melt bulk.

The few kinetic data presented above were obtained for processes differing in the nature of the substrate, the composition of the catalyst and reaction conditions. The E_a values for the formation of acetaldehyde from ethanol on a number of molten

Table 1. Activation energy for the formation of acetaldehyde from ethanol on molten and solid catalysts.⁸⁵

Catalyst composition (mol %)			T_m /K	E_a /kJ mol ^{−1}	
K_2O	V_2O_5	M_xO_y		$T < T_m$	$T > T_m$
30.7	48.8	20.5 (MoO_3)	698	76	76
37.0	59.1	3.9 (NiO)	673	113	58
37.0	59.1	3.9 (Ag_2O)	673	91	94
35.6	56.8	7.6 (SnO_2)	683	118	85
37.0	59.1	3.9 (Sb_2O_5)	673	140	79
37.0	59.1	3.9 (Mn_2O_3)	668	80	80

and solid catalysts containing V_2O_5 and other transition metal oxide additives were determined⁸⁵ (Table 1). These data were obtained under identical conditions for catalysts with similar compositions; therefore, their comparison is more vivid than a comparison of the results reported by different authors. The activation energy of the reaction remains unchanged or increases on going from the melt to the solid phase. The different influence of transition of the catalyst through the melting point on E_a can hardly be attributed to the catalytic action of the bulk of the melt. It is unlikely that the addition of 4 mass %–7 mass % of NiO , SnO_2 and Sb_2O_5 would sharply increase the solubility of ethanol in the $K_2O-V_2O_5$ melt, while the same amounts of molybdenum, silver and manganese oxides would not affect the solubility. The assumption that the mechanism of ethanol oxidation changes on passing from high to low temperatures (from 650 to 570 K) on some systems also appears doubtful in view of the fact that on other systems this mechanism is retained.

It is worth noting that the pattern of dependence of the activity of $K_3V_5O_{14}-MoO_3$ catalyst on the MoO_3 content (from 0 mol % to 60 mol %) in the ethanol oxidation is the same at 823 K (melt) and at 673 K (solid phase). Presumably, the structure of the catalyst active sites does not change significantly upon the melt solidification.

The results presented in Table 1 were obtained for catalysts in the solid and molten states. In this case, the possibility of melt solidification to give glasses cannot be ruled out. The structures of the molten and glassy catalysts are similar; therefore, their catalytic activity is the same. Raman and IR spectroscopic data show¹⁰⁰ that the local ordering is the same in both glassy and molten $ZnCl_2$, but differs from that in crystalline zinc chloride. The similarity of structures of glasses and melts for the $K_2SiO_3-KAlSi_3O_8$ systems was established¹⁰¹ on the basis of Raman spectra. The conclusion concerning the identity of the structural units of the melts and 'quenched' glasses was also derived from the IR spectra of sodium metaphosphate.¹⁰²

The results of X-ray diffraction studies of high-temperature melts led researchers¹⁰³ to conclusion that an increase in the temperature to a value 400–700 °C above the T_m changes only slightly the short-order parameters of the mutual arrangements of atoms.

In the case where cooling is accompanied by crystallisation of the system, the environment of the active sites and the distances between them can sharply change with respect to those in the liquid state. This might account for the difference in the activities of catalysts having the same composition in the solid and molten states. For example, in crystalline vanadium(V) oxide, according to the FT EXAFS X-ray absorption data, the V–O bond lengths are 0.16 and 0.19 nm, while after melting the bond lengths become equal to 0.18 nm.¹⁰⁴ Other researchers¹⁰⁵ have shown by X-ray scattering that amorphous V_2O_5 obtained by superfast cooling of the vanadium(V) oxide melt has a tetrahedral coordination with a V–O distance of 0.18 nm. The formation of either amorphous or crystalline product depends on the cooling rate of the melt. The cooling rate that is critical for the amorphisation of melts and the duration and temperature of incubation are determined by the difference between the ionic radii and the thermal conductivity of components.¹⁰⁶

This phenomenon is responsible for the increase in the activity of crystalline silicate catalysts after the 'heat shock'. For increasing the activity, the catalyst is first heated at a rate of 0.5–560 K s^{−1} to 1200 °C, kept for 0.1 to 1200 s and rapidly cooled to 500 °C.^{107, 108} A short heating of superconductor oxide compositions to a temperature of 1000 °C (above T_m) at a rate of ~2000 K min^{−1} followed by cooling at a rate of 100 K min^{−1} is also proposed in another study.¹⁰⁹

The validity of assumptions that the structure of active sites and the distances between them are crucial for the catalyst activity could be verified by investigating the transition of the catalyst from the solid to the molten state: for all catalysts of the same type,

the activation energy of the same reaction should decrease upon this transition. In addition, the dependence of E_a on the aggregation state of the system presented in Table 1 might change for the oxidation of other organic compounds on these catalysts. Unfortunately, no facts either supporting or disproving these assumptions are now available.

Thus, when working with molten catalysts, one can determine quickly and reliably the correlations between the structures of compounds present as catalyst components and the catalyst activity and to reproduce more precisely the definite ratios of the catalyst components, which is important for the search for conditions for selective formation of the target products.

V. Electrochemical control of the activity and selectivity of molten catalysts

Due to high electrical conductivity of molten metal oxides and salts, catalytic processes can be carried out under conditions of electrolysis.^{110–113} The electrochemical treatment is especially topical for catalytic oxidation of organic compounds accompanied by a change in the oxidation state of transition metals in the catalyst. For example, V_2O_5 widely used as a component of oxidation catalysts is reduced to vanadium(IV) under the reaction conditions.^{85, 110, 114–118} Vanadium(V) is regenerated ($V^{4+} \rightarrow V^{5+}$) under the action of oxygen present in the reaction mixture; as a rule, this is the rate-limiting step for the whole catalytic oxidation of organic compounds.^{80, 92, 110, 119} It has been shown⁸⁰ that in the oxidation of ethylbenzene, the vanadium(IV) concentration in the molten $KVO_3-V_2O_5$ catalyst depends on the ratio of the partial pressures of oxygen and the hydrocarbon. The redox reactions in the melts containing vanadium oxides can also occur during electrolysis; by varying electrolysis parameters, one can obtain specified phases of vanadium oxide bronzes.¹²⁰ The catalytic activity of the vanadium oxide-based melts in the oxidation of organic compounds can be controlled by varying the redox potential of the medium.¹²¹

The changes in the equilibrium potential of the $K_2O-V_2O_5-M_xO_y$ melts depend on the amount of oxygen evolved from the melt,^{83, 122, 123} which, in turn, depends on the rate constant for ethanol oxidation on these catalysts (Fig. 2). The electrochemical control of the catalyst activity includes the change in the redox potential of the medium and the shift of the equilibria in the system. The results of electrochemical studies provide grounds for predicting the catalytic activity of molten oxide–salt systems in the oxidation.

The effect of the redox potential of the $KVO_3-V_2O_5$ melt on the course of ethanol oxidation has been studied.^{111–113} The changes in the redox (for acetaldehyde and CO_2) or acid–base (for ethylene) properties of the melt can be derived from the ratio of the products.

In reality, all three reactions occur simultaneously giving rise also to by-products: C_2H_6 , CO , CH_4 , CH_3COOH .

The conversion and the ratio of the products of ethanol oxidation on melts containing 100 mass %, 90 mass % and 72 mass % of KVO_3 (823 K, molar ratio oxygen : ethanol = 1.5, contact time 0.5 s) depend on the electrode potential.

The dependence of the composition of ethanol oxidation products on the magnitude and sign of the working electrode potential indicates that the oxidation of ethanol under the conditions studied proceeds in the catalyst melt, and regeneration of the catalyst occurs upon electrochemical reactions on the electrodes. Thus, electrochemical processes yield mediators (electron carrier catalysts), which change the catalytic characteristics

Figure 2. Dependences of the emf (ΔE) of the galvanic cell $\text{Pt}, \text{O}_2 | \text{K}_3\text{V}_5\text{O}_{14} || \text{K}_3\text{V}_5\text{O}_{14} + \text{M}_x\text{O}_y | \text{Pt}, \text{O}_2$ (open circles) and rate constant (at 500 °C) for ethanol oxidation (closed circles) vs. specific desorption (D) of oxygen from the melt for $\text{K}_3\text{V}_5\text{O}_{14} + \text{M}_x\text{O}_y$ systems with different chemical composition for $\text{M} : \text{V} = 1 : 15$.

Additive (M): (1) Al, (2) B, (3) Ba, (4) Bi, (5) Ca, (6) Co, (7) Cr, (8) Cu, (9) Fe, (10) Mn, (11) Ni, (12) Pb, (13) Sb, (14) Sn, (15) Ti, (16) W, (17) Zn.

of the melt, in particular, the reaction rate, selectivity and direction.¹²⁴

The features of transformation of ethanol on the $\text{K}_3\text{V}_5\text{O}_{14}$ or NaOH melts and their solutions in the LiCl–KCl melt are determined by the nature, redox properties and the redox potential of the melt components.^{112, 113, 115} Over the whole range of potentials studied (from +1 to –1 V), the conversion of ethanol and the yield of acetaldehyde upon electrolysis proved to be higher than in the case where the melt was not subjected to electrolysis.

VI. Oxidation of organic compounds

1. Partial oxidation

a. Alkanes and alkenes

The catalytic oxidation of methane yields ethylene (oxidative dimerisation of methane) and liquid hydrocarbons (ethylene oligomerisation). This process is important for practical purposes,^{125–127} because its use on a commercial scale would provide conversion of natural gas into monomers and liquid motor fuel. However, despite the extensive research dealing with optimisation of this process, the conversion of methane in this reaction is only 3%–20%, the selectivity with respect to liquid hydrocarbons varies from 40% to 70%, and the yield of C_2 hydrocarbons does not exceed 25%.¹²⁵

A number of patents^{125, 128, 129} propose the use of melts as catalysts for the oxidative dimerisation of methane. The molten catalysts are composed of mixtures of metal oxides, alkali metal carbonates or sulfates and a reducible transition metal oxide (Mn, Sn, Sb, Pb, Bi, etc.). Transition metal oxides insoluble in the melt and not melting at the reaction temperature should better be fixed on a support that forms a suspension in the salt melt. For better dispersion of the initial gas mixture, particles inert with respect to the melt (the so-called immersed packing) can be added. When the melts are used, the methane conversion is carried out at a temperature of 500–1000 °C and at a pressure of 0.01–3 MPa. The

methane to oxygen volume ratio in the initial mixture varies from 1 to 50. The methane conversion reaches 24%, while the selectivity with respect to higher hydrocarbons, equal to 57%, increases upon a decrease in the methane conversion, as the process follows a parallel-consecutive mechanism.¹²⁵

Lithium carbonate melt was used as the catalyst of oxidative coupling of methane.¹³⁰ The experiments were carried out in a bubble column reactor. In order to keep lithium in the form of carbonate, CO_2 was added to the reaction mixture. It was found that on a Li_2CO_3 –MgO melt (powdered magnesium oxide), the selectivity with respect to hydrocarbons markedly increased with temperature, while the yield of CO decreased with the amount of CO_2 remaining the same. The researchers note that no catalyst deactivation usual for fixed-bed reactors takes place in the bubble reactor.

The oxidative dimerisation of methane on a $\text{Ba}(\text{OH})_2$ melt at a temperature of 800 °C and the ratio $\text{CH}_4 : \text{O}_2 = 3 : 1$ has been studied.¹³¹ The conversion of methane reaches 20%, while the selectivity of formation of C_2 products equals 33%–38%. The authors assumed¹³¹ that the process involves peroxide structures such as the superoxide ion $\text{O}_2^{\cdot -}$, which are stabilised upon enhanced basicity of the medium due to dehydration of $\text{Ba}(\text{OH})_2$. An increase in the basicity increases also the conversion of methane and the yield of C_2 hydrocarbons.

The oxidation of methane to give formaldehyde on a potassium nitrate melt has been studied.^{132, 133} The process is catalysed most likely by NO species formed upon decomposition of potassium nitrate.

The oxidation of methane on sodium metaphosphate-based melts containing transition metal compounds was accompanied by reduction of Cr(VI), V(V) and Co(III) to lower oxidation states.¹³³ The concentration ratio of ^{18}O and ^{16}O isotopes in the melt on bubbling of air or a methane–air mixture was studied by mass spectrometry. The results led the authors to a conclusion that the oxidation of methane on a Na_3PO_3 melt containing d-metal ions involves both reversibly dissolved molecular oxygen (extensive oxidation of methane) and oxygen incorporated into an oxygenated metal complex (partial oxidation of methane).

Oxidation of methane with oxygen on a Na_2MoO_4 melt containing V_2O_5 and $\text{K}_4\text{B}_2\text{O}_7$ has been reported.¹³⁴ Despite the changes in the temperature, catalyst composition, the volume feed rate of the reaction mixture and the methane : oxygen ratio, high yield of formaldehyde could not be attained. Similar results have been obtained on an HPO_3 melt with iron oxide additives.³² It is noteworthy that methane conversion and the selectivity of formation of partial oxidation products on solid catalysts are also low.¹³⁵

The oxidation of alkanes and alkenes in molten media are widely studied in order to develop methods of preparation of commercially important monomers, buta-1,3-diene (divinyl) and 2-methylbuta-1,3-diene (isoprene). In the oxidative dehydrogenation, oxygen and its mixtures with hydrogen sulfide, ammonia and sulfur dioxide are used as hydrogen atom acceptors. Eutectic mixtures of metal chlorides, viz., lithium and potassium, sodium and potassium, and magnesium and calcium chlorides serve as molten catalysts, which also contain up to 20 mass % of Group II, IV and VII metal chlorides as promoters.¹³⁶ Presumably,¹³³ the use of melts provides easy solution of the problem of heat withdrawal from the reaction zone owing to high thermal conductivity and melt circulation. The isothermal character of the process results in a higher selectivity with respect to the oxidative dehydrogenation products. For example, bubbling of a butane, hydrogen sulfide, air and ammonia mixture in a 1 : 4 : 2 : 8 molar ratio through molten lithium, potassium and manganese chlorides at 650 °C affords divinyl in a 52% yield, the total yield of divinyl and butenes being 70%.

The dependences of the degree of conversion of n-butane and selectivity of formation of C_4 alkenes on the nature of the melt have been studied.²⁸ The relatively high yields of alkenes are also

observed for molten sodium, potassium and cadmium chlorides (39.9 mass % Cd) or molten lithium and potassium chlorides (37.2 mass % K). The effect of addition of some other metal chlorides on the oxidative dehydrogenation of butane was studied. It was found that barium and manganese chloride additives decrease the conversion of n-butane but increase the yield of alkenes. The conversion of butane increases with an increase in the hydrogen sulfide concentration in the mixture. The selectivity with respect to C₄ alkenes is maximum at a hydrogen sulfide to butane molar ratio of four and decreases upon further increase in the amount of H₂S due to extensive oxidation of hydrocarbons and the formation of sulfur-containing compounds (mainly, thiophene) and elemental sulfur.

It has been proposed¹³⁷ to carry out the oxidative dehydrogenation of alkanes and alkylbenzenes on molten lithium and lead iodides at 500–650 °C in the presence of iodine for hydrocarbon oxidation in a two-chamber reactor. The process is described by the following reactions (for a divalent metal):

Molecular iodine is generated *in situ* upon the oxidation of metal iodides. Saturated hydrocarbons react with iodine to give the target products and HI, which is absorbed by the melt. The metal iodides present in the melt are reoxidised by oxygen in another compartment. This allows one to eliminate direct contact of the hydrocarbon with oxygen, which is a stronger oxidant than I₂ and thus to decrease the formation of complete oxidation products. The results of a study of hydrocarbon reactivity suggest a free radical mechanism of oxidative dehydrogenation of alkanes in the presence of iodine.¹³⁷ Despite the high conversions of hydrocarbons and the selectivity of alkene formation (for ethane, these values are ~80% and >90%, respectively), industrial implementation of this method is precluded by high cost, volatility and high corrosion activity of iodine.

The CuCl–KCl melt pre-saturated with air was used¹³⁸ to convert ethane into acetaldehyde in ~75% yield. On air bubbling, CuCl in the melt is oxidised to CuO·CuCl₂. Apart from acetaldehyde, this reaction affords vinyl chloride.

The results of kinetic and mechanistic studies of the oxidative dehydrogenation of propane on a LiOH–LiI melt have been reported.¹³⁹ At 600 °C and a propane:air ratio of 1:2, the selectivity with respect to propylene is equal to ~75% and that with respect to benzene is 7%–14%. The reaction proceeds by a radical mechanism, the yield of propylene being mainly governed by the concentration ratio of the (Prⁿ)[•] and (Prⁱ)[•] radicals.

A patent¹⁴⁰ describes a process of preparation of acetaldehyde from C₂ hydrocarbons (ethane with ethylene impurity) on transition metal (Mn, Ni, Fe, Cu, Co, Cr) chloride melts in an air flow in the temperature range of 370–540 °C at a pressure of 0.1–1.5 MPa and a contact time from 1 to 60 s. At a <12% conversion of ethane, the selectivity with respect to acetaldehyde reaches 50%–80%.

The oxidation of propylene with oxygen on bubbling the reaction mixture through a KVO₃ melt in the temperature range of 500–650 °C has been studied.¹⁴¹ Since the optimum temperature was lower than the melting point of the catalyst, the yield of aldehydes decreased with increasing temperature.

The partial oxidation of propane on melts representing complex mixtures of potassium, sodium, tungsten, molybdenum and vanadium oxides as well as B₂O₃, K₂Cr₂O₇ and NaOH has been studied.¹⁴² It was found that, for some melts, the conversion of propane in a flow-type bubble reactor at 580–600 °C reaches 70%–90% at rather high yields of carbonyl compounds. K₂Cr₂O₇, NaOH and B₂O₃ melts proved inapplicable for this

reaction due to irreversible changes in the catalyst, including reduction, transformation into carbonate and sublimation, respectively.

b. Aromatic hydrocarbons

Oxidative dehydrogenation. Alkylbenzenes, for example, ethyl- and isopropylbenzenes are readily converted into the corresponding alkenylarenes on LiI and PbI₂ melts in the presence of iodine. At a high conversion of the starting hydrocarbon (up to 99%), the reaction selectivity reaches 95%.¹³⁷ Propylbenzene is converted into a mixture of allyl- and *cis*- and *trans*-propenylbenzenes. As the side chain of the hydrocarbon becomes longer, the fraction of the cracking products increases. Indeed, ethane and styrene are produced in almost equal amounts upon dehydrogenation of n-butylbenzene, while the major reaction product is naphthalene resulting from dehydrocyclisation (yield 72%).¹³⁷

The oxidative dehydrogenation of ethylbenzene by oxygen on a molten KVO₃–V₂O₅ catalyst has been studied in most detail.^{46, 56, 79, 80, 96} In particular, the activities of the catalyst in the molten and the solid states were compared and the mechanism of the process and its separate steps was studied.^{56, 80, 96}

The kinetics of the oxidative dehydrogenation of ethylbenzene on an alumina-supported melt KVO₃–V₂O₅ (22 mol %) has been studied in a flow-type setup with a rotating catalyst, which ruled out the influence of mass transfer on the process rate.⁹⁶ This reaction gave styrene (St) and CO₂.

At temperatures of 450–550 °C and ethylbenzene and oxygen partial pressures of 3.7×10^{-3} – 6.7×10^{-3} MPa and 3.3×10^{-3} – 6.25×10^{-3} MPa, respectively, this process is described by the following kinetic equations:

$$V_{\text{EtPh}} = k_1[\text{EtPh}]^{1.12}[\text{O}_2]^{0.68},$$

$$V_{\text{St}} = k_1[\text{EtPh}]^{1.12}[\text{O}_2]^{0.68} - k_2[\text{St}]^{0.53}[\text{O}_2]^{0.53},$$

$$V_{\text{CO}_2} = k_2[\text{St}]^{0.53}[\text{O}_2]^{0.53},$$

where V_{EtPh} , V_{St} , V_{CO_2} are the consumption rate of ethylbenzene and the formation rates of styrene and carbon dioxide, respectively, k_1 and k_2 are the rate constants for reactions (1) and (2).

It was found⁸⁰ that the accumulation of V₂O₄ in the melt is accompanied by the formation of a complex, inactive in oxidative dehydrogenation of ethylbenzene, with a composition corresponding to the bronze χ . From the temperature dependence of the rate constants for oxygen sorption in the KVO₃–V₂O₅ melt, it was found that oxygen is sorbed by the melt in two forms differing in the activation energies: 170.8 kJ mol^{−1} at 500–550 °C and 327.3 kJ mol^{−1} at 550–600 °C. In the temperature range of 500–550 °C, the removal of oxygen from the melt results in an increase in the catalyst activity in oxidative dehydrogenation of ethylbenzene.

Molten catalysts are suitable not only for the oxidation of organic compounds, but also for the synthesis of complex molecules containing more carbon atoms than the starting compound. Alkyl-substituted aromatic hydrocarbons (for example, toluene and xylenes) and heteroaromatic compounds [for example, picolines (methylpyridines)] form dimerisation products on alkali metal hydroxide melts.^{143–145} These oxidative dehydrodimerisation reactions are currently the subject of extensive research,

because their mechanism resembles that of methane conversion into liquid hydrocarbons.

It was found¹⁴⁴ that the transformation of toluene on alkali metal hydroxide melts proceeds as follows:

The bibenzyl formation step is highly sensitive to the nature of the melt. The melts with high basicity catalyse efficiently dimerisation of toluene. The conversion of toluene on the NaOH and KOH melts and their mixtures is much higher than on the melt composed of a sodium and potassium chloride mixture. The conversion of toluene increases if up to 10 mass % of vanadium(V) or phosphorus(V) oxide is added to the alkali metal hydroxide melt.¹⁴⁴

A study of the transformations of *o*-, *m*- and *p*-xylenes on a sodium hydroxide melt has shown that, apart from the dimerisation products, the reaction mixture contains the corresponding methylstyrenes.¹²² The reactivities of the *meta*- and *para*-isomers were almost the same; the selectivity of formation of *m*- and *p*-methylstyrenes, respectively, from these isomers was also the same. The selectivity of formation of *o*-methylstyrene was almost four times lower due to steric effect on the dimerisation. This is consistent with the assumption that transformations of methylbenzenes (in particular, toluene and xylenes) involve the intermediate formation of benzyl radicals. Thus the enthalpies of formation of *meta*- and *para*-methyl-substituted benzyl radicals are 124 kJ mol⁻¹ (Ref. 146) and the enthalpy of formation of unsubstituted benzyl radical is 188 kJ mol⁻¹. This is why the observed conversion of toluene is much lower than that of xylenes.

An increase in the catalyst acidity decreases the yield of dimers, while the yield of products of more extensive oxidation of hydrocarbons increases. An acidic catalyst, namely, V₂O₅-K₂SO₄ melt supported on SiO₂ converts toluene into oxygen-containing products, benzoin (2-hydroxy-1,2-diphenylethanone) and benzil (diphenylethanedione), in the presence of atmospheric oxygen at 400–450 °C.¹⁴⁴ No stilbene or bibenzyl were detected among the reaction products.

In a similar experiment, 2-methylpyridine was converted into 2-pyridoin (1) and 2,2'-pyridil (2). The proposed reaction mechanism involves the formation of a benzyl-type heterocyclic radical (Scheme 1).

On an eutectic melt KVO₃-V₂O₅ containing 12 mass % of MoO₃, toluene is converted into benzaldehyde and benzoic acid, and methylpyridines are converted into pyridine. In the presence of γ-Al₂O₃-supported K₂CO₃, KOH, KCl and KNO₃ catalysts, methylpyridines are converted into pyridine, CO₂ and water. No methylpyridine dimerisation products were detected. An increase in the temperature, content of air in the reaction mixture or the contact time results in higher yields of 1,2-dipyridylethylenes 3. Note that the conversion of 3-methylpyridine is lower than that of 4-methylpyridine.¹⁴⁵

As noted above, the mechanisms of dehydrodimerisation of methylbenzenes and methylpyridines on basic catalysts are similar to the mechanism of oxidative dimerisation of methane. In the latter reaction, the formation and dimerisation of radicals occur on the catalyst surface and subsequently the dimerisation products pass to the gas phase. Presumably, oxygen-containing products are formed from ethane 4 and ethylene 3 derivatives (see Scheme 1), which were found among the reaction products.

Scheme 1

However, upon the toluene oxidation catalysed by V₂O₅-K₂SO₄/SiO₂, no toluene dimerisation products (bibenzyl or stilbene) were detected.

The difference between the composition of products formed on basic and acidic catalysts is due to the difference between the heats of adsorption of organic molecules on different surfaces. Higher heats of adsorption of aromatic and heteroaromatic molecules on acidic catalysts and, as a consequence, an increase in the contact time of the molecule with the catalyst account for more extensive oxidation of the dimerisation products of methylpyridines on the V₂O₅-K₂SO₄/SiO₂ catalyst.

Apparently, the reaction of toluene or picolines with a basic catalyst involves the methyl groups (as in the case of oxidative dimerisation of methane), while in the case of acidic catalysts the substrate is adsorbed upon interaction of the catalyst with the aromatic π-system.

Dimerisation of aromatic amines PhNRR' (R, R' = H, Me) in a NaCl-KCl mixture of molten salts containing Lewis acids (AlCl₃ or ZnCl₂) to give benzidines has been studied with varied temperature, reaction time, reactant ratio and salt and gas phase compositions.¹⁴⁷

R, R' = H, Me.

The highest yield of benzidines was obtained at 150–200 °C in the presence of oxygen. If amine is used as a base, small amount of chlorobenzidines is formed, whereas the use of aniline hydrochlorides results in chlorinated derivatives as the major products (> 50%). The molecular chlorine formed *in situ* upon the oxidation of HCl serves as the chlorinating agent. The dimerisation of amines is markedly influenced by the nature of the Lewis acid, weaker acids such as ZnCl₂ or SnCl₄ being inefficient in this reaction. When two different amines are introduced in the reaction, a mixture of two symmetrical and one asymmetrical benzidines is formed. High regiospecificity of aniline dimerisation was noted: the reaction involves exclusively the *para*-position with respect to the amino group of the most stable σ-complex A formed upon the reaction of aniline with the Lewis acid.

Ammoxidation process. A number of US patents describe one-step synthesis of nitriles, amides, amines and other nitrogen-containing compounds by conjugated oxidation of organic compounds and ammonia on treatment with molecular oxygen in the gas phase on transition metal oxide melts.^{61, 148–152}

For example, ammoxidation of propane on Mn, Co, Cr, Cu chloride and oxychloride melts yields acrylonitrile.¹⁴⁹ In the ammoxidation of the reaction mixture composed of propane, ammonia, air and oxygen on molten copper and potassium chlorides at a contact time of 4.8 s, the conversion of propane was 21%, while the acrylonitrile content in the products was 52.8%.

An eutectic $K_2O-V_2O_5$ mixture was proposed as the MC for ammoxidation.^{61, 150–152} In this case, the process can be carried out in the absence of oxygen in the reaction mixture.¹⁵⁰ For example, a mixture of *m*-xylene and ammonia (molar ratio ~ 0.3) was converted into a mixture (mol %) of benzonitrile (9.49), toluenitrile (58.05) and isophthalonitrile (4.02). The conversion of *m*-xylene was 15.23%.¹⁵⁰ For implementing a continuous process, simultaneous melt regeneration under the action of atmospheric oxygen has been proposed.⁶¹

Benzaldehyde and phthalic anhydride. The oxidation of alkylaromatic hydrocarbons or naphthalene to give benzaldehyde or phthalic anhydride is accompanied by evolution of a large amount of heat, resulting in a sharp increase in the temperature in the reaction zone, which may induce thermal decomposition of the target products. In order to withdraw heat evolved upon toluene oxidation, Volynkin¹⁵³ proposed placing the suspended or floating catalyst, molybdenum oxide supported on ferrochrome grains or crushed MoO_3 , into molten metals or alloys. The yield of benzaldehyde increased in this case to 20%–30% (based on the converted toluene). The product composition depended on the nature of the molten metal. In particular, the yield of benzaldehyde was higher when MoO_3 was suspended in an aluminium alloy. Meanwhile, molten lead was converted into lead oxide under the reaction conditions, and lead oxide catalysed further oxidation of benzaldehyde.

The oxidation of toluene to benzaldehyde on a series of molten catalysts consisting of vanadium or molybdenum oxide or their mixtures doped with sodium, potassium, copper, silver and tin oxides has been studied.¹⁵⁴ As the temperature of the liquid catalyst decreased from 670 to 550 °C, the yield of benzaldehyde sharply decreased, as on solid catalysts. Volynkin studied the oxidation of benzene and phenol into maleic anhydride using the same catalytic systems. The highest activity was found for the catalysts the electrical conductivity of which does not change much upon melt solidification.

The oxidation of *o*-xylene on the $K_2S_2O_7-K_2SO_4-V_2O_5$ melt using electrochemical methods has shown that potassium sulfate not only serves as the solvent for V_2O_5 but also as a reactant involved in the oxidation.¹¹⁰ Regeneration is carried out using the V^{5+}/V^{4+} redox system, which serves as a ‘relay switch’ between the S^{6+}/S^{4+} and O^0/O^{2-} electrochemical pairs. The reduction of the sulfate by the hydrocarbon and the oxidation of vanadium(IV)

by molecular oxygen may be the rate-limiting steps. The reaction orders for the overall oxidation process with respect to *o*-xylene and oxygen are 0.5 and 1.2, respectively. The activation energy is 79 kJ mol⁻¹, which almost coincides with the activation energy for the oxidation of *o*-xylene on solid vanadium catalysts reported in a review.¹⁵⁵

The major naphthalene oxidation products in a molten eutectic mixture of K_2SO_4 and $K_2S_2O_7$ in the presence of V_2O_5 include phthalic and maleic anhydrides and naphthoquinone, the last-mentioned compound being an intermediate in the anhydride synthesis.^{156, 157} For a constant air to naphthalene volume ratio, the yields of the products depend most appreciably on the V_2O_5 concentration.

c. Oxygen-containing organic compounds

The vapour-phase oxidation of C_1-C_4 aliphatic alcohols on heterogeneous catalysts is an industrial method for the production of carbonyl compounds. The oxidation of ethyl and propyl alcohols on $K_2O-V_2O_5$ (5 mass %–24 mass %) melts by a flow-type bubble method has been studied.^{45, 158–162} As the catalyst operates and vanadium(IV) is being accumulated in the melt, the yield of aldehydes somewhat increases. After the equilibrium between the oxidation and vanadium reduction has been attained, the degree of conversion of the alcohol becomes constant.

Studies of the transformation of alcohols in an oxygen and nitrogen atmosphere have shown¹⁵⁹ that the qualitative composition of the products in these reactions is the same. It was thus concluded that the process follows a redox mechanism at the expense of oxygen atoms contained in the melt components. The presence of molecular oxygen in the reaction mixture promotes oxidative dehydrogenation, while the lack of oxygen is favourable for dehydration of the alcohol.

The oxidation of isopropyl alcohol on the $KVO_3-V_2O_5$ eutectic melt in a flow mode has been studied.^{132, 163} On the basis of IR, ¹H NMR and EPR spectroscopic data, it was assumed that the alcohol is first oxidised by vanadium compounds and then the reduced forms of vanadium are reoxidised by molecular oxygen.¹⁶³

The kinetics of the oxidation of n-butanol, n-butanal and n-butyl n-butyrate ($Pr^nCO_2Bu^n$) by chemically bound (lattice) oxygen of the melt with the empirical formula $K_{21}V_{35}O_{107}$ has been studied by pulse chromatography.⁴⁷ The studies were carried out in the temperature range of 430–550 °C in a bubble-type reactor with the bubbling height of the melt varying from 2 to 16 cm. The qualitative composition of the oxidation products proved to be the same for all three compounds; however, their ratios were substantially different.⁴⁷ Under the experimental conditions, the degree of conversion (x) of the initial compounds reached 80%–90% and the reaction slowed down with time. From the decrease in the process rate with an increase in x , it follows that the kinetic dependences are described by the Frost equation

$$k = \frac{1}{\tau} \log \frac{1}{1-x} - \frac{\beta x}{\tau}, \quad (3)$$

where the parameter β (inhibition coefficient) is the slope of the straight line $(1/\tau) \log [1/(1-x)]$ vs. x/τ (τ is time).¹⁶⁴ A comparison of the k values calculated from Eqn (3) and the E_a values demonstrated that in terms of stability against oxidation, these compounds can be arranged in the sequence: butyl butyrate > butanal > butanol.

The oxidation of dimethyl ether to formaldehyde has been studied.^{165–168} The reaction was carried out with oxygen by the flow method in the bubbling mode under atmospheric pressure in the temperature range of 400–500 °C. Melts consisting of Li, K, Na, Mo, V, P oxides (>60 formulations) were used as the catalysts. In the case of melts consisting of vanadium and molybdenum oxides promoted by alkali metal oxides and small amounts of other oxides at an optimum temperature of 420–440 °C, the conversion of dimethyl ether was 45%–54% and the selectivity with respect to the target product (formaldehyde) was 90%–99%. The latter value is much higher than the selectivity (70%–80%) obtained with solid oxide catalysts. A mechanism of the process has been proposed¹⁶⁵ according to which the ether reacts with molybdenum(VI), which results from oxidation of Mo(V) with vanadium pentoxide, with transfer of electrons to the molecular oxygen. The degree of conversion of dimethyl ether increases with an increase in the number of reduced Mo and V ions.

2. Extensive oxidation of organic compounds

The extensive catalytic oxidation and destruction of organic compounds on molten catalysts are of interest, first of all, as environmentally safe methods for waste utilisation. Other applications of these reactions are to produce heat¹⁶⁹ and generate synthesis gas by the reforming of carbon black residues (tar, coke) with steam.⁶⁵

The oxidation of formaldehyde by atmospheric oxygen in molten $\text{KVO}_3\text{--KBr}$ (20 mol %) ($T_m = 491$ °C) and LiCl--KCl (47 mol %) ($T_m = 352$ °C) eutectic mixtures in a flow-type bubble reactor has been studied in the 550–800 °C and 400–800 °C temperature ranges, respectively.¹⁷⁰ At 500 °C, the conversion of formaldehyde in the lithium and potassium chloride melt exceeds 32%, whereas in the gas phase (upon thermal decomposition), it reaches 98%. The oxidation in the salt melts is more mild, as follows from the high content of CO in the products; in the gas phase, the aldehyde is oxidised to CO_2 .

Complete and fast oxidation of organic wastes to carbon dioxide and water is often carried out on MC containing vanadium pentoxide.⁵² Unlike the known methods of incineration of organic compounds in the media of molten metals, glasses and slags,¹⁷¹ the oxidation in the presence of V_2O_5 -based melts can involve not only atmospheric oxygen, but also the oxygen from vanadium(V) oxide. Hence, it is possible to supply the organic feedstock and oxygen to the reactor separately or to carry out oxidation of organic compounds with vanadium pentoxide in one reactor zone and oxidation of the formed vanadium(IV) in another zone and thus to avoid the formation of explosive mixtures.⁶³

The incineration of organic wastes on molten catalysts occurs at the interface. Chain oxidation cannot immediately propagate to the bulk of compounds fed to the reactor; therefore, the process occurs smoothly, under isothermal conditions, and the heat evolved during incineration is absorbed by the molten catalyst, which has a high heat capacity and high thermal conductivity. For example, the $\text{K}_2\text{O}_5\text{--V}_2\text{O}_5$ melt (with a V_2O_5 content of 40 mass % to 83 mass %) was used to oxidise wastes from the production of phthalic anhydride (tar)⁵² and nitrobenzene,^{52,53} while their incineration in usual furnaces is accompanied by explosion. For this reason, these wastes are usually diluted with water prior to combustion, which reduces the efficiency of using the supplied heat and requires combined fuel combustion.

Molten mixtures of inorganic salts, alkali metal oxides and transition metal oxides are also used as catalysts for the oxidation of carbon monoxide.¹⁷²

The possibility of detoxification of mixed organic wastes containing radionuclides using catalytically active melts has been studied.^{172–174} Depending on the nature and concentration, the radioactive metal ions can either be retained in the melt or precipitate, which leads to the necessity of melt regeneration.¹⁷³ The oxidation of model extractants containing uranium and

plutonium in melts based on alkali metal carbonate has been carried out. Analysis of the effluent gases and the melt composition after completion of the experiments showed high efficiency of oxidation of organic components from radioactive wastes and complete absorption of phosphorus and radionuclides by the melt.¹⁷³

A method for processing of solid urban wastes by fusion in a bubbled slag melt has been proposed.^{66–68,175,176} Owing to the manufacture of special design reactors in which unique aerohydrodynamic conditions are produced, solid urban waste particles of various sizes are captured by melt drops, get into the high-temperature region and pass to the liquid (molten) state. Fast heating to a temperature above 1250 °C in ambient atmosphere promotes complete oxidation of organic compounds, and fast cooling of the gaseous products contemplated by the process flow diagram prevents the transformation of the feedstock components into dioxins.¹⁷⁷ This process flow diagram has passed pilot tests.⁶⁸

a. Oxidation of organohalogen compounds

Let us consider extensive oxidation processes of organohalogen compounds and disposal of polymeric materials in more detail.

Molten catalysts are suitable for extensive oxidation of halogen-containing organic compounds,^{122,178–180} while their oxidation on solid catalysts is complicated by the reactions of Cl_2 and HCl formed with components of the catalyst. The demand for an effective catalyst for the oxidation of halogen derivatives is due to the fact that the amount of such wastes reaches 1.5×10^6 tpy in Russia alone.¹⁸¹ In addition, neutralisation of fluorine-containing compounds, which are components of chemical weapons now becomes a highly topical problem. Extensive oxidation on molten electrolytes is also used for this purpose. Thus exhaustive oxidation of sarin and soman in molten alkali metal salts was recommended in the USA for large-scale destruction of chemical agent stockpiles.^{182,183} As a method for extermination of chemical weapon components, their catalytic destruction by metal melts at high temperature has been considered.¹⁸⁴

An attempt to carry out extensive oxidation of polychlorobiphenyls on the molten $\text{KVO}_3\text{--V}_2\text{O}_5$ (60 mass %) catalyst supported on alumina in a flow-type tubular reactor at 600–750 °C has been undertaken.¹⁸⁵ The kinetic and energetic parameters of the process were determined. Carbon oxides and HCl were found to be the major products under these conditions.

Chlorodioxins present in wastes are neutralised by the reaction with molten salts¹⁷³ or by incineration after pre-treatment with molten metallic sodium.¹⁸⁶ Pilot plant tests carried out for a long period of time demonstrated the efficiency of oxidation of toxic organic compounds such as polychlorobiphenyls and tetrachloroethylene on melts.¹⁷³

The company ATG Inc. (USA) developed an industrial process ensuring the destruction of halogen-containing wastes based on injection of the material to be treated into a sodium carbonate melt or melts of other similar salts.¹⁸⁷ At 650–700 °C, organohalogen components are destroyed to give non-toxic salts (e.g., sodium chloride). It was noted¹⁸⁷ that this process is 30%–40% less expensive than the traditional method of waste disposal by incineration followed by gas scrubbing.

The company Molten Metal Technology Inc. (USA) proposed¹⁸⁸ performing neutralisation of toxic chlorine-containing wastes using a reactor containing a molten metal acting as the catalyst. The wastes are thus converted into utilisable products such as CO , HCl , ceramics, metallic alloys, and the exhaust gases of the reactor do not contain dioxins or chlorodibenzofurans.

Organohalogen compounds are also oxidised by treatment in a tank with a melt through which an oxygen-containing gas mixture is passed.¹⁸⁹ The melt contains an alkaline earth metal and an alkaline earth metal halide. The halogen formed upon extensive oxidation of wastes reacts with the metal; as a result, the alkaline earth metal halide is accumulated in the melt. This

method is rather expensive due to the high cost of the alkaline earth metal; however, its use for treatment of highly toxic substances seems to be cost-effective.

A method for treatment of exhaust gases from waste incinerators used for hazardous wastes (chlorinated organic compounds) has been proposed¹⁹⁰ and prepared for commercial use. The oxidation occurring on a molten eutectic mixture of Na, Li and K carbonates at 700–800 °C does not require any expensive construction materials. The effluent gases of the reactor contain less than 0.01 % of the initial organic compounds.

The results of a study on extensive oxidation of halogen-containing compounds, *viz.*, CHCl₃, CCl₄, and fluorocarbon fluid M-1, on molten catalysts I–X (Table 2) depending on the temperature, air feed rate and the nature of the substrate have been reported.^{122, 179} It was shown that the extensive oxidation of CCl₄ and CHCl₃ on catalyst I yields CO₂, Cl₂ or HCl. However, these compounds are absent in the effluent gases, as they are absorbed by the melt. In the oxidation of CCl₄ and CHCl₃ on catalyst II, carbon dioxide appears in the effluent gases in the very beginning of the experiment, and its concentration gradually increases. The degrees of conversion of CCl₄ and CHCl₃ increase from ~99.0% at 350 °C (the ratio air : substrate = 1.8) to 100% at 400 °C. The conversion of chlorohydrocarbons reaches a maximum with a decrease in the load on the catalyst. The reactor effluent gases first contain no chlorine (it reacts with sodium and potassium hydroxides) but after long-term experiment, chlorine appears. Chloride anions were found in the spent catalysts. The presence of sodium and potassium chlorides in the catalysts was confirmed by powder X-ray diffraction data. In the case of catalyst IV (*T*_m = 710 °C), no complete oxidation of halohydrocarbons is observed even at 720 °C and the reaction products contain CO.

Table 2. Composition of the molten catalysts for extensive oxidation of halogen-containing compounds.^{124, 174}

Catalyst	Primary melt	Additives (mass %)
I	NaOH–KOH (eut.)	–
II	NaOH–KOH (eut.)	V ₂ O ₅ (10)
III	NaOH–KOH (eut.)	CuO (10)
IV	Na ₂ CO ₃ –K ₂ CO ₃ (eut.)	–
V	Na ₂ CO ₃ –K ₂ CO ₃ (eut.)	V ₂ O ₅ (10)
VI	Na ₂ CO ₃ –K ₂ CO ₃ (eut.)	V ₂ O ₅ (15)
VII	LiCl–KCl (eut.)	–
VIII	LiCl–NaCl–KCl (eut.)	–
IX	LiCl–NaCl–KCl (eut.)	V ₂ O ₅ (10)
X	LiCl–NaCl–KCl (eut.)	V ₂ O ₅ (15)

When air is bubbled through melt IV containing V₂O₅ (10 mass %), the reactor effluent gases contain CO₂, resulting from thermocatalytic decomposition of carbonates. Thus, during catalyst preparation, CO₂ is removed due to the reaction of sodium and potassium carbonates with V₂O₅ and oxygen. However, CO₂ formed upon passing of CCl₄ and CHCl₃ vapours through the melt and their oxidation is absorbed by the melt. Hence, in the early period of catalyst operation, the CO₂ concentration in the reaction products is lower than that calculated theoretically, while at 650 °C, it approaches the calculated value.

The results of investigation of the oxidation of fluorohydrocarbon fluid M-1 on melts I, IV, VI–X have been reported.^{122, 179} Upon saturation of these melts with atmospheric oxygen (without supply of the fluorohydrocarbon), evolution of chlorine from catalysts IX and X was noted. The oxidation of chloride ions to molecular chlorine by V₂O₅ and atmospheric oxygen attests to the possibility of melt regeneration.

It was shown that fluorine and hydrogen fluoride formed upon decomposition of fluid M-1 are absorbed by the melt. The

best properties as regards extensive oxidation were found for the melt of sodium and potassium carbonates having the eutectic composition with the addition of 15 mass % of vanadium pentoxide. However, the chloride melt X containing 15 mass % of V₂O₅ showed better stability against fluoride ions and molecular fluorine. The transformation pathway of fluorinated fluid M-1 depends appreciably on the nature of the melt. In the case of melts IV and VIII, thermal decomposition of fluid M-1 and oxidation of the pyrolysis products by atmospheric oxygen take place. In the case of doping of alkali metal chloride or carbonate melts with vanadium pentoxide, which reacts with alkali metal ions and catalyses the formation of CO₂ from carbonates and the formation of molecular chlorine from chloride ions, fluorinated fluid M-1 undergoes catalytic oxidation.

It was shown by differential thermal, elemental and powder X-ray diffraction analyses¹⁷⁹ that the oxidation of halohydrocarbons on molten catalysts NaOH–KOH (eut.), Na₂CO₃–K₂CO₃ (eut.) or LiCl–NaCl–KCl (eut.) containing V₂O₅ affords an equilibrium mixture containing alkali metal hydroxides, carbonates, halides and vanadates and vanadium oxide bronzes, their ratio in the mixture depending on the partial pressures of the halogen, CO₂, water vapour and oxygen. Based on these studies, a catalyst for extensive oxidation of halogenated compounds stable against halogens was proposed, in particular a LiCl–NaCl–KCl (eut.) mixture containing 15 mass % of V₂O₅.

The process of gaseous chlorine evolution from melts has been described.^{122, 191} The NaCl–V₂O₅ (5 mass %, 10 mass %, 20 mass %) and NaCl–NaVO₃ (13.4 mass %) systems were studied in an inert atmosphere and in the presence of atmospheric oxygen at 820 and 880 °C as molten catalysts for extensive oxidation of organohalogen compounds. The derivatograms of the samples obtained by fusing NaCl with 10 mass % of V₂O₅ in air or with continuous air supply to the melt at a rate of 2.5 litre h^{–1} exhibit endothermic effects corresponding to the melting points of NaCl (780 °C), the NaVO₃–Na₂V₅O_{13.3} eutectics (525 °C) and sodium metavanadate (630 °C). The derivatogram of the NaCl–V₂O₅ (10 mass %) sample molten in air shows an endothermic effect indicating the presence of the NaV₆O₁₅ bronze (670 °C). The derivatogram of a sample of the NaVO₃ melt recorded after bubbling CCl₄ (fed as a liquid at a rate of 2 ml h^{–1}) for 3 h and air (2.5 litre h^{–1}) through the melt contains minima corresponding to the melting points of NaVO₃ (630 °C) and NaCl (800 °C). The endothermic effect at 525 °C is due to melting of the NaVO₃–Na₂V₅O_{13.3} eutectics. The Na₂V₅O_{13.3} bronze results from the reaction of sodium metavanadate with chlorine formed upon oxidation of CCl₄. The mass of the catalyst samples does not change over the temperature range studied.

When air is bubbled through a NaCl melt at 820 °C, no molecular chlorine is evolved. Chloride ions might be oxidised with oxygen to give oxides, peroxides and superoxides, but the equilibrium constants of these reactions are low.¹⁹² If V₂O₅ has been added to the NaCl melt, molecular chlorine does form, its amount increasing with an increase in the V₂O₅ concentration and with increasing temperature.

The initial reaction products formed in the NaCl–V₂O₅ system are oxide bronzes, β-type NaV₆O₁₅ and κ-type Na₂V₅O_{13.3}.^{193, 194}

Then the Na₂V₅O_{13.3} bronze is converted into NaVO₃:

The oxidation of chloride ions in an inert atmosphere is due to the redox reaction accompanied by partial reduction of vanadium(V) to vanadium(IV) to give the β-type NaV₆O₁₅ bronze [reaction (4)].

Figure 3. Kinetics of chlorine evolution from the NaCl + 10 mass % V_2O_5 melt depending on the nature of bubbled gas at 820 °C: (1) CO_2 then air, (2) N_2 then air. The gas feed rate is 2.5 litre h^{-1} (Ref. 117).

It has been found¹⁹¹ that the amount of chlorine evolved upon bubbling of nitrogen or carbon dioxide through the NaCl– V_2O_5 (10 mass %) melt is the same and is much lower than that in the case of passing of atmospheric oxygen through this melt (the initial sections of the curves in Fig. 3). If the gas bubbled through the melt is replaced by air, the amount of the evolved chlorine sharply increases (see Fig. 3).

The dynamics of chlorine formation in the NaCl– $NaVO_3$ (13.4 mass %) melt upon bubbling of air (volume flow rate 2.5 litre h^{-1}) has been studied.¹²² The concentrations of sodium metavanadate formed in this mixture and in the NaCl– V_2O_5 (10 mass %) system in the presence of air are the same in the case of complete transformation of V_2O_5 (Table 3). The reaction affords sodium divanadate. The amount of chlorine evolved in this case is minor and the rate constant for the reaction of $NaVO_3$ with NaCl is about two orders of magnitude lower than that for the formation of chlorine in the NaCl– V_2O_5 system. In an inert atmosphere (bubbling of pure CO_2), almost no chlorine is evolved.

Table 3. Rate constants for the oxidation of chloride ions according to reaction (4) for the NaCl– V_2O_5 systems.¹²²

Air passing mode	Content of V_2O_5 (mass %)	$T/^\circ C$	$10^4 k_1/s^{-1}$
Bubbling	5	820	0.59 ± 0.03
Bubbling	10	820	0.79 ± 0.02
	10	880	1.31 ± 0.13
Surface	10	820	0.69 ± 0.03

Presumably, under these conditions, V_2O_5 is first converted into non-stoichiometric compounds corresponding in composition to vanadium oxide bronzes and then into more stable $NaVO_3$. Thus, equal rate constants for the oxidation of Cl^- with air bubbling through the NaCl– V_2O_5 systems suggest simultaneous existence and fast interconversion of vanadium-containing compounds.

The reactivity of vanadium compounds in the oxidation of Cl^- decreases in the sequence $V_2O_5 \gg NaV_6O_{15} \gg Na_2V_5O_{13.3} \gg NaVO_3$. Upon an increase in the temperature and partial pressures of oxygen and chlorine, the rate of transition of one species into another becomes higher than the oxidation rate of the chloride ion. Therefore, when using the NaCl– V_2O_5 system as the catalyst for extensive oxidation of chlorinated organic compounds, the catalyst activity can be controlled by varying the conditions of the process and the composition of the initial mixture.

The apparent activation energy for the oxidation of Cl^- in the NaCl– NaV_6O_{15} – O_2 system was determined. The relatively high value (109 kJ mol^{-1}) indicates that diffusion has a slight influence on the chlorine evolution.

The interactions in the NaCl– M_xO_y (where $M = Cu, Co, Cr, Mo, Sb$) and NaCl–CuCl systems in air or nitrogen atmosphere were studied by differential thermal, powder X-ray diffraction and elemental analyses. The activity of these catalysts in the oxidation of chloride ions was found to depend on the nature of the metal oxide and to decrease in the sequence:¹⁹⁵ $CrO_3 > V_2O_5 > V_2O_5 + Sb_2O_5 > MoO_3 > Sb_2O_5 > Cr_2O_3 > Co_3O_4 > CuCl$.

In the absence of oxygen, the oxidation of chloride ions takes place in the reaction of sodium chloride with vanadium, chromium(VI) and molybdenum oxides. When the reaction mixture contains oxygen, metal oxides act as catalysts of the oxidation of chloride ions by oxygen; as a result, regular evolution of chlorine is observed.

The results of studies of chloride ion oxidation to chlorine indicate that one can select NaCl– M_xO_y systems containing mixtures of transition metal oxides that would ensure that a rate of chlorine formation and evolution from the melt would be commensurable with the rate of chlorine supply from extensive oxidation of halohydrocarbons. Thus, these catalysts would also be suitable for the latter process.

b. Disposal of polymers

It has been proposed⁷¹ to clean metal cord and fixtures from polymeric materials by extensive oxidation of the polymers (burning at 350–600 °C) in a molten catalyst with air bubbling through the melt. The NaOH–KOH melt with 5 mass %–10 mass % of transition metal oxide added is used as the catalyst. The relatively low temperature of the process rules out the formation of nitrogen oxides and the catalytic oxidation of compounded rubber is not accompanied by evolution of gaseous organic compounds or soot. The metal wire is recovered from the processed wastes from reinforced hoses, where the polymers contain mixed rubbers, low density polyethylene, plasticisers (dibutyl phthalate, paraffin, rosin, etc.), or from cord debris obtained from waste automobile tyres by pressing,¹⁹⁶ where different amounts of compounded rubber could be present.

The rate of extensive oxidation of compounded rubber and polymeric materials depends on the amount and the nature of transition metal oxides added. The carbon dioxide formed upon the oxidation of polymers is partly absorbed by the melt, together with the sulfur (IV and VI) oxides formed upon oxidation of compounded rubber. This yields a mixture of salts. In the presence of atmospheric oxygen and water vapour, alkali metal carbonates present as components of the melt can partially decompose to give carbon dioxide; therefore, the spent catalyst represents a mixture of carbonates, sulfites and sulfates as well as transition metal salts; as a result, the melting point of the mixture increases.

VII. Conclusion

Analysis of the properties and possible applications of MC demonstrates that molten metals, metal oxides and salts can be successfully used as the media and the catalysts for various processes. Depending on the melt composition and the nature of the organic compound that reacts with the melt, this can function as a solvent, a chemical reagent or heterogeneous or homogeneous catalyst. The high rate of heterogeneous exchange of the components of a melt containing transition metal oxides with the gas-phase oxygen, the high thermal and electrical conductivities of these systems and the simplicity and reproducibility of the catalyst preparation stage and the activity parameters allow researchers to use molten oxides and salts for mechanistic studies of catalytic reactions and for establishing the composition–catalytic activity relationships. The physicochemical properties attest to advantages of molten catalysts over other types of catalysts, especially as

regards oxidation of organic compounds accompanied by substantial heat evolution, coking or formation of explosive mixtures.

The electrical conductivity of molten oxides and salts allows one to use electrochemical methods for increasing the catalytic activity; this enhances the reliability of operation of reactors in the case of violation of the organic compound to oxygen ratio.

Promising applications of molten electrolytes are those for treatment of exhaust gases and destruction of chemical production wastes. By varying the physicochemical properties of these systems over wide limits, it is possible to use diverse techniques and equipment for the treatment processes and separate and utilise compounds with complex chemical compositions and aggregation states present in the wastes.

Molten salts and oxides demonstrate high stability and capacity (the bulk of the melt rather than only the surface, as in the solid catalysts, is involved in operation) with respect to impurities, which are often poisonous for solid catalysts even when present in minor concentrations. Therefore, the starting compounds can be used without pretreatment and complex mixtures can also be processed using melts.

The use of melts based on alkali metal chlorides containing transition metal oxides, most often V_2O_5 , appears to be promising for the oxidation of chlorine-containing organic compounds. Vanadium(V) oxide increases the catalytic activity and durability of melt performance and improves the heterogeneous exchange between the catalyst and oxygen; thus, it becomes possible to separate the zone for melt saturation with oxygen (catalyst regeneration) and the zone for oxidation of organic compounds. Besides, the addition of V_2O_5 increases the catalyst service life, as it favours the evolution of CO_2 and Cl_2 from the melt giving rise to an equilibrium mixture of K, Na, OH, CO_3 , Cl and V ions in the reactor. The presence of V_2O_5 in the molten catalyst favours oxidation of aromatic hydrocarbons.

Molten catalysts can act as reagents with respect to the halogen evolved upon extensive oxidation of organic compounds; hence, trapping of toxic products by adsorbents is not required. According to published data,¹⁷³ burial of organohalogen compounds formed in the deactivation is more cost-effective than absorption of effluent gases in absorbing towers followed by neutralisation.

Due to the specific character of the catalysts and high cost of reactors used for the melt-catalysed oxidation, it is expedient to use this technique for combusting highly toxic wastes or wastes containing metals and halogens. Thus, it is better to design small-capacity units which can be combined into blocks if necessary. For destruction of highly toxic wastes, the incineration units can be placed into boxes and an additional treatment of the gaseous products formed can be provided.

Molten catalysts are promising systems for effective disposal of solid polymeric and metal polymeric wastes.

Thus, the prospects of development of this field are related to practical implementation of extensive oxidation and destruction of diverse wastes.

In conclusion, we would like to mention one more application of molten catalytic systems, which has not yet been practically implemented, namely, their use as solvents for metal complex catalysts of high-temperature processes such as dehydrogenation.¹⁹⁷

III. Analytical applications of tetrazolium ion-associated complexes	173
IV. Miscellaneous applications of tetrazolium salts in inorganic analysis	177
V. Conclusion	177

Abstract. The use of tetrazolium salts for extraction, spectrophotometric and potentiometric determination of various elements and ions is described. The optimum conditions for extraction of tetrazolium ion-associated complexes are analysed. Chromogenic and other systems derived from tetrazolium salts and their applications in the analysis of industrial and natural samples are discussed. The bibliography includes 118 references.

I. Introduction

Tetrazolium salts (TS) are heterocyclic compounds the five-membered rings in which contain four nitrogen atoms; one of these atoms bears a positive charge. The methods for synthesis, properties and applications of TS have been described.¹ Substituted TS usually contain up to three substituents, *viz.*, at the carbon atom in position 5 and at two nitrogen atoms. The following combinations of positions of substitution in the tetrazolium ring are possible: 1, 2, 5; 1, 3, 5; 1, 4, 5 and 2, 3, 5. The most extensively studied 2,3,5-trisubstituted TS (Table 1) are the topic of the present review.

The first tetrazolium salt, *viz.*, 2,3,5-triphenyltetrazolium chloride, was synthesised in the late 19th century independently by H von Pechman and E Bamberger. Tetrazolium salts attracted the attention of investigators by virtue of their ability to be converted into coloured formazans under the action of chemical and biological reducing agents. Commercial production of TS began half a century later. Tetrazolium salts came into wide use as redox indicators for determination of enzymes and other systems.^{1,2} At present, tetrazolium salts are among the most efficient reagents in cell biology designed for determination of metabolic activities of various cells (from mammalian to bacterial).² In addition, TS have found application as catalysts and photo-sensitive materials.¹

In the 1960–1970s, a new trend in the chemistry of TS emerged, namely, the chemistry of ion-associated complexes (IAC) of tetrazolium cations with simple and complex anions.^{3,4}

Unlike the original salts, these complexes are poorly soluble in water and can selectively be extracted with appropriate organic solvents. Due to the ability to form IAC, tetrazolium salts served as the basis for the development of analytical (*e.g.*, extraction–photometric, *etc.*) techniques for the determination of metal ions and non-metal derivatives incorporated in such complexes.

The first surveys^{3,4} of the extraction and analytical applications of tetrazolium ion-associated complexes (TIAC) published before 1983 appeared in 1984. Since then, numerous data have been reported on ion-associated complexes with different tetrazolium cations and their applications for the extraction of various ions and elements. Competitive extraction–photometric and potentiometric methods making use of TIAC and photometric and catalytic photometric methods based on TS reduction were also developed.

The aim of the present review is to generalise and to systematise the data on the applications of TS in inorganic analysis published between 1984 and 2006.

II. Preparation and properties of tetrazolium ion-associated complexes

Tetrazolium ion-associated complexes are crystalline compounds that are stable under ordinary conditions, poorly soluble in water and easily soluble in diverse organic solvents. They are decomposed upon heating to 180–220 °C (Refs 5 and 6) or under direct sunlight.^{3,4,7,8} In weakly basic solutions, *e.g.*, at pH ~10, the N(2)–N(3) bond of the tetrazolium ring is cleaved to yield coloured formazans.^{1,3,4,7}

The chromophore properties of TIAC usually represent a combination of chromophore properties of the constituent ions, *viz.*, tetrazolium cations and complex anions. This suggests the predominantly ionic nature of the chemical bond in TIAC. The tetrazolium salts absorb light in the visible and UV spectral regions, their absorption maxima usually lie at 200–260 nm with exception of MTT, which has an absorption maximum in the visible region (~380 nm).

TIAC are widely employed in analytical chemistry as components of extraction systems. They are used for both isolation of ions from complex mixtures and quantitative determination of metal cations and other inorganic ions in various natural and industrial samples by extraction–spectrophotometric methods. The properties of TIAC allow their extraction from aqueous solutions and govern the extraction characteristics of systems employed in the analysis (Tables 2 and 3). In addition to the general characteristics of the method (*e.g.*, solvents, extraction time, pH, *etc.*), these tables list the extraction constants (which

Note. Here and in Table 3, K_{ex} is the extraction constant ($K_{ex} = K_D \times \beta$); K_D is the distribution constant of the ionic associate between the phases; β is the stability constant of the associate (association constant) and R is the degree of extraction.

characterise the extraction in the system under consideration on the whole), distribution constants of the ionic associate between phases (*i.e.*, the concentration ratios in organic and aqueous phases), stability constants of ionic associates (which describe the associate formation in the aqueous phase) and the degree of extraction, *i.e.*, the percentage of the substance extracted into the organic phase.

Chloroform or dichloroethane are commonly used as an organic phase for extraction; benzene and n-butanol are used less often. Sometimes, the use of mixtures of these solvents^{67, 68} or their mixtures with ethers and acetone is more preferable.^{10, 44}

The extraction time varies from several seconds to several minutes. The relatively slow extraction processes of [Sb(OH)₂Cl₄]⁻ and [ReCl₆]²⁻ represent an exception, shaking for ~1 h is required.^{5, 42, 43} The difference between extraction

^a Abbreviations: NPC is 4-nitropyrocatechol; DHN is 2,3-dihydroxynaphthalene; PC is pyrocatechol; THBA is 3,4,5-trihydroxybenzoic acid; PG is pyrogallol; TAR, 4-(2-thiazolylazo)resorcinol; PAR is 4-(2-pyridylazo)resorcinol; DNC is 3,5-dinitropyrocatechol. ^b K Gavazov, unpublished data.

times of different TIAC can be used for ion separation and identification (qualitative analysis).

The composition of the extract can differ from the composition of the aqueous phase, this depends on a number of factors, *e.g.*, the nature of the central atom of the complex, its oxidation state, concentration of the starting reagents and pH.

Contrary to amines, tetrazolium cations can be used as IAC components without preliminary protonation. Therefore, the changes in the acidity of the aqueous phase do not prevent quantitative extraction of many inorganic anions, *e.g.*, ReO₄[−], [Zn(SCN)₄]^{2−}, [HgI₃][−], *etc.* in the form of the respective TIAC. At the same time, the control over pH is important for the extraction of complexes with metal-containing anions prone to hydrolysis (as a rule, the hydrolysed forms are not extracted) as well as complexes with organic ligands. For TIAC containing organic ligands with higher molecular masses, the pH optimum range tends to be broader (see Table 3).

The optimisation of reagent concentrations plays the key role in extraction and spectrophotometric measurements.

As TS are usually taken in a large excess, their concentrations (or changes in concentrations) have little effect on the results of analysis.⁴¹ Moreover, in many cases TS have beneficial effects. Thus it inhibits the reduction of V(V) to V(IV) by polyphenolic compounds such that vanadium(V) is stable in ternary complexes with chelating polyphenolic ligands.^{67,79} In contrast to other

cationic dyes, only in rare cases the excess of TS interfere with spectrophotometric measurements.⁶⁷ The concentration of a ligand involved in the formation of a complex anion was found to depend on its stability constant, it varies in a broad range.⁴¹

The results of several studies suggest^{41,75,86,87} that the association constant of TIAC is proportional to the molecular mass of the tetrazolium cation: the higher the molecular mass the higher the association constant. This ratio can be used for the prediction of the possibility of formation of associates^{41,86} and of the association constants of newly formed complexes in a given class of compounds.^{41,86,87} However, this ratio is violated if the tetrazolium cation of TS-based extraction systems contains a nitrophenyl substituent (Refs 72 and 75 and Fig. 1).

III. Analytical applications of tetrazolium ion-associated complexes

1. 1. Extraction – photometric analysis

Some characteristics of extraction – photometric methods for determination of certain elements as TIAC are presented in Table 4. Spectrophotometric determinations with such complexes (or their decomposition products) are usually carried out by measuring absorption in the UV or visible spectral regions.

All tetrazolium complexes strongly absorb light in the UV region. However, analytical applications of UV spectra are complicated due to high absorption of the reference sample (blank experiment) and specific requirements for equipment and solvents. Therefore, very often preference is given to methods that employ compounds specially designed for spectrophotometric measurements in the visible spectral region. These include, for example, MTT complexes, TIAC containing a coloured complex anion, conversion products of TIAC (formazans formed upon reduction of tetrazolium cations in basic media),^{31,45} complexes obtained by replacement of tetrazolium cations by coloured cations (*e.g.*, rhodamine B)⁴ and complexes produced in competitive reactions or their decomposition products.^{10,47,109,110}

The following approaches are used to increase the sensitivity of determination.

(1) Selection of an appropriate extraction system containing intensely coloured TIAC and solvents ensuring recovery close to 100%. In the context of this approach, MTT complexes containing yellow-coloured anions, *e.g.*, [Ge(NPC)₃]^{2−} (Ref. 48), are especially promising, since they contain two chromophore ions absorbing in the same spectral region.

(2) Extraction of large amounts of coloured complexes by small volumes of an organic phase.

To attain the required selectivity, special attention is paid to the selection of adequate extraction-photometric conditions, *i.e.*, wavelength,^{59,62,81,103,104} pH,^{77,82} reagent concentrations,⁶⁹ the order of their addition¹⁰⁷ and extraction time.^{82,84} Masking is also popular.

Some TIAC-based procedures are sufficiently selective to allow direct determinations without additional steps.

Figure 1. Dependence of the logarithm of the association constant of TIAC (β) on the logarithm of the molecular mass of the tetrazolium cation (M).

Anions: (1, 1') [VO₂(TAR)₂]^{3−}, (2, 2') [VO₂(PAR)₂]^{3−}, (3, 3') [Cd(SCN)₄]^{2−}, (4) [TiCl₄][−], (5) [HgI₃][−], (6) [CrO₃Cl][−], (7) [Zn(SCN)₄]^{2−}.

The values of β for tetrazolium ion-associated complexes containing nitro groups (INT⁺, NBT²⁺, TNBT²⁺) are lower than expected on the assumption that the association constant increases linearly with the molecular mass (solid lines).

^a The concentration range in which the signal is proportional to the analyte concentration enables quantitative determination. ^b Wavelength. ^c ϵ is the molar extinction coefficient (litre mol⁻¹ cm⁻¹) (the values were taken from the cited papers). However, they were not always calculated using standard methods and different volumes of the aqueous and organic phases were employed.

a. Determination of cobalt

The extraction-photometric procedure for determination of cobalt in soils^{17,88,89} and plants⁸⁸ is based on the formation of ion-associated complexes (NBT)[Co(SCN)₄]¹⁷ (TV)₂[Co(SCN)₄] (Ref. 88) and (MTT)₂[Co(SCN)₄] (Ref. 89) and their subsequent extraction with 1,2-dichloroethane in a broad pH range. The relative standard deviation (RSD), detection limit (DL) and molar extinction coefficient (ϵ) for the most sensitive procedure based on the use of TV are equal to 1.15%, 1.5×10^{-3} μ g ml⁻¹ and 4×10^4 litre mol⁻¹ cm⁻¹, respectively.⁸⁸

b. Determination of chromium

The interactions of solutions of Cr(VI) in hydrochloric acid with NT,¹⁹ NBT,²⁰ MTT,²³ TT,⁹⁰ INT⁹³ and TV⁹⁴ were studied by Kamburova *et al.* The complexes were efficiently extracted with 1,2-dichloroethane. Apparently, the Cr(VI)–TV complex is the most suitable for the determination of Cr(VI) in the presence of ascorbic acid and NH₄F as masking reagents in soils,⁹⁴ steels⁹⁴ and vegetables⁹⁶ [$\epsilon_{230} = 1.22 \times 10^5$ litre mol⁻¹ cm⁻¹, RSD = (0.4%–0.7%)].

The use of a ternary chromium(III) complex with thiocyanate and MTT for the determination of chromium in soils has been described;⁹ however, the sensitivity of this method is low ($\epsilon_{235} = 4.65 \times 10^3$ litre mol⁻¹ cm⁻¹).

c. Determination of germanium

Two procedures for the determination of Ge(IV) based on formation of ternary complexes with 4-nitropyrocatechol and extraction with chloroform have been described.^{48,49} The best of them⁴⁸ employs MTT ($\epsilon_{410} \approx 5.1 \times 10^4$ litre mol⁻¹ cm⁻¹). The interfering effects of Al³⁺, Fe³⁺ and Cr³⁺ are eliminated with Na-EDTA. The presence of Mo(VI), V(IV), W(VI), I⁻ and Cl⁻ interferes with the assay.

d. Determination of mercury

Determination of mercury in soils included extraction of mercury(II) halide complexes with chloroform.^{8,26–28,97} The complexes (TV)[HgI₃] and (TV)[HgBr₃] manifested the highest molar extinction coefficients (1.02×10^5 litre mol⁻¹ cm⁻¹ and 1×10^6 litre mol⁻¹ cm⁻¹, respectively).⁹⁷ Other fast and sensitive

methods for the determination of mercury(II) are based on the use of the complexes (INT)[HgI₃],²⁶ (TT)[HgI₃]²⁷ and (MTT)[HgI₃].²⁸ Ascorbic acid and fluoride ions were used as masking reagents.

e. Determination of iodide, iodate and periodate

A sensitive method for the determination of iodide ions in soils was developed by Kamburova.²⁹ It is based on extraction, with 1,2-dichloroethane, of ion-associated TV complexes with iodide oxidation products. Hydrogen peroxide was found to be the oxidant of choice. The majority of ions, except for Hg²⁺, BrO₃⁻ and S₂O₃²⁻, do not interfere.

The optimum complexation conditions in TS–iodate–iodide–dichloroethane and TS–periodate–iodide–dichloroethane systems have been studied. Two procedures for the determination of iodates and periodates in drinking water using (TT⁺)I₃⁻ and (INT⁺)I₃⁻ have been described.^{98,99} The procedure based on TT is more sensitive:⁹⁸ $\epsilon_{295} = (1.64 \pm 0.02) \times 10^5$ litre mol⁻¹ cm⁻¹ (for IO₃⁻), $\epsilon_{295} = (1.67 \pm 0.05) \times 10^5$ litre mol⁻¹ cm⁻¹ (for IO₄⁻). The presence of other ions has no interfering effect on the assay. The RSD value lies in the range from 0.8% to 1.3%.

f. Determination of manganese

Several methods were developed for the determination of manganese(VII) in natural and industrial samples.^{8,32–35,100} All of them included extraction, with 1,2-dichloroethane, of tetrazolium ion-associated complexes with the permanganate anion. Complexes with TT³³ and INT³⁴ were used for the determination of manganese in soils^{33,34} and steels³³ at $\lambda = 530$ nm; however, the sensitivity of these methods was rather low. Higher sensitivity was achieved through the use of MTT ($\epsilon_{250} = 1.0 \times 10^4$ litre mol⁻¹ cm⁻¹),³² TV ($\epsilon_{235} = 6.67 \times 10^4$ litre mol⁻¹ cm⁻¹)³⁵ and NBT ($\epsilon_{260} = 1.0 \times 10^5$ litre mol⁻¹ cm⁻¹)^{8,100} in the UV region. The NBT complex was used for the determination of manganese in diverse vegetable samples. Interfering ions were masked using saturated solutions of ascorbic acid. The RSD value did not exceed 1.8%.

g. Determination of molybdenum

A series of sensitive spectrophotometric procedures for the determination of molybdenum [$\epsilon_{430-445} = (1.94-2.41) \times 10^4$ litre mol⁻¹ cm⁻¹] using 4-nitropyrrocatechol and various tetrazolium cations were developed by Dimitrov *et al.*^{6,50–53} In particular, this method was used for the determination of molybdenum in ferrous metallurgy products. Other TIAC-forming reagents, *e.g.*, pyrogallol,⁵² 2,3-dihydroxynaphthalene¹⁰³ and 3,4,5-trihydroxybenzoic acid, are also employed.^{54,101,102} The use of 3,4,5-trihydroxybenzoic acid and MTT for the determination of molybdenum in soils⁵⁴ and vegetables¹⁰² (RSD = 1.1% and 1.9%, respectively) has been described. A highly sensitive procedure for the analysis of soils¹⁰¹ is based on the use of 3,4,5-trihydroxybenzoic acid and NBT ($\epsilon_{260} = 1.5 \times 10^5$ litre mol⁻¹ cm⁻¹) and does not require preliminary isolation of molybdenum.

A method based on the use of thiocyanate and MTT for the determination of molybdenum in lettuce has been described.³⁶ Fe(III) and V(V) ions were masked with oxalic and ascorbic acids; the RSD value did not exceed 1.2%.

A procedure for simultaneous determination of molybdenum, tungsten and niobium in steels with the use of their ternary complexes with 2,3-dihydroxynaphthalene and TT has been developed.¹⁰³ The determination of molybdenum was carried out at 625 nm; the total content of W + Mo and W + Mo + Nb was determined at 500 and 360 nm, respectively. Interfering ions were masked with EDTA. The RSD values for molybdenum,

tungsten and niobium were equal to (0.5–1.07)%, (4.0–6.9)% and (5.2–8.0)%, respectively.

h. Determination of niobium

Several methods based on the use of Nb(V) complexes with TS and polyphenols (4-nitropyrrocatechol,⁵⁷ 2,3-dihydroxynaphthalene^{59,103} and pyrocatechol⁶⁰) for the determination of niobium in steels have been developed. 4-Nitropyrrocatechol–TV⁵⁷ and pyrocatechol–TT systems⁶⁰ are more suitable for the analysis of steels containing no molybdenum or tungsten. Other interfering ions are masked with EDTA or ascorbic acid. If a steel contains 0.021% Nb, its RSD value is equal to 4.7%.⁵⁷

If a steel contains Mo(VI) or W(VI), the 2,3-dihydroxynaphthalene–TV system is used.⁵⁹ In the presence of W(VI), absorption was measured at 400 and 490 nm; in the presence of Mo(VI), at 400 and 582 nm. This approach can also be used,¹⁰³ if a steel contains simultaneously Mo and W (see Section III.1.g).

i. Determination of rhenium

ReO₄⁻ ions form ion-associated complexes with tetrazolium cations,^{37–39} which enables reliable determination of rhenium in industrial samples, *e.g.*, copper concentrates,³⁷ copper ores³⁸ and molybdenum concentrates.³⁹ Extraction with chloroform is carried out in a broad pH range. The method based on *p*-NT is the most sensitive ($\epsilon_{255} = 2.1 \times 10^4$ litre mol⁻¹ cm⁻¹) and selective.³⁷ The assay procedure is not interfered with by Mo(VI), Ni(II), Co(II), Cu(II), Fe(II), Mg(II), Mn(II), Cd(II), V(V) or W(VI). The RSD value is 2.1% at the rhenium content of $(1.58-1.75) \times 10^{-3}\%$.

j. Determination of titanium

Determination of titanium in aluminium alloys^{61–63} and steels⁶² is based on the use of its yellow-coloured TIAC involving 2,3-dihydroxynaphthalene,^{61,62} pyrocatechol⁶² and 4-nitropyrrocatechol.⁶³ The 4-nitropyrrocatechol–TV system⁶³ is the best for extraction in respect of sensitivity ($\epsilon_{440} = 4.4 \times 10^4$ litre mol⁻¹ cm⁻¹) and reproducibility (the RSD value does not exceed 1.05%). This system was used for the determination of titanium in aluminium alloys with ascorbic acid as a masking reagent.

The 2,3-dihydroxynaphthalene–TT system was used⁶² for simultaneous determination of titanium and tungsten in steels. The values of molar extinction coefficients were as follows: $\epsilon_{380} = 2.74 \times 10^4$ litre mol⁻¹ cm⁻¹ and $\epsilon_{470} = 0$ litre mol⁻¹ cm⁻¹ for titanium and $\epsilon_{380} = 6.33 \times 10^3$ litre mol⁻¹ cm⁻¹ and $\epsilon_{470} = 4.3 \times 10^3$ litre mol⁻¹ cm⁻¹ for tungsten. Interfering ions were masked with ascorbic acid. The RSD values for titanium and tungsten were equal to 3.5% and 2.0%, respectively.

k. Determination of thallium and antimony

Two methods for the simultaneous determination of antimony and thallium in cadmium were developed by Kostova *et al.*^{44,45} They are based on extraction, with an organic solvent, *e.g.*, benzene⁴⁵ or a benzene–ether system (3:1),⁴⁴ of thallium(III) and antimony(V) TIAC. Both procedures imply preliminary addition of an oxidising reagent to the tested solution containing Tl(I) or Sb(III).

Only Tl(I) undergoes oxidation to Tl(III) in dilute solutions of hydrochloric acid. However, in hydrochloric acid solutions of moderate concentration both Tl(I) and Sb(III) are oxidised to Tl(III) and Sb(V). Thus, variation in solution acidity enables stepwise determination of Tl(III) and Sb(V) in the same sample.

The first procedure is more simple.⁴⁴ The use of ternary complexes with MTT allows direct determination of Tl(III) and Sb(V) in the visible spectral region (at 400.5 nm). The RSD values for Tl and Sb are equal to 1.01% and 1.45%.

The second, more sensitive procedure⁴⁵ includes reduction of TV with $\text{NH}_2\text{OH} \cdot \text{HCl}$ to formazan which absorbs at 520 nm. The detection limit is $1 \mu\text{g ml}^{-1}$ for Tl and $0.5 \mu\text{g ml}^{-1}$ for Sb.

I. Determination of vanadium

It was recommended to use ternary TIAC with 4-nitropyrocatechol,^{65, 104} 2,3-dihydroxynaphthalene,⁶⁹ 4-(2-pyridylazo)resorcinol^{76, 77, 105–108} and 4-(2-thiazolylazo)resorcinol^{72, 105} for the determination of V(V) in the environment and in industrial samples. It was found that 4-(2-pyridylazo)resorcinol is the most sensitive and convenient reagent for the determination and identification of vanadium. If selective determination of V(V) is required, diaminocyclohexanetetraacetic acid (DCTA)⁷⁷ or DCTA + NH_4F are added to the solution as masking reagents^{106, 107} as a result of which V(IV) is masked. This method is employed in indirect determination of the V(IV) content from the difference in the absorption measured in the presence and in the absence of the reagent used for the oxidation of V(IV) to V(V).^{106, 107} The use of NH_4F as a secondary masking reagent results in instantaneous colouration and provides better selectivity with respect to definite ions including V(IV).^{106, 107} Determination of vanadium in various natural water samples,¹⁰⁷ aluminium alloys,¹⁰⁷ catalysts,^{86, 105, 106} steels⁷⁷ and soils¹⁰⁸ was carried out by varying detection parameters, such as the nature of TS, order of addition of the reactants, *etc.*

m. Determination of tungsten

A series of procedures for the determination of tungsten in steels and ferrotungsten have been developed. These methods are based on the formation of tungsten(VI) TIAC with 2,3-dihydroxynaphthalene,^{81–83} 3,5-dinitropyrocatechol⁸² and 4-nitropyrocatechol.^{82, 84} The highest sensitivity ($\epsilon_{415} = 2.80 \times 10^4$ litre $\text{mol}^{-1} \text{cm}^{-1}$) was achieved with 4-nitropyrocatechol and MTT.⁸⁴ The interfering effects of Fe(III), Al(III), Cr(III) and V(V) were eliminated by precipitation/coprecipitation at pH 11 in the course of sample preparation. The RSD value did not exceed 0.53%.

n. Determination of zinc

A series of spectrophotometric procedures for the determination of zinc in cadmium have been developed^{10, 47, 109, 110} based on predominant formation of thiocyanate cobalt complexes with TS cations in the presence of cadmium and their selective extraction. Blue-coloured cobalt complexes are formed upon addition of a cobalt salt, an excess of thiocyanate and a small amount of a tetrazolium salt to the tested sample:

The presence of Zn^{2+} ions in the system makes the blue colouration of the solution less intensive due to a shift of the reaction equilibrium towards less soluble weakly coloured zinc complexes:

It was found that the decrease in absorption at 630 nm is proportional to Zn^{2+} concentration in the tested solution in a rather broad range: $0.5\text{--}8 \mu\text{g ml}^{-1}$ (for a TV^+ complex),⁴⁷ $3.3\text{--}18.3 \mu\text{g ml}^{-1}$ (for a MTT^+ complex),¹¹⁰ $1.7\text{--}13.3 \mu\text{g ml}^{-1}$ (for a $p\text{-NT}^+$ complex)¹⁰⁹ and $0.75\text{--}8.75 \mu\text{g ml}^{-1}$ (for a TNBT^{2+} complex).¹⁰ The detection limit for zinc in cadmium can be decreased to $6.9 \times 10^{-3}\%$ in the presence of TV.⁴⁷

2. Application in potentiometric analysis

Two sensitive and selective potentiometric methods for the determination of Hg(II)¹¹¹ and Tl(III)¹¹² based on the ability of these ions to form ion-associated complexes with TT^+ have been described.

The use of the complex $\text{TT}[\text{HgI}_3]$ in the construction of a modified mercury-selective carbon paste electrode has been

described.¹¹¹ The electrode shows a stable, near-Nernstian response for $1 \times 10^{-3}\text{--}6 \times 10^{-6}$ mol litre⁻¹ $[\text{HgI}_3]^-$ (the anionic slope in the pH range 4.0–9.0 is 55.5 ± 0.4 mV). The lower detection limit is 4×10^{-6} mol litre⁻¹; the response time is 30–50 s. The interfering effects of the majority of tested ions were negligibly small. The electrode was used for direct determination of mercury in waste waters, metal amalgams and dental alloys.

The application of a membrane sensor based on $\text{TT}[\text{Ti}^{\text{III}}\text{Cl}_4]$ dispersed in a PVC matrix plasticised with dioctyl phthalate has been described.¹¹² The electrode shows a stable, near-Nernstian response at $1 \times 10^{-3}\text{--}4 \times 10^{-6}$ mol litre⁻¹ Tl(III) (the anionic slope is 56.5 ± 0.5 mV in the pH range 3–6). The lower detection limit is 2×10^{-6} mol litre⁻¹; the response time is 30–60 s. The electrode was successfully employed for the determination of thallium in spiked waste waters and zinc concentrates. The RSD value at $10 \mu\text{g ml}^{-1}$ was 1.6%.

IV. Miscellaneous applications of tetrazolium salts in inorganic analysis

A method for the determination of trace amounts of selenium based on its catalytic effect on the reduction of TNBT with dithiothreitol has been described.¹¹³ The method proved to be a simple, fast and efficient procedure for the determination of several forms of selenium. A similar procedure using the MTT–dithiothreitol system was used in the analysis of lobsters.¹¹⁴

A procedure for photometric determination of selenium in aqueous media (at the level of $10\text{--}120 \mu\text{g litre}^{-1}$) with 2-(*p*-nitrophenyl)-3,5-diphenyltetrazolium chloride was developed by Moskvina *et al.*¹¹⁵ The sample preparation step includes gas extraction of selenium (in the form of hydrogen selenide) followed by its liquid-adsorption extraction from the gaseous phase to an aqueous solution of reagents to yield water-insoluble formazan. A similar procedure¹¹⁶ based on 5-(benzo-1,3-dioxol-5-yl)-2-(4-iodophenyl)-3-phenyl-2*H*-tetrazolium chloride was used to determine arsenic at the level of $1\text{--}120 \mu\text{g litre}^{-1}$.

A method for determination of sulfur in steels, nickel alloys, chromium, tin, sodium dihydrophosphate, galena and $\text{RbAg}_4\text{I}_{5-x}\text{S}_x$ was developed by Kolesnikova *et al.*¹¹⁷ Here, the determination makes use of formazans formed upon reduction of TT, INT and NBT.

Nagaraja *et al.*¹¹⁸ developed a highly sensitive spectrophotometric method for the determination of silver ($\epsilon_{510} = 4.51 \times 10^5$ litre $\text{mol}^{-1} \text{cm}^{-1}$) that involves silver-enhanced reduction of TT with semicarbazide hydrochloride. This procedure was used for the determination of Ag(I) in photographic process waste water.

V. Conclusion

Tetrazolium salts are popular and readily available multifunctional reagents for liquid–liquid extraction, spectrophotometric and potentiometric determination of different ions and elements in environmental objects and industrial samples. Each tetrazolium-containing extraction system has its own advantages and disadvantages in terms of sensitivity, selectivity, accuracy, reliability and rapidity. On the whole, these systems are efficient and enable solution of complex analytical problems. The characteristics of some of these methods are comparable with those of atomic absorption spectrometry (AAS) and inductively coupled plasma–atomic emission spectroscopy (ICP–AES). However, in contrast with the latter, these methods are inexpensive and do not require costly equipment.

Altogether, these data suggest that complexes of the mono-tetrazolium salts MTT, TV and INT and of the ditetrazolium salt BT hold considerable promise for further investigations. Thus MTT is a convenient reagent for extraction and spectrophoto-

metric determination of colourless anions, while TV and INT having higher molecular masses form more stable and readily extractable complexes. The properties of INT complexes are less predictable, but their application offers a significant gain in sensitivity and/or selectivity. BT complexes are the least studied; however, there are strong grounds to believe that they are more efficient in comparison with other tetrazolium salts.

The authors thank Professor A V Alexandrov, former Head of the Department of General and Inorganic Chemistry of the Plovdiv University and recognised leader in the field, for helpful discussions and inestimable experience shared to the authors of this review.

Gold nanoparticles: preparation, functionalisation and applications in biochemistry and immunochemistry

L A Dykman, V A Bogatyrev

Contents

I. Introduction	181
II. Methods of preparation of colloidal gold	183
III. Functionalisation of gold nanoparticles	184
IV. Colloidal gold in solid-phase assays	185
V. Application of colloidal gold for the quantitative protein determination	186
VI. Application of gold nanoparticles in studies of biologically active compounds by vibrational spectroscopy	186
VII. Gold nanoparticles as antigen carriers	187

Abstract. The review summarises data on the synthesis and functionalisation of gold nanoparticles and their applications in biological investigations. Particular attention is given to applications of colloidal gold in solid-phase assays, immunoassay and studies of biologically active compounds by vibrational spectroscopy. A special section deals with the use of gold nanoparticles as antigen carriers in immunisation. The bibliography includes 406 references.

I. Introduction

Gold was one of the first metals discovered by humans, and the history of its study counts several thousands of years. First data on colloidal gold (CG) can be found in treatises by Chinese, Arabic and Indian scientists, who prepared CG and used it, in particular, for medical purposes as early as 5–4th centuries B.C. In the Middle Ages, alchemists in Europe actively studied and used CG. Probably, wonderful colour changes that accompany condensation of gold atoms prepared by reduction of salt solutions led alchemists to believe in transformations of elements, CG being considered as a panacea.¹ For example, Paracelsus wrote about the therapeutic properties of '*quinta essentia auri*,' which was prepared by reduction of gold chloride by ethanolic extracts of plants. In 1583, the doctor of the French king Louis XIII, the alchemist David de Planis-Campy, recommended the use of a colloidal solution of gold in water as an elixir of longevity. The first book on colloidal gold preserved to our days was published by the philosopher and doctor of medicine Francisco Antonii in 1618.² This book contains information on the formation of CG and its medical uses, including practical advices. From the mid-17th century, CG was used for the production of red (ruby) glasses, decoration on porcelain (purple of Cassius) and silk colouration.

The beginning of scientific research on CG dates back to the mid-19th century, when Michael Faraday published an article³ devoted to methods of synthesis and properties of CG. In this article, Faraday described, for the first time, aggregation of CG in the presence of electrolytes, the protective effect of gelatin and other high-molecular-mass compounds and the properties of thin films of CG. Colloidal gold solutions prepared by Faraday are still stored in the Royal Institution of Great Britain in London.

In the late 19th century—early 20th century, Richard Zsigmondy^{4,5} published a series of fundamental papers on the properties of CG. He was the first to describe methods of synthesis of CG with different particle sizes with the use of hydrogen peroxide, formaldehyde and white phosphorus as reducing agents and report on important physicochemical (including optical) properties of gold sols. Zsigmondy used colloidal gold as the main experimental object when inventing (in collaboration with Siedentopf) an ultramicroscope. In 1925, Zsigmondy was awarded the Nobel Prize in Chemistry 'for his demonstration of the heterogeneous nature of colloid solutions and for the methods he used, which have since become fundamental in modern colloid chemistry'.

Studies by the Nobel Prize laureate Theodor Svedberg on the preparation, analysis of mechanisms of colloidal gold formation and sedimentation properties of CG (with the use of the ultracentrifuge he had invented)⁶ are also among classical studies. Svedberg investigated the kinetics of reduction of gold halides and formulated the main concepts about the mechanism of formation (chemical condensation) of colloidal gold particles.

