Nevertheless, a method of oxidation of the non-diamond carbon by ozone was reported.⁴³ The ozone–air mixture is passed through DB at 120–400 °C. Despite quite a high degree of purification of DB from the non-diamond carbon, it still contains unburnt impurities (mainly iron oxides and carbides, up to 25 mass %; CJSC ‘Alit’, Ukraine). These impurities can be dissolved using liquid oxidants (strong acids).

The liquid-phase oxidation proceeds at sufficiently high rates at high temperature. Therefore, the oxidising mixtures are prepared using high-boiling acids (HClO₄, H₃PO₄, H₂SO₄) and oxidising agents (HNO₃, nitrogen oxides, H₂O₂, NaClO₄, CrO₃, K₂Cr₂O₇, etc.). Initially, perchloric acid was widely used as the high-temperature single-component oxidising agent. However, this is a hazardous substance (operation with and storage of this acid are expensive) and therefore it is no longer used for isolation of ND despite the unique properties.

There are three conventional ND purification techniques used in industry:

(1) action of chromium anhydride (CrO₃) solution on DB in concentrated sulfuric acid (RFNC–ARITP; FSUE ‘Elektrokhimpribor’ Integrated Plant, Lesnoy, Russia; CJSC ‘Alit’, Ukraine; facilities in China);

(2) use of nitric acid/oleum mixtures (‘FRPC Altai’, Biysk, Russia); and

(3) use of dilute nitric acid (FSUE SDTB ‘Tekhnolog’, St Petersburg, Russia; CJSC ‘Sinta’, Minsk, Belarus; Beijing Technological Institute, China).

In particular, DB was mechanically filtered, treated with concentrated sulfuric acid, then heated and the non-diamond carbon was removed by adding oxidising agent (aqueous chromium anhydride solution) to the mixture of DB with concentrated sulfuric acid.⁴⁴ After the oxidation, ND were washed with water. The primary treatment of DB with sulfuric acid was carried out at 105–110 °C for 1.0–1.5 h. Nanodiamonds were first washed from acid treatment products with water to pH 5–6 at 60–70 °C and then with hot distilled water until negative reaction for chromium ions in rinse water. As a result, the amount of metal impurities in ND reduced to 0.9 mass % and the content of the major component increased to 98.5 mass %. This multistage chemical purification technique⁴⁴ is complex and expensive and produces very toxic waste.

The main advantages of the nitric acid/oleum oxidising systems consist in the availability and cheapness of the components. They are also simple in design and technological operation.⁴⁵ The drawbacks of the technique include low quality of purified ND (ND content is ~90 mass %), large

consumption of the acids (up to 57 kg per kg of DB), complexity of the regeneration and utilisation of the multicomponent mixture and contamination of the diamond surface with sulfur and nitrogen compounds.

Yet another group of methods of liquid-phase purification of ND is based on the principle of free dispersion of carbonaceous material in all stages of treatment.⁴⁶ The reaction suspensions of DB in liquid oxidising mixtures are homogeneous, colloidally stable (no ND precipitate), highly disperse and characterised by low viscosity. During the reaction, the oxidising agent has unrestricted access to the solid particles, which practically removes the diffusion limitations on the reaction rate.

High reactivity of DB allows the following oxidising systems to be used for purification:

Oxidation system	Reaction products
HNO ₃ –H ₂ SO ₄ –SO ₃ HNO ₃ –H ₂ SO ₄ HNO ₃ –H ₂ SO ₄ –H ₂ O	CO ₂ + H ₂ O + NO _x + SO _y
HNO ₃ –H ₂ O HNO ₃ –H ₂ O–H ₂ O ₂	CO ₂ + H ₂ O + NO _x
H ₂ O ₂ –H ₂ O–catalyst O ₂ –H ₂ O–catalyst	CO ₂ + H ₂ O

The total concentration of acids, specific consumption of reactants, amount and toxicity of gaseous reaction products and corrosion activity of the reaction medium decrease while the economic and environmental characteristics of technological processes are improved along the arrow.

Hydrogen peroxide is an attractive oxidising agent. Indeed, its reaction with carbon results in only two products, carbon dioxide and water.⁴⁷ The reaction also causes the development of a specific surface of the diamond material, which is free from sulfo and nitro derivatives. The use of hydrogen peroxide based oxidising systems for purification of ND significantly simplifies the process infrastructure, first of all the environmental protection system and waste reclamation. The main drawbacks of the technique include the impossibility of removal of unburnt impurities, the need of using equipment for high-pressure operation and incomplete removal of the non-diamond carbon.

These problems can be solved on going to aqueous nitric acid solutions. This fundamentally improves the quality of ND purification, because sulfur-containing derivatives cannot be formed on the diamond surface.³⁹ The process is carried out at elevated pressure. The equipment operating at high temperature is made of corrosion resistant materials.

High-purity ND (carbon content ≥ 98.5 mass %) can be obtained from DB upon 30–40 min of its residence in hot zone under high pressure. This process has been implemented in Russia, China and Belarus.

The use of complicated but efficient method of high-temperature oxidation with nitric acid under pressure makes it possible to implement a high-performance process characterised by low content of hazardous waste. The dissolution of metal-containing impurities and their transformation into water-soluble products are combined with oxidation within this method.

The simplest and the most readily available oxidising agent is atmospheric oxygen. Using specific features of the detonation blend, the non-diamond carbon was selectively oxidised by blowing air through an aqueous DB suspension in the presence of catalysts.⁴⁶ The procedure offers all advantages of the liquid-phase ND purification techniques and has the same

drawbacks as the method based on purification with hydrogen peroxide.

Analysis of the simplest, convenient and environmentally safe purification methods unambiguously shows that only dilute nitric acid should be used in large-scale production.

At present, the two-step ND purification technique based on treatment of DB with aqueous nitric acid solutions is practically implemented at some facilities. The first stage involves treatment of DB with concentrated (50–99)% nitric acid at 80–180 °C. In the second stage the material is treated with (10–40)% nitric acid at 220–280 °C.³⁹

A novel promising method of chemical purification of ND by combined treatment of DB with (2–40)% nitric acid and atmospheric oxygen at 200–280 °C under pressure (5–15 MPa) was developed.³⁷ The treatment involves renewal of the outer boundary layer of ND particles and has almost no effect on the structure of the diamond core. Therefore, purification is the key stage in the formation of the application characteristic of ND, because it is this stage that determines the possibility of preparation of various modifications of the product.

VI. Industrial synthesis of nanodiamonds

Technologically, production of ND involves the detonation synthesis, chemical purification and washing of ND from acids and conditioning of the product,^{34,36} recovery and utilisation of acid vapours and gases, pretreatment and recycling of nitric acid and water treatment.

Usually, industrial detonation synthesis (Fig. 3) is a periodic process. Every time an explosive charge equipped with electric detonator is manually loaded through a top hatch (not shown) of a hermetically closed blast chamber. Depending on the process used at the plant, a cylindrical charge (either non-armoured or surrounded by a water shell or ice armour) is suspended on strips to a hook welded at the top of the blast chamber. The charge is blasted from a distant explosion-proof room by applying an electric pulse to the detonator. The blast chambers of volume ~2 m³ are used most often.

In addition to DB, 60% nitric acid, air and desalinated water are used. The process results in ND as the end product in the form of either thickened stabilised suspension in distilled water or dry powder.

Figure 3. Detonation synthesis of nanodiamonds: flow chart of the process.³

A simplified scheme illustrating the key stages of purification process is shown in Fig. 4. Generally, the ND purification procedure involves the following steps.³⁶

1. Preparation of DB.
2. Preparation of aqueous nitric acid solutions.
3. Preparation of thin homogenated suspensions of DB in aqueous nitric acid solutions.
4. Continuous thermal-oxidation treatment of DB suspensions under pressure (~500 K, 8–10 MPa). This is the key stage, which requires the use of tailor-made equipment. The process is carried out in a flow reactor cascade with a particular temperature profile (smooth variation of the temperature along the reactor cascade) under equilibrium pressure.
5. Separation of thermal-oxidation treatment products.
6. Recycling of nitric acid.
7. Washing of ND from acids.
8. Waste processing.
9. Preparation of stabilised ND suspensions in distilled water.
10. Preparation of ND in the form of dry uniform powder.

Modern technology of ND purification by thermal oxidation using liquid-phase high-temperature oxidation of nitric acid provides high and stable characteristics of purification and is readily scalable and best practically implemented.

VII. Properties of nanodiamonds

Nanodiamonds are complex objects usually having a three-layer structure^{48,49} comprised of

- a diamond core 4–6 nm in size, containing from 70% to 90% of the total number of carbon atoms;
- a transient carbon shell (intermediate layer) surrounding the core and consisting of X-ray amorphous carbonaceous structures 0.4–1.0 nm thick, containing from 10% to 30% of the total number of carbon atoms; and
- a surface layer comprised of carbon atoms and other heteroatoms (N, O, H) that form various functional groups; the nitrogen atoms are quite uniformly distributed among all layers.

Detonation-synthesis ND are chemically inert and hardly oxidisable.⁴⁹ The diamond core can be partially decomposed by prolonged etching under severe conditions (in strong acids or acid mixtures, *e.g.*, conc. HNO₃, HNO₃ + HCl, HNO₃ + H₂SO₄ + SO₃, *etc.* at corresponding boiling temperatures for 50–100 h). Oxidation (etching) of ND has a complex character because the process does not involve a conventional layer-by-layer removal of the non-diamond and diamond phases (*i.e.*, their oxidation to gaseous products). Etching of the carbon matrix (up to the diamond phase) proceeds at structural defects within the intermediate layer. When the process involves the diamond core (mass loss of 30 mass % and more with respect to starting ND), not only the chemical composition of the surface functional groups, but also the structure of the intermediate layer is reproduced. It was shown that highly etched ND particles (mass loss of 40 mass %–60 mass %) possess nearly the same properties as the starting detonation-synthesis ND. The formation of almost the same intermediate shell was proved in many studies by various analytical methods. The oxidation processes first of all affect unstable (excited) atoms in the material. The most excited carbon atoms are on the surface of particles near structural defects. Thus, here we deal with selective etching of the most defect fragments of the near-surface structures near the most excited carbon atoms, resulting in the formation of nearly identical intermediate layer.

It should be noted that the greatest difficulties during chemical purification of detonation-synthesis ND by oxidation of DB are encountered in the oxidation of the ‘last’

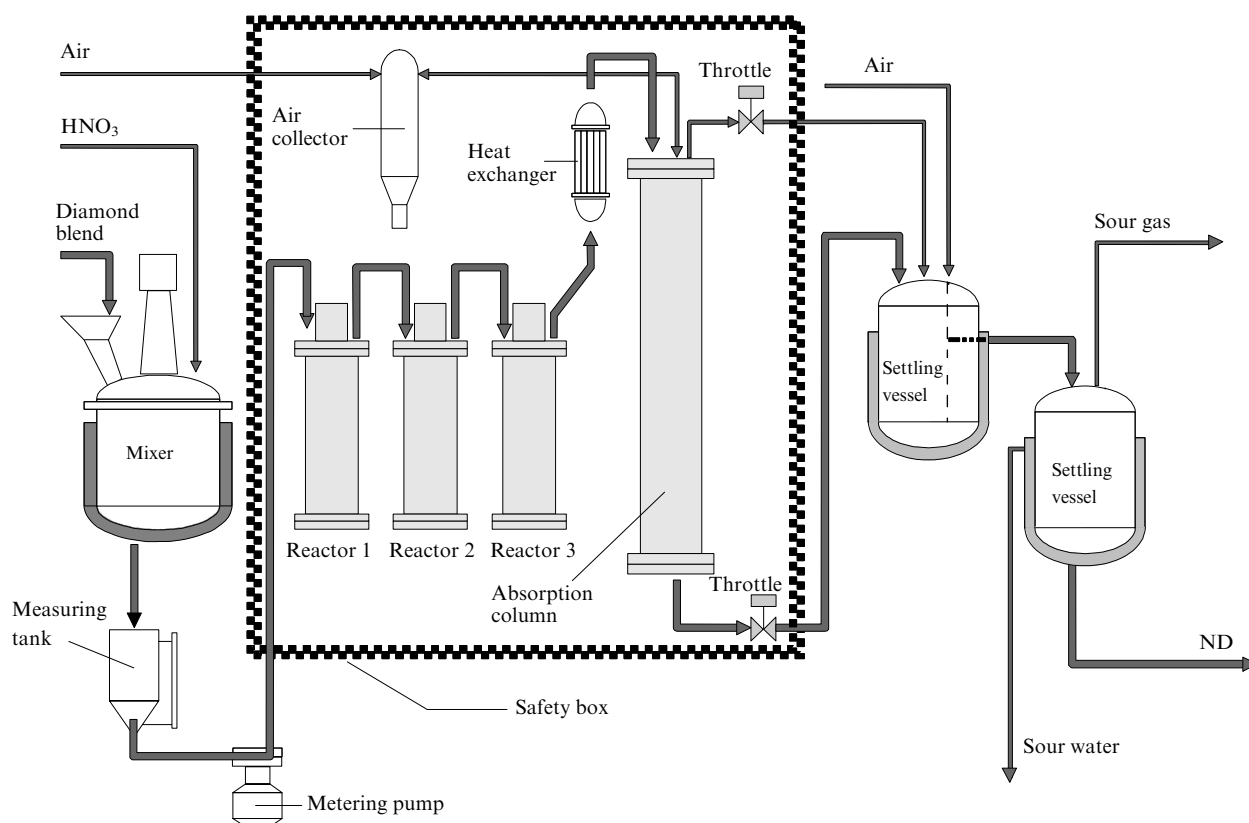

Figure 4. Simplified nanodiamond purification flow chart.³⁶

The mixer is filled with DB and HNO_3 . A suspension thus formed is fed to the measuring tank and then to Reactor 1. The ND suspension in spent HNO_3 passes through the heat exchanger and then is delivered to the adsorption column where gas separation occurs. Gases are absorbed by water and by alkali solution and the sour suspension is fed to the system of settling vessels and subsequent washing. The air collector is used to smooth pressure surges and to produce prepressure at the start-up in the operating mode, thus acting as a high-pressure throttle.

18 mass %–20 mass % of the non-diamond carbon, *i.e.*, in this case the residual carbon also shows a diamond-like behaviour.

The intermediate layer of purified ND has inhomogeneous structure. The inner sphere of the intermediate shell, which is adjacent to the diamond core, is comprised of continuous onion-like carbon (OLC) layers formed by hexagons.⁴⁸ The intermediate layer also contains graphite-like monolayers localised in peripheral regions. However, the overall structure of the intermediate layer is still to be clarified.

The complex structure of the intermediate layer is due to incomplete transformation of the carbon component of the ND particle to the diamond under the synthesis conditions. During the action of the detonation wave and in the course of the unloading step, when detonation products expand and reflected shock waves pass through them at rapidly dropping pressure but still at a very high temperature, structural fragments of the molecules of initial explosives chaotically combine with one another in the chemical reaction zone.^{1, 2, 10, 28, 36} Secondary processes, namely, graphitisation of detonation-synthesis ND and amorphisation of the crystalline phase are also highly probable under these conditions.

It is likely that the structure of the intermediate layer is comprised of a randomly combined praunits of those chemical compounds that release from ND upon extraction and thermal desorption. However, it is still unclear what these units and compounds made of them look like and how they are bonded

to one another, embedded into the intermediate-layer cage and stabilised.

Undoubtedly, it is vast variety and high reactivity of chemically bonded prastructures (in addition to the reactivity of functional groups on the surface of ND particles) that are responsible for the high reactivity of detonation-synthesis ND. Amazingly, the bulk mass concentrated in the diamond core remains chemically inert. Therefore, the behaviour of detonation-synthesis ND in various systems is hard to predict.

The average ND particle size is 4.2 nm. A simplified model for the surface of an ND particle with different functional groups is shown in Fig. 5. The number of atoms in such a particle is quite difficult to estimate owing to imperfection of the crystal, complication in the determination of the actual number and types of functional groups and uncertainty associated with characteristics of the intermediate carbon shell of the nanocrystal.

The number of carbon atoms in 4.2-nm ND particles reported by different authors varies from 300 to 20 000.^{36, 50} (Usually, the elemental composition was calculated for a perfect crystal.) The average number of atoms (including heteroatoms) in octahedral ND crystal (edge length 4.4 nm) is $\sim 20\,000$.⁵¹

A spherical ND particle of 4.2 nm size comprises nearly 7000 carbon atoms. The results of some calculations of the elemental composition of ND are listed in Table 6. According to Shenderova, the number of surface carbon atoms is ~ 1000 or $\sim 15\%$ of the total number of atoms.

Figure 5. Nanodiamond particle with different surface functional groups (according to Shenderova, International Technology Center, USA). The structure was optimised by the semiempirical quantum-chemical method PM3.

Most often, functional groups appear on the surface of ND particles during purification of DB with strong oxidising agents. All oxygen and hydrogen atoms belong to the surface groups of ND.^{36, 50, 52–55} Nitrogen atoms are incorporated not only into the diamond lattice, but also the surface groups (amide groups⁵³ and nitro groups^{54, 56}).

The surface functional groups were analysed by IR spectroscopy,^{53–59} temperature-programmed desorption,⁵³ chem-

ical titration,^{59, 60} polarography^{36, 60} and X-ray photoelectron spectroscopy.⁵⁸

The surface groups were identified as hydroxyl groups (OH) in the form of sorbed water, carboxyl group and tertiary alcohol;^{53–57, 61} amide groups [NC(O)–H];⁵³ hydrocarbon groups (C–H) in the form of CH, CH₂ and CH₃;^{53, 56, 58, 62, 63} carbonyl groups (C=O) in the form of ketone, carboxyl group, acid anhydride, ester and lactone;^{53, 55–58, 63} C–O–C groups in the form of ether, acid anhydride, lactone and epoxy group.^{54–57, 62}

A study of fluorinated ND revealed the presence of surface CF, CF₂ and CF₃ groups.⁵⁸

The electrokinetic potential (ξ -potential) is one of the key characteristics of the ND surface, which strongly depends on the surface state. Different fractions of the same ND sample and, moreover, of ND samples purified and surface-modified in different manner are usually characterised by different ξ -potentials.

The ξ -potentials of three fractions (precipitate, intermediate and aqueous suspension) of the ND produced at the RFNC–ARITP were +16, +32 and +39 mV, respectively.⁶⁴ The ξ -potential of non-fractionated ND (UDD-TAH brand) produced at the FSUE SDBT ‘Tekhnolog’ is +33 mV (aqueous medium).

Three types of modified ND (UD-HP, UD-SO and UD-M brands) are produced at the RPA ‘Sinta’.⁶⁵ The ξ -potentials of their aqueous suspensions equal –16 (UD-HP), –87 (UD-SO) and +24.9 (UD-M) mV.

Dry ND is a light-grey polydisperse powder with a bulk density of about 0.5 g cm^{–3}. It is comprised of agglomerates of size from a few to hundreds of micrometres. Two main types of impurities in ND are incombustible and oxidisable carbon (the latter remains on the surface of ND particles after chemical purification). The admissible content of each of the two impurities is at most 1.0 mass %. Well-purified ND contains at most 0.5 mass % of each type of impurity. Practical applications of ND are mainly interfered with the presence of incombustible impurities; their compositions for three commercially available ND brands is presented in Table 7.^{50, 66}

An aqueous suspension of pure ND in water cannot be neutral (Fig. 6); the ND particles should behave in water like

Table 6. Contents of chemical elements (%) with allowance for various functional groups on the surface of spherical diamond particle 4.2 nm in diameter.

Surface composition		C _{diamond}	H	O	N	C–X (hetero- atom)	C _{tot}

an acid due to the presence of surface carboxyl groups.⁶⁷ Indeed, they do behave as poorly soluble weak organic acids. The rapid coagulation threshold of ND particles, *i.e.*, the loss of sedimentation stability, corresponds to a pH value of 5.5.

Earlier (see, *e.g.*, Ref. 68), it was shown that the phase transition occurs on heating of ND from 720 to 1400 K in inert atmosphere.

The lines in the Raman spectra of ND coincide with maxima of the phonon state density functions of diamond and graphite. This indicates the presence of small amounts of amorphous diamond and graphite in the ND material. Nanodiamond clusters exist only in the form of aggregates;⁶⁹ the amorphous phase is likely to occur in the interior. The presence of the amorphous phase is also confirmed by X-ray diffractometry data; the characteristic size of this phase was estimated at about 1.5 nm.

According to X-ray diffractometry data, nucleation of the graphite phase occurs only at $T > 1200$ K. The diamond–graphite structural phase transition occurs on annealing in inert atmosphere and begins at the surface of ND clusters; the graphite phase nucleates in the form of equidistant nanoplates.

The phase transition onset temperature correlates with the electron microscopy data,⁷⁰ according to which the decrease in the size of the ND core begins only at $T > 1300$ K. The process is accompanied by transition of the outer carbon atoms to the OLC phase.

Later on, it was found that graphitisation of diamond can be induced by heat treatment and by the action of reactive gases and maintained using metal catalysts and also by emission from various sources.⁷¹ On the one hand, graphitisation sets limitations on the temperature range and conditions for efficient use of diamond. On the other hand, it provides the possibility of design of novel nanoscale carbonaceous materials. It was shown⁷¹ that annealing of 2–5-nm ND particles gives rise to the OLC phase,[†] whereas the annealing of micrometre-size diamond particles leads to formation of closed bent graphite-like structures, such as nanotubes, nanohelices, *etc.* Based on the results of molecular modeling by the molecular mechanics, molecular dynamics and Hartree–Fock methods, it was assumed that the formation of the OLC and closed bent graphite-like structures on the surface of diamond particles exhibits specific features of self-assembly processes.

Nanodiamond particles have a large specific surface area and therefore their physical and chemical properties are strongly affected by the surface groups. Controlled functionalisation provides a powerful tool of specific modification of ND particles. Using this approach, one can involve ND in various chemical reactions, enhance their interaction with solvents, components of composite materials, polymers and catalysts. The surface groups stabilise the surface of ND

particles and preclude their graphitisation. Decomposition of the surface groups causes graphitisation of ND and formation of bucky-diamonds (intermediates of the transformation of ND to OLC) and, finally, to OLC. With allowance for high stability of the hydrocarbon groups the most thermally stable ND can be prepared by surface hydrogenation.

Various graphitisation mechanisms were reported for the ‘low’- and ‘high’-temperature regions.⁷¹ In the high-temperature region, the rate of graphitisation is controlled by the detachment of a single atom from the diamond surface. In the low-temperature region, the mechanism of graphitisation involves incomplete detachment of carbon atoms from the surface of diamond particles and the external planes (faces) of diamond crystal are gradually transformed into the graphite planes. These temperature regions are separated by the Debye temperature of diamond (1910 K).

By varying the ND graphitisation rate it is possible to prepare diamond/nanographite composites with different ratios between the diamond core and bent graphite shells (so-called sp^2/sp^3 -nanocomposites). The presence of interfaces between the nanoscale diamond cores and graphite shells and, probably, high concentrations of the open graphite edges can predetermine unusual electronic properties of these composites.

Selected characteristics of the static-synthesis diamonds and detonation-synthesis ND are listed in Table 8. The differences between the particle size, specific surface area and content of volatile impurities are most pronounced.

Table 9 lists selected properties of ND and technological parameters of large-scale production of ND for three leading manufacturers of detonation-synthesis ND in the CIS.⁷² The maximum yield of ND is obtained using the novel method of synthesis at the FSUE SDTB ‘Tekhnolog’. Additionally, the content of incombustible impurities even in DB is minimum and their content in pure ND is very low.

Table 8. Characteristics of detonation-synthesis nanodiamonds and static-synthesis diamonds.⁷²

Parameter	Nanodiamonds	Diamonds
Phase composition	cubic diamond, $a = 0.3565$	cubic diamond, $a = 0.3567$
Picnometric density /g cm ⁻³	3.30	3.51
Particle size /nm	4–15	30–2000
Specific surface area /m ² g ⁻¹	200–450	13.5
Content of incombustible impurities (mass %)	< 1.5	< 0.2
Content of volatile impurities (mass %)	10–12	1–2
Temperature corresponding to the onset of intense oxidation in air /K	800	780
Maximum exothermic effect in air /K	960–1000	900
Temperature corresponding to the onset of graphitisation <i>in vacuo</i> /K	1373	1373
Electrical resistivity /Ω m	7.7×10^9	1×10^{10}
Specific magnetic susceptibility, $10^8 \chi /m^3 \text{ kg}^{-1}$	< 1.0	0.5
Surface functional groups	OH, C=O, CO ₂ H, NH ₂	HO, C=O, CO ₂ H

[†] Complete annealing results in OLC particles while partial annealing affords diamond/OLC core–shell particles.

VIII. Fields of application of nanodiamonds

Nanodiamonds incorporated into materials act as powerful structure-forming agents that ensure dispersion strengthening of composites.

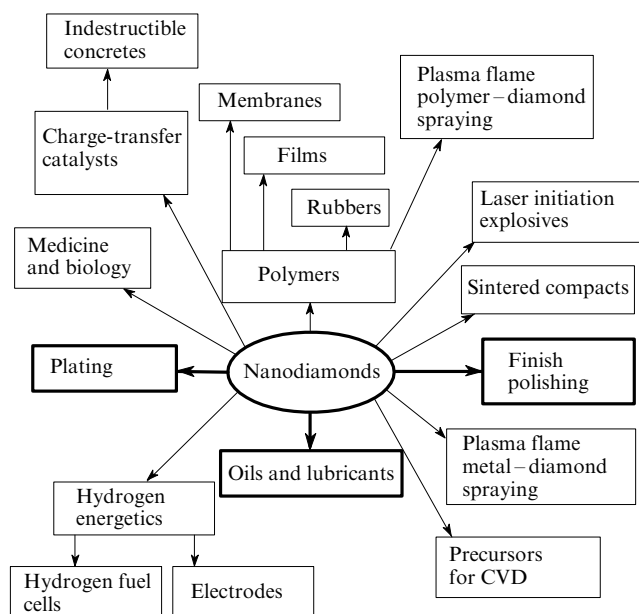

In search for optimum cost–quality relation for ND-containing products one should allow for the following:

— simple ND synthesis technology makes it possible to establish large-scale production of cheap ND the cost of which is mainly determined by the cost of explosives;

— in many fields of application ND can be replaced by crude DB, which is much cheaper than purified ND;

— positive effect is attained upon introduction of (0.1 mass %–1.0 mass %) of ND additive into the material.

Nanodiamonds have a broad spectrum of applications (Fig. 7), three of them being the major ones. These are finish polishing (~70% of the total amount of ND), metal plating (~25%) and oil composites (~5%). In the nearest future, production of polymer–diamond composites, charge-transfer catalysts and modified biologically stable concretes can develop into large-scale industries.

**Figure 7.** Fields of application of nanodiamonds.

Thick and thin arrows denote the current and future fields of application, respectively.

1. Metal plating

Nanodiamonds present in the electrolyte of a galvanic bath should be in the suspended state. To this end, an aqueous ND suspension is added to the electrolyte. In the preparation of metal–diamond composite electrochemical coatings, the suspended state of ND is maintained by gas evolution and thermal convection.

The introduction of ND into electrochemical coatings significantly improves their microhardness, wear resistance, corrosion resistance, throwing power, makes the visual appearance of goods more attractive and reduces porosity. The main reason for these changes consists in reduction of the size of metal domains in the coatings. Nanodiamond particles are small and therefore sufficiently dense and uniform distribution over the coating can be attained even at very low content of these species (few tenth of a per cent).

A number of ND-containing composite electrochemical coatings based on chromium, nickel, tin, zinc, copper, gold, silver, aluminium, iron and various alloys were developed. Selected physicomachanical characteristics of such coatings are listed in Table 10.

a. Chromium plating

Investigations on metal–diamond coatings began with the studies of electrochemical deposition of chromium and ND.^{73–75} Later on, they attracted the greatest interest because chromium coatings are most often used to provide for high wear resistance of tools and workpieces.

Table 10. Physicomechanical characteristics of metal–diamond coatings.

Coating	Wear resistance increases by a factor of n , where n is	H_V /kg mm ⁻² (see ^a)	Porosity decreases by a factor of m , where m is	Corrosion resistance increases by a factor of p , where p is
Cr + ND	2–12	up to 2300	2–3	3–6
Ni + ND	5–6	up to 600	no pores	2–5
Cu + ND	9–10	160	the same	no corrosion
Au + ND	2–5	200	6	the same
Ag + ND	10–15	180	8	"
Zn + ND	—	—	6–8	2–4
Sn + ND	4–5	150	7	1.5
Al + ND	10–13	600–700	3	no corrosion
Fe + ND	6–8	800	8–10	3–4
Ni + B + ND	6	8000	—	no corrosion
Sn + Pb + ND	—	31	no pores	5–7
Sn + Sb + ND	2.5	25	5–6	2–3
Ag + Sb + ND	1.5–1.7	150	—	—

^a Microhardness.

Either solid chromium plating electrolytes or buffer electrolytes are used as chromium/ND plating electrolytes. The content of ND in the coating is 0.3 mass %–1.0 mass %.

The content of ND in the chromium coating is analysed as follows. A chromium–diamond coating (CDC) 55–60 μm thick is deposited on a stainless steel plate. Then, the CDC is electrolytically dissolved in 10% aqueous NaOH solution at a cathode current density (i_c) of 10 A dm⁻² and a temperature of 303 K. A sodium chromate solution containing the ND suspension is passed through a preliminarily weighed Schott filter. The ND precipitate on the filter is successively washed with hot water, 10% H₂SO₄, water, 20% HCl and again water. The filter with the precipitate is dried at 423–473 K, the absolute amount of ND is determined from the mass difference and then the ND concentration in CDC is calculated (knowing the mass of the dissolved coating).

The microhardness of chromium coating depends on the ND concentration in the electrolyte, namely, the microhardness increases as the ND concentration increases.⁷⁶ As i_c increases, the microhardness also increases. The most impressive results were obtained using a composite diamond additive comprised of detonation-synthesis ND and static-synthesis diamonds (Fig. 8).⁷⁷

In Fig. 9 the wear of various chromium coatings is compared with that of titanium nitride coatings.⁷⁷

**Figure 8.** Microhardness of solid Cr-ND-ASM-coating plotted vs. cathodic current density (standard electrolyte).⁷⁷ No ND additives (1) and in the presence of ND (ND : ASM = 5 : 5) (2); ASM brand is synthetic diamond nanopowder.**Figure 9.** Wear of titanium nitride (TiN) and chromium coatings.⁷⁷ TiN (1), hard Cr (2), wear-resistant Cr (3), Cr + ND (4) and Cr + ND + ASM (5).

Chromium plating using ND is widely used in Russia, USA and South Korea.

b. Nickel plating

Analysis of the data listed in Table 11 and the plots shown in Fig. 10 reveals a positive effect of ND on the quality of nickel–diamond coatings.^{76, 78, 79}

Table 11. Effect of ND content on microhardness, wear resistance and porosity of nickel coatings at different cathodic current densities.^{76, 78}

ND content /g litre ⁻¹	H_V /kg mm ⁻²			Porosity /number of pores per cm ²		Wear resistance (rel.u.)
	1.0 ^a	1.5 ^a	5.0 ^a	1.0 ^a	1.5 ^a	5.0 ^a
No additives	251	286	308	20	15	1.0
0.5	301	312	330	15	10	1.8
1	320	331	354	15	5	2.3
2	359	380	378	15	5	3.8
5	370	408	472	10	5	5.7
10	395	467	583	6	4	6.4

^a The i_c values (in A dm⁻²).**Figure 10.** Microhardness (1) and wear resistance (2) of nickel coating plotted vs. ND concentration in sulfuric acid electrolyte.³⁶ $i_c = 5$ A dm⁻².

The content of ND in the coating increases from 0.1 mass % to 0.7 mass % as the ND concentration in the electrolyte increases from 0.5 to 10.0 g litre⁻¹. At a 5 g litre⁻¹ ND concentration in the electrolyte, the microhardness of the coating becomes nearly doubled (see Fig. 10) and the wear resistance shows a nearly sixfold increase. The coating thus prepared is fine-grained, dense and has a low porosity.

c. Gold plating

If the ND concentration in the electrolyte varies from 0.1 to 10.0 g litre⁻¹, the ND content in the gold coating changes from 0.2 mass % to 0.8 mass %. The microhardness of the coating reaches a value of 200 kg mm⁻² and the wear resistance increases two- to five-fold.^{36, 80–82}

The structure and properties of the coating vary non-monotonically. Figures 11 and 12 show bimodal plots.⁶⁵ The first peak appears at low ND concentrations and its intensity depends on both the electrolyte composition and the type of the co-deposited diamond-containing additive. The second peak appears at higher ND concentrations. Nanodiamonds can be incorporated into the coating in the form of individual particles or as large aggregates depending on their colloidal state in the electrolyte. The second peak appears in the concentration range corresponding to co-deposition of gold with ND aggregates. In this region some technological characteristics (*e.g.*,

Figure 11. Mass percentage of co-deposited ND particles in gold coating plotted vs. concentration of the diamond-containing additive in the electrolyte for two types of additives: DB (1) and ND (2).⁶⁵

Figure 12. Microhardness of gold coating plotted vs. concentration of the diamond-containing additive in the electrolyte for two types of additives: DB (1) and ND (2).⁶⁵

sedimentation rate and the yield of gold calculated with respect to electric current) are deteriorated.

The gold plating process has been implemented on a large scale.

g. Silver plating

Using ND, it is possible to prepare dense, fine-grained semi-bright silver coatings containing up to 1.0 mass % of ND.^{36, 80, 83}

Depending on the electrolysis conditions, composition and type of electrolyte, the microhardness of the silver–diamond coating increases by 200–700 MPa compared to that of microhardness of pure silver. The wear resistance of the coatings shows a ten- to fifteen-fold increase (Fig. 13), the solderability of this coating is identical to that of pure silver. The silver plating process has been implemented on a large scale.³⁶

Figure 13. Wear resistance (mass loss) of silver–diamond coating plotted vs. ND concentration in electrolyte.^{36, 80}

d. Zinc plating

The optimum concentration of ND in the zinc plating electrolyte is 10 g litre⁻¹, which corresponds to the ND content in the coating of 0.7 mass %.^{36, 76, 84} As the amount of ND in the electrolyte increases, the precipitates become more finely grained.

Passivation of zinc/ND coatings thus obtained by conventional chromium plating or phosphating significantly increases

Figure 14. Corrosion resistance (mass loss) of zinc coatings compared to that of unprotected steel and cadmium coating (NaCl fog, 60 h).^{36, 76, 84} Unprotected steel (1), Zn-coating (2), Cd-coating (3), Zn + ND (4), Zn + ND + chromating (5) and Zn + ND + phosphating (6).

their corrosion resistance (Fig. 14). Phosphating was found to be much more efficient and environmentally safe.

e. Anodic oxidation of aluminium

Anodic oxidation is the main method of corrosion protection, and increasing the strength and wear resistance of aluminium and aluminium alloys.

During oxidation, the ND particles fill pores and remain in them due to mechanical and van der Waals forces. The mass of the filled oxide film increases two- to four-fold.^{36, 76, 85} The wear resistance of such a film increases to a much greater extent (by 10 to 13 times; see Fig. 15) and so do its corrosion resistance and dielectric properties. The film turns grey.

Figure 15. Wear of anodically oxidised aluminium film based on D-16 alloy (Germany) plotted vs. ND concentration in anodic oxidation electrolyte ($i_a = 1.5 \text{ A dm}^{-2}$).^{36, 76, 85} At 10 °C (1) and at 20 °C (2).

g. Iron plating

The hardness of electrochemical iron coating approaches that of steel. Such coatings become even harder when using ND.⁸⁶ For iron plating, it is more appropriate to use DB rather than purified ND. The best results were obtained using partially oxidised DB prepared following a known procedure.⁸⁷

The effect of ND and partially oxidised DB on the microhardness and wear of iron coatings is illustrated in Figs 16 and 17. The advantage of using the cheaper product (DB) is clearly seen.

Figure 16. Effect of ND (1) and DB (2) concentration on microhardness of iron coating ($i_c = 4 \text{ A dm}^{-2}$).⁸⁶

Figure 17. Effect of various diamond-containing additives on wear of an iron coating (concentrations of all additives were 5 g litre^{-1} , $i_c = 4 \text{ A dm}^{-2}$).⁸⁶ No additives (1), ND (2), conventional DB (3) and oxidised DB (4).

2. Polishing

Introduction of ND into polishing composites improves the characteristics of chemico-mechanical polishing and the efficiency of the overall surface treatment.^{36, 50, 88–93}

The colloidal, sedimentation and mechanical properties of ND clusters aggregated into complex fractal structures depend on the procedure for preparation and on the composition of the liquid dispersion medium. Nanodiamonds introduced into the liquid (ND content of 0.1 mass %–0.3 mass %) act as powerful structure-forming agent. Using low-filled aqueous, organic and aqueous-organic ND dispersions, one can obtain ideally smooth surfaces of materials processed, in which the micro-roughness is comparable in size with interatomic distances.

The fractal structure of ND favours efficient relief of local stress produced as the working surfaces approach each other. Large loose ND aggregates easily break down upon slightest action on the suspension and appear again also easily.

The fractal ND aggregates act as a kind of damper, which makes rigid point-to-point interactions between the working surfaces less probable. This prevents the material being processed from deformations and stress in the near-surface layer.

When the polishing pads and treatment regimes on most buffing machines were chosen appropriately, all materials showed smoothing of relief and formation of flat mirror surfaces without macroscopic defects.

Preparation of polycrystalline micropowders with different nanostructures of porous particles seems to be promising for polishing. Powders are prepared by milling large aggregates formed upon compaction of ND powder.

Polishing using ND is employed to improve the operating characteristics of almost all materials, namely, composites, semiconductors, dielectrics and conductors having a crystal, polycrystal, glassy or some other structure.⁹²

The key parameters of polishing are the rate of removal of material, surface roughness, flatness and plane-parallel arrangement of surfaces of working pieces. They are determined by the properties of ND and to a great extent by the design of buffing machines, types of polishing pads, their pre-treatment and other factors. Therefore, a particular ND powder (or polishing composite) should be 'tuned' to a technology of treatment of a material in hand or working pieces made of it.

Table 12. ND-containing polishing compositions.⁹⁴

State	Medium	ND content (mass %)
Suspension	water, ethylene glycol, aqueous KOH or FeSO ₄ solution, petroleum oil	3–5
Polishing compound	lipids, polymers	3–5
Solids of specified shape	cured silicone, nitrile, <i>etc.</i> rubbers	2–3
	cured formaldehyde and epoxy resins	2–5
	metal (aluminum, nickel)	< 50

Nanodiamond-containing polishing compositions can provide a high flatness (to 1 μm) and reproducible surface roughness from a few fractions of a nanometre to a few nanometres for more than thirty crystalline substances. The number of such materials increases and the polishing quality is improved, which indicates a versatile character of this technology.

Table 12 lists the components of some polishing compositions.⁹⁴ The results of treatment of materials characterised by different hardness and plasticity are listed below.⁹⁴

Material	Surface roughness /nm
Hard alloy	1–5
Steel	5–6
Sapphire	5–6
Quartz	0.5–1.5
Molten silica	0.5–1.0
Silicon	0.5–1.5
NaCl crystal	2–3
KBr crystal	2–3

A decrease in the diamond particle size from 1 μm to 3–5 nm is accompanied by a decrease in the relief roughness and by the change in the mechanism of mass transfer on the surfaces of alloys and composite materials from anisotropic (plastic deformation) to isotropic (nanoscratching) removal of material.

3. Oils and lubricants

Nanodiamonds, as modifiers of the friction surfaces, offer the following advantages over other types of surface modifiers:^{36, 50, 95–97}

- efficiency at very low concentrations in the base oil;
- compatibility with various types of synthetic and mineral oils; and
- environmental safety of the carbon additive to oils compared to metal particles or fluorocarbons.

The addition of diamond blend containing a large number of ultrasmall graphite-like particles and ND causes the properties of lubricants and the character of the interaction between the friction surfaces to change. Namely, the viscosity of the liquid, the strength of the lubricating film and, as a consequence, the loading capacity of tribomating increase. Selected characteristics of diamond-containing lubricant compositions and their efficiency are listed below.

Parameter	Numerical value
ND content (mass %)	0.01–0.3
Particle concentration / cm^{-3}	$\sim 10^{14}$
Reduction of temperature in the contact zone (%)	16–20
Reduction of the friction coefficient (%)	20–30
Increase in limiting load of a friction pair (steel–bronze) /MPa	from 16 to 72 (approximately fourfold)
Reduction of wear of mating components by a factor of n	$n = 1.5–3.0$
Combustion engines	
Engine run-in time reduction by a factor of m	$m = 10–12$
Fuel economy (%)	3–6
Power increase (%)	4–8
Cylinder compression increase (%)	10–17
Cooling-lubricating liquids (CLL)	
Cutting torque reduction (%)	20–30
Increase in operating life of tools by a factor of p	$p = 1.5–4.0$

The most interesting parameters are the very low content of ND, considerable increase in the limiting load, reduction of wear of mating components, engine run-in time reduction and an increase in the operating life of tools. ND-containing lubricant compositions can be based on mineral or synthetic oils and CLL.

The DB in a lubricant composition produces a complex effect consisting in:

- filling of dips on the friction surfaces with carbon clusters and subsequent reduction of boundary friction and wear;

- an increase in viscosity of the lubricant composition in thin films due to dispersion structuring of carbon clusters;

- a decrease in viscosity of the lubricant composition at low temperatures due to reduction of glass transition threshold of the dispersion-filled medium;

- after-effect (duration over 60 h) upon replacement of the lubricant composition by the base oil; the effect is due to strong mechanical, adsorption and diffusion immobilisation of carbon clusters on the friction surfaces;

- operation of ND clusters as microscopic antifriction bearings under high load at maximum displacement of the liquid phase between friction surfaces, which permits an increase in the limiting load of the friction pair.

The content of DB in the lubricant composition depends on the character and operation mode of a particular device.

Diamond blend has a strong effect on most structural-mechanical and operating characteristics of almost all types of lubricants. The use of preservation greases reduces the chemical and electrochemical metal corrosion because many additives (usually, corrosive substances) are no longer used. The use of sealing greases and thread lubricants improves the tightness of joints, reduces corrosion of the contact surfaces and stabilises and reduces the shear stress and torque.

Cooling-lubricating liquids are most efficient in screw cutting and holmaking in hard-to-machine materials.^{98–100} Introduction of DB (1 mass %–5 mass %) into lubricants used in plastic metal working significantly reduces the friction coefficient and improves the quality of the surface of goods.¹⁰¹

Diamond blend-containing oil compositions are used in Russia, Germany, Italy, Turkey and China.

4. Polymer – diamond composites

Numerous studies showed efficiency of the introduction of ND and DB into polymeric composites and films based on poly(fluoroelastomers), perfluorocarbons, polysiloxanes, poly(isoprenes), butadiene–styrene rubbers, polyurethanes, polyimides, *etc.*^{36, 50, 91, 102–107}

The introduction of ND improves the overall elasticity and strength characteristics and in some cases provides polymers with unique tribotechnical properties.

The introduction of DB significantly reduces the permeability of fluoroelastomer films.^{103–105} Based on some optimisation parameters, poly(vinylidene fluoride-*co*-perfluoropropyl ether) (CVPE) filled with DB to different extent (from 2 to 50 parts by mass) was chosen as the elastomeric component. A comparative analysis of mass thermograms of the elastomer and nanocomposites based on it showed an increase in the thermal degradation onset temperature, on average, by 40 °.

At a DB content of 5 mass %, the tear resistance of the fluoroelastomer is doubled (Fig. 18). The physicochemical characteristics of the fluoroelastomers based on this DB measured in the course of thermal ageing at 522 K are identical to or better than those of non-aged conventional vulcanisates.

Figure 18. Tensile strength of perfluorinated polymer (film) CVPE plotted vs. additive concentration. Additives: diamond blend (1) and carbon black (2).¹⁰⁵

A fluoropolymer filled with DB (2 parts by mass) demonstrated a decrease in the coefficient of sliding friction at the metal–rubber interface to 7.0×10^{-3} . Rubber mixtures based on DB-modified fluoroelastomers showed an increase in the abrasive wear resistance by a factor of 1.5–2.0.

Thus, DB is the most reactive filler of fluoroelastomers and provides a highly cross-linked vulcanisation network, minimum thermal ageing, low friction coefficient of film coatings and extends their operating life by 25%–40% in the friction units.

a. Polyisoprene and butadiene–styrene copolymer

The modifying action of DB was demonstrated in relation to conventional filled polymer blends based on polyisoprene and butadiene–styrene rubbers, which are widely used in Russia.¹⁰⁸

Diamond blend-modified rubbers are characterised by higher degree of vulcanisation, a 35% higher conditional tensile strength at 300% elongation and a 30% lower degree of swelling in toluene. Such rubbers have better strength characteristics (about 30% higher than those of conventional

rubbers) under normal test conditions and better wear endurance. The addition of DB to rubber in a (2–4) : 100 ratio (by mass) is optimum from the standpoint of the overall effect on the physicochemical characteristics of rubbers.

As the DB content increases, the cohesion strength of rubbers increases by a factor of 1.3–2.0. The maximum cohesion strength is attained at the DB content of 7.5 parts (by mass). The introduction of DB into polyisoprenes causes the tear strength to increase by a factor of about 1.5.

To determine the effect of the rubber matrix on the modifying activity of DB, the latter was introduced in excess (2, 3 and 4 parts by mass) into a conventional rubber blend based on butadiene–styrene copolymer containing 30% of styrene units. The rubber blends containing 3 and 4 parts (by mass) of DB showed an increase in the cohesion strength by a factor of 1.5 to 2.0 compared to the reference samples. The tear resistance of DB-containing vulcanisates is doubled compared to that of the reference samples (Fig. 19). Thus the modifying action of DB introduced into rubber matrices of different nature manifests itself in different manner.

Figure 19. Tear resistance of butadiene–styrene rubber CKCM-30 APK (Russia) at different diamond blend content.¹⁰⁸

b. Polysiloxanes

Polysiloxanes were studied using a polyblock copolymer of ladder phenylsesquioxane and poly(dimethylsiloxane) (LPS-PDMS) as the polymer matrix.¹⁰⁶

This copolymer is cold-resistant to 200 K and thermally stable to 673 K. It can be used as the basic component of film-forming materials having a broad spectrum of applications from protective coatings to selectively permeable membranes.

Nanodiamond powders were pre-calcined and the ND particle surfaces were modified using the silylation reaction (Fig. 20).

When the modified fillers were used in their individual state, the strength parameters of the modified films increase by 20%–30% in the practically valuable interval of deformations and their elastic properties remain reasonably good. The effect is attained at filling degrees of less than 5 mass %.

Figure 20. Modification of ND surface with silylating agents.¹⁰⁶

The following silylating composites were used: Me_3SiCl : $(\text{Me}_3\text{Si})_2\text{NH}$ = 1 : 1, $(\text{CH}_2=\text{CH})_2\text{SiCl}_2$: Me_3SiNH_2 = 1 : 1; R is the functional group containing 'reactive' proton (OH, NH_2 , COOH, etc.).

c. Polyurethanes

The introduction of DB (0.2 mass %) into polyurethanes causes the conditional strength to increase by a factor of 3 upon an increase in the polymer elasticity by a factor of 1.5.

The introduction of DB (0.3 mass %) into polyurethane foams leads to an increase in the compression strength by a factor of 1.5 and improvement of process performance in the preparation of this polymer.

d. Cold-resistant butadiene–nitrile rubber

Introduction of DB (to 1 mass %) into cold-resistant butadiene–nitrile rubber causes a significant (up to 70%) increase in the relative ultimate elongation of the rubber. Additionally, the wear resistance increases and the friction coefficient is halved compared to that of gum rubber.^{109, 110} At 223 K, the cold resistance increases by 50%.

The resistance of rubbers in hydrocarbon media increases by 20% upon introduction of DB. The addition of DB (0.1%–0.5%) improves the key operating characteristics, namely, the friction coefficient decreases and the wear resistance, elasticity and cold resistance of the materials increase. Additionally, the rubbers studied had lower hysteresis losses under dynamic loading; this is responsible for longer operating life.

e. Explosive decompression-resistant rubbers

The introduction of DB (0.1 mass % to ~2 mass %) into commercially available, explosive decompression-resistant rubbers based on various polymers having an elastic modulus of up to 8 MPa causes the tear resistance and wear resistance to increase by 60% and 40%, respectively.¹¹¹

f. Plasma-flame-spraying polymeric coating

A process was developed for plasma flame spraying of single- and multilayer polymeric coatings containing disperse ND.¹¹²

Bilayer metal–polymer coatings containing 0.5 mass % of ND prepared by plasma flame spraying technique provide reliable protection of immersion pump bearings and rotors and other parts from combined action of corrosion and wear, which allows them to retain high operating characteristics over a long period of time.

5. Diamond sintered samples and compacts

Experience in sintering of diamond micropowders has shown that a decrease in the grain size causes deterioration of the physicomechanical properties of sintered polycrystals. The reason lies in high back pressure of desorbed gases at $T > 1773$ K and at pressures > 5 GPa.^{113–115}

Desorption of gases physisorbed on the surface of ND particles was achieved by heat treatment of compacts *in vacuo* for 2 h at 773 K and a residual gas pressure of 10^{-3} Pa.¹¹⁶

As the sintering temperature increases, the degree of graphitisation increases. Removal of carbonyl and hydroxyl groups from the surface of diamond particles as a result of its chemical modification decreases the degree of graphitisation of ND on sintering. Here, raising the temperature is accompanied by densification of the sintered polycrystals; as a consequence, their strength and hardness increase (maximum hardness is 28 GPa).¹¹⁶

By cold pressing of ND one can prepare compacts with a density of 1830 (at 4.5 GPa) and 1950 kg m^{-3} (at 8 GPa). At the pressing temperature of 1773 K, the density slowly increases and at 2273 and 2573 K it decreases.¹¹⁷ The samples prepared at 1273 K and higher temperatures showed graphitisation of ND, which develops at the grain boundaries. The optimum sintering duration is 36 s. The sintering of ND is governed by two parameters, the initial density of ND and the quality of purification of the particle surfaces.

The data on the ND sintering conditions and the characteristics of their structural state are listed in Table 13.¹¹⁵ Two processes occur during the sintering of ND, that is, transformation of the structural state of ND and the diamond → graphite phase transition.

A possible method of counteracting the effect of desorbed gases on the sintering of ND involves the introduction of getters (elements or compounds that form chemical bonds with gas molecules) into the reaction volume.¹¹⁸ For instance, by modifying the surface of ND particles with cobalt and nickel, a fraction of volatile oxides was replaced by non-volatile ones; as a consequence, gas evolution in the course of hot compaction reduced and the density and hardness of the compacts increased.¹¹⁹

The approach involving the introduction of compounds favouring glass formation into the ND powder proved to be fruitful.¹²⁰ In particular, the addition of B_2O_3 , SiO_2 , CaO or B (1 mass % to 3 mass %) made it possible to reduce the sintering pressure from 7 to 5 GPa and to increase the temperature and duration of sintering; graphitisation and recrystallisation of diamond slowed down.

The density and hardness of sintered ND samples can also be increased by sintering mixtures of ND with static-synthesis diamond micropowders produced on a large scale. The drawing dies for metal cord fabrication showed a halved wear compared to the dies sintered from static-synthesis diamond micropowders only.

By introducing DB into copper–graphite collectors one can eliminate the wear problems of both the collector and the copper wire (minimum wear).

Rolled tungsten + aluminium + ND composite (thickness 4 mm) is used for production of body armour.²

Table 13. Characteristics of starting ND and ND-based compacts prepared under different conditions of heat treatment under pressure.¹¹⁵

Treatment conditions			Phase composition	Composition of the diamond component					
P /GPa	T /°C	τ /s		polycrystalline particles		aggregates		single-crystal grains	
				size	content (%)	size /Å	content (%)	size /Å	content (%)
1	—	—	starting diamond	I	90				
				II	10				
4.5	1000	36	diamond + graphite	I + II	100	—		—	
4.5	1500	36	the same	I + II	80	100–150	20		
8	750	36	diamond	I + II	100	—		—	
8	1000	36	diamond + graphite	I + II	100	—		—	
8	1500	36	the same	I + II	80	100–150	20	—	
8	2000	12	"	I + II	20	100–200	70	100–300	10
8	2000	36	"	—		100–500	70	100–500	30
8	2300	12	"	—		100–500	20	500–1500	80

Note. Notations used in this Table are as follows: 'I' for particle size from 3 to 50 Å and 'II' for particle size from 100 to 150 Å.

6. Biological activity of nanodiamonds

Modern antioxidants used for chemotherapy of cancer patients are very toxic compounds. This makes the search for novel antioxidants of low toxicity topical.

Diamonds are non-toxic and non-tumourigenic species, possess no mutagenic properties and are insoluble in biological liquids. The biological activity of ND has not been studied as yet.

An ND crystal has a chemically inert classical diamond core (almost round or oval in shape) and a quite reactive surface 'fringe' comprised of functional groups that are safe for living organism and impart the surface with hydrophilic properties.^{121,122} Additionally, each ND crystal has a large number of unpaired electrons, being in essence a multiradical.¹²³

Nanodiamonds belong to fundamentally novel antitumour agents.^{124,125} They can be treated as polyfunctional supra-molecular structures bearing polar groups [OH, NH₂, C(O)NH₂] that govern the antioxidant activity and the ability to participate in free-radical processes in living cells.

A large number of functional groups on the surface of ND particles can provide both additional generation and quenching of excess radicals in metabolic processes. It is the ability to control free-radical processes under the action of ND that can appear to be a basis for their antitumour action.

In all studies, ND showed a marked beneficial effect, which manifests itself in the extension of life of cancer patients compared to predictions. Figure 21 shows the initial and final stages of the attack of ND on malignant cells in human body.

Generally, the results obtained using aqueous ND suspensions are as follows: significant or even complete relief of severe pain; normalisation of intestinal peristalsis, including recovery of gut permeability; improvement of blood characteristics; significant activation of the immune system and the mental status of patients (incredible eagerness for life was observed).

It is possible to design ND-based pharmaceuticals for activation of the enzymatic subsystem of the antioxidative cell protection system.^{126,127}

Thus, the results of a few available studies of biological activity of ND are as follows.

1. At present, ND have no analogues, with allowance for their physical state (insoluble solid powder), from the standpoint of complex action on human organism.

2. The use of ND along with chemotherapy and radiotherapy can appear to be promising in treatment of malignant neoplasms.

3. ND are highly efficient for normalisation of gastro-intestinal function.

Figure 21. Initial (a) and final (b) stage of ND attack on malignant cells in human organism.¹²⁶

Nanodiamonds are also of great interest for biochemistry as a novel kind of sorbents suitable for separation and purification of proteins.^{128–131} Nanodiamonds can selectively adsorb recombinant apoobelin from the protein extract of the cells of *Escherichia Coli*. It was found that ND particles also can adsorb phytoprotein on their surface.¹²⁹ An ND–obelin composition was grafted onto the surface of aluminium substrate and a prototype of planar luminescent sensors (biochips) was created.¹²⁸

Recently, a highly sensitive test method for determination of the presence and type of antibodies and antigen markers of different nosology using ND has been developed. The technique does not require any equipment and solutions other than analysed one.

7. Other fields of application of nanodiamonds

A novel initiation composition VS-2 based on 5-hydrazino-tetrazolylmercury(II) and poly(methylvinyltetrazole) containing ND (Table 14) was developed.^{132, 133} The substance is sensitive to low-temperature laser radiation.

Table 14. Parameters of VS-2 explosive initiation with a laser pulse.

VS-2 charge + additive		Initiation energy /μJ
additive	additive content (%)	
No additive	—	310
Soot	0.5	2450
	1	2550
	2	3050
	3	3250
Nanodiamonds	0.5	260
	1	200
	3	180
	5	340
Fullerenes	1	630
	3	830
	5	730
Nanotubes	0.5	640
	1	590
	2	640
	3	850

Laser initiation is a relatively new safe procedure for blasting explosives. It provides a high degree of isolation of the light-initiated detonator from a false pulse because of the lack of powerful random light sources suitable for blasting the detonator in the optical region. The additives to the VS-2 composition, namely, finely disperse soot, fullerenes or nanotubes (1%–3%) increase the threshold of initiation by a single pulse of a neodymium laser. On the contrary, the introduction of detonation-synthesis ND (0.5%–3%) reduces this threshold.

The composition provides simultaneous enhancement of sensitivity to the laser pulse by a factor of 1.5–1.7 and high adhesion to the contact surface due to improvement of the adhesive properties of poly(methylvinyltetrazole) caused by the presence of ND. The minimum initiation energy drops from 310 to 180 μJ for the ND-containing material.

To protect architectural monuments made of white Carrara marble, ND-containing organic–silicate coatings were developed and evaluated.^{134, 135} Nanodiamonds present in such coatings inhibit the growth of the most abundant, in urban environment, fungi and bacteria that destroy the structure of stone materials. The coatings are prepared from tetraethoxysilane-based sols containing ND. They can be used to modify the surface of particles of the powder components of cements and concretes. This permits a significant extension of the operating life of buildings, motorways, hydroelectric power plants and other facilities made of concrete.

Ion-selective electrodes in medicinal drug determination

S V Kharitonov

Contents

I. Introduction	361
II. Principles of operation of membrane ion-selective electrodes	362
III. Mechanism of electrode selectivity of ionophore-based membranes	365
IV. Components of ion-selective electrode membranes and methods of potentiometric determination of medicinal drugs	370

Abstract. Data published in the past 10 years on the use of ion-selective electrodes in direct potentiometry and potentiometric titration for the determination of organic medicinal drugs are analysed. In the vast majority of cases, ion-sensitive membranes contain associates of drug cations or anions with appropriate counter-ions. The theoretical approaches to optimisation of the characteristics of ion-selective electrodes are discussed. The mechanism of electrode response generation for neutral and charged carriers of organic ions is considered. The bibliography includes 314 references.

I. Introduction

The advance of the pharmaceutical science is marked by the appearance of 30–40 new medicinal drugs annually. At present, there are more than 10 000 medicinal drugs (MD) and over 100 000 drug preparations registered all over the world.^{1,2}

According to the data issued by the Ministry of Health and Social Development, since 1997, the number of MD registered in the Russian Federation has increased almost 1.5-fold (Fig. 1), of which ~80% pertains to reproduced preparations.² Figure 2 illustrates the dynamics in the development of original Russian MD in the period from 1997 to 2003. The average number of new MD introduced into the national health protection practice amounted to 40–60 items per year.

In line with the progressively increasing number of new MD, the problem of their identification and determination in both individual samples (*in vitro*) and living organisms (*in vivo*) becomes urgent. The demand for the accumulation, generalisation and systematisation of data on the MD monitoring and analysis resulted in the appearance of specialised scientific periodicals. Since 1983, the international *Journal of Pharmaceutical and Biomedical Analysis* (*J. Pharm. Biomed. Anal.*), which deals with the studies in the field of the MD analysis, analytical biochemistry, pharmacokinetics, forensic toxicology and other related fields, has been published. *Fresenius' Journal of Analytical Chemistry* has been published under a new title,

viz., *Analytical and Bioanalytical Chemistry* since 2002. Among the other international issues that publish the results of studies in the field of MD analysis, mention should be made of journals *American Journal of Pharmaceutical Education*, *Archiv der Pharmazie*, *Drug Information Journal*, *European Journal of Pharmaceutical Sciences*, *Il Farmaco*, *International Journal of Pharmaceutics*, *Journal of Chromatography B: Biomedical Sciences and Applications*, etc. The main Russian journal devoted to this field is the *Khimiko-farmatsevticheskii Zhurnal* [*Pharm. Chem. J. (Engl. Transl.)*], which has been published since 1967.

Considering the data published in original papers in *J. Pharm. Biomed. Anal.*, it can be stated with confidence that the chromatographic methods of analysis still occupy the leading position (more than 1500 publications in 10 years). They amount more than 50% of all methods of MD determination (Fig. 3), of which 45% fall on HPLC, 23% correspond to liquid chromatography, 14% are devoted to liquid chroma-

Figure 1. Increase in the number of registered medicinal drugs in Russia in 1997–2004 (according to the Ministry of Health and Social Development of the Russian Federation).

tography with mass spectrometric detection, 7% deal with gas chromatography and 11% fall on the rest chromatographic techniques.

According to the number of publications in *J. Pharm. Biomed. Anal.*, the electrochemical methods of the MD analysis occupy the third place after photometry and spectrophotometry, ~20% of publications being devoted to the potentiometric determination of MD.

Equilibrium electrochemical methods of the MD analysis, which include direct potentiometry (ionometry) and potentiometric titration, are extremely convenient, simple and make it

Figure 3. Distribution (%) of different instrumental methods for quantitative determination of MD (according to publications in *J. Pharm. Biomed. Anal.* in 1995–2005).

(1) Capillary (including zone) electrophoresis (6%); (2) bioanalysis and biosensors (2%); (3) HPLC (25%); (4) liquid chromatography (13%); (5) liquid chromatography with mass spectrometric detection (8%); (6) gas chromatography (4%); (7) other chromatographic methods (6%); (8) mass spectrometry (2%); (9) immunoassay and radioimmunoassay (2%); (10) IR spectroscopy and Raman spectroscopy (1%); (11) voltammetry (3%); (12) inversion voltammetry (2%); (13) ionometry (2%); (14) miscellaneous electrochemical methods (3%); (15) fluorimetry (3%); (16) NMR (2%); (17) spectrophotometry and photocolourimetry (10%); (18) flow-injection analysis (3%); (19) miscellaneous analytical methods (4%).

possible to determine those MD that can be converted into the corresponding ionic forms. As a rule, they combine sufficient selectivity with the precision of determination, which can substantially be enhanced even in the direct determination by operating the sensors *via* the mechanism of super-Nernstian response. Moreover, potentiometric detectors are capable of operation under the conditions of on-line analysis and can sufficiently easily be miniaturised to serve as micro- and ultra-microelectrodes.

In 1980–1990, many reviews were devoted to the use of ion-selective electrodes (ISE) in the pharmacological, clinical and biomedical assay. The biomedical aspects of the use of ISE and microelectrodes,^{3,4} the application of ISE in the medicinal practice and the potentiometric determinations *in vivo*^{5,6} were considered. The peculiarities of the use of ISE, including the application of potentiometric measurements with ISE and transducers in the clinical chemistry, were discussed.^{7–14} The data on the use of various ISE (with liquid and film membranes, ‘coated wire’ ISE, heterogeneous ISE with matrix-incorporated ion exchangers, pseudoliquid ISE, *etc.*) in pharmacy and pharmacological analysis were systematised.^{15–25}

However, in the past decade, a vast number of new MD appeared and different ISE types were elaborated for their determination, which necessitates the systematisation of the corresponding literature data.

II. Principles of operation of membrane ion-selective electrodes

An ion-selective electrode can be defined as an electrochemical sensor with a membrane the potential of which serves as the measure of the activity of a certain ion.²⁶ An ISE membrane may represent a crystalline or non-crystalline, homogeneous or heterogeneous phase, which, as a rule, exhibits high ionic conductivity. Crystalline membranes are based on single crystals (*e.g.*, LaF_3 for F^- -ISE), polycrystalline compounds (*e.g.*, Ag_2S for Ag^+ - and S^{2-} -ISE), heterogeneous mixtures pressed into pellets or incorporated into an inert binding material (matrix) (the Pungor electrodes). Glass, liquid and plasticised membranes are classified with non-crystalline membranes. The latter are used most extensively. The main requirement to a membrane is the ability to exchange ions of only one type. For an ISE to be selective with respect to a single type of ions, its membrane should contain a substance that can reversibly bind the ion under determination and at the same time exhibit the minimum solubility in aqueous solutions. Substances with such properties are called electroactive compounds (EAC). According to the mechanism of EAC reactions with the determined ion, the EAC are divided into charge carriers or ion-exchangers (the ion is transferred by an active ion-exchange site due to electrostatic interactions), neutral carriers or ionophores (the ion transfer follows the mechanism of selective complexation) and chelate-forming carriers (the ion transfer proceeds due to both electrostatic interactions and the complexation).²⁶

Ion-selective electrodes are classified according to the type of membranes used. Solid-phase, liquid-phase and film ISE are distinguished, which can be divided further to various groups depending on the nature of EAC used and the design of the ISE itself. Thus gas electrodes, enzyme electrodes, solid-contact electrodes and microelectrodes are often singled out into individual groups. Figure 4 shows the designs of most popular ISE types.

In addition to EAC, other components are often introduced into membranes to improve the functional properties of ISE. These can be additives that affect the electrophysical characteristics of membranes or substances capable of additional specific or non-specific interactions with the membrane or solution components.

Figure 4. Designs of main types of ion-selective electrodes.

- (a) Solid-phase ISE with crystalline or heterogeneous membranes: (1) ion-selective membrane, (2) hydrophobic graphite layer, (3) case (a PVC or PTFE tube), (4) electron conductor (steel wire).
 (b) Solid-contact electrodes of the 'coated wire' type: (1) ion-selective membrane, (2) electron conductor (Au, Pt or Cu wire), (3) case (usually glass).
 (c) ISE with a polymeric membrane and an internal liquid contact: (1) ion-selective membrane, (2) internal standard solution, (3) case, (4) internal reference electrode (Ag/AgCl).
 (d) ISE with a liquid membrane: (1) porous plate impregnated with EAC solution, (2) EAC solution in an organic solvent, (3) internal standard solution, (4) internal reference electrode (Ag/AgCl), (5) case.
 (e) Glass ISE: (1) ion-selective glass membrane, (2) internal reference electrode (Ag/AgCl), (3) internal standard solution, (4) case.
 (f) Gas-sensitive ISE: (1) gas-permeable membrane, (2) internal solution, (3) ISE with (4) standard solution and (5) reference electrode, (6) case, (7) internal reference electrode

Ion-selective electrodes can be used in the determination of both organic and inorganic ions and certain neutral molecules. As will be shown below, the vast majority of studies dealing with the ISE for medicinal drugs were associated with the development of procedures for the quantitative determination of MD in model solutions, drug preparations, more rarely, in biological fluids and raw materials used in chemical and pharmaceutical industries. Much fewer studies were aimed at relating the physicochemical, electrochemical and transport properties of selective membranes to the potentiometric characteristics of the relevant ISE.^{27–38}

In the majority of cases, the charged carriers, *i.e.*, ion associates (IA) formed by MD cations or anions with the corresponding counter-ions, are introduced into selective membranes as the EAC. In addition to ion-exchange properties and the minimum solubility in water, an EAC should be compatible with the other components of the ion-sensitive membrane. The mechanism of operation of such ISE is described by a model of charged carriers.³⁹

Pungor^{40,41} has considered the processes that occur on the membrane surface and in its bulk and assessed the contributions of individual components to the membrane potential. In discussing the anomalies that arise in the interpretation of the mechanism of ISE operation, he took into account⁴⁰ the Donnan effect, the response time, the surface morphology, *etc.* The modified electrodes the chemical reaction on which involves the potential-determining ion were found to demonstrate a surface response. For IA-based ISE, the lyotropic series rule is valid; the surface reactions are also possible; however, such electrodes not always demonstrate the Nernstian response. Such aspects as the energy of the transfer of charged species across the electrode–solution interface were also considered.

For polymeric membranes that contain charged ion-exchangers and neutral carriers as the ionophores, it was proposed^{42–45} to quantitatively describe the ISE response based on the consideration of the ion-exchange equilibrium at the membrane–solution interface. The validity range of the Nikolskii–Eisenman equation used in the calculation of the selectivity coefficient of ISE was discussed. It was shown that the derived mathematical relationships allow more accurate calculations of ISE selectivity coefficients in the presence of

interfering ions with different charges. It was concluded that this approach can be applied in assessing the selectivity of most ISE with polymeric membranes.

The studies aimed at the optimisation of electroanalytical properties of membrane ISE were largely developed in two directions, namely, the optimisation of the internal near-membrane solution and the introduction of different ions and molecules into the membrane.

The first direction was developed in the studies by Pretsch and Bakker. In 1997, Pretsch and co-workers⁴⁶ demonstrated that the introduction of hydrophilic (thus, incapable of penetrating into the membrane) complexing agents that can form stable complexes with the determined ion, into the intramembrane solution intensifies the ion fluxes from the external solution to the membrane phase and dramatically lowers the detection limit. The development of these ideas made it possible to create a new model describing the detection limit of ISE and to elaborate new sensors with superhigh sensitivity.

The processes that lead to lowering of the detection limits of ionophore-based ISE are described by a steady-state model of ion fluxes.^{47,48} It was found that the ion-exchange and extraction equilibria at both sides of a membrane stimulate the appearance of concentration gradients in the membrane phase and can affect the detection limit through the ion fluxes. The concentration variations in the near-membrane internal solution can change the ISE detection limits by more than five orders of magnitude. However, it is necessary to produce high gradients of concentration to achieve adequate ISE characteristics. It was shown that the appearance of a superlow detection limit of ISE (10^{-9} – 10^{-12} mol litre⁻¹) cannot be defined according to the IUPAC rules. The impurities present in minor concentrations in the membrane phase can have a strong effect on the ISE characteristics when the electrodes operate at the concentrations of determined substances below 1 μ mol litre⁻¹.

Mention should be made of studies^{42,49–53} on the effect of different parameters on the ISE characteristics, which were based on the steady-state model.^{47,48} The effect of interfering ions, the composition of near-membrane and intramembrane solutions, the selectivity coefficients, the analyte lipophilicity, the concentrations of ionophore and lipophilic additives in the membrane, the thicknesses of the Nernstian diffusion layer and

the membrane and the diffusion coefficients of ions in both phases were studied. Based on the results obtained, it was concluded that all these factors might contribute to the lowering of the detection limit of potentiometric sensors.⁵³

The most general theoretical description of the stationary potentiometric response of ISE membranes was presented.^{54–56} Membrane systems that contain any number of ionophores with ion-exchange centres fixed on a polymeric matrix were considered. The thermodynamic model explains the characteristics of ISE selectivity based on different diffusion-induced effects associated with trans-membrane ion fluxes at zero emf. The appearance of super- and sub-Nernstian responses and the upper and lower limits of the determined concentrations were discussed; the temporal characteristics of ISE were considered. The approach developed allows one to considerably improve the selectivity coefficients and detection limits of ionophore-containing ISE. These studies open up new possibilities and prospects for the wide application of ISE techniques, which can compete with the most sensitive analytical methods.

A non-classical interpretation of the electrode response of sensors based on ionophores was discussed.⁵⁷ Several new concepts on the development of ionophore-based ISE were considered. Various long-known ISE for simple cations and anions are widely used in the industry and clinical chemistry. However, further studies that would allow the optimisation of ISE properties for analytical purposes are necessary. These studies should be carried out in the following directions:

- reduction of the lower limit of determined concentrations by governing the analyte ion fluxes through the membrane;
- development of methods for the determination of ion concentrations using sensors that exhibit the effect of the intensification of ion fluxes to the internal near-membrane solution;
- targeted search for ionophores that can provide the super-Nernstian response to the ions determined;
- development of ion-exchange membranes sensitive to polyions according to a non-equilibrium mechanism of electrode response;
- development of membranes selective to molecules of non-ionogenic surfactants;
- development of ISE with the electrode response formed due to redox reactions between the ionophore and the detected ion.

Insofar as the current practice consists of the incorporation of membrane-active complexones (ionophores) synthesised for this purpose^{58–106} into the ISE, the results of studies mentioned above^{42–57} are of fundamental importance for the development of ionometry of MD.

The second direction in the optimisation of ISE properties dates back to the pioneering studies of 1970s in which polymeric matrices with fixed charges were used for the improvement of electrode characteristics of membranes.³⁹ Later, this idea gave impetus to the development of mobile anionic sites in the membrane by the introduction of highly lipophilic ions such as tetraphenylborate anions.^{39, 107–109} It is believed that due to the poor solubility in water, these species indeed reside in the organic phase of a membrane. Lipophilic ions should remove the analyte anions to one extent or another from the membrane rather than compete with the ionophore for the formation of complexes with cations. As a result, the effect of the anion permeability that deforms the cationic response of the ISE is diminished or totally eliminated. Such compounds proved to be promising for ISE based on dissociating ion exchangers.¹¹⁰ This made it possible not only to extend the interval of the ISE electrode response, but also to considerably enhance the electrode selectivity.

The mechanism of operation of ISE based on liquid ion-exchangers, which are incorporated in the membrane in a mixed form, *viz.*, preferentially as a salt with an ion modifier and partially as a salt with the determined ions, was considered.¹¹¹ The ion modifier should be much more lipophilic than the determined ion to ensure the virtually constant concentrations of both salts in the membrane surface layer in the course of an ion exchange reaction that occurs once the membrane is brought into contact with the aqueous solution containing ions to be determined. The boundary conditions for the linearity of the electrode function for ISE of such a kind in solutions of determined ions were formulated. It was proved theoretically and demonstrated experimentally that for electrodes under consideration, the extraction selectivity of the ion-exchanger with respect to the determined ion can be adequately converted into the potentiometric form.

At present, almost all electrodes (including ISE based on ion associates) for the determination of both cations and anions employ membranes modified with lipophilic additives, which considerably improve their characteristics. The incorporation of ionic components into ISE membranes based on neutral carriers also proved to be advantageous due to the substantial reduction of the Ohmic resistance in the membrane.

The operation limits of ISE are the important characteristics. The dynamic range of the ISE operation can be substantially extended by either modifying the membrane or introducing a special buffer into the internal solution of the ISE. In the first case,¹¹⁰ the ISE membrane will operate by the mixed mechanism, namely, the addition of a lipophilic salt will increase the ISE selectivity (due to the stabilisation of counterions in the membrane) and also decrease the negative effect of co-ions that cause degeneration of the ISE electrode function.

The studies on the effect of the intramembrane buffer on the detection limit have shown^{42, 46, 49, 50, 112–114} that the buffer can affect the ion fluxes and thus change the detection limit of conventional ISE. Such parameters as the composition of the internal electrolyte, the membrane thickness, the nature and concentration of the ion exchanger were studied with the aim of achieving the lower detection limits of ISE. The experimental data were explained based on the fundamental concepts of theoretical models of the diffusion transfer.

Reliable information on the effect of the membrane composition and the ion-exchanger properties on the electrochemical and analytical characteristics of ISE retrieved by studying the transfer of potential-determining species across interfaces under both equilibrium and non-equilibrium conditions. The state of EAC based on MD ion associates in the membrane phase,^{27–36} the nature and physicochemical properties of ion exchangers in the membrane solvent^{27–29, 33} and the processes associated with the effect of water on the properties of interfaces³⁷ were considered.

Studies on the kinetics of the ion-exchange sorption of MD cations on the surface of ion-selective membranes have shown that the degree of ion exchange is determined by the lipophilicity of the eluting ion, while the time of the establishment of the equilibrium state is controlled by the diffusion. A mechanism of the exchange of hydrophobic organic ions on the surface of liquid membranes with strongly associating active sites was proposed.³⁸

The effect of the nature of the polymeric matrix on the electroanalytical properties of ISE was discussed.¹¹⁵ The studies on the transport of organic cations through membranes involved the determination of their transport numbers. The dependences of the selectivity coefficients on the transport properties of polymeric matrices and on the coefficients of MD distribution between aqueous and membrane phases were obtained.

III. Mechanism of electrode selectivity of ionophore-based membranes

Neutral carriers (ionophores) were used as EAC in the ISE for different MD, namely, protonated amines, quaternary ammonium compounds, amino acids, peptides, nucleotides.^{58–106} The use of neutral carriers as the receptors for organic ions is based on their specific reactions and the formation of ‘host–guest’ complexes. In the formation of such complexes, the hydrophobic effects, van der Waals forces, hydrogen bonds and π -cationic interactions play the great role.¹¹⁶ The stability of complexes formed is determined by the following factors:¹¹⁷

- the correspondence between the geometrical sizes of the molecule-guest and the cavity of the molecule-host,
- the conformational flexibility of the ligand,
- the presence of functional groups in ionophore molecules,
- the nature of the solvent.

The membrane potential in a cell with an ISE based on a neutral carrier is formed as a result of processes of selective molecular recognition between the ionophore and the potential-determining ion, which occur at the interface.

To find the principles of potentiometric selectivity of ionophores with respect to organic ions and molecules, it is expedient to consider the effect of the polarity of structural fragments in organic compounds.¹¹⁸ For polar organic ions, the appearance of a specific membrane potential was associated with the electrostatic interaction and/or the formation of hydrogen bonds between the functional groups of the ionophore and the polar fragments of the organic molecule (ion). Such a mechanism of selective recognition is typical of macrocyclic polyamines with long-chain hydrocarbon substituents, which can form multicharged cations upon protonation. These ionophores are selective with respect to multicharged organic anions such as adenine nucleotides and anions of certain dicarboxylic acids.^{119–121} Moreover, the potentiometric selectivity of ionophores depends on the charge of organic ions (the potentiometric response decreases in the sequence $\text{ATP}^{4-} \gg \text{ADP}^{3-} \gg \text{AMP}^{2-}$)^{119, 121} or on the localisation of the negative charge on the organic anion [the potentiometric response decreases in the sequences *cis*- $-\text{OOC}-\text{CH}=\text{CH}-\text{COO}^- > \text{trans}-\text{OOC}-\text{CH}=\text{CH}-\text{COO}^-$; *o*- $\text{C}_6\text{H}_4(\text{COO}^-)_2 > m\text{-C}_6\text{H}_4(\text{COO}^-)_2 > p\text{-C}_6\text{H}_4.(\text{COO}^-)_2$] (Refs 120, 121). Thus macrocyclic hexamine **1** was used as the neutral carrier in the benzoate-ISE.⁵⁸ The selectivity of an electrode based on amine **1** with respect to anions decreased in the sequence $\text{PhCOO}^- \approx \text{Cl}^- \approx \text{SO}_4^{2-} \approx \text{PO}_4^{3-} > \text{AcO}^- > \text{NO}_3^- > \text{citrate}$.

Macrocyclic hexamine **1** exhibits a pronounced anionic receptor function at the pH from 4 to 6 due to the presence of amide groups in the β -positions relative to the nitrogen atoms of the polyamine ring, which enhance the affinity of the ionophore for hydrogen ions and improve its receptor function with respect to anions.¹²² The same ionophore was used as the EAC in an ion-selective electrode sensitive with respect to anions of adenosine diphosphate and adenosine monophosphate; moreover, the electrode function slope proved to be close to the theoretical slope.⁵⁹

The effect of positively charged nitrogen atoms formed upon protonation of ionophores on their complexation properties was demonstrated by the example of cyclic and acyclic polyamines.¹²¹

Porphyrine and its derivatives represent typical cyclic polyamines (azacrown compounds) with donating nitrogen atoms, which are softer bases as compared with oxygen atoms. They were used in ISE sensitive with respect to salicylate and valproate anions.^{60, 63–65} 5-*n*-{[4-(10,15,20-Triphenyl-5-porphynato)phenoxy]-1-butoxy}phenyl-10,15,20-triphenylporphyrine (**2**) and 5,10,15,20-tetrakis[2-(2,3,4,6-tetraacetyl- β -D-glucopyranosyloxyphenyl)]porphyrine (**3**) served as specific ionophores in ISE for alkaloid berberine.^{61, 62}

The studies on the reaction of ionophores **2** and **3** with berberine cations involved the analysis of electron absorption spectra of their solutions in chloroform and nitromethane, which were measured before and after these solutions were brought into contact with an aqueous solution of berberine cations.⁶² The absorption peaks of porphyrin **3** at 418, 516, 588 and 654 nm observed upon the contact with the solution of a berberine salt shifted to the long-wave region on average by 4 nm and the peak at 544.5 nm disappeared. This was also observed for ionophore **2**. At the same time, the absorption spectra of a manganese(II) complex with porphyrin **3** remained unchanged both before and after its contact with the berberine salt.

A comparison of IR spectra of PVC membranes based on ionophore **3** before and after their contact with a berberine salt revealed the shifts of absorption bands at 1643.9, 1218.7 and 707.9 cm^{-1} to 1647.1, 1221.9 and 720.0 cm^{-1} , respectively, and the appearance of a new characteristics peak at 1046.5 cm^{-1} associated with the valence vibrations of the amino group in the berberine molecule. This made it possible to assume⁶² the reversible complexation of ionophores with the berberine cation.

A more complicated process that accompanies the complexation is the formation of hydrogen bonds between the ‘guest’ and ‘host’ molecules. In this case, the potentiometric selectivity was demonstrated for liquid membranes that contained ionophore **4** with a dual receptor function and were capable of recognising guanine- and adenine-containing nucleotides with high selectivity with respect to the former.¹²³

The selectivity of ionophores with respect to organic compounds depends on the presence of non-polar fragments of different nature and structure and, in the general case, is determined by the hydrophilic–lipophilic balance in the organic molecule as a whole. Although the ability for the incorporation of organic molecules into the hydrophobic cavities of the matrices of molecules-hosts is one of the key factors in the molecular recognition, for example, for cyclodextrins and cyclophans in aqueous solutions, the membrane systems pose certain difficulties in the realisation of this selectivity mechanism due to the presence of competitive interactions between ionophores, organic molecules and membrane components. This is why the potentiometric selectivity of ionophores is associated with such properties of organic molecules as lipophilicity and chirality.^{118, 124–126}

The enantiomeric potentiometric selectivity of ionophores with respect to protonated amines and esters of amino acids was demonstrated for PVC membranes based on crown ethers,^{127, 128} natural ionophores¹²⁹ and cyclodextrins.¹³⁰ Due to the peculiarities of their three-dimensional structure, calix[n]arene derivatives exhibited selectivity with respect to primary amines and catecholamines.¹³¹

Cyclic coronands (crown ethers) such as 18-crown-6, dibenzo-15-crown-5, dibenzo-18-crown-6, dibenzo-21-crown-7, dibenzo-24-crown-8, dibenzo-30-crown-10, dicyclohexano-18-crown-6, 4',4''(5'')-di-*tert*-butylcyclohexano-18-crown-6 and dicyclohexano-24-crown-8 were used in the ISE sensitive with respect to chlorphenoxamine,⁶⁶ mexitol⁶⁷ and amphetamine stimulators.^{68, 69}

Potentiometric selectivity of crown ethers is associated with the lipophilicity of organic ions. The formation of complexes between 'guest' and 'host' molecules is accompanied by the formation of hydrogen bonds, which is typical of, *e.g.*, any protonated primary amines. Thus the selectivity of dibenzo-18-crown-6 with respect to primary ammonium cations correlates with the $\log P$ and decreases in the following sequence: octylammonium (3.06 ± 0.18) \approx adamantylammonium (2.22 ± 0.24) > phenethylammonium (1.46 ± 0.19) > benzylammonium (1.09 ± 0.21) \approx *tert*-butylammonium (0.56 ± 0.21). Its selectivity with respect to catecholamines decreases in the sequence dopamine (0.12 ± 0.22) > adrenaline (-0.63 ± 0.28) > noradrenaline (-0.88 ± 0.27) (Ref. 70).[†] The structure of resulting complexes is as follows.

In certain cases, the lipophilicity of an organic cation is not the key factor for the potentiometric selectivity of crowns. It was assumed that an ISE based on dibenzo-18-crown-6 should be more selective with respect to the hydrophobic cations of phentermine ($\log P = 2.16 \pm 0.21$) as compared with less hydrophobic cations of amphetamine ($\log P = 1.81 \pm 0.20$) and phenethylamine ($\log P = 1.46 \pm 0.19$). However, its selectivity turned out to be approximately the same with respect to all mentioned cations.⁶⁸ Here, the key role is played by the steric factor that directly affects the stability of complexes formed. In the phentermine molecule, steric accessibility of the positively charged nitrogen atom for complexation is restricted by two α -methyl groups. The use of an acyclic ionophore with carboxamide fragments made it possible to develop an ISE with the higher selectivity with respect to phentermine. The ISE selectivity decreased with the decrease in the lipophilicity of the organic cation in the series phentermine > amphetamine > phenethylamine. This suggests that the stability of complexes of a series of (phenylalkyl)amines with an acyclic ionophore is independent of the steric accessibility of the NH_3^+ group. The peculiarities of the complexation of crown ethers with nitrogen-containing organic compounds were discussed.¹¹⁷

Acyclic oxygen-, nitrogen- and phosphorus-containing podands, namely, *N,N*-bisoctadecyl-*N',N'*-dipropyl-3,6-

[†] Logarithms of coefficients of distribution in the water – n-octanol system were calculated using the ACD Labs software with a $C \log P$ predictor for the deprotonated amine form.

dioxaocanediamide (Pb^{2+} -ionophore I, ETH 322); bisdodecyl ether of triethylene glycol; N,N,N',N' -tetrakis(cyclohexyl)-oxybis(*o*-phenyleneoxy)diacetamide (Ba^{2+} -ionophore I); N,N,N',N' -tetrakis(cyclohexyl)diglycolamide (Ca^{2+} -ionophore II, ETH 129); N,N,N',N' -tetrakis(cyclohexyl)-1,2-phenylenedioxydiacetamide (Na^+ -ionophore III, ETH 2120) and tris[(2-(2-diphenylphosphinylmethyl)phenoxy)ethyl]amine, which are traditionally used in the ISE reversible with respect to metal ions, turned out to be selective ionophores with respect to amphetamine preparations,^{68,69} β -lactam antibiotics,⁷¹ anions of hydroxy-, mono- and dicarboxylic acids and surfactants.⁷²

Calix[*n*]arenes can form π -complexes due to the presence of aromatic rings. Such complexes are formed with organylammonium, -iminium and tropylium cations; their stability depends first of all on the conformational peculiarities of the calix[*n*]arene molecule.¹³² Thus complexes of amino acids, aliphatic amines, guanidine, creatinine with methyl, ethyl and propyl ethers of calix[6]arene proved to be more stable than the complexes of amino acids with cyclodextrins and crown ethers.¹³³

Theoretical calculations and the results of computer simulations have confirmed that the complexing ability of a calix[*n*]arene directly depends on the size and conformational peculiarities of its macrocycle and the presence of functional groups.^{134–137}

It was assumed that the reaction of calix[*n*]arenes with amines in solutions can be described¹³⁸ by the following sequence of reactions:

In the first stage, a mobile proton is transferred from the calix[*n*]arene molecule to the amine molecule. In the second stage, complexation with association of ions occurs, where the ammonium cation can be incorporated into the conical hollow in the ionophore matrix due to the π -cationic interaction.^{139–141}

For example, Scheme 1 illustrates the reaction of 25,26,27,28-tetrakis[*(S)*-(–)-(1)-phenylethylaminoethoxy]calix[4]arene with anions of amino acids or aliphatic amines in water–organic media.¹⁴²

Complexes with the different composition (other than 1 : 1) are formed if the reaction proceeds by the following mechanism: encapsulation of the amine molecule by a macrocycle, formation of a coordination bond between the ‘host’ molecule and another amine molecule.

As a rule, the arrangement of amine molecules is such that hydrocarbon radicals are located in the intramolecular cavities of the calixarene matrix.¹⁴³

Chemical modification of calix[*n*]arenes is a sufficiently simple, effective and versatile approach to the synthesis of receptors highly selective with respect to both cations and anions.¹⁴⁴ The introduction of different functional groups into calix[*n*]arene molecules makes it possible to change the selectivity of ionophores with respect to organic ions. Thus N,N -diethylamide of hexahomotrioxacalix[3]arene extracts 97.8% of Bu^nNH_3^+ , 48.1% of Bu^iNH_3^+ and 35.4% of Bu^tNH_3^+ from the salt mixture. The introduction of a (4-methylbenzyl)aminocarbonyl group into the same calix[3]arene results in the total loss of its specificity with respect to metal ions, whereas the selectivity with respect to nitrogen-containing organic cations such as tetrabutylammonium and trimethylphenylammonium appears as a result of higher electron density on the oxygen atom of the carbonyl group due to the conjugation in the $\text{N}=\text{C}=\text{O} \leftrightarrow \text{N}^+=\text{C}=\text{O}^-$ fragment.^{145–149} As the result of the formation of hydrogen bonds between the neighbouring NH and CO groups, the calixarene molecule loses its affinity for ‘soft’ and ‘hard’ metal cations.¹⁵⁰ In the formation of a complex with the Bu^nNH_3^+ cation, the alkyl substituent travels

through the ligand π -cavity thus causing changes in the calixarene conformation; moreover, no intramolecular hydrogen bonds are formed in this conformation. The anion (Cl^-) is located within the complex and does not leave it due to the formation of an intramolecular hydrogen bond with the NH group.

The peculiarities of complexation of calix[*n*]arenes with nitrogen-containing organic compounds (amines, quaternary ammonium cations, iminium ions, amino acids, peptides) were discussed in several reviews.^{116, 151}

Derivatives of calix[6]- and calix[8]arenes (**5** and **6**, respectively) with specific complexing properties with respect to histamine, dopamine, norephedrine, serotonin⁷³ and chlorphenoxamine⁶⁶ were synthesised and used as the specific receptors in ISE membranes.

R = H, Bu^t; $n = 6, 8$.

Calix[6]crown ethers were tested as the ISE ionophores in the determination of catecholamines (epinephrine, norepinephrine, dopamine).⁷⁴ ISE based on compound **7** exhibited the best potentiometric characteristics. The selectivity of such an electrode doped with a lipophilic compound decreased in the sequence epinephrine > K⁺ ≈ dopamine > NH₄⁺ > norepinephrine > Na⁺. The detection limit for epinephrine was 1.86×10^{-5} mol litre⁻¹. The calculated values of log P were -0.17, -0.39, -0.97 for dopamine, epinephrine and norepinephrine, respectively. The inversed order of the extraction selectivity for catecholamines suggests that the complexation of ionophores with the epinephrine cation makes the main contribution in the formation of the potentiometric response of an ISE.

Cyclodextrins (CD) are cyclic oligosaccharides that consist of D-glucopyranose residues linked with one another with α -1,4-glycosidic bonds. Their lipophilic derivatives **8** were incorporated into selective membranes for the determination of diclofenac sodium,⁷⁵ protonated physiologically active amines, namely, dopamine,⁷⁶ (S)-enalapril,⁷⁷ tricyclic antidepressants (desipramine, imipramine, trimipramine),⁷⁸ local anaesthetics (bupivacaine, lidocaine, procaine, prilocaine),⁷⁹ propranolol, acetylcholine, methacholine, metformin, norephedrine, phenformin, choline, ephedrine.⁸⁰⁻⁸³

$n = 6$: R¹ = n-C₈H₁₇, R² = H (50% or 57%) + n-C₈H₁₇ (50% or 43%);
 $n = 7$: R¹ = n-C₁₂H₂₅, R² = H;
 R¹ = n-C₈H₁₇, R² = H (48%) + n-C₈H₁₇ (52%).

α -, β -, γ -Cyclodextrins differ from one another in the number of glucopyranose residues in the molecule and, correspondingly, in the diameter of the inner cavity.¹⁵²

The presence of an inner cavity makes it possible for cyclodextrin molecules to form inclusion compounds with both inorganic and organic molecules and ions.

Cyclodextrin derivatives that exhibit enantiomeric selectivity can be used in ISE for the determination of organic compounds.⁸¹ Thus ISE based on lipophilic 2,6-diethyl- α -cyclodextrin and 2,6-bisdodecyl- α -cyclodextrin allow the selective determination of the (-)-(1*R*,2*S*)-ephedrine cation in the presence of its three stereoisomers, even though the free energies of the formation of isomer complexes differed by merely 2.5 kJ mol⁻¹. The method of proton magnetic relaxation, which was used in the studies of diastereomeric complexes of ephedrine and its analogues with lipophilic cyclodextrins, has demonstrated the difference in the degree of hydrogen bond formation between the structural fragments NH⁺...O in the complex compounds.⁸⁴ As a result of stereo-differentiation in the formation of cyclodextrin complexes with ephedrine cations, a more stable complex of the corresponding stereoisomer was formed.⁸¹

A guanidinium ion and 2,6-bisdodecyl- β -cyclodextrin form a 1:1 complex, and the ISE on its basis exhibited approximately equal sensitivity with respect to organic cations with the structures close to that of guanidine.⁸¹ The occasional independence of the ISE electrode response on the cyclodextrin structure (α -, β -, OH- and alkylcyclodextrins) was associated with the formation of a primary hydrogen bond between the positively charged nitrogen atom and the oxygen atom of the cyclodextrin molecule.⁸⁰

Certain cyclodextrin derivatives can form supramolecular polymers, intramolecular inclusion complexes and more intricate supramolecular systems, which extends the possibilities of their practical application as specific receptors.¹⁵³

Complexes of aluminium, tin(IV) and copper(II) with tetra(*tert*-butyl)phthalocyanine and oxo(phthalocyaninato)-vanadium(IV) and -molybdenum(IV) were used as ionophores in liquid⁸⁵⁻⁸⁹ and solid-contact⁹⁰ membranes of salicylate-selective electrodes. Metallocenes [bis(cyclopentadienyl) Co(II), Fe(II), Ni(II), Hf(IV), Nb(V), Ti(IV) and Zr(IV)], tribenzyltin(IV), phenolates and carboxylates, phenylboronic acid derivatives, heptyl 4-(trifluoroacetyl)benzoate, complexes of Al(III) and Sn(IV) with *N,N'*-bis(salicylidene)-*o*-phenylenediamine, complexes of Schiff base **9**, guanidine derivatives **10** and tetra-azo[14]annulene copper(II) also proved to be suitable

M = Co(III), Mn(III)

$n = 2$, X = ClO₄; $n = 3$, X = BF₄

ionophores for the ISE selective with respect to salicylate anions (Sal^-).^{91–95}

Spectrophotometry,^{63, 88, 89, 96} IR spectroscopy⁶³ and the electrochemical impedance method⁹⁷ were used for the elucidation of the mechanism of the potentiometric response of ISE to salicylate anions. Spectral methods provided information on the mechanism of complex formation, while the electrochemical impedance method afforded data on the kinetic characteristics and limiting stages of the transfer processes.

Based on experimental data, it was shown that the reaction of tetra(*tert*-butyl)phthalocyaninato(iodo)cobalt(III) with salicylate anions proceeds *via* the substitution of a salicylate ion for the axial iodide ion. This was not the case for tetra(*tert*-butyl)phthalocyaninato(chloro)rhodium(III) due to the very strong Rh–Cl bond and the hindered coordination through the free sixth axial position on the metal, because the radius of the Rh(III) ion substantially exceeds the size of the phthalocyanine cavity so that the metal ion ‘leaves’ the plane in the direction of the axial chloride ion. An ion-selective electrode based on tetra(*tert*-butyl)phthalocyaninato(chloro)rhodium(III) does not respond to salicylate anions, whereas an ISE based on tetra(*tert*-butyl)phthalocyaninato(iodo)cobalt(III) demonstrates an electrode function with a slope S of $50 \pm 2 \text{ mV (pC)}^{-1}$ and a detection limit of $6.3 \times 10^{-5} \text{ mol litre}^{-1}$ of Sal^- (Ref. 88).

An ion-selective electrode based on complex **11** formed by dibenzyltin with a Schiff base produced a super-Nernstian response [$S = 65.5 \pm 1.8 \text{ mV (pC)}^{-1}$] to salicylate anions in the range of $1.0 \times 10^{-1} - 4.0 \times 10^{-6} \text{ mol litre}^{-1}$ of Sal^- (Ref. 97).

11

The appearance of the super-Nernstian response was associated with the ability of the ionophore to form dimers and more complex aggregates in the organic phase of the membrane, while the increase in the electrode function slope is the consequence of the changes in the stoichiometry of the ionophore reaction with the salicylate anion (2 : 1 in place of 1 : 1). Based on the analysis of electron absorption spectra of ionophore solutions in chloroform measured before and after their contact with the NaSal solution, the potentiometric selectivity of a membrane with respect to Sal^- was associated with the thermodynamically preferential coordination of the Sal^- anion at the central metal atom of the ionophore. The results of impedance measurements made it possible to assume the diffusion-controlled transfer of salicylate anions.⁹⁷

The mechanism of the potentiometric response of an ISE with a membrane based on μ -oxobis[5-(*p*-hydroxyphenyl)-10,15,20-triphenylporphyrinato]manganese(III) $\{[\text{Mn(5-HP).TPP}]_2\text{O}\}$ was studied by IR and UV spectroscopic techniques.⁶³ The selectivity of the ISE electrode with respect to Sal^- was associated with the formation of charged carriers in the membrane as a result of the following reaction:

Acyclic polyether antibiotics lasalocid (**12**) and omomycin (**13**) were shown to exhibit enantiometric selectivity with respect to optical isomers of methyl esters of amino acids.⁹⁸

12

13

The electrode function of ISE in solutions of L-isomers had a slope close to theoretical. The coefficient of enantiometric selectivity for L- and D-isomers of methyl phenylalaninate was 2.38 for lasalocid-based membranes and 1.85 for membranes containing omomycin. According to the transport tests, it was shown that lasalocid can transfer protonated cations of methyl phenylalaninate across the liquid membrane–solution interface according to the antiport principle at a rate close to that of the transfer of cations by other ionophore antibiotics.

Phenylboronic acid derivatives and complexes of hydroxamic acids with boric acid were used as ionophores for ISE membranes sensitive to protonated forms of catecholamines (adrenaline, dobutamine, dopamine, noradrenaline),^{95, 99} phenolic acids (gallic, homoprotocatechuic, caffeic and salicylic acids).^{94, 99} The electrode response of ISE membranes was associated with the trend of polyhydroxycompounds for the fast and reversible formation of covalent ester bonds with boric acid derivatives.^{94, 95, 99}

Of other ionophores, 2,3,5-triphenyl-2H-tetrazolium tungstophosphate was used in the ISE for ascorbic acid,¹⁰⁰ a complex of iron(II) with 2,4,6-tri(piperidino)-1,3,5-triazine was used in ISE for diclofenac sodium,¹⁰¹ O-(2,4-dichlorophenyl) O-ethyl S-propyl dithiophosphate was employed in ISE for histamine,¹⁰² heptyl 4-(trifluoroacetyl)benzoate was used as the ionophore in salicylate-ISE.¹⁰³

Studies were carried out devoted to the development and optimisation of characteristics of ISE for polyions (heparin and protamine).^{154–164} The equilibrium response of sensors to polyions of different structure was compared for ISE based on tri(dodecyl)methylammonium chloride and tetra(dodecyl)ammonium chloride. The deviations in the emf changes were used as the basis for stating a correlation between the energy of interaction of ionic pairs and the polyion charge. A threshold mass of polyion molecules was required for reaching the maximum emf value. The effect of lipophilic additions on the ISE response was studied. It was shown that the ISE may be used in the monitoring of the enzymatic hydrolysis of protazoline with tripsin.

A modernised ISE for protamine, which was based on its associate with dinonylnaphthalenesulfonate, was developed for the whole blood analysis.¹⁶³ The electrode operates by the mechanism of non-equilibrium response in the concentration range of $0.5 - 20 \text{ mg litre}^{-1}$ and can be used in both direct potentiometry and potentiometric titration of heparin with protamine. The results of ISE determinations agreed with the data of other (independent) analytical techniques. It was shown that the procedure of potentiometric titration of heparin using this ISE allows complete automation.

The development and optimisation of solid-contact ISE for heparin was discussed.¹⁶⁴ The temporal instability of the potential is the main drawback of solid-contact ISE. To

remove this drawback, silver(I) complexes with a lipophilic derivative of *tert*-butylcalix[4]arene **14** were incorporated into the membrane in addition to EAC [tri(dodecyl)methylammonium chloride].

This complex serves as the reversible electron carrier between the polymeric membrane and the current lead and favours the stabilisation of the potential of the solid-contact sensor.

IV. Components of ion-selective electrode membranes and methods of potentiometric determination of medicinal drugs

As was mentioned above, IA formed by MD cations and anions with the corresponding counter-ions are used most often as the EAC in selective membranes. Table 1 presents different EAC types, which are incorporated into the composition of ISE membranes both directly and in the form of ion associates with MD. Tetraphenylborate and its derivatives are used most extensively in EAC for cation-selective electrodes, while the cations of quaternary ammonium bases (QAB) are employed in EAC for anion-selective electrodes.

Nitrobenzene derivatives (in ISE with liquid membranes), nitrophenol ethers, esters of *o*-phthalic, adipic, sebacic, phosphonic and phosphoric acids are used most often as the solvents-plasticisers. Table 2 shows membrane solvents used in ion-selective membranes. *o*-Nitrophenyl octyl ether, dibutyl phthalate and dioctyl phthalate are the most common plasticisers of the polymeric binder, *i.e.*, polyvinyl chloride (PVC). Depending on the particular case, one or another membrane

Table 1. Electroactive compounds incorporated into the selective membrane either directly or as ion associates with medicinal drugs.

Class of compounds	Compound	Ref.
Tetraphenylborate derivatives	sodium tetraphenylborate	86, 87, 106, 165–219
	sodium tetrakis(4-methylphenyl)borate	37, 170
	potassium tetrakis(4-chlorophenyl)borate	37, 66, 68, 73, 74, 76, 80, 83, 86, 170, 171, 191, 192, 211, 220–226
	potassium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate	37, 67, 78–82, 192, 227, 228
	sodium tetrakis[3,5-bis(1,1,1,3,3,3-hexafluoro-2-methoxyisopropyl)phenyl]borate Na[B(C ₁₄ H ₉ O ₂ F ₁₂) ₄]	64, 67, 102, 229
Heteropoly compounds	molybdophosphoric acid H ₃ [PMo ₁₂ O ₄₀]	32, 34, 36, 165, 170, 172, 175, 184, 189, 198, 230–246

Nitroaromatic compounds	2,2',4,4',6,6'-hexanitrodiphenylamine (dipicrylamine)	271, 284–286
	2,4,6-trinitrophenol (picric acid)	34, 100, 204
	3-methyl-4-nitro-1- <i>p</i> -nitrophenylpyrazol-5-one (picrolonic acid)	100, 287, 288
Miscellaneous salts (anions) and acids	sodium dodecyl sulfate	285, 288, 289
	Reinecke salt anion [Cr(NH ₃) ₂ (NCS) ₄] [–]	32, 34, 197–199, 201, 210, 214–216, 225, 242, 253, 255, 261
	tetraiodobismuthate	32, 34, 183, 204
	tetraiodomercurate	32, 34, 197, 204, 290, 291
	tetraiodocadmate	292
	trioctyloxybenzenesulfonic acid	293
	hexathiocyanoferrate(III) anion	294
	tetrathiocyanocobaltate(II) anion	242
	5-nitropyrimidine-2,3,6-trione (5-nitrobarbituric acid)	295

Table 2. Solvents-plasticisers used in membranes of liquid and polymeric ion-selective electrodes.

Plasticiser type	Name of compound	Ref.
Plasticisers with high permittivity		
Nitro compounds	nitrobenzene	284
	2-nitrotoluene	100
	1-isopropyl-4-nitrobenzene	222, 274
	2-nitrophenyl octyl ether (NPOE)	35, 61–63, 67, 71, 73–75, 78–83, 85, 91–96, 103, 104, 171, 174, 180, 182, 189, 192, 197, 207, 208, 221–225, 227, 233, 234, 243, 261, 263, 266, 269–273, 279, 281–283, 296
	2-nitrophenyl dodecyl ether	227
	2-nitrophenyl phenyl ether	213, 222, 233
	2-nitrophenyl 2-fluorophenyl ether	67, 76, 192, 229
Plasticisers with low permittivity		
Esters of <i>o</i> -phthalic acid	dibutyl phthalate (DBP)	31, 32, 34, 36, 37, 61, 105, 169, 170, 177, 179, 182, 184–186, 188, 195–197, 204, 206, 228, 239, 240, 244, 254, 262, 275–277, 281, 293
	bis(2-ethylhexyl) phthalate	65, 90
	dioctyl phthalate (DOP)	32, 34, 36, 61, 62, 66, 67, 85, 172–174, 177, 186, 187, 190, 191, 193, 195–199, 201, 202, 204, 212, 214–216, 218, 230–232, 235, 238, 239, 243, 245, 246, 256–260, 266–268, 275, 276, 279, 281, 284, 290, 291, 294, 297
	diisooctyl phthalate	62
	bis(2-ethyloctyl) phthalate	96
	dinonyl phthalate (DNP)	58, 192, 278
	diisononyl phthalate (DiNP)	36, 202, 262
Esters of adipic acid	bis(2-ethylhexyl) adipate	91, 226
	bis(1-butylpentyl) adipate	80, 83, 86, 91
Esters of sebacic acid	diethyl sebacate (DES)	85, 94, 95
	dibutyl sebacate (DBS)	197, 214, 225, 266, 281
	bis(2-ethylhexyl) sebacate (EHS)	32, 61, 66, 68, 104, 182, 192, 205, 222, 225, 227, 273, 275, 276
	dioctyl sebacate (DOS)	36, 62, 74, 202, 224
	dinonyl sebacate	86
Esters of phosphoric and phosphonic acids	tributyl phosphate	85
	dioctyl phenyl phosphonate (DOPP)	51, 277
	tritoyl phosphate (mixture of isomers) (TTP)	36, 67, 202, 230, 239
	bis(2-ethylhexyl) phosphate	225
	tris(2-ethylhexyl) phosphate	67, 69, 192, 225
	trioctyl phosphate	226
Esters of miscellaneous acids and non-ester plasticisers	chlorobenzene	181
	n-octanol	292
	heptyl benzoate	32, 34, 275
	bis(1-butylpentyl)decan-1,10-diyl diglutarate	64
	tetrakis(2-ethylhexyl) pyromellitate	192

solvent may prove to be more suitable for the achievement of optimum electroanalytical characteristics of ISE for MD.

In the organic analysis, arrays of sensors (multisensor systems of the 'electronic tongue' type) are used. A multisensor system has been developed for the determination of lysine in foodstuffs.²⁹⁸ The array of sensors comprised an enzyme electrode based on lysine oxidase with NH_4^+ -ISE and a set of solid-contact ISE for H^+ , NH_4^+ , K^+ , Na^+ , Ca^{2+} , Mg^{2+} and Li^+ cations. The response of the enzyme electrode was associated with the enzymatic reaction

Insofar as the selectivity of the enzyme electrode with respect to other cations is low, the cross-selectivity-based potentiometric response of a multisensor system can be deter-

mined using the multiversion regression analysis. Among the methods for mathematical processing of potentiometric data, the least-squares technique with partial regression, which provides the smallest prediction errors, has shown the best results.²⁹⁸

An ISE-based method of precipitation potentiometric titration was also used for the determination of MD and drug preparations. Sodium tetraphenylborate commonly used as the titrant in the cationic MD determination proved to be suitable for determination of both individual MD^{266, 268, 291} and multicomponent MD mixtures.²⁹⁹

The method of precipitation potentiometric titration was also used in the flow analysis. In the determination of ephedrine by potentiometric titration, a flow-injection cell with a tubular indicator electrode containing tetrapentylammonium tetraphenylborate dissolved in *o*-nitrophenyl pentyl ether has been developed.²¹³ An ISE-containing individual channel in the cell was provided for the ephedrine determination. The

Fentanyl		PPVCM with IA of MD cations with [B{(C ₆ H ₃ (CF ₃) ₂ -3,5) ₄ }] [−]	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 6.29×10^{-6} , $S = 57.9$	228
Flurbiprofen		PPVCM with IA of MD anions with Aliquat 336S	LR $1.0 \times 10^{-2} - 7.0 \times 10^{-5}$	280
Ethylmorphine		SC-Sensor (Si/Si ₃ N ₄ substrate) with PPVCM based on IA of MD cations with BPh ₄ [−] and addition of K[B(C ₆ H ₄ Cl-4) ₄]	LR $1.0 \times 10^{-2} - 2.5 \times 10^{-5}$, DL = $1.0 \mu\text{g ml}^{-1}$, pH 2.5–6.5	211
Antiadrenergics and dopamine mimetics				
Propranolol		PPVCM (DiNP or DOP) with IA of MD cations with [SiW ₁₂ O ₄₀] ^{4−} , [PMo ₁₂ O ₄₀] ^{3−} or [SiMo ₁₂ O ₄₀] ^{4−} PPVCM (NPOE) with a lipophilic derivative of β-CD and addition of K[B(C ₆ H ₄ Cl-4) ₄]	LR $2 \times 10^{-2} - n \times 10^{-6}$, DL = $(1.0 - 10.0) \times 10^{-7}$, $S = 30.0 - 54.7$, pH 4.0–8.0 DL = 1.0×10^{-5} , $S = 60$	231, 262 83

Table 3 (continued).

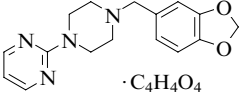

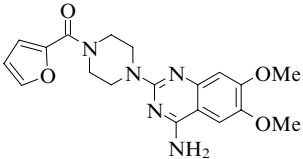

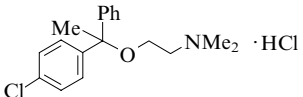

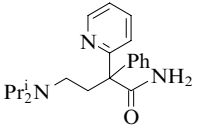

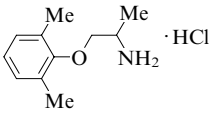

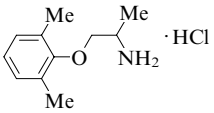

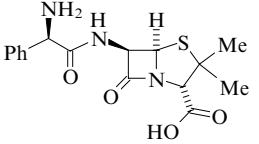

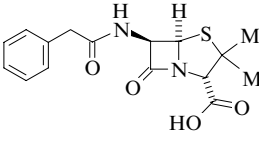

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Antiadrenergics and dopamine mimetics				
Piribedil		PPVCM (DBP and DOP) based on IA of MD cations with BPh_4^- , BiI_4^- or HgI_4^{2-}	LR $n \times 10^{-2} - n \times 10^{-6}$, $S = 30 - 57$, pH 3.0–6.4	186, 204
Prazosin		PPVCM based on IA of MD cations with $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $1.0 \times 10^{-2} - 2.7 \times 10^{-6}$, pH 1.5–6.4	248
Chlorphenoxamine		PPVCM containing a mixture of ionophores (18-crown-6, dibenzo-18-crown-6 or 37,38,39,40,41-pentakis[(diethoxythiophosphoryl)oxy]-5,11,17,23,29,35-hexakis(1,1-dimethylethyl)calix[6]arene-42-ol) with $\text{K}[\text{B}(\text{C}_6\text{H}_4\text{Cl}-4)_4]$	LR $5.0 \times 10^{-2} - 6.3 \times 10^{-6}$, DL = 5.9×10^{-6} , $S = 35 - 55$, pH 3–8	66
Antiarrhythmic drugs				
Disopyramide		PPVCM (2-nitro-2'-fluorodiphenyl ether) with $\text{Na}[\text{B}(\text{C}_{14}\text{H}_9\text{O}_2\text{F}_{12})_4]$	LR $1.0 \times 10^{-4} - 6.0 \times 10^{-6}$, DL = 8.0×10^{-7} , $S = 55 - 63$, pH 7.4 (buffer)	229
Mexitil		PPVCM with IA of MD cations with dodecyl sulfate	LR $n \times 10^{-2} - n \times 10^{-5}$, DL = 7.1×10^{-8} , pH 2.0–6.5	289
Mexitil		PPVCM based on 4',4''(5'')-di(<i>tert</i> -butyl)cyclohexano-18-crown-6 and $\text{Na}[\text{B}(\text{C}_{14}\text{H}_9\text{O}_2\text{F}_{12})_4]$	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 3.0×10^{-6} , $S = 54 - 59$, pH 7.4 (buffer)	67
Antibiotics				
Ampicillin		PPVCM (NPOE) containing tris{[2-(2-diphenylphosphonylmethyl)phenoxy]ethyl}amine PPVCM (DMP) based on IA of MD anions with $[(n\text{-C}_{10}\text{H}_{21})_4\text{N}]^+$	LR $10^{-3} - 10^{-4}$, DL = 3.1×10^{-5} , $S = 58 \pm 1$ LR $n \times 10^{-1} - n \times 10^{-6}$, DL up to 6.3×10^{-6} , $S = 58 - 62$, pH 5.0–9.2	71 31
Penicillin G		the same PPVCM (NPOE) containing $[\text{Bu}_3(n\text{-C}_{16}\text{H}_{33})\text{P}]\text{Br}$ or $[(n\text{-C}_8\text{H}_{17})_3\text{MeN}]\text{Cl}$ ISFT (Ta_2O_5 substrate) with immobilised enzyme penicillinase (β -lactamase) microsensor for FIA based on $\text{Si}-\text{SiO}_2-\text{Ta}_2\text{O}_5$ PM (NPOE) based on PVC and ethyl vinyl ether and containing manganese(III) 5,10,15,20-tetraphenylporphyrinate and lipophilic additives	the same LR $1.0 \times 10^{-1} - 2.5 \times 10^{-5}$, DL = 1.0×10^{-5} , $S = 49 - 57$, pH 4.5–8.0 LR $1.0 \times 10^{-3} - 5 \times 10^{-5}$, DL = 5.0×10^{-6} , $S = 120 \pm 10$ LR $5.0 \times 10^{-3} - 1 \times 10^{-4}$, $S = 135$ LR $1.0 \times 10^{-1} - 2.0 \times 10^{-5}$, $S = 59 - 61$	31 71 306 307 296

Table 3 (continued).

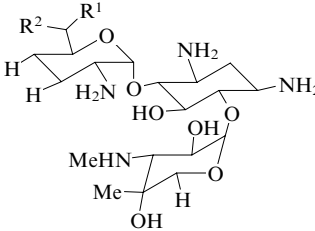

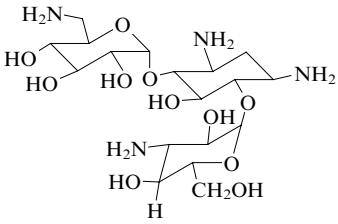

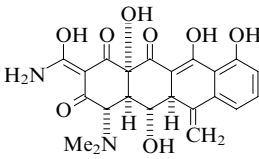

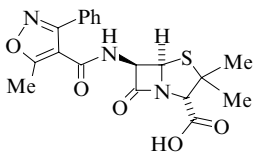

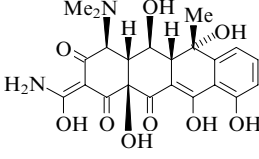

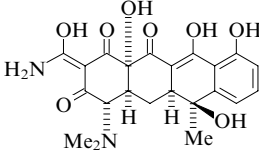

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Antibiotics				
Gentamycin	 <p> $R^1 = H, R^2 = NH_2$; $R^1 = Me; R^2 = NH_2, NHMe$ </p>	PPVCM (DBP) with IA of MD cations with BPh_4^-	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-6}$, DL = 1.0×10^{-6} , $S = 26 \pm 2$, pH 5.5–6.0	169, 188
Kanamycin		the same	the same	169, 188
Metacycline		PPVCM (DOP) with IA of MD cations and BPh_4^-	LR $3.0 \times 10^{-2} - 6.0 \times 10^{-6}$, DL = 3.4×10^{-6} , $S = 52.9$, pH 2.6	195
Oxacillin		PPVCM (NPOE) containing copper tetra(<i>tert</i> -butyl)phthalocyaninate or $[Bu_3^0(n-C_{16}H_{33})P]Br$ PPVCM(DBP) with IA of MD anions with $[(n-C_{10}H_{21})N]^+$	LR $1.0 \times 10^{-1} - 2.0 \times 10^{-5}$, DL = 8.0×10^{-6} , $S = 57 \pm 2$, pH 4.5–8.0 LR $1.0 \times 10^{-2} - 3.2 \times 10^{-6}$, DL = 3.1×10^{-6} , $S = 65 \pm 3$, pH 5.0–6.0	71 31
Oxytetracycline		SC-ISE with PPVCM (DBP) with IA of the cationic form of MD with BPh_4^- , $[PMo_{12}O_{40}]^{3-}$ or $[PW_{12}O_{40}]^{3-}$	LR $n \times 10^{-2} - n \times 10^{-7}$, $S = 59 - 62$, DL up to 1.0×10^{-7} , pH 4.0–11.0	184, 185
Tetracycline		PM (NPOE or EHS) based on a mixture of PVC and ethylene–vinyl acetate co-polymer with addition of $K[B(C_6H_4Cl-4)_4]$	LR $1.0 \times 10^{-2} - 1.2 \times 10^{-4}$, $S = 57.4$, pH 2.0–3.8	223

Table 3 (continued).

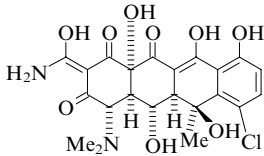

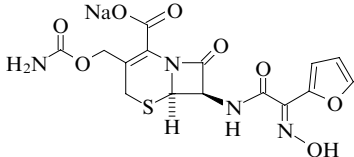

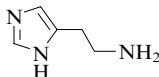

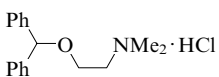

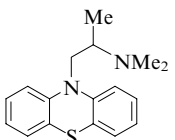

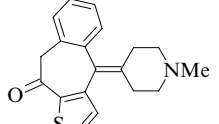

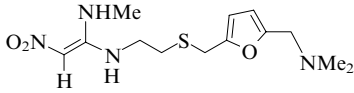

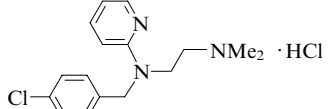

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Antibiotics				
Chlortetracycline		PPVCM based on IA of MD cations with $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ and $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-6}$, $S = 60 - 67$, pH 5.5–11.5	252
Cefuroxime		PPVCM (NPOE or EHS) (including those for FIA) with IA of MD anions with $[(n\text{-C}_8\text{H}_{17})_4\text{N}]^+$ and bis(triphenylphosphoranylidene)ammonium cations and addition of <i>p</i> -(<i>tert</i> -octyl)phenol	DL = 1.3×10^{-4} , $S = 50 - 55$, pH 3.5 ($\text{H}_3\text{PO}_4 - \text{NaH}_2\text{PO}_4$ buffer)	273
Antihistamine drugs				
Histamine		PPVCM with <i>O</i> -(2,4-dichlorophenyl) <i>O</i> -ethyl <i>S</i> -propyl dithiophosphate and $\text{Na}[\text{B}(\text{C}_{14}\text{H}_9\text{O}_2\text{F}_{12})_4]$ PPVCM (NPOE) with derivatives of calix[<i>n</i>]arenes ($n = 6, 8$) and $\text{K}[\text{B}(\text{C}_6\text{H}_4\text{Cl}_4)_4]$	LR $1.0 \times 10^{-2} - 5.0 \times 10^{-5}$, DL = 2.0×10^{-5} , $S = 56$ —	102 73
Diphenhydramine hydrochloride		PPVCM based on IA of MD cations with $[\text{PW}_{12}\text{O}_{40}]^{3-}$, BPh_4^- and $[\text{Cr}(\text{NH}_3)_2(\text{NCS})_4]^-$ SC-ISE with PPVCM (DOP) based on IA of MD with $\text{H}_3[\text{PMo}_{12}\text{O}_{40}]$ and $\text{H}_4[\text{SiW}_{12}\text{O}_{40}]$ and poly(α -naphthylamine) as the transducer	LR $n \times 10^{-2} - 3.5 \times 10^{-5}$, $S = 57.5$, pH 2.0–7.5 LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 3.0×10^{-6} , $S = 57.5$, pH 2–6	253 232
Promethazine		PPVCM (DOP) based on IA of MD cations with organic and inorganic anions PPVCM (NPOE or EHS) (including those for FIA) with IA of MD cations with BPh_4^-	LR $3.2 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 3.5×10^{-6} , $S = 41 - 55$, pH 2.5–6.0 LR $1.0 \times 10^{-2} - 5.0 \times 10^{-5}$, DL = 2.0×10^{-5} , pH 6.0 (phosphate buffer)	172 207
Ketotifen		PPVCM based of IA of MD cations with $[\text{B}\{\text{C}_6\text{H}_3(\text{CF}_3)_2-3,5\}_4]^-$	—	227
Ranitidine		Ag/AgCl SC-ISE with PPVCM (DNP) and IA of MD cations and BPh_4^-	LR $1.0 \times 10^{-1} - 5.0 \times 10^{-4}$, DL = 2.8×10^{-4} , $S = 59.7$, pH 8.2 (phosphate buffer)	192
Chloropyramine		PPVCM based on IA of MD cations with anions $[\text{B}(\text{C}_6\text{H}_4\text{Cl}_4)_4]^-$, $[\text{Cr}(\text{NH}_3)_2(\text{NCS})_4]^-$, $[\text{PW}_{12}\text{O}_{40}]^{3-}$, $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ and $[\text{SiMo}_{12}\text{O}_{40}]^{4-}$	LR $1.0 \times 10^{-2} - 2.3 \times 10^{-5}$, DL = 1.1×10^{-5} , $S = 48 - 55$, pH 2.6–5.5	225, 246

Table 3 (continued).