Later studies were concerned with various procedures for the synthesis of gold sols based on both disintegration of metallic gold by electric arc and (primarily) synthesis of colloidal particles from gold halides with the use of chemical reducing agents or irradiation.^{7–11}

Nowadays, colloidal gold is used by scientists as a perfect subject for studies of the optical properties of metal particles^{12–15} and fractal clusters¹⁶ and the mechanisms of aggregation and stabilisation of colloids.^{17–21} Colloidal gold is also applied in analytical chemistry,^{22,23} geomicrobiology, geobiochemistry²⁴ and photography.²⁵ Colloidal gold, unlike crystalline gold, shows a pronounced catalytic activity.²⁶ Colloidal gold immobilised on an electrode surface is used in investigations of catalytic processes and electron transport in biomacromolecules.²⁷

Examples of the application of CG in medicine, in particular, in colour reactions for proteins which are present in the cerebrospinal fluid and blood serum are documented.^{28,29} Methods

developed for these purposes are based on the properties of proteins to serve (depending on their physicochemical properties) as either flocculants or stabilisers of colloidal gold particles. Methods for the treatment of rheumatoid arthritis with CG solutions were developed.³⁰ Colloidal solutions of the ¹⁹⁸Au isotope (the half-life is 65 h) are successfully used for therapeutic purposes in oncology.³¹ Non-radioactive CG has found wide application in the diagnosis and treatment of cancer diseases.^{32–35}

Gold particles are used for studying the transport of substances into cells by endocytosis,³⁶ the delivery of genetic material to cell nucleus by biolistic transfection³⁷ and targeted drug delivery.³⁸

However, colloidal gold is most widely applied in medicine as an immunochemical marker. An ideal marker should be readily distinguishable with an electron microscope, have a specified size, shape and structure, be stable against aggregation, be strongly bound to biomolecules and not decrease their activity. Colloidal gold meets all these requirements. For the first time, colloidal gold conjugates with immunoglobulins were used as immunochemical markers in 1971.³⁹ After the publication in 1973 of the study by Frens⁴⁰ concerned with methods of synthesis of CG with a desired particle size, CG-based biospecific markers have found wide application in different fields of biology. Abundant information on the most important aspects of the preparation and application of CG-based immunochemical markers in biology and medicine was summarised in monographs^{41–43} and reviews.^{44–47}

A colloidal gold particle consists of the crystalline nucleus $[\text{Au}]_m$ and AuCl_4^- ions adsorbed on the surface of the nucleus. These ions determine the negative charge of colloidal gold particles, compose the inner layer of the ionic (electric) double layer and determine the adsorption potential. The H^+ ions are present in an intermicellar solution (some of them are located in the adsorption region; other, in the diffuse region of the electric double layer). The gold micelle can be represented as follows:

where $[\text{Au}]_m$ is the micelle nucleus (m is the number of gold atoms, which can vary from several hundreds to millions), n is the number of adsorbed AuCl_4^- ions ($n \ll m$), δ_0 is the adsorption layer thickness and d is the thickness of the diffuse region of the electric double layer.⁴⁸

A high electron density, the ability to scatter and emit secondary electrons, the characteristic absorption and scattering in the visible region of the electromagnetic spectrum and the intense red colour of gold-containing markers enable easy detection of gold particles by different physicochemical methods (microscopy,[†] photometry, flow cytometry, *etc.*). The possibility of preparing gold sols with different particle sizes and a narrow particle size distribution provides a high resolution of these methods and, in addition, enables simultaneous labelling of two or more antigens (or other ligands). After the corresponding immunochemical reaction, the size of CG particles can be increased by silver⁴⁹ or gold⁵⁰ enhancement (autometallography), which substantially extends the scope of these methods.

In the last 10–15 years, metal nanoparticles (particularly, gold nanoparticles) have found increasing application as efficient optical transducers of the results of biospecific interactions (for example, of an antibody with an antigen adsorbed on CG particles) into the detected optical signal in devices called biochips and biosensors.⁵¹ These devices are based on the unique optical properties of CG, in particular, the surface plasmon resonance (SPR, see below).⁵² The changes in physicochemical parameters of biochips and biosensors that occur in the course of biospecific

reactions are detected with the use of visual observations, light-scattering methods, vibrational spectroscopy, *etc.*

Biospecific interactions of biomolecules adsorbed on gold nanoparticles in systems, where nanoparticles exist as ordered self-assembled structures (thin films)⁵³ or are encapsulated in polymeric matrices,⁵⁴ have been extensively studied. Such structures are popular for the detection of biomolecules and microorganisms, for the design of DNA chips, *etc.* In these systems, the optical signal from the marker is sharply enhanced due to a strengthening of the local excitation field in an aggregate formed from gold nanoparticles.

Of nanosize structures, which are the subject of numerous fundamental studies, clusters are of particular interest. They occupy an intermediate position between individual atoms and solids and exhibit properties different from those of both atoms and solids. In particular, their physical characteristics substantially depend on the type and number of atoms involved in these structures, and this dependence becomes weaker as the number of atoms increases, which is indicative of the transformation of the material from the cluster to bulk state (quantum-size effects). Among clusters of simple substances, metal clusters (gold nanoparticles is a typical example) are of particular interest. These compounds attract considerable attention due to the characteristic features of their electronic structures and the relative simplicity of their preparation.

The present stage of development of physics of metal clusters dates back to 1993, when the electron shell structure of these clusters was discovered.^{55,56} This structure resembles in many aspects the shell structure of atoms. The experimental discovery of electron shells in polyatomic clusters was almost simultaneously confirmed by theoretical methods.

The theoretical approach was based on the property of metal valence electrons to leave the atoms (to be delocalised) and form a conduction band. It appeared that it is these shared electrons that determine the energy structure of the cluster and its unusual collective properties.⁵⁷ In particular, delocalised electrons in metal clusters have an effect on the behaviour of clusters in interactions with external fields. Recent extensive studies of interactions of metal clusters with electromagnetic fields revealed giant maxima (resonances) in electromagnetic absorption spectra. These resonances are associated with excitation of collective vibrations of the electronic system analogous to plasma vibrations of the electronic gas in the plasma and macroscopic metal bodies. These vibrations are called plasmon vibrations; the resonance, the surface plasmon resonance. The amplitude and the frequency range of plasmon resonance in clusters differ from those in macroscopic crystals.

If particles form aggregates, the corresponding plasmon peak is shifted to longer wavelengths or is broadened due to dipole–dipole interactions of light-induced dipole moments of particles in aggregates.⁵⁸ Therefore, optical excitations in aggregates composed of metal nanoparticles have a collective nature. As a result, local optical fields acting on metal particles in a fractal aggregate can be substantially higher than the mean field, which leads to giant non-linear effects.⁵⁹

It is of principal importance that the optical response of nanoparticles or their aggregates (particularly, ordered) substantially depends on the particle size and shape, the interparticle distance and the local dielectric environment of the particles.⁶⁰ This enables the tuning of the optical parameters of sensors.

The design and practical applications of biosensors based on metal nanoparticles were considered in reviews.^{51,61–68} New unique technologies, in particular, the monolayer self-assembly of metal particles,⁶⁹ nanolithography,⁷⁰ vacuum evaporation,⁷¹ *etc.*, are employed in the design of biosensor devices. Biosensors based on gold nanoparticles are used in immunoassay⁷² and for the nucleotide sequence determination.^{73,74} Recently, record sensitivities (in a zeptomole range) of such sensors have been achieved,^{75,76} and it has been demonstrated that resonance scattering spectra of individual particles can be recorded. This

[†] In addition to conventional transmission electron microscopy, scanning electron microscopy, light microscopy and different modifications of atomic force microscopy are also widely used.

opens up the possibility of observing intermolecular interactions at the single-molecule level.⁷⁷

The unique optical properties of silver and gold nanoparticles, which are determined by the localised surface plasmon resonance, are nowadays widely applied in single-electron transistors,⁷⁸ near-field optical microscopy,⁷⁹ surface-enhanced Raman scattering⁸⁰ (including at the single-molecule level⁸¹), SPR microscopy, SPR spectroscopy,⁸² *etc.* The optical properties of metal nanoparticles and their conjugates with biomacromolecules have been reviewed.^{83–88}

The present review summarises data on different methods of synthesis and functionalisation of gold nanoparticles and their applications in biological studies. Particular attention is given to applications of colloidal gold particles in solid-phase assays, immunoassays and studies of biomolecules by vibrational spectroscopy (the use of gold nanoparticles in electron microscopic methods is only briefly mentioned). A special section is devoted to applications of gold nanoparticles as antigen carriers in immunisation.

II. Methods of preparation of colloidal gold

Methods of synthesis of CG (and other metal colloids) can be arbitrarily divided into the following two large groups: dispersion methods (metal dispersion) and condensation methods (reduction of the corresponding metal salts).

Dispersion methods for the preparation of CG are based on destruction of the crystal lattice of metallic gold in high-voltage electric field. If an electric arc is created in a liquid between two gold electrodes under electric field, its blazing leads to the mass transfer between electrodes accompanied by the colloidal gold formation. The yield and shape of gold particles formed under electric current depend not only on the voltage between electrodes and the current strength, but also on the presence of electrolytes in solution. The use of direct current leads to the formation of non-uniform gold particles. The addition of even very small amounts of alkalis or chlorides and the use of high-frequency alternating current for dispersion substantially improve the quality of gold hydrosols.

Condensation methods are more commonly employed than dispersion methods. Colloidal gold is most often prepared by reduction of gold halides (for example, of HAuCl₄) with the use of chemical reducing agents and/or irradiation (ultrasonic and UV irradiation, pulse or laser radiolysis).^{47,89} Various organic and inorganic compounds serve as chemical reducing agents.²³ In the pioneering studies by Faraday and Zsigmondy,^{3,4} formaldehyde, ethanol and white phosphorus were used, *inter alia*, as reducing agents. These compounds are still successfully used for the preparation of sols with an average particle diameter of 5–12 nm.^{90,91} In addition, sodium citrate⁹² (for the preparation of CG with an average particle diameter of 20 nm), ascorbic acid⁹³ (12 nm), ethylenediaminetetraacetic acid (EDTA)⁸ (20 nm), sodium citrate in the presence of tannin (~5 nm),^{94,95} sodium borohydride,⁹⁶ borohydride in a mixture with sodium citrate⁹⁷ or EDTA⁹⁸ and cyanoborohydride⁹⁹ (for the preparation of CG with an average particle diameter of ~5 nm) have found application in the synthesis of gold sols. Ultradispersed sols (the particle diameter of 2–3 nm) can be prepared with the use of sodium or potassium thiocyanate.¹⁰⁰ Other reducing agents, such as oxalic and tartaric acids, carbon monoxide, tin chloride, hydrazine, hydrogen peroxide, carbohydrates, phenols, aromatic aldehydes, essential oils and many other compounds (up to an aqueous extract of Dutch cigars),⁹⁰ which were extensively applied in the synthesis of CG early in the 20th century, are not presently used.

Zsigmondy and Svedberg^{5,6} studied the kinetics of reduction of gold halide solutions and formulated the principal notions of the mechanism of formation of gold particles using reduction of HAuCl₄ with hydrogen peroxide as an example

This reaction produces only one electrolyte and, consequently, it can be monitored by conductometry.

According to Zsigmondy and Svedberg, ~30% of HAuCl₄ is initially reduced (to form a highly supersaturated gold solution in which the concentration of atomic metal is 6 orders of magnitude higher than that in a saturated solution), after which the reaction rate sharply decreases. The slow step involves condensation of gold to form very small particles (new phase nuclei). The latter form large but unstable aggregates (coagulation followed by peptisation), the sol solution turning blue. Particles involved in aggregates gradually enlarge and become centres of further rapid reduction of HAuCl₄. Once nuclei reach a particular critical size, a stable red sol is formed.

Taking into account the condensation mechanism of formation of a colloidal phase, several parameters determining the degree of dispersity of a gold suspension can be mentioned. Evidently, the rate of new phase nucleation depends on the concentrations of the reactants and the chemical nature of the reducing agent. At a low rate of nucleation and a rather high rate of particle condensation (the low degree of supersaturation of an HAuCl₄ solution), rather bulky particles are formed in small amount. At a high rate of nucleation and a rather low rate of particle condensation (the high degree of supersaturation of an HAuCl₄ solution), the probability of the formation of small particles increases. The increase in the concentration of the reducing agent is limited by aggregation stability of colloidal gold (rather high stability is achievable only in low-ionic-strength media).

In the case of self-nucleation, the larger the number of nucleation centres the higher the degree of dispersity of sols. In most cases, the nucleation and nucleus growth occur simultaneously (*i.e.*, reduced metal is consumed simultaneously in both processes). A decrease in the nucleation rate also leads to the formation of more coarse-dispersed hydrosols; a decrease in the nucleus growth rate, to the formation of finely dispersed hydrosols. Studies of numerous gold sols prepared by chemical reduction demonstrated that most of them were characterised by low stability and a broad particle size distribution.¹⁰¹ Relatively monodispersed particles with a diameter of 10–60 nm can be prepared only by the Frens method⁴⁰ using sodium citrate for reduction of HAuCl₄.

According to Zsigmondy, a sol with a narrow Au particle size distribution can be prepared by adding presynthesised Au seeds, on which condensation will occur, to an HAuCl₄ solution. In this method, sodium citrate or hydroxylamine can serve as reducing agents.^{102–104} Isodisperse and isomorphous sols can be prepared only if the formation of new nuclei is prevented. As a rule, it is achieved by performing the process in two steps. Initially, a new phase nucleates, and then weak supersaturation is created in the sol, due to which new nuclei are not produced any more and only the already formed nuclei grow.¹⁰⁵

Another procedure for the preparation of monodispersed gold sols was developed.¹⁰⁶ This method is based on reduction of a concentrated HAuCl₄ solution (0.5 mol litre⁻¹) by isoascorbic acid in the presence of gum arabic as the protective colloid. Under these conditions, condensation is accompanied by aggregation to form virtually monodispersed spherical gold particles with a diameter from 80 nm to 5 μm (depending on the acidity of the medium and the concentration of the reducing agent).

Gold nanoparticles can also be prepared by the two-phase microemulsion method. In the first step, metal-containing reagents are transferred from an aqueous to an organic phase. After the addition of a surfactant solution to this system, a microemulsion, *i.e.*, a dispersion of two immiscible liquids, is formed. The reduction reaction proceeds in a dispersed phase in which the drop size is at most 100 nm. As a result, virtually monodispersed sols are formed.¹⁰⁷ Later, a single-phase method without the use of aqueous solutions was developed.¹⁰⁸

In microemulsion methods of synthesis of CG, alkanethiols are often added to the reaction solution, and these additives form dense self-assembled monolayers on the gold surface. This method was employed for the preparation of self-assembled two- and three-dimensional ensembles of gold nanoparticles.^{109–111} Some ligands, such as alkanethiols, amines, silanes, phosphines and chitosan, can be involved in digestive ripening, *i.e.*, in a process in which a polydispersed colloidal suspension is transformed into monodispersed state upon refluxing in a solvent containing surfactant ligands.¹¹²

In recent years, synthetic polymers, such as polyethylene glycol (PEG), polyethyleneimine, polyvinylpyrrolidone, poly(vinyl acetate), polyamidoamine (dendrimer), polydithiafulvene, chitosan, *etc.*, have found application in the synthesis of monodispersed CG.^{113–117} Particles formed in the presence of these polymers are characterised by a higher size and shape uniformity.^{118, 119} Sodium borohydride,^{120, 121} alcohols and ethers,¹²² hydrazine¹²³ and sodium diphenylaminosulfonate,¹²⁴ as well as ultrasonic radiation,¹²⁵ can be used for reduction. A tyrosine residue of a polyfunctional peptide served as a reducing agent.¹²⁶ Colloidal gold with the required particle size can be prepared by choosing a particular reducing agent and taking into account the characteristic features of the kinetics of formation of a colloidal phase.^{127–130} A procedure for the synthesis of a marker for lectins with the use of PEG modified by carbohydrates and thiol groups was described.¹³¹

Physical (based on ultrasonic, UV, IR or ionising radiation or laser photolysis)^{8, 9, 132–138} and electrochemical¹³⁹ methods of reduction are much less commonly employed than chemical methods. The advantages of the former methods are that impurities of chemical compounds are absent in the resulting sols (on the metal particle surface).¹⁴⁰

In electron microscopic biological studies, gold clusters consisting of 11–67 atoms (undecagold, Nanogold[®]) with a diameter of 0.82–1.4 nm are used as markers. These clusters are prepared by reduction of a gold triarylphosphine complex with sodium borohydride^{11, 141, 142} or by reduction of HAuCl₄ in methanol with glutathione.^{143, 144}

The application of microorganisms and plant and animal cells for the CG synthesis is a new line of investigations in nanobiotechnology.^{145–148}

In recent years, CG particles uniformly distributed in polymeric matrices and particles consisting of the metal core and a dielectric shell,^{149–151} as well as non-spherical particles (spheroids, rods, chains)[‡] and shell and planar structures,^{152–162} have been much in demand due to the use of CG in biosensors. The latter structures can be prepared by reduction of gold salts in reverse micelles,¹⁶³ by the photochemical method¹⁶⁴ and with the use of porous aluminium or quartz templates and carbon nanotubes.^{165, 166} These methods were also employed for the synthesis of composite materials, for example, of gold–iron (possessing magnetic properties),¹⁶⁷ gold–silver^{168, 169} and other bimetallic nanoparticles.⁴⁷

III. Functionalisation of gold nanoparticles

A gold hydrosol is a typical lyophobic colloid the particles of which bear a large negative surface charge (the surface potential is ~50 mV)¹⁷⁰ and, hence, it is stable only in very low-ionic-strength solutions. In lyophobic systems, the dispersion medium and the dispersed phase are substantially different in the chemical composition and the interface structure, as a result of which the surface forces at the interface are uncompensated. These systems are thermodynamically unstable and require special stabilisation.^{17, 170, 171}

The stability of a sol can be increased by coating particles with a polymeric layer (conjugation with a polymer).^{18–21, 172} This method of stabilisation was proposed by Faraday, who studied the protective properties of gelatin.³ The addition of even a small amount of a polymer (particularly, of polyelectrolytes) to lyophobic colloids can substantially increase their aggregation stability.

The formation of an adsorbed polymeric layer on the particle surface leads to a decrease in the interphase tension due to a strengthening of interactions between the dispersed phase and the dispersion medium, resulting in a substantial increase in the entropy component of the system (due to the involvement of molecules and ions of the surface layer in thermal motion together with particles of the dispersed phase). As a result, the aggregation stability of the system increases. The adsorption layer favours the formation of a solvate layer with the result that the particle surface becomes lyophilic and the lyophobic sol becomes much less sensitive to coagulation by electrolytes (due to electrostatic and hydrophobic interactions and structural mechanical stability).

The efficiency of stabilisation depends on solubility of the protective polymer in a dispersion medium, the ability of lyophobic particles to adsorb the polymer on their surface and the degree of the surface coverage by the polymer.

Not only the molecular mass of a polymer, but also the charge of its functional groups are of importance for the protective action. Polymers containing simultaneously acidic and basic groups (for example, protein analogues) or weakly basic polycationic macromolecules having the pH-dependent protective action are the most efficient stabilisers of gold hydrosols.^{19, 20, 173}

The ability of polymers (including biospecific macromolecules) to stabilise lyophobic colloids underlies the preparation of stable bioconjugates, *e.g.*, complexes of CG with immunoglobulins, lectins, enzymes, hormones, lipoproteins, *etc.*¹⁷⁴

The attachment of biospecific probes to CG can be performed by adsorption and chemisorption methods. Each method has characteristic features of its own. It is commonly accepted that stabilisation of CG by recognising biomolecules (functionalisation) occurs through passive adsorption of a polymer on the particle surface by electrostatic and hydrophobic interactions.^{43, 90} A strong negative charge of the gold particle surface provides their strong adsorption interactions with high-molecular-mass compounds. The presence of Coulomb interactions between the NH₂ groups of lysine residues of a protein adsorbed on the gold nanoparticle surface with the citrate ions was reported.¹⁷⁵

In recent years, an important role of cysteine SH groups in binding of proteins to the surface of gold particles has been documented.¹⁷⁶

The advantage of physical adsorption is that gold particles have a minimum effect on the structure of a macromolecule (a probe). Electrostatic (rather than covalent) interaction of a label with a probe ensures to the greatest extent the conservation of the native character of the probe and, consequently, the activity and specificity of its interactions with the target molecule. However, when using this procedure for the preparation of bioconjugates, the possibility of desorption of recognising molecules from the gold nanoparticle surface and their binding to the target molecules must be taken into account. The main distinguishing feature of polymer adsorption is that polymers are usually adsorbed in amounts substantially larger than those required for the formation of a monomolecular layer. Adsorption isotherms of polymer adsorption from dilute solutions show no inflection points, which could be indicative of the formation of a discrete monolayer, as is observed for low-molecular-mass surfactants. This is due to formation of a relatively large number of contacts between macromolecules and the surface. The simultaneous cleavage of these contacts is statistically improbable,²⁰ and consequently, in most cases, adsorption of individual macromolecules is irreversible.

‡ It is known that the particle shape has a profound effect on their optical properties.

Sulfur and gold atoms are known to form dative bonds.^{22, 177} Hence, it was proposed that alkanethiol linkers $\text{HS}(\text{CH}_2)_n\text{R}$ ($\text{R} = \text{COOH}$, OH or SO_3H ; $n = 11-22$) were used to achieve stronger attachment of biomolecules to gold particles (the chemisorption method).¹⁷⁸ Interactions of these linkers with gold afford thiolates $[\text{Au}^0]_m \cdot \text{Au}^+ \text{S}^-(\text{CH}_2)_n\text{R}$,⁶⁹ which form a monolayer on the particle surface.

In 1996, Mirkin *et al.*⁷³ performed thiolation of oligonucleotides at the 5'-end before their attachment to gold particles with a size of 15 nm. As a result, very stable conjugates (resistant to high and low temperatures) were prepared, which were employed for colourimetric determination of DNA in solution. Cyclic disulfides¹⁷⁹ and tris(ω -mercaptohexyl) derivatives¹⁸⁰ were used as linkers for the preparation of bioconjugates with gold particles with sizes of 30 and 100 nm, respectively. Conjugates with gold nanoparticles (nanospheres and nanorods) were prepared from thiolated proteins, immunoglobulins and avidin.^{168, 181} In addition to alkanethiols, ligands containing phosphino, amino or carboxy groups served as linkers.⁴⁷ The advantages of chemisorption are most pronounced in the case of linear molecules (for example, DNA). Adsorption of these molecules leads to the formation of structures characterised by close spatial orientation of the attached molecules.

However, non-covalent (adsorption) conjugation is still most commonly employed for the preparation of gold markers for immunochemical studies. In this approach, the native structure of biomacromolecules and, as a consequence, their functional properties are retained to the greatest extent.

IV. Colloidal gold in solid-phase assays

In early steps of development of immunoassay methods, preference was given to liquid-phase procedures. However, in recent years, solid-phase methods have found increasing use because they enable substantial simplification of experiments and a decrease in the background signal. For the first time, the solid-phase procedure was applied in radioimmunoassays of proteins.¹⁸²

The problem is that the liquid-phase assays require the use of an antigen in solution; however, not all antigens are water-soluble.⁸ There is a large number of antigens, which can be transformed into the soluble state only in the presence of dissociating additives, such as sodium dodecyl sulfate, urea, guanidinium chloride, *etc.* These dissociating additives prevent the formation of immune complexes.¹⁸³ These difficulties can be avoided by immobilising antigens on solid supports. Microtitration plates and nitrocellulose (NC) filters have gained wide acceptance in solid-phase assays.¹⁸⁴

Radioactive isotopes (^{125}I , ^{14}C and ^3H), enzymes (peroxidase, alkaline phosphatase, *etc.*)¹⁸⁵⁻¹⁸⁷ and, in recent years, CG have found wide application as labels in membrane tests. In 1984, the use of CG as labels for solid-phase immunoassays was documented in several publications.¹⁸⁸⁻¹⁹¹ Colloidal gold conjugates have found application in solid-phase assays due to the intense red colour of gold-containing markers. The appearance of the colour in the course of the reaction enables visualisation of the process.¹⁹²⁻¹⁹⁴

Non-specific staining of proteins on NC filters was carried out using the gold stain AuroDye^{195, 196} (see[¶]). This method was further improved and modified.¹⁹⁷⁻¹⁹⁹ Non-specific staining of proteins by gold stains is rather simple, convenient and highly sensitive.²⁰⁰ The staining intensity is proportional to the logarithm of the protein concentration and its molecular mass.²⁰¹ Elution of CG-immobilised proteins and the photometric determination of

the protein concentration from the light absorption of the resulting complex at 540 nm were described.²⁰² The gold stain was used also for direct protein staining in gels,²⁰³ for detection of nucleic acids immobilised on blots,²⁰⁴ for protein determination by electron microscopy^{205, 206} and for the colourimetric determination of proteins in solution.²⁰⁷

In assays, an antigen immobilised on a membrane is incubated with a solution of the corresponding CG-labelled antibodies (or other biospecific probes). Immunoglobulins,^{189, 191, 208, 209} Fab and scFv fragments of antibodies,^{123, 210} protein A,^{188, 190} lectins,^{211, 212} enzymes,²⁰⁴ streptavidin or antibiotin antibodies (in studies of biotinylated specimens),^{213, 214} *etc.*, were applied as probes in 'gold' dot-blot assays. To visualise different antigens on a membrane, several labels can simultaneously be used (for example, CG and peroxidase^{215, 216} or alkaline phosphatase²¹⁷). Colloidal gold conjugates also have found application in tissue blots,²¹⁸ in which tissue prints are blotted onto nitrocellulose filters and the sought-for components are visualised with labelled probes, as well as in linear blots.²¹⁹

In membrane tests, CG was used for diagnosis of parasitic,²²⁰⁻²²³ viral²²⁴⁻²²⁷ and fungal^{228, 229} diseases, tuberculosis,²³⁰ melioidosis,²³¹ syphilis,²³² brucellosis²³³ and shigellosis,²³⁴ for the determination of early pregnancy²³⁵ and blood groups,²³⁶ for the identification of plant antigens^{237, 238} and for dot-blot hybridisation.²³⁹

Attempts were made (in our opinion, not quite convincing) to stain samples with CG in wells of microtitration plates²⁴⁰⁻²⁴⁴ or on the cover glass surface²⁴⁵ and to use colloidal silver²⁴⁶ or coal particles²⁴⁷ instead of CG in solid-phase immunoassays. The application of CG in assays of large series of antigens in micro-matrices (immuno-chips) holds more promise.²⁴⁸ The latter method enables the determination of analytes at a concentration of 60-70 ng litre⁻¹. In this case, up to 384 samples can simultaneously be analysed using microlitre amounts of an analyte and an immunogold marker as the detecting agent.

Depending on the form in which an antigen is immobilised on a membrane, immunodot and immunoblot assays are distinguished. The former is employed in assays of non-fractionated specimens; the latter, in assays of pre-fractionated specimens. The immunodot assay is one of the simplest methods of analysis of antigens immobilised on membranes and, in some cases, enables their quantitative estimation. The immunodot assay is most often used for soluble antigens.²⁴⁹ Studies of whole bacterial cells by dot assay with an enzymatic label or by colony blot assay were also documented.²⁵⁰⁻²⁵³ The dot assay of whole bacterial cells using visualisation of the reaction products with biospecific markers, *viz.*, CG conjugates, (cell-gold immunoblotting) was used^{254, 255} for serotyping of nitrogen-fixing soil microorganisms. More recently, this method was applied to the diagnosis of intestinal infections.²⁵⁶

The sensitivity of a label depends on the gold particle size [the light attenuation coefficient increases with increasing particle diameter (> 40 nm)].²⁵⁷ This is the reason why most of companies producing gold markers recommend to use conjugates of a probe with CG particles with a diameter of 20-30 nm in blot assays. The sensitivity in dot assays was increased by using conjugates of recognising molecules with gold nanoparticles as nanorods and nanoshells.^{258, 259}

In the 1990s, some companies began to produce immunochemical diagnostic test kits. Due to high specificity and sensitivity of the immunoassay technique, these tests have found wide application in the determination of narcotic drugs and toxins, the early pregnancy diagnosis and screening of especially dangerous infections and urogenital diseases.²⁶⁰⁻²⁶⁷ In recent years, procedures have been developed for DNA hybridisation²⁶⁸ and tuberculosis diagnosis.²⁶⁹ Immunochromatography is a technique for rapid immune tests, which is most actively developed and widely used in practice.

Immunochromatographic assays are based on the motion of an eluent along a membrane (lateral diffusion), which is accom-

§ For example, a wide class of corpuscular antigens, such as whole bacterial cells, are among water-insoluble antigens.

¶ The gold stain is a gold sol partially stabilised by polymers, such as PEG 20M, Tween-20, *etc.*

panied by the formation of specific immune complexes in different membrane regions visualised as coloured bands.²⁷⁰ Enzymes, coloured latexes and, most often, CG are used as labels in these systems.^{271, 272}

Examinations of these test systems demonstrated their high stability, reproducibility of the results and correlation with alternative methods. The degree of inhomogeneity of the detected bands estimated by densitometry is in the range of 5%–8%, which enables reliable visualisation of the results of assays. These tests are very simple and convenient in use. However, the technology of production of components of such test kits (unlike dot-blot tests) is rather complicated and is the property of manufacturers, which limits the use of these methods in routine laboratory practice.

V. Application of colloidal gold for the quantitative protein determination

Dot-blot assays with the use of CG conjugates have found increasing use and gained wide acceptance due to high sensitivity and simplicity. However, this method has some limitations, among which are difficulties of rigorous quantitative interpretation of the results and operations with low-molecular-mass ligands and considerable problems associated with the detection of components of complex biological systems (homogenates, exudates, etc.).

In 1980, Leuvers *et al.*²⁷³ developed a new immunoassay method called the sol particle immunoassay (SPIA). This method employs two important properties of gold sols: (1) the typical bright red colour of sols, which remains virtually unchanged upon adsorption of high-molecular-mass compounds on gold particles, and (2) changes in the colour of sols upon aggregation of gold particles, which is detected from changes in absorption in the visible spectral region. These changes in absorption are clearly detected both spectrophotometrically and visually.

The SPIA method is rather simple in use. Solutions of a gold-containing marker and the sample under study are mixed in a reaction vessel, and either the spectrophotometric characteristics of the suspension are monitored or the colour of the suspension is visually estimated during the incubation period (0.5–2 h). If the biospecific reaction proceeding on the CG surface is accompanied by destabilisation of the sol resulting in aggregation of gold particles (in the case of polyclonal antibodies, this process is called agglutination), the absorption spectrum of the suspension shows substantial changes associated with a noticeable change in its colour (from red to blue or gray). Antigens can be quantitatively determined with spectrophotometers and colourimeters.

Later,^{274–277} this method was modified and optimised to detect human chorionic gonadotropin in the urine in pregnancy (larger gold particles and monoclonal antibodies to different antigen regions were used). Based on the results of these investigations, home-use test kit Discretest[®] for early pregnancy is produced (Chefaro company, the Netherlands). The immunocolorimetric test kits for the rheumatoid factor and streptolysin is produced by PLIVA Lachema company (Czech Republic).

More recently, this method was applied to immunoassays of *Schistosoma*²⁷⁸ and *Rubella*²⁷⁹ antigens, the determination of affinity constants for different isotypes of mouse monoclonal IgG²⁸⁰ and quantitative determination of immunoglobulins^{281, 282} and cystatin C (an endogenous marker for the filtration ability of kidney glomeruli).²⁸³

In 2002, Thanh and Rosenzweig²⁸⁴ rediscovered this method and applied it to the quantitative determination of antibodies to protein A with the use of the conjugate of protein A with CG. In recent years, new methods for the detection of a response of a system (for example, antigen–antibody labelled by CG) to interactions, such as photothermal spectroscopy,²⁸⁵ double-beam laser absorption spectroscopy²⁸⁶ and hyper-Rayleigh scattering,²⁸⁷ have enabled an increase in the assay sensitivity. The

combined use of agglutination of latex and gold particles (heterogeneous SPIA) was proposed.²⁸⁸

All versions of the SPIA method are very simple in use and are characterised by high sensitivity and specificity. However, researchers faced with the fact that antigen–antibody interactions on sol particles not always lead to destabilisation of the system (particle aggregation). In some cases, in spite of the obvious pair complementarity, the colour of the solution and, consequently, the absorption spectra change only slightly, if at all.

After a series of preliminary experiments, it was hypothesised²⁸⁹ that in these cases a second protein layer is formed on gold particles without loss of aggregation stability of the sol. In this case, changes in the spectra due to adsorption of the second biopolymer and, correspondingly, changes in the structure of the biopolymer layer on the metal particle surface are relatively small. However, even such small changes in the absorption spectra can be recorded and used for quantitative assays in biological applications.^{290, 291}

Another version of the above-described method was proposed by Mirkin and co-workers.⁷³ This version is based on the colourimetric determination of polynucleotides interacting with complementary oligonucleotides immobilised on gold nanoparticles. This process is accompanied by the formation of an ordered three-dimensional structure of gold nanoparticles, which leads to changes in the absorption spectrum of the solution and is detected visually⁷³ or photometrically.²⁹²

The formation of ordered three-dimensional structures in the reactions of IgG-functionalised gold nanoparticles with antigens^{176, 293} or with aptamers was documented.²⁹⁴ It was demonstrated that biologically programmed ensembles of gold nanoparticles can be prepared with the use of an avidin–biotin system.^{295, 296} An analogous approach was applied for the detection of lectins.¹⁴⁶ Ca²⁺-dependent aggregation of gold nanoparticles coated with carbohydrates was described.²⁹⁷

In spite of the fact that the SPIA method is very simple in use, the real practical applications of this method during 20 years have been described in rather modest number of papers. Only in the very recent past, this method has been demonstrated to be promising as a high-performance clinical test. In our opinion, the SPIA method has little use because the physicochemical and optical mechanisms of the conversion of signals, which are generated upon the biospecific binding of target molecules to CG conjugates, into characteristics of light attenuation or scattering by suspensions are poorly understood.

A new version of the SPIA method with the use of microtitration plates and microplate reader and a trypsin (proteolytic enzyme) conjugate with CG as a specific visualising agent for proteins was proposed.²⁹⁸ This assay holds considerable promise for the rapid, sensitive and quantitative protein determination.

VI. Application of gold nanoparticles in studies of biologically active compounds by vibrational spectroscopy

Raman spectroscopy is an efficient tool to investigate molecular structures because the set of intramolecular vibrational frequencies is uniquely related to the molecular structure as well as to intermolecular and intramolecular interactions.^{299, 300} However, since the intensity of the Raman signal is relatively low, the detection of this signal is a rather complex problem and requires the use of modern laser sources and photon counting systems. In 1974, Fleischman *et al.*³⁰¹ suggested that the effective number of molecules involved in scattering from the adsorbed monolayer could be increased by increasing the real surface area with retention of the ‘visible’ surface area illuminated with pumping radiation. For this purpose, the silver surface was made coarse by anodic etching and the spectra of compounds adsorbed on this surface were recorded. The intensity of Raman scattering increased by a factor of 10⁶–10⁷, while the surface area after

etching of the silver electrode surface increased by only an order of magnitude.³⁰¹ More recently, it was demonstrated that the observed enhancement of Raman scattering is associated with a new non-linear effect called the surface-enhanced Raman scattering (SERS) effect.[†]

Surface-enhanced Raman scattering has some features distinguishing it from conventional Raman scattering. First, SERS cross-sections for vibrational modes of adsorbed molecules can be increased by a factor of 10^{10} or more compared to the analogous parameters for unadsorbed molecules. Second, the enhancement of scattering varies depending of the excitation frequency and the degree of roughness of the support according to a law specific for SERS. Third, the SERS spectra of many adsorbed molecules are substantially different from the corresponding Raman spectra of molecules in the free state. This is manifested in the selective enhancement of particular vibrations and the appearance of new bands in the SERS spectrum.

Abundant information on applications of surface-enhanced Fourier-transform IR and SERS spectroscopy in biological studies is summarised in the reviews.^{303–306} Vibrational spectroscopic methods are used for studying individual biomolecules, as well as cells and tissues.^{307–311}

In most of the cited studies, vibrations of biomolecules were enhanced due to their adsorption on metal electrodes or thin films. However, in recent years the methods in which signals are enhanced with the use of colloidal metals (primarily, gold and silver), have gained wide acceptance.^{312–316} In these methods, the signal is enhanced by giant non-linear local fields that are produced in metal clusters.^{317,318} Different versions of immunoassay with the use of antibodies or antigens adsorbed on gold nanoparticles and vibrational spectroscopic methods were developed.^{319–323}

It was demonstrated for the first time³²⁴ that Fourier-transform IR spectroscopy can be employed for the sensitive determination of interactions of protein molecules with the gold particle surface and for the reliable and simple monitoring of biospecific reactions. This method (that is called spectroimmunochemical) can serve as a basis for the development of test systems detecting biospecific antigen–antibody, enzyme–substrate, lectin–polysaccharide, *etc.* interactions. The observed changes in the spectra of biomolecules immobilised on gold particles are evidence that these biomolecules are indeed adsorbed. The proposed method along with other methods (for example, SERS) can be used for controlling the quality of gold conjugates.

VII. Gold nanoparticles as antigen carriers

Let us briefly consider two interrelated problems of modern immunology that attract the attention of many researchers. These are the preparation of antibodies against non-immunogenic low-molecular-mass compounds (haptens) and the design of new generation vaccines based on natural (microbial) or synthetic peptides.^{325–328}

The biosynthesis of antibodies in organisms is known to be induced by compounds possessing a rather developed structure (immunogenicity). These compounds include proteins and polysaccharides.³²⁹ However, many biologically active compounds (neuromediators, hormones, vitamins, antibiotics, *etc.*) have rather low molecular masses. Low-molecular-mass antigens belong to the so-called weak antigens, *i.e.*, a pronounced immune response against these antigens (biosynthesis of the corresponding antibodies) is not developed.

The preparation of antibodies against haptens has attracted interest for several reasons. First, antibodies to particular fragments of biomacromolecules can serve as a highly efficient tool for

investigating their topography and structures. Second, the preparation of antibodies to such low-molecular-mass compounds, as antibiotics, hormones and some pharmaceuticals, would enable the control of their amount in the blood of patients, in meat and dairy products and in cultural media. The drug monitoring is widely used in all developed countries. This method enables substantial enhancement of the efficiency of curing and prevention of complications. Among various procedures for the detection of such compounds, immunochemical assay is most convenient and highly sensitive, which implies the preparation of antibodies to these low-molecular-mass compounds. Antibodies to low-molecular-mass compounds hold considerable promise in immunotherapeutic practice.^{325,330} Third, attempts are made to use synthetic peptides for the design of artificial (acellular) vaccines containing only protective antigens and inert carriers.

Since haptens exhibit weak immunogenicity, the choice of an optimal carrier (a delivery system) providing a high immune response and the preparation of sufficiently pure antibodies are important problems to be solved in the preparation of antibodies to haptens. These problems are traditionally solved by covalent coupling of a hapten to a protein matrix, the so-called *schlepper* (which comes from the German word 'schleppen', which means 'to drag, lug') with the use of adjuvants and intensive schemes of animal immunisation by the resulting conjugate.^{325,331} Bovine serum albumin, ovalbumin, thyroglobulin, hemocyanin, diphtheria or tetanus anatoxins (for synthetic peptides), *etc.* are usually used as *schleppers*. However, these processes give antibodies against both a hapten and immunodeterminant sites of a carrier. The use of such carriers not necessarily gives rise to a pronounced immune response to weak antigens. In addition, the subsequent purification and screening of the resulting antibodies are time-consuming and expensive, and their titer and affinity are often low.

Most of the presently used adjuvants based on oil emulsions and suspensions of inorganic compounds are, as a rule, prone to phase separation, their immunogenic properties change with time, and many of such adjuvants cause local and systemic toxic effects.^{332,333} The application of antibody phage display is seemingly the most promising solution of the problem of the preparation of antibodies against haptens.³³⁴ However, this technique is virtually inapplicable in vaccinology.

In recent years, studies have been carried out on the design of the so-called complex antigens, *i.e.*, artificial macromolecular complexes containing both the desired antigenic determinants and carriers and/or adjuvants. In particular, synthetic polyelectrolytes [poly-L-lysine, polyacrylic acid, polyvinylpyridine, poly(styrenesulfonate), Ficoll, *etc.*] were proposed as carriers.³³⁵ For example, the influenza vaccine Grippol was designed based on the cation exchange resin 'Polyoxonium'. These polymeric compounds are synthesised by radical polymerisation of the corresponding monomers.³³⁶ The simplicity of the chemical synthesis of polyelectrolytes and the possibility of preparation of polymer chains in a broad molecular mass range (*i.e.*, of different length), solubility in water and other properties (the ability to undergo conformational transformations, complex formation with proteins, *etc.*) opened up possibilities for their application in immunological studies.³³⁷ These carrier-adjuvants can form a depot of antigens at the site of injection, enhance the presentation of antigens to immunocompetent cells and induce the production of required cytokines. However, low immunogenicity of such complexes associated with a low epitopic density stimulated a search for new non-toxic and efficient carriers having, in addition, adjuvant properties.

In our opinion, nanosized corpuscular carriers, such as polymeric nanoparticles [for example, poly(methyl methacrylate)],³³⁸ liposomes, proteosomes and microcapsules,^{339–341} fullerenes,^{342,343} carbon nanotubes,³⁴⁴ *etc.*, hold considerable promise in this respect. The use of such carriers leads to a change in the form of manifestation of immunogenicity of the required compound in the immune system of host organisms. An antigen

[†] Adsorption of molecules of the compound under study on the metal surface is accompanied also by changes in luminescence, absorption and non-linear effects and the appearance of induced optical activity.³⁰²

adsorbed to, or encapsulated in, nanoparticles can be used as an adjuvant for optimisation of the immune response of the organism upon vaccination. For example, an analysis of the dynamics of an immune response demonstrated that the titer of antibody in response to an antigen introduced together with fullerenes was equal to the titer of antibody in response to the antigen introduced together with the Freund's complete adjuvant (FCA) and was approximately an order of magnitude larger than the titer of antibody in response to the antigen introduced without an adjuvant.

In 1986, the successful preparation of antibody to glutamic acid with the use of CG particles as a carrier was reported in the pioneering study by Japanese researchers.³⁴⁵ (It should be noted that colloidal metals were used for stimulation of an immune response to haptens and complete antigens as early as 1920th by Zil'ber and co-workers.^{346–348}) More recently, this method has been applied and improved for the preparation of antibodies to the following haptens and complete antigens: amino acids,^{349,350} platelet activating factor,^{351,352} quinolinic acid,³⁵³ biotin,³⁵⁴ immunophilin,³⁵⁵ lysophosphatidic acid,³⁵⁶ endostatin,³⁵⁷ peptides of hepatitis C virus capsid,³⁵⁸ surface antigens of *Yersinia*³⁵⁹ and brucellas.³⁶⁰ In all the above-mentioned studies, haptens were directly conjugated with CG particles, mixed with FCA and used for immunisation of animals. As a result, high-titer antisera, which did not require further purification from ballast antibodies, were obtained.

In 1993, Australian scientists³⁶¹ suggested that haptens should be added to a carrier protein before conjugation with CG. More recently, this approach was applied for the preparation of antibodies against a number of synthetic^{362–365} and natural³⁶⁶ peptides, amino acids,^{367,368} citrulline³⁶⁹ and phenyl β -D-thiogluconide.³⁷⁰ In these studies, FCA or *N*-acetylmuramyl-L-alanyl-D-isoglutamine were used as adjuvants.³⁶³ Antibodies prepared according to this procedure have high specificity for antigens under examination and a higher titer (the authors of the publication³⁶¹ referred to this titer as extremely high), from 1:250 000 to 1:1 000 000, compared to antibodies prepared according to a conventional procedure (by conjugation with a schlepper).

In 1996, researchers from the Khabarovsk Research Institute of Epidemiology and Microbiology demonstrated³⁷¹ for the first time that CG particles in a viral vaccine can be used as carriers of tick-borne encephalitis virus capsid protein antigen. According to the results of this study, in spite of the fact that no adjuvants are present in the vaccine, the latter has higher protective properties compared to commercial analogues. In 2003, a new procedure for the preparation of antibodies against A β peptides, which is a molecular marker of Alzheimer's disease, was described.³⁷² The authors designed a molecular mimic of the fibrillar form of A β peptides by covalently binding prethiolated oligomers to the gold particle surface. Antibodies to antigens that were synthesised according to this procedure, have very high specificity and affinity for both soluble and fibrillar forms of A β peptides.

Numerous studies were devoted to applications of CG particles in the design of DNA vaccines. In DNA immunisation, gene constructions coding proteins to which it is necessary to prepare antibodies, are introduced into organisms. In the case of efficient gene expression, these proteins serve as antigens for the development of an immune response.^{373,374} In early studies, immunisation was performed with subcutaneous or intramuscular injections of 'naked' DNA. However, the biolistic transfection with nanoparticles began to be applied for this purpose almost at the same time. This procedure proved to be very efficient due apparently to multiple sites of interactions between a transgene and tissues. The injection material began to be administered subcutaneously, epicutaneously or intranasally.^{375,376}

Among nanoparticles, colloidal gold particles are most widely applied as DNA carriers.^{377–383} Initially, gold has been used only as a carrier, but more recently gold was demonstrated to enhance

an immune response *in vivo*.³⁸⁴ However, to our knowledge, data on the mechanisms of this action of gold particles are lacking.

Gene immunisation (it is often called DNA immunisation), which has been developed in tests on animals, is highly efficient, particularly, against viral infections, such as tick-borne encephalitis, HIV infection, hepatitis B and some other. The DNA immunisation has some advantages over conventional vaccination. One recombinant vector can simultaneously direct the synthesis of several antigens, which decreases the number of immunisations. This eliminates problems associated with the difficulties of penetration of proteins into organisms and, in addition, substantially decreases the risk of side effects, which depend on toxicity of inactive proteins introduced in the case of conventional vaccination or virulence in bacteria and viruses. In the coming years, DNA immunisation would be expected to be among the most efficient methods of gene therapy.^{37,385,386}

The preparation of antibodies to complete antigens and haptens of different nature using CG particles as carriers was documented.^{387,388} It was demonstrated that CG as an antigen carrier activates phagocytic activity of macrophages and influences the functioning of lymphocytes, which is apparently responsible for its immunomodulation effect. The most interesting aspect of manifestation of the immunogenic properties by haptens upon their immobilisation on colloidal gold is that CG particles act simultaneously as adjuvants and carriers, *i.e.*, present haptens to T-cells. Gold nanoparticles conjugated with antigens were found to influence activation of T-cells (an increase in proliferation by a factor of 10 compared to that upon the addition of the native antigen). This fact shows that the targeted activation of T-cells (for example, by antigens of *Mycobacterium tuberculosis*, HIV, *etc.*) followed by activation of macrophages and pathogen killing is possible, in principle, which holds considerable promise for the design of new generation vaccines.

The question is what is responsible for the adjuvant properties of CG. Nowadays, there is no answer to this question. However, let us give some comments.

In our opinion, conclusions about the preferable macrophage response to corpuscular antigens, unlike soluble antigens, is undoubtedly valid.³⁶¹ This fact was confirmed in the studies^{379,381,384} where the mechanism of action of DNA vaccines was elucidated and gold particles were used for delivery of genetic material into cells. In these studies, the role of the Kupffer cells and the Langerhans islets in the immune response was revealed. Moreover, CG particles were used in the studies^{389,390} of endocytosis by macrophages. (Gold particles included in phagocyte lysosomes even received their own name 'aurosomes'.) The influence of dendrite cells on the immune response to antigens conjugated with gold nanoparticles was discussed.³⁹¹ In addition, the authors mentioned that, when using nanoparticles in medical practice, it is necessary that lipopolysaccharides be absent on their surface.

However, these data do not reveal further mechanisms of presentation of antigens to T helpers. According to modern views,^{329,392} the presentation of antigens to T-cells is preceded by processing (protein cleavage into peptide fragments) followed by the formation of compounds with molecules of the major histocompatibility complex, which performs the delivery of an antigen fragment to the surface of antigen-presenting cells. Hence, it remains unclear how this process can occur with haptens. The assumption about the existence of a multivalent antigen, *i.e.*, the antigen that is formed due to a high local concentration of monovalent antigens on the gold particle surface, also does not answer this question.

At the same time, the influence of gold salts on the immune system has long been known.^{393–397} Treatment of a number of autoimmune diseases, in particular, of rheumatoid arthritis, is based on the ability of gold to change non-specific immune reactions of an organism. For example, the successful therapy of rheumatoid arthritis by a colloidal gold solution was documented.^{30,398} According to the results of another study,³⁹⁹ in this

case the function of CG is to inhibit monocyte-induced proliferation of lymphocytes. The transformation of Au(0) into Au(I) in immune system cells under the action of certain amino acids was discussed.⁴⁰⁰

Contradictory results were obtained in the studies^{401–403} aimed at examining the sensitivity of mammalian organisms to the introduction of metallic gold. In particular, it was noted^{401,402} that the injection of CG into laboratory animals can lead to inflammatory reactions, accumulation of gold in reticular cells of lymphoid tissues and activation of cellular and humoral immunity. However, in the study⁴⁰³ dealt with the influence of gold nanoparticles on the immune system cells, it was concluded that CG particles is a non-cytotoxic, non-immunogenic and biocompatible material for the potential application in different fields of nanoimmunology, nanomedicine and nanobiotechnology.

In recent years, the use of gold nanoparticles for targeted drug delivery has been considered in a number of publications (see, for example, Refs 32 and 404–406). In this connection, it should be noted that, in our opinion, this problem must be considered with caution taking into account that antibodies against the administered drug adsorbed on CG particles can be formed in animal and human organisms.

In conclusion, it should be noted that it is apparently the time to consider not only biochemistry, but also biophysics of the immune response, because it is the unique biophysical properties of metal particles, in particular, the surface charge and the electrostatic field of the particles (which influence the charge, orientation and polarisation of antigenic molecules adsorbed on the particles) that have a substantial effect on the immune response.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 04-04-48224 and 05-02-16776).

Abstract. Data on the synthesis and properties of seven-membered heterocyclic compounds containing five successive sulfur atoms and a carbon–carbon bond, 1,2,3,4,5-pentathiepines and -pentathiepanes, are generalised and described systematically. The bibliography includes 104 references.

I. Introduction

Among seven-membered polysulfur-containing heterocycles containing five sulfur atoms and two carbon atoms, there are 1,2,3,4,5-pentathiepines and -pentathiepanes and 1,2,3,4,6- and 1,2,3,5,6-pentathiepanes. Data on the two last-mentioned classes of compounds, whose properties are substantially different from those of 1,2,3,4,5-isomers, are beyond the scope of the present review. We review data on methods for the synthesis and reactions of seven-membered rings, which contain a carbon–carbon double or single bond and a chain of five sulfur atoms, *viz.*, 1,2,3,4,5-pentathiepines and their hydrogenated analogues, 1,2,3,4,5-pentathiepanes.

Fehér was the first to synthesise such derivatives: pentathiepanes in 1967 (Ref. 1) and pentathiepines in 1971.² Twenty years later, a seven-membered polysulfur-containing ring was found in natural antibiotics isolated from marine organisms (cited in Ref. 3). In recent years, pentathiepines have attracted considerable interest as antitumour, antifungal and antiseptic drugs. Apparently, it is the heterocycle that is responsible for their biological activity. In addition, 1,2,3,4,5-pentathiepines have found application in industry, for example, as cathodic materials. These compounds are also valuable starting com-

pounds in synthetic organic chemistry, because they can be used for the preparation of various sulfur-containing derivatives, both cyclic (1,4-dithiines, 1,2,4,5-tetrathiocines and 1,3-dithioles) and acyclic (vicinal 1,2-dithiols and many other compounds).

Among natural and synthetic pentathiepines, benzopentathiepine (**1a**) and its analogues containing a substituted benzene ring are best studied. Natural compounds, such as varacin (**2a**), lissoclinotoxin A (**2b**) and *N,N*-dimethyl-5-(methylthio)-varacin (**3a**), have antiseptic and antifungal activities and inhibit protein kinase C. In addition, varacin exhibits antitumour activity.

In 2004, we published a review³ on the chemistry of pentathiepines. Data on reviews on pentathiepanes are lacking in abstract journals, although data on both classes of compounds were included in chapters of the monograph *Comprehensive Heterocyclic Chemistry*.⁴ In the present review, the results of research into the chemistry of 1,2,3,4,5-pentathiepanes are analysed for the first time. Since the synthesis methods, chemical properties and spectroscopic characteristics of 1,2,3,4,5-pentathiepines and their hydrogenated analogues are rather similar, it is worthwhile to consider and compare data on these heterocycles in one paper, with a supplement of studies on pentathiepines published in the last three years.

II. Methods of synthesis

1. Sulfurisation of sulfur-containing compounds by elemental sulfur

a. Synthesis of pentathiepines from aromatic vicinal dithiols

Benzopentathiepine (**1a**) and its 7-chloro-substituted analogue (**1b**) were synthesised by Sato *et al.*⁵ by the reaction of the corresponding arene-1,2-dithiols (**4a,b**) with elemental sulfur in liquid ammonia. The reactions were performed in a titanium

autoclave at 20 °C. More recently, this method was improved (for example, dichloromethane was used as the solvent), and a wide range of monosubstituted benzopentathiepienes **1c–j** were synthesised.^{6–8} In addition to thermodynamically stable pentathiepienes **1a–j**, sulfurisation of arene-1,2-thiols with elemental sulfur affords less stable benzo-1,2,3-trithioles **5a–j** as by-products. Unfortunately, the yields of the reaction products were not reported in the cited studies.

R¹ = H; R² = H (**a**), Cl (**b**); R² = H; R¹ = SiMe₃ (**c**), SiMe₂Bu^t (**d**), SiEt₃ (**e**), SiPh₃ (**f**), CH₂CH₂NH₂ (**g**), CH₂CH₂NHBoc (**h**), CH₂Py (**i**), CH₂Pyrm (**j**)

Boc is *tert*-butoxycarbonyl, Py is 2-pyridyl, Pyrm is 2-pyrimidyl.

This method was used for the synthesis of 6-(2-aminoethyl)benzopentathiepine (**1g**) and 6,7-dimethoxybenzopentathiepine (**6a**) as structural analogues of the natural antibiotic varicin (**2a**).⁷

The reaction can be performed with *S,S*-dialkyl-substituted arene-1,2-dithiols instead of thioles. In this case, the pentathiepine ring is synthesised in two steps. Compound **7** is dealkylated by sodium in liquid ammonia, which is accompanied by reduction of the hydroxy group, and the subsequent reaction with sulfur produces pentathiepine **1k**.⁸

Recently, the synthesis of phthalocyanines fused with the pentathiepine ring by the reaction of the corresponding 4,5-(*o*-xylylenedithio)phthalonitrile derivatives with lithium amide and elemental sulfur has been documented.⁹

As an exception, let us mention the reaction ideologically similar to the above-considered method. In this reaction, aromatic monothiol was used as the starting compound. The treatment of dilithium intermediate **8**, which is generated *in situ* by the reaction of *p*-toluenethiol with butyllithium, with sulfur affords pentathiepine **1l**.¹⁰

b. Synthesis from fused 1,3-dithiole-2-thiones

R Sato *et al.*⁵ synthesised benzopentathiepine (**1a**) and its 7-monosubstituted analogues **1b,m,n** from fused 1,3-dithiole-2-thiones **9a,b,m,n** by the reaction with sulfur in liquid ammonia. The use of benzene as the solvent led to an increase in the yield of the reaction products. However, attempts to synthesise 7-nitrobenzopentathiepine according to this method failed. Interestingly, pentathiepine **1a** is derived from compound **9a** in higher yield compared to the reaction with benzene-1,2-dithiol (**4a**), although the latter is produced by hydrolysis of

benzodithiole **9a** and is, presumably, an intermediate in the synthesis of pentathiepine **1a**.

R = H (**a**, 82%), Cl (**b**, 59%), MeO (**m**, 99%), NH₂ (**n**, 91%).

The reaction of benzobis(dithiolethiones) **10a–d** with sulfur in liquid ammonia gives trithiolobenzopentathiepienes **11a–d** in high yields rather than the corresponding benzobis(pentathiepienes).¹¹ Under these conditions, the reaction of benzobis(1,3-dithiole-2-thione) containing no alkoxy groups yields only polymers of unknown structure.

R = Me (**a**, 82%), Et (**b**, 99%), Prⁱ (**c**, 99%), PhCH₂ (**d**, 62%).

Pentathiepane **12** fused with the cyclohexane ring was synthesised from 1,3-dithiole-2-thione **13** in low yield (35%) due to formation of tetrathiine **14** as a by-product.¹²

c. Synthesis from benzo-1,2,3-trithioles

Pentathiepienes can be synthesised starting from benzo-1,2,3-trithioles. For example, the treatment of benzobis(trithiole) **15** with sulfur in liquid ammonia affords pentathiepine **11e** in good yield.¹³

d. Synthesis from annulated 1,2,3-thia(selena)diazoles

A procedure for the synthesis of benzopentathiepienes from the corresponding 1,2,3-thiadiazoles was proposed and developed by Chenard *et al.*^{14,15} The reaction proceeds upon heating (160–185 °C) of benzothiadiazoles **16a,m,o–s** with elemental sulfur in decalin. In the presence of diazabicyclo[2.2.2]octane (DABCO), final products **1a,m,o–s** were obtained in higher yields. The authors attributed this fact to high nucleophilicity of the organic base necessary for the S₈ ring opening. Benzothiadiazoles react as latent *o*-mercaptodiazonium salts. Apparently, the reaction initially leads to cleavage of the heterocycle in compound **16** accompanied by elimination of the nitrogen molecule and the resulting intermediate reacts with the activated [S₈–DABCO] species.

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{H}$ (**a**); $\text{R}^2 = \text{R}^3 = \text{H}$; $\text{R}^1 = \text{Br}$ (**o**), CF_3 (**p**);

$\text{R}^1 = \text{R}^3 = \text{H}$; $\text{R}^2 = \text{OMe}$ (**m**), NMe_2 (**q**); $\text{R}^1 = \text{R}^2 = \text{H}$;

$\text{R}^3 = \text{Cl}$ (**r**), CF_3 (**s**).

This method allowed the synthesis of a series of pentathiepinanes annulated with heterocyclic rings, such as the pyrazole ring (**17**, 36%–44% yields)¹⁵ or the dihydrofuran ring (**18**, 22%).¹⁶

Analogously, 1,2,3-selenadiazoles **19** and **20** are transformed into pentathiepinanes **18** and **21**, respectively. The reaction with compound **19** proceeds very rapidly to give predominantly 1-selena-2,3,4,5-tetrathiepine **22**.¹⁷

2. Sulfurisation of vicinal dithiols with other reagents

The first compound belonging to pentathiepanes, *viz.*, perhydrobenzopentathiepane (**12**), was synthesised by Fehér and Degen¹ from *trans*-cyclohexane-1,2-dithiol (**23**) with the use of the rare reagent dichlorotrithiane (S_3Cl_2). The reaction was carried out in a mixture of diethyl ether and carbon disulfide at room temperature.

The parent compound of pentathiepinanes, *viz.*, unsubstituted pentathiepine (**24**), and benzopentathiepine (**1a**) were

synthesised for the first time by the reaction of ethylene- and benzene-1,2-dithiols, respectively, with S_3Cl_2 .²

More recently, this reaction was extended to other vicinal 1,2-dithiols. In these reactions, cheaper sulfur monochloride (S_2Cl_2) was used instead of S_3Cl_2 . The limitations of this method are associated exclusively with stability and accessibility of the starting compounds. The reaction with sulfur monochloride can be performed also with mono-*S*-alkylated derivatives, for example, with compound **25**.¹⁰ In this case, dealkylation occurs under mild conditions in the presence of a sulfur-containing reagent; the resulting benzothiepine **11** was isolated by silica gel column chromatography.

The synthesis of annulated pentathiepinanes from salts, 1,2-dithiolates, was documented.^{18–20} In particular, cyano-substituted pentathiepinisothiazole **26** was synthesised from the corresponding disodium salt **27** in almost quantitative yield.¹⁸

However, the analogous reaction with diammonium salt **28** produced pentathiepine **29** in substantially lower yield.²⁰

The reaction with the hexalithium salt of hexamercapto-benzene **30** afforded products in rather high total yield; however, pentathiepine **31** was obtained as a minor component of the mixture, and the reaction produced predominantly benzotris(trithiole) **32**.¹⁹

It should be noted that vicinal dithiols can be generated *in situ* from various 1,2-bifunctional compounds.^{10, 15, 21–26} Examples of reactions, in which intermediate dithiolate anions form the 1,2,3,4,5-pentathiepine ring, are given below. It

$\text{R}^1 = (\text{CH}_2)_2\text{NHCO}_2(\text{CH}_2)_2\text{SiMe}_3$; $\text{R}^2 = \text{Pr}^n$ (28%), Bu^n (47%).

should be noted that this reaction was described^{10, 21–23} as one of steps in the total synthesis of natural pentathiepine analogues.

B is a base [Na, NH₃ (liq), *etc.*]; R¹ = H, Me; R² = R³ = H, R⁴ = Buⁿ; R¹ = R² = OMe, R³ = (CH₂)₂NHBoc, R⁴ = iso-C₅H₁₁.

3. Cyclosulfurisation at a carbon–carbon multiple bond

a. Reactions with elemental sulfur

One of the commonly used procedures for the synthesis of pentathiepanes is based on the reactions of cyclic and linear alkenes with elemental sulfur. However, this reaction generally gives products in low yields. For example, the reactions of norbornene derivatives with sulfur in DMF afford pentathiepanes **33a–c** in low yields, whereas the corresponding trithiolanes **34a–c** are obtained as the major products.²⁷

Compound	R–R	Yield (%)	
		33	34
a	2 H	6.5	30
b	CH ₂ CH=CH	5	40

To stabilise intermediates, Fe₃(CO)₁₂ was added to the reaction mixture.^{28, 29} However, the use of this carbonyl as the catalyst for the reactions of cyclohexene²⁸ and vinyltrimethylsilane²⁹ with sulfur did not lead to an increase in the yield of pentathiepanes **12** and **35**.

The reactions with polycyclic aromatic alkenes produce fused pentathiepanes in considerably higher yields. For example, pentathiepanes **36** and **37** were synthesised by the reaction of barrelene³⁰ or acenaphtho[1,2-*a*]acenaphthylene³¹ with elemental sulfur in DMF in 46% and 88% yields, respectively.

Due to steric hindrance, the analogous reaction of 1,1,4,4-tetrasubstituted buta-1,2,3-trienes **38** with sulfur proceeds regioselectively at the central C=C double bond to give compounds **39**, as a rule, in good yields.^{17, 32}

R = Ph (87%), 4-MeC₆H₄ (65%), 4-ClC₆H₄ (56%), 1-adamantyl (19%).

It should also be noted that benzopentathiepine (**1a**) was obtained as one of products in the reaction of dehydrobenzene with sulfur at low temperature.³³ Unlike the above-considered reactions, this reaction results in the addition of elemental sulfur to the carbon–carbon triple bond.

2,3-Benzannulated five-membered heterocycles containing one heteroatom readily react with electrophilic sulfur in the presence of strong bases. In these reactions, the double bond of the starting molecule, which is involved in the heteroaromatic system, remains intact, and the process can be considered as the formal replacement of hydrogen atoms. Pentathiepinino[6,7-*c*]indoles **40a,b** were synthesised by Bergman and co-workers³⁴ from indole derivatives **41a,b** and thioxindole **42a,b**. The reaction with sulfur is preceded by the treatment of the heterocycles by butyllithium or sodium hydride.

Starting compound	R	Yield of 40 (%)
41a	H	29
41b	Me	22
42a	H	42
42b	Me	13

The reaction of benzo[*b*]thiophene with butyllithium and S₈ produces benzothienopentathiepine **43**, whereas the reaction of benzo[*b*]furan performed under analogous conditions gives only bis(benzofuro)tetrathiocine **44**.³⁵

In the presence of a mixture of elemental sulfur and iron carbonyl Fe₃(CO)₁₂, (vinyltrimethyl)silylferrocene is transformed into the corresponding pentathiepine fused with ferrocene (**45**).³⁶ In this reaction, not only the hydrogen atom, but also the silicon-containing group are replaced.

b. Reactions with sulfur monochloride

Commercially available sulfur monochloride is used as a reagent for cyclosulfurisation of various compounds to form

pentathiepinines. For example, refluxing of indene derivative **46** in toluene with S₂Cl₂ in the presence of triethylamine afforded pentathiepine **47**.³⁷ Apparently, the initial electrophilic replacement of two hydrogen atoms gives rise to a 2,3-bis(chlorodithio) derivative, which reacts with the third sulfur monochloride molecule to form the pentathiepine ring after elimination of SCl₂.

Recently, we have demonstrated^{38,39} that the reactions of five-membered electron-donating heterocycles, such as pyrrole, thiophene and their derivatives, with S₂Cl₂ in the presence of a base can be used as a one-pot method for the synthesis of annulated pentathiepinines. Pentathiepinines **48a–d** fused at positions 3 and 4 of the pyrrole ring were synthesised from *N*-substituted pyrroles and pyrrolidines. These reactions are also accompanied by the replacement of the hydrogen atoms in the β position. It should be noted that the reaction of *N*-isopropylpyrrolidine with S₂Cl₂ and DABCO produced pyrrolo-bis(pentathiepine) **49c**, which is the first representative of compounds containing two pentathiepine rings in one molecule.

In the reactions with 1,2,5-trisubstituted pyrroles, cyclo-sulfurisation products **48a,e–i** are formed in good yields.

R¹ = Cl, R² = Me (**a**); R¹ = Me: R² = Me (**e**), Et (**f**), Prⁿ (**g**), Prⁱ (**h**), CH₂Ph (**i**).

Under analogous conditions, the reaction of *N*-methylindole produced pentathiepinino[6,7-*c*]indole **40b**.

The reaction of thiophene with S₂Cl₂ in the presence of diisopropylethylamine gives pentathiepine **50** in substantially

lower yield than that obtained in the reaction of tetrahydrothiophene with S_2Cl_2 in the presence of DABCO.

Pentathiepinines fused with the pyrrole, thiophene or indole rings can also be prepared by the reactions of the corresponding heterocycles with a prestored mixture of sulfur monochloride and DABCO.⁴⁰ The authors hypothesised that 1-(4-aza-1-azoniabicyclo[2.2.2]oct-1-ylidithio)-4-aza-1-azoniabicyclo[2.2.2]octane dichloride (**51**) is the main reacting species in these transformations. The formation of the latter was established by IR spectroscopy based on the disappearance of the S–Cl absorption band. It should be noted that in these reactions, annulation products **52a–d** at positions 2 and 3 of the pyrrole ring are generated from *N*-substituted pyrrolidines.

High reactivity of salt **51** was confirmed by its unexpected transformations. For example, the addition of triethylamine to a solution of this salt in chloroform followed by heating of the reaction mixture afforded thienopentathiepine **53** and heptathiocane **54**.⁴¹ X-Ray diffraction study demonstrated that the polysulfur rings of these compounds exist as chair and crown conformations, respectively.

The reactions of other tertiary ethylamines with S_2Cl_2 proceed analogously, although these reactions afford products in lower yields. The thiophene ring in compound **53** is constructed from the ethyl groups of two amine molecules (the new C–C bond is formed between two non-activated methyl groups); the pentathiepine ring, as a result of the reaction of intermediate thiophene with salt **51** (by analogy with the above-considered examples). The probable reaction mechanisms were proposed in the cited studies.

In spite of low yields of the products, the advantage of this method is that these products are generally formed in one step from cheap starting reagents.

4. Other methods

In conclusion, let us consider several original approaches to the synthesis of pentathiepinines.

Cyclosulfurisation with elemental sulfur accompanied by the intramolecular rearrangement of the starting compound was documented. The reaction of *N*-methylazepane with sulfur in the presence of hexamethylphosphoramide (HMPA) produced pentathiepinopyrrole **55** in low yield.⁴² Unfortunately, no suggestions about the reaction mechanism were made.

In some cases, pentathiepanes and pentathiepinines were synthesised with the use of non-traditional reagents. For example, pentathiepane **33d** was synthesised from norbornadiene with the use of the sulfurising reagent S_7NH , which is more reactive than elemental sulfur (see Section II.3.a). Although the reaction was performed under mild conditions (at room temperature), pentathiepane **33d** was produced in low yield (12%), and trithiole **34d** was obtained as the major product.²⁷

Structurally similar trithiole **34a** was transformed into the corresponding pentathiepane **33a** in high yield in the reaction with triphenylmethylthiosulfenyl chloride (Ph_3CSSCl).⁴³

One of the most rational methods for the synthesis of pentathiepinines is based on the introduction of three sulfur atoms into 1,2-bis(chlorosulfonyl)benzene under the action of bis(pentamethylcyclopentadienyl)titanium dichloride trisulfide. This reaction gives benzopentathiepine (**1a**) in good yield.⁴⁴

$Cp^* = \eta-C_5Me_5$.

This method was also used for the synthesis of pentathiepane **33b** from the corresponding bis(sulfonyl chloride). This reaction produced compound **33b** in 9% yield.⁴⁵

Tetrasulfur tetranitride (S_4N_4) can also be used as the sulfurising reagent in the synthesis of benzopentathiepinines. For example, refluxing of S_4N_4 in xylene with 4-methylbenzene-1,2-dithiol and (*ortho*-mercaptophenyl)triazene⁴⁶ afforded compounds **1l** and **1a**, respectively.

Pentathiepine fused with ferrocene (**45**) was synthesised by the reaction of dithiastannole **56** with a large excess of sulfur dichloride.⁴⁷

Perchlorobuta-1,3-diene reacts with Na_2S_5 to form bis(dithiolethione) **57**. The reaction of the latter with sodium in liquid ammonia followed by the treatment with $Ph_4P^+Cl^-$ affords thienopentathiepine salt **58**.⁴⁸

Sulfurisation of 1,1,4,4-tetrasubstituted buta-1,2,3-trienes **38** to form pentathiepanes can be performed by electrolysis on a sulfur graphite electrode in DMF in the presence of Et_4NOTs .^{49, 50} The reactions with tetraaryl derivatives **38** ($R = Ar$) afforded pentathiepanes **39** ($R = Ar$) as the major products (61%–86% yields). By contrast, 1,4-bis(trifluoromethyl)-1,4-diarylbuta-1,2,3-trienes gave predominantly 1,2,5,6-tetrathiocines **59**, whereas pentathiepanes **39** ($R = CF_3$) were isolated in yields from 1% to 25%.

$R = CF_3$ or Ar ; $Ar = 4-XC_6H_4$ ($X = H, Me, Cl, MeO$).

Some approaches to the synthesis of pentathiepienes were discovered accidentally. For example, the reaction of 2,3-dichloro-1,4-naphthoquinone with sodium hydrosulfide in DMF unexpectedly produced naphthopentathiepine **60**.⁵¹

It appeared that the reaction of isatin with P_4S_{10} under reflux in pyridine does not stop at the formation of dithioisatin; instead, it produces pentathiepinino[6,7-*c*]indole **40a**. This fact is

indicative of thermodynamic stability of the final products, fused pentathiepienes.⁵²

Pentathiepinino[6,7-*c*]pyrrole **48j** was isolated as a by-product in the reaction of acetophenone oxime with sulfur monochloride in the presence of pyridine and *o*-aminophenol.⁵³ This reaction gives substituted dithiazole as the major product.

To summarise, there are several approaches to the construction of the pentathiepine ring based on different starting compounds and sulfur-containing reagents.

III. Chemical properties

Most reactions of pentathiepienes and pentathiepanes considered in this Section involve the nucleophilic or electrophilic attack on the S atom, resulting in the pentathiepine ring opening and elimination of one to five sulfur atoms.⁵⁴ These reactions proceed through the formation of various charged and neutral intermediates **A–G**.⁵⁵

1. Thermolysis and photolysis

Thermal and photochemical transformations of pentathiepienes generally lead to a loss of two, three or four sulfur atoms. These reactions produce 1,2,3-trithioles, dimeric tetrathiocines and 1,4-dithiines. For example, pyrolysis of pentathiepinisothiazole **26** affords 1,4-dithiine **61**.¹⁷

Heating of dihydronaphthopentathiepine **21** in 1,2-dichlorobenzene to 140 °C or its irradiation with a high-pressure mercury lamp (100 W) affords an equilibrium mixture of the starting pentathiepine, 1,2,3-trithiole **62** and elemental sulfur.⁵⁶

Irradiation of a solution of 6,9-diethylbenzopentathiepine (**6b**) in dichloromethane leads to successive desulfurisation, dimerisation and ring contraction. The corresponding trithiole and tetrathiocin were detected as intermediates, and 1,4-dithiine **63** was obtained as the final transformation product.⁵⁷

Under analogous conditions, dihydropentathiepin[6,7-c]-furan **18** also gave 1,4-dithiine **64**; however, compound **65** belonging to the poorly known class of 1,2,3,4-tetrathiines was isolated as the major photolysis product.¹⁶

2. Desulfurisation with bases

The reactions of pentathiepinines and pentathiepanes with bases {for example, with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and other tertiary or secondary amines} involve desulfurisation of the substrate accompanied by a loss of two to five sulfur atoms. For example, refluxing of pentathiepanes **39** in the presence of DBU in DMF affords the corresponding benzothiophenes **66** and buta-1,3-dienes **67**.³² In the authors' opinion, the mechanism of formation of these products and their

Ar	Yield (%)	
	66	67
Ph	12	52
4-MeC ₆ H ₄	33	40
4-ClC ₆ H ₄	2	32

ratio depend on the relative stability and reactivity of radical intermediates.

The reactions of benzopentathiepinines **10,p,t** substituted at position 6 with diethylamine in hexane yield the corresponding trithioles **50,p,t**.¹⁵ In the reaction with trifluoromethyl derivative **1p**, an equilibrium is established (**1p**:**5p** = 46:54).

Heating of pentathiepin[6,7-c]indole **40b** with triethylamine in ethanol affords bis(indolo)-fused 1,2,3,4-tetrathiocine **68** in high yield.³⁴ The reaction mechanism involves elimination of three sulfur atoms to form dithioindole, which undergoes dimerisation to give product **68**.

Evidently, the role of the base in these transformations is to cleave the polysulfide chain.

3. Reduction

Benzopentathiepinines are reduced most often with sodium borohydride.¹⁵ These reactions generally produce arene-1,2-dithiols. For example, 7-chlorobenzopentathiepine (**1b**) was reduced with NaBH₄ to dithiol **4b**.¹⁵

In the presence of an electrophilic reagent (for example, alkyl halide) in the reaction mixture, intermediate dithiol is readily alkylated to form stable 1,2-di(alkylthio) derivatives. *S,S*-Dialkyl-substituted arene-1,2-dithiols were synthesised from various benzopentathiepinines according to this method.^{11, 13, 15}

$R^1 = R^3 = R^4 = \text{H}; R^2 = \text{Cl}, \text{NMe}_2$;
 $R^1 = R^4 = \text{Me}; R^2-R^3 = -\text{SSS}-, -\text{SCH}_2\text{CH}_2\text{S}-$;
 $R^1 = R^4 = \text{OMe}, R^2-R^3 = -\text{SSS}-$.

1,2-Dithiol **69** was prepared from pentathiepane **33b** with the use of lithium aluminium hydride. Compound **69** is rather stable; it was isolated in almost quantitative yield and characterised by different physicochemical methods.²⁷

Varacin (**2a**) and its derivative **3a** were reduced with lithium tris(*tert*-butoxy)aluminium hydride.^{58,59} Subsequent alkylation of the intermediate with iodomethane afforded amine **70a** and quaternary ammonium salt **71a**, respectively.

Polycyclic pentathiepane **37** was reduced with lithium triethyl borohydride. The treatment of the reaction mixture with iodomethane gave the bis(methylthio) derivative of acenaphtho[1,2-*a*]-acenaphthene **72**.³¹

The reactions can be performed with acylating reagents instead of alkylating reagents. For example, the reaction of lissoclinotoxin A (**2b**) with acetic anhydride in the presence of 4-dimethylaminopyridine (DMAP) in DMF at room temperature produces compound **73b**.⁶⁰ Apparently, three sulfur atoms are eliminated through the nucleophilic attack of DMAP. In the analogous reaction (with NaBH_4 and acetic anhydride), isolissoclinotoxin A (**2c**) gives isomer **73c**.²²

It should be noted that the pentathiepine ring can be reduced in such a way that the trithiole ring remains intact. For example, mild reduction of trithiolobenzopentathiepine **11e** with sodium borohydride afforded benzobis(trithiole) **15** in good yield.¹³

Pentathiepine **47** is reduced under reflux with Raney nickel in THF with a loss of all five sulfur atoms and cleavage of the dithiole ring to form benzofulvene.³⁷

4. Reactions with compounds containing the activated methylene group

In the presence of bases (triethylamine or sodium ethoxide), compounds containing the CH -acidic methylene group (malononitrile, ethyl cyanoacetate, ethyl acetoacetate, ethyl 2-chloropropionate and acetylacetone) react with benzopentathiepine (**1a**) to form 1,4-dithiines, 1,3-dithiols and 1,2,4-trithiines.⁶¹ Under these conditions, malononitrile and ethyl cyanoacetate give dithiines **74** in high yields.

$\text{X} = \text{CN}$ (**a**, 87%), CO_2Et (**b**, 76%).

The reaction of benzopentathiepine (**1a**) with ethyl acetoacetate in the presence of triethylamine produces benzo-1,3-dithiole **75a**; the reaction with ethyl acetoacetate and acetyl-

75b: $\text{Y} = \text{CO}_2\text{Et}$ (57%);
75c: $\text{Y} = \text{Ac}$ (42%)

acetone in the presence of sodium ethoxide gives benzodithioles **75b,c**.

Dithioles **75a** (40% yield) and **75b** (42%) are formed also from benzopentathiepine (**1a**) and ethyl 2-chloroacetoacetate. However, the reaction of compound **1a** with ethyl 2-chloropropionate and sodium ethoxide gives trithiine **76** rather than dithiole **75d** as the major product. Presumably, the latter reaction proceeds through the above-considered intermediates **C**, **D** or **F** (see the beginning of Section III).

5. Reactions with unsaturated compounds

The reactions of benzopentathiepienes with unsaturated compounds (alkenes, alkynes and arenes) give rise to new S—C bonds. Benzopentathiepine (**1a**) reacts with alkenes in the presence of a Lewis acid or triethylamine. The reaction catalysed by $\text{BF}_3 \cdot \text{Et}_2\text{O}$ produces unsymmetrical benzo-1,2,5-trithiepienes **77a–d**. In this case, pentathiepine is involved in the reaction as a 1,5-dipole (**C**).⁶² Other Lewis acids are less efficient catalysts for the pentathiepine ring opening than $\text{BF}_3 \cdot \text{Et}_2\text{O}$.

Compound 77	R ¹	R ²	R ³	Yield (%)
a	H	(CH ₂) ₄		81
b	H	(CH ₂) ₃		68
c	Me	H	Me	58
d	Et	H	Et	39

In the presence of triethylamine in DMF, the reaction of compound **1a** with norbornadiene and acrylonitrile is accompanied by a loss of three sulfur atoms; 1,4-dithianes **78** and **79** are apparently formed through intermediate **D**.⁵⁵

The direction of the reaction of benzopentathiepine (**1a**) with norbornene in the presence of triethylamine depends on

the nature of the solvent. The reaction in DMF produces an equimolar mixture of 1,2,3-trithiolane **34a** and adduct **80** generated as a result of addition of two norbornene molecules at the sulfur atoms. The analogous reaction in DMSO gives not only compounds **34a** and **80**, but also dithiane **81**.

Benzopentathiepienes **1a,b,q** slowly react with dimethyl acetylenedicarboxylate (DMAD) to form benzo-1,4-dithiines **82a,b,q**, the reaction being substantially accelerated in the presence of triphenylphosphine or triethylamine in DMF.^{15, 55}

Product 82	R	Reaction conditions	Yield (%)
a	H	Et_3N , DMF	84
b	Cl	xylene	15
q	NMe ₂	Ph_3P , CH_2Cl_2	51

The reaction of electron-withdrawing alkynes with pentathiepienes fused with aromatic and heterocyclic rings in the presence of triphenylphosphine is characteristic of this class of compounds; the corresponding 1,4-dithiines are formed in high yields (64%–93%).^{41, 63} Examples of compounds prepared according to this procedure are given below.

In the presence of triphenylphosphine, pentathiepieno-[6,7-*b*]pyrroles **52a,e** regioselectively add to an unsymmetrical alkyne molecule.⁶³ For example, in compliance with the electron density distribution in the intermediates, which are generated according to the proposed reaction mechanism, the addition products of methyl propiolate, viz., fused 1,4-dithiines **83a,e**, were obtained.

$R^1 = \text{Me}, R^2 = \text{H}$ (**a**); $R^1 = \text{Et}, R^2 = \text{Cl}$ (**e**).

Apparently, triphenylphosphine, acting as a nucleophile, attacks molecule **52a**, which is accompanied by the pentathiepine ring opening and successive elimination of three sulfur atoms to give intermediate of type **D**,⁵⁵ and the latter adds to alkyne (see also Section III.6, the reaction with the Grignard reagent).

Benzopentathiepine (**1a**) reacts with benzene and some of its derivatives in the presence of a Lewis acid (for example, AlCl_3) as the catalyst. The corresponding 1,4-dithiines **84a–h** are generally formed in good yields.⁶⁴

Compound 84	R^1	R^2	R^3	R^4	Yield (%)
a	H	H	H	H	44
b	Me	H	H	Me	75
c	Pr^i	H	H	Pr^i	62
d	Me	Me	Me	Me	83
e	1,2- C_6H_4		H	H	93
f	Me	1,2- $\text{SC}_6\text{H}_4\text{S}$		Me	20
g	H	H	1,2- $\text{C}_6\text{H}_4\text{S}$		43
h	H	H	1,2- $\text{C}_6\text{H}_4\text{S}$		43

Under the action of AlCl_3 in dichloromethane, pentathiepienes **11,o,u** are transformed into radical cations **851,o,u**, which are apparently intermediates in Friedel–Crafts reactions.⁶⁵ The formation of radical cations **85** was detected by EPR spectroscopy.

$R = 7\text{-Me}$ (**l**), 6-Br (**o**), 7-CF_3 (**u**); $X = \text{Cl}$ or AlCl_4 .

6. Reactions with Grignard reagents

R Sato *et al.*⁶⁶ developed convenient procedures for the synthesis of 2-alkyl(aryl)sulfenylthiophenols. These authors demonstrated that benzopentathiepine (**1a**) reacts with alkyl- and arylmagnesium bromides under mild conditions in the presence of triphenylphosphine.

$R = \text{Alk}, \text{Ar}$.

In the absence of triphenylphosphine, the reactions give products in low yields. The presumable mechanism of these reactions involves elimination of three sulfur atoms from benzopentathiepine (**1a**) under the action of triphenylphosphine to form intermediate of type **D**, which adds a Grignard reagent. Hydrolysis of the reaction mixture leads to organyl-sulfenylthiophenols.

7. Reactions with phosphorus-containing compounds

The reactions of benzopentathiepine (**1a**) with neutral and cationic organophosphorus compounds were documented. The reactions with trialkyl phosphites regioselectively produce thiophosphonates **86** or **87** depending on the reaction conditions.⁶⁷ The former products are generated at -15°C ; the latter products, under reflux of the reagents in dichloromethane. Apparently, the reaction is accompanied by elimination of three sulfur atoms under the action of $\text{P}(\text{OR})_3$, and the resulting intermediate **D** adds the phosphite molecule.

$R = \text{Me}, \text{Et}, \text{Pr}^i, \text{Bu}^n, \text{Ph}$.

The nucleophilic attack on benzylphosphonium salts **88** in the presence of sodium hydride in pentathiepine **1a** results in a mild ring opening.⁶⁸ These reactions produce mixtures of tetrathiepienes **89** and trithiines **90** in moderate yields.

Compound	R	Yields (%)	
		89	90
a	H	15	52
b	NO_2	0	55
c	Me	19	51
d	OMe	45	25
e	Cl	7	53

8. Reactions with isothiocyanates

2-Iminobenzo-1,3-dithioles **91a–h** were synthesised in good yields from benzopentathiepine (**1a**) and isothiocyanates in the presence of triethylamine.⁶⁹ Aryl isothiocyanates react more readily than alkyl derivatives, and their reactions are accelerated in the presence of electron-donating groups in the molecule. However, unsubstituted phenyl isothiocyanate does not react with pentathiepine **1a**, and compound **91h** was synthesised with the use of phenyl isoselenocyanate.

E = S: R = Me (**a**, 81%), Et (**b**, 59%), Prⁿ (**c**, 47%), 4-MeC₆H₄ (**d**, 77%), 4-ClC₆H₄ (**e**, 84%), 4-MeOC₆H₄ (**f**, 74%), 2-MeOC₆H₄ (**g**, 86%);

E = Se, R = Ph (**h**, 78%).

9. Reactions with acetone

Condensation of pentathiepine[6,7-*c*]pyrazoles with acetone in the presence of ammonium sulfide at room temperature gives a mixture of tetrathiepines **92–94** in low yields.⁷⁰

R	Yield (%)		
	92	93	94
Me	10	15	0
Ph	22	21	14

The structures, the energies of transformation and conformational dynamics of isomeric tetrathiepines were studied. However, the mechanism of formation of these compounds remains unclear. Presumably, the pentathiepine ring is cleaved as a result of the nucleophilic attack of the sulfide ion. This reaction is accompanied by extrusion of S₂ to form bis-nucleophilic intermediates analogous to intermediates **A** and **B**, which are fused with acetone.

10. Unusual transformations of pentathiepines

Pentathiepines can serve as sources of sulfur atoms. For example, in the reactions with benzopentathiepine (**1a**), sodium alkyl- and arylsulfonates are transformed into thiosulfonates **95** in high yields.⁷¹

R = Me (78%), Ph (99%), PhCH₂ (81%), PhCH₂CH₂ (86%), Cl(CH₂)₄ (78%), 4-MeC₆H₄ (100%), 4-ClC₆H₄ (82%), 4-MeOC₆H₄ (96%), 4-BrC₆H₄ (85%), EtO₂CCH₂CH₂ (69%).

The treatment of *N*-substituted pentathiepine[6,7-*c*]pyrroles **48e–i** with a prestored mixture of sulfur monochloride and DABCO at room temperature leads to an unusual cascade transformation giving rise to bis(dithiolo)pyrroles **96e–i** in high yields.³⁹ The authors described the presumable reaction

mechanism involving oxidation of an enamine tautomer with a disulfide reagent as the key step.

R = Me (**e**, 85%), Et (**f**, 80%), Prⁿ (**g**, 74%), Prⁱ (**h**, 79%), CH₂Ph (**i**, 84%).

The treatment of pentathiepine **97** with a large excess of S₂Cl₂ unexpectedly leads to elimination of all sulfur atoms to form vicinal dichloride **98**.²⁴ At 4 °C, the reaction is completed in a few days.

Analogous transformations of other pentathiepines are unknown.

11. Reactions of substituents in aromatic rings of benzopentathiepines

a. Reactions of amino and hydroxy groups

Reactions of the phenol hydroxy group and an aminoalkyl-aromatic fragment of benzopentathiepine derivatives are of interest primarily as procedures for modifying natural pentathiepines and their analogues. It should be noted that the pentathiepine ring is very sensitive to the nucleophilic attack, for example, by the nitrogen atom of the unsubstituted amino group of a peripheral substituent.⁸ For this reason, the protection of the amino group by acylation leads to substantial stabilisation of pentathiepines. *N*-Acetylation and trifluoroacetylation of amines are generally performed with acetic^{60, 72} or trifluoroacetic (TFAA) anhydrides,^{22, 73} Ac₂O reacting also with free phenol groups.

R¹ = Me: R² = Me (**2a**), H (**2b**); R¹ = H, R² = Me (**2c**); R³ = Me, R⁴ = X = Ac; R³ = X = Ac, R⁴ = Me; R³ = R⁴ = Me, X = COCF₃; R³ = Me, R⁴ = H, X = COCF₃; R³ = H, R⁴ = Me, X = COCF₃.

Lissoclinotoxin B (**99**) is easily acylated with acetic anhydride in pyridine at room temperature. The reaction proceeds both at the nitrogen atom of the amino group and the oxygen atom of the phenol hydroxy group.²²

It should be noted that the pentathiepine ring remains intact in the transformation of the amino group of the side chain in varacin (**2a**) into the urea fragment in the course of the reaction with (*S*)-(+)-1-(1-naphthyl)ethyl isocyanate.⁷⁴

Since benzopentathiepine **1g** containing the free aminoethyl group is unstable, it is generally used as hydrochloride. By contrast, compounds **1i,j,v** containing less nucleophilic heterocyclic fragments (pyridine or pyrimidine) and thiophene are rather stable.⁸

Het = 2-Py (**i**), 2-Pyrm (**j**), 2-thienyl (**v**).

Methylation of the phenol group in compounds **2d,e** with diazomethane and ¹³C-labelled diazomethane made it possible to establish the structure of lissoclinotoxin A.⁷³ In this reaction, the pentathiepine ring also remains intact.

2d,e
 $R^1 = \text{H}, R^2 = \text{Me}$ (**d**); $R^1 = \text{Me}, R^2 = \text{H}$ (**e**);
 $R^3 = R^4 = \text{Me}$; $R^3 = \text{Me}, R^4 = {}^{13}\text{CH}_3$; $R^3 = {}^{13}\text{CH}_3, R^4 = \text{Me}$.

Derivatives of varacin and lissoclinotoxin A containing primary or secondary amino groups can be transformed into stable hydrochlorides and trifluoroacetates.^{8, 10, 22, 23}

$A = \text{CF}_3\text{CO}_2$; $R^1 = R^2 = R^5 = R^6 = \text{OMe}, R^3 = \text{H},$
 $R^4 = \text{CO}_2(\text{CH}_2)_2\text{SiMe}_3, \text{Boc}$; $R^1 = \text{OCH}_2\text{OMe}, R^2 = R^6 = \text{OMe},$
 $R^3 = \text{H}, R^4 = \text{CO}_2(\text{CH}_2)_2\text{SiMe}_3, R^5 = \text{OH};$
 $A = \text{Cl}$; $R^1 = R^2 = R^3 = R^5 = R^6 = \text{H}, R^4 = \text{Boc};$
 $R^1 = R^2 = R^5 = R^6 = \text{OMe}, R^3 = \text{CHO}, R^4 = \text{Boc}.$

b. Oxidation and reduction of the trithiole ring

Tricyclic compounds **11** containing the trithiole ring along with the pentathiepine ring were oxidised with various reagents. It appeared that the reactions with *m*-chloroperoxybenzoic acid (MCPBA)⁷⁵ or the $\text{Ti}(\text{OPri})_4$ –DET– Bu^tOOH [DET is (*R,R*)-diethyl tartrate] system⁷⁶ occur only at the trithiole ring.

Oxidant	Yield (%)			
	100a	100b	101a	101b
MCPBA	16	13	26	32
Bu^tOOH		29	18	23

Sulfoxides **100a,b** and **101a,b** were isolated from the reaction mixture. Compounds **100a,b** were demonstrated to exist as achiral centrosymmetric conformers, whereas compounds **101a,b** are unsymmetrical diastereomers containing the sulfoxide group in different conformations with respect to the pentathiepine ring (the stereochemistry is considered in more detail in Section V).

Upon oxidation with mercury acetate, the pentathiepine ring also remains intact. For example, the reaction between this reagent and 1,3-dithiole-2-thione fused with pentathiepine **102** produces the corresponding keto derivative.⁷⁷

It is known that sodium borohydride NaBH_4 can reduce the pentathiepine ring.¹⁵ However, the treatment of trithiolo-benzopentathiepine **11a** with two equivalents of NaBH_4 followed by alkylation with ethyl β -bromoacetate afforded tetrasubstituted benzopentathiepine.¹¹ This is evidence that the trithiole ring is more sensitive to reducing reagents than the pentathiepine ring.

Reactions of carboxylic acid derivatives

High stability of the pentathiepine ring to acids and nitrosating reagents was exemplified by cyanoisothiazole derivative **26**.¹⁵ For example, the cyano group was hydrolysed in concentrated sulfuric acid to give the amide group in high yield. Then the amide was transformed under the action of sodium nitrite and concentrated sulfuric acid into the acid; its treatment with thionyl chloride and methanol afforded methyl ester **103**. In all these transformations, the pentathiepine ring remains intact.

IV. Spectroscopic studies

1. UV and IR spectroscopy

The character and positions of absorption bands in UV spectra depend on the structure of pentathiepine. The spectrum of unsubstituted pentathiepine (**24**) shows weak and diffuse signals at 206 [the extinction coefficient (ϵ) is 9730], 253 ($\epsilon = 3440$) and 315 nm ($\epsilon = 1510$).¹ Most pentathiepinines are characterised by only one intense band at ~ 210 nm ($\epsilon = 25\,000\text{--}32\,000$).^{1, 15, 60, 73} The spectra of benzopentathiepinines **11e,f** annulated with the trithiole ring show absorption bands at 292–294 nm ($\epsilon = 15\,100\text{--}15\,500$).⁷⁸ For pentathiepinines fused with pyrrole, pyrazole or thiophene, the absorption maxima are observed at 230–240 nm.^{15, 42} The UV spectra of pentathiepanes fused with carbocycles (for example, compounds **12**, **33a,d** and **35**) show two characteristic bands at 231–233 ($\epsilon = 3750\text{--}5500$) and 278–281 nm ($\epsilon = 3090\text{--}3480$).^{1, 2, 29}

The IR spectra contain absorption bands of the S–S bond in pentathiepinines at $460\text{--}485\text{ cm}^{-1}$ (Ref. 29).

2. Raman spectroscopy

All pentathiepinines fused with aromatic or heterocyclic rings are characterised by strong absorption at 485 cm^{-1} in Raman spectra.¹⁵ Most often, Raman spectra of pentathiepinines show two absorption bands, the most intense band being observed at $490 \pm 5\text{ cm}^{-1}$. The Raman spectra of benzopentathiepinines have two additional characteristic absorption bands at $425 \pm 5\text{ cm}^{-1}$ (of weak to medium intensity) and $180 \pm 5\text{ cm}^{-1}$ (strong), which can be used for the identification of these compounds.

3. NMR spectroscopy

The ring protons in the ^1H NMR spectrum of unsubstituted pentathiepine (**24**) have a chemical shift (δ) of 7.42 ppm. The spectrum of benzopentathiepine (**1a**) is characterised by an AA'BB' system centred at $\delta = 7.52$.¹ The signals for the carbon atoms of the pentathiepine ring are observed in the ^{13}C NMR spectrum at low field ($\delta = 135\text{--}145$).^{18, 22, 32, 56, 59, 77}

The corresponding NMR spectra of pentathiepanes **33a,c,d** show signals for the ring hydrogen atoms at $\delta 3.93\text{--}4.06$ and signals for the carbon atoms of the pentathiepane ring at $\delta 69.8\text{--}72.7$.²⁷

4. Mass spectrometry

Mass spectrometry is one of the main methods for establishing the structures of pentathiepinines and pentathiepanes. Generally, samples are transformed into the ionised state under electron impact. Almost in all cases, the intensity of the molecular ion peak is low (from 0.6% to 25%), and the $[\text{M} - \text{S}_2]^+$ ion peak corresponding to a loss of two sulfur atoms is the most characteristic peak (the intensity is 40%–100%) upon fragmentation.^{34, 35, 42, 46, 49, 56, 60, 77–79} Pentathiepinines can also be identified by FAB (Fast Atom

Bombardment) mass spectrometry,^{72, 73} however this method has not gain wide acceptance.

5. X-Ray diffraction

The molecular structures of more than 30 compounds containing the pentathiepine or pentathiepane rings were established by X-ray diffraction. In most compounds, polysulfur-containing rings adopt a chair conformation. The S–S bond length varies from 2.039 (in benzopentathiepine **1a**)⁸⁰ to 2.063 Å (in dithiolopentathiepine **102**),⁸¹ which is similar to the bond length in the S_8 molecule (2.051 Å). The S–S–S and S–S–S–S angles are also comparable with those in S_6 and S_8 . The S–C bond lengths in pentathiepinines and pentathiepanes (1.744–1.795 Å) are comparable with the S–C(sp²) single bond length (1.78 Å).^{15, 81, 82}

6. Electrochemical methods

The electrochemical properties of pentathiepine **29** were studied by cyclic voltammetry. This compound is characterised by two pairs of reversible redox potentials with the following values: +0.69 and +1.06 V. These potentials are higher than those for the structurally similar BEDT-TTF compound (+0.53 and +0.89 V).²⁰ This indicates that the electron-donor properties of pentathiepine **29** are weaker than those of BEDT-TTF. Apparently, this fact can be attributed to the induction effect due to the larger number of sulfur atoms in the pentathiepine ring.

A comparison of the electrochemical behaviour of pentathiepineindole **40b** and 1-methylindole demonstrated that the introduction of a polysulfur-containing ring into an inactive molecule gives rise to electrochemical activity.⁸³

V. Stereochemical aspects: conformation and chirality

The ^1H NMR spectra of varacin (**2a**) and lissoclinotoxin A (**2b**) show complex signals for the protons of the benzyl group.^{73, 74} A complication of the signals is a consequence of a high energy barrier (30 kcal mol^{−1}) for inversion of the pentathiepine ring, resulting in asymmetry of the molecule and diastereotopicity of the benzyl protons. An increase in temperature from 25 to 100 °C leads to narrowing of the signals and the signals for all protons are clearly observed. The high energy barrier is apparently attributed to unfavourable overlap of the isolated orbitals of the sp³-hybridised sulfur atom during ring inversion through the half-chair transition state.⁷³

The structures of four sulfoxides (**100a,b** and **101a,b**), which were synthesised by oxidation of trithiolobenzopentathiepine **11f** with *m*-chloroperoxybenzoic acid, were estab-

lished by X-ray diffraction.⁷⁵ For pairs of 2- and 1-oxides, the activation parameters of the pentathiepine ring inversion in chloroform at room temperature were determined. It appeared that the free energy change ($^{298}\Delta G^\ddagger$) after complete inversion is from 105.0 to 113.4 kJ mol⁻¹ in each case.⁷⁶

Analogous investigations were performed for pairs of isomers of monosubstituted pentathiepanoacenaphtho[1,2-*a*]acenaphthylenes **37a–c**; for the complete inversion, $^{298}\Delta G^\ddagger$ was 103.8–108.5 kJ mol⁻¹.³¹

R = Et (**a**), Ph (**b**), (**c**).

VI. Quantum-chemical calculations of pentathiepine molecules

The conformations of pentathiepine (**24**), benzopentathiepine (**1a**) and thieno[3,4-*f*]pentathiepine (**1v**) were studied by the semiempirical AM1 method.⁸⁴ It was found that the rigid chair-like conformation of the heterocycle is the most stable one. The results of calculations by the CNDO method correlate well with the observed positions of absorption bands in UV spectra.

Ab initio molecular orbital calculations (SCF and MP-2) of the conformational behaviour of benzopentathiepine (**1a**) are in good agreement with the experimental data. According to the results of calculations, the chair conformation is more stable than the boat and twist conformations.⁷⁰ Calculations of the highest occupied molecular orbital and the lowest unoccupied molecular orbital for compound **1a** by the PM3 method demonstrated that the nucleophilic attack of trialkyl phosphites occurs predominantly on the sulfur atom at position 2 to give products **86** and **87**, as was described above (see Section III.7).⁶⁷

The structures of pentathiepinanes and their reactions were studied in detail by Greer⁸⁵ by density functional theory (DFT). The calculations demonstrated that decomposition of unsubstituted pentathiepine (**24**) upon the nucleophilic attack on the hydrosulfide anion unexpectedly starts with the attack on the S(1) atom rather than with the more expected attack on the S(2) atom. This gives rise to the delocalised enethiolate anion, which initiates the subsequent liberation of the S₃

species.[†] The S₃ molecule was detected by the reactions with norbornene and 2,3-dimethylbuta-1,3-diene; these adducts are analogous to the reaction products with S₂.⁸⁶

VII. Biological activity and practical applications of pentathiepinanes

Varacin (**2a**) isolated from the marine organisms *Lissoclinum vareau* in 1991 was the first known natural pentathiepine.⁵⁸ More recently, several structurally analogous compounds were isolated: lissoclinotoxin A (**2b**) from the ascidians *Lissoclinum* sp.,⁷³ lissoclinotoxin B (**99**) from the tunicate *Lissoclinum perforatum* found near the Palau Islands,⁶⁰ *N,N*-dimethyl-5-(methylthio)varacin (**3a**) from the ascidians *Lissoclinum japonicum*, 5-(methylthio)varacin (**3b**) in a mixture with the corresponding trithiole (in a 2:3 ratio) and demethylated varacin (**2f**) from various species of the marine organisms *Lissoclinum* and *Eudistoma* found near the Pohnpei Island, respectively.⁵⁹

R¹ = R² = Me, R³ = R⁴ = R⁵ = H (**2a**);

R¹ = R² = Me, R³ = SMe, R⁴ = R⁵ = H (**3b**);

R² = R³ = R⁴ = R⁵ = H: R¹ = H (**2f**), Me (**2b**);

R¹ = Me, R² = R⁵ = H, R³–R⁴ = CH₂ (**99**).

Synthetic and natural pentathiepinanes have various biological activities. The antitumour properties of these compounds were tested. High cytotoxicity of varacin was demonstrated with several types of cancer cells (*IC*₅₀ varies from 1 to 50 nmol litre⁻¹).⁸⁷ The cytotoxicity against HCT 116 human colon cancer cells is characterised by *IC*₅₀ = 0.05 mg ml⁻¹. Varacin is 100 times more active and 1.5 times less toxic to CHO EM9 tumour cells compared to 5-fluorouracil (the antitumour drug belonging to antimetabolites).⁵⁸

N,N-Dimethyl-5-(methylthio)varacin (**3a**) and synthetic benzopentathiepinanes **1g** (as hydrochloride), **1h** and **6a** have the cytotoxicity *IC*₅₀ = 0.26, 3.2 and 6.1 mg ml⁻¹, respectively, against HeLa53 cells. Pentathiepine hydrochloride **1g** is 10 times more active in these experiments than the corresponding starting arene-1,2-dithiol.⁷

[†] The appearance of the previously unknown S₃ species is considered as an important factor in chemical and, which is particularly important, biochemical transformations of pentathiepinanes, for example, in the explanation of the mechanism of antitumour action of varacin (**2a**). Elimination of S₃ is attributed also to the presence of the side aminoalkyl group, which was found in all natural pentathiepinanes. The intramolecular attack of the primary or secondary (but not tertiary!) amino group on the S(1) atom of fused pentathiepine is the key step of elimination of the S₃ species.

7-Methylbenzopentathiepine (**11**) has a thiol-dependent DNA-binding ability. This is the first direct evidence that pentathiepinanes can act on DNA in physiological conditions.⁸⁸ Recently, it has been demonstrated⁸⁹ that the nucleophilic attack of thiols leads to a more rapid opening of the pentathiepine ring in 7-methylbenzopentathiepine (**11**) compared to the analogous reactions with di- and trisulfides. Apparently, this is responsible for the cytotoxic role of natural pentathiepinanes interacting with endogenous cellular trisulfides. Varacin has an efficient DNA-binding ability both in the presence and in the absence of 2-mercaptoethanol, and this activity increases with increasing concentration of thiol.⁸⁷

Since all natural pentathiepinanes contain the aminoethyl fragment, the positively charged amino group of pentathiepine antibiotics is presumably favourable for their interactions with DNA.^{88,89} Demethylated varacin (**2f**) and *N,N*-dimethyl-5-(methylthio)varacin (**3a**) inhibit protein kinase C with $IC_{50} = 0.5$ and 3.0 mg ml^{-1} , respectively.⁵⁹

Lissoclinotoxin A (**2b**) and lissoclinotoxin B (**99**) are strong antimicrobial drugs, the former compound showing activity toward a number of microorganisms similar to that of cefotaxim.⁶⁰ Compounds **2b** and **99** were found to have activity against a fish pathogenic strain similar to that of ampicillin.

Varacin (**2a**), lissoclinotoxin A (**2b**) and benzopentathiepine (**1a**) exhibit high *in vitro* activity against the microorganisms *Candida albicans* and *Bacillus subtilis*.^{58,72,73} This activity of the benzopentathiepine system is independent of the presence of an amino group in the side chain. The fungicidal activity of pentathiepinoinisothiazole **26** was tested and covered by patents^{90–93} for the tomato fungus *Phytophthora infestans*⁹⁴ and the fungus *Venturia inaequalis* in infected apple trees.⁹⁵ 7-Trifluoromethylbenzopentathiepine (**1u**) at a concentration of 100 ppm provides 100% protection against the apple scab; its 7-dimethylamino analogue **1q**, 100% protection against the cucumber mosaic virus.⁹⁶

Pentathiepinanes derived from norbornene and its derivatives were proposed as catalysts for vulcanisation of diene rubbers.⁹⁷ Benzo- and perhydrobenzopentathiepinanes were used in photography as additives to emulsion layers or adjacent hydrophilic colloidal layers as antifogging agents;⁹⁸ other pentathiepinanes have found application for the improvement of properties of photographic materials.^{99–104} In 2005, Japanese researchers proposed that pentathiepinoinidole **40a** be used as a cathodic material for storage batteries.⁸³

* * *

In conclusion, it should be noted that 1,2,3,4,5-pentathiepinanes and 1,2,3,4,5-pentathiepanes are the most stable C_2S_n heterocycles because they are thermodynamically controlled products of numerous sulfurisation reactions. Although only a rather small amount of time has passed since the first synthesis of pentathiepanes (in 1967) and pentathiepinanes (in 1971) and isolation of natural antibiotics containing the pentathiepine ring from marine organisms (in 1991), a large number of studies on these compounds have been published. These compounds have attracted considerable interest because of their surprising stability, high inversion barriers of the chair-like pentathiepine ring and various biological activities.

The pentathiepine ring can easily be formed with the use of known synthetic methods; however, these heterocycles are often formed accidentally as a result of quite unexpected transformations of sulfur-containing substrates. Since there are numerous possibilities for both the nucleophilic and electrophilic attack on all five sulfur atoms, the pentathiepine ring can be involved in various chemical reactions. Unfortunately, scarce examples were documented for such transformations, the mechanisms of these transformations often

remaining unknown. Hence, further investigations in this interesting field of heterocyclic chemistry are required.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 05-03-32032).

Abstract. The experimental results concerning the mechanism and thermodynamics of formation of three classes of supramolecular systems, namely, polymers, discrete ring nanostructures and macrocyclic complexes (with crown ethers, cryptands, *etc.*) are surveyed. The thermodynamic factors, in particular, the bond energy between the ‘building blocks’, determining the stability of supramolecular assemblies are analysed. The energy contributions of the metal–ligand and metal–metal interactions and hydrogen bonds to the thermodynamics and mechanism of self-assembly are compared. The principles of design of new polynuclear assemblies of s, p, d and f elements are considered. The bibliography includes 165 references.

I. Introduction

The subject of supramolecular chemistry (SMCh) is the formation of new chemical structures upon self-assembly of molecules and molecular aggregates into supramolecular assemblies (SMA). A founder of this new scientific trend, J-M Lehn proposed^{1,2} the following definition: ‘Beyond molecular chemistry based on the covalent bond, there lies the field of supramolecular chemistry, whose goal it is to gain control over the intermolecular bond’.

Initially, the task of SMCh was formulated (according to Lehn’s views) as the study of ‘non-covalent interaction of two or more subunits’³ or ‘spontaneous interaction of molecules to give structured, stable, non-covalently bound aggregates’.⁴ However, as experimental data on the synthesis of SMA such as supramacrocycles (SMC), macrocyclic complexes (MC) and supramolecular polymers (SMP) have been accumulated, the definition of SMCh was modified. For example, it was stated⁵ that, whereas non-covalent interactions play a key role in the formation of secondary and tertiary structures in natural

macromolecules, in the case of linear supramolecular polymers, strong, highly directed interactions are more desirable in order to create materials with bonds able to make an alternative to covalent bonds. Currently, there is no consensus of opinions about this issue. It has been even doubted⁶ whether it is possible to distinguish between the chemistry of polynuclear metal complexes and SMCh. Generalisation of the proposed mechanisms of SMA formation^{1–8} shows that they include all types of interactions between structural units ranging from weak intermolecular^{1–4} to strong coordination bonds.^{5,7,8} No new, previously unknown types of interaction have been found in the SMCh.

The concepts and notions borrowed from biology have played a significant role in the formation of supramolecular chemistry as a separate field of science. The most important of such concepts are the molecular recognition and cooperativity. The formation of SMA is considered^{1–20} to be a cooperative process based on the molecular recognition of the interacting ‘building blocks’ related to the complementarity principle.

The structural blocks in SMCh include nitrogen- and sulfur-containing heteroaromatic compounds, polypyridine ligands, cyano-substituted aromatic ligands, hydroxamates, *o*-catecholamides, calixarenes, *etc.*^{6–25} Recent reviews are devoted to the synthesis and properties of crown-substituted porphyrinates and phthalocyaninates;⁷ stereochemical aspects of chiral self-assembly;⁶ development of the assembly principle of SMC;^{8,9} dendrimers;^{10,11} tetrathiafulvalenes;¹² rotaxanes;¹³ molecular ‘containers’;¹⁴ crown ethers;¹⁵ the photochromism of SMA;¹⁶ molecular wires;^{17,18} helical polycyanides and SMP¹⁹ and supramolecular fullerene aggregates.²⁰ Some studies discuss the synthesis of new SMA (including SMC) and their practical application as sensors;²¹ nanopores and mesopores; the properties of individual nanoparticles and metallic nanoclusters;²³ and plastic cylinders.²⁴ Although s-, p- and d-metal complexes are used as building blocks,²⁵ preference is given to soft (according to Pearson’s classification²⁶) metal cations: Cu⁺, Ag⁺, Au⁺, Pd²⁺, Pt²⁺, Cd²⁺, Pd⁴⁺, Pt⁴⁺, and cations having intermediate properties: Fe²⁺, Co²⁺, Ni²⁺, Ru²⁺, Os²⁺, Rh³⁺ and Ir³⁺. A number of publications deal with the SMCh of lanthanides^{7,27} and actinides.²⁸ The preparation of polymetallic SMA for Ln³⁺ and An³⁺ may provide a new solution to an important processing problem, namely, the separation of these elements by extraction.

According to Pearson,²⁶ all Ln and An cations are classified as hard acids, irrespective of the oxidation state. The

hardness of Ln and An was characterised quantitatively depending on the oxidation state.^{29,30} It was shown^{31,32} that An³⁺ ions are softer acids than Ln³⁺ and they should be better coordinated to soft bases.

Supramolecular assemblies can contain three and more metal ions. For example, a metallodendrimer containing 64 ferrocenyl ions and a polycobaltocene dendrimer with 32 cobalt ions have been obtained in solutions.¹⁰ The strategy of self-assembly allows one to prepare SMA with pre-specified properties.⁹ In these SMA, metal ions can exhibit new and unexpected redox and magnetic properties. The unique features of SMA include the selective inclusion of guest ions and molecules into the cavities to give new SMA of the guest–host type.^{1,2,8,9}

This review is concerned with SMA constructed from s-, p-, d- and f-metal ion complexes. In these SMA, discrete structures formed through coordination bonding and incorporating metal ions are combined into large stable assemblies. As the experimental data have been accumulated, it became necessary to perform quantitative analysis of the interaction energies between the building blocks, which contribute to the formation enthalpy of SMA. In this review, we attempted to compare quantitatively different mechanisms for SMA formation, in particular, the formation through weak intermolecular interactions,^{1–4,18} strong coordination and ionic interactions^{5–17,19} and mixed type interactions.^{1,2,6,18,22}

Comparison of the energetic characteristics of metal-containing building blocks and the structural fragments linking them to form SMA is an important stage in the study of the thermodynamics of SMA formation. In SMC, the metal–metal interaction even at large distances, as well as interaction through bridging ligands may play a significant role in the formation of stable SMA. All available estimates of the $D_0(\text{AB})$ bond energy are based on the structural thermodynamic model (STM).^{32–34} The basis equations include the following parameters: the radius of the maximum electron density R_0 , which can be found by solving the Schrödinger equation with allowance for relativistic corrections for free atoms in the ground state; the experimental $R_e(\text{AB})$ value, *i.e.*, the equilibrium internuclear distance for the A–B bond in the given compound; R_e^{di} is the experimental internuclear distance in the diatomic AB(g) molecule; $\chi(\text{A})$ and $\chi(\text{B})$ are the chemical potentials of atoms A and B, respectively; $\chi(\text{AB})$ is the relative chemical potential, which is close to the Pauling electronegativity; $\chi^{\text{di}}(\text{AB})$ corresponds to a diatomic AB(g) molecule.

$$\ln[D_0(\text{AB})] = \chi(\text{AB}) + \gamma(\text{AB}) = \lambda(\text{AB});$$

$$D_0(\text{AB}) = ke^{\lambda(\text{AB})}, k \approx 1 \text{ eV};$$

$$\chi(\text{AB}) = \chi(\text{A}) + \chi(\text{B}) = \chi^{\text{di}}(\text{AB})e^y;$$

$$y = (R_e - R_e^{\text{di}})(R_e + R_e^{\text{di}})^{-1};$$

$$\gamma(\text{AB}) = \gamma(\text{A}) + \gamma(\text{B});$$

$$\gamma(\text{A}) = [R_0(\text{A})][R_e(\text{AB})]^{-1} - [R_e(\text{AB})][R_0(\text{A})]^{-1}.$$

In a number of studies,^{30,32,33,35–38} the STM has been used to calculate the thermodynamic properties of d- and f-element complexes with various ligands (H_2O , NO_3 , O-, S- and N-donor ligands, F, Cl, Br). The $D_0(\text{AB})$ bond energies determine the thermodynamic properties of compounds, in particular, the standard enthalpies of their formation in solution $\Delta H_f^\circ(\text{aq})$, in the crystalline state $\Delta H_f^\circ(\text{s})$ and in the gaseous state $\Delta H_f^\circ(\text{g})$. If ΔH_f° have not been measured, they can be calculated from known $D_0(\text{AB})$ values; conversely, if ΔH_f° have been measured, they can be used to evaluate the accuracy of $D_0(\text{AB})$ by solving the inverse problem.

The following properties were calculated^{35,36} for compounds of d elements: $\Delta H_f^\circ(\text{ML}_4, \text{g})$ and $\Delta H_f^\circ(\text{ML}_4, \text{s})$, L = Cl, Br; $\Delta H_f^\circ(\text{MCl}_6^{2-}, \text{g})$, $\Delta H_f^\circ(\text{MCl}_6^{2-}, \text{aq})$ and

$\Delta H_f^\circ(\text{A}_2\text{MCl}_6, \text{s})$, where M are 4d, 5d, 6d and 5f elements (Zr, Hf, Th, Rf; Nb, Ta, Pa, Db; Mo, W, U, Sg; Tc, Re, Np, Bh; Ru, Os, Pu, Hs; Rh, Ir, Am, Mt; Pd, Pt, Cm, ¹¹⁰TAn; TAn are transactinides). The ΔH_f° values for many compounds of 3d, 4d, 5d and 5f elements have been measured. The calculations^{30,32,33,35–38} of ΔH_f° and $D_0(\text{AB})$ reproduce the experimental values to within $\pm 15 \text{ kJ mol}^{-1}$; this has stimulated the use of the STM for predicting the properties of transactinides [$D_0(\text{TAn} - \text{Hal})$ and $\Delta H_f^\circ(\text{TAnHal}_4)$]^{35,36} and the properties of SMA. The structural thermodynamic model has also been used to estimate the thermodynamic parameters for the extraction of Ln³⁺ and An³⁺ ions with amides,³² acids R₂PSSH and O-containing co-extractants such as phosphates, amides and phosphine oxides.^{30,37}

In supramolecular chemistry, polypyridine ligands, for example, 2,2':6',2''-terpyridine, are widely used as building blocks. Data on the thermodynamic properties of the complexes of f elements with this class of ligands are scarce.²⁷ The stability constants $K(\text{LnL}^{3+})$ for 70 complexes with these ligands were calculated, while for 15 complexes they were measured.³⁸ The accuracy of calculation was $\pm 10\%$ of the experimental $\log K(\text{LnL}^{3+})$ values.

II. Molecular recognition in biology and coordination chemistry

The progress in the development of nanochemistry and nanotechnology is largely due to the use of biological concepts.^{8,39–42} The idea of designing machines at the molecular level has also come to chemistry from biology: numerous biological ‘machines’, for example, cell proton pumps, transmembrane ion channels, *etc.*, are known.⁴² A classical example of molecular recognition in biology is the complementary binding of nucleotides into the DNA double helix.^{1,43} A classification of different types of molecular recognition has been proposed.^{2,44} Weak specific interactions between the receptor and the substrate play an important role in the formation of complex biological structures at the cellular level, hydrogen bonds being especially significant.^{43,45}

The supramolecular chemistry usually considers two limiting mechanisms for SMA formation: non-covalent^{1,2,45} and covalent interactions.⁴² However, this differentiation is rather conventional.^{5,6} The formation of SMA through hydrogen bonds has been discussed in the literature.^{18,41,43,45} Coordination bonds can also act as strong interactions.

The coordination mechanism of SMA formation, which is also called metal-directed self-assembly,^{8,9,42} is an alternative to the mechanism based on weak intermolecular interactions (this is called in some cases the biological mechanism). The key features of the coordination mechanism include^{8,39,42} the directional character of the metal–ligand bonds; the diversity of SMA caused by the diversity of building blocks (polydentate ligands and metals), a combination of strong and weak bonds,²² the possibility of a control over the reaction mechanism, *i.e.*, of carrying out the reaction under thermodynamic or kinetic control.^{8,9,39}

The molecular recognition principle in the coordination mechanism is based on the stereochemical model developed in a number of papers.^{8,9,39} It is noteworthy that the decrease in the free energy upon the formation of SMA according to this mechanism is due to the appearance of weak coordination bonds between the metal atoms either directly ($\text{M} \cdots \text{M}$) or through bridging ligands ($\text{M} \cdots \text{L} \cdots \text{M}$).¹⁵ The properties of cations (the electronic configuration and the size determining the geometry of the polyhedra in the local environment), the softness or hardness of cations and ligands and the chelation effects are to be taken into account in the coordination mechanism of SMA formation. Chelating polypyridine ligands have found extensive use in SMCh.^{1,2,6,8,9,14,18,39,42} It was

shown⁴⁶ that in the formation of the ML_n^{3+} complexes, where $M = Ln^{3+}$ ($Ln = La, Ce, \dots, Lu$) and An^{3+} ($An = Pu, Am, Cm$), with such ligands, the chelation effect can stabilise complexes both by increasing the entropy and by decreasing the enthalpy, depending on the cation and the number of ligands n ($n = 1-3$). The effect of chelation on the thermodynamics of self-assembly of molecules to SMA has not yet been considered.

III. Transition d and f elements as structural components of polymers

The self-assembly giving rise to supramolecular systems is a new line of research in the polymer science.⁵ This research is at the boundary of organic, bioorganic and inorganic chemistry. Polymers of new generation are synthesised based on a preset (*i.e.*, inherent in the synthetic strategy)⁴⁷ combination of intramolecular and/or intermolecular interactions.⁶ A prominent achievement in this field is the synthesis of polymers with one-dimensional structure. The search for and the targeted synthesis of quasi-one-dimensional systems is an important problem in the solid-state physics and chemistry. This Section deals with the properties of the new-generation polymers.

1. Self-assembly in the formation of inorganic polymers: the effect of the electronic structures of metals and ligands

In recent years, dinuclear metal complexes have been actively used to design molecular assemblies. The synthesis of one-dimensional tetracarboxylate SMP where the blocks containing Rh_2^{4+} or Re_2^{6+} are combined by hydrogen bonds has been reported.⁴⁷ Many polymers of this type in which dinuclear blocks are connected by bridging ligands have been studied previously. The structure of the first inorganic formate-containing polymer $Rh_2(HCOO)_4 \cdot H_2O$ (**1**) with the Rh^{2+} ions linked by bridging oxygen atoms $Rh^{2+} \dots O \dots Rh^{2+}$ has been reported in a review;⁴⁸ the references cited therein have initiated the study of SMP based on dinuclear d-element cations. Although dimeric Cr, Rh, Cu and Mo carboxylates were the first to be prepared, their structural studies were performed somewhat later. Using the results of early synthetic and structural works^{48,49} and later publications,^{47,50-52} we compared the bond energies in the polymers constructed from the same dinuclear blocks connected by either bridging ligands^{48,49} or hydrogen bonds.^{5,47,50-52}

Inorganic metal-containing SMP can exist in different conformations: helical, zigzag and so on. A theoretical model interpreting the reasons and the mechanism for the formation of a particular conformation in inorganic SMP should take into account the electronic structure of the metal cation.

As an example, consider compounds of monovalent elements of the copper group: Cu^+ , Ag^+ and Au^+ . In the crystals of $KCu(CN)_2$ (**2**), the Cu atoms have a coordination number (C.N.) of 3. The C and N atoms and the Cu atoms to which they are bonded are nearly coplanar.⁵³ One CN group is terminal and the other two groups are bridging. This gives rise to helical polymeric chains $\dots CN \dots Cu \dots CN \dots$. In the $KCu_2(CN)_3 \cdot H_2O$ crystal, the polymeric layers $[Cu_2(CN)_3]_n^-$ are composed of helical $(CuCN)_n$ chains (as in compound **2**) and zigzag $(CuCN)_n$ chains; the Cu atoms in the polymeric chains with different conformations are linked through the third cyano group. It should be emphasised that the anions in $KAg(CN)_2$ (**3**) and $KAu(CN)_2$ (**4**) are discrete and form no polymeric structures.⁵³ A linear coordination and C.N. equal to 2 have also been found for the Ag atom in $AgSCN$ and $AgCN$, which are zigzag polymers in the solid state.

A triangular coordination of the metal atom like that in compound **2** may arise in the case of ds^2 , dp^2 or sp^2 hybridisation. The Cu, Ag and Au atoms have the same electronic configuration $nd^{10}(n+1)s^1$, $n = 3-5$; however, the formation

of the $nd^9(n+1)s^2$ electronic configuration corresponding to these types of hybridisation requires different energy expenditures $\Delta E(ds)$. The $\Delta E(ds)$ value is abnormally high for Ag and is the lowest for Cu:⁵⁴

Element	Cu	Ag	Au
$\Delta E(ds) / kJ mol^{-1}$	34.4	91.8	40.2

As a result, among the three compounds with the same composition $KM(CN)_2$, compound **2** has a polymer structure (the C.N. of Cu is 3) and compounds **3** and **4** have a discrete structure (the C.Ns of Ag and Au are 2). Thus, the electronic structure determines the C.N. Note that the mechanism of formation of these inorganic polymers is determined by strong (ionic and covalent) rather than weak interactions. Thus the thermal stability and low solubility of the acetylenide polymer $Cu_2C_2 \cdot H_2O$ are due to the formation of strong π -bonds.⁵³ Transitions between conformations of inorganic polymers require, most often, large energy expenditure.

Concluding this Section, consider an interesting example in which the metal complex serves as the polymerisation catalyst of aliphatic and aromatic isocyanides.¹⁹

Complex **A** has a *trans*-configuration; however, for polymerisation to start, the complex must have two vacant *cis*-sites. Complex **B** formed under the action of an acid serves as an efficient polymerisation catalyst. The driving force of this reaction is the transformation of formally divalent carbon in the monomer into the tetravalent carbon in the polymer. The reaction readily proceeds at room temperature, the reaction heat being $81.4 kJ mol^{-1}$. It cannot be ruled out that the heat of polymerisation is related to the electron excitation energy accompanying the transition of carbon into the tetravalent state.

The considered examples demonstrate the importance of electronic effects in the thermodynamics of the formation of polymers involving metals and non-metals.

2. Coordination mechanism of the formation of inorganic carboxylate polymers containing M_2^{4+} dimers of d elements

Quasi-one-dimensional systems have long been of only theoretical interest as hypothetical models in the solid-state physics and chemistry; they were used to start the solution of many problems. However, more recently, synthetic chemists have manufactured species that can be regarded, to a first approximation, as one-dimensional solids.⁵⁵ Among these, an important place is occupied by divalent 3d-element carboxylates. For example, the compound $Cu(PhCOO)_2 \cdot 3 H_2O$ is a one-dimensional ferromagnet and is described by the Heisenberg model.⁵⁵ On the basis of M_2^{4+} carboxylate complexes ($M = Cr, Mo, Cu, Rh$), polymers with a quasi-one-dimensional chain structure have been prepared. The simplest compound, dirhodium tetraformate monohydrate $Rh_2(HCOO)_4 \cdot H_2O$ (**1**) consists of two types of complexes:⁴⁸ $Rh_2(HCOO)_4 \cdot (H_2O)_2$ (**1a**) and $Rh_2(HCOO)_4$ (**1b**). Complexes **1a** have a distorted octahedral geometry and consist of $Rh^{2+}-Rh^{2+}$ dimers connected by four bridging $HCOO^-$ groups, and two H_2O molecules occupy the *trans*-positions with respect to the $Rh^{2+}-Rh^{2+}$ bond. Complex **1b** contains no coordinated H_2O molecules; they are replaced by the O atoms of the $HCOO^-$ groups of the neighbouring complexes **1a**. The $Rh^{2+}-Rh^{2+}$ bonds are oriented either along the polymer axis or at an angle, which is favourable for binding Rh_2^{4+} dimers through the bridging O atoms: $Rh_2^{4+} \dots O \dots Rh_2^{4+}$. Compound **1** has one coordination vacancy. In the polymer, weak cooperative charge ordering is formed along the $(Rh_2^{4+\delta} \dots Rh_2^{4-\delta})_x$ axis, resulting in polymer stabilisation. The coordinatively saturated compound

$\text{Rh}_2(\text{OAc})_4(\text{H}_2\text{O})_2$ (**5**) does not form a polymer, as the 'excess' water molecule (missing from compound **1**) saturates the coordination. Numerous non-polymeric compounds $\text{M}_2(\text{RCOO})_4\text{L}_2$ ($\text{M} = \text{Cr}, \text{Mo}, \text{Cu}, \text{Rh}$, etc., L is a neutral ligand) have been prepared; they do not undergo disproportionation to give two complementary complexes.⁴⁹

The interatomic distances $R(\text{Rh}-\text{Rh}) = 2.38 \pm 0.02 \text{ \AA}$, $R[\text{Rh}-\text{O}(\text{water})] = 2.20 \pm 0.06 \text{ \AA}$, average $R(\text{Rh}-\text{O}) = 2.03 \pm 0.05 \text{ \AA}$ in polymer **1**⁴⁸ are much shorter than the $R(\text{Rh}-\text{O}) = 2.45 \pm 0.03 \text{ \AA}$ distance to the inter-moiety bridging oxygen atom. Here and below, the bond energies in the structural blocks were calculated²² based on the STM^{32,33} with experimental $R(\text{A}-\text{B})$ distances reported in the studies cited and with handbook⁵⁶ data for R_{e}^{di} : $D_0(\text{Rh}^{2+}-\text{Rh}^{2+}) = 233.5$, $D_0(\text{Rh}^{2+}-\text{O}) = 246.9$ and $D_0(\text{Rh}^{2+}-\text{OH}_2) = 178.8 \text{ kJ mol}^{-1}$, while the energy of the bridging $\text{Rh}^{2+}-\text{O}$ bonds combining these blocks into a polymer, $D_0(\text{Rh}^{2+}-\text{O})$ is equal to $111.2 \text{ kJ mol}^{-1}$.

The driving force of polymerisation is disproportionation $2\text{I} \rightarrow \text{1a} + \text{1b}$, resulting in alternation of the complementary complexes **1a** and **1b**. It follows from the bond energies that complexes **1a** and **1b** are constructed through strong coordination bonds and are connected to each other by weaker bridging bonds.

3. Mechanism of formation of supramolecular polymers containing M_2^{4+} dimers of d elements with participation of hydrogen bonds

In recent years, the trend of using combinations of strong valence bonds with weak intermolecular contacts ($\pi-\pi$ -interactions, hydrogen bonds and so on) has started to develop in the SMP synthesis. In order to connect metal-containing blocks into the SMP through hydrogen bonds, pyridinecarboxylic acids and their amides are used most often.^{57,58} Another synthetic strategy for the preparation of one-dimensional SMP using dinuclear M_2 fragments was developed in parallel.^{51,52} The two possible limiting M_2 orientations with respect to the polymeric chain dictate the range of bridging ligands: parallel (axial bridges) and perpendicular (equatorial bridges) orientations. The complexes containing Rh_2^{4+} or Re_2^{6+} dimers were used to prepare one-dimensional SMP:⁴⁷ $\text{Rh}_2(\text{OAc})_4(\text{INA})_2 \cdot 2 \text{Me}_2\text{CO}$ (**6**); $\text{Rh}_2(\text{OAc})_4(\text{NIA})_2 \cdot 2 \text{Me}_2\text{CO}$ (**7**); *cis*- $\text{Re}_2(\text{OAc})_2\text{Cl}_4(\text{INA})_2$; *cis*- $\text{Re}_2(\text{OAc})_2\text{Cl}_4 \cdot (\text{NIA})_2 \cdot 2(\text{NIA})$, where INA is isonicotinamide and NIA is nicotinamide. The idea was to replace two water molecules in complex **5**, which cannot be self-assembled due to the coordination saturation, by the ligands NIA or INA, which form hydrogen bonds like other amides. Pyridinecarboxamides are used as donors in the axial positions, while hydrogen bonds are formed due to complementarity of the amide groups. The conformation of SMP depends on the geometry of the linkers (NIA and INA). As a result, compound **6** contains linear polymer chains and complex **7** contains zigzag chains.

Presumably, the stability of the dirhodium SMP is due to the presence of a stable diamagnetic structural block, $\text{Rh}^{2+}-\text{Rh}^{2+}$. Then one can expect that $R(\text{Rh}-\text{Rh})$ in SMP **6**, **7** and in compound **5** would be different. Although these differences are slight: $R(\text{Rh}-\text{Rh}) = 2.4034(16)$ (for **6**), $2.3972(12)$ (for **7**), $2.3855(5)$ (for **5**), $2.38(2) \text{ \AA}$ (for **1**),⁴⁷⁻⁴⁹ the secondary effect is still observed, namely, the $\text{Rh}^{2+}-\text{Rh}^{2+}$ bonds in complexes **6** and **7** are slightly weaker than those in non-polymeric compound **5**, and these bonds in complex **1** are slightly stronger than those in **5**. The $D_0(\text{Rh}-\text{Rh})$ values were calculated in terms of the STM (to the accuracy of $\pm 2 \text{ kJ mol}^{-1}$): $D_0(\text{Rh}-\text{Rh}) = 224$ (for **6**) ≤ 226 (for **7**) < 231 (for **5**) $\leq 234 \text{ kJ mol}^{-1}$ (for **1**).

The average $R(\text{Rh}-\text{O})$ distances to the carboxylate oxygen atoms in the three SMP are similar:^{47,48} $R(\text{Rh}-\text{O}) = 2.03(5)$ (**1**); $2.036(6)$ (**6**) and $2.037(4) \text{ \AA}$ (**7**). The key difference between

the SMP **1** and **6**, **7** is related to the energetic properties of linkers, i.e., the $\text{Rh}_2^{4+} \cdots \text{O} \cdots \text{Rh}_2^{4+}$ bridging bonds in complex **1** and hydrogen bonds in complexes **6** and **7**. The interaction energy between the blocks upon the formation of hydrogen bonds is much lower than the bridging bond energies, which accounts for the higher stability of polymers of type **1**.

The difference between the energetic properties of linear and zigzag polymers **6** and **7** is due to the difference between the $R(\text{Rh}-\text{N})$ distances to the pyridine N atoms: $R(\text{Rh}-\text{N}) = 2.205(7)$ (INA) and $2.224(5) \text{ \AA}$ (NIA). The calculated values, $D_0[\text{Rh}-\text{N}(\text{INA})] = 240$ and $D_0[\text{Rh}-\text{N}(\text{NIA})] = 232 \text{ kJ mol}^{-1}$, differ by 8 kJ mol^{-1} . The stronger $\text{Rh}-\text{N}$ bond in SMP **6** results in weakening of hydrogen bonds: $R(\text{N}-\text{H} \cdots \text{O}) = 2.922 \text{ \AA}$ with respect to $R(\text{N}-\text{H} \cdots \text{O}) = 2.865 \text{ \AA}$ in SMP **7**.

The thermodynamic and structural properties of compounds with hydrogen bonds have been studied in numerous works.^{5,18,41,43,59-64} The first estimates of the energies of such bonds concern the peptide structure.⁶¹ Then the energies of the $\text{O}-\text{H} \cdots \text{O}$, $\text{O}-\text{H} \cdots \text{N}$, $\text{N}-\text{H} \cdots \text{O}$, $\text{N}-\text{H} \cdots \text{N}$, $\text{O}-\text{H} \cdots \text{Cl}$, $\text{N}-\text{H} \cdots \text{F}$, $\text{N}-\text{H} \cdots \text{Cl}$, $\text{F}-\text{H} \cdots \text{F}$ and other hydrogen bonds were determined from thermodynamic properties of the corresponding compounds or from spectroscopic data⁶³⁻⁶⁵ or calculated in terms of the STM.⁶⁶ In a review,⁴¹ the reference values for hydrogen bond energies have been compared with the energies of conventional single bonds. The $\text{S}-\text{S}$, $\text{C}-\text{P}$, $\text{C}-\text{N}$, $\text{C}-\text{Cl}$, $\text{C}-\text{C}$, $\text{N}-\text{H}$, $\text{C}-\text{H}$, $\text{H}-\text{H}$ and $\text{O}-\text{H}$ bond energies vary in the range of $260-460 \text{ kJ mol}^{-1}$, while hydrogen bond energies lie in the $10-65 \text{ kJ mol}^{-1}$ range; however, if the hydrogen bond is formed with an ion (for example, $\text{HCOOH} \cdots \text{F}^-$), the range is broadened to $40-190 \text{ kJ mol}^{-1}$.

It follows from the reported data^{18,41,60,63,64,66} that the dependence of the hydrogen bond energy $D(\text{AH} \cdots \text{B})$ ($\text{A} = \text{N}$; $\text{B} = \text{O}, \text{Cl}$; $\text{A} = \text{B} = \text{O}$, and so on) on the $R(\text{A} \cdots \text{B})$ distance is described by the equation

$$D(\text{AH} \cdots \text{B}) = \alpha \exp[-\beta R(\text{A} \cdots \text{B})],$$

where α and β are empirical constants.

Using this equation, $D(\text{AH} \cdots \text{B})$ can be estimated from the measured $R(\text{A} \cdots \text{B})$ values to the accuracy of $\pm 3\%$ relative to the values determined from spectroscopic and thermodynamic characteristics of the corresponding compounds.⁶³⁻⁶⁵ The hydrogen bond energies were calculated in terms of the STM.⁶⁶

The hydrogen bond energies for SMP **6** and **7** were found to be 6.5 and 7.6 kJ mol^{-1} , respectively. Since each complex is linked to two neighbouring complexes by four hydrogen bonds, the total energy difference for two conformations is equal to $\sim 5 \text{ kJ mol}^{-1}$. Hydrogen bonds formed at so long distances ($2.8-2.9 \text{ \AA}$) cannot be strong. The energies of the bridging coordination bonds [$D_0(\text{Rh}^{2+}-\text{O}) = 111.2 \text{ kJ mol}^{-1}$] in inorganic polymer **1** are much higher than the hydrogen bond energies in SMP **6** and **7** [$4 D_0(\text{N}-\text{H} \cdots \text{O}) \approx 30 \text{ kJ mol}^{-1}$]. Apart from hydrogen bonds, other non-valent contacts should also be taken into account in the structures of complexes **6** and **7**; however, they are also present in SMP **1**.

The $\text{N}-\text{H} \cdots \text{O}$ distances and the hydrogen bond energies in polymers **6** and **7** fall in the range typical of biological systems. Indeed, in the case of peptides,⁶³ the $R(\text{NH} \cdots \text{O})$ distance ranges from 2.80 to 3.16 \AA . However, a value of 2.90 \AA equal to the sum of the van der Waals radii of the oxygen and nitrogen atoms $R^{\text{VW}}(\text{NO})$ is encountered most often. Meanwhile, in the linear SMP **6**, $R(\text{N} \cdots \text{O}) = 2.922 \text{ \AA} > R^{\text{VW}}(\text{NO})$, and in the zigzag SMP **7**, $R(\text{N} \cdots \text{O}) = 2.865 \text{ \AA} < R^{\text{VW}}(\text{NO})$.

It has been noted above that the presence of axial ligands relative to the $\text{Rh}-\text{Rh}$ bonds prevents the formation of SMP, because these complexes are coordinatively saturated. This is also valid for other metal compounds. Thus all non-solvated compounds $\text{Cr}_2(\text{O}_2\text{CR})_4$ form polymeric chains in the crystalline state where $R(\text{Cr}-\text{Cr})$ varies from 2.2 to 2.5 \AA ,⁴⁹ and the

bond energy $D_0(\text{Cr}^{2+} - \text{Cr}^{2+})$ that we calculated falls in the range of 154–232 kJ mol⁻¹. However, the lack of axial ligands is a necessary but not a sufficient condition for self-assembly to give SMP. If very short bonds, $R(\text{Cr} - \text{Cr}) < 1.9 \text{ \AA}$, are formed in the complexes, their energy sharply increases and the complexes lose flexibility. These complexes contain no axial ligands but still they do not tend to self-assemble.

Thus, a comparison of the two mechanisms of SMP formation from identical dinuclear blocks (through bridging oxygen ligands or hydrogen bonds) indicates that the bridging coordination bond energy for inorganic polymer **1** is higher than the total energy of all hydrogen bonds in SMP **6** and **7** and that the stronger the coordination bonds in the initial building block, the weaker the hydrogen bonds between the blocks.

4. Self-assembly of trivalent lanthanide and actinide complexes

As mentioned above, the lanthanide ions Ln^{3+} are classified as hard acids; they form strong bonds with hard bases.^{26,67} However, in recent years, interest has arisen in Ln^{3+} compounds in which the coordination sphere contains both hard and soft donor atoms: (F, S, O),⁶⁸ (O, S, N).^{30,36–38,69,70} These compounds were found to exhibit unusual properties not inherent in Ln^{3+} compounds containing either only hard or only soft ligands. These properties have already found application in the separation of Ln^{3+} and An^{3+} ions by extraction.^{30,36–38} In sulfur-containing crystalline compounds, Sm and Eu are known to exhibit mixed valence.⁶⁷ The reactions of metallic Sm and Eu with mercury perfluorobenzenethiolate $\text{Hg}(\text{SC}_6\text{F}_5)_2$ in THF give dimer $[(\text{THF})_2\text{Sm}(\text{SC}_6\text{F}_5)_2 \cdot (\mu\text{-SC}_6\text{F}_5)]_2$ (**8**) and one-dimensional polymer $[(\text{THF})_2\text{Eu} \cdot (\text{SC}_6\text{F}_5)_2(\mu\text{-SC}_6\text{F}_5)]_n$ (**9**), respectively.⁶⁸ In dimer **8**, two thiolate ligands form rings through the Sm–S and Sm–F bonds, while the bridging thiolate ligands are not coordinated by F atoms. The coordination sphere is completed by two THF ligands. In compound **9** (unlike dimer **8**), the bridging thiolates interact with Eu atoms through F atoms, thus forming an SMP. This is a rare example where a ‘hard’ F atom is coordinated as a neutral donor and, in combination with a ‘soft’ S atom, gives rise to an eight-coordinate Eu^{2+} (4S + 2F + 2O).

The charge transfer energies from the higher occupied non-bonding molecular orbitals (MO) $\Delta E(\text{L} \rightarrow \text{M}^{3+})$ (L = S, F) in S- and F-containing lanthanide and actinide compounds (M = La, Ce, Pr, ..., Lu; Ac, Th, Pa, ..., Lr) have been discussed.^{30,37} On the basis of the $\Delta E(\text{L} \rightarrow \text{M}^{3+})$ values, one can find out what lanthanides (apart from Eu) and light actinides (from Ac to Am) could form SMP similar to polymer **9** according to the same mechanism. The $\Delta E(\text{L} \rightarrow \text{M}^{3+})$ values are known to correlate with the reduction potentials $E^\circ(3+/2+)$. It was found experimentally^{30,37} that the lowest $\Delta E(\text{S} \rightarrow \text{Ln}^{3+})$ values in the lanthanide series (in eV) are found for Eu (2.79), Yb (3.26) and Sm (3.77), while among light actinides, this is observed for Am (4.22). The corresponding $E^\circ(3+/2+)$ values are 0.35 (Eu), 1.05 (Yb), 1.55 (Sm) and 2.3 V (Am).³⁷ The measured distances, $R(\text{Sm} - \text{S}) = 2.822$ (**8**) and $R(\text{Eu} - \text{S}) = 3.034 \text{ \AA}$ (**9**),⁶⁸ correspond to the ionic radii $R_{\text{ion}}(\text{Sm}^{3+})$ and $R_{\text{ion}}(\text{Eu}^{2+})$. Using the correlation between $E^\circ(3+/2+)$ for Eu, Yb, Sm, Am and the measured $R(\text{Sm} - \text{S})$ and $R(\text{Eu} - \text{S})$ values, one gets $R(\text{Yb} - \text{S}) = 2.954$ and $R(\text{Am} - \text{S}) = 2.850 \text{ \AA}$. These distances correspond to ionic radii $R_{\text{ion}}(\text{Am}^{3+}) = 1.106$ and $R_{\text{ion}}(\text{Yb}^{2+}) = 1.186 \text{ \AA}$. The qualitative estimates lead to the conclusion that Am, like Sm, would not be reduced within the thiolates under discussion, while Yb is expected to be reduced like Eu. In the former case, the reaction gives a dimer and in the latter case, an SMP is formed. It can be seen that the polymer is formed if the $E^\circ(3+/2+)$ and $\Delta E(\text{L} \rightarrow \text{M}^{3+})$ values obey the following

conditions: $0.35 \leq E^\circ(3+/2+) < 1.55 \text{ V}$ and $2.79 \leq \Delta E(\text{L} \rightarrow \text{M}^{3+}) < 3.26 \text{ eV}$.

An exceptionally high level of cooperative $\pi - \pi$ -interaction of the thiolate rings has been noted⁶⁸ for the SMP.

IV. Complexes of d and f elements as the building blocks in macrocycles

The square planar (M = Pd^{2+} , Pt^{2+}), tetrahedral (M = Cu^+) and octahedral (M = Fe^{2+} , Co^{2+} , Ni^{2+}) complexes are used most often in self-assembly reactions. To date, supramacrocycles containing from 2 to 12 metal atoms have been prepared in the solid state and in solution. These can be classified into three types: (1) SMC in which the metal atoms are separated by bridging ligands; however, a weak $\text{M} \cdots \text{M}$ interaction exists and contributes to the thermodynamics of SMC formation; (2) SMC in which the metal atoms are shielded by bulky ligands, the distances $\text{M} \cdots \text{M} > 5 \text{ \AA}$ and $\text{M} \cdots \text{M}$ interaction is lacking; (3) SMC with short and strong $\text{M} \cdots \text{M}$ bonds making an appreciable contribution to the thermodynamics of SMC formation.

In the SMC chemistry, the principle of SMA formation is formulated^{8,9,14,39} as metal-directed self-assembly. The most typical features of the self-assembly of discrete metal-containing blocks into large cyclic aggregates have been summarised in a review:⁸ (1) upon self-assembly, the blocks are selectively bound by coordination bonds based on the molecular recognition principle; (2) self-assembly is a cooperative process; (3) the SMA formed are discrete. The above-listed publications mention all types of interactions ranging from weak intermolecular to ionic and covalent ones. Therefore, we consider it important to compare the energetic properties of the strong coordination bonds $\text{M} \cdots \text{M}$, $\text{M} \leftarrow \text{L}$ and hydrogen bonds ($\text{OH} \cdots \text{O}$, $\text{NH} \cdots \text{O}$, $\text{NH} \cdots \text{Cl}$), which contribute to the formation energy of SMC.

Note that the properties of SMC are determined by not only the nature of intermolecular interactions but also the electronic structure of the metal ions, their Lewis acid properties (soft or hard),^{26,69} their redox potentials and their dependence on the number (q) of p^q , d^q and f^q electrons.^{29,70}

It is necessary to emphasise that the macrocyclic systems we discuss differ fundamentally from the previously studied polynuclear metal complexes by the fact that the large ring system exists not only in the solid state but is also formed and retained in solutions. This feature opens up broad prospects for the use of these systems in nanotechnology and molecular-level technology.

The experimental thermodynamic data concerning the free energy or enthalpy of formation of SMC are few. As a rule, they are used to draw qualitative conclusions concerning the driving force of the formation of various SMC: some studies assume the entropy mechanism and other studies, the enthalpy or mixed (enthalpy and entropy) mechanisms. We attempted to estimate quantitatively the contribution of weak and strong interactions to the formation of SMC.

1. Mechanism of self-assembly of macrocycles

A number of mechanisms for the self-assembly of macrocycles have been considered in biology and coordination chemistry.^{8,39} A fast kinetic process and thermodynamic equilibrium between the reactants and products in every reaction stage are the key features of the self-assembly mechanism typical of coordination chemistry. This mechanism has been called³⁹ thermodynamic or strict. The ratio of the products in the final stage of self-assembly is determined by their thermodynamic stability. The thermodynamic self-assembly should result in one, most stable product to be of practical value.² Other self-assembly mechanisms characteristic of both biology and coordination chemistry also exist. They have been classi-

fied and analysed.⁷¹ (1) An irreversible or kinetically controlled mechanism of self-assembly induces a cascade of irreversible reactions and the equilibrium is not reached. (2) An assisted mechanism involving an auxiliary reagent that does not participate in either self-assembly or the formation of the final product but prevents the formation of intermediate products. (3) The directed mechanism requires the presence of a recognition pattern reagent, which directs the self-assembly without being involved in the formation of the final product. Other mechanisms assuming various ways of modification of either reactants prior to self-assembly or final products after the self-assembly (post-modification) have also been considered.⁷¹ Although many SMA have been prepared according to the thermodynamic mechanism of self-assembly, other self-assembly mechanisms (irreversible, directed, and self-assembly with post-modification) are also widely used, for example, in Sauvage's studies.^{72–74} Molecular knots, most of catenanes and some kinetically stable helical SMA have been prepared by self-assembly with post-modification.^{75, 76}

The present review considers the SMA prepared according to the thermodynamic self-assembly mechanism. Note once again that the so-called biological (*i.e.*, caused by intermolecular interactions) and coordination self-assembly mechanisms are not always easily differentiated. For example, complexes of the type MA_2X_2 , where $M = Pd^{2+}, Pt^{2+}$, A is a neutral ligand, X is an anion, are widely used in the SMC synthesis.^{1, 2, 9, 10, 39} In the solid state, these compounds form islet structures MA_2X_2 in which the complexes are linked by weak intermolecular interactions. For example, in the *cis*-isomer of dichlorodiammineplatinum, a 'column motif' is repeated.⁷⁷ In the neighbouring columns, two Cl atoms of the same complex are linked to two NH_3 groups of another complex by hydrogen bonds with the distances $R[Cl(1) \cdots N(2)] = 3.34$ and $R[Cl(2) \cdots N(1)] = 3.30$ Å.⁷⁷ The $R(Pt-Pt)$ distances are 3.372 and 3.409 Å. Each pair of complexes in the columns is linked by two hydrogen bonds the energies of which (our calculations) are as follows (in $kJ\ mol^{-1}$): $D_0[NH_3 \cdots Cl(1)] = 49.7$; $D_0[NH_3 \cdots Cl(2)] = 45.6$. The $Pt-Pt$ bonds also contribute to stabilisation of the *cis*-isomer: $D_0(Pt-Pt) = 28.7\ kJ\ mol^{-1}$ for $R(Pt-Pt) = 3.409$ Å; $D_0(Pt-Pt) = 29.9\ kJ\ mol^{-1}$ for $R(Pt-Pt) = 3.372$ Å. For each pair of complexes in neighbouring columns, the intermolecular interaction energy is relatively high: $\Sigma D_0 \approx 125\ kJ\ mol^{-1}$. This example demonstrates that weak intermolecular $M-M$ contacts may be important both for the coordination chemistry and in SMC by determining the self-assembly process.

It is emphasised in a review⁸ that self-assembly is a cooperative process. A monograph⁵⁵ devoted to the theory of cooperative processes and order-disorder type models presents the result of a quasichemical approximation in the solution of the Ising problem for the Bethe lattice, which represents a tree within the framework of the graph theory. Numerous dendrimers with this type of structural motif have been described in reviews.^{10, 11} Theoretical physicists have anticipated, to some extent, the existence of some structural motifs, which have been later considered in the SMCh. Similarly, theoretical physicists have predicted⁵⁵ some structural motifs and called them 'ladder cluster', 'ladder pseudo-assembly' and so on; more recently, the SMA called the 'ladder', 'rack' and 'grid' have been synthesised in solution and in the solid state.^{1, 39}

2. Structural factors in the formation of supramacrocycles

The structural principles of the design of SMC were developed at a qualitative level in the studies by Lehn,^{78, 79} Raymond,⁸⁰ Verkade,⁸¹ Fujita^{9, 82} and Stang.⁸ Lehn introduced into practice^{78, 79, 83} the method of SMA formation with the use of branched chelating ligands, which are highly pre-organised and have a large binding energy to metals. As compared with

monodendate ligands, the benefit in the free energy is due to the chelation effect. At an early stage of the development of SMCh, various SMA have been synthesised by mere screening diverse ligands and metals. Subsequently, rational approaches to the synthesis of these assemblies have been developed; these can be described systematically as two models.⁸

The first approach was called the symmetry interaction model.^{8, 79–83} This model considers free metal ions and ligands, most often, rather rigid bi- and tridentate chelating ligands as the starting fragments. The preferential coordination number and the preferential polyhedron for a given metal are taken into account. On the basis of analysis of the point group of symmetry of the target assembly with allowance for the mutual arrangement of the symmetry axes of various types, the synthesis is planned with particular metal ions and particular ligands. For more precise description of the geometric relations between the ligands and the metal ion, a number of special terms were defined (chelation vector, chelate plane, approach angle).^{8, 80}

The other ideology can be called a molecular library model.^{1, 2, 8, 9, 39} In this case, coordinatively unsaturated metal-containing fragments with vacant sites oriented at a definite angle rather than free metal ions are considered as the starting blocks. These are supplemented by linking fragments with different numbers of donor atoms (di-, tri- and tetrapotic) and different geometry (linear, angular, *etc.*). By combining a moderate number of such elementary blocks, one can construct a variety of cyclic and polyhedral SMA. It is assumed that the geometric parameters (first of all, the angles) of the free blocks do not change much upon association.

Thus, the use of only ditopic ligands resulted in diverse SMA (ranging from a triangle to a dodecahedron) with many d and f elements.^{83–99}

3. Macrocycles based on d and f elements and their thermodynamic properties

a. Dinuclear structures

Numerous dimers have been prepared in coordination chemistry and their physicochemical properties (spectral, thermodynamic, magnetic, and so on) were studied. The dimers $Cu_2(OAc)_4 \cdot 2H_2O$, which interact through hydrogen bonds in the solid state, have been reported;⁵³ the distance $R(Cu-Cu) = 2.64$ Å is somewhat larger than in the metal, while the exchange interaction between the Cu atoms is $\sim 300\ cm^{-1}$. The water molecules can be replaced by dioxane, pyridine or aniline.

Many dinuclear assemblies with different metals have been obtained; these metals include Cu,^{84, 98} Ag,⁸⁵ Mo,⁸⁶ Cd,⁸⁷ Zn,⁸⁸ Fe, Ga,⁸⁹ Os,⁹⁰ and, most often, Pd and Pt,^{91–97} which is not surprising, because Pd^{2+} and Pt^{2+} dimers have been studied for a very long period.^{48, 77} Let us compare the previously studied⁷⁷ dimer $[PdL_2Cl_2]_2$ (**10**) ($L = NH_2CHMeCHMeNH_2$) with the recently synthesised⁹⁶ SMC $[PdL_2Cl_2]_2$ (**11**) [L is 3,5-bis(dimethylaminomethyl)pyridine]. In SMC **11**, the Pd atoms are coordinated by two N atoms (the pyridine atom of one L and the aminomethyl N atom of the other L molecule) and two Cl atoms. The distance $R(Pd-Pd) = 4.6$ Å is rather long; therefore, the interaction between the metal ions does not contribute to dimer stabilisation. In dimer **10**, the Pd atoms also form two $Pd-Cl$ bonds and two $Pd-N$ bonds. Dimerisation is due to weak $Pd-Pd$ intermolecular interactions and hydrogen bonds,⁹⁷ which, according to a definition,^{1–4} are rather characteristic of SMCh: $R(NH \cdots Cl) = 3.29$ and 3.35 Å, and the distance $R(Pd-Pd) = 3.34$ Å is shorter than that in SMC **11**. The following energy values correspond to these distances (in $kJ\ mol^{-1}$): $D_0(Pd \cdots Pd) = 12.8$; $D_0(NH \cdots Cl) = 50.6$ and 44.7 . The overall contribution to dimerisation enthalpy is rather high: $\Sigma D_0 = 12.8 + 2(50.6 + 44.7) = 203.4\ kJ\ mol^{-1}$.

Both SMC **11** and dimer **10** contain usual Pd–N and Pd–Cl coordination bonds present in compounds of the ML_2Cl_2 type ($\text{M} = \text{Pd}, \text{Pt}$). However, the structural difference is obvious: in the case of SMC **11**, the self-assembly stops after formation of the dimer (*i.e.*, a discrete ring) both in the solid state and in solution, while in compound **10**, dimers form an infinite structure in the solid state due to weak intermolecular contacts.

The experimental thermodynamic data on the formation of dinuclear SMC in solutions are still scarce. It has been shown¹⁰⁰ that the complexes $\text{Ln}(\text{tta})_3(\text{H}_2\text{O})_2$ [tta is 2-thenoyl-(trifluoro)acetone] react with bis-bidentate bridging ligand bptz [3,6-bis(2-pyridyl)tetrazine] in aqueous ethanol to form mononuclear complexes $[\text{Ln}(\text{tta})_3(\text{bptz})]$ ($\text{Ln} = \text{La}, \text{Nd}$) for the first half of the lanthanide series and dinuclear complexes $[\{\text{Ln}(\text{tta})_3\}_2(\mu\text{-bptz})]$ (**12**) ($\text{Ln} = \text{Gd}, \text{Er}, \text{Yb}$) for the second half of the lanthanide series.

$\text{Ln} = \text{Gd}, \text{Er}, \text{Yb}$.

The stability constants (K_1 and K_2) of the complexes formed in the following reactions, respectively, were measured:

Ln	$\log K_1$	$\log K_2$
La	6.32	5.42
Yb	6.0	4.8

However, dinuclear complex **12** was isolated only with Yb but not with La. In dimer **12**, the C.N. of the Ln^{3+} ion is equal to 8 ($2\text{N} + 6\text{O}$), the coordination polyhedron has an approximate square antiprism geometry. This geometry is also characteristic of solvated cations of heavy lanthanides ($\text{Ln} = \text{Dy}, \text{Ho}, \dots, \text{Lu}$),¹⁰¹ whereas solvated cations of light lanthanides have a tricapped trigonal prismatic coordination and C.N. 9. Thus, light lanthanides do not form dimers, because the coordination geometry required for dimer formation is associated with considerable steric hindrance.

The change in the thermodynamic parameters (ΔH° , $T\Delta S^\circ$ and ΔG°) upon the formation of Ln^{3+} complexes with chelating ligands has been considered along the lanthanide series.^{27, 102} It was shown that $\gamma = |\Delta H^\circ / T\Delta S^\circ| \approx 0.25 \pm 0.1$. With this γ for dimer **12** with the measured¹⁰⁰ value of $\Delta G^\circ = -62.1 \text{ kJ mol}^{-1}$, one gets the approximate values $\Delta S^\circ \approx 165 \pm 20 \text{ J mol}^{-1} \text{ K}^{-1}$; $\Delta H^\circ \approx -13 \pm 6 \text{ kJ mol}^{-1}$. The formation of dimer **12** is mainly an entropy-driven process, like all other processes of formation of Ln^{3+} complexes in aqueous solutions.²⁷

The thermodynamics of the Eu^{3+} self-assembly in MeCN with the bis[1-methyl-2-(6-[1-(3,5-dimethoxybenzyl)benzimidazol-2-yl])pyridin-2-yl]benzimidazol-5-yl]methane ligand (L^d), composed of two tridentate bis(benzimidazolyl)pyridine fragments, has been studied.¹⁰³ The stepwise and overall stability constants were measured for the reactions:

overall reaction

From these data, it follows that

$$\log \beta_4 \approx \log K_1 + 3 \log K_3 = 4.6 + 3 \times 6.5 = 24.1,$$

which is similar to the experimental value equal to 24.3. The first step of the reaction depends on the energy expenditure for the change in the ligand conformation, while the subsequent steps, on the properties of ligands and their interactions with cations.

The relations between the stability constants of the Ln complexes with monotopic chelating ligands have been derived for the reactions below^{31, 46}

$$\log K_1 > \log K_2 > \log K_3,$$

$$\log K_1 - \log K_2 \approx \log K_2 - \log K_3,$$

$$\log \beta_3 \approx 3 \log K_2.$$

These relations hold with high accuracy for approximately 200 Ln complexes with monotopic ligands and for a Eu^{3+} complex with the ditopic ligand L^d . No other data on Ln complexes with ditopic ligands are available. The enthalpy changes upon the formation of dinuclear Eu^{3+} complexes have not been measured. Presumably, $\Delta S_f^\circ < 0$, because it is known that in MeCN, lanthanide complexes are formed by an enthalpy mechanism rather than by an entropy mechanism²⁷ as in aqueous solutions.

The thermodynamics of formation of the dinuclear Eu^{3+} complex with the ditopic ligand L^d implies an important role of ligand pre-organisation at the first stage of the reaction.¹⁰³ For the subsequent stages, the derived relations between $\log K_i$ ($i = 2, 3, 4$) and $\log \beta_3$ allow one to calculate the stability constants. Using lanthanide complexes ($\text{Ln} = \text{La}, \text{Nd}, \text{Gd}, \text{Er}, \text{Yb}$) with tta and $\mu\text{-bptz}$ as examples, the role of the cation size in the formation of dinuclear SMC in aqueous solutions has been demonstrated.¹⁰⁰

b. Trinuclear structures

Triangular structures with weak M–M bonds. According to the molecular library model, the triangular SMC may be formed based on three building blocks arranged at 60° angles and linked by three linear fragments. The M_3 building blocks are widely known in the cluster chemistry. They can be combined to form tetrahedra, octahedra and other polyhedra.^{104–110} The M_3 metal rings with the M–M or M–L–M bonds can behave as both Lewis acids and bases;¹⁰⁴ hence, they can be used for the synthesis of SMC with diverse ligands in solution and in the solid state. A number of reviews^{105–110} have discussed the concept of the ‘magic’ number of valence electrons $m = 48$ for the M_3 clusters composed of d elements. Deviations from $m = 48$ exist, *i.e.*, this number is not universal^{105–110} even for elements of the same group, for example, $\text{M} = \text{Cu}, \text{Ag}, \text{Au}$ or $\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$. Indeed, inclusion of

relativistic effects for Pt or Au metal rings would change the sequence and structure of the MO.

Two factors, *viz.*, the electronic structure of the metal and the effect of bridging groups, determine the M–M interaction.^{111–115} As was discussed in Section IV.3.a, many metals form dimeric complexes $M_2(OAc)_4L_2$ (M = Cu, Rh, Ru, Re, Cr, Mn, but not Pd or Pt). In the crystalline state, Pd^{2+} diacetate $Pd_3(OAc)_6 \cdot H_2O$ (**13**) contains trimeric ring complexes. The Pd atoms form a nearly regular triangle with the distances $R(Pd-Pd) = 3.105-3.203$ Å (on average, 3.154 Å) and $R(Pd-O) = 1.973-2.014$ Å (on average, 1.99 Å).¹¹² Although, according to STM calculations,^{32,33} the Pd–Pd bond energy is markedly lower than the energy of one Pd–O coordination bond: $D_0(Pd-Pd) = 19.5$ kJ mol^{−1}, $D_0(Pd-O) = 191.6$ kJ mol^{−1}, the contribution of three Pd–Pd bonds equal to ~ 60 kJ mol^{−1} stabilises trimer **13**. The palladium acetatoacetoneoximate $Pd_3(OAc)_3 \cdot (ONCMe_2)_3 \cdot 0.5 C_6H_6$ (**14**) has a similar structure;⁷⁷ however, the $R(Pd-Pd)$ distances (3.009 Å) are shorter and the energy of three Pd–Pd bonds [$3 D_0(Pd-Pd) = 3 \times 27.3 = 81.9$ kJ mol^{−1}] is greater than those in the acetate.

A number of SMC have been prepared on the basis of palladium acetate. The reaction of $Pd(OAc)_2$ with 1,3-bis(1-R-benzimidazol-2-yl)benzene (RbzimPh) gives the compound $[Pd(RbzimPh)(OAc)]_3 \cdot 9 MeCN$ (**15**), where R = Me, Et, CH_2D .^{39,114,115} Supramacrocycles **15** are based on the structural motifs of compounds **13** and **14**. In the solid state, the cavity is occupied by the MeCN molecules. The triangular shape of these rings is due to the acetate structure in which the carboxy groups combine three Pd^{2+} cations (rather than two, as in Cr, Mn, Cu, Ru, Rh and Re dimers).

It is noteworthy that in SMC **15**, as in trimers **13** and **14**, the Pd atoms are separated by bridging ligands but the shortest Pd–Pd distances allow the metal–metal interaction, which is weak but still stabilises the triangular shape. The $R(Pd-Pd)$ distances vary from 3.0 to 3.5 Å and the energy of one bond, $D_0(Pd-Pd)$, ranges from 28 to 10 kJ mol^{−1}.

The bis(2-mercaptoethyl) sulfide anion is a promising ligand for the synthesis of triangular SMC. The crystal structure of $Pd_3(SCH_2CH_2SCH_2CH_2S)_3$ resembles that of palladium acetate trimers.⁷⁷ Each Pd atom is coordinated by four sulfur atoms (approximately square planar geometry); the Pd atoms form a triangle with $R(Pd-Pd) = 3.41$, 3.49 and 3.66 Å, the corresponding bond energies being $3 D_0(Pd-Pd) = 11.0 + 9.3 + 6.6 = 26.9$ kJ mol^{−1}.

Platinum complexes of this type have been prepared. The acetate groups and the bis(2-mercaptoethyl)sulfide anion draw the metal atoms towards one another, shorten the M–M bonds and thus strengthen the M_3 core.

Triangular structures without stabilising M–M bonds. Bulky nitrogen-containing hetaryl ditopic bridging ligands shield the M–M interaction. Many SMC have been prepared with these ligands, in particular, $[Pd(dmpze)Cl_2]_3$ [dmpze is 1,2-bis(3,5-dimethylpyrazol-1-yl)ethane];¹¹⁶ $[Cu(tacn)(imd)]_3^{3+}$ (tacn is 1,4,7-triazacyclononane, imd is imidazolate);¹¹⁷ $[Fe(ttpO)]_3$ (ttpOH is 2-hydroxytetrakis-4'-tolylporphyrin).¹¹⁸

The triangular SMC $[(en)M(pyrXpyr)_2]_3(NO_3)_6$ (**16**) (M = Pd, Pt; en = $H_2NCH_2CH_2NH_2$, pyr is 4-pyridyl; X = *p*- C_6H_4 , $C \equiv C$, $C \equiv C-C \equiv C$) have been prepared in an aqueous solution using bis-hetaryl ligands and $Pd(en)(NO_3)_2$.¹¹⁹ In solution, these complexes occur in equilibrium with square SMC. In our opinion, the presence of flexible linking pyrXpyr ligands and the absence of M–M contacts in SMC **16** reduce the stability of these supramacrocycles. The reaction of $Pt(en)(NO_3)_2$ in H_2O with 2,2'-bipyrazine (2,2'-bpz) yields only the triangular SMC $[Pt(2,2'-bpz)]_3(NO_3)_6$, while in the case of Pd, only the mononuclear chelate complex is formed.¹²⁰

The above information leads to conclusions concerning the similarity of, and the differences between, the palladium and platinum SMA. Although Pd and Pt compounds, most often, have similar structures, thermodynamic characteristics of their SMC may be different. The difference between the cohesion energies¹²¹ of metallic palladium and platinum is ~ 200 kJ mol^{−1}; the Pt–Pt bonds are stronger than the Pd–Pd bonds. In the absence of M–M bonds in SMC and in the formation of π -bonds with polydentate ligands, it is important that the 5d atomic orbitals of platinum are more diffuse than the 4d atomic orbitals of palladium and form stronger π -bonds with ligands. In addition, platinum atom has a higher electron affinity than palladium (2.1251 and 0.5621 eV, respectively). The electron affinity of platinum is nearly equal to that of sulfur and higher than that of oxygen (1.465 eV). Thus, the effective charges on the platinum atoms are much lower than those on palladium atoms and the bonds with ligands are stronger and more covalent.

Macrocycles with strong M–M bonds. Quite a few examples of triangular macrocycles formed by d elements and stabilised through the formation of M–M bonds can be cited. Thus the $Pt_3[\mu-C(OMe)C_6H_4Me-4]_3(CO)_3$ trimers have¹²² short Pt–Pt distances (2.62 Å), the corresponding energy $D_0(Pt-Pt)$ is equal to 73 kJ mol^{−1} (*i.e.*, 219 kJ mol^{−1} for three bonds).

The first lanthanide-containing SMC were prepared not long ago.^{123,124} The hexadentate 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol ligand (H_3L) and Ln^{3+} form the $[Ln_3L_2]^{3+}$ complex (**17**) in an aqueous solution according to the reactions

$Ln = Gd, Lu.$

Structural similarity of complexes **17** for $Ln = Gd$ and Lu has been established: the Ln^{3+} cations are bound to two ligands through two N atoms and four O atoms; two water molecules complete the C.N. of the metal ion to 8. Three Ln^{3+} ions form a nearly regular triangle similarly to many other metal rings formed by d elements,¹⁰⁴ for example, $[M_3(\mu-H)_3(CO)_{12}]$ (M = Mn, Tc, Re); $[M_3(\mu-CO)_3(PR_3)_n]$ ($n = 3, 4$; M = Pd, Pt). Despite numerous studies of the triangular clusters and SMC of this type, the thermodynamics of self-assembly in solution has been reported only in two studies.^{123,124} It was found that (a) the self-assembly is a purely entropic process: $\Delta S^\circ > 0$, $\Delta H^\circ > 0$; (b) the stability of SMC **17** increases from La to Lu in parallel with a decrease in the ionic radius R_{ion} ; (c) $\Delta G^\circ [La_3L_2]^{3+}$ and $\Delta G^\circ [Lu_3L_2]^{3+}$ differ almost threefold. Such a pronounced change in the thermodynamic characteristics is unusual for the chemistry of Ln^{3+} complexes. This unexpected fact of the thermodynamics of SMC is attributable to the difference between the thermodynamic parameters of desolvation of the $[Ln_{aq}]^{3+}$ cations. The change in ΔG° during the reaction can be represented as follows:

Table 1. Change in the thermodynamic parameters of the formation of complexes **17** in the lanthanide series (at 298 K).

Parameter /kJ mol ⁻¹	Pr	Sm	Gd	Dy	Er	Lu
$\delta\Delta G^\circ$	-48	-83	-95	-104	-111	-122
$\delta\Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+}$	-27	-50	-11	-32	-66	-89
$-3\delta\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$	-21	-33	-84	-72	-45	-33
$\delta\Delta H^\circ$	-24	-58	-72	-80	-76	-88
$\delta\Delta H_f^\circ[\text{Ln}_3\text{L}_2]^{3+}$	-14.4	-3.1	-4.8	-38.6	-72.1	-67.6
$-3\delta\Delta H_f^\circ(\text{Ln}_{\text{aq}}^{3+})$	-9.6	-54.9	-67.2	-41.4	-3.9	-20.4
$-\delta T\Delta S^\circ$	-24	-25	-22.6	-24.4	-34.6	-33.6
$-\delta T\Delta S_f^\circ[\text{Ln}_3\text{L}_2]^{3+}$	-12.6	-46.9	-6.2	6.6	6.1	-21.4
$3\delta T\Delta S_f^\circ(\text{Ln}_{\text{aq}}^{3+})$	-11.4	21.9	-16.8	-30.6	-41.1	-12.6

$$\Delta G^\circ = \Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+} - 3\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}) - 2\Delta G_f^\circ(\text{L}_{\text{aq}}^{3-}) + 6\Delta G_f^\circ(\text{H}_{\text{aq}}^+),$$

where $\Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+}$, $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$, $\Delta G_f^\circ(\text{L}_{\text{aq}}^{3-})$ and $\Delta G_f^\circ(\text{H}_{\text{aq}}^+)$ are the standard free energies for the formation of the complex, the Ln^{3+} aqua ions, hydrated ligands and protons, respectively.

Then the difference between the ΔG° values of the reaction ($\delta\Delta G^\circ$) for different Ln^{3+} ions (with respect to $\text{Ln} = \text{La}$) is given by

$$\delta\Delta G^\circ = \delta\Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+} - 3\delta\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}),$$

where

$$\delta\Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+} = \Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+} - \Delta G_f^\circ[\text{La}_3\text{L}_2]^{3+},$$

$$\delta\Delta G_{\text{of}}^\circ(\text{Ln}_{\text{aq}}^{3+}) = \Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}) - \Delta G_f^\circ(\text{La}_{\text{aq}}^{3+}).$$

The corresponding values are presented in Table 1; the $\Delta G_f^\circ[\text{Ln}_3\text{L}_2]^{3+}$ values were taken from the work by Chapon *et al.*,¹²⁴ and the $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ values were reported by Morss.¹²⁵

The reaction thermodynamics is determined by the contributions of two opposite effects: the energy gain due to the formation of two $\text{Ln}^{3+}-\text{N}$ bonds and four $\text{Ln}^{3+}-\text{O}(\text{L})$ bonds and energy loss for the cleavage of six $\text{Ln}^{3+}-\text{O}(\text{OH}_2)$ bonds. The $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ values (in kJ mol⁻¹) increase on passing from La to Gd and decrease from Gd to Lu:¹²⁵ $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}) = -688$ (La), -660 (Gd); -677 (Lu). The contribution of the desolvation effect $3\delta\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ to $\delta\Delta G^\circ$ is from 30% to 70%. Two effects, *i.e.*, the decrease in the energy consumption for desolvation for heavy elements and the increase in the $\text{Ln}^{3+}-\text{N}$ and $\text{Ln}^{3+}-\text{O}(\text{L})$ bond energies in the SMC of these elements, caused by the lanthanide contraction partially counterbalance each other. The enthalpy contribution of desolvation, $3\delta\Delta H_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ (see Table 1), determines almost completely the $\delta\Delta H^\circ$ values for Sm and Gd, whereas the gain in energy caused by the formation of two $\text{Ln}^{3+}-\text{N}$ bonds and four $\text{Ln}^{3+}-\text{O}(\text{L})$ bonds ($\text{Ln} = \text{Er}$, Lu) makes the major contribution to $\delta\Delta H^\circ$ of these elements. The balance of the two contributions to the reaction enthalpy results in a monotonic variation of $\delta\Delta H^\circ$ versus the ionic radius R_{ion} of the cations (C.N. 8) and allows one to estimate the ΔH° values for the SMC of Ce, Nd, Eu, Tb, Ho, Tm, Yb, which have not been measured. The entropy contribution $T\Delta S^\circ$ to the self-assembly reaction is documented¹²⁴ with the accuracy of ± 7.5 kJ mol⁻¹. The $\delta T\Delta S^\circ$ values for Gd, Dy and Er are determined almost completely by the difference in the desolvation entropies $\delta T\Delta S_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ (see Table 1, Fig. 1). The qualitative aspects of the variation of thermodynamic parameters upon the formation of SMC have been considered.^{50, 126–128}

c. Supramacrocycles with square or rectangular geometry

Many metal complexes with square planar, trigonal bipyramidal, tetrahedral and octahedral coordination can be used as

**Figure 1.** Variation of the thermodynamic parameters of the formation of Ln^{3+} complexes with 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol depending on the Ln nature.

(1) ΔH , (2) ΔG , (3) $T\Delta S$.

angular structural fragments in the construction of homonuclear square assemblies. The tetragonal SMC were prepared for the following metals: Ti;^{8, 129} V, Cr;^{14, 81} Mn;^{14, 130, 131} Fe;^{8, 14, 39, 130, 132} Co;^{8, 14, 39, 130, 131, 133, 134} Ni;^{130, 131} Cu;^{8, 14, 39, 130, 135} Zn;^{8, 14, 39, 130} Zr, Nb, Mo;^{8, 14, 81, 136, 137} Tc, Ru;^{39, 138, 139} Rh;^{8, 140} Pd, Pt;^{8, 9, 14, 39} Ag;^{8, 39, 141} Cd;^{39, 130, 131} Hf, Ta, W;^{14, 81} Re;^{8, 142, 143} Os, Ir, Au, Hg;³⁹ Na, Cs;⁸ Ga;¹³⁷ and Mg;¹³¹ heteronuclear SMC have also been prepared: Pt–Pd, Ti–Pt, Re–Pd.⁸ The supramacrocycles with a square geometry refer to the simplest representatives of the family of nanoassemblies. The steric strain in a square SMC depends on the ligands that form the square sides; therefore, their self-assembly is not always thermodynamically favourable; in these cases, kinetically labile oligomers are formed. In the self-assembly of square SMC, flexible or semiflexible linkers are used, for example, 4,4'-bipy; 1-(2-thiouracil-4-methylene)-3,6-diazahexane; bis(4-pyridyl)methane and -ethane; bis[4-(2-diphenylphosphinoethyl)phenyl] ether; 1,4-bis(4-pyridylmethyl)-2,3,5,6-tetrafluorobenzene, amines and substituted bis-phosphonates; tetrakis(2-pyridyl)thiocarbazine and so on.

In the future, square supramacrocycles could find extensive practical use:^{1, 2, 8, 9, 14, 18, 39} they participate in the hydrophobic/hydrophilic molecular recognition; form host–guest complexes by inclusion of various molecules into the cavity where they demonstrate high selectivity; they are used to transport salts into the organic phase and as artificial receptors. A promising trend in electrochemistry is the use of square SMC which change the oxidation state depending on the M–M interaction, *e.g.*, the metallacyclophane ‘host’ with four

reduced metal centres can transfer four electrons to a guest molecule. The redox reactions in a 'host-guest' system result in the change in properties (reactivity, magnetism, optical properties). Square SMC based on imine or azine Re complexes possess luminescent properties and are of interest as new promising sensors. The influence of the guest molecules on the excited states of the host molecule is considered as a new line of research in optics. The use of paramagnetic metal ions in square SMC allows one to study intermolecular interactions inside molecular layers; porphyrin-containing SMC are used to study the photochemical properties of the bound porphyrin layers, in particular, the processes occurring in the active sites of photosynthesis and in light-accumulating bacteria are modelled in this way; finally, square assemblies are used in catalysis.

In square rings, the M–M interactions are shielded by bulky ligands, however the design of SMC as a rectangle from two dimers with relatively short M–M bonds connected by substituted aryl ligands gives SMC of a new type. This approach makes use of rhenium complexes with alkoxy¹⁴² or thiolate¹⁴³ ligands. The reaction of the dimer $[(OC)_4Re(\mu-SPr)_2]$ with 4,4'-bipyridyl (L) in chloroform gives SMC having a rectangular structure with two shorter sides $(OC)_3Re(\mu-SPr)_2Re(CO)_3$ and two longer sides, Re–L–Re [$R(Re-Re) = 3.81$ and 11.57 Å].¹⁴³ The shorter side of the rectangle, *i.e.*, the dimeric fragment, is stabilised by the Re–Re interaction, while the longer side, by Re–N coordination bonds [$D_0(Re-Re) = 2 \times 18.3 = 36.6$ kJ mol^{−1}].

The longer side of this SMC can be shortened by replacing bipyridyl by pyrazine; the Re–Re contact would also contribute to stabilisation of the ring. Generally, the development of this strategy appears to hold promise. When designing rectangular SMC, one can choose various dimers of transition d elements with strong or weak M–M bonds.⁴⁹ The length of the other two bonds in the rectangular SMC can be varied by 'elongating' the 4,4'-bipy ligand, *i.e.*, by using pyrXpyr ligands of different length, for example, X = *p*-C₆H₄, C≡C, C≡C–C≡C. Rectangular supramacrocycles are able to accommodate neutral aromatic guest molecules.

Among the factors that stabilise SMC, a new type of ligand–ligand interaction, the so-called π – π -stacking interaction, is often mentioned. However, it is difficult to confirm this effect experimentally. It was hypothesised⁸ that the ring structure of the tetranuclear assembly $[Cu_4(dppn)_4](OTf)_4$ [dppn is 3,6-bis(2-pyridyl)pyradazine, OTf = CF₃SO₃] with a distorted tetrahedral coordination of Cu(I) is stabilised by the π – π -stacking interaction of two pairs of ligands. This could be accepted if Cu⁺ compounds with C.N. 4 devoid of the stabilising π – π -stacking interactions were unstable. However, in all compounds (both with σ and with π Cu⁺–L interactions, in polymers, and in isolated molecules, and now in SMC), Cu⁺ has a tetrahedral coordination and all these compounds are stable. Now the role of π – π -stacking interactions between the aryl ligands in the SMC remains an interesting hypothesis. The variation of the stability of $[LnL_3]^{3-}$ complexes (L is pyridine-2,6-dicarboxylate) along the lanthanide series was attributed¹²⁸ to the π – π -stacking interaction between the ligands. It turned out, however, that in the complexes of heavy Ln, the conformation of the ligands changes. Probably, the π – π -stacking interaction is important for biological systems, but in the case of SMC containing metals that form strong $d\pi(M) - p\pi(L)$ bonds, multicentre $L(\pi-\pi) - M - (\pi-\pi)L$ interactions arise. The problem of π – π -stacking interactions is related to the important theoretical problem of the degree of electron delocalisation in SMC.

Although many metals form square assemblies, Pd²⁺ and Pt²⁺ complexes possess a number of specific properties. A square coordination geometry is typical of the electronic configuration d⁸. Square Pd²⁺ and Pt²⁺ complexes are self-

assembled to form a square SMC in the case where the *cis*-positions of the complex are 'protected', *i.e.*, they do not interact with other ligands.

A square supramacrocycle, $[Pd(en)(4,4'-bipy)]_4^{8+}$ (**18**), has been synthesised⁸² by the reaction between a ditopic non-chelating ligand, 4,4'-bipyridyl, and the kinetically labile Pd(en)(NO₃)₂ complex. The 4,4'-bipy ligand replaces the nitrate anions in the *trans*-positions with respect to N atoms of ethylenediamine and forms bonds with two cations.

This method of synthesis, *i.e.*, self-assembly of *cis*-protected Pd²⁺, Pt²⁺ and other metal complexes has been analysed in many publications,^{6, 8, 12, 14, 18, 39} as it allows one to prepare SMC with different types of bonds, ranging from strong coordination M–N, M–O, M–C, M–P and M–Cl bonds to weak intermolecular M···M and hydrogen bonds. However, in the Jones opinion,¹⁴ the studies^{9, 82} are not pioneering, because the first square-shaped SMC **19** were prepared, based on the same idea (the use of *cis*-protecting ligands), ten years earlier, in particular, by reactions of $M(CO)_6$ (M = Cr, Mo, W) with ditopic donor $P(OCH_2)_3P$ ligands.⁸¹

M = Cr, Mo, W.