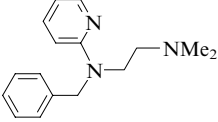

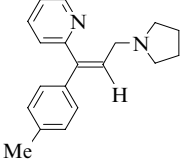

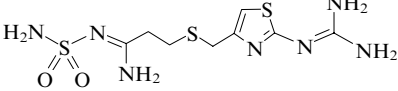

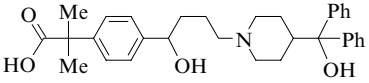

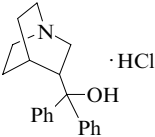

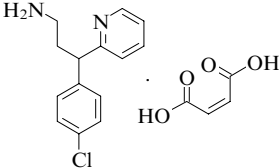

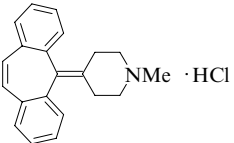

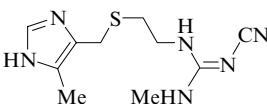

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Antihistamine drugs				
Tripelenamine		tubular and conventional ISE with PPVCM and IA of MD cations with BPh ₄ ⁻	LR $1.0 \times 10^{-1} - 4.0 \times 10^{-5}$	182
Triprolidine		membrane ISE, carbon-paste and graphite-supported electrodes; PPVCM (DBP) and IA of MD cations with BPh ₄ ⁻	LR $1.0 \times 10^{-2} - 2.0 \times 10^{-5}$, $S = 54 - 56$, pH 4.7–8.8	196
Famotidine		PPVCM based on IA of MD cations with BPh ₄ ⁻	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-5}$, pH 1.0–5.0	178
Fexofenadine		PPVCM, IA of MD cations with BPh ₄ ⁻ , HgI ₄ ²⁻ and [Cr(NH ₃) ₂ (NCS) ₄] ⁻	LR $1.0 \times 10^{-2} - 2.5 \times 10^{-6}$, DL = 1.3×10^{-6} , $S = 62$, pH 2.0–4.5	197
Quifenadine		PPVCM based on IA of MD cations with [PW ₁₂ O ₄₀] ³⁻ , [PMO ₁₂ O ₄₀] ³⁻ and [SiMO ₁₂ O ₄₀] ⁴⁻	LR $1.0 \times 10^{-2} - 5.4 \times 10^{-5}$, DL = 3.6×10^{-5} , $S = 43 - 50$, pH 2.8–5.0	219
Chlorpheniramine maleate		ion-selective piezoelectric sensors with PVC membranes based on IA of MD cations with dipicrylamine, BiI ₄ ⁻ and BPh ₄ ⁻ AgCl/Ag SC-ISE with membranes based on carbamide-formaldehyde resin with dispersed KCl and IA of MD cations with BPh ₄ ⁻	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-8}$, DL = 6.0×10^{-9} —	183 209
Cyproheptadine		PPVCM and IA of MD cations with [B(C ₆ H ₄ Cl-4) ₄] ⁻ and dipicrylamine anions	LR $n \times 10^{-2} - n \times 10^{-7}$, pH 2.5–7.0	222
Cimetidine		PPVCM based on IA of MD cations with [PW ₁₂ O ₄₀] ³⁻	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 5.0×10^{-6} , $S = 58$, pH 3.0–5.5	247

Table 3 (continued).

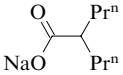

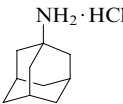

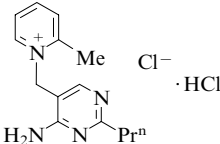

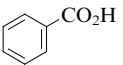

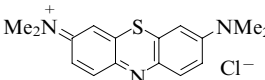

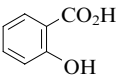

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Anticonvulsants				
Sodium valproate		PPVCM based on a Ga(III) complex with tetraphenylporphyrine and bis(1-butylpentyl)decane-1,10-diyl diglutarate (ETH 469)	LR $1.0 \times 10^{-2} - 5.0 \times 10^{-5}$, DL = 2.0×10^{-5} , $S = 55$, pH 5.5 (buffer)	64
Antiseptics and viricides				
Amantadine		PPVCM (DOP) based on IA of MD cations with BPh ₄ ⁻ and [Cr(NH ₃) ₂ (NCS) ₄] ⁻	—	173
Amprolium		PPVCM (DOP) based on IA of MD cations with BPh ₄ ⁻ and [Cr(NH ₃) ₂ (NCS) ₄] ⁻	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-5}$, pH 7.0–11.0	216
Benzoic acid		PPVCM with a macrocyclic polyamine and a lipophilic additive PPVCM based on heptyl 4-(trifluoroacetyl)benzoate	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-4}$, DL = 1.0×10^{-4} , pH 5.0 LR $5.0 \times 10^{-2} - 2.0 \times 10^{-4}$, DL = 1.0×10^{-4}	58 308
Methylene Blue		PM (DBP) with trioctyloxybenzenesulfonic acid as an ion exchanger	LR $1 \times 10^{-4} - 1.0 \times 10^{-6}$, DL = 6.2×10^{-7} , $S = 53.3 \pm 0.5$, pH 4.0–11.0	293
Salicylic acid		ISE based on complexes of Co(II) with bis(salicylaldehyde)diaminodipropylamine or Co(III) with Schiff bases as the carriers PPVCM based on IA of 3-(4-tolylazo)phenylboronic acid with tetrahexylethylenediamine PM based on Sn(IV) complexes with 8-hydroxyquinoline and tetra(<i>tert</i> -butyl)phthalocyanine PPVCM with μ -oxobis[5-(4-hydroxyphenyl)-10,15,20-triphenylporphyrinato]-manganese(III)] as the ionophore PPVCM with tribenzyltin phenolates or carboxylates as ionophores PPVCM (NPOE) with a guanidinium ionophore PPVCM with different metallocenes as ionophores PPVCM (dinonyl sebacate) with [2,9,16,23-tetra(<i>tert</i> -butyl)phthalocyaninato]tin(IV) and addition of KBPh ₄ PPVCM with heptyl 4-(trifluoroacetyl)benzoate as the ionophore and addition of tri(dodecyl)methylammonium chloride PPVCM (DBP) with a neutral carrier SCE (graphite substrate), PPVCM containing Al(III) and Sn(IV) complexes with Salophen as ionophores with addition of NaBPh ₄	LR $1.0 \times 10^{-1} - n \times 10^{-6}$, DL up to 8.0×10^{-7} , $S = 66.8$, pH 4.0 or 5.5 LR $1.0 \times 10^{-1} - 5.0 \times 10^{-5}$, DL = 1.5×10^{-5} , $S = 54 \pm 1$ — LR $1.0 \times 10^{-1} - 6.3 \times 10^{-7}$, $S = 57 \pm 3.5$, pH 6.0 (phosphate buffer) LR $1.0 \times 10^{-1} - n \times 10^{-6}$, DL up to 1.0×10^{-6} , $S = 57$, pH = 5.5 (phosphate buffer) LR $1.0 \times 10^{-1} - 1.0 \times 10^{-3}$, DL = 1.3×10^{-4} , pH 6.0 LR $1.0 \times 10^{-1} - 1.0 \times 10^{-3}$, $S = 58$, pH 5.5; 7.4 LR $1.0 \times 10^{-1} - 1.0 \times 10^{-5}$, DL = 6.3×10^{-6} , pH 5.5 LR $1.0 \times 10^{-2} - 2.0 \times 10^{-4}$, DL = 4.0×10^{-5} , $S = 55$, pH 7.4 LR $1.0 \times 10^{-1} - 2.5 \times 10^{-6}$, DL = 1.0×10^{-6} , $S = 57 \pm 2$, pH 5.0 LR $1.0 \times 10^{-1} - 1.0 \times 10^{-6}$, DL $\sim 1.0 \times 10^{-6}$, $S = 57 - 59$, pH 3.0–8.0	96, 309 94 85 63 92, 93 104 91 86 103 105 106

Table 3 (continued).

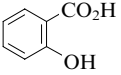

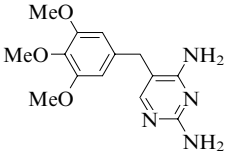

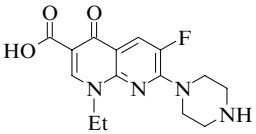

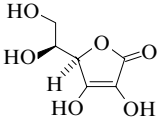

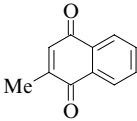

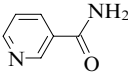

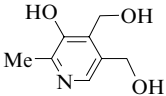

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Antiseptics and viricides				
Salicylic acid		PPVCM with chloro(tetraphenylporphyrinato)chromium(III) PPVCM with oxo(phthalocyaninato)vanadium(IV) and -molybdenum(IV) as ionophores SCE (graphite substrate), PPVCM with aluminium phthalocyaninate	LR $n \times 10^{-1} - n \times 10^{-6}$, pH 3.0–9.0 LR $n \times 10^{-1} - n \times 10^{-7}$, pH 6.0–9.0 LR $1.0 \times 10^{-1} - 5.0 \times 10^{-6}$, $S = 59 \pm 1$	65 87 90
Trimethoprim		PPVCM with IA of MD cations with $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ ion-selective piezoelectric sensor with PPVCM (DBP) based on IA of MD cations with $[\text{PW}_{12}\text{O}_{40}]^{3-}$ PPVCM (DOP) with IA of MD cations with BPh_4^- , $[\text{Cr}(\text{NH}_3)_2(\text{NCS})_4]^-$ or $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $1.0 \times 10^{-2} - 2.3 \times 10^{-6}$, $S = 56.5$, pH 1.6–6.2 LR $2.0 \times 10^{-3} - 2.0 \times 10^{-8}$, DL = 2.0×10^{-8} , pH 4.0 LR $1.0 \times 10^{-2} - n \times 10^{-6}$, DL = $n \times 10^{-6}$, $S = 57 - 59$, pH 1.8–6.3	237 254 201, 256
Cetylpyridinium chloride		PPVCM (DOP) with IA of cetylpyridinium with iron(III) thiocyanate PPVCM (DOP) with IA of MD cations with HgI_4^{2-}	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-6}$, DL = 8.0×10^{-7} , $S = 57.5 \pm 0.4$, pH 1.0–6.0 LR $1.0 \times 10^{-3} - 2.0 \times 10^{-6}$, DL = 4.0×10^{-7} , $S = 29.0 \pm 0.4$, pH 3.0–6.0	294 291
Enoxacin		PPVCM with IA of MD cations with BPh_4^- and an internal pin Ag/AgCl reference electrode	LR $1.0 \times 10^{-2} - 7.9 \times 10^{-5}$, DL = 2.0×10^{-5} , $S = 30.4$	176
Vitamins and their analogues				
Ascorbic acid		SC-ISE based on a PVC matrix modified with ionophores. A polymeric ISFT film based on MnO_2 nanoparticles immobilised on the transducer surface is fixed between the electrode and the PVC membrane ISE with liquid membrane based on 2-nitrotoluene with dissolved IA of triphenyltetrazolium with $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $5.0 \times 10^{-3} - 5.0 \times 10^{-6}$, DL = 2.0×10^{-6} LR $1.3 \times 10^{-3} - 2.0 \times 10^{-5}$, DL = 1.0×10^{-5} LR $1.0 \times 10^{-2} - 2.0 \times 10^{-4}$, $S = 56 - 58$, pH 3.0–12.0	310 167 100
Menadione		PPVCM (NPOE) with IA of MD anions with complex cations of nickel(II) or iron(II) with batophenanthroline	LR $1.0 \times 10^{-1} - n \times 10^{-5}$, DL = 2.0×10^{-5} , $S = 51 - 58$, pH 1.0–5.0	270
Nicotinamide		ion-selective piezoelectric sensor with PVC membrane based on IA of MD cations with $[\text{SiW}_{12}\text{O}_{40}]^{4-}$	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-9}$, pH 7.0	264
Pyridoxine		PPVCM (NPOE) with IA of MD cations with $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ or $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $1.0 \times 10^{-2} - 6.0 \times 10^{-5}$, DL = 4.0×10^{-5} , $S = 54$, pH 2–4	233, 234

Table 3 (continued).

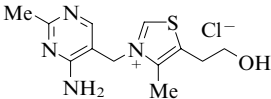

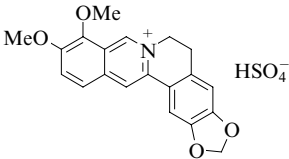

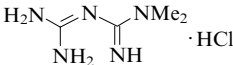

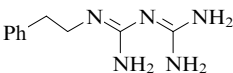

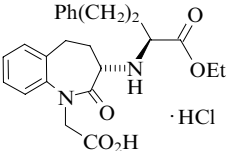

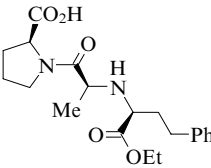

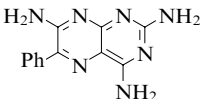

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Vitamins and their analogues				
Thiamine chloride		electrode represents a graphite disk covered with successive layers of conductive epoxy resin and ionophore-containing PVC membrane	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-6}$	311
Choline chloride	$\text{Me}_3\text{N}^+\text{CH}_2\text{CH}_2\text{OH} \text{ Cl}^-$	PPVCM (NPOE) with lipophilic β -CD derivatives and addition of $\text{Na}[\text{B}\{\text{C}_6\text{H}_3(\text{CF}_3)_2\text{-3,5}\}_4]$	DL up to 4.0×10^{-7} , $S = 61$, pH 7.0	80–82
Hepatotropic drugs				
Berberine bisulfate		PPVCM (different esters) based on porphyrins	LR $5.0 \times 10^{-3} - n \times 10^{-7}$, $S = 60 - 66$, pH 3.7–11.2	61, 62
Hypoglycemic drugs				
Metformin		PPVCM with IA of MD cations with $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ or $[\text{PW}_{12}\text{O}_{40}]^{3-}$ PPVCM (DOP, NPOE or DBS) with IA of MD cations with $[\text{Cr}(\text{NH}_3)_2(\text{NCS})_4]^-$ and $[\text{SiW}_{12}\text{O}_{40}]^{4-}$ PPVCM (NPOE) with lipophilic β -CD derivative and addition of $\text{Na}[\text{B}\{\text{C}_6\text{H}_3(\text{CF}_3)_2\text{-3,5}\}_4]$	LR $1.0 \times 10^{-2} - n \times 10^{-5}$, $S = 58$, pH 3.0–11.0 LR $n \times 10^{-1} - n \times 10^{-5}$, pH 5.0–11.0 DL = $n \times 10^{-6}$, $S = 56 - 61$	236, 251 266 80, 81
Phenformin		the same	the same	80, 81
Hypotensive drugs				
Benazepril hydrochloride (Amlodipine)		'coated wire' electrode with PVC membrane based on benazepril– BPh_4^- associate	LR $5.8 \times 10^{-3} - 1.3 \times 10^{-5}$, pH 2.5–9.2	217
Sodium nitroprusside	$\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}]$	PPVCM with IA of MD anions with cetylpyridinium	LR $1.0 \times 10^{-2} - 3.0 \times 10^{-5}$, DL = 2.0×10^{-5} , $S = 27 \pm 1$, pH 2.0–10.0	281
Enalapril		ISE based on graphite paste (a mixture of graphite powder with kerosene) impregnated with a solution of 2-hydroxy-3-trimethylammonioethyl- β -CD chloride	LR $6.4 \times 10^{-2} - 3.6 \times 10^{-5}$, DL = 1.0×10^{-5} , $S = 55 \pm 0.3$, pH 3.0–6.0	77
Diuretics				
Triamterene		'coated wire' electrode with PVC membrane and IA of MD cations with BPh_4^-	LR $3.5 \times 10^{-2} - 1.0 \times 10^{-6}$, pH 4.5–7.5	179

Table 3 (continued).

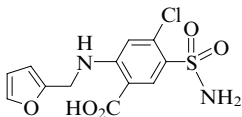

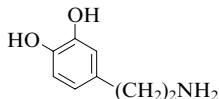

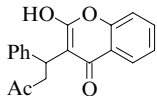

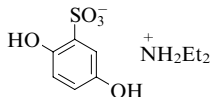

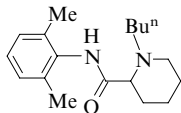

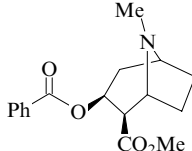

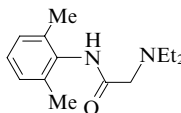

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Diuretics				
Furosemide		PPVCM (DBP or DOPP) with IA of MD anions with trioctylmethylammonium	LR $1.0 \times 10^{-2} - 1.6 \times 10^{-4}$, DL = 1.2×10^{-4} , $S = 58.9$, pH 7–10	277
Dopaminergic drugs				
Dopamine		Graphite-based SC-sensor with a membrane of carboxylated PVC with addition of β -CD, $K[B(C_6H_4Cl-4)_4]$ and 2-nitro-2'-fluorodiphenyl ether electrode for FIA, PPVCM (NPOE) with bis(triphenylphosphoranylidene)-ammonium periodate	LR $1.0 \times 10^{-1} - 5.0 \times 10^{-5}$, DL = 3.0×10^{-6} , $S = 59$, pH 2.0–7.5	76
		PPVCM (NPOE) with devivatives of calix[n]arenes ($n = 6, 8$) and addition of $K[B(C_6H_4Cl-4)_4]$	LR $2.7 \times 10^{-1} - 8.0 \times 10^{-3}$ g litre ⁻¹ , $S = 310.1 \pm 7.4$	283
			—	73
Coagulants and anticoagulants				
Warfarin		PPVCM with IA of MD anions and complex cations of Ni(II) and Fe(II) with phenanthroline	LR $n \times 10^{-1} - n \times 10^{-5}$, DL = 0.8–5.3 $\mu\text{g ml}^{-1}$, $S = 51 - 60$	268, 271
Etamsylate (Dicinone)		the same	the same	268, 271
Local anesthetics				
Bupivacaine		PVC or polyurethane membranes (NPOE) with lipophilic derivatives of β -CD and addition of $Na[B\{C_6H_3(CF_3)_2-3,5\}_4]$	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-4}$, DL = 1.3×10^{-5} , $S = 54 - 62$, pH 6.84	79
Cocaine		PPVCM [tetrakis(2-ethylhexyl) pyromellitate] with IA of MD cations with $[B\{C_6H_3(CF_3)_2-3,5\}_4]^-$	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-6}$, DL = 4.0×10^{-7} , $S = 56$, pH 1.0–8.0	192
Lidocaine		PPVCM (NPOE or DOS) modified with 2,6-disdodecyl- β -CD and $K[B(C_6H_4Cl-4)_4]$ (for FIA)	LR $1.0 \times 10^{-1} - n \times 10^{-5}$, DL = 1.6×10^{-5} , $S = 55$	224
		PVC or polyurethane membranes (NPOE) with lipophilic derivatives of β -CD and addition of $Na[B\{C_6H_3(CF_3)_2-3,5\}_4]$	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-3}$, DL up to 1.5×10^{-4} , $S = 61 - 67$, pH 6.84	79
		PPVCM based in IA of MD cations with $[Co(SCN)_4]^{2-}$, $[PMo_{12}O_{40}]^{3-}$ and $[Cr(NH_3)_2(NCS)_4]^-$	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-5}$, pH 3.0–7.0	242

Table 3 (continued).

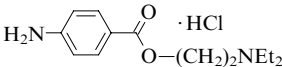

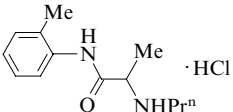

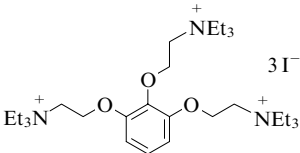

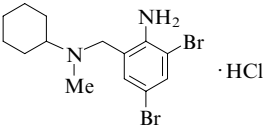

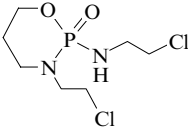

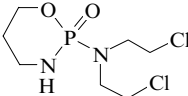

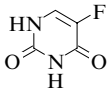

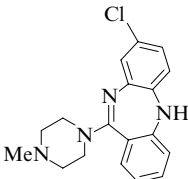

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Local anesthetics				
Procaine		piezoelectric sensor with selective PVC membrane based on IA of MD cations with BPh ₄ ⁻ PPVCM (NPOE) with lipophilic derivatives of β-CD and addition of Na[B{C ₆ H ₃ (CF ₃) ₂ -3,5 ₂ }] ₄	LR 5.0×10^{-3} – 8.3×10^{-8} , DL = 8.3×10^{-8} , pH 5.0 DL up to 1.0×10^{-5} , <i>S</i> = 61, pH 6.84	203 79
Prilocaine		the same	the same	79
Muscle relaxants				
Gallamine		carbon-paste electrode impregnated with IA gallamine–BPh ₄ ⁻	LR 1.0×10^{-3} – 2.0×10^{-6} , DL = 1.0×10^{-6} , <i>S</i> = 17.0 ± 0.7 , pH 5.0–8.0	219
Mucolytic drugs				
Bromhexine		PPVCM (DOP) with IA of MD cations with BPh ₄ ⁻	LR 1.0×10^{-1} – 4.0×10^{-4} , <i>S</i> = 57.5	218
Antitumour drugs				
Iphosphamide		PPVCM (DOP) or a membrane based on carboxylated PVC (NPOE) with IA of MD cations with BPh ₄ ⁻	LR $n \times 10^{-2}$ – $n \times 10^{-5}$, <i>S</i> = 50–55, pH 4–7	174
Cyclophosphan		the same	the same	174
Fluorouracil		PPVCM (DOP) based on IA of 5-fluorouracil with Ni(II) and Fe(II) complexes with batophenanthroline and Fe(II) complexes with phenanthroline	LR 1.0×10^{-3} – 1.0×10^{-5} , DL = 1.0×10^{-5} , <i>S</i> = 28–34, pH 5–9	267
Psychotropic drugs				
Azaleptine		PPVCM (DOP or TTP) with IA of azaleptine cations with BPh ₄ ⁻ or [PMO ₁₂ O ₄₀] ³⁻	LR 1.0×10^{-2} – 1.0×10^{-5} , DL = 2.8×10^{-6} , <i>S</i> = 45–54, pH 4.0–7.0	230

Table 3 (continued).

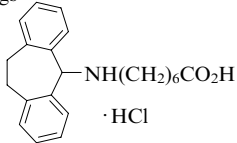

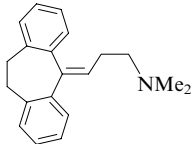

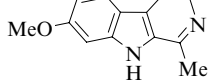

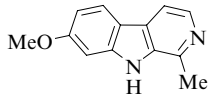

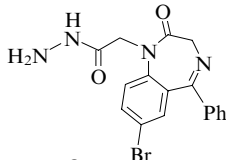

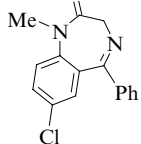

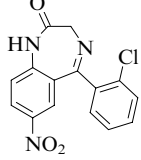

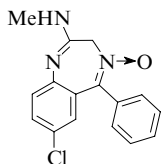

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Psychotropic drugs				
Amineptine		PPVCM (DOP or TTP) with IA of azaleptine cations with BPh ₄ [−] or [PMo ₁₂ O ₄₀] ^{3−}	LR $1.0 \times 10^{-2} - 3.2 \times 10^{-6}$, $S = 54 - 58$, pH 2.0–3.9	165
Amitriptyline		PPVCM with IA clonidine–BPh ₄ [−] against 10 ^{−3} M solution of NaCl and 10 ^{−3} M solution of clonidine	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-8}$, DL = 5×10^{-9} , $S = 58.4$	166
Garmaline		sensors for FIA with PPVCM based on IA of MD cations with BPh ₄ [−] and [Cr(NH ₃) ₂ (NCS) ₄] [−]	LR 10 ^{−2} –10 ^{−6} , DL up to 2 μg ml ^{−1} , pH 3.0–8.0	210
Garmin		the same	the same	210
Hydazepam		PPVCM (DBP) with IA of MD cations with heteropolyanions and [C ₆ H ₄ Cl-4) ₄] [−] and addition of a lipophilic compound	LR $n \times 10^{-3} - n \times 10^{-5}$, DL up to 4.8×10^{-6} , $S = 50 - 57$, pH 2.5–5.3	170
Diazepam (Relanium)		the same PPVCM (NPOE) based on IA of MD cations with BPh ₄ [−] and [PW ₁₂ O ₄₀] ^{3−}	the same LR 31.57–0.29 mg ml ^{−1} , DL up to 0.7 mg ml ^{−1} , $S = 50 - 65$, pH 4.0–7.0	170 171, 208
Clonazepam		the same PPVCM (DBP) with IA of MD cations with hereropolyanions and [C ₆ H ₄ Cl-4) ₄] [−] and addition of a lipophilic compound	the same LR $n \times 10^{-3} - n \times 10^{-6}$, DL up to 6.6×10^{-7} , $S = 48 - 60$, pH 2.5–5.3	171, 208 170
Chlordiazepoxide (Elenium)		the same SC-ISE (DOP) with ion-selective transducer [poly(<i>o</i> -aminophenol)] and IA of MD cations with [PW ₁₂ O ₄₀] ^{3−} SC-ISE (DBP) with IA of MD cations with [PMo ₁₂ O ₄₀] ^{3−} and [PW ₁₂ O ₄₀] ^{3−}	the same DL = 6.7×10^{-6} , $S = 55.6$, pH 2.4–6.3 LR $1.0 \times 10^{-2} - 3.2 \times 10^{-6}$, $S = 59 - 61$, pH 2.0–4.5	170 259 244

Table 3 (continued).

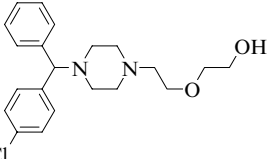

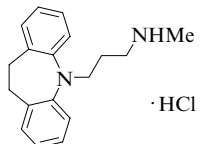

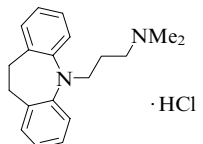

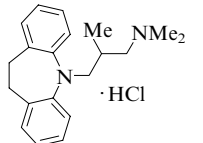

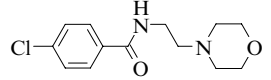

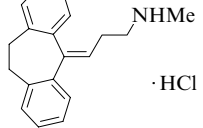

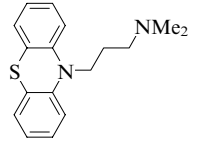

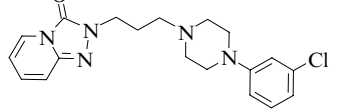

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Psychotropic drugs				
Hydroxyzine		PPVCM (NPOE) with IA of MD cations with $[\text{SiW}_{12}\text{O}_{40}]^{4-}$	LR $1.0 \times 10^{-2} - 6.0 \times 10^{-7}$, DL = 2.5×10^{-7} , $S = 57$, pH 2.8–6.9	263
Desipramine	 ·HCl	PPVCM (NPOE) with alkylated CD and addition of $\text{Na}[\text{B}\{\text{C}_6\text{H}_3(\text{CF}_3)_2-3,5\}_4]$	DL up to 2.5×10^{-6} , $S = 56 - 62$, pH 7.0	78
Imipramine	 ·HCl	the same	the same	78
Trimipramine	 ·HCl	the same	the same	78
Moclobemide		PPVCM with IA of MD cations with dodecyl sulfate	LR $10^{-2} - 10^{-5}$, DL = 1.1×10^{-10} , pH 2.0–6.5	289
Nortriptyline	 ·HCl	PPVCM (DOP) with IA of MD cations with BPh_4^- and $[\text{B}(\text{C}_6\text{H}_4\text{Cl}-4)_4]^-$	LR $n \times 10^{-2} - n \times 10^{-5}$, DL = $(8.0 - 9.0) \times 10^{-5}$, $S = 52 - 54$, pH 6.0–7.0	191
Promazine		ISE with liquid membrane based on IA of MD cations with CdI_4^{2-} in n-octanol PPVCM (EHS) with IA of MD cations with BPh_4^-	LR $1.0 \times 10^{-3} - 5.0 \times 10^{-6}$, $S = 61$, pH 4.0–7.0 LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 1.0×10^{-5} , $S = 58.0 \pm 1.5$, pH 2.0–6.0	292 205
Trazodone		'coated wire' electrode (Cu) based on PPVCM (DOP) with IA trazodone– BPh_4^-	LR $8.9 \times 10^{-3} - 1.4 \times 10^{-5}$, DL = 1.0×10^{-5} , $S = 59$, pH 2.4–9.0	193

Table 3 (continued).

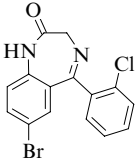

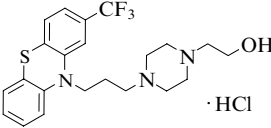

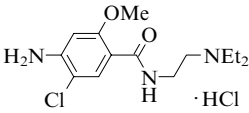

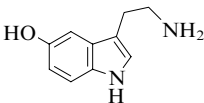

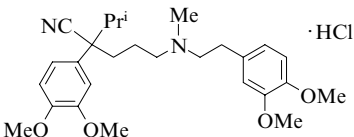

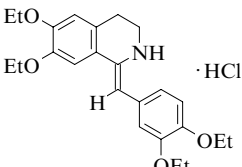

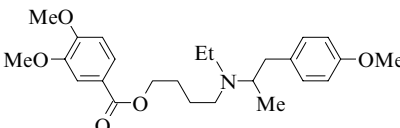

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Psychotropic drugs				
Phenazepam		PPVCM (DBP or DOP) with IA of MD cations with $[\text{PMo}_{12}\text{O}_{40}]^{3-}$, $[\text{PW}_{12}\text{O}_{40}]^{3-}$ and $[\text{SiMo}_{12}\text{O}_{40}]^{4-}$	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, $S = 43 - 54$, pH 1.0–3.0	239
Fluphenazine		PPVCM (DOP) with IA of MD cations with BPh_4^- and addition of $\text{K}[\text{B}(\text{C}_6\text{H}_4\text{Cl}-4)_4]$	LR $n \times 10^{-3} - n \times 10^{-5}$, $\text{DL} = (4.5 - 5.5) \times 10^{-5}$, $S = 59$, pH 6–7	191
Antiemetic drugs				
Metoclopramide		PPVCM (DOP) based on IA of MD cations with HgI_4^{2-} or $[\text{PW}_{12}\text{O}_{40}]^{3-}$	LR $1 \times 10^{-2} - 6.0 \times 10^{-5}$, $\text{DL} = 4.0 \times 10^{-5}$, $S = 53 \pm 0.5$, pH 3.0–7.0	258, 290
Serotonergic drugs				
Serotonin		PPVCM (NPOE) with derivatives of calix[n]arenes ($n = 6, 8$) and addition of $\text{K}[\text{B}(\text{C}_6\text{H}_4\text{Cl}-4)_4]$	—	73
Spasmolytics				
Verapamil		microsensor based carboxylated PVC and Nafion on a graphite substrate	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, $\text{DL} = 4.1 \times 10^{-6}$, $S = 56 - 57$, pH 2.0–8.0	297
Drotaverine (No Spa)				
Drotaverine (No Spa)		PPVCM based on IA of MD cations with derivatives of tetraphenylborate and organic and inorganic anions	LR $5.0 \times 10^{-2} - n \times 10^{-7}$, DL up to 1×10^{-7} , $S = 51 - 61$, pH 1.8–7.0	32, 37
		carbon-paste electrode for FIA with PPVCM (esters of phthalic acid and TTP) containing IA of MD cations with $[\text{SiW}_{12}\text{O}_{40}]^{4-}$ and BPh_4^-	LR $1.0 \times 10^{-2} - 5.0 \times 10^{-7}$, $\text{DL} = 5.0 \times 10^{-7}$, $S = 59 \pm 2$, pH 2.5–7.0	202
Mebeverine		SC-ISE (for FIA) and ISE with PM (DBP) based on IA of MD cations with heteropolyanions	LR $1.0 \times 10^{-2} - 4.0 \times 10^{-6}$, $\text{DL} = 3.1 \times 10^{-6}$, $S = 55 - 59$, pH 1.0–7.2	36

Table 3 (continued).

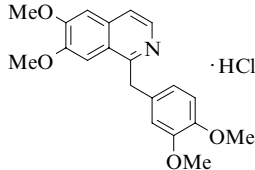

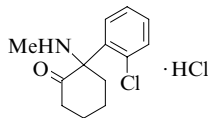

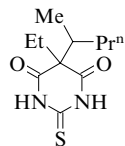

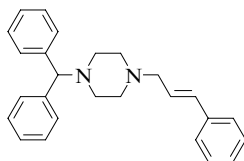

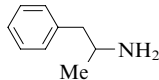

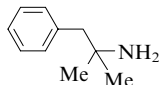

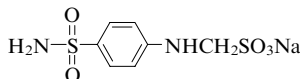

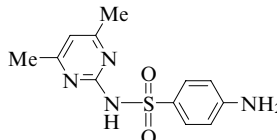

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Spasmolytics				
Papaverine		ISE with liquid membrane (chlorobenzene) based on IA of MD cations with BPh ₄ [−] PPVCM based on IA of MD cations with organic and inorganic anions	LR $5.0 \times 10^{-2} - 1.0 \times 10^{-5}$, $S = 62.6$, pH 3.5–5.5 LR $5.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 3.7×10^{-6} , $S = 42 - 56$, pH 2.0–6.0	181 34
Anaesthetics				
Ketamine hydrochloride		membrane with active ion-exchange sites synthesised by polymerisation directly in the plasticiser medium (NPOE)	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 1.0×10^{-6} , $S = 59$, pH 4.0–8.5	35
Thiopental		graphite SC sensor with polyurethane membrane based on IA of thiopental with complexes of Co(II) and Cu(II) with batophenanthroline	LR $1.0 \times 10^{-1} - 5.0 \times 10^{-5}$, DL = 5.0×10^{-6} , $S = 28$, pH 6–11	269
Drugs for improving blood circulation of internal organs and tissues				
Cinnarizine		PPVCM (DOP) with IA of MD cations with BPh ₄ [−] , flavianate, [Cr(NH ₃) ₂ (NCS) ₄] [−] and [PMo ₁₂ O ₄₀] ^{3−}	LR $n \times 10^{-2} - n \times 10^{-6}$, DL = $(1.1 - 8.1) \times 10^{-6}$, $S = 27.1 - 38.2$, pH 2.0–3.3	198
Stimulators of central nervous system				
Amphetamine		PPVCM (EHS) based on neutral carriers	LR $1.0 \times 10^{-2} - 2.0 \times 10^{-6}$, DL = 7.0×10^{-7} , $S = 53 - 55$, pH 5.0	68
		PPVCM with an <i>N,N</i> -dioctadecyl- <i>N',N'</i> -dipropyl-3,6-dioxaoctanediamide ionophore and addition of Na[B(C ₁₄ H ₉ O ₂ F ₁₂) ₄]	LR $1.0 \times 10^{-2} - 2.0 \times 10^{-6}$, DL = 1.0×10^{-6} , $S = 59$, pH 5.0	69
Phentermine		PPVCM (EHS) based on dibenzo-18-crown-6 and other ionophores with addition of K[B(C ₆ H ₄ Cl-4) ₄]	LR $1.0 \times 10^{-2} - 2.0 \times 10^{-6}$, DL = 7.0×10^{-7} , $S = 53 - 55$, pH 5.0 (acetic acid – magnesium acetate buffer)	68
Sulfonamides				
Streptocidum soluble		PPVCM with IA of MD anions with different QAB cations	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-5}$, DL up to 7.4×10^{-6} , $S = 42 - 57$, pH 7.0–11.0	29, 275, 276
Sulfamethazine		the same	the same	29, 275, 276

Table 3 (continued).

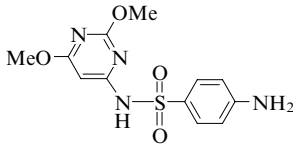

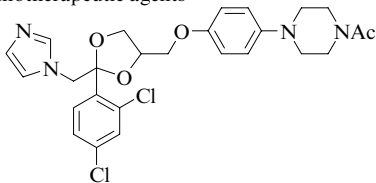

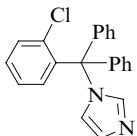

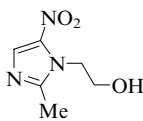

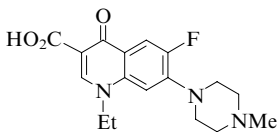

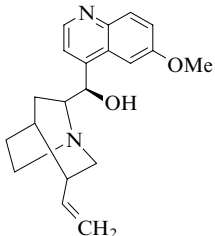

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Sulfonamides				
Sulfadimethoxine		PPVCM with IA of MD cations with different QAB cations	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-5}$, DL up to 7.4×10^{-6} , $S = 42 - 57$, pH 7.0–11.0	29, 275, 276
Miscellaneous chemotherapeutic agents				
Ketoconazole		PPVCM (NPOE) based on IA of MD cations with BPh_4^- or $[\text{PMo}_{12}\text{O}_{40}]^{3-}$	LR $6.3 \times 10^{-3} - 7.1 \times 10^{-6}$, DL = 5.0×10^{-6} , $S = 72 \pm 2$, pH 3.0–5.0	180
Clotrimazole		the same	LR $1.0 \times 10^{-3} - 1.4 \times 10^{-5}$, DL = 1.0×10^{-5} , $S = 59 \pm 2$, pH 1.5–2.5	189
Metronidazole		PVC membrane with Mn(III) complex with 5,10,15,20-tetrakis[2-(2,3,4,6-tetra- <i>O</i> -acetyl-β-D-glucopyranosyloxy)phenyl]porphyrin and with addition of graphite powder and epoxy resin	LR $2.9 \times 10^{-3} - 5.8 \times 10^{-8}$, DL = 5.8×10^{-8} , $S = 25 - 28$, pH 4.3	312
Perfloxacin		PPVCM with IA of MD cations with BPh_4^-	LR $1.0 \times 10^{-2} - 5.0 \times 10^{-5}$, $S = 23$	200
Piperazine adipate		PPVCM (DOP) based on IA of MD cations with heteropolyanions	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-4}$, DL = 3.2×10^{-5} , $S = 35$, pH 3–8	240
Quinine		PPVCM based on lipophilic derivatives of tetraphenylborate	LR $1.0 \times 10^{-2} - 6.3 \times 10^{-6}$, DL = 2.5×10^{-6} , $S = 52 - 59$, pH 4.4–8.0	312

Table 3 (continued).

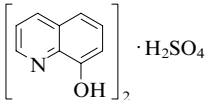

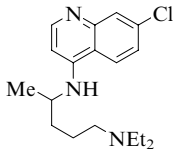

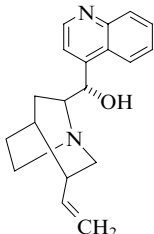

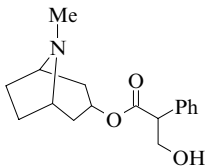

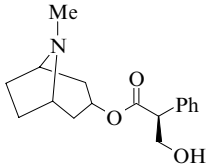

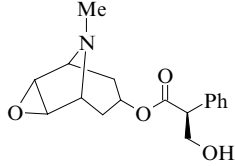

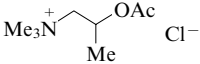

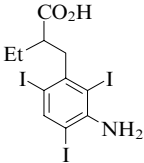

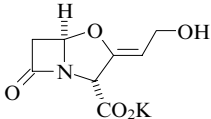

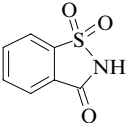

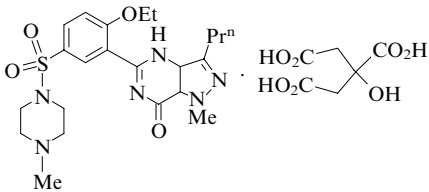

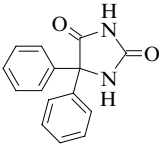

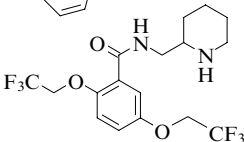

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Miscellaneous chemotherapeutic agents				
Oxine		SC-ISE (graphite substrate) with PPVCM (DOP) and IA of MD cations with BPh ₄ [−]	LR $1.0 \times 10^{-1} - 1.0 \times 10^{-6}$, DL = 4.0×10^{-7} , $S = 59.0 \pm 0.5$, pH 1.8–4.7	190
Chloroquine (Lariam)		PPVCM with IA of MD cations with [B(C ₆ H ₄ Cl-4) ₄] [−] (ISE for FIA)	DL up to 5.0×10^{-7} , $S = 28 - 32$	226
Cinchonine		IA cinchonine–picrolonate in an electropolymerised <i>o</i> -phenylenediamine film on the gold electrode surface	LR $1.3 \times 10^{-5} - 2.5 \times 10^{-7}$, DL = 1.0×10^{-7} , pH 7.0	288
Anticholinergic drugs				
Atropine		ion-selective piezoelectric microquartz sensor based on PVC membrane with IA atropine–BPh ₄ [−] and atropine–dipicrylamine anion	LR $1.0 \times 10^{-3} - 1.0 \times 10^{-8}$, DL = 5.0×10^{-9} , pH 3.0–8.0	168
Hyoscyamine		ISE and FIA sensors with PPVCM based on IA of MD cations with BPh ₄ [−] and [PW ₁₂ O ₄₀] ^{3−}	LR $1.3 \times 10^{-2} - 1.0 \times 10^{-5}$, DL = 3.9×10^{-6} , $S = 56.5 - 57.8$, pH 3.0–10.0	255
Scopolamine		PPVCM with IA of MD cations with 5-nitrobarbiturate PPVCM with IA of MD cation with [PMo ₁₂ O ₄₀] ^{3−}	LR $1.0 \times 10^{-2} - 1.0 \times 10^{-4}$ LR $1.0 \times 10^{-2} - 1.0 \times 10^{-6}$, DL = 8.0×10^{-7} , $S = 54.5 \pm 0.5$, pH 3.0–7.0	295 243
Acetylcholine chloride		PPVCM (NPOE) with lipophilic derivatives of β-CD and addition of Na[B{C ₆ H ₃ (CF ₃) ₂ -3,5}4]	DL up to 2.0×10^{-7} , $S = 60 - 62$, pH 7.0	80–82

Table 3 (continued).

Medicinal drug	Formula	Membrane composition and electrode type ^a	Major electrode characteristics ^b	Ref.
Choline mimetic				
Methacholine		PPVCM (NPOE) with lipophilic derivatives of β -CD and addition of $\text{Na}[\text{B}\{\text{C}_6\text{H}_3(\text{CF}_3)_2\text{-3,5}\}_4]$	DL up to 2.0×10^{-7} , $S = 60\text{--}62$, pH 7.0	80–82
Miscellaneous drugs				
Iopanoic acid		IA of the acid anion with $[(n\text{-C}_8\text{H}_{17})\text{N}]^+$ in <i>p</i> -isopropylnitrobenzene	LR $5.0 \times 10^{-3}\text{--}5.0 \times 10^{-5}$, pH 12	274
Potassium clavulanate		PPVCM (NPOE) based on IA clavulanate–bis(triphenylphosphoranylidene)ammonium with addition of <i>p</i> -(<i>tert</i> -octyl)phenol	LR $1.0 \times 10^{-1}\text{--}2.4 \times 10^{-3}$, DL = 8.0×10^{-4} , $S = 59.4 \pm 0.9$, pH 4.8–7.1	282
Saccharin		tubular ISE for FIA, PVC membrane with IA of MD anions with organic dye cations PPVCM (NPOE or DOP) with IA of Aliquat 336S cations with MD anions	LR $2.0 \times 10^{-2}\text{--}1.0 \times 10^{-4}$, DL = 8.0×10^{-5} , $S = 53.1 \pm 0.4$, pH 2.5 LR $1.0 \times 10^{-1}\text{--}5.0 \times 10^{-5}$, DL = 3.0×10^{-5} , $S = 59\text{--}60$, pH 4.5–11.0	313 279
Sildenafil citrate (Viagra)		PM containing IA of MD cations with BPh_4^- and $[\text{PMo}_{12}\text{O}_{40}]^{3-}$	LR $n \times 10^{-2}\text{--}n \times 10^{-5}$, $S = 54\text{--}56$, pH 3.0–6.0	175
Phenytoin		surface acoustic wave selective PVC sensor	LR $8.0 \times 10^{-4}\text{--}6.7 \times 10^{-8}$, DL = 1.0×10^{-8} , pH 10.0	314
Flecainide		PPVCM based on IA of MD cations with dipicrylamine anions and dodecyl sulfate	LR $n \times 10^{-2}\text{--}n \times 10^{-5}$, DL = $(1\text{--}830) \times 10^{-9}$, $S = 51\text{--}54$	285, 286

^a PM and PPVCM stand for the plasticised membrane and the plasticised PVC membrane (plasticiser is shown in parentheses, see Table 2; DBPhos is dibutyl phosphate), FIA is flow-injection analysis, SC-ISE is solid-contact ISE, ISFT is ion-selective field transistor.

^b LR is the linearity range of the electrode function (mol litre^{-1}); DL is the detection limit (mol litre^{-1}), S is the slope of the electrode function [mV (pC)^{-1}].

accuracy of MD determination in the flow mode was $98.6 \pm 2.5\%$. The electrode was also used in the determination of tetraphenylborate anions at pH from 2.5 to 11.5; the electrode function slope was $56.4 \text{ mV (pC)}^{-1}$, the detection limit was $3.8 \times 10^{-6} \text{ mol litre}^{-1}$.

In the mercurimetric titration of barbiturates, a $\text{Hg}(\text{ClO}_4)_2$ solution was used as the titrant and an I^- -ISE served as the indicator electrode.³⁰⁰ The titration curve demonstrated two jumps, the first corresponding to the stoichiometric reaction of mercury(II) with the titrated MD and the second, to the titrant reaction with the borate buffer solution.

Redox titration was used in the flow-injection determination of ascorbic acid, where the latter was consumed in the reduction of IO_3^- ions to I^- (Ref. 301). An I^- -ISE monitored the concentration of iodide ions. A specially developed computer-governed system of automatic control over the ascorbic acid content provided the automation of this procedure and the reduction of experimental errors. This method can be used in the acid concentration range from 7.5 to 15.0 mmol litre⁻¹ ($S_r \sim 0.01$).

The method of artificial neural networks was used in the processing of results of potentiometric titration of mixtures of derivatives of hydroxycinnamic acid (*p*-coumaric and sinapic acids) and hydroxybenzoic acid (vanillic and isovanillic acids) with a solution of tetrabutylammonium hydroxide in propan-2-ol.³⁰² A four-layer recurrent neural network with back propagation of errors was used in the modelling of the non-linear dependence between the analytical signal and the hydroxy acid concentration. To test the chosen model and train the neural network, the results of potentiometric titration of a series of standard solutions with different concentrations of the determined component were processed. The obtained results served as the basis for the formation of a random data sample, which was used in the training of the neural network. The changes in the signal elements were normalised in a range of 0.1–0.9 according to the equation

$$X_N = 0.1 + \frac{0.8(X - X_{\min})}{(X_{\max} - X_{\min})},$$

where X_N is the normalised signal (at the input and output of the network), X is the initial signal, X_{\min} and X_{\max} are the minimum and maximum signal values.

The optimisation of the network architecture involved choosing the number of layers (the input layer, one or two inner layers and the output layer) and the number of neurons in each layer. Two neurons were used in the input layer (the analytical signal and the titrant volume) as the variables independent from one another. Neurons in the inner layer were optimised for each concrete solution and their mixture, and the number of neurons was determined by the choice of the neural network (this is very important, because the correctness of the results of determination depends on the choice). The chosen network employed the algorithm of back propagation of errors, which allowed minimisation of the least-squares deviation of the current output of a multilayer perceptron from the desired output.

The developed procedure makes it possible to analyse four-component mixtures of *p*-coumaric, sinapic, vanillic and isovanillic acids with the total concentration of $n \times 10^{-3} \text{ mol litre}^{-1}$ by the acid–base potentiometric titration with 0.02 M solution of tetrabutylammonium hydroxide in propan-2-ol with the relative error of less than 5%.³⁰²

Ion associates of MD with the corresponding counter-ions were used as the EAC in membrane ISE with liquid filling and solid-contact ISE. Table 3 shows the data on the composition of selective membranes and the basic electroanalytical characteristics of ISE for the MD determination.

* * *

In the past 10 years, different versions of ISE (membrane ISE with liquid filling, solid-contact and flow ISE), which can operate under conditions of flow-injection analysis, were developed for the determination of MD in patented medicinal drugs and biological fluids. The composition of selective membranes may include both the IA of MD cations and anions with lipophilic counter-ions and the neutral carriers. The latter allows one to enhance the ISE selectivity in the presence of lipophilic ions. The linearity range of the electrode function of ISE is usually in a range of $10^{-1} - 10^{-5} \text{ mol litre}^{-1}$.

Microwave-assisted synthesis of individual and multicomponent oxides

A S Vanetsev, Yu D Tretyakov

Contents

I. Introduction	397
II. Foundations of the theory of interaction of microwave radiation with the matter	397
III. Design and key principles of operation of microwave heating systems	401
IV. Use of microwave heating for the synthesis of individual and complex oxides	403
V. Conclusion	411

Abstract. Data on the synthesis of individual and multicomponent oxides from salts with microwave initiation published over the last 15 years are analysed. The advantages and drawbacks of using microwave heating in the synthesis of oxide materials are noted. Criteria for the selection of chemical systems for microwave heating are proposed. The bibliography includes 162 references.

I. Introduction

The development of new synthetic methods that would allow decreasing the energy expenditure and increasing the rate of formation of the final multicomponent products is an important problem of modern inorganic chemistry and materials science. The rate of solid-phase reactions can be often increased by using the starting compounds in the active state (salt or hydroxide co-precipitation, cryochemical crystallisation, spray drying, hydrothermal treatment, *etc.*).¹ Another way for accelerating the reaction is additional treatment (apart from heating, *e.g.*, mechanochemical or ultrasonic treatment) of reaction mixtures, which intensifies diffusion processes *in situ*.^{2,3} It is noteworthy that the physicochemical characteristics of the compounds synthesised using these approaches are not inferior to the characteristics of substances prepared by conventional procedures and, moreover, often surpass them.

Microwave heating of reaction mixtures is a promising method of increasing the rate of solid-phase reactions.^{4–6} Microwave radiation is a non-ionising electromagnetic radiation with a frequency of 300 MHz to 30 GHz. Microwave heating is used to carry out important physicochemical processes such as dehydration, decomposition of salts and hydroxides, synthesis of multicomponent compounds and ceramics sintering. The time and energy expenditures in such processes

are much lower than those in conventional processes. Moreover, in some cases, microwave treatment provides results that cannot be achieved by other methods.^{7,8}

Microwave treatment has a number of advantages over the usual methods of heating of condensed media (solids and liquids), in particular, high speed and low inertia of heating, the absence of contact between the heated body and the heater, the uniformity of heating throughout the whole material bulk, the possibility of selective heating of mixture components and high oven efficiency (50% for the ovens with radiation frequency of 2.45 GHz and 85% for the ovens with radiation frequency of 915 MHz).^{4–7}

The first studies dealing with microwave heating of materials were performed in 1967. Ford⁹ carried out systematic research of the behaviour of oxides and sulfides under microwave heating at a 2.45 GHz frequency. Subsequently, the effect of microwave heating on many oxides¹⁰ and natural minerals¹¹ has been studied.

During the last 10–15 years, the number of publications devoted to the use of microwave heating in various fields of chemistry has increased severalfold. In particular, the synthesis of individual and multicomponent oxides using microwave radiation were documented. Nevertheless, despite the considerable interest in this method, no attempts to generalise the accumulated experience in using microwave heating for the synthesis of oxide materials or to formulate the criteria for evaluating the efficiency of microwave heating for inducing various chemical processes have been undertaken as yet. This review is aimed to fill this gap at least partially.

II. Foundations of the theory of interaction of microwave radiation with the matter

In the electromagnetic radiation scale, the microwave radiation is situated between the IR radiation and radiowaves and corresponds to the wavelengths (λ) from ~ 1 m to 1 cm.¹² The waves with frequencies of 1 to 30 GHz are actively used in radars and the rest frequency range is employed in telecommunication. On the basis of international agreement, frequencies of 2.45 GHz ($\lambda \approx 12.2$ cm) and 915 MHz ($\lambda \approx 32.7$ cm) were allocated for laboratory and domestic microwave ovens (Fig. 1).

Currently, the microwave heating theory has been fairly well developed.^{6–9,12} In this review, we will restrict ourselves to a brief description of the principal mechanisms of absorption of microwave radiation by condensed matter, related to heat

evolution due to dielectric loss on polarisation and to induced currents flowing in the material.

A set of microscopic processes of interaction of electromagnetic waves with charged particles of the matter can correctly be described only by means of quantum mechanical models. Nevertheless, for description of microwave heating, it is often sufficient to take into account the macroscopic properties of the absorbing matter, which are described in terms of classical physics.^{11, 13–17}

Electromagnetic field affects the electric charges in the matter, which are usually classified into free and bound. Free charges can be carried by electrons, vacancies or ions able to move by macroscopic distances. Under the action of an external electric field, conduction currents appear in the matter due to free charge migration

$$\vec{J}_c = \sigma_c \vec{E}, \quad (1)$$

where \vec{J}_c is the conduction current density vector, σ_c is the electrical conductivity of the matter, and \vec{E} is the electrical field vector.

The migration of bound charges is confined to the microscopic size of an atom, a molecule or a crystal cell. Under the action of an external field, the bound charges are merely displaced from their equilibrium states giving rise to macroscopic polarisation. If no free charge carriers are present, the substance is a dielectric and its capacity for polarisation is determined by the relative dielectric permittivity (ϵ_b)

$$\vec{P}_b = (\epsilon_b - 1)\epsilon_0 \vec{E}, \quad (2)$$

where \vec{P}_b is the polarisation vector resulting from bound charges (electrical dipole moment of the unit volume of the substance), $\epsilon_0 = 10^{-9}/36\pi$ (F m⁻¹) is the dielectric permittivity of vacuum.

In the case of an alternating field, the displacement of the bound charges from the equilibrium states is time-dependent; this implies effective movement of charges and, hence, an alternating electric current

$$\vec{J}_b = \frac{\partial \vec{P}_b}{\partial t}, \quad (3)$$

where \vec{J}_b is the polarisation current density.

Thus, in an alternating field, the separation of effects related to the migration of free and bound charges is rather arbitrary.

Currents of any nature in the matter give rise to heat evolution. In the case of high-frequency fields, it is convenient to use field period-averaged characteristics. Therefore, the expression for the power of heat source per unit volume (q) can be written as follows:

$$q = \langle \vec{J} \vec{E} \rangle, \quad (4)$$

where $\vec{J} = \vec{J}_c + \vec{J}_b$ is the total electric field density vector in the matter.

In general due to the inertia of free and bound charge carriers the conduction current and the polarisation vector lag behind the electric field in phase. These effects are often formally described using the so-called complex amplitude method in which all oscillating values are given by

$$\vec{E} = \text{Re}[\vec{E}_\omega \exp(i\omega t)], \quad (5)$$

$$\vec{J} = \text{Re}[\vec{J}_\omega \exp(i\omega t)],$$

etc., where ω is the field circular frequency, t is time, i is the imaginary unit, the values with the subscript ω designate the corresponding complex amplitudes. In the complex form, Eqns (1) and (2) are represented as follows:

$$\vec{J}_{c\omega} = \sigma_c(\omega)\vec{E}_\omega, \quad (6)$$

$$\vec{P}_{b\omega} = [\epsilon_b(\omega) - 1]\epsilon_0 \vec{E}_\omega,$$

where $\sigma_c(\omega) = \sigma'_c(\omega) - i\sigma''_c(\omega)$ and $\epsilon_b(\omega) = \epsilon'_b(\omega) - i\epsilon''_b(\omega)$ are the complex values describing the above-mentioned phase lag of the conduction current and the polarisation vector behind the electric field strength. In the microwave range, the dependence $\sigma_c(\omega)$ and its imaginary part can be neglected for the vast majority of materials, taking that $\sigma_c(\omega) \cong \sigma_c$. The dependence $\epsilon_b(\omega)$ and its imaginary part are determined by the type and properties of the bound charges in the dielectric and can be substantially different for different substances.

Within the complex amplitude formalism, Eqn (4) can be written in the form

$$q = \frac{1}{2}\omega\epsilon_0\epsilon''|\vec{E}_\omega|^2 = \frac{1}{2}\omega\epsilon_0\epsilon'_b\tan\delta|\vec{E}_\omega|^2, \quad (7)$$

where $\epsilon'' = \epsilon''_b + \sigma_c/\omega\epsilon_0$ is the imaginary part of the equivalent dielectric permittivity of a substance, ϵ' is its real part, $\tan\delta \equiv \epsilon''/\epsilon'_b$ is the dielectric loss tangent.

If the substance has pronounced magnetic properties, a term corresponding to the specific power of heat evolution caused by dissipative processes upon magnetisation should be introduced into Eqn (7)

$$q = \frac{1}{2}\omega\epsilon_0\epsilon'_b\tan\delta|\vec{E}_\omega|^2 + \frac{1}{2}\omega\mu_0\mu''|\vec{H}_\omega|^2, \quad (8)$$

where μ_0 is the magnetic permittivity of vacuum, μ'' is the imaginary part of the magnetic permittivity of the substance, \vec{H}_ω is the magnetic field strength complex amplitude.

It can be seen from Eqn (8) that the intensity of heat evolution in a sample being treated depends on many factors, in particular, on electrophysical properties of the material, the frequency and the intensity of the applied field. Note that this equation implies circumstantially the dependence of the heating efficiency on various parameters including the geometric size of the treated sample and the resonator cavity. As characteristics of the microwave treatment system largely depend the field amplitude in the sample, they also affect the heat evolution in its body. For irradiation of a sample with a flat electromagnetic wave with all parameters except ϵ'' being fixed, the highest heating power is observed at some ϵ'' value specific for the given substance. Below this value, the wave would pass through the sample without being significantly absorbed, while above this value, the wave would be largely reflected from the sample.

When selecting the conditions for microwave heating, it is important to take into account the depth of penetration of the electromagnetic wave into the substance under treatment. This factor greatly affects the distribution of the field amplitude in the sample and, hence, uniformity of heat distribution.^{18–21}

If the depth of field penetration into the matter (δ_E) is defined as the distance at which the field strength decreases e -fold (e is the Napierian base), then

$$\delta_E = \frac{\lambda}{\pi \sqrt{2\epsilon'(\sqrt{1 + \tan^2 \delta} - 1)}} \quad (9)$$

If $\tan \delta \ll 1$, then

$$\delta_E = \frac{\lambda}{\pi \sqrt{\epsilon' \tan \delta}} \quad (10)$$

Thus, an increase in frequency entails an increase in not only the heating power but, unfortunately, also in the heating non-uniformity; this may imply overheating of the outer layers of the sample. The penetration depth of the microwave field into material can vary over broad ranges, from several microns to several metres. For example, at 25 °C, the penetration depths of the radiation with 2.45 GHz frequency into copper and graphite are 2.6 and 38 μm , while those into epoxide resin and alumina are 0.73 and 187 m, respectively. If the geometric size of the sample is much larger than the penetration depth of the microwave radiation, heating of the sample will be non-uniform.

It is noteworthy that the δ_E value characterises the heat treatment depth only to a first approximation, because the field penetrates to a greater depth, and its energy may be sufficient for the required heating effect. The dielectric parameters of the matter, and, hence, the penetration depth depends on temperature and can change during heating. Thus, the depth of heat treatment during given technological process can be determined exactly by solving the problem of temperature field in the volume of sample. It is important not only to choose the optimal frequency and amplitude of the electromagnetic field, but also to select the resonator geometry.

In standard domestic microwave ovens with a rectangular resonator (these ovens are still used in most experiments), materials with medium conductivities, *i.e.*, semiconductors, oxides with mixed metal oxidation states, and some powdered metals, are heated more efficiently than good conductors (some metals) or dielectrics (oxides and halides) (Table 1).

This effect may be due to the fact that dielectric losses at room temperature are low for insulators; therefore, no effective heating takes place, although the microwave field penetrates to a high depth. In the case of metals, the microwave radiation is considerably reflected.⁹ Thus, effective heating of substances with low or, conversely, high ϵ'' values requires selection of

Table 1. Efficiency of microwave heating of substances with different types of conduction (radiation frequency 2.45 GHz, power 800 W).^{9,10}

optimal geometric parameters of the resonator. It is often a complicated engineering problem.

In heterogeneous systems containing phases with different dielectric properties, an external electromagnetic field may produce charges at interfaces (the Maxwell–Wagner effect). It has been shown²² that the simplest and most correct description for this type of polarisation is provided by the model of spherical particles of a highly conducting phase distributed uniformly in a dielectric. The reactive component of the dielectric permittivity of such a system can be described by the equation

$$\epsilon_i'' = \frac{(9V\epsilon\omega_{\max})\omega\tau}{1.8 \times 10^{10}\sigma(1 + \omega^2\tau^2)}, \quad (11)$$

where V is the volume fraction of the dispersed phase; ω_{\max} is the circular frequency of the electromagnetic field corresponding to the maximum loss for the dielectric phase; τ is the relaxation time of the dielectric (the time span during which the system returns to the equilibrium state after removal of the electromagnetic field); σ is the conductivity of the dispersed phase. This model was verified experimentally using paraffin with dispersed isotropic particles of copper phthalocyanine as a semiconductor.²³ A good correspondence between the theoretical and experimental results was noted (Fig. 2).

Unfortunately, the contribution of the Maxwell–Wagner effect to the solid- and liquid-phase transformations occurring under microwave irradiation has not been quantitatively

Figure 2. Frequency dependences of the reactive component of the dielectric permittivity of the copper phthalocyanine-paraffin system.²³ (1) Experimental data, (2) calculation by the Maxwell-Wagner model.

estimated as yet. Nevertheless, in some studies (see, for example, Ref. 12), it was suggested that surface polarisation is responsible for the so-called 'non-thermal' effects of microwave treatment resulting in acceleration of processes in a microwave field.

Apart from the above-described features of the propagation of microwave radiation and its interaction with the matter, an important role in microwave heating is played by thermophysical properties of the sample, because the efficiency and uniformity of microwave heating depend on not only the dielectric properties of the material, but also its ability to dissipate the evolved heat throughout the bulk. Thus a main cause of non-uniform heating is the sharp increase in the dielectric loss factor with temperature. The rate of heat dissipation in the sample bulk is insufficient, and areas with higher temperature characterised by more intense absorption of microwave radiation appear in the sample (the so-called 'hot spots'). Thus, despite the widely accepted view that microwave heating produces uniform dissipation of heat throughout the sample bulk (see above), one should thoroughly select the experimental conditions to avoid sharp temperature differences within the sample.²⁴⁻²⁶

When performing any experiments on microwave heating, it is necessary to take into account the following properties of the sample material.

1. Electronic and ionic conduction. There exists an optimal range of electronic conduction that ensures the most efficient interaction of the matter with the microwave field: good insulators are transparent for the microwave field, while substances with high electronic conductivity (metals) reflect microwave radiation. Analysis of published data on microwave heating of substances with high ionic conductivity demonstrated that these substances possess rather high absorption capacity. The absence of substances reflecting microwave field due to high ionic conductivity is attributable to the too low concentration of free ionic charge carriers and their relatively low mobility even in the best ionic conductors.

2. Dielectric permittivity and dielectric loss factor. There exists an optimal range for the dielectric loss factor, which determines the absorption capacity of a substance; an increase in this factor entails a decrease in the depth of penetration of the microwave field into the sample. Thus, the more efficiently the substance absorbs, the smaller is the sample that can be heated in a microwave field without formation of temperature gradients within the sample bulk. It should be borne in mind that at low temperatures the contribution of dielectric losses to microwave heating is quite insignificant for most of substances.

3. Heat conductivity. Heating of substances with low heat conductivity usually produces local overheating giving rise to

above-mentioned 'hot spots', because the evolved heat has no time to dissipate uniformly throughout the bulk. Uniform microwave heating requires a relatively high heat conductivity of the sample. The more efficiently the substance absorbs and the more pronounced is the temperature dependence of the absorption capacity, the higher heat conductivity is expected for this substance.

Thus, one can define the main criteria for the selection of chemical systems for microwave heating and the range of problems that can be solved using this way of heat supply to condensed matter.

1. Non-uniform temperature distribution within the sample bulk can be avoided if the microwave-treated substance has rather high heat conductivity. In each particular case, it is necessary to determine experimentally the maximum dimensions of the sample of a given substance (or a mixture of substances) that can be heated uniformly throughout the whole bulk without formation of pronounced temperature gradients.

2. The substances that can be heated by microwave radiation should possess either a high dielectric loss factor (*i.e.*, they should contain mobile dipoles with a relatively high dipole moment) or a high electronic, hole or ionic conductivity at the experimental temperature. It is noteworthy that for specific conductivity of less than $\sim 10^{-5} \Omega \text{ m}$, the sample starts to reflect the microwave radiation. The dielectric properties depend on temperature and, hence, the absorption mechanism can change during heating not only upon chemical transformations in the sample, but also due to a change in the parameters of microwave radiation absorption by the sample.

It is evident that dipole fragments with zero effective charge have the highest mobility in the crystal structure. Among inorganic compounds, water meets best of all the above requirements (high mobility of molecules and high dipole moment). The Reh binder classification, which is based on the work of isothermally reversible detachment of one mole of water from the material framework, distinguishes three main types of binding of water in solid systems: physicochemical (for example, capillary water), physicochemical (for example, adsorption water) and chemical binding (water of crystallisation, hydroxy groups). Chemically bound water is most interesting for solving synthetic problems, because this is characterised by the highest energy of detachment from the crystal lattice (from 20 to 80 kJ per mole of H_2O approximately depending on the number of water molecules removed from the crystal structure), and the supply of this amount of energy often results in decomposition of the dehydrated substance. Thus, salt crystal hydrates and hydroxides appear promising precursors for the microwave synthesis of oxide compounds.

Analysis of published data on the use of microwave heating for the synthesis of inorganic compounds has shown that, despite the large number of publications, no information that allows predicting the efficiency of the use of microwave radiation for heat treatment of chemical systems is available. Most papers discuss experimental data; the choice of starting reactants for the synthesis is not substantiated, and the discussion of the results concerns the microstructure and the structure-sensitive properties of the products but does not include any fundamental conclusions about their dependence on the physicochemical properties of the starting compounds, the way of organisation of the reaction area, or on the mechanism of interaction of microwave radiation with the sample.

Therefore, of particular interest are papers dealing with the theoretical substantiation of the microwave action on a substance. In most studies of this type, augmentation of mass transfer upon microwave treatment is attributed both to uniform heating of the whole sample bulk and creation of the reversed temperature gradient and to specific 'non-thermal' mechanisms of microwave field action on diffusion processes.

A theoretical substantiation^{27–29} of the ‘non-thermal’ activation of mass transfer under the microwave treatment has been proposed.[†] Consider one-dimensional diffusion of a substance in an alternating electromagnetic field. In this case, mass transfer equation has the form

$$\frac{\partial c}{\partial t} = D \frac{\partial}{\partial x} \left[\frac{\partial c}{\partial x} - U(t) \frac{\partial c}{\partial x} \right]. \quad (12)$$

The additional term $U(t)$ depends on external field parameters $U(t) = qE \cos(\omega t/kT)$, where q is the ion or vacancy charge, ω is the circular field frequency, k is the Boltzmann constant, T is temperature.

No analytical equation relating the rate of mass transfer to the electromagnetic field strength and frequency can be derived for the case of three-dimensional diffusion. However, approximate solution provides the conclusion that the most pronounced influence of the microwave field should be expected at an early stage of the solid-phase process and at short diffusion distances. As the time of action of microwave radiation increases, the process gradually becomes steady-state, and according to Bokhan,²⁷ the contribution of the electromagnetic field to the driving force of diffusion rapidly decreases. In conformity with this model, the diffusion fluxes in the matter are directed from regions with high electric field strength to regions with low electric field strength. The diffusion processes are fairly intense, resulting in redistribution of the electromagnetic field strength and, hence, in a change in the direction of diffusion fluxes. As a consequence, the rate of solid-phase processes increases and the temperature of the process onset decreases.

Unfortunately, this approach is too simplified for the mathematical modelling of processes taking place under microwave heating of solid systems, and the experimental verification of the assumptions made by Bokhan²⁷ is today impossible.

Another approach to the theoretical substantiation of the ‘non-thermal’ effects of microwave heating has been reported.^{30–32} It was assumed that a high-frequency electromagnetic field should create fluxes of charged species (ions or vacancies) in the matter, their intensity being changed in parallel with the strength of the external electromagnetic field. Within the sample bulk, these fluxes counterbalance one another and the overall concentration of charged species remains spatially uniform; however, near the surfaces, discontinuity of the medium gives rise to harmonic oscillations of the charged species concentrations the frequency of which coincides with (or is close to) the electromagnetic field frequency (Fig. 3).

It has been asserted³⁰ that oscillations of this type produce uncompensated fluxes of charged species along any extended crystallite imperfections (free surfaces, phase interfaces or grain boundaries). In the opinion of the researchers cited, this is responsible for the fact that microwave treatment does not increase the rate of charged species migration, but creates an additional driving force for diffusion (F), which is defined by the following expression:

$$F = \frac{c_i}{c_i^0} q_i E, \quad (13)$$

where c_i is the concentration of the i th sort of charged species at the crystallite boundary under the action of an external electromagnetic field, c_i^0 is the concentration of the i th sort of charged species at the crystallite boundary in the absence of an

Figure 3. Time dependence of the variation of the concentration of charged species (c) near the surface and in the sample bulk upon the action of high-frequency electromagnetic field (calculated).³²

external electromagnetic field, q_i is the charge of the i th sort of charged species.

According to this theory, the more dispersed the system under treatment, the stronger the ‘non-thermal’ microwave effects. The effect of an external electromagnetic field on the ionic current in the NaCl crystal was studied in order to confirm this hypothesis (Fig. 4).³² It was stated that the experimentally detected change in the ionic current density in the NaCl crystal located in an external electromagnetic field is equal to the calculated gain in the ionic current induced by the microwave field.

Figure 4. Setup for measurement of the ionic current in a NaCl crystal.³²

It is clear that the proposed model of the ‘non-thermal’ microwave effects on the diffusion processes can hardly be practically verified. Indeed, it is not clear whether the experimentally mentioned above (see Fig. 4) allows one to draw unambiguous conclusions about the change in the mass transfer mechanism during the solid-phase reaction under microwave heating. In any case, verification of this model requires additional experiments.

III. Design and key principles of operation of microwave heating systems

Almost all microwave heating facilities are designed according to a chart shown in Fig. 5. The microwave energy comes out of the source through transmission line and is directed to the working chamber into which the sample is supplied through a loading system. The fraction of energy absorbed by the sample depends on the sample size and electrophysical characteristics briefly considered above. The microwave treatment parame-

[†] The information was partially gained from a Yu I Bokhan’s private communication.

Figure 5. Microwave heating unit.¹¹

ters are controlled by the control system. Some devices envisage a 'feedback', which allows the change in the supplied power during heating following a change in the sample temperature (or pressure in the case of treatment in an autoclave).[‡]

Currently there is no generally accepted classification of microwave heating facilities. Arkhangelskii¹¹ proposed a classification (Fig. 6) in which the power, the design, the mode of operation and the technological purpose of the setup were taken as the determining features. Detailed consideration of the operation principles and the possible designs of microwave heating devices is beyond the scope of this review; therefore, we will present only a brief analysis. More detailed information on this topic can be found elsewhere.^{7, 11, 12, 19, 20} The designs and the main operation principles of magnetron systems will be considered in somewhat more detail, because most studies have been performed using domestic microwave ovens or devices based on them. An important part of the microwave heating device is the working chamber in which the sample is treated. When designing or choosing the working chamber, it is reasonable to consider its dimensions, the pattern of field distribution and type of transmission line as the principal parameters (Fig. 7).

Magnetron is used most often as the microwave radiation source for the synthesis and sintering of oxide materials. Among other sources, mention should be made of gyrotron

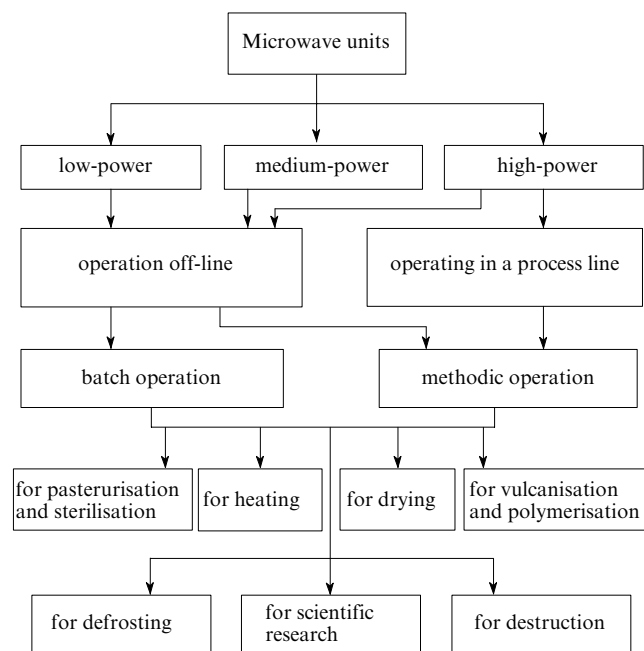

Figure 6. Classification of microwave heating units.¹¹

[‡] Unfortunately, commonly used domestic microwave ovens lack this feedback.

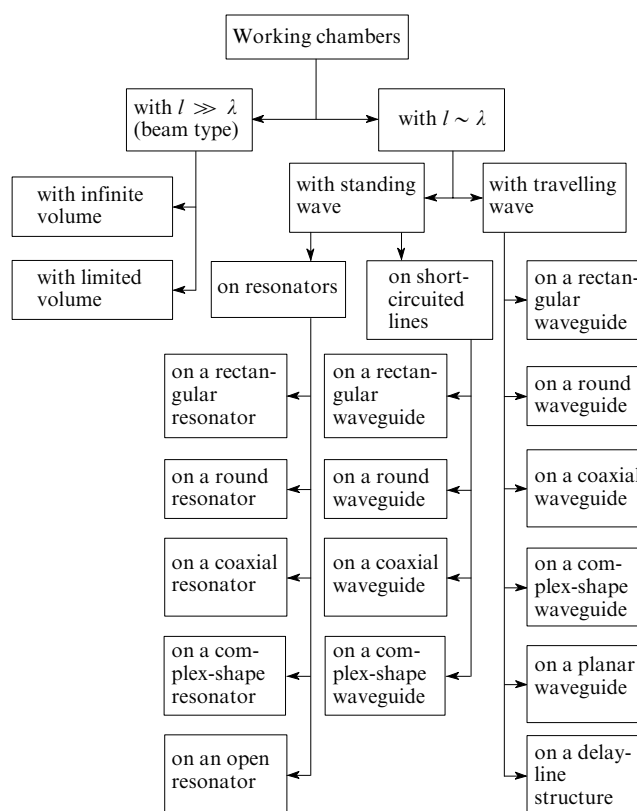

Figure 7. Classification of the working chambers of microwave heating units.¹¹

systems with a radiation frequency of ~ 30 GHz designed at the Institute of Applied Physics of the RAS, klystron tubes and microwave triodes.²⁰ Due to the high radiation frequency, treatment in gyrotron systems is more efficient and less sensitive to the electrophysical characteristics of the material. The gyrotron microwave heating systems are fairly promising for syntheses and especially for sintering. Unfortunately, the complexity of the design and high cost of gyrotron systems hamper their extensive use in scientific practice.

On the one hand, devices based on domestic microwave ovens are used most widely, but on the other hand, they are least adapted for experiments under definitely specified and reproducible conditions. Therefore, it is expedient to consider the operation principle of domestic microwave ovens and the key parameters affecting the operation, in order to find whether it is possible to carry out experiments under controlled conditions in these ovens and what should be done to achieve this goal.

The magnetron used in domestic microwave ovens is a cylindrical diode onto which a magnetic field directed along the cathode is applied. The potential between the cathode and the anode representing a ring of linked cavity resonators reaches several thousand volt. In the non-adjustable magnetron, the oscillators are designed in such a way that they emit energy with a particular frequency. Most domestic microwave devices make use of non-adjustable magnetrons with an output frequency of 2450 ± 13 MHz. This magnetron consumes ~ 1200 W from the supply line; this is converted into a 600 W electromagnetic power output. The rest is converted into heat, which is dissipated by air cooling. The designs of magnetrons and other microwave emitters are described in detail in specialised literature (see, for example, Refs 7, 19 and 20).

In estimation of the power of domestic microwave systems, the averaged rather than the full output power of magnetron is

used. The magnetron duty factor, *i.e.*, the ratio of the time the magnetron is switched on (t_1) to the sweep time (t_s), is used for this purpose. Thus if $t_1 = 5$ s and $t_s = 10$ s, the duty factor is 0.5. Hence, in order to obtain the average radiation power of 300 W (half of the output power), the magnetron of domestic microwave oven should be switched on during some time t_1 and switched off during time t_2 . Domestic microwave ovens usually have the sweep time equal to

$$t_s = t_1 + t_2 = 10 \text{ s.}$$

This long sweep time is undesirable for microwave heating of substances and materials, because with magnetron being switched off for a long period (5 s for a duty factor of 0.5), the loss of heat can be rather high. Most of laboratory microwave heating equipment have shorter sweep times, which is much more convenient for experiments, especially for heating of solids. Many modern facilities provide for the fine power adjustment without switching-off the magnetron.

The full output power of the magnetrons of domestic microwave ovens is usually about 600–700 W. A simple method for its determination is to measure the temperature of a fixed mass of water able to absorb almost all energy supplied to the resonator. Usually, the apparent output power is determined by measuring the temperature of 1 litre of water heated during 2 min at the full magnetron power.

Equation for the calculation of the apparent output power (P/W) has the form⁴

$$P = Kc_p \frac{\Delta Tm}{t}, \quad (14)$$

where K is the conversion factor of the thermodynamic units cal min^{-1} into Watts; c_p is the specific heat capacity/ cal deg^{-1} ; $\Delta T = T_{\text{f}} - T_{\text{u}}$ (the difference between the final and initial temperatures/ $^{\circ}\text{C}$); m is the sample mass/g; t is time/s. If the heated substance is water, Eqn (14) can be simplified

$$P = 35 \frac{\Delta Tm}{t}, \quad (15)$$

where the numerical multiplier includes the conversion factor and water heat capacity. The correctness of power determination depends on the arrangement of sample inside the resonator and on the identity of the containers used. Since energy scattering by a dielectric and energy loss as radiation depend on temperature, the same initial temperature and approximately equal differences ΔT should be used. Power determination is most accurate if the initial temperature of water is equal to 20 ± 2 $^{\circ}\text{C}$.

The output power of the magnetron is markedly affected by the overheating due to reflection of a part of radiation back to the magnetron. The modes that ensure energy transfer from one medium to another without reflection are called wave coupling match. A mismatch may result in magnetron overheating, loss of output power or even failure of the magnetron.⁴ For magnetron protection in case of wave coupling mismatch and for reaching the required output power, devices that eliminate reflection of microwave radiation have been designed. Domestic microwave ovens are usually devoid of such devices, but they are stipulated in industrial microwave systems. The device used most often is the output circulator (ferrite valve or the Faraday isolator), which allows microwave radiation to propagate in the forward direction but directs the reflected radiation to an absorber located outside the resonator, which is a heavy ferrite rod where energy dissipates as heat without damaging the microwave device.⁷ The magnetron-generated microwave radiation is transmitted to the working chamber (resonator) by means of a waveguide made of a reflecting material, for example, a metal sheet.

Considering the working chamber classification shown in Fig. 7, one can see that the working chamber of a domestic microwave oven is a rectangular resonator with stationary waves. In such devices, it is often rather difficult to achieve uniform heating of a sample. In most domestic devices, this problem is solved using a rotating sample holder (usually, as a dish). There exist rotating holders that continuously rotate by 360° and cyclic holders rotating in both directions by 180° . Alternating rotation is used when the sample has various detectors attached. Unfortunately, all these methods for equalisation of the field energy density throughout the resonator volume do not ensure uniform heat treatment of the sample.¹¹

In conclusion of this Section, we will consider a highly important problem of temperature measurement during microwave heating of the sample. Correct measurement of the process temperature is a very complicated problem. A faulty way of introducing a temperature indicator and perturbations induced by the microwave field on the measuring instrument may give rise to substantial errors in the temperature measurement and, hence, in the evaluation of the efficiency of microwave heating.

The use of conventional bimetallic thermocouples is precluded under microwave heating conditions, because a high-frequency electromagnetic field generates additional currents in the thermocouple and induces disturbance on measuring devices. In addition, the introduction of a metallic item into the resonator changes the distribution of the microwave field power, which may result in local overheating.⁴ The only solution to this problem is the use of a screened thermocouple grounded to the resonator wall. It is necessary to determine beforehand the position at which the thermocouple would not disturb the uniform distribution of microwave energy over the resonator volume. Currently, the patterns of electromagnetic field distribution over resonators with different geometries have been determined both experimentally and by calculations.

If the sample is relatively large, the gradients formed upon microwave heating preclude the possibility of accurate characterisation of the sample temperature using only one detector. Accurate temperature measurement requires a good contact between the sample and the measuring detector, which may pose problems if the sample changes its volume or moves during the experiment. The use of other contact methods of temperature measurement is markedly complicated by such effects as indicator heating, screening and local overheating at the site of detector contact with the heated body.^{5,9} When optical devices are used for temperature measurement, it is necessary to establish an accurate correlation between the radiating power of the sample in the given wavelength range and the sample temperature. Apart from temperature, the radiation intensity depends on the state of the sample surface and on the sample homogeneity. If the optical device for temperature measurement and the heated item are separated by a barrier (for example, in domestic microwave ovens, the working chamber door is usually made of metallic grid), it is necessary to take into account attenuation of the radiation from the heated item, as part of radiation is absorbed by the barrier. It should be borne in mind that the attenuation factor depends appreciably on the radiation wavelength. These difficulties can be overcome by using a pyrometer, which measures the temperature based on the ratio of radiation intensities of the sample at two different wavelengths.

IV. Use of microwave heating for the synthesis of individual and complex oxides

It was noted above that microwave radiation is a promising alternative to usual heating for performing various processes including sintering, dehydration, decomposition of salts and hydroxides for the synthesis of individual and multicomponent

compounds, solid-phase and liquid-phase syntheses.⁷ A rather well-developed theory allows one to predict how efficiently a particular substance will absorb microwave radiation. Nevertheless, in practice, it is very difficult to predict the system behaviour in a microwave field. This is mainly due to the fact that electrophysical characteristics that determine the absorption capacity of substances are highly temperature-dependent: as the substance is being heated in a microwave field, its absorption capacity continuously changes. Exact account of this phenomenon is complicated, and data on the temperature dependence of the absorption capacity have been fully accumulated to date only for a limited range of compounds. Apart from the electrophysical characteristics, the heat conductivity and heat capacity of substances and, in many cases, also their micromorphology also change during heating. The change in these parameters affects the absorption of the microwave energy by the substance. Elucidation of the influence of each of the listed parameters on the system behaviour in a microwave field is hardly possible; however, since these characteristics change rather smoothly and monotonically, the heating dynamics can be roughly estimated.

This task becomes much more difficult if chemical processes take place in the system during heating. Upon changes in the chemical and phase composition, electrophysical characteristics of the system change jumpwise and often uncontrollably. As the temperature rises, the sample properties also change. Therefore, it is almost impossible to predict the absorption capacity of the system in which a chemical reaction occurs. This accounts for the lack, in the vast majority of publications, of data on the system behaviour under microwave treatment or attempts at its targeted use for performing processes with allowance for this information.

From the chemical standpoint, sintering is the simplest process; it is not by chance that this application of microwave heating is best studied. Most often, sintering does not change the chemical or phase composition of the sample; the change in the absorption capacity is mainly due to a change in density and grain composition during heating. These characteristics change rather monotonically; therefore, in most cases, one can control sintering to achieve specified results.

Starting with the 1970s, a large number of publications have been devoted to the use of microwave heating for sintering of various materials ranging from weakly absorbing compounds (Al_2O_3 , TiO_2) to compounds that actively interact with the microwave field even at room temperature (SiC , TiB_2 , B_4C).^{33–66} The main advantages of microwave-assisted sintering include high rate and uniformity of heating. This gives rise to ceramics with a more homogeneous microstructure compared to ceramics produced by traditional methods.^{67,68}

Thirty years ago the first experiments on sintering of alumina and zirconia in a microwave unit with a radiation frequency of 2.45 GHz were carried out.³³ This demonstrated both the advantages (high rate of sintering, uniform heating of the whole sample bulk) and specific drawbacks (complexity of temperature measurement and risk of local overheating) of microwave heating. Subsequently, microwave sintering of β -alumina has been studied.^{34,35} It was found that microwave treatment leads to substantial (severalfold) decrease in the sintering time required to reach a nearly theoretical density of the material. Nevertheless, no fine-grain ceramics with a narrow grain size distribution have been obtained in these studies.

The temperature and time dependences of the density of yttrium and cerium oxide-doped zirconia samples during sintering in a microwave oven and in an electric resistance furnace have been considered.³⁶ In the case of low-temperature exposure, samples sintered in a microwave oven had higher density. Nevertheless, nearly theoretical densities are attained in both cases only at temperatures of about 1500 °C. Gener-

ally, the change in the time dependences of sample densities indicates that microwave-induced sintering proceeds at an appreciably higher rate. In addition, samples with equal densities are characterised by much smaller crystallites when sintered in a microwave field. Experiments on microwave field-induced sintering of alumina powders have been described.^{37,41,42} It was shown that densities and microstructures of samples sintered in a microwave oven and in an electric resistance furnace are actually equal. Upon comparison of the results of these studies, one can suggest that the influence of microwave heating on the grain shrinkage and growth during sintering is manifested to a higher extent in substances with ionic conduction than in dielectrics. This probably can be attributed to intensification of diffusion processes caused by microwave field excitation of ionic currents in samples possessing ionic conduction.

Apart from papers devoted to microwave heating of alumina, titania and zirconia, a large number of publications dealing with sintering of oxide powders with complex compositions have appeared in recent years. Microwave radiation has been successfully used^{44,45} for sintering of lead zirconate titanate- and mixed niobium and magnesium zirconate-based powders (PZT and PMNT, respectively) used as piezoelectrics. Note that the use of a microwave system with a magnetron operating at 2.45 GHz⁴⁴ did not result in better ceramic properties compared to those obtained by conventional sintering techniques. Meanwhile, ceramics with much more uniform size distribution of crystallites was produced using a gyrotron system with radiation frequencies of 30 and 83 GHz. Microwave heating was also successfully used for sintering of nanocrystalline hydroxylapatite powders.⁴⁶ The compacted samples reached a density of 95% of the theoretical after a 5-min treatment and 98% after a 15-min treatment, and the microhardness of the ceramic samples was as high as 5.9 ± 0.8 GPa.⁴⁶

Manganese nickel, nickel zinc and nickel copper zinc ferrite powders were sintered using a high-power (3 kW) microwave radiation with a 2.45 GHz frequency.^{47,48} The microstructure and the magnetic properties of the ceramic samples thus obtained were not inferior to the properties of samples annealed in a conventional furnace. The degradation during annealing is much slower for ceramics with a 'microwave' prehistory. The ceramics thus formed was used for the design of multilayer chips the magnetic properties of which were not inferior to the properties of chips manufactured using standard industrial processes, while the manufacture time was significantly reduced.

It is noteworthy that owing to the relative ease of changing the electrophysical characteristics of a sample during sintering, it is often possible to distinguish and describe the specific effects of microwave treatment. Many researchers noted a considerable decrease in temperature during microwave sintering with respect to control experiments carried out using an electric resistance furnace. The most significant result was attained by Janney and Kimrey,^{52,53} who managed to reduce the sintering temperature of an Al_2O_3 powder by 400 °C using radiation at 28 GHz. The decrease in the sintering temperature of ZrO_2 ,^{54,55} $\text{ZrO}_2 - \text{Al}_2\text{O}_3$ composite ceramics⁵⁶ and LaCrO_3 (Ref. 57) was also reported. Similar results were obtained for sintering of ceramics based on oxygen-free compounds, for example, B_4N (Ref. 58) and Si_3N_4 .^{59,60} Analysis of published data showed that the decrease in the sintering temperature is more pronounced at higher frequencies of electromagnetic radiation.^{61,62} A considerable decrease in the sintering temperature can be achieved for microwave heating of dielectrics or ionic conductors but not for electronic conductors, which suggests the influence of the microwave field on the diffusion processes taking place during sintering of powders.^{5,63,64} Unfortunately, the validity of such assumptions largely

depends on the correctness of temperature measurement in the microwave field. In most cases, even using screened thermocouples and fibre optic systems for temperature measurement, one cannot state unambiguously that a significant lowering of the sintering temperature was attained during microwave heating. Indeed, a very thorough investigation of the sintering of stabilised ZrO_2 was carried out.⁶⁹ The sample shrinkage was monitored by dilatometric measurements *in situ*. It was shown that the microwave effect that cannot be reduced to the thermal component does actually exist; however, its contribution is moderate: under identical conditions, shrinkage in a microwave field to the same density as in the case of heat treatment takes place at a 50–80 °C lower temperature. In addition, the contribution of the ‘non-thermal’ factor decreases with an increase in the temperature. This was attributed⁶⁹ to the decrease in the field strength within the sample with an increase in the temperature. Thus, the results of studies published in Refs 52–57 appear to be not quite reliable, as the temperature measurement during sintering was, most likely, improper.

Many researchers totally deny the fact of lowering of the sintering temperature in a microwave field. For example, Levinson *et al.*,⁶⁵ who studied sintering of zinc oxide powders, did not notice any substantial difference between the sintering time in a microwave field and in an electric resistance furnace. In a study³⁹ devoted to the microstructure and the ionic conduction of yttrium oxide-doped ZrO_2 ceramics sintered in a microwave field, no significant differences were noted between the microstructures and properties of samples obtained by microwave treatment and in an electric resistance furnace, except for some decrease in the sintering time. In another publication,⁴⁰ it was concluded that the difference between the properties of ceramics obtained by microwave and conventional sintering is insignificant.

In view of these different opinions, one can suggest that the effect of microwave treatment on the sintering processes depends appreciably on the chemical nature of the sample, in particular, the type of conduction. On the one hand, microwave and thermal sintering of dielectrics and substances with considerable electronic conduction almost do not differ, but on the other hand, the rate of compaction of clear-cut ionic or hole conductors is much higher in a microwave field.

On passing to more complex processes, namely, to the synthesis of individual oxides by decomposition of salts or hydroxides, it is much more difficult to control the absorption properties of the sample and to identify the effect of microwave radiation on the processes. During the synthesis of individual oxides, microwave radiation is mainly used in order to obtain more uniform grain-size composition of the resulting powders and a smaller average particle size. A few papers are devoted to the synthesis of oxide particles with a controlled habit. For example, star-like Cu_2O particles were prepared by microwave-assisted treatment of a copper sulfate solution with sodium hydroxide in the presence of a complex composition containing a surfactant and ascorbic acid as the reducing agent.⁷⁰ Well crystallised copper oxide was prepared by hydrolysis at 95 °C. On the basis of these results, it was concluded that the particle size distribution and habit depend appreciably on the method of heating and on the concentration of a copper sulfate solution. Conventional heating gives rise to cubic copper(I) oxide crystallites with a rather broad size distribution. The use of microwave heating results in practically monosized star-like crystallites. An increase in the concentration of the starting solution of copper sulfate in both cases resulted in particles with a nearly spherical habit. This was attributed to enhancement of the homogeneous nucleation in the case of microwave heating, which suppresses secondary nucleation and promotes fast uniform growth of the nuclei.

The synthesis of zirconia powders by hydrolysis of aqueous ethanolic solutions of zirconyl chloride under microwave treat-

ment has been described.^{71, 72} The uniform heating of the whole bulk of the solution in the microwave field afforded ZrO_2 powders with spherical particles having a monomodal size distribution. It is of interest that, as in the study of Fetter *et al.*,⁷³ microwave heating resulted only in the tetragonal ZrO_2 modification. However, in another study,⁷⁴ the monoclinic modification formed under similar conditions.

Nanocrystalline tin(IV) oxide⁷⁵ and SnCl_2 –graphite composites⁷⁶ were synthesised by hydrolysis of a saturated solution of tin(IV) chloride. The authors emphasised that tin oxide prepared by these procedures is formed in the nanocrystalline state only when microwave heating is used. In their opinion, this is due to acceleration of the olation–oxolation processes in amorphous precipitates under microwave treatment and also to the fact that owing to the uniform heat supply, nucleation predominates over the growth of nuclei.

The synthesis of NiO , ZrO_2 and CeO_2 powders by microwave-assisted hydrolysis of aqueous solutions of the corresponding metal salts in the presence of urea has been described.⁷⁷ It was shown that uniform heat supply to the heated solution produces oxide powders with spherical particles with a narrower size distribution compared to powders obtained by hydrolysis with conventional heating (Fig. 8).

Figure 8. Microphotographs of ZrO_2 powders synthesised by hydrolysis of an aqueous ethanolic solution of zirconyl chloride in a microwave oven (a) and in a conventional furnace (b).⁷⁷

Spatz *et al.*⁷⁸ prepared titanium dioxide nanoparticles from solutions of various titanium alkoxides in reverse micelles of polymeric molecules (Fig. 9 a). It was shown that the sharp decrease in the duration of the synthesis and selective heating of a microquantity of a titanium alkoxide solution inside the micelle allows one to avoid evaporation of HCl , which stabilises micelles, and thus prevent aggregation of TiO_2 nanoparticles in a polymeric matrix (Fig. 9 b).

In recent years, publications dealing with the synthesis of various nanodispersed materials by ‘soft chemistry’ techniques

Figure 9. Microphotograph of titanium nanoparticle images in a polymer matrix synthesised in a conventional furnace (a) and a microwave oven (b).⁷⁸

using microwave treatment have appeared more and more often. Many of these publications are devoted to the synthesis of various sulfides and nitrides,^{79–85} but some works deal with the synthesis of nanosized oxides. For example, copper(II)-oxide-based nanostructures have been synthesised.^{86,87} The micromorphology of the obtained powders was shown to be substantially affected by the chemical nature of the initial compounds and the surfactant concentration. For example, hydrolysis of copper acetate in the presence of poly(ethylene glycol) affords virtually isotropic highly aggregated CuO particles, while hydrolysis of an aqueous solution of CuCl₂ in the presence of 1-*n*-butyl-3-methylimidazole tetrafluoroborate yields slightly aggregated nanowhiskers and nanoplates with a narrow size distribution. Note that by using microwave radiation, it is possible to increase substantially the rate of synthesis and increase the degree of crystallinity of the products.

High-temperature hydrolysis of an aqueous iron chloride solution in the presence of poly(ethylene glycol) and urea as the precipitating agent gave an Fe₂O₃ powder with a particle size of 3–5 nm.⁸⁸ However, despite the presence of a surfactant in the solution, powder particles were highly aggregated as shown by transmission electron microscopy. The results of magnetic measurements showed that, as expected, iron oxide nanoparticles occurred in the superparamagnetic state. During annealing at 400 °C, the oxide was crystallised to give α-Fe₂O₃; this was accompanied by an increase in the particle size to 30–40 nm. The researchers discussed the possible mechanism of formation of iron oxide upon high-temperature hydrolysis. According to calorimetric data, the following reaction takes place as an intermediate stage of the process

More uniform heating of the solution exposed to microwave radiation favours the formation of a large number of hydrated oxide nuclei.

The synthesis of nanocrystalline SnO has been reported.⁸⁹ Hydrolysis of an aqueous solution of tin(II) chloride in the presence of ammonia as a precipitating agent afforded tin oxide powders with an average particle size of 30 nm and a specific surface area of ~40 m² g⁻¹. It is of interest that unlike usual heating, microwave heating almost does not induce the oxidation of Sn²⁺ ions to Sn⁴⁺. This was attributed to the fact that, as shown by additional experiments, tin(II) oxide absorbs microwave radiation much more intensively than tin(IV) oxide. The researchers also noted that it was impossible to establish the exact mechanism of the specific ‘non-thermal’ microwave radiation effect in this experiment. The study cited⁸⁹ is a rare example of successful use of the above-discussed change in the absorption capacity of the system upon the change in its phase or component composition.

The synthesis of nanocrystalline SnO₂ by hydrolysis of an aqueous solution of tin(IV) chloride in the presence of urea has been described.⁹⁰ Highly aggregated powders with a crystallite size of ~3 nm were obtained. During the subsequent annealing of these powders, regular particle coarsening and coalescence take place up to micron-size aggregates. The advantage of using microwave radiation is reduced in this case to an increase in the hydrolysis rate.

The synthesis of Mg(OH)₂ nanofibres by hydrolysis of a solution of magnesium hydroxide with a highly dilute aqueous solution of sodium hydroxide supplied through a semipermeable membrane has been reported.⁹¹ Microwave radiation with a relatively low power (20 W) was used and hydrolysis took place at room temperature over a period of 5 days. Owing to these mild conditions, well crystallised magnesium hydroxide powder with 100–150 nm-long and 20–40 nm-thick nanofibre-shaped particles was obtained. The control experiments carried out under similar conditions without microwave heating gave virtually isotropic crystallites with a broad size distribution. Unfortunately, the authors⁹¹ did not discuss the possible mechanism of action of microwave radiation on the crystallisation and the growth of crystallites in this system.

Analysis of the effect of the crystal structure of reactants and the phase composition of the reaction mixture on the intensity of absorption of microwave radiation has been reported.⁹² The author was able to establish the relationship between the crystal structure and absorption capacity of various modifications of Al₂O₃. In particular, it was shown that, owing to the presence of structure-bound water molecules in the mullite-like modification of alumina formed upon hydrolysis of aluminium salts in the presence of alkali metal ions, this compound absorbs microwave radiation much better than α-Al₂O₃ (this oxide is almost transparent for microwave radiation; therefore, it is used for heat insulation of samples during microwave heating). Using this effect, it was possible to perform one-stage synthesis and sintering of β-Al₂O₃-based ceramics without additives that absorb microwave radiation, which are usually added for microwave sintering of alumina-based ceramics.

Microwave heating is also successfully used for sol–gel processes. Thus microwave-induced crystallisation of the SiO₂–TiO₂ xerogel gave⁹³ the phase TS-1 used as a molecular sieve. Crystallisation was shown to proceed at a much higher rate than crystallisation induced by conventional heating (Fig. 10) and the microstructure and the catalytic properties of the product were not inferior to the properties of samples synthesised with conventional heating.

Figure 10. Crystallinity of the TS-1 sample vs. residence time in a microwave oven (1) and a conventional furnace (2).⁹³

The sol–gel synthesis of zirconia-based catalyst powders with copper oxide dispersed over the surface has been reported.⁷³ The effect of pH and the duration of microwave heating on the micromorphology and the catalytic activity of the synthesised powders was established. Upon conventional heating during the sol–gel process, particles of tetragonal ZrO_2 are formed only in the pH range from 3–4 to 13–14, while in the case of microwave heating, these particles are formed irrespective of the pH of hydrolysis of the zirconium *n*-butoxide solution. Unfortunately, the authors offered no interpretation for this finding. Note that the above result⁷³ is at variance with the generally accepted view stating that diffusion processes are intensified in the microwave field, because this field eliminates the kinetic and diffusion hindrance to the metastable modification–stable modification transition. It was also shown that the use of microwave heating results in a more even distribution of copper oxide over the ZrO_2 surface, which in turn results in an increase in the catalyst acidity.

Several papers^{94–96} devoted to the synthesis of highly dispersed cerium dioxide-based catalyst powders using microwave heating have been published. The first of the cited publications represents an attempt to use microwave and ultrasonic treatment for the targeted formation of the micromorphology of cerium dioxide powders prepared by hydrolysis of aqueous solutions of $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$ in the presence of surfactants. As in the studies cited above,^{89–91} microwave-induced high-temperature hydrolysis yielded spherical oxide particles with a rather narrow size distribution. The average particle size was 2–3 nm. Analysis of electron diffraction data showed that the powders were composed of well-crystallised cubic CeO_2 phase. The specific surface area measured by the low-temperature nitrogen adsorption technique was equal to 200–250 $\text{m}^2 \text{g}^{-1}$. Powders with approximately the same micromorphology were synthesised using ultrasonic treatment with conventional heating. The width of the band gap in the resulting nanopowders was 5.5 and 4.1 eV for samples synthesised with ultrasonic and microwave radiation, respectively; that of coarsely crystalline cerium dioxide is 3.19 eV. It is worth noting that the widths of the band gap in the samples with approximately equal average particle sizes obtained by different methods are essentially different. This was attributed⁹⁴ to activation of the surface of particles formed under the action of ultrasound caused by the collapse of cavitation bubbles and formation of microstreams during the sonochemical treatment. The key drawback of this procedure is inevitable contamination of the surface of oxide particles by the surfactant, which would obviously have an adverse influence on the catalytic activity of cerium dioxide.

Solid solutions based on cerium dioxide with partial substitution of zirconium and samarium atoms for cerium were synthesised by thermal and microwave-assisted decomposition of the corresponding nitrates mixed with urea,⁹⁵ glycine, alanine and citric acid.⁹⁶ Presumably, the mechanism of this process is similar to the mechanism of SHS synthesis where metal nitrates act as internal oxidants and urea is the reducing agent. As expected, the oxide particles formed had an order of magnitude greater average size than the particles obtained by Wang *et al.*⁹⁴ (according to X-ray diffraction data, the average particle size was 10–20 nm and the specific surface area was 40–60 $\text{m}^2 \text{g}^{-1}$). An increase in the rate of formation of the oxide phase under microwave radiation was noted.^{95,96} In addition, the effect of the chemical nature of the internal reducing agent on the micromorphology of the oxide powders formed was analysed.⁹⁶ It was noted that the use of citric acid markedly decreases the average particle size (to 6–8 nm); unfortunately, this result was not interpreted.

Hydrothermal synthesis deserves particular attention as an application of microwave radiation in inorganic chemistry. Microwave heating was used for the hydrothermal process to

prepare nanocrystalline strontium, barium and lead titanate, zirconate and niobate powders possessing piezoelectric properties,^{97–99} zinc, nickel and manganese ferrites,¹⁰⁰ various ferrates and bismuthates,^{101,102} layered double hydroxides,¹⁰³ zeolites and molecular sieves^{104–106} and metal powders.¹⁰⁷

As advantages of the microwave-assisted hydrothermal synthesis, most of the cited authors list high rates of phase formation and processes in a microwave field caused by both heat supply features and the possible acceleration of nucleation due to ‘non-thermal’ effects. Thus an order of magnitude higher rate of formation of LiMnO_2 under microwave heating of hydrothermal solutions of lithium hydroxide and $\text{Mn}(\text{O})\text{OH}$ with respect to conventional hydrothermal synthesis has been noted.¹⁰⁸ It was shown¹⁰⁹ that by varying the duration of microwave action, one can control the morphology of the resulting powders. In addition, some hydrothermal processes carried out with microwave heating gave new phases that could not be obtained by conventional methods. For example, titanium and tin phosphates were first synthesised in this way.¹⁰⁶

A promising trend in the use of microwave action is the combination with the sol–gel process. The uniformity and high rate of microwave heating favour fast decomposition of the gel with the formation of powders with narrow particle size distributions. For example, barium molybdate was prepared by precipitation of citrate gels followed by thermal and microwave-induced decomposition.¹¹⁰

The effect of parameters of microwave radiation on the synthesis of layered double hydroxides with hydrotalcite structure by co-precipitation from aqueous solutions of nitrates followed by microwave treatment of the resulting gels has been studied.¹¹¹ The authors were able to prepare layered magnesium aluminium double hydroxides with different cation ratios. For this purpose, they varied the duration and power of microwave action. It was found that the use of microwave heating increases the gel crystallisation rate, which is in line with the assumption of intensification of diffusion processes in a microwave field. Interestingly, the variation of the microwave power is accompanied by parallel variation of the cationic composition. As the power of microwave radiation (W) increases, the Mg : Al ratio in the final product approaches the rated one.[§]

W/W	200	400	600
Mg : Al	5.53	4.54	3.62

This fact was attributed to different diffusion mobility of ions. The researchers also noted¹¹¹ that an increase in the power and duration of microwave heating induces the formation of powders with smaller uniform particles.

The synthesis of LiCoO_2 and $\text{Li}_2\text{Mn}_2\text{O}_{4+\delta}$ powders (used for the preparation of cathode materials) from mixtures of lithium hydroxide hydrate with cobalt (Co_3O_4) and manganese (MnO_2) oxides has been described.^{112,113} It was noted that as regards the particle size and shape, the products of microwave synthesis do not differ much from the powder particles prepared by conventional heating at the same temperature. In both cases, the powder morphology is determined by the morphology of the starting oxides (Fig. 11).

The microwave heating of co-precipitated nickel and aluminium hydroxides was used to prepare nickel aluminate.¹¹⁴ The microwave-induced decomposition of hydroxides yields a single-phase porous nickel aluminate consisting of finely dispersed particles. The attempt to prepare nickel aluminate from gels obtained by hydrolysis of aluminium alkoxide in the presence of nickel nitrate failed: according to

§ The rated ratio of magnesium to aluminium cations is 3.

Figure 11. Photomicrographs of initial MnO_2 powder (a) and $\text{Li}_2\text{Mn}_2\text{O}_{4+\delta}$ powder synthesised in a microwave oven (b).¹¹³

IR spectroscopic data, the amorphous intermediate formed upon microwave heating of the gel contained a lot of nitrate ions. Unfortunately, no explanation for the difference between the mechanisms of interaction of various initial mixtures with the microwave field is given in the paper.

Nickel aluminate was synthesised by microwave-assisted decomposition of co-precipitated hydroxides.¹¹⁵ Despite the fairly long microwave treatment of the mixture, the final product was rather poorly crystallised, which is unusual for microwave heating.

The solid-phase reactions between substances that poorly absorb microwave radiation at room temperature are often carried out, like sintering, using the so-called 'hybrid' microwave heating, which implies addition, to the reaction mixture, of a compound that actively absorbs microwave radiation and provides the primary heating of samples. Amorphous carbon or graphite, silicon carbide, copper(I) and copper(II) oxides, MnO_2 , MoSi_2 , etc. are normally used as such additives. Two methods are used most often to introduce the additive, namely, mixing of reactant powders with the powdered absorbing substance and placing the sample into a container made of the absorbing material. Both methods have advantages and drawbacks. Mixing of the reactants with the absorbing additive ensures faster and more uniform heating of the sample; however, there is a risk of contamination of the final product. Placing of the sample into an absorbing container, although decreases the probability of formation of by-products, actually levels-off all the advantages of microwave heating, because in this case, as during of conventional heating, heat is mainly supplied to the sample from the container walls.

Despite these drawbacks, the 'hybrid' microwave heating procedure has found wide use and was employed to synthesise numerous oxide compounds. For example, magnesium aluminate with the spinel structure was prepared by solid-phase reaction of aluminium hydroxide and magnesium oxide in the presence of carbon.¹¹⁶ The optimal amount of the absorbing additive (50 mass %) was found and the micromorphologies and sintering characteristics of powders obtained by microwave and conventional heating were compared. It was shown that the use of microwave heating not only markedly reduces the duration of synthesis but also results in the formation of powders with higher sintering ability. The same method was used to prepare Sr_2CeO_4 ,¹¹⁷ $\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.83}\text{Mg}_{0.17}\text{O}_{3-x}$ (Ref. 118) and $\text{Li}_{0.35}\text{La}_{0.55}\text{TiO}_3$.¹¹⁹ In all studies, appreciable acceleration of the solid-phase synthesis upon the use of microwave treatment was noted.

Solid-phase synthesis of a number of niobates and titanates from oxides and salts in the presence of graphite to absorb microwave radiation was carried out.¹²⁰ It was noted that the use of microwave heating reduces the duration of synthesis of these compounds by 1–2 orders of magnitude. This pronounced acceleration of a solid-phase reaction can hardly be attributed to high uniformity and rate of microwave heating

alone; however, researchers¹²⁰ did not make any assumptions on this issue.

If a component of the reaction mixture actively absorbs microwave radiation at room temperature, the reaction can be carried out without an absorbing additive. However, it should be noted that the reactants and products have different absorption capacities, which gives rise to local temperature differentials in the system. This effect was studied in detail¹²¹ in relation to the solid-phase synthesis of barium and yttrium ferrites and nickel aluminate from the corresponding oxides. Each reaction mixture consisted of an oxide efficiently absorbing microwave radiation and a weakly absorbing material (Fe_3O_4 and BaCO_3 , Fe_3O_4 and Y_2O_3 , NiO and Al_2O_3 , respectively). In the researchers' opinion,¹²¹ the particles of highly absorbing oxides functioned as heat sources in the microwave field, while weakly absorbing particles were heat receivers. A permanent temperature gradient was established in the reaction area, which, in turn, resulted in redirection of diffusion fluxes during the solid-phase interaction. Control experiments with the Y_2O_3 and Fe_3O_4 diffusion pair have shown, first, that the difference between the reactant temperatures reaches, in the limiting case, 400 °C, and, second, the diffusion flux is inverted with respect to that observed with conventional heating, in particular, iron ions diffuse in yttrium oxide. It is not quite clear what makes the authors confident that in the case of conventional heating, yttrium ions diffuse into the Fe_3O_4 structure. (In a study¹²² dealing with the mechanism of ferrite formation under conventional heating, diffusion of iron ions into yttrium oxide is considered to be the predominant process.) Nevertheless, this study is of interest for elucidation of specific effects of microwave heating during solid-phase reactions. The diffusion flux is directed from the higher-temperature region to the 'cold' region. If the reaction product actively absorbs microwave radiation, this additionally intensifies the subsequent interaction. The substantial acceleration of solid-phase reactions under microwave treatment observed by many researchers was attributed to this fact.

It is quite probable that the temperature gradient formed during microwave heating of the reaction mixture between reactants with different absorption capacity has actually a considerable effect on the course of reactions, because most data on the acceleration of solid-phase processes concern systems containing both highly and poorly absorbing components. These processes include the preparation of alkali and alkaline-earth metal and lanthanide ferrites, manganites, cobaltites, vanadates, molybdates and cuprates. Uematsu *et al.*¹²³ synthesised Eu^{3+} -doped yttrium vanadate from the corresponding oxides. They also studied the dynamics of absorption of microwave radiation by the reaction mixture depending on the dielectric properties and conductivity of the reactants and the products. It was found that yttrium and europium oxides, like yttrium vanadate, poorly absorb microwave radiation, whereas vanadium oxide intensively absorbs microwave radiation even at low temperatures. After completion of the synthesis, temperature sharply drops, apparently, due to the disappearance of highly absorbing vanadium oxide from the reaction mixture. The authors recommended the use of microwave heating for performing solid-phase processes in which the reactants efficiently absorb microwave radiation, while the products, conversely, are transparent for microwaves.

Yet another approach to the investigation of the mechanisms of solid-phase interactions during microwave heating has been developed¹²⁴ in relation to the kinetics of the reaction between barium carbonate and titanium dioxide under quasi-polythermal conditions (samples were heated as fast as possible to different temperatures and quenched and then the reaction mixtures were analysed quantitatively by powder X-ray diffraction). Using kinetic data, the activation energy of the solid-

phase interaction was calculated in terms of the diffusion model proposed in another publication.¹²⁵ The activation energy of the solid-phase reaction was found to be almost 4 times lower in a microwave field than with conventional heating. The authors noted that this result attests in favour of the intensification of the surface diffusion by the electromagnetic field rather than in favour of the vacancy jump mechanism considered by Katz *et al.*,⁶⁶ as in this case, one would rather expect a change in the pre-exponential factor in the Arrhenius equation but not the activation energy for diffusion.

Solid-phase synthesis of lanthanide chromite and sodium cobaltite with partial replacement of cobalt ions by manganese ions from the corresponding oxides was carried out.^{126, 127} The researchers used a microwave system operating at 28 GHz, which, as they believed, ensured more uniform distribution of the electromagnetic field strength within the sample bulk. It was found that the synthesis of lanthanum chromite with microwave heating can be carried out at 450 °C, which is much lower than that required with conventional heating (about 1200 °C). Measurement of the sample temperature during the process showed that the temperature increases in the first stage (less than 4 min) and then remains constant throughout the whole synthesis. Note that the change in the microwave power from 0.3 to 1 kW does not affect significantly the 'saturation' temperature. Apparently, this temperature is determined by the absorption capacity of components of the reaction mixture and the intensity of heat removal from the sample surface. The latter conclusion contradicts other data,¹²¹ because the sample composition changes appreciably during microwave heating. It cannot be ruled out that these discrepancies are caused by the higher absorption capacity of lanthanum chromite compared with yttrium vanadate.

It is of interest to compare these data with the results of another work¹²⁸ in which lanthanum chromite, cobaltite and nickelate were also synthesised from oxides but in the presence of an absorbing additive (graphite). The temperature substantially increased during the synthesis (to 1100–1200 °C) and the duration of synthesis of the single-phase product was markedly reduced (to 5 min). Thus, the introduction of the absorbing additive was justified in this case.

The $\text{SrFeCo}_{0.5}\text{O}_y$ phase with a mixed conduction type used for the design of solid-state fuel cells was prepared by 'hybrid' microwave heating with SiC as the absorbing additive.¹²⁹ A powder with a narrow particle size distribution and high sintering ability was produced using this procedure.

In the synthesis of complex oxide compounds from salts, it is even more difficult to identify the specific microwave effect, as the number of processes influencing the absorption of microwave radiation by the reaction mixture increases. No studies devoted to the effect of the phase composition of such systems on the absorption of microwave radiation have been published. Most of researchers only state the fact of considerable increase in the reaction rates in the microwave field and make no attempts to determine the reaction mechanisms.

A procedure for the synthesis of a broad range of oxide compounds including individual manganese, iron, cobalt and copper oxides, multicomponent ferrites, manganites and cobaltites based on microwave heating of the corresponding nitrates has been developed.^{130–137} It was shown, that using microwave heating, it is possible not only to shorten the time of synthesis of multicomponent oxide products with various crystal structures, but also, in most cases, to substantially decrease the temperature of synthesis. The latter apparently indicates that microwave heating intensifies the diffusion owing to the appearance of circulating ionic currents on the crystallite surface ('non-thermal' action). The oxide phases synthesised with microwave heating were not inferior in

performance properties to the control samples produced by conventional thermal treatment.

The synthesis of phases based on lanthanum chromite from the corresponding nitrates has been described.^{138, 139} A considerable decrease in the time of synthesis and more uniform micromorphology of the resulting powders upon the use of microwave treatment were noted; in the authors' opinion, this was a consequence of a high uniformity of heat supply favourable for fast formation and even distribution of the oxide phase nuclei.

A method for the synthesis of a powdered MnCo_2O_4 -based catalyst by microwave decomposition of the corresponding nitrates has been developed.^{140, 141} The introduction of some amorphous carbon to the reaction mixture (5 mass % – 30 mass %) with a high specific surface area resulted in a higher rate of formation of the final product and a higher catalytic activity, probably, due to greater surface area. Analysis of the dependence of the specific surface area of the oxide powder on the carbon content demonstrated that after some limiting value has been reached, further increase in the carbon content in the initial mixture does not affect the specific surface area of the oxide powder. Unfortunately, the authors did not analyse the mechanism of microwave action on the reactions and the micromorphology of the final product.

Quite a few papers are devoted to the synthesis of various lithium-containing oxide compounds used as cathodes in lithium rechargeable batteries. The vast majority of these publications deal with the synthesis of materials based on the LiMn_2O_4 phase, which is considered to be most promising for lithium batteries. Nakayama *et al.*¹⁴² compared two procedures of microwave-assisted synthesis of the LiMn_2O_4 phase, *viz.*, decomposition of a mixture of the corresponding nitrates and a mixture of Mn_2O_3 , $\text{LiOH} \cdot \text{H}_2\text{O}$ and copper oxide as the absorbing additive. The former method was preferred, because a single-phase product was formed over a shorter period of time and no LiMnO_2 impurity phase was present. This was attributed to faster attainment of thermal equilibrium in the case of liquid-phase synthesis and to 'non-thermal' effects of microwave heating, which are more pronounced in the absence of an absorbing additive.

Detailed analysis of the effect of the chemical nature of the starting compounds on the course of the reactions in a microwave field has been carried out¹⁴³ using the synthesis of lithium nickelate as an example. Lithium carbonate and hydroxide and nickel hydrocarbonate, hydroxide and oxide in various combinations served as the reactants. Note that the use of microwave treatment markedly reduced the temperature of formation of lithium nickelate. However, in all cases, microwave heating was followed by additional annealing of the sample in a conventional furnace in an oxygen stream in order to obtain a single-phase product. In the authors' opinion, a mixture of hydroxides is the best choice for the synthesis of LiNiO_2 , as in this case slightly aggregated powders with a narrow particle size distribution were produced.

A series of publications^{144–148} report the efficiency of the synthesis of complex ferrites and manganites by microwave-assisted decomposition of nitrate mixtures in the presence of urea. The large volume of gases evolved upon decomposition of nitrates and urea favours deaggregation of the oxide powders. Despite the abundant factual data, the authors unfortunately did not consider the relationship between the microwave treatment conditions and the composition, on the one hand, and the morphology of final products, on the other hand.

A rational approach to the choice of the starting compounds for the microwave-assisted synthesis has been reported.¹⁴⁹ The $\text{La}_{0.7}\text{Ba}_{0.3}\text{MnO}_3$ phase possessing giant magnetoresistance (Fig. 12) was prepared by microwave-induced decomposition of a mixture of metal nitrates. The authors

Figure 12. Temperature dependences of the magnetic properties of the ceramics based on the $\text{La}_{0.7}\text{Ba}_{0.3}\text{MnO}_3$ phase synthesised in a microwave field.¹⁴⁹

(1) $T_p = 307\text{ K}$; (2) $H = 0.5\text{ T}$, $T_c = 318\text{ K}$.

substantiated the choice of nitrates as precursors by a large dipole moment of the nitrate ion, which should actively interact with the microwave field. In addition, nitrates readily melt in their water of crystallisation, and aqueous solutions always absorb efficiently microwave radiation. Additional heat is evolved, in the authors' opinion, upon the oxidation of manganese(II), which takes place during decomposition of manganese nitrate. Heat evolution upon oxidation is the main reason why heating does not stop after removal of water from the solution but continues up to decomposition of the precursors to give the oxide phase. It was also found¹⁴⁹ that apart from the substantial decrease in the time of synthesis, the powders obtained by microwave-assisted decomposition of a nitrate mixture have a better microstructure than the powders synthesised by the ceramic technique. It was shown that the properties of ceramics produced using the obtained powders are not inferior to the properties of samples synthesised by the traditional techniques.

In the publications^{147,150} devoted to the synthesis of ferrites $\text{Ni}_{0.25}\text{Cu}_{0.25}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$ and $\text{SrFe}_{12}\text{O}_{24}$ by pyrolysis of a metal nitrate mixture in the presence of urea, a modification of the procedure considered above was proposed. The reaction of metal nitrates and urea at elevated temperatures is accompanied by evolution of a gas mixture (NH_3 , HNCO , O_2 and NO), which spontaneously ignites after a particular critical temperature has been reached and heats the mixture of solid reaction products to 1000°C or higher. This process lasts for 10–15 min and is accompanied by the formation of single-phase powders of the corresponding ferrites. The microstructure of the synthesised powders is characterised by a loose framework composed of 3- to 6- μm aggregates. The formation of such structures is typical of pyrolysis of salts. Despite the high reaction temperature, the primary crystallites are rather small (50–75 nm) (Fig. 13), which is probably due to high rate of the process. The subsequent annealing of the synthesised samples results in a regular enlargement of particles upon recrystallisation. By correct adjustment of the temperature of the subsequent annealing of the powders, it is possible to reach saturation magnetisations and coercive forces that are rather

Figure 13. Transmission electron microscopy image (a) and electron diffraction pattern (b) for the particles of the $\text{Ni}_{0.25}\text{Cu}_{0.25}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$ sample prepared in a microwave field.¹⁵⁰

high for this type of ferrite systems (Fig. 14). Unfortunately, the authors did not compare the properties of samples prepared by microwave-assisted decomposition of a salt mixture with those treated in a conventional furnace; therefore, it is difficult to make conclusions about the advantages of microwave heating. In addition, analysis of the publication¹⁴⁹ casts doubt on the necessity of addition of urea for decomposition of a nitrate mixture in a microwave field.

Figure 14. Saturation magnetisation (M_s) and coercive force (H_c) for $\text{Ni}_{0.25}\text{Cu}_{0.25}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$ samples synthesised in a microwave field vs. temperature of their subsequent heat treatment.¹⁵⁰

The synthesis of layered aluminium and zinc double hydroxides with intercalated sodium dodecyl sulfate molecules has been reported.¹⁵¹ Crystallisation in the microwave field proceeded much faster than that with the use of conventional heating (1–2 h instead of 2–3 days). In addition, crystallisation induced by microwave heating enhances the intercalation of the organic anion into the hydroxide matrix, and thus the starting concentration of sodium dodecyl sulfate can be reduced. The product consists of smaller crystallites with a narrower size distribution than the sample prepared by the conventional heating.

The results of synthesis of the ferrite $\text{Co}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ ($0 \leq x \leq 0.8$) by precipitation of hydroxides from solutions of the corresponding salts by a solution of KOH in ethylene glycol under microwave treatment followed by separation of the precipitate and annealing at a temperature above 500°C have been reported.¹⁵² The influence of the solution pH and the duration of boiling on the micromorphology of the resulting powders has been studied. It was shown that with an increase in

the pH, the particle size of the powder increases and the degree of agglomeration simultaneously decreases. The addition of ethylene glycol to the solution led to a decrease in agglomeration of the powders.

High-temperature solvolysis of solutions of barium, lead, titanium and zirconium salts in ethylene glycol gave the double oxides BaTiO_3 , BaZrO_3 , PbTiO_3 and $\text{Ba}_6\text{Ti}_{17}\text{O}_{40}$ in the nanocrystalline state.¹⁵³ A specific feature of the synthesis is that the use of ethylene glycol, which functions simultaneously as a solvent, a complexing agent and a surfactant, allows one to vary the powder composition and morphology over a broad range. Note that with the use of microwave heating, it is possible to eliminate a key drawback of the synthesis of oxide phases from solutions in ethylene glycol, *i.e.*, the low reaction rate.