Even earlier, an extensive class of Pd and Pt metallacycles, for example, allylplatinum chloride $[(\pi-C_3H_5)PtCl]_4$ (**20**), have been studied in the solid state.¹⁴⁴ In the solid tetramer **20**, each

Pt atom is coordinated in the π -mode by the C=C bond of the allyl group, in the σ -mode by the CH₂ fragment of another allyl group and also by chlorine atoms. The bridging allyl ligands in complex **20** protect the *cis*-positions, similarly to the en and CO ligands in compounds **18** and **19**, respectively. It seems likely that the proper idea of *cis*-protection has long been used for the synthesis of tetramers with a rectangular or square coordination.⁷⁷ The Pt atoms in tetramer **20** are arranged at the corners of a square, the Pt–Pt distances being 3.270 and 3.235 Å, and the contribution of Pt–Pt bonds into the tetramer formation is essential [$D_0(\text{Pt}–\text{Pt}) = 2 \times 33.3 + 2 \times 34.6 = 135.8 \text{ kJ mol}^{-1}$].

One can compare the properties of tetramers **18** and **20**. According to NMR spectroscopy and mass spectrometry, the structure of the ring in **18** is the same in solution as in the crystalline state (determined by X-ray diffraction). No experimental data on the structure of tetramer **20** in solution are available. The sides of rings **18** and **20** are ~ 8 and < 3 Å long, respectively; note that the size of the former can be varied. The supramacrocycle **18** is capable of molecular recognition, as it can host some guest molecules such as benzene, naphthalene, and so on; the ring size in tetramer **20** is too small for the insertion of guest molecules. The difference between Pt and Pd is noteworthy.⁸ Thus Pt(en)(NO₃)₂ and 4,4'-bipy react to give a mixture of oligomers from which a thermodynamically stable square-shaped SMC can be isolated on heating. This effect was attributed to the fact that the Pd–N(bipy) bond is weaker than Pt–N. For the statistically average distances, $R(\text{Pd}–\text{N}) = 2.04$ and $R(\text{Pt}–\text{N}) = 2.06$ Å,⁷⁷ the bond energies we calculated are as follows: $D_0(\text{Pt}–\text{N}) = 274$, $D_0(\text{Pd}–\text{N}) = 238 \text{ kJ mol}^{-1}$.

Square-shaped SMC have also been synthesised from bis-phosphine derivatives [M(dppp)(OTf)₂] [M = Pt, Pd; dppp = Ph₂P(CH₂)₃PPh₂] and 4,4'-bipy in a non-aqueous solvent (CH₂Cl₂).^{145,146} The existence of the square SMC [M(dppp)(4,4'-bipy)]₄(OTf)₈ (**21**) was proved by NMR spectroscopy. The researchers cited noted a remarkable fact: even with a 100-fold excess of the 4,4'-bipy ligand, only square SMC **21** are formed in solution, *i.e.*, a fragment corresponding to a side or a corner of the SMC cannot be isolated.

M = Pd, Pt.

For solid compound **21** with M = Pt, it was shown that a square side is equal to 11.2 and the diagonal is 14.3 Å. The Pt²⁺ ions have C.N. 4: each Pt²⁺ ion is connected to two P atoms of the dppp ligand and two N atoms of the two 4,4'-bipy ligands. The N–Pt–N bond angles are equal to 84° and the P–Pt–P angles are about 90°, so that the whole ring is essentially non-planar. It was assumed¹⁴⁵ that the stability of this SMC is related to the strong π – π -stacking interaction between the ligands, in particular, between the π -electrons of

the benzene rings of the chelating bis-phosphine ligands and π -electrons of one of bipyridyl rings. If this interaction was responsible for the stability of SMC **21**, the effect would be manifested in the interatomic distances in square SMC compared to those in the Pt²⁺ and Pd²⁺ complexes studied previously.⁷⁷ Our analysis of the reported structural data^{8,9,14,77,145} has shown that the M²⁺–N and M²⁺–P distances (M = Pt, Pd) in the phosphine and pyridine complexes and in square SMC **21** are equal to within the accuracy of measurements. Indeed, in Pd[Ph₂P(CH₂)₂PPh₂](SCN)₂, the measured⁷⁷ distances are $R(\text{Pd}–\text{P}) = 2.245–2.260$ Å, while in SMC **21**, $R(\text{Pt}–\text{P}) = 2.23–2.25$ Å.¹⁴⁵ An early publication⁷⁷ reports the average $R(\text{Pt}–\text{N})$ and $R(\text{Pd}–\text{N})$ values in the Pt²⁺ and Pd²⁺ pyridine compounds to be 2.02–2.06 Å, and the $R(\text{Pt}–\text{N})$ distances in SMC are 2.03–2.07 Å.^{8,9,14,145} Thus, the assumption of stabilisation of the SMC by π – π -stacking interactions between the ligands is not confirmed.

Analogous square SMC based on *cis*-phosphine derivatives have been obtained:¹⁴⁵ [M(PEt₃)₂X]₄(OTf)₈ (M = Pd²⁺, Pt²⁺; X is 4,4'-bipy, 2,7-diazapyrene, and so on). For all square SMC considered above, the *cis*-positions in the starting complexes (*i.e.*, the square corners) are protected by bidentate (en, dppp) or monodentate (PEt₃) ligands, which form strong M–P bonds. Neutral phosphines are strong electron donors, therefore, their interaction with metals is accompanied by a substantial charge transfer.³⁷ In the initial MA₂X₂ complexes (M = Pd, Pt; A = PEt₃; X is anion), the $R(\text{Pt}–\text{P})$ and $R(\text{Pd}–\text{P})$ distances vary in the 2.22–2.34 Å range.⁷⁷ According to our estimates, the M–P bond energy is fairly high [$D(\text{M}–\text{P}) = 415–358 \text{ kJ mol}^{-1}$]; phosphine ligands protect the *cis*-positions of the structural blocks by a thermodynamic mechanism, *i.e.*, they stabilise the SMC by a great contribution of the M–PEt₃ and M–PPh₂ interaction energy. In addition, the PPh₂ ligands provide a steric protection of the *cis*-positions, which opens up broad opportunities for the synthesis of SMC using these ligands.^{8,14,39}

In the absence of groups shielding the *cis*-positions, square-coordinated SMP may form. For example, this is the case in the reaction of Co(NCS)₂ with 4,4'-bipy.¹⁴⁷

Although the properties of many palladium and platinum SMC are largely similar, note once again the difference in the self-assembly mechanisms: under the same conditions, square SMC are formed for palladium but oligomer mixtures are formed for platinum, because the Pd–N bonds are weaker than Pt–N bonds and more labile in the self-assembly processes giving SMC.⁸

The reaction of [Pd(dppp)(OTf)₂] with *p*-NC(C₆H₄)_nCN-*p* (*n* = 1, dcp; *n* = 2, dcdp) in CH₂Cl₂ produces square SMC [Pd(dppp)(dcp)]₄(OTf)₈ (**21a**) and [Pd(dppp)(dcdp)]₄(OTf)₈ (**21b**), the sides of which can be represented as follows:

Thus, although a large number of homonuclear and heteronuclear SMC based on complexes of almost all of d elements have been prepared in recent years, nitrogen-containing SMC with Pt²⁺ and Pd²⁺ are most numerous. This can be attributed to several reasons. The Pt²⁺ and Pd²⁺ ions are soft acids and the nitrogen atom, being a softer ligand than oxygen, forms numerous complexes with these ions, which is not so typical of other d elements. The Pd–N and Pt–N bond energies are higher than the Pd–O and Pt–O bond energies. This is an important thermodynamic factor affecting the self-assembly. As an illustration, one can compare the energies of

the Pd–N and Pd–O bonds having standard interatomic distances, $R(\text{Pd–O}) = 2.0$ and $R(\text{Pd–N}) = 2.05$ Å.⁷⁷ The calculated energies are as follows: $D_0(\text{Pd–N}) = 243.4$, $D_0(\text{Pd–O}) = 191.6$ kJ mol^{–1}, so that the energy gain due to the formation of two Pd–N bonds instead of two Pd–O bonds is significant: $\delta D_0 = 2[D_0(\text{Pd–N}) - D_0(\text{Pd–O})] = 2 \times (243.4 - 191.6) = 85.6$ kJ mol^{–1}.

The thermodynamics of the self-assembly process is substantially affected by the solvent. The formation of complexes of d elements and lanthanides in aqueous solutions is entropy controlled, while in non-aqueous solutions, it is enthalpy controlled.^{26, 121} Without experimental data, it is unknown whether this would be valid for the self-assembly of SMC from complexes. Various hypotheses on the thermodynamics of the self-assembly of SMC have been put forward; it was noted³⁹ that the formation of ring structures is preferred over the formation of linear structures from the enthalpy standpoint, while the formation of small rings is preferred over the formation of large rings (at low concentrations) from the entropy standpoint.^{126, 127}

Nanosized square SMC have now been prepared.^{8, 111} For example, the addition of a solution of *cis*-[(dppp)Pt{C≡C(C₅H₄N-4)}₂] in CD₂Cl₂ to the solid bis-triflates TfOPt(PR₃)₂(*p*-C₆H₄)_nPt(PR₃)₂OTf gave square SMC of different size the side of which can be represented as

R = Et: $n = 1, 2$; R = Ph: $n = 2, 3$.

This nanosquare contains 12 platinum ions; each side has four ions, two of these being common to two sides. Generally, the synthetic strategy is the same as for the smaller SMC described previously (**18**, **21** and so on), namely, *cis*-protection of the metal ion. The calculated square diagonal is ~ 36 Å long.⁸

Nanosquares of this type are promising for the design of molecular switches and molecular machines. Another possibility is to use the magnetic properties of these SMC. These macrocycles are classified as ultrathin particles with a diagonal dimension of 3.4–4.8 nm. Nanoparticles applied onto a substrate are known to form ordered one-, two- and three-dimensional structures,²³ which find application due to the possibility of magnetic transitions (paramagnet – ferromagnet – antiferromagnet) or metal – dielectric phase transition.⁷⁶

d. Polygonal supramacrocycles and three-dimensional structural motifs

Pentagonal and hexagonal supramacrocycles. The first SMC with pentagonal or hexagonal geometry were obtained by Lehn^{148, 149} in ethylene glycol using FeCl₂ or FeSO₄, respectively, in the presence of NH₄PF₆ and ligand L.

These are helical SMC $\{[\text{FeL}]_5\text{Cl}\}(\text{PF}_6)_9$ (**22**) and $[\text{FeL}]_6(\text{PF}_6)_{12}$ (**23**). In compound **22**, the Cl[–] ion resides in the SMC cavity. By analogy with SMC **22**, the compound $\{[\text{NiL}]_5\text{Cl}\}(\text{PF}_6)_9$ (**24**) was prepared.³⁹

The authors¹⁴⁸ noted that the inner cavity of SMA **22** has a radius of 1.75 Å. The size of the Cl[–] ion (the ionic radius is 1.7 Å) fits the cavity and strong binding is due to the high positive charge of the SMA. However, when FeSO₄ is used, a large six-membered SMA containing no anion is formed. Analogous SMA were synthesised with Fe(BF₄)₂ and FeSiF₆. The use of FeBr₂ resulted in an approximately equimolar mixture of five- and six-membered SMA. Thus, it was concluded that the structure of SMA is influenced by the size rather than the charge of the counter-ion. However, the mechanism of this influence remains an open question, *i.e.*, whether the anion serves as the template in the SMA formation

or the assemblies capable of strong binding of the anion (substrate) as receptors are formed owing to the reversibility of self-assembly.

Using K_2PtCl_4 , H_2NNH_2 and Bu^tNC , SMC **25** has been synthesised in an aqueous solution.¹¹² This compound possesses luminescent properties being responsible for a strong band in the visible region at 356 nm. This band was assigned to a $\text{Pt} \rightarrow \pi(\text{carbene})$ charge transfer transition. An X-ray diffraction study showed that the SMC is non-planar, its conformation resembling the 'chair' conformation. The $\text{CN}-\text{Pt}-\text{CN}$ angles are equal to 92.4° and the $\text{Pt}-\text{N}\equiv\text{C}$ and $\text{Pt}-\text{C}\equiv\text{N}$ fragments are nearly linear (angle 174°).

Six-membered SMC have also been prepared for other metals. The compound $[\text{CuL}]_6(\text{ClO}_4)_6$ (**26**) was synthesised¹³⁵ by triethylamine-induced deprotonation of the complex $\text{Cu}(\text{HL})(\text{ClO}_4)_2$, where HL is *N*-(2-phenylimidazol-4-ylmethylidene)-2-aminoethylpyridine.

The complex $[\{\text{Au}(\text{C}\equiv\text{CBu}^t)\}_6]_2$ (**27**) was isolated upon the reaction of $[\text{Au}(\text{NH}_3)_2]\text{BF}_4$ with $\text{Bu}^t\text{C}\equiv\text{CH}$ in acetonitrile.¹⁵⁰ It was found that this compound is a catenane consisting of two interlinked six-membered SMC; each SMC contains six Au^+ ions and six acetylene groups. Within each ring, metal ions form a planar hexagon in which the $R(\text{Au}-\text{Au})$ distances are 3.30–3.36 Å. Although these distances are longer than those in metallic gold (2.88 Å), the $\text{Au}-\text{Au}$ contacts determine the stability of this SMC. The energy of six $\text{Au}-\text{Au}$ bonds $D_0(\text{Au}-\text{Au})$ [for average $R(\text{Au}-\text{Au}) = 3.33$ Å] equals $6 \times 26 = 156 \text{ kJ mol}^{-1}$.

Octagonal supramacrocycles. The reaction of $[\text{Co}(\text{OAc})_2(\text{H}_2\text{O})_4]$ with the salt KL {L is bis[3-(2-pyridyl)pyrazol-1-yl]dihydroboronate} in MeOH with the addition of KPF_6 or NaClO_4 for precipitation gave¹⁵¹ SMC containing eight Co^{2+} cations, twelve L^- bridging ligands and the PF_6^- or ClO_4^- anion: $[\text{M}_8\text{L}_{12}\text{A}]^{3+}(\text{A}^-)_3$, $\text{M} = \text{Co}, \text{Ni}$; $\text{A} = \text{ClO}_4, \text{PF}_6$. The ligand $\text{L} = \text{C}_5\text{H}_4\text{N}-\text{C}_3\text{H}_2\text{N}_2-\text{BH}_2-\text{N}_2\text{C}_3\text{H}_2-\text{C}_5\text{H}_4\text{N}$ forms a bridge between the neighbouring Co^{2+} ions.

According to electrospray mass spectrometry and X-ray diffraction analysis, one anion resides in the SMC cavity of $[\text{Co}_8\text{L}_{12}(\text{ClO}_4)]^{3+}(\text{ClO}_4^-)_3$ (**28**). No $[\text{M}_8\text{L}_{12}]^{4+}$ cation without an anion in the cavity was detected; thus, the anion stabilises the eight-membered ring and, apparently, controls its size. We present our interpretation of this effect based on the thermodynamics of anion formation in solution. Note first of all that in the hexagonal SMC **26** of a smaller size, the ClO_4^- anion is not inserted in the cavity, *i.e.*, the size effect is significant for SMC **26** and **28**.

It is known that thermodynamics of formation of anions affects their outer- or inner-sphere coordination. Thus the standard free energies of formation¹²¹ $\Delta G_f^\circ(\text{ClO}_4^-)_{\text{aq}} = 7163.5$ and $\Delta G_f^\circ(\text{Cl}^-)_{\text{aq}} = -164.5 \text{ kJ mol}^{-1}$ are similar but the coordination of the ClO_4^- anion is usually outer-sphere, while the Cl^- ion can be coordinated as both an outer- and an inner-sphere ligand. The standard entropy of formation of the ClO_4^- anion in an aqueous or ethanolic solution is positive and high, while that of the Cl^- ion is negative [$\Delta S_f^\circ(\text{ClO}_4^-)_{\text{aq}} = +118.7$, $\Delta S_f^\circ(\text{Cl}^-)_{\text{aq}} = -8.7 \text{ J mol}^{-1} \text{ K}^{-1}$]. Thus, the entropy factor mainly determines the outer-sphere coordination of the ClO_4^- anion, because the inner-sphere coordination is entropically unfavourable. For insertion into an SMC, the ClO_4^- anion should be stabilised by a gain in enthalpy, *i.e.*, by the formation of strong bonds with the atoms of SMC, in order to counterbalance both the entropy and enthalpy loss. Apparently, this is the case for SMC **28** in which the ClO_4^- anion is strongly bound to atoms of the eight-membered ring⁸ and the size effect allows the anion to be inserted into the cavity. The possibility of insertion of the SO_4^{2-} , Cl^- and ClO_4^- anions has been studied from the standpoint of the size effect.^{148, 151}

However, it should be borne in mind that thermodynamics of their insertion into SMC are fundamentally different due to different thermodynamics of their formation in solutions. Thus the values $\Delta S_f^\circ(\text{SO}_4^{2-})_{\text{aq}} = -112.2$ and $\Delta S_f^\circ(\text{ClO}_4^-)_{\text{aq}} = +118.7 \text{ J mol}^{-1} \text{ K}^{-1}$ are close in magnitude but have opposite signs. The insertion of $(\text{SO}_4^{2-})_{\text{aq}}$ into SMC is entropically favourable but the enthalpy loss is high because $\Delta H_f^\circ(\text{SO}_4^{2-})_{\text{aq}} = -875.9 \text{ kJ mol}^{-1}$. The $(\text{ClO}_4^-)_{\text{aq}}$ anion has the maximum entropy of formation and the $(\text{SO}_4^{2-})_{\text{aq}}$ ion has the minimum enthalpy of formation. Hence, in order to surpass the enthalpy loss upon the insertion of SO_4^{2-} , it is necessary to select an appropriate SMC with very strong bonds between its atoms and the inserted SO_4^{2-} anion.

Apart from two-dimensional SMC, three-dimensional SMA with a tetrahedral,¹⁵² prismatic⁹¹ or cylindrical^{28,98} geometry have also been prepared. For example, SMA **29** was synthesised by the reaction of $[\text{Cu}(\text{MeCN})_4]\text{BF}_4$ with hexaphenylhexaazatriphenylene and quaterpyridine in chloroform.⁹⁸ The structure of this SMA was determined by X-ray diffraction analysis. By introduction of various fragments (acetylene, benzene and so on) into quaterpyridine, the height of SMA **29** can be increased to 33 Å.⁷⁸

29 (the phenyl groups are omitted for clarity)

As the conclusion of this Section, we would like to note that Pt^{4+} and Pd^{4+} compounds could also be used in the SMCh. However, this would require an absolutely different strategy of the preparation of SMA. The stereochemistry of these compounds, for example, R_3PtX ($\text{R} = \text{Me, Et; X} = \text{OH, Cl, I}$), shows¹⁴⁴ that the PtR_3^+ groups tend to acquire a pyramidal structure and Pt^{4+} tends to an octahedral geometry. This gives compounds with a cubane structure, which is based on a cube with vertices occupied by alternating Pt^{4+} and X^- ions. In these systems, the $R(\text{Pt}-\text{Pt})$ distances vary from 3.41 (Me_3PtOH) to 3.90 Å (Me_3PtI , Et_3PtCl), so that the contribution to the enthalpy stabilisation ranges from $D_0(\text{Pt}-\text{Pt}) = 4 \times 28.7 = 114.8$ to $D_0(\text{Pt}-\text{Pt}) = 4 \times 17.8 = 71.2 \text{ kJ mol}^{-1}$. As a result of competition between the tendency of PtR_3^+ to form a pyramidal coordination and the tendency of Pt^{4+} to an octahedral coordination, depending on the number and the coordination capacity of the anions and polar molecules, either oligomers or SMC are formed.

4. Thermodynamic factors in the formation of supramacrocycles

The role of thermodynamic factors in the formation of SMC has been considered in a number of studies.^{8,39,50,71,126,128} As noted above, several mechanisms have been proposed^{8,39,71} for the formation of supramolecular systems, which reflect to one or another extent the thermodynamics of self-assembly,

namely, these are thermodynamic, kinetically controlled and irreversible, assisted, directed mechanism, *etc.* According to the thermodynamic mechanism of the self-assembly in solution, a thermodynamic equilibrium between the starting reactants and one, thermodynamically the most stable product is attained. Thermodynamically unstable products either dissociate or are formed in minor amounts with respect to the major product. The self-assembly of the structural blocks to give SMC or a linear oligomer decreases the disorder in the system and, hence, results in a negative change in entropy, which can be counterbalanced by the enthalpy effect. In a review,⁸ it has been suggested that both the enthalpy and entropy changes are favourable for the self-assembly of SMC. It has been shown above, using numerous examples, that the metal-metal bonds present in SMC contribute considerably to the enthalpy of formation of SMC.

The thermodynamic parameters of the self-assembly process largely depend on the properties of the solvent.¹²⁴ It was found experimentally that the formation of Ln^{3+} and An^{3+} complexes in acetonitrile is characterised by the following relationship between the enthalpy and entropy contributions to the free energy:^{153–155}

$$\Delta S^\circ < 0, \Delta H^\circ < 0, |T\Delta S^\circ| < |\Delta H^\circ|.$$

However, in water, the formation of Ln^{3+} and An^{3+} complexes with various N- and O-donor ligands obeys other relations:^{125,156}

$$\Delta S^\circ > 0, \Delta H^\circ < 0, T\Delta S^\circ > |\Delta H^\circ|.$$

In water, the $3 \text{ Ln}^{3+} + 2 \text{ L}$ self-assembly to give triangular SMC **17** is entropy-driven, *i.e.*, similar to the formation of Ln^{3+} and An^{3+} complexes.¹⁵⁶ However, it is not clear whether this conclusion can be extended to the formation of SMC with other metals, a different geometry (for example, squares), and in other solvents.

The self-assembly processes often use chelating n -dentate ligands. In SMC **17**, the ligand is hexadentate ($n = 6$); two ligands form a common electronic system; therefore, for two chelating ligands, we get $n = 12$. Let us assume that the change in entropy upon self-assembly is due to the chelation effect. The entropy change caused by the chelation effect is determined¹⁵⁶ by the equation

$$\Delta S^\circ = R(n-1) \ln M = 367 \text{ J mol}^{-1} \text{ K}^{-1},$$

where R is the universal gas constant, M is the molality of water. The change ΔS° upon the formation of SMC **17** ranges¹²⁴ from 329 (La) to $442 \text{ J mol}^{-1} \text{ K}^{-1}$ (Lu). With allowance for the inaccuracy of ΔS° equal to $\pm 25 \text{ J mol}^{-1} \text{ K}^{-1}$, the average entropy of self-assembly for SMC **17** is $\Delta S^\circ = 408 \text{ J mol}^{-1} \text{ K}^{-1}$ (Ref. 124); this value is consistent with the estimate $\Delta S^\circ = 367 \pm 50 \text{ J mol}^{-1} \text{ K}^{-1}$ made using the chelation model.

The role of the solvent is highly important in both complexation and the self-assembly: the free energy of formation of SMC **17** ΔG_f° correlates with the free energy of formation of the aqua ions $3 \Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$; therefore, from the known $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ and $\Delta G_f^\circ(\text{An}_{\text{aq}}^{3+})$ values and the measured $\Delta G_f^\circ(\text{17})$ values, one can estimate the standard free energy of formation of similar SMC with other metals and, hence, the changes in the free energy ΔG° for the corresponding self-assembly reactions:

Ln	Eu	Pu	Am	Cm
$\Delta G^\circ / \text{kJ mol}^{-1}$	104	83.6	93.3	90.0

An important problem in the processing of radioactive elements is the separation of Eu^{3+} , Am^{3+} and Cm^{3+} . The obtained values $\delta \Delta G^\circ(\text{Eu}-\text{Am}) = 10.7$ and $\delta \Delta G^\circ(\text{Eu}-\text{Cm}) = 14.0 \text{ kJ mol}^{-1}$ show that using SMC, one

can achieve high selectivity in the separation of Ln^{3+} and An^{3+} ions.

The properties of solvents (dielectric constant, polarisability, the ability to form hydrogen bonds, viscosity) determine the soft or hard behaviour of the solvent.^{44, 156} Using the set of these properties, it is possible to predict that the self-assembly involving hard Ln^{3+} cations in water is an entropy-driven process, that in acetonitrile or pyridine is enthalpy-driven, the process in octanol is rather enthalpy-driven, *etc.* In addition, it was shown¹²⁴ that ΔG° and the $\Delta S^\circ/\Delta H^\circ$ ratio for the self-assembly depend on the properties of cations. It is beyond doubt that the effects of solvents on the self-assembly thermodynamics should be different for compounds of soft M^+ ($\text{M} = \text{Cu}, \text{Ag}, \text{Au}, \text{Tl}, \text{Hg}$), M^{2+} ($\text{M} = \text{Pd}, \text{Pt}, \text{Cd}, \text{Hg}$) and hard (Ln^{3+} , An^{3+}) cations. Even among the same family (soft or hard cations), the $\Delta S^\circ/\Delta H^\circ$ ratio would substantially depend on the desolvation of this cation. Ten years ago the ΔG° values for self-assembly were still calculated using two-parameter models,¹⁵⁷ which define the electron-donor (C_D) and -acceptor (C_A) properties of the interacting Lewis acids and bases

$$\Delta G^\circ = \text{const } C_D C_A.$$

As new data have been accumulated, it became clear that these simplified models do not reflect either quantitative or qualitative features of thermodynamics of the SMA formation.

V. Thermodynamic properties of macrocyclic complexes in solution

Among the macrocyclic ligands, crown ethers, cryptands, spherands, calixarenes and their derivatives have been most studied.^{1, 2, 7, 128, 158–161} The advances in the synthesis of the alkali and alkaline earth metal complexes^{1, 2, 7, 159–162} have stimulated the development of analogous studies dealing with lanthanides.^{27, 128, 161, 162} The particular interest in this field is related to the extensive use of lanthanides in catalysis, in the manufacture of glass, ceramics, optical and electronic devices, in nuclear power engineering (separation processes), in biology and medicine.

As regards the stability of Ln complexes with crown ethers containing 4, 5, 6 and 10 oxygen atoms, it has been noted¹⁶² that the plots $\log \beta$ vs. $R_{\text{ion}}^{-1}(\text{Ln})$ do not show any general trend, some passing through an extremum and some other monotonically descending or ascending. This reflects the relationship between parameters such as the ion diameter and the size of the ligand cavity. Although the idea of size fitting has not lost its importance in analysis of the selectivity of complexation of macrocyclic ligands with alkali and alkaline earth metals, the experimental data indicate that other properties of cations such as desolvation parameters and the ability to accept electron density have a substantial influence on the thermodynamic properties of MC.

1. Size selectivity of macrocyclic ligands with respect to cations

It was found that the ratio of the cation to cavity dimensions ($R_{\text{ion}}/R_c = r$) is an important factor determining the selectivity of complexation with the crown ethers, 12-crown-4 (12C4), 15-crown-5 (15C5), 18-crown-6 (18C6), 21-crown-7 (21C7) and 30-crown-10 (30C10) in solution.

The stability constants $\log \beta_1$ of lanthanide(III) complexes with a number of crown ethers in propylene carbonate (PC) were measured and the $\log \beta_1$ values were statistically processed depending on r :¹⁶²

Crown ether	21C7	18C6	15C5	12C4
$\log \beta_1(\text{La} - \text{Lu})$	5.0–7.5	7.0–9.0	6.0–7.5	5.0–5.5
r	0.6–0.75	0.75–0.95	1.20–1.40	1.70–2.0

The $\log \beta_1$ values are maximum for the complexes with 18C6. For $r \ll 1$ or $r \gg 1$, the stability of the complexes decreases. For the complexes of light lanthanides with 18C6, $r \approx 1$, which accounted for their higher stability compared to heavy lanthanide complexes. The decrease in $\log \beta_1$ of the complexes with this crown ether in methanol¹⁶⁰ following an increase in $Z(\text{Ln})$ from La to Eu could also be attributed to the better fit between R_{ion} and R_c . It may seem that the trends in variation of $\log \beta_1$ upon complexation of alkali metals with crown ethers can also be interpreted in this way; however, on going from Na^+ to Cs^+ the ionic radius increases 1.6-fold and on going from La^{3+} to Lu^{3+} , only 1.2-fold. This implies the need for essential preorganisation of macrocyclic ligands for the reaction with M^+ : in the complexes with 18C6, the K^+ cation fits in the plane of the ligand molecule with D_{3d} symmetry, while the large Cs^+ ion deviates from this plane. However, the Na^+ ion is too small for the large ring; therefore, its symmetry is highly distorted compared to D_{3d} .

The enthalpy of desolvation (ΔH_h) and electronegativity of cations play an important role in the complexation. Compare two ion pairs, $\text{Sr}^{2+}/\text{Pb}^{2+}$ and Rb^+/Tl^+ , having similar ΔH_h , R_{ion} and similar enthalpies of complexation with 18C6 [$\Delta H(18\text{C6})$]:

Sr^{2+} and Pb^{2+} :

$$\Delta H_h = -1521 \text{ and } -1556 \text{ kJ mol}^{-1};$$

$$R_{\text{ion}} = 1.18 \text{ and } 1.19 \text{ \AA},$$

$$\Delta H(18\text{C6}) = -15.1 \text{ and } -21.8 \text{ kJ mol}^{-1};$$

Rb^+ and Tl^+ :

$$\Delta H_h = -339 \text{ and } -364 \text{ kJ mol}^{-1};$$

$$R_{\text{ion}} = 1.52 \text{ and } 1.50 \text{ \AA},$$

$$\Delta H(18\text{C6}) = -15.9 \text{ and } -18.4 \text{ kJ mol}^{-1}.$$

The negative $\Delta H(18\text{C6})$ values larger in magnitude found for Pb^{2+} and Tl^+ were attributed¹⁵⁶ to higher electronegativity of Pb (1.8) and Tl (1.8) compared to Sr (1.0) and Rb (0.8); apparently, the 5d-AO of lead and thallium participate in the formation of bonds with macrocyclic ligand atoms, resulting in more exothermic complexation.

In the case of cryptands, the size fitting principle is believed¹⁵⁶ to be more significant than for crown ethers or tetraazamacrocycles, which is reflected in the stability constants $\log K_{211}$, $\log K_{222}$, $\log K_{322}$.

The highest stability is attained for smaller cations, which fit in small cavities:

$$\text{Li}^+: R_{\text{ion}} = 0.675 \text{ \AA},$$

$$\log K_{211} > \log K_{221};$$

$$\text{Na}^+: R_{\text{ion}} = 1.0 \text{ \AA},$$

$$\log K_{211} < \log K_{221} > \log K_{222} < \log K_{322};$$

$$\text{K}^+: R_{\text{ion}} = 1.376 \text{ \AA},$$

$$\log K_{221} < \log K_{222} > \log K_{322};$$

$$\text{Ca}^{2+}: R_{\text{ion}} = 0.72 \text{ \AA},$$

$$\log K_{211} < \log K_{221} > \log K_{222} < \log K_{322};$$

$$\text{Ba}^{2+}: R_{\text{ion}} = 1.389 \text{ \AA},$$

$$\log K_{221} < \log K_{222} > \log K_{322} < \log K_{332}.$$

The reason is in the greater hardness of cryptands CR111–CR322 and higher preorganisation compared to crown ethers.

2. Effect of the charge transfer energy from the ligand to the cation on the stability of macrocyclic complexes

Presumably, the interaction of macrocyclic ligands (cryptands and azacrown ethers, AC) with Ln^{3+} ions occurs through electron density transfer from the O and N atoms of the ligand to the cations. The higher the electron-acceptor capacity of the cation and the lower the electron transfer energy from the occupied MO of the ligands to vacant or partially occupied 4f-AO of the cation, the more stable the complex. If this hypothesis is valid, the charge transfer energy $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ and $\Delta E[2p(\text{N}) \rightarrow 4f(\text{Ln}^{3+})]$ should correlate with $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $\log \beta[\text{Ln}(\text{AC21})]^{3+}$. The $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ have been measured for many complexes and systematised,^{29,35} whereas no data on $\Delta E[2p(\text{N}) \rightarrow 4f(\text{Ln}^{3+})]$ are available. Figure 2 compares the trends of variation of $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ (Ref. 35) and $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ or $\log \beta[\text{Ln}(\text{AC21})]^{3+}$ (Ref. 161). It can be seen that in the first half of the series, on going from Pr to Eu, the stability of complexes $[\text{Ln}(\text{CR221})]^{3+}$ increases in line with a decrease in $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$, i.e., with an increase in the electron-acceptor ability of the cation. The extreme points of $\log \beta[\text{Eu}(\text{CR221})]^{3+}$ and $\log \beta[\text{Eu}(\text{AC21})]^{3+}$ correspond to the minimum of $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Eu}^{3+})]$. The antiparallel variation of $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Eu}^{3+})]$ in the second half of the lanthanide series from Gd to Yb is beyond doubt. The $\log \beta[\text{Lu}(\text{CR221})]^{3+}$ has not been measured: in the model considered, one can expect that $\log \beta[\text{Lu}(\text{CR221})]^{3+} < \log \beta[\text{Yb}(\text{CR221})]^{3+}$. As a conclusion of this Section, note

Figure 2. Energies of charge transfer from the oxygen atoms to the Ln^{3+} 4f-AO in the Ln^{3+} complexes (1), stability constants of the complexes with cryptand CR221 (2) and azacrown ether AC21 (3) in MeOH.

that the charge transfer energy in the MC of transition d elements has not been studied experimentally, although this could provide direct information on the electron density transfer from the ligands to the cations inserted in the cavity.

3. Effect of desolvation of cations on the stability of macrocyclic complexes

The stability of lanthanide cryptates depends on the solvent and increases in the sequence¹⁶¹ $\text{DMF} < \text{DMSO} < \text{H}_2\text{O} < \text{MeOH} < \text{MeCN} \ll \text{PC}$. In highly solvating solvents (DMF, DMSO, H_2O , MeOH), the lower the expenditure for desolvation, the higher the stability of complexes ($\log \beta$) (or the greater the magnitude of the negative ΔG° upon complexation). The free desolvation energy is determined by the free energy of formation of solvated ions; in the aqueous solution, the $-\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ values vary in the range from 576 (Eu) to 688 kJ mol^{-1} (La).^{125, 153–155}

Ln	$-\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}) / \text{kJ mol}^{-1}$	Ln	$-\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+}) / \text{kJ mol}^{-1}$
La	688	Tb	668
Ce	676	Dy	664
Pr	681	Ho	675
Nd	672	Er	673
Sm	677	Tm	671
Eu	576	Yb	639
Gd	660	Lu	677

It was noted¹⁶¹ that the dependences of $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $\log \beta[\text{Ln}(\text{AC21})]^{3+}$ on $Z(\text{Ln})$ are essentially non-monotonic. It should be emphasised that in the first half of the series, the extremal point is found for Eu in both cases. Evidently, neither the size of the cavity nor the ionic radius, which is a monotonic function $Z(\text{Ln})$, can be responsible for the non-monotonic variation of the stability of the complexes and the presence of extremal points for Eu. Probably, the variation of $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $\log \beta[\text{Ln}(\text{AC21})]^{3+}$ is determined by the desolvation parameters of the cations. Since there are no experimental data on the free energy of formation of Ln^{3+} in MeOH, we use the reported¹²⁵ experimental values of $\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})$. A comparison of $|\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})|$ for Sm, Eu and Gd shows that the extremal points in the $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $\log \beta[\text{Ln}(\text{AC21})]^{3+}$ plots corresponding to an increase in the stability of Eu complexes with respect to Sm and Gd complexes are related to the desolvation of cations. The antiparallel variations of $|\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})|$ and $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ or $\log \beta[\text{Ln}(\text{AC21})]^{3+}$ can be clearly seen (see Fig. 2).

If the correlation between $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ and $|\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})|$ is applied only to two elements, La and Yb, one

can determine $\log \beta[\text{Ln}(\text{CR221})]^{3+}$ for $\text{Ln} = \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Gd}, \text{Tb}, \text{Dy}$. The difference between these estimates and the experimental values equal to ± 0.4 for $\log \beta$ (or $\sim 2.4 \text{ kJ mol}^{-1}$ for ΔG°) signifies not only a qualitative but also a quantitative relationship between the MC stability and the desolvation energy of the cations inserted in the cavity. However, the $|\Delta G_f^\circ(\text{Ln}_{\text{aq}}^{3+})|$ values for $\text{Ln} = \text{Ho}$ (675), Er (673) and Tm (671) differ by only 2 kJ mol^{-1} (Ref. 125). This is apparently lower than the experimental error in the determination of $\log \beta$; for these three elements, the variations of $\log \beta$ can be determined by other factors.

4. Effect of the solvent on the stabilisation of the unusual oxidation states of lanthanides and actinides

The charge transfer energies $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ can serve as a quantitative characteristics of the redox potentials $E^\circ(3+/2+)$.^{153–155} The lowest $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ values for europium, samarium and ytterbium correspond to their most stable, divalent states in the series of lanthanides. The divalent state of europium, samarium and ytterbium can be stabilised upon complexation with cryptands or even coronands¹⁶¹ in H_2O , MeOH and DMF . In these solvents, the cryptates and coronates of trivalent lanthanides are reduced at higher potentials than free (solvated) cations, which attests to stabilisation of the lanthanide(II) complexes. In MeCN or PC , no systematic stabilisation of the divalent state is observed.

Therefore, it may be promising to use cryptands and coronands for the separation of $\text{Ln}^{2+}/\text{Ln}^{3+}$ and $\text{An}^{2+}/\text{An}^{3+}$ pairs by extraction based on the difference between the redox potentials $E^\circ(3+/2+)$. It has been noted above that the separation of Eu^{3+} , Am^{3+} and Cm^{3+} , which are deservedly called the ‘Bermuda Triangle’ in the extraction chemistry is a challenge. The problem is that complexes of these cations in solutions have very similar thermodynamic characteristics due to the small difference between the free energies of formation of solvated cations ΔG_f° , in particular, in aqueous solutions, $\Delta G_f^\circ = -576$ (Eu^{3+}), -603 (Am^{3+}) and -594 kJ mol^{-1} (Cm^{3+}).¹²⁵ Upon complex formation with cryptands and coronands in aqueous solutions, Am^{3+} and Cm^{3+} are not reduced, unlike Eu^{3+} . However, the heavy actinide ions (Cf^{3+} , Es^{3+} , Fm^{3+} like Sm^{3+} , and Md^{3+} like Eu^{3+}) should be reduced to the divalent state. The good prospects of using cryptands and coronands for the separation of these elements are due to the use of readily available solvents and environmentally safe extractants, which do not give rise to the third phase, unlike the classical phosphorus-containing extractants.

5. Complexation with preorganised ligands

The thermodynamic characteristics, *i.e.*, the free energy and enthalpy changes upon the formation of $[\text{Ln}(\text{CR221})]^{3+}$ complexes in MeCN and PC , were measured¹⁶¹ for $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Er}$ and for $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$, respectively. The ligand is hard and highly preorganised and both solvents are non-solvating. Presumably, the $\Delta G^\circ[\text{Ln}(\text{CR221})]^{3+}$, $\Delta H^\circ[\text{Ln}(\text{CR221})]^{3+}$ and $\Delta S^\circ[\text{Ln}(\text{CR221})]^{3+}$ values are controlled by the size effect. The experimental values of ΔG° and ΔH° for seven lanthanides depend linearly on the ionic radii of the cations (C.N. 9) with a correlation factor of 0.99. This allows one to estimate $\Delta G^\circ[\text{Ln}(\text{CR221})]^{3+}$, $\Delta H^\circ[\text{Ln}(\text{CR221})]^{3+}$ and $T\Delta S^\circ[\text{Ln}(\text{CR221})]^{3+}$ for $\text{Ce}, \text{Sm}, \text{Eu}, \text{Gd}, \text{Tb}, \text{Tm}, \text{Yb}, \text{Lu}$ in MeCN and PC . Thus, in the case of MC $[\text{Ln}(\text{CR221})]^{3+}$ we have at hand the $\Delta G^\circ[\text{Ln}(\text{CR221})]^{3+}$ values for all lanthanides in MeOH , MeCN and PC and the $\Delta H^\circ[\text{Ln}(\text{CR221})]^{3+}$ and $T\Delta S^\circ[\text{Ln}(\text{CR221})]^{3+}$ values in MeCN and PC .

In the complexation of Ln^{3+} with O- and N-donor ligands in MeCN , both the entropy and enthalpy changes are negative;^{128, 156} therefore, it is not unexpected that $\Delta S^\circ[\text{Ln}(\text{CR221})]^{3+} < 0$ and $\Delta H^\circ[\text{Ln}(\text{CR221})]^{3+} < 0$ in the

Figure 3. Enthalpy and entropy changes upon the formation of cryptates $[\text{Ln}(\text{CR221})]^{3+}$ in MeCN .

case of formation of $[\text{Ln}(\text{CR221})]^{3+}$ in MeCN (Fig. 3). However, it is difficult to explain why ΔS° for complexation in PC changes the sign: for light lanthanides, $\Delta S^\circ > 0$ ($\text{La} - \text{Nd}$), in the middle of the series, $\Delta S^\circ \approx 0$ (Eu, Gd) and in the second half of the series, $\Delta S^\circ < 0$ ($\text{Tb} - \text{Lu}$). The change in the entropy sign is rarely encountered in the chemistry of complex compounds; it is attributed to a change in the composition of complexes or the conformation of the ligands.¹⁵⁶ As regards the complexation of Ln^{3+} with CR221 in other solvents (H_2O or MeOH), the $\Delta S^\circ[\text{Ln}(\text{CR221})]^{3+}$ values may be expected to be positive and the entropy contribution to the change in the free energy of complexation would predominate over the enthalpy contribution.

6. Macrocyclic effect

When studying MC, it is general practice to estimate the macrocyclic effect by comparing the thermodynamic properties of the MC and its acyclic analogue; however, such an analogue cannot be easily selected.¹⁵⁶ We chose the lanthanide complexes with highly preorganised macrocyclic ligand CR221 synthesised in MeCN and MeOH and with a non-preorganised edta ligand in H_2O . Each ligand has six coordinating atoms ($2\text{N} + 4\text{O}$). The presence of the same donor atoms results in some linear relationships for the free energy of complexation $\Delta G_{\text{CR221}}^\circ(\text{MeCN})$, $\Delta G_{\text{CR221}}^\circ(\text{MeOH})$ ¹⁰¹ and $\Delta G_{\text{edta}}^\circ(\text{H}_2\text{O})$ ¹⁵⁶ (all values are expressed in kJ mol^{-1}):

$$\Delta G_{\text{edta}}^\circ(\text{H}_2\text{O}) = \Delta G_{\text{CR221}}^\circ(\text{MeCN}) - 23.5, \quad (1)$$

$$\Delta G_{\text{edta}}^\circ(\text{H}_2\text{O}) = 0.985 \Delta G_{\text{CR221}}^\circ(\text{MeOH}) - 36.5. \quad (2)$$

However, the trends in the variation of $\Delta H_{\text{CR221}}^\circ(\text{MeCN})$ and $\Delta H_{\text{edta}}^\circ(\text{H}_2\text{O})$ as well as $T\Delta S_{\text{CR221}}^\circ(\text{MeCN})$ and $T\Delta S_{\text{edta}}^\circ(\text{H}_2\text{O})$ are different. The change in the C.N. in lanthanide complexes with edta (C.N. is 10 for $\text{La} - \text{Nd}$, 9.5 for Sm and Gd , 9 for $\text{Tb} - \text{Lu}$)¹⁰² is responsible for the non-monotonic variation of the entropy along the series and, as a consequence, a non-monotonic variation of the enthalpy (Fig. 4). Both $\Delta H_{\text{CR221}}^\circ(\text{MeCN})$ and $T\Delta S_{\text{CR221}}^\circ(\text{MeCN})$ vary monotonically along the lanthanide series. This is a consequence of high preorganisation of the ligand and the effect of the non-solvating solvent. As long as experimental $\Delta H_{\text{CR221}}^\circ(\text{MeOH})$ and $\Delta H_{\text{CR221}}^\circ(\text{H}_2\text{O})$ values are missing, it is difficult to draw conclusions about the nature (either enthalpy or entropy) of the macrocyclic effect. It is clear that the degree of ligand preorganisation depends on the solvent. At a qualitative level, it can be noted that if a thermodynamic effect of ligand preorganisation in solvating solvents is pronounced, this can

Figure 4. Changes in entropy (1, 3) and enthalpy (2, 4) upon the formation of complexes Ln(edta) in H₂O (2, 3) and Ln(CR221) in MeCN (1, 4).

mask the non-monotonic entropy and enthalpy changes along the lanthanide series.

For predicting the macrocyclic effect, it is important that in Eqns (1) and (2), the coefficient at $\Delta G_{\text{CR221}}^\circ$ is ~ 1 . Hence, the macrocyclic effect along the lanthanide series can be estimated using known ΔG° for the appropriate ligands with the same number and nature of the donor atoms as in the macrocycle, for example, nitrilotriacetate (1 N + 3 O), ethylenediaminetetraacetate (2 N + 4 O), ethylenetriaminepentaacetate (3 N + 5 O), etc.

7. Calixarenes and crown ethers

a. Interaction of calixarenes with lanthanide aqua ions

Water-soluble calixarenes are considered as promising ligands for the synthesis of MC.¹⁶³ *p*-Sulfocalix[4]arenes (*p*-SC[4]A) form SMA with a variety of guest molecules in both solution and the solid state. Two-dimensional hydrogen-bonded SMP with $\text{Ln}_{\text{aq}}^{3+} \cdot [\text{Ln}(\text{H}_2\text{O})_8]^{3+}[\text{p-SC[4]A}]$ (Ln = Gd, Tb, Tm) have been synthesised. In the two-dimensional SMP, each aqua ion is connected by hydrogen bonds to four neighbouring sulfonate groups of *p*-SC[4]A, thus forming an infinite structure. For example, in the Tb complex, each $[\text{Tb}(\text{H}_2\text{O})_8]^{3+}$ ion forms eight hydrogen bonds with the distances $R(\text{O} \cdots \text{H} \cdots \text{O}) = 2.741 \text{ \AA}$ and the energy $\Sigma D_0(\text{O} \cdots \text{H} \cdots \text{O}) = 8 \times 12.98 = 103.8 \text{ kJ mol}^{-1}$.

The enthalpy and entropy changes upon the formation of $\text{O} \cdots \text{H} \cdots \text{O}$ bonds have been reported^{43,60} to be approximately equal, i.e., $\Delta H^\circ/T\Delta S^\circ \approx 1.0$. In view of the reported $\Sigma D_0(\text{O} \cdots \text{H} \cdots \text{O})$, the change ΔS° upon the formation of hydrogen bonds of each aqua ion with four sulfonate groups equals $\Delta S^\circ(\text{O} \cdots \text{H} \cdots \text{O}) = 174 \pm 40 \text{ J mol}^{-1} \text{ K}^{-1}$. The standard entropy of formation of the aqua ions is negative:¹¹¹ $\Delta S_f^\circ(\text{Ln}_{\text{aq}}^{3+}) = -219, -224$ and $-236 \text{ J mol}^{-1} \text{ K}^{-1}$ for Ln = Gd, Tb and Tm, respectively;¹²⁵ hence, upon binding of $\text{Ln}_{\text{aq}}^{3+}$ with *p*-SC[4]A, $\Delta S_f^\circ(\text{Ln}_{\text{aq}}^{3+})$ is largely counterbalanced by $\Delta S^\circ(\text{O} \cdots \text{H} \cdots \text{O})$.

A fundamental issue is the relationship between the coordination and hydrogen bond energies in the $[\text{Ln}_{\text{aq}}^{3+} \cdots \text{calixarene}]$ SMA and their variation along the lanthanide series. Structural data for solving this problem appeared only recently:¹⁶⁴ for the $[\text{LnL}(\text{NO}_3)_2(\text{H}_2\text{O})_2]\text{NO}_3$ complexes [Ln = Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu; L is 2,6-bis(2-pyridyl)-4-amino-1,3,5-triazine], the lengths of the coordination bonds $R(\text{Ln} \cdots \text{O})$ and the hydrogen bonds $R(\text{O} \cdots \text{H} \cdots \text{O})$ were measured. Using about 200 measured¹⁶⁴ $R(\text{Ln} \cdots \text{O})$ and $R(\text{O} \cdots \text{H} \cdots \text{O})$ values, it was established^{30,31} that the greater $R(\text{Ln} \cdots \text{O})$, the smaller $R(\text{O} \cdots \text{H} \cdots \text{O})$. Thus, the interaction of $\text{Ln}_{\text{aq}}^{3+}$ with *p*-SC[4]A is

accompanied by a decrease in $R(\text{Ln} \cdots \text{O})$ and an increase in $R(\text{O} \cdots \text{H} \cdots \text{O})$ on passing from light lanthanides to heavy ones. The energy of intermolecular hydrogen bonds $\text{Ln}_{\text{aq}}^{3+} \cdots \text{calixarene}$ decreases to the end of the series, whereas the energy of the coordination bonds increases.

b. Crown ethers and cryptands as guest molecules in calixarenes: encapsulation according to the 'matreshka doll' pattern

On the basis of a structural conformation analysis, structural reorganisation of crown ethers taking place upon the reaction of 18C6 with *p*-SC[4]A and $\text{Ln}_{\text{aq}}^{3+}$ was studied. The SMA of a complicated structure formed in the case of Ce can be represented¹⁶³ by the following formula (the sign \subset designates inclusion and the sign \cap attests to the arrangement of the crown ether molecule above the calixarene bowl):

The partially hydrated Ce(1) ion is incorporated in the 18C6 ring forming six $\text{Ce} \cdots \text{O}(18\text{C}6)$ bonds, three $\text{Ce} \cdots \text{O}(\text{H}_2\text{O})$ bonds and one $\text{Ce} \cdots \text{O}(\text{p-SC[4]A})$ bond. The Ce(2) ion is also incorporated into the 18C6 ring; remarkably, $[\text{Ce}(2) + 18\text{C}6]$ are encapsulated by two *p*-SC[4]A ligands. Atwood¹⁶³ has called such encapsulation the 'matreshka doll'. One 18C6 molecule serves as the host for the Ce(1) guest ion but $[\text{Ce}(2) + \text{other } 18\text{C}6]$ serve themselves as a guest for two *p*-SC[4]A molecules. The Ce(3) ion is bound to two sulfonate groups from two *p*-SC[4]A ligands, whereas the Ce(4) ion is completely hydrated, forms no coordination bonds with macrocyclic ligands and is involved only in the formation of hydrogen bonds. The energy spectrum of this SMA is fairly complicated (Fig. 5): the $\text{Ce}(1) \cdots \text{O}(18\text{C}6)$ bonds are weaker than $\text{Ce}(1) \cdots \text{O}(\text{H}_2\text{O})$; the encapsulation of $[\text{Ce}(2) + 18\text{C}6]$ in two *p*-SC[4]A strengthens all bonds in the inner 'doll', which is compressed by the outer one. The modification of all bonds is rather significant; for example, the hydrated $\text{Ce}(4)(\text{H}_2\text{O})_9^{3+}$ ion in SMA is distorted due to the formation of hydrogen bonds to such an extent that $R(\text{Ce} \cdots \text{OH}_2)$ varies from 2.352 to 2.674 Å. This cation does not resemble the hydrated cation with a nearly regular tricapped trigonal prismatic coordination considered in the traditional lanthanide chemistry.

As a conclusion of this Section, note that the chemistry of host–guest systems based on calixarenes, crown ethers and

Figure 5. Energies of the $\text{Ce}^{3+} \cdots \text{O}$ bonds with crown ether (1), water (2) and *p*-sulfonatocalix[4]arene (3).

cryptands represents a new field of SMC; which is most amazing, this is a new type of 'matreshka doll' encapsulation.

VI. Conclusion

The synthesis and structure of supramolecular assemblies containing ions of d and f transition elements is a relatively new and rapidly developing field of SMC. These SMA attract particular attention of researchers owing to a set of unique properties, which may enable their extensive practical use in the future.

The synthesis of quasi-one-dimensional polymeric structures, which had been previously considered to be only theoretical models, was an achievement in the supramolecular chemistry. A number of such SMP in which separate dinuclear metal-containing blocks are linked by coordination or hydrogen bonds have now been prepared. A necessary (but not sufficient) condition for the formation of SMP is the absence of axial ligands in the initial complex. The formation of SMP or discrete aggregates (for example, dimers) is determined by the electronic structure of the metal and the ligands. Depending on the geometry of the binding ligands, one can obtain SMP in various conformations (linear, zigzag and so on).

Supramolecular rings are apparently the most numerous class of SMA. The variation of metal-containing fragments and ditopic ligands connecting them gives SMC of various sizes and geometries. Currently, systematic approaches to their synthesis have been developed, which allows targeted design of the structure with a definite parameters.

Several mechanisms of the self-assembly of the structural blocks in SMC are known. Of these, thermodynamic mechanism is studied in most detail and used most often; according to this mechanism, equilibrium between the reactants and products is established in each step and, finally, the thermodynamically most stable product is formed. In the SMC synthesis, Pd^{2+} and Pt^{2+} complexes are used most widely; however, many SMC with other metals are also known (Cr, Mo, Cu, Au, etc.).

The stability of SMC depends on a number of factors among which the metal-metal interaction is the most important. In some cases, a contribution of π - π -stacking is probable. The self-assembly process depends considerably on the solvent properties.

A distinctive feature of SMC is that their structure is retained in solutions. As a result, the ring may function as the host molecule for small ions or molecules exhibiting high selectivity. This feature is of particular interest for researchers, the more so, because the SMC can be varied by selecting appropriate ligands.

Three- and four-membered SMC are best studied; however, examples of five-, six- and eight-membered and even larger rings are also known.

The advances in the synthesis and practical use of alkali and alkaline earth metal macrocyclic complexes stimulated the development of analogous research for lanthanides and actinides. Crown and azacrown ethers, cryptands, calixarenes and so on are used as macrocyclic ligands. Of particular interest is the study of the variation of MC stability along the lanthanide and actinide series. The elucidation of these trends with allowance for the electronic characteristics of metal ions and the solvent effect would open up the way to the development of an efficient method for the separation of poorly separable Ln^{3+} and An^{3+} ions. The differences between the reduction potentials $E^\circ(3+/2+)$, which correlate with the charge transfer energy $\Delta E[2p(\text{O}) \rightarrow 4f(\text{Ln}^{3+})]$ can be used for the same purpose.

Thus, a large body of experimental data on the synthesis of diverse SMA has now been accumulated. In the next stage, it is necessary to carry out in-depth studies of the mechanisms of

their formation based on the methods and concepts of chemical thermodynamics, kinetics, and theoretical and quantum chemistry.^{22, 165}

VI. Conclusion	250

Abstract. Gas discharge initiation of chemical processes in electrolyte solutions is considered. Data on the types of chemical transformations in plasma – solution systems are presented. The processes of generation of primary reactive species in solutions under gas discharge and the key routes for their further reactions are analysed. The prospects for practical application of plasma – solution systems in solving technological and environmental problems are considered. The bibliography includes 109 references.

I. Introduction

Nonequilibrium gas-discharge plasma finds practical application in implementation of numerous physicochemical processes¹ due to its extremely high chemical activity at relatively low temperatures of treated materials. As a penalty, the high reactivity entails low selectivity of chemical reactions initiated by plasma. This necessitates a search for such conditions that would combine the high reactivity of plasma with the selectivity of its effect. The fundamental way for solving this problem is presented by the plasma activation of chemical reactions in electrolyte solutions. Successful realisation of these processes requires the knowledge of physics of gas discharges (in our case, discharge that interacts with the solution), and the mechanism and kinetics of generation of active species (in liquid and gas phases) and their chemical reactions in solution. All these questions are as yet little understood, although the studies of chemical effects initiated by the simplest plasma – solution system, namely, a glow discharge with the electrolyte that plays the role of the electrode, date back to nearly 100 years ago. Güntherschulze (*e.g.*, see Ref. 2) studied the electroforming of aluminium and tantalum electrodes in electrolytic cells with dilute electrolyte solutions ($\text{Na}_2\text{B}_4\text{O}_7$ – HBO_3 and $\text{Na}_2\text{B}_4\text{O}_7$) and observed that the anodic sparkling was accom-

panied by the gas evolution on the anode at a rate higher than the value calculated based on the Faraday law and also the appearance of hydrogen peroxide in the solution. A hypothesis was advanced according to which gases were formed in a region immediately adjacent to the discharge zone as a result of the four-body recombination of oxygen and hydrogen atoms delivered from the discharge zone. Fundamental cycles of studies were accomplished by schools of Klemenc^{3–7} in Germany and Hickling^{8–16} in England. Although the interpretation of their results has now substantially changed, these studies are still of interest, the more so that no such comprehensive systematic studies were carried out since that time and no exhaustive reviews on this subject are known.

II. Plasma – solution systems

1. Specific features and types of plasma – solution systems

The interaction of a gas discharge with solutions can be realised in the following two ways:

- (1) with a discharge that contacts the liquid and is generated between two electrodes located in the gas phase;
- (2) with a discharge in which the electrolyte solution plays the role of one or both electrodes.

In both cases, the properties of the system and the achieved results substantially depend on whether we deal with a (quasi)stationary discharge or a high-voltage pulsed discharge. The present review is chiefly devoted to plasma – solution systems (PSS) with stationary discharges; however, the studies of pulsed PSS are also discussed.

The first-type processes resemble conventional heterogeneous plasma-chemical processes in which active species generated in plasma diffuse to the interface to initiate chemical reactions in the solution. In the second-type systems, the discharge current passes through the electrolyte, which substantially changes the properties of the plasma – liquid interface. In this case, plasma can be generated either in the original plasma-forming gas that contains solvent vapours or within a vapour blanket formed in the liquid phase due to the superheat instability. Figure 1 shows possible configurations of systems differing in the roles of the metal and electrolyte electrodes. The Figure also shows different orders of alternation of interfaces formed by metals, plasma and solutions in PSS of different types. A plasma – solution system can be distinguished from a classical electrochemical system by the presence of one or two plasma – solution interfaces. Note that the

Figure 1. Configurations of discharge cells. In parentheses, the order of alternation of interfaces formed between metal (M), plasma (P) and electrolyte solution (E) is shown.

(a) Glow-discharge cell (M–E–P–M): (1) electrodes, (2) plasma zone, (3) electrolyte, (4) magnetic stirrer.

(b) Diaphragm discharge cell (M–E–P–E–M): (1) electrodes, (2) quartz ampoule, (3) diaphragm (plasma zone), (4) electrolyte, (5) stirrer.

(c) Gliding arc discharge cell (M–E–P–M): (1) solution, (2) gliding arc discharge, (3) special-shape electrode (anode), (4) thermocouple entry, (5) flow meter, (6) gas inlet.

(d) Diaphragm discharge cell with buffer compartments (M–E–P–E–M): (1) electrodes, (2) plasma zone, (3) active zone, (4) buffer compartments, (5) quartz ampoules with diaphragms.

(e) Cell for initiation of volume discharges in a tube filled with a solution (M–E–P–E–P–E–M): (1) electrodes, (2) discharge zone, (3) circulation of electrolyte solution, (4) to a reflux condenser.

plasma structures in these systems may be in direct contact with neither metal electrodes nor the external atmosphere.

The glow discharge in which the electrolyte solution serves as one of the electrodes (most often, the cathode) was studied most thoroughly (see Fig. 1a).^{3–16} Apparently, anodic microdischarges that arise as a result of the breakdown of the oxide film on the surface of such metals as Al, Ta, Nb, which are immersed into the solution, can also be assigned to the same type.^{17–22} Special mention should be made of PSS in which the plasma formed in the solution has a sufficiently large volume, which allows one to treat materials by combining the impacts of plasma and the plasma-activated solution (see Fig. 1e).²³

From our viewpoint, any strict classification of plasma–solution systems is hardly possible to date. A classification based on the analysis of the number of metal–solution and plasma–solution interfaces and the order of their alternation was proposed.²⁴ It is the dynamic plasma–solution interface that is the key feature of any PSS. Few available experimental data characterising this interface were obtained only for a glow discharge with electrolyte electrodes and exclusively for the case where the electrolyte serves as the cathode. For non-stationary continuous discharges, e.g., diaphragm discharge, such studies are more cumbersome and are virtually unknown to date. According to our viewpoint, the most important

properties of the dynamic plasma–solution interface are similar for the mentioned discharge types. This is why below we consider only the glow discharge with the electrolyte as the cathode.

Drawing the analogy between a glow discharge with the electrolyte cathode and a classical low-pressure glow discharge, it should be noted that the cathodic potential drop at the electrolyte surface is determined by two characteristics, namely, the coefficient of electron emission from the solution (γ) and the Townsend coefficient of volume ionisation (α).²⁴ Measurements gave the cathodic potential drop at the electrolyte surface in the range from 300 to 800 V.²⁵ These values substantially exceed the usual cathodic potential drops obtained for glow discharges with metal electrodes, which apparently can be associated with the low coefficient γ . Estimates, which were based on an assumption that at low discharge currents (not exceeding tens of mA), the glow discharge with an electrolyte cathode can be considered as a conventional glow discharge, gave the values $\gamma = 10^{-4}–10^{-3}$ (Ref. 26).

The high potential drop at the surface of electrolyte cathodes determines the sufficiently high yields of primary active species in the thin surface layer of the solution. To our knowledge, the energy distribution of ions bombarding the

solution surface is yet unknown. However, it is evident that the maximum possible energy should correspond to the potential drop at the cathode surface.

Ionic bombardment of the solution surface not only leads to its effective chemical activation but also gives rise to an effect similar to the classical cathode sputtering, *i.e.*, the transfer of solution components into the plasma zone. According to the results of measurements,^{27,28} the transfer coefficient of solvent (water) molecules, which is determined as the number of water molecules knocked out from the solution per incident ion exceeds 10^2 ; the transfer coefficient of the solute is approximately proportional to its mole fraction in the solution. The vapour jet that arises as a result of cathodic sputtering has a linear velocity of $50\text{--}100\text{ cm s}^{-1}$. The energy consumed in its formation reaches 50% of the total discharge energy.²⁹ Estimates of average energy consumed in the transfer of a single water molecule to the plasma zone correspond to $\sim 50\text{ kJ mol}^{-1}$, which does not differ much from the thermodynamically equilibrium consumption (43.3 kJ mol^{-1} at $40\text{ }^{\circ}\text{C}$ ³⁰).

The presence of non-equilibrium vapour jet leads to the fact that regardless of the nature of the main plasma-forming gas, the ionisation of water molecules plays the key role in the formation of plasma; moreover, according to certain estimates,²⁵ the main ions in the plasma zone are $\text{H}_3\text{O}^+ \cdot \text{H}_2\text{O}$. The role played by this jet in the discharge-initiated processes in solution is of no less importance. The analysis of the mechanism of these processes requires taking into account the ion-bombardment-induced transfer of reagents and products into the gas zone.³¹ The fact that recombination processes that involve primary active species (HO^\bullet , H^\bullet , e_{soln}^-) almost exclusively occur in the cathodic spot zone necessitates the separate consideration of the rates of processes initiated by primary species in the cathodic spot and those initiated by secondary species (*e.g.*, hydrogen peroxide) in the rest solution volume.³¹

2. The mechanism of chemical activation of solutions in plasma–solution systems

Despite the substantial difference in the PSS mentioned above, the main reason for the plasma activation of solutions is their bombardment with ions accelerated near the solution surface in the vicinity of the near-electrode (mainly cathodic) potential drop. This causes non-equilibrium dissociation and ionisation of, first of all, solvent molecules. As a result, H^\bullet , HO^\bullet radicals and solvated electrons appear in the solution. This mechanism of activation followed by chemical reactions is close to that comprehensively studied in radiation chemistry.³² The yields of primary active species depend on the cathodic potential drop formed. Another important effect of ionic bombardment is the transfer of solution components into the plasma zone. The data on its kinetics under the conditions of an atmospheric-pressure glow discharge are available.^{26–28} Undoubtedly, the transfer processes initiated by ionic bombardment substantially affect the properties of other non-stationary PSS, including the migration of plasma wisps in solution. In the case of non-stationary discharges (diaphragm and volume discharges), a shock wave is initiated in the electrolyte bulk, the propagation of which can also affect the chemical processes in the solution.^{33,34}

The contact of the plasma zone with the solution surface apparently activates the solution *via* the ‘dissolution’ of active species formed in the plasma by fairly well known mechanisms. However, the quantitative contribution of this activation mechanism to the observed yields of chemical reaction products in solutions still remains unclear. Obviously, this

contribution can be higher when the plasma zone is located within the solution as in the case of anodic microdischarges or a diaphragm discharge.

3. Yields of primary active species in plasma–solution systems

Within the framework of the simplified scheme described above in the absence of discharge-initiated chain reactions in solutions, the yields of final products of redox reactions cannot exceed the yields of primary active species. Experimental results that allow one to directly check this assumption are scarce. Thus it was found^{8,9,13,14} that with an increase in the salt concentration, the yields of oxidation products of Fe^{2+} and Ce^{3+} approach the yields of HO^\bullet radicals found in the same studies. As a whole, these results do not contradict the above assumption. The only exclusion was the far too high yield observed³⁵ in the oxidation of Fe^{2+} to Fe^{3+} with a very low discharge current (0.1 mA). Table 1 shows the discussed results.

III. The effect of gas discharges on physicochemical properties of solutions

Initiation of redox reactions in solutions should be accompanied by the changes in their acidity. At the same time, the observed pH changes sometimes cannot be explained by this effect. As demonstrated for a corona discharge⁴³ and, later, for a gliding arc discharge burning between two metal electrodes in the immediate vicinity of the solution surface,⁴⁴ the pH of aqueous solutions in contact with a gas discharge decreased. In both studies, the discharge-activated gas was in contact with the aqueous solution surface but no discharge current passed through the solution. Moreover, according to the authors of these studies, the effect of a powerful gliding arc discharge on the solution pH completely resembled the titration of a strong alkali with a strong acid (*i.e.*, the pH changes were sharp and great). The simplest explanation of this effect assumes the formation of nitrogen oxides in the plasma zone followed by their dissolution.

In the studies of the effect of a glow discharge on the acidity of solutions of alkali metal chlorides,²⁶ no oxidation processes initiated in the liquid phase were found; however, in dilute solutions, a strong and steady decrease in the pH was observed, where the changes in the proton concentration in solution corresponded to the quantity of electricity passed. It was assumed⁴⁵ that the observed effect can be attributed to a redox process initiated by ion bombardment and localised in the gas phase. This process gave alkali metal atoms and chlorine molecules observed experimentally in the gas phase. Under the experimental conditions used, virtually no sodium returned to the liquid phase, in contrast to chloride. Thus, in this case, the changes in the solution acidity were determined by the transfer rate of the solute to the gas phase under the action of ion bombardment.

The changes in the acidity of solutions subjected to a gas discharge were accompanied by the changes in the solution conductivity.⁴⁶ The conductivity of concentrated acids and alkalis subjected to a diaphragm discharge decreased, whereas the conductivity of salt solutions remained unchanged.⁴⁷ Taking into account the mechanisms of conduction in these solutions, this effect was explained by the changes in the structural characteristics of acid and alkali solutions, which affected the effectiveness of the relay mechanism of charge transfer in them.

Table 1. Yields of the primary active species or the products of redox processes initiated by these species.

Species or process	Yield /mol F ⁻¹ (see ^a)	Conditions	Ref.
HO·, H·	7.3	glow discharge (25–125 Torr), FeSO ₄ solution	9
	7.6	glow discharge (25–125 Torr), Ce ₂ (SO ₄) ₃ solution	10

Mn ²⁺ → MnO ₂	"
Cr ³⁺ → Cr ₂ O ₇ ²⁻	"
Fe ²⁺ → Fe ³⁺	"
[Fe(CN) ₆] ⁴⁻ → [Fe(CN) ₆] ³⁻	neutral
Ce ³⁺ → Ce ⁴⁺	acidic
Tl ⁺ → Tl ³⁺	the same
Reduction reactions	
MnO ₄ ⁻ → MnO ₂	neutral
Cr ₂ O ₇ ²⁻ → Cr ₂ O ₃	the same
VO ₃ ⁻ → VO ²⁺	"

The number of studies devoted to chemical reactions in solutions initiated by different types of gas discharge is sufficiently large. However, the comprehensive analysis of all these data is complicated because the experimental conditions used were substantially different and often described in insufficient detail.

1. Hydrogen peroxide generation in electrolyte solutions subjected to the gas-discharge plasma

Klemenc *et al.*^{3–6} pioneered the quantitative studies of the formation of hydrogen peroxide in PSS. Hickling *et al.*^{8, 15} carried out further comprehensive investigations of the hydrogen peroxide formation in aqueous solutions subjected to a low-pressure discharge (50–75 Torr) with the anode located in the gas phase. According to their results, hydrogen peroxide was formed in an amount proportional to the quantity of electricity passed, the accumulation of hydrogen peroxide was accompanied by its decomposition, which ultimately led to its steady-state concentration. The amount of H₂O₂ formed in the solution upon the passage of a given charge through it was independent of both the current and the factors that determine the discharge nature and can be described by the following expression:

$$C_{eq} = \frac{F}{k} \left[1 - \exp\left(-\frac{akq}{V}\right) \right],$$

where C_{eq} is the steady-state concentration of H_2O_2 , F is the Faraday constant, k is the rate constant for the hydrogen peroxide decomposition, a is a numerical coefficient equal to 1.1–1.9 which corresponds to the number of hydrogen peroxide equivalents primarily formed per Faraday of electricity (the initial yield is G_0), q is the quantity of electricity in Faradays, V is the solution volume.

The process followed the same mechanism in the pH range from 1 to 9. However, beyond this range, the H_2O_2 yield decreased. In strongly alkaline solutions, no hydrogen peroxide was detected. Presumably, this can be associated with its anodic decomposition at the discharge of hydroxyl ions. The primary formation of hydroxyl radicals dimerisation of which yields peroxide was assumed to occur in the solution. At high concentrations, hydrogen peroxide decomposed in the reaction with the mentioned HO^\bullet radical. The hydrogen peroxide yield was observed to depend relatively weakly on the electrolyte concentration (including aqueous ammonia and sulfuric acid solutions) and also on the nature of the primary plasma-forming gas and its pressure.^{11–16}

Considering the formation of hydrogen peroxide as a result of dimerisation of HO^\bullet radicals, one can expect the appearance of H_2O_2 in alcohol solutions. However, in the glow-discharge-treated solution of 0.3 M $LiClO_4$ in methanol, formaldehyde was the main product and no hydrogen peroxide was detected.³³ A totally different situation was observed upon plasma treatment of aqueous ethanol in the presence of oxygen.³⁸ The action of an anodic glow discharge on ethanol in its neutral aqueous solution (a phosphate buffer) afforded acetaldehyde, butane-2,3-diol and hydrogen peroxide. The yields of these products strongly depended on both the oxygen flow and stirring. With the increase in the discharge current, the maintenance of the hydrogen peroxide yield at a constant level requires the increase of the oxygen consumption. Under experimental conditions, the amount of formed H_2O_2 linearly increased with the increase in the quantity of electricity passed, *i.e.*, no discharge-induced decomposition of hydrogen peroxide took place.

Kinetic curves of hydrogen peroxide accumulation measured^{8, 15, 40, 48} under different conditions were processed in our studies with the use of an exponential relationship similar to that proposed by Hickling^{8, 15}

$$C = C_{lim} [1 - \exp(-BQ)],$$

where C is the current concentration of hydrogen peroxide, C_{lim} is the maximum concentration of hydrogen peroxide obtained by using this processing procedure, B is the empirical coefficient, Q is the quantity of electricity passed through the system. Table 3 shows the obtained results.

Table 3. Kinetic characteristics of the hydrogen peroxide accumulation under different conditions.^a

Experimental conditions	$10^3 C_{lim}$ /mol litre ⁻¹	$10^3 B$ /F ⁻¹	v (see ^b) /mol F ⁻¹	Ref.
Contact discharge (1 atm), 0.05 M K_2SO_4	0.2	1.88	0.376	8
Glow discharge (50 Torr), current 75 mA, 0.4 M H_2SO_4	1.7	0.405	0.688	15
Glow discharge (50 Torr), current 110 mA, 0.05 M $NaHSO_4$	2	0.403	0.806	40
Contact discharge (1 atm), current 110 mA, 0.02 M H_2SO_4	10	0.189	1.89	48

^a Initial current yield of H_2O_2 were practically the same (~ 1.5 mol F⁻¹);

^b v is the formation rate of H_2O_2 .

For similar discharge currents, the initial current yields of hydrogen peroxide were virtually the same, whereas its limiting concentrations differed by more than an order of magnitude. Moreover, the maximum difference was observed for only one type of discharge, namely, the contact discharge, *i.e.*, the explanation should be sought in the discharge as such. This means that even for the same discharge type, the rates of discharge-induced hydrogen peroxide decomposition can differ by two orders of magnitude.

In the aforementioned studies, Hickling also examined the decomposition of hydrogen peroxide for the cases where 0.05 M solutions of H_2SO_4 , Na_2HPO_4 and $NaOH$ with different starting H_2O_2 concentrations were subjected to the discharge. It was found that in discharge-treated sulfuric acid and sodium phosphate solutions, the amount of hydrogen peroxide changed until its steady-state concentrations corresponding to those found in experiments on the peroxide synthesis were reached. In the alkaline solution, decomposition of hydrogen peroxide with the current efficiency equal to 1 persisted, which was explained by the following anodic processes:

2. Oxidation processes initiated by a gas discharge in aqueous solutions of inorganic substances

A gas discharge initiates both oxidation and reduction reactions in solution (see Table 2). According to available data, the discharge initiates all thermodynamically permissible redox reactions that involve primary active HO^\bullet species. At the same time, the rate of the process strongly depends on the ratio of redox potentials of the corresponding half-reactions.

The oxidation of $FeSO_4$, NaN_3 and $Ce_2(SO_4)_3$ initiated by a glow discharge at reduced pressure (125–250 Torr) in the argon atmosphere was studied.^{9, 10, 13, 14, 35, 44}

It was found⁹ that the yield of oxidation products of $FeSO_4$ (G /equiv F⁻¹) can be described by the relationship

$$G = 1 + n \frac{[Fe^{2+}] + A}{[Fe^{2+}] + A + B},$$

where n is the number of equivalents of the oxidant, which were formed per Faraday of electricity, A and B are empirical constants.

Presumably, the majority of obtained experimental results can be explained based on the assumption that the HO^\bullet radical is the primary oxidation agent. The kinetic model, which was developed based on the experimental data, has led to a relationship similar to that shown above and allowed the empirical kinetic characteristics for the oxidation of three substrates mentioned above to be found. The initial yield of HO^\bullet (mol F⁻¹) was determined to be 7.3 for iron sulfate, 7.6 for cerium sulfate and 8.3 for sodium azide (the limiting yields obtained at the maximum salt concentration are shown).^{9, 10}

Glow-discharge-induced oxidation of $K_4[Fe(CN)_6]$ was studied.⁴¹ With the increase in the concentration of oxidised ions, the yield of oxidation products tended to a limit of 7 mol F⁻¹ (at the salt concentration of 0.45 mol litre⁻¹). Presumably, the main oxidation reactions were as follows:

The reduction of $K_3[Fe(CN)_6]$ under the action of hydrogen atoms was neglected.

The oxidation of $K_4[Fe(CN)_6]$ to $K_3[Fe(CN)_6]$ initiated by a 'positive' atmospheric-pressure glow discharge between an electrode-tip in the gas phase and the surface of an aqueous electrolyte solution was studied⁴² as a function of the gas discharge current and the concentration of the starting compound. The currents of 5 and 10 mA were used, the voltage at electrodes did not exceed 5 kV. Table 4 shows the results obtained.

Table 4. Initial oxidation rates (v_0) of potassium hexacyanoferrate(II) and current yields (G) for different discharge conditions.⁴²

Discharge current /mA	$10^3 C_0$ /mol litre ⁻¹ (see ^a)	$10^7 v_0$ /mol litre ⁻¹ s ⁻¹	G^b
10	5	2.27	0.88
	2	1.91	0.74
	1	1.99	0.77
	0.5	2.34	0.90
	0.25	2.45	0.94
5	0.5	0.904	0.70
	0.25	0.728	0.56
	1	0.683	0.53

^a C_0 is initial concentration of $K_4[Fe(CN)_6]$.

^b Average current yield is expressed as the number of $K_3[Fe(CN)_6]$ molecules formed per incident ion.

The oxidation of ammonium ions under the discharge conditions was studied.³⁷ Air-saturated stirred aqueous ammonia (50 ml) served as the working solution. In the 'positive' discharge, the main products were hydrogen peroxide, hydrazine, hydroxylamine and nitrite ions. In the 'negative' discharge, neither hydrogen peroxide nor hydrazine were detected. In both cases, no formation of nitrate ions was observed. Both anodic and cathodic discharges afforded nitrogen and hydrogen as the gaseous products. In a cooled trap behind the discharge cell, only NH_3 and H_2O were detected.

Sulfuric acid oxidation was studied back in the work by Klemenc and Eder.⁴ They have found that the oxidation products of sulfuric acid under the action of a glow discharge were (in addition to hydrogen peroxide) peroxydisulfuric ($H_2S_2O_8$) and peroxymonosulfuric (H_2SO_5) acids. The effect of minor additives on this process was studied⁵ (see below). Denaro and Hough⁴⁸ studied the oxidation of sulfuric acid under a glow discharge in 0.4 M H_2SO_4 under a nitrogen atmosphere, at a pressure of 50 Torr and a discharge current of 57 mA. The authors observed the formation of the same products; however, according to their data, hydrogen peroxide was produced in the highest yield, whereas the yield of peroxydisulfuric acid was very low. The total yield of oxidation products, which was assumed equal to the sum of yields of hydrogen peroxide and peroxydisulfuric acid was found as well as individual yields of each product mentioned. Figure 2 shows the dependence of the overall concentration of oxidation products on the quantity of electricity passed.

The following reactions that lead to the formation of oxidation products were considered:⁴⁸

Figure 2. Dependence of the overall concentration (C) of sulfuric acid oxidation products ($H_2SO_5 + H_2O_2$) under a glow discharge on the quantity of electricity (Q) passed.

Using the values of rate constants $k_1 \approx 8 \times 10^5$, $k_2 = 1 \times 10^{10}$, $k_3 = 3.2 \times 10^{10}$ litre mol⁻¹ s⁻¹ and assuming that the thickness of the active layer at the cathodic spot was ~ 1 nm, the authors assessed the rate (R_i) of generation of radicals and their concentrations to be $R_i = 261$ mol litre⁻¹ s⁻¹, $[HO^\bullet] = 8.17 \times 10^{-5}$, $[H^\bullet] = 6 \times 10^{-5}$ mol litre⁻¹ (the latter quantity pertains to the primary reaction zone with a thickness of ~ 400 nm).

Oxidation of potassium iodide solutions was also studied.⁴⁰ The effect of a glow discharge on acidic and neutral KI solutions in hydrogen atmosphere was explored. Solutions were prepared from 0.4 M H_2SO_4 and a neutral phosphate buffer (0.1 M $Na_2HPO_4 + 0.1$ M KH_2PO_4). The formation of molecular iodine and hydrogen peroxide was expected. Hydrogen peroxide complicated the analysis because it could react both during the discharge and after its quenching. To solve this problem, 1 ml of 20% ammonium molybdate solution was added to the cell as the catalyst of the hydrogen peroxide reaction with iodide ions. Under these conditions, I_2 was expected to become the only product of this process. Figure 3 shows the measured total yields of oxidation products. In contrast to other cases [oxidation of bivalent iron, potassium hexacyanoferrate(II), *etc.*], the dependences of the yield of oxidation products passed through the maximum rather than tended to a limit.

Oxidation of potassium iodide subjected to a gliding arc discharge was studied.⁴⁴ For a discharge power of 1 kW dissipated in 50 ml of solution, the steady-state concentration of oxidation products was attained in ~ 1 h.

Spectrophotometric studies^{29, 49–51} were devoted to the oxidation of iodide ions under a glow discharge. The changes in the absorption of a neutral potassium iodide solution subjected to a stationary discharge were studied at a wavelength of 460 nm for different starting concentrations. During the plasma treatment, the optical density of the solution passed through a maximum the height and position of which strongly depended on the starting concentration of iodide ions. The initial segments of optical density curves were almost linear. The curves' segments at greater times described the optical density to descend by approximately the exponential law.

Figure 3. Dependences (a) of the overall concentration of KI oxidation products under the action of a glow discharge on the quantity of electricity passed through the solution and (b) of the initial current efficiency on the KI concentration in solution. Hydrogen atmosphere (50 Torr), current 75 mA.
(1) Acidic medium, (2) alkaline medium.

Table 5 shows the characteristics of gas-discharge-initiated oxidation of iodide ions calculated from experimental results.

Due to a high rate of the transformation of molecular iodine to triiodide ions,⁵² the initial segments of absorption curves measured at moderate starting concentrations of iodide ions directly illustrated the accumulation of triiodide ions. This conclusion was confirmed by the absorption spectra of KI

Table 5. Oxidation rates (v) of iodide ions and current yields (G_0) of the oxidation product (stationary glow discharge, discharge current 6 mA).²⁹

$10^3 C_0(KI) / \text{mol litre}^{-1}$	$10^7 v / \text{mol litre}^{-1} \text{ s}^{-1}$	$G_0 / \text{mol F}^{-1}$
0.9	1.57	0.45
1.8	0.63	0.18
3.6	1.38	0.4
7.23	9.8	2.88
15	3.4	0.96

solutions treated in plasma. At short treatment times, merely the absorption of triiodide ions was observed, which monotonically increased with an increase in the exposure time. Experiments at low starting concentrations of iodide ions showed that the optical density of solutions descended for the greater doses of treatment, *i.e.*, the formation of polyiodide ions was merely the first stage of oxidation. Qualitative chemical analysis of solutions thus treated indicated the formation of iodates.

Studies of the effect of plasma formed in a stationary glow discharge and a gliding arc discharge on aqueous solutions of sodium sulfide have shown²⁹ that plasma-initiated oxidation of sulfide ions proceeds *via* sulfur and polysulfide ions to ultimately afford sulfites and sulfates. These conclusions were drawn based on spectral measurements and the qualitative chemical analysis of treated solutions.

3. Reduction of inorganic compounds

Plasma-initiated reduction reactions in solutions were far less studied as compared with oxidation reactions. Early studies by Klemenc^{3,4} provided the most systematic data. The precipitation of metal or metal oxide from salt solutions and the reduction of certain acids (HClO_3 , HBrO_3 , HClO_4 , HNO_3 , *etc.*) were investigated.³

The reduction of potassium chlorate in a neutral solution yielded chloride ions. The reduction of KBrO_3 proceeded quite efficiently even in neutral solutions (like the reduction of chlorates in acidic solutions). Chromic acid was reduced almost completely to a chromium(III) salt. Perchloric acid failed to be reduced in the conventional electrolysis. A glow discharge initiated its reduction with the conversion degree dependent on the concentration. Table 6 compares the reduction processes that occur in the classical electrolysis and with the plasma activation.

The studies⁴ of the reduction of perchloric and chloric acids and their salts have revealed the following specific features.

1. The discharge-induced reduction of perchloric and chloric acids and their salts can occur with either anode or cathode located in the gas phase.

2. The reduction of perchloric acid in the region of the cathodic potential drop (when the anode is located in the gas

Table 6. Features of reduction under conditions of classical electrolysis and glow discharge.³

Electrolyte	Classical electrolysis	Glow discharge ^a	Notes
KNO_3	the products are NH_3 and NH_2OH	the products are HNO_2 , NO and N_2O	alkaline solution
$\text{Fe}_2(\text{SO}_4)_3$	easily reduced	reduced insignificantly	sulfuric acid solution
KClO_3	no or insignificant reduction on a Cu–Pt electrode, substantial reduction on a Fe electrode	reduction (12%)	neutral solution
KBrO_3	readily reduced on a Pt electrode	reduction (90%)	acidic solution
H_2CrO_4	reduction to $\text{Cr}_2(\text{CrO}_4)_3$	reduction (90%)	neutral or acidic solution
HClO_4	no reduction	reduction (88%)	—
		stepwise reduction (up to 40%)	Cu or Pt electrode

^a In parentheses, the yield of reduction products is shown.

Table 7. Reduction of perchloric and chloric acids and their salts under conditions of classical electrolysis in a glow discharge.⁴

Electrolyte	Classical electrolysis	Reduction in a glow discharge (%)	
		cathode in the gas phase	anode in the gas phase
HClO ₃ , 1 M	insignificant reduction on a Pt electrode	500	2600
HClO ₄ , 1 M	is not reduced on a Cu–Pt electrode	20	200
KClO ₃ , 0.26 M	insignificant reduction on conventional electrodes	90	500
NaClO ₄ , 0.5 M	is not reduced on a Pt electrode	insignificant reduction	60
	insignificant reduction on a Ni–Fe electrode	the same	no noticeable reduction

phase) demonstrates the strongest (40-fold in 2.5 M solution) increase in the yield of products over the faradaic yields.

3. The reduction of perchloric acid corresponds to its decomposition to HCl and O₂.

4. Side reactions that produce detonating gas occur at a rate, which is the higher the slower the corresponding reduction reaction in the electrolyte.

5. The ratio of current efficiencies observed in the anodic and cathodic compartments is the same for the oxidation of sulfuric acid solutions and the reduction of perchloric acid.

Table 7 compares the reduction processes that occur in the classical electrolysis with the corresponding plasma-electrolytic reactions.

The reduction of inorganic ions under the action of a stationary glow discharge at atmospheric pressure was studied^{53,54} (the discharge current was 10 mA, the solution volume was 400 ml). The following processes were observed:

4. Gas evolution processes

In 'classical' electrolysis of aqueous electrolyte solutions, the evolution of main gaseous products (oxygen and hydrogen) is associated with the electrode processes of the discharge of hydroxyl and hydronium ions. The situation changes crucially when the electrode represents the plasma in contact with a solution. Ions accelerated in the region of the potential drop at the solution surface initiate dissociation of solvent molecules. This gives rise to many effects including the evolution of gaseous products, which does not obey the Faraday law. At the same time, ions that came to solution from the plasma zone and underwent thermalisation can either be solvated or recombine with solution counter-ions, which ultimately affords gaseous products in yields corresponding to the Faraday law. Hence, the analysis of the gas evolution in the course of the plasma treatment of solutions might shed light on the behaviour of ions injected into the solution from the plasma zone and answer the question on the role of their solvation.

It was noted⁵ that, if exclude the secondary effects, the gas evolution was never observed in the cathodic spot region on the solution surface. This makes the bulk recombination of ions injected into the plasma zone quite unlikely.

It was shown⁷ that in addition to the faradaic ('polar', according to the authors of Ref. 7) gas evolution, the electrolysis in a glow discharge always produces the detonating gas. The cathodic spot is the source of active species that lead to the formation of the latter gas. The amount of evolved detonating gas can be many times increased if one surrounds the cathodic spot with a narrow glass cylinder. The effect manifests itself to the full extent only if the cylinder is completely immersed into the electrolyte. Based on these experiments, it was concluded⁵ that the 'non-polar' formation of detonating gas occurs only as a result of a heterogeneous process.

The formation of oxygen and hydrogen in the anodic and cathodic discharges was studied.¹² A solution of 0.05 M K₂SO₄ served as the electrolyte. Figure 4 shows the dependences of the oxygen and hydrogen yields on the quantity of electricity passed through the solution and the potential drop in the discharge gap for a 'positive' contact discharge. As seen from the Figure, the processes that do not obey the Faraday law make the main contribution to the formation of gaseous products. In a 'negative' contact discharge, the yields of oxygen (1.84 mol F⁻¹) and hydrogen (2.73 mol F⁻¹) also substantially exceeded their faradaic yields.

Figure 4. Dependences of (1) oxygen and (2) hydrogen yields on the quantity of electricity passed under the action of a glow discharge on a K₂SO₄ solution; (3) and (4) corresponding 'faradaic' yields.

5. Oxidation processes initiated by a glow discharge in solutions of organic compounds

a. Oxidation of alcohols

The effect of a glow discharge on a methanol solution was studied.³⁸ In the cathodic glow discharge, the main products were formaldehyde and formic acid. The anodic discharge produced fomadehyde and insignificant amounts (~1% of the HCOH yield) of formic acid, ethylene glycol and dimethoxy-methane. No hydrogen peroxide formation was observed. In both cathodic and anodic discharges, hydrogen, methane and carbon monoxide were the main gaseous products. Trace amounts of ethane, ethylene and acetylene were detected.

The medium becomes acidic under the action of a 'positive' discharge and alkaline when subjected to a 'negative' discharge.

The effect of a glow discharge on the ethanol solution was considered in the same publication. Oxygen and argon at a pressure of 100 Torr served as the working gas. The main

reaction products included acetaldehyde, hydrogen peroxide and butane-2,3-diol. Their yields strongly depended on the presence of oxygen in this system and the intensity of its flow. The other key factors were the gas pressure, the intensity of stirring, the discharge current and the quantity of electricity passed. The hydrogen peroxide yield increased with an increase in the oxygen flow rate. The following mechanism of the processes was put forward. In the absence of oxygen and at a sufficient concentration of ethanol, the main initial reaction was the capture of hydroxyl radicals by ethanol molecules. The reactions of hydrogen atoms and solvated electrons proceeded more slowly. The reaction of H^\bullet and HO^\bullet radicals with ethanol is sufficiently well studied. A HO^\bullet radical abstracts a hydrogen atom from an ethanol molecule to form the following products: $\text{CH}_3\text{CH}_2\text{O}^\bullet$ (2.5%), $\text{CH}_3\text{CHOH}^\bullet$ (84.3%), $\text{CH}_2\text{CH}_2\text{OH}^\bullet$ (13.2%). The rate of the reaction of hydrogen atoms with ethanol molecules was lower by approximately two orders of magnitude. The main process was the elimination of a hydrogen atom from the CH_2 group to afford molecular hydrogen and a $\text{CH}_3\text{CHOH}^\bullet$ radical. In turn, radicals $\text{CH}_3\text{CH}_2\text{O}^\bullet$ and $\text{CH}_2\text{CH}_2\text{OH}^\bullet$ abstracted a hydrogen atom from an ethanol molecule. In the second case, this led to the conversion of the HO^\bullet radical into the 1-hydroxyethyl radical.

The action of a glow discharge on a water–ethanol solution of a neutral phosphate buffer under the argon atmosphere produced hydrogen peroxide, butanediol and acetaldehyde.³⁸

The following solvated electron reactions were considered:

The hydroperoxyl radical HO_2^\bullet played an important role in the discussed processes.

Thus, the presence of oxygen in the system gives rise to two additional channels for the formation of hydrogen peroxide. One channel is associated with the intermediate formation of organic peroxy radicals and the second corresponds to the formation of hydroperoxyl radicals.

Bugaenko *et al.*^{21,55} studied the conversion of 0.1–3 M solutions of methanol and ethanol in a carbonate electrolyte under the action of microdischarges on an aluminium anode. Table 8 shows the main reaction products and their energy yields. The products of ethanol conversion were formed both within gas-vapour bubbles and in the near-surface liquid layer (the yield of the latter amounted to no more than 20% of the total yield).

The results shown above allow one to qualitatively compare the effects of a glow discharge (at reduced pressure) and anodic microdischarges on methanol and ethanol solutions. The reaction products for both PSS types by and large coincided. However, it should be mentioned that the reaction

Table 8. Energy yields of reaction products of 2 M ethanol and 2 M methanol in a 0.03 M solution of sodium carbonate under the action of microdischarges on an aluminium anode (voltage 500 V, current 90 mA, error of yield determination < 10%).^{21,55}

Product	Yield /number of molecules per 100 eV	
	ethanol solution	methanol solution
H_2	1.90	2.60
CO	0.72	1.30
CH_4	0.29	0.27
C_2H_6	0.17	—
C_2H_4	0.40	—
$\text{C}_2\text{H}_6 + \text{C}_2\text{H}_4$	—	0.11
C_3H_8	0.056	0.0086
$\text{C}_2\text{H}_2 + \text{C}_3\text{H}_6$	0.19	0.010
C_4H_{10}	0.13	—
CH_3OH	0.030	—
$\text{CH}_3\text{CH}(\text{OH})\text{CH}_2\text{OH}$	0.015	—
$\text{CH}_3\text{CH}(\text{OH})\text{CH}(\text{OH})\text{CH}_3$	0.015	—
CH_2O	0.041	0.28
$(\text{CH}_2\text{O})_2$	—	0.098
HCOOH	—	0.058
CH_3CHO	0.260	—
CH_3COOH	0.050	—
H_2O_2	0	0

Note. The consumption of ethanol and methanol (calculated from the yields of products) was 1.83 and 2.38 molecules per 100 eV of energy, respectively.

products formed under the action of a glow discharge on a methanolic solution of LiClO_4 included dimethoxymethane, which was absent when methanol in aqueous sodium carbonate solutions was subjected to anodic microdischarges. The quantitative comparison of yields of products in these PSS is complicated by the fact that the yields are expressed in different units, namely, per 100 eV of consumed energy (anodic microdischarges) and in mol F^{-1} (glow discharge). However, bearing in mind that the authors of these studies^{21,55} assessed the average energy of ions that have passed to the solution from the anodic microdischarge zone as 100 eV, it can be assumed that the yield per 100 eV coincides with the yields expressed as the number of moles per Faraday of electricity. This allows one to compare certain values found for the glow discharge and anodic microdischarges (Table 9).

Table 9. Yields of products (mol F^{-1}) under the action of a glow discharge³⁸ and anodic microdischarges^{21,55} on an aqueous ethanolic solution.

[$\text{C}_2\text{H}_5\text{OH}$] /mol litre ⁻¹	CH_3CHO			Butane-2,3-diol	
	glow dis- charge in O_2	glow dis- charge in Ar	anodic micro- discharge	glow dis- charge in Ar	anodic microdis- charges
0.01	0.18	0.25	—	0.05	—
0.1	2.39	1.83	0.024	0.90	0.0007
0.3	6.47	4.67	0.043	1.14	0.0015
0.9	6.44	4.56	—	1.20	—
1.0	—	—	0.14	—	0.078

The difference between the yields obviously exceeds the possible errors and may point to a difference in the mechanisms of processes in these PSS.

b. Oxidation of aromatic compounds under pulsed discharges

Since the early 1990s, in line with the solution of environmental problems, keen attention has been paid to the oxidation of aromatic compounds in aqueous solutions under the action of either pulsed discharges in liquids or pulsed discharges between a metal electrode located in the gas phase and the solution surface.^{55–69} These studies preferentially dealt with phenol and its derivatives. In the phenol oxidation generated by pulsed discharges, pyrocatechol, hydroquinone, *p*-benzoquinone and (in small amounts) resorcinol were detected as the primary products.^{60, 68} Figure 5 shows the kinetics of decomposition of phenol and accumulation of its primary destruction products. Presumably, the first stage of this process is the hydroxyl radical reaction with a phenol molecule, which results in either the addition of HO• to the benzene ring to afford a dihydroxycyclohexadienyl radical or the elimination of a hydrogen atom from the OH group to form a phenoxyl radical. The radical reactions produced the intermediates listed above. Subsequent stages involved the benzene ring opening to form acyclic products

and also oxalic and formic acids, acetaldehyde and formaldehyde. Figure 6 illustrates the kinetics of accumulation of formic acid in aqueous phenol subjected to a corona discharge.⁶⁰

The oxidation of phenol in aqueous solutions under anodic microdischarges was described.^{22, 70} For relatively low initial phenol concentrations ($\sim 10^{-5}$ – 10^{-2} mol litre⁻¹), its concentration was found to decrease in time according to the exponential law; however, for high initial concentrations, two characteristic kinetic regions were observed, namely, the initial fast and the subsequent slow regions. Presumably, the deceleration of the oxidative destruction of phenol observed in its concentrated solutions was associated with the accumulation of stable intermediates and their competition with phenol molecules for HO• radicals.

Figure 5. Kinetics of oxidation of phenol and accumulation of its primary destruction products: (1) phenol, (2) pyrocatechol, (3) hydroquinone, (4) *p*-benzoquinone.

c. Oxidation of organic dyes in aqueous solutions

The corona-discharge generated oxidation of Methylene Blue and Malachite Green dyes in aqueous solutions was studied⁷¹

Figure 6. Kinetics of formic acid accumulation under the action of a pulsed corona discharge on an aqueous phenol solution: (1) in argon, (2) in air.⁶⁰

(the solution volume was 100 ml, the starting concentrations of dyes was 6 mg litre⁻¹, the discharge current was varied from 40 to 150 μ A). The kinetics of this process was monitored by following variation of the light absorption by the dissolved dye. The results strongly depended on stirring and the distance between the electrode and the solution surface. Chloride ions inhibited this process. Presumably, ozone, oxygen atoms, HO• radicals and hydroxyl ions were the active species that initiated the dye oxidation. After the treatment, the solution ceased to absorb light at 200–900 nm.

The oxidation of an aqueous solution of Monochlorotriazine Blue (or Bright Blue) dye (MCTB) under glow or gliding arc discharges was considered.^{72, 73} In all experiments, the dye was decolourised (Fig. 7). However, the initial period of this process could be different for different discharge currents and types. Thus when the times of MCTB exposure did not exceed 2–3 min, the absorption could uniformly decrease over the whole visible spectrum range; however, the process could lead to a decrease in the absorption in the vicinity of the maximum (~ 600 nm) and its simultaneous increase in the vicinity of the

Figure 7. Changes in the absorption spectrum of a solution of Chlorotriazine Blue under a gliding arc discharge. Exposure time (min): (1) 0, (2) 2, (3) 4, (4) 6, (5) 8, (6) 10, (7) 12.5, (8) 15, (9) 17.5.

absorption minimum (~ 450 nm). For long-term exposure, the absorption at 450 nm passed through a maximum and the absorption in the near UV range increased. The changes in the absorption spectrum of the dye could be observed for several hours after the cessation of the plasma treatment.

Based on the results of spectrophotometric measurements, kinetic curves that reflect the changes in the dye concentration were plotted. In doing so, it was assumed that oxidative destruction products of a dye do not absorb in the long-wave region. Figure 8 shows the examples of kinetic curves.

Figure 8. Kinetics of destruction of Monochlorotriazine Blue under a glow discharge with the plasma zone of different length (mm): (1) 1.34, (2) 2.3, (3) 3.8.

Experimental kinetic curves were interpreted within the framework of a simple model that assumes the plasma-initiated formation of an oxidant and its one-stage reaction with the dye, which is of the first order with respect to the oxidant. The rate of oxidant formation (ω_o) is constant within the framework of this model. The accumulation of oxidant after switching on the discharge is determined by ω_o and the oxidant lifetime (τ_o). The model gives the following expression for the time dependence of the relative dye concentration (C/C_0):

$$\ln \frac{C}{C_0} = -\left(\frac{k\omega_o\tau_o}{2}\right)t^2 - (k\omega_o\tau_o^2)(e^{-t/\tau_o} - 1),$$

where k is the effective rate constant for oxidation.

Figure 8 shows the dependence of the dye oxidation rate on the distance between the anode and the solution surface. An increase in the discharge current results in the substantial acceleration of the dye destruction (Fig. 9). Extrapolation to the zero inter-electrode distance gives the reaction rate for the solution activation by exclusively the ions accelerated in the region of the near-surface potential drop and injected into the liquid phase. The increase in the reaction rate with the increase in the plasma column height points to the possibility of initiation of the reaction by neutral active species generated in the gas phase.

The effect of the pre-treatment of a MCTB solution with a corona discharge on the rate of the MCTB oxidation under a stationary glow discharge was studied.²⁹ For the treatment

Figure 9. Initial destruction rate of Monochlorotriazine Blue during the plasma treatment vs. discharge current (the rate was assessed from the changes in the optical density of solution).

time of no longer than 30 min, the decolouration of the solution under the direct action of a corona discharge with a current of 50–100 μ A was hardly visible. At the same time, the subsequent oxidation of the dye under the action of a glow discharge sharply accelerated.

The oxidation of Methylene Blue in aqueous solutions under the action of glow and diaphragm discharges was considered^{74,75} (the current was varied in a range of 20–50 mA). The kinetics of dye destruction was studied using a spectrophotometric technique in wavelength ranges of 220–350 and 450–750 nm ($\lambda_{\max} = 667$ nm) with periodic sampling of the solution.

Discharges of both types favoured a decrease in the optical density of solutions in the visible spectrum of the dye. In an acidic medium ($\text{pH} < 4$), the increase in the discharge current led to the acceleration of dye destruction. It should be noted that for all other factors equal, the decolouration was faster at the diaphragm discharge. The absorption spectra in the region of 450–750 nm remained virtually unchanged, being identical for both discharge types. At the same time, the changes in the UV spectrum substantially depended on the discharge type. The increase in the optical density of solutions with the increase in the time of their exposure to plasma was one order of magnitude greater for the glow discharge (for equal exposure times and similar discharge currents and pH values). This fact can be interpreted as a result of the deeper oxidative destruction of the dye under the action of a diaphragm discharge. Presumably, these results point to the difference in the mechanisms of processes initiated by glow and diaphragm discharges. This was assumed to be due to the effect of a shock wave that appears during the burning of a diaphragm discharge.

In the same publications, the post-effect, which was observed in solutions treated with a discharge was discussed. The studies were carried out by several methods.

1. Dye solutions ($\text{pH } 3$) were exposed to the plasma of the glow and diaphragm discharges at a current of 50 mA for 2, 5 and 10 min, then samples were taken and the time variations of the absorption spectra in the absence of plasma treatment were studied.

2. Electrolyte solutions ($\text{H}_2\text{O} + \text{H}_2\text{SO}_4 + \text{Na}_2\text{SO}_4$) with $\text{pH } 3$ were exposed to discharges of both types for 2, 5 and 10 min; immediately a dye was added up to a concentration of

0.01 g litre⁻¹. Then, solution samples were taken and their absorption spectra were analysed in certain time intervals.

3. Experiments were carried out as described above (point 2), but the dye was added in 20 min rather than immediately.

The deviations in the effects of glow and diaphragm discharges also showed up in the post-effect characteristics. Under the same conditions, the diaphragm discharge produced a stronger effect (Fig. 10). Upon the cessation of the discharge, the dye concentration decreased to the same level for both the direct plasma treatment of dye solutions and when the dye was added to the electrolyte pre-activated by a discharge. At the same time, the kinetics of the post-effect strongly depended on the experimental conditions, *e.g.*, on the illumination (Fig. 11).

Figure 10. Changes in the optical density of a Methylene Blue solution upon its exposure to plasma (discharge current 50 mA, pH ~ 3, $\lambda_{\text{max}} = 667$ nm): (1) glow discharge, exposure time 5 min; (2, 3, 4) diaphragm discharge (exposure times 2, 5 and 10 min, respectively).

Figure 11. Changes in the optical density of a plasma-pre-activated Methylene Blue solution.

(1) Glow discharge: exposure time 10 min, the solution was kept in the dark; (2–5) diaphragm discharge: exposure time 10 min (2) in the dark and (3) in the light; exposure time 5 min (4) in the dark and (5) in the light.

To explain the results obtained, it was assumed that, in principle, the exposure of solutions to gas discharges can give rise to three different effects, namely, solution activation, solute activation and changes in the solution structure. Among these effects, only the solution activation is sufficiently well studied. Insofar as the differences between the glow and diaphragm discharges were observed both at their direct action on dye solutions and as the post-effect in preliminary treated dye solutions and also as the changes in the destruction rate of a dye added to electrolyte solutions (pre-treated with a discharge in the absence of the dye), the role of direct activation of the solute can hardly be great. At the same time, the post-effect could not be caused by short-lived primary active species; and, moreover, the addition of hydrogen peroxide to a dye solution, which was not pre-treated with a discharge, did not lead to results resembling the post effect. Thus, the reason for the long-term and strong post-effect should be sought in the effect of the discharge on the solution structure, which can cause changes in both thermodynamic and kinetic characteristics of processes that occur in solutions. This effect can be stronger in the presence of a shock wave at the diaphragm discharge.

d. Syntheses of organic compounds initiated by a gas discharge in electrolyte solutions

Harada and co-workers^{76, 77} studied the asparagine formation under the action of a glow discharge on a solution containing a mixture of amino acids (glycine, alanine and β -alanine) with amides of simple carboxylic acids.

Denaro and Hough⁷⁸ studied the acrylamide polymerisation initiated by a glow discharge between the air-located metal anode and an aqueous solution of the monomer. They have found the dependences of the polymer yield and its average molecular mass on the quantity of electricity passed, the acrylamide concentration and the air pressure. The results obtained were explained within the framework of a simple kinetic model. Two reaction zones were singled out. The first zone represented a thin near-surface solution layer in the vicinity of the cathodic spot. No polymerisation was observed in this zone. The concentration of radicals in this zone was very high; hence, their recombination prevailed. Only ~0.2% of radicals reached the second zone with a volume of ~0.4 cm³. Here, the radicals initiated the chain polymerisation reaction. The polymer yield increased virtually linearly with the increase in both the quantity of passed electricity and the acrylamide concentration. The average molecular mass also increased linearly with the increase in the monomer concentration. Under the conditions of the experiment described, the polymer yield reached 15 mol F⁻¹. With the increase in the air pressure, these characteristics decreased. Moreover, the efficiency of this process also decreased in the alkaline medium.

V. Potentials and prospects of plasma initiation of industrial processes in aqueous solutions

The surface modification of polymeric materials including fabrics with natural and synthetic fibres (pre-treatment of fabrics before printing, dyeing, *etc.*), bleaching (especially of linen), delignification of wood, *etc.* may be assigned to the heterogeneous processes presumably initiated by the plasma – solution treatment. At present, this field remains virtually unexplored.

1. Plasma modification of starch glue. Treatment of microcrystalline cellulose

The modification of starch by different reagents is one of the methods used in practice for the preparation of starch and its products with desired properties. The treatment of starch with oxidants, for example, sodium or potassium hypochlorites, is most popular. Hydrogen peroxide, potassium permanganate

in alkaline media, chloramine T, *etc.* are also used. The diverse goals of starch modification, the long time required when traditional methods are used and the environmental problems associated with the use of such reagents as hypochlorites send the scientists in search for alternative methods of modification. The effect of the glow-discharge plasma treatment on the properties of starch glue was studied.^{79,80} The glue viscosity was considered as the criterion of its modification degree. The viscosity was observed to increase in the initial period of treatment. The decrease in the viscosity at long-term treatment pointed to the predomination of destruction processes. Note that it takes a short time to reach the maximum viscosity even for discharges with quite moderate power densities.

The use of atmospheric-pressure plasma in processing of cellulose-containing materials attracts attention because cellulose is one of the basic raw materials used in the pharmaceutical, textile and food industries. The surface modification of cellulose by the gas-discharge activation can change its reactivity.

The effect of gas-discharge activation on the electrokinetic properties of aqueous suspensions of cellulose powder (electrophoresis mobility of cellulose particles) was considered.⁸¹ Glow and diaphragm discharges served as the sources of activation. A 0.04% solution of cellulose powder with colloid particles <63 µm in diameter was studied. The required solution conductivity was achieved by adding sodium chloride (10^{-3} mol litre⁻¹). The acidity of the dispersed medium was controlled by the addition of sodium hydroxide or hydrochloric acid. The studies of the electrophoretic mobility of processed cellulose have shown that the isoelectric point is at pH 2.5 and the maximum electrophoretic mobility is reached at pH 6.5. The exposure (20 min) of the dispersed system studied to the discharge led to the increase in the electrophoretic mobility of cellulose particles as compared with the reference untreated solution; moreover, the greatest effect was observed for the glow discharge. The latter effect can be associated with the fact that a diaphragm discharge not only generates reactive species but also gives rise to a shock wave in the solution.

2. Destruction of aqueous emulsions of hydrocarbons in anodic microdischarges

Under the action of an anodic microdischarge (aluminium cathode) on a pentadecane emulsion in a carbonate electrolyte, the alkane is destroyed to form hydrogen, carbon monoxide, gaseous hydrocarbons and an insoluble product, namely, a polycondensate that gives rise to the formation of spherical hollows filled with gas.^{82–85}

It was assumed that the primary process is the reaction between pentadecane and a hydroxyl radical, which consists of the elimination of a hydrogen atom from the alkane. A secondary aliphatic radical formed can either dimerise to afford a branched product or add an oxygen molecule. In turn, the peroxide radical gives rise to various secondary products, namely, alcohols, ketones, acids, hydroperoxides. The appearance of spherical particles points to the formation of a three-dimensional network; hence, dimeric products are subjected to the secondary attack of HO• radicals and decomposition products of hydroperoxides or react with fragment radicals formed in gas – vapour bubbles (GVB).

The energy yields of gaseous hydrocarbons C₁–C₅ and CO were independent of the emulsion concentration in the liquid phase. The overall curves of accumulation of gaseous products were linear for degrees of pentadecane conversion not exceeding 50% (at higher degrees of conversion, the curves tended to a certain limit). The partial curves of accumulation of individual gases with the exception of hydrogen were linear. The sum of energy yields of gaseous products increased non-linearly with the increase in the pentadecane concentration. The destruction of pentadecane to form light hydrocarbons almost

totally proceeded within gas – vapour bubbles. Hydrogen molecules were largely formed in the pentadecane layer on the GVB surface upon the reaction of the hydrogen atoms formed in GVB with pentadecane molecules. Carbon monoxide was also formed in GVB but upon the oxidation processes.

The microdischarge treatment of an emulsion containing 0.0012 mol litre⁻¹ of pentadecane and 0.005 mol litre⁻¹ of styrene resulted in the destruction of both pentadecane and styrene in energy yields of 0.16 and 0.50 molecules, respectively, per 100 eV of consumed energy, which was close to their yields in emulsions containing only individual components.⁸⁶

3. Plasma treatment of cellulose-containing and other phytogetic materials in aqueous media. Refining of textile materials

In addition to the search for new kinds and sources of raw materials, the development of fundamentally new methods for processing of traditional raw materials is of great importance. The processing of wood and resulting cellulose (including microcrystalline cellulose) forms the basis of many industrial processes (in pulp and paper industry, manufacturing of synthetic fibres, *etc.*).

Traditional processing of wood into cellulose, which involves mechanical grinding of wood, removal of lignine, (*e.g.*, by sulfite-alkaline digestion), bleaching, washing and drying, is an energy-consuming process accompanied by the formation of vast amounts of toxic sewage.

Thus, the plasma – solution activation of the listed processes in the stationary (or quasi-stationary) plasma or pulsed-discharge plasma in the liquid phase attracts attention. In these two cases, the chemical activation conditions are different; moreover, pulsed discharges give rise to a shock wave, *i.e.*, lead to the mechanochemical activation.

The studies of the effect of pulsed discharges in aqueous media on raw plant materials date back to the 1970s. Thus it was shown⁸⁶ that the processing of winter wheat straw in water and weak alkaline solutions leads to the partial destruction of the lignocarbon complex in straw and can form the basis of an industrial process of straw treatment for feeding livestock. It was proposed⁸⁷ to use high-voltage pulsed discharges in aqueous media for washing and degreasing wool. It was shown⁸⁸ that the electrohydraulic treatment of chlorella improves the digestibility of nitrogen-containing substances, while the similar processing of pine needles⁸⁹ makes it possible to produce a vitamin – protein concentrate. The action of pulsed discharges in water on kitchen herbs (parsley, dill) leads to the formation of a protein – lipid complex, a precursor of the vitamin – protein paste.⁹⁰ It was found⁹¹ that the electrohydraulic treatment of aqueous solutions of saccharose and glucose results in their hydrolysis, where a part of molecules decompose to afford formaldehyde. The possibility of using pulsed discharges at different stages of the wet treatment processes in industry, including textile production, was studied.⁹² A method for production of fibres from stems of fibre crops in which the wetting procedure was combined with high-voltage discharges at a voltage of 30–50 kV has been developed.⁹³

Detailed studies of the pulsed-discharge treatment of plant raw materials in aqueous media were carried out later.^{94,95} Wheat straw (coarse chopped, 3–10 mm) was subjected to pulsed discharges in water and the aqueous solutions of NH₄OH (0.5%–5%) and hydrogen peroxide (1%–5%). A stainless-steel reactor served as the cathode, a cylindrical anode was placed at the reactor axis above the solution surface. A power source allowed application of voltage pulses of 20–35 kV at a frequency of 0.1–0.5 Hz, period of 4–5 µs and energy of 120–2500 J. The treatment involved series of 100–1000 pulses. Both liquid and solid phases of the system formed upon the action of pulses were analysed. Table 10

Table 10. Liquid phase characteristics (in % of the original straw mass) after 100 discharge pulses as a function of single-discharge energy.⁹⁴

Determined characteristics	Discharge energy /J				
	120	240	540	960	2500
Extractive substances	0.04	0.09	0.55	0.13	0.58
Lignine	0.32	0.27	0.25	0.42	0.6
Polysaccharides	0.05	0.06	0.07	0.08	0.04
Colloidal suspension	1.1	1.2	1.0	1.5	1.5
Ash content	0.33	0.51	0.56	0.69	1.0

shows the results of the analysis of the liquid phase after 100 pulses with different energies.

Under the electrohydraulic impact, wheat straw is effectively chopped and its lignine–carbon complex is destroyed. The solid residue is freed from nitrogen-containing (proteins and their products) and silicon-containing compounds that enter into the ash composition. The short-term destruction of the lignine–carbon complex is the characteristic feature of the electrohydraulic treatment of plant biomass. The deeper destruction of the lignine–carbon complex was observed in the processing of wheat straw in NH_4OH and H_2O_2 solutions; although, due to the high conductivity of these solutions, a part of energy was consumed in the pre-breakdown stage, which affected the effectiveness of the electrohydraulic impact.

Similar processes occurred in alkaline aqueous suspensions of hydrolytic lignine, which were subjected to high-voltage pulsed discharges.⁹⁵ Lignine was dispersed and freed from mineral and organic low-molecule substances. However, gummy and lignohumic compounds were not removed. The gummy substances were washed out in alkalis, which was considerably accelerated under the simultaneous treatment with electric pulses.

All aforementioned studies devoted to the use of pulsed discharges failed to separate the contributions of chemical process and mechanochemical activation.

The effect of the solution activation in a glow discharge on the surface properties of cellulose-containing materials placed in solutions and also on the extraction of lignine was studied.^{29,96} Linen and roving fabrics were studied as well as wood in the form of sawdust. The process was carried out in aqueous NaOH at constant stirring, either without the gas flow or with oxygen bubbling through the solution. A 'positive' stationary glow discharge was used. It was found that the plasma–solution treatment allows one to increase the capilarity of fabrics; moreover, the effect strongly depended on the solution pH and might not correlate with the lignine destruction.

To check the selectivity of the effect of an activated solution on the cellulose-containing materials, the products obtained in the treatment of delignified cellulose and wood-extracted lignine, which have passed to solution, were analysed separately. The effect was followed by the analysis of absorption spectra of treated solution samples. Figure 12 shows the results obtained in an alkaline solution after the treatment of cellulose (with and without plasma activation) and lignine. According to these data, a plasma-activated aqueous solution that contains no specially added oxidants exerts a selective effect on the cellulose-containing materials.

The presence of such selectivity allows one to assume the possibility of using the mentioned method in the bleaching of fabrics. The samples of linen fabric were treated in the plasma-activated solution in the absence of specially added oxidants. The absorption spectra of the solution and the scattering spectra of the fabrics were studied simultaneously. The results obtained confirmed that the effect of fabric bleaching is present

**Figure 12.** Absorption spectra of solutions of (1) lignine and (2) cellulose upon treatment in a glow discharge (NaOH solution with concentration 1 g litre⁻¹, discharge current 20 mA, exposure time 20 min) and (3) spectrum of a solution of cellulose unexposed to plasma.

and the products accumulated in solution substantially affect this process.

The use of a volume discharge described quite recently in the treatment of cellulose-containing materials in the plasma–solution system was discussed.⁹⁷ Presumably, to achieve the greatest effect in the modification of polymeric materials, it is necessary to develop a PSS in which the reactions in the activated solution would occur simultaneously with the direct effect of plasma on the material modified. The discharge was ignited in a tube of silicon rubber that connected two stainless-steel vessels, which served as the electrodes; the circulation of solution was performed using a peristaltic pump. Linen roving of four-fold milling and purified cellulose were studied. The average degree of polymerisation, the lignine content and the moisture absorption were measured for the case of linen roving. In the case of cellulose, the measured characteristics included the degree of polymerisation and the contents of α -cellulose and the aldehyde and carboxyl groups. The treatment time was 10 min.

The treatment of linen roving in a PSS with a discharge in the electrolyte volume (NaOH) resulted in a greater decrease in the lignine content as compared with the conventional thermal

Table 11. Properties of linen roving treated in a plasma–solution system (volume discharge).⁹⁷

Sample	C_{NaOH} /g litre ⁻¹	Lignine content ^a (%)		Degree of poly- merisation	Moisture absorp- tion (%)

treatment in alkali with a longer exposure time. The plasma–solution treatment in the volume discharge sharply reduced the degree of polymerisation; however, the moisture absorption changed insignificantly (Table 11). Table 12 shows the data obtained in the studies of cellulose.

4. The use of plasma–solution systems in cleaning and sterilisation of water, aqueous solutions and articles

The use of plasma discharges in aqueous media for their sterilisation and also for the sterilisation of articles was extensively studied since the beginning of the 1970s.^{98–106}

High-voltage electropulsed discharges can be considered as an environmentally clean source of UV radiation the short-wave spectrum of which is not ‘cut off’ by glass walls as in the case of UV lamps. Under the action of reactive species formed in water, decomposition of amino acids and proteins, depolymerisation of nucleic acids and destruction of other biologically active substances take place. Moreover, a pulsed discharge generates intense acoustic waves capable of tearing apart bacterial cells thus destroying them. The disinfecting effect persists for a long time after the cessation of the discharge treatment (days, weeks and longer) due to the effect of the microorganism decomposition products obtained in the active phase of the process. According to the data of Ref. 106, the pronounced antibacterial effect was observed at a discharge energy of $(0.6–0.8) \times 10^2$ J. In the same study, quantitative estimates of energy consumed in the water disinfection were obtained. The calculated relationships were derived under the assumption that the main effect is associated with the shock wave impact and that the destruction of simplest unicellular microorganisms requires an acceleration of 100–1000 *g*. The pressure in the compression wave front was assessed by the semi-empiric relationship

$$P = 0.6 \times 10^{-5} E_0^{0.6} \tau^{-0.8} r^{-1},$$

where P is the pressure (mPa), E_0 is the discharge energy (J), τ is the time of energy generation (s), r is the distance from the discharge centre to the measurement point (m).

If ρ_0 and a_0 are the density of the liquid and the sound velocity in it, then the liquid acceleration in the wave is

$$W = \frac{2P}{\rho_0 a_0 \tau}.$$

Hence, for the relative acceleration K_p , we obtain the following expression:

$$K_p = \frac{2P}{g \rho_0 a_0 \tau} = 0.8 \times 10^{-5} \frac{2E_0^{0.6}}{g r \rho_0 a_0 \tau^{1.8}}.$$

The volume of water cleaned is assessed from the distance at which the acceleration of the liquid in a wave is not lower than a given critical value.

The disinfecting efficiency of an atmospheric-pressure glow discharge that burned over the water surface in a flow-through system was assessed.¹⁰⁷ The concentration of hydrogen peroxide formed under the discharge (the discharge current was 200 mA, the output voltage reached 5 kV) was taken as the criterion of water decontamination efficiency. For a discharge gap of 10 mm and the power of ~ 90 W, the maximum accumulation of hydrogen peroxide was observed, namely, 3.6 g m⁻³ (1×10^{-4} mol litre⁻¹) at the minimum energy consumed in its formation (~ 250 kW h kg⁻¹). The fact that the maximum H₂O₂ concentration was achieved under these conditions was attributed to the maximum area of the cathodic spot. The hydrogen peroxide concentration decreased with an increase in the water consumption, whereas the efficiency with respect to H₂O₂ increased. This was explained by the fact that a part of hydrogen peroxide synthesised in the discharge was destroyed by the discharge itself. As a result, at the higher water consumption, the larger amount of H₂O₂ was brought out from the discharge zone without destruction. The overall content of hydrogen peroxide also depended on the electrode erosion products, which often catalyse H₂O₂ decomposition.

Sterilisation of conducting solutions and objects immersed in them under a glow discharge or a low-voltage diaphragm discharge (alternating current) was studied.^{33, 108, 109} The inhibiting effect of the atmospheric-pressure glow and diaphragm discharges on asporogenic microorganisms *Escherichia coli* M-17 was discussed. Microbiological studies of strains of the culture tested revealed that totally sterile solutions were obtained in 1–20 min depending on the exposure time, the type and intensity of discharge, the nature of the object sterilised and the nature and concentration of the bacterial culture. (Table 13).

Table 13. Results of gas-discharge sterilisation of solutions containing microorganisms *Escherichia coli* M-17 (see ^a).¹⁰⁹

Composition of the medium ^b		Treatment time ^d /min

^a Discharge parameters. Glow discharge: current 50 mA, voltage 1500 V; diaphragm discharge: current 50 mA, voltage 500 V; ^b Composition of the medium: (I) aqueous NaOH solution (1.5 g litre⁻¹) and nitrilotrimethylphosphonic acid; (II) physiological solution of NaCl (2 g litre⁻¹); ^c C is relative concentration of microorganisms (number of colonies in 1 ml of solution); ^d treatment time necessary for a decrease in the density of colonies (DDC), for observation of rare individual formations (RIF), for reaching the effect of complete sterility (ECS).

VI. Conclusion

Plasma–solution systems in which an electrolyte solution plays the role of one or both gas-discharge electrodes represent non-equilibrium systems where the chemical activation predominantly proceeds in a thin near-surface solution layer and is substantially determined by the parameters of the gas discharge and related processes on the plasma–solution interface. The combination of the chemical activity of plasma with the possibility of carrying out selective processes in solutions allows one to use plasma–solution systems in cleaning of water and aqueous solutions from organic and inorganic impurities, sterilisation of solutions and objects immersed in them and also in the modification of surface properties of natural and synthetic polymeric materials.

The physical chemistry and physics of PSS were studied far less comprehensively than the corresponding properties of the classical reduced and atmospheric pressure plasma in contact with solid objects. The most important trends in the physico-chemical studies of PSS are associated with the kinetics of generation of reactive species in both the solution surface layer and the adjacent plasma layer and also with the reactions of these species depending on the type of initiating gas discharge and the properties of the solution. It is the processes at the plasma–solution interface that are the governing factor.

Abstract. The main types of post-metallocene catalysts for olefin polymerisation based on bis(imino), bis(imino)pyridyl, bis(phenoxyimino), bis(pyrrolylimino) and other complexes of transition metals developed in the last 10–15 years and having prospects for practical use are considered. Modern views on the mechanism of action of these catalysts are discussed. The bibliography includes 375 references.

I. Introduction

During the last 30 years the main attention of scientists studying catalytic olefin polymerisation has been attracted to the catalysts based on metallocene complexes of Group 4 elements in combination with activators, namely, Lewis acids [methylaluminoxane (MAO), fluoroarylboron derivatives and some others],^{1–11} which have replaced the Ziegler–Natta catalysts. The cationic nature of the active sites (an activator should form a non-coordinating anion) and the correlation between the ligand structure and the structure of polymer are typical of metallocene-based catalytic systems. Such properties of metallocene systems as high catalytic activity, narrow range of molecular masses of the obtained polyolefins, the ability of catalysing co-polymerisation of ethylene with higher α -olefins, the possibility of controlling the catalytic properties by variation of ligand structure, have stimulated their broad industrial production in the 1990s,^{12, 13} which was even called a ‘metallocene revolution’.^{11, 14} However, at present the scope of industrial applications of metallocene systems is smaller than it was predicted. This is a result of some disadvantages of such systems, namely, significant consumption of expensive activators increasing the cost of products and the oxophilicity of Group 4 metals, which makes them unsuitable for the synthesis of co-polymers with functionalised olefins. Obviously, catalysts of other classes are required in order to increase the

variety of polyolefins. This has inspired the search for more effective and inexpensive catalysts. Moreover, in view of the higher resistance of complexes of the so-called ‘late’ transition metals (Ni, Pd, Co) to heteroatomic fragments compared to that of complexes of ‘early’ transition metals (Ti, Zr, V), one could hope for the development of catalysts that would be active in co-polymerisation of ethylene and olefins with polar functional groups.^{14, 15}

Thus as early as the first half of the 1990s the interest in the synthesis of a new type of homogeneous one-centred catalysts of polymerisation, *viz.* of a non-metallocene (or, according to the chronology, post-metallocene), catalysts increased. During this period, a significant attention was paid to complexes of Group 4 metals with one cyclopentadienyl ligand and other ligands containing donor heteroatoms. An important event in the development of post-metallocene systems was the synthesis of nickel(II) bis(imine) complexes capable of catalysing ethylene polymerisation.¹⁶ Later, systems based on nickel complexes and not requiring an activator have been found.¹⁷ At the end of the 1990s, iron bis(imino)pyridyl complexes highly active in ethylene polymerisation were discovered.^{18, 19} In addition, it was found that not only MAO but also trialkylaluminium derivatives may be used as activators.^{20–22} This substantially simplified and decreased the cost of a catalytic system.

In recent years, significant interest has arisen in titanium and zirconium bis(phenoxyimine) complexes²³ and titanium bis(pyrrolylimino) complexes.²⁴ These compounds are able to catalyse the so-called ‘living’ polymerisation of olefins²⁵ and produce polymers with narrow molecular mass distribution (the ratio M_w/M_n is around 1.1) and high molecular masses.

In order to convert post-metallocene catalysts to an active form (as for metallocene catalysts), co-catalysts are required. These co-catalysts are Lewis acids, which produce cationic active centres with a high olefin affinity. Immobilisation of active catalytic systems on a solid support is of a great practical importance, as it facilitates the system handling, simplifies the catalyst composition (as the support itself may work as an activator; both a catalyst and an activator may be deposited on the same support), increases the resistance of the system against adverse external effects (*e.g.*, heating and oxidation) and also improves the morphology of the product.

To date, a series of reviews,^{14, 15, 26} books^{27, 28} and generalising reports^{23, 24} on the non-metallocene olefin polymerisa-

K P Bryliakov G K Boreskov Institute of Catalysis, Siberian Branch of the Russian Academy of Sciences, prosp. Acad. Lavrentieva 5, 630090 Novosibirsk, Russian Federation. Fax (7-383) 330 80 56, tel. (7-383) 330 68 77, e-mail: bryliako@catalysis.ru

tion catalysts have been published. However, these papers were written before 2003 and usually discuss only one particular type of catalytic systems and reflect the contribution of only one research group. The author of the present review has aimed at following the development of studies of post-metallocene catalytic systems of olefin polymerisation during the recent years. The attention is focused on the most scientifically and industrially important systems. To this end, it appeared expedient to abandon the traditional systematisation of the post-metallocene complexes according to the metal position in the Periodic Table^{15,26} and classify them according to the type of ligand, because catalysts based on different metals with several main types of ligands are known. The order of discussion of the ligands in the present review mainly corresponds to the chronology of their appearance in the literature.

It should be noted that some caution is needed when comparing the properties of catalysts reported by different authors, because no universal procedure of catalyst testing exists and the experimental data are affected by particular reaction conditions, such as the reactor configuration, stirring speed, the method of activation, *etc.* Quite often the authors do not report the kinetics of polymerisation (or even the lifetime of a catalyst), but provide, for example, the data about the activity of a catalyst during the first 1–5 min of the reaction, which may create an inadequate idea of the catalytic properties of a complex in the case of its rapid deactivation. A slightly modified scale suggested by Gibson and co-workers²⁶ is used here for the activity classification: very low, low, medium (moderate) and high, which correspond to the following values < 1, 1–10, 10–100, 100–1000 and higher in terms of (kg of polymer) (1 mol of catalyst)^{–1} h^{–1} bar^{–1} units (or in the abbreviated form, kg mol^{–1} h^{–1} bar^{–1}), respectively.

II. Monocyclopentadienyl complexes

Up to the mid-1990s, most papers on the catalytic olefin polymerisation dealt with metallocene (**1**), including *ansa*-metallocene (**2**), and monocyclopentadienyl catalysts, particularly with ‘half-titanocenes’ (**3**) and the so-called ‘constrained geometry’ complexes (**4**).^{1–11}

M = Ti, Zr, Hf; X = Cl, Alk; R = Alk.

To date, the processes that take place upon the activation of metallocene complexes with alkylaluminium chlorides,^{29–31} methylaluminoxane^{32–41} and the trialkylaluminum–tetrakis(pentafluorophenyl)borate system,^{42–45} have been studied in detail. The cationic complexes that are the precursors of active intermediates have been detected and identified by NMR spectroscopy. The genuine intermediates, *i.e.*, the complexes in which the central atom is coordinated by the growing polymeric chain, were also detected.^{33,36,46}

Naturally, the initial attempts of the search for new catalysts were aimed at the synthesis of non-metallocene complexes of Group 4 metals. Monocyclopentadienyl complexes of titanium and zirconium and of some other metals with additional donor atoms are discussed in this Section. Generally, the monocyclopentadienyl complexes are less active in olefin polymerisation than their bis(cyclopentadienyl) ana-

logues, but more active in ethylene co-polymerisation with α -olefins. The incorporation of additional donor atoms into catalysts often adds new important properties, for example, high thermal stability (as in the case of complexes **4** with constrained geometry) and high polymerisation activity.

1. Complexes of Group 4 metals with one cyclopentadienyl ligand and an additional ligand containing a donor atom

As noted above, titanium(IV) and zirconium(IV) monocyclopentadienyl complexes **3** are less active in olefin polymerisation than their bis(cyclopentadienyl) analogues.^{47–49} Complexes **4** and **5** (R = H, X = Cl) with the activity of about 2500 kg mol^{–1} h^{–1} bar^{–1} (Ref. 50) were obtained by introduction of an additional ligand containing a donor atom (for example, N). However, such complexes are highly sensitive to traces of oxygen which deteriorates the process.⁵¹ Another possible modification is introduction of a non-coordinating substituent into the cyclopentadienyl ring (complex **6**).⁵² Interestingly, complex **6** (X = Cl, *n* = 0) is able to catalyse highly selective ethylene trimerisation when activated by MAO.⁵³ The role of pendant phenyl ring in this process is discussed comprehensively in a review.⁵⁴

The monocyclopentadienyl systems in which an additional ligand containing a donor atom is covalently bonded to the metal have also become popular. Such catalysts (*e.g.*, complex **4**) are applied in industry due to their high thermal stability and ability to initiate co-polymerisation.^{55,56} The catalytic properties of the complexes may be controlled by introducing substituents (including heteroatoms) into the cyclopentadienyl ring. Thus the application of fluorenyl complex **7** in the co-polymerisation of ethylene with higher α -olefins yields ethylene co-polymers with cycloolefins^{57–65} and also with oct-1-ene (the octene content > 70 mol %, Ref. 61).

Several attempts at changing the nature of the bridging and the donor atom were described. For instance, linear high-molecular-mass polyethylene (PE) was obtained by using complex **8**,⁶⁵ while complex **9** and its titanium analogue catalyse the co-polymerisation of ethylene with octene.⁶⁶ The presence of a bulky aromatic substituent in complex **10** facilitates the polymerisation of propylene with a relatively high degree of isotacticity (*[mmmm]* = 56%).⁶⁷ Complex **11** containing the C-donor bridge C₂B₁₀H₁₀ is able to initiate the ϵ -caprolactone polymerisation besides being a catalyst of ethylene polymerisation.⁶⁸ The activity of complexes with ligands similar to phosphinimide (**12**)⁶⁹ and guanidinate (**13**)⁷⁰ is > 1000 (kg PE) mol^{–1} h^{–1} bar^{–1}.

The aryloxy complexes **14**^{71,72} and **15**⁷³ should be mentioned; in the latter complex, the aryloxy group is linked to the cyclopentadienyl ligand. The complexes of type **14** are highly active in ethylene polymerisation [>2000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ for M = Ti and >4000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ for M = Zr], while the activity of complex **15** is somewhat lower. Complexes **14** and **15** are also able to catalyse propylene and styrene polymerisation.

M = Ti, Zr; R¹ = Alk; R² = H, Alk.

2. Complexes of Group 4 metals with one cyclopentadienyl ligand and an additional ligand containing several donor atoms

Among derivatives of Group 4 metals with one cyclopentadienyl ligand, complexes **16** proposed by Bergman and co-workers⁴⁹ should be noted. The zirconium complex with a tropidinyl fragment, isoelectronic to cyclopentadienyl, is highly active in ethylene polymerisation in the presence of MAO (comparable with the activity of Cp₂ZrCl₂, Cp = η⁵-C₅H₅); the corresponding titanium complex is less active.⁴⁹

Nakazawa *et al.*⁷⁴ have described complex **17** with a tris(pyrazolyl)borate ligand, which is active in ethylene polymerisation. The complexes LZrCl₃ and LTiCl₃ with additional bulkier mesityl-substituted tris(pyrazolyl)borate ligands L are slightly more active in ethylene polymerisation; they are able to catalyse the co-polymerisation of ethylene with hex-1-ene.^{75,76} In the presence of an activator B(C₆F₅)₃, complex **17** yields high-molecular-mass polyethylene [$M_w = (4-6) \times 10^5$]. Moderately active catalysts **18** can be activated by both MAO (X is a halogen)⁷⁷ and perfluoroarylborate compounds

(X = Me).⁷⁸ Structurally similar complexes **19** (R = Alk, Ar) are able to catalyse living polymerisation of hex-1-ene with [PhMe₂NH][B(C₆F₅)₄] as an activator.⁷⁹

Among other monocyclopentadienyl complexes of Group 4 metals, compounds **20–22**^{80–82} with alkoxy and aryloxy ligands deserve attention. They exhibit moderate activity in ethylene polymerisation.

3. Monocyclopentadienyl complexes of other metals with additional ligands containing donor atoms

Group 5 metals in the formal oxidation state +4 and +5 form monocyclopentadienyl complexes that are active in ethylene polymerisation (it should be noted that the metal oxidation state may change during activation of the catalyst¹⁵). Thus complex **23** (Y = Me)⁸³ is slightly active [27 (kg PE) mol⁻¹ h⁻¹ bar⁻¹] when activated by MAO; the fast deactivation of the catalyst is caused by the formation of inactive dinuclear vanadium complexes.⁸⁴ Immobilisation of the active centres of complex **23** on polystyrene (Y is polystyrene) increases the lifetime of the active species which results in the production of high-molecular-mass polyethylene ($M_w = 1.9 \times 10^6$) when activated by diethylaluminium chloride.⁸⁵ Among vanadium(IV) derivatives, complex **24**, isostructural to the 'constrained geometry' catalysts based on Group 4 metals should be noted. This complex is less active in ethylene polymerisation than its titanium analogue.⁸⁶

Chromium(III) complex **25** is almost catalytically inactive in ethylene polymerisation⁸⁷ and is able to catalyse only oligomerisation or isomerisation of higher α-olefins, while complex **26** is relatively active [8300 (kg PE) mol⁻¹ h⁻¹ bar⁻¹] when activated by MAO.⁸⁸ Structurally similar complex **27** is even more active in these reactions.⁸⁹ Compounds **28** are able to catalyse the polymerisation of ethylene⁹⁰ and propylene⁹¹ (to give atactic polypropylene).

Complexes with phosphine ligands **29**,^{92,93} which provide ethylene conversion into oligomers and low-molecular-mass polyethylene upon activation by methylaluminoxane, and complex **30**,⁹⁴ which ensures the formation of linear saturated hydrocarbons due to the chain transfer from MAO to aluminium are also known. Complex **31** with an additional pyridyl ligand is active in ethylene polymerisation [up to 1000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹, Ref. 95]. In general, chromium cyclopentadienyl complexes containing an additional ligand with a donor atom exhibit significant polymerisation activity.^{96,97}

The monocyclopentadienyl complexes of late transition metals should also be noted. Thus complexes **32** show low activity in living ethylene polymerisation ($M_w/M_n = 1.1-1.2$).⁹⁸ The polymerisation activity of complexes **33** and **34**⁹⁹ is several orders of magnitude lower than the activity of their chromium analogues.⁹⁹ Branched polyethylene (up to 10 branches per 1000 carbon atoms) was obtained when complex **35** with a sulfide donor fragment was used,¹⁰⁰ and the application of nickel complex **36** with monoindenyl and phosphine ligands yielded high-molecular-mass polyethylene [the activity of the complex was up to 130 (kg PE) mol⁻¹ h⁻¹ bar⁻¹].¹⁰¹

III. Complexes of late transition metals

The catalysts briefly discussed in Section II are generally not used in industry (except for the constrained geometry catalysts of type **4**). The discovery of nickel and palladium bis(imino) complexes **37** and their analogues by Brookhart and co-workers¹⁶ has become an important event in the search for new catalysts of polymerisation. The complexes with bis(imino) ligands are widely used due to the specific properties of ligands, namely, their ability to effectively stabilise organometallic compounds, relatively high steric hindrance and the possibility of fine tuning of their electronic and steric properties by introduction of substituents into the aryl rings. A number of such complexes were found to be active in polymerisation of ethylene, linear α -olefins, styrene, norbornene, and in co-polymerisation of ethylene with higher olefins and polar co-monomers.

The complexes that do not require activation (the transformation into cationic form) were developed. The main types of nickel and palladium bis(imino) and other complexes are discussed below as well as the development of the views on the mechanism of polymer chain growth and the effect of ligand structure on the catalytic properties.

1. Nickel and palladium bis(imino) complexes

The first studies of nickel and palladium bis(imino) complexes were published by Brookhart.^{16, 102-105} The simplest way of their synthesis is the reaction of a ligand with a metal derivative, for example, (DME)NiBr₂, (COD)PdMeCl (DME is 1,2-dimethoxyethane, COD is cycloocta-1,5-diene) and others.¹⁴

Active centres in these complexes are formed upon alkylation and then activation by transformation into a cationic form. Both boron derivatives {NaBAF, H(Et₂O)₂BAF, BAF = [B(3,5-(CF₃)₂C₆H₃)₄]⁻} and MAO may be used as activators. Nickel(II) complexes **37** are highly active [up to 11 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹] in ethylene polymerisation.¹⁶ β -Elimination of a hydrogen atom with subsequent secondary 2,1-addition (see below) results in the formation of branched polymers with up to 70 and more branches per 1000 carbon atoms. Polyethylene with molecular mass of up to 10⁶ may be obtained by varying the temperature and pressure as well as the structure of the ligand. The polymerisation of α -olefins at low temperatures (-10°C) follows a living mechanism (the polypropylene obtained had $M_n = 1.6 \times 10^5$ and

$M_w/M_n = 1.13$), which allows one to produce di- and tri-block co-polymers.^{104, 106} The living polymerisation of a series of α -olefins (from but-1-ene to oct-1-ene) with catalysts **38** ($R^1 = \text{H}$, $R^2 = \text{C}^*\text{HMePh}$, $R^3 = \text{Me}$) was observed in the temperature range from -30 to -40 °C by Coates and co-workers.¹⁰⁶ Besides, the syndiotactic polypropylene may be obtained at low temperature.¹⁰⁷

Palladium(II) complexes **37** are usually less active and produce highly branched amorphous polyethylene with up to 100 branches per 1000 carbon atoms.^{16, 108, 109} Palladium complexes are able to catalyse co-polymerisation of ethylene with α -olefins and with functionalised co-monomers (methyl acrylate, methyl vinyl ketone).^{102, 103} Thus the incorporation of up to 25% of co-monomer was achieved in co-polymerisation of ethylene with methyl acrylate. The activity of such catalysts in co-polymerisation of ethylene with α -olefins is substantially lower than that in homopolymerisation; the introduction of a co-monomer sharply reduces the polymer molecular mass and narrows its molecular mass distribution. The suggested mechanism of co-polymerisation of ethylene with methyl acrylate includes 2,1-insertion of co-monomer with the formation of an intermediate cyclic adduct followed by the insertion of ethylene molecule.¹⁰³

Note that palladium bis(imino) complexes are also active in the living polymerisation. For example, polyethylene with polydispersity of 1.05 was obtained by Gottfried and Brookhart in polymerisation of ethylene at 5 °C in the presence of palladium(II) bis(imino) complex **37** ($R^1 = 2,6\text{-Pr}_2$; $R^2 = \text{X} = \text{Me}$; $\text{Y} = \text{Cl}$) activated by NaBAF.¹¹⁰

The ability of nickel(II) and palladium(II) bis(imino) complexes to catalyse the formation of branched polymers is unique: the topology of the resulting polymers varies from

linear with a small number of branches up to the hyper-branched one (in the latter case, oils are formed). A migratory insertion mechanism of the ethylene polymerisation into branched polyethylene (Scheme 1) was suggested on the basis of low-temperature ^1H NMR studies.^{16, 111} A key feature of the mechanism is that the main form of the catalyst is alkyl-ethylene complex **39**. Note that for early transition metals such intermediates have never been observed. The limiting step of the reaction is the addition of ethylene to complex **39**; therefore, the rate of the chain growth is of zero order with respect to ethylene. The energy barrier to ethylene insertion is 17–18 kcal mol⁻¹ for $\text{M} = \text{Pd}$ ^{16, 112} and 13.5–14 kcal mol⁻¹ for $\text{M} = \text{Ni}$.¹¹² This explains the difference between the observed activities of the polymerisation catalysts. The β -elimination of a hydrogen atom leading to the formation of alkenyl hydride complex may follow the ethylene insertion. The repeated 2,1-addition of coordinated olefin may take place in the coordination sphere of this complex resulting in branching of the polymer chain.

The effect of conditions of the process on the activity of the catalyst and the properties of the polymers formed was studied.^{113–121} Various aspects of the mechanism of polymerisation were discussed in a number of theoretical studies (see for example, Refs 122–129).

In all of the previously discussed schemes, MAO, ionic tetrakis(aryl)borate derivatives or alkylaluminium chlorides were used as activators. If $\text{B}(\text{C}_6\text{F}_5)_3$ is used, the activity of the ethylene polymerisation catalyst is significantly lower.¹³⁰ Nevertheless, $\text{B}(\text{C}_6\text{F}_5)_3$ was used in co-polymerisation of ethylene with acrylates in the presence of nickel bis(imino) complexes,^{131, 132} and the achieved degrees of co-monomer incorporation were higher than those in the presence of palladium complexes.

The substituents in the aromatic rings greatly affect the catalytic properties of bis(imino) complexes: the shielding of a vacant coordination position of the central atom due to an increase in the bulk of the *ortho*-substituents decreases the catalytic activity; at the same time, the chain propagation rate decreases and, as a consequence, the molecular mass of the polymer increases. The size of the *ortho*-substituent does not affect the number of short-chain branches very much; however, this number rapidly increases with temperature. Oligomeric products are obtained in the presence of complexes with one *ortho*-substituent.^{14–16, 26, 133} Complexes **37** containing aliphatic substituents in the aromatic rings are able to function at temperatures up to 50 °C, but at higher temperatures, their activities significantly decrease. Ivanchev and co-workers have shown^{133–136} that the incorporation of bulky *o*-cycloalkyl substituents into 1,2-bis(arylimino)acenaphthyl complexes **38**

slightly increases the thermal stability of the catalysts. Other nickel and palladium complexes (such as **40–42**)^{137–139} and different bis(imino) ligands (for example **43–45**)^{16,28} are also in use.

X are electron-withdrawing substituents

44: $R^1 = R^2 = \text{Alk}$, $R^3 = \text{H}$;
45: $R^1 = \text{Alk}$, $R^2 - R^3 = 1,4\text{-benzo}$.

The nickel and palladium bis(imino) complexes are applied in the production of polymers by the so-called in-reactor blending methods. In essence, most of these methods consist of the introduction of a composite catalyst containing a metallocene complex of earlier transition metal in combination with a complex of later transition metal, into the reactor.^{135, 140–143} The resulting polymeric product possesses an extended molecular mass distribution, which facilitates its processing.

The bis(imino) complexes are catalytically active in polymerisation of cycloolefins and in co-polymerisation of linear olefins with cycloolefins. Thus complexes **38** catalyse polymerisation of cyclopentene in the presence of ethylaluminium chloride.¹⁴⁴ In co-polymerisation of ethylene with norbornene, nickel bis(imino) complexes are inactive. At the same time, palladium complexes **37** are able to catalyse this process. Depending on the structure of the ligand, the molecular mass of the resulting co-polymers of ethylene with norbornene was up to 8×10^5 (and higher) and the degree of incorporation of norbornene was as high as 90%.¹⁴⁵

2. Miscellaneous nickel and palladium N,X-donor chelate complexes

A series of complexes with other *N,N*-chelate ligands (**46–51**) deserve attention. It should be noted that efficient olefin polymerisation requires sterically hindered ligands; otherwise, β -elimination with subsequent dissociation of the coordinated olefin will result in the predominant formation of higher α -olefins.¹⁴⁶ Complexes **46** with various (alkyl, aryl and other, including polar) substituents in the pyridine and benzene rings of the ligand are less active in ethylene polymerisation than bis(imino) complexes and produce polymers with lower molecular masses.^{147–153} Complexes **47–49** in the presence of

various co-catalysts [MAO, modified methylaluminoxane (MMAO), $\text{Al}_2\text{Et}_3\text{Cl}_3$] produce mainly α -alkenes.^{144, 146, 154, 155} Ethylene oligomerisation proceeds slowly in the presence of complex **50** without a neutral co-catalyst.¹⁵⁶ Complex **51** is active in the polymerisation and oligomerisation of hex-1-ene.¹⁵⁷ The catalysts with this type of ligand are described in patents; the corresponding references can be found in a review.¹⁴ Various types of post-metallocene catalysts immobilised on polymeric supports have been discussed.¹⁵⁸

$R^1 = \text{Alk}$, Ar etc.;
 $R^2 = \text{Alk}$, Ar .

$R = \text{Alk}$.

$R^1 = R^2 = R^3 = \text{H}$,
 Alk ; $X = \text{Cl}$, Br

$R = \text{H}$, Alk .

Complexes with *N,P*-chelating ligands **52–54** have been reported.^{159–161} Among the variety of catalysts, compounds with bis(imino), *N,N*-chelate (see above) and *N,O*-chelate ligands, which will be discussed later, turned out to be most active.

3. Nickel salicylaldimine and other N,O-chelate complexes

In 1998, Grubbs and co-workers¹⁶² have prepared catalysts based on nickel salicylaldimine complexes **55** with bulky substituents. Ethylene polymerisation has been performed in the presence of two equivalents of a co-catalyst [$\text{Ni}(\text{COD})_2$ or $\text{B}(\text{C}_6\text{F}_5)_3$]. The productivity of the catalyst (13.3–253 kg PE per 1 mol of catalyst in 40 min under ethylene pressure from 7 to 14 atm) and the molecular mass of the polymer ($M_w = 4 \times 10^3 - 3.6 \times 10^4$) strongly depended on the substitu-

ent. The number of branches in the obtained polyethylene samples varied from 5 (for $R^1 = \text{Ph}$, $X = \text{H}$) to 55 per 1000 carbon atoms (for $R^1 = \text{Bu}^t$, $X = \text{H}$). The molecular mass distribution fluctuated from 1.4 to 12.4. Theoretical studies have shown that elimination of the donor group PPh_3 from complex **55** takes place in the initial step of the process.¹⁶³ Catalysts **56** (R^1 is anthracenyl, $R^2 = \text{Ph}$) turned out to be more active: their productivity was up to 6400 (kg PE) $\text{mol}^{-1} \text{h}^{-1}$ under the pressure of 17 atm.¹⁷ Triphenylphosphine as well as acetonitrile may be used as the ligand L.

$R^1 = \text{H, Alk, Ar, CHO, NO}_2$;
 $R^2 = \text{H, Pr}^i$;
 $X = \text{H, OMe, NO}_2, \text{Cl}$;

$R^1 = 9\text{-anthracenyl}$;
 $R^2 = \text{Ph, Me}$;
 $L = \text{PPh}_3, \text{MeCN}$.

Some of the discussed catalysts are able to function without a co-catalyst (the testing was continued for 1–2 h).^{17, 164} The following catalytic cycle of polymerisation with nickel salicylaldimine complexes has been suggested on the basis of ^{31}P NMR studies.

Data on dinuclear complex **57** which exhibits similar catalytic properties, have been published recently.¹⁶⁵ Catalysts of this type are quite resistant to the effect of polar functional groups; this makes it possible to obtain co-polymers of ethylene with substituted norbornenes and α,ω -functionalised olefins^{17, 166, 167} and also to perform polymerisation in polar and protic solvents.^{168, 169} However, the co-polymerisation of olefins with vinyl-functionalised co-monomers turned out to be impossible due to the catalyst deactivation.¹⁷⁰ Nevertheless, Li

$R^1 = \text{Ph, CF}_3$;
 $R^2 = \text{Me, CF}_3$.

*et al.*¹⁷¹ have managed to perform homo- and co-polymerisation of ethylene with methyl metacrylate (the incorporation of co-monomer was up to 16.7%) on catalyst **58** and MMAO as a co-catalyst. The co-polymerisation of ethylene with methyl metacrylate on nickel catalysts activated by $\text{Ni}(\text{COD})_2$ and then by methylaluminoxane has been discussed.¹⁷² It was shown¹⁷³ that complexes containing a vinyl substituent in the aromatic ring are transformed into 'self-immobilised' catalysts **59** during ethylene polymerisation.

$X = \text{H, NO}_2, \text{Me}$; $R^1 = \text{H, Bu}^t, \text{Ph, NO}_2$; $R^2 = \text{Me, Pr}^i$.

Hicks and Brookhart¹⁷⁴ have reported nickel anilinetropolone complex **60**, which does not require a co-catalyst in olefin polymerisation. This complex produces polyethylene with molecular mass $M_n = 1 \times 10^5 - 3 \times 10^5$, a rather narrow molecular mass distribution ($M_w/M_n = 1.7 - 2.0$) and the number of branches ranging from 8 to 100 per 1000 carbon atoms. Later, it was shown that the polymerisation has a migratory mechanism (see Scheme 1), the predominant state of the catalyst being the complex $\text{LNiR}(\text{C}_2\text{H}_4)$ (L is the anilinetropolone ligand, R is the polymeric chain); the activation parameters of separate stages of the process were also evaluated.¹⁷⁵

The effect of reaction conditions on ethylene polymerisation in the presence of dinitro-substituted nickel catalysts **55** ($R^1 = X = \text{NO}_2$, $R^2 = \text{H, Pr}^i$) and methylaluminoxane has been studied.¹⁷⁶ A linear polyethylene of high molecular mass has been obtained and the activity of the catalyst was as high as 200 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$. A tenfold increase in the activity of the catalytic system was achieved by varying the content of trimethylaluminium in MAO.¹⁷⁷ It was shown¹⁷⁸ that complex **55** ($R^1 = \text{cyclo-C}_6\text{H}_{11}$, $R^2 = \text{H}$, $X = \text{Me}$) is able to catalyse ethylene polymerisation and its co-polymerisation with functionalised substrates (*tert*-butyl undec-10-enoates, methyl undec-10-enoates, pent-4-en-1-ol) when activated by $\text{Ni}(\text{COD})_2$. A similar catalyst ($R^1 = \text{cyclo-C}_6\text{H}_{11}$, $R^2 = \text{H}$, $X = \text{Cl}$) is active in the homo- and co-polymerisation of ethylene with esters of undecenoic acid when $\text{Ni}(\text{COD})_2$ or AlBu_3 are used as co-catalysts.¹⁷⁹ Nickel *N,O*-chelates are very convenient as they are applicable to various substrates. For instance, β -ketoiminate complexes **61** are inactive in olefin polymerisation; however they catalyse the norbornene polymerisation when activated by MAO. The activity of such system may reach 1600 (kg polynorbornene) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ with $M_w/M_n = 1.3 - 2.0$.¹⁸⁰

60

61

$R^1 = \text{Me, Ph}$; $R^2, R^3 = \text{Me, Pr}^i$.

Among other nickel *N,O*-chelates, worthy of note are complexes **62**¹⁶⁰ and **55** ($X = \text{Cl}$, $R^1 = \text{CHO}$, Ar is 1-naphthyl),¹⁸¹ which are active in ethylene oligomerisation with $\text{B}(\text{C}_6\text{F}_5)_3$ and MAO co-catalysts, respectively. The results of a systematic study of the effect of substituents in various positions of salicylaldimine ligands (complexes **63**) on the structure of the polymers obtained were reported.^{17, 162, 182–184}

Thus the introduction of bulky substituents in the *ortho*-position of aryl ligand at the nitrogen atom results in the increase in linearity and molecular mass of polyethylene. A linear polyethylene with the highest molecular mass was obtained using catalysts with bulky substituents in the *ortho*-position relative to the phenoxy group. These catalysts also possess the longest lifetimes. More branched polyethylene was obtained when a halogen atom was placed in the *ortho*-position of the aryl substituent or when primary imino group was replaced by a secondary one. The activity of these catalysts remained almost the same; however, the molecular mass of the polymer decreased. Besides, the catalytic activity of nickel salicylaldimine complexes increased when substituents such as Cl and NO_2 , were placed in the *ortho*- and *para*-positions of the phenoxy ring.

Thus, unlike polymerisation catalysts based on Group 4 metals, complexes of the late transition metals are able to catalyse not only homopolymerisation of linear olefins, but also other processes such as oligomerisation, co-polymerisation of olefins with polar co-monomers, living polymerisation, polymerisation in polar media and may produce branched polymers if the mechanism of β -elimination followed by repeated 2,1-insertion takes place. However, unlike Group 4 metal complexes, no obvious correlation between the ligand structure and the microstructure of the obtained polymers has yet been established for the late transition metal complexes.

IV. Complexes with bis(imino)pyridyl and similar ligands

In 1998 the groups of Brookhart¹⁸ and Gibson¹⁹ published independently the first studies dealing with olefin polymerisation catalysts based on iron(II) and cobalt(II) complexes **64** with bis(imino)pyridyl ligands and MAO as a co-catalyst.

$M = \text{Fe}, \text{Co}$; $R^1, R^2, R^3 = \text{H}, \text{Alk}$.

The extremely high activity of such systems [up to $11\,000\text{ (kg PE mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1})$, which is higher than the activity of Group 4 metal complexes] has attracted attention of scientists and chemical industry professionals. This type of catalysts produce linear polyethylene with wide molecular mass distribution ranging from oligomers to a high-molecular-mass polyethylene. The presence and the bulk of substituents in the phenyl rings at the imine nitrogen atoms strongly affect the activity of the catalyst and the molecular mass of the polymer. Later, it was shown that simpler and cheaper activators, particularly trialkylaluminium, may be used for these catalysts;^{20–22, 185, 186} supported catalysts were developed as well as the catalysts based on complexes of other metals (V, Cr) with bis(imino)pyridyl ligands.

1. Iron(II) bis(imino)pyridyl complexes and their analogues

Iron(II) complexes **64** catalyse ethylene polymerisation producing linear polyethylene with M_w up to 6×10^5 (Ref. 187), which usually has a broad molecular mass distribution ($M_w/M_n = 2.3–144$), including a bimodal distribution.^{26, 187} This can be explained by the suggestion that besides β -elimination,¹⁸⁸ chain transfer to aluminium may take place in this type of systems.¹⁸⁷ The following processes are possible in catalytic systems based on iron bis(imino)pyridyl complexes:

$R = \text{Me}, \text{Bu}^i$; LM^+ is the active catalyst.

The complexes containing two substituents in the *ortho*-positions of aryl rings at the nitrogen atom ($R^1 = R^3 = \text{Alk}$, $R^2 = \text{H}$) are more active than complexes with one *ortho*-substituent ($R^1 = \text{Alk}$, $R^2 = R^3 = \text{H}$), and the introduction of a *para*-substituent increased the catalyst activity and the molecular mass of the polymer to even a greater extent.^{18, 19} Meanwhile, iron bis(imino)pyridyl complexes are able to catalyse the oligomerisation of ethylene to give α -olefins with high selectivity if the aryl rings contain one small substituent in the *ortho*-position ($R^1 = \text{Me}$, $R^2 = R^3 = \text{H}$) or if the ligand is non-symmetric (*i.e.*, two different amines are used in the synthesis of the ligand).^{189–191}

Predominant formation of oligomeric products was also observed when only 3- and 4-substituents are present in the aryl fragments at the nitrogen atoms in complexes **64**.¹⁹² It was established¹⁹² that in the presence of acetylaminopyridine complexes **65**, ethylene oligomerisation proceeds with high selectivity (the content of α -alkenes is up to 82%).

The mechanism of activation of iron(II) bis(imino)pyridyl complexes is shown in Scheme 2. In order to explain the observed bimodal molecular mass distribution of the polymerisation products, Wang and co-workers²¹⁴ have suggested, on the basis of electron microscopy data, the formation of two types of catalytically active species (Scheme 3) in the activation of iron(II) bis(imino)pyridyl chloride complexes by triethylaluminium. Barabanov *et al.*^{215, 216} have made an attempt to establish the nature of active centres in such systems. They estimated the concentration of these centres and the rate constant for chain propagation with inhibition of polymerisation by the addition of ¹⁴CO. Two types of active centres were found in the system with AlEt₃. Presumably, the most active (less stable) centres are responsible for the formation of the low-molecular-mass polyethylene fraction. Similar measurements were performed for supported systems and the relative amount of active centres in the supported systems turned out to be significantly lower than that in homogeneous systems.^{199, 217}

Scheme 3

The diversity of bis(imino)pyridyl complexes is based on the variety of ligand structures. Thus the cationic complex **68** is highly active in ethylene polymerisation when activated by MAO or by the AlMe₃–B(C₆F₅)₃ system.²¹⁸ The replacement of the pyridine ring by a pyrimidine ring (complex **69**) somewhat decreases the catalyst activity.²¹⁹

The attempts to isolate complexes with ligands containing a five-membered heterocycle (compounds **70**) instead of the pyridine ring were unsuccessful.²¹⁹ The replacement of methyl groups in the ketimine fragments by bulkier substituents resulted in the formation of highly active catalysts of ethylene polymerisation **71**.²²⁰

X = N, H, O, S.

R¹, R² = H, Me, CH₂Ph.

However, *N,N'*-bis(diphenylmethyl)-2,6-bis(imino)pyridyl complexes do not react with ethylene, while *N,N'*-difluorophenyl-2,6-bis(imino)pyridyl complexes are highly active in its oligomerisation.^{193, 221} Non-symmetric iron bis(imino)pyridyl complexes exhibit high activity in ethylene polymerisation.^{193, 222} If one (or both) imine fragments are replaced by neutral amino groups (complex **72**), the observed decrease in activity is 1–2 orders of magnitude.²²³ Series of studies were performed to elucidate the influence of various substituents at the imine nitrogen atoms in iron and ruthenium bis(oxazoline)pyridine (**73**)^{224, 225} and bis(hydrazono)pyridine^{226, 227} complexes on their activities. Several attempts were made to explain the effect of substituents in aromatic rings^{228–230} and activators^{231, 232} on the behaviour of the polymerisation catalysts and also on the structure and molecular mass of the polymers.

R = H, Me.

M = Fe, Ru.

Iron bis(imino)pyridyl complexes are fairly active in propylene polymerisation.^{233, 234} Small and Brookhart²³³ have reported the activity of up to 950 (kg propylene) mol^{−1} h^{−1} bar^{−1}, the polymerisation proceeding with a high proportion of 2,1-insertion; the content of the *[mm]* diads in the resulting low-molecular-mass propylene (*M*_n ≈ 6500) was as high as 67%. These catalysts show low degree of α -olefin insertion, therefore, they are unsuitable for co-polymerisation.¹⁵

2. Cobalt(II) bis(imino)pyridyl complexes

The catalysts of olefin polymerisation based on cobalt(II) bis(imino)pyridyl complexes **64** (M = Co) were discovered simultaneously with similar iron(II) complexes.^{18, 19} Very often, the new iron and cobalt bis(imino)pyridyl ligands were studied in parallel.^{18, 19, 187, 218, 219, 226, 228–230, 235–239} Some papers describe supported iron and cobalt catalysts.^{205, 239} Interestingly, cobalt complexes with ligands containing bulky polynuclear aromatic substituents at the nitrogen atoms are relatively active in ethylene polymerisation; indeed, the activity of cobalt complex **74** was up to 673 against 950 (kg PE) mol^{−1} h^{−1} bar^{−1} for the similar iron complex when activated by MAO.²⁴⁰ The activity decreases and the polymer molecular mass increases with an increase in the bulk of the *ortho*-substituents in the phenyl rings at the nitrogen atom. The presence of both *ortho*-substituents is required in order to obtain polyethylene, while in the case of only one substituent, lower oligomers predominate among the products. Generally, the cobalt complexes are an order of magnitude less active than similar iron complexes and produce linear polymers with somewhat narrower molecular mass distribution (*M*_w/*M*_n for cobalt complexes rarely exceeds 10, while it is as high as several tens for iron complexes).

Cobalt bis(imino)pyridyl complexes are rather active in the polymerisation of vinyl ethers in the presence of MAO (iron complexes are significantly less active)²⁴¹ and in the copolymerisation of ethylene with methylcyclopropanes.²⁴² The cobalt catalysts containing electron-withdrawing substituents are extremely active in selective dimerisation and oligomerisation of α -olefins. Particularly, the selectivity of propylene dimerisation to give hex-1-ene catalysed by complex **75** is 72% and the activity of the catalyst is 19.3 (kg products) (g Co)⁻¹ h⁻¹ bar⁻¹; this catalyst is also active in ethylene polymerisation, its activity being up to 129 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ (however, only for polymerisation time of 2 min).²⁴³ This is a record value for Group 9 metals, complex **75** being the first example of a system where a cobalt complex is more active than its iron analogue. Catalysts **64** (M = Co; R¹ = Me; R² = Me, OMe) are highly active in α -olefins formation. Such complexes in combination with [*rac*-ethylene-bis(indenyl)]zirconium(IV) dichloride²⁴⁴ or with a constrained geometry complex²⁴⁵ (the reactor blending) are used in ethylene polymerisation to produce linear low-density polyethylene with ethyl, butyl and other long alkyl branches in the side chain.

Of the analogues of cobalt(II) bis(imino)pyridyl complexes, compounds **76** deserve attention: the introduction of phosphinimide fragments results in the formation of moderately active catalysts.^{246, 247} In contrast to similar nickel compounds, branched oligomeric products are formed when cobalt bis(imino) complexes **77** are used in ethylene polymerisation in the presence of MAO.²⁴⁸

R = Ph, cyclo-C₆H₁₁;
Ar = 2,6-Pr₂C₆H₃, 2,4,6-Me₃C₆H₂.

The structure of the active intermediates in cobalt-based systems has not been determined so definitely as in the case of similar iron(II) complexes. Some authors claim that cobalt(I) derivatives may be the active species.^{249, 250} The activation process suggested for systems based on cobalt bis(imino)pyridyl complexes is shown in Scheme 4. Gibson *et al.*²⁴⁹ have synthesised cobalt(I) complex **78**, a supposed precursor of the active intermediate, and have shown that after MAO activation, the same polymer is formed at the same rate as in the case of the starting cobalt(II) complex. Complex **78** itself is unable to add ethylene, it must be transformed into an active cationic form **79**.^{249, 251} According to NMR data, the observed intermediates represent ionic pairs of the types LMeCo(II)Cl-MAO or LMeCo(II)Me-MAO.²² The activation of cobalt bis(imino)pyridyl complexes by methylaluminumoxanes was also studied by electronic spectroscopy.²⁵²

Scheme 4

3. Vanadium(III) and chromium(III) complexes with bis(imino)pyridyl and other nitrogen-containing chelating ligands

Soon after the discovery of iron(II) and cobalt(II) bis(imino)pyridyl complexes, similar catalysts based on other metals were developed. Thus Gambarotta and co-workers²⁵³ have observed high activity of vanadium complex **80** in ethylene polymerisation [up to 3300 (kg PE) mol⁻¹ h⁻¹] in the presence of MAO. The resulting polymers possessed a bimodal molecular mass distribution and the value of M_w/M_n was as high as 50. Several years later, Schmidt *et al.*^{254, 255} have studied systematically the effect of substituents in aromatic rings on the activity of catalysts **81** and the properties of the products. It was found that in contrast to similar iron(II) complexes, oligomeric products are formed predominantly when vanadium complexes are used.²⁵⁵ Low-molecular-mass polyethylene was formed only if the aromatic rings contained two or more relatively bulky substituents (Et, Prⁱ). The introduction of electron-withdrawing substituents into the *ortho*- and *para*-positions of the phenyl ring sometimes increased the activity.²⁵⁵ Grassi and co-workers²⁵⁶ have reported low activity of similar complexes in the presence of MAO or Al₂Et₃Cl₃ in the processes of homo- and co-polymerisation of butadiene with ethylene. The mechanism of activation of vanadium catalysts is not yet clear. It was found²⁵³ that alkylation of the ligand takes place when the excess of MAO is added to catalyst **80**. It was suggested that it is complex **82** formed (X = Cl) that catalyses ethylene polymerisation. The activation processes of vanadium catalysts were studied by electronic spectroscopy.²⁵⁷ The results were interpreted by assuming the formation of complex **82** (X = Me) as the precursor of the active intermediate.

Ar = 2,6-Pr₂C₆H₃; X = Cl, Me.

R¹, R² = H, Alk; X, Y, Z = H, Alk, Cl, Br.

Vanadium(III) bis(imino) complexes **83** have shown low activity in ethylene polymerisation in the presence of MAO and AlEt₂Cl.²⁵⁸ On the contrary, catalyst **84** supported on modified MgCl₂ was rather active [up to 3100 (kg PE) mol⁻¹ h⁻¹ bar⁻¹]; polyethylene formed had high molecular mass and a narrow molecular mass distribution (M_w up to 7×10^5 , $M_w/M_n = 2.0-2.3$).²⁵⁹ Vanadium(III) bis(benzimidazole) complexes **85** are highly active in ethylene polymerisation in the presence of AlMe₂Cl and produce polyethylene with M_w up to 10^6 and $M_w/M_n = 2.4-3.3$.²⁶⁰

R = H, Me.

X = Y = Cl; X = OPrⁱ, Y = O.

There are very few studies on chromium(III) bis(imino)pyridyl complexes. The first publications on the synthesis of chromium(III) bis(imino)pyridyl complexes **86**²⁶¹ and on the study of their catalytic activity in ethylene polymerisation in the presence of MAO, AlBu₃ and triisobutylaluminum²⁶² appeared in 2002–2004. The resulting polymers usually possess low molecular masses (M_w up to several tens of thousands) and narrow molecular mass distribution [the ratio $M_w/M_n = 1.3-1.9$ is the lowest among bis(imino)pyridyl complexes of various metals] and the activity of the catalysts is very high [for R¹ = R² = R³ = Me, the activity was up to 25 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ in the presence of MAO and 15 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ in the presence of AlBu₃, polymerisation time 30 min]. A systematic study of the effect of substituents revealed general trends for all bis(imino)pyridyl complexes: the presence of *ortho*-substituents in the aromatic rings is required to achieve high activity and an increase in the bulk of these substituents results in a decrease in the activity and an increase in the molecular masses of the polymers.

X = Me, Ph; R¹, R², R³ = H, Alk, AlkO, CF₃.

Small *et al.*²⁶³ have studied the catalytic properties of a series of other complexes of the type **87**, including non-asymmetrical ones, mainly in the reaction of ethylene oligomerisation. It was found that at room temperature the monoimine complexes **87** (X = O) are moderately active in ethylene polymerisation ($M_w = 34 \times 10^3-103 \times 10^3$) and at higher temperatures (80–100 °C) they behave similarly to the bis(imine) complexes [produce low-molecular-mass PE, the catalyst activity being up to 14 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹].

X = O, NAr'; n = 2, 3.

Nakayama *et al.*²⁶⁴ have studied a number of chromium(III) complexes with halo-substituted bis(imino)pyridyl ligands. The activity of such complexes in the presence of MMAO ranged from moderate to high. Among the analogues of bis(imino)pyridyl complexes, compound **88** has to be noted. This complex produces a mixture of oligomeric products alongside with low-molecular-mass polyethylene.²⁶⁵ The chromium(II) and chromium(III) complexes with tris(pyridylmethyl)amine (TPA) **89** show low activity in ethylene polymerisation.^{266, 267} Complexes **90** containing a donor sulfur atom are moderately active in the presence of MMAO [72–188 (kg PE) mol⁻¹ h⁻¹ bar⁻¹] and yield relatively high-molecular-mass linear product (M_w up to 3.94×10^5).²⁶⁸

R¹, R², R³ = H, Alk.

R¹, R² = H, Me.

It should be noted that chromium and vanadium bis(imino)pyridyl complexes are not currently used for ethylene polymerisation as extensively as the iron complexes. This is attributable, first, to the fact that they were discovered later than iron and cobalt complexes and, second, to the fact that they are less active and the molecular masses of the obtained polymers are lower. The zirconium(IV), titanium(III), titanium(IV) and manganese(II) bis(imino)pyridyl complexes have also been reported;^{269, 270} however, due to their low activity, they would hardly find any industrial application.

Taking into account the above-mentioned features of bis(imino)pyridyl complexes, one may conclude that the iron(II) and chromium(III) complexes are the most active in ethylene polymerisation; the iron-based catalysts produce polyethylene with a broad molecular mass distribution ($M_w/M_n > 10$), while the chromium derivatives produce polyethylene with a narrow molecular mass distribution ($M_w/M_n < 10$, sometimes even 1.3–1.9). The cobalt(II) and vanadium(III) complexes are less active and the polymers formed usually have $M_w/M_n < 10$ and a lower molecular mass than those obtained with iron- and chromium-based catalysts. The vanadium-based catalysts mainly produce oligomeric products. The product characteristics strongly depend in all cases on the substituents in the aromatic rings at the imino-group nitrogen atoms.

V. Complexes with phenoxyimine, pyrrolylimine and similar ligands

The first catalysts of ethylene polymerisation based upon titanium(III), titanium(IV) and zirconium(IV) complexes with N,O-donor bis(hydroxyphenyloxazoline) ligands **91** were synthesised by Floriani's research group in 1995; however the activities of these catalysts were very low.^{271, 272}

(a) $\text{TiCl}_3(\text{THF})_3$, (b) $\text{TiCl}_4(\text{THF})_2$, (c) $\text{ZrCl}_4(\text{THF})_2$, (d) $\text{VCl}_3(\text{THF})_3$.

Later, at the end of the 1990s, the synthesis of new highly active catalysts of olefin polymerisation based on complexes of Group 4 metals with bis(phenoxyimine) ligands **92** was reported.^{273, 274} The activity of these catalysts was equal to or even higher (depending on the substituents) than the activity of metallocene-based systems. Some complexes were able to catalyse living polymerisation of ethylene, stereospecific polymerisation of propylene and even co-polymerisation of ethylene and α -olefins with polar co-monomers.^{23, 275} Later, highly effective bis(pyrrolylimine) catalysts **93** have been synthesised.²⁴

$\text{R} = \text{Ph}, \text{polyfluorophenyl}, 2\text{-MeC}_6\text{H}_4, 2\text{-Pr}^i\text{C}_6\text{H}_4$; $\text{M} = \text{Zr}, \text{Ti}$.

$\text{R} = \text{Alk}$.

1. Zirconium complexes with phenoxyimine ligands

The optimal structure of the ligand for complexes **94** which makes them active catalysts in ethylene polymerisation upon activation with MAO was found even in the first studies of Fujita and co-workers.^{276–278} Whereas the titanium and hafnium complexes were highly active [3300 and 6500 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ respectively], the zirconium complex has shown a unique activity of 519 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ at 25 °C and polymerisation time of 5 min. Zirconium catalyst **94** effectively maintained the activity for at least 30 min at room temperature. In the presence of MAO, the maximum activity was observed at 40 °C [587 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$]; the polyethylene obtained had $M_w = 10^4$. However, if the $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4\text{-AlBu}_3$ combination was used as an activator, the activity drastically decreased [down to 11 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ at 50 °C] and ultrahigh-molecular-mass polyethylene was obtained.²⁷⁹ The catalytic properties were strongly affected by the presence of substituents in the aromatic ring and the aniline fragment. Thus, the introduction of alkyl substituents ($\text{R}^1 = \text{Alk}$) in the *ortho*-position of the aniline ring (complex **95**) resulted in a decrease in the catalyst activity and in an increase in the polymer molecular mass in the presence of MAO.²⁸⁰

$\text{M} = \text{Ti}, \text{Zr}, \text{Hf}$.

Further development of this catalytic system involved mainly the modification of ligands. The activity was increased by selecting bulky R^2 substituents and the activity of complex **95** ($\text{R}^1 = \text{H}$, $\text{R}^2 = \text{CMe}_2\text{Ph}$, $\text{R}^3 = \text{Me}$) reached 2.1×10^6 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ (Ref. 279). The replacement of aniline by cyclohexylamine increased the activity of these catalysts even more. In the presence of MAO, complex **96** ($\text{R}^1 = \text{R}^2 = \text{Ph}$, $\text{R}^3 = \text{OMe}$) has shown the activity of 9 350 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1}$ under a pressure of 9 bar at 75 °C during 15 min of polymerisation.^{23, 280, 281} Matsui and Fujita²⁷⁹ have called these highly active catalysts 'FI Catalysts'.

Polyethylene with a relatively narrow molecular mass distribution ($M_w/M_n = 1.1\text{--}2.5$) is obtained in the presence of most zirconium bis(phenoxyimine) complexes. However, polyethylene obtained in the presence of complexes **97** possesses a trimodal distribution (each maximum has $M_w/M_n \approx 2$) and the content of the high-molecular-mass fractions may be controlled by temperature variation.²⁸² It was suggested that this effect is caused by existence of equilibrium of several coordination isomers of the catalyst.

In the presence of MAO and $\text{Ph}_3\text{C}[\text{B}(\text{C}_6\text{F}_5)_4] - \text{AlBu}_3^i$, zirconium systems are able to catalyse propylene polymerisation²⁷⁷ and also co-polymerisation of ethylene with propylene^{279, 280} (with 20%–30% of propylene content) including co-polymerisation which produces an ultrahigh-molecular-mass co-polymer ($M_w = 10.2 \times 10^6$).²⁸³ The catalytic properties of phenoxyimine catalysts and the structures of the resulting polymers have been surveyed.^{284, 285}

It was found that these catalysts may also be activated by activators other than MAO and $\text{Ph}_3\text{C}[\text{B}(\text{C}_6\text{F}_5)_4]$, for example, by AlEt_3 and a phosphomolybdenum heteropoly compound²⁸⁶ or even by trialkylaluminium derivative alone.²⁸⁷ In the latter case, the molecular masses of the products are higher and their molecular mass distribution is broader than those in the case of MAO activation, while the activity of catalysts remains approximately the same. The $\text{MgCl}_2 - \text{R}_m\text{Al}(\text{OR})_n$ system was used as an activator and a support for zirconium, titanium and vanadium bis(phenoxyimine) complexes.^{288, 289} Also, highly active ‘self-immobilised’ zirconium and titanium systems containing an allyl substituent in the aniline ring were proposed, the molecular mass distribution ($M_w/M_n = 3.5 - 19.2$) attained with the ‘self-immobilised’ catalysts being wider than that for similar homogeneous systems ($M_w/M_n < 3$).²⁹⁰

The mechanism of polymerisation with zirconium bis(phenoxyimine) complexes is little studied. Makio and Fujita²⁹¹ have attempted to detect active intermediates by ^1H NMR spectroscopy, but the results were not highly informative.

Bis(ketimine) complexes **98**, which are moderately active in ethylene polymerisation, should be noted among the analogues of zirconium bis(phenoxyimine) complexes.²⁹² Highly active bis(phenoxyketimine) complexes **99** were synthesised; the introduction of the R^1 substituents into the imine group results in an increase in the catalyst activity and the molecular mass of polyethylene.²⁹³

It is remarkable that removal of one phenoxyimine ligand or its replacement by cyclopentadienyl results in a significant decrease in the activity of complexes **100** and **101**.^{82, 294} Complexes **102** with tridentate N,O,O-donor ligands are highly active in ethylene polymerisation and co-polymerisation of ethylene with propylene in the presence of MAO [up to 5700 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ at 25 °C for polymerisation time of 5 min] and $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4 - \text{AlBu}_3^i$ [up to 36 590 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ under similar conditions].

The increase in temperature has resulted in a decrease in the polymer molecular mass and in the narrowing of the molecular mass distribution due to acceleration of chain transfer processes.²⁹⁵ The catalysts containing phenoxyimine ligands linked by a polymethylene bridge were also highly active.²⁹⁶ The zirconium complexes containing bis(phenoxyimine) ligands linked by different types of bridges were moderately active in the polymerisation^{297–299} and oligomerisation of ethylene.^{300, 301}

2. Titanim complexes with phenoxyimine ligands

In contrast to zirconium complexes, titanium complexes with bis(phenoxyimine) ligands are not highly active in polymerisation but produce polymers with higher molecular masses. Thus the activity of titanium complexes **94**^{276–280, 302} in ethylene polymerisation in the presence of MAO was equal to 2280–4150 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$; a high-molecular-mass polyethylene ($M_w = 2.9 \times 10^5 - 8.8 \times 10^5$) was obtained at 25–75 °C. This complex is less active in the presence of $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4 - \text{AlBu}_3^i$; however, the resulting polyethylene had an ultrahigh molecular mass ($M_w = 3.9 \times 10^6 - 5.9 \times 10^6$). Note that titanium complex **94** may be reduced by triisobutylaluminium to a phenoxyamine derivative, which is active in polymerisation of higher olefins, particularly, hex-1-ene.³⁰³ Structurally related *N*-benzylidene complex **103** is also highly active in ethylene polymerisation in the presence of MAO or $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4 - \text{AlBu}_3^i$ yielding high-molecular-mass polyethylene.³⁰⁴

The most interesting properties were found for catalysts with electron-withdrawing substituents in the aniline ring. Thus it was established that complexes **104** ($R^1 = \text{Bu}^t$, $R^2 = \text{H}$) are able to catalyse living polymerisation of ethylene³⁰⁵ and propylene with high syndiospecificity ($[rr]$ of up to 87%–93%, $M_w/M_n \sim 1.1$) in the presence of MAO.^{306, 307} The presence of even one fluorine atom in the *ortho*-position of the aniline fragment is sufficient to trigger the living polymerisation mechanism; the highest activity [up to 36 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ at 50 °C] was achieved with a catalyst containing a pentafluorinated phenyl ring, and the polymer molecular mass was also the highest in this case ($M_n = 4.24 \times 10^5$).^{23, 308} Complexes containing fluorine atoms only in the *meta*- and/or *para*-positions of the aniline ring are also highly active but do not catalyse living polymerisation ($M_w/M_n = 1.78 - 2.18$).^{23, 305–308} It is characteristic that upon introduction of electron-withdrawing substituents into the

salicylaldimine ring, polymerisation in the presence of titanium bis(phenoxyimine) complexes **104** ($R^1 = R^2 = \text{I}$; $F_n = 2,6\text{-F}_2$) is no more living and the activity of the catalyst decreases. Complexes **104** are able to catalyse the production of block co-polymers with styrene.^{309–311} It should be noted that in all cases, the polymerisation time was very short (from 1 to 5 min).