V. Conclusion

The range of physicochemical problems solved successfully by means of microwave radiation is exceptionally broad. This review covers only a small portion mainly related to the synthesis of oxide materials. Not only studies dealing with the synthesis of sulfides,^{80–84} nitrides,^{50, 154} selenides¹⁵⁵ or silicides,¹⁵⁶ but also the applications of microwave treatment such as organic synthesis,^{4, 7, 157–159} analytical chemistry^{4, 160–162} and so on remained beyond the scope of the review. Each of these fields deserves separate consideration and comprises an extended subject matter.

Nevertheless, a general problem should be considered, namely, the possibility to control the processes taking place during microwave treatment of chemical systems, and a closely related problem of evaluating the efficiency of microwave treatment.

Evidently, a satisfactory solution to this problem can now be obtained only for the microwave heating of very simple, more precisely, single-phase systems the physicochemical state of which is not changed much during heating. A good example of such process is the preparation of dense ceramics by sintering of compacted powders, because only the sample morphology is changed most often during compaction, which undoubtedly affects the absorption capacity but this effect is slight and can be taken into account. Similar conditions exist during solution treatment, because these processes usually take place in a rather narrow temperature range and the physicochemical properties of the system do not change much. This range can be supplemented by reactions in inert matrices the specific features of which caused by microwave heating have been poorly studied. In the case of multicomponent systems, it is rather difficult to control the results of microwave treatment due to the large number of processes taking place simultaneously, each affecting significantly the absorption capacity of the whole system. The only practicable way is to accumulate the empirical information on the behaviour of various systems under microwave heating. This would provide an at least qualitative estimate for the efficiency of using such heating. Therefore, systematisation of the accumulated experimental data appears a topical task, which was fulfilled, to some extent, by this review.

Thus, to be able to control the microwave heating in the synthesis or sintering, one should choose systems with the smallest number of components or attain artificially a greater system uniformity by diluting it with an inert matrix or a 'buffer' component the absorption capacity of which depends slightly on the processes that take place. This type of microwave treatment has much in common with the above-mentioned 'hybrid' microwave heating; however, in this case, the added inert component not only enhances the absorption of radiation, but also allows one to control the microwave heating. Thus, the buffer medium should satisfy the same requirements,

namely, it should be chemically inert, absorb efficiently the microwave radiation and be easily separable from the synthesis products after heating has been completed. This route seems especially attractive, as in the future, it may be extended to a rather broad range of physicochemical processes.

This review was written with the financial support of the Russian Foundation for Basic Research (Project No. 06-03-33042), the programme 'Development of the Scientific Potential of Higher School' (government contract No. RNP 2.1.1.1205), the Complex Scientific Research Program of the RAS and the Foundation for the Support of Russian Science. The authors are grateful to Doctor of Science (Physics and Mathematics) V E Semenov for the assistance and valuable remarks made during preparation of the review and to the staff of the Laboratory of Chemical Synergetics of the Institute of General and Inorganic Chemistry of the RAS and the Laboratory of Inorganic Materials Science of the Department of Chemistry, Moscow State University, for fruitful discussion on the issue.

Abstract. The results of studies of composite ionic conductors are considered. The relationship between their properties and the ionic salt disordering and the interfacial interaction between the components of the material is analysed. Special attention is paid to models that describe the surface disordering and the mechanism of defect formation. The methods of calculation of physicochemical characteristics of composites, the thermodynamic stability and peculiarities of the genesis of the nanocomposite morphology are discussed. The bibliography includes 188 references.

I. Introduction

Ionics, *i.e.*, a science that studies ionic processes in systems and materials, is a comparatively new and rapidly progressing field of knowledge.^{1–3} Although it ranks much below electronics in the practical application, its role tends to increase. This is caused first of all by the demands for new and more efficient electrochemical systems for the accumulation and conversion of energy at a constant threat of the shortage of natural energy resources. This problem can be solved given a wide spectrum of electrolytes with different functional characteristics that can be adapted to the specific conditions of operation of various electrochemical systems. Solid electrolytes that exhibit high mechanical strength, thermal stability, unipolar ionic conductivity and can be used in chemical power sources, gas sensors and other electrochemical devices occupy a special place among these electrolytes.

Heterogeneous doping of ionic compounds with dispersed dielectrics that are chemically inert with respect to the ionic salt is known to enhance the conductivity in most cases. Composite solid electrolytes of the ionic salt–oxide (MX–A) type can be considered as a new class of ionic conductors with high ionic conductivity. The combination of high conductivity with the

enhanced mechanical strength together with the wide prospects for the targeted modification of the electrolyte properties by varying the type and concentration of the dopant makes these composites promising materials for real electrochemical systems. The composites LiI–Al₂O₃ synthesised by Liang in 1973 proved to be convenient solid electrolytes for chemical power sources.^{4,5} This achievement has triggered a scientific boom, and a large number of composite ionic conductors were studied in the subsequent years. Actually, doping with dispersed oxides was shown to enhance the conductivity of virtually all composites based on classical (non-superionic) ionic salts, *i.e.*, it is a general effect, which requires scientific explanation and theoretical substantiation.

There are several reviews devoted to the description and the analysis of the ion transport in polycrystalline and composite solid electrolytes.^{6–22} The increase in the ionic conductivity upon heterogeneous doping can be explained within the framework of the space charge model proposed by Wagner and Maier,^{6,7,9,10,12,13,15} which represents a version of the classical Frenkel's model.²³ This model allows the interpretation of many phenomena observed in composites and is the best suited for the explanation of experimental data for composites containing oxides with relatively coarse grains. However, the space charge model in its classical version is correct only for ideal crystals in contact with vacuum or a structure-free medium and obviously ignores the real features of the interphase contact, namely, changes in the structures of ionic crystals (*e.g.*, for epitaxial contacts), the effect of elastic strains, the formation of dislocations, *etc.* Moreover, if the surface concentration of defects is sufficiently high, it is impossible to ignore the interaction between the defects, which results in their ordering and the formation of superstructures and even metastable surface phases.

It is known that the conductivity of composites increases as the size of dopant particles increases. Hence, composites with nanosized grains (about 10 nm) are of particular interest for practice. Obviously, uniform mixing of such an oxide with an ionic component should produce a nanocomposite the properties of which strongly depend on the energy of surface interaction and the peculiarities of the interface between the phases. For composites with coarse-grained dopants, the presence of surfaces or interphase contacts has virtually no effect on the bulk properties of the ionic salt; hence, the

increase in the conductivity is of the purely surface nature. However, in many cases, it still remains unclear whether the enhanced conductivity is primarily caused by the specific interactions at the interface or by the trivial increase in the surface conductivity as such. To answer this question, information on the conductivity of polycrystals is necessary. In nanocomposites, an ionic salt is virtually totally located at the interface. This is why its structure and thermodynamic characteristics can substantially change. Particularly, for ionic compounds containing high-temperature disordered phases, the latter may prove to be stable at low temperatures in nanocomposites. Therefore, it is important to understand the thermodynamic reasons for the appearance of a disordered phase. To this end, it is necessary to elucidate how the thermodynamic parameters of crystals, particularly, the enthalpy and entropy of phase transitions are related to the lattice disorder.

In this review, the problems of thermodynamic stability of nanocomposites and the genesis of the composite morphology during its sintering are discussed; possible mechanisms of the interfacial interaction and the general trends for the changes in the ionic salt properties are analysed for a wide series of ionic salt – oxide systems; size effects and methods for the quantitative estimation of conductivity and other physicochemical characteristics of composites are considered.

II. General criteria for the choice of composite electrolytes with high ionic conductivity

Even in their first stage, the studies have revealed the following relationships typical of the composite solid electrolytes $\text{MX} - \text{A}$:^{6–8, 10–15}

- due to heterogeneous doping, a region of low-temperature conductivity with a lower activation energy (E_a) appears in the Arrhenius plots of conductivity in addition to the region of intrinsic conductivity (at high temperatures);

- in the low-temperature region, the concentration dependence of the conductivity has a maximum at a dopant concentration of 10 vol.% – 40 vol.%; in certain systems, the maximum is observed at lower dopant concentrations (1 vol.% – 10 vol.%);

- in the high-temperature region, the conductivity monotonously decreases with the increase in the dopant concentration; an analogous effect is observed in superionic phases;

- the conductivity of composites usually increases with the decrease in the size (L_A) of particles of the heterogeneous dopant or with the increase in its specific surface (S_A).

All composite solid electrolytes known can arbitrarily be divided into two groups:²⁴

(1) Composites $\text{MX} - \text{A}$ with the properties similar to those of polycrystals MX (e.g., $\text{LiI} - \text{Al}_2\text{O}_3$, $\text{AgCl} - \text{Al}_2\text{O}_3$, $\text{AgBr} - \text{Al}_2\text{O}_3$ and $\text{TlCl} - \text{Al}_2\text{O}_3$). In this case, the activation energy of the composite $\text{MX} - \text{A}$ is close to E_a of polycrystalline MX and virtually coincides with the enthalpy of migration of a cationic vacancy (E_{cv}) in the single crystal MX . This is an argument for the applicability of the space charge model for the explanation of the conductivity mechanism in composites.^{6–8, 10, 12–15}

(2) Composites with unusual properties. In certain composites, the physicochemical properties of ionic salts substantially differ from those of single-crystal and polycrystalline samples. The activation energy often substantially depends on the type and concentration of a fine-grain dopant and may far deviate from both E_{cv} and E_a . In certain cases, the observed deviations were apparently due to the insufficiently wide temperature ranges in which the conductivity was measured. However, the specific interaction between the composite components can also be a reason for the dramatic changes in the E_a values. For example, in composites $\text{AgI} - \text{Al}_2\text{O}_3$, the temperature of the

β - AgI phase transition into the superionic state was observed to decrease, which was accompanied by a decrease in the enthalpy of the phase transition.^{25, 26} For composites $\text{AgI} - \text{Fe}_2\text{O}_3$ both the changes in the parameters of the AgI phase transition and the increase in the Néel temperature for Fe_2O_3 were observed.²⁷ This suggests that the thermodynamic parameters of both bulk phases are different in composites. In certain composites, in addition to the conventional phases, new phases non-typical of pure ionic crystals were revealed.

These facts suggest that the interfacial interaction in composites may substantially affect the bulk physicochemical properties of the ionic component in a composite. However, so far, no systematic studies were carried out aimed at the synthesis of composites and the investigation of anomalous properties of the constituent ionic salts. The majority of studies were focused on the increase in the ionic conductivity. The theoretical models that describe the increase in the ionic conductivity are usually tested on quite different objects that usually exhibit no high conductivity.

Insofar as the thermodynamic parameters of ionic salts in composites can substantially change, it is important to study their relationship with the surface disordering. The deeper insight into the mechanism and thermodynamic peculiarities of the formation of defects in the crystal bulk, on its surface or on intergrain boundaries requires the knowledge of how the point defects affect the thermodynamic properties of crystals. One may consider the inverse problem, namely, judge on the degree of disordering of a solid based on the analysis of the thermodynamic data. The most distinct changes in vibrational spectra and the degree of disordering occur during the phase transitions and give rise to easily measurable changes in the entropy and enthalpy of a crystal. The presence of grain and phase boundaries affects the concentration of defects in a crystal and can lead to changes in the thermodynamic parameters of phase transitions. Thus, it is expected that the thermodynamic studies of phase transitions would provide information on the disordering of the ionic component in a composite.

In contrast to crystals in which the self-diffusion coefficients may differ by several orders of magnitude, the transport properties of melts are approximately the same for all substances. In this respect, the molten state is universal, most disordered, and the thermodynamic parameters of melting (or crystallisation) contain information on the degree of disordering of a crystal at the melting temperature. Hence, it is the correlations between the parameters of melting and the transport properties of solids that attract the prime interest. Elucidation of the factors responsible for melting allows one to get a clearer insight into the processes that occur in the transition of a substance into the superionic or orientationally disordered state in both pure crystals and ionic salts brought in contact with the surface of another phase.

It was shown^{28–33} that for a wide range of substances a linear correlation is observed between the enthalpy of melting (H_{melt}) and the enthalpy of formation of Schottky defects (h_0) (Fig. 1)

$$h_0 = \beta H_{\text{melt}}. \quad (1)$$

The ratio $h_0/H_{\text{melt}} = \beta = 8.6 \pm 0.6$ is independent of the type of the substance and remains unchanged in binary ionic substances, metals and molecular crystals. In contrast to the correlations such as $h_0 = aT_{\text{mp}}$, which are cited most often but are fulfilled for a limited range of substances, correlation (1) is more general. Within the framework of the phenomenological quasicrystalline model, the melting process can be presented as an abrupt increase in the mole fraction of point defects in a crystal (c) up to a certain critical value c_L followed by the relaxation of the structure around defects. In this approximation, the parameter β has a simple physical meaning and is defined as $\beta = 1/c_L$. The constancy of $c_L = 0.12 \pm 0.02$ for

Figure 1. Correlation between the enthalpy of melting (H_{melt}) and the enthalpy of formation (h_0) of the Schottky defects in crystals presented in (a) linear and (b) logarithmic scales.

substances with different types of interatomic interactions may be assumed as a characteristic feature of the liquid state. The relative changes in the volume upon melting ($\Delta V/V$) are associated with the volume of the defect formation v_0 (Ω is the molecular volume)

$$\frac{\Delta V}{V} = c_L \frac{v_0}{\Omega}.$$

This relationship was confirmed experimentally for metals and crystalline alkali metal halides (in this case, v_0 is the volume of formation of the Schottky defect).³³ Melting with the formation of the Schottky defects or the vacancy melting is always accompanied by an increase in the volume. Some substances (H_2O , Bi, Sb, Si, Ge, RbNO_3) melt with a decrease in their volumes. In this case, the melting apparently follows the interstitial mechanism, *i.e.*, involves the formation of Frenkel defects, the volume of formation of which (in contrast to the Schottky defects) can be negative.

If we assume that the vibrational frequencies of atoms or ions in a liquid are equal to those of atoms around a defect in a crystal, it is possible to assess the entropy of the defect formation (s_0) and the concentration of defects in crystals at the melting temperature (c_{mp}). The calculated s_0 and c_{mp} values agree sufficiently well with experimental data for metals and ionic crystals.^{34,35} Insofar as for metals and alkali metal halides, a linear correlation is observed between the enthalpy of defect formation and the enthalpy of migration, one can estimate the absolute magnitudes of the coefficients of self-diffusion or ionic conduction based on H_{melt} .^{28–30,36} The correlations mentioned can be found in the well-known reference book.³⁷

Superionic conductors form an unusual class of ionic conductors characterised by the high conductivity comparable with that of ionic melts and aqueous solutions. The equilibrium concentration of current carriers in superionic conductors is high and comparable with the total amount of mobile ions in the lattice, *i.e.*, h_0 is close to zero. Superionic conductors and ionic melts are known to exhibit common features, for example,

- a diffuse distribution of the ion density along the conduction channels, which is analogous to the broad radial distribution function of the same ions in melts;
- close values of ionic conductivity and, hence, only minor changes in the conductivity in the melting;
- substantial changes in the thermodynamic parameters of substances upon their transition into the superionic state, which are comparable in the magnitude with the corresponding effects in the melting.

High-temperature phases of AgI and Li_2SO_4 are typical examples of superionic conductors. On the qualitative level, a superionic conductor may be represented as a partly ordered system built of two sublattices, one of which is entirely ordered and forms a rigid frame and the other is strongly disordered and resembles a liquid phase that fills the frame. The expressions for the melting temperature, which were derived within the framework of the quasicrystalline model of melting are similar to those obtained by Gurevich for a ‘strong’ superionic transition.^{38–40} This similarity forms the basis for the prediction (if only on the qualitative level) of certain properties of superionic conductors. Apparently, the assumption that $c \approx 1$ is not true for superionic conductors. By analogy with melts, it can be expected that $c \approx c_L = 0.12$. Because no reliable methods were developed so far for the estimation of the defect concentration in superionic conductors, it remains unclear what is the concentration of defects in superionic phases.

An interesting class of ionic conductors is formed by the phases that contain orientationally disordered anions. Obviously, the orientational disordering should entail an increase in the free volume in crystals, which will favour the increase in the diffusion coefficients and in the ionic conductivity. Moreover, the of anion reorientation event may additionally facilitate the transfer of the neighbouring cation by the ‘paddle-wheel’ mechanism proposed by Lunden.⁴¹ The thermodynamic parameters of phase transitions are related to the extent of the crystal disorder at a temperature below the phase transition. This relationship manifests itself most clearly in a series of alkali metal nitrates for which a decrease in the enthalpy and entropy of melting is accompanied by an increase in the conductivity of high-temperature phases.^{24,42} Alkali metal nitrates form an unusual class of inorganic salts, being characterised by phase transitions with orientational disordering in the anionic sublattice.⁴³ Among the nitrates, rubidium nitrate has the lowest H_{melt} and demonstrates three phase transitions associated with the orientational disordering of NO_3^- ions.⁴² The thermodynamic data correlate well with the ionic conductivity, *i.e.*, rubidium nitrate exhibits the highest ionic conductivity in the series of nitrates⁴² and is promising for the development of ionic conductors with the high rubidium conductivity.⁴⁴ This is why, in this review, attention is focused on rubidium nitrate and composites on its basis.

In composites and, particularly, nanocomposites, the interfacial interaction affects the energy of an ionic crystal thus favouring the stabilisation of high-temperature disordered phases. The phase-transition temperature and enthalpy may serve as the convenient parameters that characterise the degree of disordering and the changes in the energy characteristics of a crystal in a composite. For this reason, compounds containing high-temperature superionic or orientationally disordered phases were chosen as the best candidates for the ionic salt component in the ionic salt – oxide composites.

III. Surface disordering of ionic crystals

Embarking on the discussion of the effect of heterophase additives, it is necessary to consider the possible mechanisms of disordering, *i.e.*, the formation of point defects on the free surface of an ionic crystal. It is known that in many cases the conductivity of polycrystalline samples exceeds that of single crystals. Hence, simple dispersion of an ionic crystal MX may be one of the reasons for the increase in its conductivity in composites. This is accompanied by the formation of a large number of free surfaces or grain boundaries MX–MX, which are characterised by the enhanced surface or intergrain conductivity. As a rule, the increase in the concentration of surface defects is associated with the formation of an electrical double layer in the near-surface region of a crystal.

Currently, the interpretation of surface phenomena in ionic crystals widely employs the Frenkel–Kliwer model.^{23, 45–48} This model was first proposed by Frenkel²³ and is based on the assumption that different types of defects can form separately and independently in the crystal bulk due to the difference in their chemical potentials. Frenkel assumed this to be associated with the appearance of an electrical potential in the crystal bulk, which may be considered as a contact potential drop in the crystal surface layer, caused by the difference in the energies of formation of positive and negative defects that appear on the surface.²³ Figure 2a illustrates the changes (in terms of the Frenkel model) in the energy parameters, the defect concentration and the electrical potential on going from the ionic crystal surface to its bulk. This model was analysed most comprehensively in the studies by Kliwer.^{47, 48}

Figure 2. Changes in the energy parameters (g), potential (ϕ) and defect concentration ($[V]$) on going from the surface to the bulk of an ionic crystal.

(a) The Frenkel model; the surface potential ϕ_s is equal to the potential difference between the surface (ϕ_0) and the bulk (ϕ_∞) of a crystal; (b) the Stern model; a case of a diffuse layer enriched with cationic vacancies is considered.

According to this model, the surface potential ϕ_s , *i.e.*, the potential difference between the surface and the bulk of an ionic crystal MX containing intrinsic Schottky defects is

$$e\phi_s = \frac{g_{vX} - g_{vM}}{2}, \quad (2)$$

where e is the electron charge, g_{vX} and g_{vM} are the partial energies of the formation of anionic and cationic vacancies in the crystal bulk the sum of which is equal to the energy of formation (g_0) of the Schottky defect. This expression is remarkable because it contains no characteristics directly related to the surface properties, namely, the quantities g_{vM} and g_{vX} (as well as g_0) are the bulk parameters of the substance; hence, the quantity ϕ_s should be a universal constant of a given substance. However, it is well known that the real surface properties are determined by several specific factors such as the crystal plane type, defects, adsorbed impurities, *etc.*, which casts doubt on the validity of the Frenkel–Kliwer model.

The surface potential can be calculated using a more realistic Stern model,⁴⁹ which implies that the physical properties of a crystal and all its components (native and foreign ions, point defects) on the surface differ from those in the bulk. Particularly, the energies of formation of individual defects on

the surface ($g_{vX})_s$, ($g_{vM})_s$ and the energy of the proper surface disordering $g_s = (g_{vX})_s + (g_{vM})_s$ will differ from the corresponding parameters in the crystal bulk. This difference is the reason for the adsorption (positive or negative) of defects on the crystal surface. If the adsorption energies of oppositely charged defects differ, the excessive defects with the most negative adsorption energies are concentrated on the surface, while the opposite-sign defects form a diffuse layer under the surface. Figure 2b shows the corresponding energy diagram and the distribution of defects in a crystal. According to the Stern model, the surface charge (Q_s) is defined as a sum of contributions of different defects each calculated based on the Langmuir isotherm

$$Q_s = N_s \sum_i q_i \left[1 + \frac{1}{x_i} \exp\left(\frac{\Delta g_i - q_i \phi_s}{kT}\right) \right]^{-1},$$

where N_s is the concentration of accessible surface sites (adsorption centres), q_i is the effective charge of defects, x_i is the mole fraction of defects in the crystal bulk, Δg_i is the adsorption energy of the i th defects (*i.e.*, the excess Gibbs energy of a crystal due to the transition of a defect of the i th kind from the crystal bulk to the surface), k is the Boltzmann constant, T is the absolute temperature; summation is carried out over all possible charged defects. The surface charge is compensated by the charge (Q_d) of a diffuse layer, which is formed under the crystal surface and described by the Gouy–Chapman equation for the diffuse layer charge

$$Q_d = A \left\{ \sum_i N_{0i} x_i \left[\exp\left(-\frac{q_i \phi_{s-1}}{kT}\right) - 1 \right] \right\}^{1/2},$$

where $A = (2\epsilon\epsilon_0 kT)^{1/2}$, ϵ is the dielectric permittivity, ϵ_0 is the dielectric constant; N_{0i} is the bulk concentration of the i th ions in the crystal; ϕ_{s-1} is the potential of the outer Helmholtz plane. The assumption that the surface charges are equal to the diffuse layer charge allows one to obtain a transcendental equation the solution of which gives the surface potential.

The analysis of solutions of this equation⁵⁰ showed that the form of the dependence $\phi_s(T)$ is entirely determined by the values of Δg_i , g_0 and N_s . For positive adsorption energies ($\Delta g^- > 0$, $\Delta g^+ > 0$, negative adsorption), the defect concentration on the crystal surface is lower than in its bulk. In this case, the surface charge and potential are close to zero. For negative adsorption energies of defects ($\Delta g^- < 0$, $\Delta g^+ < 0$, positive adsorption), the cationic and anionic vacancies are concentrated on the surface to form a negative (at $|\Delta g^-| > |\Delta g^+|$) or positive (at $|\Delta g^-| < |\Delta g^+|$) surface charge. Figure 3 shows the dependences of the surface potential on the temperature for a crystal of the NaCl type with the Schottky defects, which were calculated for fixed parameters $g_0 = 1.0$ eV, $\Delta g^- = -0.1$ eV and different values of Δg^+ ($\Delta g^+ < 0$). The analysis has shown that the form of $\phi_s(T)$ curves changes as follows depending on the ratio between g_0 and Δg^+ :

1. For small energies of defect adsorption ($|\Delta g^+| < g_0/4$; $\Delta g^+ < 0$), the quantity $\phi_s(T)$ increases monotonically with the temperature; at $T \rightarrow 0$, $\phi_s \rightarrow 0$ (Fig. 3a). Such a behaviour of the surface potential cannot be explained within the framework of the Frenkel–Kliwer model^{48, 49} and is described by the following approximate formula obtained⁵⁰ for the case of the low potentials $e\phi_s/kT \ll 1$:

$$\phi_s \approx \frac{2kT}{AN_0} N_s \left[\exp\left(-\frac{\Delta g^+}{kT}\right) - \exp\left(-\frac{\Delta g^-}{kT}\right) \right] \times \sqrt{N_0} \exp\left(-\frac{g_0}{4kT}\right). \quad (3)$$

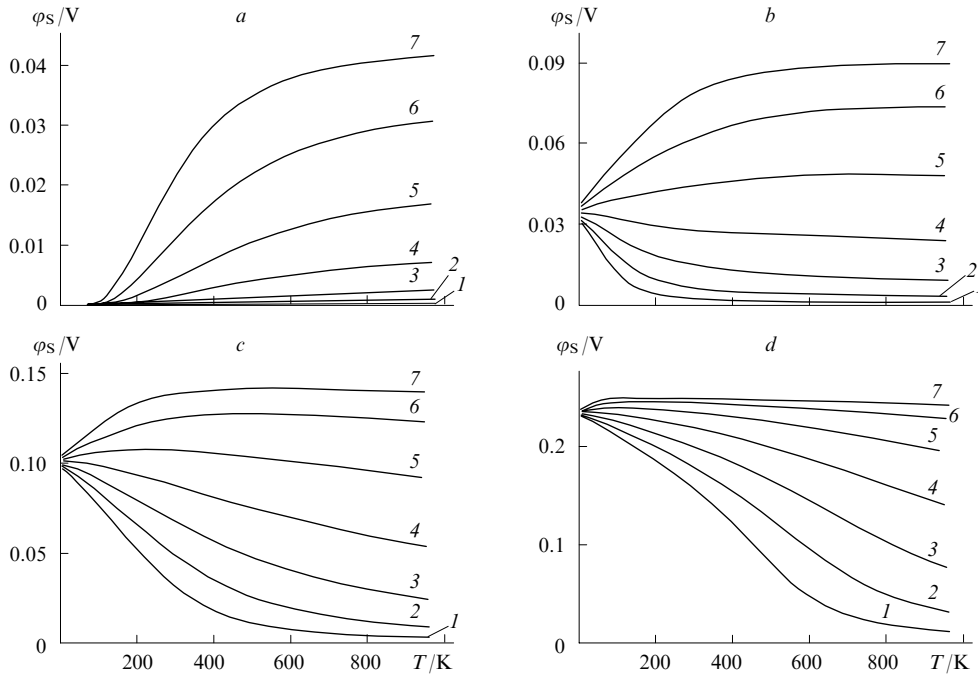

Figure 3. Temperature dependences of the surface potential calculated in terms of the Stern model for $g_0 = 1.0$ eV, $\Delta g^- = -0.1$ eV and $\Delta g^+ = -0.2$ (a), -0.3 (b), -0.4 (c) and -0.6 eV (d). Concentration of surface sites (N_S) is (cm^{-2}): (1) 1×10^{12} , (2) 3×10^{12} , (3) 1×10^{13} , (4) 3×10^{13} , (5) 1×10^{14} (6) 3×10^{14} and (7) 1×10^{15} .

This equation is identical to the expression derived by Lifshits and Geguzin.⁵¹ According to Eqn (3), the surface potential is determined not only by the difference between Δg^+ and Δg^- but also by the energy of defect formation. The quantity ϕ_s increases with the increase in the concentration of surface sites in proportion to the square root of the Schottky defect concentration in a crystal. Thus, for a low adsorption energy, the formation of a double layer is limited not only by the number of surface sites but also by the capacity of the crystal to form a diffuse layer, *i.e.*, by the density of bulk defects.

2. For high adsorption energies ($|\Delta g^+| > g_0/4$; $\Delta g^+ < 0$), the shape of $\phi_s(T)$ curves substantially changes (Fig. 3 b–d). In the limit at $T \rightarrow 0$, the dependence $\phi_s(T)$ tends not to zero but to a certain value ϕ_s^* determined by the relationship

$$e\phi_s^* = \frac{2}{3} \left(-\Delta g^+ - \frac{g_0}{4} \right).$$

In the general case, the surface potential can either increase or decrease depending on the quantities Δg^+ and N_S . For very high adsorption energies $|\Delta g^+|$, the temperature dependences $\phi_s(T)$ differ insignificantly from the curves obtained within the framework of the Poeppele–Blakely model,⁵² which makes an attempt to take into account the effect of the limited number of accessible surface sites on the surface potential. This case is shown in Fig. 3 d, namely, at small N_S , the number of surface sites becomes the limiting factor and the surface potential falls to zero with the increase in the temperature, whereas at large $N_S \sim 10^{15} \text{ cm}^{-2}$, the function $\phi_s(T)$ tends to the high-temperature limit determined by the equation

$$\phi_s = \frac{\Delta g^- - \Delta g^+}{2e}. \quad (4)$$

A comparison of expressions (4) and (2) shows that they are identical under the assumption that

$$\Delta g^- - \Delta g^+ = (\Delta g_{VM})_S - (\Delta g_{VX})_S = g_{VX} - g_{VM}.$$

Thus, for sufficiently high $|\Delta g^+|$ and N_S values and after the renormalisation of the energy values, the Stern model leads to the same result as the Frenkel–Kliwer and Poeppele–Blakely models.

The Stern model allows one to calculate the surface potential in different types of ionic crystals. In the general case, the calculated parameters of this model include the energy of defect formation, the energy of adsorption of defects and impurity ions, the concentration of surface sites, the concentration of impurities and the temperature. This model allows one to calculate ϕ_s in NaCl crystals containing admixed bivalent metals and to assess the isoelectric temperature. The Stern model can be used for the interpretation of experimental ϕ_s values for AgCl and AgBr and also for the calculation of the surface defect concentration in a model superionic oxygen conductor $M_{1-c}^{4+}M_c^{3+}O_{2-0.5c}$. The main advantages of the Stern model are that all its parameters have clear physical meaning, its solution can be found relatively simply and it can be applied to a wide range of problems that include the investigation of segregation effects and the interaction of defects on interfaces.

In the first approximation, the conductivity of a real polycrystalline specimen can be described in terms of a model of cubic blocks by the following expression:^{9, 53}

$$\sigma \approx 2\sigma_{\perp}(4\sigma_{\parallel} + \sigma_b)(2\sigma_{\perp} + \sigma_b)^{-1},$$

where σ_{\perp} and σ_{\parallel} are the contributions of double layers oriented normally and in parallel to the electric field, respectively, to the conductivity; σ_b is the conductivity in the crystal bulk. Usually, for crystals $\sigma_{\perp} \gg \sigma_{\parallel}$, and the conductivity of a specimen is determined by the sum of bulk and surface conductivities. If the same carriers are responsible for the conductivity in the crystal bulk and in the diffuse layer, the conductivity of a polycrystal is expressed by the equation

$$\sigma = \sigma_b \left[1 + \frac{8\lambda_D}{L} \exp\left(\pm \frac{e\varphi_S}{2kT}\right) \right] \quad (5)$$

and is determined by the effective layer thickness equal to the double Debye length of screening ($2\lambda_D$), the block size (L) and the surface potential. The Debye length depends on the concentration of carriers in the crystal bulk and, in the general case, on the temperature. It was shown that the activation energy of conduction of an impurity-free MX crystal is

$$E_a = \frac{h_0}{4} - \frac{e\varphi_S}{2} + E_m, \quad (6)$$

i.e., it is determined by the bulk characteristics of the solid, namely, the enthalpies of formation (h_0) and migration (E_m) of a defect and the surface potential (φ_S).

Studies of polycrystalline AgCl have shown²⁴ that the conductivity of specimens non-subjected to long-term annealing is determined by the conductivity of intergrain boundaries. The estimates of the surface potential based on relationship (6) produce quite reasonable values $\varphi_S = 0.1-0.2$ V, provided the conductivity is assigned to interstitial cations that form the diffuse layer. Polycrystalline specimens demonstrated the dielectric relaxation with a small increment $\Delta\varepsilon/\varepsilon_0 \approx 3$. On annealing, the activation energy of conduction was observed to increase monotonically and the quantity $\Delta\varepsilon/\varepsilon_0$ vanished.

Studies of polycrystalline AgI have shown⁵⁴⁻⁵⁶ that the conductivity of mechanically dispersed samples far exceeds the conductivities of β - and γ -phases of AgI cited in the literature. Upon heating or storage at room temperature, the conductivity decreased, which was accompanied by a gradual increase in the activation energy of conduction from 0.23 to 0.31 eV. For specially purified specimens, the Arrhenius plots demonstrated a bend at a temperature T_b in the range from 0 to 40 °C. After sintering at $T > 150$ °C, the absolute magnitudes of conductivity virtually coincided with that of a β -AgI single crystal. The static permittivity (ε_s), which does not depend on the electrode polarisation, substantially increased to $\varepsilon_s/\varepsilon_0 \sim 50-200$ after the specimens were pressed or mechanically treated, whereas the high-frequency permittivity (ε_∞) ($\varepsilon_\infty/\varepsilon_0 = 8 \pm 2$) was close to the permittivity of pure β -AgI. The observed changes can be explained by the formation of β - γ -polytypes containing randomly alternating closely packed layers (in contrast to the regular packing ABABAB or ABCABCABC in the β - and γ -phases, respectively). Insofar as the unit cells in both phases (in both γ -AgI and β -AgI) possess no inversion centres, the mechanical activation of polytypes can shift the closely packed layers. This is accompanied by changes in the polar axis direction and may result in the formation of a contact between two layers $I^- - Ag^+$. The cations on two sides of the contact plane are in different tetrahedral positions. This contact represents an antiphase boundary, *i.e.*, a boundary between antiphase domains. In this case, the strong Coulomb interaction between the $Ag^+(T_+)$ and $Ag^+(T_-)$ layers is compensated by the partial transition of Ag^+ ions from their regular positions to the vacant tetrahedral and octahedral positions, *i.e.*, to form the Frenkel defects at the antiphase boundary. The accumulation of the space charge at antiphase boundaries is the reason for the high dielectric permittivity of this material.

The presence of a small concentration of a heterogenic admixture (*e.g.*, metallic silver) stabilises the antiphase domains. A qualitatively similar effect was observed in the AgI-poly(tetrafluoroethylene) system.^{57, 58} The mechanism of stabilisation of antiphase boundaries resembles that of dispersion strengthening in metals where fine heterogeneous inclusions prevent the annealing of grain boundaries.

IV. Disorder of ionic crystals at interfaces. Conductivity of microcomposites

The physical reason for the surface interaction in a composite of the ionic salt-oxide type lies in the trend of both substances to decrease their surface energy due to the interaction of surface ions with the ions of the neighbouring phase. The surface energy of the interface between an ionic salt MX and alumina is determined in the first approximation as a sum of the cation-cation ($M^+ - Al^{3+}$), cation-anion ($Al^{3+} - X^-$ and $M^+ - O^{2-}$) and anion-anion ($X^- - O^{2-}$) interactions (E_{M-Al} , E_{X-Al} , E_{M-O} and E_{X-O} , respectively)

$$G_{MX-A}^s = \gamma_{MX-A} S_{MX-A} \approx E_{M-Al} + E_{Al-X} + E_{M-O} + E_{X-O},$$

where γ is the specific surface energy and S is the surface area.

For the sake of simplicity, we assume that, as a result of their interaction, the lattices of MX and A phases are fitted to one another at the interface. Because the energies E_{M-Al} , E_{X-Al} , E_{M-O} and E_{X-O} are different in the magnitude (due to the different energies of interaction in the ion pairs $M^+ - Al^{3+}$, $Al^{3+} - X^-$, $M^+ - O^{2-}$ and $X^- - O^{2-}$), in the interface layers, the ideal structure inherent in individual phases will be distorted in such a way as to provide a gain in the surface energy due to the mutual approach or removal of surface atoms. The relative displacement of ions from their ideal positions is determined by the balance of energies E_i . Insofar as in alumina and in majority of salts MX under discussion, anions exceed cations in size, it can be expected that for close packing, the interface cations will have the larger free volumes and be displaced by longer distances than anions. As a result, in the space between the surface layers, an intermediate positively charged layer enriched with cations is formed, the charge of this layer being compensated by the cationic vacancies (V_M')s that constitute the diffuse layer. The process of structural relaxation can be presented as the following quasichemical reaction:

which describes the stage of the surface disordering of MX at the MX-A interface (the superscripts ' and ' correspond to the positive and negative charges of a species, respectively, as compared with the stoichiometric charge of a given lattice site). If an anion is adsorbed on the surface, another reaction proceeds

The isoelectric point of an oxide pE was proposed⁵⁹ as a measure of its surface activity. Indeed, equations similar to Eqns (7) and (8) may be written for the surface interaction of an oxide with water

The first reaction predominates for oxides with $pE > 7$, for instance Al_2O_3 , CeO_2 ; the second prevails for oxides with $pE < 7$ (ZrO_2 , SiO_2). By analogy with aqueous solutions, one can expect that the surface reaction (7) will occur in composites containing basic oxides ($pE > 7$), whereas for acidic oxides ($pE < 7$) the interface interaction will follow the mechanism (8). Unfortunately, to date, due to the insufficient amount of experimental data, it is difficult to check the correctness of the direct transfer of the model of acid-base equilibria in aqueous solutions to the case of composites. Nonetheless, the competition between processes (7) and (9)

can be responsible for the deterioration of the ionic conductivity of composites $\text{AgCl}-\text{Al}_2\text{O}_3$ (Ref. 60) and $\text{AgI}-\text{Al}_2\text{O}_3$ (Ref. 61) and the appearance of the protonic conductivity in composites $\text{Li}_2\text{SO}_4-\text{Al}_2\text{O}_3$ (Ref. 62) and $\text{M}(\text{NO}_3)_n-\text{Al}_2\text{O}_3$ (M is an alkali metal)⁶³ in humid atmosphere.

In essence, reactions (7) and (8) describe the formation of the electrical double layer on the surface of MX in contact with Al_2O_3 . The changes in the energy (Δg_A) upon the displacement of an ion from its normal position into the interfacial space can be considered as the energy of cation adsorption in terms of the Stern model; hence, the quantity Δg_A is related to the surface potential (φ_{SA}) at the interface of a crystal MX

$$\varphi_{SA} \sim -\frac{\Delta g_A}{q_i}, \quad (10)$$

where q_i is the charge of the displaced ion. Insofar as the exact φ_{SA} value is determined not only by the quantity Δg_A but also by the contribution of the relaxation of oxide ions, expression (10) can be considered as merely a correlation between the values Δg_A and φ_{SA} , *viz.*, the surface potential increases with the increase in Δg_A . For $T = 0$ K, on the surface of a salt MX in contact with an oxide, a dense layer similar to the Helmholtz layer exists. With the increase in the temperature, the cationic vacancies form a diffuse layer, which provides the enhanced conductivity of the composite.

Insofar as ions in the dense layer are bound to the surface of oxide A and have limited mobility, the conductivity of MX in composites is determined by the defects that dominate in the diffuse layer. The mobility of defects in the diffuse layer is assumed equal to their mobility in the crystal bulk.^{6, 7, 10, 12, 13, 15} This statement is based on the assumption that the defect concentration in the surface layer remains low; hence, the crystal structure does not change (the absence of deformations, surface phase transitions, *etc.*). Within the framework of these assumptions, the conductivity across the diffuse layer in the composite is described by expression (5), where φ_{SA} should be substituted for φ_S and the migration energy E_m pertains to the defects that form the diffuse layer. For low φ_{SA} , *i.e.*, for a relatively weak surface interaction, the absolute magnitudes of conductivity are low and the activation energy of conduction is

$$E_a = \frac{h_0}{4} - \frac{e\varphi_{SA}}{2} + E_m.$$

The quantity E_a can vary within the limits $(h_0/4 + E_m) > E_a > (h_0/4 + E_m - e\varphi_{SA}/2)$ and is sensitive to the surface state of the $\text{MX}-A$ contact, *i.e.*, to the presence of structural defects, adsorbed admixtures, *etc.*; the measured parameters of conductivity are often characterised by poor reproducibility. Such effects are observed in insufficiently sintered composites.

If as a result of surface interaction, the surface potential increases to its limiting value $e\varphi_S = h_0/2$, the activation energy of conduction decreases to $E_a = E_m$ [see Eqn (6)]. As was shown by Maier,^{10, 13, 15} the activation energy of conduction in composites $\text{MX}-A$ is close to the energy of migration of a cationic vacancy, which indirectly confirms the fact that the surface potential is sufficiently high and reaction (7) proceeds on the interface to afford a diffuse layer built of cationic vacancies.

Most composites considered in the early studies can be classified with microcomposites, because they were prepared from oxides with the average particle size of 0.06–10 μm . The properties of microcomposites are similar to those of polycrystalline specimens, and all physicochemical properties of ionic salts (except for the ionic conductivity) in these systems are analogous to the properties of pure starting compounds. A

typical example of such systems is the composites $\text{AgCl}-\text{Al}_2\text{O}_3$. The dependence of the conductivity (σ) on the mole fraction (x) of the oxide has a maximum at $x = 0.30$, the activation energy of conduction is close to the energy of migration of cationic vacancies.^{6, 60} The estimates of the energy of formation of silver chloride in a composite, which were obtained using an electrochemical cell $\text{Pb}/\text{PbCl}_2/(1-x)\text{AgCl}-x\text{Al}_2\text{O}_3/\text{Ag}$, showed that the thermodynamic properties of AgCl in composites remain virtually unchanged.⁶⁴ The exposure of composites to a humid medium lead to the reduction of their conductivity, particularly, at $x > 0.5-0.6$.⁶⁰

Based on correlations obtained earlier^{65, 66} and an assumption that $E_a = E_m$, it is possible to assess the concentration of current carriers in composites. The following relationship between the conductivity at 25 °C ($\sigma_{25}/\text{S cm}^{-1}$), the defect concentration (n/cm^{-3}) and the activation energy (E_a/eV) was proposed:⁵³

$$\log \sigma_{25} = \log n - 14.5 E_a - 20.55.$$

In composites with the highest conductivity, the concentration of defects proved to be high and comparable with their concentration in superionics. This suggests that additional channels for the defect formation exist in composites so that the correct interpretation of experimental data requires that the specifics of interphase interactions and the real structure of the interface were taken into account. It cannot be ruled out that the disordered surface phases formed at the interface will manifest most strongly their specific properties on going from micro- to nanocomposites. These effects are discussed below.

V. Calculations of physicochemical properties of composites

The model of cubic blocks,^{53, 67} which is similar to that used earlier to describe the conductivity of polycrystalline specimens, may be applied for the quantitative calculation of the physical characteristics of composites $\text{MX}-A$. If a layer with a thickness λ and properties differing from those of the MX phase in the substance bulk exists near the interface, this layer can be conditionally assumed to be the surface phase. The model of cubic blocks allows one to estimate the volume and mole fractions of the surface phase (f_S and x_S , respectively) for the uniform random distribution of equal-size particles MX and A in a composite

$$f_S = \frac{2\beta\lambda f(1-f)}{L_A},$$

$$x_S = \frac{2\beta\lambda\delta x(1-x)}{L_A[1+x(\delta-1)]},$$

where β is the constant determined by the particle geometry, for cubic or spherical particles, $\beta \approx 3$; λ is the surface phase thickness; f and L_A are the volume fraction and the size of particles of the component A in the composite; the coefficient δ is determined by the ratio of densities (d) and molecular masses (μ) of components, namely, $\delta = (\mu_A d_{MX})/(\mu_{MX} d_A)$; x is the mole fraction of the component A . The volume fraction of an ionic salt $(f_{MX})_{\text{bulk}}$ beyond the surface layer can be determined using the expression

$$(f_{MX})_{\text{bulk}} = 1 - f - f_S = \left[1 - \frac{2\beta f \lambda}{L_A}\right](1-f), (f_{MX})_{\text{bulk}} \geq 0, \quad (11)$$

which is very convenient for the estimation of the surface layer thickness provided the size of particles A is known. In real systems, L_A corresponds to the size of an aggregate of particles A and d_A corresponds to the average density of aggregates.

Figure 4. Concentration dependences of (1, 2, 4, 6, 8) bulk (f_{bulk}) and (3, 5, 7, 9) surface (f_s) phases in composites calculated based on the model of cubic blocks for different ratios λ/L_A . $\lambda/L_A = 0$ (1), 0.1 (2, 3), 0.2 (4, 5), 0.3 (6, 7), 0.4 (8, 9).

Expression (11) allows one to determine the ratio λ/L_A based on the concentration dependence of any extensive characteristic of the MX phase; moreover, provided the average size of A particles is known, the absolute magnitude of the surface phase thickness λ can be found (Fig. 4).

To assess the conductivity of composites, the models of effective medium or the theories of percolation, which were adapted to the specific features of the morphology of composites, are used. The most precise calculations of the conductivity of conventional composites of the conductor–dielectric type $(1-f)\text{M}-f\text{A}$ can be performed for the limiting cases ($f \rightarrow 0$ and $f \rightarrow 1$), where the particles of phases A or M pertain to the second-phase matrix and are isolated from one another. As the volume fraction of the second phase increases, its particles are no longer isolated and the calculations of the conductivity of composites require the use of more intricate models. A simpler method for the calculation of the composite conductivity based on the well-known mixing equation was proposed^{68, 69}

$$\sigma^\alpha = (1-f)\sigma_M^\alpha + f\sigma_A^\alpha, \quad (12)$$

where the parameter α is determined by the empirical fitting of dependence (12) to experimental values. The comparison of Eqn (12) with the exact solutions obtained for the limiting cases showed that the parameter α depends on the composite morphology. The morphology of real composites changes as the content of the second component increases, which makes extremely difficult the theoretical calculations of the conductivity within the framework of models mentioned above. The use of rules of mixing allows one to solve this problem by introducing the linear dependence of the power index α in Eqn (12)

$$\alpha \equiv \alpha(f) = \alpha_1(1-f) + \alpha_2 f, \quad (13)$$

where α_1 and α_2 are the constants corresponding to the morphology of composites in the regions of limiting dilution (for $f \rightarrow 0$ and $f \rightarrow 1$, respectively). Taking into account expression (13), it is possible to represent expression (12) in the general form

$$\sigma^{\alpha_1(1-f)+\alpha_2 f} = (1-f)\sigma_M^{\alpha_1(1-f)+\alpha_2 f} + f\sigma_A^{\alpha_1(1-f)+\alpha_2 f}. \quad (14)$$

In the limiting cases, Eqn (14) is reduced to expressions obtained within the framework of the effective medium model. The form of dependences $\log(\sigma/f)$ and $\sigma(f)$ shown in Figs 5a,b is entirely determined by α_1 and α_2 . These dependences allow one to describe the conductivity of composites the morphology of which is determined by quite different factors including the percolation effect. The theoretical curves are close to those obtained using the McLachlan equation,⁷⁰ which is widely employed for the description of the percolation behaviour of composites. Figure 5c shows the experimental conductivity of different composites⁷¹ in comparison with calculated curves.

As in the case of conductor–dielectric composites, the most accurate calculations of the conductivity of solid electrolytes $(1-f)\text{MX}-f\text{A}$ can be performed for the limiting cases ($f \rightarrow 0$ and $f \rightarrow 1$), where isolated particles of phases A or MX are located in the second phase matrix. In the general case, the conductivity of model systems is described in terms of a percolation model¹¹ with two percolation thresholds, namely, p_1 (dielectric MX–ionic conductor) and p_2 (ionic conductor–dielectric A). The most serious difficulties in calculations

Figure 5. Calculated dependences of the relative conductivity (σ/σ_M) of composites MX–A on the bulk concentration of dielectric (f), shown in (a) logarithmic and (b) linear scales and (c) their comparison with experimental conductivity of composites AgI–Al₂O₃ (1)⁶¹ and AgI–poly(tetrafluoroethylene) (2).^{57, 58}

The curves were obtained for different (α_1, α_2) : (1) (1, 1), (2) (2/3, 2/3), (3) (2/3, 1/3), (4) (2/3, 0), (5) (2/3, −1/3), (6) (0, 0), (7) (−1/3, 2/3), (8) (−1/3, 1/3), (9) (−1/3, 0), (10) (−1/3, −1/3), (11) (−1, −1); curve (5') was calculated using the McLachlan equation.⁷⁰

emerge in the vicinity of percolation thresholds at $f \approx p_1$ or p_2 . In these regions, intricate models^{72–81} are used. Moreover, even for composites with simple morphologies, rather cumbersome analytical expressions with a large number of fitting parameters should be used, which complicates the testing and practical application of these models. The mixing equation can be applied for the description of composite ionic conductors. The additional contribution of the surface conductivity can be taken into account in terms of the model of cubic blocks, which allows one to assess the concentration of the surface conducting phase. The mixing equation should take into account the contribution of this phase and can be presented as follows:

$$\sigma^\alpha = \left[1 - f - 6f(1-f) \frac{\lambda}{L_A} \right] \sigma_M^\alpha + 6f(1-f) \sigma_S^\alpha \left(\frac{\lambda}{L_A} \right) + f \sigma_A^\alpha. \quad (15)$$

For $6(\lambda/L_A)\sigma_S \gg \sigma_{MX}$, the expression takes a simpler form

$$\sigma = \left[6f(1-f) \frac{\lambda}{L_A} \right]^{1/\alpha} \sigma_S. \quad (16)$$

For $\alpha > 0$, dependence (16) has a symmetrical form with the maximum at $f = 0.5$. The introduction of the linear dependence $\alpha = \alpha(f)$ [expression (15)], which takes into account the changes in the morphology, allows one to obtain a modified mixing equation suitable for the description of conductivity of composite solid electrolytes. Analysis showed that the form of curves substantially depends on the parameters α_1, α_2 and that theoretical curves allow one to describe the conductivity as a function of the composition for specimens with totally different morphologies (Figs 6a,b). It is interesting that the conductivity of a composite should increase with the increase in the size of particles of the oxide additive according to the exponential law $\sigma \sim (1/L_A)^\beta$, where $\beta = \alpha^{-1} \geq 1$, and only in the limiting case $\alpha(f) = 1$, it is expressed by the relationship $\sigma \sim (1/L_A)$ conventionally used in the literature.^{15, 22, 25, 26}

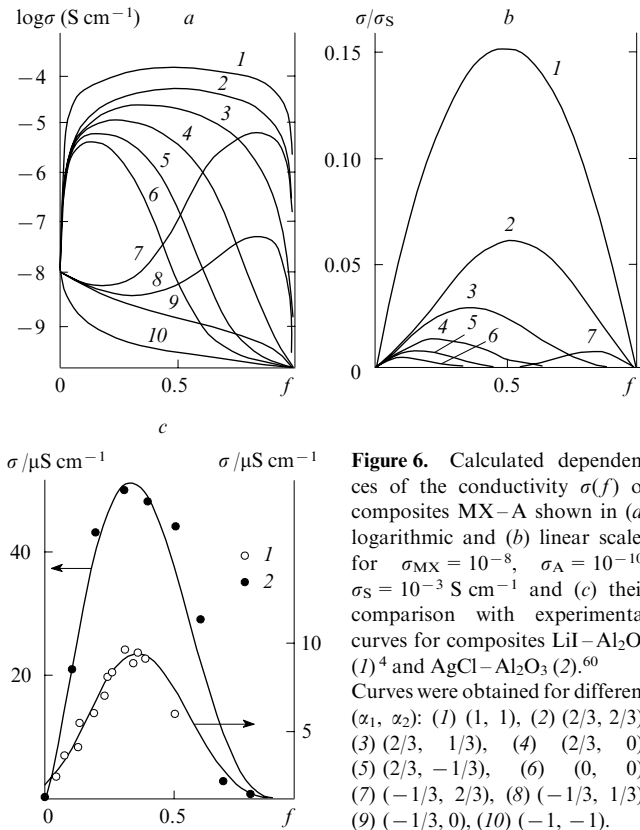

Figure 6. Calculated dependences of the conductivity $\sigma(f)$ of composites MX–A shown in (a) logarithmic and (b) linear scales for $\sigma_{MX} = 10^{-8}$, $\sigma_A = 10^{-10}$, $\sigma_S = 10^{-3}$ S cm⁻¹ and (c) their comparison with experimental curves for composites LiI–Al₂O₃ (1)⁴ and AgCl–Al₂O₃ (2).⁶⁰ Curves were obtained for different (α_1, α_2) : (1) (1, 1), (2) (2/3, 2/3), (3) (2/3, 1/3), (4) (2/3, 0), (5) (2/3, -1/3), (6) (0, 0), (7) (-1/3, 2/3), (8) (-1/3, 1/3), (9) (-1/3, 0), (10) (-1, -1).

Equation (15) type describe well the experimental data for composites LiI–Al₂O₃ (Ref. 4) and AgCl–Al₂O₃ (Ref. 60) (Fig. 6c). The mixing equation in the form (15) is qualitatively consistent with the basic expressions obtained within the framework of the effective medium model and the percolation theory and also with the results of computer calculations.

VI. Thermodynamic description of composites. The effect of self-dispersion of ionic salts. Synthesis of nanocomposites

In the general case, a solid-phase composite represents a complex multicomponent system that comprises several real solid phases. By a real solid phase is meant a combination of single crystals of different sizes, which contain admixtures, lattice defects (point defects and pores), free surfaces, cracks and grain boundaries. Many properties of composites depend on their morphology, viz., the size distributions of particles of each phase and the mutual spatial arrangement of monophase domains. In the presence of the surface interaction between the phases MX and A, the expression for the excess Gibbs energy of the composite can be presented as follows:^{24, 82–84}

$$G = (G_{MX}^\circ + \gamma_{MX} S_{MX} + \Delta G_{MX}^{\text{elas}}) + (G_A^\circ + \gamma_A S_A + \Delta G_A^{\text{elas}}) + \gamma_{MX-A} S_{MX-A}. \quad (17)$$

Here, G_{MX}° and G_A° are the standard changes in the Gibbs energies of the formation of individual components MX and A; $\gamma_{MX} S_{MX}$ and $\gamma_A S_A$ are their excess surface energy determined by the specific surface energy (γ) multiplied by the free surface area; $\Delta G_{MX}^{\text{elas}}$ and ΔG_A^{elas} are the elastic strain contributions; $\gamma_{MX-A} S_{MX-A}$ is the energy of the interface, where γ_{MX-A} is the specific surface energy at the interface; S_{MX-A} is the area of the contact between components MX and A; the contribution of the elastic energy is taken into account by terms $\Delta G_{MX}^{\text{elas}}$ and ΔG_A^{elas} . The expression for the Gibbs energy of the component MX can be obtained from Eqn (17), if we assume that the interface energy is evenly distributed between the components

$$G_{MX} = G_{MX}^\circ + \gamma_{MX} S_{MX} + \frac{\gamma_{MX-A} S_{MX-A}}{2} + \Delta G_{MX}^{\text{elas}}. \quad (18)$$

The contribution of elastic strains ($\Delta G_{MX}^{\text{elas}}$) to the total energy of the MX phase is largely determined by the elastic energy of the misfit in lattice parameters at the interface and the energy of dislocations that arise in the interface regions. The calculations of G^{elas} even for thin films with simple morphologies are very tedious; hence, it is difficult to assess this contribution in composites. Nonetheless, in all the cases irrespective of the nature of elastic strains (dilatational or compression strains), the quantity $\Delta G_{MX}^{\text{elas}}$ is positive and should increase with an increase in S_{MX-A} . Hence, the last two terms in expression (18), which determine the energy of the MX phase depend on the area of the interphase contact in the composite.

Sintering of a mixture of a low-melting component MX (with the higher self-diffusion coefficients) with the nanoparticles of a high-melting component A can be accompanied by both a decrease and an increase in the interface area. In the former case, the sintering is reduced to simple recrystallisation of phases. The latter case is more interesting for solid-state chemistry. The process of the formation of an interphase contact (Fig. 7) is thermodynamically favourable if $dG/dS_{MX-A} < 0$. In this case, the sintering is accompanied by an increase in the interface area S_{MX-A} . If we ignore the dependences of the specific surface energies and the elastic energy on the surface area (or the particle size) [γ_{MX} , γ_A ,

Figure 7. Illustration of self-dispersion of an ionic salt MX at its contact with a nanocrystalline oxide A (see the text).

γ_{MX-A} , G_{MX}^{elas} , $G_A^{elas} \neq f(S_{MX-A})$ and express γ_{MX-A} through the free energy of adhesion (γ_a)

$$\gamma_a = \gamma_{MX} + \gamma_A - \gamma_{MX-A},$$

we can find the change in the Gibbs energy of a composite with the increase in the interface area by dS_{MX-A}

$$\frac{dG}{dS_{MX-A}} = \gamma_{MX} \frac{dS_{MX}}{dS_{MX-A}} + \gamma_A \frac{dS_A}{dS_{MX-A}} + \gamma_{MX} + \gamma_A - \gamma_a. \quad (19)$$

Pines⁸⁵ and Geguzin⁸⁶ considered in detail the mechanism of sintering, *i.e.*, the formation and the growth of the interface. The mechanism and kinetics of sintering differ for two cases determined by the conditions $\gamma_a < 2\gamma_{MX}$ and $\gamma_a > 2\gamma_{MX}$. In the former case, a neck is formed between two grains the shape and size of which are determined by the shape and size of particles and the absolute magnitudes of γ_{MX} , γ_A and γ_a .

The expression

$$\gamma_a > 2\gamma_{MX} \quad (20)$$

is known as the Gibbs–Smith condition for complete spreading. It can be derived from Eqn (19), provided that $dG/dS_{MX-A} < 0$, $dS_A/dS_{MX-A} = -1$, $dS_{MX}/dS_{MX-A} \approx 1$, *i.e.*, if the decrease in the free energy of a component A (substrate) is accompanied by the formation of the equivalent free surface of a component MX (film). The same condition is prerequisite for the stable layer-by-layer growth of films according to the Frank–van der Merve mechanism. Figure 7(1) shows the corresponding changes in the morphology. However, upon sintering of mixtures with an arbitrary microstructure, the newly formed free surfaces of the component MX can overlap if the distances between the surfaces of phase A are sufficiently small [Fig. 7(2)]. At the complete overlap of free surfaces, the derivative dS_{MX}/dS_{MX-A} approaches zero, and the following expression can be derived from Eqn (19):

$$\gamma_a > \gamma_{MX}, \quad (21)$$

which represents a condition of the feasibility in principle of spreading of the component MX over the surfaces of the phase A in a composite. A comparison of condition (21) with the condition (20) for the complete spreading (or epitaxy) in films shows that the interfacial interaction in composites should proceed more actively and at lower energies of adhesion in contrast to ordinary film structures. The surface roughness is known to improve wettability. The roughness coefficient is equal to the ratio of the true contact area to its apparent area and can take values in the range from zero to unity. Equa-

tion (21) corresponds to the limiting roughness coefficient of the phase A equal to unity.

If conditions (20) or (21) are met, the interface area in the system spontaneously increases or the sufficiently well developed surface of nanocrystals A is ‘wetted’ with the substance MX. A comparison of values $\gamma \approx 100–300 \text{ erg cm}^{-2}$ for alkali metal halides⁸⁷ with the specific surface energies of oxides Al_2O_3 , FeO, MgO and SiO_2 ($\gamma \approx 600–1200 \text{ erg cm}^{-2}$) (Refs 88 and 89) suggests that the wetting condition (20) should be fulfilled for composites that consist of ionic halides and high-melting oxides including alumina.

If substance A is in the nanocrystalline state, the effective size of particles of the phase MX should decrease to very small values, *i.e.*, an unusual effect, the self-dispersion of component MX to form a two-phase nanocomposite is observed.²⁴ Indeed, the self-dispersion effect was observed during the solid-phase sintering of composites $\text{AgCl–Al}_2\text{O}_3$,⁶⁰ $\text{AgI–Al}_2\text{O}_3$ (Refs 61, 71 and 90–92) and $\text{Li}_2\text{SO}_4\text{–Al}_2\text{O}_3$,^{82,83,93,94} A similar effect was observed in heterogeneous systems based on alkali metal nitrates [$\text{LiNO}_3\text{–Al}_2\text{O}_3$, $\text{NaNO}_3\text{–Al}_2\text{O}_3$,⁹⁵ $\text{RbNO}_3\text{–Al}_2\text{O}_3$,^{67,96,97} $\text{CsNO}_3\text{–Al}_2\text{O}_3$ (Ref. 96)] and halides [$\text{NaCl–Al}_2\text{O}_3$, $\text{KCl–Al}_2\text{O}_3$ and $\text{RbCl–Al}_2\text{O}_3$ (Ref. 24)], which points to the good adhesion of ionic salts to the alumina surface. Self-dispersion serves as the indicator of strong interfacial interaction in the system and occurs at long-term sintering until the whole surface of the component A is covered with substance MX. In this limiting case, the quantity S_{MX-A} approaches S_A , and the system spontaneously reaches firm metastable equilibrium where

$$G = (G_{MX}^o + G_A^o) + \gamma_{MX-A}S_A + (\Delta G_{MX}^{elas} + \Delta G_A^{elas}),$$

$$G_{MX} = G_{MX}^o + \frac{\gamma_{MX-A}S_A}{2} + \Delta G_{MX}^{elas}. \quad (22)$$

According to the latter expression, the properties of an ionic salt are determined not only by the standard thermodynamic parameters of the substance, but also by the contribution of the energy of interfacial interaction, which increases in proportion to the surface area of the oxide A (or in the inverse proportion to the size of its particles). If the components taken in a volume ratio of 1 : 1 are uniformly mixed so that the total surface of a component A is completely wetted with a component MX, the effective size of MX grains is approximately equal to $L_A/2$. In composites with oxide nanoparticles ($L_A/2 \approx 10 \text{ nm}$), the size of MX particles becomes sufficiently small for the manifestation of pronounced size effects.

VII. Size effects in composites

Size effects in heterogeneous systems⁸⁴ are determined by many factors, namely, the chemical nature of components in the heterogeneous mixture, the morphology of the system and the interfacial interaction between the components. Since it is difficult to take into account these factors, no adequate theoretical description of the size effect in composites has been developed so far. As in the case of pure substances, the most pronounced changes in the properties are observed in nanocomposites, *i.e.*, heterogeneous systems with the average size of particles of both phases below 100 nm. In recent years, the interest in the unusual effects observed in nanosize systems has arisen.^{17–22, 24, 84, 85, 88, 98–128} This is not surprising, since the processes that involve nanosystems form the basis for future solid-state nanotechnologies.

Size effects can conditionally be divided into two types.

1. Weak effects, where the physicochemical properties of a substance change insignificantly with an increase in the specific surface area (or a decrease in the particle size) and all the changes observed can be explained by the additive effect of the

surface on the basic properties of a crystal. According to the classification proposed by Shcherbakov,^{129, 130} these effects may be assigned to capillary effect of the first kind. As a rule, these effects are observed in crystals with the size above 10 nm.

2. Strong phase size effects or, according to the Shcherbakov classification, capillary effects of the second kind responsible for the qualitative changes in the substance properties, which are impossible to explain in terms of ordinary surface phenomena. As a rule, these effects are observed in very small particles the size of which does not exceed 10 nm. It is these systems that should be considered as truly nanosize systems. The concept of Shcherbakov was qualitatively confirmed by the subsequent experimental and theoretical studies^{84, 100–104, 116, 117, 124, 126}.

As a result of spreading or self-dispersion, the Gibbs energy of an ionic salt increases to a value described by expression (22). The excess energy is determined by two main factors, namely, the interface energy, which depends on the nature and the energy of interactions between the surface atoms of phases in contact, and the elastic strains that arise in the bulk of contacting phases.

The mechanism of interactions in composites MX–A is determined by the contribution of non-dispersion interactions, namely, ion–ion, donor–acceptor, dipole–dipole, *etc.* The correct estimation of the interface energy requires consideration of the structure of the contact plane and the real potentials of ion–ion interactions in the contact region, which is an extremely complicated and still unsolved problem. It was shown²⁴ that lithium salts in systems with alumina exhibit a stronger trend for the formation of nanocomposites as compared with rubidium and caesium salts, while iodides more readily form nanocomposites as compared with chlorides and fluorides. This suggests that the polarising power of the cation and the polarisability of the anion in the ionic component play an important role in the surface interaction mechanism.

Studies of thin films have demonstrated that the structure of a solid in the near-interface region depends substantially on the features of the crystallography and energy of planes in contact. As a rule, in very thin films, the epitaxial contact between phases is energetically favourable and the film structure is determined by the effect of the support and can differ from the structure of the same substance in the individual state. With the increase in the film thickness, elastic strains are accumulated in its bulk, which results in the film restructuring upon reaching a certain critical thickness h_{cr} . For a minor misfit in the structural parameters, the film acquires a structure corresponding to the pure component and a network of misfit dislocations is formed on the interface. For a 1%–0.1% misfit in the lattice parameters, the thickness of the epitaxial layer was calculated to be $h_{cr} \approx 5–25$ nm.^{131–133} If the structural parameters of the substrate and the film differ substantially, h_{cr} becomes very small, and the relaxation of the elastic energy of the growing epitaxial layer necessitates the formation of a very large number of dislocations, which becomes energetically unfavourable. In this case, the relaxation of elastic strain energy can proceed through different channels, namely, the film can be divided into separate blocks the size of which increases with the increase in the film thickness or an amorphous surface phase is formed.^{100, 133}

In the above-mentioned cases, the formation of thin epitaxial, nanocrystalline or amorphous films may be considered as the manifestation of the phase size effect in heterogeneous systems, *viz.*, with the increase in the characteristic size (film thickness), new surface phases are formed.

In the composites MX–A the distance between the grains of the oxide component A plays the role of the MX layer thickness. If the size of particles A far exceeds h_{cr} , the properties of the ionic component are similar to those of thick MX

films. If the oxide grains are sufficiently small and comparable with h_{cr} , then at sufficiently high oxide concentrations, the MX phase is localised in nanopores between oxide particles, *i.e.*, under the conditions similar to those of the existence of a thin MX layer on the surface of A. In a real composite, two states always coexist (a ‘normal’ state of coarse MX grains and an ‘interfacial’ state with anomalous properties) in a quantitative ratio determined by the composition and morphology of the composite.

The thermodynamic properties of substances deposited on a solid support to form adsorbed layers or thin films differ from those in the bulk.^{85, 98–100, 131} The characteristic grain size at which noticeable deviations in the thermodynamic properties are observed is ~ 10 nm.^{84, 100–102, 105, 107–111, 113, 116, 117, 124} The temperature of a phase transition (T_t) that occurs in the bulk of an ionic salt MX can be estimated^{24, 100, 115} using the following approximate relationship:

$$\frac{T_t}{T_t^0} = 1 - \left[(\gamma_{MX}^\beta S_{MX}^\beta - \gamma_{MX}^\alpha S_{MX}^\alpha) + \frac{1}{2} (\gamma_{MX-A}^\beta S_{MX-A}^\beta - \gamma_{MX-A}^\alpha S_{MX-A}^\alpha) + \Delta G^{\text{elas}} \right] \frac{1}{H_t},$$

where T_t^0 is the standard temperature of the transition, superscripts α and β correspond to high-temperature and low-temperature phases, respectively, ΔG^{elas} is the difference between the excess elastic energies of phases β and α , H_t is the enthalpy of the phase transition. The interface energies γ_{MX} and γ_{MX-A} decrease with the increase in the temperature; this is why if the phase transition is accompanied by only small changes in the bulk and ΔG^{elas} ($S_{MX}^\alpha \approx S_{MX}^\beta \sim L_{MX}^{-1}$; $S_{MX-A}^\alpha \approx S_{MX-A}^\beta \sim L_A^{-1}$; $\Delta G^{\text{elas}} \approx 0$), the temperature of transformation to the high-temperature α -phase will decrease, which indeed was usually observed for thin films where the layer thickness plays the role of the particle size. The literature offers two types of phase diagrams plotted in coordinates $T_t(T, L^{-1})$ for supported films of different metals;^{85, 98–100} the phase transition temperatures can decrease by hundreds of degrees as L decreases to 10 nm. In the general case, the phase transition temperatures in a composite can either decrease or increase depending on the concrete form of functions $G^0 = f(T)$; $\sigma = f(T)$; $\Delta G^{\text{elas}} = f(T)$ in different phases of a given composite.

The above-described self-dispersion effect caused by the surface interaction of ionic salts with nanodispersed oxides (the particle size not exceeding 10 nm) allowed a wide range of nanocomposites of the MX–A type to be synthesised and studied.^{24, 84, 134–148} Ionic salts in the nanoheterogeneous systems mentioned exhibited several specific features.

1. Crystal structure and morphology. In sintered composites AgI–Al₂O₃,^{61, 71, 90–92} either various polytypes or an amorphous phase were formed depending of the oxide particle size and the conditions of the composite synthesis. Nanocomposites synthesised at 600 °C comprised globular AgI particles measuring 2–5 nm and uniformly distributed over the composite volume (Fig. 8). According to the results of structural studies of composites LiX–Al₂O₃ ($X^- = F^-, Cl^-, Br^-, I^-, 1/3 PO_4^{3-}, 1/2 SO_4^{2-}$) synthesised by decomposition of a precursor, the size of particles in both phases of the composite did not exceed 10 nm, *i.e.*, solid-phase nanocomposites were formed.⁵³ The most thoroughly studied nanocomposites Li₂SO₄–Al₂O₃ exhibited the highest conductivity among these nanocomposites.^{53, 82, 83, 93, 94} On the interfaces of these composites, regardless of the method of their synthesis [by decomposition of the precursor Li₂SO₄·2n Al(OH)₃·m H₂O or by simple mixing of components followed by sintering], an intermediate aluminate layer with a thickness of about 1–2 monolayers was formed to provide a good epitaxial contact

Figure 8. Morphology of the nanocomposite 0.2 AgI–0.8 Al₂O₃ synthesised at 600 °C.

between Li₂SO₄ and Al₂O₃. The average particle size varied in the range of 3–10 nm (Fig. 9). In composites CsCl–Al₂O₃, according to the X-ray diffraction data, a high-temperature face-centred CsCl phase with the particle size in the range of 20–80 nm was stabilised.¹⁴⁴ In nanocomposites based on alkali metal nitrates, amorphous phases of ionic salts were formed.^{67,95–97}

Figure 9. Microstructure of the composite Li₂SO₄–Al₂O₃.

2. Thermodynamic properties. Rubidium nitrate attracts attention because in the temperature range of 25–330 °C it undergoes three polymorphous transitions (at 164, 219 and 286 °C) before melting at 315 °C. The results of differential scanning calorimetry (DSC) studies of composites RbNO₃–Al₂O₃ showed⁶⁷ that sintering did not virtually affect the temperatures of all phase transitions of rubidium nitrate including the melting temperature, while the corresponding enthalpies dramatically decreased (Fig. 10 *a*). At a relatively low mole fraction of the oxide ($x \geq 0.7$), the curves demonstrated no heat effects that would point to the presence of crystalline rubidium nitrate in the composite. In line with the decrease in the enthalpy of crystalline RbNO₃, the DSC curves acquire a new strongly broadened peak at 250 °C. The mentioned effects were not observed in composites containing coarse-grained alumina (with the grain size of several micrometres); hence, the effects were intrinsic in the oxide surface (Fig. 10 *b*). In composites RbNO₃–Al₂O₃, an amorphous phase was formed and the heat effect at 250 °C was caused by the phase transition, namely, its vitrification. The formation of an amorphous phase in nanocomposites was also confirmed by

Figure 10. (*a*) DSC curves of composites $(1-x)\text{RbNO}_3-x\text{Al}_2\text{O}_3$ [$x = 0.1$ (1), 0.3 (2), 0.5 (3), 0.7 (4)] containing nanocrystalline alumina ($S_{\text{sp}} = 270 \text{ m}^2 \text{ g}^{-1}$), which were heated at 350 °C and (*b*) segments of DSC curves in the region of phase transition $\text{RbNO}_3\text{-IV} \rightleftharpoons \text{RbNO}_3\text{-III}$ for the composites 0.3 RbNO₃–0.7 Al₂O₃ containing (1) coarse-grain and (2) nanocrystalline alumina.

the disappearance of the heat effect associated with salt melting. The amorphisation of an ionic salt also occurred in composites RbNO₃–SiO₂,¹⁴⁵ CsHSO₄–SiO₂ (Refs 146 and 147) and LiClO₄–Al₂O₃ (Ref. 148). In composites CsCl–Al₂O₃, with the increase in the oxide concentration, the enthalpy of the transition to the high-temperature phase gradually decreased, which was accompanied by the broadening of the hysteresis loop of the phase transition temperature.¹⁴⁴

Expression (11) allows one to assess the ratio λ/L_A and, for a given particle size (L_A), the thickness of the surface phase (λ), based on the concentration dependence of the enthalpy of phase transitions in composites. The λ estimates were 3 and 4 nm in composites AgI–Al₂O₃ (Ref. 92) and RbNO₃–Al₂O₃ (Ref. 97), respectively. For a sufficiently high concentration of the oxide ($x > 0.6–0.7$, which corresponds to the volume ratio $f > 0.5–0.6$), the effective size of MX particles was comparable with λ and virtually the whole volume of the ionic salt was in the amorphous state (Fig. 11).

Self-dispersion of rubidium nitrate in contact with nanocrystalline alumina (the specific surface of $200 \text{ m}^2 \text{ g}^{-1}$) was studied^{97,149} *in situ* by the DSC method; the results are shown in Fig. 12. For non-mixed starting components, the surface interaction began at the rubidium nitrate melting temperature, as indicated by the appearance of the exothermic effect. In the melting, the liquid-phase spreading occurred being accompanied by liberation of the heat of wetting. The DSC curves obtained in the repeated heating of the same specimen corresponded to a mixture of the residual crystalline and amorphous phases. When the starting components were mixed more thoroughly, the surface dispersion and self-dispersion proceeded at noticeable rates even at temperatures substantially

Figure 11. Mole fractions of (1, 2) bulk (x_{bulk}) and (3, 4) surface (x_s) phases in composites (1, 3) $(1-x)\text{AgI}-x\text{Al}_2\text{O}_3$ (Ref. 92) and (2, 4) $(1-x)\text{RbNO}_3-x\text{Al}_2\text{O}_3$ (Ref. 67) as a function of the additive content. Experimental values were calculated from the enthalpy of phase transitions. Theoretical curves were obtained based on Eqn (11). The dashed curve corresponds to the case of $\lambda/L_A = 0$ where the composite altogether lacks the surface phase.

below T_{mp} , *i.e.*, where rubidium nitrate was in the crystalline state. Due to the solid-phase spreading, the amorphous phase was formed, *i.e.*, the crystalline phase spontaneously passed to the amorphous state. The solid-phase spreading to form the amorphous phase was also observed upon sintering of composites $\text{AgI}-\text{Al}_2\text{O}_3$.⁹²

The possible reason for the spontaneous amorphisation of an ionic salt MX in the composites MX-A due to the liquid-phase or solid-phase spreading could be the relaxation of elastic strains that arise in the MX volume formed as a result of the salt spreading over the surface and in the pores of the oxide matrix. If the lattices of the contacting phases do not match one another, the contribution of the elastic energy becomes substantial. Moreover, in contrast to thin films, the MX particles in nanopores are adhesively bound with the randomly oriented oxide surfaces surrounding a pore, which should lead to rather active formation of microdomains of particles and provide the excess surface energy. Apparently, the structural relaxation can occur by spontaneous amorphisation of an ionic salt. This process may be illustrated by a phase diagram shown in Fig. 13.^{97, 139, 140} The amorphisation is possible if with the decrease in the effective particle size, the free energy of the crystalline MX phase becomes higher than the energy of the amorphous phase. A concept of the spontaneous transition from the crystalline to the amorphous state was discussed earlier in the literature in context of the reasons for the mechanical alloying of ionic salts.^{150–158} The data on the amorphisation of alkali metal halides^{159, 160} and certain other inorganic crystalline hydrates^{161–167} in nanopores are available. Amorphous hydrates incorporated into nanoporous matrices turned out to exhibit unusual thermodynamic properties, which are responsible for the changes in the parameters of chemical processes of hydration and dehydration.

3. Ionic conductivity and dielectric properties. In the low-temperature range, all the nanocomposites $(1-x)\text{AgI}-x\text{Al}_2\text{O}_3$ studied exhibited enhanced ionic conduc-

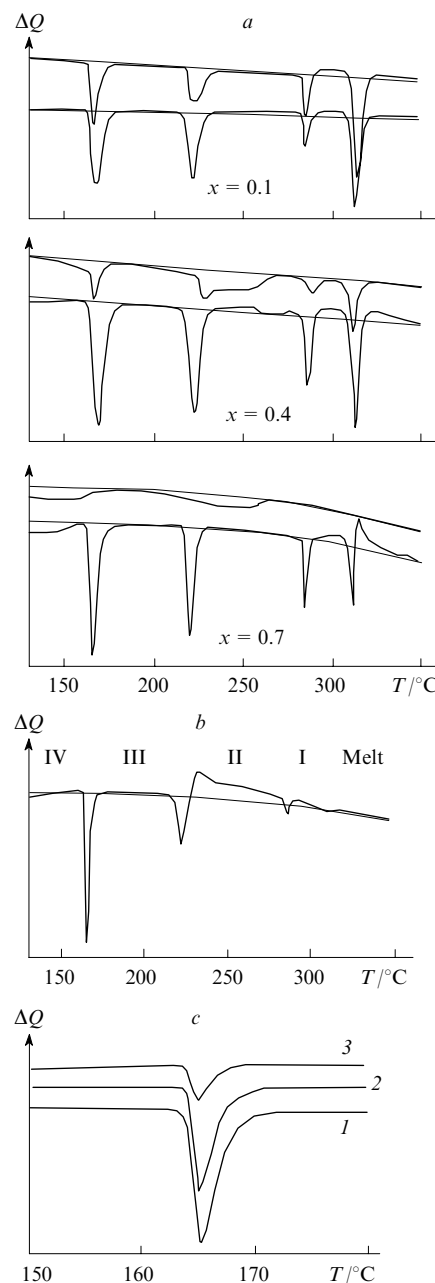

Figure 12. (a) DSC curves of original $\text{RbNO}_3-\text{Al}_2\text{O}_3$ mixtures (lower curves) and the same mixtures in repeated heating (upper curves) for different component ratios; (b) a DSC curve of a thoroughly ground mixture $0.6\text{RbNO}_3-0.4\text{Al}_2\text{O}_3$ obtained in the first heating and (c) a comparison of a segment of this curve (I) with the corresponding segments of DSC curves measured after 1-h exposure of this mixture to temperatures (2) 200 and (3) and 250 °C.

tivity.^{61, 71, 90–92} A comprehensive analysis of the temperature dependence of conductivity and the results of calorimetric studies of composites revealed the presence of two phase transitions. The temperature dependences of conductivity had a non-trivial shape, namely, with the increase in x , the phase-transition hysteresis gradually widened and the conductivities of the high-temperature (superionic) and low-temperature phases gradually became equal, *i.e.*, the phase transition of a salt to the superionic state gradually disappeared^{61, 71, 91} (Fig. 14a). The conductivity maximum ($\sim 10^{-3} \text{ S cm}^{-1}$ at 25 °C) was situated not at $x = 0.20-0.30$ as was observed earlier but at a higher mole fraction of the oxide, $x = 0.5-0.6$

Figure 13. State diagram of an ionic salt in a composite; the changes in the energy of the system in the amorphisation of ionic compounds are indicated.

(Fig. 14b). The activation energy of conduction in both superionic and low-temperature phases increased monotonically with the increase in x . The concentration dependence of

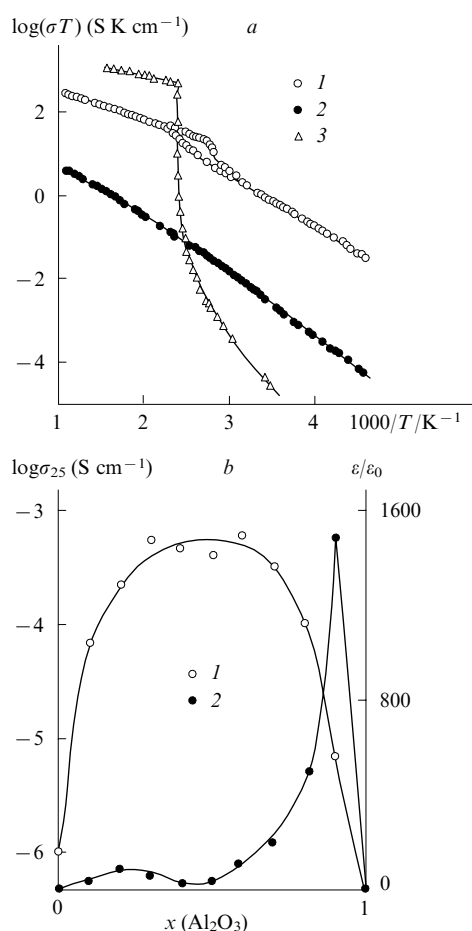

Figure 14. (a) Temperature dependences of conductivity (σT) of composites $(1-x)\text{AgI}-x\text{Al}_2\text{O}_3$ [$x = 0.60$ (1), 0.80 (2), 0 (3)] and (b) isotherms of their (1) conductivity and (2) permittivity at room temperature.⁹²

the dielectric permittivity $\varepsilon(x)$ had two maxima, namely, the first weak maximum at $x = 0.2$ and the second more pronounced maximum at $x = 0.9$ (see Fig. 14b).⁹² These results are consistent with the percolation model¹¹ according to which the permittivity maxima corresponding to two percolation thresholds should be observed at the oxide volume fractions $p_1 = 0.1$ and $p_2 = 0.9$ (i.e., at $x = 0.12$ and 0.94).

The temperature dependence of conductivity of the nanocomposite $\text{Li}_2\text{SO}_4-\text{Al}_2\text{O}_3$ lacked the conductivity jump at 575°C associated with the transition of lithium sulfate to the superionic state (Fig. 15).^{82, 83, 93, 94} The $\sigma(T)$ dependence had a shape typical of solid electrolytes with the fluorite structure in the vicinity of the 'diffuse' phase transition.

Figure 15. Temperature dependences of conductivity of (1) pure lithium sulfate and (2) a nanocomposite $\text{Li}_2\text{SO}_4-\text{Al}_2\text{O}_3$.⁸²

Studies of the conductivity of composites based on alkali metal nitrates $\text{MNO}_3-\text{Al}_2\text{O}_3$ ($\text{M} = \text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{Cs}$) have shown^{95, 96} that doping of nitrates with alumina with a specific surface area of $270 \text{ m}^2 \text{ g}^{-1}$ is accompanied by a sharp increase in the conductivity (Fig. 16). The dependences of the conductivity on the dopant concentration had a maximum at $x = 0.5-0.7$, and the relative increase in the conductivity

Figure 16. Arrhenius plots of conductivity for (1, 3, 5, 7, 9) pure alkali metal nitrates and (2, 4, 6, 8, 10) a 1:1 composite $\text{MNO}_3-\text{Al}_2\text{O}_3$.^{95, 96} $\text{M} = \text{Li}$ (1, 2), Na (3, 4), K (5, 6), Rb (7, 8), Cs (9, 10).

(σ/σ_0) at 343 K depended on the cation type and varied in the range from 10^2 (in composites $\text{CsNO}_3\text{--Al}_2\text{O}_3$) to 10^8 (in composites $\text{LiNO}_3\text{--Al}_2\text{O}_3$). For $x > 0.5\text{--}0.6$, the Arrhenius plots $\sigma(T)$ of all composites studied were not linear and lacked conductivity jumps at phase transition temperatures. The physicochemical properties of composites based on rubidium nitrate were studied in more detail. The decomposition voltage $U_d = 4$ V assessed from voltammetric curves was close to the corresponding values in fused alkali metal nitrates and halides which allows one to assume that rubidium cations are the main current carriers in the composites $\text{RbNO}_3\text{--Al}_2\text{O}_3$.

In the composites $\text{CsCl--Al}_2\text{O}_3$, with the increase in the oxide concentration, the conductivity jump associated with the transition to the high-temperature phase gradually disappeared, which was associated with the stabilisation of the latter phase (Fig. 17).¹⁴⁴

Figure 17. Dependences of conductivity of composites $(1-x)\text{CsCl--}x\text{Al}_2\text{O}_3$ (a) on the temperature and (b) and the oxide concentration. (a) $x = 0$ (1), 0.60 (2); (b) $T = 573$ (1), 673 (2) and 773 K (3).

Thus, in all systems under study, the nature of conduction was observed to change at sufficiently high concentrations of the fine-grain additive. These changes can be associated with either the appearance of new highly conductive amorphous phases atypical of pure ionic compounds (composites based on nitrates, $\text{AgI--Al}_2\text{O}_3$) or with the stabilisation of high-temperature phases (the phase-transition hysteresis in $\text{Li}_2\text{SO}_4\text{--Al}_2\text{O}_3$ and $\text{AgI--Al}_2\text{O}_3$, the formation of a face-centred cubic phase in $\text{CsCl--Al}_2\text{O}_3$) in composites. Moreover, the properties of high-temperature phases stabilised in nanocomposites differed from those of the same phases in pure salts, namely, the former had higher activation energies and modified lattice parameters. A clear trend for the levelling of the characteristics of high-temperature and low-temperature phases was observed, the phase transition region widened and the transition itself became diffuse approaching the second-order phase transitions. Nanocomposites differ basically from polycrystals and microcomposites in their properties; this is explained by the increasing effect of surface interactions on the bulk properties of ionic salts. Under certain conditions, this leads to the appearance of phase size effects or capillary effects of the second kind. Figure 18 illustrates the changes in the ionic salt structure in the vicinity of the MX–A interface, which were observed as the surface interaction increased, *i.e.*, on going from micro- to nanocomposites.

Computer simulation methods can be used for the elucidation of the nanocomposite structure and the conduction mechanism. Nanocomposites $\text{LiI--Al}_2\text{O}_3$ were studied¹⁶⁸ by the molecular dynamics techniques. It was shown that the phase contact was epitaxial, the electrical double layer was

Figure 18. Changes in the ionic salt structure in the vicinity of the MX–A interface with the increase in the effect of surface on the bulk properties of MX, *i.e.*, on going from micro- to nanocomposites.

formed at the interface and the activation energy of diffusion of lithium cations was close to the experimental value.

The molecular dynamics methods were also applied¹⁶⁹ for the simulation of the $\text{CsCl--}\alpha\text{-Al}_2\text{O}_3$ interface. The calculation model represented a two-layer heterostructure that comprised 22 080 ions (3840 ions of Cs^+ and Cl^- each and the balance number of Al^{3+} and O^{2-} ions). The calculations were performed for cyclic boundary conditions and involved the use of the Born–Mayer potential. The parameters of the potential were taken from the literature and refined in the preliminary simulation of individual starting components Al_2O_3 and CsCl . The heterostructure was obtained as a result of spontaneous crystallisation of a model CsCl melt, which was followed by the long-term isothermal exposure at $T = 0.8T_{\text{mp}}$ up to the establishment of the steady state (Fig. 19). Caesium chloride crystallised to form a high-temperature phase structure of the NaCl type and did not pass to the low-temperature state as the temperature decreased. The $\text{CsCl--}\alpha\text{-Al}_2\text{O}_3$ interface was realised along the $(110)\text{CsCl} \parallel (10\bar{1}0)\text{Al}_2\text{O}_3$ planes which were off-oriented by a small angle of $\sim 10\text{--}13^\circ$ and contained boundary dislocations at a distance of ~ 5 nm from one another. The boundary dislocations corresponded to the sites of the surface exposure of low-angle boundaries localised in the caesium chloride bulk. Although the bulk of caesium chloride as a whole represented a monolithic crystal, the low-angle boundaries divided it into two microdomains disoriented by $3\text{--}3.5^\circ$.

Figure 19. Heterostructure $\text{CsCl--Al}_2\text{O}_3$ calculated by the molecular dynamics method.¹⁶⁹

(a) For temperatures above the melting point of caesium chloride; (b) immediately after its hardening and isothermal exposure at $T = 0.8T_{\text{mp}}$.

In contrast to the system $\text{LiI}-\text{Al}_2\text{O}_3$, no double layer was formed on the interface. Nonetheless, the ions located in the vicinity of the interface and on low-angle boundaries exhibited enhanced mobility. The self-diffusion coefficients of caesium and chloride ions were approximately the same, *i.e.*, equal to $\sim 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ at 700 K, which is smaller than the corresponding values in molten CsCl by merely an order of magnitude. Apparently, the main difference of the system $\text{CsCl}-\text{Al}_2\text{O}_3$ from the system $\text{LiI}-\text{Al}_2\text{O}_3$ is the weak interface interaction. In this case, it is the energy of elastic strains the relaxation of which favours the appearance of intergrain dislocations and small-angle boundaries that makes the main contribution to the changes in the ionic salt properties. Hence, the real composite structure and the mechanism of ionic conduction in nanosized systems depend not only on the energy of interactions, but also on the energy of elastic strains that arise in the interface zone.

The spectrum of phenomena observed in nanocomposites is very wide. Particularly, nanocomposites with protonic conductivity, which are based on acid salts, were shown to exhibit interesting properties.^{146, 170–176} In our studies, we have shown that the physicochemical characteristics of ionic salts depend on the pore size in the silica gel used as the dispersed additive, *viz.*, there is an optimum pore size ($\sim 2 \text{ nm}$) corresponding to the maximum changes in the thermodynamic, structural and transport properties of CsHSO_4 .¹⁷⁰ In our studies, we deliberately ignored the systems with chemical interactions between the components. The chemical reactions make possible the formation of three or four-layer components that include the starting reagents and interfacial phases.¹⁷⁷ Recent years were marked by the discovery of metacomposites, *i.e.*, heterogeneous systems the interfacial interaction in which brings substantial changes into the physicochemical properties of both components.^{149, 178} Moreover, such a heterosystem as a whole exhibits the properties typical of none of its individual components. Such materials form a new interesting class of metamaterials. The transport properties of metamaterials synthesised by the layer-by-layer deposition of nanolayers $\text{CaF}_2/\text{BaF}_2$ were studied.^{179, 180} Nanostructured solid solutions^{181–183} the lattices of which contain separate nanodomains coherently attached to one another and divided by interdomain boundaries are of special interest for solid-state ionics. Highly doped superionic fluorides that comprise extended clusters in their structure are another example of nanoheterogeneous systems.¹⁸⁴ It is not improbable that nanostructuring is the general property of highly doped solid solutions.

Nanoheterogeneous solid-phase systems are of great interest for practice. Like all composite solid materials, they are characterised by the enhanced mechanical strength and thermal stability and can be used in chemical power sources, gas sensors and other electrochemical devices. The high ionic conductivity is among the most important characteristics of nanocomposite solid electrolytes. Nanocomposites based on conventional ionic salts far surpass the corresponding polycrystalline materials and microcomposites in the conductivity. Another valuable characteristics of these materials is that the phase transitions in them are absent or levelled off, which prevents the loss of their mechanical strength at thermal cycling. In model medium-temperature fuel cells with a nanocomposite solid electrolyte $\text{CsHSO}_4-\text{SiO}_2$, sufficiently high current densities were reached.^{185, 186} The performance of a fuel cell with a composite electrolyte compares well with the performance of a cell that employs pure salt as the electrolyte.¹⁸⁷ Nanocomposites $\text{LiClO}_4-\text{Al}_2\text{O}_3$ exhibit high lithium conductivity at 150–200 °C.¹⁴⁸ Studies of medium-temperature lithium cells with solid electrolytes and oxide electrodes

were initiated.¹⁸⁸ Further miniaturisation of these devices, the decrease in the electrolyte thickness and the optimisation of characteristics of electrode materials may provide high power of batteries.

VIII. Conclusion

Summarising the results of studies of composite ionic conductors, it may be concluded that the properties of composite solid electrolytes are determined by both the intrinsic disordering of an ionic salt and the interfacial interaction between the composite components. The intrinsic disordering of a conventional ionic crystal involves the stages of the defect formation in the bulk and on the surface of the crystal. The surface disordering is well described by the Stern model, which allows the surface potential to be easily calculated. The same model can be employed for the description of the mechanism of defect formation as the main stage of the interfacial interaction. Methods for the estimation of the conductivity and other physicochemical characteristics of composites were proposed. The problems of the thermodynamic stability of nanocomposites and the genesis of their morphology during the sintering were considered. The general peculiarities of the variation of ionic salt properties in a wide series of the ionic salt–oxide systems were analysed as well as the size effects.

In heterogeneous systems with sufficiently strong interfacial interaction, the effect of self-dispersion of an ionic salt was observed, which allowed the nanocomposites to be synthesised by the method of liquid-phase or solid-phase spreading. The nanosize state of a salt in systems thus obtained is thermodynamically stable if the size of oxide particles remains constant. Based on the combined studies of a wide series of composites $\text{MX}-\text{A}$ with different ionic compounds, it was shown that nanocomposites are characterised by considerable changes in the thermodynamic and structural properties of ionic salts. These changes manifest themselves most clearly in compounds that contain high-temperature disordered phases, namely, AgI , Li_2SO_4 and alkali metal nitrates. Disordered crystalline surface phases are stabilised in silver iodide and lithium sulfate, whereas the amorphous state is stabilised in nitrates. Rapid quenching of nanocomposites $\text{AgI}-\text{Al}_2\text{O}_3$ allowed amorphous silver iodide to be obtained for the first time. This convincingly proves that the pronounced size effects can be observed on going from microsystems to nanoscale systems, which opens up the possibility for the synthesis of new materials with unusual properties.

I am grateful to my teachers, academician V V Boldyrev and Dr. E F Hairtdinov for their help and constant supervision and also to the scientists of the Institute of Solid State Chemistry and Mechanochemistry of the Siberian Branch of the Russian Academy of Sciences (Novosibirsk) V G Ponomareva, G V Lavrova, L I Brezhneva, V P Isupov, A A Politov, B B Bokhonov, A P Nemudry, V V Zyryanov, I I Gainutdinov, Yu T Pavlyukhin, Yu G Mateishina, A S Ulihin and others who took active part in carrying out experiments and their discussion. I would like to express my sincere gratitude to academician V M Bouznik, corresponding member of RAS Yu A Kotov and professors A Ya Neiman, Yu I Aristov, A K Ivanov-Shits, I V Murin and Yu M Baikov for fruitful discussions of different aspects of these studies; to foreign scientists W Bollmann (Germany), A K Shukla and K J Rao (India), J Maier (Germany), P Vaněk, J Petzelt (Czech Republic) and G Meng (China) for the possibility of carrying out joint studies within the frames of various International programmes and also to academician Yu D Tretyakov for the proposal to publish this review in the special issue of this journal.

XIV. Properties and application of nanomaterials	453
XV. Conclusion	456

Abstract. The review summarises the main methods for the preparation of nanostructured metals, alloys, semiconductors and ceramics. The formation mechanisms of nanostructures based on two different principles, viz. the assembly principle (bottom-up) and the disintegration principle (top-down), are analysed. Isolated nanoparticles, nanopowders and compact nanomaterials produced by these methods possess different properties. The scope of application of various classes of nanostructured materials is considered and the topicality of the development of nanoindustry is emphasised. The bibliography includes 271 references.

I. Introduction

A large body of the available experimental data on nanomaterials and nanotechnologies provided the basis for the generalisation of fundamental and applied results in reviews and monographs.^{1–20}

Due to the development of the nanoscience in recent years, the data on nanotechnologies and nanomaterials become more abundant and new, sometimes unexpected, properties are revealed. Hence, the present review begins with the author's point of view on the nomenclature and comparative characterisation of the concept of nanomaterials and other similar (often related) notions.

Uspekhi Khimii 76 (5) 474–500 (2007); translated by T N Safonova

The term nanotechnology refers to the methods used for the construction of nanomaterials and nanodevices and methods of handling of nanoobjects. Nanotechnologies produce nanometre-size particles. These technologies are based on methods allowing the construction of objects with sizes that are thousand or even million times smaller than those visible to the human eye. The systematic and purposeful development of the fundamentals of nanotechnologies started several decades ago. Nowadays, the results of investigations in this field are introduced in industry. In the present review, emphasis is given to procedures for the preparation of nanostructured materials, their properties and promising fields of application.

Nanotechnologies aimed at preparing nanostructured materials can arbitrarily be divided into the following two groups: bottom-up and top-down. This classification takes into account the key step (or the process) of nanotechnology where a nanostructure is formed. The former group includes methods, in which nanoparticles are formed from atoms and molecules, i.e., the starting species are enlarged to nanometre sizes; the latter group, methods in which nanometre sizes are achieved by disintegration of larger particles, powders or grains. The former group of methods of nanotechnology are based primarily on the chemical approach, while the latter group of methods, on the physical approach. In many cases, nanomaterials with the same chemical composition but with different properties can be prepared using these two different in principle groups of technologies.

A decrease in the particle size of a solid below a certain threshold leads to a considerable change in its properties. For most known materials, the threshold at which a jumpwise change in the properties occurs (the so-called size effect) varies from 1 to 100 nm.

Of course, all materials composed of nanometre-size building blocks can be referred to as nanomaterials. Large molecules, clusters, material particles or polycrystalline grains can

serve as building blocks. However, in this case, the term 'nanomaterial' would be narrowed to the simple statement of the block size, and it would be unclear why the development of nanotechnologies is considered as a new technology revolution. Hence, it is necessary that the concept of a nanomaterial include not only the size of building blocks, but also a jumpwise change in properties of materials that occurs as the nanometre size is achieved.

In some publications, the term nanomaterials refers to highly dispersed, ultrafine-grain, superfine-grain or ultrathin materials. This is unjustified because the concept of nanomaterials includes a quantitative parameter, *viz.*, the size of a particle, grain or building block, reflected in the prefix 'nano'. In the other above-mentioned systems, the building block size is reflected only qualitatively (a small or supersmall size without mentioning its particular value), *i.e.*, the sizes are uncertain and relative. Consequently, the use of the term nanomaterials in relation to these systems should be avoided wherever possible.

The concept of nanomaterials should not be also confused with another commonly accepted concept of submicrocrystalline materials. The properties of submicrocrystalline materials, like those of nanomaterials, differ from the properties of coarsely crystalline, coarse-grain and single-crystalline materials. However, the difference in the properties is associated primarily with increased specific surface area which results in acceleration of various processes, *e.g.*, chemical reactions, but does not lead to a decrease in the activation energy (*i.e.*, to a decrease in the temperature of the beginning of the reaction). In submicrocrystalline materials, the particle, grain or building block size is assumed to be smaller than a micrometre. A micrometre, like a nanometre, is a quantitative characteristic. However, there is a difference in principle between nanomaterials and submicrocrystalline materials. It is the nanostate rather than the submicrocrystalline state that is intermediate between the molecular and solid states. The properties of solids are manifested at nanometre distances. This is also the physical reason of substantial changes in the properties observed on the nanometre-size scale. The fact is that the lengths at which the main physical forces act in materials vary from 1 to 100 nm. It should be noted that different types of interactions, *viz.*, electron–electron, electron–phonon, phonon–phonon, magnon–magnon, *etc.*, are extended to different distances in the same material. Hence these interactions can be observed for different nanoparticle sizes. It is evident that the nanoparticle size is of no fundamental importance for the same or different materials.

Nanomaterials are often called nanocrystalline materials. This is also not always justified. Crystalline particles or grains serve as building blocks in nanocrystalline materials. However, nanomaterials are, as a rule, thermodynamically non-equilibrium systems and, consequently, their building blocks do not necessarily have perfect crystal structures.²¹ It is more likely that the situation is opposite. Building blocks in nanomaterials often have highly defective structures. Sometimes, their state is close to amorphous. In other words, the long-range order in building blocks of nanomaterials can be violated, and multi-particle correlations in the atom arrangement are determined by the short-range order. Hence, the more correct and complete name for nanomaterials should be 'nanostructured materials'.

Different classifications of nanomaterials are associated with their diversity. The most appropriate classification is based on the size of building blocks or their constituent structural elements. The main types of nanomaterials are zero- (0D), one- (1D), two- (2D) and three-dimensional (3D). Nanocluster materials and nanodispersions composed of isolated nanoparticles belong to a zero-dimensional type; nano-

fibre (nanorod) and nanotubular materials, to a one-dimensional type, the fibre (rod) or tube length varying from 100 nm to tens of micrometres. Nanometre-thick films belong to two-dimensional nanomaterials. Nanoparticles in 0D, 1D and 2D nanomaterials are often embedded in a liquid or solid matrix or are deposited onto a support. Powders, fibre, multi-layer and polycrystalline materials, in which 0D, 1D and 2D particles are closely packed together to form interfaces, belong to three-dimensional nanomaterials. A polycrystal containing nanometre-size grains is an example of three-dimensional nanomaterials. In such polycrystals, the total bulk is occupied by nanograins, the free surface of grains is virtually absent, and only grain interfaces are present. The formation of interfaces and the 'disappearance' of the nanoparticle surface in three-dimensional nanomaterials is of fundamental importance for the understanding of the nature of their properties. Actually, the properties of a strongly agglomerated nanopowder can be substantially different from those of a compact nanomaterial consisting of particles of the same size as the powder. In the last two decades, considerable attention was given to the preparation of 3D nanomaterials. It is three-dimensional nanomaterials that will be used in the hard-alloy production, the aircraft construction and hydrogen power engineering in the nearest future.

Nowadays, a rather wide range of nanomaterials is available.^{11–20} In the present review, methods for the preparation of dense three-dimensional and two-dimensional nanostructured materials are considered.

II. Vapour condensation and gas-phase synthesis

One of the simplest procedures for the preparation of nanoparticles is based on vapour condensation in an inert atmosphere under reduced pressure. This method can be applied to the preparation of nanoparticles of both simple and complex compounds. Synthesis of nanoparticles of metal compounds, for example, of oxides, nitrides, carbides, *etc.*, requires that the corresponding reaction gas (oxygen, nitrogen, carbon dioxide, methane, *etc.*) be added. The simplest way to a material vapour is evaporation. The atoms of vaporised substances rapidly lose the kinetic energy and form nanoparticles. In the case of metal compounds, the metal atoms react with the reaction gas. Particles of the desired size can be formed by adjusting the inert gas pressure. The formation of nanoparticles according to this method was systematically studied for Zn, Cd, Se, As and Au. Particles with sizes from 2 to 100 nm were prepared,^{22–24} the optimum inert gas pressure being in the range from 40 to 400 Pa.

It is difficult to collect nanoparticles formed upon condensation because nanoparticles are not deposited under the force of gravity but exist in the suspended state in the Brownian motion. Nanoparticles are usually collected on a cold surface or on filters.

Nanoparticles can also be prepared by dispersing a metal in a liquid with the use of an electric arc followed by condensation of a metal vapour in a liquid vapour.²⁵ The features of condensation in a supersaturated vapour, which proceeds through the nucleation and nucleus growth, were considered in the reviews.^{26–28}

The shapes of nanoparticles prepared by the gas-phase method depend on their size. Nanoparticles with size < 20 nm are spherical in shape due to a change in the relative contribution of the surface energy to the total energy of nanoparticles as their sizes decrease. Larger particles are faceted. Yet another interesting fact associated with the small size of isolated nanocrystals and related to the energy is the absence of dislocations, which are energetically less favourable than disclinations.²⁹

In the gas-phase synthesis, nanoparticles are formed upon cooling of a vapour–gas mixture containing one, two or more chemical elements along with an inert gas. Cooling occurs in the condensation zone the size of which in a particular reaction vessel can be controlled by varying the inert gas pressure. The condensation zone increases with a decrease in pressure and *vice versa*. The influence of the change in the inert gas pressure on the resulting nanoparticle size is manifested both directly and through the condensation zone size. An increase in the gas pressure leads to an increase in density, acceleration of heat removal, a decrease in the formation rate of crystallisation centres in the gas phase, but an increase in the growth rate of crystals and, consequently, the resulting particle size. In the gas-phase synthesis of rather small particles (20–30 nm), the inert gas (usually, helium) pressure is maintained at 40–60 Pa.

Preparation of nanoparticles of metal compounds requires that a reaction gas be added to the inert gas medium. Single-crystalline nanoparticles of metal compounds with different morphologies are formed in these reactions. The particle shape can be controlled by varying the composition of the gas phase. For example, CdS can be prepared as prismatic plates, ribbons, needles, whiskers, threads or tubes upon variation of the temperature and deviation of the Cd:S ratio in the gas phase from the stoichiometric ratio (1:1) toward an increase in the cadmium content.^{30,31} The intermediate clusters $[\text{CdS}]_n$, $[\text{Cd}_2\text{S}]_n$ and $[\text{Cd}_3\text{S}]_n$ serve as the structural basis of the growth of crystals of different shapes. Thus, the ratio of the starting components of the gas phase and the temperature are the main factors determining the particle shape, whereas their size more strongly depends on the inert gas pressure.

Monodisperse nanoparticles with size <2 nm can be prepared by mass separation of clusters in a mass spectrometer. For example, metal vapour is passed through a cell filled with helium under a pressure of ~1000–1500 Pa and then introduced into a vacuum chamber (~10⁻⁵ Pa). The mass of clusters is determined from the flight time by a particular distance in the mass spectrometer. This method was used for the preparation of antimony, bismuth and lead clusters containing 650, 270 and 400 atoms, respectively. The helium gas temperature in the case of Sb and Bi vapour was 80 K; in the case of a Pb vapour, 280 K.³²

Diamond nanoparticles can be synthesised from a gas phase supersaturated with respect to carbon (CO₂, methane, acetylene, propane and other hydrocarbons) under a sub-atmospheric pressure.^{33,34} Condensation of carbon from the gas phase and diamond nucleation are favoured by an excess surface energy at the solid–gas interface. Deposition of diamond nanoparticles is widely used for the construction of diamond and diamond-containing films and coatings.³⁵

Nanocrystalline powders of oxides Al₂O₃, ZrO₂ and Y₂O₃ were prepared by evaporation of oxide targets in a atmosphere helium,³⁶ magnetron sputtering of zirconium in a mixture of argon and oxygen³⁷ and controlled oxidation of yttrium nanocrystals.³⁸ Highly dispersed powders of transition metal nitrides can be synthesised by electron-beam heating of the corresponding metal targets, evaporation being performed in an atmosphere of nitrogen or ammonia at a pressure of 130 Pa.³⁹

Metal carbide, oxide and nitride nanoparticles can be synthesised by pulsed laser heating of metals in an atmosphere of methane (for carbides), oxygen (for oxides), nitrogen or ammonia (for nitrides) under reduced pressure.⁴⁰ Pulsed laser evaporation of metals in an atmosphere of an inert gas (He or Ar) and reaction gases (O₂, N₂, NH₃ and CH₄) affords mixtures of nanocrystalline metal oxides and oxide–nitride and carbide–nitride mixtures. The composition and size of nanoparticles in these mixtures can be controlled by varying the pressure, the composition of the atmosphere, the laser pulse

power and the temperature gradient between the evaporated target and the surface onto which condensation occurs.

Nanoparticles of Fe–Ni, Fe–Mn, Fe–Cr, Fe–Pt and Fe–Co iron-rich alloys are prepared under argon at a pressure of 400 Pa.⁴¹ Deposited particles are spherical in shape. Their average size is 25 ± 5 nm. As a rule, nanoparticles are two-phase (with bcc or hcc lattices), which corresponds to the thermodynamic equilibrium between the components in these alloys.

An yttrium oxide-doped zirconium oxide film with an average crystallite size of 10–30 nm was prepared by pulsed laser evaporation of metals in an oxygen ion beam followed by deposition of oxides onto a support at 350–700 K.⁴²

Nanopowders of ceramic materials can be prepared from organometallic and organoelement compounds. For example, nanocrystalline SiC_xN_y powders were prepared as follows. The starting compound (hexamethyldisilazane) was mixed with an inert carrier gas in a heated tubular reactor serving as an evaporator. Its thermal decomposition affords a continuous cluster or nanoparticle flow, which escapes from the reactor into a working chamber and is condensed in a refrigerator constructed as a rotating cylinder. Nanopowders of SiO₂, SiC and Si₃N₄ can be synthesised by adding water, hydrogen or ammonia, respectively, along with the same precursor to the carrier gas. The success of the reaction is provided by a low concentration of the organoelement compound in the inert gas, fast expansion and cooling of the gas flow at the exit from the reactor into the working chamber and a low pressure in the working chamber.⁴³

III. Plasmochemical synthesis

The plasmochemical synthesis is most commonly used for the synthesis of highly dispersed boride, carbide, nitride and oxide powders. This method makes use of low-temperature (4000–10 000 K) nitrogen, ammonia, hydrogen, hydrocarbon or argon plasmas produced by arc, glow, high-frequency and superhigh-frequency discharges. The characteristics of the resulting powders depend on the nature of the starting material, the technology and the reactor type. Particles of such powders are most often prepared as single crystals with sizes from 10 to 100–200 nm and larger. For nanoparticles to be synthesised by this method, the reaction should be far from equilibrium and the rate of solid-phase nucleation should be high, whereas the rate of nucleus growth should be low. The plasmochemical synthesis provides high formation and condensation rates of compounds and sufficiently high output. Broad particle size distribution (*i.e.*, low selectivity of the process) and heavy contamination of the powder are the main drawbacks of this method. Highly dispersed powders of titanium, zirconium, hafnium, vanadium, niobium, tantalum, boron, aluminium and silicon nitrides, titanium, niobium, tantalum, tungsten, boron and silicon carbides and magnesium, yttrium and aluminium oxides were prepared by the plasmochemical method.^{32,36–51}

At high plasma temperature, all starting compounds pass into the ionised gas state due to which the reaction rates are high and the reaction times are short (10⁻³–10⁻⁶ s). Active particles are formed in arc, high-frequency and superhigh-frequency plasma reactors. Arc plasma reactors are characterised by the highest power and efficiency; however, materials prepared in such reactors are contaminated by electrode erosion products. Electrodeless high-frequency and plasma ultrasonic reactors are free from this drawback. In the next step, quenching results in the isolation of the reaction products. Powders with the desired composition and with a particular particle shape and size can be prepared by varying the quenching region and rate.

Since nanoparticles synthesised by the plasmachemical method have a large excess energy, their chemical and phase compositions can be inconsistent with the equilibrium phase diagram. Additional short-term annealing of the product in a controlled atmosphere helps in preparing nanoparticles of the required stoichiometry. For example, a tungsten carbide powder was synthesised by the plasmachemical method from tungsten oxide (WO_3) and methane in a low-temperature ($\sim 4000\text{--}5000\text{ K}$) hydrogen plasma flow.⁵² A nanocrystalline powder with an average particle size of 20–40 nm was obtained. An X-ray powder diffraction study (Fig. 1 *a*) showed that the powder contained two carbide phases, *viz.*, W_2C ($> 75\text{ mass \%}$) and WC ($\sim 5\text{ mass \%}$), and tungsten ($\sim 18\text{ mass \%}$). Chemical analysis revealed the presence of free carbon in the powder. To achieve the single-phase state, the synthesised powder was additionally annealed under argon at 800–1000 K. The annealed powder contained only hexagonal (space group $P6m2$) tungsten carbide (Fig. 1 *b*). The size of coherent scattering regions in the annealed powder remained virtually unchanged compared to that in the starting powder, but the particle size determined by scanning electron microscopy⁵³ increased to 60–120 nm. This suggests agglomeration of nanoparticles in the annealed powder. The retention of the nanoparticle size of WC in the powder after annealing at 800–1000 K is associated with high thermal stability of this compound, as was demonstrated by magnetic susceptibility measurements.⁵³

Figure 1. X-Ray powder diffraction patterns of tungsten carbide powders prepared directly by the plasmachemical synthesis (*a*) and after additional homogenising annealing (*b*).⁵² The resulting powder is multiphase; after additional annealing under argon, a single-phase powder was obtained; the average nanoparticle size of the powder was 20–40 nm.

The gas-phase synthesis involving laser heating of a reaction mixture is a version of the plasmachemical synthesis.^{54, 55} This method is highly competitive with other methods due to its reliability and high efficiency. Laser heating excludes contamination of the reaction mixture and allows the control over homogeneous nucleation. Other advantages of laser heating are that surfaces inducing heterogeneous nucleation are absent and the process can be controlled. A laser is a source of high-intensity monochromatic radiation due to which a high degree of its conversion to heat is achieved. The laser-induced synthesis of nanocrystalline Si, Si_3N_4 and SiC powders was described in detail.⁵⁴ Silicon powders were prepared by pyrolysis of gaseous silane (SiH_4) using a CO_2 laser. Silicon grains

were spherical in shape with a diameter of $50 \pm 20\text{ nm}$ and consisted of several crystallites with the size of $\sim 15\text{ nm}$. Silicon nitride powders were synthesised from a gas mixture of silane and ammonia. The resulting powder was amorphous, and the grains were spherical with a diameter of $17 \pm 4\text{ nm}$, the size distribution of grains being narrower than that in a silicon powder (for Si_3N_4 , the size distribution of grains varied from 10 to 25 nm). Unlike silicon nanoparticles, Si_3N_4 grains had no internal structure. Silicon carbide was synthesised from gas mixtures of silane with methane or ethylene. The grain size in the resulting crystalline SiC powder varied from 18 to 26 nm; the average size was 21 nm. The nanoparticle size was demonstrated⁵⁴ to decrease as the intensity of the laser radiation increased due to an increase in the temperature and the heating rate of the reagent gases. Grains of nanopowders synthesised by laser heating are characterised by a narrow size distribution and a spherical shape.

The plasmachemical gas-phase synthesis with the use of laser radiation for the plasma production and maintenance proved to be efficient for the preparation of molecular clusters. The latter have polymorphic cage atomic structures and occupy special place among nanoparticles. Fullerenes, which are allotropes of nanocarbon and differ from the known carbon modifications (graphite and diamond), have received most attention.^{56–58}

Fullerenes can be synthesised by sputtering of graphite in an electric arc under helium at a pressure of $1.33 \times 10^4\text{ Pa}$. Arc burning affords soot that is condensed on a cold surface. The soot is collected and treated with refluxing toluene or benzene. The extract is concentrated to give a black residue containing a mixture of fullerenes C_{60} and C_{70} ($\sim 10\text{--}15\%$). Electron-beam evaporation and laser ablation can be used instead of electric arc sputtering. The diameter of the C_{60} fullerene molecule is 0.72–0.75 nm. Crystallisation of C_{60} affords molecular crystals with a fcc lattice; the unit cell parameter is 1.417 nm. Among carbon nanoparticles fullerene C_{60} is characterised by higher stability, which has been predicted theoretically.^{59, 60}

The plasmachemical synthesis was also used for the preparation of other important molecular nanoclusters, such as fullerene-like $\text{C}_{48}\text{N}_{12}$,⁶¹ the endohedral complex $\text{Ti}@\text{C}_{28}$ (Ref. 62) and the stable charged cluster $\text{Ti}_8\text{C}_{12}^+$ with the linear size of $\sim 0.5\text{ nm}$.^{63, 64}

The clusters M_8C_{12} , where $\text{M} = \text{Zr}, \text{Hf}, \text{V},^{65, 66} \text{Cr}, \text{Mo}$ or $\text{Fe},^{67}$ are called metallocarbohedrenes (Met–Car). In these compounds, transition metal and carbon atoms form a cage-like structure. Metallocarbohedrenes were characterised and the methods for their synthesis were summarised in reviews.^{68, 69}

Interestingly, the plasmachemical gas-phase synthesis^{63, 65, 66} produced predominantly the clusters M_8C_{12} and M_mC_n ($\text{M} = \text{Ti}, \text{Zr}, \text{Hf}$ or V) with a ratio $\text{M}:\text{C} \approx 1.5\text{--}2.0$ rather than nanoparticles of carbides TiC , ZrC , HfC or VC with the structure *B1*. Analogous synthesis in $\text{Ta}\text{--}\text{C}$ and $\text{Nb}\text{--}\text{C}$ systems affords the clusters Ta_mC_n and Nb_mC_n , respectively the composition of which is similar to that of M_8C_{12} along with small amounts of nanoparticles M_mC_n ($m \approx n$) with a cubic structure. Conventional plasmachemical synthesis (without laser heating of a plasma) yields only carbide nanoparticles. Thus, the gas-phase synthesis in transition metal–carbon systems can afford both cubic structures and metallocarbohedrene-like structures.

Metallocarbohedrenes are formed at a high hydrocarbon concentration and a high laser power.⁷⁰ These conditions favour an increase in the carbon content in the plasma. A decrease in the hydrocarbon concentration or a decrease in the laser power leads to a decrease in the carbon content in the plasma. If carbon is present in a deficient amount, carbide

nanoparticles MC with the cubic structure $B1$ are formed. The carbon content in these particles is lower than that in the molecular clusters M_mC_n . This suggests that the formation of cubic or dodecahedral structures in systems $M-C$ under conditions of the gas-phase synthesis is determined primarily by the kinetic rather than thermodynamic factors. The correct answer to the question about the factors responsible for the predominant formation of a particular structure is of practical importance because it allows the targeted synthesis of the desired modification of nanostructured materials.

A version of deposition from a plasma is based on magnetron sputtering, which allows the use of not only metal or alloy cathodes, but also of cathodes made of different compounds, thus decreasing the substrate temperature by 100–200 K. This allows the synthesis of a wider range of nanostructured films. However, the degree of ionisation, the kinetic energy of ions and the deposition rate of the product in the case of magnetron sputtering are lower than those obtained with the use of an arc discharge plasma. Intermetallic Ni_3Al films with an average crystallite size of ~ 20 nm were synthesised by magnetron sputtering of the $Ni_{0.75}Al_{0.25}$ target and deposition of a metal vapour on an amorphous substrate.⁷¹

Conventional methods for deposition of films are based on chemical vapour deposition (CVD) and physical vapour deposition (PVD). These methods have long been used for the preparation of films and coatings for different purposes. Generally, crystallites in these materials are rather large in size, but nanostructures can be prepared in multilayer or multiphase CVD films.^{8,72} Vapour deposition is generally associated with high-temperature reactions of metal chlorides in an atmosphere of hydrogen and nitrogen or hydrogen and hydrocarbons. The temperature range of deposition of CVD films is 1200–1400 K, and the deposition rate is $0.03\text{--}0.2\ \mu\text{m min}^{-1}$. The use of laser radiation leads to a decrease in the deposition temperature to 600–900 K, which is favourable for the formation of nanocrystalline films.

IV. Deposition from colloidal solutions

Chemical deposition from colloidal solutions is widely used for the preparation of highly dispersed powders as well as of discrete and continuous films. To prepare nanoparticles from colloidal solutions, the chemical reaction between the solution components is interrupted at a particular instant of time,⁷³ after which the system is converted from the liquid (colloidal) state to the solid (dispersed) state. The method for the preparation of stable colloidal gold solutions and their optical properties were described for the first time by Faraday.⁷⁴

Deposition from aqueous colloidal solutions is used for the synthesis of various metal chalcogenides (sulfides, selenides and tellurides) having semiconducting properties. For example, the synthesis of nanocrystalline sulfide powders involves the reaction of water-soluble metal salts with a sulfidising reagent (a sulfur atom donor). Hydrogen sulfide and sodium sulfide are the simplest sulfidising agents. For example, deposition from a mixture of solutions of cadmium perchlorate and sodium sulfide by the reaction

affords nanostructured cadmium sulfide. The growth of CdS nanoparticles can be interrupted by a jumpwise increase in pH of the solution.

In the synthesis of sulfide nanoparticles of a specified size, thiocarbamide (thiourea) and its derivatives (for example, thiosemicarbazide, thiocarbazine, thioacetamide, allylthiourea, acetylthiourea and sodium thiosulfate) are used as sulfidising reagents. Each of them is characterised by particular formation rates and properties of the resulting films (precip-

itates). In addition, each sulfidising reagent is characterised by particular optimal deposition conditions of metal sulfide. Metal sulfides are deposited as a result of the irreversible reaction; the positive chemical affinity serves as the criterion of the spontaneous formation of sulfide.⁷⁵ [The chemical affinity is equal to the product of the gas constant and the absolute temperature (RT) and the natural logarithm of the ratio of the equilibrium constant of the process under consideration to the product of the concentrations and activities of all components.]

The sizes of PbS particles can be controlled using thiourea and varying the chemical affinity for deposition of the sulfide (Fig. 2). The sulfide particle size, which is equal to the size of coherent X-ray scattering regions at a wavelength λ , was determined^{76–78} by the Williamson–Hall method (Fig. 3) from the dependence of the reduced broadening

$$\beta^*(2\theta) = \frac{\beta(2\theta) \cos \theta}{\lambda}$$

on the scattering vector

$$s = \frac{2 \sin \theta}{\lambda};$$

for the quantitative analysis, the X-ray diffraction line profile was described by the pseudo-Voigt function.^{77,79}

Figure 2. Linear approximation (solid line) of the dependence of the particle size (coherent scattering region) on the chemical affinity for deposition of lead sulfide powders.⁷⁵ (1) X-Ray diffraction, (2) scanning electron microscopy.

The size of cadmium sulfide nanoparticles synthesised by chemical deposition from colloidal solutions with thiourea varied from 2 to 10 nm.^{77,80–83} The structures of nanofilms were studied by a new X-ray diffraction method, the so-called X-ray grazing incidence diffraction, which is also called X-ray scattering under total external reflection conditions. This method was used for studying deposition on a substrate and the atomic structures of films several nanometres thick (Fig. 4)^{21,78,82} and for confirming the hydroxide mechanism of the formation of cadmium sulfide films.⁸²

After deposition of a cadmium sulfide film, the precipitates contained hexagonal prismatic particles several micrometres in size (Figs 5 and 6)⁸⁰ where self-organisation of nanoparticles differed substantially from that observed in analogous compounds prepared by chemical deposition^{84–87} and from that found in SiO_2 (Ref. 88) and TiO_2 (Ref. 89). This is because CdS nanoparticles of several nanometres in size, which form a colloidal crystal several micrometres in size, are arbitrarily

Figure 3. Dependence of broadening of reflections $\beta^*(2\theta)$ on the scattering vector (s) for submicrocrystalline PbS with a particle size of 300 ± 50 nm (1) and nanocrystalline PbS with a particle size of 60 ± 25 nm (2).⁷⁵ The Miller indices for the structure B1 are given.