Titanium fluorinated phenoxyimine complexes were used for the production of ethylene-propylene block co-polymers.³¹² Trifluoromethyl groups (complex **105**) can also be used as substituents that increase the activity; the higher the number of electron-withdrawing groups the higher the catalyst activity and the polymer molecular mass.³¹³ Coates and co-workers³¹⁴ have found that titanium complexes **106** with phenoxyketimine ligands without electron-withdrawing substituents in the aniline ring may be used as catalysts of living polymerisation of ethylene. Complexes **107** produce polyethylene with a relatively broad molecular mass distribution ($M_w/M_n = 4-5$).³¹⁵

$R^1 = \text{CF}_3$, $R^2 = \text{H}$;
 $R^1 = \text{H}$, $R^2 = \text{CF}_3$.

$R = \text{H, Me, Et, Ph}$.

$R = \text{H, CF}_3$.

A number of interesting properties were found for fluorinated phenoxyimine catalysts **104** in living polymerisation of propylene.^{306, 307} Particularly, the syndiotactic polypropylene with a high melting point (up to 149–156 °C) was obtained in the presence of MAO.³¹⁶ It is quite remarkable that chain propagation occurs according to the 2,1-insertion mechanism.^{317, 318} If the $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4\text{-AlBu}_3$ system is used as a co-catalyst, a high-molecular-mass atactic polypropylene is produced; the zirconium and hafnium analogues of complex **104** in combination with this co-catalyst form isotactic polypropylene.³¹⁹ This was attributed to the reduction of the imine bond leading to compounds **108**, which possess different catalytic properties.³²⁰ Particularly, these compounds are less active than phenoxyimines and their activity in the polymer-

isation of higher olefins increases in the series hex-1-ene < oct-1-ene < dec-1-ene < 4-methylpent-1-ene.

$R^1 = \text{Alk}$; $R^2 = \text{X} = \text{Bu}^i$.

Bis(phenoxyimine) complexes may be used as catalysts of ethylene co-polymerisation with higher olefins. Co-polymerisation of ethylene with propylene, hex-1-ene and norbornene catalysed by titanium bis(phenoxyimine) complexes **94** has been studied.³²¹ Complexes **109** may catalyse the production of block co-polymers with hex-1-ene, oct-1-ene, dec-1-ene with narrow molecular mass distributions ($M_w/M_n = 1.1-1.3$) and co-monomer contents of up to 30%.³²² The homopolymerisation of higher α -olefins ($\text{C}_6\text{-C}_{10}$) in the presence of titanium bis(phenoxyimine) complexes and $\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4\text{-AlBu}_3$ have been discussed by Fujita and co-workers;³²³ atactic polyolefins with high molecular mass were obtained ($M_w = 8.5 \times 10^5 - 1.5 \times 10^6$).

$R = \text{H, Me, Bu}^i, \text{Pr}^i, \text{cyclo-C}_6\text{H}_{11}$.

The search for other co-catalysts has brought some results. Particularly, polyethylene³²⁴ and syndiotactic polypropylene³²⁵ were obtained with fluorinated catalysts activated by isobutylaluminium 2-ethylhexyloxide [$\text{Bu}_m^i\text{Al}(\text{OR})_n$] with MgCl_2 . Similar co-catalyst systems were used for activation of titanium, zirconium and vanadium phenoxyimine complexes.²⁸⁸ The first papers on the solid-phase phenoxyimine systems have appeared. For example, Klapper and co-workers³²⁶ supported titanium bis(phenoxyimine) complex on latex particles and obtained ultrahigh-molecular-mass ($M_w > 6 \times 10^6$) polyethylene with $M_w/M_n = 3$.

The structure of phenoxyimine ligands was varied in a number of studies. Complexes **110** with bulky substituents in the aniline ring had a low activity.³²⁷ Bravaya and co-workers³²⁸ synthesised dinuclear titanium complex **111**, which was highly active in ethylene polymerisation in the

$R^1 = \text{H}$, $R^2 = \text{Ph}$,
2,6- $\text{Me}_2\text{C}_6\text{H}_3$, 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$,
2,6- $\text{F}_2\text{C}_6\text{H}_3$, 1- C_{10}H_7 ;
 $R^1 = \text{F}$, $R^2 = 2,6\text{-F}_2\text{C}_6\text{H}_3$.

presence of MAO and produced high-molecular-mass polyethylene ($M_n = 2.5 \times 10^6$).

Bochmann and co-workers⁸² have synthesised titanium monocyclopentadienyl monophenoxyimine and phenoxyamine complexes similar to zirconium complexes **101**; these compounds were active in the polymerisation of 1-alkenes in the presence of MAO. The monosalicylaldimine compounds, for example, the titanium analogues of complexes **100**, exhibit relatively low activities [up to 440 (kg PE) mol⁻¹ h⁻¹ bar⁻¹].^{294, 329} The hybrid salicylaldiminato pyrrolyliminate catalysts **112** are highly active [up to 85 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹, polymerisation time 2 min, 20 °C]; however, they are unable to activate living polymerisation.³³⁰ Recently, it has been found that the titanium and zirconium complexes L₂MCl₂ with salicyloxazoline ligands **113** bearing substituents R¹, R², R³ = H, Me, Prⁱ, Bu^t are highly active catalysts of ethylene polymerisation [up to 280 000 (kg PE) mol⁻¹ h⁻¹ bar⁻¹, polymerisation time 1 min, 22 °C].³³¹

R = Ph, C₆F₅.

Tang and co-workers³³² have shown that titanium complexes **114** with tridentate N,O,P-donor ligands are active in ethylene polymerisation in the presence of MMAO and are also able to catalyse co-polymerisation of ethylene with propylene, hexene and norbornene.

X–Y = CH=N, CH₂–NH.

It should be noted that zirconium phenoxyimine and other related complexes particularly, titanium complexes are usually rapidly deactivated; therefore, most of the authors use only the initial parts of polymerisation curves (1–5 min) in the calculation of catalytic activities.

In the case of titanium phenoxyimine catalysts, active intermediates have been studied in more detail than their zirconium analogues. Thus Fujita and co-workers²⁸⁹ have identified a series of titanium(IV) complexes in the catalytic system **109** (R = Bu^t) with MAO by ¹H NMR spectroscopy. Later, Talsi and co-workers³³³ have used ¹H, ¹³C and ¹⁹F NMR to detect and identify a series of cationic intermediates, including species **115**, in the catalytic systems comprising compound **109** (R = Bu^t) and MAO (Scheme 5) and also with AlMe₃–Ph₃CB(C₆F₅)₄. It was established that reduction of the metal to titanium(III) and the transfer of the phenoxyimine ligand to aluminium, resulting in the formation of LAlMe₂, are the main routes of deactivation of the active species.

3. Group 4 metal complexes with pyrrolylimine ligands

The first complexes of Group 4 metals with pyrrolylimine ligands were synthesised and tested in polymerisation by Fujita and co-workers^{24, 334, 335} and Bochmann and co-workers.³³⁶ Zirconium complex **116** was moderately active in ethylene polymerisation in the presence of MAO [63.8 (kg PE) mol⁻¹ h⁻¹ bar⁻¹], while titanium complexes **117** proved to be much more active [up to 33 200 (kg PE) mol⁻¹ h⁻¹ bar⁻¹ in the presence of MAO, R¹ = cyclo-C₈H₁₅] to produce linear high-molecular-mass polyethylene ($M_w = 3.1 \times 10^6$). When Ph₃CB(C₆F₅)₄–Bu₃Al was used as a co-catalyst, the activity decreased severalfold and M_w increased (up to 4.9×10^6), as in the case of phenoxyimine catalysts (see above). Later, it was shown³³⁷ that complex **117** (R¹ = cyclo-C₆H₁₁) is able to catalyse living polymerisation of ethylene with norbornene, the co-monomer content being up to 44%–48%, and the product formed has M_n up to 8×10^5 and $M_w/M_n = 1.1$ –1.2. Fujita and co-workers²⁴ have generally termed the bis(pyrrolylimine) catalysts as ‘PI Catalysts’.

Ar = 2,6-Pr₂C₆H₃.

117: R² = H; R¹ = Et, Ph, n-C₆H₁₃, cyclo-C₆H₁₁, cyclo-C₈H₁₅;

118: R¹ = Ph; R² = H, Me, Bu^t, SiMe₃.

Titanium bis(pyrrolylimine) complexes are more active than their zirconium analogues and, hence, it is studies of titanium complexes that are the most advanced. Attaining high activity of such complexes does not require necessarily the presence of a bulky substituent in the vicinity of the active centre. Indeed, the complex with R² = H is the most active in the series of catalysts **118**.²⁴ Probably, the higher content of propylene (up to 20%–30% against 4.5% for phenoxyimine systems) and hex-1-ene (up to 1.9% against 0.4% for phenoxyimine systems) obtained upon co-polymerisation of ethylene with these co-monomers may be explained by greater steric accessibility of the central atom in pyrrolylimine complexes.^{24, 321} A similar picture was also observed in co-polymerisation of ethylene with norbornene.²⁴ Details of studies on living co-polymerisation of ethylene with norbornene have been reported.^{24, 337} Analysis of the co-polymer structure has revealed that alternating norbornene–ethylene units predominate. Interestingly, the homopolymerisation of ethylene is not living polymerisation (the obtained polymer has $M_w/M_n = 2.1$) and norbornene is not polymerised at all.³³⁸ For the first time, the authors have managed to obtain block co-polymers of ethylene with norbornene that contained polyethylene and alternating ethylene–norbornene segments.^{338, 339} The cal-

culations for ethylene insertion into the metal–carbon bond, which take place in the polymerisation on bis(pyrrolylimine) catalysts, were performed in a theoretical study.³⁴⁰

Apart from the titanium bis(pyrrolylimine) complexes, similar hafnium and zirconium complexes have been studied. In contrast to complexes **117**,³³⁶ compounds **119** are extremely active in ethylene polymerisation when activated by MAO or $\text{B}(\text{C}_6\text{F}_5)_3\text{-AlBu}_3^i$ [up to 22 900 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$] and zirconium complexes are approximately an order of magnitude more active than the hafnium ones.^{341, 342}

A study of titanium complexes **112** with one pyrrolylimine and one phenoxyimine ligands has shown that they are able to catalyse co-polymerisation of ethylene not only with norbornene, but also with hex-1-ene or cyclopentene (in the latter case, the co-monomer content reached 37 mol %).^{329, 343} Mashima and co-workers^{344–346} have synthesised and studied a series of complexes **120** and **121**, which are active in polymerisation of ethylene in the presence of MAO or MMAO. However, their activity is lower than those of titanium bis(pyrrolylimine) complexes.

Ar = 4-MeC₆H₄, 4-MeOC₆H₄.

M = Zr, Hf; Ar = 2-MeC₆H₄,
4-MeC₆H₄, 4-MeOC₆H₄,
2,6-Me₂C₆H₃, 2,6-Pr₂C₆H₃.

Thus, the titanium bis(pyrrolylimine) complexes are quite attractive as catalysts: they are more active in ethylene polymerisation than the metallocene systems, they are able to catalyse living co-polymerisation of ethylene with norbornene yielding the products with high norbornene content, and are suitable for production of block co-polymers of ethylene and norbornene.

4. Phenoxyimine and pyrrolylimine complexes of other metals and their analogues

Titanium and zirconium compounds are catalytically the most active in ethylene polymerisation among metal phenoxyimine and pyrrolylimine complexes known so far. Similar complexes of other metals are also able to catalyse this process. Thus the activity of chromium bischelat complex **122** was up to 96 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ with AlEt_2Cl as an activator.³⁴⁷

Monochelate phenoxyimine complex **123** is more active [130 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$],³⁴⁸ and AlEt_2Cl is also more efficient as an activator than MAO.

Monochelate complex **124** containing a bulky anthracenyl substituent is better activated by methylaluminoxane yielding ultrahigh-molecular-mass polyethylene.³⁴⁹ Complex **125** (and a number of similar complexes) with the tridentate O,N,N-donor ligand was found during screening of a wide variety of ligands. Such complexes are highly active in ethylene polymerisation [6970 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$] producing linear low-molecular-mass polyethylene.^{349, 350}

Chromium pyrrolylimine complexes are less active than similar titanium complexes. The activity of catalyst **126** combined with AlEt_2Cl is up to 70 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ (Ref. 351). Subsequently, it was shown³⁵² that AlMe_2Cl may be used for activation of complex **126**; this results in an increase in the polymer molecular mass and in narrowing of the molecular mass distribution. Complex **126** shows no noticeable activity in the presence of MAO.³⁵²

Among other catalysts, vanadium bis(phenoxyimine) complexes should be noted; in particular, compounds **127** (R = H, Ar = Ph) in combination with a heterogeneous activator, $\text{MgCl}_2\text{-Et}_m\text{Al}(\text{OEH})_{3-m}$ (OEH is 2-ethylhexyloxy), is highly active in ethylene polymerisation at high temperature [65 000 (kg PE) $\text{mol}^{-1} \text{h}^{-1} \text{bar}^{-1}$ at 75 °C] and also in the co-polymerisation of ethylene with propylene ($M_w = 697\,000$, propylene content 21.3 mol %). It should be noted that compounds **127** are the first vanadium-based highly active ther-

mally stable single-centred catalysts of polymerisation.^{285, 353} Redshaw *et al.*³⁵⁴ have used AlMe_2Cl for activation of complexes **127** [$\text{R} = \text{CH}(\text{OHC}_6\text{H}_4)_2$, $\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3$]. The activities were somewhat lower [up to $24\,900\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$ at $75\text{ }^\circ\text{C}$]; ethyl trichloroacetate, which increases the catalyst thermal stability and service life, was added as a re-activator.

Aluminium(III) mono(phenoxyimine) complexes, which showed low activity in the polymerisation of ethylene and propylene in the presence of AlEt_3 or AlMe_3 and $\text{B}(\text{C}_6\text{F}_5)_3$, should also be noted.^{355–357}

VI. Miscellaneous complexes

We discussed the key complexes used as catalysts of olefin polymerisation and synthesised in the late 1990s and in the early 2000s. However, a number of other complexes, which have been synthesised recently and may turn out to be perspective in the future, should be noted. Thus titanium(IV) complexes **128** containing aminotropolone ligands were synthesised. These complexes combined with MAO are able to to catalyse polymerisation of ethylene and propylene and their activities are comparable with those of metallocene catalysts.^{174, 358, 359}

Carpentier and co-workers³⁶⁰ have synthesised and characterised a series of titanium and zirconium complexes with dialkoxy ligands containing a sulfur bridge. In the presence of MAO, some of these complexes were highly active in ethylene polymerisation [for example, the activity of complex **129** was $7190\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$]. Titanium complex **130** effectively catalyses polymerisation of hex-1-ene in the presence of MAO, the resulting polymer having a narrow molecular mass distribution ($M_w/M_n = 1.07\text{--}1.11$). This implies that polymerisation follows a living mechanism; the isotacticity of the *mmmm*-pentad was 80%–85% (for the C_2 -form of the catalyst).³⁶¹

Gibson and co-workers³⁶² have described Group 4 metal complexes **131** with P,O-donor ligands that are active in olefin polymerisation. The activity of the catalyst with $\text{M} = \text{Zr}$, $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Ph}$ in ethylene polymerisation during 1 h at $20\text{ }^\circ\text{C}$ was equal to $26\,700\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$. This is a very high value for non-metallocene systems.

Titanium complexes **132** with the tris(pyrazolyl)methane ligand show varying activities depending on the substituent at the nitrogen atom. The complexes with $\text{R} = \text{CF}_3$, Bu^t were

extremely active under nearly industrial conditions ($100\text{ }^\circ\text{C}$, 7 bar, 10 min), their activities being $133\,700$ and $152\,500\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$ (Ref. 363). Titanium and vanadium complexes **133** catalyse ethylene polymerisation in the presence of MAO or the $\text{AlBu}_3\text{--MAO}$ system, their activity exceeding $10^4\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$. High-molecular-mass polyethylene ($M_w = 1.2\text{--}1.6 \times 10^6$) may be obtained with the vanadium complex ($\text{X} = \text{NBu}^t$).³⁶⁴

The synthesis and the catalytic activity in ethylene polymerisation for several tens of imidotitanium complexes **134** containing triazacyclic ligands have been reported³⁶⁵ (only triazacyclononane complexes are shown but triazacyclohexane complexes were also studied). The activities of some complexes reached $4000\text{--}10\,000\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$ at $100\text{ }^\circ\text{C}$ for a polymerisation time of 10 min.

A series of complexes containing vanadium in various oxidation states ranging from +2 to +5 with O,N,N,O-donor ligands **135** have recently been reported. In the presence of AlEtCl_2 , these complexes are moderately active in ethylene polymerisation and in co-polymerisation of ethylene with hex-1-ene and norbornene (the content of norbornene is up to 29 mol%).³⁶⁶

Catalysts **136–138** based on mono- and dinuclear vanadium complexes synthesised and studied by Redshaw and co-workers^{355, 367} may be of considerable interest. Complex **136** is highly active in ethylene polymerisation in the presence of AlMe_2Cl and ethyltrichloroacetate as the reactivator [up to $96\,500\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$ at $80\text{ }^\circ\text{C}$, polymerisation time 15 min, $\text{Al}:\text{V} = 2500$]; a decrease in the temperature to $25\text{ }^\circ\text{C}$ results in a 3.5-fold decrease in activity; however, the molecular mass increases by more than an order of magnitude ($M_w = 5.18 \times 10^6$).³⁵⁴

The activity of dinuclear complex **137** was similar under similar conditions.³⁵⁴ The activity of complex **138** ($\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Me}$) was formally a record [up to $640\,000\text{ (kg PE) mol}^{-1}\text{ h}^{-1}\text{ bar}^{-1}$ at $80\text{ }^\circ\text{C}$], but only in the presence of a huge excess of AlMe_2Cl ($\text{Al}:\text{V} = 150\,000$) and polymerisation

time of 1 min. The melting point of the product obtained under these conditions was 135 °C, which is typical of linear ultra-high-molecular-mass polyethylene.³⁶⁷ Among other new complexes, vanadium complexes with tris(pyrazolyl)borate ligands supported on SiO₂ should be noted. These systems are highly active [up to 1900 (kg PE) mol⁻¹ h⁻¹ bar⁻¹] in the presence of MAO, AlMe₃, AlPr₃ (Ref. 368).

R¹ = Bu^t, R² = Me; R¹ = R² = Bu^t.

No copper complex-based catalysts of olefin polymerisation are discussed in this review because the activity of even the most active ones (complexes **139**³⁶⁹ and **140**³⁷⁰) does not exceed 300 (kg PE) mol⁻¹ h⁻¹ bar⁻¹. However, copper bis-(benzimidazole) complexes **140** are able to catalyse co-polymerisation of ethylene with acrylic acid esters in the presence of MAO.^{370, 371} Recently, studies of copper complexes with other *N,O*-³⁷² and *N,N*-chelating³⁷³ ligands were reported. The state-of-the-art of the studies into olefin polymerisation catalysts based on rare earth metal complexes, including non-metallocene ones, has been reviewed.³⁷⁴

R = Alk; X = CH₂,
CHOH, 2,2'-biphenyl.

VII. Conclusion

At the boundary of the century, a great number of new non-metallocene catalytic systems for olefin polymerisation have emerged. Among these systems, the transition metal bis(imine) and bis(imino)pyridyl, bis(phenoxyimine) and bis(pyrrolylimine) complexes stand out. These systems have overcome their metallocenic predecessors in the activity and variety of the obtained polymer products. New classes of ligands have appeared that allow one to control the catalytic properties of the active centres over a broad range by variation and modification of the ligands' structure. In contrast to metallocene systems, which use expensive Lewis acids (methylaluminoxane, perfluoroarylboron derivatives) as activators, much cheaper activators such as trialkylaluminium, alkoxylaluminium derivatives on MgCl₂, etc., may be used for activation of post-metallocene systems. At present, the main target of the studies of these systems is maximum control over the parameters (molecular mass, composition, structure) of the resulting products. Undoubtedly, very soon we can expect new achievements in this field, as big research groups have started a systematic search for new catalytic systems by employing the 'high-throughput screening' methodology.^{15, 350} The experimental and theoretical studies of the structures of active intermediates and the mechanisms of catalytic polymerisation are also in progress.

In an early review on the new catalytic systems, Gibson has mentioned that overcoming of the stereotype that the search for new catalysts should be limited by a narrow class of metals, which have already proved themselves in the formation of active polymerisation centres, and that the development of new systems will be restricted only by imagination of a scientist, would form the distinctive features of the 'post-metallocene age' of olefin polymerisation catalysts.²⁶ Some research groups proceeded, from the very beginning, from the assumption that the ligand structure is the most important factor because the olefin affinity is pronounced for all transition metals.²⁴ According to this ligand-oriented approach, high polymerisation activity requires a suitable ligand with balanced electron-releasing and -withdrawing properties. Indeed, up to now, among all complexes of the first row transition metals, the highly active catalytic systems for olefin polymerisation are practically unknown only for manganese complexes. However, this situation is already changing: manganese(I) hydrotris(pyrazolyl)borate complexes are reported.³⁷⁵

At the same time, it should be noted that the development of studies of post-metallocene systems has not resulted so far in a broad commercial application of these systems. On the one hand, some time is required for bringing new processes to large-scale industrial production. On the other hand, the industry demands, first of all, active systems stable at higher temperatures (preferably supported). At present, most of the post-metallocene catalytic systems do not meet these criteria. Therefore, it is obvious that the traditional processes based upon Ziegler–Natta and metallocene catalysts will not be quickly replaced and mainly those post-metallocene systems that produce valuable polyolefin-based materials with new properties will be used by industry in the future.

The author is grateful to professors V A Zakharov and E P Talsi for important comments during the preparation of the present review.

RNA bulges as targets for selective cleavage by metal ions and organic compounds

I L Kuznetsova, M A Zenkova, V V Vlassov

Contents

I. Introduction	279
II. Structure of RNA bulge loops	279
III. Phosphodiester bond cleavage in RNA bulges	282
IV. Conclusion	287

Abstract. The results of studies of RNA bulge structures are reviewed. Cleavage of the phosphodiester bonds within RNA bulges is considered. Attention is focused on the factors influencing the cleavage efficiency. The state-of-the-art of the problem of targeted RNA cleavage induced by various reagents is discussed. The bibliography includes 101 references.

I. Introduction

Most RNA molecules are single-stranded polynucleotide chains with a complex three-dimensional structure (tertiary structure) stabilised through hydrogen bonds between complementary or partially complementary sequences (Watson–Crick complementary base pairing), stacking interactions between loops and binding of loops to metal ions.^{1–3} A combination of various interactions gives rise to a unique RNA packaging, which can be compared with a complex protein packaging.

Short double-stranded regions (or stems) and four types of single-stranded regions, *viz.*, single-stranded fragments, hairpin loops, internal loops (symmetric or asymmetric) and junctions, are typical elements of the RNA secondary structure.¹

Bulges are a special case of asymmetric internal loops, *i.e.*, RNA regions where the adjacent stems are stacked. Bulges are frequently occurring secondary structure elements. They provide flexibility for the ribose phosphate backbone necessary for RNA folding. RNA bulge loops containing nucleotides that lack complementary bases in the opposite RNA strand play an important biological role. They determine the RNA tertiary structure,⁴ represent specific RNA–protein binding sites^{5,6} and form active sites of ribozymes.^{7,8}

Single-base bulges were studied and characterised in most detail. Single-adenosine bulges most frequently occur in natural RNAs. Bulged adenosine residues (bulge A) serve as specific protein-binding sites, for example, in *E. coli* ribosomal

RNAs (5S rRNA–protein L18 and 16S rRNA–protein S8)^{9,10} and in the operator region of mRNAs encoding the capsid proteins of bacteriophage MS2.⁵ Single-uridine bulges were found in many RNAs. For example, this bulge is present in the catalytic site of RNase P,^{11,12} in the high-affinity binding sites for the Rev protein to HIV-1 RNA^{13,14} and for the Tar protein to HIV-2 RNA.¹⁵ Single-cytosine or -guanine bulges are much more rare; however, such bulges play an important role in organisation of the tertiary structure of natural RNAs.^{16,17}

Numerous low-molecular-weight compounds capable of RNA cleavage under physiological conditions (pH 7.0, 37 °C) have been synthesised in recent years.^{18–25} RNA cleavage induced by these compounds occurs predominantly at regions that are not involved in secondary structure formation. RNA cleavage within apical hairpin loops has been most extensively studied. RNA cleavage at linkages in bulge loops has been studied to a lesser degree, although bulges have advantages when used as targets for selective RNA cleavage. Both bulges in natural RNAs and tailor-made bulges in RNAs by hybridisation with partially complementary DNA or RNA oligonucleotides can serve as such targets.

II. Structure of RNA bulge loops

1. Methods of investigation of the bulge structure in DNA and RNA duplexes

X-Ray diffraction analysis is most commonly used in studies of DNA and RNA duplex structures.^{26–28} In spite of high accuracy of this method, X-ray crystallography of nucleic acids offers only an approximate estimate of general structural parameters of duplexes. It is impossible to construct a satisfactory structural model based on these parameters without invoking data from other methods. Potential energy calculations provide a general insight into internal mobility of RNA molecules. Among spectroscopic methods, NMR is used most often.^{29–31} Analysis of nucleic acid structures by NMR spectroscopy provides insight into the molecular dynamic structure in solution and complements X-ray diffraction data, which are somewhat limited due to the static state of the subjects under study. The influence of bulges on the RNA tertiary structure is analysed by gel retardation assay,³² fluorescence resonance energy transfer (FRET)³³ and transient electric birefringence (TEB).³⁴ The classification of structural elements of RNAs and their abundance in natural and synthetic RNAs studied by X-ray diffraction and NMR spectroscopy is available through

the Internet (SCOR: Structural Classification of RNA, <http://scor.lbl.gov/index.html>).

2. Structures of single-nucleotide bulges

Single-nucleotide bulges appear in RNAs if one nucleotide in the polynucleotide chain lacks a complementary base and is located between two classical Watson–Crick or non-canonical base pairs.³⁵ This unpaired nucleotide can adopt two main conformations, *e.g.*, can be either looped out of the helix (Fig. 1 *b*) or be stacked into the helix with adjacent bases (Fig. 1 *a*).³⁶ The conformation of the bulged nucleotide depends on both the nature of the nitrogen base and the adjacent bases. There are examples when the same bulge adopts different conformations, which change depending on intermolecular interactions.

Figure 1. Three-dimensional structure of the RNA double strand containing a single-nucleotide bulge, which is stacked in the helix (*a*) or is looped out from the helix (*b*).³⁶

About 30 single-adenine bulges that are present in RNA structures studied by NMR spectroscopy and X-ray diffraction were derived from the SCOR database. In 11 structures, adenosine is located within the helix; in the other structures it is looped out. Generally, the X-ray diffraction method^{13,28,37–41} shows that in crystals, a bulged adenosine residue is looped out from the RNA helix (Fig. 2), whereas the NMR method^{42–45} indicates that this adenosine is located within the helix and is involved in stacking interactions with

Figure 2. Sequence (*a*) and the three-dimensional structure (*b*) of the RNA–DNA duplex containing a single-nucleotide A bulge.²⁸

Hereinafter, G bases are green, A bases, red; C bases, yellow; U bases, dark blue (or pale blue).

adjacent bases. Apparently, a bulged adenosine residue is highly mobile, and its position at each instant of time is determined by intra- and intermolecular interactions. Therefore, the discrepancy between the data can be attributed to different conditions in which RNAs exist during experiments: in solution (NMR experiments) or in the solid phase (X-ray diffraction analysis).

In crystals, the duplex structure is stabilised by intermolecular bonds. In addition, intermolecular stacking interactions between flipped-out nucleoside bases located in different duplexes can exist. The looped-out conformation of a bulged adenosine residue in crystals can also be due to the fact that crystallisation is performed in the presence of divalent metal cations, for example, of Mg^{2+} , which can stabilise this structure.³⁸ NMR spectroscopic studies of duplex structures are performed in solution, where RNA molecules adopt the energetically most favourable conformation. In this conformation, a duplex contains a bulged adenosine oriented inside the helix. As a result of high mobility of a bulged adenosine, different conformations of a bulged adenosine were established in the same RNA duplexes.^{27,46,47}

To understand which conformation is adopted by a bulged adenosine depending on its environment, an attempt was made to determine the energetically most favourable conformation by computer simulation methods.^{48,49} An hierarchical approach was used⁴⁹ to investigate various sterically possible low-energy conformations of single-base bulge loops. The method is based on the assumption that a bulge and adjacent base pairs are responsible for the conformational deformation of the double helix. Computer simulations and calculations of all possible conformations were performed for 6-mer RNA duplexes containing one bulged adenosine. The duplex in which the bulged adenosine lies inside the helix and is involved in stacking interactions with adjacent nucleotides has the lowest energy. Higher Gibbs energies were obtained for RNA duplexes in which the bulged adenosine is located inside the helix and forms a triplex with a base pair at the 5' end (in the minor groove). According to the calculations, duplexes containing a bulged-out adenosine are characterised by the highest energies. It should be noted that a somewhat different situation was observed for analogous DNA duplexes containing a bulged adenosine. The stacked conformation of a bulged adenosine was also energetically most favourable. However, next in the Gibbs energy was the conformer with a bulged-out adenosine, whereas the conformer in which the bulged adenosine forms a triplex was energetically least favourable.

Single-guanosine bulges (bulge G) have been much less studied. In the structures of all known duplexes containing a bulged guanosine, this nucleoside is looped out from the helix.^{16,50,51} In natural RNAs, a bulged guanosine was found in the α -sarcin loop region 23–28 S of rRNA, where it forms the so-called G-bulged motif.¹⁶ This motif is located in an imperfect stem of a 29-mer hairpin in the 5'GGAACC·3'CAUGACU sequence, where the bulged guanosine (printed in boldface type) is flanked by non-canonical A–A, C–C and U–C base pairs (Fig. 3).

G-Bulged motifs have an important biological function (interactions with α -sarcin and elongation factor G). These motifs were found in the rRNA large subunits of rat and *E. coli* ribosomal RNAs and in the E loop of 5 S rRNA from the frog *Xenopus laevis*.^{9,16,52–54} The specific structural feature of the G-bulged motif is that the bulged guanosine is flanked by the non-canonical purine-purine base pair A–A on the 5' side and forms the G·U·A triplex with the adjacent base pair on the 3' side (see Fig. 3). This leads to a widening of the major groove of RNA by 5 Å, the groove depth remaining typical of the A-form RNA structure.¹⁶ An analysis of mutant 28 S rRNAs demonstrated that a conserved bulged guanosine, which allows RNAs to fold into a unique tertiary structure, is absolutely

Figure 3. Sequence (*a*) and the three-dimensional structure (*b*) of the α -sarcin loop of the rat 28S rRNA containing a single-nucleotide G bulge.¹⁶

The PDB code for the bulge G structure is 430D (<http://www.rcsb.org/pdb/explore.do?structureId=430D>).

necessary in the α -sarcin hairpin for rRNAs to exhibit biological activity (binding with the elongation factor).¹⁶

According to X-ray diffraction data, an uridine residue in single-nucleotide bulges (bulge U) is generally looped out, and it is not only looped out from the helix, but also forms a complex intramolecular structure (for example, it can be directed inward the minor groove).^{13,55} The main distinguishing feature of this conformation of the bulged uridine is that it is stabilised by intramolecular (rather than intermolecular) interactions, to be more precise, by hydrogen bonds between adjacent nucleotides either directly or through aqua bridges. The bulged uridine directed inward the minor groove changes the conformations of adjacent nucleotides. The twist angle of the helix near this bulge increases to 50° (over-twist).⁵⁵ The only bulged uridine adopting a stacked conformation inside the helix was found in a ribozyme (Fig. 4).⁵⁶ Interestingly, the

Figure 4. Sequence (*a*) and the three-dimensional structure (*b*) of the duplex containing a bulged uridine.⁵⁶

The PDB code for the bulge U structure is 1J9H (<http://www.rcsb.org/pdb/explore/images.do?structureId=1J9H>).

replacement of this uridine by any other nucleoside does not change the activity of the ribozyme, which is not typical of single-stranded regions of catalytic RNAs.⁵³

A conserved single-cytidine bulge (bulge C) was found in 5S rRNA.^{17,57} The structure of this bulge was studied in detail in an 8-mer RNA duplex (Fig. 5) corresponding to the helix II region of 5S rRNA from the frog *Xenopus laevis*.⁵¹ Crystals of the duplex were studied at 2.2 and 1.7 Å resolution. In both crystal structures, the bulged cytidine is looped out, and the helix axis deviates from the straight line by an angle smaller than 10°. In the crystals studied at 2.2 Å resolution, the bulged base is directed toward the 3' end of the duplex; in the crystals studied at 1.7 Å resolution, to the 5' end. The existence of two conformations of the bulged cytidine was attributed to its mobility. In crystal, the bulged cytidine, like the bulged uridine, is involved in several intermolecular hydrogen bonds with nucleotides of the adjacent duplexes as well as in stacking interactions with purine bases.

Figure 5. Sequence (*a*) and the three-dimensional structure (*b*) of the duplex containing a bulged cytosine.¹⁷

The PDB code for the bulge C structure is DQH1 (<http://www.rcsb.org/pdb/explore.do?structureId=DQH1>).

The structure of single-nucleotide bulges in RNA·DNA duplexes was established by X-ray diffraction study of the homopyrimidine·homopurine heteroduplex d(C¹TCCTC·TTC⁹)·r(G¹⁰AAGAGA¹⁶GAG¹⁹) containing a bulged adenosine (printed in boldface type) (see Fig. 2).²⁸ It was demonstrated that the bulged adenosine adopts a looped-out conformation, the ribose ring of the adenosine being almost perpendicular to the helix axis. A comparison of the structure of this duplex with the structure of the RNA·DNA duplex with the same sequence but lacking a bulged adenosine demonstrated that the presence of a bulge has only a slight effect on the bend angle of the helix axis of the RNA·DNA duplex (6°). This behaviour of a bulged adenosine in the RNA·DNA duplex substantially differs from that in RNA·RNA and DNA·DNA duplexes. In crystals, the bulged adenosine (A¹⁶) forms the (C⁹·G¹⁰)·A¹⁶ triplex with the terminal C⁹·G¹⁰ base pair of the symmetrically arranged molecule of the heteroduplex through intermolecular hydrogen bonds.

3. Structures of bulges containing two or more nucleotides

As mentioned above, one of the functions of bulges in nature is to organise the RNA tertiary structure, to be more precise, to provide orientation of two adjacent double-stranded RNA regions relative to one another.^{1,58} The influence of the length and the nucleotide composition of a bulge on the RNA

structure was characterised in the studies^{32–34,59} dealing with electrophoretic mobility of bulge-containing RNA·RNA duplexes. An analysis of homo-A and homo-U bulges containing from 1 to 7 nucleotides demonstrated that an increase in the length of the bulge leads to a decrease in electrophoretic mobilities of duplexes,³² duplexes with U_n bulges always having a higher electrophoretic mobility than duplexes with A_n bulges.⁵⁹

The X-ray data on changes in the bend angle of the axis of a bulge-containing helix were confirmed by the data obtained by the FRET³³ and TEB³⁴ methods. It appeared that the bend angle depends on two parameters, *viz.*, the length of the bulge (an increase in the number of nucleotides in the bulge leads to an increase in the bend angle) and its nucleotide composition (bulges containing primarily purine bases bend the helix axis to a lesser extent than bulges containing pyrimidine bases).³⁴

X-Ray diffraction and NMR spectroscopic data demonstrated that bulges consisting of several nucleotides are generally stabilised by a complex system of intermolecular hydrogen bonds, intra- and intermolecular stacking interactions and interactions with metal ions.^{38,51,60–62} The diversity of nucleotide sequences and the environments of bulges consisting of several nucleotides is responsible for the infinite diversity of their structural forms. The structures of two motifs with particular sequences and structures are known: the above-described G bulges in the α -sarcin hairpin of rRNA and the 'kink-turn' or 'K-turn' structure. The K-turn structure was found for a three-base bulge flanked by two G·C base pairs at the 5' end and by two or three non-canonical G·-A base pairs at the 3' end.⁵¹ As a result, the helix axis is bent by 120° at the bulge (Fig. 6). The K-turn motifs play an important biological role. For example, five K-turn motifs were found in 23S rRNA, and all these motifs serve as binding sites for ribosomal proteins.

Therefore, an analysis of X-ray diffraction and NMR spectroscopic data shows that the looped-out conformation rather than stacked into a helix is more typical of single-nucleotide uridine, guanosine and cytidine bulges. Single-adenosine bulges have higher mobility and can adopt different conformations. Double-stranded RNA regions containing bulges are highly mobile. The major groove of the A helix in the bulge region is widened (predominantly, on the 5' end of the bulge) due to which it is accessible for interactions with other molecules. In addition, the helix axis is bent at bulges. Numerous multi-membered bulges are known; however, except for the K-turn motif, there are no clear criteria for

predicting the three-dimensional structure of bulges with an arbitrary nucleotide sequence.

III. Phosphodiester bond cleavage in RNA bulges

1. Geometric parameters of internucleotide bonds and RNA stability

RNA cleavage occurs predominantly in single-stranded regions (hairpin loops, mismatches, internal loops, bulges, junctions and single-stranded fragments). However, it is difficult to determine which bonds and in which sequences are cleaved more rapidly because of complexity of the secondary and tertiary structure of natural RNAs. Many ribozymes and natural and artificial ribonucleases cleave RNA by phosphodiester bond transesterification.⁶³ It is hypothesised that RNA transesterification can occur only when the attacking oxygen atom of the 2'-hydroxy group of the nucleophile is in-line with the 5'-oxy anion of the leaving group, *i.e.*, the arrangement of the leaving group (the oxygen atom of the 5'-hydroxy group), the phosphorus atom and the nucleophile (the oxygen atom of the 2'-hydroxy group) is strictly linear.⁶⁴

Double-stranded RNAs and RNAs involved in RNA·DNA duplexes generally assume an A-form helix, in which the 2'-oxy anion and the 5'-oxy anion of the leaving group are arranged so that the formation of a linear conformation is hindered, resulting in higher stability of double-stranded regions of RNAs and RNA·DNA duplexes compared to single-stranded RNA regions, in which the phosphodiester bonds are labile and can spontaneously adopt an in-line configuration. Therefore, the rate of phosphodiester bond cleavage in RNA bulges would be determined by their ability to adopt an in-line configuration. A phosphodiester bond can spontaneously assume an in-line configuration in the case of sufficient mobility of the corresponding region of the RNA structure. The mobility of a bulge is determined by its size, the nucleotide sequence and the efficiency of intra- and intermolecular stacking interactions between bases.⁶⁴

Nowadays, it is impossible to predict theoretically the sensitivity of the bonds in each particular RNA bulge to cleavage and, much less, to suggest the geometric parameters for the design of a catalytic group capable of performing selective cleavage. In spite of the fact that the specificity toward the RNA structure is always determined for all new compounds exhibiting ribonuclease activity, the dependence of the site and efficiency of cleavage on the RNA primary and secondary structure was studied systematically mainly for divalent metal ions.^{65–70}

2. RNA cleavage at bulge sites by metal ions

RNA cleavage by metal ions or metal ion complexes can occur either by the transesterification mechanism^{71,72} or by metal-dependent redox reactions.^{73,74} Many metals catalyse cleavage of internucleotide phosphodiester bonds in RNAs.^{75,76} Initially, oligomers containing a 2',3'-cyclophosphate at the 3' end are formed and these oligomers are then hydrolysed to give a mixture of 2'- and 3'-phosphates (Zn^{2+} ions)⁷⁷ or only 3'-phosphate (for example, in the presence of Pb^{2+} ions).⁷⁸

Among divalent metal ions, lead ions most efficiently cleave RNA under physiological conditions.⁷⁹ Cleavage of various oligoribonucleotides containing bulges of different length by lead ions (Fig. 7a) was analysed.⁶⁷ The oligoribonucleotides differed not only in the length, nature and nucleotide sequence of bulges, but also in flanking bases. Adenine bulges flanked by G·C base pairs on both sides are not cleaved by Pb^{2+} ions. The replacement of the G·C base pair on the 5' side by the U·A or U·G base pair facilitates phosphodiester bond cleavage in bulges. This fact was attributed to the difference in staking interactions between a bulged base and flanking bases. The efficiency of stacking interactions decreases in the series

Figure 6. Sequence (a) and the three-dimensional structure (b) of the K-turn motif of the protein-binding site of 23S rRNA *Haloarcula marismortui*.⁵¹ The G·C base pairs at the 5' end are red, the G·A base pairs at the 3' end are green and nucleotides in the bulge are blue.

Figure 7. Sensitivity of the phosphodiester bonds in RNA bulges to cleavage by lead ions (a)⁶⁷ and magnesium ions (b).⁶⁸ The arrow thickness corresponds to the cleavage efficiency of a particular phosphodiester bond.

$\text{Pu} \cdot \text{Pu} > \text{Py} \cdot \text{Pu} > \text{Py} \cdot \text{Py}$,⁸⁰ the base on the 5' side of the bulge making the largest contribution. If a base in a bulge takes part in stacking interactions with adjacent bases, the phosphodiester bonds of the nucleotide in the bulge adopt a configuration similar to that in double-stranded RNA and become slightly sensitive to cleavage.

All known oligoribonucleotides with two-membered bulges (AA, CC, UU and CA) located between two G·C base pairs were cleaved by Pb^{2+} ions, all three phosphodiester bonds in the bulge being cleaved. The bond in the middle of the bulge was cleaved most efficiently. The same situation was observed for three-membered bulges. Phosphodiester bonds in

bulges and hairpin loops containing the same nucleotide sequences substantially differ in sensitivity to cleavage by metal ions. For example, the UUCG sequence in an apical hairpin loop is stable and does not undergo cleavage, whereas this sequence in a bulge is readily cleaved by lead ions.⁶⁷

The sensitivity of the phosphodiester bonds in RNA bulges to cleavage by magnesium ions was studied.⁶⁸ The formation of bulges composed of 1–4 nucleotides in the 5'-end region of a 132-mer RNA was induced by hybridisation with oligodeoxyribonucleotides. Magnesium ions at a concentration of 2.5 mmol litre⁻¹ in weak alkaline solutions (pH 8.0) at 60 °C can cleave RNAs at single-stranded regions,⁶⁸ all bulges in RNA·oligonucleotide complexes being cleaved (Fig. 7b).

In single-nucleotide bulges, cleavage occurs predominantly at the phosphodiester bonds on the 3' side for bulged nucleotides, whereas cleavage of these bonds on the 5' side for bulged nucleotides is less efficient. The appearance of secondary cleavage sites on the 5' side for bulges was attributed to the increased flexibility of the bulged nucleotide after cleavage of the most sensitive bond (primary cleavage). When a bulge is flanked on the 3' side by A·U(T) base pairs, secondary cleavage sites are observed also at sites involved in binding of oligodeoxyribonucleotides, which is attributed to stability of heteroduplexes with a single cleavage site.

Unlike lead ions, magnesium ions cleave all single-nucleotide bulges with the same efficiency independently of the type of the bulged base and the flanking base pairs. When the length of an artificial bulge is increased up to 2–4 nucleotides, primary RNA cleavage at the phosphodiester bond on the 3' side of the bulge occurs simultaneously with extensive cleavage of the analogous bond in the double-stranded region adjacent to the bulge on the 5' side. It should be noted that phosphodiester bond cleavage in artificial bulges is accompanied by cleavage of these bonds in all other single-stranded regions in a 132-mer RNA. A comparison of phosphodiester bond cleavage in RNA bulges with cleavage in artificial mismatches demonstrated that, as opposed to bulges, cleavage of sequences flanking mismatches is induced.⁶⁸

The study⁸¹ dealt with phosphodiester bond cleavage by zinc ions in 1–5-nucleotide bulges of a 2'-O-methyl oligoribonucleotide, in which only one nucleotide was not modified at 2' position. Since cleavage of 2'-O-methyl oligoribonucleotides occurs not by the transesterification mechanism, the use of such model RNAs allowed the authors to analyse the sensitivity of each particular phosphodiester bond in bulges. The most efficient cleavage was observed for the phosphodiester bond formed by an unmodified uridine residue (rU), which was located in the middle of a five-base bulge. This bond is cleaved two times more rapidly than the analogous bond in a single-stranded oligoribonucleotide. Four- and three-nucleotide bulges containing riboadenosine or ribouridine in the apical position are cleaved by zinc ions at approximately the same rate. In the case of single- and two-nucleotide bulges, the cleavage rate sharply decreases.

The computer analysis⁸¹ of the structures of bulge-containing oligoribonucleotides demonstrated that five-base bulges with a ribose unit, which is either in the apical position or located closer to the 5' side of a bulge, adopt the same conformation in which all nucleotides are located inside the helix. Two-nucleotide bulges have a similar structure. The cleavage rates of two- and five-nucleotide bulges in which a ribonucleotide is located closer to the 5' end are, respectively, 3 and 6 times lower than the cleavage rate of a five-nucleotide bulge with ribose in the apical position. The geometric parameters of phosphodiester bonds determined by molecular dynamics methods for all types of bulges are substantially different from the parameters typical of the in-line configuration of these bonds.⁸¹ Presumably, the lability of phospho-

diester bonds in bulges is an important feature responsible for sensitivity of these bonds to cleavage.

The above-considered data show that most bulges in RNAs and RNA·DNA complexes can be cleaved by divalent metal ions, cleavage of bulges being different from that of mismatches and apical hairpin loops. Cleavage of bulges has a random character. Thus, phosphodiester bonds located on the 3' side (in some cases, on the 5' side) from bulges are cleaved. In addition, some phosphodiester bonds in an RNA·DNA duplex located near a bulge loop can undergo cleavage. In most cases, RNA cleavage at the bonds in bulges has no effect on the pattern (level) of phosphodiester bond cleavage in other RNA regions.

3. RNA cleavage within artificial bulge loops by metal complex – oligonucleotide conjugates

One of promising approaches to selective RNA injury is based on RNA cleavage by antisense oligonucleotide conjugates containing RNA-cleaving groups. First conjugates containing an RNA-cleaving group covalently bound to the 5' end of oligonucleotides were constructed in the mid-1990s.^{82,83} These conjugates cleaved RNA targets at bonds located in a single-stranded region on the 3' side from heteroduplexes. However, the conjugates described^{82,83} cannot cleave RNAs in a catalytic manner because of slow dissociation of complexes of the conjugate with the cleavage product. To cleave RNAs in a catalytic manner, it is necessary that an RNA·conjugate complex be more stable than the cleavage product·conjugate complex. In other words, RNA cleavage should occur within RNA·oligonucleotide duplexes. However, such duplexes are poor substrates for cleavage because the catalytic (imidazole- or metal-containing) group in such substrates occurs in the double-stranded RNA region.^{84–86}

This problem can be solved by creating artificial bulges in RNAs using hybridisation with partially complementary oligonucleotides containing RNA-cleaving groups. Haner and co-workers were the first to apply this approach.⁸⁶ They used oligodeoxyribonucleotides that contained thymidine

modified by a La^{3+} or Eu^{3+} macrocomplex in the middle of the sequence (Fig. 8a). Upon binding to RNA, these conjugates induced the formation of two-nucleotide AA or GA bulges. In this case, a modified thymidine bearing a metal complex was located not exactly opposite to the artificial bulge in the RNA target but was shifted to the 3' or 5' end of RNA by 4 nucleotides, due to which the RNA-cleaving group can approach the bulged bonds from the side of either the minor or major groove of the duplex.

Conjugates of oligonucleotides entirely complementary to a 32-mer RNA target (except for two nucleotides that form a bulge in the RNA) efficiently cleave the phosphodiester bonds in this bulge and near the bulge (the extent of cleavage is 92%, 16 h), the conjugates containing the Eu^{3+} complex (see Fig. 8a) performing more efficient RNA cleavage compared to conjugates containing the La^{3+} complex.

The experiments demonstrated that the most favourable position of a modified base bearing an RNA-cleaving group is such that provides cleavage through the minor groove of a heteroduplex.⁸⁶ Interestingly, the conjugate, in which the Eu^{3+} complex was covalently attached to the 5' end of a bulge forming oligonucleotide, also efficiently cleaved RNA at the phosphodiester bonds in the bulge. It should be noted that binding of RNA to the conjugate gave rise to a free 10-mer single-stranded fragment at the 5'-end region of the conjugate, which was subjected to cleavage to an insignificant extent. The cleavage occurred primarily at the bonds in the region of the artificial bulge. The above data demonstrate that the phosphodiester bonds in bulges are more sensitive to cleavage than those in other single-stranded RNA regions. This is apparently attributed to the fact that the phosphodiester bonds in bulges assume a configuration more favourable for transesterification compared to their configuration in single-stranded RNA regions.

RNA cleavage by Eu^{3+} complex – oligodeoxyribonucleotide conjugates occurred efficiently; however, the reaction proceeded in a non-catalytic manner. The replacement of an oligodeoxyribonucleotide by 2'-methoxyethoxy derivatives

Figure 8. Structure of modified nucleotide units containing an RNA-cleaving group.^{86, 89, 91, 92}

having a higher affinity for RNA enabled a decrease in the length of an antisense oligonucleotide by a factor of two.⁸⁷ The conjugate of this 10-mer oligonucleotide with the Eu^{3+} complex cleaved a 23-mer RNA target in a catalytic manner; one molecule of the conjugate was able to cleave 39 RNA molecules under physiological conditions in 64 h.⁸⁸

Another type of RNA-cleaving conjugates includes oligonucleotides in which one nucleotide is modified by phenanthroline (Fig. 8b) or terpyridine complexes of Cu^{2+} or Zn^{2+} . It was demonstrated⁸⁹ that site-directed RNA cleavage at the phosphodiester bond in an artificial single-base bulge can be performed with the use of oligonucleotide conjugates containing serinol modified by phenanthroline or terpyridine Cu^{2+} complexes instead of one of nucleotides. As opposed to conjugates described earlier,⁸⁶ metal complexes in the conjugates under consideration were attached not to ribose but to its analogue (serinol) incorporated into the ribose-phosphate backbone of an antisense oligodeoxyribonucleotide.⁸⁹ This non-nucleotide insertion was located directly opposite to artificial RNA bulge. Depending on the nature of the copper complex, the efficiency of cleavage decreased in the series: 2,9-dimethyl-*o*-phenanthroline complex \gg terpyridine complex $>$ *o*-phenanthroline complex. The extent of site-directed 159-mer RNA cleavage by the 2,9-dimethyl-*o*-phenanthroline complex was as high as 80%. Unfortunately, the authors failed to perform this reaction in a catalytic fashion. Efficient RNA cleavage was observed only in the presence of a 500-fold excess of the conjugate with respect to the RNA substrate.

Stromberg and co-workers^{90,91} synthesised 2'-*O*-methyl-oligoribonucleotides containing a modified uridine (Fig. 8c) or cytidine residue bearing the 2,9-dimethylphenanthroline zinc complex in the middle of the nucleotide sequence. The oligoribonucleotides used were completely complementary to the RNA under study, except for nucleotides involved in homo-A bulges containing from 1 to 5 nucleotides. These conjugates cleave RNAs at the phosphodiester bonds in bulges containing from 2 to 5 nucleotides in a catalytic fashion, single-base bulges remaining uncleaved.

Unlike macrocyclic Ln^{3+} complex-oligonucleotide conjugates, which cleave RNAs at the phosphodiester bonds in bulges or near the bulges, conjugates with zinc complexes cleave RNAs only at the bonds in bulges.⁹⁰ The cleavage rate depended on the length of an artificial bulge and the mode of attachment of the 2,9-dimethylphenanthroline Zn^{2+} complex to the antisense oligonucleotide. Four-nucleotide AAAA bulges were cleaved most efficiently, the phosphodiester bonds between the first three adenosine residues were cleaved much more rapidly than the last bond in the bulge.

A comparison of different modes of covalent binding of the 2,9-dimethylphenanthroline zinc complex to heterocyclic bases demonstrated that the attachment at the C(5) atom of uracil is most favourable (see Fig. 8c). Apparently, this arrangement of the complex allows the Zn^{2+} ion to approach the internucleotide bonds in bulges at the shortest distance. A conjugate containing two nucleotides modified by the 2,9-dimethylphenanthroline Zn^{2+} complex (in the middle and at the 5' end of the oligonucleotide chain) was synthesised to increase the efficiency of RNA cleavage. Surprisingly, the presence of the second RNA-cleaving group led to a sharp decrease in the extent of RNA cleavage, which was attributed to steric factors.⁹⁰

Phenanthroline zinc complex-oligonucleotide conjugates efficiently cleaved RNAs in the presence of a 4-fold excess of an RNA with respect to the conjugate. However, due to weak complexation of Zn^{2+} ions with phenanthroline, the presence of a 25-fold excess of Zn^{2+} ions in the reaction mixture is necessary for the reaction to proceed efficiently. To decrease the concentration of Zn^{2+} ions in the reaction mixture, complexes of macrocyclic polyamines, in particular, 1,5,9-

triazacyclododecan-3-yl (aza crown) zinc complexes (Fig. 8d),⁹² were used instead of phenanthroline zinc complexes. In solution, these complexes are four times more stable than phenanthroline complexes. These conjugates also cleaved oligoribonucleotides at the phosphodiester bonds in artificial bulges, but the reaction rate was an order of magnitude lower than that achieved with conjugates containing phenanthroline complexes.

Stromberg and co-workers⁹³ suggested that antisense oligonucleotides, which bear not only an RNA-cleaving group, but also a group that decreases mobility of an RNA bulge, be used for RNA cleavage. It was found that oligonucleotides containing 2'-(1-naphthylmethyl)-2'-deoxytubercidin can specifically stabilise artificial bulges.

Other authors used an adenosine derivative containing a phenylurea substituent at position 6 of the heterocyclic base.⁹⁴

This modified adenosine has a high ability of stacking interactions with adjacent bases and corresponds in size to the complementary A · T base pair. When this nucleoside is present in a duplex, it pushes the opposite nucleotide out of the helix. The phosphodiester bonds on the 3' and 5' sides with respect to these bulged-out nucleotides are cleaved by magnesium ions at a higher rate than the phosphodiester bonds in a single-base bulge or a mismatch. The construction of conjugates, which contain simultaneously nucleosides (adenosine) bearing groups that stabilise bulges and nucleosides bearing an RNA-cleaving group, is presently underway.

4. RNase A- and artificial RNase-induced cleavage at bulge sites

Earlier, it has been demonstrated that RNA cleavage under physiological conditions proceeds efficiently in the presence of small synthetic molecules bearing RNA-cleaving groups. These molecules mimic active sites of natural RNases.^{21, 22, 25} Imidazole is the simplest RNA-cleaving agent. In concentrated solutions of this compound (1 or 2 M), RNA undergo random cleavage at the phosphodiester bonds located in single-stranded regions.⁶⁹ More complex RNA-cleaving compounds (artificial RNases, artificial ribonucleases; hereinafter referred to as aRNases) generally contain an RNA-binding fragment

(for example, an intercalator, a cationic structure or an oligonucleotide).^{21, 22, 24, 95}

The sensitivity of RNA bulges to imidazole, RNase A and various aRNases was examined.^{96, 97} A 96-mer RNA fragment of influenza virus M2 protein mRNA was used as an RNA target. In this fragment, bulges of different length (from 1 to 7 nucleotides) and sequences were formed by hybridisation with partially complementary oligodeoxyribonucleotides (Fig. 9) analogously to a procedure used earlier.⁶⁸

It was demonstrated that the character of RNA cleavage within the bulges induced by imidazole is similar to the cleavage by metal ions, *i.e.*, all phosphodiester bonds in bulges and all bonds in a single-stranded RNA regions are cleaved. However, unlike RNA cleavage by magnesium ions, imidazole does not induce cleavage of the bonds adjacent to the bulges (< 5 nucleotides). Cleavage of RNA containing longer bulges (from 5 to 7 nucleotides) by imidazole occurs at the phosphodiester bonds both in the bulges and adjacent regions. Presumably, this is associated with the fact that RNA oligonucleotide complexes containing short bulges are more stable than complexes containing longer bulges. In the latter complexes, RNA remaining in the dissociated state over a long period of time ('breathing' complexes).⁹⁶

Natural RNase A cleaves RNAs at the phosphodiester bonds in all bulges except for single-base bulges. In addition to the phosphodiester bonds in bulges, RNase A cleaves phosphodiester bonds in other single-stranded RNA regions. Similar pattern of RNA cleavage was observed for aRNases. The extent of phosphodiester bond cleavage in bulges depends on the length and the nucleotide sequence of the bulges.

The concept 'selectivity' was introduced to estimate the difference in sensitivity of the phosphodiester bonds in artificial bulges and other phosphodiester bonds. The selectivity means the ratio of the extent of RNA cleavage at the bonds in a bulge to the total extent of RNA cleavage including all other

phosphodiester bonds. It appeared that the selectivity of cleavage depends on the type of aRNase. RNase A cleaves the bonds within bulges with a low selectivity (no higher than 0.1). In other words, cleavage at the bonds in bulges occurs at a rate lower than or similar to that at the other cleaved phosphodiester bonds in RNAs.

The selectivity of RNA cleavage by artificial RNases, which are short cationic peptides, was also low.⁹⁷ The highest selectivity of cleavage was observed for aRNases containing the 1,4-diazabicyclo[2.2.2]octane residue.^{98, 99} The CA phosphodiester bond in a four-membered bulge was cleaved with the highest selectivity (0.4). The cleaved phosphodiester bond was in the apical position. The presence of the second CA motif in a bulge increases the selectivity of phosphodiester bond cleavage up to 0.5.

Interestingly, the selectivity of cleavage in RNA · oligonucleotide complexes, in which the oligonucleotide contains a non-complementary adenosine residue opposite to the bulge, was always higher than that in complexes in which this non-complementary base was absent. It should be noted that, according to the data from gel shift analysis, binding of oligonucleotides containing an additional adenosine residue to RNAs does not differ from binding of oligonucleotides in which a non-complementary adenosine residue is absent.⁹⁶ Consequently, in this case high selectivity of cleavage can be attributed to a more flexible structure of the bulge, which provides for efficiency of transesterification. Therefore, artificial ribonucleases containing the 1,4-diazabicyclo[2.2.2]octane residue, unlike short cationic peptides, predominantly cleave bonds in bulges.

5. RNA cleavage at bulge sites by artificial RNases in the presence of magnesium ions

It is known that Mg^{2+} ions stabilise the RNA structure by decreasing its mobility,¹⁰⁰ resulting in a decrease in efficiency

Figure 9. Sensitivity of the phosphodiester bonds in RNA bulges to cleavage by artificial RNases (the arrow thickness corresponds to the cleavage efficiency of a particular phosphodiester bond).^{96, 97}

of RNA cleavage by different agents. At the same time, magnesium ions stabilise such RNA structural elements as bulges. In the presence of magnesium ions, the total extent of M2-96 RNA cleavage by artificial RNases decreases. However, in the presence of MgCl_2 at a concentration of 10 mmol litre^{-1} , RNA·oligonucleotide complexes are cleaved by aRNases containing 1,4-diazabicyclo[2.2.2]octane predominantly at the bonds in bulges, whereas cleavage at other regions is suppressed to a substantial degree.^{96,97} In the presence of magnesium ions, the selectivity of cleavage of four- and seven-membered bulges increases to 0.68 and 0.75, respectively, *i.e.*, the formation of bulges in RNAs entirely changes the cleavage pattern by aRNases containing 1,4-diazabicyclo[2.2.2]octane. An increase in selectivity of cleavage in the presence of magnesium ions was observed for neither RNase A nor short cationic peptides.⁹⁷

These data correlate with the X-ray diffraction data for the single-nucleotide A bulge in the $[\text{r}(\text{GCG})\text{d}(\text{ATATA})\text{r}(\text{CGC})]_2$ duplex. In the presence of Mg^{2+} ions, the phosphodiester bond in the bulge adopts a nearly in-line configuration, unlike the configuration observed in the crystals grown in the presence of spermine.⁴¹ Apparently, Mg^{2+} ions can stabilise the in-line configuration of the phosphodiester bonds in bulges, which is favourable for transesterification.

IV. Conclusion

The idea for construction of specific catalysts for RNA cleavage has attracted attention for many years. Theoretical studies demonstrated that oligonucleotides that contain RNA-cleaving groups and form artificial bulges in a complementary RNA sequence can selectively inactivate RNAs in a catalytic manner and do not require additional enzymes or cofactors. However, there are problems with implementation of this approach in practice. The sensitivity of the phosphodiester bonds in bulges depends not only on the length and the nucleotide sequence of the bulge, but also on the nature of the RNA-cleaving group. An RNA-cleaving group should not only be an efficient catalyst for cleavage, but also be in an optimal orientation with respect to the cleaved bond. One of requirements imposed on the oligonucleotide moiety of the conjugate is that the DNA·RNA complex should be sufficiently stable before cleavage and readily dissociate after cleavage. In the case of long RNAs, this problem is complicated by a search for RNA regions accessible for binding with oligonucleotides. Therefore, the construction of efficient artificial RNases performing site-directed RNA cleavage requires a complex approach.

Two main approaches are available for site-directed RNA cleavage by artificial RNases. One approach is based on the synthesis of antisense oligonucleotides containing RNA-cleaving groups (see Section III.3). Another approach consists in constructing binary systems composed of a low-molecular-weight RNA-cleaving unit and a complementary oligonucleotide. The latter contains a group enhancing the sensitivity of a particular region or particular bonds in RNAs to cleavage.^{96,97,101} Site-directed RNA cleavage with the use of this system was first exemplified by cleavage of a short model 36-mer RNA in which all bonds, except for the bond subjected to cleavage, were protected by complexation with complementary oligonucleotides.⁹³

The approach proposed by Vlassov *et al.*⁹⁶ is based on an increase of sensitivity of phosphodiester bonds in RNAs to cleavage due to their bulging. It was demonstrated that in the presence of magnesium ions, the phosphodiester bonds in (4–7)-member bulges, which are formed in RNAs by hybridisation with a partially complementary oligonucleotide, are selectively cleaved by aRNases at a rate several times higher than the rate of cleavage of other phosphodiester bonds in

RNA molecules. Selective RNA cleavage within a bulge occurs apparently due to the appearance of constraints, which is necessary for efficient transesterification, and stabilisation of the other parts of the RNA molecule in the presence of magnesium ions. As a result, the RNA molecule becomes poorly sensitive to cleavage at all bonds except those in bulges.^{96,97} To summarise, selective RNA cleavage at phosphodiester bonds in bulges can be performed with the use of a binary system consisting of aRNase and an oligonucleotide partially complementary to RNA.

V. Reactions of polybromo[60]fullerenes	309

Abstract. Methods for the synthesis of polyfluoro(chloro, bromo) derivatives of C₆₀ fullerene and their structures are described. The reactivity of these compounds is demonstrated considering redox reactions, nucleophilic substitution, radical addition, cycloaddition and electrophilic arylation. The bibliography includes 185 references.

I. Introduction

Polyhalofullerenes are the best studied fullerene polyadducts, and halogenation reactions were among the first reactions of fullerenes performed in the early 1990s.^{1–8} These compounds have attracted interest primarily because they hold promise for the design of new materials, which would be expected to exhibit unique properties. In particular, an idea of the synthesis of chemically inert perfluorinated fullerene C₆₀F₆₀ similar in properties to Teflon (the so-called ‘Teflon Buckyballs’) was very popular at one time.^{1,9} However, later it has been found^{10,11} that polyfluorofullerenes are not as chemically stable as polyfluoroalkanes, and it is impossible to prepare exohedral C₆₀F₆₀. Nevertheless, polyhalofullerenes have continued to attract attention, and investigations into halogenation of fullerenes for more than one decade led to the development of efficient methods for the synthesis of polyfluoro-, polychloro- and polybromofullerenes. The structures of individual polyhalofullerenes were established.

Compounds containing an aromatic annulene fragment bearing conjugated C=C bonds only in *trans* configuration (all-*trans* annulenes or trannulenes) were first synthesised based on polyfluorofullerenes.¹² It has been repeatedly suggested^{12–15} that polyhalofullerenes hold promise for the synthesis of donor–acceptor dyads with improved electron-

withdrawing properties and for the design of molecular devices. This has stimulated studies of the redox,^{16,17} electrochemical^{18–21} and photophysical^{22–24} behaviour of polyhalofullerenes and their derivatives. The design of new polyhalofullerene-based materials requires that both physical and chemical properties of these compounds were known. The aim of the present review is to systematise and analyse methods for the synthesis, structural features, chemical properties and characteristics of chemical transformations of polyhalo derivatives of the C₆₀ ([60]fullerene) molecule.

II. Synthesis, structures and physical properties of polyhalo[60]fullerenes

Being polyunsaturated compounds, fullerenes are prone to be involved in radical and nucleophilic addition and cycloaddition reactions, but they very rarely react with strong electrophilic reagents.^{25,26} Polyhalofullerenes are usually synthesised by the reactions of fullerene with a wide range of halogenating agents. Preparative procedures for the synthesis of various polyfluoro-, polychloro- and polybromofullerenes are available. Polyiodofullerenes are presently unknown, although the existence of molecular crystals with the composition C₆₀·2 I₂ was proved.^{27,28} In spite of the fact that the number of possible geometric isomers of polyhalofullerenes is very large, in practice only a few of them were prepared by halogenation of fullerene. The formation of particular isomers is generally controlled by thermodynamic factors and only in rare cases by kinetic factors.

The present review deals only with polyhalo derivatives of C₆₀ fullerene. Polyhalogenated C₇₀ fullerenes and polyhalogenated higher fullerenes have been studied in much less detail. However, the available data suggest that their chemical properties are analogous to those of polyhalo[60]fullerenes.

1. Synthesis and structures of polyfluoro[60]fullerenes

Polyfluorofullerenes are most numerous of all isolated and characterised polyhalofullerenes (Fig. 1).^{29–36} For example, the structures of C₆₀F₁₈ with the symmetry group C_{3v},^{37–39} three isomers of C₆₀F₃₆ (with *T*, *C*₃ and *C*₁ symmetry)^{40–42} and *D*₃ and *S*₆ isomers of C₆₀F₄₈ (Refs 43 and 44) were studied. Polyfluorofullerenes C₆₀F_{2n} (*n* = 1–4),^{45,46} C_s-C₆₀F₁₆

Figure 1. Schlegel diagrams of polyfluorofullerenes $C_{60}F_{48}$ [D_3 (a) and S_6 isomers (b)], $C_{60}F_{36}$ [C_{3v} (c), C_3 (d) and C_1 isomers (e)], C_{3v} - $C_{60}F_{18}$ (f) and two projections of D_{5d} - $C_{60}F_{20}$ (g, h). Hereinafter, the solid circles indicate the binding sites of halogen atoms.

(see ‡),⁴⁷ D_{5d} - $C_{60}F_{20}$,^{48,49} T_h - $C_{60}F_{24}$ (Ref. 50) and $C_{60}F_{38}$ (Ref. 51) were isolated and partially characterised.

The methods for the synthesis of polyfluoro derivatives of fullerenes can be divided into three groups: (1) fluorination of fullerene by molecular fluorine either directly or in metal fluoride matrices, (2) fluorination of fullerene by fluorides of transition metals in high oxidation states and (3) fluorination of polychloro- and polybromofullerenes.

Higher polyfluorofullerenes, in particular, $C_{60}F_{48}$, can easily be synthesised by the reaction of fullerene with molecular fluorine (see Section II.1.a).⁴³ However, attempts to use this procedure for the synthesis of less fluorinated fullerenes led to the formation of complex mixtures of products. This is due to

the fact that direct fluorination occurs by a radical mechanism. The range of synthetically accessible polyfluorofullerenes was substantially extended due to the use of high-oxidation-state metal fluorides as fluorinating agents. In this case, the reaction apparently proceeds by a mechanism of single-electron oxidation of fullerene (and its partial fluorination products) by metal cations followed by the addition of the fluoride ion to the intermediate radical cation. This assumption is consistent with the observed dependence of the degree of fluorination of fullerene on the metal oxidation potential.^{35,52} The selective formation of polyfluorofullerenes $C_{60}F_{18}$, $C_{60}F_{36}$ and $C_{60}F_{48}$ was also observed in the reactions of fullerene with molecular fluorine in MnF_2 , CoF_2 or NiF_2 matrices.^{53–55} The advantage of this approach is the possibility to synthesise polyfluorofullerenes in a flow reactor, which is of importance for the development of industrial apparatus. Fluorination of polyhalofullerenes under mild conditions affords thermodynamically unstable but kinetically stable T_h - $C_{60}F_{24}$ (see Sections II.1.d and V).⁵⁰

a. Polyfluorofullerene $C_{60}F_{48}$

Fluorination of [60]fullerene with molecular fluorine was historically one of the first studied functionalisation reactions of C_{60} . Early experiments on fluorination of this fullerene often gave complex mixtures of fluoro derivatives of [60]fullerene, the composition of the products varied depending on the reaction temperature and time.^{1,11,56,57} In 1994, Tuinman and Gakh⁴³ developed a preparative procedure for the selective synthesis of $C_{60}F_{48}$ involving two fluorination steps.

The reaction was performed in the presence of NaF to decrease the exothermicity of fluorination, which made it possible to decrease the degree of ‘combustion’ of fullerene in fluorine atmosphere and increase the yield of the target product. Initially, C_{60} and NaF were heated in a stream of fluorine at 250 °C for 20 h. The resulting mixture of isomers of higher polyfluorofullerenes $C_{60}F_{46}$ and $C_{60}F_{48}$ was extracted with $CFCl_3$ and subjected again to fluorination but at higher temperature (275 °C, 30 h). Polyfluorofullerene $C_{60}F_{48}$ was obtained in yields up to 60%. All attempts to perform further fluorination of $C_{60}F_{48}$ at high temperatures failed. Decomposition of the carbon skeleton of the molecule giving rise to a complex mixture of polyfluorocarbons C_nF_m ($n = 16–30$, $m = 30–50$) occurred instead of the addition of the fluorine atom.⁵⁸ Based on this fact, it was concluded that the maximum possible degree of fullerene fluorination is achieved in polyfluorofullerene $C_{60}F_{48}$. Improved procedures for the synthesis of $C_{60}F_{48}$ were described.^{55,59}

One- and two-dimensional ^{19}F NMR correlation spectroscopy demonstrated that polyfluorofullerene $C_{60}F_{48}$ thus synthesised is a mixture of isomers with the point groups D_3 and S_6 (see Fig. 1 a, b).⁴³ The structures of the D_3 and S_6 isomers were conclusively established by X-ray diffraction.⁴⁴ These molecules are characterised by the presence of six shortened double bonds (1.301 Å), which are located in six five-membered rings of the fullerene cage and are completely shielded by the surrounding fluorine atoms. The F...F distance between the opposite fluorine atoms at the double bond is 4.2 Å. Since the van der Waals diameter of the fluorine atom is 2.7 Å, the open space around the C=C bond is at most 1.5 Å. Such a substantial steric shielding of the double bond is one of the factors that preclude further fluorination of $C_{60}F_{48}$ without destruction of the fullerene cage.¹¹

‡ The point symmetry group of the compound is given in italics as a prefix to the formula.

b. Polyfluorofullerene C₆₀F₃₆

Heating of C₆₀ with MnF₃,⁶⁰ CeF₄³⁵ or MPbF₆ (M = Mg, Ca, Sr or Ba)⁶¹ at 380 °C under dynamic vacuum affords a mixture of *T*, C₃ and C₁ isomers of C₆₀F₃₆ in a yield of > 70% (see Fig. 1 *c–e*).

The structures of the isomers have been initially suggested based on ¹⁹F NMR spectroscopic data.^{40, 62} More recently, the structures of *T*- and C₃-C₆₀F₃₆ were established by X-ray diffraction.^{41, 42} Each isomer contains isolated cyclohexatriene fragments. An analysis of the C–C bond lengths in these rings demonstrates that all these distances are averaged and are similar to the typical bond lengths in aromatic compounds (for example, 1.373 Å for *T*-C₆₀F₃₆ and 1.368 Å for C₆F₆). Taking into account efficient π -electron density delocalisation and small deviations from planarity (about 0.01 Å) of the cyclohexatriene fragments, these rings can be considered as benzenoid. In the most symmetrical isomer *T*-C₆₀F₃₆, the fluorine atoms are arranged so that four isolated benzenoid fragments are retained. The molecules of the less symmetrical isomers (C₃-C₆₀F₃₆ and C₁-C₆₀F₃₆) contain three such fragments, whereas the remaining three double bonds are localised in the five-membered rings. It should be noted that all three isomers of C₆₀F₃₆ are structurally related to each other and can easily be derived from each other as a result of the 1,3-shift of one fluorine atom (interconversions of the C₃ and C₁ isomers)⁶³ or three fluorine atoms (interconversions of the *T* and C₃ isomers) within one or three five-membered rings, respectively. These rearrangements are also confirmed by the fact that fluorination of isomers of C₆₀F₃₆ by molecular fluorine affords higher polyfluorofullerenes D₃- and S₆-C₆₀F₄₈, which cannot occur without migration of the fluorine atom over the surface of the fullerene sphere.⁶⁴ It should be noted that analogous mechanisms were proposed for the explanation of interconversions of polyhydrofullerenes C₆₀H₃₆ isostructural to isomers of C₆₀F₃₆.⁶⁵

c. Polyfluorofullerenes C₆₀F₁₈ and C₆₀F₂₀

Polyfluorofullerene C₆₀F₁₈ can be prepared in yields of up to 60% by heating (465 °C) a mixture of C₆₀ and K₂PtF₆ under dynamic vacuum.^{37, 39} The compounds Cs₃PbF₇,⁶¹ Rb₂PtF₆ and Cs₂PtF₆ (Ref. 66) can be recommended as alternative fluorinating agents for the synthesis of C₆₀F₁₈. The use of KMnF₄,⁴⁶ K₃CoF₆,⁶⁷ Li₄CeF₈ or the KF–MnF₃ system^{49, 67} leads to an increase in the percentage of low-fluorinated by-products or a decrease in the degree of conversion of C₆₀. Hence, these reactions are less attractive for the synthesis of C₆₀F₁₈.

The only isomer of polyfluorofullerene C₆₀F₁₈ with symmetry C_{3v} (see Fig. 1 *f* and 2) was isolated. An important difference between this compound and the above-considered polyfluorofullerenes is that all fluorine atoms in this compound are located in one half of the fullerene cage, whereas another hemisphere remains unfunctionalised. As a result, the molecule assumes a large dipole moment estimated to be 8–15 D.^{38, 68} According to the X-ray diffraction data,^{38, 39} the fullerene hemisphere containing fluorine atoms is substantially flattened (see Fig. 2 *b*). This hemisphere includes the cyclohexatriene pole, in which the bond lengths are equalised and are typical of aromatic systems (1.372 Å). Therefore, like isomers of C₆₀F₃₆, polyfluorofullerene C₆₀F₁₈ contains a

Figure 2. Three-dimensional structure of C_{3v}-C₆₀F₁₈: top view (*a*) and side view (*b*).

benzenoid fragment. The bond lengths and the shape of the pole of the fullerene hemisphere free of fluorine atoms are very similar to the corresponding parameters of non-modified fullerene. The C₆₀F₁₈ molecule contains four types of fluorine atoms, one of which is sterically most accessible, and the distance from such fluorine atoms to the carbon atoms bearing them (1.396 Å) is larger than the lengths of the other fluorine–carbon bonds (1.361–1.385 Å). Evidently, this longest bond is the weakest one, *i.e.*, this type of fluorine atoms is most reactive in the C₆₀F₁₈ molecule. The higher reactivity of this type of atoms compared to other fluorine atoms is also attributed to the fact that the involvement of the latter in chemical transformations results in a deviation from planarity and destabilisation of the aromatic π system of the benzene-like fragment.

Polyfluorofullerene C₆₀F₂₀ was isolated from fluorination products of C₆₀ with complex manganese and cerium fluorides in 5%–8% yields.^{48, 49, 66, 69} (It should be noted that this compound was found in trace amounts, if at all, among the reactions products of fullerene with K₂PtF₆ and Cs₂PtF₆, but it was detected in the analogous reaction with Rb₂PtF₆). A ¹⁹F NMR spectroscopic study demonstrated that all 20 fluorine atoms in the C₆₀F₂₀ molecule are equivalent. This is consistent with the structure shown in Figs 1 *g, h* and 3.⁴⁸ Fullerene D_{5d}-C₆₀F₂₀ contains the equatorial belt of sp³-hybridised carbon atoms (CF)₂₀, which divides the fullerene cage into two equivalent dehydrocorannulene fragments. Although the alternative structure of C₆₀F₂₀ described in Ref. 48 formally satisfies the condition of equivalence of 20 fluorine atoms, conclusive evidence in favour of the initially proposed structure containing the equatorial (CF)₂₀ belt was

Figure 3. Three-dimensional structure of D_{5d}-C₆₀F₂₀: top view (*a*) and side view (*b*).

given in a more recent study.⁴⁹ Evidently, polyfluorofullerene D_{5d} - $C_{60}F_{20}$ cannot be generated from C_{3v} - $C_{60}F_{18}$ without substantial rearrangements of the fluorine atoms. This suggests that the pathways giving rise to these two compounds include different intermediate fluorination products.⁴⁸

Due to the presence of two dehydrocorannulene fragments, which are located at the poles of the $C_{60}F_{20}$ molecule and can independently bind donor or acceptor groups, these derivatives are promising starting compounds for the formation of donor–acceptor complexes and polymers.⁷⁰

d. Polyfluorofullerene T_h - $C_{60}F_{24}$

A possible method for the synthesis of polyhalofullerenes is based on the replacement of one halogen atom by another halogen. In early studies,^{71, 72} it has been demonstrated that chlorine (bromine) atoms in polychloro(bromo)fullerenes can be replaced by fluorine atoms in reactions with molecular fluorine or XeF_2 . However, the authors failed to isolate individual compounds. By contrast, bromination of lower polychloro derivatives $C_{60}Cl_n$ ($n = 6, 8, 12$ or 14) by liquid bromine affords T_h - $C_{60}Br_{24}$,⁷³ the chlorination of which by antimony pentachloride at high temperature gives rise to T_h - $C_{60}Cl_{24}$.⁷⁴

Fluorination of T_h - $C_{60}Br_{24}$ with xenon difluoride in anhydrous HF at room temperature is the only known example of the successful selective formation of polyfluorofullerene by the substitution reaction.⁵⁰

Under the above-mentioned conditions, bromine atoms in polyhalofullerene are replaced by fluorine atoms. According to the ^{19}F NMR spectroscopic data, this reaction produces the highly symmetrical T_h - $C_{60}F_{24}$ compound isostructural to the starting $C_{60}Br_{24}$ compound (Fig. 4). According to quantum chemical calculations,⁵⁰ this polyfluorofullerene is metastable and, consequently, can undergo isomerisation or disproportionation to form more stable structures. However, this process is kinetically hindered; at least, it was not detected at room temperature.

Figure 4. The Schlegel diagram of T_h - $C_{60}F_{24}$.

e. Other polyfluoro derivatives of [60]fullerene

In addition to $C_{60}F_{18}$ and $C_{60}F_{20}$, fluorination of C_{60} fullerene by complex metal fluorides (K_2PtF_6 , $KMnF_4$, Cs_2PbF_6 , Li_4CeF_8 , etc.) gives other lower polyfluorofullerenes [$C_{60}F_{2n}$ ($n = 1-3$),^{45, 46} two isomers of $C_{60}F_8$,^{45, 46, 75} $C_{60}F_{12}$, $C_{60}F_{14}$,⁴⁹ $C_{60}F_{16}$ (Ref. 47)], oxopolyfluorofullerenes [$C_{60}F_2O$,⁴⁵ $C_{60}F_{2n}O$ ($n = 2-4$),⁷⁶ $C_{60}F_{16}O$,⁷⁷ $C_{60}F_{18}O$,⁷⁸⁻⁸⁰ $C_{60}F_{18}O_2$ (Ref. 81)] and mixed perfluoroalkylfluoro derivatives [$C_{60}F_7CF_3$,^{45, 46} $C_{60}F_{17}CF_3$, $C_{60}F_{17}C_2F_5$ (Ref. 82)]. Impurities

of oxopolyfluorofullerenes and perfluoroalkylpolyfluorofullerenes are always present in certain amounts among fluorination products of fullerenes. These compounds are formed because of imperfections in vacuum apparatus used for their preparation, due to the presence of traces of oxygen in crystalline fullerene, reagents or on the surface of the reactor and as a result of thermal destruction of polyfluorofullerenes (for more details, see Section III.4.b). Although the percentage of these compounds is low (the yields are usually lower than 5%), they were isolated by chromatography and partially characterised. The structures of most of these compounds were proposed based on ^{19}F NMR spectroscopic data. The structures of some derivatives were confirmed by the results of other spectroscopic methods (for example, by IR and Raman spectroscopy) interpreted with the use of quantum chemical calculations. The structures of some compounds were established by X-ray diffraction. For example, it was demonstrated that the C_s and C_1 isomers of fullerene $C_{60}F_{17}CF_3$ are isostructural to $C_{60}F_{18}$. These molecules contain the CF_3 group instead of one of three sterically most accessible fluorine atoms.⁸² An X-ray diffraction study showed that oxohomofullerene C_s - $C_{60}F_{18}O$ dominates among oxygen-containing products.⁸⁰ In this compound, the oxygen atom is introduced into the longest [5,6] C(F)–C(F) bond[§] of the $C_{60}F_{18}$ molecule, which is accompanied by cleavage of this bond.

2. Solubility of polyfluoro[60]fullerenes

Only a few studies were concerned with the determination of solubility of polyfluorofullerenes and investigation of their stability in solution.⁸³⁻⁸⁵ It should be noted that the lack of information on stability of polyfluorofullerenes in different solvents led to erroneous interpretation of the experimental data in some early studies in favour of the formation of $C_{60}F_{60}$.^{1, 86, 87}

Stability of polyfluorofullerenes in solution depends on the chemical properties of these compounds. As will be demonstrated below, polyfluorofullerenes are prone to nucleophilic substitution reactions, in particular, to hydrolysis and can act as oxidising agents. Hence, to prevent non-destructive dissolution of polyfluorofullerenes, it is necessary to avoid the use of nucleophilic or protic solvents (for example, alcohols, amines, pyridine, etc.), solvents that are difficult to purify from traces of water or alcohols (for example, acetone and chloroform) and solvents that are readily involved in redox reactions (ethers, particularly, for higher polyfluorofullerenes).

Among the solvents recommended for use in experiments with polyfluorofullerenes, hydrocarbons (alkanes and arenes) and their halogeno derivatives should be mentioned. The solubilities of C_{60} and polyfluorofullerenes $C_{60}F_{18}$, $C_{60}F_{36}$ and $C_{60}F_{48}$ in some organic solvents are given in Table 1.

3. Synthesis and structures of polychloro[60]fullerenes

Unlike polyfluoro[60]fullerenes, polychloro derivatives of fullerene C_{60} have been less studied. For example, only $C_{60}Cl_6$ has been synthesised (by the reaction of fullerene with iodine monochloride) so far and reliably characterised.⁸⁹⁻⁹¹

Fullerene C_{60} is known to react only with highly reactive electrophiles; however, this compound is readily involved in radical addition reactions. Hence, it is reasonable to suggest

§ The carbon–carbon bond between the five- and six-membered rings is enclosed in brackets [5,6].

Table 1. Solubility of C₆₀ and polyfluoro[60]fullerenes in organic solvents at 25 °C (in mg ml⁻¹).

that chlorination of C₆₀ proceeds by a radical mechanism.⁸⁹ This assumption is consistent with the influence of solvents on the reaction rate. It was found that the reaction proceeds more rapidly in benzene or chlorobenzene than in toluene. Evidently, toluene captures part of the radicals, resulting in a decrease in the rate of chlorination of fullerene. Since ICl is a weak Lewis acid, chlorination of C₆₀ in benzene or toluene gives aryl-containing fullerenes as by-products.^{91,92} Apparently, this reaction proceeds analogously to arylation of fullerenes and polychlorofullerenes in the presence of aluminium chloride⁹³ (see Section IV.2). The yields of aryl-containing fullerenes that are formed as by-products can be substantially decreased using monochloro- and dichlorobenzenes, which are less reactive in Friedel–Crafts reactions, and by removing unconsumed ICl from the reaction mixture as quickly as possible.^{91,94}

The structure of polychlorofullerene C₆₀Cl₆ (Fig. 5a) was established by ¹³C NMR spectroscopy⁸⁹ and was then confirmed by X-ray diffraction.⁹⁵ In the molecule, five chlorine atoms surround one of the pentagonal faces of the fullerene, whereas the sixth chlorine atom is directly attached to this five-membered ring to form a 1,2 contact with the adjacent chlorine atom (this structure is generally described as a truncated pentagonal pyramid). This addition pattern of addends to the fullerene cage was demonstrated⁹⁶ to be energetically most favourable in the presence of bulky substituents, including chlorine atoms. To the contrary, the formation of *trans*-chains of 1,2 contacts (the so-called *S* addition pattern) is favourable for small substituents, such as H and F atoms. This difference is evidently associated with steric strain due to interactions between the adjacent bulky groups. The presence of one 1,2 contact between chlorine atoms in the C₆₀Cl₆ molecule leads to

**Figure 5.** The Schlegel diagrams of C₅-C₆₀Cl₆ (a), D_{3d}-C₆₀Cl₃₀ (b), C₁-C₆₀Cl₂₈ (c) and C₂-C₆₀Cl₃₀ (d).

a slight elongation of the corresponding C–Cl bond and, as a consequence, to its weakening. At the same time, most reactions with C₆₀Cl₆ consist of the replacement of all five chlorine atoms surrounding the five-membered ring with retention of the chlorine atom in the ring. This is due to the fact that elimination of this atom as the chloride anion should give rise to a fragment of the cyclopentadienyl cation with pronounced antiaromatic properties. By contrast, elimination of other chlorine atoms affords stable allyl-type cations.

Syntheses of a series of polychloro derivatives of fullerene C₆₀ with a larger number of chlorine atoms [for example, C₆₀Cl₈, C₆₀Cl₁₀,⁹⁴ C₆₀Cl₁₂,^{4,94,97} C₆₀Cl₁₄,^{94,97} C₆₀Cl₂₄,² C₆₀Cl₂₆ (Ref. 94)] were documented. However, only indirect evidence for the formation of these molecules was presented, and these data can be interpreted ambiguously. Higher polychlorofullerenes, *viz.*, T_h-C₆₀Cl₂₄, C₁-C₆₀Cl₂₈, C₂-C₆₀Cl₃₀ and D_{3d}-C₆₀Cl₃₀ (see Fig. 5), have been synthesised and structurally characterised only very recently.⁷⁴ These compounds can be prepared by heating fullerene with such chlorinating agents as ICl, PCl₅, SbCl₅, VCl₄, KICl₄, MoCl₅ or VOCl₃.^{74,98} Polychlorofullerene T_h-C₆₀Cl₂₄ is isostructural to the halogeno derivatives T_h-C₆₀Br₂₄ and T_h-C₆₀F₂₄. The structure of the compound D_{3d}-C₆₀Cl₃₀ (see Fig. 5b) contains two benzenoid poles and the [18]trannulene ‘equator’ (see Section III.2.c) with a high degree of delocalisation. The aromatic character of these fragments is confirmed by the C–C bond lengths (1.368 and 1.375 Å in the six-membered rings and 1.386 and 1.392 Å in the trannulene ring).⁹⁹ In the D_{3d}-C₆₀Cl₃₀ molecule, the C=C double bonds are involved only in aromatic rings, due to which this polychlorofullerene is thermally more stable (*T*_{decomp} = 450–500 °C) than other polychlorofullerenes (*T*_{decomp} = 280–350 °C).^{74,99,100} Although the reactivity of these compounds remains unstudied, their unusual structures will undoubtedly attract attention of researchers in the nearest future.

4. Synthesis and structures of polybromo[60]fullerenes

Polybromo[60]fullerenes can be synthesised by the reaction of C₆₀ with liquid bromine or its solution in an appropriate

solvent. For example, dissolution of C_{60} in liquid Br_2 affords orange crystals of $C_{60}Br_{24} \cdot n Br_2$.⁷

The structure of $C_{60}Br_{24}$ was established by X-ray diffraction.^{7, 101} All the attached bromine atoms are located in the fullerene cage so that 1,2 contacts between these atoms are absent (Fig. 6a). There is the only possible arrangement for 24 attached bromine atoms without 1,2 contacts. It corresponds to the structure with high symmetry T_h . The average C—Br, C—C and C=C bond lengths are normal for these types of bonds (1.994, 1.510 and 1.344 Å, respectively). Further addition of the bromine atoms leads to appearance of 1,2 contacts between these atoms, and, as a result, to destabilisation of the molecule due to strong steric strains caused by repulsions between the bulky substituents. Therefore, the highest degree of bromination of C_{60} is apparently achieved in polybromofullerene $C_{60}Br_{24}$.