X-Ray diffraction spectra of cadmium sulfide films prepared at 325 K by deposition from the reaction mixture during different periods of time.⁸² The concentrations of the components of the reaction mixture /mol litre⁻¹: $[\text{CdCl}_2]$ is 0.005, $[(\text{NH}_2)_2\text{CS}]$ is 0.025, $[\text{NH}_3]$ is 1.50, $[\text{NaOH}]$ is 0.074; the deposition time /min: (1) 2, (2) 3, (3) 3.

oriented with respect to each other, are irregular in shape and are different in size. Cadmium sulfide nanoparticles are packed closely together in coagulates with the size of ~ 150 nm (Fig. 7).⁸⁰

Self-organisation is a common natural phenomenon.^{90, 91} In recent years, the self-organisation processes in chemistry^{17, 18} have attracted considerable attention because these processes are intended for the use in nanotechnologies for self-assembly of highly efficient schemes for nanoelectronics. The self-assembly mechanism of nanoparticles remains unclear. Emphasis is given to the elucidation of the nature of forces of interparticle interactions, which result in self-organisation and ordering of nanoparticles to form one-, two- and

three-dimensional assemblies.⁸⁷ Van der Waals, capillary, electrostatic, steric, *etc.* forces are considered as such forces.

Colloidal metal oxide particles are formed by hydrolysis of salts.^{92–95} For example,

Nanocrystalline titanium, zirconium, aluminium and yttrium oxides can be prepared by hydrolysis of the corresponding chlorides or hypochlorites. Titanium oxide nanoparticles can also be prepared by hydrolysis of titanyl sulfate followed by calcination of the amorphous precipitate at 1000–1300 K. Coagulation of nanoparticles can be prevented by addition of polyphosphates, amines and hydroxide ions to colloidal solutions.

Figure 7. A photomicrograph of coagulates in a chemically deposited CdS powder.⁸⁰ Nanoparticles with the size of 7 nm densely fill the volume inside the coagulates.

Deposition from colloidal solutions is highly efficient for the synthesis of isolated nanoparticles and allows the preparation of nanoparticles characterised by a very narrow size distribution.

Metal and semiconductor clusters with a narrow size distribution can be prepared inside pores of molecular sieves (zeolites), isolation of clusters inside the pores being retained upon heating to very high temperatures. This method was used for the synthesis of, for example, the semiconductor clusters $(\text{CdS})_4$.⁹⁶ The properties of clusters prepared in zeolite pores were considered in a review.⁹⁷ Larger semiconductor nanoparticles can be synthesised upon attachment of additional molecules to the starting clusters pre-stabilised by organic ligands. This synthesis of large nanoparticles can be considered as polymerisation of inorganic compounds.

Isolated nanoparticles can also be obtained by ultrasonic treatment of colloidal solutions containing large particles.

Deposition from colloidal solutions can be used for the synthesis of nanocrystalline heterostructures, *viz.*, nanoparticles with mixed composition where the core and the shell are formed by semiconductors with different structures of the electron levels (for example, CdSe/ZnS or ZnS/CdSe , HgS/CdS , ZnS/ZnO and $\text{TiO}_2/\text{SnO}_2$). For this purpose, con-

trolled deposition of a semiconductor onto pre-synthesised nanoparticles of a semiconductor of another type should be performed.^{98–101}

An important problem encountered in the deposition from colloidal solutions is prevention of coalescence of the resulting particles and clusters. The chemical synthesis of large stabilised metal clusters with the use of colloidal solutions was described in detail in a review.¹⁰² Generally, colloidal particles and clusters are stabilised by ligands L represented usually by polymers. The reaction scheme for the synthesis of ligand-stabilised metal clusters M_n is as follows:

Metallic gold, platinum and palladium clusters synthesised by this method contain from 300 to 2000 atoms and have cubic or hexagonal close-packed structures. Ligand-stabilised clusters contain the metal core and the external shell formed by the metal atoms that are partially coordinated by ligand molecules. For example, reduction of palladium acetate in acetic acid with hydrogen in the presence of phenanthroline affords stabilised palladium nanoclusters.¹⁰³ The phenanthroline molecules form a shell around the core consisting of the palladium atoms (Fig. 8).

Figure 8. A photomicrograph of a stabilised palladium nanocluster formed by seventeen closely packed atom rows and coated by an eight-layer shell composed of phenanthroline molecules.¹⁰³ The cluster boundaries are indicated by arrows.

Highly dispersed powders can be prepared by calcination of precipitates from colloidal solutions consisting of agglomerated nanoparticles at 1200–1500 K. For example, a nanocrystalline silicon carbide powder ($D \sim 40 \text{ nm}$) was obtained upon hydrolysis of organosilicon compounds followed by calcination in argon at 1800 K.¹⁰⁴ Highly dispersed titanium and zirconium oxide powders are often synthesised by deposition with oxalates.

Nanopowders can also be prepared by cryogenic drying of colloidal solutions.^{9, 11} In this case, a solution is sprayed into a chamber containing a cryogenic medium where the solution is frozen as small particles. Then the gas pressure is reduced to a value lower than the equilibrium pressure above the frozen solvent. Then the material is heated (with continuous evacuation of gases) to remove the solvent. As a result, thinnest porous granules possessing the same composition are formed. Calcination of the latter affords powders.

Various nanostructured mixtures can be synthesised by deposition. An efficient procedure was developed^{105, 106} for the

synthesis of nanocrystalline composites of tungsten carbide and cobalt, which are intended for the preparation of nanostructured solid alloys. Since the synthesis begins in solution, mixing of the components (WC and Co) occurs at the molecular level. Colloidal solutions of tungsten and cobalt salts [for example, $(\text{NH}_4)_6(\text{H}_2\text{W}_{12}\text{O}_{40}) \cdot 4\text{H}_2\text{O}$, CoCl_2 , $\text{Co}(\text{NO}_3)_2$ and $\text{Co}(\text{AcO})_2$] are dried by spraying. Then the resulting powder is subjected to low-temperature carbothermal reduction in a suspended state due to which high dispersity is retained. This technology is covered by a patent¹⁰⁷ under the name the spray conversion process (SCP). A carbidised powder is amorphous. To retard the grain growth and decrease solubility of WC in cobalt, up to 1 mass % of non-stoichiometric vanadium carbide was added to the mixture. The solid alloy prepared from this nanocrystalline composite is characterised by an optimum combination of high hardness and stability. The hardness (H_V) of this alloy is as high as 21.5 GPa, whereas the maximum hardness of the alloy with the same composition prepared from a WC powder is at most 19.5 GPa.^{105–108} An increase in the percentage of vanadium carbide in the alloy leads to an increase in the hardness and a decrease in the grain size of WC. The size distributions of grains in samples of WC alloys containing 6 mass % Co, which were sintered from a nanostructured mixture with 0.83 mass % VC, and in samples of a WC alloy with 6 wt% Co and an additive of 0.32 mass % VC are shown in Fig. 9.¹⁰⁹ As can be seen from Fig. 9, the average grain size of WC in the alloy prepared from an amorphous nanopowder is 250 nm; in the usual alloy, the grain size is almost twice as large (450 nm).

Figure 9. The size distribution of grains in samples of a tungsten carbide alloy; 6 mass % Co.¹⁰⁹

(1) An alloy sintered from a nanostructured mixture of WC and Co with 0.83 mass % VC, which was prepared by co-deposition from a colloidal solution followed by drying and carbothermal reduction (the sample contained 1000 grains); (2) a usual fine-grain WC alloy with 6 mass % Co and 0.32 mass % VC, the sample contained 948 grains.

Each WC–Co nanoparticle with the size of $\sim 75 \mu\text{m}$ was demonstrated^{109,110} to consist of several millions of nanocrystalline WC grains with the size $< 50 \text{ nm}$ distributed in a cobalt matrix (Fig. 10). This nanocrystalline WC–Co powder with a carbide grain size of 20–40 nm is produced in the USA on a commercial scale under the trademark NANOCARB™.

Sintering of a nanostructured mixture of tungsten carbide with 6.8 mass % Co and 1 mass % VC afforded alloys in which 60% of WC grains had sizes of $< 250 \text{ nm}$ and 20% of WC grains, sizes of $< 170 \text{ nm}$. An alloy containing, in addition to tungsten carbide, 9.4 mass % Co, 0.8 mass % Cr_3C_2 and

Figure 10. Distribution of nanometre-sized tungsten carbide grains in large particles of an amorphous mixture of WC with 6 mass % Co and 0.83 mass % VC, which was prepared by deposition from a colloidal solution followed by drying and carbothermal reduction.^{109,110}

(1) A particle of a WC–Co composite powder with the size of $75 \mu\text{m}$, (2) fragments of the particle after powder milling, (3) a polycrystalline cluster composed of WC grains in a cobalt matrix, (4) a grain of carbide WC with the size of 30 nm .

0.4 mass % VC had an even finer grain structure. After sintering at 1670 K, 60% of tungsten carbide grains in the alloy had sizes of $< 140 \text{ nm}$ and 20% of grains, sizes of $< 80 \text{ nm}$. Thus, the use of nanostructured WC–Co mixtures synthesised by chemical deposition from colloidal solutions proved to be very efficient for the preparation of nanostructured solid alloys.

Oxide semiconductor films are formed upon deposition onto a support from colloidal solutions. The method involves the preparation of the solution, deposition, drying and annealing. Deposition of oxide nanoparticles afforded ZnO , SnO_2 , TiO_2 and WO_3 semiconductor films.^{111–115} Nanostructured films containing different semiconductor nanoparticles can be synthesised by co-deposition of the latter. The procedure for the preparation of nanocrystalline ZrO_2 films was documented.¹¹⁶

Pulsed electrodeposition is an efficient procedure for the application of coatings and films. This method is also widely used for the preparation of nanostructured metals. A support is soaked in a solution containing ions of an element to be precipitated, and the time-variable (pulsed) potential difference is created between the support and the electrode placed in the solution. The pulsed voltage favours the formation of a

homogeneous coating. A study of the influence of the deposition parameters on the structure and properties of a nickel coating¹¹⁷ demonstrated that the size distribution of grains is narrow, the nickel grain size varying from 13 to 93 nm. Heating of the resulting coating to 380 K did not result in grain growth. The cited study showed also that the grain size and the chemical composition of the nanocrystalline alloy $\text{Ni}_{1-x}\text{Cu}_x$ deposited at room temperature can be controlled by varying the parameters of the pulsed mode and adding organic compounds to the reaction solution.

V. Pyrolysis

In the preparation of nanocrystalline metal powders and their compounds by pyrolysis (thermal decomposition), complex organoelement and organometallic compounds, polymers and metal hydroxides, carbonyls, formates, nitrates, oxalates, amides, imides and azides are generally used as the starting compounds. These compounds contain all or almost all chemical elements, which should be present in the target product. Heating of the starting compounds to a particular temperature results in their decomposition to form the target product and evolution of gaseous compounds.

Highly dispersed metal powders are synthesised by thermal decomposition of various salts.¹¹⁸ For example, metal powders with an average particle size of 100–300 nm were prepared by pyrolysis of iron, cobalt, nickel and copper formates under vacuum or in an inert gas at 470–530 K. Other combinations of pyrolysis and condensation are also used for this purpose. Decomposition of organometallic compounds occurs in a percussion fuse, after which free metal atoms are condensed from a supersaturated vapour, or during supersonic gas flow from a chamber through a nozzle into vacuum.¹¹⁹ The preparation of nanocrystalline metal powders by reduction of metal hydroxides, chlorides, nitrates and carbonates in a hydrogen flow at < 500 K can be considered as a modification of pyrolysis. Low impurity content and a narrow size distribution of particles are advantages of this method.

Thermal decomposition combined with reduction is used for the preparation of supported metal catalysts. This technology is widely employed in industry. In this case, a porous material (silica gel, zeolite, *etc.*) is impregnated with a solution of hydroxide or another compound of the required metal. The impregnated porous support is dried and then calcined in a hydrogen flow to reduce the metal. As a result, catalytically active metal nanoparticles are formed in pores of the support.

However, pyrolysis is most often used for the preparation of nanocrystalline powders of ceramic materials, such as various oxides, carbides, nitrides, borides, carbonitrides, borocarbides, borocarbonitrides, *etc.*

The synthesis of oxide nanomaterials starting from metal carboxylates and their chemical modification products by ethylene glycol was documented.¹²⁰ The compound $\text{Ti}(\text{OCH}_2\text{CH}_2\text{O})_2$ proved to be an efficient precursor for the synthesis of titanium dioxide nanofibres with a diameter from 20 to 100 nm.¹²¹ Titanium glycolate nanofibres were synthesised by heating hydrated titanium dioxide $\text{Ti}(\text{OH})_4$ with ethylene glycol in air. Then titanium glycolate nanofibres were subjected to thermal decomposition in air at a temperature from 400 to 900 °C to prepare TiO_2 nanofibres. Depending on the thermal decomposition temperature, titanium dioxide had a crystal structure of either anatase or rutile, the morphology of the precursor being retained.

A nanocrystalline powder of titanium carbide TiC can be synthesised by pyrolysis of the coordination organometallic compound $(\eta\text{-C}_5\text{H}_5)_2\text{TiMe}_2$ under argon or by pyrolysis of the polymer $[(\text{C}_6\text{H}_4\text{O}_2)_2\text{Ti}]_n$ under argon with the use of hydrogen as the reducing agent.¹²²

Nanocrystalline SiC powders can be prepared by thermal decomposition of polycarbosilanes and polycarbosiloxanes; nanocrystalline silicon nitride Si_3N_4 is produced by pyrolysis of polysilazanes.^{123–125} Since polycarbosiloxanes contain oxygen atoms, their pyrolysis is performed under hydrogen according to the scheme

Initial heating is carried out using a high-temperature plasma or laser radiation followed by additional annealing of pyrolysis products at ~ 1600 K.

Nanocrystalline boron carbide B_4C is obtained upon decomposition of poly(vinylpentaborane) $[\text{C}_2\text{H}_3(\text{B}_5\text{H}_8)]_n$. Polyborazine-, polyborazole- and polyvinylborazine-type boron-containing polymers were suggested¹²⁵ for the use in the synthesis of highly dispersed boron nitride powders and as additives to a titanium powder for the synthesis of nanocrystalline composites $\text{TiN} + \text{TiB}_2$. A nanocrystalline aluminium nitride powder with an average particle size of 8 nm was synthesised by decomposition of $[\text{Al}(\text{NH}_2)_3\text{NH}]_n$ in ammonia at 900 K.¹²⁶

To stabilise the composition and structure of the powders prepared by pyrolysis of monomeric and polymeric compounds, it is necessary to perform their additional annealing; the annealing temperature of nitrides and borides varies from 900 to 1300 K and that of oxides and carbides, from 1200 to 1800 K. The main drawback of thermal decomposition is that the selectivity of the reaction is rather low so that the reaction product represents a mixture of the final product and intermediates.

Nowadays, thermal decomposition is applied to the synthesis of multicomponent amorphous and nanocrystalline ceramic materials. For example, the complex ceramic material $\text{Si}_3\text{B}_1\text{C}_{4.3}\text{N}_2$ was synthesised by decomposition of polyvinylsilazane $[\text{B}(\text{C}_2\text{H}_4\text{SiMeNH})_3]_n$ at 523 K for 1 h and at 623 K for 3 h followed by milling of the product and its dehydrogenation at 1673 K for 2 h.¹²⁷ The influence of annealing on nanocrystallisation and the free volume change in ceramics were examined in detail for the Si–C–B–N system by X-ray diffraction methods and positron annihilation.¹²⁸

A nanostructured mixture of WC and Co can be prepared by pyrolysis of various precursors.¹²² In particular, heating can simultaneously afford WC and Co

where En is ethylenediamine.

VI. Mechanochemistry

Mechanochemistry is one of the most efficient ‘dry’ chemical technologies requiring no or a minimum amount of solvents for chemical reactions. The mechanical treatment of solid mixtures is accompanied by dispersion of substances, acceleration of the mass transfer, mixing of the components at an atomic level and, as a consequence, activation of their chemical reaction.^{129,130} The mechanisms of mechanochemical reactions are characterised by the involvement of many steps. The most important steps are as follows: initial deformation of the crystal structures of the reactants, the formation, accumulation and interactions of point and linear defects, disintegration of substances, the formation of metastable states in the contact zone of different phases, chemical homogenisation and relaxation of the reaction products to the equilibrium state.¹³¹ The reactivity of solids in the course of their deformation and decomposition is the subject of mechanochemistry.

Mechanical milling can result in a decrease in the size of microcrystalline blocks to 10 nm (and smaller), which is equivalent to a decrease in the diffusion length necessary for the reaction.¹²⁹ Simultaneous mechanical treatment of several components of the mixture causes deformation mixing and mechanochemical reactions. The characteristic features of low-temperature mixing of solid reactants associated with the formation of intermediate metastable states and the possibilities of the mechanochemical synthesis of various compounds were covered in detail in the reviews.^{129, 130}

The mechanical milling is an efficient procedure for the preparation of large amounts of nanopowders of various materials, such as metals, alloys, intermetallics, ceramics and composites. Complete solid-state solubility of elements mutual solubility of which under equilibrium conditions is negligibly small can be achieved by mechanical milling and mechanical fusion.^{132, 133} Various mills (reactors) in which the specific mechanical energy imparted to a powder can be as high as 10^2 – 10^3 kJ g⁻¹ are most popular for mechanical activation of powders and mechanochemical processes.

During mechanical milling of powders, the plastic deformation is developed by the dislocation mechanism and it is initially localised in slip bands containing multiple dislocations. As a particular stress level is achieved, these dislocations annihilate, are combined and recombine as small-angle grain boundaries, which separate individual grains, entrapping impurity atoms. In this step of milling, particles with a diameter of 20–30 nm are formed, and their number increases as the particles are ground. In plastic metals, intergrain boundaries are formed by the polygonisation mechanism.¹³⁴ In the next step of milling, the orientation of individual crystallites with respect to each other becomes random due to a slip along the grain boundaries. This behaviour in the course of milling is typical of metals and intermetallics with a bcc lattice.¹³³

The mechanical action during milling of materials is pulsed in character. Hence, the stress field does not act during the entire residence time of particles in the reactor but only at the instant of their collision. During a short period after the collision, partial relaxation occurs. Hence, the character of formation of the stress field in time and the kinetics of subsequent relaxation processes should be taken into account in the mechanochemical synthesis. The mechanical action is not only pulsed, but also local, because it occurs not in the total bulk of the solid, but only where the stress field appears and then relaxes.

Let us consider some results of milling and mechanochemical synthesis with the use of high-energy planetary and vibration mills. A nanocrystalline powder of barium titanate (BaTiO₃) with an average particle size of 25 nm was prepared by the mechanical treatment in a planetary ball mill.¹³⁵ According to the results of electron microscopy, BaTiO₃ nanoparticles contain almost no dislocations. Nanoparticles were combined to form dense aggregates up to 1 µm in size, which in turn form large agglomerates >2 µm in size. The agglomeration is a characteristic property of nanocrystalline powders prepared by mechanical milling.

Mechanochemical synthesis of transition metal boride, carbide, silicide and sulfide powders from powdered mixtures of metals with boron, carbon, silicon and sulfur, respectively, was performed by the so-called explosion method in vibration mills.¹³⁶ In essence, the explosion mechanosynthesis is analogous to the self-propagating high-temperature synthesis; however, unlike the latter method, the fast reaction in the explosion mechanosynthesis is initiated by mechanical activation of powders of the starting components (metal and carbon, boron, silicon or sulfur) for a few minutes rather than by a short-term powerful thermal pulse. X-Ray diffraction and electron microscopic studies of boron, titanium, zirconium,

hafnium, vanadium, tantalum and tungsten carbide powders prepared by the mechanochemical synthesis in eccentric and planetary ball mills demonstrated that the average particle size in these powders varied from 6 to 20 nm.¹³⁷ Metal powders were mechanically milled in planetary and vibration mills under oxygen and nitrogen, respectively to prepare nanocrystalline oxides and nitrides with a particle size of several nanometres.¹³⁸

The mechanochemical synthesis of nanocrystalline carbides TiC, ZrC, VC and NbC with an average particle size of 7 ± 1 nm was carried out by 48-h milling in a planetary ball mill of a mixture of metal and carbon powders.¹³⁹ The formation of carbides starts 4–12 h after the beginning of milling. The study of thermal stability of dispersed nanocrystalline carbides demonstrated¹³⁹ that niobium carbide is the most heat-resistant of all the synthesised carbide nanopowders. The grain size of NbC increases from 7–10 to 30 nm as the temperature increases from 300 to 1300 K. Vanadium carbide is the least thermally stable. Extensive recrystallisation at 1000–1200 K resulted in the VC grain growth to 90 nm.

Vibration ball milling of mixtures of metal powders for 300 h afforded nanocrystalline (the grain size was 5–15 nm) Fe–Ni and Fe–Al alloys with bcc lattices.¹⁴⁰

The synthesis of amorphous nanocrystalline Ni₃Al powders by mechanical milling of an ordered intermetallic alloy Ni₃Al was documented.¹⁴¹ The coarse-grained (with a particle size of ≤ 45 µm) powder had an ordered Cu₃Au-type cubic structure (*L*₁₂) with a long-range parameter of 0.96. After its ball milling for 5 h, superstructure reflections in the X-ray diffraction pattern disappeared (complete ordering of the powder) and the structure reflections corresponding to the fcc lattice broadened. The average crystallite size and the lattice strains were estimated¹⁴¹ from the broadening of the structure reflections of a Ni₃Al powder by the Williamson–Hall method.^{142–144} After 5-h milling, the average crystallite size was 19 nm, and the microstrain was 2×10^{-4} (0.02%). An increase in the milling time to 50 h led to a further broadening of the most intense structure reflections (111) and (200) and the disappearance of other structure reflections. The size of the coherent scattering regions decreased to 8–10 nm. A study of the milled powder by scanning and transmission electron microscopy demonstrated that the nanoparticle size was 2–3 nm, and the electron diffraction pattern for nanoparticles is typical of an amorphous state. Thus, mechanical milling of a coarse-grained powder of the ordered intermetallic Ni₃Al initially resulted in its disorder (the formation of a disordered fcc alloy with an *A*1-type structure) followed by the formation of a nanocrystalline fcc alloy and, in the final step of milling, an amorphous Ni₃Al powder with an average nanoparticle size of ~ 2 nm.

The mechanochemical synthesis can be combined with the synthesis of a nanostructured mixture.¹⁴⁵ In an argon-filled ball mill, a nanostructured mixture of cobalt and tungsten carbide grains with an average size of 11–12 nm is formed after milling of a mixture of coarse-grained (~ 75 µm) tungsten, graphite and cobalt powders for 100 h. In the solid alloy prepared by cold pressing followed by sintering of this mixture at 1310 K, most of WC grains had a size of < 200 nm, *i.e.*, they were several times smaller than those in usual alloys of the same composition. The sintered samples of the alloy had a hardness of ~ 18 GPa and a relative density of 80% of the theoretical value. It was hypothesised¹⁴⁵ that the lower sintering temperature of a nanostructured powdered WC–Co mixture compared to that of a coarse-grained mixture is a consequence of the lower melting point of nanocrystalline cobalt compared to that of the coarse-grained metal.

A complex methodologically correct study of the mechanosynthesis of a nanocrystalline cubic titanium carbide powder was documented.¹⁴⁶ The results of this study deserve a more

detailed discussion. Metallic titanium and graphite powders in a ratio of 44:56 were milled in a sapphire ball mill at room temperature under argon.

After milling for 2×10^3 s, the X-ray diffraction pattern of the reaction mixture (Fig. 11) showed only broad reflections corresponding to elemental Ti and C. After milling for 11×10^3 s, the reflections corresponding to graphite almost disappeared; after milling for 15×10^3 s, reflections of a new cubic phase with the structure B1 (titanium carbide) appeared. This is consistent with the results of investigation¹³⁹ in which the formation of carbide phases was observed after milling of powdered mixtures of transition metal and carbon for four–six hours. An increase in the milling time to 4×10^4 s led to the complete disappearance of X-ray reflections of titanium metal and an increase in the intensities of reflections of titanium carbide. Further increase in the milling time was accompanied by an increase in mechanical deformation of powder particles and a sharp decrease in the grain size, as evidenced by a noticeable broadening of X-ray reflections. Milling for 72×10^4 s afforded nanocrystalline titanium carbide and subsequent increase in the milling time to 10^6 s did not lead to changes in the resulting carbide.

Figure 11. Changes in the X-ray diffraction pattern of powdered 44 Ti + 56 C mixtures prepared at different milling times.¹⁴⁶ The changes in the X-ray diffraction patterns are associated with changes in the phase composition resulting from the formation of titanium carbide and with disintegration of carbide particles to nanometre sizes. The milling time/s: (1) 2×10^3 , (2) 6×10^3 , (3) 8×10^3 , (4) 11×10^3 , (5) 15×10^3 , (6) 22×10^3 , (7) 4×10^4 , (8) 8×10^4 , (9) 72×10^4 .

The changes in the grain size of powders during milling are illustrated in Fig. 12. The formation of nanocrystalline titanium carbide involves four steps presented in Fig. 13. The starting powder (Fig. 13 a) consists of randomly distributed particles of different size and shape. In the first step (the milling time up to 11×10^3 s), very large (with the size of ~ 1 mm) composite Ti/C particles are formed (Fig. 13 b). A metallographic study demonstrated that these particles consist of numerous titanium and carbon layers. The second step (the milling time from 11×10^3 to 2×10^4 s) involves a solid-phase

Figure 12. The plot of the particle size of a milled powder containing titanium and carbon particles (44:56) vs. the milling time in the mechano-synthesis of titanium carbide.¹⁴⁶

(1) The particle size determined from the broadening of X-ray reflections; (2) the particle size determined by electron microscopy.

reaction during which titanium and carbon react almost completely with each other to form large titanium carbide grains from 800 to 1000 nm in size. In the third step (the milling time from 2×10^4 to 8×10^4 s), extensive dispersion of large titanium carbide grains affords a finely dispersed powder with a rather broad size distribution of grains (from 5 to 100 nm); the carbide grains form particles with the size of 5–10 μm (Fig. 13 c). In the last step (the milling time from 8×10^4 to 1×10^6 s), the nanocrystalline powder is homogenised with respect to the grain size resulting in the average grain size of $\sim 2 \pm 1$ nm; the grains agglomerate to form spherical particles with the size no larger than 300 nm (Fig. 13 d).

Figure 13. Photomicrographs of particles of the starting powdered mixture of titanium and carbon (44:56) (a) and a powder after ball milling during different periods of time (b–d) see the text.¹⁴⁶

The titanium carbide powder thus prepared was sintered in an activated plasma. The sintering afforded compact titanium carbide samples with high densities (up to 5.2 g cm^{-3}) and hardnesses (up to 3.2 GPa), the average grain size of $< 70 \text{ nm}$ being retained.

The results of the study¹⁴⁶ demonstrated high efficiency of the mechanosynthesis of nanocrystalline titanium carbide. However, it should be noted that the authors' hypothesis that the composition of the starting mixture is identical with that of the synthesised titanium carbide casts doubt, because if this were the case, the superstoichiometric carbide $\text{TiC}_{1.27}$ or the carbide $\text{Ti}_{0.79}\text{C}_{1.00}$ with a defect metal sublattice would be synthesised. The lattice period of the synthesised titanium carbide (0.4326 nm) is somewhat smaller, whereas the measured density (5.2 g cm^{-3}) is higher than the corresponding parameters (0.4328 nm and 4.91 g cm^{-3} , respectively) of the conventional stoichiometric carbide $\text{TiC}_{1.0}$. An excess of carbon atoms in the carbide and its high density can be attributed to the presence of interstitial carbon atoms in the structure B1.

VII. Detonation-induced synthesis

Shock waves is yet another type of mechanical action that creates the conditions for both disintegration of the starting compounds and the synthesis of the final product. Detonation of explosives (the explosion energy) is widely used for performing phase transitions and the synthesis of new compounds. The detonation-induced synthesis of nanopowders proceeds under dynamic conditions where kinetic processes play an important role.

The detonation-induced synthesis of diamond from rhombohedral graphite using a shock wave (the pressure of up to 30 GPa was achieved) was documented.¹⁴⁷ The shock-wave treatment of mixtures of graphite and metals (the duration of a shock wave was 10–20 μs and the produced pressure was 20–40 GPa) afforded¹⁴⁸ diamond powders. These powders were shown to contain single crystals with the size no larger than 50 nm along with assemblies and tightly bound agglomerates with the size of up to 5 μm consisting of individual crystals with sizes of 1–4 and 10–160 nm, respectively.

The 'dry synthesis' based on detonation of condensed carbon-containing explosives with a negative oxygen balance followed by cooling of the detonation products under an inert atmosphere was documented.^{149, 150} Presently, this process is used for industrial production of diamond nanopowders for different technical purposes. The synthesis is performed in explosion chambers with a volume of no smaller than 2–3 m^3 . In the so-called 'aqueous synthesis', which is another version of the detonation-induced synthesis of diamond powders, the diamond particles are cooled with water.

Diamond powders are formed in the zone of chemical decomposition of the starting compounds within $< 0.4 \mu\text{s}$. These powders consist of compact cubic particles with an average size of $\sim 4 \text{ nm}$. Large (up to 1 μm) diamond particles can be prepared with the use of powerful explosives.¹⁵¹

The detonation-induced synthesis of various morphological forms of carbon as well as of aluminium, magnesium, titanium, zirconium and zinc oxide nanopowders was described.^{152, 153} A shock wave passing through a layer of the starting compound (highly porous metal, a chemical compound or a metal hydroxide sol or gel) causes compression and heating of highly porous metals or decomposition of the starting compound to form oxide followed by stabilisation of oxide phases. After the escape of the shock wave on the free surface of the starting compound, materials disperse in the gas atmosphere of the explosion chamber. In a CO_2 atmosphere, carbon nanotubes, spherical carbon particles and thread-like MgO crystals were obtained. The average diameter of thread-

like MgO crystals was 60 nm, and the length to diameter ratio reached 100.

Reactions with chemical compounds as the starting reactants are performed with the use of gaseous and liquid media neutral with respect to the final products, due to which the compounds are rapidly cooled and high-temperature and metastable crystal modifications are stabilised. For example, an yttrium oxide-stabilised cubic ZrO_2 nanopowder was synthesised^{152, 153} by the detonation method. The average particle size was 30 nm.

VIII. Self-propagating high-temperature synthesis

Self-propagating high-temperature synthesis (SHS) is rapidly propagating combustion of solids (of a metal and carbon in the synthesis of carbides or of a metal under nitrogen in the synthesis of nitrides) at a temperature from 2500 to 3000 K.^{154, 155} Since the particle size in the self-propagating high-temperature synthesis products is usually 1–5 μm , it was believed that this method is inapplicable to the preparation of compounds in the nanocrystalline state.

It was suggested¹⁵⁶ that titanium carbide nanopowders would be synthesised by the SHS method in the presence of an inert diluent preventing the particle growth, *e.g.*, using a $\text{Ti} + \text{C} + m\text{NaCl}$ mixture, where $m = 0.2\text{--}0.7$. The particle sizes of the starting Ti, C and NaCl powders were at most 50, 0.1 and 150 μm , respectively. Pellets with a diameter of 30 mm and a height of 40 mm were pressed from the powder mixture. The synthesis was carried out in a standard reactor under argon at a pressure of 0.5 MPa. Combustion was initiated by a current pulse (the voltage was 15–20 V and the pulse duration was 1.0–1.5 s), which was supplied to the sample with a tungsten wire. The combustion temperature decreased from 2500 to 1950 K as the amount of sodium chloride increased (as m changes from 0.2 to 0.7).

The combustion was accompanied by spontaneous homogenisation of the starting mixture due to melting of Ti and NaCl. A microscopic study demonstrated that the resulting titanium carbide particles are distributed in a NaCl melt and are isolated from each other by a thin layer of this melt, which prevented their further growth. No intermediate phases were found. The titanium carbide particle size decreased with the increase in the amount of NaCl in the starting mixture. After washing off NaCl, the titanium carbide powder was studied by X-ray diffraction and electron microscopy. The resulting titanium carbide had the cubic structure B1 with a lattice parameter of 0.433 nm. The powder consisted of particles of irregular shape with a size from 20 to 300 nm; the average particle size was $\sim 100 \text{ nm}$. The optimum amount of NaCl for the synthesis of titanium carbide nanoparticles (m) was found¹⁵⁴ to be 0.4 (or $\sim 30 \text{ mass}\%$). The chemical composition of titanium carbide synthesised in the study¹⁵⁶ was not determined.

IX. Compaction of nanopowders

A method for the preparation of compact dense three-dimensional (3D) nanocrystalline materials named after Gleiter, who was the first to suggest this method,¹⁵⁷ involves the following steps: condensation of nanoparticles under a low-pressure inert gas atmosphere, deposition of particles onto a cold surface of a rotating cylinder and scraping of nanoparticles from the cylinder surface to a collector.¹⁵⁸ After evacuation of the inert gas from the chamber, a nanocrystalline powder was pre-pressed (under a pressure of $\sim 1 \text{ GPa}$) and finally pressed under a pressure of up to 10 GPa. This method can be used for the preparation of cylinders with a diameter from 5 to 15 mm, a thickness of 0.2–3.0 mm and a density of 70%–90% of the theoretical density of the corresponding material. In partic-

ular, the density of nanocrystalline metal powders reaches 97%; the density of nanoceramics, 85%.³ Depending on the evaporation and condensation conditions, compact nanomaterials consist of particles with an average size from 1–2 nm to 80–100 nm. This method was applied to the preparation of compact nanocrystalline nickel with an average particle size of 60 nm.¹⁵⁹

The contact of substances with the environment in the synthesis of nanopowders and their pressing is excluded due to which compact nanocrystalline samples remain uncontaminated. The apparatus described in the papers cited^{157, 158} can be used for the preparation of compact nanocrystalline oxides and nitrides.

The porosity of nanoceramics prepared by pressing of powders is determined primarily by the pores located at triple joints of crystallites and the grain boundaries.² Powders of lower dispersity are less compressible.¹⁶⁰ A uniform porosity distribution is achieved by pressing ceramics at high temperature at which no extensive recrystallisation occurs. For example, conventional sintering of a highly dispersed zirconium oxide powder with a particle size of 40–60 nm at 1370 K for 10 s afforded a material with a relative density of 72% and an average grain size of 120 nm. Hot pressing at the same temperature under a pressure of 1.6 GPa afforded a material with a relative density of 87% and an average grain size of 130 nm.¹⁶¹ Compact oxide ZrO_2 with a relative density of >99% and an average grain size of 85 nm was obtained when the temperature was lowered to 1320 K and the sintering time was increased to 5 h.¹⁶² The most dense (with a relative density of 98%) samples of titanium nitride could be obtained by sintering samples pressed from finely dispersed nanopowders with a grain size of ~8–25 nm and a minimum deviation of the grain size from these values.¹⁶³

Sintering of powders at a high (up to 10 GPa and higher) pressure holds promise for the preparation of dense compact finely grained materials.^{164, 165} For example, a TiN powder with an average particle size of 40 nm was sintered at 3 and 4 GPa at a temperature from 1000 to 1800 K. The maximum density of sintered samples was achieved at 1670 K. An increase in the pressure was accompanied by an increase in the density to 94% of the theoretical value, the crystallite size was 200–300 nm. It should be noted that the crystallite size in samples sintered at 1400–1500 K was at most 60 nm, and the relative density of samples was as high as 92%–93%.

Pressing followed by high-temperature sintering holds promise for the synthesis of compact nanomaterials, particularly, of ceramic materials. To prevent grain enlargement during sintering of pressed samples, it is necessary to use high-density pressing and low sintering temperature $T \leq 0.3T_m$ (T_m is the melting point). The preparation of high-density compact materials presents a serious problem because it is difficult to press nanopowders by conventional static pressing methods. Poor compressibility of nanopowders is associated with adhesion forces the contribution of which to interparticle interactions sharply increases with a decrease in the particle size.

The magnetic pulse method is rather efficient for compaction of nanopowders.^{166–168} This method consists of concentrating the force action of magnetic field of powerful pulse currents, resulting in the appearance of compression waves with an amplitude of up to 5 GPa and a duration of a few microseconds. The parameters of compression waves can rather easily be controlled in this method. The magnetic pulse pressing is environmentally safe, it is much safer than dynamic methods.

Unlike stationary pressing methods, the magnetic pulse method results in extensive heating of powders due to rapid energy release caused by particle friction during packing under the action of a compression wave. If particles are sufficiently

small (≤ 300 nm), the time of their heating is substantially shorter than the characteristic duration of pulse compression waves. Under the same pressure, the magnetic pulse method sometimes allows the preparation of denser compact samples than those prepared by stationary pressing. Aluminium nitride powders prepared by electric explosion (see below) are pressed by the magnetic pulse method under a pressure of 2 GPa to the density of 95% of the theoretical value; Al_2O_3 powders, to the relative density of 86%. This method is applied to the preparation of articles of different shape, which, as a rule, require no additional mechanical treatment. In particular, articles of a complex shape with a density of >95% of the theoretical value were formed from powders of superconducting oxide ceramics.¹⁶⁷ In the general case, interparticle forces are efficiently overcome in the case of rapid motion of a powder medium under the action of pressure pulses due to which the resulting samples have higher density than samples prepared by static pressing. Heating of nanopowders lasts for a short while, which favours a decrease in its recrystallisation at high temperature and the retention of a small particle size.

The magnetic pulse method was used for pressing nanocrystalline Al_2O_3 (see Refs 169 and 170) and TiN powders.¹⁷¹ An increase in the pressing temperature to ~900 K was demonstrated¹⁷¹ to be more efficient than an increase in the pressure in cold pressing. Compact samples of nanocrystalline titanium nitride with a grain size of ~80 nm and a density of ~83% of the theoretical value were prepared under a pulsed pressure of 4.1 GPa at 870 K. A decrease in the pressing temperature to 720 K was accompanied by a decrease in the density to 81%.

A comparative study of compaction of ultradispersed TiN powders by magnetic pulse pressing, high-pressure pressing and conventional pressing was reported.¹⁷² The average particle sizes of the starting powders were 70 and 80 nm. A decrease in the particle size led to a decrease in the degree of compression of samples. An increase in the pressing pressure was accompanied by an increase in the relative density. An increase in the density becomes slower at a pressure of >4 GPa, the density being no higher than 85% even at 7 GPa. It was noted that cold pressing according to different procedures gives very similar results at a pressure of >1 GPa. At 1 GPa, the density of samples prepared by the magnetic pulse method appeared to be somewhat lower than that of samples prepared by static pressing.

Gas-tight ceramic tubes with an external diameter of up to 15 mm and a length of up to 100 mm were produced from nanopowders by radial magnetic pulse pressing.¹⁷³ Powders were placed in a cylindrical gap between a rigid metallic rod and an external cylindrical copper shell. The pressing was performed by radial compression of the external shell under current pulses, the developed pulse pressure being 2 GPa. Aluminium oxide nanopowders and an Y_2O_3 – ZrO_2 mixture with an average particle size of 10–30 nm were used as the starting materials. Radial magnetic pulse pressing of these nanopowders afforded tubes with a relative density of ceramics of >95%.

Ceramic nanopowders can be compacted by dry cold ultrasonic pressing.^{174, 175} Under the action of an ultrasonic field with a power of several kilowatts, interparticle frictions and frictions between particles and walls of the press form decrease, agglomerates and large particles are disintegrated, the surface activity of the powder particles increases and the volume distribution of particles becomes more uniform. This results in an increase in the density of pressed articles, acceleration of diffusion processes, limitation of the grain growth in subsequent sintering and retention of the nanostructure. For example, ultrasonic pressing of an Y_2O_3 -stabilised ZrO_2 nanopowder followed by sintering of samples in air at 1923 K afforded a ceramic material with a relative density of ~90%.

The average particle size in the initial nanopowder was ~ 50 nm.

An interesting procedure for sintering of ceramic compact nanomaterials based on heating of sintered samples with the use of microwave radiation was documented.^{176, 177} Heating is performed by millimetre-range radiation with frequencies from 24 to 84 GHz in a technological gyrotronic device with a power of several kilowatts. The volume energy absorption of microwave radiation provides simultaneous uniform heating of samples because the heating rate is not limited by heat conductivity, as opposed to conventional sintering methods. This allows the preparation of sintered ceramics with a homogeneous microstructure.

Compact samples of Al_2O_3 were prepared by cold isostatic and magnetic-pulse pressing of a nanopowder with an average particle size of 26 nm.¹⁷⁷ The relative densities of the pressed samples were 52% and 70%, respectively. Microwave sintering at maximum temperatures of 1570 and 1770 K afforded samples of Al_2O_3 with a density of 99% of the theoretical value and an average crystallite size of ~ 80 nm.

Conventional sintering methods do not always allow strong connection of different ceramic materials. For example, it is impossible to prepare a mechanically stable composite of ZrO_2 and Al_2O_3 , which is required for the design of devices such as thermal barriers, by conventional methods. This problem can be solved with the use of nanocrystalline materials and microwave sintering.¹⁷⁷ Oxides ZrO_2 and Al_2O_3 are bound to each other with the use of a sintered interlayer made from the nanosized composite ceramic material 60 vol.% ZrO_2 + 40 vol.% Al_2O_3 with an average grain size of 100 nm. The relative density of the interlayer was 96%–98% of the theoretical value. Microwave heating of the ZrO_2 /interlayer/ Al_2O_3 structure over a short period of time to 1700 K afforded a stable composite consisting of oxides ZrO_2 and Al_2O_3 .

X. Crystallisation of amorphous alloys

The above-described methods are based on the assembly principle, *i.e.*, belong to 'bottom-up' nanotechnologies. Methods of 'top-down' technologies are described below.

Nanostructures can be formed in amorphous alloys by crystallisation.¹⁷⁸ Amorphous metal alloys can be prepared by rapid (at a rate of $\geq 10^6$ K s⁻¹) cooling of alloys on the surface of a rotating disc or drum. This method is called spinning. Nanostructures are created by annealing in such a way as to form a large number of crystallisation centres and the crystal growth rate is low.

The amorphous magnetically hard alloy $\text{Fe}_{90}\text{Zr}_7\text{B}_3$ can be referred to as an example.¹⁷⁸ The amorphous alloy was prepared by spinning and then subjected to relaxation annealing at 673 K for 2 h. A nanocrystalline structure formed when the alloy was additionally annealed at 873 K under vacuum (10^{-5} Pa) for 1 h. The transformation of the $\text{Fe}_{90}\text{Zr}_7\text{B}_3$ alloy from the amorphous to the nanocrystalline state results in a change in the X-ray diffraction pattern (Fig. 14): very broad diffuse X-ray reflections become sharp and narrow.¹⁷⁸ The grain size of the crystalline bcc phase α -Fe(Zr) that is formed in the amorphous matrix was ~ 10 nm (results of high-resolution electron microscopy). Considerable attention was given to investigation of the structure of an amorphous matrix containing α -iron nanoparticles.¹⁷⁸ In particular, a study of the atomic structure of the matrix by modern electron–positron annihilation methods revealed a high content of zirconium concentrated at the nucleation sites of the bcc phase α -Fe(Zr).

Crystallisation of amorphous alloys is extensively studied in view of the possibility of constructing nanocrystalline ferromagnetic Fe–Cu–M–Si–B alloys (M = Nb, Ta, W, Mo or Zr) with a very low coercive force and high magnetic permeability, *i.e.*, of magnetically soft materials. The magnetic

The grain size of the bcc phase α -Fe(Zr) is ~ 10 nm.

properties of thin films of the Ni–Fe alloy were demonstrated¹⁷⁹ to be improved as the effective magnetocrystalline anisotropy decreases. This can be achieved by increasing the number of grains involved in exchange interactions in thin magnetic films. In other words, a decrease in the grain size results in an increase in exchange interactions, a decrease in magnetocrystalline anisotropy and, consequently, an improvement of the properties of magnetically soft materials. More recently, this idea has been implemented in targeted crystallisation of multicomponent amorphous alloys.

Silicon-containing steels are magnetically soft materials. Initial attempts to improve the properties of these materials by crystallisation of amorphous alloys were undertaken for alloys of the Fe–Si–B system with addition of copper. However, no alloys with nanocrystalline structures could be obtained in this system. It is only after the introduction of Group IV–VII transition metals along with Cu that a nanostructure was prepared by crystallisation of this system.¹⁸⁰ Crystallisation of amorphous Fe–Cu–Nb–Si–B alloys at 700–900 K afforded an alloy with a homogeneous nanocrystalline structure. In this alloy, grains of the bcc α -Fe(Si) phase with the size of ~ 10 nm and copper clusters with the size of < 1 nm are uniformly distributed in an amorphous matrix.

Positron annihilation studies demonstrated⁷⁹ that $(\text{Fe}_3\text{Si})_{95}\text{Nb}_5$ alloys are thermally stable due to segregation of Nb atoms at the interfaces. Due to the high melting point, niobium hinders complete recrystallisation of the alloy.

The preliminary (before crystallisation annealing) rolling deformation of amorphous Fe–Cu–Nb–Si–B alloys (or their low-temperature annealing) allows a decrease in the grain size to ~ 5 nm.¹⁸¹

Crystallisation of rapidly solidifying aluminium alloys Al–Cr–Ce–M (M = Fe, Co, Ni or Cu) containing 92 at.% Al gave a structure containing an amorphous phase and icosahedral aluminium-rich nanoparticles with the size of ~ 5 –12 nm.¹⁸²

XI. Severe plastic deformation

Severe plastic deformation is a very attractive procedure for the preparation of compact nano- and submicrocrystalline materials.^{19, 183–186} This method is based on the formation of strongly fragmented and disoriented structures with signs of a recrystallised amorphous state. Large deformations of materials can be achieved with the use of the following methods:

twisting under quasi-hydrostatic pressure, equal-channel angular pressing, rolling and three-dimensional forging. These methods consist of performing multiple intense plastic shear deformation of materials, the true logarithmic deformation (e) being 4–7. The use of severe plastic deformation allows not only a decrease in the average grain size but also the production of massive samples with a virtually pore-free structure, which cannot be achieved by compaction of nanopowders.

Twisting under high pressure of disc-shaped samples with the radius R and the thickness l creates shear deformations. The geometric shape of samples is such that the main bulk of materials is deformed under quasi-hydrostatic compression and, hence, the samples are not destroyed in spite of a high degree of deformation. The true logarithmic deformation achieved upon twisting under high pressure is calculated by the equation¹⁸³

$$e = \ln \frac{\theta R}{l}, \quad (7)$$

where θ is the twist angle in radians. The results of numerous investigations demonstrated that after several turns, the structure of samples is disintegrated both at the periphery and in the central part so that it becomes homogeneous throughout the bulk.¹⁹

The most homogeneous structure is formed upon steady-state simple shear deformation. In this method, a material is pressed through two channels of equal cross-section intersecting at an angle of $2\Phi = 90^\circ - 150^\circ$. The intersection plane of the channels contains a homogeneous localised simple shear deformation with an intensity of

$$\Delta\Gamma = 2\cot\Phi. \quad (8)$$

Multiple cycling treatment of a material according to this scheme provides superhigh intense deformations

$$\Gamma = N\Delta\Gamma = 2N\cot\Phi,$$

where N is the number of cycles. The resulting sample exists in a homogeneous stressed deformed state, but its cross-section sizes remain unchanged. The true logarithmic deformation is calculated by the equation

$$e = \operatorname{arsh} \frac{\Gamma}{2} = \ln \left\{ \frac{\Gamma}{2} + \left[\left(\frac{\Gamma}{2} \right)^2 + 1 \right]^{1/2} \right\}. \quad (9)$$

It is most reasonable to use angles 2Φ close to 90° , at which the maximum intensity of deformations is achieved, an increase in the contact pressure being insignificant. A grease is used to minimise contact frictions. This deformation scheme is called equal-channel angular pressing. This method was described for the first time by Segal¹⁸⁷ and was developed further.^{188, 189}

The results of investigations of the structures and properties of submicrocrystalline materials were analysed in reviews.^{19, 185, 190} Annealing of nanocrystalline materials leads to evolution of their microstructures, which can arbitrarily be divided into two steps. In the first step, annealing at a temperature equal to approximately one third of the melting point leads to stress relaxation, the transformation of the grain boundaries from the nonequilibrium to a more equilibrium state and a slight grain growth. In the second step, further increase in the annealing temperature or an increase in the annealing time cause collective recrystallisation (grain enlargement). The first annealing step can readily be observed from the results of microhardness measurements of plastically deformed materials, for example, of Cu, Pd and Ti (Fig. 15).

The severe plastic deformation was applied to obtain nano- and submicrocrystalline structures of metallic Cu,^{191–193}

Figure 15. Plots of the microhardness of plastically deformed metals Cu (1), Pd (2) and Ti (3) vs. the annealing temperature.

Pd,^{194–197} Fe,¹⁹⁸ Ni^{191, 193, 199} and Co,²⁰⁰ aluminium-,¹⁸⁴ magnesium-,²⁰¹ and titanium-based^{202, 203} alloys and a number of brittle compounds. Interestingly, after plastic deformation of similar strength, the grain size in brittle compounds was smaller than in metals. For example, a compact nanocrystalline sample with a grain size of $\sim 30 - 40$ nm was prepared for the first time^{204, 205} from a coarsely dispersed nonstoichiometric powder of carbide $\text{TiC}_{0.62}$ (with a particle size of $\sim 2 - 5$ μm) by twisting under quasi-hydrostatic pressure.

The synthesis of nanocrystalline titanium monoxide by twisting under quasi-hydrostatic pressure of 8 GPa was documented.²⁰⁶ The size of coherent scattering regions estimated from the Williamson–Hall plot was ~ 40 nm. In addition, it was found that the cubic lattice parameter of titanium monoxide was increased by 0.0004 nm after mechanical treatment (Fig. 16), which is indicative of a substantial change in the concentration of titanium vacancies.²⁰⁶ Particular attention is given to structural vacancies in this compound, because they are responsible for the properties of the monoxide.

Figure 16. Plot of the lattice parameter of titanium monoxide a_{B1} vs. the concentration of structural vacancies in the metal sublattice for the equilibrium state (I) and the stoichiometric monoxide subjected to a pressure of 8 GPa at high temperature (2).²⁰⁶

The increase in the lattice parameter of titanium monoxide $\text{TiO}_{1.23}$ (I) and the decrease in the concentration of titanium vacancies (II) after severe shear deformation under a pressure of 8 GPa at room temperature are indicated by arrows.

XII. Electric explosion

Nanopowders can be prepared by electric explosion of conductors caused by passing a powerful current pulse with density of 10^4 – 10^6 A mm $^{-2}$ and duration of 10^{-5} – 10^{-7} s.^{207–209} For this purpose, a wire with a diameter of 0.1–1.0 mm is used. An electric explosion of a conductor is accompanied by a sharp change in the aggregation state of metal as a result of intense energy release and by the shock wave generation, enabling rapid (at a rate of higher than 1×10^7 K s $^{-1}$) heating of metals to high temperatures ($T > 10^4$ K). In the initial step of electric explosion, heating of conductors is accompanied by their linear expansion at a rather low rate (1–3 m s $^{-1}$). In the explosion step, the metal is overheated to a temperature higher than the melting point, expansion of the compound occurs at a rate of up to 5×10^3 m s $^{-1}$ and the overheated metal is explosively dispersed.²¹⁰ The pressure and temperature at the shock wave front achieve several hundreds of megapascals (thousands of atmospheres) and $\sim 10^4$ K, respectively. Condensation in a flow of rapidly expanding vapour affords very small particles. Powders with a particle size from 100 μ m to 50 nm can be prepared by controlling the explosion conditions. The average particle size monotonically decreases with an increase in the current density and decrease in the pulse duration. Metal and alloy powders can be prepared by electric explosion in an inert atmosphere. Finely dispersed powders of metal oxides, nitrides and carbides or their mixtures can be prepared by introducing additional reagents (air, a mixture of oxygen and an inert gas, nitrogen, distilled water, decane, paraffin or a technical oil) into a reactor. Copper powders with the maximum of the size distribution corresponding to ~ 20 nm and aluminium powders with an average particle size of ~ 50 nm were prepared by electric explosion at a pressure of 200 Pa.²⁰⁸

According to experimental data,²¹¹ submicrocrystalline powders prepared by electric explosion of a wire have a very high excess energy. For example, the excess energy of aluminium powders with an average particle size of 500–800 nm is 100–200 kJ mol $^{-1}$ and of silver powders with an average particle size of ~ 120 nm is 40–80 kJ mol $^{-1}$, which is several times higher than the heat of melting of a massive substance. This excess cannot be attributed to a contribution of only the surface energy. The observed accumulation of a large excess energy by finely dispersed powders prepared by electric explosion²¹¹ remained unexplained. It was hypothesised²¹² that the excess energy is accumulated as the surface energy, internal defects and charge states. The size distribution of powders is logarithmically normal, and the maximum of distribution is in the range of 10–500 nm. Particles of metal and alloy powders prepared by electric explosion are spherical, whereas particles of nitride powders are faceted.

In recent years, the electroerosion method was developed for the preparation of nano- and submicrocrystalline metal and alloy powders.

XIII. Ordering of non-stoichiometric compounds as a method for the construction of nanostructures

Group IV, V and VI transition metal carbides hold promise for the construction of nanocrystalline ceramic materials having rather high hardness, low fragility and stability against cracking. These ceramics belong to highest-melting compounds and they are inferior only to diamond and cubic boron nitride in hardness.

Group IV and V transition metal monocarbides MC $_x$ are strongly non-stoichiometric compounds.^{213–215} In the disordered state, these compounds have the cubic structure *B1* and contain up to 50% structural vacancies in the non-metal sublattice.^{51, 213–220} At temperatures below 1300 K, the struc-

ture *B1* becomes unstable, and non-stoichiometric carbides undergo first-order disorder–order phase transitions accompanied by a jumpwise change in the volume and the formation of ordered phases with complex superstructures.^{213–221} Since the ordering is a diffusion process, the transformation occurs during a particular temperature-dependent period of time. Carbides are synthesised at 1400–1800 K, which is above the disorder–order phase transition temperatures (T_{trans}). Cooling of carbides to room temperature is accompanied by ordering. In the rapid cooling, ordering is not completed and non-stoichiometric carbide persists in a metastable disordered state. A difference in the lattice parameters of disordered and ordered phases gives rise to stresses, which can lead to cracking of crystallites at interfaces. Nanostructured powders of non-stoichiometric carbides can be prepared by decreasing the domain size of the ordered phase.

An idea of the nanostructure formation by atom-vacancy ordering of non-stoichiometric compounds was applied for the first time to non-stoichiometric vanadium carbide.²²² The latter was chosen for investigation because ordering in this compound is the most pronounced.^{221, 223, 224} In nanocrystalline solids and nanopowders, not only bulk effects (associated with the particle size), but also surface effects (associated with the state and structure of interfaces)^{9–12} play an important role. This is why particular attention was given to the surface state of compounds in the studies on physicochemical properties of vanadium carbide.^{222, 225}

Particles of nanostructured powdered vanadium carbide VC $_{0.875}$ were obtained by carbothermal reduction of oxide V $_2$ O $_5$ followed by cooling to room temperature. Vanadium carbide is nanostructured, and its nanoparticles are curved and petal-shaped. The petals are joined to each other to form a coral-like structure (Fig. 17). An electron microscopic study revealed small deviation of the nanoparticle size. Nanostructured vanadium carbide is unique because this structure has not been found earlier.

Figure 17. Morphology of particles of the vanadium carbide powder VC $_{0.875}$.²²²

Particles with the size of ~ 1 μ m are two-dimensional nanocrystallites having a shape of curved petal discs with a diameter from 400 to 600 nm and thickness of ~ 15 –20 nm.

The crystal structure of vanadium carbide was studied by X-ray diffraction using CuK $\alpha_{1,2}$ radiation.^{225, 226} The X-ray diffraction spectra of disordered, coarse-grained ordered and nanostructured carbide VC $_{0.875}$ are presented in Fig. 18. The X-ray diffraction pattern of a VC $_{0.875}$ nanopowder (Fig. 18c) shows, along with structure reflections of the basic phase *B1*, only superstructure reflections corresponding to the cubic ordered phase V $_8$ C $_7$ with the space group $P4_332$. The lattice parameter of the disordered phase is

Figure 18. X-Ray powder diffraction patterns of disordered (a), ordered coarse-grained (b) and nanostructured carbide $\text{VC}_{0.875}$ (c) ($\text{CuK}\alpha_{1,2}$ radiation, the intensity is shown on the logarithmic scale; the structure reflections of the phase B1 are indicated).²²⁶ The superstructure reflections in the X-ray diffraction patterns (b) and (c) correspond to the cubic ordered phase V_8C_7 : a_{B1}/nm : (a) 0.41638, (b) 0.41682, (c) 0.41685.

0.8337 ± 0.0001 nm. The ideal M_8C_7 -type cubic superstructure with the space group $P4_332$ has the doubled (compared to the disordered basic phase B1) lattice parameter.^{219, 220, 224} Hence, the lattice parameter of the basic phase a_{B1} of the vanadium carbide under study is 0.41685 nm. This parameter is substantially (by 0.00047 nm) larger than the lattice parameter of disordered carbide $\text{VC}_{0.875}$. Such a large difference can be observed only in the case of the maximum (or nearly maximum) degree of ordering.^{217, 219, 220}

The intensity of superstructure reflections of coarsely crystalline ordered carbide $\text{VC}_{0.875}$ decreases with the increase in the diffraction angle 2θ (Fig. 18 b), whereas the intensity of superstructure reflections of the nanopowder in the angle range $2\theta > 100^\circ$ even increases rather than decreases (Fig. 18 c). This fact remains unexplained.

In spite of the nanometre thickness of nanocrystallites, an analysis of X-ray reflections did not reveal their broadening. Since all atoms in the crystallite scatter coherently, the absence of broadening of X-ray lines is consistent with the presence of a rather large number of atoms in nanocrystallites, as evidenced by a large size of the latter in two other dimensions.

Electron–positron annihilation is the most efficient and sensitive method for studying defects at interfaces and on the surfaces of nanoparticles. The positron trapping by such defects as vacancies or nanopores results in an increase in the positron lifetime compared to that in defect-free materials²²⁷ and in changes in the Doppler broadening spectra of annihilation γ quanta.²²⁸ The defect type can be judged from the lifetime.

The positron lifetime was measured with the use of a $\text{VC}_{0.875}$ carbide powder pre-calcined at 400 K to remove

Figure 19. Positron lifetime spectra of nanostructured (1) and coarse-crystalline (2) powders of ordered carbide V_8C_7 .²²² t is the current time.

water.^{222, 225} For comparison, the positron lifetimes were measured in a coarse-grained sintered sample of $\text{VC}_{0.875}$. The positron lifetime spectra are shown in Fig. 19. The average positron lifetime in the nanopowder is substantially longer than that in the polycrystal. The spectrum of the coarse-grained sample of vanadium carbide shows only a short-lifetime component with 157 ± 2 ps, which corresponds to positron annihilation of a structural vacancy in the carbon sublattice.^{229, 230} The spectrum of the nanocrystalline sample contains a short-lifetime component along with a long-lifetime component with 500 ps and a relative intensity of 7%. The long-lifetime component is attributed²²⁷ to positron annihilation in defects on the particle surface. The positron trapping by a structural vacancy is evidence of the absence of long-distance diffusion of positrons. In this case, the intensities of the components are proportional to the volume fractions of phases containing different types of defects. Thus, the relative intensity of the long-lifetime component is consistent with the volume fraction of the surface

$$\Delta V_{\text{surf}} = \delta \frac{S}{V}$$

in the nanopowder. The surface layer was estimated to have thickness $\delta = 0.5\text{--}0.7$ nm or 3–4 atomic monolayers. The results of determination of the positron lifetime show that the inner part of vanadium carbide nanocrystallites contains only non-metal structural vacancies and the surface layer involves vacancy agglomerates as defects.

The observed morphology of the nanocrystalline powder of non-stoichiometric vanadium carbide may be a consequence of grain cracking at the interfaces between the disordered and ordered phases. Actually, high-temperature X-ray diffraction measurements demonstrated²²¹ that a jumpwise increase in the lattice parameter of the fcc sublattice by 0.0004 nm occurs at 1413 ± 20 K as a result of the disorder–order phase transition. The domain size of the ordered phase is ~ 20 nm. It was shown²²³ that ordering occurs according to the mechanism of the first-order phase transition at 1368 ± 12 K. At 300 K, the parameter a_{B1} of the basic crystal lattice of quenched disordered carbide $\text{VC}_{0.875}$ is 0.0002 nm smaller than that of ordered carbide with the same carbon content. The difference between the volumes of the disordered and ordered phases is responsible for the appearance of stresses and subsequent cracking at the interfaces.

The nanostructure formation can proceed according to another mechanism. Unlike the above-considered mechanism associated with the presence of domains of disordered and ordered phases, the mechanism under discussion involves the formation of antiphase domains of the ordered phase. The first-order disorder–order phase transition affords domains of the ordered phase between which stresses occur due to a mismatch of the atomic structures of antiphase domains. In due course, stresses lead to cracking of grains of the initial disordered phase at the antiphase domain boundaries of the ordered phase.

According to this mechanism, the nanostructure formation of a non-stoichiometric $\text{VC}_{0.875}$ powder (see Fig. 17) can be attributed to the $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$ phase transition. Nanocrystallites of ordered non-stoichiometric vanadium carbide are formed as curved discs with a diameter of < 600 nm and thickness of 15–20 nm through cracking of particles with the size of up to 1 μm . The inner part of nanocrystallites consists of ordered carbide V_8C_7 with a high degree of long-range order and a negligibly small amount of dissolved oxygen. The surface layer of nanocrystallites with a thickness of 0.5–0.7 nm contains chemisorbed oxygen and a large amount of vacancy agglomerates, *i.e.*, has a loose structure.

The ordering allows the nanostructure formation in compact samples of non-stoichiometric compounds.

The structures of annealed and quenched compact samples of $\text{VC}_{0.875}$ were studied by X-ray diffraction. After both annealing and quenching, the X-ray diffraction spectra contain, along with the structure reflections, weak additional reflections (Fig. 20). The positions of additional reflections correspond to superstructure reflections and are assigned to the ordered cubic phase V_8C_7 with the space group $P4_332$. The superstructure reflections for annealed and quenched samples are similar in the integral intensity but strongly differ in the width.

According to the equilibrium phase diagram of the V–C system,²³¹ the ordered V_8C_7 phase is formed after the disorder–order phase transition at 1380 K; the experimental phase transition temperature is 1413 ± 20 K.²²¹ Rapid cooling from 1420 and 1500 to 300 K could result in quenching of non-stoichiometric vanadium carbide $\text{VC}_{0.875}$ and its retention in a metastable state. However, even quenching from 1500 K gives rise to the ordered V_8C_7 phase, the relative intensities of superstructure reflections being approximately equal to those for samples obtained after quenching from 1420 K or annealing at 1370 K (see Fig. 20).

As a consequence of ordering, each grain of the basic disordered phase is divided into domains of an ordered phase. The degree of ordering in domains is high, whereas the mutual spatial arrangement of domains is random to a degree allowed by the ratio between the structures of the ordered phase and the disordered matrix. X-Ray diffraction studies showed that the width of structure reflections is independent of the conditions of thermal treatment of compact $\text{VC}_{0.875}$ samples. Hence, the grain size of the basic phase presumably remains unchanged upon ordering. However, the superstructure lines are substantially broadened, which can be attributed to a small domain size of the ordered phase formed under different conditions of thermal treatment. Since the width of reflections depends on the domain size and the resolution of the instrument used for measurements, the domain size can be determined by measuring the broadening. Let us assume that the deformation broadening is absent in the first approximation and the observed broadening β is associated only with a small domain size, *i.e.*, $\beta = \beta_s$. In this case, the broadening

$$\beta_s(2\theta) \equiv 2\beta_s(\theta),$$

measured in radians is related to the average domain size $\langle D \rangle$ by the Scherrer equation.

Figure 20. X-Ray diffraction patterns of compact samples of $\text{VC}_{0.875}$ prepared by hot pressing and subjected to additional thermal treatment ($\text{CuK}\alpha_{1,2}$ radiation, the structure reflections of the phase B1 and the superstructure reflections of the phase V_8C_7 are indicated).²²⁶

(a) Annealing at 1370 K for 2 h followed by slow cooling to 300 K; (b) quenching from 1420 to 300 K at a cooling rate of 100 K s^{-1} ; (c) quenching from 1500 to 300 K at a cooling rate of 100 K s^{-1} ; all X-ray diffraction patterns show superstructure reflections of the ordered cubic phase of V_8C_7 ; the most broadened superstructure reflections are seen in the X-ray diffraction pattern of a sample of $\text{VC}_{0.875}$ quenched from 1500 K.

The largest broadening of superstructure reflections is observed for a sample quenched from 1500 K; the least broadening, for a sample annealed at 1370 K. This suggests that the ordered phase in the former sample has the minimum domain size. Annealed vanadium carbide is characterised by the maximum domain size because annealing followed by slow cooling provide more favourable conditions for the domain growth. The determination of the broadening β_s and an estimation of the average domain size of the ordered phase gave the following results: the domain size in annealed samples (see Fig. 20 a) is 127 ± 10 nm with 95% confidence probability; in samples prepared by quenching from 1420 K (see Fig. 20 b) and 1500 K (see Fig. 20 c), the domain sizes are 60 ± 9 and 18 ± 12 nm, respectively, with the same confidence probability.

Thus, annealing and quenching of compact samples of non-stoichiometric carbide $\text{VC}_{0.875}$ from $T_{\text{trans}} \pm 100$ K are accompanied by the nanostructure formation, the nanostructure being composed of domains of the ordered phase. The higher the annealing (quenching) temperature or the higher the cooling rate, the smaller the domain size. The nanostructure

formation in compact non-stoichiometric $\text{VC}_{0.875}$ is associated with the $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$ phase transition.

The disorder–order transitions accompanied by a change in the volume can be used for the formation of the nanostructured state not only in strongly non-stoichiometric compounds, but also in substitution solid solutions. It was suggested²³² that polymorphic phase transitions would be used for the nanostructure formation in compact compounds.

XIV. Properties and application of nanomaterials

The properties of nanomaterials are substantially different from those of other materials because the properties of nanoparticles differ from those of large particles. In addition, nanoparticles interact with each other in a fashion different from that of large particles because the distances at which interactions occur in electron, phonon and magnon subsystems are comparable with the sizes of nanoparticles. The properties of the latter differ from those of atoms or associations of atoms but are still different from the properties of compounds consisting of a large number of atoms (solid materials). In addition, nanoparticles have no thermodynamically equilibrium atomic-molecular structure due to which their properties can assume a number of values for the same particle size depending on the conditions of synthesis and the temperature prehistory.

Due to high energy of nanoparticles, their structures are not necessarily equilibrium. Accumulation of experimental data on this problem is presently underway. For example, it was demonstrated²¹ that the structure of cadmium sulfide nanoparticles differs from those of this compound in the wurtzite (equilibrium under normal conditions) and sphalerite phases. The atomic structure of nanoparticles is actually disordered to a large degree although the short-range order is almost completely retained. The atomic structure of cadmium sulfide nanoparticles can be represented as disordered superimposed close-packed planes consisting of cadmium and sulfur atoms. The three-dimensional model of CdS nanoparticles containing 3038 cadmium atoms with a disordered structure of the metal sublattice (*ACABCBC*) was described.²¹ The particle height (h) is 2.3 nm, the distance (d) between the lateral faces is 5.7 nm, and the aspect ratio of the particle sizes $d/h \sim 2.5$. Calculations by the Debye equation demonstrated a good agreement between X-ray diffraction spectra and experimental data. A lattice with the space group $P6/mmm$ can be considered as an average crystal lattice of the cadmium sulfide nanophase (Fig. 21).

The properties of isolated nanoparticles along with a disorder are also determined to a large extent by the contribution of the surface layer. For a spherical particle with a diameter D and surface layer thickness δ , the surface layer fraction (ΔV) in the total particle bulk (V) is

$$\frac{\Delta V}{V} = \left[\frac{\pi}{6} D^3 - \frac{\pi}{6} (D - 2\delta)^3 \right] \left(\frac{\pi}{6} D^3 \right)^{-1} \approx \frac{6\delta}{D}.$$

If the surface layer thickness is equal to 3–4 atomic monolayers (0.5–1.5 nm) and the average nanocrystallite size is 10–20 nm, up to 50% atoms of a substance are located in the surface layer.²²² Hence, the properties of nanoparticles are determined by their large specific surface area and the strong effect of the near-surface atoms. The coordination of these atoms and their interatomic distances differ from those of atoms located far from the surface. In many cases, the near-surface atoms have high energy, resulting in a decrease in the temperature of chemical reactions between nanoparticles, and the reaction intensity increases as a consequence of a large specific surface area of nanoparticles.

Figure 21. The experimental X-ray diffraction spectrum of a CdS powder (a) and linear spectra of different structures.²¹

(a) The linear spectrum of a disordered structure, the space group of the average lattice is $P6/mmm$; (b) the linear spectrum of the wurtzite structure B4, the space group $P6_3mc$; (c) the linear spectrum of the sphalerite structure B3, the space group $F\bar{4}3m$.

Interactions between nanoparticles differ from those between microparticles. The interfaces between nanoparticles make a large contribution to the properties of assemblies of nanoparticles. For example, the structure of high-angle interfaces between nanoparticles often determines the mechanical properties of nanomaterials. The electric and magnetic properties depend to a large degree on the ratio between the coherence lengths of electron, phonon and magnon interactions and the distances between the centres of nanoparticles. In many cases, the microstructures of nanomaterials are determined by interactions between nanoparticles. For example, the van der Waals forces are responsible for the mutual arrangement of nanoparticles. The interactions result in self-organisation of nanoparticles in nanomaterials.^{17, 18, 80, 87}

In studies of compact nanomaterials, solid materials are considered as assemblies of interacting grain-boundary defects. For example, the symmetry properties of polycrystals in relation to changes in the characteristic scale of structural heterogeneity, *i.e.*, the grain size, are analysed²³³ using the calibration field theory,^{234, 235} which was developed for the description of the structural and physical properties of materials with defects. An increase in the grain size to several nanometres was demonstrated²³³ to lead to the topological transition from isolated waves of orientation shear instability, which are characteristic of the usual polycrystalline state, to spatially periodic defect structures. This topological transition in an assembly of grain-boundary defects is accompanied by a sharp change in the connectivity characteristics and scaling parameters. The validity of this approach is associated with the fact that the concentration of defects in nanomaterials is so high that interactions occur between the defects. For a few nanomaterials in which the concentration of defects is low the application of the calibration field theory is unjustified.

The use of the size effects is convenient for analysing changes in different properties of solids. Actually, there is abundant evidence of the influence of the nanostate on the magnetic properties of ferromagnets, the Curie temperature, coercive forces, the saturation magnetisation and the magnetic

susceptibility of weak para- and diamagnets, the memory effects on the elastic properties of metals, substantial changes in the heat capacity and hardness, changes in the optical and luminescence characteristics of semiconductors and the plasticity of boride, carbide, nitride and oxide materials, which are rather brittle in the usual coarse-grained state.

It has long been known that the properties of small particles differ from those of massive substances. This fact is used in industry. Aerosols, colouring pigments and colouration of glass melts by colloidal metal particles for the preparation of colour glasses can be referred to as examples. Suspensions of metal nanoparticles (generally iron or its alloys) with the size of 30 nm and larger are used as engine oil additives for restoring worn-out details of internal combustion engines directly during operation. Small particles and nanometre-sized elements are used in the production of different aircraft materials, for example, of radio-absorbing ceramics the matrices of which contain randomly distributed metal nanoparticles.

Polymerised rhombohedral fullerene $\text{Rh}-\text{C}_{60}$ has the Curie temperature of 500 K and the hysteresis curve typical of ferromagnets.²³⁶ A light magnet operating at room temperature can be constructed from this nanomaterial. In fullerene crystals, C_{60} molecules are linked to each other by weak van der Waals forces, whereas the presence of nitrogen atoms in the fullerene-like nanomaterial $\text{C}_{48}\text{N}_{12}$ is responsible for the appearance of strong covalent bonds. Hence, the latter material can be employed when a combination of strength and elasticity is required.

Carbon nanotubes show high mechanical stability. Hence, they can be used for the construction of high-strength composites. It is expected that nanotubes will find application in the construction of various mechanical nanodevices.²³⁷ Carbon nanotubes are already used as nanoindenters in microhardness measurements and as probes in atomic-force microscopes.²³⁸ Carbon nanotubes exhibit semiconductivity or metal conductivity depending on the arrangement of carbon atoms in their walls. Due to this fact, these nanotubes are used as conducting elements in nanoelectronics.

Various structures having different properties can be prepared by connecting carbon nanotubes. The synthesis of such structures is of importance for application in electronic technique. Carbon nanotube T-junctions²³⁹ can operate as contact devices. Due to a defect structure, Y-nanotubes²⁴⁰ allow current to pass in one direction at the junction of teeth and operate as diodes.²⁴¹ The stem of Y-nanotubes has a diameter of ~ 60 nm. The diameter of branches is ~ 40 nm. If a controlling voltage is applied to one tooth of an Y-nanotube, the latter will operate as a current stabiliser. The possibility of controlling the current holds promise for the use of Y-nanotubes in nanoelectronics.

Bundles of multilayer carbon nanotubes with a diameter of 20–30 nm that were grown on a substrate coated with a SiO_2 layer, can find application in next generation integrated microcircuits and in microelectromechanical devices.²⁴² Nanotubes can be used as atomic-molecular pumps for depositing individual molecules, atoms or ions onto the surface.²⁴³ The results of investigations and applications of various carbon and non-carbon nanotubes were summarised in reviews.^{244–246}

Catalysis of chemical reactions is an important field of application of metal, alloy and semiconductor nanoparticles.

High catalytic activity of small particles is attributed to the electronic effect. Actually, the number of atoms in an isolated metal particle is small and, consequently, the distance between the energy levels $\delta \approx E_F/N$ (E_F is the Fermi energy and N is the number of atoms in the particle) is comparable with the energy kT . In the limit, when $\delta > kT$, the energy levels are discrete and the particle loses metallic properties. Nanoparticles begin to exhibit catalytic activity at $\delta \approx kT$. For metals, the Fermi

energy is 10 eV. At ~ 300 K, δ is 0.025 eV and, hence, $N \approx 400$. The particle consisting of 400 atoms has a diameter of ~ 2 nm.

As a rule, nanoparticles exhibit catalytic activity in a very narrow size range. For example, rhodium catalysts, which are synthesised by decomposition of the $\text{Rh}_6(\text{CO})_{16}$ clusters deposited on the surface of dispersed silica, catalyse benzene hydrogenation only if the particle size is 1.5–1.8 nm, *i.e.*, only Rh_{12} particles are actually catalytically active in this reaction. High selectivity of the catalytic action is typical also of nanoparticles of such popular catalysts as palladium and platinum. For example, a study of ethylene hydrogenation at 520 K under a hydrogen pressure of 1 atm catalysed by platinum deposited on SiO_2 or Al_2O_3 revealed a pronounced maximum of the reaction rate corresponding to the platinum nanoparticle size of ~ 0.6 nm. Such a high sensitivity of the catalytic action to the size of small particles demonstrates the importance of the development of selective procedures for the preparation of nanoparticles with an accuracy to one atom. Materials characterised by a very narrow size distribution of nanoparticles are required not only for catalysis, but also for nanoelectronics.

A detailed analysis of the size effect of small metal and alloy particles deposited on a support was performed;²⁴⁷ the reviews^{248–250} deal with catalysis involving metal alloys and palladium.

A new field of catalysis on nanoparticles, *viz.*, photocatalysis with the use of semiconductor particles and nanostructured films, holds promise for purification of water from organic contaminants by photocatalytic oxidation and mineralisation. For example, colloidal solutions of semiconducting oxide and sulfide nanoparticles (without deposition on a substrate) and the nanocrystalline heterostructures ZnS/CdSe , HgS/CdS , ZnS/ZnO and $\text{TiO}_2/\text{SnO}_2$ are used in the photocatalytic synthesis and destruction of organic compounds as well as in decomposition of water.^{98–101}

Polymeric composites containing metal nanoparticles are used as conducting film composite materials, the possible amount of the filling agent in the matrix being as high as 90 vol.%. Hybrid metal–polymer composites can be synthesised by the nanoparticle formation in a polymeric matrix.^{251,252} Coloured light guides for computer techniques are produced by introducing metal ions into polymeric fibres. The optical properties of polymers filled with metal, alloy or semiconductor (CdS , CdSe , InP or InAs) nanoparticles are of interest. Such polymers are easily subjected to mechanical treatment and can be used for the preparation of films. Hence, such polymers hold promise as optical elements and light filters.

Multilayer nanostructures are widely applied in the microelectronic device manufacturing. Layered inhomogeneous nanostructures, *viz.*, superlattices consisting of alternating solid superthin layers (with a thickness from several to one hundred crystal lattice parameters or $\sim 1–50$ nm) of two different compounds, can be referred to as an example. This crystal structure contains, along with a usual lattice of periodically arranged atoms, a superlattice consisting of repeated layers with different compositions. Since the nanolayer thickness is comparable with the de Broglie wavelength of the electron, the quantum size effect is manifested in the electronic properties of superlattices. The use of this effect in multilayer nanostructures allows the design of fast-operating electronic devices with a high information capacity. The double-barrier diode $\text{AlAs}/\text{GaAs}/\text{AlAs}$ consisting of a gallium arsenide layer with a thickness of 4–6 nm, which is located between two aluminium arsenide layers with a thickness of 1.5–2.5 nm, is an example of the simplest electronic devices.

Magnetic nanostructures showing giant magnetoresistance are of interest. These nanostructures are multilayer films

composed of alternating layers of ferromagnetic and non-magnetic metals. For example, ferromagnetic Co–Ni–Cu layers and non-magnetic Cu layers alternate in the Co–Ni–Cu/Cu nanostructure. The layer thickness is approximately equal to the electron free path, *i.e.*, to several tens of nanometres. The magnetic configuration of multilayer nanostructures can be changed by varying the external magnetic field intensity from 0 to a particular value H so that the conductivity varies in a very broad range. These films can be used as magnetic field detectors. In the nanostructure under consideration, the largest giant magnetoresistance was achieved for very thin (~ 0.7 nm) copper layers.

In modern microcircuits produced on a large scale, ~ 1000 electrons are required for transistor switching on/off. Due to miniaturisation of microcircuits, the number of required electrons would be decreased to ten in the nearest future.²⁵³ Besides, studies aimed at constructing single-electron transistors are presently underway.²⁵⁴

A device consisting of two condenser plates and a metalised ball hanged between these plates was developed. Under the action of direct-current voltage applied to the plates, the ball swings and transfers the charge. In the nanoversion, such nanopendula (or electronic shuttles) can operate at a frequency of ~ 100 MHz and transfer individual electrons.^{16,255} Such devices would be expected to serve as elements of quantum computers or current interrupters.

Semiconducting heterostructures consisting of two or more different materials are of particular interest. In these heterostructures, a transition layer, *viz.*, the interface between two materials, plays an important role. Moreover, the interface in semiconducting heterostructures can be used as a technical device.²⁵⁶

Molecular-beam and liquid-phase epitaxies allow the growth of heterostructures with a sharp interface. Two interfaces can be located so close to each other that the quantum size effects become to play the key role. Such structures are called quantum wells. In quantum wells, the thickness of the medium layer is several tens of nanometres, resulting in electron level splitting due to the size quantisation effect. This effect, which is manifested as a characteristic stepwise structure of optical absorption spectra of the semiconducting heterostructure GaAs–AlGaAs with a hyperfine GaAs layer (a quantum well), was observed for the first time in 1974.²⁵⁷ In this study, it was also found that characteristic energies are shifted as the thickness of the quantum well (a GaAs layer) decreases. In quantum wells, superlattices and other structures with very thin layers, large deformations are not necessarily accompanied by the appearance of dislocations and, hence, correspondence of the lattice parameters is not required.²⁵⁸ The fundamental characteristics of semiconducting crystals, such as the gap width, the effective masses and the charge carrier mobility, can be controlled with the use of heterostructures, particularly double structures, including quantum wells, quantum wires and quantum dots.

In three-dimensional semiconductors, the density of states $N(E)$ is a continuous function. A decrease in the dimensionality of a semiconductor results in a change in the energy spectrum from continuous to discrete due to its splitting (Fig. 22). The quantum well is a two-dimensional structure in which the charge carrier motion is restricted in the direction perpendicular to the layers, but the charge carriers can freely move in the plane of the layers. In quantum wires, the charge carrier motion is limited in two directions and the charge carriers freely move only along the wire axis. Quantum dots are quasi-zero-dimensional ('0D') structures. In such structures, the charge carrier motion is limited in all three directions and these structures are characterised by completely discrete energy spectra.

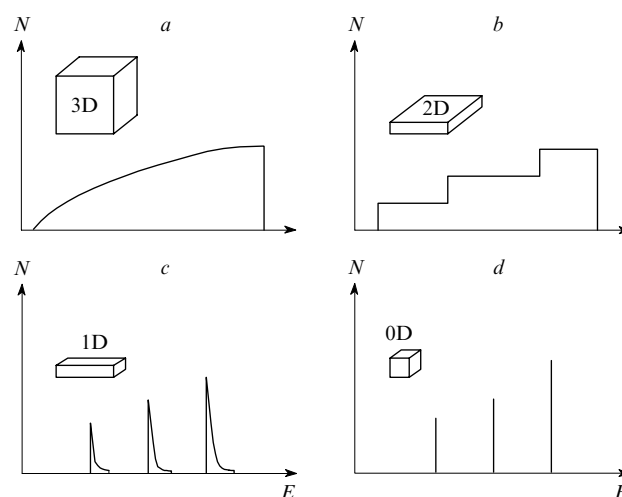

Figure 22. The density of states of N charge carriers as a function of the dimensionality of the semiconductor.¹²

(a) A three-dimensional semiconductor, $dN/dE \sim E^{-1/2}$; (b) a quantum well, $dN/dE \sim \text{const}$; (c) a quantum wire, $dN/dE \sim E^{1/2}$; (d) a quantum dot, $dN/dE \sim \delta(E)$.

The sizes of quantum dots obtained by molecular-beam epitaxy and lithography vary from 100 to 10 nm; smaller quantum dots (1–10 nm) the surface of which is protected by organic molecules preventing particle aggregation can be prepared by methods of colloid chemistry.²⁵⁹

Only nanotechnologies allow a decrease in the size of elements of electronic devices to several nanometres with the use of quantum dots. Time instability of nanostructures at high temperatures is a practical problem to be solved in the construction of quantum dots. Stability of quantum dots is determined by quantum jumps or diffusion of small amounts of atoms, which occur very rapidly on the surface and at interfaces of quantum electronic elements. As a result, destruction of elements or even their migration on a substrate is observed at room temperature.²⁶⁰ The problem of stability of nanoelectronic circuits can be solved with the use of multi-component materials including metal oxides, carbides and nitrides. These compounds have high melting points and low diffusion mobility of atoms and, consequently, show high thermal and time stability.

Special lenses and mirrors with multilayer coatings of alternating thin layers of elements with higher and lower densities (for example, of tungsten and carbon, molybdenum and carbon or nickel and carbon) are used in X-ray and UV optics. Two layers have thicknesses of ~ 1 nm; the layers should be smooth at the atomic level. Multilayer X-ray lenses and mirrors are required in X-ray lithography, which is one of the fields of nanotechnology, and in astrophysical studies. The formation of X-ray mirrors was described in sufficient detail;²⁶¹ this study dealt with multilayer Ni/C nanostructures with a period of ~ 4 nm. The Fresnel zone plates with a minimum zone width of ~ 100 nm and diffraction lattices with a period of < 100 nm are yet other optical devices with nanometre-sized elements intended for use in X-ray diffraction microscopy.

Heterostructures F/S are formed by alternating nanolayers of a ferromagnet (F) and a superconductor (S). Ferromagnetic interlayers of F are generally constructed of Fe, Co, Gd or Ni the Curie temperatures of which are higher than the superconducting transition temperature of metals (Nb, Pb or V) that form an S layer. Experimental studies of such heterostructures were initiated by Hauser *et al.*²⁶² The construction of F/S-type

superlattices can be performed with the use of molecular-beam epitaxy, electron-beam coating or magnetron spraying at direct current.²⁶³ It should be noted that F/S-type heterostructures with layers of atomic thickness can be applied in next generation electronics as logical elements and superconducting current switches.^{264,265} In this case, the superconductivity can be controlled with a weak external magnetic field.²⁶⁶ The properties of multilayer F/S systems including the superconducting transition temperature depend on the thicknesses of the ferromagnetic and superconducting layers. The thickness of a ferromagnetic layer is generally < 1 nm, and the thickness of a superconducting layer varies from 10 to 40–50 nm.²⁶⁶ In F/S heterostructures, the superconducting transition temperature (T_c) not only monotonically decreases but also oscillates as the thickness of the F layer increases. For example, an increase in the thickness of the iron layer in the three-layer system Fe/Nb/Fe from 0.1 to 0.8 nm initially leads to a lowering of T_c from 7 to 4.5 K. Then the temperature rises to 5 K as the layer thickness increases to 1.0–1.2 nm followed by a decrease in the temperature to 3.2–3.4 K as the thickness further increases to 3 nm. In F/S heterostructures, metal and alloy ($\text{Nb}_x\text{Ti}_{1-x}/\text{Co}$ or $\text{V}/\text{Fe}_x\text{V}_{1-x}$) layers can alternate with each other. Superconductor/ferromagnetic semiconductor (for example, NbN/EuO/Pb or NbN/EuS/Pb) heterostructures with the Josephson tunnel transition²⁶⁷ are also of interest. The layer thickness of the ferromagnetic superconductor (EuO, EuS) in these heterostructures is 10–50 nm and the thickness of superconducting layers is > 200 nm.

Ceramic nanomaterials are widely used for the production of components operating at high temperatures, under non-uniform thermal stresses and in corrosive media. Due to superplasticity, these nanomaterials can be used for the preparation of complex-configuration products with highly precise dimensions, in particular, for aerospace technique. Due to biocompatibility and high stability, hydroxylapatite-based nanoceramics are applied in orthopedy for the production of artificial joints and in dental surgery for the production of dental prostheses. Nanocrystalline ferromagnetic alloys Fe–Cu–M–Si–B (M is a Group IV–VI transition metal) have found use as soft magnetic materials for transformers with a very low coercive force and high magnetic permeability.

A method for the manufacture of a detonation diamond nanopowder is implemented in Russian industry. As a result of high pressure and temperature developed during explosion in special chambers, nanodiamond is synthesised from carbon-containing explosives catalysed by particles and metal vapour from ammunition shells.

Ultrasonic pressing of nanopowders is particularly efficient in the construction of complex-shaped articles such as sockets, conical gears, helices, etc.²⁶⁸ The resulting ceramic articles have homogeneous microstructure and density.

The hydrothermal synthesis belonging to 'mild chemistry' methods holds promise for the preparation of nanoceramics. The synthesis proceeds at high temperature and pressure. Oxide nanoceramic materials, for example, TiO_2 , ZrO_2 and HfO_2 ,²⁶⁹ including nanorods can be obtained by this method.²⁷⁰ Nanocrystalline titanium, zirconium and hafnium dioxide powders and composites on their basis have found use as catalysts, gas sensors, dielectric ceramics, dyes, solid electrolytes, diffusion barriers and optical coatings. The development of the hydrothermal synthesis would be expected to expand the field of application of oxide nanoceramics.

To summarise, the analysis of the scope of modern nanotechnologies and prospects of application of different classes of nanostructured materials shows the topicality of the development of nanoindustry.

XV. Conclusion

Studies performed in the last decades provided a deeper insight into the mechanisms of size effects. Emphasis has long been placed on nanoparticles the properties of which are intermediate between those of isolated atoms and polycrystalline solids. The development of methods for the production of compact nanomaterials composed of nanometre-sized building blocks enabled researchers to investigate the properties of solids in the nanostructured state. Nowadays, the following methods are mainly used for the preparation of compact nanomaterials: compaction of isolated nanoclusters, which are obtained by evaporation and condensation, precipitation from solutions or decomposition of precursors, crystallisation of amorphous alloys, severe plastic deformation and ordering of strongly non-stoichiometric compounds and solid solutions. Each method has advantages and drawbacks, and neither is universal.

For a theoretical interpretation of experimental results obtained in studies of isolated nanoparticles and compact nanomaterials, the separation of the surface (associated with interfaces) and bulk (associated with particles sizes) effects is of considerable importance. Nowadays, this problem is far from being solved.

Nanomaterials are characterised by exceptionally high diffusion mobility of atoms along the grain boundaries. This mobility is 5–6 orders of magnitude higher than that in usual polycrystals. However, the mechanisms of diffusion processes in nanomaterials are far from being completely understood, and different explanations of these processes were provided in the literature. The microstructure of nanocrystals, *i.e.*, the structure of interfaces and the atomic density, and the influence of nanopores and the free volume on the properties of nanocrystals are still debated.

The above-considered data suggest that new nanomaterials stable at high temperature will be constructed based on multi-component systems with the use of refractory metals and compounds. Metal oxides, nitrides and carbides with high melting points and thermal stability will be of particular importance in future nanotechnologies. These compounds will find application as components of nanocrystalline materials. The construction of stable-operating systems, which retain their properties throughout the service life, becomes possible with the use of the above-mentioned compounds.

Studies in the field of nanotechnologies and investigations of the nanostate of substances should provide the basis for a new interdisciplinary area of knowledge based on fundamental laws of physics, chemistry and biology.²⁷¹

I. Introduction	463
II. Multicomponent nanostructured films for mechanical engineering	464
III. Multifunctional nanostructured films for medicine	467

Abstract. The state-of-the-art of investigation into multifunctional (multicomponent) nanostructured films used in mechanical engineering and medicine is considered. The bibliography includes 113 references.

I. Introduction

New materials form the basis for the technology of the 21st century, and the industry of nanomaterials is a priority field of development of science and engineering. An important vigorously developing trend in the nanomaterial and nanotechnology sciences is the surface engineering, in particular, the design of multicomponent (multifunctional) nanostructured films (MNF) with a characteristic crystallite size of 1 to 100 nm (Fig. 1).¹

What makes nanostructured films unique is the high volume fraction and strength of interfaces, the absence of dislocations inside the crystallites, the possibility of changing the ratio of the volume fractions of the crystalline and amorphous phases and the mutual solubility of metal and non-metal components. The presence of a large interfacial area (the volume fraction may reach 50%) in nanostructured films allows one to change their properties either by material and electronic structure modification[†] or by doping. The strength of the interfaces favours the stability of nanostructured films against deformation. The lack of dislocations inside the crystallites increases the elasticity of these films. These factors altogether allow the production of nanomaterials with improved physicochemical and physicomechanical characteristics, namely, with high hardness ($H > 30$ GPa), elastic recovery ($W_e > 70\%$), strength, thermal stability, and heat and corrosion resistance.

An important feature of the ultrahard nanomaterials based on MNF is that materials with the same hardness may differ in the elastic modulus (E), resistance against elastic strain to failure (H/E) and resistance against plastic deformation (H^3/E^2).²

Received 10 November 2006

Uspekhi Khimii 76 (5) 501–509 (2007); translated by Z P Bobkova

Multifunctional nanostructured films are used to protect surfaces of articles and tools exposed simultaneously to elevated temperatures, corrosive media and various types of wear. This refers, first of all, to the cutting and press forming tools, mill rolls, parts of aircraft engines, gas turbines and compressors, friction bearings, glass and mineral fibre extrusion nozzles, *etc.* These films are also indispensable in the development of new-generation biocompatible materials, namely, orthopedic and dental implants, craniofacial and maxillofacial surgery implants, fixation of cervical and lumbar spines and so on.

Figure 1. Crystallite with a 1.5 nm size in the Ti–Al–B–N film.¹

Methods for the production of nanostructured materials and films and methods for the investigation of their structures, compositions, and properties have been widely addressed in Russian and foreign publications (see, for example, Refs 3–9).

[†] By changing the charge of the interfaces (by application of an electric field), one can affect the electronic structure of the films and, hence, their magnetic, optical and electric properties and also the mutual solubility of separate components and the formation of new phases.

This review presents a critical account of the promising trends in the application of MNF (based on refractory compounds) in mechanical engineering and medicine, *i.e.*, in those fields where the multifunctional properties of thin-film materials are manifested in full measure. Note that some MNF are used in other fields of technology, for example, in magnetooptics and electronics.

II. Multicomponent nanostructured films for mechanical engineering

Currently, titanium nitride-based films are widely used in industry. The introduction of a third component (for example, Si or B) into the films may markedly improve their physico-mechanical properties and thus extend the scope of application. The interest in the Ti–Si–N films is mainly caused by their high hardness,^{10–12} thermal stability,^{13–15} resistance against high-temperature oxidation^{14, 15} and substantial abrasive wear resistance.¹⁶ Nanostructured Ti–B–N films possess a series of important performance characteristics including high hardness,^{17–19} thermal stability up to 1000 °C (*in vacuo*),^{20–22} heat,¹⁵ wear^{23–26} and corrosion resistance,²⁷ impact resistance²⁸ and high electrical resistance.²⁹ Chromium is known to have a beneficial effect on the stability of titanium carbides, borides and nitrides against oxidation³⁰ and on the wear resistance of articles made of them at elevated temperatures.³¹

Thus, the introduction of doping elements (Al, Si, B and Cr) into protective TiN films provides a combination of high hardness and wear resistance with relatively low friction coefficient (K_f).^{32, 33} In terms of their physico-mechanical and tribological properties, MNF substantially surpass the conventional titanium nitride and carbonitride films. Thus the Ti–B–N and Ti–Cr–B–N films obtained under optimal conditions have hardnesses of 31–34 and 40–47 GPa, elastic moduli of 378 and 506 GPa, friction coefficients of 0.49–0.60 and 0.45–0.52, dry wear rates of $(3.4–4.6) \times 10^{-7}$ and $(6.0–6.8) \times 10^{-7}$ mm³ N^{−1} min^{−1} and substrate adhesion (maximum critical load) of 50 and 42 N, respectively.³²

The nanostructured films are prepared using both physical and chemical methods, among which physical vapour deposition methods (reactive and non-reactive magnetron deposition, cathode sputtering, laser ablation, *etc.*) are used most often. Ion plasma sputtering is an effective method for the synthesis of MNF. The use of multicomponent composite

targets in the magnetron sputtering (MS) process and high-power metal ion beam-assisted MS gives nanostructured Ti–(Si, Cr, Al)–(B, N, C) coatings with controlled composition and high mechanical and tribological parameters.^{33–36}

Coatings of the tribological use must possess high hardness, high fatigue strength and deformation and fracture resistance. All these requirements are satisfied for the tribological ultrahard ($H_v \geq 40$ GPa) nanostructured films composed of immiscible phases (or phases with limited mutual solubility), namely, nanocrystalline (*nc*) and amorphous (*a*) phases. The preparation of these films depends on the possibility of simultaneous deposition of nanocrystalline and amorphous phases. Transition metal nitrides (TiN, CrN, AlN, ZrN, TaN, *etc.*), carbides (TiC, VC, WC, ZrC, *etc.*), borides (TiB₂, CrB₂, WB, ZrB₂, *etc.*), oxides (Al₂O₃, TiO₂, SiO₂, MgO, Y₂O₃, ZrO₂, *etc.*) and silicides (TiSi₂, CrSi₂, ZrSi₂, *etc.*) are used as nanocrystalline phases, and Si₃N₄, BN, C and other substances can act as the amorphous matrices (Table 1).

Veprek *et al.*¹⁴ proposed a theoretical concept for the design of ultrahard nanomaterials according to which these materials should be composed of dislocation-free nanocrystallites (solid phases) of 3–10 nm size separated by a thin (1–2 nm) amorphous phase layer. An idealised model of the ultrahard nanostructured film is shown in Fig. 2. It is noteworthy that complete phase segregation is usually observed when the films are deposited at high temperatures (500–600 °C), while upon deposition at lower temperatures, the interfaces may include both ordered and disordered sections, the amorphous phase being mainly formed as localised areas rather than as thin amorphous interlayers along the crystallite boundaries.⁴²

It has been noted above that the hardness and the elasticity of nanostructured materials depend on the nanocrystallite size. The existence of the characteristic size of nanocrystallites (d_c) ensuring the highest hardness of nanostructured coatings is due to the continuous transition, at distances close to d_c , from the macroscopic dislocation nucleation and motion processes (for $d > d_c$) described by the known Hall–Petch law ($H \approx d^{-1/2}$) for conventional polycrystalline materials to intercrystallite local sliding processes along grain boundaries and interfaces (for $d < d_c$).

Nanocrystallites with a size less than 10 nm are considered to contain no sources of generation of dislocations.⁴⁰ Note that the characteristic size of nanocrystallites as applied to nanocrystalline metallic materials can vary within 2–24 nm.⁴⁸ The

Note. In most cases, films were prepared by magnetron sputtering from the targets in an Ar or N₂/Ar atmosphere. ^a The films were obtained by chemical vapour deposition (CVD). ^b The films were obtained by thermal annealing of the amorphous W–Si–N films.

Figure 2. Idealised model of ultrahard nanostructured films. (1) Nanocrystalline phases, (2) amorphous phase.

experimental data on this issue available from the literature are rather scarce and contradictory. Thus a study of the structure of Ti–B–N films by high-resolution transmission electron microscopy⁴⁹ demonstrated the existence of a large number of internal edge dislocations in 5–15-nm crystallites. Figure 3 clearly shows the edge dislocation with the Burgers vector [100] within a 5-nm crystallite. Note also that the interfaces of nanostructured films often accommodate misfit dislocations (see Fig. 3), giving rise to long-range elastic stress fields.

Figure 3. Edge dislocation inside the crystallite (large circle) and misfit dislocation at the crystallite boundary (small circles) in the Ti–Si–B–N film.⁴⁹

The appearance of the amorphous phase in a nanostructured film is usually accompanied by a change in the film structure, namely, transition from the columnar structure,[‡] representing a set of interconnected columns, to a composite structure in which nanocrystallites of one or several phases are separated by thin amorphous interlayers. Controlled introduction of ‘amorphisers’, for example, boron or silicon, allows targeted variation of the structure and properties of nanostructured films. Thus the highest hardness of M–Si–N films (M is a transition metal) was attained in composite nanostructured nc-MN + α -Si₃N₄ films with the characteristic crystallite size

‡ It is believed that undesirable stresses parallel to the substrate surface arise in the films with columnar structure.

$d_c \approx 10$ nm at a silicon content within the 7 at.%–10 at.% range.⁵⁰

Although the reasons for ultrahigh hardness of some composites are not fully understood, the key factors favourable for the increase in hardness can be listed. These include high compression stresses arising due to the difference between the thermal expansion coefficients of the substrate and the coating; distortion of the crystal phase lattice caused by the change in the mutual solubility of elements; high internal stress (or growth stress) and chemical bonds between some phase components.

In addition to high hardness, tribological nanostructured films are expected to have low elastic moduli and high elastic recovery values (W_e), reaching 90%. The numerical values of these characteristics can be measured using a nanohardness tester. Using known parameters E and W_e , one can calculate H/E and H^3/E^2 . The dependences $H = f(E^*)$ [$E^* = E(1 - \nu^2)$ is the effective elastic modulus, where ν is the Poisson coefficient], $H^3/E^2 = f(H)$ and $W_e = f(H)$ are the principal relations describing the mechanical properties of the films.⁵¹

For a series of oxide, carbide, nitride and composite nanostructured films obtained by magnetron sputtering, the dependence $H = f(E^*)$ can be approximated by a straight line, while the dependence $H^3/E^2 = f(H)$, by a parabola.^{44, 45}

$$H = 0.15 E^* - 12,$$

$$\frac{H^3}{E^2} = 4.3 \times 10^{-4} H^2.$$

These equations are useful for predicting the mechanical behaviour of films.

Plastic deformation (W_p) is yet another important characteristics of nanostructured films. No quantitative relationship (as approximating equations) exists between the W_p , H and H^3/E^2 values,⁵² but only a qualitative relationship. As H and H^3/E^2 increase, the W_p value decreases; films with $H > 25$ GPa have relatively low plastic deformation values ($\sim 30\%$).

The local deformation mechanisms in nanostructured thin films have been investigated.^{19, 53} The existence of two local deformation mechanisms for such films was established, namely, homogeneous (with weak chemical bonds between structural elements) and non-homogeneous (with strong bonds between the crystallites). Both deformation mechanisms are implemented by sliding of the structure elements, *i.e.*, separate grains (homogeneous mechanism) or multigrain domains (columnar elements) (non-homogeneous mechanism), parallel to the applied load. In the case of weak chemical bonds between the neighbouring grains, some structure elements can be expelled to the outside as a result of elastic stress relaxation upon load release. In the case of strong chemical bonds between neighbouring grains, the deformation occurs through sliding of the columnar elements, resulting in the formation of shear steps.

The tribological properties of films largely depend on the phase composition of the nanocomposite. Thus for the Ti–B–N and Ti–Cr–B–N films, the friction coefficient decreases to 0.40 with a decrease in the boron content and an increase in the nitrogen content. This low K_f value is due to the presence of the hexagonal α -BN phase.³³ The presence of silicon also enhances the tribological properties of nanostructured films. For example, the friction coefficient of the Ti–Si–B–C–N films in the friction couple with a WC–Co carbide ball decreases to 0.15 as the silicon concentration grows to 12 at.%. Silicon promotes the formation of intermediate solid lubricant layers resulting from tribochemical reactions during friction. Silicon compounds such as TiSi₂, SiC and SiB₄ as the film constituents are known to react with water

and oxygen to give self-lubricated tribolayers of the SiO_2 or $\text{Si}(\text{OH})_4$ type.

An enhanced wear resistance of a material can also be indicated by high values of H/E . This correlation has been confirmed both theoretically and experimentally for a large number of materials.⁵⁴

A number of publications^{43,55,56} describe the first synthesis of 'chameleon' type nanostructured films. These tribological nanocomposite films with low K_{fr} values represent mixtures of hard and soft self-lubricated phases. The hard phases (nitrides, carbides or boride) are responsible for high wear resistance under high load, while soft phases ($a\text{-C}$, $a\text{-WSi}_2$, $a\text{-Si}_3\text{N}_4$, $a\text{-BN}$) significantly decrease K_{fr} of the contact friction couple.

Sputtering of multilayer or functionally gradient nanostructured films with alternating ultrahard and self-lubricated layers is a promising trend in the design of tribological coatings with ultimately low K_{fr} values (<0.05). As an example, consider bilayer WSe_x/TiC , WSe_x/TiCN and $\text{WSe}_x/\text{TiSiN}$ films in which the WSe_x layer consists of WSe_2 and W_3O nanocrystalline phases incorporated in the amorphous $a\text{-WSe}_x$ matrix.⁵⁷ These bilayer compositions had a low friction coefficient both in air ($K_{\text{fr}} = 0.015\text{--}0.05$) and in water ($K_{\text{fr}} = 0.06\text{--}0.07$) throughout the whole series of tribological investigations. A distinctive feature of these films is the absence of starting (break-in) friction coefficient in the beginning of testing, which is usually the highest.

An important factor for increasing the service life of articles at high temperatures is to ensure their thermal stability and high-temperature oxidation resistance (heat resistance). These parameters depend on the elemental and phase composition of the films and on the thermal stability of the constituent individual phases. The thermal stability of nanostructured films has been considered in detail in a review by Andrievskii.⁵⁸

As an example, Fig. 4 shows the dependence of the average crystallite size in nanostructured Ti–B–N and Ti–Cr–B–N films on the annealing temperature. It can be seen that the average size of crystallites does not exceed 5 nm even after annealing of the films *in vacuo* at 1000 °C for 1 h. The same figure shows the dependence of film hardness on the annealing temperature. Both films showed an increase in hardness with an increase in the annealing temperature to 800 °C; for the Ti–Cr–B–N films, this high hardness was retained up to 1000 °C, the hardness of the Ti–B–N films at 1000 °C was

somewhat lower than at 800 °C but nevertheless it was rather high.³³ This extremal pattern of hardness variation with temperature is in good agreement with previous results, indicating the presence of a hardness peak for the Ti–Al–Si–N⁵⁹ and W–Si–N films⁶⁰ at 800 and 900–950 °C, respectively.

The microcrystalline TiN, TiC, TiCN and TiAlN films obtained by physical deposition are known to demonstrate a monotonic decrease in hardness with an increase in temperature.^{61,62} The increase in the hardness of nanostructured films with the increase in temperature may be due to the change in the thickness of intergrain amorphous interlayers and the concentration-induced separation of metastable phases.⁷ In addition, hardness can be affected by stoichiometry of the crystalline phase. Thus the maximum hardness of the Ti–Si–B–N films was achieved at the strictly stoichiometric composition of the $\text{Ti}(\text{B,N})_2$ phase.⁶³

In some publications (see, for example, Ref. 12), it was suggested that the high hardness of the nanostructured films obtained by low-temperature magnetron sputtering is related to the presence of high compression stresses. As the temperature is increased (to 450 °C), elastic stress relaxation takes place and, as a consequence, the hardness of films decreases down to values typical of polycrystalline materials. However, this assumption is at variance with the data obtained for nanostructured Ti–B–N and Ti–Cr–B–N films; these films retain high hardness up to 1000 °C.

The heat resistance of the films has a critical temperature above which the film is completely oxidised and destroyed. The heat resistance varies over a broad range from 400 to 950 °C (Table 2). A common feature of nanostructured films is the polycrystalline structure, which provides direct oxygen access to the substrate along the grain boundaries (by the surface reactive diffusion mechanism). This accounts for the relatively low heat resistance of polycrystalline films.

An efficient way for increasing the heat resistance of solid films is suppression of the recrystallisation of nanocrystallites by creating a dense composite structure in which the crystallites occur in the amorphous matrix containing elements (Si, Al, Cr, B) with high oxygen affinity. It has been shown^{67–70} that the $nc\text{-MN}_x + a\text{-Si}_3\text{N}_4$ ($M = \text{Ta, Zr, Mo}$) compositions with high (>50 at.%) contents of the amorphous phase meet these requirements. These films have a high heat resistance (~ 1000 °C), while retaining high hardness within the 20–40 GPa range.

The positive influence of amorphising elements (Si, Al and B) on the heat resistance of nanostructured Ti–B–N, Ti–Si–B–N, Ti–Si–C–N, Ti–Al–C–N and Ti–C–B films is manifested as an increase in the content of amorphous phases ($a\text{-Si}_3\text{N}_4$, $a\text{-AlN}$, $a\text{-BN}$, $a\text{-B}_4\text{C}$); an increase in the thermal stability of the nanocrystalline state; the formation of a protective oxide layer on the film surface preventing the oxygen access to the substrate.^{36,41,71–74} For example, in the $(\text{Ti,Al})_{1-x}(\text{C,N})_x$ nanostructured films, oxygen is dissolved in

Figure 4. Average size of crystallites (curves 1, 2) and hardness (curve 1', 2') of the Ti–Cr–B–N (1, 1') and Ti–B–N (2, 2') films vs. annealing temperature.

Table 2. Heat resistance of some nanostructured films.

Film	Heat resistance / °C	Ref.
TiC	400	64
TiN	650	30
TiAlN	850	30
(Ti,Al,Y)N	950	65
MSiN ^a	950	66

(M = Ti, Zr, Cr, W, Ta, Mo, Nb)

^a The silicon content does not exceed 10 at.%.

the fcc lattice at 800 °C,[§] while at 1000 °C, aluminium diffuses toward the film surface to form a protective Al₂O₃ layer, which prevents further oxidation.

The results of measurements of the oxidation depth of nanostructured Ti–B–N and Ti–Si–B–N films at various temperatures are presented in Fig. 5. It can be seen that the oxidation resistance of Ti–B–N and Ti–Si–B–N films is higher than that of TiN films, which are oxidised to depth of 800 nm at 550 °C. The Ti–Cr–B–N and Ti–Al–Si–B–N films are even more resistant against high-temperature oxidation: the depth of oxygen penetration into these films did not exceed 800 nm even after annealing at 800 °C. The high heat resistance of the Ti–Cr–B–N and Ti–Al–Si–B–N films is due to the formation of (Ti,Cr)BO₃ and Ti_xAl_ySiO_z oxide-based protective layers on their surfaces. In terms of the high-temperature oxidation resistance, these films can be arranged in the order TiN > Ti–B–N > Ti–Si–B–N > Ti–Cr–B–N > Ti–Al–Si–B–N (the authors' data).

Figure 5. Oxidised layer thickness in the Ti–B–N (I), Ti–Si–B–N (II), Ti–Cr–B–N (III) and Ti–Al–Si–B–N (IV) films vs. annealing temperature. For comparison, the oxidation depth for the TiN coating after annealing at 550 °C is given.

(1) Film thickness, (2) thickness of the oxidised layer after film annealing at a temperature of 600 °C, (3) the same at 700 °C, (4) at 800 °C.

For a number of practical applications, for example, for high-speed cutting or for mechanical tooling in a fluid lubricant, it is important that the films combine high heat resistance with corrosion resistance. The electrochemical testing of the Ti–B–N films carried out in 1 N H₂SO₄ at room temperature demonstrated advantages of chromium-doped films over non-doped or silicon- and aluminium-doped films.³⁶ The Ti–Cr–B–N films have greater positive free corrosion potentials and fourfold lower current density (corrosion rate at the passivation potential) compared to those of the Ti–B–N films, whereas the Ti–Si–B–N and Ti–Al–Si–B–N films have low corrosion and passivation resistances. The corrosion rates of the Ti–Si–B–N and Ti–Al–Si–B–N films under passivation conditions were 6.6 and 14 times higher, respectively, and the free corrosion potentials were more negative than those of the Ti–B–N film. This experiment shows that introduction of chromium in the Ti–B–N films results in stabilisation of the protective oxide layer on the film surface under anodic polarisation conditions.

The above data indicate that the progress in the design of solid wear-resistant nanostructured coatings implies imparting qualitatively new properties and multifunctional character to these coatings. In addition to high hardness and wear resistance, these coatings have low friction coefficients, and high thermal stability and heat and corrosion resistances.

III. Multifunctional nanostructured films for medicine

A topical scientific and technological task of modern biology and materials science is the design of new biomaterials able to accelerate the adaptation of artificial implants to living tissues and markedly increase their service life. The complexity of the problem is due to the fact that none of the materials currently used to produce implants possesses all properties of the bone tissue. New biomaterials for implants should combine the advantages of various materials, in particular, biocompatibility, bioactivity, corrosion stability in physiological media, high fatigue strength and rupture strength, low elastic modulus and friction coefficient, high wear resistance.

Metals and alloys are used most often to produce implants. The use of titanium, stainless steel 316-L and the Cr–Co–Mo alloy (vitallium) in medical practice for the manufacture of implants started back in 1937. However, pure titanium has a relatively low wear resistance; therefore, in medicine it has been replaced by the Ti–Al–V alloys, which are not only biocompatible but also show high mechanical strength, corrosion resistance, fatigue strength and wear resistance. However, the toxicity of vanadium and the side effects caused by the presence of aluminium ions (high risks of thrombus formation and neural disorder) restrict the use of Ti–Al–V alloys in medicine.^{75, 76} In order to eliminate the adverse effect of Al and V ions, new titanium alloys were developed, e.g., Ti–Nb–Zr⁷⁵ and Ti–In–Nb–Ta.⁷⁷

The Ni–Ti, Ni–Cr–Mo and Au–Pt alloys and BT1-0, BT5 and BT14 titanium alloys are often used in medicine. Note that the metal or alloy surface is bioinert and cannot adsorb biological molecules or form chemical bonds with living tissues; therefore, in order to increase the bioactivity of metals and alloys, a hydroxyapatite layer [Ca₁₀(PO₄)₆(OH)₂, HAP], is often applied on their surface.[¶] Unfortunately, HAP cannot be applied on the surfaces of implants operating under load, as it has low strength and crack resistance compared to those of bone tissue.^{78, 79}

Yet another class of materials widely used in medicine includes ceramic materials TiN, TiO₂, SiO₂, Al₂O₃, ZrO₂ and SiC. Thus owing to its excellent mechanical properties, zirconia-based ceramics has been used in endoprosthesis replacement (as parts of artificial joints and couplings) since the late 1960s.^{80, 81} In 2003, the United States Food and Drug Administration (FDA) approved the use of Al₂O₃ in medicine. However, neither ZrO₂ nor Al₂O₃ can form chemical bonds with the bone tissue. Ceramics based on TiN is better suited for medical purposes. Titanium nitride (as a thin coating) is widely used to protect the surface of dentures, artificial hip joints and cardiac valves.^{82–85} This is due to the combination of several useful properties in TiN films, e.g., high hardness, relatively high corrosion stability and biocompatibility. In addition, TiN (Refs 86, 87) and TiO₂ (Ref. 88) films possess high hemocompatibility. However, TiN has a too high friction coefficient and too low wear resistance to ensure a long service life. It is significant to note that SiO₂ and TiO₂ coatings have a negatively charged surface within the human body (environ-

[§] A 800-nm thick titanium oxide layer is formed on the surface of the standard titanium nitride film under the same conditions.

[¶] A layer of HAP and calcium phosphate is often used as a bioactive boundary between the implant and the surrounding tissue due to the close similarity of their chemical and mineral components.

ment acidity pH 7), resulting in the formation of a hydroxyapatite layer.⁸⁹ Amorphous silicon carbide-based alloys are used to improve the biocompatibility of artificial cardiac valves.⁹⁰ The drawbacks of the ceramics include enhanced brittleness, high elastic modulus and low bioactivity if any.

Carbon-based coatings deserve special note. Diamond-like carbon, a metastable form of amorphous carbon containing a considerable number of $C(sp^3)-C(sp^3)$ bonds, is a solid wear- and corrosion-resistant material with a low friction coefficient, chemical inertness and biocompatibility.^{91,92}

Bioactive ceramics initiates the formation of a bone-like apatite layer on its surface, and through this layer the material is bound to the bone tissue. The formation of an apatite layer on the ceramic surface is possible if the ceramics contains some Ca, Si, P, C and O atoms.^{93,94} The formation of an apatite layer is related to the formation of OH groups on the charged surface of bioactive ceramics in the living organism.^{95–97} The silicate ceramics $CaO-SiO_2$ (Refs 95 and 96) and $CaO-MgO-2SiO_2$ (Ref. 98) show good bioactivity and biocompatibility. The introduction of bioinert additives such as ZrO_2 into the bioactive matrix may improve mechanical properties.⁹⁹ A drawback of this ceramics is enhanced brittleness, high elastic modulus, limited plasticity and low cracking resistance.

A possible way of improving the properties of metallic implants operating under load is their coating with protective films with multifunctional properties. Recently a fundamentally new approach to the design of biocompatible thin-film materials has been developed; according to this approach, additional elements (Ca, Zr, Mn, O, P) are introduced into titanium carbide-, carbonitride- or silicide-based films to improve the mechanical and tribological properties of the material and ensure the bioactive properties and biocompatibility of the surface.^{100–104} Inorganic additives, CaO , ZrO_2 , TiO_2 , $KMnO_4$ and HAP, are introduced during the self-propagating high-temperature synthesis (SHS) of composite targets, which are subsequently used for the ion plasma film deposition. The use of high-power metal ion beam-assisted magnetron sputtering of such composite targets allows one to modify the surface of the metallic implants. This process gives dense films with high adhesion strength and controlled elemental composition. The nanocomposite $TiC-CaO$ films can also be manufactured by a mixed PVD/PACVD process, which represents a combination of the magnetron sputtering from a composite target $Ti_{0.5} + CaO$ and plasma assisted chemical vapour deposition (PACVD). The activated plasma is used to increase the ionisation degree of the sputtered particles.^{105–108}

Since the bulk ceramic materials have high Young modulus and rather low plasticity, their deformation is accompanied by the formation and propagation of cracks resulting in fast destruction of the material. An important advantage of MNF is that they possess high hardness and rather low elastic modulus, which is much lower than that of Al_2O_3 , TiN , SiC or ZrO_2 ceramic materials. The low Young modulus of the MNF, similar to that of bone tissue (30 GPa), results in a better bearing of functional loads by a bone tissue and stimulates growth of the bone tissue. Thus, MNF represent a new unique type of material for medical applications combining high hardness with elastic recovery. Whereas the H^3/E^2 parameter of bulk ceramics (TiN , TiO_2 , SiO_2 , ZrO_2 and SiC) does not exceed 0.2 GPa, in the case of MNF, it varies from 0.1 to 0.9 GPa. Multifunctional nanostructured films exhibit high resistance against elastic strain to failure as compared with bulk ceramics.⁵⁴ The H/E parameter is also a measure of the wear resistance of a material.¹⁰⁹

The biocompatibility of new materials is now estimated by two types of testing, first, studies of the *in vitro* cytocompatibility (cytotoxicity) and of the *in vivo* biocompatibility. The adhesion of cells followed by spreading on the implant surface is the first stage of interaction between the organism cells and

the implant. This stage is crucial, as this determines the material biocompatibility. The shape and degree of cell spreading on the substrate depends on the actinic cytoskeleton. Since artificial implants are used most often to replace the bone tissue, of particular interest is their interaction with fibroblasts (connective tissue cells) and osteoblasts (bone tissue cells). The effective spreading of cells is necessary for proliferation and, in the case of osteoblasts, for the subsequent differentiation resulting in the formation of bone tissue from hydroxyapatite.¹¹⁰

Effective implantation requires integration of the implants into the tissue medium and their firm connection to the bone without interlayers, *i.e.*, osteointegration. The effect of the implant material on the capability of bone cells (osteoblasts) for differentiation is estimated in *in vitro* experiments using various cell systems, for example, MC3T3-E1 mice osteoblasts or primary cultures of rat osteoblasts isolated from newborn animals.

The biocompatibility is usually estimated in *in vivo* studies by hypodermic implantation of the materials tested in animals.^{100,101} These studies are necessary, first of all, because the implantation of artificial materials in a living organism usually induces acute and chronic inflammatory processes, the degree of which depends directly on the biocompatibility of the implants. The inflammatory responses are due to polymorphonuclear leucocytes (neutrophils) and lymphocytes, which are accumulated in the inflamed area. Macrophages are also accumulated on the surface of the foreign object; they can be combined to form multinucleate giant cells. It is considered that these giant cells of foreign objects are most active and play the crucial role in the implant destruction.¹¹¹ The activated macrophages produce cytokines ($TNF\alpha$), which accumulate neutrophils and lymphocytes, promoting the inflammation.¹¹² Macrophages can release osteoinductive signals, in particular, bone morphogenetic proteins.^{111,112} Bone osteoinductive proteins are known to stimulate the differentiation of osteoblasts and the formation of bone tissue.¹¹³ The amount of macrophages, neutrophils, lymphocytes and multinucleate giant cells on the implant surface is an important characteristics for the estimation of biocompatibility of the studied materials.

The osteointegration process is evaluated by implanting the tested materials into the bone tissue of laboratory animals. The degree of osteointegration is judged by the degree of resorption of the bone material around the implant, the structure and the maturity of the connective tissue and the newly formed cell structures. Figure 6 shows the interface between the bone and

Figure 6. Interface between the bone and the titanium implant surface with the nanostructured $Ti-Ca-P-C-O-N$ coating.

the titanium implant surface with the nanostructured Ti–Ca–P–C–O–N coating 30 days after the implantation. One can see areas of tight contact between the implant and the bone without the formation of coarse-fibred structures, gaps or voids.

The biocompatible MNF obtained to date have high hardnesses (25–40 GPa) and adhesion strengths (critical load > 30 GPa), low elastic moduli (150–250 GPa), low friction coefficients (0.1–0.25) and wear rates ($< 10^{-5}$ mm³ N⁻¹ min⁻¹) in physiological media, high resistances against elastic strain to failure (> 0.1) and plastic deformation (> 0.2 GPa). They are characterised by negative charge on the surface at the acidity of the medium of pH 6–8, surface hydrophilicity and bioactivity, biocompatibility and accelerated osteointegration.^{100, 101}

Thus, MNF have a number of advantages over known bulk and thin-film analogues, which makes them promising materials for implants operating under load.

Abstract. Different theories of stability of liquid nanolayers, disperse and colloidal systems are considered. Limitations intrinsic in the classical Derjaguin–Landau–Verwey–Overbeek (DLVO) theory (in particular, calculations of the van der Waals forces acting between macroscopic bodies separated by a thin liquid interlayer) are briefly outlined. Studies devoted to the analysis and calculations of non-DLVO interactions of different nature are reviewed. Particular attention is paid to the forces caused by the inhomogeneity of liquid interlayers. The applicability of the known approaches for solving the nanotechnology challenges (namely, calculations of interaction forces acting through nanolayers and between nanoparticles) is discussed. The bibliography includes 174 references.

I. Introduction

Nanoscience and nanotechnology are two relatively young fields of science and technology. They are based on a theoretical assumption that reduction of the particle size to nanoscale leads to significant changes in the known properties of the corresponding materials and to the appearance of new properties that are not inherent in the bulk state. Later, this assumption was confirmed experimentally. Progress in these new fields of natural science concerns almost all avenues of human activity from biology and medicine to production of polymeric materials, metallurgy, microelectronics, space research, *etc.* Although formally nanoscience and nanotechnology emerged only 20–25 years ago, studies concerned with the dependence of the properties of nanosystems on their size date back to the 1940s. For instance, at that time Derjaguin repeatedly pointed to the dependence of the structure of water in thin liquid interlayers on the interlayer thickness. Manufacture of ultra-disperse powders, a new production area established in the

USSR in the 1950s, was based on the observed dependence of the properties of nanoparticles on the particle size.

A specific feature of small objects is that the smaller the particles the greater the percentage of the molecules (atoms) in the near-interface layer that strongly interact with the phases that bound the object under study. Therefore, reduction of the size of such an object leads to an increase in the surface-to-volume ratio and to a more pronounced effect of the surface phenomena on the properties of the object. Yet another feature of such systems is a stronger effect of the size of small particles on the character of collective phenomena and on the density of states of elementary excitations in the systems.

These features point to the key role of two-phase and three-phase surface phenomena in nanotechnological processes. A considerable proportion of physicochemical studies on these phenomena are carried out using the methods of physics of fluids and colloid chemistry. This is due to the fact that fluids are active participants of liquid-phase chemical synthesis of nanoparticles. The properties of fluids affect the size and stability of particles produced, the course of chemical reactions on the surface of such particles and the strength and character of adsorption at interfaces. In addition, solid nanoparticles prepared using all the known methods¹ were designed for operation under atmospheric conditions or in industry rather than laboratories with controllable gaseous medium. When nanomaterials are exposed to atmosphere, the small size of the objects made of them becomes of crucial importance, because it causes the formation of either capillary condensate in nanoporous media or wetting films on the surfaces of certain particles. As a result, a nanomaterial with well-studied (under laboratory conditions) properties is replaced by a composite nanosystem comprising the solid nanomaterial and a liquid interlayer or capillary bridges. The properties of the system as a whole are determined by the properties of not only the solid phase, but also the liquid interlayer, the character of the interaction between the liquid and the solid nanoparticles and, finally, the character of the interaction between nanoparticles separated by the liquid interlayer. The presence of liquid interlayers can play a decisive role in, *e.g.*, self-organization of nanoparticles, their flowability, *etc.*

Even the examples given above point to particular importance of the studies on the properties of liquids in the nano state

for further progress in nanotechnology. In spite of a variety of challenges in this field, here we will dwell on one problem, namely, stability of liquid nanofilms and disperse and colloidal systems. We believe that this problem is of paramount importance for the development of scientific foundations of nanotechnology; in addition, the author of this review was directly involved in research in this field.

II. The surface forces and stability of disperse systems

A modern physical theory that describes the state and stability of liquid films and the disperse and colloid systems is based on the analysis of the surface forces acting across thin liquid interlayers separating particles or macroscopic surfaces. Here, the surface forces play the same role as the intermolecular interaction forces in condensed systems. In the 1940s, Derjaguin showed² that consideration of the interactions between two surfaces approaching each other is equivalent to consideration of the dependence of the disjoining pressure on the interlayer thickness. The dependence of the disjoining pressure on the thickness of the liquid interlayer is the key thermodynamic characteristic of the thin interlayer that distinguishes it from the bulk liquid. In particular, if the interlayer thickness is such that its medium fragment retains the properties of the bulk phase and, therefore, there is no overlap of the boundary layers adjacent to the interfaces, the disjoining pressure in the interlayer is zero. On the contrary, overlap of the boundary layers leads to anisotropy of the pressure tensor in the interlayer and to appearance of the disjoining pressure $[\Pi(h)]$ dependent on the thickness of the liquid interlayer,

$$\Pi(h) = P_N(h) - P_0, \quad (1)$$

where $P_N(h)$ is the normal component of the pressure tensor in the thin interlayer with thickness h and P_0 is the pressure in the bulk isotropic fluid that is in equilibrium with the interlayer. The character of the dependence of the disjoining pressure on the liquid film thickness characterises the physical nature of the forces that govern the interaction between two surfaces separated by the liquid interlayer. The nature of the interaction forces is naturally determined by three factors, namely, characteristics of the interacting bodies, properties of the fluid, constituting the interlayer and the character of the interaction between the fluid and the boundary phases and, as a consequence, by the dependence of the properties of fluid in the interlayer on the interlayer thickness.

Quantitative analysis of the surface forces is based on the Gouy–Chapman^{3–5} theory of diffuse ionic atmospheres and the theory of molecular forces by London.⁶ These two approaches underlie the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory of stability of lyophobic colloids.^{7,8} In the framework of the DLVO theory, the total interaction energy is determined by the dispersion (van der Waals) and electrostatic mechanisms. Now we will consider them in more detail.

III. Dispersion (van der Waals) forces

The dispersion forces are universal in character and act in all systems. In 1930, London reported a general quantitative theory of the van der Waals forces.⁶ Since then the theory of dispersion interactions between macroscopic bodies separated by an interlayer was developed using two different approaches, a microscopic and a macroscopic one.

The former approach is associated with de Boer⁹ and Hamaker.¹⁰ Here, the force of molecular attraction between identical macroscopic bodies is treated as the resultant of the London attraction forces acting between all pairs of molecules in the body. Details of calculations are available from original

studies and monographs.^{2,8,11} This approach allowed one to derive analytical expressions for calculation of the force of the interaction between two spheres, a sphere and a plane and two planes separated by a vacuum interlayer for both thin and thick interlayers (in the non-retarded limit and with allowance for electromagnetic retardation).[†] Hamaker's interaction constant addition rule¹⁰ makes it possible to extend the microscopic approach to the interactions of condensed bodies separated by a condensed-phase interlayer. However, the state-of-the-art in physics of condensed media is such that the additivity of the London forces in the calculation of the interactions between macroscopic bodies separated by dense-phase interlayers is quite a rough approximation. Thus, the simplicity of the microscopic method of calculations does not compensate for quantitative (in the case of absorbing interlayers, also qualitative) errors in the results of interaction force calculations.

A rigorous macroscopic approach to calculations of dispersion interactions between two bodies separated by a vacuum interlayer or an absorbing condensed phase was reported by Lifshitz *et al.*^{12,13} [Dzyaloshinskii–Lifshitz–Pitaevskii (DLP) theory]. The formalism treats the bodies separated by a thin interlayer as continuous media interacting through fluctuating electromagnetic field. The interlayer thickness is assumed to be much greater than the size of the molecules constituting the bodies. Dzyaloshinskii, Lifshitz and Pitaevskii¹² took into account that the force of the interaction between bodies in vacuum coincides with the zz -component of the averaged Maxwell stress tensor, which was calculated by solving the Maxwell equations with inclusion of fluctuation field sources. To perform the field averaging procedure, the fluctuation-dissipation theorem was applied to the field sources. Later,¹⁴ it was shown that the problem of determination of the stress tensor in the case of two macroscopic bodies separated by vacuum and by an interlayer is reduced to calculations of corresponding Green functions. Since the DLP theory is based on exact Maxwell equations, the retardation effects are included by default. The expression for calculating the disjoining pressure $\Pi(h)$ equal to the specific force of the interaction between macroscopic bodies separated by a homogeneous plane-parallel liquid interlayer of thickness h has the form¹³

$$\begin{aligned} \Pi(h) = & -\frac{kT}{\pi c^3} \sum_{N=0}^{\infty} \xi_N^3 \varepsilon_3^{3/2} \int_1^{\infty} p^2 \left\{ \left[\frac{(s_1+p)(s_2+p)}{(s_1-p)(s_2-p)} \times \right. \right. \\ & \times \exp\left(\frac{2p\xi_N h \varepsilon_3^{1/2}}{c}\right) - 1 \left. \right]^{-1} + \left[\frac{(s_1+ap)(s_2+bp)}{(s_1-ap)(s_2-bp)} \times \right. \\ & \times \exp\left(\frac{2p\xi_N h \varepsilon_3^{1/2}}{c}\right) - 1 \left. \right]^{-1} \left. \right\} dp. \end{aligned} \quad (2)$$

Here k is the Boltzmann constant; T is temperature; c is the speed of light; p is the integration variable, $\xi_N = 2\pi k T N / \hbar$ (N is a natural number, \hbar is the Planck constant); ε_1 , ε_2 and ε_3 are the dielectric permittivities of the macroscopic bodies 1 and 2 and of the liquid interlayer 3 considered as functions of the imaginary field frequency ($\omega = i\xi$), *i.e.*, $\varepsilon = \varepsilon_f(i\xi_N)$; $s_1 = (a - 1 + p^2)^{1/2}$, $s_2 = (b - 1 + p^2)^{1/2}$, where $a = \varepsilon_1/\varepsilon_3$, $b = \varepsilon_2/\varepsilon_3$. The prime at the sum points that the first term in the sum corresponding to $N = 0$ is to be taken with a factor of 0.5. Note that direct substitution of $N = 0$ into Eqn (2) leads to uncertainty because ξ_N equals zero, whereas the integral with

[†] In principle, methods of numerical calculations in the framework of the microscopic approach allow one to calculate the interaction between bodies of arbitrary geometry.

respect to dp diverges. Once the uncertainty is disclosed,¹³ the term with $N = 0$ takes a finite value.

From relation (2) it follows that calculations of the dispersion forces only require knowledge of the frequency dependence of the dielectric permittivities of the contacting media $\varepsilon_j(i\xi_N)$. These can be determined using the Kramers–Kronig relationships[‡] and the values of the imaginary part of dielectric permittivity measured for a broad spectral range.

Analysis of relation (2) shows that the dispersion interaction between identical bodies ($\varepsilon_1 = \varepsilon_2$) is always attractive. However, in the case of different bodies (e.g., wetting films) both attractive and repulsive forces are possible depending on the behaviour of the functions $\varepsilon_j(i\xi_N)$. Moreover, since the behaviour of the functions $\varepsilon_1(i\xi_N)$, $\varepsilon_2(i\xi_N)$ and $\varepsilon_3(i\xi_N)$ in the frequency range important for these bodies is not related to the static dielectric permittivities of the contacting bodies, for certain systems the sign of the interaction force changes with variation of the liquid interlayer thickness (Fig. 1).

Figure 1. Change in sign of the molecular component of the disjoining pressure (dispersion forces) plotted vs. film thickness (curve 1). Shown are the results of $\Pi(h)$ calculations using Eqn (2) for the air–water–fluorite system. Curves 2 and 3 are calculated using Eqns (3a) and (3b), respectively.

Expression (2) can be simplified using integration over $d\xi = (2\pi kT/\hbar)dN$ instead of summation. However, the force calculation error due to neglect of the contribution of the term with $N = 0$ to the net integral can be significant for the polar fluid interlayers that exhibit strong absorption in the low-frequency range of electromagnetic vibrations. If we compare the interlayer thickness to the main wavelength (λ_0) in the absorption spectra of the contacting media and consider two limiting cases, namely, the thin and thick interlayer limits

‡ These are the integral relationships relating the real and imaginary parts of the complex dielectric permittivity $\varepsilon = \varepsilon'(\omega) + i\varepsilon''(\omega)$. A particular case of the Kramers–Kronig relations is the expression

$$\varepsilon(i\xi_N) = 1 + \frac{2}{\pi} \int_0^\infty \frac{\omega \varepsilon''(\omega)}{\omega^2 + \xi_N^2} d\omega,$$

which determines the values of the ε function of the imaginary argument $\omega = i\xi$. It is these $\varepsilon(i\xi_N)$ values that appear in relation (2).

($h \ll \lambda_0/2\pi$ and $h \gg \lambda_0/2\pi$, respectively), expression (2) is reduced to asymptotic relationships (3a) and (3b) for the delayed and non-delayed dispersion forces, respectively.

$$\Pi(h) = -\frac{\hbar}{8\pi h^3} \int_0^\infty \frac{(\varepsilon_1 - \varepsilon_3)(\varepsilon_2 - \varepsilon_3)}{(\varepsilon_1 + \varepsilon_3)(\varepsilon_2 + \varepsilon_3)} d\xi = -\frac{A_{132}}{6\pi h^3} \text{ at } h \ll \frac{\lambda_0}{2\pi}, \quad (3a)$$

$$\Pi(h) = -\frac{B(\varepsilon_{10}, \varepsilon_{20}, \varepsilon_{30})}{h^4} \text{ at } h \gg \frac{\lambda_0}{2\pi}. \quad (3b)$$

Here ε_{10} , ε_{20} and ε_{30} are the electrostatic dielectric permittivities of the contacting media, A_{132} and $B(\varepsilon_{10}, \varepsilon_{20}, \varepsilon_{30})$ are the dispersion force constants in the non-retarded and retarded limits, respectively. The constant B is determined by the electrostatic dielectric permittivities of the contacting media in the low-frequency range. Analysis of the disjoining pressure values calculated using exact relation (2) shows that marked deviations of the $\Pi(h)$ dependence from the h^{-3} law [expression (3a)] begin at distances of 2–3 nm. As to the h^{-4} law [relationship (3b)], the correctness of the application of this expression to a wide variety of systems is doubtful.¹⁵ In particular, if the systems are characterised by the same sign of the van der Waals forces and the contacting bodies show weak absorption in the radiofrequency and IR region, this law is reasonably obeyed at film thicknesses of 30–40 nm.² At the same time if the van der Waals forces change the sign as h increases, the h^{-4} law can be used as an asymptotic relation only at interlayer thicknesses of the order of hundreds of nanometres (see Fig. 1). From expression (3a) it follows that the dispersion force increases as the dielectric contrast (differences $\varepsilon_1 - \varepsilon_3$ and $\varepsilon_2 - \varepsilon_3$) between the contacting phases increases. As an example, Table 1 lists the Hamaker constants A_{132} of certain systems calculated using relations (2) and (3a).

An alternative approach to calculations of dispersion interactions was proposed by Van Kampen *et al.*¹⁹ The method is based on calculations (in the harmonic approximation) of the excess energy of the normal modes of surface oscillators as function of the interlayer thickness. The approach is somewhat more simple and clear compared to that used in the DLP theory,¹³ however, it proved itself as ‘heuristic and intuitive’.²⁰

Table 1. Hamaker constants of various systems.

System	Hamaker constant (A_{132})/J	Ref.
Gold–water–gold	2.5×10^{-19}	16
Gold–KCl solution–gold	4.0×10^{-19}	17
Platinum–KCl solution–platinum	1.4×10^{-19}	17
Platinum–MgSO ₄ solution–platinum	8.5×10^{-20}	17
Silicon–water–silicon	1.2×10^{-19}	17
Quartz–water–quartz	7.5×10^{-21}	16
Quartz–water–quartz	8.5×10^{-21}	18
Sapphire–water–sapphire	5.3×10^{-20}	18
Poly(vinyl chloride)–water–poly(vinyl chloride)	1.2×10^{-20}	16
Polystyrene–water–polystyrene	1.3×10^{-20}	16
Polyisoprene–water–polyisoprene	7.4×10^{-21}	18
Fluorite–water–fluorite	1.0×10^{-20}	18
Polytetrafluoroethylene–water–polytetrafluoroethylene	3.3×10^{-21}	18
Ice–water–gold	1.6×10^{-21}	16
Ice–water–silicon	-1.7×10^{-21}	16
Ice–water–quartz	3.0×10^{-23}	16
Ice–water–polystyrene	1.2×10^{-22}	16
Quartz–water–air	-1.0×10^{-20}	18
Fluorite–water–air	-1.2×10^{-20}	18

Later, Barash and Ginzburg²¹ reported a substantiation of the Van Kampen approach and analysed its applicability to the solution of new problems with arbitrary media.

Experimental studies of dispersion interactions between bodies were carried out using various model systems containing both symmetrical liquid and gaseous interlayers and wetting films. Comprehensive analysis of these studies was done in a monograph.² Without dwelling on details, note that by and large the interactions between macroscopic bodies separated by vacuum or air and the dispersion interactions of neat non-polar fluids in wetting films can well be described using the macroscopic theory of the van der Waals forces with an error of 15%–30%. Deviations in the behaviour of macroscopic bodies separated by vacuum or air interlayer from the theoretically predicted in the thin interlayer limit are associated^{22–24} with both the effect of the roughness and heterogeneity of the surface of solids and with the formation of the adsorption or oxide layers on the surface (Fig. 2). Although in each case shown in Fig. 2 the experimental data are reasonably described by the inverse cube law, the calculated Hamaker constants differ appreciably and only for curve 3 the value of this constant ($A_{132} = -0.88 \times 10^{-20}$ J) is in good agreement with the theoretical estimates for a hexane wetting film immobilised on fused quartz. At the same time, in some cases the behaviour of solids separated by liquid interlayers strongly differs from that predicted by the theory of the van der Waals forces (Figs 3 and 4). The reasons for the deviation seem to be due to the assumptions underlying the theory in the case of liquid interlayers.

Detailed analysis of the key assumptions in the DLP theory was reported by Barash and Ginzburg.²¹ They used the Green functions for the Maxwell equations to determine the contribution of the long-wavelength equilibrium electromagnetic fluctuations in matter to the free energy of a system comprising macroscopic bodies separated by a thin liquid interlayer. The solutions of the Maxwell equations were expanded over the eigenfunctions of an auxiliary system.²¹ This made it possible to reduce an infinite series for free energy calculations to a rather simple expression suitable for further analysis and reveal limitations on the use of the equations¹³ for calculating the interaction forces acting between two macroscopic bodies.

First, the DLP theory ignores the contribution of the interaction between the long-wavelength fluctuation field and matter to the dielectric permittivity (in essence, the spatial dispersion for an arbitrary system is ignored). Second, the expressions for the energy of the system and the interaction

Figure 2. Disjoining pressure isotherms of hexane films on a polished substrate (roughness of about 5 nm) (1) and on molecularly smooth films-substrates (roughness at most 0.5 nm) in the presence of water vapour (2) and in anhydrous nitrogen atmosphere (3).

Figure 3. Adsorption isotherm of n-heptan-1-ol on an optical glass K-8. Experimental data by Derjaguin and Zorin²⁵ (1) and theoretical curve for the dispersion component of the disjoining pressure (2).

Figure 4. Reduced force (F/R) plotted vs. distance between two mica surfaces in white oil (mixture of branched alkanes) at 22 °C under different experimental conditions.²⁶

Solid circles correspond to completely anhydrous liquid existing in equilibrium with air dried over P_2O_5 , open circles correspond to completely anhydrous liquid in anhydrous nitrogen atmosphere, and the dashed line corresponds to the van der Waals forces.

Here and in Figs 5 and 9, the reduced force is the ratio of the measured force (F) of the interaction between cylindrical surfaces to the surface radius R . The shaded region between the solid lines denotes the limits of scatter of the measured values. The dotted lines denote the expected behaviour of the forces in the case of thick films.

forces derived by Dzyaloshinskii, Lifshitz and Pitaevskii assume that the volumes and dielectric permittivities of the bodies in the system do not change upon the change in the distances between the bodies. This limitation is valid for interacting macroscopic bodies, but in the case of a thin interlayer it is non-rigorous and leads to significant underestimation of the forces produced in the system. Thus, if the dielectric permittivity of the interlayer depends on the interlayer thickness and/or if the interlayer shows a spatial dispersion, the approach developed by Dzyaloshinskii, Lifshitz and Pitaevskii appears to be somewhat incorrect for the description of the interaction forces in a real system.

Both these factors act, as a rule, in complex molecular liquids, especially in the case of thin interlayers. This causes deviations of the experimental interaction curves from the dependences predicted by the DLP theory. In addition, interlayers a few Ångström thick violate one of the DLP theory conditions, according to which the film thickness much exceeds the size of the molecules. In this case, treatment of the liquid as a continuous medium is somewhat incorrect. Finally, calculations of dispersion interactions in the framework of the DLP theory ignore the existence of surface layers of the interacting bodies (dielectric permittivities of these layers can differ appreciably from the corresponding bulk characteristics used in calculations). Thus, theoretical calculations of dispersion interactions between bodies separated by a liquid or gaseous interlayer^{13,19} are reliable only for the interlayers tens of nanometres thick. In the case of thinner interlayers, such calculations are of limited use.

IV. Ionic electrostatic interactions

In the case of ionic fluids and particles having charged surfaces the stability of a liquid film is to a great extent governed by the electrostatic forces due to the overlap of the electric double layers in the liquid interlayer. The main difficulty in calculating these forces consists of the need of determining the spatial arrangement and concentration of ions in the interlayer with allowance for deformation of ionic atmospheres as the surfaces approach each other.

Rigorous calculations of the ionic electrostatic component of the disjoining pressure Π_e based on the solution of the Debye–Hückel equation for strong electrolytes were first reported by Derjaguin.²⁷ He derived equations for calculating the interactions between two identical spheres or two plates separated by a liquid interlayer. Derjaguin used the linearised Debye–Hückel equation, therefore the equations derived by him are only applicable to calculations of electrostatic forces in weakly charged sols.

The interaction of strongly charged particles in electrolyte solutions was studied by Derjaguin and Landau.^{7,28} Using the constant potential approximation for the surfaces brought closer together, they derived relationships for calculating the repulsive forces and the energy of the interaction between flat plates and convex macroscopic surfaces, formulated the coagulation criterion and substantiated the Schulze–Hardy rule according to which the coagulating concentration of electrolyte rapidly decreases as the valence of the counterion increases. Verwey and Overbeek reported an independent study⁸ of the interaction between identical plates in potentials with arbitrary magnitudes, which was also carried out in the constant potential approximation. Additionally, they introduced the Stern correction, which allows for the dense component of the electric double layer.

It should be noted that in solving the problem of electrostatic interaction of charged surfaces separated by an ionic interlayer the boundary conditions are first of all determined by the charging mechanism. In particular, if the surface charging occurs by adsorption of ions from solution and the entropy contribution to the free energy of the system is independent of the amount of adsorbed ions, the charged surfaces will approach each other under the constant-potential boundary condition. If the charging occurs by complete dissociation of surface groups, the constant-charge boundary conditions are applied. In the case of incomplete dissociation of ionised groups or if the entropy depends on the concentration of adsorbed ions, the charge-regulation boundary condition is used.^{29,30} Yet another type of boundary conditions corresponds to the interaction of ‘soft’ ion-permeable particles or polyelectrolyte particles.³¹ If the particle size much exceeds the Debye wavelength, the potential in the bulk of the particle is always equal to the Donnan potential.

The classical theory of ionic electrostatic interactions is restricted to consideration of the first two types of boundary conditions. Both analytical and numerical solutions to the problem of electrostatic interaction between charged identical surfaces (in symmetrical and non-symmetrical electrolytes, see Refs 2 and 31) were derived in the framework of this theory. There is a feature that permits essential simplification of the procedure for evaluation of the ionic electrostatic component of the disjoining pressure Π_e in the systems with unknown or interlayer-thickness-dependent surface charging mechanism. For instance, all possible dependences of Π_e on the interlayer thickness obtained under different boundary conditions lie between the curves corresponding to the constant potential of the diffuse layer boundaries and to the constant density of the surface charge and the charge of the dense Stern monolayer. The former and latter cases correspond to minimum and maximum repulsive forces, respectively.

Later, calculations of the ionic electrostatic component were generalised to electrostatic interactions between different-type particles, which are of particular value in the case of particle–electrode interaction and in electrofiltering and electrophoretic sedimentation. Derjaguin² proposed a graphical method of isodynamic curves, which allows one to estimate the magnitude and character of hetero-interactions at constant potentials of diffuse ionic layers. A feature of the case in point is that the ionic electrostatic forces acting between two likely charged particles bearing non-equal charges are repulsive in character at long distances. The repulsive forces increase as the interlayer thickness decreases, pass through a maximum and then change their character to attractive. The attractive forces increase without limit as the interlayer thickness tends to zero. Analysis showed that the maximum repulsion is determined by the surface potential of the particle bearing the smaller charge.

Considering weakly charged surfaces, an analytical solution to the problem was obtained using the linearised Poisson–Boltzmann equation for both flat interlayers (under constant potential³² and constant charge³³ boundary conditions) and spherical particles of different radii. A simple equation for calculating the energy of the interaction between spherical particles at constant potentials on both surfaces was obtained by Hogg *et al.*³² The problem with the constant charge boundary conditions was first solved by Usui.³⁴ Kar *et al.*³⁵ considered a complex case corresponding to a constant potential on one surface and a constant charge on the other surface for the case of thin (compared to the particle radii) double layers. It should be noted that the solutions were obtained for the problem of the interaction between spherical particles the radii of which much exceed the thicknesses of the liquid interlayers between them.

A general numerical method of solving the non-linear Poisson–Boltzmann equation developed by McCormack *et al.*³⁶ makes it possible to calculate electrostatic interactions between different-type surfaces in flat interlayers of symmetrical electrolytes at large surface charges not only for the abovementioned cases of constant potential and charge at both interfaces simultaneously, but also in the case where the surface of one particle has a constant charge while the other particle has a constant potential. However, it should be emphasised that a wide variety of the laws of variation of the ionic electrostatic component of the disjoining pressure with the interlayer thickness and the dependence of these changes on the boundary conditions^{2,31} can only be observed if the film thickness is smaller than or comparable to the Debye screening length.[§] At long distances, the interaction between both flat and spherical particles exponentially decreases as the interlayer thickness increases irrespective of the surface charging mech-

§ The Debye screening length is the action range of the electric field of a single charge in electrolyte.

anism; this was confirmed by numerous experiments (see, *e.g.*, Ref. 37).

The mechanisms of the van der Waals forces and electrostatic interactions considered above underlie the theory of stability of lyophobic colloids. It is lyophobic surfaces and colloids (their particles are treated as weakly interacting with the dispersion medium) that usually permit a correct description of the stability of interlayers (Fig. 5), kinetics of coagulation and the destabilising effect of electrolyte additives using the two approaches to calculations of surface forces (see above). We believe that the last stage of the evolution of the DLVO theory in its classical form should be dated to the early 1960s; at that time, the macroscopic theory of the van der Waals forces was already elaborated and various theories of calculations of electrostatic interactions between same-type and different-type particles separated by uniform liquid or solvent interlayers were developed. However, the development of the DLVO theory was accompanied by accumulation of experimental data that not only showed poor quantitative agreement, but in some cases qualitatively contradicted the predictions of the classical DLVO theory. Examples are provided by recent studies on the stability of foam films,^{38, 39} wetting films and interlayers between solid surfaces.^{40–44}

Figure 5. Reduced forces of interaction (F/R) between two crossed cylindrical mica surfaces of radius 1 cm in water (curves 1, 1') and in dilute potassium nitrate solution (10^{-4} M KNO_3 , curves 2, 2') and calcium nitrate solution [10^{-4} M $\text{Ca}(\text{NO}_3)_2$, curves 3 and 3', respectively].¹¹ The open and solid circles denote the experimental data, the solid lines correspond to the results of force calculations using the DLVO theory (the Hamaker constant $A_{132} = 2.2 \times 10^{-20}$ J) in the constant potential (Ψ_0 , curves 1–3) and constant surface charge (curves 1'–3') approximations. For thick interlayers, both approximations give the same results. $\Psi_0 \approx -150$ mV (1, 1'), $\Psi_0 \approx -120$ mV (2, 2') and $\Psi_0 \approx -50$ mV (3, 3').

Attempts to attain agreement between the theory and experiments led, on the one hand, to allowance for specific features of real experimental systems in the framework of the evolution of the classical approaches and, on the other hand, to development of some new mechanisms of long-range surface forces that have a common name 'non-DLVO'-forces.

V. Progress in the theory of dispersion forces

Non-uniformity of a real liquid interlayer due to the change in the film density across the interlayer thickness and to monomolecular or diffuse adsorption of a solution component near the boundary media was included in calculations of the van der Waals interactions in the framework of the model layered systems. Calculations were carried out either assuming identical dielectric properties within each layer^{20, 45–48} or using different laws of the changes in the dielectric properties along the normal to the layers.^{49, 50} In all cases, the results obtained with allowance for non-uniformity were appreciably different from those obtained in the homogeneous interlayer approximation. For instance, the interaction energies calculated using these models for films a few nanometres thick differed by almost an order of magnitude from the values calculated using the DLP theory¹³ with the bulk dielectric permittivities.

An alternative microscopic approach to evaluation of the non-uniformity of the liquid interlayer is based on the molecular statistics methods.^{51, 52} Here, the non-uniformity of the film can be taken into account by augmentation of the equations for interaction energy calculations with an additional term proportional to the inverse cube of the interlayer thickness. This term becomes of particular importance as the interlayer thickness decreases.

Eventually, Derjaguin and Churaev^{2, 53} developed a method of inclusion of the non-uniformity of the interlayer, which involves thermodynamic treatment of adsorption and evaluation of the interaction between components of non-polar solutions and the boundary phases in the framework of the macroscopic approach. Later, the method was extended to solutions of polar substances dissolved in a non-polar solvent.^{54–58} Additional interactions due to non-uniform distribution of the solution components across the interlayer thickness were named 'adsorption component of the disjoining pressure'. Depending on the ratio of the dielectric permittivities of the solvent and solute and on the ratio of the dielectric permittivities of the solvent and boundary phases, these interactions can either stabilise or destabilise the liquid interlayer. It should be noted that the effect of these additional forces is significant only in the case of interlayers a few nanometres thick.

Calculations of dispersion interactions with allowance for the spatial dispersion of dielectric permittivity appeared in the electrolyte solution films were carried out by Gorelkin and Smilga^{59, 60} using either the Dzyaloshinskii–Lifshitz–Pitaevskii method (based on calculations of the temperature Green functions) or the Bogolyubov functions. An analytical solution was obtained for electrolytes modelled by the Debye plasma and collisionless plasma with mirror reflection from the boundaries assuming neutral film boundaries and diagonal dielectric permittivity tensor within the electrolyte interlayer.

A comparison of the equations derived in Refs 59 and 60 with Eqn (2) derived using the DLP theory revealed significant difference only for the term with zero frequency. Therefore, the inclusion of spatial dispersion is of particular importance in studies of the systems where this term plays a significant role. In addition, the spatial dispersion also manifests itself in the appearance of specific effect of interfaces on the character of the frequency dependence of the dielectric permittivity of the interlayer. The effect is expected only for films a few nanometres thick in specific systems, such as metal solutions in ammonia. According to calculations, the presence of dilute electrolyte solution in the system leads to screening of the van der Waals forces at long distances (10^{-7} – 10^{-6} m). At these distances, the molecular forces decrease exponentially rather than in proportion to $\Pi(h) \sim h^{-4}$, as follows from relationship (3b).

VI. Progress in the theory of ionic electrostatic interactions

The evolution of the classical theory of electrostatic interactions between surfaces immersed in electrolyte solutions has been accompanied by revision of its foundations, such as the continuity of charge distribution along the particle surfaces, constant surface potential or constant charge of the approaching surfaces, treatment of ions in solution as point charges and consideration of other (non-Poisson) potentials determining the ion distribution in solution, *etc.*

In particular, Muller showed (see Ref. 2) that drawing colloidal particles closer together is accompanied by rearrangement of not only the diffuse charge, but also the surface charge of the electric double layer except for the chemisorbed part of this layer. He derived an exact parametric equation relating the repulsive energy to the distance between flat plates assuming that the changes in the adsorption of ions as the plates approach each other are described by the Stern isotherm.

Healy and co-workers⁶¹ reported the need of using a charge regulation model instead of the constant potential approximation in calculations of ionic electrostatic interactions at short distances between the charged surfaces.^{29–31} Based on this model, a correction to the DLVO forces of the interaction between hydrophilic surfaces in water was calculated in the framework of constant dielectric permittivity of the solvent with inclusion of the Nernst layer of hydroxyl groups near the interface (this makes the position of the charge plane more distant from the surface).⁶² This approach made it possible to explain the appearance of an additional minimum on the energy curve, which is located between the primary and secondary minima predicted by the DLVO theory.

A general thermodynamic consideration of changes in the charge of the interlayer in the course of approach of differently charged flat surfaces was reported by Lyklema and Duval²⁹ who assumed charge regulation in the Gouy–Stern layer. The approach was used for calculating the potential and charge distributions in plane-parallel interlayers and the forces and energy of the interaction between different-type surfaces in various model systems that simulate the behaviour of complex real systems, *e.g.*, the interaction of clay and metal oxide particles. The constant charge or constant potential approximations of the diffuse double layer were shown to be correct only in the case of thick interlayers. Systems with thin interlayers exhibit deviations from both boundary conditions. To characterise the charge regulation processes occurring within the interlayer as the surfaces approach each other, it is appropriate to introduce the notion of the regulation capacity characterising the possibility of establishment of a new charge distribution in the interlayer without significant change in the potential. The higher the regulation capacity of the interlayer the more correct the description of the behaviour of the system in the constant potential approximation.

The next step in considering ionic electrostatic interactions between surfaces immersed in electrolyte solution is the inclusion of various factors determining the ion distribution in the liquid interlayer. For instance, the theory of the interaction of electric double layers, which is based on the classical Poisson–Boltzmann equation, assumes that ions obey the Boltzmann distribution with the interaction potential obeying the Poisson equation. This theory ignores the effects due to specific nature of the ions in solution. At the same time, experimental data on the stability of disperse systems in electrolyte solutions and on the forces of the interaction between such systems separated by electrolyte interlayers indicate that electrostatic forces depend not only on the valence of ions and the ionic force of the solution, but also on the type of the cations and anions present in the solution.^{63–65}

To describe the specific order of ions with respect to the character of their effect on the interaction between the double layers, it was suggested to augment the Poisson–Boltzmann equation with additional potentials that include, in one way or another, the nature of the ion.^{66–72} For instance, Ninham and Yaminsky⁶⁶ proposed to include the potential of the van der Waals forces acting between the ion and the remaining part of the system in the description of the ion distribution in the solution. In addition to the potential of ion-dispersion interaction including the potential of the van der Waals forces and the Poisson potential, Karraker and Radke⁷² also proposed to take into account the potential of the interaction between ions and their ‘images’ in air, which causes additional repulsion of ions from the water/air interface. Manciu and Ruckenstein^{70,71} considered not only the long-range ion-dispersion potential (see above), but also the short-range ion hydration potential, which describes the ion hydration free energy difference between the solution bulk and the near-interface region.

Thus, the ion redistribution in the solution interlayer in the potentials of ion-dispersion and ion hydration interactions depends on the type of ions. Such a redistribution causes changes in the surface charges and surface potentials and, therefore, affects the interaction between the double layers. Interestingly, the authors of all the approaches mentioned above get satisfactory descriptions for the experimentally observed dependence of the surface tension of electrolyte solutions on the ionic strength of the solutions in spite of different choice of the additional potentials.^{68,70,72}

Correlations in mutual arrangement of ions in the electric double layers and the related additional forces were studied.^{73–75} Additional contributions to the energy of ion–ion interactions in the liquid interlayer are due to correlations of charge density fluctuations in the double layers formed on the opposite surfaces of the liquid interlayer. Taking into account the ion size (passage from point ions presentation to the ions with finite sizes) also causes the energy to change due to additional repulsion between ion shells near the mid-plane of the film. The ‘image’ forces cause deformation of diffuse ionic atmospheres with the corresponding energy contribution. Finally, the ion concentration difference between the actual film and the value predicted using the conventional Poisson–Boltzmann approach leads to a change in the Debye screening length. Analysis showed^{73–75} that the effect of ion–ion correlations mainly involves the appearance of additional attraction between the charged surfaces. This effect is most pronounced in di- and multivalent electrolyte solutions and leads to significant decrease in repulsion between the double layers or to the change in the sign of the interaction. The effect of ion size on the interaction force manifests itself to the greatest extent in the case of thin interlayers, large ionic radii and/or large surface charges. The influence of ion–ion correlations on stability of colloidal solutions with multivalent counterions was experimentally established⁷⁶ by direct measurements of interaction forces between mica surfaces in 0.15 M CaCl₂ solution.

Rejection of the uniformly ‘smeared’ surface charge model led to the development of a family of models^{77–81} that allow for discrete structure of the dense part of the electric double layer at the interface.

For instance, Zhiguleva and Smilga⁷⁹ used the modified Evald method for two-dimensional geometry and analysed the electrostatic field and potential distributions in the electric double layer for various regular flat charge distribution lattices. According to calculations,⁷⁹ the inclusion of discrete structure of the double layer in many systems is necessary because the actual interaction force can be two orders of magnitude higher than the values obtained using the smeared charge model. Similar results were also reported by Kostoglou

and Karabelas⁸⁰ who considered the interaction of surfaces characterised by discrete distribution of round or square-planar potential-determining ions occupying regular lattice sites. They found that the interaction energy differences between the surfaces with discretely distributed and smeared charge are more pronounced (over a wider range of film thicknesses) at a constant potential of the approaching surfaces rather than in the constant charge approximation.

Derjaguin and Muller² established that in the case of delocalised adsorption of ions the discreteness of the surface charge distribution causes correlations in the arrangements of the ions on the opposite film surfaces. According to calculations, these correlations are responsible for the appearance of additional attraction forces that decrease as $\Pi(h) \sim h^{-4}$. In the case of thin interlayer, these correlation forces not only reduce the electrostatic repulsion, but in some cases cause a change in the sign of the interaction.

Analysis of the effect of discreteness of the surface charge distribution on the electrolyte/insulator interface showed⁸¹ that the structure of the diffuse layer in counterions is determined by not only the exponential decay of the field due to the Debye screening, but also additional asymptotics with amplitudes depending on the dielectric permittivity of the insulator.

According to the results of theoretical studies,^{82–84} the electric double layer near the surface bearing a non-uniformly distributed charge has a modified structure compared to the double layer near a uniformly charged surface. The deviation of the structure of the diffuse part of the counterion layer is particularly pronounced in the presence of multiply charged ions and at large average surface charges.

Basu and Sharma⁸⁵ found that repulsive forces additional to those given by the DLVO theory, acting between surfaces can also be due to changes in the static dielectric permittivity of the solvent near the charged interface. Henderson and Lozada-Cassou⁸⁶ attempted to take into account the structure of the thin solvent interlayer by analysing the preferred orientation of the dipole moments of the solvent molecules near the interface, which is interpreted in the framework of the continuum models as dielectric saturation. It was shown that this phenomenon, which manifests itself in a decrease in the static dielectric permittivity, causes an extra repulsion between surfaces (in addition to the DLVO forces) and can be used for explanation of the appearance of hydration forces in electrolyte solutions.

Paunov *et al.*^{87–89} analysed the role of the size of hydrated ions in solution near the interface and showed that the ion size affects the ion distribution not only near the charged interface, but also outside the electric double layer. Redistribution of ions across the film thickness due to the ion size effect and to the changes in the static dielectric permittivity of the solvent near the charged interface requires introduction of a correction to the electrostatic component of the disjoining pressure. The correction describes the additional repulsive in thick and additional attraction in thin interlayers provided that the overlap of the double layers is small.⁸⁹

Discrete dipole distributions along interfaces were studied by different authors.^{54–58, 77, 90–93} For instance, Jönsson and Wennerström⁹⁰ analysed the contribution of image forces to the interaction between surfaces covered with surfactants having bipolar terminal groups using the continuum electrostatic model and pointed that these forces lead to appearance of repulsive forces that can be responsible for the swelling of phospholipid bilayers in aqueous solutions. Kjellander and Marcelja⁹¹ restricted themselves to consideration of dipoles oriented normal to the surface in the hyperchain approximation and showed that the correlation attraction of dipoles located on different surfaces predominates over repulsion between the dipoles and their images. Similar results were obtained by Attard and Mitchell⁹² and by Jönsson *et al.*⁹³ using methods of the perturbation theory and by Martynov and Smilga⁷⁷ who

used the electrostatic approach. As was reasonably argued by Martynov and Smilga,⁷⁷ attraction between dipoles in a symmetrical system is a general result. Since the strength of the field created by the layer adsorbed on one dipole surface alternates in the plane of the second adsorption layer (this is a consequence of the Gauss theorem), at a constant interlayer thickness the dipole lattices on the opposite surfaces are displaced relative to each other in such a manner that the potential electric energy of their interaction be minimum. This in turn causes the appearance of attractive forces acting between the dipole lattices, *i.e.*, a negative disjoining pressure. Jönsson *et al.*⁹³ showed that the inclusion of orientation rotation of dipoles in the framework of perturbation theory (long-wavelength approximation) can cause either attraction or repulsion between the dipole layers. However, in a symmetrical system the repulsion forces are much weaker than the van der Waals attraction.⁹³ It should be noted that the authors of studies^{77, 90–93} considered only symmetrical systems assuming that adsorption is independent of the interlayer thickness and ignoring specific features of the structure of dipole molecules.

VII. Electrostatic interactions in non-polar media

Specific features of ionic electrostatic interactions in non-polar media consist in that usually the bulk ion concentrations in such systems are low and, correspondingly, the Debye screening lengths are of the order of a few thousand nanometres,⁹⁴ which much exceeds the thickness of the interlayers under study. In this case, the interaction between charged surfaces can be treated as the Coulomb interaction ignoring screening. Analysis of the interaction between small charged particles, a polarisable particle and a charged electrode and between polarisable particles in a nonuniform electric field using this approach in the smeared surface charge approximation was reported in a recent review by Adamczyk.⁹⁵ Another approach is based on consideration of the interaction between electric double layers having diffuse parts comprising counterions only.^{94, 96} If the source of counterions is the surface and no ion exchange with the bulk reservoir occurs, the energy of the interaction between two flat charged surfaces can be calculated using the total entropy maximisation approach⁹⁷ with the assumption of charge regulation or constant charge condition.⁹⁶ According to calculations, the long-range repulsion between surfaces separated by non-polar liquid interlayer is more than an order of magnitude weaker compared to ionic electrostatic interaction through a water interlayer. The repulsive forces asymptotically decrease with the interlayer thickness following a power law rather than exponential law predicted by the classical DLVO theory.

The mechanisms of appearance of additional forces of the interaction between surfaces separated by a non-polar liquid interlayer in the presence of polar molecules were considered.^{54–58} This case is of particular importance in the analysis of stability of suspensions in dispersion media represented by solutions of polar components in non-polar solvents. Discrete distributions of the dipoles simulating polar molecules across the interfaces and interlayer thickness cause the appearance of various types of image forces and to dipole–dipole interactions within the interlayer. Both symmetrical and asymmetrical systems characterised by different magnitude and, in some cases, type of adsorption at different interfaces were considered.^{54–58} Equilibrium adsorption calculations were carried out with allowance for not only the specific potential of the interaction between polar adsorbable molecules and active sites at the interface, but also the potentials of the image forces and dispersion interaction of these molecules with the boundary phases. The last two potentials cause a significant dependence of the equilibrium adsorption on the thickness of the liquid interlayer.

The contribution of electrostatic interaction between layers of adsorbed dipole molecules and their images in the confining phases to the disjoining pressure can be rather large even in highly dilute solutions of polar substances in non-polar solvents. Generally, this contribution is a non-monotonic function of the concentration of polar molecules (Fig. 6) and decreases in a $\Pi(h) \sim h^{-4}$ mode as the film thickness decreases. It can cause either attraction or repulsion between film boundaries depending on the character of the changes in the adsorption of the solute across the interlayer thickness, on the ratio of the static dielectric permittivities of the contacting media and on the magnitude of dispersion interaction between the dipole molecules and the confining phases.

Figure 6. Contribution to the disjoining pressure related to the interaction between the adsorbed monolayer and its images plotted vs. mole fraction of polar solute for films 1 (a) and 2 nm (b) thick. Curves (1, 1') correspond to in-plane and curves (2, 2') correspond to normal orientation of dipoles in the monolayer. Curves (3, 3') correspond to dispersion interaction of bodies (the Hamaker constant $A_{132} = 5 \times 10^{-21}$ J) taken with the opposite sign. Disjoining pressure calculations were carried out for wetting films of solutions of alcohols in oil on the water surface.^{57,58}

Analysis of the expressions derived and numerical calculations carried out for monolayers of adsorbed molecules using different magnitudes and orientations of the dipole moments relative to the interfaces showed^{54–58} that in non-symmetrical thin interlayers (e.g., wetting films) at both in-plane and normal orientations of the dipoles in the monolayer the forces of the interaction between the monolayer and its images can

Figure 7. Various components of the disjoining pressure acting in the wetting films of pentanol solution in pentane on water surface plotted vs. film thickness.

Contribution related to the interaction between the adsorbed monolayer of dipole molecules and its images (1); molecular component calculated using published data⁴⁵ (2); adsorption component calculated using the constants of the interaction between pentanol molecules and the boundary phases (taken from Ref. 55) (3); contribution related to excess electrostatic energy of diffusely distributed alcohol molecules (4); and contribution of the correlation attraction of adsorption monolayers (5).

much exceed other types of interaction forces including the forces of the interaction between the diffuse adsorption layers, correlation attraction forces acting between the monolayers adsorbed on the opposite sides of the interlayer and the dispersion forces (Fig. 7). However, the force of dispersion interaction dominates over the image forces in 2–3 nm and thicker films because it decreases in proportion to $\Pi(h) \sim h^{-3}$ as the film thickness decreases.

VIII. Interaction forces caused by modified structure of liquid interlayer

1. Treatment of liquid in a continuum approximation

The assumptions of structural differences between the liquid in the thin interlayer and in the bulk phase and of the existence of long-range surface forces due to this difference were first made by Derjaguin.² Later, these assumptions were repeatedly (and fruitfully) used in discussing the nature of hydration, solvation and structural repulsive forces and hydrophobic attractive forces due to deviations of various structural parameters from the corresponding values in the bulk. One of the first theoretical studies of the processes occurring in a polar solvent as a result of decrease in the thickness of the liquid interlayer was reported by Marcelja and Radic.⁹⁸ They calculated the free energy density using the Landau expansion in the order parameter and showed that the inclusion of only quadratic expansion terms (with respect to the order parameter and its gradient) permits a correct description of the exponentially decreasing repulsive forces acting between the surfaces confining the liquid interlayer provided that variations of the order parameter are small. Later, other authors interpreted the order parameter as a characteristic of the local polarisation of water.^{99–102}

The idea of surface-induced polarisation of water molecules as the source of hydration forces was used by different authors.^{103–106} For instance, Kornyshev and Leikin^{105,106} proposed two different mechanisms of polarisation of water molecules near the interface. One mechanism is based on consideration of the contribution of the interaction between

oppositely charged groups of one electrically neutral surface of a lipid membrane and their images in a non-polar medium separated from the membrane surface by a water interlayer.¹⁰⁵ Spatial correlations of water polarisation fluctuations were included using the methods of non-local electrostatics. It was shown that lateral ordering of polar groups on the membrane surfaces plays the key role in determining the character of the interaction forces between them (Fig. 8). The other, 'chemical', mechanism of ordering of water molecules is based on the use of the Landau free energy functional and introduction of a phenomenological order parameter and inhomogeneous boundary conditions. This approach allowed differences between the states of water near the polar surface and in the bulk phase to be analysed.¹⁰⁶ Both mechanisms predict an exponential decrease in repulsive forces with an increase in the thickness of the water interlayer. These forces are related to the character of ordering of the polar groups on the surface of lipid membranes. Both pre-exponents and correlation lengths depend on the nature and structure of the surfaces confining the interlayer.

Figure 8. Comparison of theoretically predicted disjoining pressure (solid lines) calculated taking into account the forces of dispersion attraction between membranes¹⁰⁵ with experimental data for various lipids: POPE (I), egg PEt (II), egg PEt – Me (III) and SOPC (IV). Calculated using the following parameters: 8×10^{-21} J for Hamaker constant; 0.5 nm correlation length of water polarisation fluctuations; 0.4 nm for the distance between positively and negatively charged centres in the polar group; 0.5 nm for the distance between the dipole plane and interface; and 0.65 nm^2 for the average surface area per polar group. Theoretical curves were calculated at the following lateral correlation lengths of the polar groups: 0 (I), 0.2 (2), 0.3 (3), 0.5 (4), and 2 nm (5).

Mitlin and Sharma¹⁰⁷ studied the interaction between flat plates separated by a liquid interlayer. They combined, in the framework of the gradient theory, the Cahn approach proposed for analysing wetting transitions at an interface between two media¹⁰⁸ and the approach used by Marcelja and Radic.⁹⁸ The new analytical method¹⁰⁷ made it possible to derive asymptotically exact dependences of the disjoining pressure, free energy and order parameter profile on the interlayer thickness for an arbitrary dependence of the free energy density on the order parameter. It was found that in the general case the disjoining pressure can be described by a sum of exponents with the characteristic lengths proportional to the correlation radius in bulk liquid, the pre-exponent being dependent on both the deviation of the free energy density from the quadratic form in the expansion and on the parameters of the interaction between the liquid in the interlayer and both surfaces confining

the interlayer. The interaction forces between the plates can be either attractive or repulsive. In addition, the sign of the forces changes as the interlayer becomes thinner.

A new approach to account for the interaction between the liquid and the confining surfaces in calculations of forces additional to DLVO was made by Kuklin.¹⁰⁹ The free energy of the system was modelled by the harmonic approximation of the Landau – Ginzburg functional, which depends on the order parameter. In addition to the free energy density expansion terms considered by Marcelja and Radic⁹⁸ and by Kornyshev and Leikin,¹⁰⁶ Kuklin proposed to augment the functional with functions characterising the contribution of direct short-range interaction between the near-surface layers of the liquid and the surface of the solid phase. It was shown¹⁰⁹ that the forces acting between surfaces of different nature can be either attractive or repulsive depending on the interlayer thickness. These forces depend on four scaling parameters, namely, two extrapolation lengths characterising the depth to which the field produced by each surface penetrates into the liquid phase and two field parameters that describe the effect of the solid surface on the properties of the nearest molecular layer in the liquid. When these parameters and the interlayer thickness are chosen appropriately, the forces show a nearly exponential dependence on the thickness of the liquid interlayer.

The approach proposed by Eriksson *et al.*¹¹⁰ is conceptually similar to that developed by Marcelja and Radic. Here, the order parameter characterises the relative local increase in the number of hydrogen bonds per water molecule in the thin interlayer compared to the corresponding characteristic of the bulk phase. Eriksson *et al.*¹¹⁰ considered a system comprising the water interlayer and hydrophobic surfaces confining it and expanded the free energy of the system in terms of the order parameter, minimised it and concluded that an increase in the order parameter near the hydrophobic wall causes the appearance of long-range attractive forces. The action range of such forces is much shorter than that of hydrophobic attraction reported in the literature.

Yushchenko *et al.*¹¹¹ suggested another mechanism of the appearance of hydrophobic attraction forces acting at longer distances. This involves the formation of a cavity filled with vapour of the liquid under study (or with gas) between the interacting lyophobic particles. The hydrophobic attraction forces appeared in this case are in essence capillary forces. This mechanism is possible if the wetting angle exceeds 90° and the cavity is formed only after the interacting bodies are brought into contact. According to calculations,¹¹¹ the cavity is also thermodynamically stable even in the initial appearance of a gap between the plates; however, the energy barrier to cavity formation is as high as tens of kT before the bodies are brought into contact. We believe that this is responsible for the fact that the cavity formed only after the hydrophobic surfaces have preliminarily been brought into contact in water.¹¹²

It should be noted that hydrophobic attraction in the case of thick interlayers was also observed without explicit cavity formation.¹¹³ The cavity formation mechanism proposed to explain the experimental data was based on the hypothesis that the formation of a vapour-filled cavity is preceded by nucleation in the liquid interlayer. Forsman *et al.*¹¹⁴ also reported a decrease in the density of the liquid near the lyophobic wall, which was associated with the presence of gaseous nuclei. Analysis of the density functional of the liquid in the thin interlayer showed that non-uniform decrease in the density across film thickness causes the appearance of attractive forces which can be much stronger than the van der Waals forces for thin films. It is noteworthy that these forces increase rather than decrease (as is traditionally accepted in the literature) in absolute value as the temperature increases.

Other mechanisms leading to appearance of long-range hydrophobic forces related to formation of cavities and micro-bubbles between the interacting surfaces were also proposed.^{115–118}

2. The accounting for discrete structure of liquid

The studies analysed in the preceding Section treated the solvent or the liquid (*i.e.*, the liquid interlayer) in the continuum approximation. However, extensive literature is also available (see, *e.g.*, Refs 119–129) in which the discrete structure of the liquid in the interlayer is included in the framework of the model of the Lennard-Jones fluid or the model of hard spheres. Here, irrespective of the model employed, both analytical methods and computer-aided calculations allow one to reproduce the oscillating character of the interaction forces (Fig. 9) observed in experiments with the liquid interlayers of different nature (see, *e.g.*, Refs 11 and 130).

Figure 9. Oscillating forces of the interaction between mica surfaces separated by a propylene carbonate interlayer without electrolyte (a) and upon adding 10^{-4} mol of tetraethylammonium bromide (b).¹³⁰

The circles and triangles denote the results of measurements obtained as the surfaces move away from or approach each other, respectively. The solid and dashed lines connect the experimental points. The dotted lines correspond to theoretically predicted DLVO forces with the Hamaker constant $A_{132} = 10^{-20}$ J.

The main problem in theoretical calculations of the interaction between two solid walls separated by a liquid interlayer consists of maintaining a constant chemical potential of the liquid as the interlayer thickness varies. If for Monte Carlo simulations this condition is explicitly met in the framework of the grand canonical ensemble,¹¹⁹ it is hardly possible in the case of calculations based on analytical theories. There are also some exceptions, namely, approximate theories (*e.g.*, various versions of the mean field theory¹²⁰ and simple theories of

integral equations for inhomogeneous systems¹²¹) in which the closure of the unary distribution functions is attained using the pair distribution functions of the bulk phase. However, the pair distribution functions characteristic of liquid interlayers are anisotropic in nature and therefore the results of corresponding calculations can be incorrect.¹²² In this connection, a number of approaches were proposed, which permit a more correct inclusion of the anisotropy of the liquid in the thin layer.

Kjellander and Sarman¹²³ did their research in the framework of the theory of integral equations based on the solution of the exact Ornstein–Zernicke equation for anisotropic pair correlation function and proposed to use the Percus–Yewick anisotropic closure. Attard¹²⁴ showed that the use of a hyper-chain approximation and its versions in solving the Ornstein–Zernicke equation permits a correct reproduction of the oscillating character of the forces using the model of hard spheres and the Lennard-Jones model of fluid. It should be noted that some authors (see, *e.g.*, Ref. 122) cast doubt on the correctness of the use of the hyperchain approximation for calculations of interaction forces in dense fluids with short-range potentials.

To study molecular liquids having non-spherical molecules, Chandler and Andersen¹²⁵ developed the reference interaction site model (RISM), which is a molecular analogue of the Percus–Yewick approximation of hard spheres for a simple fluid. According to the RISM model, the equilibrium correlations between molecules in the dense fluid are determined by the short-range repulsive component of the intermolecular potential. This model was used for calculating the solvation forces for liquid interlayers comprised of diatomic molecules based on the theory of integral equations.¹²⁶ The results of calculations revealed a high damping of oscillations on going from the model of hard spheres to the RISM model (Fig. 10), which allows for asymmetry of molecules of the liquid.

Figure 10. Reduced force of the interaction between two interfaces plotted vs. reduced distance between them for fluids with a reduced density of 0.3584:¹²⁶ the dashed line corresponds to a diatomic fluid with an interatomic distance of 0.6σ (σ is the atom diameter) and the solid line corresponds to the fluid of hard spheres (sphere diameter 1.2146σ).

3. Phonon mechanism of surface forces

As mentioned above, Derjaguin, Churaev and their scientific school (see, *e.g.*, a monograph² and articles^{131, 132} and references cited therein) repeatedly used the idea of the structural

difference between the liquid in the thin interlayer and in the bulk phase in discussing the stability of certain colloidal systems. However, in these studies the structural differences meant static deviations of the local polarisation, intermolecular distances and orientations of molecules relative to interfaces in the interlayer from the corresponding bulk characteristics. Thus, additional surface forces appeared in the system were associated with the overlap of the structure-modified boundary layers in the film.

Another approach to the problem of structuring of the liquid in a system of restricted dimension is based on consideration of the dynamic structure of the liquid.^{133–138} Here, the dynamic structure of the liquid is treated as the set of vibrational and rotational motions of all atoms and molecules in the liquid confined within a thin interlayer. The dynamic structure of liquid strongly depends on both the interlayer thickness and the surface-induced changes in the intermolecular interactions. The dynamic structure differences between bulk liquid and the liquid in the state of restricted dimension manifest themselves in, *e.g.*, the absorption spectra of the liquid in the corresponding state (Fig. 11).

Figure 11. IR spectra of ethanol in the region of OH stretching vibrations.¹³⁶ The dotted curve is the spectrum of the bulk liquid and the dashed line is the spectrum of ethanol interlayer (25 nm thick) separating two fluorite plates. The points connected by the solid line are the sum-frequency generation (SFG) spectrum of ethanol–air interface.

Clearly, these two types of structuring in the thin liquid interlayer complement rather than exclude each other. Therefore, understanding of the character of molecular motions in thin layers of molecular liquids is important for the description of various properties of liquid films and the development of detailed mechanism of structure-induced surface forces.

Generally, molecular motions in bulk liquid are anharmonic. However, if the observation time is short compared to the characteristic relaxation times of the corresponding type of motion^{139, 140} or the region under consideration is small,¹⁴¹ the complex picture of intra- and intermolecular motions in the liquid can quite correctly be represented by a set of collective vibrational states, or normal modes, associated with acoustic waves in the liquid medium. The fruitfulness of this approach to the description of many phenomena in liquids has been well documented. The most important studies are based on the normal-mode approach, *e.g.*, the description of solvation dynamics,¹⁴² calculations of diffusion constants¹⁴³ and

absorption spectra¹⁴⁴ and the description of the nature of the glassy state.¹⁴⁵

The approach developed in our studies^{133–138} also treats the intra- and intermolecular motions in liquids as harmonic processes characterised by corresponding characteristic times and normal-mode spectra. Each normal mode is determined by the parameters of an oscillator involved in a vibrational (rotational) motion and by its interaction with neighbouring oscillators. The probability of realisation of a normal mode of an arbitrary oscillator depends on the ratio of the liquid interlayer thickness (h) to the free path length (L) of phonon corresponding to the normal mode in question, being equal to $\exp(-h/L)$. Because of the normalisation condition for the total number of degrees of freedom at each time instant any oscillator in the film is either involved in collective vibration of the entire ensemble of oscillators propagating normal to the interface or oscillates at a frequency characteristic of the bulk liquid and determined by both the internal force field of the whole molecule and the effective average field produced by the surrounding molecules.

The dynamic structure differences between bulk liquid and the liquid in the thin film are due to the fact that the free path lengths of phonons, orientations of molecules relative to one another and to interfaces and intermolecular distances in the thin interlayer are changed due to the interaction between the molecules and the surface. In addition, the surfaces that bound the thin liquid interlayer induce changes in the conformational states of molecules. All these factors affect the normal-mode spectrum and give rise to an additional contribution to the film free energy, which depends on the interlayer thickness and is given by

$$F^E = \sum_j \int_0^\infty kT \ln \frac{\text{sh}(\hbar\omega/2kT)}{\text{sh}(\hbar\omega_{j0}/2kT)} Z_j(\omega) \exp\left(-\frac{h}{L_j(\omega)}\right) d\omega, \quad (4)$$

where ω_{j0} are the eigenfrequencies of corresponding molecular vibrations in the bulk liquid, $Z_j(\omega)$ is the thermodynamically averaged density of vibrational states determined from the dynamic matrices of instantaneous film states and L_j is the free path length of photons for the j th type of oscillators. Summation is carried out over all types of oscillators (j) associated with branches of the dispersion curve for the liquid interlayer. The product $Z_j(\omega) \exp(-h/L_j(\omega)) d\omega$ is the number of vibrational modes of the j th type per unit surface area of the liquid interlayer with allowance for finite relaxation time of the vibrational mode. For linear waves the free path lengths of phonons are given by the following transcendent relationship

$$L_j(\omega) = v_j(\omega)\tau_0 \left[\int_{L_j(\omega)} \rho(z) \exp\left(\frac{U(z)}{kT}\right) dz \right]^{-1}, \quad (5)$$

where $v_j(\omega)$ is the absolute value of the group velocity of collective vibration at the frequency ω , τ_0 is the average lifetime of oscillators between thermal jumps in the bulk liquid, $\rho(z)$ is the linear density of oscillators along the normal to the film boundaries and $U(z)$ is the excess (compared to bulk liquid) potential barrier to thermal jumps due to the interaction between the oscillators and the boundary phases. Integration is carried out along the chain of oscillators. In the harmonic approximation we neglected the phonon–phonon interaction. In this case the contribution of collective vibrational excitations to the disjoining pressure in the film is given by^{133, 135}

$$\Pi(h) = \sum_j \int_0^\infty \left(-\frac{dK_j}{dh} - \frac{K_j h}{L_j^2(\omega)} \frac{dL_j(\omega)}{dh} + \frac{K_j}{L_j(\omega)} \right) \times \exp\left(-\frac{h}{L_j(\omega)}\right) d\omega, \quad (6)$$

where

$$K_j = Z_j(\omega) kT \ln \frac{\text{sh}(\hbar\omega/2kT)}{\text{sh}(\hbar\omega_{j0}/2kT)}.$$

The contribution to the disjoining pressure described by expression (6) is due to collective vibrational excitations (phonons) in the film; therefore, it was called the phonon component of the disjoining pressure.

From relations (4) and (6) it follows that the excess free energy and the disjoining pressure are calculated as the sums of the contributions of different types of phonons. The signs of the summands are determined by the ratio of the mode frequencies in the film to the corresponding frequencies in the bulk liquid. The magnitudes of the summands are determined by not only the frequency difference, but also the density of phonon states in the nanofilm, the latter contribution being decisive.

Numerical analysis revealed great differences (several orders of magnitude) between the contributions of different types of oscillators. Usually, only a few less localised optical modes essentially contribute to the total disjoining pressure. According to relation (5), the contribution of a certain type of oscillators will first of all be determined by the coupling between these oscillators (both within the same molecule and within neighbouring molecules), which affect the group velocity of phonons. Calculations using the model of coupled oscillators^{135–137} and the force constants of intermolecular interaction characteristic of associated liquids showed that in some cases the contribution of the phonon component of the disjoining pressure to stability of the liquid interlayer can be much larger than that of molecular forces.

From expressions (4) and (6) it follows that the contributions of different oscillators to the disjoining pressure and to the free energy of the film depend exponentially on the film thickness and also implicitly depend on the thickness (this is expressed through the dependence on the free path length of phonons and on the density of vibrational states).

Three terms in square brackets in Eqn (6) describe three different types of the disjoining pressure – film thickness interrelations. The third term dominates in the case of thick films.[¶] Here, the phonon mechanism provides an exponential decrease in the disjoining pressure as the film thickness increases. In a broad range of thicknesses the phonon component of the disjoining pressure is usually described by the sum of several exponentially decreasing terms. This theoretically predicted type of dependence is in good agreement with numerous experimental data (see, e.g., a monograph² and references cited therein).

The first term plays the decisive role for thin films where the discrete structure of the liquid should be taken into account. This discreteness leads to inhomogeneous distribution of molecules across the interlayer due to both the interaction of the liquid with the confining phases and the excluded-volume effect. The last-mentioned factor causes oscillations of the local density across the film thickness. This leads to oscillations of the force constants in the dynamic matrix, which in turn initiates oscillations of the density of vibrational states and,

as a result, oscillations of the excess free energy and disjoining pressure. The use of the phonon mechanism for analysis and description of solvation forces in thin films¹³⁸ made it possible to explain many details of experimental observations, such as anharmonicity of oscillations, changes in the oscillation period with variation of the film thickness and similar oscillations periods for different liquids. Calculations¹³⁸ also clarified the mechanism of disappearance of such oscillations near rough surfaces and in wetting films.

However, it should be emphasised again that the approach under consideration predicts oscillations of forces in thin films with respect to some exponentially decaying function of the film thickness rather than zero. The role of the decaying function is played by the third term in square brackets in Eqn (6).

Eventually, at intermediate thickness of the liquid interlayer the contribution of the oscillations of the density of collective vibrational states can be neglected, but the changes in the mean free path of phonons with variation of the film thickness cannot be ignored. Here, a significant role is played by the second term in square brackets in Eqn (6). The magnitude and sign of this term are determined by the derivative, dL/dh , which mainly depends on the character of the interaction between the oscillators and the phases confining the film.

The effect of the character of the interaction between the liquid and the confining phases on the magnitude and sign of the phonon component of the disjoining pressure deserves particular attention. This effect is first of all due to significant changes in localisation of normal modes near interfaces owing to the interaction between the oscillators and the confining phases. For instance, the free path of phonons increases near the lyophilic surface due to an increase in the energy barrier to thermal jumps and, hence, a significant increase in the relaxation time of the entire ensemble of the oscillators involved in collective vibrations. On the contrary, the energy barrier to thermal jumps decreases near the lyophobic surface, which leads to higher mobility of the molecules near corresponding interface.

Figure 12 shows the normalised relaxation times of a linear ensemble of oscillators in a liquid film plotted vs. film thickness for different constants of the van der Waals interaction between the molecules and the phases confining the film. As can be seen, the effect of the lyophobic substrate manifests itself at much longer distances provided equal, in absolute value, interaction constants. However, the effect of the hydrophobic substrate is not restricted to shortening of the relaxation time of the ensemble of oscillators, but also manifests itself in significant strengthening of intermolecular interactions (e.g., marked strengthening of hydrogen bonds in aqueous media near the hydrophobic surface¹⁴⁶). In turn, the latter factor causes an increase in the group velocity of phonons associated with the O–H vibrations in water molecules. Therefore, for not too thick films the $L_j(\omega)$ parameter, which is sensitive to the interaction of oscillators with the film-confining phases, can vary over a rather wide range as the properties of the confining phases vary only slightly. This was found experimentally for water interlayers separating various lipid membranes.^{147, 148} In the case of inhomogeneous boundary conditions, the free path lengths should fluctuate along the interface; however, these variations of $L_j(\omega)$ can hardly be measured experimentally because in actual experiments we usually measure the integrated characteristics.

Yet another factor affecting the magnitude and sign of the phonon component of the disjoining pressure is the orientation effect of substrate on the molecules in the near-wall layers of the liquid. As a result, the frequency distribution of the density of vibrational states changes significantly. Apparently, this distribution is a consequence of configuration averaging over

¶ Thick films are the films for which the dependence of L and K on the film thickness can be ignored.

Figure 12. Relaxation time ratio of a linear molecular chain in symmetrical liquid film (t) and in bulk liquid (t_0) plotted vs. film thickness at different constants of dispersion interaction between the liquid molecules and the boundary phases: 1×10^{-49} (1), 2×10^{-50} (2), -2×10^{-50} (3) and $-5 \times 10^{-50} \text{ J m}^{-3}$ (4).

all possible orientations of the molecules in chains (corresponding to instantaneous static structure) with allowance for the statistical weight of each state. For instance, the orientations of molecules and their fragments (oscillators) relative to one another in bulk liquid are only determined by intermolecular interactions. In a liquid film, the field of surface forces of the substrate superimposes the field of intermolecular forces and thus causes redistribution of the statistical weights of different orientations.

We have shown that static structuring even in the first layer of a liquid film strongly affects the dynamic structuring of liquid in the whole film. Therefore, changes in the wettability of the interface resulting in redistribution of the density of vibrational states over frequencies can induce changes in not only the magnitude, but also the sign of the phonon component of the disjoining pressure. In the framework of the phonon mechanism we explained the experimentally observed effect of temperature on the oscillating and exponentially decreasing forces (to a first glance the effect is somewhat contradictory). For instance, theoretical analysis showed¹³⁴ that if the parameters of the dynamic matrix are independent of temperature (neglect of thermal expansion and changes in the state of the surface), the increase in the temperature causes damping of oscillations (Fig. 13) and a decrease in the magnitude and correlation lengths for the exponentially decreasing forces (Fig. 14).

The results of molecular dynamics calculations¹⁴⁹ and measurements of oscillating forces reported by Christenson and Israelachvili¹⁵⁰ (they studied the interaction between mica cylinders separated by an octamethylcyclotetrasiloxane interlayer in the temperature interval 14–40 °C) and by Nakada *et al.*¹⁵¹ (for the interaction between the Si_3N_4 and highly oriented pyrolytic graphite surfaces separated by interlayers of normal alcohols in the temperature range 25–60 °C) are in agreement with the results of theoretical studies indicating a slight damping of oscillations with an increase in temperature.

It is important that the decrease in the disjoining pressure with an increase in temperature, which is theoretically predicted for thick films in the framework of the approach we have developed (see Fig. 14), was repeatedly observed in experi-

Figure 13. Damping of oscillations of the disjoining pressure with an increase in temperature: $T = 20$ (1), 50 (2), 70 °C (3). Calculated using the coupled oscillator model.¹³⁷

Figure 14. Changes in the non-oscillating portion of the disjoining pressure isotherm with temperature: $T = 20$ (1), 30 (2), 50 °C (3). Calculated using the coupled oscillator model.¹³⁷

ments. Moreover, weakening of the surface forces in water interlayers with an increase in temperature was for long treated as a characteristic property of structural forces and interpreted as a result of partial breakdown of the structure (*e.g.*, disruption of the network of hydrogen bonds).²

The mechanism we have proposed does not contradict this interpretation and provides a better insight into the physical sense of the structural changes occurring in the liquid with an increase in temperature. In particular, an increase in temperature is accompanied by a decrease in the ratio of the energy of hydrogen bonds to kT ; therefore, an increase in the frequency of thermal jumps is accompanied by redistribution of the density of vibrational states over frequencies.

However, the approximation of constant boundary conditions under temperature variation is not always valid. For instance, changes in the boundary conditions with an increase

in temperature can cause significant changes in the density of vibrational states for the interlayers bounded by bilayers, surfactant-coated surfaces, *etc.* This effect is most pronounced near the phase transition temperature in the surface layers. Calculations and theoretical analysis revealed¹³⁴ the possibility of strengthening rather than weakening of exponentially damping forces. Apparently, it is changes in the density of vibrational states that are responsible for the experimentally observed swelling of dipalmitoylphosphatidylcholine¹⁴⁷ and egg phosphatidylcholine¹⁵² bilayers on heating above the melting point.

Thus, the phonon mechanism of surface forces is based on consideration of changes in the frequency spectrum of the liquid upon restriction of its dimension, which was repeatedly observed in the model and real experiments (see, *e.g.*, Refs 146 and 153–155). This mechanism provides better insight into the dynamic processes occurring under limitation of the characteristic sizes of the liquid medium and makes it possible to assess the role of the interaction between the liquid interlayer and the confining phases in the formation of the dynamic structure of the liquid. It should be noted that this mechanism allows one to describe the oscillating (solvation) forces and various manifestations of the exponentially decreasing forces, such as the hydration-induced repulsion between hydrophilic surfaces and hydrophobic attraction.

4. Forces associated with the presence of long-chain surfactants and high-molecular-mass polymers in a liquid interlayer

There is yet another type of forces, which is ignored by the DLVO theory but has a great practical value for colloidal and disperse systems. These are forces associated with the presence of high-molecular-mass polymers and long-chain surfactants in a thin liquid interlayer. In this case the non-DLVO forces are mainly determined by the character of the interaction between polymers (long-chain surfactants) and the surfaces of particles separated by the liquid interlayers. Theoretical analysis of the forces arising in such systems involves consideration of three different cases, namely, reversible and irreversible adsorption of polymers on particles and the 'no adsorption' case.

Determination of the magnitude, sign and action range of forces requires the inclusion of (i) character of the polymer–solvent interaction, which is determined by the Flory–Huggins interaction parameter; (ii) degree of surface coverage with the polymer, (iii) evaluation of the proportion of polymer segments contacting the surface and the adsorption energy per segment and (iv) estimation of the thickness of the adsorption layer and the concentration of the polymer in solution. Finally, the size ratio of colloidal particles to polymer molecules should also be taken into account.

De Gennes¹⁵⁶ and Fleer *et al.*¹⁵⁷ proposed models that describe the interaction between large particles coated with a polymer irreversibly adsorbed from solution. The approach by de Gennes is based on scaling theory methods, being restricted to the case where the polymer occupies a fraction of the available adsorption sites on the surface of a particle and the adsorption energy of each polymer chain is high. The second approach uses the self-consistent field theory and is not restricted to low adsorptions. Both methods are applicable to the case where the phases confining the interlayer approach each other rapidly compared to the rate of establishment of the adsorption equilibrium on the surface but slowly compared to the rate of establishment of the conformational equilibrium in the adlayer. Various types of forces can appear in this case. At low polymer concentrations in a good solvent, bringing the surfaces closer together at constant surface coverages with the polymer causes the appearance of repulsive forces that decrease in proportion to the inverse cube of the separation between the surfaces (the interlayer thickness should be com-

parable with the doubled thickness of the adsorption layer).¹⁵⁸ At high polymer concentrations or under chemisorption conditions, the interaction between surfaces will have another character. An increase in the polymer concentration in solution leads to an increase in the interface coverage and to formation of brush structures (polymer molecules are arranged normal to the interface) under chemisorption conditions. In the latter case the elastic energy of the initially stretched chains in the brush structures decreases as the interlayer thickness decreases. This provides a negative contribution to the disjoining pressure in the film (attraction), which decreases in proportion to $h^{3/4}$. In addition, the osmosis contribution, which includes the change in the entropy of mixing and solvation energy of the polymer segments, and steric effects due to limitation of the number of possible conformations of the polymer molecules confined within the thin interlayer cause the appearance of repulsive forces that increase in proportion to $h^{-9/4}$ as the interlayer thickness decreases. Thus, the sign of the resultant force is determined by competition of the factors mentioned above and the interlayer thickness normalised to the thickness of the adlayer.¹⁵⁸ Numerous experimental data (see, *e.g.*, Refs 159–161) revealed the key role of the steric factor.

It should be noted that the idea of elastic repulsion between the surfactant and polymer adsorption layers was proposed by Reh binder¹⁶² in discussion of the effect of surfactants and polymers on the stability of colloids long before elaboration of theories of steric stabilisation. Recently, Huang and Ruckenstein¹⁶³ showed that changes in the polymer concentration over a wide range can induce a sequence of (re)stabilisation–destabilisation processes. For instance, on the one hand, a considerable increase in the polymer concentration causes an increase in adsorption of the polymer on the surface of particles and thus increases steric repulsion between them. On the other hand, it induces aggregation of the polymer in solution resulting in the appearance of attractive forces due to depletion forces (see below).

As to reversibly adsorbable polymers (usually, homopolymers), both theories, by Fleer¹⁵⁷ and by de Gennes,¹⁵⁶ predict attraction of the surfaces owing to bridging bonding through polymer molecules under equilibrium approach and free desorption of the polymer from the interface.

The effect of non-adsorbable polymers on the interaction between flat plates and spherical particles has been a subject of extensive research (see, *e.g.*, Refs 164–174). In this case, the sign and magnitude of the interaction depend on the thickness of the liquid interlayer, the shape of particles, the charge state of polymer molecules and the ratio of the gyration radius of the polymer to the radius of the colloidal particle. For instance, if macroscopic surfaces immersed in a liquid approach each other and the interlayer thickness is smaller than the length of a free polymer molecule, the concentration of the polymer in the interlayer decreases compared to its concentration in the bulk phase.^{165–168} The osmotic pressure produced in this case causes the appearance of attractive forces (the so-called 'depletion forces'). These forces considerably increase (i) as the polymer concentration increases,^{165, 167–168} (ii) on going from spherical polymer molecules to polymer chains or asymmetrical molecules,^{165, 166} (iii) in the case of charged polymer molecules^{166, 168} and (iv) if the particle–solution interface is covered with an adlayer of a polymer having a higher molecular mass compared to that of the free polymer.¹⁶⁷ Contrary to this, for thick interlayers bringing the surfaces closer together leads to an increase in the concentration of free polymer in the interlayer due to displacement of the solvent, which in turn causes the appearance of repulsive forces.^{167, 168} It should be noted that the repulsive forces at thick interlayers are always weaker than attractive forces at thin interlayers. Nevertheless, an increase in long-range repulsion with an increase in the concentration of a charged polymer at polymer

concentrations > 1 vol.% favours stabilisation of suspensions.¹⁶⁸

The methods and approaches mentioned above are applicable to macroscopic colloidal particles. The interaction of small (compared to the gyration radius of the polymer) particles was also studied.^{169–171} The polymer was treated as an ensemble of monomer units involved in manybody interactions. If the particle size is comparable with the gyration radius of the polymer, the theoretical analysis of the interactions in question is much more complicated.^{172–174} For instance, Tuinier and Fleer¹⁷³ used the notion ‘depletion thickness’ in the framework of the mean-field theory and derived an analytical expression for calculating the potential of depletion forces acting between two disperse particles. This method was also used¹⁷⁴ in a study of the effect of the polymer chain length, bulk concentration and solubility on the polymer segment distribution density across the liquid interlayer and on the magnitude of the depletion forces. It was pointed out that if the disperse particles, polymer molecules and the correlation length in the polymer solution are comparable, the actual magnitudes of depletion forces much exceed those reported in the literature.^{165–168} Thus, for nanodispersions the destabilising role of depletion forces is much more significant than for microdisperse systems.

Summing up, it should be noted that poor understanding of all specific features of the interactions between disperse particles in solutions of polymers or long-chain molecules is to a great extent due to a non-equilibrium character of the approach of the surfaces of particles in polymer solutions.

IX. Conclusion

Usually, the classical DLVO theory permits reliable calculations of the destabilising effects of electrolytes in classical colloidal and disperse systems characterised by a particle size of 100 nm and more and weak particle–dispersion medium interaction.

However, modern nanotechnology deals with much more complex objects. The use of nanocolloidal and nanodisperse systems comprising solid (or liquid) particles comparable in size with not only the Debye screening length, but also the thickness of the liquid interlayer between them requires the introduction of significant corrections for the curvature of the particle surfaces in calculations of the van der Waals and ionic electrostatic interactions and simultaneous inclusion of the specific features of the charge distributions along the surface of particles and across the interlayer separating them.

One of the key problems in nanotechnology is reliable manipulation of the size and properties of the surface of nanoparticles. This involves the use of multicomponent dispersion media characterised by strong interaction between particles and the medium (when it possesses lyophilic or lyophobic properties). This significantly reduces the efficiency of the classical theory in prediction and control of the stability of complex nanocolloidal and nanodisperse systems.

The author hopes that this review of modern theoretical approaches to calculations of surface forces of different nature acting in nanoscale liquid interlayers will help researchers and nanotechnologists to reasonably choose procedures for, and regimes of, treatment of systems containing nanoobjects in order to attain the desired results.

Chemical research at the Siberian Branch of the Russian Academy of Sciences

This issue is devoted to the 50th anniversary of the Siberian Branch of the Russian Academy of Sciences the foundation of which was an outstanding event in the history of Russian science. The intensive exploration of Siberia including mineral resources and development of industry and agriculture, which started in the 1950s and was preceded by evacuation of many factories and scientific institutions from the USSR central regions to Siberia during the World War II, brought about numerous problems to be solved by Russian science. This required creation of an adequate scientific potential of Siberia. Outstanding scientists, Academicians M A Lavrentiev and S A Khristianovich proposed the foundation of a new scientific centre in Siberia. The government supported this proposal and on May 18, 1957, the USSR Council of Ministers established the Siberian Branch of the USSR Academy of Sciences, which was the first regional Branch of the Academy. The Siberian Branch comprised the already existing West-Siberian, East-Siberian, Yakutia and Far Eastern (remained a part of the Siberian Branch of the USSR Academy of Sciences up to 1970) subsidiaries of the USSR Academy of Sciences.

From the very beginning, the activity of the Siberian Branch (SB) was based on advanced principles, which have not still lost their value. These include interdisciplinary fundamental research, integration of science and education and development of the required infrastructure for the practical implementation of scientific achievements, the famous ‘Lavrentiev triangle’.

As soon as the first year of existence of the SB of the USSR Academy of Sciences, it was decided to establish a number of chemistry-oriented institutes in Siberia, namely, the Institute of Chemical Kinetics and Combustion, the Institute of Inorganic Chemistry and the Institute of Organic Chemistry in Irkutsk. However, the first chemistry-oriented Institute of the Academy appeared in Siberia back during World War II (in 1943). This was the Chemicometallurgical Institute founded in Novosibirsk, together with four other Institutes of the Academy within the bounds of the West-Siberian subsidiary of the USSR Academy of Sciences. Today, this institute is called the Institute of Solid State Chemistry and Mechanochemistry of the SB RAS and is among the eleven actively functioning chemical institutes of the Siberian Branch of the RAS, six of which are located in the Novosibirsk Akademgorodok and refer to the Novosibirsk Scientific Centre of the SB RAS. These are the Joint Institute of Catalysis comprising the G K Boreskov Institute of Catalysis, St Petersburg and Volgograd Branches of the Institute, and the Institute of Problems of Hydrocarbon Processing; the A V Nikolaev Institute of Inorganic Chemistry, the N N Vorozhtsov Novosibirsk Institute of Organic Chemistry, the Institute of Chemical Kinetics and Combustion, the International Tomography Centre, and the above-mentioned Institute of Solid State Chemistry and Mechanochemistry. The rest are parts of other scientific centres of the SB RAS, namely, the Irkutsk (A E Favorsky Irkutsk Institute of Chemistry), Krasnoyarsk (Institute of Chemistry and Chemical Technology), Tomsk (Institute of

Oil Chemistry) and Omsk centres (Institute of Problems of Hydrocarbon Processing); the most recently founded Institute for Problems of Chemical and Energetic Technologies is situated in Biysk.

The largest one is the Institute of Catalysis whose staff counts almost 1000. The Institute is a leader in the research of catalytic processes. The works of its founder and the first Director, Academician G K Boreskov, and his school are known all over the world. Boreskov's rule of approximate invariability of the specific catalytic activity of chemicals with invariable chemical and phase composition has underlain the modern theory of heterogeneous catalysis. The Institute's works on mathematical modelling of catalytic processes and development of the strategy for switching from laboratory studies to industrial scale production changed fundamentally the approach to the design of catalytic reactors and prompted the ways for increasing the efficiency of existing industrial processes. A large contribution to the development of physical methods for investigation of catalysts and elaboration of non-traditional ways for performing catalytic reactions was made by Academicians K I Zamaraev and V N Parmon and their co-workers. In particular, they determined the structure of numerous active catalytic sites, developed the methods for stimulation of catalytic processes with light or ionising radiation. Among recent, practically valuable achievements of the Institute of Catalysis, mention should be made of the development of highly efficient titanium–magnesium catalysts for the preparation of a superstrength polymer: ultrahigh-molecular-mass polyethylene. A priority trend in the Institute's activity is the development of environment-oriented processes, in particular, numerous catalytic processes for detoxification of wastes from industry, power engineering and transport.

The history of foundation and development of the Institute of Chemical Kinetics and Combustion (ICKC) is tightly connected with the names of Academician V V Voevodsky, a founder of chemical radiospectroscopy in the USSR, and first Director of the Institute, Corresponding Member of the USSR Academy of Sciences A A Koval'sky. Chemical radiospectroscopy and related studies of the magnetic interactions of molecules, the effect of magnetic field on chemical reactions and the synthesis of stable radicals and molecular magnets are essential priority lines in the research of this Institute. Under direction of Academician Yu D Tsvetkov, the first USSR and European electron spin echo spectrometer specially adapted for investigation of paramagnetic crystals at cryogenic temperatures was devised at the ICKC in 1965. New modifications of the electron spin echo spectroscopy designed and developed at the Institute allow one to study the motion of spin-labelled lipid molecules in biological membranes, the permeability of these membranes, to determine protein conformations and to study electron transfer at the photosynthesis centres. Quantum beats spectroscopy in recombination fluorescence was also developed at the ICKC. This method allows one to study superfast processes in radical ion pairs taking place in solutions over billionth of a second. The works dealing with spin

chemistry carried out at the Institute under the supervision of Academicians Yu N Molin and R Z Sagdeev have gained broad recognition. Studies of the combustion processes in gases and combustion of energetic materials is yet another important scientific trend in the activity of the ICKC. Of special note are works dealing with filtration combustion of gases. In addition, the mechanisms of photochemical reactions and the reactivity of active intermediate species are studied at the Institute. Using a laser on free electrons designed at the G I Budker Institute of Nuclear Physics of the SB RAS, an original method for the investigation of biological macromolecules using terahertz radiation, which does not destroy large molecules, has been developed.

A number of international scientific centres were organised at the base of the Siberian Branch institutes that occupy leading positions in their field of science. One of these centres, the International Tomography Centre (ITC), was founded in 1996 under initiative of Academician R Z Sagdeev in cooperation with the Bruker group of companies. The key lines of research of the ITC include the theory of chemical bond, the reactivity of chemical compounds, the mechanisms of chemical reactions; magnetic phenomena in chemistry and medicine, spin and exchange phenomena, in particular, those in multi-spin coordination compounds; diagnostic NMR imaging and NMR microtomography for physicochemical applications. The unique 3D MYUR procedure developed at the ITC allows visualisation of the peristaltic motion dynamics of free fluid along the hollow biostructures and direct estimation of the physiological rhythm parameters. The development of new contrasting means based on stable aminoxyl radicals for magnetic resonance imaging (MRI) of living organisms is in progress. Magnetic resonance imaging is widely used for chemical investigations, as it makes it possible to study the internal structure and behaviour of samples without their destruction. The method has been successfully used for *in situ* studies of mass transfer within porous materials and also for studies of gas and liquid structure. Using aminoxyl radicals and paramagnetic metal ions, the researchers of the ITC were able to prepare heterospin coordination compounds, which represent a new type of molecular magnets. Pioneering studies on the design of layered polymeric and framework structures were carried out at the ITC. A new in principle class of objects was discovered, the so-called breathing crystals, which tend to change their volume unusually strongly around magnetic transitions upon temperature variation.

A key trend in the activity of the A V Nikolaev Institute of Inorganic Chemistry (NIIC) is the physicochemical research of materials for electronics. A research group of the Institute headed by Academician F A Kuznetsov carried out a large series of works in this field, in particular, they developed the strategy of chemical vapour deposition, which is among the techniques most widely used in industry for the manufacture of microelectronic devices. Yet another important project of the Institute is the development of a crystal growth process for laser technology by the Chokhralsky low-gradient method. A new trend in the NIIC activity is supramolecular chemistry concerned with large molecular arrays self-assembled from geometrically and chemically complementary fragments. Typical examples of supramolecular compounds are 'host-guest' complexes. These complexes are studied at the Institute, in particular, transition metal complexes incorporated into a hydrophobic cavity of large molecular containers, cucurbiturils. It was shown experimentally that the molecules that get in the cavity of such a molecular container can change essentially their physicochemical properties. This method can be used to prepare complexes containing metals in unusual oxidation states with unique reactivity. At the Institute, a method has been developed and a table-top spectrometer NMR-micro has been designed for nanosystem porometry and for studying the

dynamics of nanoliquids under quantum constraint conditions and the properties of the mobile subsystem in ultrathin channels of nanoporous items and heterostructures. Using this method and quantum chemistry methods, the trigger properties of metal nanoclusters, proton and superionic conductors, superconducting systems, nanoporous crystals of the natural zeolite family were studied.

All research trends at the Novosibirsk Institute of Organic Chemistry (NIOC) are associated with the name of its founder, Academician N N Vorozhtsov, a prominent scientist in the chemistry and technology of aromatic compounds, organic intermediates and dyes. He and his followers developed the synthetic chemistry of aromatic compounds, a general approach to the preparation of polyfluorinated aromatic compounds starting from available polychlorinated analogues. One more line of research initiated by N N Vorozhtsov was concerned with the mechanisms of most important reactions of aromatic compounds and the structures and properties of carbocations. This subject was further developed in Academician V A Koptug's studies. The series of studies dealing with carbocations carried out under his supervision was awarded in 1990 the Lenin prize, the most prestigious prize in the USSR. Since Siberian flora is a source of an enormous number of biologically active compounds, N N Vorozhtsov established the Laboratory of Natural Physiologically Active Compounds at the Institute. This research started by Professors V A Pentegova and V A Barkhash was successfully continued by Academician G A Tolstikov. Currently, target-directed synthesis of drugs and modification of plant metabolites form an important field of investigations carried out at the NIOC. In particular, Academician G A Tolstikov supervised the synthesis of new derivatives of betulonic acid, which was synthesised from betulin extracted from the birch bark. Many amides and peptides of betulonic acid are active inhibitors of tumour cell growth. Studies on transformation of readily available plant di- and triterpenoids and diterpene isoquinoline alkaloids aimed at the elaboration of promising antiviral, anaesthetic, cardiostimulating and antitumour drugs are carried out at the Institute.

The main field of research carried out at the Institute of Solid State Chemistry and Mechanochemistry (ISSCM) is related to solid-phase transformations. Academician V V Boldyrev and co-workers elucidated the influence of defects in a solid on the mechanism and the rate of solid-phase transformations. By selecting the methods for the production and pretreatment of solids, they succeeded in carrying out many solid-phase processes not only absolutely without wastes, but also with a considerable decrease in the number of stages and the time of the processing cycle. Among the most recent ISSCM studies, one can mention those of nanoparticle formation upon explosion carried out in cooperation with the G I Budker Institute of Nuclear Physics and the M A Lavrentiev Institute of Hydrodynamics of the SB RAS in the real-time mode using synchrotron radiation. These studies provided a deeper insight into the nature of fast processes and ensured the development of a number of explosion-based industrial processes, in particular, controlled synthesis of nanodiamonds.

The A E Favorsky Irkutsk Institute of Chemistry of the SB RAS (IriC) is among the most prominent Russian centres for fundamental research in organic and organoelement chemistry. A leading Russian scientific school, which continues the tradition of the great Russian organic chemist A E Favorsky, has formed at the Institute. The research carried out at the Institute from the day it was founded has been mainly concerned with acetylene and complex organic and organoelement molecules synthesised based on acetylene. The chemistry of organic compounds of silicon with unusual valence represents yet another leading research trend of the Institute. Under the supervision of Academician

M G Voronkov, compounds with pentacoordinated silicon, the so-called silatranes, were prepared at the IrIC. Many new chemical reactions were discovered, the best known being the reaction of ketoximes with acetylene discovered by Academician B A Trofimov. This reaction gives rise to pyrroles, key fragments of important life-supporting metal complex systems (chlorophyll and haemoglobin) and has been included into monographs and handbooks as the Trofimov reaction. Numerous drugs, environmentally safe pesticides, plant growth regulators, polymers, fragrances, sorbents, complexones and metal and pollutant extractants, corrosion inhibitors, fuel and oil additives, new-generation materials for microelectronics and lithium batteries and energetic compounds for rocket propellants were developed at the Institute. Among new pharmacological agents prepared by Irkutsk chemists, mention should be made of Acyzole, which possesses antidote properties with respect to carbon monoxide, Cobazole, which actively stimulates haemogenesis, and Anavidin, a new-generation antiseptic and disinfectant. A new highly efficient antituberculosis agent Perchlozon active with respect to mycobacteria that are stable against standard antituberculous drugs is under clinical trials.

The setting of research of Siberian chemical institutes have always included a regional component. First of all, this implies systematic studies into the composition of diversified fossil and renewable raw materials and development of the methods for reasonable use of these resources, in particular, development of environmentally safe methods for their processing. The Institute of Chemistry and Chemical Technology of the SB RAS (ICCT) has accumulated highly valuable experience in the processing of plant biomass to produce various target products; in particular, methods for the production of microcrystalline cellulose from wood wastes were developed. The Institute contributed significantly to the development of the theory of structure of the surface and near-surface layers of minerals, in particular, those formed on sulfides in chemical and electrochemical reactions. On the basis of microscopic cenospheres present in the ash from carbon-based heat electric generation plants, microspherical zeolite sorbents, encapsulated inorganic ion-exchange materials and organic extractants for purification of liquid radioactive wastes of nuclear plants and waste waters of hydrometallurgical plants from radionuclides and nonferrous and noble metal ions were developed.

The Institute of Problems of Hydrocarbon Processing (recently, this was the Omsk Branch of the Institute of Catalysis of the SB RAS), together with the Institute of Catalysis were engaged in a highly important State innovation project in 2003–2006 and thus developed (and prepared for commercialisation) new catalysts for two important oil refining processes, namely, cracking and reforming; engine fuel production at Russian plants was successfully upgraded.

The Institute of Petroleum Chemistry of the SB RAS carries out extensive fundamental and applied studies directed at the creation of new science-intensive, environmentally safe, energy-saving processes for enhanced oil refining. Large-scale industrial use of these processes would extend the period of commercial production from fields at later stages of development and start the development of fields with oil reserves which are difficult to refine, in particular, with high-viscosity oils. The development and perfection of physicochemical, hydrodynamic, steam and microbiological methods for reservoir development and integrated processes that combine these ways of stimulation are in progress.

An essential contribution to the production of new highly energetic substances was made by one of the youngest Institutes of the SB RAS, the Institute for Problems of Chemical and Energetic Technologies, founded in 2001 by the Siberian Branch in close cooperation with the Federal State Unitary Enterprise 'Altay' in order to pursue the fundamental and

applied studies in the development and use of energetic compounds, development of the methods of fine organic synthesis, and manufacture of new materials. An achievement of the Institute is the design of new high-enthalpy polymers and other components of rocket propellants with the record-breaking characteristics accomplished by Academician G V Sakovich.

When considering the chemistry-related studies carried out at the Siberian Branch of the RAS, it should be noted that they are far from being limited to the above-listed chemical institutes. For example, extensive advanced studies in bioorganic chemistry and physicochemical biology are carried out at the Institute of Chemical Biology and Fundamental Medicine (formerly, this was the Institute of Bioorganic Chemistry formed from a department of the Novosibirsk Institute of Organic Chemistry) and also in a number of other biological institutes.

The works on the design of new materials including nanomaterials and nanotechnologies are carried out at physical institutes. At some institutes of the SB RAS, research into the chemical essence of natural phenomena and objects is actively carried out (chemistry of atmosphere, geochemistry, *etc.*). Noteworthy are very promising studies of gas hydrates in permafrost zones and aquatic areas representing inexhaustible reserves of methane and physicochemical and analytical studies dealing with Baikal.

Finally, institutes of different disciplines make a great contribution to the development of new instruments and procedures and their adapting to the investigation of chemical processes and materials, as was mentioned above.

The principles of work of the Siberian Branch established by its founders allowed the Branch to survive during the hard years of perestroika and to adapt to work under market. The high level and the integrated character of fundamental research allow the Institutes to compete for, and win grants from, Russian and foreign funds and to award contracts with leading foreign companies. The system of training of scientific staff in the SB RAS ensures preservation of the scientific potential of the Branch at a high level, and the engineering design and pilot departments established at the institutes allow one to bring the scientific results to the level required for commercialisation, thus opening the way for new science-intensive industrial processes and attraction of investments. An important achievement of the SB RAS is the active functioning of world-level scientific schools. The works of scientists of the Branch have been repeatedly rewarded with prestigious prizes, prizes of the RF government and the Russian Academy of Sciences. Many scientists of the SB RAS are international prize winners, members of foreign Academies and international scientific associations.

This issue of the journal composed with significant participation of Professor V P Fedin includes reviews prepared by senior researchers of the chemical institutes of the SB RAS. Of course, this covers only a minor portion of results of studies carried out at these institutes. The subsequent issues of the journal would continue to acquaint the readers with the scientific results obtained by chemists of the Siberian Branch of the RAS.

Abstract. Possible fields of application of the phenomenon of quantum beats in spin-correlated radical pairs in studies of the properties of short-lived radicals (lifetimes of up to a few nanoseconds) in liquid solutions are considered. The theoretical approaches to the description of this phenomenon and modern experimental data are analysed. The bibliography includes 82 references.

I. Introduction

Shortly after the discovery of chemically induced dynamic nuclear polarisation (CIDNP) in the late 1960s it was established that the course of radical reactions in solutions may be affected by external magnetic fields, resonance microwave radiation and hyperfine interactions (magnetic isotope effect). The new field of research on the effects of electron and nuclear spin dynamics on elementary chemical reactions is for brevity called ‘spin chemistry’ or ‘dynamic spin chemistry’. Recent advantages, research potential and specific features of this field of chemical science have been well documented (see monographs^{1–4} and reviews^{5–21}).

Most phenomena studied by spin chemistry are due to dynamic (not associated with paramagnetic relaxation) transitions between different states of electron spins in a radical pair (RP) emerged in a coherent (singlet or triplet) spin state. Corresponding methods of investigation also employ this feature. These dynamic transitions, or quantum beats, are similar to quantum beats in other systems, which allows spin chemistry to be considered as a ‘companion’ to yet another new avenue of research, namely, femtochemistry, and to some spectroscopic methods of investigations that also utilise quantum interference. In both spin chemistry and femtochemistry the quantum beats in the populations of reactant states modulate the yield of reaction products. To describe these

phenomena, one should allow for the oscillation phase of the wave function. This unusual, for chemistry, feature offers basically new opportunities for control of chemical reactions through variation of the phase relations in the wave packet by varying external factors. In addition, frequency analysis of quantum beats provides information on the properties of reacting species and offers new horizons for experimentalists.

Most experimental approaches used in spin chemistry involve analysis of time-average manifestations of the spin evolution in RPs. A typical example is provided by measurements of the magnetic field effect (dependence of the yield of final products of radical reactions on the magnetic field strength). The magnetic field affects positions of electron-spin energy levels and, as a consequence, the evolution of the spin state of the RP. Since the reaction is spin selective, the yield of reaction products changes with the magnetic field strength. The change in the product yield is thus an integrated ‘fingerprint’ of the temporal evolution of the spin state in the RP.

Development of pulsed methods of generation of radical pairs and relevant detection instruments with nanosecond temporal resolution permitted real-time monitoring of manifestations of quantum oscillations of the spin state in RP. In this review we will consider methods of detection of quantum beats based on recombination luminescence of RPs and the results of recent studies obtained by these techniques.

II. The nature and detection of quantum beats in radical pairs

1. A qualitative model

Dynamic singlet–triplet transitions in spin-correlated RPs are related to the quantum nature of electron spins. Spin-correlated pairs are produced upon rupture of chemical bonds or after ionisation of molecules. The total spin of the unpaired electrons remains unchanged, which means that the state (singlet or triplet) of a radical pair is the same as that of its precursor.

Quantum beats are due to the fact that the singlet and triplet states of RP are superpositions of several stationary states. In turn, this is due to the spin–orbit and hyperfine couplings in radicals. Quantum beats occur in any system whose states are coherent superpositions of stationary states.^{22,23} In the simplest case the initial state of a quantum system

$$|\Psi(0)\rangle = c_a|a\rangle + c_b|b\rangle,$$

V A Bagryansky, V I Borovkov, Yu N Molin Institute of Chemical Kinetics and Combustion, Siberian Branch of the Russian Academy of Sciences, ul. Institutskaya 3, 630090 Novosibirsk, Russian Federation. Fax (7-383) 330 73 50, tel. (7-383) 333 23 81, e-mail: vbag@kinetics.nsc.ru (V A Bagryansky), tel. Received 9 April 2007

Uspekhi Khimii 76 (6) 535–549 (2007); translated by A M Raevskiy

is a superposition of two vectors of the stationary states $|a\rangle$ and $|b\rangle$ of the system with the energies E_a and E_b , respectively (c_a and c_b are constants). At arbitrary instant $t > 0$, the state of the system is described by the vector

$$|\Psi(t)\rangle = c_a|a\rangle e^{-iat} + c_b|b\rangle e^{-ibt}, \quad (1)$$

where $a = E_a/\hbar$, $b = E_b/\hbar$. Let x be the operator of an observable quantity and let x have no explicit dependence on time. The average value of x in the state (1) is given by

$$\begin{aligned} \langle x(t) \rangle &= \langle \Psi(t) | x | \Psi(t) \rangle = \\ &= |c_a|^2 x_{aa} + |c_b|^2 x_{bb} + 2|c_a^* c_b x_{ab}| \cos[(a-b)t + \varphi]. \end{aligned} \quad (2)$$

The first two terms in the right side of Eqn (2) are the weight-average of x and the last term is the cross-term modulated by the frequency of the transition between the states a and b (here φ is the relative phase of the complex coefficients c_a and c_b). If the initial state is composed of more than two vectors of stationary states, the average value of the physical quantity is modulated by several frequencies.

The simplest example of quantum beats in a radical pair is provided by two noninteracting radicals differing in their isotropic g -factors. The energies of the stationary states of the pair in a strong magnetic field are shown in Fig. 1. Two states of the pair, with the energies E_1 and E_4 , are the triplet states T_+ and T_- , whereas the other two states with the energies E_2 and E_3 are mixed states composed of the spin states S and T_0 taken with equal weights. This means that emergence of a radical pair in, e.g., the singlet state will cause coherent population of two energy levels, E_2 and E_3 . This will be accompanied by the onset of singlet–triplet oscillations at the frequency

$$\omega = \frac{\beta B}{\hbar} (g_1 - g_2),$$

corresponding to the difference E_2 and E_3 . If isotropic hyperfine couplings (HFC) occur in the radicals, the oscillation frequencies are given by

$$\omega = \frac{\beta B}{\hbar} (g_1 - g_2) + \sum_{i1} a_{i1} m_{i1} - \sum_{i2} a_{i2} m_{i2},$$

where β is the Bohr magneton, B is the induction of external magnetic field, g is the g -factor, a_i is the constant of HFC with the i th nucleus, and m_i is the projection of the spin of the i th nucleus on the direction of the magnetic field; the subscripts '1' and '2' enumerate different radicals in the pair.

Figure 1. Energy levels of a radical pair comprising radicals with different g -factors in strong magnetic field.

The visual pattern of beats in an RP in a constant magnetic field (magnetic field strength much exceeds the constants of HFC in the radicals in the pair) is illustrated by the vector

Figure 2. Vector diagram illustrating the onset of $S-T_0$ oscillations of the spin state of a radical pair in strong magnetic field. Oscillations are due to the Larmor frequency difference between electron spins in different local magnetic fields.

diagram shown in Fig. 2. The pair emerged in the singlet (S) spin state corresponds to the antiparallel orientation of the radical spins in the vector diagram (Fig. 2a). Then, in a strong magnetic field the spins undergo precession about the magnetic field direction. However, the spin precession frequencies differ due to differences between the 'internal magnetic fields' owing to different spin–orbit and hyperfine interactions in radicals. As a result, the pair periodically goes to the T_0 state in which the vector sum of the spins differs from zero and is oriented normal to the magnetic field direction (Fig. 2b).

2. Quantum beats in recombination luminescence

The possibility of experimental observation of quantum oscillations in RP is due to the fact that the yield of the products of recombination of the radicals in the pair depends on the total spin of the radicals at the instant of recombination. This means that oscillations of the singlet state population of the RP can be monitored by observing the kinetics of formation of the product of singlet recombination.

Experiments involving detection of recombination luminescence of radical ion pairs formed upon the action of a pulse of ionising radiation on non-polar solutions of electron donors and acceptors appeared to be the most fruitful for observation of quantum beats in the spin state of RP. The formation and recombination of radical ion pairs can be described by the following scheme:

In the first stage (3), irradiation of dilute solutions of electron donors (D) and acceptors (A) causes ionisation of solvent molecules (Solv) and formation of a primary RP comprised of an electron and the solvent hole ($\text{Solv}^{+\bullet}/e^-$). Since the solvent molecule was in the singlet spin state before irradiation, the primary RP emerged upon ionisation is also in the singlet state.

This correlation also holds for the secondary pairs ($D^{+\bullet}/A^{\bullet-}$) if the rates of reactions (4) and (5) are higher than the rate of the singlet–triplet transition. To monitor the spin state of this pair using recombination luminescence, the electron donor or acceptor should be a luminophore with a rather short fluorescence time. Then, recombination (6) of the singlet radical pair resulting in a singlet-excited product A^* (or D^*) will be followed by emission of a fluorescence quan-

tum. As a consequence, the dynamic singlet–triplet transitions responsible for the oscillations of the singlet state population will induce modulation of the kinetics of recombination fluorescence. The recombination products of triplet pairs usually show no intense phosphorescence in solution.

Solutions in non-polar solvents are the most convenient systems for carrying out these experiments. The reasons are as follows. First, the separation between radical ions in the primary RPs generated in a non-polar medium is shorter than the Onsager radius. Therefore, they mainly recombine in a geminate fashion, *i.e.*, with the spin-correlated partners. Second, the solvation energy of the recombining radical ions in the non-polar medium is minimum, which favours the release of energy sufficient for recombination luminescence.²⁴ In addition, recombination immediately follows the first collision between radical ions irrespective of their spin state due to strong Coulomb attraction. Therefore, the effects of secondary collisions almost do not manifest themselves,¹ and the rate of formation of the singlet-excited products of recombination (6) can be represented by the product of the recombination rate to the singlet state population of the RP. This essentially simplifies the analysis of the kinetics of recombination luminescence in order to detect the quantum beats due to the singlet–triplet transitions in the spin state of the RP. Finally, the partners emerge and spend most time at a long distance from each other. Under these conditions the effect of the dipole–dipole and exchange interactions between partners can be ignored, which also essentially simplifies the theoretical description of the spin evolution in radical pairs.

3. Methods and instruments

Advances in detection of quantum beats were to a great extent due to the use of the single photon counting technique²⁵ for detection of recombination fluorescence. The method permits detection of fluorescence with high temporal resolution in high dynamic range of intensities ($>10^5$). Quantum beats are detected using radioactive sources of fast electrons^{13, 14, 17, 26–48} and controllable sources of ionising radiation,^{13, 14, 17, 41, 49–66} the latter providing a much higher performance of experimental installations.

At rather short excited-state lifetimes of recombination products, the experimental procedures involving detection of recombination fluorescence in fact detect the derivative of the accumulation kinetics of the product of the spin-dependent reaction. This improves the detection of quantum beats. An analogy is provided by radiospectroscopy. Namely, going to phase-sensitive detection (here, the derivative of the signal is recorded) provides enhanced resolution and improves the signal-to-noise ratio. Clearly, relevant mathematical processing of the data obtained by other methods will also allow quantum beats in reactions of spin-correlated RPs to be observed. Analysis of the temporal dependence of the fluorescence intensity ratio in nonzero and in zero magnetic field rather than the kinetics of recombination fluorescence offers additional advantages in the interpretation of experimental results (see below). This ratio was called the time-resolved magnetic field effect (TRMFE).

As an example of experimental setup for TRMFE studies, Figure 3 presents a block diagram of an X-ray fluorimeter designed at the same Institute, Siberian Branch of the Russian Academy of Sciences. This instrument was used to obtain many of the results discussed below. The electron gun was also designed at the Institute of Chemical Kinetics and Combustion, Siberian Branch of the Russian Academy of Sciences and is used to generate X-ray pulses in the ~ 20 keV energy range. X-Ray radiation incident on the sample placed between the poles of an electromagnet causes fluorescence, which passes through the light guide and light filter to the photomultiplier

Figure 3. Blok diagram of a nanosecond X-ray fluorimeter.⁴⁹

Synchronisation and control unit (1), electron gun (2), fluorescence detection unit (3), converter of time intervals (4), multichannel analyser (5) coupled with a computer (6), magnetic field and temperature control unit (7), light guide (8), electromagnet (9), and sample (10).

and the fluorescence detection unit. The fluorimeter makes it possible to detect the kinetics of radiofluorescence on the time scale from 10 to 10^4 ns at the magnetic field induction ranging from 0 to 1.1 T and provides temperature stabilization in the 223–353 K range.

4. First observations of quantum beats

Quantum beats due to hyperfine coupling were first observed by Klein and Voltz^{26, 27} in 1976 and independently by Brocklehurst.^{28, 29} Klein and Voltz^{26, 27} measured the kinetics of recombination fluorescence induced by irradiating a cyclohexane solution of a dye [2,5-bis(4-butylphenyl)-1,3,4-oxadiazole, bPPD] with fast electrons in magnetic field by the single photon counting technique at times up to 700 ns. Having plotted the TRMFE curve, the authors revealed a kink. The nonmonotonic character of the TRMFE curve was associated with magnetic-field-dependent singlet–triplet transitions in the secondary radical ion pairs $\text{bPPD}^{+\bullet}/\text{bPPD}^{-\bullet}$. These transitions determine the multiplicity of the RP at the instant of recombination and, as a consequence, the multiplicity of the recombination product, *i.e.*, an excited bPPD molecule. As a result, fluorescence due to emission of singlet-excited molecules of this dye is modulated, the modulation frequencies being equal to the singlet–triplet transition frequencies.

Brocklehurst reported similar experiments with other luminophores (*p*-terphenyl and biphenyl) in various non-polar solvents.^{28, 29} Researchers from both groups used radicals with complex hyperfine structures characterised by a number of different HFC constants. As a result the TRMFE curves exhibited a single peak of oscillations (Fig. 4), thus providing a little information on the phenomenon under study.¹¹ The authors of the pioneering and subsequent studies (see a review¹¹) clearly demonstrated the possibility of observation of the spin evolution in RPs using the TRMFE technique.

Studies reported by Anisimov *et al.*^{30, 31} in 1983 gave a new impetus to the development of the method of quantum beats in recombination fluorescence. Anisimov *et al.* observed a number of quantum beat peaks in the kinetics of recombination luminescence of the solutions of tetramethylethylene

Figure 4. Magnetic field effect ($B = 100$ mT) in recombination fluorescence for squalane solutions of *p*-terphenyl (curves 1 and 2) and *p*-terphenyl- d_{14} (curve 3). Solute concentration: $5 \text{ mmol litre}^{-1}$ (1) and $1 \text{ mmol litre}^{-1}$ (2, 3).¹¹

(2,3-dimethylbut-2-ene) and *p*-terphenyl- d_{14} in *trans*-decalin, *cis*-decalin, squalane and pentadecane in strong (Fig. 5) and zero magnetic field.

Tetramethylethylene chosen as hole scavenger forms a radical cation containing twelve equivalent protons. Therefore, the pattern of quantum beats in a strong magnetic field is formed by oscillations with the multiple frequencies and looks quite simple. Similar results were obtained^{30,31} in studies of a solution of durene (its radical cation also contains twelve equivalent protons) and *p*-terphenyl- d_{14} in *trans*-decalin. Both the shape and period of oscillations corresponded to the theoretically predicted ones, but the amplitude of beats observed in the experiments was much smaller than it follows from theory.

Figure 5. Quantum beats in recombination fluorescence of tetramethylethylene and *p*-terphenyl- d_{14} solutions in *trans*-decalin in a magnetic field of 0.33 T, detected as the ratio of the fluorescence kinetics to the smooth function $F(t)$ simulating the recombination kinetics (a) and theoretical curve for the singlet state population of the RP (b).³⁰

Figure 6. Recombination fluorescence kinetics of a isoctane solution of mixture of *p*-terphenyl- d_{14} ($1 \text{ mmol litre}^{-1}$) with diphenyl sulfide- d_{10} ($30 \text{ mmol litre}^{-1}$) in magnetic field of 0.017 (1), 0.24 (2), 0.48 (3) and 0.96 T (4).³⁶ For clarity, the curves are arbitrarily shifted along the Y axis.

Researchers from this group also detected quantum beats due to the g -factor differences between radicals in the solutions of diphenyl sulfide- d_{10} and *p*-terphenyl- d_{14} in various solvents (Fig. 6).^{32,33,35–38}

The (diphenyl sulfide- d_{10})⁺⁺ and (*p*-terphenyl- d_{14})^{–•} radical ions produced in such solutions are characterised by negligible HFC constants and significantly different g -factors. The amplitude of beats was found to be much larger compared to the results of the earlier studies.^{30,31} In this case the frequency of beats is proportional to the induction of external magnetic field.

III. Theory of quantum beats in recombination luminescence of spin-correlated radical ion pairs

Theory of quantum beats in the spin states of radical pairs has been well developed for isotropic HFC.² No analytical solution for the general case of arbitrary magnitudes of HFC constants and magnetic fields is available. However, most of experimental data can be approximately described using analytical solutions derived for some particular cases. These analytical results are of paramount value because the computational cost of the available algorithms of numerical solution to this problem is very high. This strongly complicates calculations and makes them of limited use in simulating experimental curves.

The possibility of manifestation of singlet–triplet transitions in recombination of radical pairs was first reported by Brocklehurst in 1969.⁶⁷ He analysed a radiation-chemical process of geminate recombination of an electron (or radical anion) with the parent radical cation and assumed that in this case the S–T transitions in the pair can affect the product ratio and that these transitions are induced by paramagnetic relaxation of electron spins. In the mid-1970s, interest in the singlet–triplet evolution in RPs increased after carrying out the pioneering experiments on observation of recombination fluorescence.^{26,27,43} At that time, Brocklehurst^{44,68} and Schulten and Wolynes⁶⁹ calculated the effect of HFC on the singlet–triplet transitions for some particular cases. Further development of the theory of singlet–triplet evolution is associated with the studies by Salikhov, his followers and colleagues who succeeded in deriving analytical solutions for

a broader range of hyperfine interactions (key results were reported in a monograph²). Some practically valuable relationships were derived recently.^{42, 70–72}

A salient feature of radical ion pairs produced in solution upon the action of a pulse of ionising radiation is that only a fraction of them is in the spin-correlated singlet state. Theoretical models usually assume that recombination of both correlated and uncorrelated pairs obeys the same kinetic law and that fluorescence of the excited molecules of recombination products occurs instantaneously. Then, the experimentally observed kinetics of the fall-off of recombination fluorescence intensity $I(t)$ is given by^{42, 50, 51}

$$I(t) \propto F(t) \left[\theta \rho_{ss}(t) + \frac{1}{4}(1 - \theta) \right].$$

Here $F(t)$ is the rate of pair recombination, θ is the fraction of singlet-correlated pairs, $\rho_{ss}(t)$ is the temporal dependence of the singlet state population of the spin-correlated pair, which is determined by both dynamic spin processes and the spin relaxation and strongly depends on the strength of the applied magnetic field. The second term in the square brackets includes the contribution of the singlet component of spin-uncorrelated pairs to fluorescence.

As mentioned above, the $I_B(t)/I_0(t)$ ratio (time-resolved magnetic field effect) is more convenient for analysis. This ratio is independent of the function $F(t)$, being determined only by the evolution of the spin state.

$$\frac{I_B(t)}{I_0(t)} = \frac{\theta \rho_{ss}^B(t) + 1/4(1 - \theta)}{\theta \rho_{ss}^0(t) + 1/4(1 - \theta)} \quad (7)$$

Here the superscripts ‘B’ and ‘0’ indicate that the system is in external nonzero and zero magnetic field, respectively. This simplifies the situation and allows the spectral parameters to be determined by fitting relation (7) to the experimentally measured TRMFE using the singlet state populations $\rho_{ss}(t)$ calculated in the framework of a particular model for hyperfine coupling in radical ions of the pair.

When calculating the singlet state population $\rho_{ss}(t)$, one should allow for the fact that the initial spin state of the radical pair is correlated (sometimes, it is called ‘entangled’ state), *i.e.*, the corresponding density matrix cannot be represented as the product of the density matrices of subsystems. This means that, generally, it is impossible to write the solution as the product of the functions, each of them corresponding to a single radical. At the same time the absence of interactions between electron spins of radicals in the pair, which is characteristic of the examples considered in this review, simplifies the solution and it can be written in the form reported by Schulten and Wolynes,⁶⁹

$$\rho_{ss}(t) = \frac{1}{4} + \sum_{i,k} T_{ik}^{(1)}(t) T_{ik}^{(2)}(t), \quad (8)$$

where $i, k = \{x, y, z\}$, and the components of the correlation tensor are

$$T_{ik}^{(1)}(t) = \langle \text{Tr}_e \{ \hat{S}_{1i}(t) \hat{S}_{1k}(0) \} \rangle, \quad (9)$$

$$T_{ik}^{(2)}(t) = \langle \text{Tr}_e \{ \hat{S}_{2i}(t) \hat{S}_{2k}(0) \} \rangle.$$

Here $\hat{S}(t)$ are the operators of the electron spins of the radicals in the Heisenberg representation. The superscripts ‘1’ and ‘2’ in the tensors and the subscripts ‘1’ and ‘2’ in the spin operators correspond to different radicals in the RP; Tr_e denotes the trace over electron spin variables and the angle brackets denote the averaging over projections of the magnetic nuclei. Equa-

tion (8) makes it possible to obtain the solution to the problem of the spin evolution of the RP using the components of the correlation tensor, each of them depending only on the Hamiltonian of one radical.

As mentioned above, there is no general analytical solution for the components of the correlation tensor at arbitrary HFC in each radical in the RP and arbitrary magnetic field. Now we will consider some particular cases of isotropic HFC with the known analytical solutions.

1. One magnetic nucleus or equal HFC constants for all magnetic nuclei in arbitrary external magnetic field

The results for the case of HFC with one magnetic nucleus were reported earlier;^{2, 68} the corresponding expressions written in a more convenient form⁷⁰ are as follows:

$$T_{xx} = T_{yy} = \frac{1}{2} \text{Re}(h(t)), \quad (10)$$

$$T_{xy} = -T_{yx} = \frac{1}{2} \text{Im}(h(t)),$$

$$T_{zz} = \frac{1}{2} g(t),$$

where

$$g(t) = 1 - \frac{a^2}{2I+1} \sum_{m=-I}^I \frac{I(I+1) - m(m+1)}{(2R_m)^2} [1 - \cos(2R_m t)],$$

$$h(t) = \frac{1}{4(2I+1)} \sum_{m=-I}^I \left[(1 + D_m) e^{iR_m t} + (1 - D_m) e^{-iR_m t} \right] \times$$

$$\times \left[(1 + D_{m-1}) e^{iR_{m-1} t} + (1 - D_{m-1}) e^{-iR_{m-1} t} \right] \quad (11)$$

and

$$2R_m = \sqrt{\omega_0^2 + a\omega_0(2m+1) + a^2 \left(I + \frac{1}{2} \right)^2},$$

$$D_m = \frac{\omega_0 + a(m+1/2)}{2R_m}.$$

In the last two relationships $\omega_0 = g\beta B/\hbar$ is the Larmor precession frequency of electron spin in external field, g is the g -factor of the radical, β is the Bohr magneton, B is the magnetic field induction, \hbar is the Planck constant, a is the isotropic HFC constant expressed in circular frequency units, m is the nuclear spin projection on the magnetic field direction and I is the spin of the magnetic nucleus in the radical.

This result can also be used in the case of a group of nuclei with equal HFC constants. Here, expressions (10) and (11) should be averaged over the spin I treated as the total spin of the magnetic nuclei. The weight P_I of each I value can be found by adding the spins of magnetic nuclei characterised by equal HFC constants. In particular, for n nuclei with the spin 1/2 (see Ref. 42) one has

$$P_{n,I} = \frac{(2I+1)^2 n!}{2^n [(n/2) - I]! [(n/2) + I + 1]!}.$$

In weak magnetic fields, a specific situation of weak HFC in one and strong HFC in the other radical in the pair is also possible (for both radicals the HFC constant is compared to the induction of external magnetic field). It was theoretically predicted and experimentally confirmed that in this case quantum beats at a frequency similar to the frequency of Larmor precession of electron spin manifest themselves in recombination fluorescence.^{64, 65}

2. The singlet state population of a radical pair in zero magnetic field

In zero external magnetic field we deal with the diagonal tensor (9) having equal principal values. Therefore, in zero magnetic field one gets

$$\rho_{ss}^0(t) = \frac{1}{4} + 3T_{zz}^{(1)}(t)T_{zz}^{(2)}(t). \quad (12)$$

In the presence of a HFC with only one nucleus with the spin I (HFC constant a) in zero magnetic field one has²

$$T_{zz}(t) = \frac{3 + 4I(I+1) + 8I(I+1)\cos[a(I+1/2)t]}{6(2I+1)^2}. \quad (13)$$

In the case of several magnetic nuclei with equal HFC constants, expression (13) should be averaged over the total nuclear spin I . For instance, the expression for a group of n nuclei with the spin $1/2$ and equal HFC constants a , has the form⁴²

$$T_{zz}(t) = \frac{1}{6} \left[\frac{n+3}{n+1} + \frac{2n(n+2)}{n+1} \left(\cos \frac{at}{2} \right)^{n+1} - 2n \left(\cos \frac{at}{2} \right)^{n-1} \right]. \quad (14)$$

Schulten and Wolynes derived⁶⁹ an approximate solution for the case of a large number of magnetic nuclei characterised by small, but not necessarily equal, HFC constants; this corresponds to an unresolved EPR spectrum of a radical. To allow for zero magnetic field in this approximation, expression (12) should be written using the quantity

$$T_{zz} = \frac{1}{6} [1 + 2C(\sigma t)],$$

where

$$C(x) = (1 - x^2)e^{-0.5x^2},$$

and the parameter σ^2 is the second moment of the EPR spectrum of the radical:

$$\sigma^2 = \frac{1}{3} \sum_n a_n^2 I_n(I_n + 1). \quad (15)$$

An approximate solution to the problem of the spin evolution in a singlet-correlated pair of noninteracting radicals in zero magnetic field was derived for the case where one nucleus (or a group of equivalent nuclei) in the radical is involved in isotropic HFC characterised by a large HFC constant and other nuclei have relatively small (not necessary equal) HFC constants.⁷¹ In EPR and NMR spectroscopy this is called ‘inhomogeneous line broadening’. Simulation⁷¹ showed that this type of broadening affects the spin dynamics similarly to phase relaxation.

An analytical solution for $T_{zz}(t)$ in the case of isotropic HFC with two groups of equivalent nuclei in zero magnetic field is also available.⁷² In the two last-named cases, the solutions are cumbersome, so we have to address the reader to the original studies.^{71, 72}

3. The singlet state population of a radical pair in a strong magnetic field

Considering the case of a strong magnetic field whose strength much exceeds the HFC constants of the radicals in the RP, one can use the high-field approximation² to simplify the Hamiltonian of the RP. Here, assuming an isotropic HFC tensor and g -tensor, expression (8) takes the form

$$\rho_{ss}(t) = \frac{1}{2} + \frac{1}{2} \cos[(\omega_{01} - \omega_{02})t] G_1(t) G_2(t), \quad (16)$$

where ω_{01} and ω_{02} are the frequencies of Larmor precession of electron spins in the magnetic field and the functions $G(t)$ are determined by the HFC constants (a_n) and the spins of the magnetic nuclei (I_n) in each radical in the RP

$$G(t) = \prod_n \left\{ \frac{1}{(2I_n + 1)} \frac{\sin[a_n(2I_n + 1)t/2]}{\sin(a_n t/2)} \right\}. \quad (17)$$

Here the subscript n enumerates the magnetic nuclei.