Bromination of [60]fullerene by molecular bromine in some organic solvents affords polybromofullerenes $C_{60}Br_6$ and (or) $C_{60}Br_8$, the selectivity being dependent on the nature of the solvent.⁵ In CS_2 or $CHCl_3$, dark-brown crystals of $C_{60}Br_8$ containing solvated bromine molecules precipitate from the reaction mixture (in 80% and 50% yields, respectively).⁵

Bromination of C_{60} in benzene or CCl_4 gives rise to $C_{60}Br_6$ (in ~50% and 92% yields, respectively) as dark-claret plates.⁵

In the study cited,⁵ the observed selectivity of the formation of polybromofullerenes in various solvents was attributed to selective precipitation of insoluble polybromofullerene, due to which it does not undergo further transformations. However, more recent investigations demonstrated¹⁰² that the reagent ratio also has a principal effect on the selectivity of formation of polybromofullerenes. In particular, both $C_{60}Br_6$ and $C_{60}Br_8$ were synthesised in nearly quantitative yields with the use of 1,2-dichlorobenzene as the solvent in the reactions with a 40- and 400-fold excess of Br_2 , respectively.¹⁰²

The structures of polybromofullerenes $C_{60}Br_6$ and $C_{60}Br_8$ (see Fig. 6b,c) were unambiguously established by X-ray diffraction.^{5, 101, 103} The molecules have C_s and C_{2v} symmetry, respectively. The C—Br bond lengths vary in a narrow range (1.986–1.998 Å). The changes in the C—C bond lengths in the molecule C_s - $C_{60}Br_6$ compared to those in C_{60} fullerene are substantial only for the brominated hemisphere, the largest elongation being observed for the bonds involving sp^3 -hybridised carbon atoms. Five bromine atoms surround the five-membered ring containing the butadiene fragment with two double $C(sp^2)=C(sp^2)$ bonds (1.350 Å) and one elongated $C(sp^2)-C(sp^2)$ single bond (1.462 Å). The characteristic features of the addition pattern of the bromine atoms in the molecule C_{2v} - $C_{60}Br_8$ are responsible for the presence of the isolated $C=C$ double bonds with typical lengths of 1.333 and 1.339 Å in the brominated fragment of the fullerene cage. The $C(sp^2)-C(sp^3)$ bonds of predominantly ordinary character have an average length of 1.510 Å. The remote region of the fullerene sphere is characterised by the C—C bond lengths typical of [60]fullerene.

Polybromofullerenes are the thermally least stable polyhalo derivatives of fullerenes and decompose to give C_{60} and molecular bromine upon heating to 100–200 °C, the thermal stability being increased in the series $C_{60}Br_6 < C_{60}Br_8 < C_{60}Br_{24}$.^{7, 102} Polybromofullerenes are characterised by low solubility and low stability in solution, which limits their use in organic synthesis.⁸⁹⁻

III. Reactions of $C_{60}F_{18}$ and other polyfluoro[60]fullerenes

In the previous sections, it was noted that $C_{60}F_{18}$ is a synthetically accessible, rather stable and reactive polyfluorofullerene. Its structure is characterised by the presence of a flattened fluorine-substituted fragment and the unfluorinated fullerene hemisphere. These structural features are responsible for the diversity of chemical transformations of this compound, such as redox, nucleophilic substitution, arylation and cycloaddition reactions. Hence, it is not surprising that the chemical properties of this compound have been studied in most detail. In addition to $C_{60}F_{18}$, scarce published data on the chemical properties of other polyfluoro[60]fullerenes are considered below.

1. Redox reactions

It is known that C_{60} fullerene exhibits oxidation properties and forms the $C_{60}^{\cdot -}$ radical anion at a relatively positive potential [the first half-wave potential $E_{1/2}^I = -0.59$ V in CH_2Cl_2 vs. the saturated calomel electrode (SCE)].^{18, 19, 21} The addition of electronegative groups to the fullerene cage should, on the

Figure 6. Three-dimensional structures and the Schlegel diagrams of polybromofullerenes T_h - $C_{60}Br_{24}$ (a), C_{2v} - $C_{60}Br_8$ (b) and C_s - $C_{60}Br_6$ (c).

whole, lead to an increase in electron-withdrawing properties. As a result, the reduction potentials of polyfluorofullerenes are more positive. This shift achieves 1.38 V for C₆₀F₄₈ against C₆₀.²¹ The high electron affinity of polyfluorofullerenes is also confirmed by the fact that long-lived polyfluorofullerene dianions^{20, 21, 104–106} and even the C₆₀F₄₈^{3–} trianion¹⁷ were detected in the gas phase by mass spectrometry.

The processes that occur during electrochemical reduction of polyfluorofullerene C₆₀F₄₈ were studied in detail.²¹ One-electron reversible reduction of C₆₀F₄₈ giving rise to the C₆₀F₄₈^{•–} radical anion occurs at the potential $E_{1/2}^I = 0.79$ V (CH₂Cl₂, SCE). Since the reduction potential of C₆₀F₄₈ is more positive than the oxidation potentials of the I[–]/I₃[–] (0.26 V, SCE) and I₃[–]/I₂ pairs (0.65 V, SCE), the reaction of C₆₀F₄₈ with the iodide anion occurs with elimination of molecular iodine.^{21, 107} This process is accompanied by the formation of the long-lived (> 20 s) C₆₀F₄₈^{•–} radical anion.

Further reduction of C₆₀F₄₈ at potentials $E_{1/2}^{II} = 0.44$, $E_{1/2}^{III} = 0.37$ and $E_{1/2}^{IV} = -0.12$ V (CH₂Cl₂, SCE) leads to irreversible processes accompanied by defluorination of polyfluorofullerenes.²¹ To elucidate the mechanism of these processes, the reaction products of C₆₀F₄₈ with various reducing agents were studied by electrospray ionisation mass spectrometry. The reducing agents were chosen in such a way that their oxidation potentials were as close to the potential of the corresponding process as possible. For example, reduction of C₆₀F₄₈ with ferrocene (Fc) with the oxidation potential [$E(\text{Fc}/\text{Fc}^+) = 0.31$ V vs. SCE] close to the second reduction potential of polyfluorofullerene affords the C₆₀F₄₇[–] anion. It was hypothesised that the reaction initially produces the unstable C₆₀F₄₈^{2–} dianion, which decomposes to form the F[–] and C₆₀F₄₇[–] anions. The latter yields C₆₀F₄₇^{2–}. The reaction of C₆₀F₄₈ with the stronger reducing agent, viz., decamethylferrocene [$E(\text{DmFc}/\text{DmFc}^+) = -0.11$ V vs. SCE], produces C₆₀F₄₆^{2–}. In the authors' opinion, the latter is formed as a result of elimination of F[–] from the initially formed C₆₀F₄₇^{3–} trianion. The schemes of the reactions involved in the successive reduction of C₆₀F₄₈ and their reduction potentials in CH₂Cl₂ vs. SCE are given below.

It should be noted that the process is not stopped at this moment, and the percentage of polyfluorofullerenes containing a smaller number of fluorine atoms increases with time.

Electrochemical transformations of polyfluorofullerenes containing smaller amounts of halogen have been investigated.^{16, 18, 19, 108} Reduction of these compounds was demonstrated to be accompanied by a loss of fluorine atoms. For example, the reaction of C₆₀F₁₈ with chloroanil produces the C₆₀F₁₇[–] ion,¹⁰⁸ and reduction of C₆₀F₂ and C₆₀F₄ affords the C₆₀^{•–} anion.¹⁸

The reduction potential of polyfluorofullerenes monotonically increases with increasing number of the attached fluorine atoms or upon introduction of other electron-withdrawing fragments into the molecule (Table 2). The arrangement of the fluorine atoms at the fullerene cage also has an effect on the potential. For example, of the three studied isomers of C₆₀F₃₆, it is most difficult to reduce the *T* isomer; the *C*₁ and *C*₃ isomers are reduced at 30 and 80 mV higher potentials, respectively.¹⁰⁸ This fact correlates with higher chemical stability of the *T*-C₆₀F₃₆ isomer compared to the *C*₁ and *C*₃ isomers (see Section III.2.a).^{109, 110}

Interesting results were obtained in the study of the trannulene dyads C₆₀F₁₅[C(CO₂Et)₂CO₂R]₃ (R = Et, pyrene-,

perylene-, ferrocene- or tetrathiafulvalene-containing fragments).^{14, 22, 111} The first reduction potential of these compounds corresponding to the single-electron reversible transfer varies from –0.005 to –0.10 V (CH₂Cl₂, SCE), which is substantially higher than the reduction potential of C₆₀F₁₈ (–0.33 V, CH₂Cl₂, SCE).¹⁰⁸ The observed process is attributed to reduction of the [18]trannulene fragment in the compounds under study.

Polyfluorofullerenes are stronger oxidising agents than fullerene, which was demonstrated back in early studies. A mixture of higher polyfluorofullerenes C₆₀F₄₄ and C₆₀F₄₆ was found to oxidise the iodide anion to I₂.¹⁰⁷ Reduction of polyfluorofullerenes is accompanied by a loss of fluorine atoms to form a complex mixture of compounds, from C₆₀F₃₆ to C₆₀F₄₀. The reactions of higher polyfluorofullerenes with Br[–] proceed with difficulty and are accompanied by elimination of only a small amount of Br₂.

Organic compounds can also be oxidised and even fluorinated by higher polyfluorofullerenes. For example, heating of a mixture of C₆₀F₄₄ and C₆₀F₄₆ in PrOH affords acetone,¹⁰⁷ whereas heating of solutions of polyfluorofullerenes in aromatic solvents in the presence of Lewis acids leads to defluorination of fullerenes^{112–114} accompanied by partial fluorination of solvent molecules. Under these conditions, even pyridine, which exhibits low reactivity in electrophilic substitution reactions, gives 2-fluoropyridine in a yield of up to 10%.¹⁰⁷ In the presence of higher polyfluorofullerenes, polymerisation of THF occurs;^{87, 110, 115} an analogous process is also observed upon dissolution of these compounds in acetone (in the latter case, a polymer is formed as a result of aldol condensation induced by HF).¹

Therefore, polyfluorofullerenes are very strong oxidants, the redox reactions involving these reagents being accompanied by defluorination of the starting polyfluorofullerenes. The degree of defluorination is generally determined by the strength of the reducing agent and the possibility of competitive substitution and addition reactions. Some other examples of reduction of polyfluorofullerenes observed in the course of nucleophilic substitution and cycloaddition reactions are given in Sections III.2 and III.4.a.

2. Nucleophilic substitution reactions

The mechanisms of nucleophilic substitution in polyhalofullerenes are virtually unknown. The ideas about the processes involved in these reactions changed with time. However, numerous uncertainties and ambiguities concerning these

mechanisms still persist. The problem is that the substitution of different nucleophiles and polyhalofullerenes occurs apparently by different pathways. Hence, there is good reason to discuss the most probable mechanisms of these reactions in the present review. We expect that further experimental studies will provide conclusive information on these mechanisms.

a. Reactions with O-nucleophiles

Even in early studies, it was found that polyfluorofullerenes, which have initially been believed to be chemically inert, are involved in nucleophilic substitution reactions.^{56, 86, 115, 116} These reactions have been discovered accidentally. The mass spectrometric analysis of fluorination products of C₆₀ fullerene revealed the presence of oxopolyfluoro derivatives containing from 1 to 18 oxygen atoms.^{8, 57, 117}

It is unlikely that oxygen atoms are inserted into polyfluorofullerene molecules upon oxidation by atmospheric oxygen because solid samples of polyfluorofullerenes were found^{29, 59, 86} to be unchanged in air for an indefinitely long period of time. However, dissolution of highly fluorinated fullerenes in polar solvents (for example, THF) containing traces of water is accompanied by an exothermic reaction resulting in a loss of fluorine atoms.^{110, 115} Hence, it was hypothesised that oxo derivatives of polyfluorofullerenes are formed through the nucleophilic displacement of F by OH followed by elimination of HF from the adjacent F and OH substituents.^{57, 115, 116} This transformation occurs so easily that oxopolyfluorofullerenes have long been considered as primary reaction products.^{57, 117} However, hydroxypolyfluorofullerenes are precursors of these compounds, as has been recently exemplified by the individual isomers C₃- and C₁-C₆₀F₃₆.¹⁰⁹

The discovery of 'accidental'³⁴ epoxidation of polyfluorofullerenes has inflated studies of targeted nucleophilic displacement of fluorine atoms by oxygen-containing nucleophiles. It was found that C₆₀F₃₆ (Ref. 40) and higher polyfluorofullerenes^{115, 116} are easily hydrolysed in the presence of organic co-solvents (the presence of the latter is necessary because polyfluorofullerenes are insoluble in water). For example, dissolution of C₆₀F₃₆ in wet toluene or chloroform affords the compounds C₆₀F₃₅OH, C₆₀F₃₃(O)OH and C₆₀F₃₂(O)₂.¹¹⁸ The treatment of polyfluorofullerenes with methanolic NaOMe leads to methoxydefluorination. The nucleophilic displacement of fluorine atoms with sodium acetate in acetic acid was also documented.¹¹⁵ Therefore, unlike polyfluoroalkanes and most of their derivatives, polyfluorofullerenes are rather good substrates for nucleophilic substitution reactions. The mechanism of this reaction deserves a detailed discussion.

The nucleophilic substitution involves the carbon–leaving group bond cleavage and the carbon–nucleophile bond formation. These processes can be either concerted (the so-called S_N2 mechanism) or sequential. The concerted mechanism is impossible for polyhalofullerenes because it involves the backside attack of a nucleophile with respect to the leaving group, *i.e.*, from the inside of the fullerene sphere. In early studies on nucleophilic substitution in polyhalofullerenes, the direct nucleophilic displacement of halogen has been believed to be a result of the frontal attack of a nucleophile. However, this mechanism was rejected in more recent studies. Actually, the frontal attack of a nucleophile is a forbidden process according to the orbital symmetry rules. *Ab initio* quantum chemical studies with an extended basis set taking into account diffuse and polarisation functions demonstrated that the energy barrier to the frontal attack is 165–190 kJ mol^{−1} higher than that to the backside attack even in simplest halomethanes.¹¹⁹

Nucleophilic substitution reactions at a carbonyl carbon atom or at a silicon atom proceed by an addition–elimination mechanism (the leaving group is eliminated only after the

formation of a bond with a nucleophile). However, it is evident that this mechanism is impossible for polyfluorofullerenes. The S_N1 mechanism can also be rejected. First, the formation of carbocations from electron-deficient polyfluorofullerenes in the absence of Lewis acids is hardly probable. Second, the substitution reaction rate was found to depend on the strength of a nucleophile. For example, up to 65% of fluorine atoms are replaced in the reaction with sodium methoxide in methanol for 12 h, whereas only 15% of fluorine atoms are replaced in the reaction with the weaker nucleophilic agent, *viz.*, sodium acetate, in acetic acid (which is often used as the solvent in S_N1 reactions) even after 550 h.¹¹⁵

The nucleophilic substitution reaction can be considered as a single-electron transfer from a nucleophile to the leaving group. Before the reaction, the nucleophile bears a lone electron pair, whereas the leaving group contains one electron of the R–X bond. After completion of the reaction, the nucleophile bears one electron of the R–Y bond, whereas the leaving group contains a lone electron pair. This electron density shift can occur either simultaneously with the bond cleavage–formation steps or independently of these processes (or one of these processes).

All possible nucleophilic substitution mechanisms can be represented by a three-dimensional reaction diagram (Fig. 7).^{120–122} The degree of the R–Y bond formation is on the *x* axis; the degree of the R–X bond cleavage, on the *y* axis; the degree of electron density transfer from one fragment to another, on the *z* axis. The S_N1 mechanism is described by the movement of the system from the point *A* to the point *C* through the point *B*. The movement along the *ADC* path corresponds to the addition–elimination mechanism. The transformation of the system from the state *A* to the state *C* without intersections of other nodes in the diagram corresponds to the concerted S_N2 reaction.

If the electron shift from the nucleophile (Y:) to the substrate (RX) is not accompanied by the Y–R bond formation and the R–X bond cleavage, the mechanism involves the single-electron transfer (path *A–F*). If the electron shift is not accompanied by the formation of the Y–R bond but is accompanied by the cleavage of the R–X bond, the mechanism involves the dissociative electron transfer (path *A–G*). The strong electron-withdrawing properties of fullerene and, particularly, of polyfluorofullerenes suggest the possibility of the single-electron transfer mechanism.

Figure 7. Three-dimensional reaction diagram for nucleophilic substitution reactions. See comments in the text.

The single-electron transfer from various donors to polyfluorofullerenes is rather well known (see Section III.1).^{16, 18, 19, 21} These reactions are usually accompanied by complete or partial defluorination. Actually, it was found that hydrolysis of S_6 - and D_3 - $C_{60}F_{48}$ in aqueous acetone affords a complex mixture of products, including $C_{60}F_{42}O$, $C_{60}F_{40}O$, $C_{60}F_{38}O$, *etc.*¹¹⁰ These data can be considered as evidence for the single-electron transfer mechanism in the case of hydrolysis of the strongest electron-withdrawing polyfluorofullerene, $C_{60}F_{48}$.

The C_{3v} - $C_{60}F_{18}$ and T - $C_{60}F_{36}$ compounds are stable with respect to hydrolysis. Hydrolysis of the C_3 and C_1 isomers of $C_{60}F_{36}$ proceeds without a loss of additional fluorine atoms.^{109, 110} This would be impossible in the case of the single-electron transfer mechanism. Consequently, the nucleophilic substitution reactions of these substrates proceed by another pathway. A comparison of the structures of the T - $C_{60}F_{36}$ isomer, which withstands hydrolysis, and the hydrolysable isomers C_3 - $C_{60}F_{36}$ and C_1 - $C_{60}F_{36}$ (see Fig. 1 *c-e*) gives the answer to this question. In the T - $C_{60}F_{36}$ molecule, all double bonds adjacent to the fluorine atoms are involved in the aromatic benzenoid six-membered rings. This isomer contains only $Ph-C(F)RR'$ -type fragments. In two other isomers, there are three isolated double bonds containing the $C(F)RR'$ fragment in the allylic position. It is known that nucleophiles can attack allyl halides both at the α - and γ -carbon atoms. The latter attack leads to the shift of the $C=C$ double bond (the so-called S_N2' mechanism). The nucleophilic substitution in polyhalofullerenes should proceed by this mechanism.

Actually, dissolution of C_3 - $C_{60}F_{36}$ in wet toluene affords C_1 - $C_{60}F_{35}OH$ (**1**), which is consistent with the S_N2' mechanism.¹⁰⁹

The isomers of hydroxypolyfluorofullerene C_1 - $C_{60}F_{35}OH$, *viz.*, compounds **1** and **2** (Fig. 8), obtained upon hydrolysis of C_3 - and C_1 - $C_{60}F_{36}$, respectively, were isolated and characterised.¹⁰⁹ It was found that only the allylic fluorine atoms are

Figure 8. The Schlegel diagram of C_1 - $C_{60}F_{35}OH$ (**2**).

replaced. On the contrary, the fluorine atoms that are surrounded only by other fluorine atoms or benzenoid rings remain intact.

Compounds **1** and **2** easily undergo dehydrofluorination to give $C_{60}F_{34}O$. In this case, the oxygen atom is, apparently, involved in the epoxide ring. However, it should be borne in mind that some oxopolyfluorofullerenes generated as by-products in fluorination reactions of [60]fullerene, *viz.*, $C_{60}F_{2n}O$ ($n = 1-4$),⁴⁵ $C_{60}F_{18}O$ ⁸⁰ and $C_{60}F_{36}O$,¹⁰⁹ contain an oxygen atom as an intramolecular ether group.

It was hypothesised^{36, 57} that epoxide is formed by elimination of HF from the adjacent OH and F groups. Therefore, the overall process of epoxide formation is described by reaction (1).

However, we are doubtful about this mechanism because the formation of the epoxide ring from halohydrins generally occurs by the S_N2 mechanism, which, as demonstrated above, is impossible in the case under consideration. Hence, the S_N2' mechanism described by reaction (2) seems to be more probable. Unfortunately, it is impossible to draw an unambiguous conclusion about the mechanism of this step because it is necessary to establish the structures of the resulting epoxides.

The further substitution of fluorine atoms can also occur. The $C_{60}F_{33}(O)OH$ and $C_{60}F_{32}O_2$ compounds were also detected among the hydrolysis products of the polyfluorofullerene $C_{60}F_{36}$.¹¹⁸ The formation of these compounds is accompanied by migration of double bonds, which destabilises the molecule as a whole. Hence, the percentage of the latter compounds is low.

The analogous S_N2' mechanism of the substitution of fluorine atoms is observed for dissolution of D_3 - and S_6 - $C_{60}F_{48}$ in THF or acetone in the presence of water.¹¹⁰ This treatment leads to the replacement of up to 12 halogen atoms. This is consistent with the presence of six double bonds, for which the S_N2' mechanism is possible. Subsequent elimination of HF gives fragments containing up to six epoxide rings.

Calculations of the formation energies of possible intermediates containing a hydroxy group demonstrated that the energy difference between these intermediates is small. Consequently, hydrolysis of $C_{60}F_{48}$ can afford complex mixtures of isomers.¹¹⁰

Thus, the nucleophilic substitution in polyfluorofullerenes occurs by the S_N2' mechanism or *via* the electron transfer and is possible only in the presence of the activated carbon–carbon double bond that is not involved in the aromatic ring and occupies the β position with respect to the leaving atom. Hence, the C_3 - and C_1 - $C_{60}F_{36}$ isomers containing three allylic fragments are much more reactive in nucleophilic substitution reactions than T - $C_{60}F_{36}$ in which the π -electron density is completely delocalised over the aromatic rings. It should also be noted that the double bonds containing several fluorine atoms in the nearest environment are more reactive. As a result, O-nucleophiles react more readily with higher polyfluorofullerenes than with lower polyfluorofullerenes, in particular, with $C_{60}F_{18}$, which are less reactive in these reactions.^{109, 110}

b. Reactions with N-nucleophiles

The reactions of polyfluorofullerenes with N-nucleophiles are less studied than the reactions with O-nucleophiles. It is known that higher polyfluorofullerenes react readily with primary and secondary amines. For example, up to 55% of fluorine atoms are substituted in reactions of higher polyfluorofullerenes with Et_2NH during 1 h (^{19}F NMR spectroscopic data), and the percentage of the replaced fluorine atoms increases to 65% when the reaction time is increased to 12 h.¹¹⁵ Pyridine also reacts slowly with higher polyfluorofullerenes $C_{60}F_{44}$ – $C_{60}F_{46}$ with selective formation of 2-fluoropyridine.¹⁰⁷ To explain this fact, the authors suggested the mechanism involving the N addition followed by the migration of the fluorine atom.

This unexpected result may be of importance in the preparative chemistry of pyridine, because it is virtually impossible to synthesise 2-fluoropyridine by other methods. Besides, this is the first example of the use of higher polyfluorofullerenes as fluorinating agents for heterocyclic compounds.

c. Reactions with C-nucleophiles

Reactions with organometallic compounds. The formation of a new carbon–carbon bond is the most important reaction in synthetic chemistry of fullerenes. Hence, the reactions with C-nucleophiles attract the largest interest among nucleophilic substitution reactions of polyfluorofullerenes. Alkyl- and aryllithium compounds are known to be very reactive nucleophiles. In an early study on the chemical properties of polyfluorofullerenes,¹¹⁵ it was demonstrated that these compounds react readily with typical C-nucleophiles, such as Grignard reagents and organolithium compounds. However, the products have not been isolated and analysed. Further detailed studies on the reaction of polyfluorofullerenes $C_{60}F_{44}$ – $C_{60}F_{46}$ with alkyllithium reagents showed that this is one of the most efficient routes to polymethylated and polyphenylated [60]fullerenes with high degree of addition.¹²³

Products with the compositions $C_{60}Me_n$ ($n = 2$ –28) and $C_{60}Ph_n$ ($n = 2$ –20) were synthesised by the reactions of a mixture of polyfluorofullerenes $C_{60}F_{44}$ – $C_{60}F_{46}$ with an excess of MeLi and PhLi, respectively.¹²³ The formation of compounds with the number of methyl (phenyl) groups smaller than the number of fluorine atoms in the starting polyfluorofullerene is evidence for partial defluorination of the substrate in the course of the reaction. This suggests that the reactions of polyfluorofullerenes with organolithium compounds proceed by the single-electron transfer mechanism. This reaction pathway is also supported by the fact that a considerable amount of biphenyl was detected in the reaction with phenyllithium.¹⁰⁷ Fullerene methylation (or phenylation) products are orange (or brown), very readily soluble in non-polar organic solvents, thermally stable at least up to 300 °C and storage-stable in air over a long period of time. It is of note that refluxing of polyfluorofullerenes in diethyl ether for 3 h is required to achieve the complete substitution of methyl groups for all fluorine atoms. At room temperature, mixed derivatives $C_{60}F_xMe_y$ are formed. The necessity of prolonged heating of the reaction mixture for the complete substitution of fluorine atoms is attributed to the fact that the electron-withdrawing properties of fullerene are decreased as the degree of substitution of methyl groups for the fluorine atoms increases and, as a consequence, to the incomplete reaction under milder conditions (*cf.* Ref. 115).

Arylation of $C_{60}F_{18}$. An alternative procedure for the introduction of aryl substituents into the fullerene cage is the Friedel–Crafts reaction. In this reaction, polyfluorofullerenes and aromatic compounds act as electrophiles and nucleophiles, respectively. In other words, the arylation reactions of polyfluorofullerenes belong to nucleophilic substitution reactions. Many arylated fullerenes, which are of practical interest, were synthesised by the reactions of fullerenes or polyhalofullerenes with aromatic compounds in the presence of Lewis acids. Arylfullerenes are soluble in organic solvents and storage-stable.

The Friedel–Crafts reaction with polyhalofullerenes was first described for polychlorofullerenes² (arylation of polychlorofullerenes is considered in detail in Section IV.1). Since alkyl fluorides are more reactive in the Friedel–Crafts reaction than analogous chlorides,¹²⁴ it can be expected that polyfluorofullerenes would also be involved in this reaction. Actually, it was found that the electrophilicity of polyhalofullerenes increases in the series $Br < Cl < F$.¹²⁵

It can also be expected that of all polyfluorofullerenes the lower polyfluorofullerenes would be most reactive in the Friedel–Crafts reaction because fluorine atoms in these compounds are sterically more accessible. For example, $C_{60}F_{18}$ reacts with benzene in the presence of $FeCl_3$ at room temperature. On the contrary, attempts to replace fluorine atoms in higher polyfluorofullerenes $C_{60}F_{36}$ and $C_{60}F_{48}$ by phenyl groups using the Friedel–Crafts reaction failed.¹¹²

The trefoil-shaped triphenyl derivative $C_{60}F_{15}Ph_3$ (**3**), which was called triumphene (Fig. 9), was isolated from arylation products of polyfluorofullerene C_{3v} - $C_{60}F_{18}$ and completely characterised.¹¹²

Based on the ^{19}F NMR spectroscopic data, which are indicative of the C_{3v} symmetry of this molecule, evidence for the direct nucleophilic substitution of fluorine atoms according to the S_N1 mechanism was reported.¹¹² This mechanism is facilitated by the Friedel–Crafts catalyst. An increase in the reaction temperature results in the formation of $C_{60}Ph_{18}$, in which all fluorine atoms are replaced by phenyl groups. It was hypothesised^{36, 112} that, in spite of presumable steric hindrance, the phenyl groups occupy the positions of fluorine atoms in the precursor. However, this is doubtful. The mass spectra of the reaction products show a low-intensity peak of

Figure 9. The Schlegel diagram of $C_{3v}\text{-C}_{60}\text{F}_{15}\text{Ph}_3$ (**3**).

the $\text{C}_{60}\text{Ph}_{19}^+$ ion. Apparently, this compound is formed as a result of further phenylation of the fullerene cage. This reaction is analogous to the well-known reaction of fullerene with benzene in the presence of AlCl_3 .⁹³ In addition, $\text{C}_{60}\text{F}_{15}\text{Ph}_7$ and other phenylation products of polyfluorofullerene were detected in the reaction mixture.¹¹²

In studies of the reaction of polyfluorofullerene $\text{C}_{60}\text{F}_{18}$ with a wide range of aromatic compounds catalysed by FeCl_3 , mono-, bis- and tris(aryl) derivatives **4**–**6** (Fig. 10) were detected.^{112, 113} The results of these experiments are summarised in Table 3.

The degree of substitution of F atoms depends on the nature of the aromatic reagent. For example, the reactions of $\text{C}_{60}\text{F}_{18}$ with bulky arenes, such as naphthalene, biphenylene, pyrene or fluoranthene, yield monosubstituted compounds **4** as the major products. On the contrary, bis- (5) and/or trisubstituted (**6**) products dominate in the reactions of $\text{C}_{60}\text{F}_{18}$ with smaller arenes, such as benzene, chloro- and 1,2-dichlorobenzenes, toluene, biphenyl, fluorene, *etc.* Some aromatic compounds do not give arylation products because of steric hindrance (for example, mesitylene), self-condensation side reactions¹¹³ or low reactivity of the substrate (for example, trifluoromethylbenzene). Serious steric hindrance or self-con-

densation and chlorination of arenes in the presence of FeCl_3 as side reactions precluded synthesis of the substitution products of $\text{C}_{60}\text{F}_{18}$ with thiophene, perylene and azulene.

The reactions of $\text{C}_{60}\text{F}_{18}$ with hydroxyl-containing aromatic compounds (phenol, hydroquinone and 2-naphthol) are not stopped after electrophilic defluoroarylation, but are accompanied by elimination of HF to give benzofuran derivatives of fullerene **7**, **8** and **9**, respectively (Fig. 11).^{113, 125} The elimination of HF was described as a result of the direct attack of the OH group on the F atom, which becomes adjacent to the 2-hydroxyphenyl substituent after the 1,3-shift (Scheme 1). The possibility of the 1,3-migration of the fluorine atom was exemplified⁶³ by the transformations of isomers of $\text{C}_{60}\text{F}_{36}$.

Scheme 1

An alternative step of dehydrofluorination of the intermediate **A** involves the attack of the OH group on the adjacent

Figure 11. The Schlegel diagrams of compounds 7–9 prepared by the reactions of $C_{60}F_{18}$ with phenol, hydroquinone and 2-naphthol, respectively.

double bond accompanied by the migration of the electron pair and elimination of the fluorine atom (S_N2' reaction). Taking into account the discussion in Section III.2.a, the second pathway seems to be more probable.

The reaction of $C_{60}F_{18}$ with 2-naphthol affords naphtho[2,1-*b*]furano[*d*-1,2][60]fullerene as a by-product, which is formed as a result of complete defluorination of polyfluorofullerene.¹²⁵ The formation of this compound can be considered as evidence for the competitive single-electron transfer from naphthol to polyfluorofullerene. This process is not observed in the reaction of $C_{60}F_{18}$ with water, because water molecules are hard acids and non-polarisable nucleophiles and are rarely involved in electron transfer reactions. To the contrary, readily oxidisable 2-naphthol is much more prone to donate electrons to an appropriate acceptor.

The reaction of $C_{60}F_{18}$ with benzene in the presence of $SbCl_5$ afforded the expected $C_{60}F_{15}Ph_3$ product (3) along with two oxygen-containing derivatives.¹¹⁴ One of these products is fluoroxyfullerene $C_{60}F_{14}OFPh_3$ (10) (Fig. 12); the second, a mixture of oxahomo derivatives (intramolecular ethers) $C_{60}F_{14}O_2Ph_3$.

Figure 12. The Schlegel diagram of $C_{60}F_{14}OFPh_3$ (10).

Anomalous Bingel reaction. Since $C_{60}F_{18}$ can serve as a precursor for the formation of donor–acceptor dyads having stronger electron-withdrawing properties, attempts were made to involve this compound in reactions, which are generally used for the synthesis of analogous structures from C_{60} . The Bingel reaction is most often used for this purpose. This reaction involves the nucleophilic addition of the stabilised α -halocarbocation to the fullerene cage followed by the intramolecular substitution of the halogen atom to give methanofullerenes.^{126, 127}

However, it appeared that the reaction of diethyl bromomalonate with $C_{60}F_{18}$ in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) proceeds by a mechanism different from the [2 + 1]-cycloaddition.¹² The reaction was found to give mono-, di- and trisubstitution products of diethyl bromomalonate groups for the fluorine atoms, *viz.*, the compounds $C_{60}F_{18-n}[CBr(CO_2Et)_2]_n$ ($n = 1–3$) (Fig. 13). The degree of substitution can be regulated by the rate of addition of the base.^{12, 128} Due to the presence of a leaving group (even a

Figure 13. The Schlegel diagrams of $C_{60}F_{17}[CBr(CO_2Et)_2]$ (a), $C_{60}F_{16}[CBr(CO_2Et)_2]_2$ (b) and $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ (11) (c).

poor leaving group, such as the fluoride anion) in fullerene, after the addition of the diethyl bromomalonate carbanion to the polyfluorofullerene cage the reaction proceeds not as cyclopropanation. This follows a pathway analogous to the S_N2' reaction considered above in the discussion of the formation of epoxides from polyfluorofullerenes in the presence of atmospheric moisture (see Section III.2.a).^{109, 110} The only difference is that the fluoride ion is eliminated as a result of the nucleophilic attack not on the γ -carbon atom, but on the more distant ε -carbon atom (to emphasise this fact, some authors used the notation S_N2'' mechanism, Scheme 2).^{12, 14, 129}

Scheme 2

Apparently, the attack of the bulky nucleophiles $-CBr(CO_2Et)_2$ on the γ -carbon atom (the S_N2' mechanism) is hindered due to steric effects caused by adjacent fluorine atoms. On the contrary, the attack on the ε -carbon atom (the S_N2'' mechanism) remote from fluorine atoms occurs without noticeable steric repulsions. As a result, one to three most sterically accessible fluorine atoms, which are adjacent to the double bond and are bound to carbon atoms bearing the largest positive charge are subjected to nucleophilic substitution in the $C_{60}F_{18}$ molecule. Semiempirical quantum chemical calculations by the AM1 and PM3 methods demonstrated¹²⁸ that among the carbon atoms of the $C_{60}F_{18}$ cage, the carbon atoms that lose fluorine atoms bear the largest positive charge. Of the fluorine atoms in the $C_{60}F_{18}$ molecule, the largest negative charges are accumulated on the leaving atoms.¹²⁸ Therefore, the reaction involves the successive replacement of three fluorine atoms and finally gives the trisubstituted product, which is not prone to further reactions.

The structure of the C_{3v} -symmetrical trisubstituted derivative $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ (**11**) established by X-ray diffraction deserves special attention.¹² This compound is characterised by the presence of the equatorial [18]annulene belt (see Fig. 13 c). Since all double bonds involved in the belt are in *trans* configurations, this fragment is called [18]trannulene according to the term proposed in the early theoretical study.¹³⁰ An analysis of the C—C bond lengths in the [18]trannulene fragment in $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ shows that these bonds are substantially equalised (the maximum difference is 0.018 Å) and vary from 1.392 to 1.410 Å. By contrast, these bonds in the starting $C_{60}F_{18}$ vary in a wider range (from 1.368 to 1.528 Å, *i.e.*, the difference is as large as 0.160 Å).³⁹

It should be noted that π -electron delocalisation in the [18]trannulene fragment resulting in the equalisation of the bond lengths can be explained as a result of the formation of a single aromatic π -system. However, commonly known aromatic systems are annulenes, in which C=C bonds are either in *cis* (for example, benzene), or *cis,trans* configurations (for example, [18]annulene). These conformations are more favourable because the π orbitals involved in aromatic conjugation are perpendicular to the plane of the annulene ring. Nevertheless, the possibility of the existence of aromatic systems, which are additionally stabilised due to overlap of the π orbitals lying in the $[n]$ annulene plane, has theoretically been predicted earlier.^{131, 132} In particular, it was theoretically demonstrated¹³⁰ that aromatic stabilisation can be achieved

by fixing the *trans* configuration of the $[n]$ annulene ring (*i.e.*, the formation of $[n]$ trannulene) upon its involvement in the molecular cage. The calculated geometry, energy and magnetic properties indicate that $[n]$ trannulenes obey the Hückel rule, *e.g.*, $(4n+2)$ π -electron systems are aromatic, whereas $4n$ π -electron systems are antiaromatic. Therefore, due to the rigid fullerene cage and the arrangement of the addends in the $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ molecule, [18]annulene adopts the *trans* configuration, which satisfies the Hückel rule, resulting in aromatic conjugation. The aromaticity of the [18]trannulene fragment in the $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ molecule leads to a slight bond-length alternation in this ring,^{12, 23} gives rise to the diamagnetic ring current induced by the external magnetic field¹³³ and leads to an increase in chemical stability of the $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ molecule compared to the starting polyfluorofullerene $C_{60}F_{18}$.^{23, 110} Analogous [18]trannulene structural fragments were found in the fullerene derivatives $D_{3d}-C_{60}Cl_{30}$,⁹⁹ $S_6-C_{60}[CMe(CO_2Et)_6]$ and $S_6-C_{60}[CMe.(CO_2Bu^t)_6]$ synthesised more recently.¹³⁴ The mono- and disubstituted products $C_{60}F_{18-n}[CBr(CO_2Et)_2]_n$ ($n = 1$ or 2), unlike trisubstituted compound **11**, do not contain the [18]trannulene belt because of the presence of $C(sp^3)$ atoms disrupting the equatorial π -conjugation system (see Fig. 13 a,b).

Turning back to the discussion of the Bingel reaction mechanism, it should be noted that the formation of the [18]trannulene fragment is one of the factors responsible for the regiochemistry of nucleophilic substitution in $C_{60}F_{18}$. Actually, one of the three most activated fluorine atoms can be subjected to the nucleophilic displacement through the attack of a nucleophilic species both on the ε - and γ -carbon atoms (see Scheme 2). However, the formation of the aromatic [18]trannulene fragment is possible only upon the addition of a nucleophile at the ε -carbon atom, resulting in additional thermodynamic and kinetic stabilisation of the fullerene. After the formation of $C_{60}F_{15}[CBr(CO_2Et)_2]_3$, the fluorine atoms that remain in the molecule are separated from double bonds by aromatic π -systems of the benzenoid and [18]trannulene rings, which prevents further nucleophilic substitution.

The nucleophilic displacement of three fluorine atoms in the C_{1v} - and C_s - $C_{60}F_{18}O$ isomers by $-CBr(CO_2Et)_2$ anions afforded the corresponding [18]trannulenes, *viz.*, C_{1v} - and C_s - $C_{60}F_{15}O[CBr(CO_2Et)_2]_3$, and these products were characterised.¹²⁹ These results demonstrate that the presence of the oxygen atom in the molecule results in neither steric nor electronic effects hindering the formation of trannulenes.

The reactions of $C_{60}F_{18}$ with a large number of malonates $HCX(CO_2R)_2$, with different ester $[R = Me, Et, PhCH_2$ or $3,5-(MeO)_2C_6H_3CH_2]$ and acceptor groups $[X = F, Cl, Br, CN, CO_2Et, NO_2, P(O)(OMe)_2, SO_2CH_2Ph$ or $C(O)CH_2.(CH_2Ph)]$, were studied to elucidate the influence of the nature of substituents and the size of the $-CX(CO_2R)_2$ carbanion on the possibility of the synthesis of trannulenes.^{14, 23, 129}

Almost all known malonates [except for oxomalonate $HC(C(O)CH_2CH_2Ph)(CO_2Et)_2]$ were found to be involved in nucleophilic substitution reactions with $C_{60}F_{18}$. The inactivity of the oxomalonate under these conditions was attributed to the keto–enol tautomerism of the reagent.¹⁴ The anions derived from fluoro- and cyanomalonates do not form trannulenes; instead, they give mono- or disubstituted products, *viz.*, $C_{60}F_{17}[CF(CO_2Et)_2]$, $C_{60}F_{17}[C(CN)(CO_2Et)_2]$ and $C_{60}F_{16}.[C(CN)(CO_2Et)_2]_2$, in low yields. Based on the differences in the ^{19}F NMR spectra of the fullerene derivatives $C_{60}F_{17}[C(CN)(CO_2Et)_2]$ and $C_{60}F_{17}[CBr(CO_2Et)_2]$, it was concluded¹²⁸ that cyanomalonate reacts at the γ position, *i.e.*, by the S_N2' mechanism.¹⁴ However, it should be noted that the determination of the structure of $C_{60}F_{17}[C(CN)(CO_2Et)_2]$ only from ^{19}F NMR spectroscopic data is insufficiently reliable.

The reactions of $C_{60}F_{18}$ with $HC(SO_2CH_2Ph)(CO_2Et)_2$ and $HC[PO(OMe)_2](CO_2Et)_2$ afford trannulene-containing products in low yields.¹⁴ The reaction of phosphorus-containing malonate is accompanied by dephosphonylation giving rise to $C_{60}F_{15}[CH(CO_2Et)_2]_3$. This is confirmed by the absence of signals in the ^{31}P NMR spectrum and resonances of the methoxy groups in the 1H NMR spectra of the isolated product. Since potassium fluoride is known to induce dephosphonylation of tertiary phosphonates,¹³⁵ dephosphonylation of the trannulene belt is apparently initiated by fluoride anions generated in the reaction.¹⁴

Good yields of the corresponding trannulenes ($\sim 30\%$) were achieved in the reactions of $C_{60}F_{18}$ with $HCBBr(CO_2R)_2$, where $R = CH_2Ph$ ¹²⁹ or $CH_2C_6H_3(OMe)_2$,²³ or with $HCHX(CO_2Et)_2$, where $X = Cl$,¹²⁹ Br ,^{12, 128} CO_2Et or NO_2 .¹⁴ It should be noted that an increase in the bulk of the ester group leads to a decrease in the degree of substitution in $C_{60}F_{18}$. This can be overcome by increasing the malonate-to-fullerene ratio or introducing a bridge into malonate, resulting in an increase in the distance between the bulky substituent and the carbanionic centre.²³

A series of trannulenes were synthesised by the reactions of $C_{60}F_{18}$ with methanetricarboxylates containing various photoactive functional groups.^{22, 23} Methanetricarboxylates serve as an attractive alternative to halo- and nitromalonates. The advantages of the latter compounds are low pK_a , high nucleophilicity of anions, the absence of the keto–enol tautomerism, a rather large steric demands and stability. To achieve the efficient formation of trannulenes from $C_{60}F_{18}$, CH-acids should meet these requirements.

The starting methanetricarboxylates can easily be synthesised from the corresponding alcohols (Scheme 3). Commercially available alcohols **12a–i** containing photoactive fragments were used. Treatment of these alcohols with ethyl malonyl chloride afforded the corresponding malonates **13a–i**, which were deprotonated and coupled with ethyl chloroformate to form methanetricarboxylates **14a–i**. Trannulenes **15a–i** were synthesised from methanetricarboxylates **14a–i** and $C_{60}F_{18}$.

The results of the above studies demonstrate that the larger the bulk of the substituent shielding the nucleophilic carbanionic centre, the larger the amount of methanetricarboxylate **14** required for the synthesis of trannulene. Attempts to use perylene ester **14h** for the synthesis of trannulene **15h** failed in spite of a variation of the reaction conditions over a wide range. In all cases, bis-adduct **16** was obtained as the major product due to the size of the perylene fragment (Scheme 4).

The steric barrier was overcome by removing the bulky fragment from the reaction centre after the introduction of the phenylacetylene bridge between the perylene moiety and the methanetricarboxylate group. For example, the reaction of ester **14i** with $C_{60}F_{18}$ in the presence of a base produces trannulene **15i** in 31% yield.

All compounds **15** are emerald-green, which is typical of fullerene trannulenes^{12, 23, 129, 134} due to intense absorption of the [18]trannulene fragment at 610–670 nm. In addition, the presence of this fragment leads to an increase in electron-withdrawing properties of the molecule, which is manifested in a substantial increase in the first potential of single-electron reversible reduction (from -0.005 to -0.10 V, CH_2Cl_2 , SCE)^{14, 22, 111} compared to that for $C_{60}F_{18}$ (-0.33 V, CH_2Cl_2 , SCE).¹⁰⁸ To summarise, fullerene trannulenes have better chromophoric properties, more efficiently stabilise the negative charge compared to traditional fullerene derivatives prepared by the Bingel reaction and retain low reorganisation energy for transition into the charge-separated state due to the rigid fullerene cage. Based on this fact, it was suggested that

Compound	14 : $C_{60}F_{18}$: DBU ratio	Yield of 15 (%)
a	1.0:1.0:1.0	41
b	1.6:1.0:1.3	34

e	1.5:1.0:1.0	28
f	1.8:1.0:1.7	26
g	1.6:1.0:1.3	28
h	2.0:1.0:1.7	traces
i	1.6:1.0:1.3	31

trannulene derivatives of $C_{60}F_{18}$ are promising molecular 'building blocks' for the design of components of single-electron devices, molecular switches and sensors.^{14, 22, 23, 136} In particular, studies of single-electron transfer in the tetrathiafulvalene–trannulene dyad demonstrated that these molecules can accumulate energy of photoexcitation in the long-lived (870 ns) charge-separated state.²² However, it should be borne in mind that the use of fullerene trannulenes as electron-withdrawing building blocks is sometimes complicated by considerable activation barriers to the transition into the charge-separated state.¹¹¹

In conclusion of this section, it should be noted that the anomalous Bingel reaction (synthesis of trannulenes) can be accompanied by the formation of classical cyclopropanation products. For example, the reaction of $C_{60}F_{18}$ with diethyl bromomalonate generated *in situ* (from diethyl malonate and CBr_4) in the presence of DBU affords the usual cyclopropanation product $C_1-C_{60}F_{18}C(CO_2Et)_2$ in low yield.¹²⁸ It was hypothesised that the classical Bingel reaction proceeds as a result of the attack of the carbanion on the fluorine-free fullerene hemisphere. In addition, the $C_{60}F_{16}C(CO_2Et)_2$ adduct, which was generated as a result of a loss of two fluorine atoms upon cyclopropanation, was detected. The formation of this compound was attributed to defluorination of $C_{60}F_{18}$ with a base.

3. Cycloaddition to lower polyfluoro[60]fullerenes

The development of efficient methods for the synthesis and isolation of lower polyfluorofullerenes in the individual state allowed investigation of a number of cycloaddition reactions, which are widely used for functionalisation of C_{60} .¹³⁷ On the one hand, the presence of a large number of the attached fluorine atoms in polyfluorofullerene molecules leads to a strong increase in the electron affinity of these compounds compared to C_{60} and, consequently, to an increase in their electron-withdrawing properties. On the other hand, the presence of large fluorine-free fragments of the fullerene cage in lower polyfluorofullerenes allows the cycloaddition reactions to proceed without substantial steric hindrance, which is unlikely in the case of higher polyfluorofullerenes. Therefore, lower polyfluorofullerenes would be expected to be involved in cycloaddition reactions analogously to C_{60} . Due to lower symmetry of polyfluorofullerenes, a larger number of isomeric products can be formed. In addition, the reactions with electron-donating reagents can be accompanied by competitive complete or partial defluorination of substrates.

a. [2 + 3]-Cycloaddition (the Prato reaction)

One of the most widely used methods for the fullerene cage functionalisation is based on the Prato reaction (annulation of the pyrrolidine ring by the reaction of fullerene with azomethine ylides derived from α -amino acid esters and carbonyl compounds).¹³⁸

The reaction of $C_{60}F_{18}$ with *N*-methylaminoacetic acid (sarcosine) and formaldehyde or benzaldehyde produced the corresponding fulleropyrrolidines, which were isolated and partially characterised by 1H and ^{19}F NMR spectroscopy.¹³⁹ It should be noted that, unlike the anomalous Bingel reaction,¹²⁸ the Prato reaction with $C_{60}F_{18}$ proceeds by a traditional pathway, no products of substitution or elimination of fluorine atoms being detected. Cycloaddition to the $C_{60}F_{18}$ molecule at the fluorine-free fullerene hemisphere affords mono- and bis-adducts.

To interpret the structures of the resulting cycloadducts, it is necessary to consider possible cycloaddition patterns of azomethine ylide at $C=C$ double bonds to form the pyrrolidine fragment. It is reasonable to exclude the double bonds involved in the benzenoid ring and the [5,6] bonds from consideration because the cycloaddition at these types of bonds reduces stabilisation due to aromatic conjugation and leads to an increase in strains in the fullerene cage. Consequently, the formation of a monoadduct can occur at one of four non-equivalent bonds, *a*, *b*, *c* or *d* (Fig. 14).

Two products prepared by annulation of the pyrrolidine ring to the $C_{60}F_{18}$ molecule (at the *a* and *c* bonds) should have C_s symmetry, whereas two other annulation products (the addition at the *b* and *d* bonds) are non-symmetrical. It is reasonable to suggest that steric hindrance does not allow the reaction to proceed at the *d* bond. Hence, the formation of three isomeric monoadducts would be expected; the bis-addi-

Figure 14. Possible cycloaddition sites in the $C_{60}F_{18}$ molecule.

tion would be expected to give five symmetrical and eight non-symmetrical bis-adducts.

Two monoadducts of three possible adducts were found experimentally (Fig. 15).¹³⁹ This reaction affords C_s -symmetrical monoadduct **17** as the major product as a result of the cycloaddition at the *a* bond most remote from the fluorine atoms. Non-symmetrical cycloadduct **18**, which is formed with the involvement of the *b* bond, is the minor product. The C_s -symmetrical cycloaddition product at the *c* bond was not detected in the reaction mixture. Apparently, the addition to this bond close to the flattened fragment of $C_{60}F_{18}$ leads to an increase in steric hindrance in the fullerene cage.

Figure 15. The Schlegel diagrams of the $C_{60}F_{18}(C_3H_7N)$ monoadducts.

Polycycloaddition products were also found, three C_s -symmetrical and four non-symmetrical bis-adducts being isolated. As in the case of monoadducts, the addition of azomethine ylide occurs predominantly at the *a* bond, whereas the addition products at the *c* and *d* bonds are absent. In other words, all bis-adducts are formed as a result of different cycloaddition patterns at the *a* and *b* bonds. For example, annulation of the pyrrolidine fragment at two *a* bonds (Fig. 16a) was proposed¹³⁹ for one of the C_s -symmetrical isomers, *viz.*, compound **19**. However, it should be noted that in this case the pyrrolidine rings are bound to one six-membered ring resulting in destabilisation of this isomer due to repulsion between these rings. Hence, it cannot be ruled out that C_s -symmetrical bis-adduct **19** is formed as a result of cycloaddition at the *b*₁, *b*₄ or *b*, *b*₁ bonds (see Fig. 16b). Unfortunately, no ^{13}C NMR spectroscopic data were reported.¹³⁹

The Prato reaction of $C_{60}F_{18}$ with sarcosine and benzaldehyde proceeds analogously to give a complex mixture of isomeric adducts.¹³⁹ Six major products and four minor

Figure 16. The Schlegel diagrams of two possible C_s -bis-adducts $C_{60}F_{18}(C_3H_7N)_2$ (**19**) (see the discussion in the text).

products were identified. These products were isolated in amounts insufficient for the structure elucidation.

Monoadduct **17** produced by the reaction of $C_{60}F_{18}$ with sarcosine and formaldehyde was unexpectedly detected in the reactions with other aldehydes.¹³⁹ This can be attributed to either the presence of an impurity of formaldehyde in sarcosine or the *in situ* formation of formaldehyde as a result of oxidation of sarcosine catalysed by fluorofullerene. The latter is evidenced by the fact that the major product (monoadduct) of the reaction of $C_{60}F_{18}$ with sarcosine and benzaldehyde is formed by refluxing a toluene solution of $C_{60}F_{18}$ with sarcosine in the absence of benzaldehyde in the reaction mixture! This result is attributed to the presence of traces of benzaldehyde in toluene (0.05%, HPLC data), the amount of which increases due to oxidation of toluene under the reaction conditions.

To summarize, the Prato reaction of lower polyfluorofullerenes is not accompanied by defluorination and produces complex isomeric mixtures of mono- and bis-adducts. The cycloaddition occurs predominantly at the sterically most accessible and fluorine-free fragment of the fullerene cage.

b. [2 + 4]-Cycloaddition reactions

Electron-deficient fullerene and its derivatives can be involved in the Diels–Alder reaction.^{140–142} Polyfluorofullerenes are no exception.^{13, 70} For example, refluxing of a toluene solution of $C_{60}F_{18}$ with anthracene under argon produced monocycloadducts **20** and **21**, which were isolated and partially characterised (in a ratio of 3:2, the total yield was 40%, Fig. 17).¹³ Anthraquinone was found among by-products. The latter compound was also detected in the reactions of anthracene with C_{60} and $C_{60}Cl_6$. Apparently, fullerene or its halogen derivatives either act as oxidants in these reactions or catalyse oxidation of anthracene.

In the electron ionisation mass spectra of **20** and **21**, the molecular ion peak is absent, but the spectra show ions corresponding to $C_{60}F_{18}$ and anthracene, which is evidence that thermodesorption is accompanied by the retro reaction. This process is also typical of cycloadducts of non-halogenated C_{60} .¹⁴²

The structures of monocycloadducts **20** and **21** were proposed based on the analysis of ¹H and ¹⁹F NMR spectroscopic data. In this case, as in the Prato reaction, defluorination products are not observed. The major C_s -symmetrical (**20**) and minor non-symmetrical (**21**) isomers are produced by cycloaddition at the *a* and *b* bonds, respectively (see Fig. 17). Quantum chemical calculations (by the semiempirical AM1 method) of the thermal effects of the Diels–Alder reactions of $C_{60}F_{18}$ with anthracene, butadiene or benzene confirmed that the cycloaddition at the *a* bond is more favourable and this adduct is more stable.¹⁴³ Cycloadducts **20** and **21** partially

Figure 17. The Schlegel diagrams of monocycloadducts formed in the the Diels–Alder reaction of $C_{60}F_{18}$ with anthracene.

decompose on storage. For example, the degree of decomposition of major compound **20** after two weeks of storage at room temperature is 5.5%. Minor product **21** is much less stable. Virtually immediately after isolation of compound **21** from the reaction mixture, a considerable amount of anthracene was detected by ¹H NMR spectroscopy. Moreover, spontaneous isomerisation of minor product **21** was observed. As a result, compound **20** and a new cycloadduct were obtained. The ¹⁹F NMR spectroscopic study demonstrated that the latter compound has C_s symmetry although it differs from major product **20**. Apparently, this product is generated by the retro Diels–Alder reaction followed by cycloaddition at the *c* bond.

Fullerene $C_{60}F_{20}$ is another promising substrate for cycloaddition reactions. Due to high D_{5d} symmetry of the $C_{60}F_{20}$ molecule, the monoadduct can be formed as a result of cycloaddition to one of two non-equivalent [6,6] bonds (see Fig. 1 g). Since the approach of the reagent to one of these bonds is sterically hindered, the only cycloadduct would be formed.

The [2 + 4]-cycloaddition reaction of anthracene with polyfluorofullerene $C_{60}F_{20}$ was demonstrated⁷⁰ to proceed only under illumination and in the presence of dissolved oxygen. Oxidised non-symmetrical cycloadduct **22** was obtained in a yield of <40%. The structure of this product was proposed based on ¹H and ¹⁹F NMR spectra (Fig. 18). The 'normal' C_s -symmetrical cycloadduct of anthracene and $C_{60}F_{20}$ was detected as an impurity.

Figure 18. Structure of cycloadduct **22** (for clarity, the C–F bonds are represented as stereobonds).

Scheme 5

4. Miscellaneous reactions

a. Unusual cycloaddition reactions

The use of tetrathiafulvalene (TTF) as an electron donor plays an important role in studies on the photoinduced electron transfer involving fullerene. Attempts to perform the reaction of $C_{60}F_{18}$ with tetrathiafulvalene led to the discovery of the previously unknown cycloaddition reaction.¹⁵ Concentration of a solution of $C_{60}F_{18}$ and tetrathiafulvalene in toluene afforded products **23** and **24**. The non-symmetrical [$C_{60}F_{16}$ -tetrathiafulvalene] adduct (**23**) was obtained as the major product (Scheme 5).

Apparently, this reaction involves at least two steps. Initially, $C_{60}F_{18}$ undergoes partial defluorination due to the redox reaction of $C_{60}F_{18}$ with tetrathiafulvalene. Indeed, dehalogenation of $C_{60}Cl_6$, $C_{60}Br_6$ or $C_{60}Br_8$ with tetrathiafulvalene has been documented earlier,¹⁴⁴ although the reaction products were not isolated and characterised. Intermediate polyfluorofullerene $C_{60}F_{16}$ exhibits high reactivity with respect to tetrathiafulvalene and gives the [2 + 2]-cycloaddition product.

Storage of product **23** leads to its rearrangement to form two compounds with identical molecular masses. The unstable minor adduct was not studied in detail. Major adduct **25**, which is formed upon elimination of the thioketene fragment from derivative **23**, is a new type of fullerene derivatives, *viz.*, thiirano[2,3-*a*]cyclobuta[*c*-1,2]fullerene.

The structure of compound **24** was determined by ¹H NMR spectroscopy and electron ionisation mass spectrometry. In this bis-adduct, unsaturated dithiolactone **26** generated from tetrathiafulvalene by elimination of CS_2 serves as the second addend (Scheme 6).

TTF is tetrathiafulvalene.

An analogous replacement of two fluorine atoms is also observed in the reaction of $C_{60}F_{18}$ with 2-methoxyethoxy-

methyl azide.¹⁴⁵ The reactions of non-modified C_{60} with azides (in particular, with 2-methoxyethoxymethyl azide) generally produce open-cage fulleroid adducts, *viz.*, azahomofullerenes, upon the [2 + 3]-cycloaddition of the azide followed by extrusion of N_2 (see, for example, Ref. 146). As in many above-considered examples, the use of polyfluorofullerenes as the substrate substantially changes the reaction pathway because of the ease of a loss of fluorine atoms giving rise to aziridino-polyfluorofullerene $C_{60}F_{16}N(CH_2OCH_2CH_2OMe)$.

b. Radical reactions

Fullerenes are readily involved in radical addition reactions.²⁵ In particular, the reactions of C_{60} with molecular fluorine^{1, 11, 43} and with radical species generated *in situ* by decomposition of peroxides,¹⁴⁷ alkyl and perfluoroalkyl iodides,^{6, 148} metal trifluoroacetates,¹⁴⁹ *etc.* were documented.

Polyfluorofullerenes are also involved in radical addition reactions but they are less reactive than fullerene. As mentioned above, fluorination of C_{60} with molecular fluorine proceeds by a radical mechanism. Evidently, fluorination of lower polyfluorofullerenes by fluorine also proceeds by a radical mechanism. The transformation of $C_{60}F_{36}$ into $C_{60}F_{48}$ is an example of such reactions.⁶⁴ As was discussed in Section II.1.a, further fluorination occurs under more drastic conditions due to steric strains and is accompanied by decomposition of the fullerene cage.^{11, 58}

The formation of the mixed compounds $C_{60}F_x(R^F)_y$ ($R^F = CF_3$ or C_2F_5), which were detected in the reaction of C_{60} with high oxidation state metal fluorides, is yet another interesting example.^{45, 82, 150} The 1,9- and 1,7- $C_{60}FCF_3$, C_1 - $C_{60}F_5CF_3$,^{150, 151} C_1 - $C_{60}F_7CF_3$ (see Refs 45, 46 and 150) and C_s - $C_{60}F_{17}C_2F_5$ isomers and three isomers of $C_{60}F_{17}CF_3$, *viz.*, one C_s -symmetrical isomer (65% of the total amount) and a pair of C_1 enantiomers (35%),^{82, 152} were isolated from these reaction mixtures by HPLC. The structures of the compounds

Scheme 6

were proposed based on ^{19}F NMR spectroscopic data and results of quantum chemical calculations. It should be noted that $\text{C}_{60}\text{F}_{17}\text{CF}_3$ has initially been considered¹⁵² as the difluoromethanofullerene derivative $\text{C}_{60}\text{F}_{18}\text{CF}_2$. However, more recent X-ray diffraction study demonstrated⁸² that this compound is an analogue of $\text{C}_{60}\text{F}_{18}$, with the only difference that one of the sterically most accessible fluorine atoms is replaced by the CF_3 group.

In a number of studies,^{36, 82, 152} it was hypothesised that mixed fluoro- and perfluoroalkyl derivatives are generated through the insertion of the difluorocarbene $:\text{CF}_2$ into polyfluorofullerene at C–F bonds. The origin of difluorocarbene is attributed to thermal destruction of polyfluorofullerenes. This reaction can proceed analogously to the insertion of methylene into the C_{60} molecule upon hydrogenation¹⁵³ with the only difference that the methylene group is inserted at the double bond of fullerene, whereas difluoromethylene is inserted at the C–F bond. However, it should be noted that the more probable pathway of the formation of perfluoroalkylated fullerene derivatives involves the addition of the $\cdot\text{CF}_3$ or $\cdot\text{C}_2\text{F}_5$ radicals that are generated upon thermal destruction of polyfluorofullerenes to fullerene or its fluorination products. Actually, these radicals were detected upon decomposition of polyfluorofullerenes.^{8, 58, 154, 155} Convincing evidence for the formation of mixed derivatives in the reaction of [60]fullerene with $\cdot\text{CF}_3$ was reported.⁶⁷ It was demonstrated that the independent generation of the $\cdot\text{CF}_3$ radicals at the moment of fluorination of fullerene with K_2PtF_6 gives rise predominantly to mixed fluoro and CF_3 derivatives of fullerene with the compositions $\text{C}_{60}\text{F}_{18-n}(\text{CF}_3)_n$ and $\text{C}_{60}\text{F}_{20-m}(\text{CF}_3)_m$ ($n = 1-5$, $m = 1-6$).

IV. Reactions of polychloro[60]fullerenes

Until recently, C_{60}Cl_6 has been the only polychlorofullerene that was available in preparative amounts in high purity form.⁸⁹ Because of this, the reactions of polychlorofullerenes were studied in most detail for this compound. Higher chlorides, for example, $\text{C}_{60}\text{Cl}_{24}$,¹⁰⁰ $\text{C}_{60}\text{Cl}_{28}$ (Ref. 74) and two isomers of $\text{C}_{60}\text{Cl}_{30}$, were synthesised and isolated in the individual state.⁹⁹ This will help in studying their reactivity in detail and synthesising new derivatives of the fullerene series.

1. Arylation of polychlorofullerenes

Polychlorofullerenes readily enter the Friedel–Crafts reaction.² For example, ^1H and ^{13}C NMR spectroscopic studies demonstrated that stirring of a benzene solution of C_{60}Cl_n with catalytic amounts of AlCl_3 at room temperature for 2 h leads to the formation of polyphenylfullerenes (according to mass-spectrometric data, up to 22 phenyl groups are attached).

The Friedel–Crafts reaction of fullerene C_{60}Cl_6 with various aromatic substrates was studied in detail.^{156–158} The reactions of C_{60}Cl_6 with arenes in the presence of FeCl_3 were demonstrated to give the corresponding C_s -symmetrical aryl derivatives $\text{C}_{60}\text{Ar}_5\text{Cl}$ in yields ranging from 48% (Ar is thienyl) to 63% (Ar = 4- FC_6H_4). The reaction with toluene proceeds both at the *para* and *ortho* positions. The reactions with anisole and fluorobenzene gave exclusively *para*-substituted products, which were isolated and completely characterised.¹⁵⁷ The replacement of chlorine atoms by aryl groups at the same positions as those occupied by chlorine atoms in C_{60}Cl_6 , indicates that the reaction proceeds through the cationic fullerene intermediate.

Ar = XC_6H_4 (X = H, Me, MeO, Bu^t, F, Me₃Si), thienyl.

In a more recent detailed study¹⁵⁸ of the reaction of C_{60}Cl_6 with fluorobenzene in the presence of FeCl_3 , the major product [$\text{C}_{60}(4\text{-FC}_6\text{H}_4)_5\text{Cl}$] was detected along with two C_s -symmetrical isomers of 1,4-(4- FC_6H_4)₂ C_{60} , one non-symmetrical isomer of $\text{C}_{60}(4\text{-FC}_6\text{H}_4)_4$ and a small amount of $\text{C}_{60}(4\text{-FC}_6\text{H}_4)_4\text{H}_2$. The following scheme was proposed for the explanation of the formation of the latter compound. Initially, two chlorine atoms are replaced by a hydrogen atom, which is most likely generated from the solvent. The resulting intermediate enters the Friedel–Crafts reaction with fluorobenzene.¹⁵⁹ The substitution of hydrogen for chlorine atoms was also observed in the reaction of $\text{C}_{60}\text{Ar}_5\text{Cl}$ with triphenylphosphine.¹⁵⁷

Ar = 4- FC_6H_4 .

The steric hindrance in C_{60}Cl_6 , which is the presently known bulkiest electrophile, plays an important role. For example, no reaction occurs with sterically hindered mesitylene.¹⁵⁸ At the same time, reagents with lower steric demands can replace all six chlorine atoms. For example, the reaction of C_{60}Cl_6 with an excess of allyltrimethylsilane in the presence of TiCl_4 produces hexaallylfullerene $\text{C}_{60}(\text{CH}_2\text{CH}=\text{CH}_2)_6$ in good yield.¹⁶⁰

In this case, the steric factors are less significant, which facilitates the complete replacement of chlorine atoms. The pentasubstituted compound $\text{C}_{60}(\text{CH}_2\text{CH}=\text{CH}_2)_5\text{Cl}$ was isolated as a minor reaction product.

A comparative study of the geometry and electronic structures of the compounds $C_{60}Cl_6$, $C_{60}Ph_5Cl$ and $C_{60}Ph_5H$ by quantum chemical calculations (the AM1 method) demonstrated that the nature of functional groups has no noticeable effect on the bond lengths in the fullerene cage (the difference in the lengths of the analogous C—C bonds is at most 0.01 Å).¹⁶¹ For these derivatives, the addition of functional groups leads to a loss of the icosahedral (I_h) symmetry, cleavage of five carbon–carbon double bonds and the appearance of the isolated cyclopentadienyl fragment. The C—C bonds involving sp^3 -hybridised carbon atoms (1.50–1.55 Å) are longer than those in C_{60} . The 1H NMR spectroscopic study revealed free rotation of the phenyl groups at room temperature. This is consistent with the results of calculations by the AM1 method, according to which there is a large number of conformations in a narrow energy range. Therefore, the molecules $C_{60}Ph_5Cl$ and $C_{60}Ph_5H$ are ‘pseudo- C_s -symmetrical’.¹⁵⁶

Calculations of the Mulliken charges illustrated the almost neutral character of chlorine atoms relative to the fullerene cage in $C_{60}Cl_6$ and a weak donor character of the phenyl groups in $C_{60}Ph_5Cl$ and $C_{60}Ph_5H$. Each phenyl group in these compounds donates, on the average, 0.038 (in $C_{60}Ph_5Cl$) and 0.02 electrons (in $C_{60}Ph_5H$) to the carbon cage. The hydrogen atom bound directly to the fullerene cage acts as a strong donor (+0.217 e) and the chlorine atom, as a weak acceptor (−0.044 e). Unlike $C_{60}Ph_5H$, in which the negative charge is almost uniformly distributed over the functionalised fragment, the total charge in $C_{60}Ph_5Cl$ (0.150 e) donated by the addends is mainly redistributed to the intact part of the cage (−0.143 e).

Due to a combination of the aryl substituents and the reactive chlorine atom in the molecules $C_{60}Ar_5Cl$, the latter can be used as the starting compounds for further functionalisation.^{162, 163} For example, a new pathway of spontaneous oxidation of $C_{60}Ph_5X$ ($X = H$ or Cl) to the benzofuran derivative of C_{60} , in which the oxygen atom forms a bridge between the carbon cage and one of the benzene rings, was found (see Section IV.2).¹⁶³

The treatment of $C_{60}Ph_5Cl$ with cyanogen bromide allows the annulation of the quinoline fragment onto the fullerene cage.¹⁶² The reaction is accompanied by a loss of the chlorine atom and the formation of the bromine-substituted CN bridge between the carbon cage and the *ortho* position of the adjacent benzene ring to form 1-bromoisoquinoline derivative **27**.

The structure of this derivative was confirmed by the synthesis of amide **28** by the nucleophilic substitution of a hydroxy group for the bromine atom.¹⁶² Like the other amides, compound **28** is poorly soluble and crystallises from benzene as orange-red plates.

The proposed¹⁶² mechanism of the formation of compound **27** (Scheme 7) is based on the experimental facts that the reaction does not proceed in the absence of $FeCl_3$ and that $C_{60}(4-FC_6H_4)_5Cl$ does not undergo this transformation. The dependence of the process on the presence of a strong Lewis acid is indicative of the involvement of a carbocationic intermediate in this reaction. In this case, the intermediate

can be generated in the reaction of $FeCl_3$ with either $C_{60}Ph_5Cl$ or $BrCN$.

It should be noted that if the complex of $BrCN$ with iron(III) chloride were an intermediate of this reaction, an electrophile would be formed and the latter would attack the phenyl group in $C_{60}Ph_5Cl$ predominantly at the most accessible *para* or (taking into account the electron-withdrawing character of the fullerene substituent) *meta* position. However, the absence of these products in the reaction mixture suggests that the transformation of $C_{60}Ph_5Cl$ into product **27** proceeds by a different mechanism involving the formation of the $C_{60}Ph_5^+$ cation.

Due to considerable steric hindrance, the $C_{60}Ph_5^+$ cation cannot react with the phenyl group of another $C_{60}Ph_5Cl$ molecule, but can react with the small $BrCN$ molecule at the nitrogen atom. Then the electrophilic attack of the resulting iminium cation on the adjacent phenyl group occurs. The strong electron-withdrawing properties of fullerene hinder the electrophilic substitution in the aryl moiety bound to the fullerene cage. Nevertheless, high electrophilicity of the bromoiminium cation and the intramolecular character of the reaction (the entropy factor) do make this cyclisation possible.¹⁶⁴ In $C_{60}(4-FC_6H_4)_5Cl$, the electronegative fluorine atom is in the *meta* position to the site of attack and has a negative inductive effect, which makes the electrophilic attack even more difficult. In combination with the electron-withdrawing effect of the fullerene cage, this is sufficient for deactivation of the benzene ring even toward the intramolecular attack by the iminium electrophile.

2. Nucleophilic substitution reactions

Polychlorofullerenes are sensitive to hydrolysis and readily react with nucleophiles.² For example, the reaction of a mixture of polychlorofullerenes with excess KOH under reflux in methanol produced polymethoxyfullerenes, the most substituted product containing 26 methoxy groups (mass spectrometric data).²

This reaction proceeds simultaneously with partial hydroxylation of the substrate.

The reaction of a benzene solution of $C_{60}Cl_6$ with sodium alkoxide in the corresponding alcohol ROH ($R = Me, Et$) produces $C_{60}(OR)_5Cl$ in moderate yields (15%–20%).¹⁶⁵ The reaction proceeds rather rapidly under reflux, but several days are required for its completion at room temperature. The reaction of $C_{60}Cl_6$ with EtO^- yields $1,4-(EtO)_2C_{60}$ as a by-product. Therefore, the substitution reaction is competitive with elimination of chlorine atoms. When $C_{60}Cl_6$ is heated with an alcohol in the absence of alkoxide ions, which are stronger nucleophiles, dechlorination becomes the main reaction. For example, the reaction of a benzene solution of $C_{60}Cl_6$ with methanol or isopropyl alcohol under reflux for 140 h produces $1,4-(MeO)_2C_{60}$ or $1,4-(Pr^iO)_2C_{60}$ in 11%–30% yields.¹⁶⁵ The

reaction of $C_{60}Cl_6$ with secondary aliphatic amines gives 1,4-diaminofullerenes (in 5%–20% yields) and an inseparable mixture of tetra- and hexaaminofullerenes.¹⁶⁶

The reaction of $C_{60}Cl_6$ with an excess of methylolithium in a THF–cumene mixture at room temperature affords a complex mixture of products.¹⁶⁷ The completely alkylated derivative $C_{60}Me_6$ and chloropentamethylfullerene $C_{60}Me_5Cl$ are among the major reaction products. Since the arrangement of the addends typical of $C_{60}Cl_6$ is retained in these compounds, it was hypothesised that the reaction involves the frontal replacement of chlorine atoms by nucleophilic species. However, as mentioned above, we are doubtful about this mechanism.

As discussed above, the reactions of higher polyfluorofullerenes with nucleophiles proceed by the S_N2' mechanism. This mechanism is also possible for the transformation of $C_{60}Me_5Cl$ into $C_{60}Me_6$. However, it is inconsistent with the retention of the arrangement of the addends upon the transformation of $C_{60}Cl_6$ into $C_{60}Me_5Cl$, since it is known that alkylolithium compounds are involved in exchange reactions with alkyl halides rather than give coupling products. Presumably, the transformation of $C_{60}Cl_6$ into $C_{60}Me_5Cl$ involves the halogen–metal exchange step:

This process was found to partly proceed in the reaction of phenyllithium with polyfluorofullerenes,¹⁰⁷ as evidenced by the presence of a certain amount of fluorobenzene as one of by-products. It is also known^{168–173} that alkali metal fullerenes smoothly react with alkyl halides to form the corresponding alkylfullerenes.

The compound $C_{60}Me_5Cl$ readily undergoes hydrolysis and oxidation.^{165, 167, 174, 175} In the presence of atmospheric oxygen, epoxides with the compositions $C_{60}Me_5(O)OH$, $C_{60}Me_5O_2OH$ and $C_{60}Me_5O_3H$ were obtained. The X-ray diffraction study showed that the hydroxy group in the molecule $C_{60}Me_5O_2OH$ (**29**) occupies the position of the chlorine atom in the molecule $C_{60}Me_5Cl$, and two oxygen atoms form epoxide functions attached at the double bonds of the butadiene fragment in the five-membered ring.¹⁷⁴

The compound $C_{60}Me_5O_3H$ (**30**) isomeric to bis(epoxy)fullerenol **29** is bis-epoxy ketone containing the open-cage fullerene, and compounds **29** and **30** undergo interconversions through the 1,3-tautomeric shift of the hydrogen atom of the hydroxy group.¹⁷⁵ It should be noted that the compounds $C_{60}Ph_5Cl$ and $C_{60}Ph_3H$ containing a truncated pentagonal pyramidal fragment undergo oxidation too. The high reactivity of this fragment is apparently attributed to a high π -electron density on the double bonds.¹⁷⁶ The tendency of these oxygen-containing compounds to undergo decarbonylation during thermolysis, which can lead to an opening of the fullerene cage, is an important but, unfortunately, poorly studied characteristic feature of such compounds.^{158, 167, 174}

The reactions of $C_{60}Cl_6$ with phenols (PhOH, 4-FC₆H₄OH or 4-MeOC₆H₄OH) and aniline in the presence of water and KOH represent an unusual example of the nucleophilic displacement of chlorine atoms followed by cyclisation.¹⁷⁷ The reactions with phenol or its substituted analogues produce benzofuran derivatives **31** (Scheme 8), while aniline gives indolofullerene. It should be noted that, although the reaction can lead to the nucleophilic displacement of several chlorine atoms by phenoxy or anilino groups, only one of these groups undergoes cyclisation to give a heterocyclic (benzofuran or indole) functional group. Other chlorine atoms are either eliminated or are subjected to the nucleophilic substitution without the ring formation. It was demonstrated that thiophene, being a weak nucleophile, does not react, and the

Scheme 8

reaction rate increases in the series $\text{PhOH} < 4\text{-FC}_6\text{H}_4\text{OH} < 4\text{-MeOC}_6\text{H}_4\text{OH} < \text{PhNH}_2$ in accordance with an increase in the nucleophilicity of the reagent.

It was hypothesised¹⁷⁷ that a derivative with a chlorine atom bound to the fullerene cage in the *ortho* position with respect to the arene group, is formed as an intermediate in this reaction, and cyclisation occurs as a result of a loss of the *ortho*-hydrogen atom of the aromatic ring and the chlorine atom (see Scheme 8, path *a*).¹⁷⁷ In our opinion, it is more probable that this reaction involves the initial nucleophilic attack on the polychlorofullerene cage by the *ortho*-carbon atom of the phenoxide ion followed by the substitution of the phenoxide for the chlorine atom (see Scheme 8, path *b*) according to one of the above-considered nucleophilic substitution mechanisms.

V. Reactions of polybromo[60]fullerenes

Unlike reactions of polyfluoro and polychloro derivatives of fullerenes, chemical transformations of polybromofullerenes have not been adequately studied because the use of the latter as synthons is limited by their poor solubility and instability in most of organic solvents.⁸⁹ For example, dissolution of C_{60}Br_6 in chloroform, dichloromethane, 1,2-dichlorobenzene, carbon disulfide or cyclohexane is accompanied by its complete decomposition into C_{60} and Br_2 .^{103, 144} Disproportionation of C_{60}Br_6 giving rise to C_{60} and C_{60}Br_8 upon dissolution in organic solvents was also documented.^{5, 103} Decomposition of C_{60}Br_8 to the starting fullerene and molecular bromine occurs upon heating in organic solvents to 70–80 °C, whereas $\text{C}_{60}\text{Br}_{24}$ does not decompose even upon prolonged refluxing in 1,2-dichlorobenzene (180 °C).¹⁰³ Therefore, thermal stability of polybromofullerenes in organic solvents increases in the series $\text{C}_{60}\text{Br}_6 < \text{C}_{60}\text{Br}_8 < \text{C}_{60}\text{Br}_{24}$, which is consistent with the thermogravimetric data for crystalline polybromofullerenes.¹⁰² Thermal decomposition of polybromofullerenes under an inert atmosphere or under vacuum leads to molecular bromine and C_{60} fullerene. In the presence of oxygen, this process is accompanied by the formation of fullerene oxides, which, under these conditions, are readily involved in the cycloaddition reaction to form difullerenofuran derivatives.¹⁷⁸ It should be noted that thermolysis of polybromofullerenes in the presence of oxygen affords rather easily fullerene oxides. On the contrary, C_{60} fullerene is involved in these reactions only in the presence of strong oxidising agents, *e.g.*, ozone or peroxides, or as a result of photochemical or electrochemical reactions.^{179, 180}

Like other halogen derivatives of fullerenes, polybromofullerenes enter the Friedel–Crafts reaction with arenes catalysed by AlBr_3 or similar Lewis acids.^{2, 181} The reactions of $\text{C}_{60}\text{Br}_{24}$ with benzene, toluene or fluorobenzene in the presence of AlBr_3 produce polyarene derivatives C_{60}Ar_n ($n = 2–16$; $\text{Ar} = \text{Ph}$, MeC_6H_4 or FC_6H_4).¹⁸¹ In the presence of organic electron donors of the tetrathiafulvalene series, C_{60}Br_6 and C_{60}Br_8 undergo debromination accompanied by the formation of C_{60} and the donor radical cation.¹⁴⁴

The reaction of polybromofullerene $\text{C}_{60}\text{Br}_{24}$ with methanolic KOH produces a complex mixture of polymethoxyfullerenes $\text{C}_{60}(\text{OMe})_n$ ($n = 2–26$).¹⁸¹ The treatment of polybromofullerenes with aqueous alkalis or aqueous dioxane leads to their complete hydrolysis to form fullerlenols with complex composition.¹⁸² In the case of aqueous dioxane, the substitution of bromine atoms in fullerenes C_{60}Br_8 and $\text{C}_{60}\text{Br}_{24}$ is the main reaction giving rise to compounds of compositions similar to $\text{C}_{60}(\text{OH})_{10}$ and $\text{C}_{60}(\text{OH})_{26}$, respectively. In reactions with aqueous alkalis, the nucleophilic substitution of bromine atoms is accompanied by the additional attachment of hydroxy groups to the fullerene cage to give fullerlenols containing a large number of hydroxy groups, whatever the composition of the starting polybromofullerene. An elemental analysis

demonstrated that alkali metal fullerlenolates are present among the products obtained by alkaline hydrolysis of polybromofullerenes. This fact accounts for higher solubility of these fullerlenols in water compared to fullerlenols prepared according to other procedures. It should be noted that pH of aqueous solutions of alkali metal fullerlenolates is close to neutral, which is typical of salts of strong acids. This is apparently due to the strong electronegative nature of the fullerene cage functionalised by a large number of electron-withdrawing hydroxy groups.

It was demonstrated that polybromofullerenes react with silver trifluoroacetate upon heating in aromatic hydrocarbons.¹⁸² In the case of C_{60}Br_8 and $\text{C}_{60}\text{Br}_{24}$, the compounds with the compositions $\text{C}_{60}(\text{CF}_3\text{COO})_{2–3}(\text{OH})_{6–5}$ and $\text{C}_{60}(\text{CF}_3\text{COO})_{2–4}(\text{OH})_{6–7}$ were obtained as the major products. It can be seen that the compositions of the resulting compounds do not correlate with the number of the replaced bromine atoms. The formation of hydroxy derivatives was attributed to high sensitivity of the intermediates to atmospheric moisture. However, the products do not undergo further hydrolysis in the presence of HCl . Analogously, phosphorylation of $\text{C}_{60}\text{Br}_{24}$ and C_{60}Br_6 in THF by $(\text{EtO})_2\text{P}(\text{OLi})$ leads to the addition of up to six diethoxyphosphoryl groups $\text{PO}(\text{OEt})_2$ to the fullerene cage.¹⁸¹

The selective substitution of bromine atoms in polybromofullerenes is exemplified by the reactions of $\text{C}_{60}\text{Br}_{24}$ with SbCl_5 (or with KICl_4) at 140–150 °C^{74, 100} and with XeF_2 in liquid anhydrous HF at room temperature.⁵⁰ In both cases, the $T_h\text{-C}_{60}\text{Cl}_{24}$ and $T_h\text{-C}_{60}\text{F}_{24}$ compounds isostructural to the starting polybromofullerene were obtained as the major products. Polychlorofullerenes, in turn, can be transformed into $T_h\text{-C}_{60}\text{Br}_{24}$ by the reactions with liquid bromine.⁷³ In earlier studies,^{71, 183} attempts have also been made to replace bromine and chlorine atoms by fluorine; however, individual compounds have not been obtained.

It should be noted that, according to quantum chemical calculations, fullerene $T_h\text{-C}_{60}\text{F}_{24}$ is thermodynamically unstable and can undergo disproportionation to $\text{C}_{60}\text{F}_{18}$ and $\text{C}_{60}\text{F}_{36}$. Apparently, that is why this compound was not isolated from products of high-temperature syntheses of polyfluorofullerenes under thermodynamic control.^{34, 183} However, $T_h\text{-C}_{60}\text{F}_{24}$ can be synthesised by the reaction of $\text{C}_{60}\text{Br}_{24}$ with XeF_2 under mild conditions, which is evidence for its kinetic stability to further rearrangements. Unfortunately, the mechanism of this reaction remains unknown and it can only be hypothesised that the reaction involves the concerted $\text{Br}–\text{F}$ exchange at the sp^3 -carbon atom or(and) a sequence of addition and elimination reactions.⁵⁰ It cannot be ruled out that the reaction of $\text{C}_{60}\text{Br}_{24}$ with XeF_2 is of the radical cation nature, analogously to that assumed for fluorination of bromopentafluorobenzene $\text{C}_6\text{F}_5\text{Br}$ or bromotetrafluorobenzenes $\text{C}_6\text{F}_4\text{HBr}$ with xenon difluoride in liquid HF.^{184, 185} The reaction of benzene derivatives with XeF_2 is not accompanied by debromination, which is apparently associated with a higher $\text{C}–\text{Br}$ bond energy in these compounds. In the case of polybromofullerenes, in which the bromine atoms are bound to tertiary carbon atoms and cause steric strain in the cage, the $\text{C}–\text{Br}$ bond energy is substantially lower, resulting in elimination of bromine atoms. Nevertheless, mixed compounds with the composition $\text{C}_{60}\text{F}_{25}\text{Br}$ were detected among the reaction products of $\text{C}_{60}\text{Br}_{24}$ with XeF_2 . Therefore, under these conditions, not only the substitution of fluorine for bromine atoms, but also the addition of fluorine atoms to the fullerene cage is observed.

Abstract. Methods for the synthesis of substituted and unsubstituted indoloindoles are considered. Characteristic features of electrophilic substitution in the indoloindole system and some transformations in the side chains are discussed. The bibliography includes 86 references.

I. Introduction

In recent years, considerable attention has been paid to the study of diverse synthetic analogues of indole, which was stimulated by their potential biological activities.^{1,2} Of particular interest among these compounds are indoloindoles in which indole fragments are fused so as to have in common either carbon atoms of the pyrrole rings {e.g., 5*H*,10*H*-indolo[3,2-*b*]indole (**1**)} or carbon and nitrogen atoms of the pyrrole rings {e.g., 10*H*-indolo[1,2-*a*]indole (**2**)}, or carbon atoms of the benzene rings {e.g., 1*H*,6*H*-indolo[7,6-*g*]indole (**3**), 3*H*,8*H*-indolo[4,5-*e*]indole (**4**), etc.}. The last-mentioned compounds are of interest because the reactive pyrrole rings in their molecules remain unsubstituted and capable of various transformations.

Natural compounds containing an indoloindole fragment in which the fused indole rings have the carbon atoms of the benzene rings in common have not yet been found.

Sh A Samsoniya, M V Trapaidze I Javakishvili Tbilisi State University, I Chavchavadze ave. 3, 0128 Tbilisi, Georgia. Fax/tel. (995-32) 22 68 10, e-mail: shotasamsonia@yahoo.de (Sh A Samsoniya), tel. (995-32) 27 87 18 (M V Trapaidze)

The present review generalises data on the synthesis and properties of the above-mentioned indoloindoles and related compounds in which two indole fragments are fused so that three or four carbon atoms of the benzene and pyrrole rings are in common simultaneously. Compounds of the type

in which the pyrrole ring of one indole molecule is fused to the benzene ring of the other molecule are beyond the scope of this review, because in conformity with the IUPAC rules, they are called pyrrolocarbazoles.

Since no reviews on indoloindoles have been published as yet, we did not restrict ourselves to consideration of only recent studies but also included the results of earlier studies.

II. Synthesis and use of indoloindoles with carbon atoms of the pyrrole rings in common

The first reported synthesis of indoloindoles dates back to 1884 when P Golubeva³ obtained a neutral compound with the molecular formula $C_{14}H_{10}N_2$ by the reduction of *o,o'*-dinitrobenzil (formed upon oxidation of dinitrodeoxybenzoin) with tin and hydrochloric acid in ethanol

Golubeva³ suggested that this compound is a tolan derivative and called it 'diiminotolan'.

Later, Kliegl and Haas⁴ prepared a compound identified as dinitrobenzil, according to elemental composition, by oxidation of *o,o'*-dinitrotolan with a mixture of chromic and glacial acetic acids. The reduction of this product with tin gave a compound identical to Golubeva's 'diiminotolan'. They suggested that reduction of dinitrobenzil does not give 'diiminotolan', as Golubeva believed, but is accompanied by ring closure to give compound **1**, which they called 'doubly fused indole'.

The targeted synthesis of 5H,10H-indolo[3,2-b]indole (**1**) was first performed by Ruggli.⁵ He used *o,o'*-dinitrotolan (**5**), as the starting compound, which was oxidised with bromine to give 1,2-dibromo-1,2-di(*o*-nitrophenyl)ethylene. The reduction of this product with tin(II) chloride[‡] in hydrochloric acid afforded product **1**,

which was almost identical to the 'diiminotolan' obtained by Golubeva in the physicochemical properties.

Later, Ruggli and Zaeslin⁷ reported an improvement of the method for the synthesis of indoloindole **1** from *o,o'*-dinitrotolan (**5**). They first prepared 2-(*o*-aminophenyl)indolenin-3-one (**6**) by refluxing compound **5** in an aqueous solution of sodium sulfide followed by reduction with tin(II) chloride in a mixture of hydrochloric and glacial acetic acids at 70 °C to give 5H,10H-indolo[3,2-b]indole (**1**) (yield 78%). Compound **1** was formed as colourless crystals poorly soluble in conventional organic solvents. According to Ruggli and Zaeslin,⁷ it was not 2-(*o*-aminophenyl)indolenin-3-one (**6**) that cyclised in this reaction but its reduced form, compound **8** formed after acidification.

Compound **6** can also be obtained by the reduction of *o,o'*-dinitrobenzil **7** in a neutral solution in the presence of Ni.

Dehydrogenation of indoloindole **1** on treatment with chloranil⁶ results in a product for which a quinonoid structure

and the name dehydroindoloindole were proposed. The structure of 5,10-didehydroindolo[3,2-*b*]indole (**9**) was confirmed by IR and UV spectroscopic data. Oxidative dehydrogenation of indoloindole **1** (in boiling acid) was also carried out by Treibs.^{8,9} Subsequently, he attempted to develop a more convenient method for the synthesis of 5,10-didehydroindolo[3,2-*b*]indole (**9**). To this end, he investigated the following reactions:⁹

However, it turned out that compound **9** is formed in low yield from indolin-3-one phenylhydrazone (**10**) and is not formed at all from glyoxal diphenylhydrazone (**11**).

Compound **9** and some derivatives of indoloindole **1** were synthesized by Hünig and Steinmetzer^{10–13} in a study of various redox systems, in particular, the system

Cadogan *et al.*¹⁴ proposed a new method for the synthesis of carbazoles, indoles, indazoles and related compounds, which involved the reduction of appropriate nitro compounds with triethyl phosphite. It was found that reduction of mono-nitro derivatives gives products in high yields, while in the case of dinitro compounds, the yields are moderate. Thus *o,o'*-dinitrostilbene was converted into indoloindole **1** in a very low yield (2%), whereas treatment of 1-methyl-2-(*o*-nitrophenyl)indole (**12**) and its 3-isomer **13** with triethyl phosphite in cumene at 160 °C resulted in the formation of 10-methyl-5H-indolo[3,2-*b*]indole (**14**) and 6-methyl-5H-indolo[2,3-*b*]indole (**15**), respectively, in good yields.¹⁵

Kaszynski and Dougherty¹⁶ prepared diethyl 5H,10H-indolo[3,2-*b*]indole-2,7-dicarboxylate (**16**) from diethyl 2,2'-diaminostilbene-4,4'-dicarboxylate (**17**) according to the following scheme:

[‡] Heller⁶ proposed the use of zinc dust in acetic acid for the reduction of *o,o'*-dinitrobenzil.

The cyclisation of diazide **18** took place in *o,o'*-dichlorobenzil at 155 °C. In this reaction, indolo[1,2-*b*]indazole derivatives were obtained as by-products. Diester **16** can also be obtained by simultaneous reduction (SnCl_2) and cyclisation of compound **19** in a mixture of hydrochloric and acetic acids.

Kaszynski and Dougherty¹⁶ also synthesised the *N,N'*-dimethyl derivative of compound **16** and studied its electrochemical oxidation in CH_2Cl_2 in the presence of $\text{Bu}_4\text{N}^+\text{ClO}_4^-$ to give stable radical cation **16**^{•+}. It was assumed that the indoloindole obtained could find use in the synthesis of polaronic ferromagnets.

A new synthetic route to indolo[3,2-*b*]indole derivatives based on *N*-substituted indoxyls and phenylhydrazines has been proposed.¹⁷ Refluxing of 1-acetylindolin-3-one (**20**) with substituted phenylhydrazines in acetic acid for 10 min gave the corresponding indolo[3,2-*b*]indoles (**21**).

R = Me, PhCH_2 .

The process involves the formation of hydrazones, which then undergo the Fischer reaction to be converted into the corresponding indoloindoles. The acetyl derivative **20** may be replaced by the tosyl derivative;¹⁸ in this case, the yield of indolo[3,2-*b*]indole is 50%.

The Fischer method has found use in the synthesis of diverse fused heterocycles. In particular, this approach was employed to prepare indolo[3,2-*b*]indolo[1,7*a*,7-*ab*]tetrahydropyridine (**22a**) and indolo[3,2-*b*]indolo[1,7*a*,7-*ab*]diazepinone (**22b**).¹⁹

X = $(\text{CH}_2)_3$ (**22a**), $\text{NHC(O)(CH}_2)_2$ (**22b**).

Cyclisation of phenylazindoles **23** in acetic acid at 60–70 °C in the presence of $\text{Na}_2\text{S}_2\text{O}_4$ gave 10-amino-5-tosylindolo[3,2-*b*]indoles **24**.²⁰

$\text{R}^1, \text{R}^2 = \text{H, Hal, Alk.}$

Yet another route to indolo[3,2-*b*]indole derivatives is electrochemical reduction of bis-Schiff bases.²¹ The reduction of 6,12-diphenyldibenzo[*b,f*][1,5]diazocine (**25**) and its 2,8-dichloro derivative **26** gives 4*b*,9*b*-diphenyl-4*b*,5,9*b*,10-tetrahydroindolo[3,2-*b*]indole (**27**) and its 3,8-dichloro derivative (**28**) in 94% and 69% yields, respectively.²²

R = H (**25, 27**), Cl (**26, 28**).

Previously, compounds **27** and **28** were obtained in relatively low yields^{23–25} by the reduction of compounds **25** and **26** with zinc in acetic acid or by platinum oxide-catalysed reduction.

Recent publications describe the use of indolo[3,2-*b*]indoles in the synthesis of high-spin polymeric materials for light emitting diodes. Thus the synthesis and electroluminescent properties of a high-spin polymer, poly(5,10-dihexylindolo[3,2-*b*]indole-2,7-diyl) (**29**), have been reported.²⁶ This

(a) $n\text{-C}_6\text{H}_{13}\text{Br}$, NaH, THF; (b) Br_2 , pyridine, CCl_4 ; (c) Ni(COD)_2 , COD, 2,2'-bipyridine.

polymer possessed good optical and electroluminescent properties, but unfortunately had a low molecular mass and formed poor-quality polymeric films.

Earlier, high-spin polymers with a similar structure containing an indolo[3,2-*b*]indole fragment in the monomer unit were prepared by Murray *et al.*,²⁷ who have called them the prototypes of polaronic ferromagnets.

A study of the hole conduction of various heterocyclic systems related to the class of 5,10-dihetera-5,10-dihydroindeno[3,2-*b*]indenes²⁸ has shown that 5,10-dihydroindeno[3,2-*b*]indole possesses the best characteristics (luminescent properties and the lifetime).

Dobrin and co-workers^{29–32} studied the photophysical properties of 5*H*,10*H*-indolo[3,2-*b*]indole (**1**) and its derivatives (in particular, 5,10-dimethylindolo[3,2-*b*]indole and its 2,7-diethoxycarbonyl derivative) using the spectral and quantum-chemical methods. These compounds can be considered to be stilbene analogues, as they contain a stilbene chromophore as a part of a tetracyclic system.

III. Indoloindoles with carbon and nitrogen atoms of the pyrrole rings in common

The interest in indoloindoles with carbon and nitrogen atoms of the pyrrole rings in common is due to their biological activities. The first derivative with this type of fusion, namely, 10*H*-indolo[1,2-*a*]indol-10-one (**30**), was prepared in 40% yield back in 1953 by Shirley and Roussel³³ upon treatment of *N*-phenylindole with excess *n*-butyllithium and saturation with carbon dioxide. The oxime of compound **30** was also prepared. It was suggested that indoloindole **30** is formed upon the reaction of 2,2'-dilithiated *N*-phenylindole with CO₂.

Thermolysis of dilute solutions of 2-(hydroxydiphenylmethyl)indole (**31**) in boiling bromobenzene did not give the expected dimer **32**, but afforded instead a mixture of products **33–37** comprising 11-phenyl-10*H*-indolo-[1,2-*a*]indole (**34**) and its derivatives **35–37**.³⁴ The structures of compounds **34–37** were proposed based on the data from IR and UV spectroscopy.

IV. Indoloindoles with carbon atoms of the benzene and pyrrole rings in common

In order to study the possibility of preparing fused heterocyclic compounds with two pyrrole rings upon cyclisation of substituents located in the *peri*-position of the naphthalene nucleus, an attempt was made to synthesise indolo[5,4,3*a*,3-*cde*]indole-2,6-dione (**38**).³⁵ 5-Amino-2-oxobenzo[*c,d*]indoline-6-carboxylic acid (**39**), which was obtained from 5-bromobenzo[*c,d*]indolin-2-one (**40**), was subjected to the cyclisation.

Lactam ring closure in the *peri*-positions of the naphthalene nucleus was attained only by refluxing compound **39** in acetic anhydride. This gave 1,5-diacetyl-1,5-dihydroindolo[5,4,3*a*,3-*cde*]indole-2,6-dione (**41**) in 59% yield. This amide proved unstable; in an acidic medium it was converted into the starting compound **39**. Heating of compound **41** in aniline did not give unsubstituted indolo[5,4,3*a*,3-*cde*]indole-2,6-dione (**38**); instead, opening of one lactam ring took place to give compound **42**.

Yet another indoloindole fused so as to have the carbon atoms of the benzene and pyrrole rings in common, namely, 4-benzoyl-7-methyl-5,5*a*,6,6*a*-tetrahydroindolo[6,5,4-*cd*]indol-8-one (**43**), was isolated at a stage of synthesis of lysergic acid³⁶ by the reaction of 1-benzoyl-5-methoxycarbonylmethyl-

4,5-epoxy-1,2,2a,3,4,5-hexahydrobenz[*c,d*]indole (**44**) with a large excess of methylamine in an autoclave (100 °C, 6 h).

An attempted synthesis of lysergic acid from enamine **45** resulted in indolo[6,5,4-*cd*]indole **46** as one of the products.³⁷

Japanese researchers^{38–40} prepared indolo[6,5,4-*cd*]indole derivatives and used them as prolactin secretion inhibitors and intermediate compounds in the synthesis of drugs. In one study,⁴⁰ they used tetrahydrobenzo[*c,d*]indole **47** (R = NO₂) as the starting compound; refluxing of compound **47** with zinc amalgam in 2 M HCl gave the corresponding amine (R = NH₂). Cyclisation of this product in aqueous methanol containing NaHCO₃ resulted in indolo[6,5,4-*cd*]indole **48** in high yield (87%).

A patent⁴¹ describes the preparation of a large group of substituted hexahydro-4*H*-indolo[6,5,4-*cd*]indoles **49** from agroclavine and ergoline derivatives.

The synthesis of a series of tetracyclic indole derivatives, in particular indolo[3,2,1-*hi*]indoles, using the Fischer reaction has been described; their anticonvulsant activities have been studied.⁴²

V. Indoloindoles with carbon atoms of the benzene rings in common

1. Synthesis of substituted indoloindoles

The first indolo[7,6-*g*]indole derivatives, namely, 1*H*,6*H*,2,3,7,8-tetrahydroindolo[7,6-*g*]indole-2,3,7,8-tetraone

(**50**) and its monophenyl- and diphenylhydrazones, were prepared in 1922.⁴³ Compound **50** is formed on heating 1,5-naphthylenediamine with diethyl oxalate in acetic acid followed by hydrolysis of diester **51** with potassium hydroxide and neutralisation with HCl.

Subsequently, indolo[7,6-*g*]indole tetraoxo derivatives **52** substituted in the benzene ring were prepared⁴⁴ using the classical Sandmeyer synthesis of isatins from diamionaphthalene as shown below.

X, Y = H, Hal, Alk, AlkO, NO₂, CN.

Kossmehl and Manecke⁴⁵ prepared indolo[7,6-*g*]indole-tetraone **50** in the same way and then converted this product into polymer **53** containing fragments of this indoloindole. Compound **50** was coupled with thiophene in a mixture of glacial acetic and concentrated sulfuric acids. Polymer **53** was obtained in 84% yield as a dark purple powder, which did not melt up to 600 °C and was insoluble in conventional organic solvents (Scheme 1).

A new approach to the synthesis of substituted indolo[7,6-*g*]indoles using readily available 1,5-dihydroxynaphthalenes as the starting compounds has been proposed.⁴⁶

The Fischer cyclisation of isopropyl methyl ketone 1,5-, 1,6-, 1,7- and 2,6-naphthylenedihydrazones gave isomeric hexamethylindoloindoles: 2,3,3,7,8,8-hexamethyl-3*H*,8*H*-indolo[7,6-*g*]indole (**54**), 2,3,3,6,6,7-hexamethyl-3*H*,6*H*-indolo[6,7-*e*]indole (**55**), 2,3,3,9,10,10-hexamethyl-3*H*,10*H*-indolo[7,6-*e*]indole (**56**) and 1,1,2,6,6,7-hexamethyl-1*H*,6*H*-indolo[5,4-*e*]indole (**57**), which were used as hetero residues in the synthesis of carbocyanine dyes.⁴⁷

The researchers cited⁴⁷ were unable to prepare hexamethylindoloindoles from isopropyl methyl ketone 2,7-naphthylenedihydrazone, because only one pyrrole ring was closed in this case due to steric hindrance. Only recently,⁴⁸ was 1,1,2,9,10,10-hexamethyl-1,10-dihydroindolo[4,5-*e*]indole (**58**) synthesised in 35% yield by the Fischer reaction of 2,7-naphthylenedihydrazine and isopropyl methyl ketone in acetic acid without isolation of the dihydrazone.

Substituted indolo[6,7-*g*]indoles **59a,b** were prepared using photolysis of 1,1'-(1,8-naphthylene)bis(1*H*-1,2,3-triazoles) (**60a,b**) (450 W, high-pressure Hg lamp, quartz, 20 °C).⁴⁹ The reaction occurs in two steps, one pyrrole ring being closed first followed by closure of the other ring.

R = Et (**a**), Prⁱ (**b**).

The structure of compound **59a** was confirmed by X-ray diffraction analysis.⁵⁰

2. Synthesis of unsubstituted indoloindoles

The systematic investigation into the synthesis of unsubstituted indoloindoles in which the indole fragments have the carbon atoms of the benzene rings in common was started in 1977 simultaneously at the Chairs of Organic Chemistry of the D I Mendelev Russian University of Chemical Technology and the I Javakhishvili Tbilisi State University.

Isomeric unsubstituted indoloindoles **3**, **4** and **61** were obtained by cyclisation of pyruvic acid or ethyl pyruvate 1,5-, 2,6- and 2,7-naphthylenedihydrazones (**62a,b**), which were prepared from the corresponding naphthylenedihydrazines under conditions of the Fischer reaction (Scheme 2).^{51–53}

Scheme 2

The cyclisation of pyruvic acid naphthylenedihydrazones **62a** was carried out in a mixture of concentrated sulfuric and glacial acetic acids, while the cyclisation of ethyl pyruvate dihydrazones **62b** was performed in a mixture of esters of polyphosphoric acid. The subsequent thermal decarboxylation of diacids **63**, **64a** and **65a** yielded unsubstituted 1H,6H-indolo[7,6-g]indole (**3**), 3H,8H-indolo[5,4-e]indole (**61**) and 3H,8H-indolo[4,5-e]indole (**4**).

Theoretically, one could suggest that cyclisation of pyruvic acid 1,5-naphthylenedihydrazones followed by decarboxylation would give compound **66** with four six-membered rings; however, ¹H NMR spectroscopic data attest to a structure in which protons occur in six- and five-membered rings, which is consistent with structure **3**.⁵⁴

The cyclisation of 2,6- and 2,7-naphthylenedihydrazones may give six isomeric indoloindoles, four symmetrical (two linear and two angular) and two asymmetric ones. Chromatographic monitoring of the cyclisation of dihydrazones showed the presence of several products; however, only one isomer was isolated in each case (namely, compounds **64** and **65**), i.e., in both cases, cyclisation involved more reactive α-positions of the naphthalene nucleus.⁵²

As an attempt to obtain linear indoloindoles, cyclisation of cyclohexanone 2,7-naphthylenedihydrazones was carried out.^{55, 56} In this case, due to the steric influence of the cyclohexane ring, cyclisation of the dihydrazones to give linear structure **67** seemed more likely. Indeed, one-pot reaction carried out in a mixture of concentrated acetic and sulfuric acids gave this compound without isolation of the extremely unstable dihydrazones **68**.

Angular isomer **69** was formed in this reaction as an admixture, which was proved by ¹H NMR spectroscopy.

Similarly, compound **70** was prepared from 1,5-naphthylenedihydrazine and cyclohexanone.⁵⁷

3. Quantum-chemical calculations for unsubstituted indoloindoles

The molecules of indoloindoles **3**, **4** and **61** are tetracyclic fused conjugated hetero systems. According to Albert's classification,⁵⁸ indoloindoles are π-excessive heterocycles, as the number of π-electrons in their aromatic system exceeds the number of atoms in the rings. In this respect, they resemble indoles and benzindoles, but differ from them by the presence of the second heteroatom. Pozharskii⁵⁹ classified these fused π-excessive heterocycles as a separate group, as in these cases, the benzene rings also become π-excessive due to the shift of the π-electron density in the heterocycle. In the molecules of indoloindoles **3**, **4** and **61**, the π-excessive character extends to the naphthalene nucleus.

Quantum-chemical calculations for the molecules of 1H,6H-indolo[7,6-g]indole (**3**),⁶⁰ 3H,8H-indolo[4,5-e]indole (**4**)⁶¹ and 3H,8H-indolo[5,4-e]indole (**61**)⁶² were carried out. The electronic structure of the indoloindole molecule **3** was calculated by the CNDO MO and those of molecules **4** and **61** were determined using the SCF MO method in the CNDO/2 approximation.⁶³ The calculations for molecules **3** and **4** were carried out using the Maslov programme,⁶⁴ those for molecule

61, using software developed at the Department of Chemistry of the Moscow State University (Ref. 65).[§]

It can be seen from the molecular diagrams of indoloindoles **3**, **4** and **61** (Figs 1–3) that the introduction of an additional pyrrole ring into the [4,5]- and [6,7]-benzindole molecules results in a more pronounced electron delocalisation. The charge density and the overall ($\sigma + \pi$) charges are maximum for the atoms located at the β -positions of the pyrrole rings; the electron density is also increased at positions 5,10 (compound **3**), 4,9 (compound **61**) and 4,7 (compound **4**) of the naphthalene nucleus.

Figure 1. Molecular diagram of indoloindole **3**. (a) Overall ($\sigma + \pi$) charges, (b) π -electron densities, (c) bond orders.

Figure 2. Molecular diagram of indoloindole **61**. (a) Charge density on the atoms, (b) Wiberg indices.

Unlike indole, pyrroloindole⁶⁶ or other indoloindole isomers, in the molecule of indoloindole **4**, the highest π -electron densities occur on the α -carbon atoms of the pyrrole rings,⁶⁷ which is abnormal for the indole ring.

4. Reactions of indoloindoles with the carbon atoms of the benzene rings in common

a. Cycloaddition and cyclocondensation

The reactions of indoloindoles **58** and **54** with 2',3'-dimethoxycarbonylspirofluorene cyclopropene yielded dispiropoly-

Figure 3. Molecular diagram of indoloindole **4**. (a) Charge density on the atoms, (b) Wiberg indices.

cyclic photochromic systems, namely, compounds **71** and **72**.^{48, 68, 69}

[§] A programme package Viking was designed at the NMR laboratory of the Department of Chemistry of the Moscow State University for the calculation of physicochemical properties of molecules by semiempirical quantum-chemical methods including CNDO/2.

Yet another method for the preparation of spirocyclic compounds based on indolo[7,6-*g*]- and indolo[4,5-*e*]indoles is the condensation of indoloindoles with substituted salicylaldehydes.^{70, 71} To this end, isomeric hexamethyldihydroindolo-

loindoles **54**, **58** were first converted into bis-quaternary salts, which were then treated with a warm solution of alkali to obtain the Fischer bases, viz., 1,3,3,6,8,8-hexamethyl-2,7-dimethylideneindolino[7,6-*g*]indoline (**73**) and 1,1,3,8,10,10-hexamethyl-2,9-dimethylideneindolino[4,5-*e*]indoline (**74**). The latter compound was condensed with 5-nitro-, 3,5-dinitro- or 3,5-dibromosalicylaldehyde to be converted into spiro compounds **75** and **76** substituted at the pyran fragment.

$R^1 = \text{NO}_2, \text{Br}; R^2 = \text{H}, \text{NO}_2, \text{Br}.$

b. Electrophilic substitution in the pyrrole ring

In a study of the chemical properties of indoloindoles with the carbon atoms of the benzene rings in common, it was of interest to elucidate the influence of the mode of fusion of the indole rings on the specific features of various reactions, in particular, electrophilic substitution. It follows from the molecular diagrams of indoloindoles **3**, **4** and **61** that the molecules of these compounds contain two reactive sites most favourable for the electrophilic attack, namely, the β -positions of the pyrrole rings. Since the molecules are symmetrical, these positions are equivalent from both the electronic and steric standpoints. Therefore, it is of interest to find the conditions for selective formation of mono- or disubstituted derivatives and determine the ratios of the yields of mono- and disubstituted products when they are formed simultaneously. One should also take into account the possibility of competitive substitution in the α -positions of the pyrrole rings or in the naphthalene nucleus.

The Vilsmeier reaction. Among numerous methods of formylation of organic compounds, the Vilsmeier–Haack reaction is one of the most synthetically important methods. Indoloindoles **3**, **4** and **61** were formylated using different molar ratios of these compounds to formamide complexes

with POCl_3 (Vilsmeier complexes, VC). On treatment of indoloindoles **3** and **61** with a threefold excess of VC, symmetrical dialdehydes, viz., 3,8-diformyl-1*H*,6*H*-indolo[7,6-*g*]indole (**77**) and 1,6-diformyl-3*H*,8*H*-indolo[5,4-*e*]indole (**78**), respectively, were formed in high yields.^{61,72} Note that dialdehyde **77** was obtained in highly pure state under these conditions and did not require additional treatment for the use in subsequent transformations.⁵⁴

At the same time, indoloindole **4** was converted into a mixture of 1,9- (**79**) and 1,10-diformyl-3*H*,8*H*-indolo[4,5-*e*]indoles (**80**).⁷²

With equimolar amount of VC, indoloindole **4** is converted into α - (**81**) and β -monoaldehydes (**82**). Chromatographic monitoring of the formylation showed also the presence of diformyl derivatives **79** and **80** among the reaction products.^{61,72}

Indoloindole **3** is converted under the same conditions into a 1:1 mixture of 3-formyl- (**83**) and 3,8-diformyl-1*H*,6*H*-indolo[7,6-*g*]indoles (**77**). An attempt has been made⁶⁰ to obtain monoformyl derivative **83**. To this end, the formylation temperature was reduced to 55–60 °C and the reactants were taken in a 1:1 ratio. Under these conditions, the yield of aldehyde **83** was 43%, 2-formyl-1*H*,6*H*-indolo[7,6-*g*]indole (**84**) being formed as a by-product.

Indolo[7,6-*g*]indole (**3**) does not react with *N,N*-dimethylacetamide at 70–100 °C. An increase in temperature results in the resinification of the starting compound, no acetylation products being detected in the reaction mixture.⁷²

The presented data show that indoloindoles undergo the Vilsmeier–Haack reaction more readily than indole, as indicated by the formation of α -substituted aldehydes in addition to β -substituted products. This is due to the rather high π -electron density on the carbon atoms of the pyrrole ring.

Acetylation. Acetylation of indoloindoles **3**, **4** and **61**^{61,72} with acetic anhydride in the presence of acetic acid affords mixtures of acetyl derivatives in low yield. In the case of

acetylation of indolo[7,6-*g*]indole (**3**), both mono- (**85** and **86**) and disubstituted (**87** and **88**) derivatives were isolated from the reaction mixture by column chromatography.

The acetylation of indolo[5,4-*e*]indole (**61**) with acetyl chloride in the presence of AlCl_3 yields only monosubstituted α - and β -acetyl derivatives **89** and **90**, while acetylation of indolo[4,5-*e*]indole (**4**) under the same conditions affords only α -acetyl derivatives **91**. In the latter case, minor amounts of *N*-acetyl derivatives **92** and **93** are also formed.

The acetylation of compound **4** at the β -position of the pyrrole ring does not take place, unlike acetylation of indoloindoles **3** and **61**. This is apparently due to steric hindrance created by the closely arranged pyrrole rings in compound **4**. In all cases, the yield of monoacetylated derivatives was substantially higher than the yield of diacetylated products.

The formation of product substituted in the naphthalene nucleus (compound **88**) upon the acetylation of compound **3** is attributable to an increase in the π -electron density and an additional activation of the naphthalene α -position due to the electronic influence of the pyrrole ring.

Azo coupling. Azo coupling tends to be highly selective. Studies of azo coupling of indoloindoles **3**, **4** and **61** with different diazo components in a neutral medium at a 1 : 3 molar ratio of the substrate to the diazonium salt have been reported.^{61, 72} Under these conditions, indoloindole **3** is converted into the expected monosubstituted β -phenylazo derivatives **94a–c**, while azo coupling of indoloindole **4** follows an abnormal route with a predominant formation of monosubstituted α -phenylazo derivatives **95a–c**. The reaction of indoloindole **61** with phenyldiazonium chloride furnishes 1-phenylazo- (**96**) and 2-phenylazo-3*H*,8*H*-indolo[5,4-*e*]indoles (**97**)

in a 1 : 4.5 ratio; the reaction with *p*-nitrophenyldiazonium chloride results in polymeric products.

R = H (**a**), Cl (**b**), NO_2 (**c**).

The predominant formation of monosubstituted derivatives in azo coupling may be caused by low electrophilicity of the ArN_2^+ ion, which is insufficient for the subsequent interaction with the monosubstituted phenylazo derivatives formed, in which the electron density of the aromatic system has been reduced by the introduction of the first phenylazo group. The formation of 2-substituted derivatives from compounds **61** and **4** may be due to the steric influence of the pyrrole ring and naphthalene nucleus.

The Mannich reaction. Indoloindole **3** undergoes the Mannich reaction with formaldehyde and amines (dimethylamine, piperidine and morpholine) to give the corresponding disubstituted derivatives **98–100** in high yields.^{73, 74} The reaction is carried out in acetic acid at 60 °C.

$\text{NR}_2 = \text{NMe}_2$ (**98**), N-piperidine (**99**), N-morpholine (**100**).

Indoloindoles **61** and **4** are converted into 1,6-bis-(dimethylaminomethyl)-3*H*,8*H*-indolo[5,4-*e*]indole (**101**) and 1-dimethylaminomethyl-3*H*,8*H*-indolo[4,5-*e*]indole (**102**), respectively, with the same ease and in high yields.⁶¹

In order to study the probable biological activities, salts of gramine analogues were prepared, namely, 3,8-bis(dimethylaminomethyl)-1*H*,6*H*-indolo[7,6-*g*]indole dihydrochloride, dimethosulfate, dimethiodide and diethiodide,^{73, 74} 1-dimethylaminomethyl-3*H*,8*H*-indolo[4,5-*e*]indole methiodide and

1,6-bis(dimethylaminomethyl)-3*H*,8*H*-indolo[5,4-*e*]indole dimethiodide.

Alkylation. The alkylation of indoloindoles **3**, **4** and **61** was carried out using alkyl halides.⁷⁵ In non-polar solvents (for example, under conditions of phase transfer catalysis in a 50% aqueous solution of NaOH), the reactions proceed slowly (~12 h) despite vigorous stirring at a temperature of 60–65 °C. Probably, this is caused by poor solubility of indoloindoles in non-polar solvents. The alkylation of compounds **3**, **4** and **61** in 1,2-dichloroethane at a catalyst (tetrabutylammonium bromide): substrate molar ratio of 1:5 at 40–45 °C yields mainly *N,N'*-dialkylindoloindoles.⁷⁵ Indolo[4,5-*e*]indole **4** undergoes *N,N'*-dialkylation more easily than compounds **3** and **61**, which is due to its better solubility in 1,2-dichloroethane. Compounds **103–105** were synthesised by alkylation.^{75–77}

R = Et (**a**), Bn (**b**), CH₂=CHCH₂ (**c**), CH≡CCH₂ (**d**).

Apart from the purely theoretical interest, compounds **103–105** are of considerable practical value because of their probable biological activities and the use for preparation of polymers. For example, 3,8-dipropargylindolo[5,4-*e*]indole (**104d**) was used as an example in the Glaser–Eglinton reaction to give polyacetylenes **106** containing fused indoloindole fragments in the monomeric unit,⁷⁸ whereas in the case of 3-propargylindole, symmetrical diacetylene was isolated.⁷⁹

N,N'-Dibenzyl-substituted indoloindoles **107** and **108** were obtained by direct Fischer cyclisation of the corresponding naphthylenedihydrazines and alkyl ketones followed by benzylation of the cyclisation products **109** and **110**.^{57, 68, 80}

The same publications describe the synthesis of *N,N'*-dibenzyl derivatives **111** and **112** from compounds **67** and **70**.

c. Transformations in side chains

Synthesis of heteroauxin analogue. The synthesis of a heteroauxin analogue, *viz.*, 3,8-bis(carboxymethyl)-1*H*,6*H*-indolo[7,6-*g*]indole (**113**), has been reported.⁷³ 3,8-Bis(dimethylaminomethyl)-1*H*,6*H*-indolo[7,6-*g*]indole (**98**) was used as the starting compound.

After refluxing of an ethanolic solution of compound **98** in the presence of KCN for 17 h, 3,8-bis(carbamoylmethyl)-1*H*,6*H*-indolo[7,6-*g*]indole (**114**) resulting from partial hydrolysis of the intermediate dinitrile **115** precipitates from the reaction mixture. Due to the poor solubility in an alkaline medium, compound **114** does not undergo further hydrolysis; however, in an acidic medium, the Bouveault reaction of amide **114** yields an oily product in which diacid **113** was detected by chromatography.

Condensation involving indolo[7,6-*g*]indole aldehydes. Aldehydes **77** and **83** are readily coupled with primary amines to give Schiff bases. The reactions of compounds **77** and **83** with aniline resulted in 3,8-diformyl-1*H*,6*H*-indolo[7,6-*g*]indole dianil (**116**) and 3-formyl-1*H*,6*H*-indolo[7,6-*g*]indole anil (**117**), respectively, in high yields.⁶⁰ The reaction proceeds without a catalyst.

The condensation of compounds **77** and **83** with thiosemicarbazide in the presence of a catalytic amount of an ethanolic solution of HCl (pH 4–5) occurs equally smoothly giving rise to thiosemicarbazones **118** and **119**.

R = NHC(S)NH₂ (**118**, **119**), OH (**120**, **121**).

The reaction of monoaldehyde **83** with hydroxylamine proceeds smoothly to yield a mixture of 3-formyl-1*H*,6*H*-indolo[7,6-*g*]indole oxime (**120**) isomers, which could not be separated.⁶⁰ The reaction is carried out in ethanol in the presence of sodium hydrogencarbonate. The condensation of dialdehyde **77** takes place only with a strong oximating reagent, *viz.*, a mixture of hydroxylamine hydrochloride with pyridine. The reaction yields geometric isomers of 3,8-diformyl-1*H*,6*H*-indolo[7,6-*g*]indole dioxime (**121**); both isomers were isolated by chromatography. According to NMR spectroscopy, these isomers had *syn,syn*- and *anti,anti*-configurations and existed in the cisoid conformation,⁶⁰ which is sterically more favourable than the transoid conformation of the aldoxime groups.

The condensation of monoaldehyde **83** with excess nitromethane (or nitroethane) proceeds in the presence of a catalytic amount of ammonium acetate yielding 3-(2-nitrovinyl)- (**122a**) or 3-(2-nitroprop-1-enyl)indolo[7,6-*g*]indole (**122b**) (the nitroalkane serves as the solvent).^{81,82} The reactions of dialdehyde **77** with these nitroalkanes follow different routes depending on the amount of the nitroalkane. When a stoichiometric amount of nitroalkane is used and the reaction is carried out in DMF in the presence of ammonium acetate, disubstituted derivatives **123a,b** are formed.

R = H (**a**), Me (**b**).

With a large excess of nitromethane and a 50% solution of NaOH as the catalyst, the reaction of dialdehyde **77** with nitromethane does not stop after the formation of compound **123a**, but proceeds further to give small amounts (isolated yields 5%–8%) of the addition products of nitromethane to compound **123a**, namely, 3,8-bis(1,3-dinitroisopropyl)-1*H*,6*H*-indolo[7,6-*g*]indole (**124**) and 3-(1,3-dinitroisopropyl)-8-formyl-1*H*,6*H*-indolo[7,6-*g*]indole (**125**), as followed from their elemental composition and spectroscopic data. The addition of nitromethane to 3-(2-nitrovinyl)indole follows a similar route.⁸³

The condensation of dialdehyde **77** with malonic acid in pyridine in the presence of piperidine affords 3,8-divinyl-1*H*,6*H*-indolo[7,6-*g*]indole (**126**), which is the key compound in the synthesis of various monomeric and polymeric products.⁸⁴ Presumably, the condensation gives diacid **127**, which is decarboxylated under the reaction conditions to give compound **126**.

Synthesis and transformations of indoloindole dihydrazides. Refluxing of diesters **64b** and **65b** with hydrazine hydrate in propan-2-ol yielded 2,7-di(hydrazinocarbonyl)-3*H*,8*H*-indolo[5,4-*e*]indole (**128**) and 2,9-di(hydrazinocarbonyl)-3*H*,8*H*-indolo[4,5-*e*]indole (**129**).^{85, 86}

Nitrosation of dihydrazide **129** using sodium nitrite and concentrated HCl gives 2,9-di(azidocarbonyl)-3*H*,8*H*-indolo[4,5-*e*]indole (**130**).⁸⁵ Treatment of dihydrazide **128** with ethyl methyl ketone or hexanone resulted in dihydrazones **131** and **132**, respectively.

$\text{R}_2\text{C=NNHC(O)}$ **131, 132**
 $\text{N=CR}_2 = \text{N=CMeEt}$ (**131**), N= (cyclohexyl) (**132**).

Synthesis of arylenephosphamacrocycles using tri- and pentavalent phosphorus compounds

E E Nifantsev, P V Slitkov, E N Rasadkina

Contents

I. Introduction	327
II. Syntheses using trivalent phosphorus compounds	327
III. Syntheses using pentavalent phosphorus compounds	337
IV. Conclusion	337

Abstract. Key results of research into the reactions of cyclophosphorylation of dibasic phenols and related compounds with tri- and pentavalent phosphorus compounds are analysed. Structural features and chemical modification of macrocyclic systems obtained are considered. The bibliography includes 63 references.

I. Introduction

Research into macrocyclic phosphorus-containing systems began after the discovery of plasmids that are giant DNA molecules containing cyclic structures.¹ Probably, this fact and considerable advances in the synthesis and investigations of crown ethers and other macroheterocycles gave an impetus to intensive studies dealing with the design and chemical properties of cyclic systems containing tri- and pentavalent phosphorus acid residues.^{2–5} It should be noted that the attention of researchers was focussed on the products of cyclophosphorylation of dibasic phenols. The results obtained in this field allow one to relate the reactivities of the cyclic compounds to their sizes, mutual position of phosphorus-containing groups and other factors. Now one can expect the design of original supramolecular assemblies based on novel phosphorus-containing macrocycles, observation of molecular recognition effects,^{6,7} discovery of novel catalytic systems, *etc.*

At present, cyclic compounds of different nature are available. Their molecules comprise two to six phosphorus-containing fragments and the same number of arylene substituents. In this review we will dwell on the studies devoted to the synthesis and investigations of the properties of such systems that mainly include the phosphite and phosphonite moieties.

II. Syntheses using trivalent phosphorus compounds

1. Syntheses of diphosphamacrocycles

This problem attracted the attention of scientists from several research centres. They studied the reactions of dibasic phenols with equivalent and inequivalent amounts of phosphorylating agents (direct cyclophosphorylation and molecular assembly techniques, respectively).

a. Cyclophosphorylation of dihydroxybenzenes and 4,4'-dihydroxybiphenyl

The first phosphacyclophanes comprising two resorcinol (**1**) residues linked by two phosphoramidite bridges were synthesised in 1997 by the reactions of **1** with hexaalkylphosphorous triamides **2** taken in a 1 : 2 molar ratio.^{8–10} Then, 1,3-bis(phosphordiamidite)benzene **3** formed in the first stage was introduced into the reaction with an equimolar amount of **1**:

R = Me, Et.

In addition to this process (we will call it ‘molecular assembly’), a direct reaction between equimolar amounts of resorcinol and phosphorous triamide is also possible. This reaction, which can be called ‘direct cyclophosphorylation’ or ‘direct synthesis’, is more convenient and often gives better results. Both reactions proceed in acetonitrile or 1,4-dioxane at room temperature.

Cyclic bis(phosphoramidites) **4** are oily substances characterised by good solubility in conventional organic solvents and high oxidisability.

Cyclic phosphoramidites **5** based on hydroquinone **6** were also synthesised by the molecular assembly and direct phosphorylation techniques (from this point on, figures in parentheses above or below the arrow denote the reactant ratio).¹¹

R = Me, Et.

The direct phosphorylation method resulted in higher yields of compounds **5** compared to the molecular assembly technique.

The structures and individuality of the reaction products as well as cyclic phosphoramidites and their derivatives (see below) were proved by physicochemical methods (¹H and ³¹P NMR spectroscopy, IR spectroscopy and mass spectrometry) and confirmed by the results of elemental analysis. Cyclic phosphoramidites **5** synthesised in different ways exhibited identical physicochemical characteristics. These are solid, low-melting and poorly soluble substances that are unstable upon storage even in inert atmosphere. Probably, the labile behaviour of these compounds is due to strain in the macrocycle caused by the proximate arrangement of two aromatic rings. This assumption was confirmed by the results of calculations of the most stable conformations, according to which the molecules of cyclic bis(phosphoramidites) **5** have an eclipsed cyclophane structure.¹²

Compounds **5** readily add oxygen and sulfur to give corresponding cyclic bis(phosphoramidates) and bis(phosphoramidothioates).

Similar heterophanes (hereafter, phosphacyclophanes) **7** are formed in the reactions of 4,4'-dihydroxybiphenyl with phosphorous triamides **2**.¹¹

Compounds **5** and **7** were introduced into the oxidation reactions and into complexation with Mo(CO)₆ and Rh(CO)₂(acac) (acac stands for acetylacetonate). The oxidation and complexation with Rh(CO)₂(acac) occurred in dichloromethane at room temperature. Complexes with Mo(CO)₆ formed only on heating in dioxane (95 °C) in the presence of excess carbonyl. All derivatives were isolated and studied by physicochemical methods (¹H and ³¹P NMR spectroscopy and IR spectroscopy).

Nitrogen-containing phosphacyclophanes **8** were obtained from (*N*-benzylidene)-*p*-aminophenol and dialkylphosphorochloridites (RO)₂P(O)Cl.¹³ The reactions proceeded in chloroform at room temperature and completed in 5 days.

R = R' = Et; (RO)₂ = OCH₂CH₂O, R' = CH₂CH₂Cl.

Phosphacyclophane **9** was synthesised by phosphorylation of *N*-(β-hydroxypropyl)-*o*-aminophenol with hexamethylphosphorous triamide.¹⁴ Monitoring by ³¹P NMR spectroscopy revealed the formation of cyclic compound **10** with one phosphorus-containing fragment. When heated, compound **10** transformed into heterobicyclic **11** which in turn experienced spontaneous dimerisation into phosphoramidite **9**. The structure of compound **9** was proved by X-ray analysis.

At 20 °C, the transformation **11** → **9** takes a very long time to complete (about a year).

b. Cyclophosphorylation of organylenebisphenols

Among the first examples of this type of chemical transformation is the reaction of 1,7-bis(2-hydroxyphenyl)-1,4,7-trioxaheptane with 1-adamantyldibromophosphine (AdPBr₂).¹⁵

Ad is 1-adamantyl.

This cyclophosphorylation results in the fourteen-membered adamantylphosphonous acid diester **12** (yield 10%) and

diphosphorus cyclic compound **13** (yield 11%–44%). The structures of the products were confirmed by NMR spectroscopy and by measuring the molecular mass (ebullioscopy). Substance **13** appeared to be a stable and convenient reactant, which can be oxidised, alkylated, *etc.*

The cyclophosphorylation of an available commercial product, namely, 2,2-bis(*p*-hydroxyphenyl)propane (DIAN) (**14**) with phenylphosphonous acid tetraethyldiamide was studied in the 1990s.¹⁶

The reaction was carried out in toluene under (relatively) severe conditions (115–120 °C). The structure of cyclophenylphosphonite **15** was studied by X-ray analysis.¹⁷ The phosphorus atoms and the quaternary carbon atoms approximately occupy the corners of a square. The angle between the DIAN aromatic rings is 35° so the whole system has a cavity. The diphosphonite macrocycle **15** was found to be a stable compound.

This allowed one to extend the range of dinuclear bisphenols used in cyclocondensation and synthesise new macrocycles **16** containing not only isopropylidene, but also sulfide, imide and other bridges.¹⁸

Cyclic bis(phenylphosphonites) **16** were introduced into the complexation, oxidation and sulfurisation reactions, easily

resulting in cyclophosphonates and their thio analogues. An X-ray diffraction study revealed considerable changes in the cavity volume and configuration for cyclic bis(phosphonates) compared to the starting cyclic bis(phenylphosphonites).¹⁸ Some cyclic bis(phenylphosphonites), *e.g.*, compounds **15** and **16**, can form complexes with CuBr.^{19,20} The assumption of metal coordination to two phosphorus atoms was confirmed by ³¹P NMR data.

Complexes **17** exhibit high catalytic activity in the reactions accompanied by transfer of hydrogen atoms in homogeneous media.

Phosphorylation of bisphenol **14** with equimolar amount of phosphorous triamides **2** under mild conditions results in reactive cyclic phosphoramidites **18**.²¹

This approach can be extended to molecular assembly of unsymmetrical bis(phosphoramidite) macrocycles (Scheme 1).

Using bisphenols **19** and **20** as matrices and 2,6-di-*tert*-butyl-4-methylphenylphosphonous dichloride (**21**) and diethylamidophosphonous dichloride as phosphorylating reagents, in the last decade Habicher and Bauer^{22–25} synthesised a series of even more complex macrocycles **22–24**. The syntheses were carried out at room temperature in toluene in the presence of triethylamine upon high dilution (Scheme 2).

Habicher and Bauer also established that many unsymmetrical macrocycles undergo spontaneous symmetrisation. For instance, the interaction of bisphenol **14** with bis(phosphorodiamidite) based on bisphenol **20** results in cyclic phos-

Scheme 1

Scheme 2

phoramidite **15** and free bisphenol **20**. When carried out on heating, this reaction affords acyclic oligomeric products.

The above series of reactions is completed by the synthesis of phosphorus-containing cryptands **25a–c** by the reaction of bisphenol **20** with phosphorus trichloride.²⁶

Analysis of the structures of cryptands **25** revealed the ‘in–out’ isomerism. All three stereoisomers were chromatographically separated. The structures of isomers **25a–c** were proved by NMR spectroscopy and X-ray diffraction analysis. In addition, all three cryptands were introduced into the

reactions characteristic of simple phosphites.²⁷ The synthesis and investigations of the chemical features of cyclic phosphites and phosphorus-containing cryptands have been well documented in a review.²⁸

At present, cyclophosphorylation reactions are carried out using phosphorochloridites and phosphoramidites, the latter often being more convenient because they react with phenols at room temperature in various solvents and do not require removal of amines released. Additionally, the amide groups show different reactivities, namely, the first amide group is replaced rapidly while the third amide group remains almost unsubstituted. At the same time the use of reaction mixtures based on phosphorochloridites requires introduction of acceptors in order to bind hydrogen chloride evolved, all chlorine atoms being almost equally reactive. Probably, the next stage of research and development in this field of synthetic chemistry will require optimisation of reaction conditions, *e.g.*, the search for appropriate catalysts.

Progress in the synthesis of complex macrocyclic diphosphorus systems using phosphorous triamides **2** led to the preparation of multinuclear chiral structures **26** based on the

Z = O, S, CMe₂, CPh₂.

available bisphosphorylated 1,4;3,6-dianhydro-D-mannitol derivative.^{29–31} The reaction was carried out in benzene with distillation of diethylamine (75 °C) in inert atmosphere.

Products **26** were converted *in situ* into corresponding bis(thiophosphates), which were isolated from the reaction medium in 60%–88% yields by column chromatography.

Structures with large cavities were also synthesised starting from silylated β -cyclodextrin derivative **27** and various dinuclear phosphorylated bisphenols.³² The reactions in benzene at 75 °C completed in 6 h and resulted in the so-called ‘capped’ cyclodextrins **28** isolated in 62%–75% yields by column chromatography. ‘Capping’ of the cyclodextrin molecule enhances its ability to form inclusion complexes with various ‘guest’ molecules.

R = Me, Ph.

In addition to bisphenols, aromatic diamines were also employed to design related macrocyclic systems. For instance, bis(2-amino-5-methylphenyl)methane (**29a**) and its phenyl analogue **29b** served as building blocks for the synthesis of 16-membered nitrogen-containing macrocycles **30a,b**.³³ The reaction was carried out using the molecular assembly technique in dioxane in the presence of triethylamine at 5 °C with ethyl phosphorodichloridite as phosphorylating agent.

R = H (a), Ph (b).

The best results were obtained in the phosphorylation of primary amines with alkyl phosphorodichloridites. ³¹P and ¹H NMR studies showed that the macrocycles synthesised exist as mixtures of two conformers.

c. Cyclophosphorylation of dihydroxynaphthalenes and dihydroxyanthracenes

The cyclophosphorylation of dihydroxynaphthalenes is a promising method for the synthesis of previously unknown phosphacyclophanes. At present, it has been shown that both symmetrical (1,5-; 2,6-; 2,7-) and unsymmetrical (1,3-; 1,6- and 1,7-) dihydroxynaphthalenes **31** efficiently react with phosphorous triamides **2** following the single-step or two-step (involving intermediate amido esters **32**) schemes.^{17, 34–39}

All reactions were carried out in acetonitrile at room temperature and completed in 3 to 40 h depending on the substituent in the phosphorylating agent. The cyclic products **33a–f** were obtained in 70%–80% yields.

R = Me, Et, Prⁱ; R–R = (CH₂)₅; Ar = *i,j*-naphthylene;
i = 1; *j* = 7 (**a**), 6 (**b**), 3 (**c**), 5 (**d**); *i* = 2; *j* = 7 (**e**), 6 (**f**).

Cyclophosphorylation of 1,7-dihydroxynaphthalene (**31a**) results in two structural isomers with differently arranged naphthylenedioxy groups, namely, a series arrangement in compound **33a** (1,7,1,7) and a pairwise arrangement in compound **33a** (1,1,7,7). The former isomer was isolated and studied by NMR spectroscopy and X-ray diffraction analysis.^{36, 37} Its ³¹P NMR spectrum exhibits a singlet. The second isomer was characterised by ¹H NMR spectroscopy in the form of thio derivative. The ³¹P NMR spectrum of **33a** (1,1,7,7) exhibits two singlets.

Products of cyclophosphorylation of 1,6- or 1,3-dihydroxynaphthalene exist as single structural isomers [compounds **33b** (1,6,1,6) or **33c** (1,3,1,3), respectively] with a series arrangement of naphthylenedioxy groups in the ring.^{38, 39}

The molecular assembly technique was also used for the synthesis of phosphacyclophanes **34** the molecules of which comprise different arylene moieties. A number of 'non-uniform' naphthophosphacyclophanes containing two different naphthylenedioxy units were obtained.⁴⁰

Ar = *i,j*-naphthylene, Ar' = *i',j'*-naphthylene; {*ij*} ≠ {*i'j'*}.

Similarly to the case of 'uniform' naphthophosphacyclophanes based on 1,6- and 1,3-dihydroxynaphthalenes, cyclophosphorylation of unsymmetrical 1,7-, 1,6- and 1,3-dihydroxynaphthalenes only resulted in structural isomers with a series arrangement of the naphthylenedioxy groups in the ring.

The reaction is regioselective; therefore, the products were isolated in a pure state. The naphthophosphacyclophanes **33** and **34** were oxidised and sulfurised. The reactions in dichloromethane at room temperature took a short time (20 h) to complete. Thiophosphoramidates were isolated by column chromatography (yields ~55%) and cyclophosphoramidates were isolated by reprecipitation (yields ~90%). The structures and individual character of all macrocycles **33**, **34** and their thio and oxo derivatives were confirmed by ¹H, ¹³C and ³¹P NMR spectroscopy and by MALDI mass spectrometry. MM2 calculations of the steric energies of the 'uniform' and 'non-uniform' naphthophosphacyclophanes made it possible to predict the stabilities of corresponding phosphites, thiophosphates and phosphates.

Cyclic phosphoramidites **33** and **34** readily form complexes with Mo(0) and Rh(I). The complexation of 'uniform' naphthophosphacyclophanes occurs more easily than that of 'non-uniform' compounds.

Recently, the syntheses of naphthalene-based phosphacyclophanes using dismutation of bis(phosphoramidites) were reported.^{41, 42} The process can be described as follows:

The rate of this reaction depends on position of substitution in naphthylenedioxy groups and on the nature of the substituent at the phosphorus atom. In particular, the reaction of unsymmetrical 1,7-dihydroxynaphthalene results in one structural isomer with a series arrangement of naphthylenedioxy groups in the ring.³⁷

As mentioned above, the direct synthesis and molecular assembly techniques afford a mixture of two structural isomers, one with a series (1,7,1,7) and the other with a pairwise (1,1,7,7) arrangement of naphthylendioxy groups in the ring. Therefore, the dismutation is a regioselective reaction.

The dismutation of bis(phosphoramidites) based on dibasic phenols and naphthols has been studied in considerable detail.^{41, 42} The process is governed by many factors including the nature of the aromatic fragment, the substituent at the phosphorus atom, the solvent and especially the existence of conjugation in the starting reactant molecule. The derivatives of condensed aromatic systems undergo dismutation faster than their mononuclear analogues. Dismutation of the amide derivatives with aliphatic substituents at nitrogen also proceeds more readily than that of their heterocyclic analogues. The reaction in dichloromethane proceeds at the highest rate irrespective of the aromatic component and substituents at phosphorus. Non-polar solvents (benzene, diethyl ether) do not favour dismutation. Temperature does not affect the duration of the dismutation reaction. In the presence of a catalyst (amine hydrochloride) the process time is shortened by a factor of 1.5–2.

In addition, MM2 calculations of the steric energies were carried out for all the compounds synthesised. Generally, the steric energies of phosphorous diamido esters **32** are higher than those of phosphorous amido diesters **33**, **34**.

Cyclic phosphoramidites **36** were synthesised from bisphosphorylated aromatic diols **3**, **32a,c,e** and 2,2'-dihydroxy-1,1'-dinaphthylmethane (**35**) by the molecular assembly technique at room temperature in dioxane.⁴³

Ar = 1,3-phenylene, 1,7-, 1,3- or 2,7-naphthylene; X = S, O.

The oxidation occurred in dioxane or dichloromethane at room temperature and completed in 24 h. The structures of the resulting macrocycles **37** were confirmed by ¹H, ¹³C and ³¹P NMR spectroscopy and by MALDI mass spectrometry.

Phosphacyclophanes were also synthesised from dihydroxyanthracenes. For instance, the reaction of 2,6-dihydroxyanthracene with hexaethylphosphorous triamide results in a symmetrical ring system **38**.⁴⁴ This compound is similar in

chemical properties to the naphthalene analogues studied earlier.

A cage product **39** comprised of two anthracene residues linked by two phosphoramidite bridges at positions 9,10 was prepared from 9,10-diacetoxyanthracene, which was used instead of very unstable 9,10-dihydroxyanthracene, and hexamethylphosphorous triamide.^{45, 46}

The reaction proceeded at 20 °C and completed after 96 h. Phosphacyclophane **39** was isolated in a 42% yield using two methods, at equimolar reactant ratio and by dismutation.

Product **39** appeared to be unstable in solution and decomposed with release of anthraquinone. This is consistent with the results of MM2 calculations.

A dimer based on 1,4-dihydroxyanthracene was also synthesised from its diacetate derivative **40** using the molecular assembly technique involving bis(phosphoramidite) **41** and the direct synthesis.^{46, 47}

The reaction was carried out at room temperature. Phosphacyclophane **42** was isolated in 37% (molecular assembly technique) and 58% (direct synthesis) yields. A MALDI mass spectrometric study showed that the cyclic product contains two anthracene moieties and two phosphorus-containing groups. Compound **42** is much more stable than compound **39**, because the aromatic fragments in the former can be more distant from each other.

Macrocycle **43** is based on dianthrone **44**, a bisphenol containing two mutually perpendicular 9-anthrone residues

linked by a C—C bond at positions 10.⁴⁸ It was phosphorylated with phosphorous amides **2** in pyridine only on heating in the temperature range of 50–120 °C depending on the substituent in the phosphorylating agent. Cyclic systems **43** were only synthesised by the molecular assembly technique using corresponding bisphosphorylated derivatives **45**.

The direct synthesis affords a mixture of cyclic systems containing two to four dianthracene residues. It was established that oxidation of cyclic compound **43** ($R = \text{Me}$) results in a 'cross-linked' structure **46** containing a five-membered ring with two quaternary carbon atoms. It was assumed that in this case one deals with isomerisation, which obeys the pattern of intramolecular Diels–Alder reaction and is similar to intramolecular cycloaddition of some compounds with two anthracene residues.

$X = \text{S}, \text{O}$.

Metallaphane complexes **47** containing bridging $\text{Pt}(\text{II})$ atoms are based on dihydroxynaphthalene derivatives **32a–f** and bisphosphorylated dihydroxyanthracenes **41** and **45**. The synthesis was carried out in dichloromethane or pyridine at room temperature with diacetonitriledichloroplatinum(II) as the starting complex.^{35, 49–51}

Complexes **47** are powder-like compounds which decompose upon melting. They were isolated in 60%–80% yields. The structures and compositions of the complexes were confirmed by ^1H and ^{31}P NMR spectroscopy and by cryoscopy. The spin–spin coupling constants $^1J_{\text{PPt}}$ equal to 3441 and 3347 Hz indicate that the complexes are *trans*-isomers.

2. Synthesis of triphosphamacrocycles

Recently, macrocyclic compounds larger than molecule **4** containing regularly arranged phosphoramidite groups and resorcinol fragments have been synthesised. The resulting compounds resemble Pedersen's crown ethers.⁶ Therefore, they or corresponding pentavalent phosphorus derivatives can find practical applications in supramolecular chemistry.

The simplest representatives of these macrocyclic compounds were synthesised following the scheme:

$R = \text{Me}, \text{Et}$.

The reactions of resorcinol and phosphorous amides **2** were carried out at 1:2 molar ratio of the reactants at room temperature. Then, phosphorodiamidite **3** was introduced into the reaction with resorcinol. Linear reaction product **48** undergoes cyclisation in the reaction with phosphoramidite **2**.^{52–54}

Sulfurisation of macrocyclic tris(phosphoramidite) **49** results in a crystalline *cis,cis,trans*-product (one P atom is above and the other two P atoms are below the macrocycle plane); its structure was established by X-ray diffraction analysis.⁵³ Later on, dismutation of macrocyclic pentakis(phosphoramidite) (see Section II.3) afforded the *cis,cis,cis*-isomer of heterocycle **49** (all P atoms are on one side of the macrocycle), which significantly differs from the *cis,cis,trans*-isomer in properties.^{54, 55}

Mention should be made of the possibility of bis(phosphoramidite) **4** formation in the first stage of this reaction. Unfortunately, other procedures for the synthesis of cyclic phosphoramidites are also non-selective. For instance, the reactions of resorcinol with phosphorous triamides **2** in acetonitrile result in cyclic bis(phosphoramidite) **4** and cyclic tris(phosphoramidites) **49** as the major products.^{8, 9}

Cyclic tris(naphthylenephosphoramidites) have also been synthesised (Scheme 3).^{51, 56} One route to these compounds begins with the synthesis of linear bis(phosphoramidite) **50** containing three naphthylene fragments, two of which bear hydroxyl groups, at a 1:3 ratio of the starting reactants (this is

Scheme 3

a necessary condition). Otherwise, the reaction results in cyclic bis(phosphoramidite) **33e**. Bisphenol **50** was sulfured and product **51** was isolated by column chromatography. Phosphocyclisation of **51** with phosphorous triamides **2** resulted in compound **52** which was again sulfured. Tris(thiophosphate) **53** was isolated by column chromatography in ~60% yield.

The second method involves the synthesis of stable acyclic *O,O*-bis(7-hydroxy-2-naphthyl) *N,N*-dialkyl thiophosphoramidates **54**. Cyclisation of **54** with bisphosphorylated 2,7-dihydroxynaphthalene **32e** followed by sulfuration affords the desired cyclic tris(thiophosphate) **53**.

Cyclic thiophosphates **53** synthesised using both methods exhibited fully identical physicochemical characteristics.^{51, 56} These tris(thiophosphates) can be used as, *e.g.*, ligands for binding 'soft' metals or as starting compounds in syntheses of cyclic tris(phosphites).

Bisphenol **14**, $P(NEt_2)_3$ and phenylphosphonous dichloride were used for the synthesis of a phosphorylating agent **55**, which was then employed in the phosphorylation of 1,4;3,6-dianhydro-D-mannitol³¹ in order to obtain a chiral large-cavity system **56**.

The reaction was carried out in benzene, the second and third stages being conducted in the presence of triethylamine. Macrocycle **56** was isolated in 40% yield and characterised by ³¹P and ¹H NMR spectroscopy.

3. Synthesis of higher phosphorus-containing macrocycles

Higher macrocyclic systems were designed using the molecular assembly technique starting from resorcinol and phosphorous triamides **2** (see above). The oligomer chain terminated with hydroxyl groups at both ends was extended in a sequential manner. Then, the diols thus obtained were cyclophosphorylated with phosphorous triamides **2**. One-pot synthesis under control of the composition of intermediates **57–59** resulted in cyclic pentakis(phosphoramidites) **60** (Scheme 4).^{53, 54}

The reaction was carried out in acetonitrile or benzene at room temperature. Cyclic compound **60a** is unstable and undergoes a rearrangement resulting in cyclic bis- and tris(phosphoramidites) when stored in benzene solution.

In contrast to this, cyclic pentakis(phosphoramidite) **60b** does not undergo rearrangement.^{54, 55}

Scheme 4

R = Me (a), Et (b).

Regarding even more complex macrocycles, it is appropriate to synthesise them from two fragments of a target system with similar compositions. An example is provided by the synthesis of cyclic hexakis(phosphoramidites) **61** (Scheme 5).

Cyclic oligomeric phosphoramidites considered above were introduced into the sulfurisation and oxidation reactions. Some of them were introduced into the complexation reactions with $\text{Rh}(\text{CO})_2(\text{acac})$. The results of cryoscopic determination

Scheme 5

R = Me, Et.

Scheme 6

of the molecular masses and the NMR spectra confirm the structures of these compounds.

Macrocycles **62** were synthesised based on 2,2',7,7'-tetrahydroxy-1,1'-dinaphthylmethane **63**. Macrocycles **62** contain four phosphorus atoms, two of them form phosphocine fragments. Phosphorous triamides **2** served as phosphorylating agents. Macrocycles **62** can be synthesised using two procedures, by direct phosphorylation at 1 : 2 reactant ratio and in a stepwise reaction using the action of calix[4]resorcinarene (K[4P] with bulky hydrophobic substituents in the lower rim on the phosphate derivative **64** in the second stage.⁵⁷ All reactions were carried out in dioxane under argon at room temperature (Scheme 6). The yields of the target products **62** were 55%–63%.

III. Syntheses using pentavalent phosphorus compounds

Compared to trivalent phosphorus compounds, pentavalent phosphorus derivatives are usually poor phosphorylating agents. Nevertheless, in some cases it is more appropriate to synthesise complex phosphorus-containing macrocyclic systems using phosphochloridates, phosphoramidates and other pentavalent phosphorus derivatives. This is confirmed by the stereochemical features of the pentavalent phosphorus derivatives and by their stabilities against oxidation and disproportionation and, therefore, by the stability upon storage. Recently, novel polyfunctional crown ethers representing macrocyclic phosphates and phosphonates have been synthesised. For instance, arylenephosphate **65** and bis(arylenediphosphate) **66** were synthesised in two stages by the reactions of various arylenediols **67** with phosphorus oxochloride in the presence of triethylamine followed by hydrolysis of intermediate phosphochloridates **68**, **69** (compounds **69** were not isolated).⁵⁸

Pentavalent phosphorus derivatives were also employed to design polyfunctional phosphate-phosphonate macrocyclic systems **70** and **71** reported by Caminade *et al.*^{59–61} Of particular interest are those systems that can be readily modified due to the presence of aldehyde groups (*e.g.*, compound **71**), which favour chain extension and formation of bulky cryptands, crown ethers and dendrimers (Scheme 7).^{62, 63}

IV. Conclusion

Summing up, an original field of chemistry of phosphorus-containing macroheterocycles has emerged in the last decade. Progress in this research avenue is due to the availability of reactants and efficiency of synthetic methods. The strategies of synthesis have been well developed, the molecular assembly technique being used more often. In turn, the alternative route, the direct synthesis of bismacrocyclic systems, is sometimes more preferable because it ensures higher yields of end products. Carrying out reactions at high temperatures and under solvent-free conditions can result in macrocycles containing more than two phosphorus-containing groups. Usually, the best results are obtained in phosphorylation and cyclophosphorylation with amides, which results in a smaller content of side products. Research on the synthesis of novel phosphorus-containing heterocycles revealed a number of interesting chemical facts including the 'in-out' structural isomerism of cage structures and dismutation of unsymmetrical aromatic mono- and bisphosphorus systems.

Abstract. The review outlines the theoretical foundations and industrial implementations of modern detonation synthesis of nanodiamonds and chemical purification of the nanodiamonds thus obtained. The structure, key properties and promising fields of application of detonation-synthesis nanodiamonds are considered. The bibliography includes 135 references.

I. Introduction

Detonation-synthesis nanodiamonds (ND) were first synthesised by researchers from the USSR in 1963 by explosive decomposition of high-explosive mixtures with negative oxygen balance in a non-oxidising medium.^{1,2} Nanodiamonds are characterised by nanoscale particle sizes and have chemically inert cores and reactive peripheral regions called shells. A micrograph of a typical ND particle is shown in Fig. 1.

The detonation synthesis offers the following advantages over the static synthesis of ND: (1) high performance due to the lack of limitations associated with the size and the weight of charges; (2) no need for expensive and scarce expendable materials (hard alloys, alloy steels) and metal catalysts (nickel, manganese); and (3) possibility of preparation of unique polycrystalline ND powders under strongly non-equilibrium conditions.

A drawback of the technique consists in potential explosion risk when carrying out blasting operations, fabrication and transportation of charges.

II. Detonation synthesis of nanodiamonds: mechanisms

No commonly accepted theory of the detonation synthesis of ND is available at the moment. Different authors propose

different (sometimes, significantly different) ND formation mechanisms. In this Section we will consider a number of theoretical models for ND formation.

A mechanism of ND formation from TNT–hexogen (RDX) mixtures is as follows.^{3,4} In the zone of the detonation wave the explosive molecules disintegrate into atoms. Carbon atoms thus released are condensed into an amorphous carbon phase by means of diffusion and liquid droplet coalescence. Subsequently, amorphous carbon particles undergo a phase transition to diamond. It is believed that the degree of conversion increases from 0% to 100% in the pressure range 17–23 MPa. The formation of the diamond phase in this pressure range (it corresponds to the region of chemical peak of the detonation wave) was confirmed in other studies.^{5–7} According to the data mentioned above, the formation of ND takes a time of 0.2 to 0.5 μ s.

The diamond phase repeatedly experiences the action of reflected shock waves, and the ND temperature increases. As a

consequence, the thermodynamic state of detonation products corresponds to the graphite stability region and partial graphitisation of ND occurs.

A study of the isotopic composition of the condensed products formed upon detonation of a TNT/octogen (HMX) mixture (TNT was labelled with ^{13}C at methyl group) showed that detonation-synthesis ND are mainly formed from the carbon atoms of TNT.⁸ Similar conclusions were made in the studies of ND synthesis from a mixture of RDX with TNT labelled with ^{14}C at position 1 of the benzene ring.^{9,10} It was also established that the yield of condensed carbon linearly decreases as the TNT content in the mixtures decreases, while the ND content in the diamond blend (DB), an intermediate product of ND synthesis, monotonically increases and reaches a constant value (for mixtures with RDX and HMX denoted TNT/RDX and TNT/HMX, respectively).¹¹

The addition of heterocyclic and aliphatic nitramines has a little effect on the formation of ND. The role of the additives is to produce the necessary pressure and temperature for the phase transition to occur.¹²

The dispersion of ND depends on the nature of the carbon source.¹³ For instance, the average particle size of the diamond phase formed upon detonation of mixtures of HMX with liquid organic additives varied from 1.8 (for glycerol) to 4.1 nm (for ethanol).

The maximum yield of ND was obtained using TNT/HMX or TNT/RDX mixtures containing 60 mass % to 70 mass % of TNT (density 1630 kg m^{-3}).¹¹

According to Lin,¹⁴ the key step in ND formation is the appearance of cyclohexane molecules (nuclei of the diamond structure). Collisions between the nuclei cause their aggregation into small clusters followed by growth of mesoscopic structures with long-range crystal order. Subsequent interaction of the mesoscopic structures with one another and with nuclei causes the formation of ND.

Anisichkin¹⁵ put forward an original hypothesis, according to which the initial decomposition stages of explosive materials occur with the release of hydrogen as methane and carbon in the diamond phase. Then, these products are oxidised. The extent of carbon conversion to the diamond phase is determined by the detonation parameters.

It was shown that the chemical reaction zone extends as the dimensions of the explosive charge increase and that energy release also continues behind the Chapman–Jouguet plane.¹⁶ Carbon coagulation and crystallisation can occur upon adiabatic expansion of detonation products. This was established in the studies^{2,17} of the effect of the mass of the charge and the heavy shell surrounding it on the ND particle size. For instance, an increase in the charge mass from 0.6 to 10 kg using a water shell causes the particle size to increase from 4 to 6 nm (specific surface area is reduced from 330 to $200\text{ m}^2\text{ g}^{-1}$, see Ref. 2). The detonation of a 140-kg charge in water shell afforded ND particles with an average size of about 8 nm and individual polycrystals of size up to 85 μm .¹⁷

According to Danilenko,¹⁸ the formation of ND can proceed by the known mechanism of homogeneous condensation of ultradisperse phases in highly supersaturated vapour (vapour–liquid–crystal mechanism) and result in spherical particles. Because of rapid exhaustion of the gas–vapour medium the average particle size does not increase with increasing duration of existence of the particle-growth conditions.

Crystallisation from vapour usually gives spherical nanoparticles of size $\leq 20\text{ nm}$, which also holds for ND.¹⁹

Additionally, Danilenko reported¹⁸ that the assumption of ND crystallisation from the liquid phase was substantiated by

the fact that the shape of the ND particle size distribution is typical of liquid droplet coalescence.²⁰

The most probable values of the detonation pressure and temperature in the Chapman–Jouguet plane are listed in Table 1. The Chapman–Jouguet parameters of TNT/RDX alloys correspond to liquid nanocarbon.¹⁸ At higher densities of explosive materials (ρ), carbon condensed in the reaction zone consists of nanodroplets only.

Table 1. Parameters of the ideal detonation in the Chapman–Jouguet plane.¹⁸

Explosive	$\rho/\text{kg m}^{-3}$	P/GPa		T/K	
		experi- ment	calcula- tions	experi- ment	calcula- tions
TNT	1600–1640	18–19	18.3–20.1	3700 ^a	3500–3618
RDX	1780–1800	34.5–35.4	34.7–35.0	4500 ^b	4200
TNT/RDX					
36:64	1713–1730	27–29.2	27.4–29.3	—	3931–4063
50:50	1670–1680	24.6	24.4–25.5	—	3225–3900
Tetryl	1700	—	23.9–25.4	3700, 4300 ^c	3991–4063

$\rho = 1510,^a 1660^b$ and 1610^c kg m^{-3} .

The formation of ND in the detonation wave involves the following processes:¹⁸

- condensation of carbon in the reaction zone with the formation of primary clusters ($d < 1\text{ nm}$);
- cluster–cluster interaction (liquid droplet coalescence) with the formation of nanodroplets;
- crystallisation of nanodroplets with formation of ND provided a sufficiently long period of cooling by turbulent detonation products or amorphisation of nanodroplets and clusters resulting in free and bound soot.

Possible reasons for soot release in DB are (i) imperfect detonation in certain regions of the charge volume (initiation zone, boundary regions) characterised by low P and T values and leading to carbon condensation by the vapour–amorphous carbon mechanism and (ii) formation of methane,¹⁵ which decomposes to soot upon detonation according to the reaction

Detonation in real systems occurs in non-ideal and non-steady-state regimes. Here, carbon is oxidised to CO rather than CO_2 . The process is characterised by lower pressures and temperatures and, correspondingly, by lower content of free carbon in detonation products and a decrease in the yield of ND. For instance, calculations²¹ showed that the $P_{50}:P_{100}$ and $T_{50}:T_{100}$ ratios are respectively equal to 0.337 and 0.546 at 50% conversion, *i.e.*, the pressure decreases about twice faster than the temperature.

As the mass of the water shell surrounding the charge increases, the ND yield increases and reaches a maximum value at the shell mass equal to ten charge masses.^{22,23} Optimum conditions for the synthesis of ND require the use of explosive charges with minimum porosity (highest density) and the blast conditions that provide the minimum possible imperfection of detonation.

The general conditions for optimum synthesis resulting in the maximum ND yield and the corresponding experimental methods are listed below.

Synthesis conditions	Implementation methods
Condensation of maximum possible, for a given explosive, amount of free carbon. Carbon condensation in the liquid nanocarbon region.	Detonation of explosive charges with the minimum porosity and imperfection. Use of TNT/RDX or TNT/HMX alloys with pressures higher than 22 GPa in the Chapman–Jouguet plane.
Maximum possible times of existence of liquid nanocarbon conditions in the detonation products and crystallisation of nanocarbon at pressures higher than 10 GPa in detonation products.	Detonation of explosive charges heavier than 5 kg in a water shell weighing more than ten charges.
Blasting under conditions that ensure the absence of amorphisation, oxidation and graphitisation.	Blasting charges in a massive water shell.

Thus, the chemical reaction zone of the detonation wave involves formation of carbon nanodroplets, which then crystallise into ND upon adiabatic expansion of detonation products in the pressure range from 16.5 to 10.0 GPa and in the temperature range from 3400 to 2900 K (ND stability region).¹⁸ When the charge is surrounded by a water shell, the unloading (pressure drop) in this pressure interval slows down and the temperature of detonation products is halved. As a consequence, the degree of oxidation of ND decreases and the effect of chamber walls on the yield of ND becomes less pronounced. Soot in the resultant mixture is treated as the product of amorphisation of carbon nanodroplets rather than graphitisation of ND. In the case of adiabatic expansion of detonation products, crystallisation of nanodroplets with $d < 1$ nm is impossible at all, amorphisation of nanodroplets with $d < 2$ nm occurs under conditions corresponding to the diamond region in the phase diagram of carbon, while amorphisation of nanodroplets with $d > 2$ nm, under conditions corresponding to the graphite region.

Another model for ND formation was proposed by Breusov.²⁴ A comparison of the energy released upon detonation of explosives with the energies of chemical bonds in the starting (explosive) molecules revealed impossibility of release of free carbon. Indeed, the energy released upon detonation is at most 809 kJ mol⁻¹ for TNT and 1240 kJ mol⁻¹ for RDX.²⁵

The energies of some chemical bonds (in kJ mol⁻¹)²⁶ are listed below.

C–H	CC	C–N	C=N	N=O	N–N
413.6 (in alkanes)	346.1 (in alkanes)	305.0	615.9	188.6 (in nitro com- pounds)	163.4
421.9 (in benzene)	487.7 (in benzene)				

Cleavage of all C–H and C–N bonds in the molecule requires a total of 3000 kJ mol⁻¹ for TNT and 3071 kJ mol⁻¹ for RDX; *i.e.*, the energy released upon detonation of each explosive or their mixture is several times lower than that needed for intermediate formation of elemental carbon. Therefore, a fraction of volatile chemically bonded components should not be consumed in the initial stages of the process.

In the shock-wave front zone certain bonds in the starting molecules can break down. According to Breusov,²⁴ radicals thus produced favour the formation of the carbon cage to which many molecules of volatile products are chemically bonded in the initial stages. Depending on the P – T detonation conditions and corresponding electronic hybridisation of carbon atoms, one can deal with either a graphite-like or a diamond-like frame.

Nucleation and growth of diamond particles are accompanied by accumulation of volatile low-molecular-mass detonation products (nitrogen, hydrogen, CO, CO₂, N_xO_y, H₂O, *etc.*) in the interparticle space, which precludes the delivery of carbon-containing ‘building’ material to the growing particles and finally the growth ceases.

It is believed²⁴ that methane and methyl radical are most suitable for growth of diamond particles and ‘healing’ their structural defects.

III. Detonation synthesis of nanodiamonds: key features and regularities

The design of the blast chamber is of great importance for the synthesis of nanodiamonds. Roughly, 1 to 4 m³ of the chamber volume are required per kg of explosive.²

In design of large blast chambers (> 50 m³) one should allow for the fact that the larger the chamber volume the lower the mechanical strength of the chamber.² The effect of the scale factor can be explained by brittle fracture of large items made of plasticised steel in the elastic deformation region. The thicker the chamber walls the more probable the appearance of structural defects that reduce the fracture stress.

The effect of the scale factor can be significantly reduced using blast chambers with multilayer walls made of, *e.g.*, steel strips or glass fibre. This significantly increases the crack resistance of the material.

Industrial blast chambers are usually relatively small and have a volume of 2 m³ [FSUE ‘Federal Research and Production Centre (FRPC) Altai’, FSUE ‘Elektrokhimpribor’ Integrated Plant, FSUE SDTB ‘Tekhnolog’, facilities in China]. They have long operating life (failure-free operation since mid-1980s). The mass of the explosive charges varies from 0.5 to 1.0 kg; this allows up to 2.5 kg of nanodiamonds to be synthesised over a period of 8 h. These chambers are reliable and simple in operation.

Larger blast chambers, *e.g.*, 11 m³ in volume, are also used [RPA ‘Sinta’, Belarus; Russian Federation Nuclear Centre – All-Russian Research Institute of Technical Physics (RFNC – ARITP), Snezhinsk, Russia]. Here, the explosive charges have a mass of 2 kg and therefore such blast chambers are characterised by higher performance. However, they are unreliable in service.

The Closed Joint-Stock Company (CJSC) ‘Alit’ (Kiev, Ukraine) successfully employs for more than a decade a 100 m³ blast chamber (mass of explosive charge is 10 kg), which provides a high performance with respect to ND. However, the blast chamber has a complex hand-driven charging system; sometimes, ice armour weighing at least 60 kg is used. The blast chamber looks like a railway tank and is rail tracked. The charge is blasted at the centre of the ‘tank’. The action of the shock waves on the blast chamber walls is non-uniform and the undesired effects are quenched by spraying water in the chamber upon explosion. As a result, the content of incom-bustible impurities (products of chamber wall corrosion) in the condensed carbon is rather high (16 mass % to 26 mass %).²

Thus, in choosing the volume and design of industrial blast chambers one should allow for not only the performance, but also simplicity and safety of operations with explosives and the content of impurities in the condensed carbon.

Nanodiamonds can be synthesised using various individual explosives and high-explosive mixtures. The type of the explosive governs the detonation characteristics and the composition of detonation products. In the case of adiabatic (isentropic) expansion of detonation products the temperature drop rate also depends on the type of the explosive, the state of the charge surface and the charge shape and on the atmosphere in the blast chamber. The key parameters affecting the final temperature and the corresponding rate constant (and, hence,

Table 2. Yields of diamond blend (M_{DB}) and ND (M_{ND}) as functions of the type of explosive.²⁷

the yield of ND) include the heat capacity, the content and the reactivity of the medium. An increase in the volume of the gas, its initial pressure and heat capacity in the blast chamber favour efficient reduction of the residual temperature and improves the yield of ND. The most pronounced effect is attained using CO_2 .

A general rule is as follows: the larger the ratio of the mass of the medium surrounding the blasting charge to the mass of the explosive charge, the higher the yield of ND.

The possibility of synthesis of ND upon detonation of the following aromatic nitro compounds: 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), bis(2,4,6-trinitrophenyl)diazine (HNAB) and 2,4,8,10-tetranitro-5*H*-benzotriazolo[2,1-*a*]benzotriazolium (*z*-Takot) was studied.²⁷ To improve the detonation parameters, in some cases the explosives were mixed with HMX and then used in the experiments.

Analysis of experimental data (Table 2) showed that the syntheses of ND upon detonation of the explosives under study and TNT obey the same pattern. Indeed, if the detonation parameters of an explosive and TNT are similar, the ND yields are also similar. The data for *z*-Takot show that, similarly to the TNT/RDX and TNT/HMX compositions, the content of the diamond phase in the DB released increases as the HMX proportion in the charge increases.

In the case of HNAB the thermodynamic parameters produced are sufficiently high to efficiently form ND without HMX additives. However, in this case the overall yield of DB is nearly halved compared to that obtained using TNT and *z*-Takot; therefore, the yield of ND is somewhat lower than the yields reached using optimum TNT/RDX compositions.

The results obtained using TATB deserve particular attention. Despite the higher detonation pressure (compared to *z*-Takot and TNT), the content of the diamond phase in DB was lower. This is probably due to the lower detonation temperature, which hampers efficient growth of the diamond particles.

Nanodiamonds are also formed upon detonation of hexanitrostilbene,²⁹ picric acid,³⁰ tetryl³¹ and TNT/nitroguanidine, RDX/polybutadiene and RDX/aluminum mixtures.³²

Long experience in industrial synthesis of ND has shown that TNT/RDX mixtures remain the most appropriate explosives. Indeed, these substances have well-known characteristics and are produced on a large scale. Processing of these explosives faces no problems, charges are castable and mouldable and can be shaped in any desired fashion. The yield of industrially synthesised ND can be as high as about 14%.

The synthesis of ND in the presence of organic admixtures to high explosives (RDX or HMX) is of considerable interest. The yield of ND produced in the presence of benzene, benzyl alcohol, allyl alcohol, allylamine, acetonitrile, nitrobenzene, propargyl alcohol and aniline admixed to HMX (~25 vol.%) is 6%–10% per unit mass of the mixture. Lower yields (~3%) were obtained with paraffin admixtures (hexane, decane),

alcohols (pentyl and octyl alcohols) and the lowest yield (~2%) was obtained using tetradecane.

The temperature and pressure developed upon detonation of explosives reach up to 4000 K and 30 GPa, respectively.

Table 3 lists the yields of diamond blend and ND obtained under different detonation synthesis conditions, namely, in the atmosphere of gaseous detonation products or an inert gas; in a water shell surrounding the explosive charge; and in an ice armour.^{33, 34} High yield of ND in the presence of a water shell or ice armour is due to prolonged action of pressure in the diamond stability region.

As shown above, the process affords the raw carbonaceous material (DB) consisting of ND, graphite-like particles and contaminants (metals and metal compounds).

The yields of ND and DB also depend on the charge mass-to-chamber volume ratio and on the site where the explosion is initiated. The ND content in diamond blend is plotted vs. water shell thickness at different charge geometries (TNT : RDX = 40 : 60) in Fig. 2. In the case of long cylindrical charge ($l/d > 2$) the amount of ND is much higher compared to those obtained

Table 3. Yields of DB and ND under different detonation synthesis conditions.^{33, 34}

Quality parameters of final product	Synthesis conditions		
	inert gas medium	aqueous medium	ice armour
DB yield (mass %)	3–8	6–12	8–14
ND content in DB (mass %)	20–40	40–63	55–75
ND yield calculated with respect to explosive	0.6–3.2	2.4–7.6	4.4–10.5

Figure 2. ND content in diamond blend plotted vs. water shell thickness at different charge geometries (TNT : RDX = 40 : 60 charge, mass 100 g).³⁵ Charge shape: cylinder (1), disc (2) and sphere (3).

with disc-like of spherical charges under identical explosion conditions.³⁵

To obtain the maximum possible yield of ND and DB, one should use long cylindrical charges of the highest possible density, a water shell or an ice armour surrounding the charge and a hardest booster pulse.

The yield of ND and DB also depends on the procedure used for cooling of detonation products in the blast chamber. If the charge is surrounded by a water shell or ice armour (so-called 'wet' synthesis), intense cooling of detonation products is due to transformation of their energy to heat (heating and vapour formation) and the kinetic energy of water and turbulent mixing with water. Additionally, water and ice are convenient substances, because they do not damage the walls of the blast chamber and ice does not require a container.

'Wet' synthesis (in water) can be carried out in optimum manner using a TNT/RDX charge with a TNT content of 40%. The composition produces a high synthesis temperature, while rapid cooling with water provides a higher degree of conservation of ND.

The so-called 'dry' synthesis involves blasting of a charge in gaseous medium. Here, carbon dioxide is the most efficient coolant of ND. Detonation products of a preceding blast can be used as coolant gas. A TNT/RDX charge containing 60% of TNT is optimum for the 'dry' method. Since for this alloy the detonation pressure and detonation temperature are lower than those reported for the composition with 40% of TNT, the yield of ND is nearly halved.

As the number of blasts in unventilated chamber increases, the composition of the gaseous atmosphere significantly changes. Namely, the concentrations of carbon dioxide, nitrogen and oxygen decrease, while the concentration of carbon monoxide increases, which makes the cooling of detonation products less efficient.³⁵ Therefore, it is desired to introduce carbon dioxide into the chamber after each series of four or five blasts.

The synthesis takes at most 0.5 μ s, which approximately corresponds to the time of chemical reaction (or chemical peak) in the detonation (explosive) decomposition of TNT.⁶

The elemental composition of DB is governed by hetero-phase endothermic processes of gasification of the blend with carbon dioxide and water vapour

which can be described by the overall reaction

At high temperature, two competing processes proceed in the chamber, namely, gasification of DB (first of all, gasification of the non-diamond carbon as the more reactive DB component) and graphitisation of ND.

In the course of chemical purification (on going from DB to ND) the texture of the material changes non-monotonically (in stepwise fashion), which distinguishes the DB from other carbonaceous materials.³⁶ This is due to the fact that DB is an organised three-dimensional structure formed as a result of multistage aggregation of primary particles rather than a mixture of ND and non-diamond carbon.

IV. Novel method of synthesis and revised elemental compositions of nanodiamonds and diamond blend

A novel method of synthesis of ND^{37,38} permits significant improvement of the qualitative and quantitative characteristics of ND and DB. Namely, it allows one to change the elemental

composition towards higher content of carbon as the major element, to considerably increase the yield of ND and DB and to reduce the content of incombustible impurities.

A charge made of TNT – RDX alloy containing 40 mass % of TNT (TNT/RDX 40) was blasted in a blast chamber surrounded by a water shell (chamber volume 1 m³, charge mass 0.6 kg, blast atmosphere: products of previous detonations). The explosive : water mass ratio was maintained at 1 : 6. A number of readily oxidisable reducing agents (hydrazine hydrate, urotropin, urea, ammonia) were added to water, the explosive : reducing agent ratios being 1 : (0.1 – 10.0). The DB was purified to ND by dilute nitric acid at 513 K and a pressure of ~ 80 atm.³⁹

Additionally, a new procedure for elemental analysis of DB and ND was elaborated. It differs from conventional procedure by more severe conditions.^{37,38} Namely, a weighed sample is kept *in vacuo* (0.01 – 10.0 Pa) at 120 – 140 °C (DB) or 423 – 453 K (ND) for 3 – 5 h and then treated with oxygen passing at a flow rate that ensures complete combustion of the sample at 1323 – 1473 K over a period of 40 – 50 s. Subsequent determination of the elemental composition is carried out by conventional analytical techniques.

According to published data,^{36,40} the detonation synthesis of ND involves four stages. In the first stage, the detonation transformation of the explosive mainly occurs within the volume occupied by the charge. When using a condensed shell (water or ice), the detonation products are for some time confined within this volume, which favours a more complete transformation of carbon into the diamond prastructure.

Completion of the detonation process requires rapid gas-dynamic cooling of products to protect ND formed in the chemical reaction zone (or behind this zone¹⁸). The second stage consists in adiabatic expansion of gaseous detonation products.

The third stage of the detonation synthesis of ND involves circulation of the shock wave reflected from the chamber walls and turbulent mixing of detonation products with the medium in the chamber.

The fourth stage of the process involves intense cooling of the blast-heated medium surrounded (and thus confined) by the cold shell. In addition to various gaseous products (CO₂, CO, O₂, H₂, N₂, CH₄, NO, NO₂, NH₃, H₂O), the blast chamber contains highly disperse suspension of carbon particles possessing high radiating capacity. Therefore, cooling of this medium occurs through simultaneous heat transfer by convection and radiation.

The retention of condensed carbon is governed by hetero-phase gasification reactions with carbon dioxide and water vapour. Two competing processes proceed in the blast chamber in the third and fourth stages at the high residual temperature. These are gasification of condensed carbon (first of all, non-diamond carbon as the most reactive component) and graphitisation (or amorphisation¹⁸) of ND.

At a constant composition and density of the explosive, it is impossible to influence the first stage of the synthesis (*i.e.*, the formation of ND) by adding various admixtures to the condensed phase (water, ice) surrounding the charge. The processes occurring in the second stage can also hardly be affected by the substances in the condensed phase even with allowance for non-ideal character of gas-dynamic cooling of detonation products upon expansion. On the contrary, the addition of more readily oxidisable compounds (reducing agents) in the third stage (turbulisation of products), where condensed carbon reacts with CO₂, H₂O and other corrosive (under these conditions) compounds, will strongly affect the results of the synthesis. Of course, the oxidising agents (CO₂, H₂O, O₂, NO₂, N₂O₃) first of all react with more readily oxidisable reducing agents (in our case, hydrazine hydrate, urotropin, urea, ammonia) rather than with hardly oxidisable

Table 4. Elemental compositions and the DB and ND yields upon blasting of TNT/RDX 40 charges surrounded by water shell with different reducing agents.³⁸

Reducing agent	Explosive : reducing agent ratio (mass to mass)	Elemental composition of DB (mass %)				Content of incombustible impurities in DB (mass %)	Content of ND in DB (mass %)	DB yield calculated with respect to explosive (mass %)	ND yield calculated with respect to explosive (mass %)
		C	H	N	O				
Hydrazine hydrate	1:0.1	90.2	3.3	3.0	0.4	3.1	51.1	14.4	7.36
	1:0.5	90.5	3.0	2.9	0.8	2.8	54.7	15.8	8.64

	1:0.5	91.2	3.0	2.6	0.9	2.3	51.7	12.2	6.3
	1:1	92.7	2.8	2.8	0.3	1.4	51.9	16.3	8.46
Urea	1:0.5	90.1	3.6	3.1	0.5	2.7	51.2	14.1	7.22
Ammonia	1:0.5	91.1	3.0	2.8	0.9	2.2	51.0	13.4	6.83
No additive	—	84.2	0.9	8.3	3.1	3.5	45.0	7.2	3.24

carbon, especially ND. Therefore, one should expect an increase in the yield of DB and, hence, ND and quantitative changes in the elemental composition.

Additionally, the presence of readily oxidisable reducing agents among the detonation products also affects the fourth stage of the process, namely, the temperature of the products decreases due to decomposition of a fraction of the reducing agent, which favours protection of ND and a decrease in the extent of its graphitisation.

The elemental compositions of DB and the content of the major impurity (incombustible metal oxides and carbides) are listed in Table 4. As can be seen, introduction of organic or inorganic reducing agents (at least 10 mass %, calculated with respect to the initial explosive) causes a significant increase (by ~4 mass %–7 mass %) in the content of carbon in DB. The content of hydrogen remains almost unchanged, but those of nitrogen and oxygen decrease dramatically (3- to 10-fold). The amount of incombustible impurities also decreases 1.5–2-fold, which makes the DB thus produced suitable for immediate use in plating, finish polishing, polymer chemistry, oil composites, etc. Additionally, this DB can be much more readily purified, which leads to high-quality ND.

The content of ND in the DB synthesised in the presence of reducing agents increases by about 5 mass %–7 mass %, whereas the overall mass of the DB is doubled and therefore the yield of ND calculated with respect to the starting explosive increases 2.5-fold.

The elemental compositions and amount of impurities in the ND isolated by chemical purification of the DB produced by the novel method are listed in Table 5. The content of the

major component (carbon) in the detonation-synthesis ND prepared by the new technique is considerably larger (by 4 mass %–6 mass %) and amounts to 96.0 mass %. Irrespective of the synthesis conditions, the content of nitrogen varies in a narrow region, from 2.2 to 2.9 mass %, which indicates a quite uniform distribution of this element within all ND layers. Contrary to this, the amounts of hydrogen and oxygen change considerably (from 0.4 mass % to 2.4 mass % and from 0.7 mass % to 2.3 mass %, respectively). This points to accumulation of H and O in the outer layers of ND particles and to strong dependence of the contents of these elements on the synthesis conditions.

The lowest amount of incombustible impurities was found in the ND produced in the presence of urotropin. This is due to the fact that urotropin is a strong complex-forming agent, which reacts with metal impurities (Fe, Ni, Cr, Cu, etc.) to form soluble complexes which can be easily removed during chemical purification (upon treatment with nitric acid).

Because of the low content (0.1 mass %–0.3 mass %) of incombustible impurities (metal oxides and carbides) ND thus produced can be used in all technologies. At the same time the content of the non-diamond carbon in ND is almost constant (0.8 mass %–1.4 mass %) and has no effect on the technologies that use ND. The content of the diamond phase in the purified ND can be as high as 99.1 mass %.

The elemental compositions of a large number of ND samples produced at different facilities in Russia, China, Ukraine and Belarus were determined using the recently proposed procedure.^{37,38} The contents of the constituent elements in ND vary within the following limits (in mass %):

Table 5. Elemental composition and purity of ND isolated by nitric-acid purification from DB prepared using different types of reducing agents.³⁷

Reducing agent	Explosive : reducing agent (mass to mass ratio)	Elemental composition of ND (mass %)				Content of incombustible impurities in ND (mass %)	Content of oxidisable carbon in ND (mass %)	ND purity (ND content in the solid phase) (mass %)
		C	H	N	O			
Hydrazine hydrate	1:0.1	93.6	1.2	2.3	1.7	1.2	1.0	97.8
	1:0.5	94.4	0.4	2.5	2.3	0.4	1.1	98.5

90.3–93.8 for C, 0.4–4.8 for H, 1.5–2.3 for N and 2.3–4.5 for O.

The actual elemental composition of ND is as follows:

Element	C	H	N	O
Content (mass %)	93–95	1–2	~2.5	2–3.5

V. Chemical purification of nanodiamonds: theory vs. practice

The specific features of DB include high dispersion, defectness of the carbon structures, developed active surface and, as a consequence, enhanced reactivity.

Besides, the detonation blend contains metal particles resulting from wear of the operating surfaces of the blast chambers and foreign impurity particles.

All the known ND purification techniques are based on the use of different stability of the diamond and non-diamond forms of carbon to oxidants.⁴² Liquid-phase oxidants offer an undoubted advantage over gas–solid systems, because they allow one to obtain higher reactant concentrations in the reaction zone and, therefore, provide high reaction rates.