The solution (16), (17) was first reported by Brocklehurst⁶⁸ in the form of a relation for the singlet state population at particular I values. In a particular case where one radical contains n_1 and the other radical contains n_2 equivalent nuclei with the spin $I = 1/2$ and the HFC constants a_1 and a_2 , respectively, one gets

$$\rho_{ss}(t) = \frac{1}{2} + \frac{1}{2} \cos[(\omega_{01} - \omega_{02})t] \left(\cos \frac{a_1 t}{2} \right)^{n_1} \left(\cos \frac{a_2 t}{2} \right)^{n_2}.$$

In the quasi-classical approximation,⁶⁹ which is valid for many magnetic nuclei having small HFC constants, the functions (17) take the form

$$G(t) = e^{-(\sigma^2 t^2)/2},$$

where the second moment of the EPR spectrum σ^2 is given by Eqn (15).

4. Taking into account the effect of paramagnetic relaxation

The effect of paramagnetic relaxation on the singlet state population of RPs in a strong and zero magnetic field was also included as follows.^{13, 17, 42, 45, 46, 50–61} Let $\rho'_{ss}(t)$ be the singlet state population calculated ignoring paramagnetic relaxation. The singlet state population with allowance for relaxation in a strong magnetic field is given by

$$\rho_{ss}(t) = \frac{1}{4} + \frac{1}{4} e^{-t/T_1} + e^{-t/T_2} \left(\rho'_{ss}(t) - \frac{1}{2} \right), \quad (18)$$

and the corresponding expression for zero magnetic field has the form

$$\rho_{ss}(t) = \frac{1}{4} + e^{-t/T_0} \left(\rho'_{ss}(t) - \frac{1}{4} \right), \quad (19)$$

where T_1 and T_2 are, respectively, the longitudinal and transverse paramagnetic relaxation times in the strong magnetic field and T_0 is the transverse paramagnetic relaxation time in zero magnetic field.

Although some theoretical background substantiating relations (18) and (19) is available,^{5, 11, 45} one must admit that these equations are based on semiempirical considerations only. Namely, in the strong magnetic field the transverse relaxation mixes the singlet state of the RP with only one of the three triplet states in which the spin projection on the magnetic field direction is zero. This means that the asymptotic $\rho_{ss}(t)$ value in the presence of transverse relaxation is $1/2$. In Eqn (18), this is included by the exponent e^{-t/T_2} . At the same time longitudinal relaxation equilibrates the populations of the singlet state and all the three triplet states [see the exponent e^{-t/T_1} in Eqn (18)]. In zero magnetic field there is no preferred axis and the rates of longitudinal and transverse relaxation should be equal to each other.

This approach usually provides a satisfactory description of experimental results using a minimum number of relaxation rate parameters, namely, two and one for the case of a strong and zero magnetic field, respectively. At the same time this may appear to be insufficient for rigorous treatment of a particular physical mechanism of paramagnetic relaxation.⁷³

IV. Spectroscopy of quantum beats in radical pairs

Spectroscopic information on the partners of a radical pair extracted by the method of quantum beats is similar to that obtained in EPR studies. The key advantages of the title method are much higher sensitivity and the possibility of detecting species characterised by the lifetimes of up to a few nanoseconds. Development of this technique made it possible to study short-lived radical ion species in liquid solutions at ambient temperatures.

1. Determination of hyperfine coupling constants and g -factors of radical ions

The simple TRMFE curves for the case of hyperfine coupling with a number of equivalent protons in one partner of the radical pair were analysed.⁴² It was shown that in this case quantum beats manifest themselves as a sequence of peaks in the TRMFE curve. The position of the first peak on the time scale is determined by the second moment of the EPR spectrum of this radical. For even number of protons, the next peak is more intense and its position is determined by the HFC constant. If the number of protons is odd, a trough occurs instead of the peak. Then the beats show a periodic damping pattern due to relaxation. These predictions were checked in the same study⁴² taking radical cations of nine compounds (alkanes, alkenes and aromatics) with equivalent protons. The p -terphenyl- d_{14} radical anion, whose HFC constants are small and make a negligible contribution to the spin evolution of the pair, served as the geminate partner. Figure 7 presents some examples of the TRMFE curves. The HFC constants determined from the instants corresponding to the appearance of the second peak are listed in Table 1. It should be noted that the obtained HFC constants coincided with the published data measured by other methods.

The possibility of determining both the HFC constants and the g -factor differences between radical ions was demon-

Figure 7. TRMFE curves for dilute cyclohexane solutions of mixtures of p -terphenyl- d_{14} with 9,10-octalin (1), tetramethylethylene (2), octamethylcyclohexa-1,4-diene (3) and *cis*-decalin (4).⁴² The arrows show the theoretical positions of the second (main) peak.

strated⁵² taking the hexamethylethane (2,2,3,3-tetramethylbutane) radical cation as an example. The EPR spectrum of this species is governed by isotropic HFC with eighteen equivalent protons. The HFC constant was calculated from positions of peaks in the TRMFE curve, and the g -factor difference between the (hexamethylethane)⁺⁺ and (p -terphenyl- d_{14})^{−−} radical ions was determined from analysis of the dependence of the shape of the TRMFE curve (Fig. 8) on the magnetic field strength. These results coincided with the data obtained in the same study by the optically detected EPR (OD EPR) technique and with the published data.

Figure 8. TRMFE curves of dilute *n*-hexane solutions of mixture of hexamethylethane with p -terphenyl- d_{14} in magnetic field of 0.1 (1), 0.5 (2) and 0.7 T (3).⁵² Smooth solid curves represent the results of simulation of experimental data.

The TRMFE method was used to study radical anions of 1,2,3,4-tetraphenylcyclopenta-1,3-diene (**1a**) and its heteroorganic analogues containing silicon (**1b**) and germanium (**1c–e**) in *n*-decane solutions.^{50, 51}

 R¹ = R² = Cl (**d**);
 R¹ = Me, R² = Cl (**e**).

Simulation of experimental curves (Fig. 9) gave the following HFC constants:

Compound 1	<i>a</i> /mT
a	2.50 ± 0.04 (2H)
b	1.56 ± 0.03 (2H)
c	1.50 ± 0.03 (2H)
d	0.7 ± 0.1 (2Cl)
e	1.14 ± 0.1 (Cl)

Reliable detection of this type of radical anions by the TRMFE method indicates that their lifetimes in solution are at

Figure 9. TRMFE curves of solutions of 1,2,3,4-tetraphenylcyclopenta-1,3-diene (**1a**) and its heteroorganic analogues **1b** (**2**) and **1c–e** (**3–5**) in *n*-decane.⁵¹ Smooth solid curves represent the results of simulation of experimental data.

least of the order of tens of nanoseconds. This is of great importance for chemistry of such compounds, because attempts to detect these species (except for radical anion **1a**) by other methods failed and the possibility of their formation in solutions cast some doubts.

The contributions of each radical in the pair to the spin evolution [see Eqns (14) and (16)] can be separated.⁵³ Figure 10 shows the TRMFE curves obtained for an *n*-octane solution of mixture of hexamethylethane (0.1 mol litre^{−1}) with tetraphenylcyclopentadiene (3 × 10^{−4} mol litre^{−1}) at a magnetic field induction of 0.1 and 0.7 T at room temperature. The spin evolution is determined by the hyperfine coupling in the (hexamethylethane)⁺·/(tetraphenylcyclopentadiene)[−]· pair. The former species is involved in HFC with eighteen equivalent protons (HFC constant *a*₁ = 1.24 mT), while the latter has two equivalent protons (HFC constant *a*₂ = 2.46 mT). The smooth curves in Fig. 10 represent the results of approximation of experimental data by a relevant model. Although the pattern of beats is more complicated, experimental data are well described by the theory.

Figure 10. TRMFE curves of solutions of hexamethylethane and tetraphenylcyclopentadiene in *n*-octane [*B* = 0.1 (**1**) and 0.7 T (**2**)].⁵³ Smooth solid curves represent the results of simulation of experimental data.

The 2,3-dimethylbutane, 2,2,4,4-tetramethylpiperidine and diisopropylamine radical cations containing two groups of magnetically equivalent nuclei were studied.⁷² In addition to the calculation of absolute values of the HFC constants, the authors of this study confirmed the theoretically predicted possibility of determining the signs of the HFC constants for groups of nuclei. In Fig. 11 we present the experimental curve

Figure 11. TRMFE curve for an *n*-hexane solution of mixture of 2,3-dimethylbutane with *p*-terphenyl-d₁₄ (**1**) and best fits of experimental data using a model with the HFC constants *a* (12H) and *a* (2H) of the same sign (**2**) and of different signs (**3**).⁷²

of TRMFE due to hyperfine coupling in the 2,3-dimethylbutane radical cation. The best approximation of experimental data with the '12H + 2H' model gave the same signs of the HFC constants for these groups of protons, which was confirmed by quantum chemical calculations. Calculations with the HFC constants of different sign led to poorer agreement with the experiments.

Radical cations of branched alkanes and their heteroorganic analogues Me_4E and Me_3EEMe_3 ($\text{E} = \text{C}, \text{Si}, \text{Ge}, \text{Sn}$) in hexane were studied by the TRMFE method⁵⁴ and the g -factors and HFC constants of the heteroorganic radical cations were obtained. Fast degenerate electron exchange (DEE) was observed in the Me_4E compounds, whereas this was not observed in the Me_3EEMe_3 compounds. It was found that, in contrast to the alkane radical cations, the heteroorganic ones are characterised by short phase relaxation time of the order of 10 ns. The authors believed that a large contribution to relaxation comes from the spin-rotational interaction and degenerate electron exchange. The last-mentioned mechanism is particularly efficient due to a considerable proportion of magnetic isotopes ^{29}Si , ^{73}Ge , ^{117}Sn and ^{119}Sn .

A number of radical cations of branched alkanes were studied.⁶⁶ The formation of such species upon radiolysis of solutions was confirmed and their HFC constants were also determined (see Table 1).

2. Studies of fast chemical reactions involving radical ions by the method of time-resolved magnetic field effect

Along with spectroscopic data, monitoring of quantum beats in recombination luminescence makes it possible to obtain spectroscopic data and information on reactions of short-lived radical ions in solutions. The reaction causes changes in the spin Hamiltonian of the pair, which leads to changes in the character of quantum beats and in the shape of the TRMFE curve. In the text below we present some examples of the reactions of electron transfer and degenerate electron exchange in solutions.

To determine the rate of the transfer of the solvent hole (or an electron) to acceptor, the acceptor concentration should not be too high. In this case the secondary pairs are generated not instantaneously and the scatter of the corresponding formation times should cause a decrease in the amplitude and the appearance of phase shifts of quantum beats. By analysing the changes in the TRMFE pattern it is possible to determine the rate constant for charge transfer.

This approach was first employed in measuring the phase shift of the Δg beats as function of the concentration of diphenyl sulfide- d_{10} used as hole trap.^{35–38} This dependence was used to determine the rate constant for solvent (isooctane) hole scavenging by the diphenyl sulfide molecule, which was found to be similar to the value corresponding to the diffusion-controlled process.

A study of alkane solutions of 9,10-octalin revealed a rather strong peak of quantum beats due to hyperfine couplings in the 9,10-octalin radical cations even at rather low concentrations of this compound.⁴⁶ The large peak amplitude was explained by the contribution of fast non-stationary stage of electron transfer [reaction (4)] from the 9,10-octalin molecule to the primary radical cation and by the fact that the electron-transfer radius exceeds the geometric radius. The electron-transfer radii determined for three n -alkanes from experimental data using the model proposed are 15.1, 13.9 and 10 Å for octane, decane and dodecane, respectively. A decrease in the electron transfer radii for hydrocarbons C_8 , C_{10} , C_{12} was associated with the decrease in the ionisation potential difference between the alkane and 9,10-octalin in this series, which is consistent with the predictions based on the Marcus theory.⁷⁴

The degenerate electron exchange

between n -alkane, norbornane and tetramethylsilane molecules and their radical cations was studied by the method of quantum beats.^{54–57} In EPR spectroscopy, slow degenerate electron exchange causes broadening of spectral lines, whereas fast degenerate electron exchange leads to the exchange narrowing of the spectrum. These changes in the EPR spectra correspond to characteristic features in the TRMFE curves; by simulating such curves one can determine the rate constant for the exchange reaction.

Figure 12 shows the transformation of the TRMFE curves measured in hexane solutions of n -nonane with an increase in the n -nonane concentration from 0.07 to 3 mol litre⁻¹ and in neat n -nonane. The shift of the maximum in the MFE curves following an increase in the nonane concentration is due to the narrowing of the EPR spectrum of the nonane radical cation with an increase in the DEE rate [reaction (20)]. This was also confirmed by calculations (smooth lines in Fig. 12). The theoretical curves were obtained using a mathematical model developed by Schulten and Wolynes.⁶⁹ Details of simulation were documented.⁵⁵

Figure 12. Time-resolved magnetic field effect obtained in hexane solutions of n -nonane at a concentration of 0.07 (1), 0.3 (2), 0.6 (3), 1 (4) and 3 mol litre⁻¹ (5) and in neat n -nonane.⁵⁵ Smooth curves represent the results of simulation using the DEE rates shown in Fig. 13.

The dependence of the DEE rate (τ^{-1}) on the concentration of n -nonane established in Ref. 55 is shown in Fig. 13. Linear character of the rate–concentration plot confirms the bimolecular character of the DEE reaction for n -nonane. n -Alkanes are characterised by much lower DEE rates (two orders of magnitude lower than the rate of diffusion-controlled process). This was explained by the effect of numerous conformations of neutral n -alkane molecules and a rather high activation barrier to electron transfer in the collisional complex between the radical cation and the molecule.⁵⁵

Modulation of the HFC constants due to DEE can induce not only the phase relaxation, but also noticeable spin–lattice relaxation even in a relatively strong magnetic field.⁵⁷ The DEE reaction involving the norbornane radical cation containing four equivalent protons with non-negligible HFC constants was studied. The authors reported exact calculations

Figure 13. DEE rate for n-nonane radical cation plotted vs. n-nonane concentration in hexane solution.⁵⁵ The straight line is the best linear approximation obtained at a rate constant of $2.6 \times 10^8 \text{ litre mol}^{-1} \text{ ns}^{-1}$.

of the evolution of the spin state of the radical pair under DEE conditions. The asymptotic behaviour of the exact dependence of the singlet state population is satisfactorily described by an exponent with a single time parameter, which can be treated as the spin–lattice relaxation time T_1 . The T_1 value obtained was similar to that calculated in the framework of the Redfield theory.⁷⁵

Figure 14 shows the TRMFE curves for an n-hexane solution of mixture of norbornane ($0.2 \text{ mol litre}^{-1}$) with *p*-terphenyl- d_{14} ($30 \mu\text{mol litre}^{-1}$) plotted vs. magnetic field induction. The fall-off of the TRMFE curves is determined by the rate of spin–lattice relaxation of the norbornane radical cation. Analysis of the dependence of spin–lattice relaxation rate on the magnetic field induction at different norbornane concentrations (Fig. 15) showed that the magnetic field-dependent contribution to relaxation is due to DEE in the norbornane radical cation. The rate constant for DEE was $1.5 \times 10^{10} \text{ litre mol}^{-1}$, which is similar in magnitude to the

Figure 14. TRMFE curves for an n-hexane solution of mixture of norbornane ($0.2 \text{ mol litre}^{-1}$) with *p*-terphenyl- d_{14} ($30 \mu\text{mol litre}^{-1}$) at a magnetic field induction of 0.05 (1), 0.1 (2), 0.2 (3) and 1 T (4).⁵⁷ Straight lines are the exponential approximation of the TRMFE curves in the range of 10 to 50 ns.

Figure 15. Spin–lattice relaxation time of norbornane radical cation plotted vs. magnetic field induction at a norbornane concentration of 0.04 (1), 0.2 (2) and 0.6 mol litre^{-1} (3).⁵⁷ Solid lines represent the results of approximation in the framework of the Redfield theory.

diffusion-controlled rate constant. The relaxation time of the norbornane radical cation in the strong magnetic field tended to a value of $\sim 180 \text{ ns}$. The nature of the magnetic field independent contribution remains unknown. Probably, it is due to the spin–orbit interaction, as in the case of some cycloalkanes (see below).

The DEE reaction involving the tetramethylsilane (TMS) radical cation in n-hexane was studied.⁵⁴ The TRMFE curves obtained for the solution of TMS are shown in Fig. 16. Good agreement between theory and experiment (curve 1) was attained only assuming that hyperfine coupling in the TMS radical cation is averaged almost to zero due to DEE that occurs under diffusion control.

Figure 16. Experimental and theoretical TRMFE curves for a solution of tetramethylsilane and *p*-terphenyl- d_{14} in n-hexane.⁵⁴ Calculated for fast DEE (1) and no exchange (2).

A radical cation of alicyclic amine, namely, 2,2,4,4-tetramethylpiperidine was studied by the TRMFE and quantum chemistry methods.⁵⁸ Based on the changes in the spectra observed upon an increase in the amine concentration and temperature variation, the formation of dimeric radical cations of unusual structure was suggested. A collision between the amine radical cation and the amine molecule is accompanied by proton transfer to the molecule and results in the formation

Figure 17. Experimental TRMFE curves obtained for a solution of 2,2,4,4-tetramethylpiperidine and *p*-terphenyl- d_{14} in *n*-octane ($B = 0.1$ T).⁵⁸ Amine concentration/mmole litre⁻¹: 30 (1), 10 (2) and 3 (3).

of a rather stable distonic dimer in which the charge and spin are localised on different molecules. The rate constant for dimerisation reaction determined by simulating the changes in the shape of quantum beats pattern with an increase in the amine concentration (Fig. 17) was similar to the diffusion-controlled rate constant.

3. Studies of paramagnetic relaxation in radical ions

The TRMFE technique has unique potential for measuring the spin–lattice relaxation rates of short-lived radical ions in solutions over a wide range of change in the magnetic field induction. Some examples were considered above. Mention can be made of a pioneering study⁴⁷ in which the relaxation times of a number of aromatic radical ions (about 1 μ s) were measured. Most results can be satisfactorily described in the framework of the relaxation mechanisms known from EPR spectroscopy.

Unusually fast spin–lattice relaxation in the cyclohexane and adamantane radical cations and their alkyl-substituted analogues detected recently by the TRMFE technique appeared to be a surprising exception.^{59–61} Figure 18 shows the TRMFE curves obtained for solutions of some cycloalkanes. The exponential decay of the TRMFE curves is determined by the T_1 -relaxation. In all cases a three-fold change in the cycloalkane concentration and temperature variation in the 250–320 K range had almost no effect on the rate of T_1 -relaxation. The T_1 -relaxation times of various cycloalkanes are listed in Table 2.

Using the known data on the EPR spectrum of cyclohexane radical cation and the Redfield theory,⁷⁵ it was shown that the relaxation time $T_1 = 9$ ns obtained for the cyclohexane radical cation at a magnetic field induction of 1 T is due to neither modulation of HFC constants or the g -tensor anisotropy nor degenerate electron exchange involving the radical cations. Earlier, unusually fast relaxation was observed by EPR spectroscopy in radical anions of some symmetrical aromatic molecules.⁷⁶

Although quantitative theory of unusually fast relaxation has not been developed so far, it is believed^{76,77} that the phenomenon can be due to strong spin–orbit interaction in symmetrical radical ions. The unusually fast relaxation in some cycloalkane radical cations provides an explanation for unsuccessful attempts to record their OD EPR spectra.⁷⁸

Figure 18. Experimental TRMFE curves ($B = 1$ T) obtained for C_6F_6 solutions in *n*-hexane in the presence of adamantane (1), cyclohexane (2), ethylcyclohexane (3), methylcyclohexane (4) and *cis*-decalin (5).⁵⁹ Solid lines represent the results of exponential approximations.

Table 2. Paramagnetic relaxation times of radical ions generated from corresponding compounds in nonpolar solvents.^{59–61}

Compound	T_1 /ns	$T_2 = T_0$ /ns
Hexafluorobenzene ^a	350 ± 15	15 ± 5
<i>cis</i> -Decalin	390 ± 15	10 ± 5
Cyclohexane	9 ± 2	9 ± 2
Methylcyclohexane	57 ± 10	5 ± 2
Ethylcyclohexane	21 ± 3	10 ± 5
Propylcyclohexane	38 ± 4	7 ± 3
Isopropylcyclohexane	280 ± 20	20 ± 5
<i>cis</i> -1,2-Dimethylcyclohexane	280 ± 20	20 ± 5
Adamantane	6.5 ± 1	5 ± 3
1,3-Dimethyladamantane	8.2 ± 1	5 ± 3

^a A radical anion is produced in this case; all other entries in this Table correspond to radical cations.

4. Manipulation of the spin state of a radical pair

As mentioned above, the character of the spin evolution in a radical pair depends strongly on the external magnetic field. The spin evolution can also be affected by the resonance alternating magnetic field. Pulsed switching-on and(or) switching-off of the magnetic field makes it possible to immediately tamper with the elementary step of RP recombination. The TRMFE technique involving detection of recombination fluorescence permits real-time observation of these effects.

The procedure and results of the first experiments (Fig. 19) on observation of the dynamics of the spin state of a radical ion pair upon fast (~ 20 ns) switching-off of external magnetic field (initial magnetic field induction 4 mT) were reported.⁶² Prior to switching the magnetic field off the system shows a conventional TRMFE pattern determined by the spin evolution in the pair in both zero or nonzero external magnetic field. The fall-off of the TRMFE curves after switching the magnetic field off depends only on the spin evolution in zero field. As should be expected, the fall-off rate is determined by the second moment of the EPR spectrum of radical ions. Deuterated *p*-terphenyl- d_{14} is characterised by a much longer fall-off time compared to non-deuterated *p*-terphenyl.

Figure 19. Curves of $I_{B \rightarrow 0}(t)/I_0(t)$ ratio obtained for a solution of *p*-terphenyl (10^{-3} mol litre $^{-1}$) in *n*-decane at field switching-off delays of 100 (1) and 225 ns (2) and for a solution of *p*-terphenyl- d_{14} (10^{-3} mol litre $^{-1}$) in decane at 100-ns delay of the field switching-off (3).⁶²

The arrows denote the instants of the magnetic field switching-off.

A procedure for control of the course of a spin-dependent reaction using the pulses of alternating resonance magnetic field was studied taking radical ion pair $(C_8H_{18})^{+ \cdot}/(p\text{-terphenyl})^{- \cdot}$ as an example.⁶³ The relative change in the fluorescence intensity (Fig. 20) characterises the change in the singlet state population in the pair in the resonance field. Prior to switching the resonance field off, damping oscillations are observed (see Fig. 20), the oscillation frequency being determined by the amplitude of the magnetic field in the rotating frame.⁶³ At the instants corresponding to the switching-off of the resonance field (arrowed), the spin state of the pair is 'frozen'. Then, the spin populations are equilibrated at the rate determined by spin–lattice relaxation.

Figure 20. Effect of microwave field, $I_{RF}(t)/I_0(t)$, obtained for a solution of 2,2,4-trimethylpentane and *p*-terphenyl- d_{14} in *n*-hexane at the resonance UHF field switching-off delays of 300 (1), 45 (2) and 25 ns (3).⁶³

5. Radiation chemistry applications

In the examples considered above, ionising radiation only served a convenient instrument of pulsed generation of spin-correlated radical ion pairs. Meanwhile, from the very beginning it was clear that TRMF studies can provide valuable

information on specific features of fast reactions in tracks of ionising particles.

The key role in the development of this avenue of research was played by the studies by Brocklehurst who used the TRMF technique in recombination luminescence to solve some stubborn problems in radiation chemistry and physics of non-polar solutions. These include the structure of tracks, the origin of superdiffusion mobility of positive charges (solvent holes), the role of excited states in delayed luminescence, the possibility of spin correlation of non-geminate RP in radiation tracks, *etc.* The results obtained by Brocklehurst were summarised in reviews.^{11, 14} Due to complexity of the problems under study, some of these results are ambiguous. However, in the cited reviews, Brocklehurst touches upon almost all significant details of the processes the radical pairs in radiation tracks are involved in. A thorough study of the dependence of the fraction of the RPs recombining in the spin-correlated state (geminate pairs in the track) on the type and energy of ionising radiation deserves particular attention.

The fraction of geminate radical ion pairs in radiation tracks was determined from the amplitude of quantum beats.^{39–41} When different non-polar solutions were irradiated with fast electrons, this quantity was 1.3–2.8 times higher than that found for irradiation with X-rays.⁴¹

The kinetics of recombination luminescence of non-polar solutions and the magnetic field effect on these kinetics were reported in a study⁴⁸ aimed at investigating the formation of radical ion pairs under the action of vacuum ultraviolet; the magnetic field effect observed was used for substantiation of his statement that the primary radical pair is formed from singlet-excited solvent molecule.

6. Quantum beats in laser generation of radical pairs

Laser photolysis undoubtedly belongs to the most widely used methods of pulsed generation of spin-correlated radical pairs and radical ion pairs. However, data on observation of quantum beats in recombination of pairs under laser irradiation are scarce. Most experiments were characterised by low temporal resolution and a complex structure of EPR spectra of the pair partners, which excluded the possibility of obtaining a clearly seen pattern of quantum beats.

Clearly observed beats were reported in a study of time-resolved magnetic field effect on the delayed fluorescence of *N,N,N',N'*-tetramethyl-1,4-phenylenediamine (TMPD) in alcoholic solutions.⁷⁹ Fluorescence was excited by a pulse of a UV laser operating at 308 nm. Irradiation with light resulted in ionisation of TMPD and generation of a spin-correlated pair $(TMPD)^{+ \cdot}/e^{- \cdot}$. The spin evolution in this pair caused oscillations at times shorter than 150 ns; at longer times, a magnetic field effect due to triplet–triplet annihilation of excited TMPD molecules was observed.

Real-time observations of manifestations of the spin dynamics of radical pairs were also reported in fast switched magnetic field CIDNP studies.^{80–82} A solution irradiated with a laser pulse was placed in a Helmholtz coil that allowed the magnetic field to be switched within the limits of ± 2 mT (switching time 1 ns) with variable delay between the pulse and the switching of magnetic field. Then, the solution was rapidly transferred to the magnet of an NMR spectrometer for CIDNP measurements. In the experiments with radical ion pairs $(naphthalene-d_8)^{+ \cdot}/(1,2\text{-}cis\text{-dicyanoethylene})^{- \cdot}$, switching of the magnetic field from 2.3 to 0 mT was followed by oscillations of the CIDNP plotted *vs.* delay time due to the hyperfine interactions in the radical anion. The shapes of these curves (Fig. 21) depend on the concentration of the electron acceptor, which was explained by the effect of degenerate electron exchange.

Figure 21. Magnetic field switch CIDNP kinetics observed in photolysis of solutions containing different concentrations of 1,2-*cis*-dicyanoethylene (a) and simulation with allowance for DEE (b).⁸¹ Concentration /mmol litre⁻¹: 1 (1), 2 (2) and 8 (3); DEE time /ns: 220 (1), 110 (2) and 28 (3).

V. Conclusion

The method of quantum beats in recombination luminescence proved itself as a powerful tool in the solution studies of short-lived radical ions (lifetimes up to a few nanoseconds). Theoretical foundations of extraction of unique information on these species from experimental data were developed and relevant experimental approaches were implemented. Using the quantum beats technique, one can determine the magnitudes and, in some cases, the signs of the HFC constants of radical ions, the *g*-factors, the paramagnetic relaxation times and the fraction of spin-correlated radical pairs in radiation tracks. The main advantages of the method of quantum beats over conventional EPR spectroscopy consist in the high sensitivity and temporal resolution. The former factor is due to the possibility of carrying out light intensity measurements on the single-photon scale. Therefore, the quantum beats technique makes it possible to study very low concentrations of radical ion pairs (up to about 100 pairs per sample), being enormously more sensitive than EPR spectroscopy. Compared to the OD EPR technique, which is based on the same properties of radical ion pairs, the method of quantum beats provides the possibility of monitoring the course of the chemical reactions involving RPs on the nanosecond time scale.

An apparent limitation of the title method is the necessity of tuning the conditions for a rather high quantum yield of recombination fluorescence and short fluorescence time (it should be shorter than the desired temporal resolution in the experiments). In most cases the radical ions of interest are produced from molecules that do not possess the properties of luminophores. This limitation can be eliminated with ease by choosing an appropriate luminophore as partner (*i.e.*, acceptor of the opposite charge). One can face some difficulties in studies of radical ions in polar solvents. For instance, in this case the energy released in recombination of radical ions may appear to be too low to form an excited luminophore molecule owing to high polarisation energy. These problems are still to be studied, because almost no experiments in polar solvents were carried out as yet.

Prospects for the use of the method of quantum beats are first of all associated with an increase in the number of those radical ions that cannot be studied in solution by other methods due to the short lifetimes. These can be radical ions of heteroorganic or halogen-containing compounds, spin traps, biologically active substances, *etc.*

Yet another promising avenue of research involves the use of laser methods for generation of radical ion pairs. Photoionisation processes attract considerable attention of chemists and physicists and the methods considered above could find wider application. The results of photochemical experiments involving photogeneration of pairs may appear to be simpler to interpret because of the lack of cross-recombination effects typical of radiation tracks. Here, the method of quantum beats could provide additional information on the primary act of formation of radical pairs in solutions upon photoionisation, because many details of this key step remain unknown so far.

Abstract. The latest results in the field of classical reactions of acetylene are analysed. Attention is focused on reactions catalysed by strong bases (vinylation, alkynol synthesis, acetylene–allene isomerisation) and related syntheses. The bibliography includes 347 references.

I. Introduction

Chemistry of acetylene, a versatile building block of the organic synthesis, is continued to be rapidly developed.¹ As compared with ethylene, highly reactive acetylene and its derivatives better match the trends in the development of chemical industry, which is more and more oriented to the production of science intensive chemicals for modern technologies, medicine and agriculture. Acetylene can be considered as an accumulator of high-density energy, *i.e.*, the heat consumed in its formation is liberated in chemical reactions thus promoting them and providing the shortest and the least power-consuming way to the target products.

Although quite recently, acetylene was virtually beyond competition as the basic chemical used in the industry, now it has lost its leading position. At the same time, according to certain analysts, acetylene might again become the leader.^{2–7} Future will show whether or not this happens and to the full extent or only partly, however, there are objective prerequisites for this to happen.

Acetylene is mainly produced from oil and natural gas by oxidative pyrolysis in an electric discharge, in plasma, by laser technologies and using solar energy. Moreover, acetylene is the main side product in the ethylene synthesis.² At the same time, acetylene can also be produced from coal. Accounts of natural

energy resources show that oil and natural gas fields are being rapidly exhausted, while the coal resources may last for centuries. Hence, the return to coal-based technologies seems quite likely.^{2,5,6} Acetylene is obtained from coal by both the traditional carbide method and the modern plasma technologies as well as by hydrogenation, gasification or *via* the synthesis gas. Moreover, different types of biomass such as lignine and various carbon-containing industrial and domestic waste may be transformed into acetylene by their fast pyrolysis in plasma. The latter method seems especially attractive, being associated with the solution of environmental problems.

Long-term economical prognoses allow one to assume that new, constantly modernised plasma technologies for the production of acetylene from coal have a sufficient potential for making acetylene once again the chief chemical in the manufacturing of commercial products such as vinyl chloride, vinyl acetate, acrylates, chloroprene and chlorinated solvents.^{2,5–7}

To make the quest for new synthetic approaches to the chemistry of acetylene more effective, the theoretical studies based on high-level *ab initio* quantum-chemical calculations are invoked with increasing frequency.^{8,9}

Among the popular synthetic methods actively elaborated today, classical reactions of the addition of nucleophiles to the triple bond, the acetylene–allene–diene isomerisation and the transformations of acetylene and allene-derived carbanions deserve mention. Recent reviews^{10,11} show numerous examples of syntheses of heterocyclic and carbocyclic compounds by the addition of different nucleophiles to acetylenes.

The quest for new reactions of the formation of C–C bonds that involve acetylene-derived carbanions (metal acetylenides) and especially those based on the addition of acetylene to the carbonyl group (the Favorsky alkynol synthesis and its analogues) is carried on.¹² Numerous studies on transition metal acetylenides were summarised in several reviews.^{13,14}

Unconventional prospects for the organic synthesis are opened up by acetylenic sugars, which were the subject of hundreds of publications (*e.g.*, for a review, see Ref. 15).

The progressively greater efforts are directed to the quest for new organic semiconductors and optoelectronic materials based on acetylene polymers and oligomers. Today, high expectations are placed on polyarylene ethynyls, *i.e.*, polymers containing alternating triple bonds and arene

groups,^{16–19} and unique polyne structures, which can be synthesised through alkylidenecarbenes and -carbenoids.^{20, 21} The interest in polyynes^{22, 23} and arylene–ethynylene systems²⁴ is explained by their prospects as the molecular wires and also in the context of studies of carbyne and its analogues as the allotropic forms of carbon.

The appearance of new synthetic approaches to the design of new acetylenic structures, which are based on cross-coupling reactions catalysed by transition metal complexes, has revolutionised the assembling of different acetylene-containing systems and ensembles.^{25–27}

In the recent decades, systematic studies were carried out aimed at further development of classical reactions of acetylene with the use of superbasic catalysts and reagents. The present review is devoted to the brief analysis of achievements in this field. At the same time, due to the limited volume, it chiefly deals with the addition reactions to the triple bond (vinylation), addition of acetylene-derived carbanions (alkynol synthesis) and acetylene–allene–diene isomerisation, which serve as the basis for the most popular synthetic methods in the acetylene chemistry and are used most widely in laboratories and the industry.

The elaboration of a new approach to the enhancement of the reactivity of nucleophilic reagents, which is associated with the use of superbasic catalysts, have led not only to the refining of most important base-catalysed reactions of acetylene but also to the discovery of new reactions involving the triple bond and the development of synthetic methods based on them.^{7, 28–43}

II. Acetylene reactions in superbasic media

The concept of superbasicity was first formulated by Trofimov⁴⁴ in 1977: ‘a medium consisting of a strong base and a solvent or a reagent that specifically binds cations thus ‘stripping’ the conjugated anions is considered superbasic...’. Later, this concept was systematically used in the refinement of classical reactions involving triple carbon–carbon bonds (Refs 7, 28–30, 33, 41 and 43).

Obviously, within the framework of this concept, the definition of superbasicity is the ‘mirror image’ of superacidity, *i.e.*, a superbase is a complex of a strongly ionised base (the Brønsted base) with a ligand that can specifically interact with the cation of this base (the Lewis base) in a medium capable of weak solvation of anions (as a rule, in a medium of a polar hydroxyl-free solvent).^{33, 41}

M = Li, Na, K, Rb, Cs; B is a carbanion, H, OH, OR, NH₂, NR₂; Y correspond to ethers (polyethers), amines (polyamines), NH₃, cryptands, sulfoxides, sulfones, amides, phosphine oxides, *etc.*

Systems with the Hammett acidity function (*H*₀) higher than 18.5, *i.e.*, the systems with the basicity unattainable in hydroxyl-containing solvents (water and alcohols) due to the limitations imposed by the intrinsic acidity of the medium, were assigned^{33, 41} to superbases.

Among diverse superbasic systems, the system KOH–DMSO proved to be the most suitable for the systematic application in the acetylene chemistry as the simplest, most easily prepared and versatile system.^{7, 28–30, 32, 33, 41–46} Its upper basicity limit is determined by the DMSO acidity (*pK*_a = 35.1); however, the acidity does not usually exceed 32 (in the *H*₀ scale) unless special measures have been undertaken for the removal of water liberated in the formation of dimethylpotassium.

A great advantage of the system KOH–DMSO is its controllable basicity. As the water content in DMSO decreases to 25%, the system passes to the superbasicity region (*H*₀ > 20). With further decrease in the water concentration, the value of *H*₀ sharply increases approaching 30–32 for 99% DMSO.⁴¹

Yet another advantage of the system KOH–DMSO is its ability for autostabilisation (self-adjustment), *i.e.*, its basicity is maintained on a constant level due to the absorption of water (if water is liberated in the reaction) by the solid phase (KOH); the KOH concentration in the liquid phase is low (~0.04 mol litre⁻¹ in pure DMSO) and the consumed KOH is replenished from the solid phase, *i.e.*, its concentration is automatically kept constant. Thus, the reactions in this system often acquire the features of the phase-transfer catalysis.⁴¹

1. Development of classical acetylene reactions

a. The Favorsky acetylene–allene isomerisation

The selective isomerisation of propargyl ethers to allenyl ethers was first carried out under the action of KOBu^t on propargyl vinyl ethers of ethylene glycol oligomers.^{47, 48}

The superbasicity of the reaction mixture was achieved due to the formation of chelate complexes of potassium cations with the polyether chain.

The use of the superbasic system KOH–DMSO in the isomerisation of propargyl ethers have led to the development of an efficient and highly selective method for the synthesis of alkyl allenyl ethers.⁴⁹

This reaction made accessible the alkyl allenyl ethers, which so far pertained to the insufficiently explored class of substances.^{7, 50–52} Obviously, their synthetic potential as the reactive monomers and building blocks is more multifaceted as compared with the corresponding vinyl ethers that have found wide application in both the organic synthesis^{2, 28, 53–58} and polymer chemistry.^{59–67}

It was shown that the system KOH–DMSO allows one to selectively isomerise the propargyl group of an allyl propargyl ether to the allenyl group, leaving intact the allyl fragment. When carried out at higher temperatures, this reaction can shift the double bond to afford allenyl prop-1-enyl ether.⁴¹

N-Allenylpyrroles **1**, the promising monomers⁶⁸ and building blocks in synthetic chemistry, which were difficult to synthesise until recently, were easily obtained in high yields by the isomerisation of *N*-propargylpyrroles catalysed by the system KOH–DMSO.⁶⁹

R ¹	R ²	Yield of 1 (%)	R ¹	R ²	Yield of 1 (%)
H	H	63	Me	Me	49
Me	H	68		(CH ₂) ₄	88
Ph	H	70			

N-Allenylpyrroles **1** can be synthesised in a one-pot procedure using both propargyl chloride⁷⁰ (which is sufficiently obvious) and much cheaper 2,3-dichloroprop-1-ene⁷¹ and 1,2,3-trichloropropane,⁷² which are the side products of the industrial synthesis of epichlorohydrin. In this case, the system KOH–DMSO serves not only as the catalyst, but also as the reagent and, hence, should be taken in a superstoichiometric amount.

R¹ = H, Me, Ph; R² = H, Me; R¹–R² = (CH₂)₄;
R³ = CH₂C≡CH, CH₂CCl=CH₂, CH₂CHClCH₂Cl.

The same superbases and the same reagents allowed the one-pot allenylation of other azoles to be carried out.^{73, 74} For example, *N*-allenylimidazole was synthesised from imidazole and propargyl chloride in the yield of 75%.

1,2,4-Triazole behaves in a similar way, namely, its reaction with propargyl chloride produces *N*-allenyl-1,2,4-triazole (**2**) in the yield of 31%.^{73, 74} The use of trichloropropane in allenylation allows one to stop the reaction after the formation of *N*-chloroallyl derivative **3** (yield 21%).⁷³

b. Nucleophilic addition to a triple bond (vinylation)

Superbasic catalysts have extended in principle the potentials of the classical Favorsky reaction of vinylation.⁷⁵ For example, vinylation of acetylenic alcohols with acetylene is impossible in the presence of common bases (alkali metal hydroxides or alkoxides); however, in superbasic systems such as KOH–DMSO this reaction proceeds sufficiently smoothly.⁴¹

As a rule, it is rather difficult to stop this reaction in a stage of the formation of a vinyl ether of acetylenic alcohol **4** (this requires special measures to be undertaken). Usually, the acetylene–allene isomerisation proceeds simultaneously to afford the corresponding allenyl vinyl ethers **5** (yields up to 80%).^{76, 77}

R = H, Me, Et, Prⁿ, Prⁱ, Bu^t.

This reaction is the most promising for the transformation of commercially available propargyl alcohol into vinyl-oxyallene.

A new generation of superbases, the catalytic systems CsF–MOH–DMSO (M = Li, Na, K) have been developed recently. As a rule, they are more active^{41, 78–83} than the system KOH–DMSO. In a simple way, their enhanced activity can be explained by the formation of caesium hydroxide (a base stronger than potassium hydroxide) due to the shift of the equilibrium to the formation of poorly soluble fluorides, particularly, lithium fluoride.⁴¹

M = Li, Na, K.

A comparison of the activity of two superbasic catalytic systems, namely, KOH–DMSO and CsF–NaOH–DMSO, in the vinylation of acetone oxime shows that the caesium system is much more active. In the presence of this system, the optimum reaction temperature was lower (by ~10 °C) and the yield of *O*-vinyl acetone oxime (**6**) was higher (by 20%)^{78, 80} as compared with the system KOH–DMSO.

B	T / °C	Yield of 6 (%)
CsF–NaOH–DMSO	70–72	85
KOH–DMSO	78–80	65

Yet more impressive difference in the activities of these two superbasic catalytic systems was observed in the vinylation of polyhydric alcohols. Thus the vinylation of glycols **7** at 100 °C and atmospheric pressure in the presence of the system CsF–NaOH–DMSO afforded divinyl ethers **8** in the yields from 45% to 90% (depending on the glycol structure), whereas in the KOH–DMSO system, the yield of divinyl ethers was at the level of 10%.^{41, 83}

R = (CH₂)₃, (CH₂)₄, MeCH(CH₂)₂, (CH₂)₇;
B = CsF–NaOH–DMSO, KOH–DMSO.

In the reaction of acetylene with pentaerythritol carried out at 130–135 °C and the atmospheric pressure in the system CsF–NaOH–DMSO, the yield of tetravinyl ether of pentaerythritol (**9**) exceeded 60%, whereas in the system KOH–DMSO, its yield was 5%.⁴¹

B = CsF–NaOH–DMSO, KOH–DMSO.

The reaction of glycerol with acetylene in the system CsF–NaOH–DMSO produced 1,2-bis(vinyl)oxyprop-1-ene (**10**) rather than the expected trivinyl ether of glycerol.⁸¹ Thus, this reaction represents a new type of vinylation, namely, the eliminative vinylation.⁸⁴ In the presence of the system KOH–DMSO as the catalyst, only traces of compound **10** were obtained.

Recently, tetravinyl ether **11** was synthesised from methyl α -D-glucoside in the presence of superbasic catalysts KOH–DMSO and KOH–THF.⁸⁵

B	<i>T</i> / °C	<i>t</i> / h	Yield of 11 (%)
KOH–DMSO	85–87	1	75
KOH–THF	135–140	6	52

Superbasic catalytic systems that allow one to perform isopropenylation of methanol with methylacetylene (the second most readily accessible acetylenic hydrocarbon) at the atmospheric pressure and 100–120 °C have been developed.⁸⁶ This made it possible to synthesise⁸⁶ 2-methoxyprop-1-ene (**12**), a valuable monomer and reagent, which has found its application in the industrial syntheses of fragrant compounds, vitamins and carotenoids.^{87–90} Complexes of potassium and caesium *tert*-alkoxides with *N*-methylpyrrolidone (NMP) proved to be the most active in this reaction.

B = KOBu^t–NMP (the yield of compound **12** is 87 %), CsOCMe₂Et–NMP (87%), KOH–DMSO (60%), CsOMe–NMP (22%), CsF–NaOH–NMP (11%), 2 KOH·H₂O–NMP (6%).

Apparently, this is associated with the formation of a charge-transfer complex between NMP and alkoxides. This is evidenced by the presence of the charge transfer bands (283, 543, 580 nm; bright purple colour) in the UV spectrum of a KOBu^t solution in NMP and also by the high-frequency shift of vibrations of the C=O group (1683 cm^{–1} → 1693 cm^{–1}, probably due to the contribution of the vibrations of the ⁺N=C group) observed in the IR spectrum.⁴¹

At present, the superbasic catalytic system KOH–DMSO is the most versatile for the vinylation reactions.^{7, 41, 43} Thus this allowed the vinylation of cholesterol **13** to be carried out under mild conditions (without epimerisation and migration of the double bond) to afford the quantitative yield of optically active liquid-crystalline vinyl ether **14**, which is used as a monomer and a highly reactive intermediate in the synthesis of new compounds of the steroid series.⁹¹ In the presence of the same catalytic pair, pregnenolone **15** and acetylene gave vinyl ether **16** with retention of the keto group and configurations of all asymmetric centres. This is the first example of the successful vinylation of a hydroxy ketone.^{41, 92}

R = C₈H₁₇ (**13**, **14**), Ac (**15**, **16**).

In the presence of the system KOH–DMSO, pyrroles were vinylated for the first time under relatively mild conditions with a methylacetylene–allene mixture to produce *N*-isopropenylpyrroles **17** in good yields.⁹³

R¹ = R² = H, Me; R¹–R² = (CH₂)₄.

This catalyst can also be used in the isopropenylation of other azoles (105–145 °C, 5–15 h), namely, indoles, imidazoles, pyrazoles, triazoles. The corresponding *N*-isopropenyl derivatives **18–22** were obtained in yields of 20%–70% (non-optimised yields).⁹⁴

The above (hardly exhaustive) examples illustrate the impressive advances in the studies of vinylation with acetylenes, which were observed in the past decades due to the use of superbasic catalytic systems.^{7, 41}

c. The Favorsky alkynol synthesis and its analogues

The quantum-chemical analysis^{95–97} shows that in the gas phase or a weakly solvating medium the formation of acetylide anions from acetylene under the action of superbases at low temperatures is more preferential than the alternative nucleophilic addition of anions to the triple bond. Hence, superbases should accelerate the Favorsky ethynylation of aldehydes and ketones (the addition of acetylide anions to the C=O bond).

Indeed, it was shown that in the superbasic medium KOH–DMSO, acetylene reacts quickly and quantitatively with paraform at the atmospheric pressure and room temperature to form propargyl alcohol^{98–100} and/or but-2-yn-1,4-diol.^{33,41} In contrast to the classical vinylation of formaldehyde, which proceeds in the presence of an explosive copper acetylide under a pressure of up to 70 atm and at a temperature of 90–130 °C, the new method allows one to make, if required, propargyl alcohol the main reaction product (yield up to 90%).⁹⁹

Other aldehydes and ketones also react with acetylene more actively in the presence of the system KOH–DMSO than under conventional conditions; moreover, different acetylenic alcohols and glycols can be synthesised in high yields with no recourse to high pressures, cooling and large volumes of solvents,^{7,33,101} *i.e.*, in the absence of all attributes inherent in the classical ethynylation.

In the system KOH–DMSO, the one-pot synthesis of glycidyl propargyl ether (**23**) was carried out from paraform, acetylene and epichlorohydrin.¹⁰²

Acetylide anions generated from acetylene in superbasic media add to the C=N bond. Thus anilides^{103–105} and anilines¹⁰⁶ react with acetylene in the presence of their potassium derivatives (at 160 °C, under enhanced pressure, in THF or dioxane) to form 3-arylaminoabutynes **24a–c**.

Ar = Ph (**a**), 2-MeC₆H₄ (**b**), 4-MeC₆H₄ (**c**).

It was proved that these reactions proceed through the intermediate formation of the Schiff base that adds the acetylide anion to the C=N bond (the aza analogue of the Favorsky reaction).^{103,105}

2. New reactions

Several new general reactions of acetylene that occur in superbasic media and produce promising monomers and synthons for the fine organic synthesis have been discovered.^{7,28–36,40–43}

a. Hydrative trimerisation of acetylene

It was found that in the presence of the complex 2 KOH·H₂O–DMSO (80–115 °C, 10–15 atm), three acetylene molecules and one water molecule undergo a single-stage formation of 2-vinyloxybuta-1,3-diene that simultaneously contains a 1,3-diene fragment and a vinyl group.^{107,108}

Mild acid-catalysed hydrolysis of 2-vinyloxybuta-1,3-diene (1% HCl, 20 °C) affords methyl vinyl ketone in the quantitative yield.³³

b. Direct vinylation of chalcogens and elemental phosphorus

The use of superbasic systems made it possible to carry out a series of unconventional acetylene reactions, particularly, the direct vinylation of chalcogens and elemental phosphorus in the presence of a minimum amount of a proton donor (usually, water). These studies were initiated by the discovery of a reaction of acetylene incorporation into the S–S bond of disulfides in the system KOBu^t–DMSO. The reaction is stereoselective and produces *Z*-isomers of 1,2-bis(alkylthio)-ethenes **25**.^{109–111}

R = Me, Et, Buⁿ, Bu^t.

As was found later, this reaction is general and may be extended to dialkyl diselenides¹¹² and elemental S₈, Se and Te.^{111,113–115} Being a supernucleophile, the polysulfide anion formed from the cyclic octamer S₈ is easily captured by acetylene. As a result of subsequent transformations, the polysulfide anion transforms into divinyl sulfide in the presence of proton donors.^{111,113,114} Selenium and tellurium are vinylated to divinyl selenide and divinyl telluride, respectively, in the presence of the system KOH–HMPT (HMPT is hexamethylphosphotriamide).^{111,114,115} In this reaction, superbases act not only as the catalysts but also as the reagents, being involved in the redox disproportionation of selenium or tellurium.

Under these conditions, elemental phosphorus behaves in a similar way. Under the action of an activated hydroxide

ion, the P–P bonds of both white and red phosphorus are easily cleaved to form phosphide and phosphinite anions,[†] which react with the appropriate electrophile (complementary with respect to symmetry and population of unoccupied valence molecular orbitals).^{35, 116–120}

For phosphide anions, acetylenes proved to be these complementary electrophiles. Thus the reaction of phosphide anion with phenylacetylene at 60–65 °C proceeds by a stereoselective mechanism to form a *Z,Z,Z*-isomer of tristyrylphosphine (**26**).^{35, 117–119}

c. Synthesis of *O*-vinylketoximes

Nucleophilic addition of ketoximes **27** to acetylene in superbasic media to form *O*-vinylketoximes **28** made the latter easily accessible.^{42, 121–124}

R¹, R² = Alk, Ar, Het; M = Li, Na, K; X = Cl, F.

The highest yield of vinyloximes **28** was reached due to the modification of the superbasic system MOH–DMSO by the addition of a non-polar solvent (pentane) and caesium halides. Pentane extracts the *O*-vinyloximes formed and thus prevents their further transformation to pyrroles, while caesium salts are converted to CsOH due to the exchange processes thus providing the high basicity of the system.^{121–123}

d. Synthesis of *O*-vinylamidoximes

The use of superbasic catalysts made it possible to vinylate amidoximes, which are prone to tautomeric transformations under ordinary conditions.^{125, 126}

R = Me (46%), Ph (89%).

[†] In the first stages, phosphide and phosphinite anions represent super-nucleophilic anionic clusters.

Chemoselective vinylation at the hydroxyl group occurs at a temperature unusually low for this reaction (75 °C) very quickly, virtually instantaneously (it takes about 5 min for the reaction to be completed).^{125, 126} The resulting *O*-vinylamidoximes form a new class of promising monomers and synthons, particularly, for designing heterocycles. For example, they are easily cyclised to oxodiazolines,⁴¹ although the attempts to rearrange them into imidazoles (analogously to the rearrangement of *O*-vinyloximes to pyrroles^{42, 127}) failed so far.

e. Acetylene reactions with ketoximes: synthesis of pyrroles

A new general reaction of ketoximes with acetylenes, which proceeds in superbasic media such as MOH–DMSO (M is an alkali metal) and afford pyrroles **29** and *N*-vinylpyrroles **30**, was discovered.^{30, 32–34, 37, 41, 42 127–144} An excess of acetylene favours direct formation of *N*-vinylpyrroles **30**. Actually, this reaction represents a two-stage transition from ketones to diverse pyrroles.

By this reaction, virtually any ketone that has at least one methylene or methyl group in the α-position with respect to the carbonyl function and contains no strong base-sensitive substituents can be transformed into the corresponding pyrrole or *N*-vinylpyrrole. If necessary, a one-pot synthesis can be carried out in the system MOH–DMSO. For this purpose, a ketone is treated first with hydroxylamine (or its hydrochloride) and then with acetylene.¹⁴³

R¹, R² = Alk, Ar, Het; R³ = H, Me, Ph; M = Li, Na, K, Rb, Cs.

This reaction has provided a facile route to pyrroles with alkyl, cycloalkyl, aryl and hetaryl substituents and pyrroles annulated with common rings, macrocycles and fused systems.^{7, 30, 41, 140–146}

At present, this reaction is widely referred to in the literature as the Trofimov reaction (*e.g.*, see Refs 147–157).

Alkali metal hydroxides were used as the MOH component of the superbasic catalytic system MOH–DMSO. Rubidium and caesium hydroxides are more active than KOH but the latter is much cheaper; this is why the system KOH–DMSO is used, as a rule. Lithium and sodium hydroxides are less active; however, they allow one to obtain NH pyrroles more selectively, because they virtually do not catalyse their vinylation. In the absence of DMSO, pyrroles are not formed, *i.e.*, the intrinsic basicity of alkali metal hydroxides is insufficient and this reaction requires superbasicity.⁴¹

In place of acetylene, methylacetylene and allene can be employed.⁹³

This reaction was successfully used for the synthesis of pyrroles **31a–c** with terpenoid substituents.^{7,41,131} For this purpose, terpenoid ketones were treated first with hydroxylamine and then with acetylene in the system KOH–DMSO.

This reaction was also used to prepare recently unknown steroid pyrrole compounds including those containing highly reactive *O*- (compound **32a**) and *N*-vinyl (**32a–c**) groups capable of polymerisation and further chemical modification.^{41,134,136,137}

f. Synthesis of δ -carboline from 3-acetylindole oxime and acetylene
The reaction 3-acetylindole oxime with acetylene in the superbasic catalytic system KOH–DMSO opened up a new way

(one-pot assembling) to the synthesis of δ -carboline system, namely, pyridoindole **33**, which was difficult to synthesise earlier.¹⁵⁸

Apparently, this reaction proceeds through the homolytic cleavage of the N–O bond in the intermediate *O*-vinoxime **A** followed by the intramolecular attack of iminyl radical **B** on the pyrrole ring. After this, the homolytic opening of the spiroazirine intermediate **C** and the addition of the second acetylene molecule to radical **D** complete closure of the pyridine ring.¹⁵⁸

Carboline structures are present in many natural compounds and medicinal drugs; however, so far the synthesis of δ -carbolines remained an unsolved problem in the chemistry of indole alkaloids. An important advantage of this reaction is the possibility of the one-stage synthesis of the hitherto unknown *N*-vinyl- δ -carbolines.⁴² The latter combine the properties of an *NH*-protected δ -carboline with those of highly reactive synthons and monomers, which opens up wide prospects for the development of the fundamental and synthetic chemistry of indole alkaloids and high-molecular-weight compounds of the carboline series.

g. Eliminative vinylation of 1,2-diols and polyols

The eliminative vinylation of 1,2-diols and polyols opened up a rational way to divinyl ethers, namely, vinyloxyalkenes **34**.³³ The formal elimination of vinyl alcohol from the intermediate divinyl ethers proceeds only in the presence of superbases such as KOH–DMSO; moreover, the elimination proceeds more smoothly in the presence of acetylene.^{159,160}

R = H (**a**), Me (**b**).

Due to this reaction, divinyl ethers, the promising monomers and synthons, have become accessible for the first time and the reaction itself, being general, has supplemented the arsenal of methods of organic chemistry.³³

h. Cyclo-co-oligomerisation of acetylene with acetonitrile

The cyclisation of acetylene with three acetonitrile molecules pertains to the new reactions of acetylene that proceed in superbasic media. The cyclisation occurs under mild conditions (from -10 to 20 °C, atmospheric pressure, a superbasic system KOH–MeCN) and leads to 2-amino-3-(2-iminoethyl)-6-methylpyridine (**35**), the first representative of pyridines that simultaneously contains an imine and an amine functions, and 3-acetyl-2-amino-6-methylpyridine (**36**).¹⁶¹

i. Rearrangement of *O*-propargylketoximes

In the presence of a specific superbasic system KO^tBu –THF, propargyl ethers of ketoximes **37** are rearranged to *N*-vinylacrylamides **38** rather than to the expected allenyl ethers (room temperature, exothermic process). This rearrangement is general.¹⁶²

$\text{R}^1 = \text{Alk, Ar}; \text{R}^2 = \text{H, Alk.}$

In turn, *O*-propargylketoximes **37** are obtained in quantitative yields from oximes and propargyl chloride in the superbasic system KOH–DMSO.^{41, 163} It is amazing that this virtually universal catalytic system fails to induce the rearrangement of *O*-propargylketoximes formed.

III. Chemistry of acetylenic hydroxy acids and their derivatives

1. Oxidative methoxycarbonylation of acetylenic alcohols

The direct catalytic synthesis of methyl esters of acetylenic hydroxy acids **39** was carried out by the reaction of acetylenic alcohols with carbon monoxide in methanol in the presence of

$\text{R}^1, \text{R}^2 = \text{Alk, cyclo-Alk, Ar.}$

palladium and copper chlorides.^{31, 33} In contrast to the classical Reppe carbonylation, which affords the acrylic systems, in this case, the triple bond remains intact. The presence of an acceptor group near the triple bond in compounds **39** dramatically enhances the reactivity of this bond, which makes these compounds the promising reagents for the fine organic synthesis.

The reaction of oxidative methoxycarbonylation of acetylenic alcohols provided reliable synthetic grounds to the chemistry of acetylenic hydroxy acids and their derivatives.^{31, 38}

2. Addition of nucleophiles

The addition of different nucleophiles (alcohols, thiols, amines, cyanide anion) to esters and nitriles of α, β -acetylenic γ -hydroxy acids followed by the cyclisation under biomimetic conditions (room temperature, aqueous medium) opened up new approaches to the synthesis of functionalised heterocycles, which were difficult to prepare. Below, the examples of compounds synthesised by this approach are shown.^{7, 31, 38, 164–172}

This strategy can be applied to the directed synthesis of biologically important derivatives of tetrone, ascorbic and penicillic acids and other antibiotics of this series, particularly, the promising anti-HIV drugs.³⁸

The nucleophilic addition of amines to nitriles of hydroxy acetylenic acids affords conjugated poly(iminodihydrofurans) **40** with unusual electrophysical properties.^{173–178}

3. Synthesis of fused pyridine systems

An unexpected regiospecific cyclisation of nitriles of hydroxy acetylenic acids with pyridine and its methyl derivatives (α -, β - and γ -picolines), which occurs at room temperature in the absence of catalysts and solvents, leads to the formation of (*Z*)-cyanomethylidene-1,3-oxazolidino[3,2-*a*]-1,2-dihydropyridines **41** in high yield. The latter compounds serve as the reactive building blocks in the fine organic synthesis, the promising biologically active compounds and polydentate ligands for the design of metal-complex catalysts.¹⁷⁹

$R^1 = R^2 = \text{Me}$, $R^1 - R^2 = (\text{CH}_2)_5$; $R^3 = \text{H}$, 2-Me, 3-Me, 4-Me.

Later, this reaction was extended to the functional pyridine derivatives^{180–184} and 1-substituted benzimidazoles.¹⁸⁵ Hence, this is a general reaction. It was used for the syntheses of oxazolidinoquinolines **42**,¹⁸¹ bis(oxazolidino)quinoxalines

43,¹⁸¹ substituted (oxazolidinopyridinyl)piperidines **44**,¹⁸³ oxazolidinobenzimidazoles **45**.¹⁸⁵

IV. Acetylene- and allene-derived carbanions

In the past decade, a considerable contribution was made to the chemistry of carbanions of the acetylene and allene series.^{186–192}

The functionalisation of the pyrroloacetylene dianion with trimethylchlorosilane and chalcogens afforded 2-trimethylsilyl-1-trimethylsilylthiopyrrole, pyrrolo[2,1-*b*]thiazole and the hitherto unknown fused heterocyclic systems, namely, pyrrolo[2,1-*b*]selenazole and pyrrolo[2,1-*b*]tellurazole.¹⁸⁶

$X = \text{S}, \text{Se}, \text{Te}$; $Y = \text{S}, \text{Se}, \text{Te}$.

A direct reaction of elemental phosphorus with the acetylenide ions generated from acetylenes under the action of a strong base served as the basis of a new convenient approach to the formation of the $\text{C}_{\text{sp}}-\text{P}$ bond and the synthesis of acetylenic phosphines **46** and **47**, the promising monomers, reagents, intermediates and ligands for the production of effective metal-complex catalysts, which were difficult to synthesise.^{187, 188, 190}

$R^1 = \text{Alk}, \text{Ph}$; $R^2 = \text{Alk}$; $M = \text{Li}, \text{Na}$; $X = \text{Br}, \text{Cl}$.

A new direction in the organic and organometallic chemistry has been developed. This concerns the low-temperature reactions of carbanions derived from alkynes and allenes with isothiocyanates.^{7, 189, 191, 192} Based on these reactions, new convenient approaches to the synthesis of fundamental heterocyclic systems, namely, derivatives of pyrrole, pyridine, quinoline and thiophene, were developed.^{189, 191–204} Thus the copper salt-catalysed cyclisation of azatrienes **48** produced 1-alkyl-3-methoxy-2-methylthiopyrroles **49** and their isomers, 2,3-dihydropyridines **50** in the total yield of 80%.

Azatrienes **48** are easily formed from 1-lithio-1-methoxyallene (**51**) and alkyl thiocyanates **52**.^{189, 191–193, 203}

$R^1, R^2 = \text{Alk.}$

V. New reactions involving pyrrole

The systematic elaboration of acetylene reactions with ketoximes (the Trofimov reaction) made accessible a virtually unlimited series of substituted pyrroles, which served as a new impetus for further development of the chemistry of pyrrole compounds.^{7, 30, 32–34, 37, 39–46, 129, 205–208} Although the discussion of pyrroles is beyond the frames of this review, we, nonetheless, decided to discuss several new reactions involving these compounds.

1. Ambident pyrrole anions in the synthesis of alkyl pyrrole-2-dithiocarboxylates

A method was developed for the synthesis of alkyl pyrrole-2-dithiocarboxylates **53** by the pyrrole reaction with carbon disulfide and alkyl halides at room temperature in the superbasic system KOH–DMSO.^{209–211}

$R^1 = \text{Me, Ph; } R^2 = \text{H, Me; } R^1 - R^2 = (\text{CH}_2)_4;$
 $R^3 = \text{Et, Bu, CH}_2=\text{CHCH}_2.$

In the presence of substituents in both α -positions of the pyrrole ring, pyrrole-3-carbodithioates **54a–g** are exclusively formed in yields of 36%–61%.²¹²

Compound	R^1	R^2	R^3
54a	Me	H	Et
54b	Me	Me	Et
54c		$(\text{CH}_2)_4$	Et
54d		$(\text{CH}_2)_4$	Bu
54e	Ph	H	Et
54f	2-furyl	H	Et
54g	2-thienyl	H	Et

2. Synthesis of functional 2- and 3-vinylpyrroles

A simple, general and reliable approach to the synthesis of 2-(**55**) and 3-(1-alkylthio-2-cyanovinyl)pyrroles (**56**) has been found, which is based on the reaction of pyrrole-2- (**53**) and pyrrole-3-carbodithioates (**54**) with nitriles containing an active methylene function (with malononitrile and cyanoacetamide) followed by alkylation of the intermediate thiolate.^{39, 40, 213–216}

$R^1 = \text{Me, Ph; } R^2 = \text{H, Me; } R^1 - R^2 = (\text{CH}_2)_4;$
 $R^3, R^4 = \text{Alk; } X = \text{CN, CONH}_2.$

$R^1 = \text{Me, Ph, 2-furyl, 2-thienyl; } R^2 = \text{H, Me; } R^1 - R^2 = (\text{CH}_2)_4;$
 $R^3, R^4 = \text{Alk; } X = \text{CN, CONH}_2.$

3. Cyclisation of functionally substituted 2-vinylpyrroles to 3H-pyrrolizin-3-ones and 3H-iminopyrrolizines

On heating (55–100 °C) in the system KOH–DMSO, the functionally substituted 2-vinylpyrroles **57** undergo intramolecular cyclisation to form earlier unknown 3H-pyrrolizin-3-ones **58**.^{217, 218}

$R^1 = \text{Ph, } R^2 = \text{H; } R^1 - R^2 = (\text{CH}_2)_4; R^3 = \text{Alk; } X = \text{CN, COMe, CO}_2\text{Et.}$

By the example of 2-[(alkylthio)cyanovinyl]pyrroles **55**, it was shown that cyclisation in the system $\text{Et}_3\text{N} - \text{MeOH}$ leads to 3H-iminopyrrolizines **59**.^{218, 219}

$R^1 = \text{Ph, } R^2 = \text{H; } R^1 - R^2 = (\text{CH}_2)_4; R^3 = \text{Alk; } X = \text{CN, CONH}_2.$

4. Nucleophilic substitution of an amino group for the alkylthio group in 3H-pyrrolizin-3-ones

Under mild conditions (20–25 °C, 15 min), 3H-pyrrolizin-3-ones **58** react quickly and quantitatively with secondary amines to form aminopyrrolizin-3-ones.²¹⁸

$R^1 = \text{Ph}$, $R^2 = \text{H}$; $R^1 - R^2 = (\text{CH}_2)_4$; $R^3 - R^5 = \text{Alk}$;
 $X = \text{CN}$, CONH_2 , CO_2Et .

A similar exchange was observed for 3-imino-4,5,6,7-tetrahydrocyclohexa[*c*]-3*H*-pyrrolizines.^{219–222}

5. Enols of the pyrrole series

On treatment with NaOH, the alkylthio group in 2-[(alkylthio)cyanovinyl]pyrroles **55** is easily (40–45 °C, 1 h) displaced by a hydroxide ion to form stable enols, namely, 2-(1-hydroxy-2-cyanovinyl)pyrroles **60** in the yield of up to 90%.²²³

$R^1 = \text{Me}$, Ph ; $R^2 = \text{H}$, Me ; $R^1 - R^2 = (\text{CH}_2)_4$; $R^3 = \text{Alk}$;
 $X = \text{CN}$, CONH_2 .

This reaction opened up a new way to the new class of stable enols with pyrrole substituents, which are the promising subjects for studying the fundamental problems of reactivity, the theory of chemical bonds, the electron transfer in conjugated systems, the hydrogen bond and tautomerism. The synthesised enols are also highly reactive building blocks for targeted synthesis of new medicinal drugs and materials.

On heating, enols **61** are rearranged into 3-isomers **62**. This is the first example of the migration of a functional substituent from the α - to β -position in the pyrrole ring.²²⁴

$R^1 = R^2 = \text{H}$; $R^1 - R^2 = (\text{CH}_2)_4$.

Obviously, the easy migration of the enol fragment is due to the enhanced acidity of the hydroxyl function (the effect of two strong electron-withdrawing CN groups in the conjugated

system) and the sensitivity of the pyrrole ring with respect to protonation.²²⁴

6. 2-Arylazo-1-vinylpyrroles

To extend the synthetic potential of 1-vinylpyrroles and assess the relative reactivity of the vinyl group and the pyrrole ring with respect to different cations, the reaction of 1-vinylpyrroles with aryldiazonium salts was studied. The use of this reaction made possible a highly efficient synthesis of 2-arylazo-1-vinylpyrroles **63**,^{225,226} which are promising compounds for the development of electrochromic devices, optical switches and materials for non-linear optics.

$R^1 = \text{H}$; $R^2 = \text{H}$, Me , Ph , 4- MeOC_6H_4 , 2-furyl, 2-thienyl;
 $R^1 - R^2 = (\text{CH}_2)_4$; $R^3 = \text{H}$, Br , Me , OEt , NO_2 , 4- $\text{N}_2\text{C}_6\text{H}_4$.

Based on 2-arylazo-1-vinylpyrroles, coloured polymers were synthesised as well as palladium complexes, which are promising catalysts of cross-coupling reactions.²²⁵

7. 1-Vinylpyrrole-2-carbaldehydes

The efficient formylation of *N*-vinylpyrroles was carried out under mild conditions (0–20 °C) according to the modified Vilsmeier–Haack reaction to produce a new, previously unknown class of functional pyrroles, namely, 1-vinylpyrrole-2-carbaldehydes **64**.²²⁷

$R^2 = \text{H}$; $R^1 = \text{Me}$, Ph ; $R^1 - R^2 = (\text{CH}_2)_4$.

The simultaneous presence of two reactive groups (vinyl and aldehyde) in vinylpyrrolecarbaldehydes **64** makes them promising reagents for the fine organic synthesis.²²⁸

VI. The use of acetylenes in the synthesis of phosphines and phosphine chalcogenides

A new approach to the formation of the C–P bond, which was discovered by the example of the reaction of phenylacetylene with elemental phosphorus, has been systematically developed.^{35, 116–119, 229} This approach is based on the use of phosphorus-centred anions generated from elemental phosphorus in heterogeneous superbasic media such as KOH–DMSO or KOH–H₂O–organic solvent–phase-transfer catalyst. These studies allowed the commercially manufactured electrophiles to be directly phosphorylated with elemental phosphorus (or with a phosphine generated from phosphorus) and also the highly efficient syntheses of phosphines and phosphine chalcogenides.^{230–240} The thus obtained primary and secondary phosphines and phosphine chalcogenides are the promising PH-addends for the addition to multiple bonds.

1. Nucleophilic addition of primary and secondary phosphines to acetylenes

Superbases proved to be good catalysts for the vinylation of phosphines under the action of aryl- and hetarylacetylenes.

At 60 °C and atmospheric pressure, the reaction is stereo-selective to afford *Z,Z,Z*-isomers of tristyrylphosphine (**26**) and its analogues **65a–d** in the yields of up to 80%.^{36, 117, 119, 240–243}

R = Ph (**26**), 4-FC₆H₄ (**65a**), 2-Py (**65b**), 2-furyl (**65c**), 2-thienyl (**65d**).

Primary alkyl- and arylphosphines add to phenylacetylene in the system KOH–DMSO (60 °C, 1–4 h) to form *Z,Z*-isomers of distyrylphosphines **66**.²⁴⁴

R = n-C₆H₁₃, Ph(CH₂)₂, PhCH(Me)CH₂.

An activated alkyne [cyano(phenyl)acetylene] reacts with alkylphosphines under mild conditions (KOH–dioxane, 20–22 °C) to form either secondary (compound **67**) or tertiary (compounds **68**) phosphines in the *Z*-configuration (yield 70%–91%) depending on the reactant ratio.²⁴⁵

R = Alk.

It was experimentally proved (based on the EPR and UV spectroscopic data) that the reaction proceeds through a single-electron transfer.²⁴⁵

Secondary phosphines readily react with cyano(phenyl)acetylene in the absence of catalysts to form monoadducts **69** preferentially in the *Z*-configuration.²⁴⁶ According to the results of EPR and UV spectroscopic studies, this reaction also involves the single-electron transfer stage.²⁴⁶

R = Ph(CH₂)₂, PhCH(Me)CH₂.

Based on the reaction of secondary phosphines with 4-hydroxy-4-methylpent-2-ynonitrile, a convenient, efficient and stereo-controlled method for the synthesis of functionally substituted tertiary phosphines **70** containing hydroxyl and nitrile groups has been developed.^{245, 247}

R = Bu, Ph(CH₂)₂, 2-Py(CH₂)₂.

2. Nucleophilic addition of primary and secondary phosphine chalcogenides to acetylenes

Secondary phosphine oxides **71** [X = O, R¹ = Ph(CH₂)₂], **72** (X = O, R¹ = Ph) and phosphine sulfides **73** [X = S, R¹ = Ph(CH₂)₂] react virtually quantitatively with methylacetylene (**74**) (R² = H, R³ = Me)²⁴⁸ and cyano(phenyl)acetylene (**75**) (R² = Ph, R³ = CN)²⁴⁹ in the presence of superbases KOH–DMSO (Ref. 248) or KOH–THF (Ref. 249) to form phosphine oxides **76**, **77** and phosphine sulfide **78** containing chiral carbon centres.

Compound	X	R ¹	R ²	R ³
76	O	Ph(CH ₂) ₂	H	Me
77	O	Ph	Ph	CN
78	S	Ph(CH ₂) ₂	Ph	CN

Compounds **76–78** are the promising intermediates for the synthesis of optically active phosphine ligands, which are widely used in the catalytic stereospecific synthesis.

VII. Acetylene derivatives of silicon and germanium

M G Voronkov and co-workers have developed the synthetic approaches to macrocyclic silaalkynes^{250–273} and silicon-and-chalcogen-containing heterocyclic compounds.^{274–277}

1. Synthesis of acetylene- and silicon-containing macrocycles

Based on the condensation reaction of the bromomagnesio derivatives of dimethyldiethynyl- and methyl(vinyl)diethynylsilane, bis(dimethylethynylsilyl)ethyne, dimethylbis(dimethylethynylsilyl)ethynylsilane, *etc.* with dialkyl-, ethyl(methyl)-, methyl(trimethylsilyl)ethynyl- and methyl(2-trimethylsilylvinyl)dichlorosilanes, a general method of synthesis of methyl-organylcyclosilaalkynes **79–84** ($\text{MeRSiC}\equiv\text{C}$)_{*n*} (*n* = 4–8) containing exocyclic substituents (*R* = H, Me, Et, $\text{CH}_2=\text{CH}$, $\text{Me}_3\text{SiC}\equiv\text{C}$, $\text{Me}_3\text{SiCH}=\text{CH}$) was developed.^{257–259, 261, 263}

12-Membered cyclosilaethyne **85** of the propellane type was synthesised by the reaction of 1,1-bis(bromomagnesioethynyl)silacyclopentane with 1,1-dichlorosilacyclopentane.²⁶⁵

Spiromacrocylic polysilaalkynes **86** and **87** were synthesised by the condensation of bromomagnesio derivatives of dialkylbis(dimethylethynylsilyl)ethynylsilane with silicon tetrachloride.²⁶⁴

R = Me (**86**), Et (**87**).

The (*E*)-1,2-bis(bromomagnesioethynyldimethylsilyl)ethene reaction with 1,2-bis(methyldichlorosilyl)ethane produced an unusual macrobiocyclic compound **88**, which contained both unsaturated and saturated endocyclic groups ($\text{SiC}\equiv\text{CSi}$, $\text{SiCH}=\text{CHSi}$, $\text{SiCH}_2\text{CH}_2\text{Si}$).²⁷⁰

2. New five-membered silicon-and-chalcogen-containing heterocycles

New unsaturated heterocycles of the fulvene (compounds **89–91**) or cyclopentene (compound **92**) types, which contain silicon, selenium and tellurium atoms, were synthesised from dimethyldiethynylsilane and selenium and tellurium tetrahalides under mild conditions (20–25 °C, CHCl_3) in good or moderate yields.^{274–277}

3. Silicon- and germanium-containing acetylene aldehydes

The reactivity of 3-(trimethylsilyl)- (**93**, *X* = Me_3Si) and 3-(triethylgermyl)prop-2-ynals (**94**, *X* = Et_3Ge), which are easily prepared by the oxidation of the corresponding 3-trimethylsilyl- and 3-(triethylgermyl)prop-2-ynols^{278–285} with the activated system MnO_2 – SiO_2 ²⁸⁶ or pyridinium chlorochromate²⁸⁷ under microwave radiation in the absence of a solvent, was studied. Being ambident 1,3-biselectrophiles, propynals **93** and **94** react with nucleophiles chemoselectively involving the triple bond, the carbonyl group or both reaction centres.^{288–298}

By the example of secondary phosphine chalcogenides, it was shown that the chemoselective addition of P-centred nucleophiles to the carbonyl groups in propynals **93** and **94** can efficiently proceed under mild conditions (10–50 °C, THF, without catalyst) to afford earlier unknown multifunctional chiral tertiary phosphine chalcogenides **95–101** containing ethynyl and hydroxyl functions.^{290, 296}

Compound	X	Y	R	Compound	X	Y	R
95	SiMe_3	O	Ph	99	GeEt_3	O	Ph
96	SiMe_3	O	2-Py	100	GeEt_3	S	Ph
97	SiMe_3	S	Ph	101	GeEt_3	Se	Ph
98	SiMe_3	Se	Ph				

The reactions of propynals **93** and **94** with ethylenediamine and 1*H*-1,2,4-triazol-3-ylamine to afford the corresponding

X = Me_3Si (**93**, **102**, **104**), Et_3Ge (**94**, **103**, **105**).

bis(azomethines) **102**, **103** and triazolylaldimines **104**, **105** also involve the carbonyl group.²⁹⁷

Azomethines **106**, **107** and their cyclisation products, namely, 1,3-thiazolidines **108**, **109**, were prepared from propynals **93**, **94** and 2-aminoethanethiol.²⁹⁷

X = Me₃Si (**93**, **106**, **108**), Et₃Ge (**94**, **107**, **109**).

Under microwave radiation (420 W, 12 min), the reaction can be directed to the exclusive formation of heterocycles **108**, **109**.²⁹⁷

By the example of the same propynals, the possibility of using acetylenic aldehydes in the Biginelli reaction was demonstrated. Thus, on refluxing with urea and ethyl acetoacetate in methanol in the presence of HCl (5 mol %), polyfunctional tetrahydropyrimidines **110** and **111** were obtained in high yields.²⁹⁸

X = Me₃Si (**93**, **110**), Et₃Ge (**94**, **111**).

The use of LiClO₄ (20 mol %) instead of HCl led to the selective formation of the Knoevenagel adducts, *i.e.*, ethyl 2-acetyl-5-(trimethylsilyl)- and ethyl 2-acetyl-5-(triethylgermyl)pent-2-en-4-ynoates.²⁹⁸

Under the conditions of the Baylis–Hillman reaction (TiCl₄, Me₂S), propynals **93** and **94** react with 1-phenylprop-2-yn-1-one to form 3-hydroxy-1-phenyl-2-[(*Z,E*)-chloromethylidene]-5-X-pent-4-yn-1-ones **112**, **113**.²⁸⁹

X = Me₃Si (**93**, **112**), Et₃Ge (**94**, **113**).

Regiospecific 1,3-dipolar cycloaddition of trimethylsilyl azide involves the triple bond of propynal **93** and produces 4-trimethylsilyl-1*H*-1,2,3-triazole-5-carbaldehyde (**114**).²⁹²

By the example of propynal **93**, unusual cascade assembling of new multifunctional heterocyclic compounds were developed. Thus under microwave radiation, the propynal **93** reacts with 2-aminopyridine in the system Bu^tOH–H₂O–4-MeC₆H₄SO₃H (5 mol %) to produce *N*-(2-pyridinyl)-2-(trimethoxyylethynyl)-1,2-dihydropyridine-3,5-dicarbaldehyde (**115**) in the yield of 75%.²⁹³ In the presence of a basic catalyst [5 mol % of diazabicyclooctane (DABCO)] and trace amounts of water, propynal **93** is quantitatively trimerised to 4-trimethylsilylethynyl-4*H*-pyran-3,5-dicarbaldehyde (**116**).²⁹⁵

VIII. New acetylene-based technologies

New modifications of classical acetylene reactions made it possible to develop simple and commercially feasible methods of the synthesis of unique monomers and intermediates that were implemented in laboratory and in pilot plants.³³ As a result, commercially feasible technologies were developed for the synthesis of pentaerythritol tetravinyl ether (**9**),^{33, 299–301} ethylene glycol glycidyl vinyl ether (**117**) ('Vinylux'),^{53, 302, 303} 2-vinylxyethyl methacrylate (**118**),^{33, 304, 305} potassium (sodium) *N*-[2-(vinylxy)ethyl]dithiocarbamate (biocide 'Vinditat') (**119**),^{33, 306} divinyl sulfide (**120**),^{29, 111, 307} divinyl sulfide (**121**),^{308, 309} tetrahydroindole (**122**) and *N*-vinyltetrahydroindole (**123**).^{30, 32, 310, 311}

New effective methods were developed for the preparation of certain other valuable monomers and intermediates, namely, methyl vinyl and ethyl vinyl ethers,^{312–314} propargyl alcohol,^{99, 315} *N*-vinylcarbazole,^{33, 316, 317} 3-methylbut-1-yn-3-ol,^{318, 319} 1-ethynylcyclohexanol,³¹⁹ dehydrolinalool^{33, 320} and other acetylenic alcohols and their derivatives.⁴³

Based on the developed technologies, ethylene glycol monovinyl ether (2-vinylxyethanol),^{28, 33} 2-methyl-1,3-dioxolane divinyl ether,^{28, 33, 43} diethylene glycol^{28, 33, 160} and ethanolamine vinyl ether (2-vinylxyethylamine)^{314, 321} were produced on a pilot scale ('Karbid', Temirtau).

IX. Conclusion

In this review, the progress in the studies on several classical acetylene reactions in the past 10–15 is surveyed, although it is evident that certain new modifications of these reactions rely on the achievements of earlier decades. From this review, it is evident that the interest in many directions developed by the Favorsky school is quickened. First of all, this concerns the field of base-catalysed reactions of vinylation, ethynylation and prototropic migration of a triple bond through the allene and diene structures. The systematic use of superbasic catalysts and the development of a concept of superbasicity made it possible to develop new, in principle, versions of the classical Favorsky reactions and convert them into more efficient and practically feasible synthetic methods. New processes that employ acetylene at the atmospheric or reduced pressure were carried out on the experimental and commercial scales (the vinylation of alcohols, glycols, glycerol, pentaerythritol, carbazole and ethanolamines; the preparation of divinyl sulfide; the synthesis of acetaldehyde *via* vinyl ethers).⁴³

Together with the development of classical reactions, new base-catalysed reactions of acetylene, which are genetically linked to their classical prototypes, were discovered. These are the vinylation of sulfur, selenium, tellurium and phosphorus, the hydrative trimerisation of acetylene (vinylation of water), the synthesis of pyrroles and *N*-vinylpyrroles from ketones and acetylene *via* ketoximes, *etc.*⁴³ These reactions substantially extend the synthetic potential of acetylene.

Methods for the synthesis of macrocyclic silaalkynes that utilise the corresponding sodium and bromomagnesium derivatives of acetylene (the Iotsich complexes) were developed. Based on bis(ethynylsilanes), new unsaturated heterocyclic compounds that contain silicon and chalcogen atoms in their rings were prepared. Chemistry of silicon and germanium-containing acetylenic aldehydes has been developed further.

Some of these directions have a considerable effect on the development of the chemistry of acetylene all over the world, although, naturally, hardly embrace the whole vast field of chemistry of compounds with triple carbon–carbon bonds. The best studies carried out within the scope listed above are actively cited and many research groups successfully explore these directions.

The studies on the modification of classical acetylene reactions are in progress. In addition to superbases (KOBu^t) conventionally used in the synthesis of acetylenic alcohols (*e.g.*, from ferrocenylacetylene³²²), the current attention is focused on the alkynol synthesis (the addition of acetylenes to the C=O bond) in the presence of either metal complexes particularly those with chiral ligands (the asymmetric version of the Favorsky reaction),^{323–326} or zinc salts and organozinc compounds,³²⁷ triphenylphosphine,³²⁸ organic catalysts.³²⁹ The recently published review³³⁰ is devoted to alkynylation of chiral aldehydes (including those with alkoxy, amino and thio groups) under the action of metal acetylides.

The addition of amines to a triple bond successfully employs the catalysis with metal complexes.^{331–336} Recently, the addition of hydroselenides and diselenides to acetylenes in the presence of InBr₃ was accomplished.³³⁷

Superbases (KOH–DMSO,³³⁸ KOBu^t–THF,³³⁹ KOH–THF³⁴⁰) are successfully used in the synthesis of amides of the allene series and the corresponding propargyl compounds. The base-catalysed acetylene–allene isomerisation (acetylene ‘zipper’), which employs lithium 2-aminoethylamide, is the easy way for the synthesis of 1,3-alkadiynes and their internal isomers.³⁴¹

It should be stressed that the metal-complex catalysis now becomes the main trend in the modification of classical acetylene reactions and opens up new horizons in the tradi-

tional chemistry of acetylene;³⁴² however, its discussion is beyond the scope of this review.

The popularity of chemistry of acetylene increases, which is associated with the progressive extension of the use of acetylenic compounds in the organic synthesis, particularly, in the synthesis of medicinal drugs (*e.g.*, enediyne antibiotics),³⁴³ optoelectronic materials,^{344–346} molecular machines and other nanostructured objects,^{27, 347} including porphyrins with acetylene bonds.

The authors hope that this review will help a wide circle of chemists and technologists in solving the topical problems of the organic synthesis and modern technologies based on the use of acetylene and its derivatives.

VI. Conclusion	547

Abstract. The state-of-the-art and prospects of the development of chemistry of chalcogenide clusters of Group 5–7 metals of the Periodic Table are discussed. The main structural types, methods of synthesis, the reactivity and possible applications of vanadium, niobium, tantalum, chromium, molybdenum, tungsten and rhenium chalcogenide clusters with nuclearity of three and larger are considered. The bibliography includes 363 references.

I. Introduction

The achievements of chemistry in the second half of the 20th century are mostly associated with the foundation of basics of cluster chemistry. In 1964, F Cotton introduced the term ‘cluster’ for compounds the molecules of which contain a core of metal atoms linked by metal–metal bonds.¹ The development of cluster chemistry was a revolutionary step in coordination chemistry.² The complexes in which metal clusters are coordinated by chalcogenide or polychalcogenide ligands occupy a special place among numerous types of cluster compounds. Chalcogenide clusters are a typical example of so-called inorganic or high-valence clusters and are most characteristic of 4d- and 5d-metals of Groups 5–7. The present review discusses methods of synthesis, structures and properties of sulfide, selenide and telluride cluster compounds of vanadium, niobium, tantalum, chromium, molybdenum, tungsten and rhenium. The review includes only the metal clusters with nuclearity equal, to or larger than, three.

The present review is dedicated to the 50th anniversary of the A V Nikolaev Institute of Inorganic Chemistry, Siberian Branch of the Russian Academy of Sciences (NIIC) and it is

not a coincidence: from the date of its foundation and up to now systematic studies of chalcogenide clusters of transition metals have been carried out in the Institute and several new key types of chalcogenide clusters have been discovered here. In the mid-1960s, trinuclear molybdenum complexes $\text{Mo}_3\text{Q}_7\text{X}_4$ ($\text{Q} = \text{S}, \text{Se}; \text{X} = \text{Cl}, \text{Br}, \text{I}$)^{3,4} were synthesised in NIIC, which became a beginning of massive studies of triangular chalcogenide clusters. At the same time lower molybdenum chalcogenides of the Mo_6Q_8 ($\text{Q} = \text{Se}, \text{Te}$) type have been found,^{5,6} which turned out to be predecessors of a group of numerous closely related ternary cluster compounds later called the Chevrel phases (these compounds were also intensively studied because of their properties as superconductors).⁷ The studies of hexa- and tetranuclear rhenium clusters $\text{Re}_6\text{Te}_{15}$,⁸ $\text{Re}_6\text{Q}_4\text{X}_{10}$,⁹ $\text{Re}_4\text{Q}_4(\text{TeX}_2)_4\text{X}_8$ (Ref. 10) and chalcocyanide complexes $[\text{Re}_6\text{Q}_8(\text{CN})_6]^{4-}$ (Ref. 11) and $[\text{Re}_4\text{Q}_4(\text{CN})_{12}]^{4-}$ (Ref. 12) should be noted among the pioneering investigations of NIIC. Recently, new types of square vanadium and tantalum clusters $\text{V}_4\text{S}_9\text{Br}_4$ (Ref. 13) and $\text{Ta}_4\text{Q}_9\text{X}_8$ ($\text{Q} = \text{S}, \text{Se}; \text{X} = \text{Br}, \text{I}$)¹⁴ were discovered in NIIC and the unique 12-nuclear rhenium clusters $[\text{Re}_{12}\text{CS}_{17}(\text{CN})_6]^{8-/6-}$ (Ref. 15) containing an interstitial carbon atom were synthesised.

Chalcogenide clusters of Group 5–7 transition metals are typically obtained by high-temperature synthesis. Such clusters usually possess polymeric structures and therefore they are insoluble, low-reactive and their chemical properties could not be studied for a long period. The breakthrough in this area occurred after the discovery¹⁶ of synthetic methods of transformation of polymeric cluster complexes into soluble molecular complexes by introduction of new ligands. In addition, the substitution of atoms of the cluster core was performed, including preparation of heterometallic clusters. Inorganic ligands (SSe^{2-} , STe^{2-} , TeCl_2 , TeBr_2 , TeI_2 , Te_6), previously unknown in coordination chemistry were discovered. Most of the studies of tellurium containing cluster complexes were also performed in NIIC.^{11, 17–20}

In the present review we summarise the forty years of development of chemistry of chalcogenide clusters of early transition metals. A particular attention is paid to the new advances in chemistry of this class of compounds that emerged during the last years and to the prospects of development of basic studies and practical applications of these compounds.

II. Main structural types of chalcogenide clusters

1. Triangular clusters with the cluster core M_3Q_4

The cluster core $M_3(\mu_3-Q)(\mu_2-Q)_3$ contains a triangular metal cluster M_3 , which coordinates four chalcogenide ligands Q (one μ_3-Q and three μ_2-Q). Cluster complexes with the core M_3Q_4 are most typical of molybdenum, tungsten and rhenium, while for Group 5 metals (V, Nb, Ta) such complexes are uncommon and are represented only by sulfide clusters of vanadium $[V_3S_4(edt)_3]^{3-}$ (H_2edt is ethane-1,2-dithiol)²¹ and niobium $[Nb_3SO_3(NCS)_9]^{6-}$ (Ref. 22). Numerous examples of sulfide and selenide clusters of molybdenum and tungsten are known, but so far only one telluride cluster, $\{Mo_3Te_4[(Pr^iO)_2PS_2]_3(\mu-o-NH_2C_6H_4CO_2)(PBu_3^t)\}$, has been described.²³

Metal ions in triangular clusters with the number of valence electrons available for metal–metal bond formation (N_e) equal to 6 (*i.e.*, there are three two-electron bonds) possess d^2 electron configuration. Accordingly, the charge of the cluster core $M_3Q_4^{n+}$ is determined by the position of the metal in the Periodic Table: for V and Nb, $n = 1$, for Mo and W $n = 4$, for Re, $n = 7$. The $M-M$ metal bond lengths correspond to those of single bonds. Besides, in the case of monodentate ligands each metal atom coordinates three ligands. Anionic complexes with single-charged anionic ligands $[M_3Q_4L_9]^{5-}$, where L is cyanide,²⁴ thiocyanate,^{25–29} formate,³⁰ *etc.*, are typical examples of such clusters. There are two types of ligands L in such complexes: *cis*- and *trans*-oriented relative to the μ_3-Q ligand. The well-known aqua complexes of molybdenum and tungsten $[M_3Q_4(H_2O)_9]^{4+}$ ($M = Mo, W; Q = S, Se$) (Fig. 1)^{25, 31, 32} are examples of cluster complexes with neutral ligands.

The cluster complexes $[Mo_3S_4(C_2O_4)_3(H_2O)_3]^{2-}$ contain simultaneously both bidentate ($C_2O_4^{2-}$) and monodentate (H_2O) ligands; the monodentate ligands in these complexes occupy only *trans*-positions relative to μ_3-Q (Fig. 2).^{33–35} The complexes with chelating O-, N-, P- and S-donor ligands are most abundant among triangular cluster compounds. The complexes with oxalate,^{33–35} iminodiacetate,³⁶ nitrilotriacetate,^{25, 37, 38} triethylenetetraaminohexaacetate³⁹ and other ligands belong to this class. A number of complexes with

Figure 1. Structure of the complex $[Mo_3(\mu_3-S)(\mu_2-S)_3(H_2O)_9]^{4+}$.

Figure 2. Structure of the complex $[Mo_3S_4(C_2O_4)_3(H_2O)_3]^{2-}$.

Figure 3. Structure of the complex $[Re_3S_4Cl_6(PEt_3)_3]^-$.

phosphine ligands are also known. Usually the bulky monodentate phosphine ligands occupy *trans*-positions relative to the chalcogenide μ_3 -ligand as, for instance, in $(HPEt_3)_3[Re_3S_4Cl_6(PEt_3)_3]^{40}$ (Fig. 3). In contrast to oxalate complexes, one phosphorus atom in complexes with bidentate phosphine ligands is in *trans*-position and another in *cis*-position relative to the chalcogenide μ_3 -ligand. This results in the chirality of the cluster cations formed $[M_3S_4X_3(dmpe)_3]^+$ and $[M_3S_4X_3(dppe)_3]^+$ [$M = Mo, W; X = Cl, Br$; $dmpe$ is 1,2-bis(dimethylphosphino)ethane, $dppe$ is 1,2-bis(diphenylphosphino)ethane] (Fig. 4).^{18, 41}

Figure 4. Structure of the complex $[W_3S_4Cl_3(dppe)_3]^+$ (the phenyl groups are omitted).

The $Mo-Mo$ bond lengths (2.807 Å) in the cluster $Mo_3S_4^{3+}$ of the paramagnetic reduced electron-rich complex $[Mo_3S_4Cl_3(dppe)_2(PEt_3)]$ ($N_e = 7$) are slightly longer than those in its phosphine analogues with the cluster core $Mo_3S_4^{4+}$ (2.776 Å).^{42, 43}

There is also a significant number of compounds with S-donor ligands, including dithiophosphate, dithiolate, dithiophosphate and dithiocarbamate complexes.¹⁸ The tetrasulfide ligand in compound $(NH_4)_2[W_3S_4(S_4)(NH_3)_3] \cdot H_2O$ is bidentate and an ammonia molecule is also coordinated to the tungsten atom (Fig. 5).⁴⁴

2. Triangular clusters with the cluster core M_3Q_7

This structural type is most typical of molybdenum and tungsten compounds; here the metal cluster M_3 coordinates one chalcogenide μ_3 -ligand and three dichalcogenide μ_2 -ligands $M_3(\mu_3-Q)(\mu_2-Q)_3$ (Fig. 6).

Bidentate bridged dichalcogenide ligands asymmetrically coordinate metal–metal bonds according to the $\mu_2-\eta^2:\eta^2$ -mode, which results in structural and chemical non-equivalence of the chalcogen atoms of these ligands. Thus, the distances $Mo-S_{eq}$ and $Mo-S_{ax}$ complex $(Ph_4P)_2[Mo_3S_7Cl_6]$ are equal to 2.485 and 2.391 Å, respectively.⁴⁵ The bond force

Figure 5. Structure of the complex $[\text{W}_3\text{S}_4(\text{S}_4)_3(\text{NH}_3)_3]^{2-}$.

Figure 6. Structure of the complex $[\text{Mo}_3(\mu_3\text{-S})(\mu_2\text{-S}_2)_3\text{Cl}_6]^{2-}$.

constant of the $\text{Mo}-\text{S}_{\text{eq}}$ bond is also smaller⁴⁶ and the equatorial sulfur atoms are quite labile in chalcogen substitution and elimination reactions.^{44, 47–49} This makes possible their selective substitution by selenium atoms resulting in the formation of the cluster core $\text{Mo}_3(\mu_3\text{-S})(\mu_2\text{-SSe})_3$.⁴⁷ Another feature of the M_3Q_7 core is its predisposition to the formation of specific non-valence interactions of the $\text{M}_3\text{Q}_7\cdots\text{Y}$ type with short contacts between axial chalcogen atoms and atom Y (Y may be a halide or chalcogenide ion). These interactions may be described as electrostatic or as a charge transfer from $\mu_3\text{-Y}$ to the σ^* -orbital of the dichalcogenide ligand Y_2^{2-} (Ref. 50).

For the first time, compounds with the core M_3Q_7 were synthesised as polymeric chalcogenides $\text{Mo}_3\text{Q}_7\text{X}_4$ (Q = S, Se; X = Cl, Br, I).^{3, 4} The cluster cores M_3Q_7 in these compounds are linked together into infinite zigzag chains by bridging halogen atoms (Fig. 7). A number of complexes containing anions $[\text{M}_3\text{Q}_7\text{X}_6]^{2-}$ (M = Mo, W; Q = S, Se; X = Cl, Br, I, NCS) is known nowadays.¹⁸ However, there are very few complexes with N-donor ligands. Complexes with aniline $[\text{Mo}_3\text{S}_7\text{Br}_3(\text{PhNH}_2)_3]^+$,⁵¹ pyridine,⁵² 1,10-phenanthroline $[\text{M}_3\text{Se}_7(\text{phen})_3]^{4+}$ (Ref. 53) and ethylenediamine⁵⁴ were synthesised. On the contrary, the cluster compounds in which the

Figure 7. Structure of the polymer $\text{Mo}_3\text{S}_7\text{Cl}_4$.

cores M_3Q_7 coordinate S-donor ligands are fairly numerous and include complexes with various thio-ligands: polysulfide $[\text{Mo}_3\text{S}_7(\text{S}_2)_3]^{2-}$, dithiophosphate $[\text{Mo}_3\text{S}_7(\text{dtp})_3]^+$, dithiocarbamate $[\text{M}_3\text{Se}_7(\text{dte})_3]^+$, dithiophosphinate $[\text{Mo}_3\text{S}_7(\text{R}_2\text{PS}_2)_3]^+$ (R = Et, Prⁿ, Buⁿ) and other.^{55–58}

Triangular clusters of molybdenum and tungsten with the core M_3Q_7 are well studied; similar complexes of vanadium and rhenium are also known. The metal–metal bond lengths in $[\text{V}_3^{\text{III}}\text{S}_7(\text{bipy})_3]\text{PF}_6$ (Fig. 8) are equal to 2.75–2.78 Å;⁵⁹ the cluster fragment $\text{V}_3\text{S}_7^{2+}$ corresponding to the oxidised form is found in $(\text{Et}_4\text{N})[\text{V}_3\text{S}_7(\text{Me}_2\text{NCS}_2)_3]$, where the V–V distances are slightly shorter (2.74–2.75 Å).⁶⁰

Figure 8. Structure of the complex $[\text{V}_3(\mu_3\text{-S})(\mu_2\text{-S}_2)_3(\text{bipy})_3]^+$.

A series of isostructural rhenium complexes $\text{Re}_3\text{Q}_7\text{X}_4$ (Q = S, Se; X = Cl, Br, I) were synthesised.^{61–63} In these compounds, the cluster core $\text{Re}_3\text{Q}_7^{7+}$ is isoelectronic to that of $\text{Mo}_3\text{Q}_7^{4+}$, but the distance $\text{Re}-\text{Re}$ in $\text{Re}_3\text{S}_7\text{Cl}_4$ (2.698 Å) is slightly shorter than the distance $\text{Mo}-\text{Mo}$ in $\text{Mo}_3\text{S}_7\text{Cl}_4$ (2.758 Å) probably because of the difference in atomic radii of Re^{V} and Mo^{IV} .

There are very few telluride complexes M_3Q_7 . The complexes $\text{Mo}_3\text{Te}_{10}\text{I}_{10}$, $[\text{Mo}_3\text{Te}_7(\text{CN})_6]^{2-}$, $[\text{W}_3\text{Te}_7(\text{CN})_6]^{2-}$ and $[\text{Mo}_3\text{Te}_7((\text{EtO})_2\text{PS}_2)_3]\text{I}$ containing the $\text{M}_3(\mu_3\text{-Te})(\mu_2\text{-Te}_2)_3^{4+}$ core were synthesised and their structures were established.^{50, 64–67}

3. Other examples of triangular chalcogenide clusters

There are some mixed chalcogenide compounds among M_3Q_4 clusters.⁶⁸ In the triangular cluster $[\text{Nb}_3(\mu_3\text{-S})(\mu_2\text{-O})_3(\text{NCS})_9]^{6-}$, only the sulfur atom occupies the μ_3 -position.²² Compounds $[\text{M}_3(\mu_3\text{-S})(\mu_2\text{-O})_x(\mu_2\text{-S})_{3-x}(\text{H}_2\text{O})_9]^{4+}$ (M = Mo, W; $x = 1–3$) and $[\text{Mo}_3(\mu_3\text{-Se})(\mu_2\text{-O})_x(\mu_2\text{-Se})_{3-x}(\text{H}_2\text{O})_9]^{4+}$ are also known.^{18, 69–71} Dithiophosphate derivatives of the cluster $\text{Mo}_3(\mu_3\text{-O})(\mu_2\text{-S})_3^{4+}$ were described as well.⁷² Recently the complex $[\text{W}_3(\mu_3\text{-Te})(\mu_2\text{-Se})_3(\text{CN})_9]^{5-}$ has been synthesised.⁶⁷ Mixed-chalcogen clusters M_3Q_7 are more diverse, they include $\text{Mo}_3(\mu_3\text{-O})(\mu_2\text{-S}_2)_3^{4+}$, $\text{Mo}_3(\mu_3\text{-S})(\mu_2\text{-Se}_2)_3^{4+}$, $\text{M}_3(\mu_3\text{-S})(\mu_2\text{-SSe})_3^{4+}$, $\text{M}_3(\mu_3\text{-Se})(\mu_2\text{-SSe})_3^{4+}$ (M = Mo, W), $\text{Mo}_3(\mu_3\text{-S})(\mu_2\text{-Te}_2)_3^{4+}$, $\text{Mo}_3(\mu_3\text{-O})(\mu_2\text{-Te}_2)_3^{4+}$ and $\text{W}_3(\mu_3\text{-Te})(\mu_2\text{-TeSe})_3^{4+}$ (Refs 47, 49, 50, 54, 67, 73 and 74). The substitution of the μ_3 -chalcogen atom by an atom of lighter chalcogen results in significant shortening of metal–metal bonds in the M_3 triangle. This shortening corresponds approximately to the difference in size of the bridged chalcogen atoms. For example, the shortening in dithiophosphate complexes $[\text{Mo}_3\text{Q}(\text{S}_2)_3\{(\text{EtO})_2\text{PS}_2\}_3]\text{X}$

Figure 9. Cluster core in the complex $[\text{Cr}_3(\mu_3\text{-S})_2(\mu_2\text{-S})_3(\text{dmpe})_3]$ (the dmpe ligands are omitted).

($\text{X} = \text{Cl}, \text{I}, \text{I}_3$) is equal to $\sim 0.1 \text{ \AA}$: from 2.723 \AA for $\text{Q} = \text{S}$ to 2.626 \AA for $\text{Q} = \text{O}$.⁷³

Along with most typical triangular clusters M_3Q_4 and M_3Q_7 , a number of other metal chalcogenide clusters are known. The cluster $[\text{Cr}_3(\mu_3\text{-S})_2(\mu_2\text{-S})_3(\text{dmpe})_3]$ contains two μ_3 -bridging chalcogen atoms (Fig. 9).⁷⁵ Similar ‘double-capped’ coordination was also observed in $(\text{Et}_4\text{N})_2[\text{Cr}_3(\mu_3\text{-Se})_2(\text{CO})_{10}]$ and $[\text{Re}_3(\mu_3\text{-S})_2(\mu_2\text{-S})_2(\mu_2\text{-Cl})\text{Cl}_3(\text{PET}_3)_3]$.^{76, 77} An equilateral triangle Nb_3 in compound $[(\eta^5\text{-C}_5\text{EtMe}_4)_3\text{Nb}_3\{\mu_3\text{-BS}_3(\text{SH})\}(\mu_2\text{-S})_3]$ is symmetrically ‘covered’ by the $[\text{BS}_3(\text{SH})]^{4-}$ ligand.⁷⁸ Only two electrons are available for metal–metal bonding in this cluster. Very similar tantalum cluster was found in the compound $[(\eta^5\text{-C}_5\text{EtMe}_4)_3\text{Ta}_3.(\mu_3\text{-BS}_3(\text{H}))(\mu_2\text{-S})_3]$. In this cluster the ‘cap’ is represented by the hydridotriethioborato anion $[\text{BS}_3(\text{H})]^-$.⁷⁹

Polymeric chalcogenides of niobium and tantalum M_3QX_7 contain the cluster core $\text{M}_3(\mu_3\text{-Q})(\mu_2\text{-X})_3^{4+}$.^{80–83} The structure consists of parallel planes containing triangular clusters Nb_3 (the Nb–Nb bond length is 2.776 \AA). The triangles are linked together into a two-dimensional network by bridging halogen atoms (Fig. 10).

Figure 10. Fragment of the polymer Nb_3TeI_7 .

4. Tetrahedral metal clusters with the core M_4Q_4

Each face of the M_4 tetrahedron in tetrahedral clusters with the core $\text{M}_4(\mu_3\text{-Q})_4$ coordinates μ_3 -chalcogen atoms in such a way that the metal and chalcogen atoms form a distorted cubane structure. The cubane clusters are topologically (and often genetically) related to previously discussed clusters of the $\text{M}_3(\mu_3\text{-Q})(\mu_2\text{-Q})_3$ type, which may be regarded as defective cubane clusters (without one metal atom). Such type of cluster compounds is known for all discussed transition metals. Twelve valence electrons ($N_e = 12$) are required for the formation of six two-electron two-centre covalent metal–metal bonds in a tetrahedral cluster M_4 . The stoichiometry of most of the stable complexes with d^3 electronic configuration of metal ions supports this rule. However, there are numerous examples of clusters where this simple model does not work and these compounds are formally electron-deficient.

Figure 11. Structure of the cluster fragment $\text{Re}_4\text{S}_4\text{Te}_{12/3}$ in the compound $\text{Re}_4\text{S}_4\text{Te}_4$.

Polymeric ternary chalcogenides and chalcogenides of the types $\text{M}_4\text{Q}_4\text{X}_4$ ($\text{M} = \text{Nb}, \text{Mo}$; $\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$),^{84–86} $\text{Re}_4\text{S}_4\text{Te}_4$ (Fig. 11)⁸⁷ and MMo_4Q_8 ($\text{M} = \text{Al}, \text{Ga}$)^{88–91} are an abundant group of tetrahedral cluster compounds. All these compounds are isostructural and form spinel-type cubic crystal structures. The cubane cluster groups are linked into a three-dimensional framework by bridging halogen atoms or by excess chalcogen atoms according to the $[\text{M}_4\text{Q}_4\text{X}_{12/3}]_{\infty\infty\infty}$ -type. Interestingly, only sulfur atoms occupy μ_3 -positions in the cluster core of rhenium telluride $\text{Re}_4\text{S}_4\text{Te}_4$. Part of rhenium atoms of this cluster may be replaced by molybdenum atoms, which results in the formation of heterometallic cluster $\text{Re}_{4-x}\text{Mo}_x\text{S}_4\text{Te}_4$ ($0 \leq x \leq 1.25$).⁹² The metal–metal distances in these clusters are correlated with N_e values (Table 1). The electronic and magnetic properties are determined by the successive filling of the d shell.

Table 1. Number of metal–metal bonding valence electrons and the metal–metal distances in tetrahedral metal clusters.

Compound	N_e	M–M bond length / \AA
GaNb_4Se_8	7	3.03
$\text{Nb}_4\text{Se}_4\text{I}_4$	8	2.96
GaMo_4Se_8	11	2.89
$\text{Mo}_4\text{S}_4\text{Br}_4$	12	2.80
$\text{Re}_4\text{S}_4\text{Te}_4$	12	2.78

The rhenium atoms of the cluster core Re_4Q_4 of molecular rhenium chalcogenide complexes $[\text{Re}_4\text{Q}_4(\text{TeX}_2)_4\text{X}_8]$ ($\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{X} = \text{Cl}$ and $\text{Q} = \text{Te}, \text{X} = \text{Br}$; $N_e = 12$) additionally coordinate two halide ligands and the ligand TeX_2 .^{10, 93} The tetrahedral chalcogenide clusters $[(\eta^5\text{-C}_5\text{H}_4\text{R})_4\text{M}_4\text{Q}_4]$ with monosubstituted cyclopentadienyl ligands are known for some metals discussed: V ($\text{Q} = \text{S}, \text{R} = \text{Me}$),⁹⁴ Cr ($\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{R} = \text{Me}$),^{95–100} Mo ($\text{Q} = \text{S}, \text{Se}$; $\text{R} = \text{Pr}^i$).¹⁰¹ The cyclopentadienyl cluster complexes of the Group 5 elements are represented only by vanadium cyclopentadienyl(thio) complexes $[(\eta^5\text{-C}_5\text{H}_4\text{R})_4\text{V}_4\text{S}_4]$ ($\text{R} = \text{H}, \text{Me}$).⁹⁴ The N_e value in neutral complexes is equal to 8 for vanadium and 12 for chromium and molybdenum.

A large number of chalcocyanide cluster complexes $[\text{M}_4\text{Q}_4(\text{CN})_{12}]^{n-}$, where $\text{M} = \text{Mo}, \text{W}, \text{Re}$; $\text{Q} = \text{S}, \text{Se}, \text{Te}$ (Fig. 12) is studied in detail.^{102–107} The cluster core of the complexes $[\text{Re}_4\text{Q}_4(\text{CN})_{12}]^{4-}$ coordinates terminal cyano groups through the carbon atom. The cluster M_4 becomes electron-deficient in the corresponding molybdenum complexes $[\text{Mo}_4\text{Q}_4(\text{CN})_{12}]^{6-}$. The cyano complexes $[\text{M}_4\text{OTe}_4(\text{CN})_{12}]^{6-}$ containing the metal core $\text{M}_4(\mu_4\text{-O})$. $(\mu_3\text{-Te})_4^{5+}$ with an interstitial oxygen atom were obtained for niobium and tantalum.¹⁰⁸ In these clusters, $N_e = 4$, and the M–M distances are significantly longer than those in the

Figure 12. Structure of the complex $[\text{Re}_4\text{Te}_4(\text{CN})_{12}]^{4-}$.

corresponding metals or in the compounds containing single M–M bond.

A series of the complexes $\text{M}_4\text{Q}_4\text{L}_{12}$ with various terminal ligands L such as H_2O ($\text{M} = \text{Mo}, \text{W}$; $\text{Q} = \text{S}, \text{Se}$),^{109–111} Cl ($\text{M} = \text{Re}, \text{Q} = \text{Te}$; $\text{M} = \text{Mo}, \text{Q} = \text{S}$),^{22, 70, 112–119} NCS ($\text{M} = \text{Re}$; $\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{M} = \text{Mo}, \text{Q} = \text{S}$)^{111, 116, 120} are known for the cubane clusters of molybdenum, tungsten and rhenium. Complexes $[\text{Re}_4\text{S}_4(\text{S}_3)_6]^{4-}$ and $[\text{Re}_4\text{Q}_4(\text{S}_3)_4(\text{S}_4)_2]^{4-}$ with polysulfide ligands are known for rhenium.^{121–123} The edges of the tetrahedron Re_4 in the complex $[\text{Re}_4\text{Se}_4(\text{S}_3)_4(\text{S}_4)_2]^{4-}$ coordinate four bidentate polysulfide ligands S_3 and two S_4 ligands in *trans*-position relatively to each other (Fig. 13).

Figure 13. Structure of the complex $[\text{Re}_4\text{Se}_4(\text{S}_3)_4(\text{S}_4)_2]^{4-}$.

Sulfur-containing ligands stabilise the electron-deficient cluster core $\text{Mo}_4\text{S}_4^{6+}$ ($N_e = 10$): this cluster core was found in dithiophosphate $[\text{M}_4\text{S}_4(\mu_2\text{-dtp})_2(\text{dtp})_4]$ ($\text{M} = \text{Mo}, \text{W}$; $\text{Q} = \text{S}$)^{115, 124} and in dithiocarbamate $[\text{Mo}_4\text{S}_4(\mu_2\text{-Et}_2\text{NCS}_2)_2 \cdot (\text{Et}_2\text{NCS}_2)_4]$ ¹¹⁵ complexes.

A unique series of high-valence cubane clusters based on *p*-tolylimide (tolN^{2-}) derivatives of $\text{Mo}(\text{V})$ and $\text{W}(\text{V})$, were synthesised.^{125, 126} Each metal atom in the structure of $[\text{Mo}_4\text{S}_4(\text{tolN})_4(\text{S}_2\text{P}(\text{OEt})_2)_4]$ is bound to one terminal $=\text{NC}_6\text{H}_4\text{Me-}p$ group, to one chelating dithiophosphate and to three bridging sulfide ligands of the cluster core. Four electrons available for M–M-bonding are localised in such a way that two single Mo–Mo (2.862 Å) bonds are located at the opposite edges of the tetrahedron. The four remaining metal–metal distances are significantly longer (3.69 Å). The complex $[\text{W}_4\text{S}_4(\text{en})_4(\text{S}_4)]\text{S}$ (en is ethylenediamine) containing a

distorted metal cluster ($N_e = 6$; W–W 2.801–2.878 Å) is another example.¹²⁷ Alternatively, one can regard this compound as $[\text{W}_4\text{S}_4(\text{en})_4(\text{SH})_4]\text{S}$ with a more conventional cluster core $\text{W}_4\text{S}_4^{6+}$.

5. Square metal M_4 clusters

The complex $\text{Li}_4[\text{Nb}_4\text{S}_2(\text{SPh})_{12}]$ in which the square metal cluster coordinates two $\mu_4\text{-S}$ -ligands was the first discovered compound of this rare type.¹²⁸ Four Nb^{III} atoms in this diamagnetic compound provide eight electrons for the formation of four metal–metal bonds with distances Nb–Nb equal to 2.83 Å. Another example is the $[\text{Nb}_4\text{S}_2(\text{SPh})_8(\text{PMe}_2\text{R})_4]$ complex ($\text{R} = \text{Me}, \text{Ph}$).¹²⁹

The polymeric vanadium compound $\text{V}_4\text{S}_9\text{Br}_4$ contains the metal core $\text{V}_4(\mu_4\text{-S})(\mu_2\text{-S}_2)_4^{4+}$ (Fig. 14).¹³ Four ligands S_2 are coordinated asymmetrically. The bridging bromine atoms link the clusters into the layer $[\text{V}_4(\mu_4\text{-S})(\mu_2\text{-S}_2)_4\text{Br}_{8/2}]_{\infty}$. The vanadium oxidation state in this complex is equal to +3.5 and only two electrons take part in the metal–metal bonding (the distances V–V are equal to 3.01 Å). The remaining four non-bonded electrons are located at the metal centres (one per each metal atom), which makes the compound paramagnetic. The oxidation state of tantalum atoms in the cluster core $\text{Ta}_4(\mu_4\text{-Q})(\mu_4\text{-Q}_2)_4^{8+}$ of molecular diamagnetic compounds

Figure 14. Structure of the cluster fragment $\text{V}_4(\mu_4\text{-S})(\mu_2\text{-S}_2)_4\text{Br}_8$ in the compound $\text{V}_4\text{S}_9\text{Br}_4$.

$\text{Ta}_4\text{Q}_9\text{X}_8$ ($\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Br}, \text{I}$) is +4.5 and therefore only two electrons are available for bonding in the metal cluster.¹⁴ Long distances Ta–Ta (3.30–3.39 Å) are typical of such electron-deficient square clusters.

6. Other examples of tetranuclear chalcogenide clusters

Tetranuclear complexes containing the cluster core $\text{M}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4^{2+}$ with planar arrangement of metal atoms were synthesised. The complexes $[\text{Mo}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4 \cdot (\text{SH})_2(\text{PMe}_3)_6]$ (Fig. 15)¹³⁰ and $[\text{W}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4(\text{SH})_2 \cdot (\text{PMe}_2\text{Ph})_6]$ belong to this class.¹³¹ These clusters provide ten electrons for the formation of five localised metal–metal bonds; the bond lengths lie in the narrow interval (Mo–Mo 2.83–2.85 Å; W–W 2.81–2.84 Å). The two-electron oxidation of the complex $[\text{W}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4\text{Cl}_2(\text{PMe}_2\text{Ph})_6]$ yields the salt of double-charged cationic cluster $[\text{W}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4\text{Cl}_2 \cdot (\text{PMe}_2\text{Ph})_6](\text{CF}_3\text{SO}_3)_2$.¹³¹ The reduction of the same cluster by excess of sodium amalgam results in the formation of the tungsten(III) complex $[\text{W}_4(\mu_2\text{-S})_6(\text{PMe}_2\text{Ph})_6]$, containing tetrahedral metal cluster W_4 ($N_e = 12$, the distances W–W are equal to 2.634 Å).¹³¹

The cluster M_4 core of a ‘butterfly’ type with two $\mu_3\text{-S}$ -ligands was found in the complex $[\text{Mo}_4(\mu_3\text{-S})_2(\mu\text{-CO})_4 \cdot (\eta^5\text{-C}_5\text{H}_5\text{CO}_2\text{Me})_4]$; the edges also coordinate four $\mu_2\text{-carbonyl}$ groups (Fig. 16).¹³²

Figure 15. Structure of the complex $[\text{Mo}_4(\mu_3\text{-S})_2(\mu_2\text{-S})_4(\text{SH})_2(\text{PMe}_3)_6]$.

Figure 16. Structure of the complex $[\text{Mo}_4(\mu_3\text{-S})_2(\mu\text{-CO})_4.(\eta^5\text{-C}_5\text{H}_4\text{CO}_2\text{Me})_4]$.

7. Octahedral clusters

The octahedral clusters (Fig. 17) are the most numerous among hexanuclear cluster complexes. The metal cluster M_6 in these complexes is surrounded by eight $\mu_3\text{-L}^i$ ligands coordinated to triangular faces of the metal octahedron. Additionally, the metal atoms coordinate the terminal ligands L^a producing a cluster complex $[\{\text{M}_6\text{L}_8^i\}\text{L}_6^a]$. [The indices i and a were introduced by Schäfer and Schnering¹³³ and derived from German words inner (inner) and ausser (outer); the ligands of the $\mu_2\text{-L}$ type, coordinated to the edges of metal cluster, were classified as inner.] Then the cluster core may be regarded as a combination of the metal cluster and L^i ligands. The total

Figure 17. Structure of the octahedral cluster complex $[\text{M}_6\text{Q}_8]\text{L}_6^a$.

number of the ligands surrounding the M_6 octahedron is equal to 14. Accordingly, the cluster compounds with $\text{L}:\text{M} = 14:6$ possess the molecular structure with isolated cluster complexes {for example, $[\text{Re}_6\text{S}_4\text{Br}_{10}]$, $\text{Cs}_4[\text{Mo}_6\text{S}_2\text{Br}_{12}]$,¹³⁴ $[\text{W}_6\text{S}_8(\text{py})_6]$,¹³⁵ *etc.*}. When the ratio $\text{L}:\text{M}$ is smaller, the polymeric structures are formed. In these structures, both L^i and L^a may play the role of bridging ligands. The examples of such structures are given below.

Twenty-four valence electrons ($N_e = 24$) are required for the filling of 12 bonding molecular orbitals (MO) corresponding to metal–metal bonds in a metal cluster M_6 . This situation exists in compounds in which the metal ions possess the d^4 electron configuration, for instance, in the octahedral Re^{III} complexes that contain the $\text{Re}_6\text{Q}_8^{2+}$ cluster core.¹³⁶ Compounds with electron-deficient cluster cores ($N_e = 20\text{--}22$) are stable in the case of chromium, molybdenum and tungsten chalcogenide complexes; the most spectacular examples of such compounds are molybdenum chalcogenides, Mo_6Se_8 ($N_e = 20$) and PbMo_6S_8 ($N_e = 22$).

The octahedral chalcogenide clusters of the Group 5 metals are virtually unknown, probably, because of the considerable deficit of electrons required for the formation of the $\text{M}–\text{M}$ bonds in the cluster. The complex $[\text{V}_6\text{Se}_8(\text{O})(\text{PMe}_3)_6]$ (Fig. 18), in which the metal cluster V_6 contains an interstitial (μ_6) oxygen atom, is the only example of such chalcogenide clusters.¹³⁷ The octahedral geometry of this electron-deficient cluster ($N_e = 12$) is retained due to the formation of $\text{V}–\text{O}$ bonds.

Figure 18. Structure of the complex $[\text{V}_6\text{Se}_8(\text{O})(\text{PMe}_3)_6]$.

Isocharged or non-isocharged substitution of chalcogenide ligands in the cluster core M_6Q_8 results in the formation of isomers which are very hard to separate. Thus in the case of $\text{M}_6\text{Q}_6\text{Q}'_2$ three geometric isomers are possible (Fig. 19), and in the case of $\text{M}_6\text{Q}_4\text{Q}'_4$ the number of isomers is six. Typically, the heteroatoms in the solid state structure of the clusters with mixed ligands are disordered over all possible positions. However, there are some examples of ordered structures. These compounds are usually formed in the cases of significant difference in atomic radii of the ligands L^i : Te and Cl in $\text{Re}_6\text{Te}_8\text{Cl}_{10}$ (Ref. 138) or Se and O in $[\text{Re}_6\text{Se}_4\text{O}_4\text{Cl}_6]^{4-}$.¹³⁹ The metal cluster Re_6 in compound $\text{Cs}_{11}(\text{H}_3\text{O})$. $[\text{Re}_6\text{Se}_4\text{O}_4\text{Cl}_6]_3 \cdot 4\text{H}_2\text{O}$ is surrounded by four oxygen atoms and four selenium atoms, localised at the opposite faces of the Se_4O_4 cube (Fig. 20).¹³⁹ Such ligand environment results in a significant distortion of the metal cluster and the $\text{Re}–\text{Re}$ distances in this compound vary from 2.46 Å (in the faces coordinating the $\mu_3\text{-oxygen}$ atoms) to 2.62 Å (in the faces coordinating the $\mu_3\text{-selenium}$ atoms).

Figure 19. Geometrical isomers of the cluster core $[M_6Q_6Q'_2]$.

Figure 20. Structure of the complex $[Re_6Se_4O_4Cl_6]^{4-}$.

There are several examples of heterometallic octahedral clusters: $Mo_{6-x}M_xQ_8$ ($M = Re$: $Q = S, Se, Te, x = 4$; $M = Ru$: $Q = Se, Te, 0 \leq x \leq 2$; $M = Rh$, $Q = Te, x = 0.5, 1.33$),¹⁴⁰ $Nb_{6-x}Ru_xTe_8$ ($2.50 \leq x \leq 3.17$),¹⁴¹ $Cs_5[Re_{6-x}Mo_xS_8(CN)_6]$,¹⁴² $Cs_3[Re_5OsS_{11}]$,¹⁴³ $Cs_3[Re_{6-x}Os_xSe_8Cl_6]$ ($x = 1, 2$) and $K_2[Re_3Os_3Se_8Cl_6][Re_4Os_2Se_7Cl_7]$.¹⁴⁴ The phosphine and cyanide complexes were studied for rhenium–osmium clusters.^{144, 145}

A great number of molecular complexes of molybdenum, tungsten and rhenium with the cluster core M_6Q_8 were studied. Ions (halides, cyanide, thiocyanate, hydroxide) or neutral molecules (phosphines, pyridines, *etc.*) play the role of ligands L^a in these complexes.^{19, 135, 136, 139, 146–178} Usually, the terminal ligands are coordinated in a monodentate mode or as bridging ligands linking adjacent clusters. The study of coordination of diphosphine $Ph_2P(CH_2)_nPPH_2$ with octahedral rhenium clusters has shown that the chelate complexes are formed if $n \geq 6$.¹⁵³

8. Miscellaneous hexanuclear clusters

The metal cluster V_6 in compound $(Et_4N)_3[V_6S_4(edt)_6(O)_2]$ is essentially planar. Nine valence electrons take part in the formation of five V–V bonds (2.82–2.86 Å) (Fig. 21).¹⁷⁹ Four triangles Mo_3 with shared edges in the topologically related hexanuclear molybdenum clusters $[Mo_6S_{10}(SH)_2.(PET_3)_6]$ coordinate four μ_3 - and six μ_2 -chalcogen atoms (Fig. 22).¹³⁰ There are 14 electrons per nine Mo–Mo bonds in this cluster, which results in the shortening (in comparison

Figure 21. Structure of the complex $[V_6(\mu_3-S)_4(edt)_6(O)_2]^{3-}$.

Figure 22. Structure of the complex $[Mo_6(\mu_3-S)_4(\mu-S)_6(SH)_2(PET_3)_6]$.

with the vanadium structure) of the distances Mo–Mo (2.73–3.06 Å). Similar structure of the cluster core was also observed in compounds $[Mo_6Q_8Cl_6(PET_3)_6]$.¹⁸⁰

The metal cluster Mo_6 in an unusual complex $[Mo_6S_6(CN)_{16}]^{8-}$ (Fig. 23) may be represented by two edge-sharing tetrahedrons. Four edges coordinate sulfur atoms according to the μ_3 -type and two pairs of fused faces (*i.e.* those with the shared edge) coordinate sulfur atoms according to the μ_4 -type.¹⁸¹

Two triangles Nb_3 in the hexanuclear cluster $[Nb_6SBr_{17}]^{3-}$ (Fig. 24) are linked together by a μ_6 -sulfur atom.¹⁸² The Nb–Nb bond lengths in the triangles are in the range of 2.95–2.98 Å, the distances between the triangles are longer and equal to 3.276 Å.

9. Compounds based on polymeric octahedral cluster complexes

The decrease of the number of ligands in molecular complexes $[\text{M}_6\text{L}_8]\text{L}_6^a$ results in the formation of polymeric-bridged structures. According to Schäfer,¹³³ the inter-cluster bridging ligands are designated as L^{a-a} , L^{i-a} and L^{a-i} depending on their structural role in each of the metal clusters linked by them.

a. Linking of the octahedral cluster cores through bridging halide ligands L^{a-a}

One of the most common methods of linking of cluster cores M_6L_8 into polymeric chains, layers and frameworks (when the ratio $\text{L}:\text{M}$ is decreasing) is the linking through apical halide ligands which become bridging between two cluster cores (Table 2). If all six apical ligands are bridging, then the compounds form 3D frameworks (Fig. 25), if four equatorial ligands are bridging then layered 2D polymers are formed and in the case of two bridging ligands 1D chains are formed.

The ternary systems $\text{Re}-\text{Q}-\text{Y}$ ($\text{Q} = \text{S}, \text{Se}; \text{Y} = \text{Cl}, \text{Br}$) are models in the studies of the influence of the number of shared ligands on the polymeric structure type. Depending on the ratio $\text{Q}:\text{Y}$, all possible types of structures are formed in these systems: the frameworks in $\{(\text{Re}_6\text{Q}_7^i\text{Y}^i)\text{Y}_{6/2}^{a-a}\}$,¹⁸⁴ the layers in $\{(\text{Re}_6\text{Q}_6^i\text{Y}_2^i)\text{Y}_4^{a-a}\}$,¹⁸⁴ the chains in $\{(\text{Re}_6\text{Q}_5^i\text{Y}_3^i)\text{Y}_4^{a-a}\}$ ¹⁸⁴ and isolated cluster complexes in $(\text{Re}_6\text{Q}_4^i\text{Y}_4^i)\text{Y}_6^a$.¹⁸⁶⁻¹⁹⁰ The structures and properties of these compounds are discussed in details in reviews.^{16, 136, 191}

b. Linking of the octahedral cluster cores through chalcogenide and polychalcogenide inter-cluster ligands

The compounds with bridging chalcogenide and polychalcogenide ligands were obtained only for rhenium and technetium;¹⁹² some crystal data on these compounds are listed in Table 3. The examples of the compounds with unusual bridging ligands, viz., spiro- Te_7^{2-} and Te_6 , are shown in Figs 26 and 27.^{8, 206}

Figure 25. Fragment of the structure of $\text{Re}_6\text{Se}_7\text{Br}_4$ (the 'inner' ligands are omitted).

Figure 27. Linking of the metal clusters Re_6 through Te_6 ligands in the structure of $\text{Re}_6\text{Te}_{16}\text{Cl}_{18}$.

Linking of the cluster cores into layered or 3D-framework structures through chalcogen atoms is typical of ternary rhenium sulfides and selenides. The cluster cores in $\text{Cs}_4[(\text{Re}_6\text{Se}_8^i)\text{Se}_{2/2}^{a-a}(\text{Se}_2)_{4/2}^{a-a}]$ are linked together by two selenide and four diselenide bridges yielding a 3D structure (Fig. 28).²⁰¹

Recently, octahedral rhenium chalcocyanide complexes with bridging chalcogenide ligands have been obtained: the layered structure of $\text{K}_4[\text{Re}_6\text{S}_{10}(\text{CN})_2]$ and chain structures of

c. Linking of the octahedral cluster cores through ‘inner’ ligands

The metal coordination sphere of lower chalcogenides contains the ligands of an adjacent cluster core which thus become the inter-cluster bridges. The less is the L : M ratio the more ‘inner’ ligands are involved in the formation of these inter-cluster bridges. Examples of such compounds are given in Table 4.

Each molybdenum atom in the compound Mo₆Se₈ is bonded to the inner ligand of the adjacent cluster, which thus may be regarded as an apical ligand.^{213, 214} As a result, the clusters are strongly linked together due to the formation of rhombic fragments Mo₂Se₂ⁱ (Fig. 30) and the Mo–Mo distances between the molybdenum atoms of the neighbouring metal clusters are shortened (3.266 Å).

Other compounds with strong inter-cluster bridges are represented by rhenium chalcogenides Re₆S₈Cl₂, Re₆Se₈Cl₂, Re₆S₈Br₂ and Re₆Se₈Br₂.^{207–209} The cores Re₆S₈ⁱ in crystals of Re₆S₈Cl₂ are linked in chains by two centrosymmetrical Re–S

bonds. The chains are combined into a 3D structure by Re—Cl^{a-a}—Re bridges. The rhombic bridges Re₂Q₂ were also found in some other compounds. The structure TlRe₆.Se₈Cl₃, *i.e.* Tl{(Re₆Se₅^{i-a}Se_{3/2}^{i-a}Se_{3/2}^{i-a}Cl₃^a)}, consists of layers linked by three Re₂Se₂ bridges.²¹² The cores Re₆Se₈ in crystals of Cs₂Re₆Se₈Br₄ are *trans*-linked in chains by rhombuses Re₂Se₂ (Fig. 31).²¹¹

**Figure 31.** Fragment of polymer chain {Re₆Se₈Br₄}_∞²⁻ in the structure of Cs₂Re₆Se₈Br₄.

The complex Nb₆I₉S containing the electron-deficient 19-electron cluster core Nb₆I₆^{i-a}S₂^{i-a} occupies a special place among the polymeric chalcogenides. The sulfide ligands Lⁱ in this compound are shared between adjacent clusters (Fig. 32). In addition, the apical iodine atoms also make bridges between the clusters; this results in the formation of unusual linear chains [Nb₆I₆^{i-a}S_{2/2}^{i-a}I_{6/2}^aI_{6/2}^{i-a}].²¹⁷

**Figure 32.** Fragment of a polymeric chain {Nb₆I₆^{i-a}S_{2/2}^{i-a}I_{6/2}^aI_{6/2}^{i-a}} in the structure of Nb₆I₉S.

10. High nuclearity clusters

A homologous series of the clusters Mo_{6+3x}Q_{8+3x} (Q = S, Se; x = 1–3), which was found in ternary molybdenum chalcogenides, may be described as a product of the progressive condensation of triangles Mo₃. The first member of the series, Mo₉Se₁₁, contains a dioctahedral metal cluster Mo₉.²¹⁸ Eight selenium atoms are bonded to the metal cluster according to the μ₃-mode, and three selenium atoms, which are located in the plane of the middle Mo₃ triangle, are μ₄-mode coordinated. The metal atoms of the outer triangles Mo₃ of the cluster core Mo₉Q₁₁ in a crystal are additionally coordinated by six bridging Se atoms, which link together the adjacent cluster fragments Mo₉Q₁₁. The structures of clusters Mo₉Q₁₁, Mo₁₂Q₁₄ and Mo₁₅Q₁₇ are shown in Fig. 33.^{218–221} The condensation continues up to joining together 11 octahedra in the structure of Rb₁₀Mo₃₆S₃₈.²²² The ultimate case of the condensation of the triangles Mo₃ is represented by compounds M[Mo₃Q₃] (M = Li, In, Tl; Q = Se, Te) containing infinite chains [Mo₃Q₃]_∞.²²³

**Figure 33.** Structures of the cluster cores Mo₉Se₁₁ (a), Mo₁₂Se₁₄ (b), Mo₁₅Se₁₈ (c).

The mixed-valence cluster complex [Re₉Se₁₁Br₆]²⁻ consists of eight Re^{III} atoms and one Re^{II} atom. This is the only example of a rhenium cluster in the family of condensed octahedral clusters.²²⁴ The complex contains a cluster core similar to that of the Mo₉Se₁₁ and only the bromine ligands occupy terminal positions.

The unique twelve-nuclear cluster complex [Re₁₂CS₁₇(CN)₆]⁸⁻ (Fig. 34) consists of two Re₆ octahedra

Figure 34. Structure of the complex $[\text{Re}_{12}\text{CS}_{17}(\text{CN})_6]^{8-}$.

Figure 35. Structure of the complex $\text{trans-}[\text{Re}_{12}\text{Se}_{16}(\text{PEt}_3)_8(\text{MeCN})_2]^{4+}$ (the ethyl and MeC groups are omitted).

linked by three μ_2 -S-bridges and a μ_6 -carbon atom.¹⁵ Each Re_6 -cluster coordinates seven μ_3 -S-atoms and a μ_6 -C-ligand attaining environment typical of octahedral Re clusters Re_6Q_8 . The Re_6 prism formed by 'inner' triangles and centred by the μ_6 -carbon atom is an important part of the structure. The mean distance between metal clusters in the anion $[\text{Re}_{12}\text{CS}_{17}(\text{CN})_6]^{8-}$ is equal to 3.17 Å. This distance is very sensitive to the charge of the cluster anion and decreases to 2.90 Å after two-electron oxidation of the cluster.¹⁵ The cluster $\text{Mo}_{12}\text{S}_{18}$, which was found in the compound $\text{Ba}_4\text{Mo}_{12}\text{S}_{18}$, possesses a similar structure.²²⁵

The dodecanuclear clusters of a different type are formed in the condensation of the octahedral clusters with labile apical ligands. Thus thermolysis of $\text{cis-}[\text{Re}_6\text{Se}_8(\text{PEt}_3)_4(\text{MeCN})_2]$ containing two labile MeCN ligands results in the formation of dimers of $\text{trans-}[\text{Re}_{12}\text{Se}_{16}(\text{PEt}_3)_8(\text{MeCN})_2]^{4+}$ (Fig. 35).^{152, 226}

III. Methods of synthesis of chalcogenide clusters

The methods of synthesis of the cluster compounds may be divided into two main groups: the high-temperature synthesis, which is carried out in closed systems (usually, in sealed evacuated tubes), and the solution synthesis. The high-temperature reactions are extremely important for the synthesis of clusters of the Group 5–7 metals because quite often a chalcogenide cluster core, especially a high-nuclear one, cannot be formed in solution. Further chemical modifications of a cluster compound obtained by high-temperature synthesis may be carried out in solutions or in melts.

1. High-temperature synthesis

The method is based on the fact that a phase that is thermodynamically stable under certain experimental conditions may be obtained from different starting compounds taken in the appropriate ratio. The elements and compounds (for example, metal halides, chalcogenides and chalcogenides) are used as the starting compounds in the synthesis of chalcogenide clusters. In addition to the ratio of the starting compounds in the reaction mixture, the right choice of temperature of the synthesis is very important. A standard procedure for the synthesis of cluster chalcogenides is as follows: a quartz tube is loaded with starting compounds and then evacuated and sealed. If necessary, the tube is cooled down by liquid nitrogen prior to evacuation in order to avoid the loss of volatile components. The sealed tube is placed into a furnace and heated according to the chosen protocol. The reaction mixture is kept at certain temperature for the required period, usually from several tens of hours up to several days, in order to complete the reaction. Such processes, particularly in the case of chalcogenide systems, are accompanied sometimes by mass-transfer processes, which results in the concentration of a solid phase in a cool area. Usually, such gas-transport reactions produce crystals of high quality suitable for X-ray crystallographic and other physicochemical studies.

The chalcogenides of niobium Nb_3QX_7 ($\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$)^{80, 83, 227} and tantalum Ta_3QI_7 ($\text{Q} = \text{Se}, \text{Te}$)²²⁸ Ta_3SBr_7 ,⁸² $\text{Ta}_4\text{SI}_{11}$,²²⁹ $\text{Ta}_4\text{S}_9\text{Br}_8$, $\text{Ta}_4\text{Se}_9\text{I}_8$ (Ref. 14) were obtained from the elements at 450–550 °C.

Trinuclear molybdenum and tungsten complexes $\text{M}_3\text{Q}_7\text{X}_4$ ($\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$) were synthesised at 350–400 °C. The choice of this temperature interval is caused by both kinetic and thermodynamic factors because these compounds are unstable at higher temperatures. Wide variety of compounds that ensure the correct stoichiometry may be used as the starting components: elementary compounds, lower halides (MoCl_3 or $\text{Mo}_6\text{Cl}_{12}$, W_6Cl_{12}) with sulfur or selenium, sulfides MS_3 ($\text{M} = \text{Mo}, \text{W}$) with PCl_5 as well as other systems.^{3, 230, 231}

High-temperature synthesis affords the telluride complexes $[\text{Mo}_3\text{Te}_7(\text{TeI}_3)_3]$,⁶⁶ $[\text{Mo}_3\text{Te}_7(\text{TeI}_3)_3]_2(\text{TeI}_3)_1$, $[\text{Mo}_3\text{Se}_7(\text{TeI}_3)_2]\text{I}$ and $[\text{Mo}_3\text{Se}_7(\text{TeBr}_3)\text{Br}_2]_2[\text{Te}_2\text{Br}_{10}]$ as single crystals in which the cluster fragments are coordinated by TeX_3^- ligands.²³² The triangular clusters $\text{Re}_3\text{Q}_7\text{X}_7$ ($\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}$) were synthesised from ReX_4 or ReOCl_4 , elemental sulfur or selenium and the corresponding sulfur and selenium halides Q_2X_2 or SeX_4 ($\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}$) at 130–250 °C.⁶¹ Compounds $\text{Re}_3\text{S}_7\text{Br}_7$ and $[\text{Re}_3\text{S}_7\text{Cl}_6][\text{AlCl}_4]$ were obtained in the reaction of Re_2O_7 with S_2Br_2 and with the solution of AlCl_3 and S_2Cl_2 , respectively.^{62, 63}

The high-temperature synthesis is used for the preparation of various types of tetranuclear cluster compounds: rhombic, square and tetrahedral clusters. The rhenium dichalcogenides ReQ_2 ($\text{Q} = \text{S}, \text{Se}$) containing rhombic clusters were obtained by the high-temperature synthesis from elements at 600–800 °C.^{233, 234} The vanadium and tantalum chalcogenides $\text{V}_4\text{S}_9\text{Br}_4$ (Ref. 13) and $\text{Ta}_4\text{Q}_9\text{X}_8$ ($\text{Q} = \text{S}, \text{Se}$)^{14, 235} containing square clusters were synthesised by the same method but at lower temperatures (400–450 °C).

The cubane clusters form the most abundant group of tetranuclear chalcogenide clusters. A series of Mo and Nb chalcogenides $\text{M}_4\text{Q}_4\text{X}_4$ ($\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$) was obtained by high-temperature synthesis (880–1000 °C) from various starting compounds providing the required proportion of the metal, chalcogen and halogen.^{84, 85} The isostructural rhenium mixed chalcogenide $\text{Re}_4\text{S}_4\text{Te}_4$ was synthesised by heating a stoichiometric mixture of metallic rhenium, sulfur and tellurium for three weeks at 900 °C.⁸⁷ A series of ternary chalcogenides AM_4Q_8 ($\text{A} = \text{Al}, \text{Ga}$; $\text{M} = \text{Mo}, \text{Nb}, \text{Ta}$; $\text{Q} = \text{S}, \text{Se}$), $\text{GaMo}_4(\text{Q}, \text{Q}')_8$ ($\text{Q}, \text{Q}' = \text{S}, \text{Se}, \text{Te}$) and $\text{MMo}_2\text{Re}_2\text{S}_8$ ($\text{M} = \text{Zn}$,

Ni, Co, Fe) belong to the same group of compounds (Refs 88–91, 236–238).

The synthesis of $\text{Re}_4\text{Te}_4(\text{TeBr}_2)_4\text{Br}_8$ from elements at 550 °C was also described.⁹³ The tetrahedral cluster-type rhenium chalcogenides $\text{Re}_4\text{Q}_4(\text{TeCl}_2)_4\text{Cl}_8$ were obtained from ReCl_5 by the reaction either with tellurium or with a mixture S–Te or Se–Te at 350–400 °C:¹⁰

Chalcocyanide cluster complexes can also be prepared by high-temperature synthesis. The niobium and tantalum tellurocyanide tetrahedral complexes $[\text{M}_4\text{OTe}_4(\text{CN})_{12}]^{6-}$ are formed in the reaction of higher tellurides NbTe_4 and TaTe_4 with KCN at 440–460 °C and 340–360 °C, respectively.^{108, 239} The tetrahedral tellurocyanides $[\text{Mo}_4\text{Te}_4(\text{CN})_{12}]^{7-}$ and $[\text{W}_4\text{Te}_4(\text{CN})_{12}]^{6-}$ were obtained from the ditellurides of these metals by heating with KCN at 400 °C.¹⁰² Interestingly, the interaction of trinuclear chalcogenides $\text{M}_3\text{Q}_7\text{X}_4$ (M = Mo, W) with KCN at 400 °C also yields the clusters $[\text{M}_4\text{Q}_4(\text{CN})_{12}]^{n-}$ of higher nuclearity.¹⁰²

The high-temperature synthesis is the main method for the preparation of octahedral chalcogenide clusters of Mo, W, Re. The binary and ternary molybdenum chalcogenides Mo_6Q_8 (Q = Se, Te) and $\text{M}_x\text{Mo}_6\text{Q}_8$ (M is a transition or post-transition metal) as well as phases with condensed clusters containing two, three, four and more fused octahedra up to the phase MMo_3Q_3 (M is an alkali metal), which consists of infinite chains $(\text{Mo}_3\text{Q}_3)^-$, were synthesised from the simple compounds.^{214, 223} The temperature of the synthesis of these compounds is in the range of 900–1500 °C. The synthesis of clusters of higher nuclearity usually requires higher temperatures. The octahedral chalcogenide complexes of the type $\text{A}_4\text{M}_6\text{S}_x$ (A is an alkali metal or thallium; M = Tc, Re; $x = 11, 12, 13, 13.5$) were synthesised at 800–1400 °C. Hydrogen sulfide or hydrogen selenide were used as sources of chalcogen, which were passed over the mixture of a powder metallic rhenium with an alkali metal carbonate.^{192, 196, 197, 199, 201, 203, 240} The cluster-type rhenium telluride $\text{Re}_6\text{Te}_{15}$ was obtained by heating metallic rhenium with tellurium for two weeks at 900 °C.⁸ The reaction rate increases significantly if highly reactive highly-dispersed rhenium powder is used. The chalcogenides $\text{Re}_6\text{Q}_{8-n}\text{X}_{2+2n}$, where Q = S, Se; $n = 1, 2, 3, 4$, were synthesised from elements or from the corresponding compounds at 800–900 °C. ReCl_5 is typically used as a source of chlorine in the synthesis of chalcogenides.¹³⁶ The tellurohalide complexes $\text{Re}_6\text{Te}_8(\text{Te}_8\text{Cl}_{18})$, $\text{Re}_6\text{Te}_8(\text{Te}_6)(\text{TeCl}_3)_2$ and $\text{Re}_6\text{Te}_8(\text{TeBr}_2)_6\text{Br}_2$ with unusual ligands TeX_2 , Te_6 , $\text{Te}_8\text{Cl}_{18}^{2-}$ were obtained from ReCl_5 or Re_3Br_9 at 450–500 °C.^{138, 189, 206, 241} It should be noted that the octahedral rhenium chalcogenides are formed exclusively in the high-temperature reactions. Besides the synthesis from simple compounds, the octahedral rhenium chalcogenides are formed in the condensation of triangular clusters: in the reaction of rhenium bromide Re_3Br_9 with cadmium or lead chalcogenides at 500–550 °C.¹⁹⁰ The nonanuclear dioctahedral complex $[\text{Re}_9\text{Se}_{11}\text{Br}_6]^{2-}$ is also formed.²²⁴ The dodecanuclear sulfido-carbide cluster $[\text{Re}_{12}\text{S}_{17}\text{C}(\text{CN})_6]^{8-/6-}$ was obtained by the reaction of ReS_2 with KCN at 750 °C.¹⁵

2. Methods of solution synthesis

The methods of synthesis in aqueous solutions or in organic solvents are mainly used for chemical modifications of cluster-type complexes obtained by high-temperature synthesis. The reactions in solutions used specially for the synthesis of chalcogenide clusters are significantly less common, as the yields in these reactions are usually low and are well developed only for a limited number of clusters. Solution syntheses are used most often for the preparation of thio complexes, less

often for seleno complexes and only in very few cases for telluro complexes. Mononuclear tetrathiomallate complexes, metal halides or organometallic compounds are used as starting components of these reactions. In some cases, reductive condensation of bi- or trinuclear complexes into cluster complexes of higher nuclearities are also carried out in solutions.

a. Synthesis of triangular cluster complexes

At present, trinuclear vanadium complexes are obtained only in solutions. Usually, VCl_3 or $(\text{NH}_4)_3\text{VS}_4$ are used as the starting compounds. For instance, the compound $(\text{Et}_4\text{N})[\text{V}_3\text{S}_7(\text{Me}_2\text{NCS}_2)_3]$ was obtained in low yield in the reaction of $(\text{NH}_4)_3\text{VS}_4$ with CuCl , PhSNa , $\text{Na}(\text{Me}_2\text{NCS}_2)$ and Et_4NCl in DMF,⁶⁰ and the complex $(\text{Et}_4\text{N})[\text{V}_3\text{S}_7.(\text{Et}_2\text{NCS}_2)_3]$ was synthesised from $(\text{NH}_4)_3\text{VS}_4$, $\text{Na}(\text{Et}_2\text{NCS}_2)$ and Et_4NCl in methanol with passage of H_2S through the reaction mixture.²⁴² The reaction of $[\text{V}(\text{SPh})_2(\text{bipy})_2]\text{PF}_6$ with sulfur in MeCN furnishes $[\text{V}_3\text{S}_7(\text{bipy})_3]\text{PF}_6$ in 35%–40% yield.⁵⁹ The unique cluster-type complex $(\text{Et}_4\text{N})_3[\text{V}_3\text{S}_4.(\text{edt})_3] \cdot 2 \text{MeCN}$ with the core $\text{V}_3\text{S}_4^{3+}$ was isolated in 20% yield from a multicomponent reaction mixture containing $\text{Na}_2(\text{edt})$, Et_4NBr , VCl_3 and sulfur.²¹

The cluster-type niobium complex $[\text{Nb}_3\text{SO}_3(\text{NCS})_9]^{6-}$ was obtained by dissolution of $[\text{Nb}_2\text{Cl}_6(\text{THT})_3]$ (THT is tetrahydrothiophene) in hydrochloric acid followed by treatment with NH_4NCS .²² The triangular complex $[\text{Cr}_3\text{S}_5(\text{dmpe})_3]$ was synthesised in the reaction of anhydrous CrCl_2 with NaSH (78 °C, methanol) with subsequent addition of the phosphine.⁷⁵ The selenide cluster $(\text{Et}_4\text{N})_2[\text{Cr}_3(\mu_3\text{-Se})_2(\text{CO})_{10}]$ was obtained in 52% yield by the reaction of SeO_2 with $\text{Cr}(\text{CO})_6$ in a methanolic alkaline solution with subsequent addition of Et_4NBr .⁷⁶

The cluster aqua complexes, obtained preliminarily by reductive condensation of mono- or binuclear chalcogenide complexes, are used in the synthesis of triangular Mo and W complexes. In most cases these reactions are non-selective and result in mixtures of products that can be separated by chromatography with difficulty. Thus, the aqua complex $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ was obtained in 15% yield alongside with $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ (20%) in the reaction of $[\text{Mo}(\text{CO})_6]$ with anhydrous Na_2S in acetic anhydride.³⁵ The cluster $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ was synthesised with the yield of 20% by the reduction of $(\text{NH}_4)_2[\text{Mo}_2(\text{S}_2)_2\text{Cl}_8]$ with Pb or In in concentrated HCl.²⁴³ The compound $(\text{NH}_4)_2\text{MoS}_4$ can be reduced with NaBH_4 in aqueous hydrochloric acid yielding $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$. Oxidation of the latter with atmospheric oxygen results in $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ isolated by ion-exchange chromatography in 50% yield.²⁵ The selenium analogue $[\text{Mo}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$ is difficult to obtain and it was synthesised by the reduction of $[\text{Mo}_2\text{O}_2\text{Se}_2(\text{cys})_2]^{2-}$ (cysH is L-cysteine) with NaBH_4 in a solution of hydrochloric acid. Cation-exchange chromatography afforded a mixture of species, viz., $[\text{Mo}_3\text{O}_2\text{Se}_2(\text{H}_2\text{O})_9]^{4+}$, $[\text{Mo}_3\text{OSe}_3(\text{H}_2\text{O})_9]^{4+}$, $[\text{Mo}_3\text{Se}_4.(\text{H}_2\text{O})_9]^{4+}$ and $[\text{Mo}_4\text{Se}_4(\text{H}_2\text{O})_{12}]^{5+}$ in a total yield of 10%. The cluster $[\text{Mo}_3\text{O}_2\text{Se}_2(\text{H}_2\text{O})_9]^{4+}$ was obtained in 70% yield by the reaction of $[\text{Mo}_2\text{O}_2\text{Se}_2(\text{cys})_2]^{2-}$ with $[\text{MoCl}_6]^{3-}$ (90 °C, 1 h, 1 M HCl), and the complex $[\text{Mo}_3\text{O}_3\text{Se}(\text{H}_2\text{O})_9]^{4+}$ was synthesised by electrochemical reduction of $[\text{Mo}_2\text{O}_4(\text{cys})_2]^{2-}$ in the presence of grey selenium powder in 3% yield or by treatment of $[\text{Mo}_3\text{O}_2\text{Se}_2(\text{H}_2\text{O})_9]^{4+}$ with a 30-fold excess of NaBH_4 .^{28, 29} The cationic complex $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ was obtained in the reduction of a solution of $(\text{NH}_4)_2[\text{WS}_4]$ with NaBH_4 in the presence of HCl. The reaction produces a mixture of complexes, viz., $[\text{W}_3\text{O}_2\text{S}_2(\text{H}_2\text{O})_9]^{4+}$ (0.3%), $[\text{W}_3\text{OS}_3(\text{H}_2\text{O})_9]^{4+}$ (5%) and $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ (25%).²⁵ The complex $(\text{NH}_4)_2[\text{Mo}_3\text{S}_7(\text{S}_2)_3]$, which is a starting compound in the synthesis of other $\text{Mo}_3\text{S}_4^{4+}$ derivatives, was obtained by the reaction of $(\text{NH}_4)_6[\text{Mo}_7\text{O}_{24}]$ with $(\text{NH}_4)_2\text{S}_x$ at 90 °C,²⁴⁴ and the selenide analogue $[\text{Mo}_3\text{Se}_7(\text{Se}_2)_3]^{2-}$, by the hydrothermal

synthesis from Mo or MoO₃ and a polyselenide.²⁴⁵ The cluster [Mo₃O(Te₂)₃·(en)₃]In₂Te₆ was synthesised by heating the mixture of Li₂Te, K₂Te, MoCl₅, InCl₃ and Te in ethylenediamine (180 °C, 7 days).⁵⁴

b. Synthesis of tetranuclear cluster complexes

The solution synthesis is extremely important for the preparation of vanadium and chromium tetrahedral complexes because the high-temperature methods of synthesis of these compounds are yet to be developed. The vanadium cyclopentadienyl complexes [(η⁵-C₅H₄R)₄V₄S₄] were obtained from the corresponding mononuclear vanadium complexes by the reactions with thiols (as a source of sulfur) in hydrocarbon solvents. Thus refluxing of [(η⁵-C₅H₄Me)₂V] with Bu^tSH in heptane yields [(η⁵-C₅H₄Me)₄V₄S₄] (with a small amount of pentanuclear [(η⁵-C₅H₄Me)₅V₅S₆]).²⁴⁶ The compound [Cp₄V₄S₄] was obtained from the vanadocene and MeC(S)SH or H₂S.^{247, 248} The cluster V₄S₄⁵⁺ was isolated as the dithiocarbamate complex (Et₄N)[V₄S₄(C₄H₈NCS₂)₆] in 67% yield from (NH₄)₃VS₄, ammonium pyrrolidinodithiocarbamate and PPh₃ in the presence of Et₃N.²⁴⁹

Tetranuclear vanadium clusters can be synthesised by reductive dimerisation of binuclear complexes. For example, the complex [(η⁵-C₅H₄Me)₄V₄S₄] was obtained by the reaction of [(η⁵-C₅H₄Me)₂V₂S₂] with Bu₃P.²⁴⁷ The selenide [Cp₂V₂Se₂] also reacts with PBu₃ in CH₂Cl₂ yielding [Cp₄V₄Se₄] (72% yield).⁹⁴ The tellurides [(η⁵-C₅H₄R)₄V₄Te₄] (R = H, Me) were obtained by thermolysis of [(η⁵-C₅H₄R)₂V₂(CO)₄(μ-Te)₂] in toluene at 50–60 °C in virtually quantitative yields.⁹⁴

Only the cyclopentadienyl derivatives of the cubane-type clusters Cr₄Q₄ⁿ⁺ (n = 4, 5) are known. The compounds [(η⁵-C₅H₄R)₄Cr₄S₄] (R = H, Me) were obtained from the corresponding chromocenes [(η⁵-C₅H₄R)₂Cr] and elemental sulfur or Bu^tSH by heating in high-boiling organic solvents.^{250, 251} Thermolysis of [Cp₂Cr₂(μ-S)₂(CO)₅] in toluene at 100 °C yields [Cp₄Cr₄S₄].^{95–97} The cluster [(η⁵-C₅H₄Me)₄·Cr₄S₄] was obtained upon thermolysis of [(η⁵-C₅H₄Me)₂·Cr₂(SBu^t)₂S] or upon its reaction with CuBr₂ in THF in the presence of triethylamine.²⁵² The complexes [(η⁵-C₅H₄R)₄·Cr₄Se₄] (R = H, Me) were formed upon heating [Cp₂Cr₂(CO)₆] or [(η⁵-C₅H₄Me)₂Cr] with grey selenium.^{95, 97} The reaction of [(η⁵-C₅H₄Me)₂Cr] with H₂Se in toluene produces complex [(η⁵-C₅H₄Me)₄Cr₄Se₄] in the yield of 90%.^{252, 253} The cluster [Cp₄Cr₄Se₄] was obtained from [Cp₂Cr₂(CO)₆] and Ph₂Se.^{98, 99} For tellurium, only mixed oxide-telluride clusters [Cp₄Cr₄Te₃O], [Cp₄Cr₄Te₂O₂] and [Cp₄Cr₄TeO₃], obtained by thermolysis of [CpCr(CO)₃TePh], are known.¹⁰⁰

In contrast to the derivatives of the Group 5 metals and chromium, the tetrahedral clusters of Mo and W are so resistant against oxygen and water that they can also be obtained in aqueous solutions. Mononuclear carbonyls, halides or chalcogenides are used as the starting compounds. Reductive condensation of binuclear chalcogenide complexes and the addition of a mononuclear fragment to a triangular cluster are also potentially very important as the synthetic methods. The methods of synthesis of tetrahedral Mo and W complexes are numerous, well developed and described in detail in several reviews.^{18, 19} It should be noted that in most cases the solution syntheses of the cubane-type cluster are non-selective and afford complex mixtures of products requiring laborious separations.

There is an example of synthesis of the complex [W₄S₄(en)₄(S₄)S] by a reaction of [W(CO)₆] with K₂S₄ in supercritical ethylenediamine at 300 °C.¹²⁷ The complex [(η⁵-C₅H₄Prⁱ)MoCl₂]₂ reacts with LiHS or LiHSe producing [(η⁵-C₅H₄Prⁱ)₄Mo₄Q₄] (Q = S, Se) in high yield.^{101, 253}

A unique method of synthesis of Cs₆[Mo₄S₄(S_x)₆] (x = 3, 4) by the reaction of Mo₆Br₁₂ with Cs₂S₃ in water was found. So

far this is the only example of the transformation of a hexanuclear halide cluster into a tetranuclear chalcogenide cluster.²⁵⁴

The tetrahedral polysulfide cluster complex [Re₄(μ₃-S)₄·(μ-S₃)₆]^{4–} was obtained by heating a solution of NH₄ReO₄ with an aqueous solution of ammonium polysulfide.^{122, 123} The cyanide complex [Re₄S₄(CN)₁₂]^{4–} was prepared by the reaction of trinuclear thiobromide Re₃S₇Br₇ with KCN in aqueous solution at room temperature.¹⁰⁴

c. Synthesis of octahedral cluster complexes

The molecular octahedral vanadium complex [V₆Se₈O(PMe₃)₆] with an interstitial oxygen atom was obtained from [CpVCl₂(PMe₃)₂] and (Me₃Si)₂Se.¹³⁷ Octahedral clusters with the Cr₆(μ₃-Te)₈ core were synthesised by either the reaction of [CrCl₂(PET₃)₂] with alkyl magnesium chloride and TePET₃ (the source of tellurium) or the reaction of bis(2,4-dimethylpentadienyl)chromium with TePET₃ in the presence of excess PET₃.²⁵⁵ The reaction of anhydrous CrCl₂ with Na₂Se or NaSH followed by treatment with PET₃ in methanol yields a mixture of complexes [Cr₆Q₈(PET₃)₆] and [Cr₆Q₈(H)(PET₃)₆].²⁵⁶

The first molecular octahedral molybdenum clusters [Mo₆S₈(PET₃)₆] and [Mo₆Se₈(PET₃)₆] stable in air were obtained by the reductive dimerisation of trinuclear clusters [Mo₃Q₄Cl₄(PET₃)_x] (x = 3, 4; Q = S, Se) with Mg.^{257–259} The substitution of halogen atoms in octahedral molybdenum dihalide is yet another approach to the synthesis of chalcogenide clusters. The cluster [Mo₆S₈(py)₆] was obtained by the reaction of Mo₆Cl₁₂ with NaSH and NaOBU^t in pyridine,¹⁷⁶ and complexes Cs₅[Mo₆Se_{3,6}Cl_{4,4}(CN)₆] and Cs₅[Mo₆Se_{3,4}·Br_{4,6}(CN)₆], by refluxing metal dihalides and Cs₂Se₃ in water followed by the addition of KCN to the reaction mixture.²⁶⁰

The methods of solution synthesis are particularly important for the preparation of octahedral chalcogenide tungsten clusters. The reaction of W₆Cl₁₂ with NaSH and NaOBU^t in pyridine yields [W₆S₈(py)₆] via complexes [W₆Cl₆S₂Cl₂(py)₆] and [W₆S₆Cl₂(py)₆].¹³⁵ The octahedral tungsten telluride clusters [Na(py)₆][W₆Te₈(py)₆]·py and [W₆Te₈(pip)₆]·6(pip) were obtained by the reaction of Na₂Te with W₆Cl₁₂ [3 days, refluxing in pyridine (py) or piperidine (pip)].^{175, 178}

IV. Reactivity of chalcogenide clusters

Diverse chemical transformations of the chalcogenide cluster complexes may be divided into two large groups, *viz.*, transformations occurring with and without changes in the metal chalcogenide cluster core. The reactions of the former type for the clusters of various nuclearity have much in common but the changes in cluster cores are highly specific for different types of clusters.

1. Substitution of terminal ligands

Similarly to the classic coordination chemistry, the reactions of ligand substitution in clusters are the most abundant and allow an access to compounds with virtually any cluster–ligand combinations. In the present review, we will discuss general features of these reactions for each cluster type, specially highlighting only the most important or unusual cases.

The substitution of halide or aqua ligands proceeds most easily. Therefore, it is not surprising that the chemistry of clusters stable in such environment is the most well studied. Three main classes of compounds belong to such clusters: the triangular chalcogenide clusters M₃Q₄ and M₃Q₇ (M = Mo, W), the tetrahedral clusters M₄Q₄ (M = Mo, W, Re) and the octahedral clusters M₆Q₈ (M = Mo, Re). However, in some cases as, for example, for [Mo₃(μ₃-S)₂(μ-Cl)₃Cl₆]^{2–},¹⁸ such studies have not been carried out yet. The octahedral clusters [M₆S₈L₆] containing highly labile inorganic (hydroxide and

halide) and organic (acetonitrile, amines, *etc.*) ligands that can easily be substituted by other ligands (for example, phosphines) are quite perspective in studies of the ligand substitution reactions.¹⁸

a. Triangular clusters M_3Q_4

The substitution of water molecules in aqua complexes $[M_3Q_4(H_2O)_9]^{4+}$ is studied in detail.²⁶¹ The exchange of the coordinated water in $[Mo_3S_4(H_2O)_9]^{4+}$ was studied by ^{17}O NMR spectroscopy. Different exchange rates were observed for the ligands in non-equivalent positions. The exchange rate of the molecules in *trans*-positions relative to the μ_3 -sulfur atom (*c*- H_2O) is approximately 10^5 times slower than that for the water molecules in the *cis*-position relative to μ_3 -S and therefore in the *trans*-position relative to the bridging sulfur atom (*d*- H_2O). It was suggested that the conjugated base $[Mo_3S_4(H_2O)_8(OH)]^{3+}$ is formed in which the positions *d* rather than *c* are activated. The dissociation constant value (K_a) of $[Mo_3S_4(H_2O)_9]^{4+}$ was equal to $0.18 \text{ mol litre}^{-1}$ ($25^\circ C$, ionic strength $I = 2.00 \text{ mol litre}^{-1}$) when the formation of this conjugated base was taken into account.²⁶¹ Depending on the concentration of HCl in the solution, equilibrium mixtures of aqua chloride complexes are produced up to $[Mo_3S_4 \cdot (H_2O)_2Cl_7]^{3-}$, which can be isolated by the formation of supramolecular systems of hydrogen bonds with the macrocyclic cavitands cucurbit[*n*]urils. So far, all attempts to isolate the complexes with completely substituted anions $[M_3Q_4Cl_9]^{5-}$ were unsuccessful.²⁶² The small value of the formation constant for the complex $[Mo_3S_4(H_2O)_8Cl]^{3+}$ (3.0) indicates low competitiveness of the chloride ligands in aqueous solutions.²⁶²

The substitution of thiocyanate for coordinated water was studied in detail for a series of complexes $[Mo_3O_xQ_{4-x}(H_2O)_9]^{4+}$ and $[W_3O_xQ_{4-x}(H_2O)_9]^{4+}$. The following regularities were found: the substitution of μ_3 -S and further of μ_3 -Se for μ_3 -O in the series from $[Mo_3O_4(H_2O)_9]^{4+}$ to $[Mo_3Se_4(H_2O)_9]^{4+}$ decreases the rate of *d*-ligand, substitution by 6 and 11 orders of magnitude for S and Se, respectively. At the same time, the substitution of μ_2 -bridging ligands increases the substitution rate by 10 (for S) and 20 (for Se) orders of magnitude per bridging atom.⁶⁹ In the mixed-metal complexes $[Mo_2WS_4(H_2O)_9]^{4+}$ and $[MoW_2S_4(H_2O)_9]^{4+}$, the substitution of the ligands bonded to the molybdenum atom is faster than of those bonded to the tungsten atom.²⁶⁴ The kinetic data of the reaction of $[W_3S_4(H_2O)_9]^{4+}$ with NCS^- were explained by the formation of an intermediate complex with S-coordinated thiocyanate ligand and its subsequent transformation into more stable N-bonded isomer.²⁶³ The complexes $[M_3Q_4(NCS)_9]^{5-}$ are easily formed upon the treatment of thiocyanate aqua complexes, and in all isolated solid products the ligand is coordinated by nitrogen atom.^{25–28, 265, 266} The substitution of formate for water results in the formation of η^1 -formate complexes, which were isolated and structurally characterised in the form of salts $K_4[Mo_3S_4(HCO_2)_8(H_2O)]$ and $K_6[W_3S_4(HCO_2)_9](HCO_2) \cdot 3 H_2O$.³⁰ No complexes of this type with other carboxylate ligands are known. The anion pts^- in the known toluene-*p*-sulfonates is always located in the outer coordination sphere as follows from structural studies of the corresponding aqua complexes $[M_3Q_4(H_2O)_9](pts)_4 \cdot x H_2O$.^{31, 118, 267} The cyclopentadienyl derivatives $[Cp_3M_3S_4](pts)$ and their analogues with substituted cyclopentadienyl ligands were synthesised from the complex $Mo_3S_4(pts)_4 \cdot THF$ obtained *in situ* by its reaction with $TiCp$ and $Ti(\eta^5-C_5H_4Me)$.²⁶⁸

The substitution of oxalate or acetylacetonate for water molecules yields the complexes $[M_3Q_4(C_2O_4)_3(H_2O)_3]^{2-}$ and $[M_3Q_4(acac)_3L_3]^+$ ($L = py, NH_3$; $M = Mo, W$; $Q = S, Se$), respectively.^{33, 34} The complexes $[Mo_3S_4(dtp)_3(\mu-dtp)(H_2O)]$ and $[Mo_3OS_3(dtp)_3(\mu-dtp)(H_2O)]$ (*dtp* is diethyldithiophos-

phate) are formed in the reactions of the corresponding aqua complexes with $(EtO)_2PS_2H$. The remaining water molecule is easily substituted by other neutral ligands and the bridging diethyl dithiophosphate, by carboxylate.^{269, 270} A number of complexes obtained from $[Mo_3S_4(dtp)_3(\mu-dtp)(H_2O)]$ and related compounds by substitution of various (predominantly, nitrogen-containing heterocycles and carboxylates) ligands for coordinated water and bridging dithiophosphate have been described.¹⁸ The complex $[Mo_3Se_4(dtp)_3(\mu-AcO)(py)]$ was obtained from the aqua complex $[Mo_3Se_4(H_2O)_9]^{4+}$ similarly.²⁷¹ The attempt to synthesise the dithiophosphate complexes $[M_3Se_4(\mu-dtp)(dtp)_3(H_2O)]$ ($M = Mo, W$) from solutions of $[M_3Se_4(H_2O)_9]^{4+}$ in hydrochloric acid by the addition of P_4S_{10} in the corresponding alcohol yielded the complexes $[M_3(\mu_3-Se)(\mu-Se_qSe_{ax})_3(dtp)_3]Cl$ as a result of sulfur addition to the cluster core $M_3(\mu_3-Se)(\mu-Se_{ax})_3$.²⁷¹

Quite complicated molecules can be obtained on the basis of polynuclear carboxylates, such as the complexes $[\{ Mo_3S_4(dtp)_3L \}_2(\mu-COO(CH_2)_nCOO)]$ ($n = 3, 4$) containing two cluster units linked by bridging glutarate or adipinate ligands.²⁷² Two bridging ligands, glutarate and 1,3-bis(4-pyridyl)propane, link simultaneously two cluster units in $[\{ Mo_3(\mu_3-O)S_3(dtp)_3 \}_2(\mu-COO(CH_2)_3COO)(\mu-py'(CH_2)_3py')]$ (py' is 4-pyridyl).²⁷³

The tridentate ligand diethylenetriamine (*dien*) reacts with $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Mo_3OS_3(H_2O)_9]^{4+}$ yielding $[Mo_3S_4 \cdot (dien')(dien)_2]Cl_3 \cdot 4 H_2O$ and $[Mo_3OS_3(dien')(dien)_2]Cl_3 \cdot 3 H_2O$ where one of three ligands (*dien*) is deprotonated (*dien'*).²⁷⁴ The reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Mo_3OS_3(H_2O)_9]^{4+}$ with $KHB(pz)_3$ (*pz* is pyrazolo) results in the formation of the corresponding pyrazoloborate complexes $[Mo_3Q_4\{HB(pz)_3\}_3]^+$.²⁷⁵ Due to partial hydrolysis of the ligand, the compound $[\{ (HB(pz)_3)_2Mo_3S_4 \}_2(\mu-O)(\mu-pz)_2]$ is also formed. Two cluster fragments of this compound are linked by a bridging oxygen atom and two pyrazolyl ligands.²⁷⁶

Of the ligands containing both nitrogen oxygen donor atoms only polyaminocarboxylates were the subject of fairly detailed studies. A series of iminodiacetate (*H_2ida*) and nitrilotriacetate (*H_3nta*) complexes $[Mo_3S_xO_{4-x}(ida)_3]^{2-}$ and $[M_3S_xO_{4-x}(Hnta)_3]^{2-}$ were synthesised.¹⁸ The nitrilotriacetate is a tridentated ligand leaving one CH_2COOH group free. In all cases, the nitrogen atoms occupy the *trans*-positions with respect to the μ_3 -sulfur atom. Complexes of $W_3S_4^{4+}$ and $W_3O_3S^{4+}$ with polyaminocarboxylate ligands [ethylenedioxybis(ethylenenitrilo)tetraacetate, triethylenetetramine hexaacetate, oxybis(ethylenenitrilo)tetraacetate, 1,4-butylenediaminotetraacetate, 1,3-propylenediaminotetraacetate and its 2-methyl-, 2-methoxy- and 2-carboxymethyl derivatives] were suggested as X-ray contrast diagnostic agents of a new generation.^{39, 277, 278}

Complexes of $Mo_3S_4^{4+}$ with 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (*taci*) and its hexa-*N*-methyl derivative were synthesised. Three bond isomers with ligands coordinated in the *N,N,N*-, *N,N,O*-, and *N,O,O*-mode are present in aqueous solution of $[Mo_3S_4(taci)_3]^{4+}$.²⁷⁹

The lacunar anions $[SiW_{11}O_{39}]^{6-}$ and $[P_2W_{17}O_{61}]^{10-}$ can also serve as the ligands to form, with $[Mo_3S_4(H_2O)_9]^{4+}$, nanosized hybrid polyoxometallate cluster complexes $[\{ (SiW_{11}O_{39})Mo_3S_4(H_2O)_3(\mu-OH) \}_2]^{10-}$ and $[\{ (P_2W_{17}O_{61})Mo_3S_4(H_2O)_3(\mu-OH) \}_2]^{14-}$. In these structures, the polyoxometallate ligands are coordinated around the central core, which consists of two fragments $Mo_3S_4(H_2O)_3^{4+}$ linked by two hydroxyl bridges (both are in the *cis*-positions with respect to μ_3 -S). These complexes are stable in solutions in the pH range of 1–7, but in more acidic solutions form $[Mo_3S_4(H_2O)_9]^{4+}$ quantitatively.²⁸⁰

The halide ligands in the phosphine complexes $[W_3Q_4Cl_3(dmpe)_3]^+$ and $[W_3Q_4Br_3(dppe)_3]^+$ may be substituted by the hydride by the reaction with $NaBH_4$ to yield the

salts $[\text{W}_3\text{Q}_4\text{H}_3(\text{dmpe})_3]^+$ and $[\text{W}_3\text{Q}_4\text{H}_3(\text{dppe})_3]^+$.²⁷⁶ The halide complexes can be recovered upon treatment with hydrohalide acids. According to the kinetic data, in the presence of water the reaction proceeds through several stages and the dihydrogen complex $[\text{W}_3\text{Q}_4(\text{H}_2)\text{H}_2(\text{dmpe})_3]^+$ is formed initially. In the absence of water, this does not happen and the bond $\text{H}\cdots\text{H}$ is formed between the hydride complex and the dimer $(\text{HCl})_2$.^{281–283} The reaction with NaOH in acetonitrile yields $[\text{W}_3\text{Q}_4(\text{OH})_3(\text{dmpe})_3]^+$.^{281, 283}

b. Triangular clusters M_3Q_7

In the presence of sources of halide ions, the coordination polymers $\text{M}_3\text{Q}_7\text{X}_4$ can be transformed into discrete anionic complexes $[\text{M}_3\text{Q}_7\text{X}_6]^{2-}$ under rather drastic conditions: in melt, upon mechanochemical treatment or upon radiolysis.^{45, 53, 231, 284, 285} The salts $[\text{M}_3\text{Q}_7\text{X}_6]^{2-}$ in turn can be transformed into aqua complexes $[\text{M}_3\text{Q}_7(\text{H}_2\text{O})_6]^{4+}$ that are quite stable in an aqueous solution of TsOH , but could not be isolated in the solid state.^{24, 32} The rate constants of substitution of the halide ion for the coordinated water in the molybdenum aqua complexes $[\text{Mo}_3\text{Q}_7(\text{H}_2\text{O})_6]^{4+}$ do not depend on $[\text{H}^+]$ [for Cl^- : 1.83×10^{-4} ($\text{Q} = \text{S}$); 6.7×10^{-4} ($\text{Q} = \text{Se}$); for Br^- : 2.07×10^{-4} ($\text{Q} = \text{S}$); 33×10^{-4} litre $\text{mol}^{-1} \text{s}^{-1}$ ($\text{Q} = \text{Se}$)].³² The observed kinetic data agree with the suggestion that the replacement of the water molecule in *cis*-position relative to $\mu_3\text{-Q}$ proceeds in one step yielding $[\text{Mo}_3\text{Q}_7\text{Cl}_3(\text{H}_2\text{O})_3]^+$. The halide complexes $[\text{M}_3\text{Q}_7\text{Br}_6]^{2-}$ are convenient starting materials for the synthesis of other $\text{Mo}_3\text{S}_7^{4+}$ derivatives by the ligand substitution reactions. The complexes $[\text{Mo}_3\text{Q}_7(\text{NCS})_6]^{2-}$ [$\text{Q} = \text{S}$,^{51, 286} Se (Ref. 44)] are formed in the reactions with thiocyanate and the reaction with aniline furnishes the complex $[\text{Mo}_3\text{S}_7\text{Br}_3(\text{PhNH}_2)_3]\text{Br} \cdot \text{Et}_4\text{NBr}$.^{51, 286} The ligand exchange reactions were used for the synthesis of dithiocarbamates $[\text{Mo}_3\text{S}_7(\text{Et}_2\text{NCS}_2)_3]\text{X}$, $[\text{Mo}_3\text{S}_7(\text{pdtc})_3]\text{X}$ (pdtc is piperidine-1-dithiocarboxylate), dithiophosphates and diselenophosphates.^{53, 287–290} The compounds $[\text{Mo}_3\text{Q}_7\{\text{N}(\text{QPPH}_2)_2\}_3]\text{Br}$ containing six-membered chelate rings were synthesised from $(\text{Et}_4\text{N})_2[\text{Mo}_3\text{Q}_7\text{Br}_6]$ and $\text{K}\{\{\text{Ph}_2\text{P}(\text{Q})\}_2\text{N}\}$ ($\text{Q} = \text{S}$, Se).^{287, 291} The complex $(\text{Et}_4\text{N})_2 \cdot [\text{Mo}_3\text{S}_7(\text{MeC}_6\text{H}_4\text{S}_2)_3]$ with toluene-3,4-dithiolate as a ligand was synthesised and its structure was studied.²⁹² Catecholate complexes are also known.^{293, 294} Trischelate complexes of Mo_3S_7 with bidentate ligands [2-mercaptosuccinic acid (H_3msa), *meso*-2,3-dimercaptosuccinic acid (H_4dsa), 2-mercaptobenzoic acid, 3,4-dihydroxybenzoic acid, 8-hydroxyquinoline and 6-mercaptopurine] were obtained by exchange reactions from $(\text{Et}_4\text{N})_2[\text{Mo}_3\text{S}_7\text{Br}_6]$ in acetonitrile or DMF.^{293–295} Although the presence of only one isomer of the compound $(\text{Et}_3\text{NH})_2[\text{Mo}_3\text{S}_7(\text{Hmsa})_3]$ in which the sulfur atoms of the three ligands are coordinated in *cis*-positions with respect to $\mu_3\text{-S}$ was established, the results of potentiometric titration of $[\text{Mo}_3\text{S}_7(\text{dsa})_3]^{2-}$ better correspond to the behaviour of less symmetric isomer in which two chelate rings are closed through the sulfur atoms (S, S') and the third one through the S and O atoms.²⁹³ The coordination of the redox-active ligands 4,5-dimercapto-1,3-dithiole-2-thione (dmit) and dimercaptomaleonitrile (mnt) results in the complexes $[\text{Mo}_3\text{S}_7(\text{dmit})_3]^{2-}$ and $[\text{Mo}_3\text{S}_7(\text{mnt})_3]^{2-}$.^{296, 297}

The oxalate complexes $[\text{M}_3\text{Q}_7(\text{C}_2\text{O}_4)_3]^{2-}$ ($\text{M} = \text{Mo}$; $\text{Q} = \text{S}$, Se ; $\text{M} = \text{W}$, $\text{Q} = \text{S}$) were obtained by mechanochemical synthesis from the corresponding coordination polymers and potassium oxalate or the solution synthesis from the bromide complexes and oxalate.^{34, 297} The oxalate ligands can subsequently coordinate ions of other transition metals, lanthanides and actinides yielding in some cases nanosized complexes and porous coordination polymers.²⁹⁸

Melting of selenobromides $\text{M}_3\text{Se}_7\text{Br}_4$ ($\text{M} = \text{Mo}$, W) with 1,10-phenanthroline produces very stable complexes $[\text{M}_3\text{Se}_7(\text{phen})_3]^{4+}$ isolated as salts with anions X^- or ZnX_4^{2-}

($\text{X} = \text{Cl}$, Br) after the extraction of the melt with hot concentrated solutions of HCl or HBr .⁵³

The chalcogenides $\text{Mo}_3\text{Te}_7\text{I}_4$ and $\text{W}_3\text{Te}_7\text{Br}_4$ produce the cyanide complexes $[\text{M}_3\text{Te}_7(\text{CN})_6]^{2-}$ when heated with aqueous solution of KCN . The cluster $[\text{Mo}_3\text{Te}_7(\text{TeI}_3)_3]\text{I}$ forms $[\text{Mo}_3\text{Te}_7\{(\text{RO})_2\text{PS}_2\}_3]\text{I}$ in a solid-state reaction with dithiophosphates $\text{KS}_2\text{P}(\text{OR})_2$ ($\text{R} = \text{Et}$, Pr^i) at 100°C . The mechanochemical reactions of $\text{Mo}_3\text{Te}_7\text{I}_4$ or $\text{W}_3\text{Te}_7\text{Br}_4$ with $(\text{EtO})_2\text{PS}_2\text{K}$ also result in the ‘cutting out’ of the M_3Te_7 cluster fragment and formation of $[\text{Mo}_3\text{Te}_7\{(\text{EtO})_2\text{PS}_2\}_3]\text{I}$ or $[\text{W}_3\text{Te}_7\{(\text{EtO})_2\text{PS}_2\}_3]\text{Br}$ in low yields.^{50, 64, 67, 299, 300}

c. Cubane-type clusters M_4Q_4

The cubane-type molybdenum aqua complexes $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{n+}$ exist in three oxidation states with $n = 4, 5$ (the most stable state) and 6. The chloride ion is weakly coordinated to $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ ($K_1 = 1.98$, which is approximately 1000 times less than the corresponding value for thiocyanate). According to the kinetic data, the rate of substitution of thiocyanate for water molecule increases by several orders of magnitude in the series $5+ < 4+ < 6+$. The substitution of Se for S in the aqua complex $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ increases the rate of substitution approximately tenfold. In all cases, the full substitution is accompanied by oxidation of the cluster core to the state $\text{M}_4\text{Q}_4^{6+}$ and the formation of isothiocyanate complexes $[\text{M}_4\text{Q}_4(\text{NCS})_{12}]^{6-}$, although the kinetic data indicate probability of the intermediate formation of an S-coordinated isomer.⁷⁰ The salts $[\text{Mo}_4\text{S}_4(\text{NCS})_{12}]^{6-}$, $[\text{Mo}_4\text{Se}_4(\text{NCS})_{12}]^{6-}$, $[\text{W}_4\text{Q}_4(\text{NCS})_{12}]^{6-}$, $[\text{MoW}_3\text{Q}_4(\text{NCS})_{12}]^{6-}$ ($\text{Q} = \text{S}$, Se), $[\text{Mo}_3\text{WS}_4(\text{NCS})_{12}]^{6-}$ were synthesised and their structures were studied.^{22, 116–118} The oxidation of the cluster $\text{M}_4\text{Q}_4^{5+}$ into $\text{M}_4\text{Q}_4^{6+}$ also occurs upon addition of the dithiophosphates $(\text{RO})_2\text{PS}_2^-$ ($\text{R} = \text{Et}$, Pr^i) to solutions of aqua complexes in HCl . This results in the dithiophosphate complexes $[\text{M}_4\text{Q}_4(\text{dtp})_6]$, which exist in the form of two isomers $[\text{M}_4\text{Q}_4(\mu\text{-dtp})_2(\text{dtp})_4]$ and $[\text{M}_4\text{Q}_4(\mu\text{-dtp})_3(\text{dtp})_3]$.¹¹⁶ Similarly to the triangular clusters M_3Q_4 , the bridging dithiophosphate ligand in $[\text{Mo}_4\text{S}_4(\mu\text{-dtp})_2(\text{dtp})_4]$ is rather labile and can be easily replaced by other bidentate ligands such as, for example, acetate or benzoate. As a result, the paramagnetic complexes $[\text{Mo}_4\text{S}_4(\mu\text{-OOCR})_2(\text{dtp})_4]$ are formed.^{114, 124} The bridging dithiocarbamate ligands can be selectively substituted by xanthate producing a mixture of $[\text{Mo}_4\text{S}_4(\mu\text{-Et}_2\text{NCS}_2)(\mu\text{-EtOCS}_2)(\text{Et}_2\text{NCS}_2)_4]$ and $[\text{Mo}_4\text{S}_4(\mu\text{-EtOCS}_2)_2(\text{Et}_2\text{NCS}_2)_4]$.¹¹⁵ On the contrary, treatment of the aqua complex $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ with concentrated aqueous ammonia results in the reduction of the cluster core and formation of the complex $[\text{Mo}_4\text{S}_4(\text{NH}_3)_{12}]^{4+}$.¹¹³ Reaction of the aqua complex $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ with potassium tris(pyrazolo)borate proceeds without any redox processes in the cluster core and yields $[\text{Mo}_4\text{S}_4\{\text{HB}(\text{pz})_3\}_4(\text{pz})]$.³⁰¹ An attempt to coordinate oxalate to $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ resulted in the isolation of the triangular cluster $[\text{Mo}_3\text{S}_4(\text{C}_2\text{O}_4)_3(\text{H}_2\text{O})_3]^{2-}$ as the only product.³⁵

The molecular complexes $[\text{Re}_4\text{Q}_4(\text{TeCl}_2)_4\text{Cl}_8]$ ($\text{Q} = \text{S}$, Se , Te) are very convenient starting compounds in the chemistry of tetranuclear rhenium complexes:¹²¹ the coordinated TeCl_2 molecules and chloride ions can easily be substituted for other ligands.^{106, 107, 120, 302–304}

d. Octahedral clusters Re_6Q_8

The halide complexes $[\text{Re}_6\text{S}_8\text{X}_6]^{4-}$ ($N_e = 24$) and $[\text{Re}_6\text{Se}_8\text{I}_6]^{3-}$ ($N_e = 23$) are the most common starting compounds for the substitution reactions.¹³⁶ The substitution rarely proceeds completely and even in the excess of the ligand di- and trisubstituted products are often formed. The addition of Ag^+ ions for binding of the halide ions allows complete substitution of the terminal ligands. This method was used for the synthesis of the complexes $[\text{Re}_6\text{S}_8(\text{H}_2\text{O})_6]^{2+}$ (from $[\text{Re}_6\text{S}_8\text{X}_6]^{4-}$ and AgClO_4 in HClO_4),¹⁴⁷ $[\text{Re}_6\text{Se}_8(\text{MeCN})_6]^{2+}$

(from $[\text{Re}_6\text{Se}_8\text{Br}_6]^{3-}$ and AgBF_4 in MeCN; in this case the substitution is accompanied by the cluster reduction).¹⁴⁶ The reaction of $\text{Cs}_3[\text{Re}_6(\text{S}_7\text{Br})\text{Br}_6]$ (the 'inner' ligands L^i of the cluster complex are given in parentheses) with aqueous ammonia results in step-by-step substitution of NH_3 for all terminal ligands and in the formation of $[\text{Re}_6(\text{S}_7\text{Br})(\text{NH}_3)_6]^{3+}$.¹⁴⁸ The reactions of $[\text{Re}_6\text{S}_8\text{Cl}_6]^{3-}$ with pyridine affords a mixture of *cis*- and *trans*-isomers of $[\text{Re}_6\text{S}_8\text{Cl}_4(\text{py})_2]^{2-}$ as well as facial isomers of trisubstituted complexes $[\text{Re}_6\text{S}_8\text{Cl}_3(\text{py})_3]^{n-}$ ($n = 0, 1$).^{149, 150} In the case of phosphines, more complete substitution is possible. Thus in the reaction of $[\text{Re}_6\text{Se}_8\text{I}_6]^{3-}$ with PET_3 the following complexes were obtained: *fac*- and *mer*- $[\text{Re}_6\text{Se}_8(\text{PET}_3)_3\text{I}_3]^-$, *cis*- and *trans*- $[\text{Re}_6\text{Se}_8(\text{PET}_3)_4\text{I}_2]$, $[\text{Re}_6\text{Se}_8(\text{PET}_3)_5\text{I}]^+$ and completely substituted $[\text{Re}_6\text{Se}_8(\text{PET}_3)_6]^{2+}$. The reaction of $[\text{Re}_6\text{Se}_8\text{I}_6]^{3-}$ with a bidentate 1,6-bis(diphenylphosphino)hexane ligand also results in the monochelate, *cis*- and *trans*-bischelate and trischelate complexes and is accompanied as usual, by one-electron reduction of the cluster core.¹⁵³ The remaining unsubstituted halogen atoms in the mixed-ligand phosphine complexes can be substituted by other ligands. For example, the solvolysis of $[\text{Re}_6\text{Se}_8(\text{PET}_3)_4\text{I}_2]$ in donor solvents yields cationic complexes $[\text{Re}_6\text{Se}_8(\text{PET}_3)_4\text{L}_2]^{2+}$ ($\text{L} = \text{MeCN}$, DMF, DMSO).^{152, 154} The bicluster derivatives $\{[\text{Re}_6\text{Se}_8(\text{PET}_3)_5]_2(\text{L}-\text{L})\}^{4+}$ were obtained from $[\text{Re}_6\text{Se}_8(\text{PET}_3)_5(\text{MeCN})]^{2+}$ using the bidentate bridging (ditopic) ligands [4,4'-bipyridyl and 1,2-disubstituted ethane, ethylene and acetylene with 4-pyridyl substituents ($\text{L}-\text{L}$)].¹⁵⁴ These reactions with $[\text{Re}_6\text{Se}_8(\text{PET}_3)_4(\text{MeCN})_2]^{2+}$ result in the formation of tetrakiscluster complexes in which the clusters and bipyridyl bridges form molecular squares.¹⁵⁵ The substitution of 4-(3,4,6-tribenzyloxy)benzyloxy pyridine for acetonitrile molecules in the complex $[\text{Re}_6\text{Se}_8(\text{MeCN})_6]^{2+}$ is the first step in the synthesis of dendrimers based upon redox-active sixnuclear clusters.¹⁴⁶

Highly nucleophilic cyanide ion is able of substituting all bridging ligands even in the three-dimensional structures $[\text{Re}_6\text{Q}_8\text{Br}_2]$ ($\text{Q} = \text{S}, \text{Se}$) and $\text{Re}_6\text{Te}_{15}$ yielding $[\text{Re}_6\text{Q}_8(\text{CN})_6]^{4-}$ (Refs 156, 157 and 305). Similarly compound $[\text{Re}_6\text{Q}_8(\text{OH})_8]^{4-}$ is formed in a melt of KOH .¹⁵⁸ In the case of $[\text{Re}_6\text{Se}_8\text{Br}_2]$, the reaction can also result in partial substitution of oxide bridges for the selenide yielding $\text{Re}_6\text{Se}_4\text{O}_4^{2+}$ derivatives. Remarkably, the selective substitution of selenium atoms of just one face of the Se_8 cube takes place.¹³⁹ Another method for the synthesis of hexacyanide complexes is based on the reactions of the salts $[\text{Re}_6\text{Se}_8\text{I}_6]^{4-}$ and $[\text{Re}_6\text{S}_8\text{Br}_6]^{4-}$ with a melt of NaCN .³⁰⁶ The telluride $[\text{Re}_6\text{Te}_8(\text{Te}_7)]$ forms $[\text{Re}_6\text{Te}_8(\text{CN})_6]^{4-}$ in the cyanide melt.¹⁶³ Similarly, the chalcogenides ZnMo_6S_8 and Mo_6Se_8 give $[\text{Mo}_6\text{S}_8(\text{CN})_6]^{7-}$ and $[\text{Mo}_6\text{Se}_8(\text{CN})_6]^{7-}$ in a sodium cyanide melt, the latter complex is readily oxidised to $[\text{Mo}_6\text{Se}_8(\text{CN})_6]^{6-}$.^{162, 307}

The interaction of the cluster complexes $\text{Cs}_4[\text{Re}_6\text{S}_8\text{Br}_6] \cdot 2\text{H}_2\text{O}$, $\text{Cs}_3[\text{Re}_6\text{S}_8\text{Br}_6] \cdot 2\text{H}_2\text{O}$, $\text{Cs}_3[\text{Re}_6(\text{Q}_7\text{Br})\text{Br}_6] \cdot \text{H}_2\text{O}$ and $\text{K}_2[\text{Re}_6(\text{S}_6\text{Br}_2)\text{Br}_6]$ with the melts of 3,5-dimethylpyrazole (3,5-Me₂pzH) and triphenylphosphine results in complete or partial substitution of the halide ligands. The complexes $[\text{Re}_6\text{Q}_8(3,5\text{-Me}_2\text{pzH})_6]\text{Br}_2 \cdot 2(3,5\text{-Me}_2\text{pzH})$, $[\text{Re}_6(\text{Q}_7\text{O})(3,5\text{-Me}_2\text{pzH})_6]\text{Br}_2 \cdot (3,5\text{-Me}_2\text{pzH})$ (with the substitution of $\mu_3\text{-O}$ for $\mu_3\text{-Br}$), *trans*- $[\text{Re}_6\text{Q}_8(\text{PPh}_3)_4\text{Br}_2]$, *fac*- $[\text{Re}_6(\text{Q}_7\text{Br})(\text{PPh}_3)_3\text{Br}_3]$, *cis*- $[\text{Re}_6(\text{S}_6\text{Br}_2)(\text{PPh}_3)_2\text{Br}_4]$ and *trans*- $[\text{Re}_6(\text{S}_6\text{Br}_2)(\text{PPh}_3)_2\text{Br}_4] \cdot 4\text{H}_2\text{O}$ were isolated and their structures were studied.^{159–161}

2. Redox reactions

Cyclic voltammetry (CV) of triangular clusters $\text{M}_3\text{Q}_4^{4+}$ shows two waves of reduction, which can be explained as sequential reduction $\text{M}_3^{\text{IV}}\text{O}_4^{4+} \rightarrow \text{M}_2^{\text{IV}}\text{M}^{\text{III}}\text{Q}_4^{3+} \rightarrow \text{M}^{\text{IV}}\text{M}_2^{\text{III}}\text{Q}_4^{2+}$. The reduction ability decreases in the series $\text{Mo}_3\text{S}_4^{4+} > \text{Mo}_3\text{Se}_4^{4+} > \text{W}_3\text{Se}_4^{4+} > \text{W}_3\text{S}_4^{4+}$ (Refs 24, 38, 269 and 308). In some cases the one-electron reduction products may be isolated and their structures can be established.^{42, 309, 310} Usually,

the reduction of the clusters $\text{Mo}_3\text{S}_7^{4+}$ is irreversible and is accompanied by elimination of sulfur yielding $\text{Mo}_3\text{S}_4^{4+}$ (Ref. 293).

Cyclic voltammetry revealed the possibility of reversible one-electron reduction (to $n = 4$) and oxidation (to $n = 6$) of the clusters $[\text{Mo}_x\text{W}_{4-x}\text{Q}_4(\text{H}_2\text{O})_{12}]^{n+}$ ($x = 0-4$).^{116, 117} For both of the pairs $5+/4+$ and $6+/5+$, the value of half-wave potential ($E_{1/2}$) almost linearly decreases with the increase in the number of tungsten atoms in the cluster: each additional tungsten atom causes a negative potential shift of approximately 0.2 V. It reflects the predisposition of tungsten to higher oxidation states. The effect of the substitution of selenium for sulfur in the cluster core is less pronounced: the substitution of four Se atoms for S decreases the potential by less than 0.1 V.^{116, 117} Two waves of one-electron reduction of the cyanide clusters $[\text{M}_4\text{Q}_4(\text{CN})_{12}]^{6-}$ ($\text{M} = \text{Mo}, \text{W}$; $\text{Q} = \text{S}, \text{Se}, \text{Te}$) were also observed by CV. Interestingly, the substitution of the cyanide ions for coordinated water molecules results in a significant positive shift of the potentials (0.6–0.7 V), which makes possible the reduction of $[\text{W}_4\text{Q}_4(\text{CN})_{12}]^{7-}$ to $[\text{W}_4\text{Q}_4(\text{CN})_{12}]^{8-}$ ($\text{Q} = \text{S}, \text{Se}, \text{Te}$). The cyanide ligands damp the effect of the metal change on the electrode potential: while for the pair $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{6+}/[\text{W}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{6+}$ $\Delta E_{1/2}$ is equal to 825 mV, it is only 411 mV for the pair $[\text{Mo}_4\text{S}_4(\text{CN})_{12}]^{6-}/[\text{W}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{6-}$. Presumably, this is caused by the participation of the cyanide ion π -orbitals in the charge redistribution within the cluster core. The transition from $\text{Q} = \text{S}$ to Se and Te regularly (by approximately 100 mV) decreases the redox potential stabilising the most oxidised state of the cluster ($\text{M}_4\text{Q}_4^{6+}$).¹⁰² However, in the case of $[\text{Mo}_4\text{Q}_4(\text{edta})_2]^{n-}$ ($n = 2-4$), the substitution of Se for S does not affect the $E_{1/2}$ value.³¹¹ The reversible two-electron oxidation was also observed in the case of cyclopentadienyl clusters $[(\eta^5\text{-C}_5\text{H}_4\text{Pr})_4\text{Mo}_4\text{Q}_4]$ ($\text{Q} = \text{S}, \text{Se}$); the selenium clusters undergo oxidation at significantly more negative potentials.^{101, 253} In contrast to the molybdenum and tungsten analogues, no reversible redox transformations were observed for rhenium tetrahedral clusters.

One-electron oxidation proceeds relatively easily in the case of the chalcogenide clusters Re_6Q_8 ($N_e = 24$).¹³⁶ The reversible one-electron reduction at the negative potentials was detected by CV for the compounds $[\text{Re}_6(\text{Q}_5\text{Cl}_3)\text{Cl}_6]^-$ ($\text{Q} = \text{S}, \text{Se}$), but no oxidation occurs.¹⁸⁸ Such behaviour is in keeping with both the increase in the negative charge of the cluster anion with the increase in the number of chalcogen atoms in the cluster core and lower electronegativity of the chalcogen atoms. In some cases, stable oxidation products, such as $(\text{Bu}^t\text{N})_3[\text{Re}_6\text{S}_8\text{Cl}_6]$, $(\text{Ph}_4\text{P})_3[\text{Re}_6\text{S}_8(\text{CN})_6]$, $(\text{Ph}_4\text{P})_2(\text{H}) \cdot [\text{Re}_6\text{Se}_8(\text{CN})_6] \cdot 8\text{H}_2\text{O}$ and $(\text{Et}_4\text{N})_2(\text{H})[\text{Re}_6\text{Te}_8(\text{CN})_6] \cdot 2\text{H}_2\text{O}$, can be isolated.^{312, 313} It was found that the oxidation potential of complexes with heterocyclic amines increases in accord with the basicity of the ligand. The reduction of heterocyclic ligands takes place in the region of negative potentials and the electronic interaction of two heterocyclic ligands through the cluster was observed.¹⁴⁹ The oxidation of the cyanide complexes $[\text{Re}_6\text{Q}_8(\text{CN})_6]^{4-}$ occurs at significantly lower potential than that of their halide analogues. The transition from a sulfide cluster to the telluride drastically (by 0.5 V) reduces the oxidation potential.³¹⁴

Both reversible one-electron reduction and one-electron oxidation are possible for the electron-deficient molybdenum clusters $[\text{Mo}_6\text{Q}_8(\text{PET}_3)_6]$ ($\text{Q} = \text{S}, \text{Se}$; $N_e = 20$). In spite of a strong electron-deficient character of the clusters, reduction occurs at highly negative potentials. Both electrode processes occur at virtually the same potentials for sulfide and selenide clusters.²⁵⁹ On the contrast, the monochalcogenide clusters $[\text{Mo}_6(\text{QX}_7)\text{X}_6]^{3-}$ ($\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}$) can reversibly lose one or two electrons. The introduction of the second chalcogen atom results in a strong negative shift of the potentials, as in the

case of the cyanide clusters $[\text{Mo}_6\text{Q}_2\text{X}_6(\text{CN})_6]^{4-}$ ($\text{Q} = \text{S}, \text{Se}$).¹³⁴ It should be noted that there is virtually no difference in $E_{1/2}$ values for $[\text{Mo}_6(\text{QCl}_7)\text{X}_6]^{3-/2-}$, whereas for two geometrical isomers of $[\text{Mo}_6(\text{Se}_2\text{Cl}_6)\text{Cl}_6]^{4-/3-/2-}$, the difference in $E_{1/2}$ values is as large as $\sim 0.1 \text{ V}$.^{164, 165}

3. Clusters of clusters, coordination polymers and supramolecular compounds

Cyanide derivatives of chalcogenide clusters attract attention as ‘building blocks’ in the synthesis of coordination polymers, particularly those with big cavities and high porosity. Both tetrahedral clusters $\text{M}_4\text{Q}_4(\text{CN})_{12}$ and octahedral clusters $\text{M}_6\text{Q}_8(\text{CN})_6$ ($\text{M} = \text{Mo}, \text{W}, \text{Re}$; $\text{Q} = \text{S}, \text{Se}, \text{Te}$) are used for these purposes.^{11, 12, 315–330} Recently, coordination polymers based on the aqua complexes $[\text{Re}_6\text{Q}_8(\text{OH})_6]^{4-}$ ($\text{Q} = \text{S}, \text{Se}$) have been synthesised.³³¹

The condensation of clusters takes place during thermolysis of $[\text{Re}_6\text{Se}_8(\text{PEt}_3)_5(\text{MeCN})_2]^{2+}$ and *cis*- $[\text{Re}_6\text{Se}_8(\text{PEt}_3)_4.(\text{MeCN})_2]^{2+}$. Here, the labile acetonitrile molecules are substituted by the μ_3 -Se atom of the other cluster core yielding $[\text{Re}_{12}\text{Se}_{16}(\text{PEt}_3)_{10}]^{4+}$ and *trans*- $[\text{Re}_{12}\text{Se}_{16}(\text{PEt}_3)_8(\text{MeCN})_2]^{4+}$ (Ref. 152). Similar process resulting in the formation of $[\text{Mo}_{12}\text{Q}_{16}(\text{PEt}_3)_{10}]$ was observed in the elimination of coordinated triethylphosphine from the complex $[\text{Mo}_6\text{Q}_8(\text{PEt}_3)_6]$ under the action of sulfur.³³²

Due to the formation of complementary bonds between the carbonyl groups of the macrocyclic cavitand cucurbit[6]uril and water molecules of aquachloride complexes, the isolation of the cluster complexes $[\text{M}_3\text{Q}_4(\text{H}_2\text{O})_{9-x}\text{Cl}_x]^{(4-x)+}$ ($x = 1–3$) in the form of supramolecular adducts with cucurbit[6]uril from solutions in 2–4 M HCl and studies of their structures become possible. The size and the symmetry of six carbonyl groups of cucurbituril correspond well to six aqua ligands in *cis*-positions with respect to μ_3 -bridging chalcogen atom in the triangular cluster aqua complexes. In the case of bulkier and less water-soluble cucurbit[8]uril, the aquachloride complexes with higher chloride content (up to $x = 7$) were isolated in spite of the loss of complementarity, because the cluster aquachloride complexes occupied the voids between differently packed large cucurbit[8]uril molecules and the hydrogen bonds provided additional stabilisation of the structure.^{262, 333, 334}

4. Substitution of ‘inner’ bridging ligands

The reactions of the sulfohalides $[\text{M}_3\text{S}_7\text{X}_6]^{2-}$ with PPh_3Se or KNCS result in the selective substitution of selenium for the equatorial sulfur atom of the disulfide ligand. This reaction is irreversible and even the excess of KNCS or PPh_3S does not transform the clusters $\text{Mo}_3\text{S}(\text{SSe})_3^{4+}$ back into $\text{Mo}_3\text{S}_7^{4+}$. The synthesis of the compound $[\text{Mo}_3\text{S}_4\text{Se}_3(\text{Et}_2\text{NCS}_2)_3]^{+}$ from $[\text{Mo}_3\text{S}_7(\text{Et}_2\text{NCS}_2)_3]^{+}$ and KNCS in MeCN at room temperature is an example of such reaction.^{47, 49} High lability of the equatorial sulfur atom was confirmed by selective isotope exchange in the reaction of $(\text{NH}_4)_2[\text{Mo}_3\text{S}_7(\text{S}_2)_3]$ with a solution of ammonium polysulfide containing the isotope ^{34}S .^{44, 48} The substitution of chalcogen atoms of $\text{Mo}_3\text{S}_7\text{Br}_4$ in KNCS melt at 200–220 °C proceeds further *via* $[\text{Mo}_3\text{S}_4\text{Se}_3(\text{CN})_6]^{2-}$ and $[\text{Mo}_3(\mu_3\text{-S})\text{Se}_6(\text{CN})_6]^{2-}$ and yields finally $[\text{Mo}_3\text{Se}_7(\text{CN})_6]^{2-}$.⁶⁷ The relative lability of the chalcogen atoms in three different positions of the cores $\text{M}_3(\mu_3\text{-Q})(\mu\text{-Q}_{\text{ax}}\text{Q}_{\text{eq}})_3^{4+}$ decreases in following order $\text{Q}_{\text{eq}} > \text{Q}_{\text{ax}} > \mu_3\text{-Q}$. Seleno cyanate serves simultaneously as a source of selenium for the formation of selenide clusters and a source of cyanide ions. A similar order of substitution of Se for Te was found in the reaction of $\text{M}_3\text{Te}_7\text{Br}_4$ with KNCS . The complex $[\text{W}_3(\mu_3\text{-Te}).(\mu_2\text{-TeSe})_3(\text{CN})_6]^{2-}$, containing a new inorganic ligand TeSe^{2-} was isolated and its structure was studied.⁶⁷ The molten KNCS transforms the chalcobromides $\text{W}_3\text{S}_7\text{Br}_4$ and

$\text{W}_3\text{Se}_7\text{Br}_4$ into $[\text{W}_3\text{S}_4(\text{NCS})_9]^{5-}$ *via* $[\text{W}_3\text{S}_2\text{Se}_{4-x}(\text{NCS})_9]^{5-}$ ($x = 1–3$).³³⁵ The transformation of the cluster $\text{Mo}_3\text{Se}_7^{4+}$ into $\text{Mo}_3\text{S}_7^{4+}$ was also observed in the reaction of $\text{Mo}_3\text{Se}_7\text{Br}_4$ with $(\text{NH}_4)_2\text{S}_x$ under hydrothermal conditions.⁴⁴

The substitution of ions Q^{2-} ($\text{Q} = \text{O}, \text{S}, \text{Se}, \text{Te}$), NR^{2-} , P^{3-} , As^{3-} for μ_3 -bridging halogen atoms is typical of octahedral rhenium complexes. This reaction proceeds more easily in the case of the most halogen-rich cluster cores. Thus $[\text{Re}_6(\text{Se}_4\text{O}_2\text{Cl}_2)\text{Cl}_6]^{2-}$ is formed upon mere heating of the compound $[\text{Re}_6(\text{Se}_4\text{Cl}_4)\text{Cl}_6]$ in wet DMF, both isomers, which differ in mutual position of the oxygen atoms, being isolated. $[\text{Re}_6(\text{S}_7\text{Br})\text{Br}_6]^{3-}$ is one of the products of a complex reaction of the sulfobromide $[\text{Re}_6(\text{S}_4\text{Br}_4)\text{Br}_6]$ with KNCS in a melt.³³⁶

The clusters $[\text{Re}_6(\text{Q}_5\text{Cl}_3)\text{Cl}_6]^{-}$ ($\text{Q} = \text{S}, \text{Se}$) are studied in most details. They readily form the complexes $[\text{Re}_6(\text{Q}_5\text{Q}'\text{Cl}_2)\text{Cl}_6]^{2-}$ ($\text{Q}' = \text{O}, \text{S}, \text{Se}, \text{Te}$) in the reactions with the silylated chalcogen carriers $[(\text{Me}_3\text{Si})_2\text{Q}]$.³³⁷ With the silylamide reagents $[(\text{Me}_3\text{Si})_2\text{NR}]$, where $\text{R} = \text{H}, \text{Me}, \text{Bu}^n$, the complexes $[\text{Re}_6(\text{Q}_5\text{EX}_2)\text{Cl}_6]^{2-}$ ($\text{E} = \text{NSiMe}_3, \text{NMe}, \text{NBu}^n$) are formed. The trimethylsilyl group can be removed by treatment of the reaction mixture with Bu_4^+NF^- yielding $[\text{Re}_6(\text{Q}_5(\text{NH})\text{X}_2)\text{Cl}_6]^{2-}$. The nitrogen atom in this cluster remains nucleophilic and can be alkylated by butyl chloride in the presence of a base yielding the complex $[\text{Re}_6(\text{Q}_5(\text{NBu}^n)\text{X}_2)\text{Cl}_6]^{2-}$.³³⁸ In the case of the oxide cluster, the substitution of one of the terminal chloride ligands also takes place and the complex $[\{\text{Re}_6(\text{S}_5\text{OCl}_2)\text{Cl}_5\}_2\text{O}]^{4-}$ is formed.³³⁹ The substitution of O, S, NH for two μ_3 -chlorine atoms in the chalcogenide clusters $[\text{Re}_6(\text{S}_6\text{Cl}_2)\text{Cl}_6]^{2-}$ is possible in the reactions with silyl reagents. The clusters $[\text{Re}_6(\text{S}_6\text{E}_2)(\text{PPR}_3)_6]^{2+}$ ($\text{E} = \text{P}, \text{As}$) containing μ_3 -atoms of Group 15 elements in the cluster core were obtained when $\text{PhAs}(\text{SiMe}_3)_2$ or $\text{P}(\text{SiMe}_3)_3$ were used.¹³⁶

The bridging chalcogenide ligands are less labile and can be substituted only under drastic conditions. For instance, the reaction of $[\text{Re}_6\text{Te}_8(\text{Te}_7)]$ with a melt of KNCS results in the substitution of sulfur for μ_3 -tellurium atoms and produces a mixture of $[\text{Re}_6\text{S}_8(\text{CN})_6]^{4-}$ and $[\text{Re}_6\text{S}_6\text{Te}_2(\text{CN})_6]^{4-}$.^{163, 340} The formation of the mixed-chalcogen clusters was confirmed by ^{77}Se and ^{125}Te NMR spectroscopy.³⁴¹ The reaction of $[\text{Re}_6\text{Te}_8(\text{Te}_7)]$ with bromine yields $[\text{Re}_6(\text{Te}_4\text{Br}_4)\text{Br}_6]$.^{8, 187} Iodine, being a weaker oxidant, transforms the *spiro*-anion Te_7^{2-} into the ligand TeI_2 without affecting the cluster core to give the cluster $[\text{Re}_6\text{Te}_8(\text{TeI}_2)_6]\text{I}_2$.³⁴²

In the series of the octahedral molybdenum chalcogenide clusters Mo_6Q_8 ($\text{Q} = \text{S}, \text{Se}, \text{Te}$), the telluride possesses the highest reactivity and can be transformed into $\text{Mo}_6\text{Cl}_{12}$ with chlorine or other chlorinating reagents. The experiments with isotopomeric compounds have shown that the octahedron of Mo_6 remains intact.^{343, 344}

5. Elimination of chalcogens from the clusters M_3Q_7

A well studied transformation of triangular clusters M_3Q_7 into M_3Q_4 in the reaction with such reagents as cyanide ion or phosphines belongs to this class of processes.¹⁸ It was shown by isotope exchange method that it is the equatorial atom of dichalcogenide ligand that is eliminated.^{46, 48} The selenium atom is eliminated from the clusters $\text{Mo}_3(\mu_3\text{-S}).(\mu\text{-S}_{\text{ax}}\text{Se}_{\text{eq}})_3^{4+}$.^{32, 47} The proneness to chalcogen elimination decreases in the order $\text{Mo}_3\text{S}_7 > \text{Mo}_3\text{Se}_7 > \text{Mo}_3\text{Te}_7$. In the case of telluride clusters, no elimination of tellurium atom in reactions with cyanides or phosphines usually occurs. The only exception is the reaction of $[\text{Mo}_3\text{Te}_7\{(\text{Pr}^i\text{O})_2\text{PS}_2\}_3]\text{I}$ with tributylphosphine (in the presence of benzoic acid), which results in the formation of the complex $[\text{Mo}_3\text{Te}_4. \{(\text{Pr}^i\text{O})_2\text{PS}_2\}_3(\mu\text{-C}_6\text{H}_4\text{CO}_2)(\text{PBu}_3^i)]$.²³

The aqua complex $[\text{Mo}_3\text{S}_7(\text{H}_2\text{O})_6]^{4+}$ quantitatively yields $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ in the reaction with water-soluble phosphine PR_3^{3-} ($\text{R} = \text{C}_6\text{H}_4\text{SO}_3$). The following equation describes the dependence of the rate of this reaction on $[\text{H}^+]$

$$k = k_1[\text{H}^+] + k_{-1}[\text{H}^+]^{-1}$$

($k_1 = 3.14 \times 10^4 \text{ litre}^2 \text{ mol}^{-2} \text{ s}^{-1}$; $k_{-1} = 2.78 \times 10^4 \text{ s}^{-1}$). It was thus suggested that both the $\mu\text{-S}_2$ -protonated form of $[\text{Mo}_3\text{S}_5(\text{HS}_2)(\text{H}_2\text{O})_6]^{5+}$ and the conjugated base $[\text{Mo}_3\text{S}_7 \cdot (\text{H}_2\text{O})_5(\text{OH})]^{3+}$ are involved. The rate of this reaction in the case of the selenide complex $[\text{Mo}_3\text{Se}_7(\text{H}_2\text{O})_6]^{4+}$ is approximately 1000 times lower than for the sulfide analogue.³² The reactions with cyanide and phosphines usually produce the corresponding cyanide or phosphine complexes.^{18, 24, 308, 345} Even coordination polymers react in this way.^{24, 53} The complexes $[\text{M}_3\text{Q}_4(\text{dmpe})_3\text{X}_3]^+$ obtained in the reaction with dmpe are convenient starting compounds for the synthesis of heterometallic cubane-type clusters.³⁴⁶ Recently, complexes with chiral phosphines have been obtained.³⁴⁷ The isotope labelling studies suggest that the formation of $[\text{Mo}_3\text{S}_7(\text{S}_2)_3]^{2-}$ from $\text{Mo}_3\text{S}_7\text{Br}_4$ and $(\text{NH}_4)_2\text{S}_x$ proceeds as the elimination–addition in the equatorial position, *i.e.*, *via* the cluster Mo_3S_4 .^{44, 48} In the case of $\text{W}_3\text{S}_7\text{Br}_4$ and $(\text{NH}_4)_2\text{S}_x$ the complex $[\text{W}_3\text{S}_4(\text{S}_4)_3(\text{NH}_3)_3]^{2-}$ is the reaction product.^{44, 231} Generally, the tungsten clusters W_3Q_7^+ are less stable and readily eliminate three chalcogen atoms yielding the clusters $\text{W}_3\text{Q}_4^{4+}$, for example, in the synthesis of oxalate complexes.³³ The complex $[\text{W}_3\text{S}_7\text{Br}_6]^{2-}$ yields $[\text{W}_3\text{S}_4(\text{NCS})_9]^{5-}$ even upon heating with KNCs in acetonitrile.²³¹ The sulfobromide $\text{Mo}_3\text{S}_7\text{Br}_4$ eliminates sulfur atoms from the disulfide ligands in a melt of KHF_2 furnishing $[\text{Mo}_3\text{S}_4\text{F}_7(\text{FHF})_2]^{5-}$.³⁴⁸

The reaction of $[\text{Re}_3\text{S}_7\text{Cl}_6]\text{Cl}$ with an ionic liquid (a mixture of 1-ethyl-3-methyl-imidazolium bromide and AlBr_3) results in the formation of the anionic complex $[\text{Re}_3\text{S}_4\text{Br}_9]^{2-}$.³⁴⁹ The reactions with phosphines are accompanied by reduction and transformation of the cluster core.³⁵⁰

6. Reactions with the change in of the number of metal atoms

The incorporation of Group 6–15 metals (more than 20 elements) in low oxidation states into the cluster core is typical of triangular clusters M_3Q_4 and results in the formation of heterometallic cubane-type clusters. These reactions were intensively studied and the results were summarised in several reviews.^{18, 19, 346} In the case of a transition metal (Cr, Mo, W, Re, Fe, Ru, Os, Co, Rh, Ir, Ni, Pd, Pt, Cu) that is incorporated, this is involved in bonding Mo (W) to form a metallotetrahedron. Group 12–15 metals do not form metal–metal bonds. In the case of transition metals, the clusters in which the total number of valence electrons (NVE) including those provided by the ligand is equal to 60 are the most stable. This corresponds to the scheme of MO of tetrahedral clusters. The derivatives of $\text{Mo}_3\text{CuQ}_4^{4+}$ (NVE = 61), $\text{Mo}_3\text{CoQ}_4^{4+/3+}$ (NVE = 58 and 59), $\text{Mo}_3\text{FeS}_4^{4+}$ (NVE = 58) are exceptions to the rule. When an atom of post-transition element is incorporated, the heterometallic clusters are formed only if the metal is in the formally zero oxidation state (Zn, Cd, Hg, In, Tl, Ge, Sn, Pb, As, Sb, Bi) or possesses a lone pair of electrons (Ga^{I} , In^{I} , Ge^{II} , Sn^{II} , Pb^{II} , Sb^{III} , Bi^{III}). The tendency towards the formation of heterometallic clusters decreases in the order $\text{Mo}_3\text{S}_4^{4+} > \text{Mo}_3\text{Se}_4^{4+} > \text{W}_3\text{Se}_4^{4+} > \text{W}_3\text{S}_4^{4+}$, *i.e.* similarly to the order of decrease in the rate of cluster core reduction.^{18, 19, 346}

Oxidation of heterometallic cubane-type clusters recovers readily the starting triangular clusters $\text{M}_3\text{Q}_4^{4+}$.¹⁹ The ease of oxidation increases in the same order as the tendency to reduction of a triangular cluster decreases. In the case of heterocubane clusters $[\text{Mo}_x\text{W}_{4-x}\text{Q}_4(\text{H}_2\text{O})_{12}]^{6+}$ ($x = 1-3$), oxidation always proceeds with elimination of the tungsten atom. This reaction can be used for selective synthesis of

otherwise hardly accessible mixed heterometallic triangular clusters $[\text{Mo}_x\text{W}_{3-x}\text{Q}_4(\text{H}_2\text{O})_9]^{4+}$ ($\text{Q} = \text{S}, \text{Se}$; $x = 1, 2$).^{116, 117} The first heterometallic clusters Re_3MS_4 ($\text{M} = \text{Ni}, \text{Co}, \text{Cu}$) were obtained.^{40, 351, 352}

In some cases the cubane-type clusters M_4S_4 are formed from triangular clusters as a result of complicated reactions in attempted reduction or ligand exchange reactions. Thus, the reduction of the aqua complex $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ affords a mixture of a cubane-type and a heptanuclear bis-cubane clusters $[\text{Mo}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{4+}$ and $[\text{Mo}_7\text{S}_8(\text{H}_2\text{O})_{18}]^{8+}$,³⁵³ and an attempt to synthesise Re_3S_4 derivatives from $[\text{Re}_3\text{S}_7\text{Cl}_6]\text{Cl}$ by the reaction with KCN unexpectedly yields $[\text{Re}_4\text{S}_4(\text{CN})_{12}]^{4-}$.⁸⁷ The cyanide cluster complexes $[\text{M}_4\text{Q}_4(\text{CN})_{12}]^{6-}$ were obtained by high-temperature reactions of triangular coordination polymers $\text{M}_3\text{Q}_7\text{X}_4$ ($\text{Q} = \text{S}, \text{Se}, \text{Te}$; $\text{X} = \text{Br}, \text{I}$) with KCN.¹⁰²

The reduction of phosphine complexes $[\text{Mo}_3\text{Q}_4 \cdot (\text{PET}_3)_{3-4}\text{X}_4(\text{MeOH})_{1-2}]$ ($\text{Q} = \text{S}, \text{Se}$) with magnesium results in the reductive fusion of two metal triangles into an octahedron and the formation of phosphine cluster complexes $[\text{Mo}_6\text{Q}_8(\text{PET}_3)_6]$, which are molecular analogues of the Chevrel phases.²⁵⁷ Formally, octahedral clusters M_6Q_8 are the dimerisation products of reduced triangular clusters M_3Q_4 . If the reaction takes place at low temperatures, then the dimerisation of two triangular clusters happens at the stage of one-electron reduction. This reaction affords the compounds $[\text{Mo}_6\text{Q}_8\text{Cl}_6 \cdot (\text{PET}_3)_6]$ in which two metal triangles are linked by one metal–metal bond.¹⁷⁹ The cluster $[\text{Mo}_6\text{S}_{10}(\text{SH})_2(\text{PET}_3)_6]$ of a similar structure was obtained from $(\text{NH}_4)_2[\text{Mo}_3\text{S}_7(\text{S}_2)_3]$ and triethylphosphine.¹³⁰

The cases of transformation of tetrahedral clusters into octahedral clusters are extremely rare. One example is the formation (simultaneously with the chalcogen atom replacement in the cluster core) of the complex $[\text{Re}_6\text{Se}_8(\text{CN})_6]^{4-}$ from $[\text{Re}_4\text{Te}_4(\text{TeCl}_2)_4\text{Cl}_8]$ and KNCSe (the latter is the reducing agent as well as the source of selenium and cyanide ions) in acetonitrile at 200 °C. The cluster $\text{Re}_4\text{S}_4\text{Te}_4$ reacts with KCN at 850 °C yielding the octahedral cluster complex $[\text{Re}_6\text{S}_6(\text{S}_{0.34}\text{Te}_{0.66})_2(\text{CN})_6]^{4-}$. This reaction was used for the synthesis of heterometallic clusters $[\text{Re}_5\text{MoS}_8(\text{CN})_6]^{5-}$ and $[\text{Re}_4\text{Mo}_2\text{S}_8(\text{CN})_6]^{5-}$ from $\text{Re}_3\text{MoS}_4\text{Te}_4$.¹⁴²

V. Potential applications of chalcogenide clusters

The progress in chemistry of chalcogenide clusters of early transition metal is very important for better understanding of the processes that occur in living systems with involvement of transition metals. It is well known that at least seven metals (V, Mo, W, Fe, Ni, Cu and Zn) in living systems are bonded quite often to sulfur (and/or selenium) atoms and are vital for various biological functions. Among the early transition metals, molybdenum is particularly important as a part of different enzymes. Tungsten is the heaviest element with reliably determined biological role. Chalcogenide clusters are also of interest as models of solid-state metal chalcogenides; besides they are used in the synthesis of new catalysts and advanced materials (superconductors, X-ray contrast diagnostic agents and non-linear optic materials).

Catalysis. Supported transition metal sulfides are catalysts of hydrorefining of crude oil.³⁵⁴ CoMoS and NiMoS supported onto alumina are widely used in industry for desulfurisation. Traditionally they are prepared by impregnation of $\gamma\text{-Al}_2\text{O}_3$ with ammonium heptamolybdate and cobalt or nickel nitrate with subsequent calcination and transformation of oxides into sulfide phases by heating in an atmosphere of H_2S and H_2 at 400 °C. More effective catalysts were obtained in the reactions of the sulfide cluster $[\text{Mo}_3\text{S}_{13}]^{2-}$ with various salts, including those with complex nickel- or cobalt-containing cations.³⁵⁵ The metal ratio in the heterometallic cubane-type clusters M_3NiS_4 and M_3CoS_4 corresponds to the composition

of the best hydrotreating catalysts and the coordination of heterometal is thought to be similar to that of cobalt or nickel atom in the active site of such catalysts.³⁵⁶ The triangular and heterometallic cubane-type cationic aqua complexes $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ and $[\text{Mo}_3\text{NiS}_4(\text{H}_2\text{O})_{10}]^{4+}$ were incorporated into zeolites by an ion-exchange reaction.^{357–359} It was shown that the activity of such catalysts in hydrogenation of thiophene strongly depends on the zeolite type. The complex $[\text{Mo}_3\text{NiS}_4(\text{H}_2\text{O})_{10}]^{4+}$ incorporated into the zeolite cavity catalyses also the synthesis of ethane and ethylene in the hydrogenation of CO.

The triangular pentamethylcyclopentadienyl cluster $[\text{Cp}^*\text{Mo}_3\text{S}_4]^+$ reacts with $[\text{Ni}(\text{cod})_2]$ (cod is cycloocta-1,5-diene) in dichloromethane at room temperature yielding the cubane-type heterometallic cluster $[(\text{Cp}^*\text{Mo}_3\text{NiS}_4)_2(\text{cod})]^{2+}$, which is a highly effective catalyst of intramolecular cyclisation of alkynoic acids into the corresponding enolactones in the presence of Et_3N . Presumably, an intermediate nickel alkyne complex is formed in this reaction.³⁶⁰

The 1,4,7-triazacyclononane (tacn) heterometallic cluster $[\text{Mo}_3(\text{PdCl})\text{S}_4(\text{tacn})]^{3+}$ possesses a unique ability of coordinating and activating such π -acidic ligands as CO, isonitriles, alkenes and alkynes under very mild conditions. Thus the solution reaction with CO proceeds even at room temperature and yields the brown complex $[\text{Mo}_3(\text{PdCO})\text{S}_4(\text{tacn})_3]^{3+}$. Activated alkynes (for example, $\text{HC}\equiv\text{CCO}_2\text{Me}$ and $\text{MeO}_2\text{CC}\equiv\text{CCO}_2\text{Me}$) also coordinate only the palladium atom of the cluster, but form very labile complexes, which could not be isolated. However, selective nucleophilic addition of methanol to methyl propiolate result in (Z)- $\text{MeOCH}=\text{CHCO}_2\text{Me}$ in virtually quantitative yield takes place in the presence of methanol. It is important that the reactions of nucleophilic addition are catalytic processes and more effective than the catalytic reactions of mononuclear palladium complexes.³⁶¹

Unique catalysts possessing a chiral metal chalcogenide cores can be obtained from chalcogenide clusters.³⁴⁷ Each diphosphine ligand in the triangular molybdenum and tungsten diphosphine complexes $[\text{M}_3\text{Q}_4(\text{diphosphine})_3\text{X}_3]^+$ ($\text{M} = \text{Mo}, \text{W}$; $\text{Q} = \text{S}, \text{Se}$; $\text{X} = \text{Cl}, \text{Br}$) links to only one metal atom, while the phosphorus atoms are located in *cis*- and *trans*-positions with respect to the μ_3 -chalcogen atom. These diphosphine clusters are chiral. From the chiral diphosphine (+)-1,2-bis[(2*R*,5*R*)-2,5-(dimethylphospholan-1-yl)]ethane [(*R,R*)-MeBPE], the chiral triangular cluster $[\text{Mo}_3\text{S}_4\{(\text{R,R})\text{-MeBPE}\}_3\text{Cl}_3]^+$ and heterometallic derivative $[\text{Mo}_3\text{CuS}_4\{(\text{R,R})\text{-MeBPE}\}_3\text{Cl}_3]^+$ were obtained. This heterometallic cluster turned out to be an effective catalyst of two reactions: the intramolecular cyclisation of 1-diazohex-5-en-2-one and the intermolecular cyclopropanation of styrene or 2-phenylpropene with ethyl diazoacetate. The reactions proceed in high yields of the corresponding cyclopropanes (up to 95%), the enantiomeric excess being in the range from 12% to 25%.³⁴⁷

Conductors and superconductors. A unique substance was obtained by two-electron oxidation of the anionic molybdenum cluster $[\text{Mo}_3\text{S}_7(\text{dmit})_3]^{2-}$.³⁶² Electrochemical oxidation of its *tert*-butylammonium salt yields deep-violet needle-shaped crystals stable in air. Chemical oxidation with iodine in dichloromethane is yet another method of its synthesis in quantitative yield. The neutral cluster molecules crystallise in a hexagonal space group and the structure is built of chains. The molecules in the chains are linked by short $\text{S}\cdots\text{S}$ contacts between axial sulfur atoms of the bridging disulfide ligands and μ_3 -sulfur atoms. The $\text{S}\cdots\text{S}$ contacts between the sulfur atoms of the cluster complexes of different chains combine the chains into honeycomb-like framework with spacious vacant channels ~ 10 Å in diameter. The room-temperature conductivity measurements have shown that $[\text{Mo}_3\text{S}_7(\text{dmit})_3]$ is a quasi-one-

dimensional semiconductor with a very low value of activation energy. The magnetic susceptibility measurements reveal the presence of antiferromagnetic exchange interactions between unpaired electrons of the neutral clusters $[\text{Mo}_3\text{S}_7(\text{dmit})_3]$. It is expected that chemical modification of this unique cluster (for example, by the replacement of the metal, chalcogen or redox-active ligand) and application of high pressure will eventually result in the stabilisation of the metal state.

Non-linear optical properties. The triangular molybdenum and tungsten chalcogenide clusters and their heterometallic cubane derivatives were systematically studied in this respect. All triangular clusters $[\text{M}_3\text{Q}_4\text{L}_3\text{X}_4]^+$ ($\text{M} = \text{Mo}, \text{W}$; $\text{Q} = \text{S}, \text{Se}$; $\text{L} = \text{dmpe}, \text{dppe}$) and their copper-containing cubane-type derivatives $[\text{M}_3\text{CuQ}_4\text{L}_3\text{X}_4]^+$ turned out to be promising optical limiters and the value of threshold limiting flux decreases on going from the cubane-type clusters to triangular ones and from tungsten clusters to molybdenum analogues.^{296, 308, 346}

X-Ray contrast agents. The cluster-type tungsten thio complexes ($\text{W}_3\text{S}_4^{4+}$ derivatives) represent a new class of X-ray contrast diagnostic agents. The cluster compounds of heavy metals ($Z > 50$) possess a high X-ray absorption coefficient, which results in a significant improvement of the image quality and/or reduction of X-ray irradiation dose. Triangular tungsten thio clusters are highly soluble in water, do not hydrolyse in aqueous solutions and form stable chelate complexes with various ligands. It is very important that the $\text{W}_3\text{S}_4^{4+}$ derivatives are significantly less toxic in comparison with water-soluble tungsten heteropolyanions.³⁶³

VI. Conclusion

The data presented show that the chemistry of chalcogenide cluster complexes of Group 5–7 metals is extensive and diverse. Many specific properties of cluster compounds are determined by the structure, geometry and electronic features of the cluster core. The possibility of modifying the cluster core by isovalent and non-isovalent substitution of both 'inner' ligands and metal atoms allows one to change the properties of cluster complexes. Such approach underlies the directed synthesis of materials with preset properties in which the cluster complexes are used as building blocks with predetermined spatial, electronic, optical or magnetic characteristics. The list of useful properties of chalcogenide cluster compounds is already quite remarkable and will undoubtedly be extended with the further studies of this class of compounds. More and more, not only synthetic chemists, but also physicists, theoreticians, materials scientists are involved in these studies and, owing to their efforts, the first steps towards the design of new materials and better understanding of the principles which control the properties of these compounds are being made.

The data presented show the progress in the studies of cluster chalcogenide complexes of transition metals. Quite interesting is the evolution of studies of such systems. Whereas after the discovery of the key compounds, they were studied predominantly by the methods of solid state chemistry the set of which was rather small, nowadays the main attention is paid to the chemistry of solutions due to the development of methods of transformation of polymeric cluster compounds into molecular complexes. New research groups became involved into this field of chemistry, which increases the ability to detect specific properties of cluster complexes.

At the first glance, it seems that, as a result of intensive studies, the chemistry of chalcogenide cluster complexes of Group 5–7 metals has been exhausted. However, recent syntheses of cluster metal complexes of unexpected types, such as square vanadium $\text{V}_4\text{S}_9\text{Br}_4$ and tantalum $\text{Ta}_4\text{Q}_9\text{X}_8$ ($\text{Q} = \text{S}, \text{Se}$) clusters, dodecanuclear rhenium complexes $[\text{Re}_{12}\text{CS}_{17}(\text{CN})_6]^{8-/6-}$ with interstitial carbon atom, indicate that further discoveries are awaiting.

Abstract. A fundamental approach to the development of heterogeneous catalysts consisting of the study of the structure – activity relationships using surface science methods and techniques is proposed. According to this approach, a study should start with an investigation into well-ordered single crystals under ultrahigh vacuum conditions and then move along the way of both increasing the gas phase pressure (to address the ‘pressure gap’ problem) and complicating the samples under study from single crystals to supported clusters (to address the ‘material gap’ problem). The case studies cited in the review prove the efficacy of the proposed approach to investigations into the reactivity of active component particles for the subsequent molecular design of catalysts with improved performance (activity, selectivity and stability) and demonstrate that it conforms with the modern trends in the development of surface science as applied to heterogeneous catalysis. The bibliography includes 198 references.

I. Introduction

Traditionally, the term ‘Surface Science’ implies the application of specific instrumental techniques that are intrinsically surface sensitive to studies of the surface structure and composition of solids. In contrast to standard analytical techniques, such methods yield information on a few surface layers (with a thickness of up to 10 nm) of a sample rather than on its total bulk. The tremendous progress in this field started in the 1970s when serial ultrahigh vacuum spectrometers equipped with one or several surface science techniques appeared on the market. That time, Auger electron spectroscopy (AES), low-energy electron diffraction (LEED), X-ray and UV photoelectron spectroscopy (XPS and UPS, respectively), electron energy loss spectroscopy (EELS) were among the most popular techniques. Their wide utilisation in the practice of the experimental studies of solid surfaces enabled the retrieval of

important information at the atomic or molecular level. Fundamentals of instrumental techniques for surface studies (ITSS) as well as specific examples of their application, which demonstrate general trends in this field by the end of the 20th century are nicely described in a series of reviews published in 1994 in a special issue of the journal ‘Surface Science’ devoted to its 30th anniversary.¹

As applied to catalysis, it is the interactions between simple gases (*e.g.*, CO, O₂, NO, C₂H₄, *etc.*) and clean single-crystalline metal surfaces (Pt, Pd, Ag, Cu) that were the central problem of surface science in that period (see Refs 2–4 and references therein). These studies gave rise to the identification of a large number of adsorbed species, which helped to rationalise diverse surface phenomena, such as physical and chemical adsorption, lateral interactions in adsorbed monolayers and chemical interactions on surfaces.

The results obtained were immediately appreciated by specialists in catalysis such that the knowledge gathered on the ‘intimate’ life of atoms and molecules became a basis for the improvement on the performance of catalysts. Since then, attempts at the molecular design of catalysts with improved characteristics were often preceded by in-depth elucidations of the interactions between the reaction media and smooth solid surfaces in order to understand the nature of the catalytic action of specific active components in specific catalytic reactions. Recently, such an approach referred to as the fundamental one in contrast to the empirical approach became very popular.

Despite the fact that ITSS provide detailed information at the atomic and molecular levels, their efficient application to the description of real catalytic processes is hindered by two major factors commonly referred to as ‘pressure gap’ and ‘material gap’. The former problem consists of the difference in pressures typical of the majority of surface science studies ($P \leq 10^{-6}$ mbar) and of real catalytic processes ($P \geq 1$ mbar). As a result, concentrations of important intermediates as well as rates of certain reaction steps under the measurement conditions can appear substantially lower than the sensitivity threshold of the instrumental techniques applied. In this case, the information gathered often inadequately reflects the chemistry behind the processes on the surface of a functioning catalyst.

Yet another problem encountered by many surface science researchers refers to the use of metal single crystals as subjects of catalysis-related studies instead of small metal particles

supported on an inert matrix, which represent real catalysts in most cases. Since all heterogeneous reactions proceed on the surface of a solid, the surface/volume ratio has to be increased in order to enhance the utilisation coefficient of the active metal. Therefore, metal particles in real practically applicable catalysts are often so small (3–5 nm) that deviations in their properties from those of the bulk metal have to be taken into account, which is referred to as the size effect and gives rise to the ‘material gap’ problem.

Starting from the end of the 1980s, these two problems were seriously addressed. In particular, high-pressure reactors and cells integratable into standard ultrahigh vacuum (UHV) equipment were designed, which enabled measurements of catalytic reaction rates at atmospheric pressures followed by an *ex situ* analysis of the catalyst composition avoiding its contact with air. Thus it became possible to systematically compare the surface composition and morphology of catalysts before and after the reaction with the respective changes in the catalytic activity. Such a combined *ex situ* approach was applied by Over *et al.*^{5–7} to address the ‘pressure gap’ problem in the case of CO oxidation on the Ru(0001) surface. By using temperature-programmed desorption (TPD), scanning tunneling microscopy (STM), LEED and XPS, they demonstrated that the clean Ru(0001) surface, which is inert under UHV conditions, is oxidised to RuO_x under the action of the reaction medium. The latter proved to be even more reactive with respect to the CO oxidation than platinum, which is a prototypical catalyst for this reaction. Such an oxidised surface cannot be formed spontaneously under UHV conditions. Another example of the efficiency of this approach to the studies of model catalytic systems was demonstrated by Campbell *et al.*^{8–10} for the oxygen and ethylene adsorption on single-crystalline (111) and (110) faces of silver. In this study, a special design of the electron spectrometer was used, which made it possible to transfer samples from a high-pressure microreactor to an UHV analytical chamber for the characterisation of the preprocessed surfaces with various instrumental techniques very fast (in less than 20 s). Still, such experiments are not free from the major drawback of the post-reaction analysis: evacuation of the reaction medium effectively eliminates weakly bound adsorbed species that could act as key species governing the catalyst reactivity under the reaction conditions.

A different in principle approach to address the ‘pressure gap’ problem was utilised by the British company ‘Vacuum Generators’, which is a recognised world-leading manufacturer of UHV equipment. This company designed and put into production a ‘high-pressure’ electron spectrometer,[†] which enabled the *in situ* registration of photoelectron spectra at pressures of up to 1 mbar,¹¹ *i.e.*, 6 orders of magnitude higher than in serial spectrometers. With such spectrometers that operate at pressures close to that of typical catalytic reactions, the quantitative determination of the relationships between the composition of the surface layer of a sample and its catalytic performance became possible. It is apparent that this approach to the solution of the ‘pressure gap’ problem is very promising.

The necessity to address the size effects within the context of the ‘material gap’ problem became apparent in the end of the 20th century, when studies of catalytic properties of supported metal catalysts as a function of the size of the active component (see Refs 14, 15 and references therein) revealed that the rates of many catalytic reactions normalised to the number of surface atoms vary upon changes in the size of supported metal particles. Boudart¹⁴ introduced the term structure-sensitive reactions to designate this phenomenon and distinguish it from structure-insensitive reactions, the rates of which

were independent of the size of catalytic metal particles. Interestingly, the size effect can be both positive (*i.e.*, the reaction rate increases with a decrease in the size of supported metal particles) and negative (*i.e.*, the reaction rate decreases). It was size effects that encouraged extensive investigations into the electronic, structural and adsorption properties of small metal clusters in comparison with those of bulk metals.

However, only low efficiency and slow progress in this field were achieved with traditional supported catalysts. Indeed, real catalysts that are usually prepared by impregnation of a support with a large specific surface area with aqueous solutions of salts of the active component followed by the drying and reduction of the salt to the metal state refer to colloidal systems. The collection of fully reproducible data on such systems is naturally very difficult. This fact together with possible contamination of the catalytic systems by undesired admixtures either coming from the substrate material or introduced at the steps of catalyst synthesis likely explain the large contradiction in data on catalytic activities of nominally identical catalytic systems reported by different authors.¹⁵ Poor reproducibility of the results can be overcome if the synthesis of supported catalysts and their subsequent characterisation are repeated many times. Furthermore, it has to be taken into account that the preparation of a series of catalysts with a systematically varying mean size of metal particles is a time-consuming procedure by itself.

As an alternative, model supported catalysts can be prepared in a reproducible way by vacuum deposition of disperse metal particles onto the surface of a planar substrate. Thin oxide films grown on the surface of metal single crystals or surfaces of oxide single crystals can be used as the substrates.^{16,17} Indeed, the preparation of metal nanoparticles directly in a UHV spectrometer makes it possible, first, to carefully pre-clean the substrate and deposition system and, second, to transfer the sample into an analytical chamber without its contact with air. This preparation scheme avoids introduction of undesired contaminants and enables quick production of series of samples with variable sizes of metal clusters. This way of the simulation of real catalysts is widely applied to the analysis of the electronic properties and morphology of metal nanoparticles as a function of their size (for example, see Refs. 16–20). Several attempts have been undertaken to study the specificity of adsorption on disperse metal particles.^{18–21} It is of note that the inconsistency between the model and real substrates intrinsic to the preparation method has not only negative, but also positive aspects, since it allows a wider choice of the substrate material. For instance, an oxide substrate can be replaced by a carbon-based one. This makes it possible to appeal to supplementary instrumental techniques to probe the adsorption properties of metal clusters. With graphite substrates instead of oxide ones, XPS can be efficiently applied to study the oxygen adsorption on metal clusters since in this case relatively weak O1s signal from the adsorbate is not superimposed on the prevailing background signal from Al₂O₃ or SiO₂ substrates. And thus adsorbed oxygen species can be identified based on an analysis of the O1s spectra.

The low specific surface area of single crystals prevents measurements of the specific catalytic activity of single crystal-based model systems in many catalytic reactions. Nevertheless, the chemistry underlying the catalytic action of metals cannot be understood without comparison of the results on model objects with the catalytic properties of real catalysts. Investigations into the reactivity of small clusters towards the reactants and reaction products, necessarily as a function of their size, can help to fill the gap between surface science studies and the real catalysis.

Therefore, the nature of the catalytic action of metals can efficiently be analysed using an approach depicted schemati-

[†] Two such spectrometers were purchased by Cardiff University (UK)¹² and G K Boreskov Institute of Catalysis (Novosibirsk, Russia).¹³

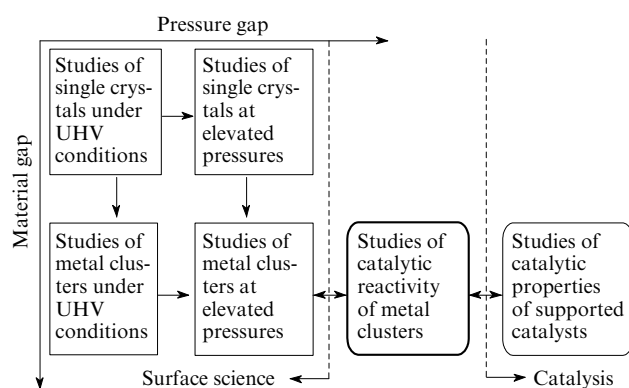

Figure 1. A scheme of the suggested approach aimed at establishing the structure–activity relationship in heterogeneous catalysts.

cally in Fig. 1. A study should start with well-ordered single crystals under UHV conditions and then move along both increasing the pressure of the reaction medium (*i.e.*, from left to right) and complicating the object under study (*i.e.*, from top to bottom). The movement from left to right implies the elimination of the ‘pressure gap’ problem, whereas that from top to bottom addresses the ‘material gap’ problem. Finally, instrumental techniques for surface studies have to be applied to elucidate the structure of the active sites in real catalysts during their formation, activation and deactivation and these data are to be compared to the results of model studies.

It is evident that in order to retrieve reliable data on the structure of functioning catalysts, not only ITSS but also bulk-sensitive techniques, such as transmission electron microscopy (TEM), X-ray diffraction and X-ray absorption methods (EXAFS, XANES), have to be applied.

Examples of studies accomplished over recent years in the Laboratory of surface science of the G K Boreskov Institute of Catalysis as well as in other world-renowned research centres specialised in the field, which are described in detail below, demonstrate that the above approach conforms with the modern trends in surface science as applied to catalysis by helping to establish the structure–activity relationship in heterogeneous catalysts and advancing towards purposeful design of highly active, selective and deactivation-resistant catalysts.

It has to be however noted that several methodological problems non-typical of traditional surface science, which hinder the retrieval of required information, emerge in the implementation of this approach in practice. Possible solutions of these problems are often highly specific and cannot be generalised and standardised. With this regard, in the description of experimental results below, we shall put an emphasis (somewhat greater than in traditional reviews) on relevant technical details of the respective measurements.

II. The ‘pressure gap’ problem

As has been stated in the Introduction, the development or optimisation of surface science techniques capable of *in situ* monitoring of processes directly in the course of a chemical reaction represents the most promising way to address the ‘pressure gap’ problem.^{22–38} Among techniques working at pressures close to those of real catalytic reactions ($P > 0.1$ mbar), Infrared Reflection-Absorption Spectroscopy (IRAS),^{22–24} in particular, in the polarisation modulation mode, Sum-Frequency Generation (SFG) spectroscopy,^{25–28} X-ray Absorption Near-Edge Structure (XANES),^{29–31} X-ray

Photoelectron Spectroscopy (XPS)^{11–13, 32–36} and scanning tunneling microscopy^{37, 38} are of special note.

X-Ray photoelectron spectroscopy occupies a special place in this list being one of the best analytical techniques for studies of the chemical composition and electronic structure of solid surfaces. The physical limit of pressure at which an XPS spectrum can still be measured is determined by the photoelectron mean-free path. The latter value is of the order of a few millimetres at a pressure of 1 mbar. Meanwhile, the typical pressure in the vast majority of XPS spectrometers is $\sim 10^{-9}$ mbar, which required for the safe operation of an X-ray source, an electron energy analyser and a secondary electron multiplier. Due to fundamental difficulties in combining these two requirements in one spectrometer design, the *in situ* mode of XPS data collection had been inaccessible for a long time. The situation has changed only recently and there are currently several research groups worldwide running XPS spectrometers capable of measuring spectra at a pressure range from 10^{-9} mbar to 1 mbar.^{11–13, 32–36} One of such dedicated high-pressure machines manufactured by ‘Vacuum Generators’ is installed at the Boreskov Institute of Catalysis in Novosibirsk. Its preliminary adaptation to the *in situ* studies of catalytic reactions at pressures of up to 10^{-2} mbar was accomplished in the Laboratory of metal catalysts.¹³ The additional cycle of spectrometer optimisation enabled the extension of the operational pressure range to 0.2–0.3 mbar (Refs 34–36). This value is only severalfold lower than the maximum achievable operational pressure realised in advanced spectrometers installed at the synchrotron radiation beamlines[‡] in ALS (Berkeley, USA)³³ and BESSY (Berlin, Germany).³⁵

A few illustrative examples of the application of XPS in the *in situ* mode to the elucidation of mechanisms of catalytic reactions are given below.

1. Interaction of CO with the Pd surface

As the first example, let us consider the combined application of XPS and SFG to the elucidation of interactions of CO and CH_3OH with the palladium surface in a wide range of temperatures and pressures. Simultaneous utilisation of several complementary instrumental techniques, which increases the reliability of conclusions derived from the experimental results, reflects one of the trends in contemporary surface science. Sum-frequency generation spectroscopy based on the irradiation of a sample surface with two pulse lasers operated in visible and IR spectral ranges is a rather complicated but still very promising non-linear optical technique suitable for the *in situ* studies of adsorbed complexes. The physical background of this method is described in detail elsewhere.^{25–28} During the measurements, the frequency of the visible-light laser is kept constant ($\lambda = 532$ nm), whilst that of the IR laser is scanned over a certain range, which gives rise to the appearance of characteristic SFG resonances under specific conditions associated with the vibrational excitations of adsorbed molecules.^{25, 26} The SFG is a second-order non-linear optical process, which has a non-vanishing probability exclusively in a non-centrosymmetrical medium. The requirement of the absence of the local inversion symmetry is always met for an interface and, as a rule, violated for an isotropic gas and the bulk of a solid, which provides the ultimate surface sensitivity of this method. According to the selection rules, both IR- and Raman-active vibrations are manifested in the SFG spectra. With SFG, vibrational spectra of adsorbed species can be collected in the *in situ* mode at high pressures up to the

‡ The extreme brilliance of synchrotron radiation makes it possible to approach to the theoretical limit of pressures in the *in situ* experiments (1–2 mbar).

atmospheric pressure, which is an evident advantage of this technique.

On the other hand, XPS provides direct quantitative information on chemical composition of the adsorbed and near-surface layers of the catalyst under study and its variation under high pressures (*vide supra*).

The mechanism of activation of the C–O bonds on the surfaces of transition metals attracts keen attention from specialists working in the field of heterogeneous catalysis. It plays a key role in the carbon monoxide hydrogenation as well as methanol oxidation and dehydrogenation, which are the important steps of large-scale industrial processes of production of hydrocarbons, aldehydes, alcohols and hydrogen.^{39–44} In particular, the C–O bond activation (followed by its cleavage) is a necessary step in the synthesis of hydrocarbons according to the Fischer–Tropsch process. Meanwhile, the progressive carbon deposition on the catalyst surface as a result of the CO dissociation often reduces its catalytic activity due to the shielding of active surface sites. Actually, the activity and selectivity of all of the above reactions is governed by the activation of the C–O bonds depending on the catalyst nature, gaseous medium composition and reaction conditions. With this regard, deep understanding of the mechanism of the C–O activation on the surface of transition metals is a prerequisite to the prediction of the catalytic action and consequently to the purposeful design of catalysts with improved efficiencies for specific reactions.

Figure 2 shows SFG and XPS spectra measured *in situ* during the CO adsorption on atomically smooth Pd(111) single-crystalline face at 400 K. At low pressure ($P_{\text{CO}} = 10^{-6}$ mbar), the SFG spectrum reveals a single line at 1910 cm^{-1} attributable to stretching vibrations of bridge-bonded CO molecules. At the same time, a narrow symmetrical line centred at 285.6 eV emerges in the C1s XPS spectrum (Fig. 2b), which can thus also be ascribed to adsorbed CO molecules in bridging positions. Upon an increase in pressure, a new SFG resonance at $2075\text{--}2080\text{ cm}^{-1}$ appears, which is indicative of the appearance of terminally bound species due to the higher surface concentration of CO_{ads} . Meanwhile, the C1s XPS line broadens due to the emergence of a new component of terminally bound CO with $E_{\text{b}} = 286.3\text{ eV}$ (according to the deconvolution of the spectra into the components I' and I''). Such an attribution of the C1s components agrees with the results of high-resolution XPS obtained by Surnev *et al.*,⁴⁵ who demonstrated that the three-fold hollow, bridge-bonded and on-top CO molecules on Pd(111) are characterised by similar C1s binding energies of $285.6 \pm 0.1\text{ eV}$, 285.85 eV and 286.3 eV , respectively. The C1s feature at around 290 eV appearing at even higher pressures $P_{\text{CO}} > 5 \times 10^{-2}$ mbar (the component I in Fig. 2b) can be assigned to gaseous carbon monoxide.⁴⁶

SFG and XPS spectra registered *in situ* during the CO adsorption on the atomically smooth Pd(111) crystal face at 200 K and $P_{\text{CO}} = 1\text{ mbar}$ (SFG) or 0.1 mbar (C1s) are shown in Fig. 3. These experimental conditions (*viz.*, high pressure and low temperature) provided the maximum possible coverage of palladium surface with CO molecules of 0.75 monolayers. The respective SFG spectrum reveals two vibrational bands at 1895 cm^{-1} and 2107 cm^{-1} assigned to three-fold and on-top species, respectively. The conclusion on the presence of terminally coordinated CO molecules on Pd(111) is supported by the comparison of the C1s XPS spectrum measured under similar conditions with that measured at $T = 400\text{ K}$ and $P_{\text{CO}} = 10^{-6}\text{ mbar}$, *i.e.* where such species are surely absent (see the SFG spectrum in Fig. 3a). The difference spectrum (spectrum 3 in Fig. 3b) obtained by subtracting the contribution of the three-fold CO species from the total C1s spectrum is characteristic of the terminal adsorbed CO species. This conclusion is supported by the quantitative estimation of relative

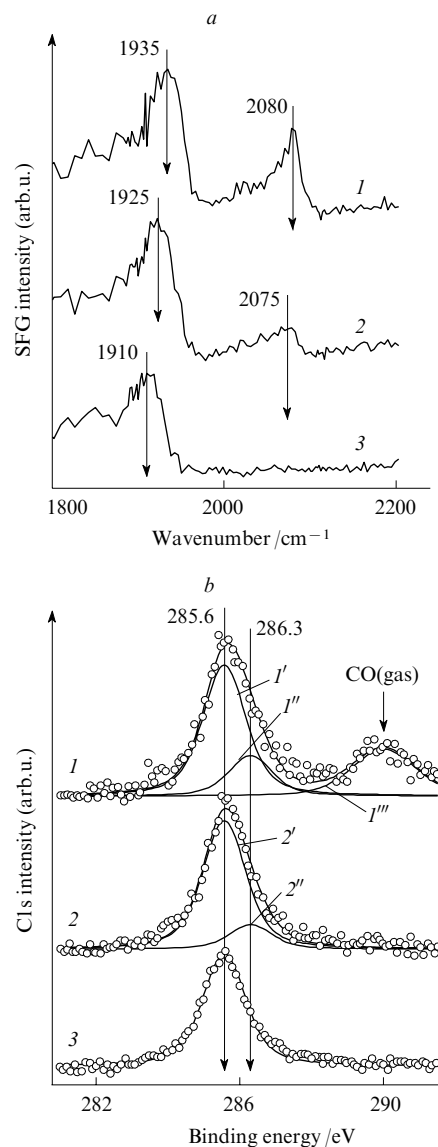

Figure 2. SFG (a) and C1s XPS (b) spectra measured *in situ* during CO adsorption on the atomically smooth Pd(111) surface at 400 K as a function of P_{CO} .

P_{CO} /mbar: (a) 1 (1), 10^{-3} (2), 10^{-6} (3); (b) 0.1 (1), 5×10^{-3} (2), 10^{-6} (3). Lines (1–3) are experimental data, (I' , I'') and ($2'$, $2''$) are deconvolution of the experimental curve into two components corresponding to bridge-bonded (I' and $2'$) and on-top (I'' and $2''$) CO molecules; (I''') is a component attributed to gaseous CO. Hereinafter, all C1s spectra are normalised to the integral intensity of the respective Pd3d lines.

surface concentrations of the three-fold (spectrum 2) and on-top (spectrum 3) CO_{ads} . The respective ratio of ~ 1.9 obtained from the experimental XPS spectra is close to the value 2 determined earlier for the $(2 \times 2)\text{-}3\text{CO}$ surface structure, which corresponds to the maximum coverage of Pd(111) with the CO molecules ($\theta = 0.75$ monolayers). It is also of note that this clear separation of the C1s spectral component responsible for the terminally coordinated CO species ($E_{\text{b}} = 286.3\text{ eV}$) validates the spectral deconvolution procedure utilised in the analysis of the XPS spectra shown in Fig. 2.

The application of XPS to the *in situ* studies of the CO adsorption on Pd(111) helped to answer the important question whether the dissociation of C–O bonds can proceed on palladium. In a number of earlier publications (for instance, see Refs 47–50), a dissociative character of the CO adsorption

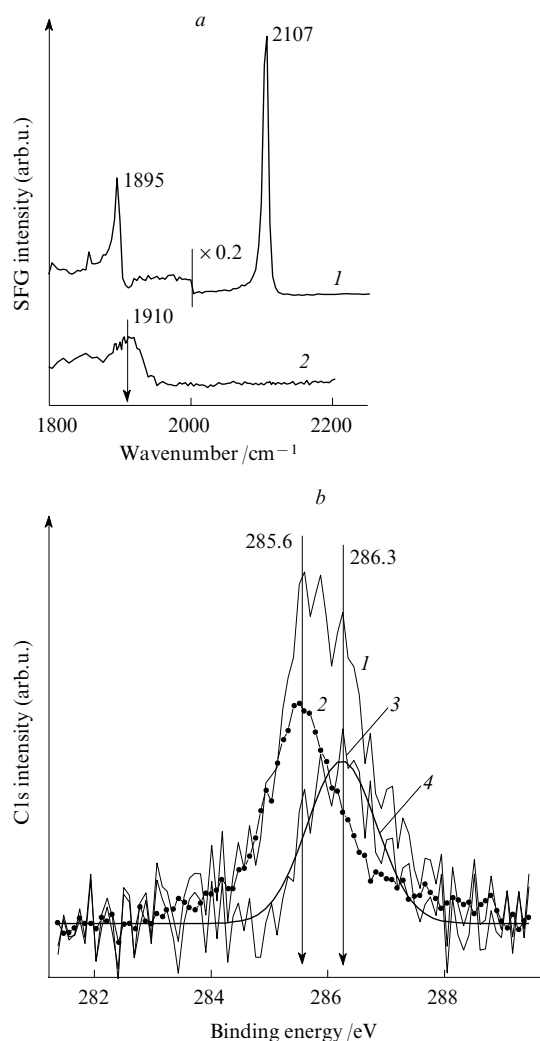

Figure 3. SFG (a) and C1s XPS (b) spectra measured *in situ* during CO adsorption on the atomically smooth Pd(111) surface at 200 K and 1 mbar (curve 1) and at 400 K and 10^{-6} mbar (curve 2). The curve (3) is calculated by the direct subtraction of the respective C1s spectra, (4) is the averaged spectrum (3).

on the surface of highly disperse palladium particles was suggested. On the other hand, no CO dissociation was observed in other studies,^{51–53} despite the detection of weakly bound adsorbed CO species on palladium particles with a size of 2–3 nm. A strong influence of pressure on the adsorption process can be a reason for this apparent discrepancy. The rate of the CO disproportionation under UHV conditions is quite low, such that very often no respective products can be detected. Indeed, the probability of CO dissociation on the palladium surface is very low according to theoretical calculations.^{53–55} However, the combined application of SFG and XPS decisively rules out this explanation since only lines of molecularly adsorbed CO are observed in all the C1s XPS spectra, including those measured *in situ* at pressures of up to 1 mbar.⁴⁶ In the cases of CO dissociation or formation of carbonyl structures [e.g., Pd(CO)₂], the appearance of additional photoemission components at about 284 eV and 287 eV, respectively, is expected.^{56,57} Thus, no indication of the CO dissociation or the formation of other adsorbed species on the Pd(111) surface was found by *in situ* measurements over the pressure range from 10^{-6} mbar to 1 mbar and temperature range from 200 K to 400 K.

2. Interaction of CH₃OH with the Pd surface

Despite the fact that the interaction of methanol with the palladium surface has been the subject of intense investigations by many research groups for a long time, the mechanism of catalytic methanol decomposition remains disputable.^{58–70} The majority of specialists have a consensus that it is the dehydrogenation of methanol to CO and H₂ that is the predominant pathway of this reaction.^{58–62} As has been established,⁵⁸ at low temperature, methanol is adsorbed on the palladium surface molecularly through the oxygen lone pair. A layer of adsorbed methanol and formaldehyde molecules as well as methoxy groups is formed following methanol adsorption at 170 K.^{59,60} An investigation into the decomposition of methanol on Pd(111) by means of Secondary-Ion Mass Spectrometry (SIMS)⁶¹ and EELS⁶² revealed that the cleavage of the O–H bond in an adsorbed methanol molecule occurs as the first step of the reaction to yield the CH₃O groups, which further decompose to CO and H₂ by the stepwise detachment of the hydrogen atoms upon heating. The reaction proceeds *via* CH₂O and CHO. Such a mechanism is supported by the TPD and EELS data.^{59,60}

Nevertheless, some authors believe that the methanol decomposition on Pd(111) occurs as the C–O bond cleavage to yield adsorbed CH_x ($x = 0–3$) species.^{54,63–65} The probable dissociation of the C–O bond in a methanol molecule upon its adsorption on the Pd(111) surface has been suggested by Winograd *et al.*^{54,63} based on the XPS, SIMS and TPD data. Species CH_{3,ads} were detected on Pd(111) (in a concentration of $\theta = 0.04$ monolayers) after methanol adsorption at 110 K (to $\theta \approx 0.5$ monolayers) followed by annealing *in vacuo* at 175 K. Further annealing resulted in the dehydrogenation of the CH₃ species to CH_{2,ads}, CH_{ads} and C_{ads}.

Notwithstanding, no cleavage of the C–O bond in methanol molecules upon adsorption on Pd(111) was detected in a TPD study of isotopically labelled compounds ¹³CH₃¹⁶OH and ¹²CH₃¹⁸OH over a wide temperature range (87–265 K), which provided a very high sensitivity of ~ 0.01 monolayers.⁶⁴ It was suggested that this apparent discrepancy is due to different rates of competing pathways of the methanol decomposition on the palladium surface. For instance, the rate of methanol dehydrogenation to CO is approximately two orders of magnitude higher than the decomposition through the C–O bond cleavage,⁶⁶ and thus it is nearly impossible to detect the formation of CH_{x,ads} species under UHV conditions at low temperatures and small methanol exposures.

This hypothesis was verified in a combined XPS and SFG study of the methanol interaction with the atomically smooth Pd(111) surface at variable temperatures and pressures.^{67,68} The SFG (a) and C1s XPS (b) spectra measured *in situ* during the methanol decomposition on Pd(111) is shown in Fig. 4. The methanol adsorption at room temperature and 10^{-6} mbar gives rise to the emergence of a vibrational SFG resonance at 1915 cm^{−1} corresponding to bridging adsorbed CO molecules at a coverage of $\theta \approx 0.5$ monolayers.^{27,28,45,46,69} Meanwhile, the C1s XPS spectra reveal two components with binding energies of 284 eV and 285.6 eV, which can be assigned to hydrocarbon CH_{x,ads} ($x = 0–3$) and oxygen-containing CH_xO_{ads} ($x = 0–3$) species based on an analysis of the literature data.^{45,46,56} Quantitative agreement between the coverages ($\theta \approx 0.5$ monolayers) estimated from the relative intensity of the C1s line at $E_b = 285.6$ eV and from the SFG data allowed the authors to limit the range of potential species and assign the C1s component with $E_b = 285.6$ eV to adsorbed CO.⁶⁷ This assignment is supported by numerous studies indicating that the decomposition of the CH₃O groups to CO_{ads} on palladium proceeds efficiently already at 200–250 K.^{60,62,70} With an increase in residence time, the intensity of the XPS signal at 284 eV progressively increases, whereas that of the component at 285.6 eV remains virtually constant.

Figure 4. SFG (a) and C1s XPS (b) spectra measured *in situ* during the methanol decomposition on the atomically smooth Pd(111) surface.

(1) $P = 10^{-6}$ mbar and $T = 300$ K; (2) $P = 10^{-6}$ mbar and $T = 400$ K; (3) $P = 0.1$ mbar and $T = 300$ K; (4) $P = 0.1$ mbar and $T = 400$ K. The SFG spectrum was registered at 300 K and a methanol pressure of 10^{-6} mbar. The experimental C1s spectra (curves 1–4) and their deconvolution into components (1', 1'', 2', 2'', 3', 3'', 3''') and (4', 4'', 4''') are shown.

An increase in temperature up to 400 K or in the methanol pressure up to 0.1 mbar results in an abrupt increase in the surface concentration of the CH_x species (see Fig. 4b). In

particular, the absolute intensity of the C1s component with $E_b = 283.8$ eV corresponds to $\Theta \approx 1.0$ monolayer at 300 K and $P_{\text{MeOH}} = 0.1$ mbar (the spectrum 3). Despite this large apparent coverage of the Pd(111) surface with the CH_x species, a part of the surface remains covered with adsorbed CO molecules ($\Theta \approx 0.4$ –0.5 monolayers). The total concentration of adsorbed species (including both CH_x and CO) exceeding one monolayer was explained by either partial dissolution of carbon in the near-surface region of palladium⁷¹ or formation of three-dimensional carbon structures. The amount of carbon-like species further increases at 400 K ($\Theta \approx 1.5$ monolayers), which is accompanied by a small shift of the respective line towards higher binding energies ($E_b = 284.0$ eV). This change probably reflects some chemical transformations of the carbon particles.

These results clearly demonstrate that the C–O bond of the methanol molecule is activated on the atomically smooth Pd(111) surface at a measurable rate even at 300–400 K. The methanol decomposition rate and the amount of deposited carbon increases with an increase in methanol pressure. Carbon particles formed as the methanol decomposition product lead to the progressive coking of the metal surface and ultimately to its complete deactivation. Due to this process, no products of the catalytic methanol decomposition on Pd(111) (*i.e.*, CO and H_2) were detected by means of gas chromatography at elevated pressures (15–30 mbar of methanol in a helium atmosphere) and temperatures (300–600 K) even after their accumulation for several hours.⁶⁸ On the other hand, the introduction of oxygen into the reaction mixture immediately resulted in the appearance of the methanol total oxidation products, *viz.*, CO_2 and H_2O .

Based on these experimental results, the following scheme of the methanol interaction with the Pd(111) surface can be proposed. The first step of the decomposition is cleavage of the O–H bond to yield the methoxy groups.^{59, 60, 62, 64} The adsorbed methoxy groups as well as methanol molecules are bound to the palladium surface through the oxygen lone pairs. They are oriented nearly perpendicular to the surface.⁶² As the dehydrogenation proceeds, the molecular axis of the adsorbed complex is rotated by 90° , such that formaldehyde molecules ($\text{CH}_2\text{O}_{\text{ads}}$) and formyl groups (CHO_{ads}) are oriented parallel to the palladium surface.^{65, 66} The final dehydrogenation product, CO, is oriented again perpendicular to the surface but it is bound to the metal atoms through the carbon atom.^{72, 73}

The formation of carbon deposits on the atomically smooth Pd(111) surface observed experimentally^{67, 68} supports the activation mechanism of the C–O bonds upon the methanol interaction with the palladium surface schematically depicted in Fig. 5. It is evident that an increase in the lifetime of the reaction intermediates should give rise to a higher probability of the C–O bond dissociation. Likely, this is a reason for the experimentally observed increase in the rate of carbon accumulation on the Pd(111) surface at high reaction pressures

Figure 5. A model of the methanol decomposition on the Pd(111) surface.

(see Fig. 4) and in the presence of defects on the surface of supported palladium clusters.⁶⁶

Taking into account the principle of microscopic reversibility of reaction steps, it might be assumed that the CO hydrogenation on palladium

can also be accompanied by the C–O bond dissociation and catalyst deactivation due to the accumulation of carbon deposits. The emergence of the respective C1s signal with ($E_b \approx 284$ eV) was indeed detected in the XPS spectra measured *in situ* during the interaction of CO + H₂ mixtures with Pd(111) surfaces.⁷⁴

All these results are well explained within the Blyholder model, which describes the interaction of CO with transition metal surfaces as an electron density exchange between the metal d orbitals and $5\sigma/2\pi^*$ molecular orbitals of CO. Presumably, the geometry of the adsorption complex is the key factor governing this interaction, especially, the electron back donation from the metal d orbitals to the $2\pi^*$ -antibonding molecular orbitals of CO. In the case of an adsorbed CO molecule, the orientation perpendicular to the palladium surface suppresses the back donation contribution and thus provides the inertness of palladium towards the C–O bond dissociation. The formation of intermediates like CH_xO ($x = 1-3$) in the course of the methanol dehydrogenation (or CO hydrogenation) promotes the electron transfer from the metal to the $2\pi^*$ -antibonding orbital of CO, which weakens the C–O bond and ultimately gives rise to its dissociation and formation of carbon deposits on the palladium surface.

3. Ethylene epoxidation over silver

It has to be stressed that the collection of spectral data in the presence of a reaction medium over the sample (at $P = 0.1-1$ mbar) in the *in situ* mode does not *a priori* provides information on the mechanism of catalytic reactions. Indeed, adsorbed species detected on the surface of a catalyst at high pressure are not necessarily catalytically active species or reaction intermediates. This issue can be effectively solved by combining the studies of the state of a catalyst surface with measurements of its catalytic properties (such as activity and selectivity) by means of mass spectrometry or gas chromatography. The efficiency of such an approach is demonstrated below by the example of a combined study of the ethylene epoxidation reaction on silver using mass spectrometry and a number of spectral techniques (including XPS, UPS, AES and XANES).^{30, 75-77}

Despite numerous studies devoted to the ethylene epoxidation on silver by diverse instrumental techniques,^{8-10, 12, 13, 78-82} a number of key questions on the mechanism of this reaction remain disputable in the literature. Recent kinetics measurements have clarified some important points, but due to the lack of direct experimental data, there are still a few issues unaddressed. In particular, neither the nature of actual oxygen species driving the epoxidation,^{8-10, 78-79} nor the structure of the key intermediate⁷⁸⁻⁸² yielding ethylene oxide were unambiguously established. Ethylene coordinated in a way similar to π -complexes⁷⁸⁻⁸⁰ or an oxametallacycle^{81, 82} were regarded as such intermediates. This stipulates the necessity of *in situ* measurements during the reaction to establish direct quantitative correlations between the yield of ethylene oxide and surface composition. Recently, the results of a series of studies on the ethylene epoxidation on silver using XPS and Proton-Transfer Reaction Mass Spectrometry (PTR-MS) jointly conducted by specialists from the G K Boreskov Institute of Catalysis SB RAS and the Department of Inorganic Chemistry, the Fritz Haber Institute (Berlin, Germany) have been published.⁷⁵⁻⁷⁷

Figure 6 shows ethylene and ethylene oxide partial pressures in the reaction cell of a photoelectron spectrometer as a function of temperature and reaction duration. The final regions of the plots were measured in the flow of pure ethylene (no O₂ was supplied) at $T = 470$ K (a) and 520 K (b), respectively. The partial pressure values were calculated from the respective PTR-MS signals corresponding to $m/z = 45$. The ionisation of gaseous species for the subsequent separation in a mass analyser in this relatively uncommon variant of mass spectrometry, was achieved through the proton transfer from H₃O⁺ ions generated in a special source to the molecules subject to analysis. The reaction

where S is the substrate, yields a molecular ion SH⁺ with a mass larger (due to a surplus proton) than that registered by traditional mass spectrometry by 1 a.m.u.. This specific ionisation mechanism guarantees that only substances with proton affinities higher than that of hydroxonium ions (*e.g.*, ethylene oxide but not CO₂) contribute to the mass spectra. Furthermore, this ionisation method virtually completely avoids the fragmentation of the molecular ion into lower-molecular-mass fragments, which greatly facilitates quantitative analysis of the experimental data. The high sensitivity of PTR-MS technique to organic molecules, such as ethylene oxide, is yet another its advantage. A detailed description of this modification of mass spectrometry can be found elsewhere.⁸³

The PTR-MS data presented in Fig. 6a indicate that the signal of ethylene oxide is negligible at ≤ 370 K but is reliably detected at $T = 420$ K. Further increase in temperature results in an abrupt increase in the ethylene oxide partial pressure, whereas a slow but continuous decrease in the partial pressure of C₂H₄O starts above $T \geq 470$ K, which is explained by the deactivation of the catalyst at these temperatures. After stop of

Figure 6. Changes in partial pressures of ethylene oxide and ethylene at $P_{\text{C}_2\text{H}_4} = 0.1$ (a) and $P_{\text{C}_2\text{H}_4} = 0.24$ mbar (b) (the oxygen pressure is 0.25 mbar in both cases) as a function of temperature. T/K : 370 (I), 420 (II), 470 (III), 500 (IV), 520 (V). The last regions of the spectra (regions III' and V') were collected after cessation of the oxygen supply. The partial pressures were recalculated from ion currents measured by mass spectrometry (see text).

the oxygen flow, the PTR-MS signal of ethylene oxide rapidly drops down to the background value. These results imply that ethylene oxide forms as a product of the direct catalytic ethylene oxidation on silver at a pressure in the range of 0.1–0.5 mbar, and the epoxidation rate increases with an increase in temperature. This conclusion is supported by test measurements, which showed that no ethylene oxide is formed upon heating of ethylene in the temperature range of 300–600 K in the absence of silver. In order to analyse the composition of adsorbed layers, full sets of XPS spectra were collected in the regions of constant temperatures (see Fig. 6).⁷⁷

The respective O1s and C1s XPS spectra measured *in situ* at $P_{\text{C}_2\text{H}_4} = 0.1$ mbar and $P_{\text{O}_2} = 0.25$ mbar are plotted in Fig. 7. All O1s spectra are normalised to the integral intensity of the

Figure 7. O1s (a) and C1s (b) XPS spectra measured *in situ* in $\text{C}_2\text{H}_4 + \text{O}_2$ reaction mixtures at $P_{\text{C}_2\text{H}_4} = 0.1$ mbar and $P_{\text{O}_2} = 0.25$ mbar as a function of temperature.

T/K : 370 (1), 420 (2), 470 (3). The spectrum 4 was measured at 470 K in a flow of pure ethylene after cessation of the O_2 supply. The difference O1s spectrum (curve 5 and its components) exhibit only signals of species present on the Ag surface under reaction conditions.

$\text{Ag}3d_{5/2}$ spectra. At 370 K, the XPS spectra reveal only one O1s component with $E_b = 530.5$ eV and three types of carbon-containing species corresponding to the C1s components with $E_b = 284.2$ eV, 285.8 eV and 287.3 eV, respectively (spectra 1 in Figs 7a and b). The spectra change dramatically upon heating of the sample to 420 K: the dominant component in the O1s spectrum shifts to 530.0 eV and a shoulder appears at 528.5 eV. Meanwhile, two components with $E_b = 285.8$ eV and 287.9 eV (spectra 2 in Figs 7a and b) are observed in the C1s spectrum. Upon further increase in temperature 470 K, the shape of the O1s signal becomes more complicated, which implies the emergence of additional components from other types of oxygen-containing species (spectrum 3 in Fig. 7a). After removal of oxygen from the gas mixture, two components with $E_b = 529.1$ eV and 530.6 eV appear in the O1s spectrum (spectrum 4 in Fig. 7a). The difference spectrum (spectrum 5 in Fig. 7a) indicates that two O1s peaks with $E_b = 530.0$ eV and 528.5 eV present in the spectra under reaction conditions at a lower temperature disappear. In the C1s spectrum measured in a flow of pure ethylene (spectrum 4 in Fig. 7b), a single peak at 285.8 eV is revealed.

It has to be noted that the large number of spectral components and the resultant ambiguities in their assignment is a common problem of the interpretation of spectra registered *in situ*. This problem can be solved by making use of supplementary reference data from traditional adsorption experiments, which in some cases requires additional measurements on special model systems. The ethylene epoxidation reaction clearly demonstrates why this supplementary information is needed.

Indeed, despite the apparent complexity of the pattern of temperature changes in the XPS spectra, numerous experimental data available in the literature^{8–10, 78–81, 84–86} make it possible to quite reliably assign the components observed in the XPS spectra to different surface and gaseous species. The XPS signals coming from gas molecules, which start to make appreciable contribution at $P > 0.05$ mbar,^{33–36} can be differentiated from those of adsorbed species by their significantly smaller FWHM (full width at the half maximum). It is for this reason, as well as taking into account possible compositions of the mixture under the catalytic reaction, that the components with $E_b = 285.7$ eV and 287.9 eV observed in the C1s spectrum (spectrum 2) were attributed to gaseous ethylene and ethylene oxide, respectively.⁷⁷ Indeed, rather similar binding energies of free ethylene and ethylene oxide ($\Delta E_b \approx 2$ eV) were reported earlier by Siegbahn *et al.*⁸⁵ This assignment is additionally supported by the spectral changes following cessation of the oxygen supply. The signal of gaseous ethylene ($E_b = 285.8$ eV) remains virtually unaffected, whereas that of ethylene oxide rapidly drops down to the background value (spectrum 4 in Fig. 7b), which is in keeping with the disappearance of one of the reactants. The direct observation of gaseous ethylene oxide in the XPS spectra is a significant merit of the *in situ* measurements, since it solidly confirms the assignment of the PTR-MS signal with $m/z = 45$ to ethylene oxide rather than its isomer, acetaldehyde, which was reported by some authors.^{8–10, 12, 13}

Other signals in the C1s and O1s spectra (see Fig. 7) were assigned to adsorbed species.⁷⁷ Temperature ranges of their existence can be used as a supplementary criterion for their assignment. In particular, the peaks at ~ 530.5 eV (O1s) and ~ 287.5 eV (C1s) observed at $T = 370$ K were attributed to surface carbonates CO_3^{2-} , not only based on the binding energy values, but also taking into account that they disappear upon heating to 420 K.⁸ Furthermore, the atomic ratio

§ Carbonate anions adsorbed on silver are known to be stable only below 420 K.^{13, 78, 84}

O : C = 2.8–2.9 calculated from the absolute intensities of the respective components corresponds to the stoichiometric value expected for carbonates (3.0). The low-binding energy peak observed in the C1s spectrum measured at 370 K ($E_b = 284.2$ eV) was attributed to carbon deposits (elementary carbon or hydrocarbon residues), which can accumulate on the silver surface at moderately low temperatures. It was concluded⁷⁷ that the screening of the silver surface with carbon deposits and adsorbed carbonate groups is primarily responsible for the lack of catalytic activity of silver below 370 K (see Fig. 6).

The O1s signals observed in the XPS spectra measured at $T > 370$ K were assigned to atomic oxygen, taking into account the absence of any Cs1 signal from adsorbed carbon species. The attribution of lines with $E_b = 528.5$ eV and 530.0 eV to the nucleophilic and electrophilic forms of adsorbed oxygen was made on the basis of earlier publications devoted to the studies of surface interactions of polycrystalline silver foil with reaction media.^{75, 76, 79} The line with $E_b \approx 529.0$ eV was ascribed to the so-called O_γ form, which has been elucidated in detail by Schlögl *et al.*^{86, 87} within the context of partial methanol oxidation over silver. This species was formulated as a strongly bound atomic oxygen substituting the silver atoms in the fcc lattice. An additional O1s signal that emerges at $T > 470$ K was attributed to the near-surface oxygen O_{ss} (or O_β)[†] incorporated into the octahedral cavities of the silver fcc lattice near the surface. The subsurface location of the O_γ and O_β oxygen species explains their inertness towards ethylene. It is these forms of oxygen that remain on the silver surface after the oxygen supply is stopped. In contrast, the nucleophilic (O_{nuc}) and electrophilic (O_{elec}) oxygen species (see the difference spectrum 5 in Fig. 7a) rapidly disappear from the silver surface in the absence of O_2 in the reaction mixture, which clearly indicates their high reactivity towards the ethylene oxidation.

To clarify the roles played by the nucleophilic and electrophilic oxygen species in the ethylene oxidation reaction, a quantitative comparison of the XPS and PTR-MS data collected at variable $C_2H_4 : O_2$ ratios in the gaseous reaction mixture has been carried out. The absolute intensities of the respective peaks normalised to that of the $Ag3d_{5/2}$ line were used as measures of the surface concentrations of these species. This procedure was necessary to account for the decrease in the XPS absolute line intensities for different compositions and pressures of the gas phase. The partial pressure of ethylene oxide was taken as a measure of the reaction yield. The ethylene oxide yield is correlated with the relative amounts of the nucleophilic and electrophilic oxygen species (Fig. 8). A dependence of the ethylene oxide yield on the concentration of the electrophilic oxygen is apparent: the larger the $O1s/Ag3d_{5/2}$ ratio for the component with $E_b(O1s) = 530.0$ eV, the higher the partial pressure of C_2H_4O . This dependence can readily be approximated by a straight line passing through the point of origin. This correlation clearly proves the involvement of the electrophilic form of the adsorbed oxygen in the ethylene oxide formation, which supports the epoxidation mechanism proposed by Bukhtiyarov *et al.*⁷⁹

Note that the linear dependence of the ethylene oxide yield on the surface concentration of the electrophilic oxygen species was also observed at other temperatures (470 K and 520 K),⁷⁷ the slopes of the respective lines being increased for higher temperatures. These slopes were used to calculate the activa-

Figure 8. The yield of ethylene oxide as a function of surface concentrations of the nucleophilic (1) and electrophilic (2) oxygen species.⁷⁷ The measurements were performed at $T = 420$ K and variable partial pressures of oxygen and ethylene.

tion energy of the epoxidation reaction, which appeared in excellent agreement with the known E_{act} values measured for the epoxidation reaction over real $Ag/\alpha-Al_2O_3$ catalysts.^{8–10, 78, 82} Even a decrease in the E_{act} value from 14 kcal mol^{–1} to 11.3 kcal mol^{–1} with an increase in temperature from 450 K to 500 K is reproduced.^{77, 82}

The surface concentration of the nucleophilic oxygen species correlates with the ethylene oxide yield in a more complex way (see Fig. 8). As has been found, in different experiments silver can demonstrate dramatically different catalytic activities at nearly identical surface concentrations of the nucleophilic oxygen. In particular, for $I(O1s)/I(Ag3d_{5/2}) \approx 0.02$ the partial pressure of ethylene oxide is 0.0013 mbar (which is still a reliably measured value) in one experimental point A (Fig. 8), but drops far below the detection threshold ($< 10^{-5}$ mbar) in another point B. It has to be noted that the latter case was realised at low pressure and thus the concentration of the electrophilic oxygen was negligible. If only data point in the pressure range of 0.1–1 mbar are taken into account, then a negative correlation of the ethylene oxide yield with the surface concentration of nucleophilic oxygen species is observed. Such a correlation can be rationalised by assuming that the nucleophilic oxygen catalyses the total ethylene oxidation. A similar conclusion was derived in earlier studies^{3, 8–10, 78, 79, 88} based on the results of titration of this type of adsorbed oxygen species with ethylene. Only CO_2 and H_2O were registered as the titration products in numerous experiments. However, other authors^{75, 76, 79} recognised the positive role played by the nucleophilic oxygen in the ethylene epoxidation, since it is involved in the formation of the $Ag^\delta+$ ions,^{89, 90} which further act as adsorption sites for ethylene. According to this scheme, adsorbed ethylene then reacts with the electrophilic oxygen species to yield ethylene oxide.

The possible co-existence of two forms of oxygen atomically adsorbed on the silver surface has been substantiated for the first time by Carter and Goddard.^{91, 92} Using quantum chemical calculations, they demonstrated stability of two distinct states of atomically adsorbed oxygen, *viz.*, oxide-like and oxyradical-like. The electronic structures of these forms depend on the coordination of the oxygen atom to the silver atoms. The oxyradical anion is active towards the selective alkene oxidation and is essentially equivalent to the electrophilic form of the adsorbed oxygen. The oxide oxygen, as will be shown below, can be associated with the nucleophilic oxygen form.

The specificity of chemical interactions of silver atoms with the electrophilic and nucleophilic adsorbed oxygen species were studied using X-ray Absorption Near-Edge Structure

[†] This form of oxygen is referred to as O_β , according to the classification adopted in earlier publications.^{86, 87}

spectroscopy (XANES, the term NEXAFS is also frequently used in the literature^{75,76}). This method provides direct information on vacant orbitals of atoms and molecules with element sensitivity. According to the dipole selection rules ($\Delta l = \pm 1$), the oxygen *K*-edge XANES spectra are formed by the electron transitions from the O1s core level to vacant oxygen p-orbitals.⁹³

Figure 9*a,b* shows the oxygen *K*-edge XANES spectra collected under conditions providing the selective formation of either nucleophilic (spectrum 1) or electrophilic (spectrum 4) oxygen species. In the case of O_{nuc} , the XANES spectrum reveals two distinct resonances at ~ 531 eV and ~ 539 eV (Fig. 9*a*). According to the literature data,^{94,95} the presence of a narrow low-energy resonance below the main absorption edge at ~ 531 eV indicates the effective hybridisation between the oxygen 2p and silver 4d electrons. The broader signal just above the main absorption edge is due to the hybridisation of oxygen p and silver 5sp electrons. The presence of a narrow absorption pre-edge peak in the spectrum of O_{nuc} clearly indicates that its 2p shell is not filled completely. In fact, in the case of a purely ionic Ag–O bond,

the transfer of two electrons from the silver atoms to the oxygen atom should give rise to the electronic configuration $O1s^2 2s^2 2p^6$, and the transition $1s \rightarrow 2p$ responsible for the pre-edge peak in the XANES spectrum will be formally forbidden. With this regard, a value of the partial negative charge on the oxygen atom estimated from the Auger spectra^{75,76} (~ 1.65 e per oxygen atom) is in complete accordance with its nucleophilic nature, and the involvement of the silver 4d electrons into the formation of the Ag–O bonds explains its high ionicity and the observed shift of the Ag3d line by 0.5 eV.⁷⁵

The oxygen XANES spectrum of bulk Ag_2O is very similar, which suggests similar electronic structures of $O(Ag_2O)$ and O_{nuc} (Fig. 9*a*). The involvement of the silver 4d electrons into the formation of the Ag–O bonds in Ag_2O is also supported by the emergence of a ‘white line’ in the Ag *L*₃-edge XANES spectrum (3.352 keV, see inset to Fig. 9*a*), which corresponds to the dipole-allowed electron transition $2p_{3/2} \rightarrow 4d$ ($\Delta l = 1$). An increase in the intensity of this line with an increase in the ionicity of the bond reflects the degree of the actual involvement of the silver 4d electrons in its formation.^{96,97} The transition $2p_{3/2} \rightarrow 4d$ is forbidden for an Ag^+ ion characterised by the electronic configuration $4d^{10}5s^0$. However, the formation of the chemical bond Ag–O results in electron density transfer from the 4d to the 5s orbitals. As a result, the electronic configuration of the Ag^+ ion can be formulated as $4d^{10-\delta}5s^\delta$, which features partly vacant 4d states near the Fermi level responsible for the emergence of a narrow X-ray absorption resonance at 3.352 keV.

The conclusions derived from the experimental XANES spectra are fully supported by quantum chemical calculations of the electronic structure of Ag_2O .⁹⁸ Indeed, the weak population of the Agd_{z^2} and $Ag5s$ states indicates appreciable charge transfer from the Ag atom to the O atom associated with the Ag–O ionic bond formation. It is of note that this type of hybridisation (*viz.*, sd_{z^2}) is rather frequently observed for metals but rarely for ionic semiconductors like Ag_2O due to the wide energy gap between the occupied d-band and vacant sp-states. In terms of the molecular orbital theory, this can be reformulated in the following way. The O2p and Agd_{z^2} states are hybridised to form the $pd\sigma$ bond, whereas the hybridisation of the O2p and Agd_{xz}, d_{yz} yields the $pd\pi$ bonds. These interacting orbitals are split into bonding and antibonding states with partial p- and d-characters. The $Agd_{x^2-y^2}$ and Agd_{xy} orbitals remain essentially non-bonding.⁹⁸

The *K*-edge XANES spectrum of electrophilic oxygen species displays a broad peak around 541 eV (spectrum 3 in Fig. 9*b*). The absence of distinct pre-edge peaks (around 531 eV) strongly implies that the Ag–O bonds are formed by the hybridisation of the oxygen 2p and silver 5sp electrons, whereas the metal 4d electrons remain unaffected. The respective $Ag3d_{5/2}$ spectrum does not show additional ‘ionic’ lines, such that the electronic state of the silver atoms is similar to that in the bulk metal⁷⁵ (the electronic configuration of silver atoms is $4d^{10}5s^1$). In the metallic state, the 5s electrons of silver are delocalised in the conduction band. Most likely, it is these delocalised conductivity electrons that participate in the formation of Ag– O_{elec} bonds.

According to the literature data, a similar oxygen XANES spectrum is characteristic of oxygen adsorbed on the copper surface in the suboxide state.⁹⁹ The respective Cu *L*_{2,3}-edge XANES spectra reveal no characteristic ‘white line’ in contrast to the spectra of CuO or Cu₂O (which are similar to that of Ag_2O), which means that the copper atoms in this structure indeed preserve essentially metal-like properties and only outermost 4sp electrons are involved in the Cu–O bond formation. Therefore, in both these cases, the M–O bonds are formed by the interaction of the oxygen 2p and metal outermost sp orbitals and characterised by the essentially covalent character.

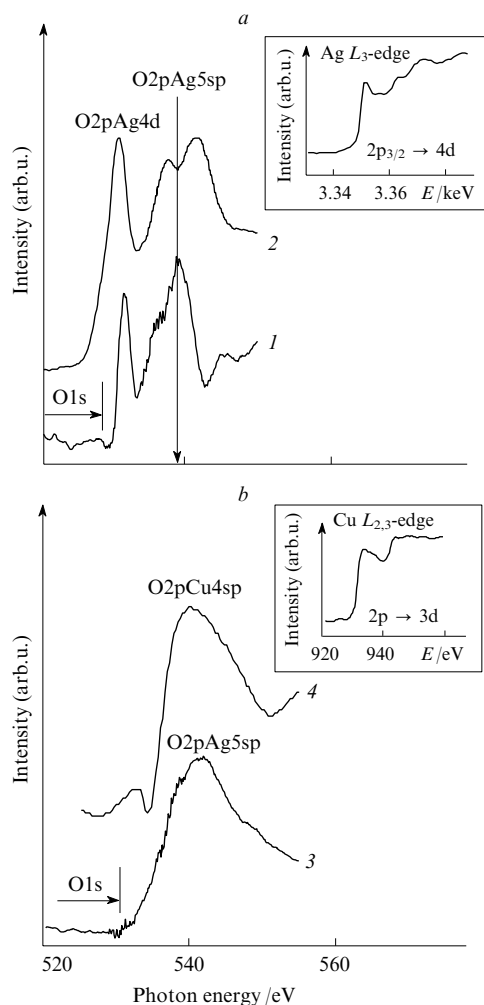

Figure 9. *K*-Edge XANES spectra of the nucleophilic form of adsorbed oxygen (O_{nuc}) (a, spectrum 1) and oxygen within Ag_2O (a, spectrum 2), electrophilic form of adsorbed oxygen (O_{elec}) (b, spectrum 3) and oxygen adsorbed on the copper surface (b, spectrum 4).

Insets: *L*-edge spectrum of Ag_2O (a) and *L*-edge spectrum of the copper surface with adsorbed oxygen (b).^{2,3} The O1s binding energies from the XPS measurements for the respective samples are shown with horizontal arrows.

Then another important question arises, what geometries can be ascribed to the adsorption complexes of O_{nuc} and O_{elec} . According to the literature data, the binding energy of O_{nuc} is $E_b(O1s) = 528.4 \pm 0.1$ eV (calibrated against the $Ag3d_{5/2}$ line with $E_b = 368.2$ eV) independent of the type of the silver surface [different polycrystalline foils, single-crystalline faces $Ag(111)$, $Ag(110)$ or $Ag(100)$ and even graphite-supported silver particles]. The small scatter of the experimental data suggests the common character of the nucleophilic oxygen species adsorbed on different silver faces. The majority of researchers agree that the formation of the nucleophilic oxygen state is directly related to silver surface reconstruction. In particular, the oxygen adsorption on the $Ag(110)$ crystal face at 300–500 K can give rise to the superstructures of the type $Ag(110)-(n \times 1)-O$, where n decreases from 7 to 2 with an increase in the O_2 exposure.^{78, 100, 101} The $Ag(110)-(2 \times 1)-O$ reconstruction due to the appearance of supplementary atomic rows going along the $[001]$ direction with the oxygen atoms residing nearly in the plane of the supplementary rows has been reliably established with scanning tunneling microscopy and photoelectron diffraction. The $Ag-O$ bond length is 2.044 Å, which is nearly identical to the respective value typical of bulk Ag_2O (2.05 Å).¹⁰² The formation of such a surface structure with $\theta = 0.5$ monolayers results in a substantial (by 0.8 eV) increase of the work function as compared to clean silver surface, which indicates a significant charge transfer from the metal to oxygen atoms.¹⁰⁰ The linear increase in the work function with an increase in coverage implies that the surface dipole moment per adsorbed oxygen species is independent of coverage,¹⁰¹ i.e., the electronic structure of nucleophilic oxygen adsorbed on $Ag(110)$ remains constant over the entire coverage range and is close to that in oxide. The adsorption of oxygen in the nucleophilic form on the densely packed $Ag(111)$ face gives rise to the $p(4 \times 4)$ surface reconstruction. The nature of the $Ag-O$ bonds in this surface structure is also believed (for instance, see Refs 10, 103 and 104) to be similar to that in bulk Ag_2O .

Thus, the nucleophilic form of oxygen is formed on the silver surface as a result of the reconstructive adsorption giving rise to linear fragments $Ag-O-Ag$ (Fig. 10a). Indeed, the angle $Ag-O-Ag$ in both the bulk Ag_2O oxide and in the $Ag-O_{\text{nuc}}-Ag$ surface structure are close to 180° . Such a geometry favours the rather strong interaction between the silver 4d and oxygen 2p orbitals associated with the substantial

charge transfer. The high ionicity of the $Ag-O$ bonds in such a structure, on the one hand, provides the conversion of the silver atoms into the ionic form Ag^+ required for the ethylene adsorption and, on the other hand, determines the nucleophilic properties of the oxygen atoms in the ethylene epoxidation.

The geometry of the electrophilic oxygen state is less elucidated. It is only known from the experimental data that oxygen in the electrophilic form is adsorbed directly on the silver surface.^{76, 79, 103} Most likely, the adsorption does not induce surface reconstruction and the oxygen atom is located above the triangle of silver atoms (three-fold hollow, Fig. 10b). For instance, the adsorbed oxygen species with $E_b(O1s) = 530.1$ eV have been detected on the $Ag(111)$ face.¹⁰³ The absence of a surface reconstruction in that case was evidenced by LEED, whereas surface location of the oxygen atoms was confirmed by angular-resolved XPS. The absence of additional components in the $Ag3d$ spectrum was consistent with the covalent character of the $Ag-O_{\text{elec}}$ bonds.

This model agrees well with the results of quantum chemical calculations. Zilberberg *et al.*^{105, 106} found a stable state of atomically adsorbed oxygen on the non-reconstructed $Ag(111)$ surface. The oxygen atoms are located symmetrically above a three-centre cavity and bound to three silver atoms [the three-fold axial symmetry is governed by the symmetry of the $Ag(111)$ face]. The $Ag-O$ bond length is 2.109 Å (note that the $Ag-O_{\text{nuc}}$ is 2.044 Å). The charge transfer from the metal to the adsorbate in this case should be much smaller than that in the binding of Ag to O_{nuc} . The aforementioned oxyradical oxygen adsorbed on $Ag(110)$ is characterised by a similar geometry.^{91, 92} In this case, oxygen is also localised on the three-centre position of the non-reconstructed surface, i.e., the oxygen adsorption on $Ag(110)$ proceeds dissociatively without reconstruction. Such a geometry of the adsorption complex determines the essential covalency of the $Ag-O$ bond and consequently the electrophilic properties of this oxygen form in the ethylene epoxidation to ethylene oxide.

The experimental efforts aimed at the elucidation of the structure of the active site and the mechanism of the ethylene epoxidation have been described in so much detail to demonstrate that the *in situ* measurements provide correlation dependences sufficient to establish the structure–activity relationship in heterogeneous catalysis, despite they are associated with greater difficulties and ambiguities in data interpretations as compared to traditional UHV measurements. It is also evident that it is the application of several instrumental techniques to one system that gives a chance of success in establishing this relationship.

4. Reaction of partial methanol oxidation into formaldehyde over copper

As another example of efficient determination of the mechanism of a catalytic reaction using *in situ* measurements, we describe the methanol oxidation into formaldehyde over the copper surface studied by XANES, XPS and mass-spectrometry.^{29, 35, 107} A brief survey of experimental facts available in the literature indicates that:

- a Cu catalyst has to be activated prior to use;
- the methanol conversion pathway depends on the ratio of methanol/oxygen partial pressures in the reaction mixture and on the sequence of the reactants supply;
- stoichiometric copper oxides (Cu_2O and CuO) demonstrate low selectivity in the formaldehyde synthesis;
- Cu catalysts are transformed into Cu_2O after evacuation of the reaction medium or its fast cooling aimed at the freezing of the active state of the copper surface.

This means that the forms of adsorbed oxygen responsible for the copper activity towards the selective methanol oxidation are formed directly under the reaction conditions. Thus, the catalytic system represents a dynamic system, which exists only

Figure 10. A structural model of adsorbed oxygen species. (a) Nucleophilic oxygen on the reconstructed $Ag(110)$ surface, (b) electrophilic oxygen on the unreconstructed $Ag(111)$ surface. Top panels is top view, bottom panels is side view.

Figure 11. A model of the active surface of a copper catalyst with various co-existing oxygen species.¹⁰⁷

The arrows indicate routes of mutual transformations of various oxygen species and interaction paths of $\text{CH}_3\text{OH}(\text{gas})$ with the copper surface. Bulk (Ox_{bulk}) and surface (Ox_{surf}) oxide forms of oxygen catalyse the total methanol oxidation into CO_2 and H_2O . Formaldehyde is formed upon the interaction of methanol with weakly bound oxygen species (SubOx) adsorbed on the copper surface.

in the contact with the reaction medium and thus the ‘pressure gap’ problem is very important for this system.

As a result of studies, various forms of adsorbed oxygen have been identified and correlations between their concentrations and yields of respective products of the methanol oxidation via different pathways (*i.e.*, total or partial oxidation, *etc.*) have been determined. The surface oxygen species identified include two oxide forms (a surface and a bulk forms) and one suboxide form. The assignment of the latter to the a suboxide oxygen state was based on the absence of a characteristic $\text{O}1s \rightarrow \text{O}2p\text{Cu}3d$ peak in the oxygen K-edge XANES spectra. Judging from the linear correlation between the surface concentration of suboxide oxygen and formaldehyde yield, it was concluded that it is this form that catalyses the partial methanol oxidation.^{29, 107} Similar dependences of the formaldehyde yield on the concentration of the oxide forms were far from the linear character, which allowed a conclusion that these forms catalyse the total methanol oxidation.

A generalised scheme of various species present on the copper surface in the course of the catalytic methanol oxidation and responsible for different reaction pathways is shown in Fig. 11.¹⁰⁷ It is of note that the suboxide oxygen form on the copper surface was detected by means of XANES only in the presence of the reaction medium, which additionally demonstrates the importance of *in situ* studies.

A great interest of researchers to the state of active catalyst surfaces during their operation (even in the case of model systems) is reflected in the appearance over recent years of numerous monographs and special issues of scientific journals devoted to the application of instrumental techniques to studies of the catalytic activity in the *in situ* mode with surface-sensitive techniques occupying a notable place among them.^{107–111}

III. The ‘material gap’ problem

The intermediate state occupied by nanoparticles in the row metal–atom determines their unique physicochemical properties (electronic, magnetic, optical, *etc.*) clearly distinguishable from those of both bulk metals and isolated atoms. No doubt, it is the changes in the surface structures and electronic properties of metal catalysts upon transition from bulk samples to nanoparticles that are of primary interest for catalysis

specialists,^{18–20} since it is these characteristics that govern the features of the interaction of reactants with the active component, the nature and reactivity of adsorbed species and ultimately the activity and selectivity of nanostructures in heterogeneous catalysis.

1. CO oxidation over nanoparticles of the platinum-group metals

According to investigations into the catalytic activity of palladium particles supported on $\alpha\text{-Al}_2\text{O}_3$ with respect to the CO oxidation as a function of the mean particle size,¹¹² a decrease in the particle size from 30 nm to 5 nm accelerates the reaction three fold. This experimental fact was explained within the Langmuir–Hinshelwood mechanism, which assumes that any adsorption–desorption steps of a heterogeneous catalytic reaction are in equilibrium and the total rate is limited by the reaction between the adsorbed species:

In the case of CO oxidation of single-crystalline surfaces, the validity of this mechanism has been established earlier.^{1, 113} An increase in the rate of the CO oxidation on Pd particles was explained by weaker binding of the CO molecules to the Pd atoms of small clusters. This conclusion was derived from a comparative TPD analysis of the CO adsorption on Pd(111) single crystal and disperse palladium samples.^{1, 49} In the case of Pd nanoparticles with a size of 2.5 nm, the TPD spectrum of carbon monoxide reveals additional weakly bound states that are characterised by lower desorption temperatures as compared to adsorption states on the single-crystalline surface. Meanwhile, in the case of large particles with $d = 27$ nm, the TPD spectrum was identical to that measured with the single crystal.

A different in principle picture was observed for Pt particles supported on alumina⁴⁷ or mica:¹¹⁴ the TPD spectra of CO desorption showed that a weakly bound state typical of a single-crystalline surface or large supported particles virtually disappears for Pt particles smaller than 3 nm. This observation is in accord with a more than seven fold deceleration of the CO oxidation on small Pt nanoparticles.¹¹⁵ According to TPD studies of the CO adsorption on supported platinum and rhodium particles,¹¹⁶ relative populations of weakly and strongly bound CO_{ads} is virtually independent of the mean size of rhodium dispersed particles. This explains why the reaction of $\text{CO} + \text{O}_2$ on the rhodium surface is structure-insensitive.¹¹⁷

The above example demonstrates that the use of model catalysts prepared by the thermal deposition of a metal on planar substrates is extremely efficient for the analysis of size effects for reactions catalysed by supported metal particles. This statement can be most spectacularly illustrated with a study of the CO oxidation on gold particles. Presently, this reaction became a canonical example of the ‘nanosize’ effect.

2. CO oxidation over gold nanoparticles

For a long time, gold was considered as one of the most inert metals. Nevertheless, as was discovered in the 1990s, gold nanoparticles with a size of <5 nm supported on titania manifested high catalytic activity in a series of practically important reactions exceeding that of platinum catalysts traditionally applied in the field (the CO oxidation was the first reaction of this series^{118, 119}). Figure 12 plots the atomic catalytic activity of nanosized gold particles for the CO oxidation reaction as a function of the mean particle size.^{120, 121} It is clearly seen that the reaction rate rapidly increases with a decrease in the mean size of gold particles to

Figure 12. Turnover frequency (TOF) of the supported Au/TiO₂ catalysts with high specific surface areas in the CO oxidation at 300 K as a function of the mean Au particle size.¹²¹

3.5 nm. Further decrease in the particle size results in a decrease in the catalytic activity. Such an unusual catalytic behaviour of ultrasmall Au particles remained unexplained at the atomic level for a long time despite enormous efforts put forth. The understanding of the size effect has been achieved owing to a transition to Au/TiO₂ model systems.^{122–127} These brilliant results have been obtained by a group of researchers from the A&M University (Texas, USA) headed by Prof. Goodman.

A typical STM pattern for a model sample composed of gold nanoparticles with a diameter of 2.6 nm and a height of 0.7 nm (which constitutes only 2–3 atomic layers) dispersed on the TiO₂(110)-1 × 1 single-crystalline face and covering

Figure 13. A structural model of bilayer Au islets on the TiO₂(110) surface (a) and STM image of the Au/TiO₂(110)-(1 × 1) surface at $\Theta(\text{Au}) = 0.25$ monolayers (b).¹²⁷

25% of its surface is shown in Fig. 13. Such a morphology of the gold particles is explained by the fact that the growth proceeds in two steps: first two-dimensional (2D) islets are formed and only then as the surface concentration of gold increases, the particles start to grow in the third dimension.^{128, 129} By changing the surface concentration of deposited gold, a series of model samples was prepared with the mean particle size systematically varying from 1.5 nm to 6 nm.

These model catalysts Au/TiO₂(110)-1 × 1 were assayed in the catalytic activity in the CO oxidation. The reaction rate as a function of the gold particle size obtained (Fig. 14) was nearly identical to that measured for real supported catalysts, which justifies the utilisation of model systems in the analysis of the size effects. The apparent activation energy in the temperature range of 350–450 K increases from 1.7 kcal mol⁻¹ to 5 kcal mol⁻¹ with an increase in the mean Au particle size from 2.5 nm to 6 nm.

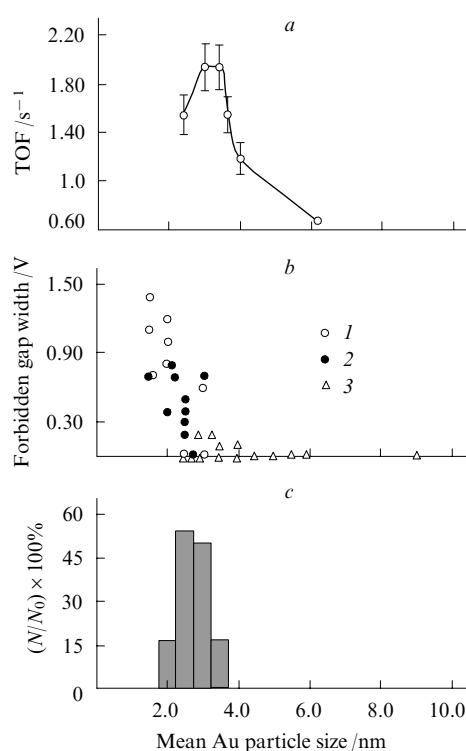

Figure 14. Turnover frequency (TOF) of the Au/TiO₂(100) catalyst in the CO oxidation as a function of the mean Au particle size assuming their dispersion (a); changes in the band gap widths according to the STM measurements (b); relative coverage of the TiO₂(100) surface with bilayer Au particles (c) as functions of the mean Au particle size. The data points 1–3 correspond to three samples with different gold concentrations.

These measurements on model samples helped to shed light upon the reasons for the extraordinary activity of gold nanoparticles. Variations in the mean size of particles in a range from 2 nm to 4 nm are accompanied by changes in the band gap (Fig. 14b).^{122, 127} With a decrease in the mean Au particle size below < 3.5 nm, a metal–insulator transition occurs:[†] particles with a height of one atomic layer are characterised by

[†] The metal–insulator transition, which is a particular case of the quantum size effect, was observed earlier for many metal catalysts.^{124, 130, 131}

a rather wide band gap, whereas particles with heights of 3 layers and more are essentially metallic.

Furthermore, the strength of the CO–Au bond was shown to be dependent on the Au particle size. This conclusion was derived based on IR absorption spectroscopy of CO molecules adsorbed on gold nanoparticles with a size from 1.8 nm to 3.1 nm.^{125, 126} The specific heat of absorption abruptly increased from 12.5 kcal mol^{−1} to 18.3 kcal mol^{−1} with a decrease in the particle size, and the maximum is observed at the same size (~3 nm) as the catalytic activity maximum and the onset of the metal–insulator transition.¹²² The final conclusion about the structure of active sites was made based on an analysis of the relative distribution of bilayer gold particles as a function of the mean particle size, which is also shown in Fig. 14c. The maximum of this distribution falls on the same mean size (2.5–3.0 nm) as the maximum strength of the CO–Au bonds and activity of model catalyst in the CO oxidation.

Further arguments in favour of the suggestion that it is the bilayer gold particles that are active in the CO oxidation^{33, 101} were gathered in an LEED study of gold particles deposited into an ultrathin single-crystalline film of TiO₂. The film was prepared by mild oxidation of a titanium monolayer grown on a Mo(112) single crystal.¹²⁷ The surface was characterised by a distinct (8 × 2) LEED pattern. Two-dimensional gold islets and bilayer particles were identified by the appearance of (1 × 1) and (1 × 2) LEED patterns, respectively. The sample containing bilayer gold particles manifested an unprecedented catalytic activity in the CO oxidation (Fig. 15). Thus, it was demonstrated that in order to provide high activity of nanosized gold catalysts in the low-temperature CO oxidation, gold particles composed of exactly two layers of Au atoms have to be selectively prepared. This finding initiated extended experiments aimed at the development of methods for the synthesis of nanoparticles supported on porous alumina and design of advanced catalysts on their base (see Section V).

Figure 15. Turnover frequency (TOF) of the Au/Mo(112)-(8 × 2)-TiO_x catalysts in the CO oxidation at 300 K as a function of coverage of the surface with gold nanoparticles.

Model samples synthesised by the UHV deposition of metals on planar supports were used to study many aspects of the catalytic action of supported metal catalysts. Only a few of them will be addressed in the present review, including the catalytic synergism in the CO oxidation on bimetallic Pt–Rh

catalysts,^{132–135} the size effects[‡] in the ethylene epoxidation on silver catalysts^{20, 136–138} and the deactivation mechanism of Pt/Al₂O₃ catalysts for neutralisation of exhaust gases in the presence of SO₂.^{139, 140}

3. CO oxidation on bimetallic Pt–Rh catalysts

The synergism in the CO oxidation on supported Pt–Rh/Al₂O₃ catalysts used for the exhaust gases neutralisation has been reported for the first time by Oh and Carpenter,¹⁴¹ who studied this reaction under conditions of excess of oxygen. They showed that catalysts prepared by successive impregnation of alumina with solutions of platinum and rhodium salts manifest significantly higher activities than mechanical mixtures of two catalysts with individual metals. This result was later reproduced by Cai *et al.*¹⁴²

On the other hand, Nieuwenhuys *et al.*^{143, 144} observed no synergistic effect in the Pt–Rh/Al₂O₃ catalytic system. They noted only a monotonic change in the catalytic properties between two limiting points represented by monometallic platinum and rhodium systems. This apparent discrepancy was likely due to variations in the nature of studied samples, experimental conditions and procedures used for the catalysts preparation.^{141–144} Nieuwenhuys *et al.*^{143, 144} employed simultaneous impregnation of alumina with a solution of platinum and rhodium salts, whereas Oh and Carpenter¹⁴¹ and Cai *et al.*¹⁴² performed the impregnation successively in two steps. It would be reasonable to assume that a statistical distribution of alloy particles over the alumina surface is realised in the case of the simultaneous impregnation and subsequent reduction, whereas isolated Pt and Rh particles are generated upon successive impregnation.

In order to verify this assumption, Bukhtiyarov *et al.*^{132–135} carried out a comparative analysis of the CO oxidation on continuous polycrystalline films of Pt and Rh, their alloy and heterophase Pt–Rh bimetallic surfaces at a reaction mixture pressure below 10^{−5} mbar. The high-vacuum conditions were necessary to exclude surface oxidation of the catalysts, which cannot be avoided with porous supports.^{141, 142} Continuous polycrystalline films of Pt and Rh were prepared by UHV deposition of the respective metals on a Ta foil. In order to suppress the diffusion of the noble metals into tantalum, the surface of clean Ta foil was covered with a thin alumina film prior to metal deposition.¹³²

The alloy with a composition of 56 at.% of Pt and 44 at.% of Rh was prepared by successive deposition of platinum and rhodium from two independent sources. Prior to experiments, the alloy was annealed at 800 °C for 10 min under UHV to equilibrate the atomic distribution.

The preparation of heterophase Pt–Rh surfaces included several steps: (a) vacuum deposition of a continuous rhodium film on the Al₂O₃/Ta substrate; (b) total oxidation of rhodium to Rh₂O₃ by exposure to oxygen for 30 min at *P* = 10 mbar and *T* = 400 °C; (c) vacuum deposition of Pt on the oxidised rhodium surface until the Pt4f_{7/2}/Rh3d_{5/2} line intensity ratio in the XPS spectrum becomes equal to 0.38 and (d) subsequent reduction of the surface in hydrogen at *P* = 10^{−6} mbar and *T* = 300 °C. The heterophase surface prepared in this way can be regarded as a model of catalysts synthesised by successive impregnation, whereas the alloy surface mimics the catalysts produced by simultaneous impregnation.

According to an STM study of these samples, the heterophase surface is composed of platinum particles with a size of

[‡] As has been demonstrated earlier, the rate of ethylene oxide formation decreases by more than one order of magnitude with a decrease in the mean size of supported silver particles below 50 nm.

Figure 16. STM Images of the Pt–Rh alloy (a) and the Pt–Rh heterophase surface (b) prepared by the UHV Pt and Rh co-deposition on a thin alumina film grown on a Ta foil (see text).

10–20 nm dispersed on a flat rhodium substrate and covering 50% of its surface; the alloy is characterised by a smooth surface with a roughness of < 1 nm (Fig. 16). The heterophase surface is stable against heating up to 350 °C but converts into the homogeneous alloy at higher temperatures.

Typical plots of the CO oxidation rates (measured as a CO_2 partial pressure) for the platinum sample measured at a constant O_2 pressure (10^{-6} mbar) and variable CO pressures as a function of temperature are shown in Fig. 17. All curves reveal three distinct regions. At low temperatures, the reaction is very slow and the CO_2 concentration is below the detection limit of the mass spectrometer. With an increase in temperature up to a certain threshold value, CO_2 appears in the gas phase, then the reaction rate rapidly increases reaching the maximum value. After that, the reaction rate smoothly decreases. Similar dependences were obtained for all the samples under study.

Figure 17. Temperature dependences of the CO oxidation rates (expressed as CO_2 partial pressures) on Pt as a function of P_{CO} at a constant oxygen pressure ($P_{\text{O}_2} = 10^{-6}$ mbar). $10^7 P_{\text{CO}}$ /mbar: 0.07 (1), 0.17 (2), 0.35 (3), 0.47 (4), 0.96 (5), 3.6 (6), 8.6 (7).

Such a character of the reaction rate vs. temperature plots is typical of platinum metals and explained by the adsorption mechanism of the CO oxidation (the Langmuir–Hinshelwood mechanism), which involves steps of reversible molecular adsorption of CO, dissociative adsorption of O_2 and a reaction between the adsorbed species on the metal surface.¹ At low temperature, the metal surface is covered by adsorbed CO molecules, which screen surface areas accessible to the O_2 adsorption. As a consequence, the reaction rate is low.

With an increase in temperature, CO_{ads} species partly desorb freeing adsorption sites for O_2 . Under these conditions, the reaction rate is limited by the carbon monoxide desorption, i.e., CO inhibits the reaction. With further increase in temperature, the reaction rate rapidly increases reaching the maximum value, which is accompanied by a change in the

composition of the adsorbed layer from purely CO_{ads} to $\text{CO}_{\text{ads}} + \text{O}_{\text{ads}}$.¹⁴⁵ Further smooth decrease in the reaction rate with increasing temperature is usually attributed to the screening effects of adsorbed oxygen. At high temperatures, the reaction is characterised by the zero order with respect to the concentration of the excess of the reactant and nearly first order with respect to the concentration of the deficient reactant.¹

Due to the validity of the Langmuir–Hinshelwood mechanism for the CO oxidation, the temperature dependences of the CO conversion known as the ‘light-off curves’ came in use as an industrial test of properties of catalysts for the after-burning of exhaust gases. Typically, the light-off curve has a shape similar to the above curves of the CO oxidation rates measured in a chamber of an XPS spectrometer serving as a catalytic reactor (see Fig. 17): the CO conversion is negligible at low temperature but rapidly increases reaching 100% when temperature is increased above the critical value. This fact can easily be rationalised taking into account that CO_2 is the only product of the CO oxidation. A catalyst that provides the minimum temperature of the 100% CO conversion is considered to be the best one (the half-conversion temperature is routinely used in quantitative comparisons).

In order to verify the probable synergistic effects for the heterophase surfaces, the temperature dependences of the CO oxidation rates were compared for different model surfaces, including monometallic Pt and Rh films, the Pt–Rh alloy and the Pt–Rh heterophase surface (Fig. 18). For the sake of comparison, Fig. 18 also shows a calculated temperature dependence of the CO oxidation rate on a bimetallic Pt–Rh sample with two independent platinum and rhodium domains with areas twice smaller than those in the individual monometallic samples (curve 5). The number of platinum and rhodium surface sites in the case of the calculated curve was adjusted to be the same as in the heterophase surface. All experimental curves were measured under identical conditions for equimolar CO and O_2 mixtures ($P \approx 10^{-6}$ mbar).

Figure 18. Temperature dependences of the CO_2 formation rates at $P_{\text{CO}} = P_{\text{O}_2} = 10^{-6}$ mbar on Rh (curve 1), Pt (2), Pt–Rh alloy (3), Pt–Rh heterophase surface (4).

The simulated dependence for a heterophase Pt–Rh surface assuming independent Pt and Rh domains with relative coverages of 0.5 (curve 5, see text).

As it becomes clear from Fig. 18, rhodium manifests much higher activity than platinum. Importantly, high oxidation rates are observed on the Rh catalyst at relatively low temperature. In particular, the activity of rhodium is maximum at $T = 200$ °C where platinum exhibits nearly zero activity. The activity of the alloy is intermediate between those of individual Rh and Pt. The CO oxidation rate on the heterophase surface is

close to that on rhodium at low temperatures and exceeds that on rhodium above 250 °C. Nevertheless, it has to be taken into account that the accessible area of rhodium in the case of the heterophase samples is twice smaller than in the case of the purely rhodium sample. Therefore, a comparison of the activity of the heterophase sample (curve 4 in Fig. 18) with the calculated curve (curve 5) would be more informative. The calculated curve has a kink at $T = 200$ °C corresponding to the maximum reaction rate on pure rhodium and a maximum at $T = 300$ °C (corresponding to the maximum reaction rate on platinum).

The curves 4 and 5 are nearly identical at $T < 200$ °C, while the CO oxidation rate on the heterophase Pt–Rh surface starts to significantly exceed the respective value expected for the bimetallic surface under assumption of the independent behaviour of Pt and Rh domains at higher temperatures, *i.e.*, there is a prominent synergistic effect. This result was explained by a specific structure of the adsorption layer and its evolution in the course of the reaction (Fig. 19). At the ignition temperature, the adsorbed CO molecules are oxidised by O_{ads} species adsorbed on the rhodium regions that become vacant due to the CO desorption. The CO oxidation rate is maximum at $T = 200$ °C, which corresponds to the T_{max} for pure Rh. At this temperature, the reaction rate on platinum is low (since Pt particles are covered with CO_{ads}). At $T > 200$ °C, the reaction between CO_{ads} (on platinum) and O_{ads} (on rhodium) takes place (see Fig. 19). The experimentally observed synergism in this case is due to the involvement of the Pt particles into the overall process as a supplier of one of the reactants (*i.e.*, CO_{ads}).

Figure 19. A structural model for the active Pt/Rh surface explaining the synergism in the CO oxidation.

In summary, the enhanced activity of the bimetallic catalyst can be explained by the selective adsorption of the reactants on different surface sites (O_{ads} preferably on rhodium whilst CO_{ads} preferably on platinum) and a reaction between the O_{ads} and CO_{ads} proceeding at the interface between Pt and Rh.

4. Interaction of oxygen with silver nanoparticles

The size effects in the ethylene epoxidation on silver catalysts were elucidated on model catalysts prepared by vacuum deposition of silver on the graphite substrate.^{20, 136–138} The use of the carbon substrate instead of the oxide (Al_2O_3) helped to suppress the charging effects, which hampers studies of the electronic properties of supported metals by means of XPS for dielectric samples, and get rid of the masking O1s signal from the substrate. The absence of the spurious O1s from the substrate makes the XPS method highly informative for the elucidation of O_2 adsorption on the surface of supported silver particles.^{137, 146} Sputtering of silver and subsequent oxygen adsorption on model Ag/C specimens was performed directly in a UHV chamber of a photoelectron spectrometer avoiding air exposure of the specimens. Only the STM characterisation of the supported silver particles was performed in a vacuum chamber of the tunneling microscope

following transfer of the samples from the chamber of the photoelectron spectrometer.

A typical STM pattern of the graphite surface after the silver deposition (relative coverages were estimated according to ratios of the silver and carbon line intensities in the XPS spectra; the current sample corresponds to $I_{Ag3d}/I_{C1s} = 0.13$) is shown in Fig. 20. The originally rather smooth graphite surface becomes substantially rough after the silver deposition due to the formation of three-dimensional silver nanoparticles with a mean size of 1–3 nm. A statistical treatment of several (> 10) STM pictures afforded a size distribution histogram of silver particles depicted in Fig. 20b. This sample is characterised by a mean silver particle size of 1–1.2 nm. Samples with larger mean particle sizes were prepared using longer deposition times, although this necessarily resulted in broadening of the size distribution.

Figure 20. A typical STM image of the highly oriented pyrolytic graphite surface with deposited silver particles (a) and the respective size distribution histogram of the silver particles (b).

The O1s XPS spectra recorded just after the O_2 adsorption on Ag particles (within 10 min) at $P_{O_2} = 0.1$ mbar and $T = 420$ K are shown in Fig. 21. Only nucleophilic O_{ads} species are formed under these conditions on the bulk silver

Figure 21. O1s XPS Spectra after exposure of graphite-supported silver particles to O_2 for 10 min at $T = 420$ K and $P_{O_2} = 0.1$ mbar as a function of coverage (estimated as the I_{Ag3d}/I_{C1s} line intensity ratio). Coverage (particle size): (1) 0.13 (1–2 nm), (2) 1.5 (5–7 nm), (3) 2.4 (~10 nm), (4) 13.1 (>20 nm). The mean size of Ag particles (in parentheses) was estimated from STM.

surface, whereas the electrophilic species are found on the nanoparticles, which is evidenced by the appearance of the O1s component with $E_b \approx 530.5$ eV in the XPS spectra. The electrophilic form of adsorbed oxygen remains prevailing for silver nanoparticles with sizes of up to 30 ± 10 nm. Only for larger Ag particles, the line characteristic of the nucleophilic oxygen species emerges in the spectra.

This result indicates that the same two species of adsorbed oxygen (*viz.*, the nucleophilic and electrophilic ones) can be detected on the surface of supported silver nanoparticles as on bulk samples. They are formed directly upon adsorption of pure O_2 rather than of a mixture of oxygen and ethylene, which was necessary for the formation of the O_{elec} species in the case of bulk silver. This enables the collection of reliable TPD data for the electrophilic oxygen to estimate the strength of the Ag– O_{elec} bonds. This was impossible for bulk silver due to a parasitic desorption contribution from oxygen dissolved in silver and O_{elec} elimination through the interaction with near-surface carbon (both dissolved oxygen and near-surface carbon are generated upon the activation of the bulk silver surface by the reaction medium).

The procedure used for the preparation of Ag/C samples was slightly modified for the determination of the strength of the Ag–O bonds by means of TPD. A thin film of graphite (with a thickness of a few hundred nm) was deposited on a Ta foil by pyrolysis of ethylene at $T = 1100$ K and $P = 50$ mbar.¹³⁷ The Ta foil was used as a resistive heater, which provided a sample heating rate of $2–3$ K s^{-1} sufficient for the TPD data acquisition. The time of ethylene pyrolysis was monitored by repeating survey XPS scans: the pyrolysis was stopped when the tantalum line was completely suppressed. The graphite-like nature of the carbon deposit was confirmed by XPS: the position of the C1s line and the appearance of a characteristic shake-up satellite were fully consistent with the respective features in the spectrum of bulk graphite.¹⁴⁶ The graphite layer was prepared in the same UHV chamber where subsequent vacuum deposition of silver and oxygen adsorption were carried out.

Figure 22 shows the curves of temperature-programmed desorption of electrophilic oxygen measured using mass spectrometry by the appearance of O_2 in the gas phase (heavy line) and as changes in the intensity of the O1s component with $E_b = 530.5$ eV (fine line) after its differentiation and inversion (the procedure used for the conversion of XPS data into TPD spectra is described in detail elsewhere¹⁴⁷). The full agreement

Figure 22. TPD Spectra of electrophilic oxygen adsorbed on Ag particles measured by mass spectrometry (heavy line) and as changes in the XPS O1s line intensity for a relative coverage $I_{Ag3d}/I_{C1s} = 2.4$ [thin lines; (1) after differentiation, (2) after inversion].

of the TPD spectra obtained by mass spectrometry with that calculated from the XPS data confirms that the signal in both cases is due to the desorption of the electrophilic oxygen. According to these results, the electrophilic form of atomically adsorbed oxygen is characterised by a lower desorption temperature as compared to the nucleophilic form (500 K vs. 580 K), which means that this form responsible for the ethylene epoxidation is bound to the silver surface less strongly than the nucleophilic form, which is active in the total ethylene oxidation to CO_2 and H_2O . This conclusion is of great importance, since it confirms the compliance with the thermodynamical requirement of the possible participation of electrophilic oxygen in the formation of ethylene oxide: the upper limit of the bond strength for an oxygen species driving the epoxidation was estimated to $25–27$ kcal mol^{-1} (Refs 148 and 149).

The changes in relative amounts of the electrophilic and nucleophilic forms of O_{ads} on Ag/C catalysts dependent on the silver particle size is yet another feature of these catalysts. The character of this dependence (*i.e.*, the disappearance of O_{nuc} with a decrease in the Ag particle size below 200–300 Å) explains within a common mechanism the decrease in the rate of the ethylene epoxidation on Ag/ α - Al_2O_3 catalysts by more than an order of magnitude with a decrease in the mean size of silver particles down to 50 nm.¹³⁶ Indeed, the disappearance of the nucleophilic form of adsorbed oxygen on silver particles with a size < 50 nm results in a decrease in the concentration of adsorbed ethylene, which in turn results in deceleration of the key step of the epoxidation reaction, according to the active surface law. This result is another illustration that both the electrophilic and nucleophilic forms of oxygen adsorbed on silver are involved into the ethylene epoxidation.^{136–138}

Based on the results of fundamental investigations into the nature and reactivity of adsorbed oxygen species on supported silver particles, a mechanism of the ethylene epoxidation reaction was proposed (Scheme 1), which takes into account the silver surface morphology ensuring the formation of two forms of adsorbed oxygen.

Scheme 1

(a) Ag surface restructuring; (b) oxygen diffusion; Ag_{reg} and Ag_{def} are regular and defect domains of the supported silver particle surface.

The oxygen adsorption on a regular surface yields the nucleophilic adsorbed oxygen species, which promotes ethylene adsorption but is active only with respect to the total ethylene oxidation. Only transformation of regular surface domains into defect ones due to the silver activation under the action of the reactants enables the formation of the electrophilic form of O_{ads} , which upon interaction with adsorbed ethylene, affords the target partial oxidation product, ethylene oxide. Alternatively, the formation of the electrophilic form is also possible upon the direct adsorption of O_2 on defect sites of the silver surface. In particular, the surface of supported silver nanoparticles with a size of < 50 nm consists of electron density-deficient low-coordinated Ag atoms.¹³⁸

The understanding of the molecular mechanisms of catalytic reactions makes it possible to predict catalytic properties of specific catalysts and suggest possible ways of the improve-

ment of the existing catalytic systems. In particular, the yield of the target product, ethylene oxide, is one of the key characteristics of the epoxidation reaction on the industrial scale. In order to optimise the catalytic system as regards this parameter, the factors affecting the selectivity of the overall process have to be analysed. The selectivity of the reaction (S) with respect to ethylene oxide

$$S = \frac{R(\text{C}_2\text{H}_4\text{O})}{R(\text{C}_2\text{H}_4\text{O}) + R(\text{CO}_2)}$$

is determined by the rate ratio of two competing reaction pathways, *viz.*, epoxidation [$R(\text{C}_2\text{H}_4\text{O})$] and total oxidation [$R(\text{CO}_2)$].

In the case of bulk silver samples, the nucleophilic oxygen species are formed efficiently, while the rate of the electrophilic form formation due to the modification of surface by components of the reaction medium is rather low. This favours the total oxidation pathway of the reaction. As a result, the selectivity of the epoxidation reaction rarely exceeds 30%–40% with silver single crystals, despite its relatively high rate.^{8–10, 150}

When supported catalysts are used, the epoxidation reaction is decelerated by two orders of magnitude due to the low concentration of sites suitable for the ethylene chemisorption. But at the same time, the rate of the ethylene total oxidation by nucleophilic oxygen species also decreases and decreases more abruptly than that of the epoxidation. This is due to different stoichiometries of the two oxidation pathways: the total oxidation of a C_2H_4 molecule to CO_2 and H_2O requires six oxygen atoms, whereas only one oxygen atom is needed for the partial oxidation. This results in a substantially enhanced selectivity of the partial oxidation of C_2H_4 in the case of supported catalysts¹⁵¹ (S drops below 50% only in rare cases). If the mechanism of the ethylene oxidation reaction described above is valid, further decrease in the mean silver particle size (especially down to 50 nm and smaller) should further enhance the selectivity of the partial C_2H_4 oxidation (>86%, which is the maximum possible value realisable for molecular oxygen as the ethylene epoxidising agent; $S < 6/7$).^{9, 10}

Notwithstanding, several authors (for instance, see Ref. 152) reported on a decrease in the selectivity on going to very small silver particles, which cannot be rationalised without postulated secondary reactions of ethylene oxide after-oxidation on the alumina surface. Ethylene oxide is formed exclusively on the silver surface (see above). Meanwhile, the total oxidation products, CO_2 and H_2O , can be generated in at least two pathways, *viz.*, the interaction of C_2H_4 with the nucleophilic oxygen species adsorbed in silver and the after-oxidation of ethylene oxide. It is well known that it is the reaction proceeding on the alumina surface that makes the dominant contribution to the afteroxidation pathway. Its rate is independent of the mean size of supported silver particles. This implies that the side reaction of the ethylene oxide after-oxidation has to be suppressed in order to increase the selectivity of the partial ethylene oxidation. Taking into account that this reaction is catalysed by acidic OH-sites present on the alumina surface,¹⁵³ the use of surfaces devoid of such sites can serve as a possible solution of the problem. Indeed, Balzhinimaev *et al.*¹⁵⁴ achieved the selectivity of the ethylene epoxidation as high as 85%–88% by using a carbon substrate (sibunit) instead of alumina. Even higher selectivity (>90%) was achieved by the utilisation of utradispersed silver particles with a mean size close to the optimum (50–100 nm).¹⁵⁴ This results are the best confirmation of the validity of the proposed reaction mechanism and consequently of the efficiency of the fundamental approach to the design of

catalysts based on experimental studies of model systems with surface science techniques discussed in the present review.

IV. Investigations into the structure of active sites in porous catalysts

The elucidation of the formation and evolution of active sites during the preparation, activation and deactivation of porous catalysts with surface science techniques constitutes an important part of the proposed investigation scheme (see Introduction), since it enables the transition from model objects to real catalytic systems. However this task is very demanding from the experimental viewpoint. First of all, difficulties in the interpretation of the experimental results have to be taken into account, which are due to the complex stoichiometry and phase composition of real catalysts, low concentrations of the active component and high concentrations of promoters therein. In our opinion, a rational compromise between catalytic characteristics of a model catalyst and the relative simplicity of its structure is needed to make an advance in these investigations. Although preparation of such catalyst results in a decrease in its activity (however, this should not be dramatic), this is compensated for by more straightforward interpretation of the experimental results. In order to improve the reliability of structural information provided, one should supplement surface science techniques with traditional techniques of catalyst characterisation, such as TEM, X-ray diffraction, *etc.*

The history of ITSS application to the characterisation of porous catalysts is nearly as long as their utilisation for studies of chemical interactions on the surface of model samples; pioneering works in both directions date back to the 1970s. The number of studies in this field is so large that any their systematic analysis is near to impossible. Often the experimental results are reported as a mere characteristics of specific catalyst samples without recourse to respective results on appropriate model objects. Nevertheless, even these results are in some cases valuable for establishing the structure–activity relationships in heterogeneous catalysts within the fundamental approach discussed in the present review. First of all, this concerns systems where model catalysts do not possess sufficient catalytic activity under conditions accessible to instrumental characterisation (even in the *in situ* mode), *i.e.*, where a catalytic reaction proceeds at a measurable rate only on a catalyst with high specific surface area. Ruthenium catalysts of the ammonia synthesis are typical examples of such systems. Indeed, all attempts at the elucidation of the structure of possible ruthenium active sites with traditional model experiments failed due to the negligible activity of Ru single crystals with respect to N_2 adsorption (the respective N_2 sticking probabilities reported in the literature lie in the range of 10^{-12} – 10^{-9}).^{155–157} Meanwhile, catalytic, structural and spectral studies performed on porous Ru/MO_x , $\text{Ru}-\text{Cs}^+/\text{MO}_x$ ($\text{MO}_x = \text{MgO}$, Al_2O_3 or SiO_2) catalytic systems revealed important details of the promoter–metal and promoter–support interactions and helped to determine the active site structure.^{158–160}

1. The promotion mechanism of ruthenium catalysts in the ammonia synthesis

Ruthenium-containing supported systems are widely recognised as the most promising and practical catalysts of the gas-phase ammonia synthesis at moderate pressures and temperatures. It is known that the activity of such catalysts in the ammonia synthesis is dependent on the chemical nature of the support: higher activity is provided by supports with prominent basic properties. The highest activity was achieved with magnesia.¹⁶¹ The use of technologically more suitable supports, such as alumina or carbonaceous materials, instead of MgO results in a dramatic decrease in the activity of ruthenium

Figure 23. Steady ammonia concentration in the reaction mixture at the reactor outlet for the $\text{Ru}-\text{Cs}^+/\text{MgO}$ (curve 1) and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ (curve 2) catalysts as a function of temperature. Equilibrium of the ammonia curve yield (3) calculated for the reaction conditions used in the experiment.

catalysts.^{162, 163} The activity of supported ruthenium catalysts can be enhanced to a level sufficient for industrial applications by doping with alkali metals or their compounds. The activity of ruthenium catalysts increases with an increase in the basicity of the dopant along the series $\text{Na}^+ < \text{K}^+ < \text{Rb}^+ < \text{Cs}^+$.¹⁶⁴

The reasons and mechanisms underlying the influence of the support material and dopant type on the activity of supported ruthenium catalysts in the ammonia synthesis remains a subject of vivid scientific discussions, but no consensus has been reached so far. In order to make progress in this field, three types of interactions have to be considered: (1) between the catalytically active metal and promotor, (2) between the metal and support and (3) between the promotor and support.^{158–160} Within the context of this study, magnesia, alumina and silica were tested as support materials, $\text{Ru}(\text{OH})\text{Cl}_3$ and Cs_2CO_3 were chosen as precursors of the active component and promotor, respectively.

Studies of catalytic properties of promoted and non-promoted supported ruthenium systems differing in supports and precursors revealed $\text{Ru}-\text{Cs}^+/\text{MgO}$ samples to be the most active. Al_2O_3 -Supported ruthenium is significantly less active than MgO -supported. Temperature dependences of the catalytic activities of two catalysts, *viz.*, $\text{Ru}-\text{Cs}^+/\text{MgO}$ and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$, expressed as steady-state ammonia concentrations in the reaction mixtures are presented in Fig. 23 together with the equilibrium curve of ammonia yield calculated for the reaction conditions. In the presence of the $\text{Ru}-\text{Cs}^+/\text{MgO}$ catalyst, the yield of ammonia nearly reaches

Table 1. Performance of the ruthenium catalysts in the ammonia synthesis measured at ambient pressure and a ratio of $\text{H}_2:\text{N}_2$ partial pressures of 3:1.

Temperature / °C	$\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ /ml(NH_3) g(cat) ⁻¹ h ⁻¹	$\text{Ru}-\text{Cs}^+/\text{MgO}$ /ml(NH_3) g(cat) ⁻¹ h ⁻¹
250	0 ^a	0.4
300	0	4.4
350	0	19.8
400	0	12.7

^a The lowest detection limit was less than 0.1 ml(NH_3) g(cat)⁻¹ h⁻¹ (the volume of NH_3 under normal conditions).

its equilibrium value at $T = 350^\circ\text{C}$, whereas the $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ catalyst is inert under these conditions. The performances of these two catalysts in the ammonia synthesis expressed as the amount of ammonia (ml) per g of the catalyst in 1 hour are listed in Table 1. The tabulated data also clearly confirm that $\text{Ru}-\text{Cs}^+/\text{MgO}$ is characterised by a significantly higher activity than $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$. A combination of instrumental techniques was used to analyse the reasons for the so different catalytic properties of the samples.

The results of XPS and AES studies on the electronic states of different ruthenium catalysts are given in Table 2. The binding energy of the ruthenium core level $E_b(\text{Ru}3d_{5/2})$ changes from 280.2 eV typical of bulk ruthenium to 279.0 eV or 280.4 eV in the $\text{Ru}-\text{Cs}^+/\text{MgO}$ and $\text{Ru}/\text{Al}_2\text{O}_3$ catalysts, respectively. The shift of $\text{Ru}3d$ binding energies in MgO -supported catalysts (279.2–279.5 eV) with respect to bulk ruthenium suggests that the high activity of these samples is due to the charge transfer from the basic support (MgO) to the ruthenium nanoparticles.¹⁶³ The access of electron density on the ruthenium atoms facilitates the activation of a nitrogen molecule owing to the electron transfer from the 3d orbitals of Ru to the antibonding orbitals of N_2 (which is the first step of the dissociative N_2 adsorption). It is generally accepted that it is the nitrogen activation that is the rate-limiting step in the ammonia synthesis. In contrast to the Ru/MgO catalysts, the $\text{Ru}/\text{Al}_2\text{O}_3$ and Ru/SiO_2 samples are characterised by standard (normal) values of the binding energy close to that in bulk ruthenium (280.2–280.5 eV).^{160, 163, 165}

Although the negative shift in the position of the core-level line in XPS spectra can indeed indicate an excessive electron density on the supported metal due to its interaction with the support, there are several other reasons (including non-chemical ones), which could be responsible for the effect observed. These include a change in the relaxation energy (which is the

Table 2. Relevant XPS parameters of the ruthenium catalysts.

Sample	$E_b(\text{Ru}3d_{5/2})_{\text{exp}}/\text{eV}$	$E_{\text{kin}}(\text{Ru}MNN)/\text{eV}$	α/eV	$\Delta E_{\text{relax}}/\text{eV}$	$\Delta E_{\text{dif}}/\text{eV}$	$E_b(\text{Ru}3d_{5/2})_{\text{corr}}/\text{eV}$
Ru_{bulk}	280.2	274.5	554.7	0	0	280.2
Ru/MgO	279.5	275.3	554.8	0	+1.0	280.5
$\text{Ru}/\text{Al}_2\text{O}_3$	280.4	274.3	554.7	0	+0.1	280.5
$\text{Ru}-\text{s}^+/\text{MgO}$	279.0	274.6	553.6	−0.6	+1.3	279.7
$\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$	280.2	274.5	554.7	0	+0.4	280.6

Notations adopted: $E_b(\text{Ru}3d_{5/2})_{\text{exp}}$ is the $\text{Ru}3d_{5/2}$ core-level binding energy observed experimentally; $E_{\text{kin}}(\text{Ru}MNN)$ is the kinetic energy corresponding to the $\text{Ru}MNN$ Auger peak (with the AlK_{α} excitation at 1488.6 eV); α is the modified Auger parameter calculated as $\alpha = E_b(\text{Ru}3d_{5/2}) + E_{\text{kin}}(\text{Ru}MNN)$; ΔE_{relax} is a change in the relaxation energy calculated as $\Delta E_{\text{relax}} = 0.5\Delta\alpha$, where $\Delta\alpha$ is a difference in α between a supported catalyst and bulk Ru; ΔE_{dif} is a differential charging value determined from a comparison of the valence-band spectra as a difference between the Fermi edge positions for a supported catalyst and bulk Ru; $E_b(\text{Ru}3d_{5/2})_{\text{corr}}$ is the $\text{Ru}3d_{5/2}$ core-level binding energy corrected for the final state effects, *i.e.*, $E_b(\text{Ru}3d_{5/2})_{\text{corr}} = E_b(\text{Ru}3d_{5/2})_{\text{exp}} + \Delta E_{\text{relax}} + \Delta E_{\text{dif}}$.

energy of the electron redistribution in the presence of a core hole generated upon photoemission, it is also referred to as the final-state effect) and a differential charging,[§] *i.e.*, a smaller positive electrostatic potential of the surface of metal particles with respect to that of the dielectric support, which gives rise to different shifts of the respective core-level lines (a sample surface during XPS measurements is always charged positively to a certain steady value dependent on the dielectric properties of the material due to the constant emission of photoelectrons).

Neither relaxation nor differential charging effects can be estimated using the internal standard method (the positions of XPS lines in the spectra of supported catalysts are usually referenced to a selected line of an element from the support material). The change in the relaxation energy (ΔE_{relax}) can be determined from the change in the modified Auger parameter α for the supported metal with respect to the bulk metal. The modified Auger parameter α is calculated as the sum of the binding energy of a metal core-level and the kinetic energy of the respective Auger peak:¹⁶⁶

$$\Delta E_{\text{relax}} = \frac{1}{2} \Delta \alpha = \frac{1}{2} \Delta [E_b(\text{Ru}3d_{5/2}) + E_{\text{kin}}(\text{RuMNN})].$$

The extent of the differential charging (ΔE_{dif}) can be determined from the Fermi edge shift in the valence-band spectrum of supported metal particles with respect to its position in the spectrum of the bulk metal.^{167, 168}

The values of parameters α , ΔE_{relax} and ΔE_{dif} determined for the Ru/MO_x and Ru–Cs⁺/MO_x supported systems from the XPS spectra are compiled in Table 2. The values of α for Ru/MO_x and Ru_{bulk} are identical to within 0.1 eV (554.7–554.8 eV), which implies that $\Delta E_{\text{relax}} \approx 0$ for non-promoted systems. Non-zero differential charging of Ru particles was observed only in the case of Ru/MgO ($\Delta E_{\text{dif}} = +1.0$ eV), whereas it equals to zero for Ru/Al₂O₃ and Ru/SiO₂. Thus the original experimental values of $E_b(\text{Ru}3d_{5/2})$ for Ru/Al₂O₃ and Ru/SiO₂ are correct, whereas the respective value for Ru/MgO has to be corrected to the differential charging:

$$\begin{aligned} E_b(\text{Ru}3d_{5/2})_{\text{corr}} &= E_b(\text{Ru}3d_{5/2})_{\text{exp}} + \Delta E_{\text{dif}} = \\ &= 279.5 + 1.0 = 280.5 \text{ eV.} \end{aligned}$$

Therefore, taking into account the necessary corrections, the binding energy of the Ru atoms in the Ru/MgO system is essentially the same as in other Ru/MO_x systems studied exceeding the respective value of bulk ruthenium by $\Delta E = 0.3 \pm 0.1$ eV. The latter value means that the surface ruthenium atoms in the Ru/MO_x systems are slightly oxidised, which disproves the earlier assumption of the excess electron density on the MgO-supported Ru particles.

In the case of promoted samples (see Table 2), the experimental ruthenium binding energies $E_b(\text{Ru}3d_{5/2})$ are 279.0 eV and 280.2 eV for Ru–Cs⁺/MgO and Ru–Cs⁺/Al₂O₃, respectively. The modified Auger parameter α for Ru–Cs⁺/MgO differs from that of bulk ruthenium by -1.2 eV, *i.e.*, in this case, $\Delta E_{\text{relax}} = -0.6$ eV. Furthermore, a non-zero differential charging was identified for both promoted systems Ru–Cs⁺/MgO ($\Delta E_{\text{dif}} = +1.3$ eV) and Ru–Cs⁺/Al₂O₃ ($\Delta E_{\text{dif}} = +0.4$ eV). The true binding energies after all corrections, $E_b(\text{Ru}3d_{5/2})_{\text{corr}}$, are 279.7 eV and 280.6 eV for Ru–Cs⁺/MgO and Ru–Cs⁺/Al₂O₃, respectively. Thus, a negative shift in the ruthenium binding energy with respect to bulk metal is observed for the promoted MgO-supported catalyst.

§ This possible reason for negative shifts of XPS lines is most frequently ignored, which is not actually justified.

The reasons for the negative shifts of the Ru3d_{5/2} binding energy in this sample were found in additional studies, primarily, using TEM. Histograms of the size distributions of Ru particles revealed that, in both supported Ru/MO_x systems and promoted samples, ruthenium particles are characterised by sizes in the range of 2–10 nm¹⁶⁰ or several nanometres, respectively, which rules out the possible assignment of the Ru3d line shift to a change in the mean Ru particle size. More details on the structure of the active component have been obtained using high-resolution TEM. The respective micrographs of promoted catalysts are shown in Fig. 24. In the case of Ru–Cs⁺/MgO (Fig. 24a), it is clearly seen that the Ru particles are coated with a thin layer of a substance, while the Ru particles in the Ru–Cs⁺/Al₂O₃ sample are devoid of such a coating (Fig. 24b).

Figure 24. Electron micrographs of the surface of the Ru–Cs⁺/MgO (a) and Ru–Cs⁺/Al₂O₃ (b) catalysts.

The nature of the surface coating of the Ru particles was identified by the Energy-Dispersive X-ray fluorescence analysis (EDX) implemented in an attachment to a transmission electron microscope (it provides a spatial resolution of <100 nm).¹⁶⁰ The EDX spectra measured in the proximity of ruthenium particles for the Ru–Cs⁺/MgO and Ru–Cs⁺/Al₂O₃ catalysts are compared in Fig. 25. In the case of Ru–Cs⁺/MgO, the EDX spectrum reveals a weak peak attributed to Cs in addition to the dominant ruthenium signal, whereas no additional signal was detected for Ru–Cs⁺/Al₂O₃. This result was consistently reproduced for a larger number of ruthenium particles.¹⁶⁰

Data on CO chemisorption provide another experimental evidence for the formation of a Cs-compound on the surface of Ru particles in the catalyst Ru–Cs⁺/MgO. It was

Figure 25. EDX Spectra from areas in the proximity of ruthenium particles for the Ru–Cs⁺/MgO (spectrum 1) and Ru–Cs⁺/Al₂O₃ (spectrum 2) catalysts (see Fig. 24).

found that the degrees of dispersion D defined as $D = (N_{\text{surf}}/N_{\text{tot}}) \times 100\%$, where N_{surf} is the number of surface Ru atoms and N_{tot} is the total number of Ru atoms, in the promoted and non-promoted Al_2O_3 -supported samples are nearly identical ($D = 25.0\%$ and 23.6% , respectively). Meanwhile, a totally different picture is observed for the analogous MgO -supported catalysts: the degree of dispersion D in the promoted sample decreases to 9.9% from 27.3% in the non-promoted sample despite no significant changes in the mean size of ruthenium particles is detected by TEM. This observation suggests that the surface of Ru particles accessible for CO adsorption in the latter sample is partly screened by the promotor. Presumably, this interaction between ruthenium and the promotor plays a key role in the formation of the active catalytic state, which is manifested in the negative shift of the $\text{Ru}3d_{5/2}$ line.^{158–160}

The speciation of the promotor chemical state was accomplished based on the $\text{Cs}3d_{5/2}$ XPS data. Figure 26 shows the respective core-level spectra for $\text{Ru}-\text{Cs}^+/\text{MgO}$ (a) and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ (b) measured both immediately after loading of the samples into the spectrometer and after their reduction with hydrogen directly in the spectrometer. The efficiency of XPS for the identification of the caesium chemical state is demonstrated by Table 3, which compiles the $E_b(\text{Cs}3d_{5/2})$ values for various caesium compounds with oxygen.^{169–171} The data given in Table 3 indicate that inverse chemical shifts in the binding energy are typical of caesium, as well as for some other metals (Ag, Cd, Ba, etc.), i.e., the binding energy decreases rather than increases upon oxidation. The reasons for this phenomenon lie beyond the scope of this review and will not be discussed here. It is important that the data from Table 3 help to assign the experimentally observed $\text{Cs}3d$ spectral features to specific states of the caesium atoms or caesium compounds.

Figure 26. The $\text{Cs}3d_{5/2}$ XPS spectra of the $\text{Ru}-\text{Cs}^+/\text{MgO}$ (a) and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ (b) before (1) and after (2) hydrogen treatment directly in the spectrometer.

The XPS spectra of the $\text{Ru}-\text{Cs}^+/\text{MgO}$ and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ catalysts measured immediately after their loading into the spectrometer reveal nearly identical positions of the $\text{Cs}3d_{5/2}$ lines with binding energies of 724.8 eV and 724.9 eV , respectively (see Fig. 26). This caesium state can be attributed to Cs^+ (suggestedly, as caesium peroxide). Caesium in caesium oxide Cs_2O is characterised by a similar binding energy $E_b(\text{Cs}3d_{5/2}) = 725.0\text{ eV}$, but it is known that caesium oxide readily converts into peroxide upon exposure to oxygen

Table 3. $E_b(\text{Cs}3d_{5/2})$ and $E_b(\text{O}1s)$ values for various caesium compounds.^{166–170}

Binding energy / eV	Cs compound					
	Cs_{met}	Cs_{2+x}O	Cs_2O	Cs_2O_2	Cs_2O_4	CsOH
$E_b(\text{Cs}3d_{5/2})$	726.1	725.5	725.0	724.5	724.2	724.1
$E_b(\text{O}1s)$	—	531	528.2	530.6	532.9	—

(exposure doses of $(5-10) \times 10^{-6}\text{ Torr s}$),¹⁷⁰ which quite decisively rules out its presence in the catalysts under study.

The reduction of the $\text{Ru}-\text{Cs}^+/\text{MgO}$ sample with hydrogen directly in the spectrometer leads to a shift of the $\text{Cs}3d_{5/2}$ line to larger binding energy, which is indicative of caesium reduction, whereas the spectrum of $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ remains unchanged upon similar treatment. Meanwhile, the $\text{Cs}3d_{5/2}$ binding energy in promoted ruthenium-free samples on different supports shows no shifts due to oxidative or reductive treatments. The shift of $\text{Cs}3d$ lines upon reduction of $\text{Ru}-\text{Cs}^+/\text{MgO}$ also supports the existence of direct caesium–ruthenium interactions.¹⁶⁰ Presumably, during the reduction, hydrogen molecules dissociate on the surface of ruthenium particles, which enables the subsequent reduction of caesium ions with atomic hydrogen.

The details of the interaction of caesium with ruthenium were established by XPS studies of model samples prepared by the deposition of caesium onto a polycrystalline ruthenium foil either in vacuum or in an oxygen flow. The $\text{Cs}3d_{5/2}$ and $\text{O}1s$ binding energies and the $\text{Cs}:\text{O}$ atomic ratios were determined. An analysis of these spectral data and, especially of the $E_b(\text{O}1s)$ values, which are highly specific for different caesium compounds with oxygen^{170,171} revealed that the vacuum deposition yields caesium suboxide Cs_{2+x}O , whereas that in an oxygen flow affords caesium peroxide Cs_2O_2 . Some deviations of the experimental $\text{Cs}:\text{O}$ atomic ratios from the stoichiometric values were attributed¹⁶⁰ to a partial oxidation of the suboxide due to an insufficiently high vacuum or concomitant formation of caesium superoxide Cs_2O_4 (in the cases of the $\text{Cs}_{2+x}\text{O}/\text{Ru}$ and $\text{Cs}_2\text{O}_2/\text{Ru}$ layers, respectively). The presence of superoxide in the sample is evidenced by the emergence of an additional component with $E_b = 533.5\text{ eV}$ in the $\text{O}1s$ XPS spectrum.^{172,173}

Taking these results of model studies into account, it might be concluded that the $\text{Cs}3d_{5/2}$ binding energy in the range of $725.4-725.8\text{ eV}$ can be attributed to caesium suboxide (although its partial contamination with oxide cannot be ruled out), whereas the values in the range of $724.7-725.2\text{ eV}$ are due to caesium peroxide.

However, it has to be noted that, for the suboxide, this assignment means only the formation of surface species rather than an individual phase. Otherwise it would have been possible to observe these compounds by X-ray diffraction. At the same time, only metallic ruthenium and the respective support (MgO or Al_2O_3) were identified in the diffraction patterns of both non-promoted and promoted samples.^{158–160} In earlier works devoted to Cs -promoted silver catalysts of the ethylene epoxidation, Podgornov *et al.*¹⁷³ suggested that silver atoms are capable of substituting for the Cs atoms in the $\text{Cs}-\text{Cs}$ fragment present in the bulk structure of caesium suboxide to form the $\text{Cs}-\text{Ag}$ bond.

Following this analogy, it might be suggested that bonds between the caesium and ruthenium atoms are formed in the catalyst $\text{Ru}-\text{Cs}^+/\text{MgO}$. This suggestion is further supported by the fact that the $E_b(\text{Cs}3d_{5/2})$ binding energy in promoted ruthenium blacks (i.e., in support-free materials) increases from 725.0 eV to 725.5 eV upon their reduction in the spectrometer. Similar results were observed for thin films of caesium on the surface of bulk ruthenium. At the same time,

in the alumina-based systems, the $\text{Cs}3d_{5/2}$ binding energy remains constant irrespective of the oxidative or reductive treatment applied.

The experimental evidence presented above indicate that it is the ruthenium–promotor rather than ruthenium–support interactions that are responsible for the observed shift of the $\text{Ru}3d_{5/2}$ line to a smaller E_b .^{158,160} The formation of a thin alkali metal film on the surface of a transition metal is known to decrease the work function (*e.g.*, S1 caesium–silver photocathodes are formed in a similar way).¹⁷¹ Thus, the downshift of the binding energy can also be due to a decrease in the work function of the electron escape from the surface of Ru particles covered with a promotor layer.

If this suggestion is valid, a next question arises, why ruthenium effectively interacts with caesium only with magnesia as a support, whereas no such interaction occurs on alumina. An answer to this question was given by an X-ray diffraction study of the $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ and $\text{Ru}/\text{Al}_2\text{O}_3$ samples. The diffraction pattern of the promoted catalyst reveals some increase in the scattering background in the angle range of $20-40^\circ$,¹⁶⁰ which is typical of caesium aluminate. Most likely, caesium cations in this sample are incorporated into the aluminate structure due to a chemical reaction of the promotor with Al_2O_3 . The $E_b(\text{Cs}3d_{5/2})$ value of 724.9 eV found for $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$ also does not contradict to its assignment to caesium aluminate.

The following important conclusion can be derived from the above extensive studies^{158–160} of supported ruthenium catalysts of the ammonia synthesis. An analysis of the mechanisms of the formation of active sites schematically depicted in Fig. 27 has to take into account the promotor–ruthenium and promotor–support interactions in addition to more common support–ruthenium interactions. Indeed, magnesia, due to its prominent basicity, is expected to be quite inert as regards its reaction with caesium oxides, which are themselves strong bases. This largely facilitates the migration of caesium over the magnesia surface to react with ruthenium particles thus generating active sites for the $\text{N}_2 + \text{H}_2$ reaction (Fig. 27*a*). The dissociative adsorption of N_2 should be accelerated on such sites due to a decrease in the electron escape work function.

Figure 27. A scheme of interaction of the promotor with the support and active component in the catalysts $\text{Ru}-\text{Cs}^+/\text{MgO}$ and $\text{Ru}-\text{Cs}^+/\text{Al}_2\text{O}_3$.

On the contrary, acidic sites present on the alumina surface strongly bind the promotor thus preventing them from the reaction with ruthenium particles (Fig. 27*b*). Consequently, non-promoted ruthenium particles manifest a lower activity in the dissociative nitrogen adsorption, which determines to the overall low activity of such catalysts in the ammonia synthesis. It is of note that alumina-based catalytic systems can manifest high activity in the ammonia synthesis, but only at high promotor content (promotor: metal ≥ 3.0).¹⁷⁴ Very likely, at high concentrations, a fraction of the promotor remains unbound to the support and thus capable of ruthenium activation.

Despite the prominent success of the post-reaction analysis of the mechanism of formation of active component in porous catalysts with surface-sensitive techniques, future progress in this field relates to the extensive usage of *in situ* measurements. For instance, the structure of active sites of barium-promoted ruthenium catalysts supported on BN has been determined by *in situ* TEM studies.¹⁷⁶ In the as-prepared catalysts, ruthenium particles were incorporated into boron nitride. TEM micrographs measured under the reaction conditions of the ammonia synthesis reveal restructured catalyst surfaces and support-free ruthenium particles covered with the barium promotor in the form of either amorphous particles or a monolayer coating. It was concluded that barium is an electron promotor for ruthenium.¹⁷⁶

Additional examples of highly efficient *in situ* XPS investigations into the state of active components in porous catalysts can be found in recent publications by Schlögl *et al.*^{177–179}

2. Hydrogen sulfide oxidation of iron-based catalysts

The use of model objects instead of real catalysts for monitoring the formation of active sites becomes inefficient for catalytic reactions involving aggressive reaction media. The inadmissibility of aggressive gases into UHV chambers due to safety reasons prevents *in situ* measurements thus eliminating one of the most important merits of model experiments, *viz.*, the absence of exposure to air of samples after their activation. This limits the research capabilities to the traditional post-reaction analysis with a necessary comparison of as-prepared, activated and sometimes deactivated catalysts. It is always desirable to avoid exposure to air of the samples upon their transfer from a catalytic reactor to the analytical UHV chamber. This requirement was fulfilled in a study of the formation of active sites of supported iron catalysts for the H_2S oxidation, such as $\text{Fe}_2\text{O}_3/\text{SiO}_2$ and $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$.^{180,181}

According to the XPS data, the reaction of the iron-containing catalysts with gas mixtures containing a large fraction of water vapour in addition to hydrogen sulfide and oxygen, gives rise to the sulfidation of surface layers of iron oxide(III) particles.^{180,181} Such a change in the chemical state of the active component was identified by the appearance of a $\text{Fe}2p_{3/2}$ component with a binding energy of 708.8 eV, which is typical of FeS_2 .^{182,183} At the same time, an intense signal of sulfide ions emerges in the $\text{S}2p$ XPS spectra ($E_b \approx 163$ eV). The spectral line attributable to Fe_2O_3 with $E_b(\text{Fe}2p_{3/2}) = 711.2$ eV remains dominant in the spectra, which suggests the surface sulfidation of the active component.

A comparison of the XPS results with data on the catalytic activity revealed that oxide forms of the active site catalyse the selective oxidation of H_2S to sulfur, whereas the formation of FeS_2 alters the oxidation pathway. The total oxidation product, SO_2 , becomes dominant in this case. It is of note that both the selective and total hydrogen sulfide oxidation are of practical interest, although for different applications. The application of instrumental techniques, such as XPS, to the elucidation of the sulfidation process revealed important details regarding the effects of the support type, precursor

nature, annealing temperature and amount of water on the rate of formation and depth of FeS₂ formation.^{180, 181}

V. Development of methods of the purposeful synthesis of highly active catalysts

The purposeful design of catalysts based on the knowledge of the structure of active sites gathered in model studies is an extremely important task, since it allows the easiest verification of the performance of intuitively envisaged active site structures in practice. Indeed, the correctness of the structure–activity relationship adopted in the molecular design enables the development of convenient methods for the synthesis of highly active and selective catalysts with a prolonged service life. Without this knowledge, such methods affording advanced practical catalysts will remain elusive. Instrumental techniques of surface studies within this approach are necessary to control the results of the molecular design aimed at the preparation of active sites with a desirable composition and structure. The productivity of this approach is demonstrated below with some examples.

1. Bimetallic Ni–Au catalyst for the steam reforming of hydrocarbons

The purposeful improvement of Ni catalysts for the steam reforming of hydrocarbons is one of the most striking examples of the efficacy of the fundamental approach to the improvement of the catalyst performance.^{184–186} Nickel is widely used as a component of industrial catalysts of the steam reforming of natural gas (primarily, methane). As has been shown, the steam reforming starts with the methane activation on nickel. This is accompanied by the progressive deposition of graphite on the surface of Ni catalyst followed by the growth of filamentous carbon and ultimately by the catalyst deactivation.^{187, 188}

The deactivation of Ni catalysts due to the formation of graphite layers on early steps of the catalytic reaction was established unambiguously using TEM. The deactivation of Ni catalysts can be suppressed by introducing minor amounts of hydrogen sulfide into the reaction mixture. Sulfur adsorbed on the Ni particles poisons the catalyst, which, on the one hand, decelerates the overall steam conversion reaction but, on the other hand, inhibits the graphite formation, thus significantly prolonging the service life of the catalyst. Despite some promise of this approach, it has not found wide application since sulfur-containing compounds poison various catalytic reactions, in particular those combined with the steam reforming into technological scheme, such as ammonia synthesis.

Another possible approach to overcome the problem of the fast deactivation of Ni catalysts in the steam reforming relates to a modification of the active component by, for example, alloying nickel with another metal. The best results are expected for metals forming only surface rather than bulk alloys with nickel. As has been shown by Besenbacher *et al.*^{190–192} in an STM study of model objects, nickel indeed forms surface alloys in a series of binary systems, such as nickel–gold. The reason for the formation of this surface alloy is a decrease in the surface tension energy of nickel due to the electron density transfer from the gold atoms to the low-coordinated nickel atoms at the surface. These simple qualitative speculations were supported by quantum chemical calculations at the DFT level, which demonstrated that the bonding of carbon to the nickel atoms having adjacent Au atoms is much weaker than that to Ni atoms in the exclusively nickel environment.

As a result of these model studies,^{190–192} the porous Ni–Au catalysts were suggested. They were prepared by depositing 16.5 mass.% of a nickel–gold mixture (0.3% of gold) on the surface of magnesium aluminate.¹⁹³ The incorpo-

ration of gold atoms in the surface layers of nickel particles yielding a surface alloy was unambiguously confirmed by EXAFS. Further assay of these Ni(Au)/MgAl₂O₄ catalysts in the steam reforming of *n*-butane demonstrated a stably high activity of the bimetallic systems in contrast to the standard nickel catalysts.¹⁹³ Butane was used rather than methane due to its easier graphitisation.

Thus, the understanding of the structure–activity relationships indeed enabled the molecular design of advanced nickel-based catalysts for the steam reforming of hydrocarbons characterised by significantly improved stability against deactivation.

2. Nanosized Au/Al₂O₃ catalysts for the low-temperature CO oxidation

The synthesis of Au/Al₂O₃ catalysts for the low-temperature CO oxidation represents yet another example of the purposeful design of an advanced catalyst for specific catalytic processes.^{194–196} The molecular design of this system was based on the results of fundamental investigations into the reasons governing the catalytic activity of gold nanoparticles,^{120–123} which revealed a pronounced size effect in the activity of Au/TiO₂ catalysts. Taking into account some technological inconvenience of TiO₂ as a support for industrial applications, alumina was chosen as the support material. Therefore, it became necessary to develop efficient methods for the preparation of nanosized gold particles on the surface of alumina particles, including γ - (microspherical particles) and θ -Al₂O₃ (fine powder).^{194–196} Three major synthetic procedures were tested: the Deposition-Precipitation (DP), Chemical Liquid-Phase Grafting (CLPG) and Chemical Vapour Deposition (CVD) from volatile gold complexes.

Hexachloroauric acid was selected as a precursor of the active component in the DP synthesis, whereas dimethylgold acetylacetonate was used for CLPG and CVD due to its high volatility, thermal stability [the saturated vapour pressure of (CH₃)₂Au(acac) is 5.5×10^{-4} Torr at 25 °C, while the decomposition point in the solid state is 54 °C] and accessibility.¹⁹⁴

The mean sizes of gold particles in the catalysts were determined using X-ray diffraction and TEM. X-ray diffraction was also used to control the phase composition of the samples. Since the most intense diffraction peaks of bulk gold (*i.e.*, 111, 200 and 220) overlap with the reflexes of Al₂O₃, the sizes of Au crystallites were determined from the width of the Au(311) peak at $2\theta \approx 78^\circ$ using the Selyakov–Scherrer equation.

Preliminary TEM study of the Au/Al₂O₃ catalysts showed that standard procedures of TEM images measurement appeared unsatisfactory: the Au particles with a diameter smaller than ≤ 5 nm were nearly undistinguishable on the background of the support. Therefore, special techniques of the contrast enhancement were applied. In particular, the use of Fresnel scattering suppression on the Al atoms helped to decrease the brightness of the Al₂O₃ surface background with respect to that Au particles. Furthermore, the TEM micrographs used for the size distribution analysis of the Au particles were obtained in the so-called Z-contrast mode, *i.e.*, at a specific electron collection angle providing that only electrons scattered on the Au atoms contribute to the image. In this mode, the gold particles occur in the micrographs as bright spots on the uniform black background coming from the support and thus the particle size can be determined quite precisely. Typical micrographs of the catalysts prepared by the DP method and annealed at 673 K are shown in Figs. 28 and 29. From a series of TEM micrographs, histograms of the gold particle size distribution were obtained in both cases, which are also shown in Figs 28 and 29.

It is apparent that the Au/ θ -Al₂O₃ catalyst (sample 1, Fig. 28a) mainly contains gold particles with a size of

Figure 28. TEM Image of the Au/ θ - Al_2O_3 catalyst (sample 1) (a) and the respective Au particle size distribution (b) (hereinafter, N is the number of particles).

The catalyst was prepared by the deposition precipitation method from Au(III) hydroxo complexes. The image was acquired in the Z-contrast mode. The mean linear diameter of the Au particles is 3.8 nm.

Figure 29. TEM Image of the Au/ γ - Al_2O_3 catalyst (sample 2) (a) and the respective Au particle size distribution (b).

The catalyst was prepared by the deposition precipitation method from Au(III) hydroxo complexes. The image was acquired in the normal contrast mode. The mean linear diameter of the Au particles is 6.6 nm.

2–4 nm and single particles with a size from 5 nm to 8 nm. The particles are characterised by a nearly spherical shape. The size distribution is relatively narrow and has a Gaussian shape; the mean linear diameter of the Au particles $\langle d_{\text{Au}} \rangle = 3.8$ nm (Fig. 28 b). In the case of the Au/ γ - Al_2O_3 catalyst (sample 2, Fig. 29 a), the TEM micrographs reveal microaggregates composed of primary globules of the support covered with mainly small gold particles with a size of 2–4 nm. At the same time, larger particles of up to 10–15 nm are also present in the sample. As a result, the size distribution of Au particles in this case is bimodal with two maxima at 4 nm and 12 nm (Fig. 29 b).

The mean sizes of Au particles in the Au/ Al_2O_3 catalysts determined from TEM and X-ray diffraction data are compared in Table 4. In the case of samples prepared by deposition-precipitation, the mean volume-surface diameter ($\langle d_{\text{vs}} \rangle$) of Au particles estimated from TEM was larger than that calculated from the broadening of the Au(311) diffraction line. The maximum discrepancy between the TEM and diffraction estimates is observed for sample 2. In this case, the contribution of relatively large metal particles into the diffraction broadening is small, although total numbers of small and large particles are comparable according to the TEM estimate.

Table 4. The mean diameters of supported gold particles in the Au/ Al_2O_3 catalysts estimated from X-ray diffraction (XRD) and TEM data.

Sample	Preparation method	Support	Au content (mass %)		Mean diameter of Au particles /nm		
					XRD	TEM ^a	
						$\langle d_l \rangle$	$\langle d_s \rangle$ $\langle d_{\text{vs}} \rangle$
1	DP	θ - Al_2O_3	1.4	≤ 3	3.8 ± 1.3	4.1	4.5
2	DP	γ - Al_2O_3	1.3	6.6	6.6 ± 4.7	8.1	12.5
3	CLPG	γ - Al_2O_3	3.8	12	13.3 ± 2.8	13.6	14.5
4	CVD	γ - Al_2O_3	1.2	> 5	20–25		5.6
5	CVD	γ - Al_2O_3	0.7	≤ 3	2.9 ± 0.9		3.5

$$^a \langle d_l \rangle = \frac{\sum_i f_i d_i}{\sum_i f_i}, \langle d_s \rangle = \sqrt{\frac{\sum_i f_i d_i^2}{\sum_i f_i}} \text{ and } \langle d_{\text{vs}} \rangle = \frac{\sum_i f_i d_i^3}{\sum_i f_i d_i^2},$$

where f_i is the number of particles with a diameter d_i encountered in TEM images.

Sample 3 prepared by the CLPG method from $(\text{CH}_3)_2\text{Au}(\text{acac})$ and annealed at 673 K in air contained predominantly Au particles with a size of 8–18 nm characterised by a normal distribution and single particles with a larger size of ~ 20 nm (Fig. 30 b). This sample was nearly devoid of metal particles with a size ≤ 5 nm. The mean diameters of Au particles estimated by TEM and X-ray diffraction were nearly identical (see Table 4).

Figure 30. TEM Image of the Au/ γ - Al_2O_3 catalyst (sample 3) (a) and the respective Au particle size distribution (b).

The catalyst was prepared by the chemical liquid-phase grafting of $(\text{CH}_3)_2\text{Au}(\text{acac})$ on the γ - Al_2O_3 surface. The mean linear diameter of the Au particles is 13 nm.

The chemical vapour deposition was performed according to two procedures. Sample 4 was synthesised by passing $(\text{CH}_3)_2\text{Au}(\text{acac})$ vapour through an immobile layer of γ - Al_2O_3 kept at room temperature. The process was accompanied by a change in the vapour colour indicative of a partial decomposition of the complex by water molecularly adsorbed on the support surface. A chemical analysis of several probes of the sample 4 taken in different places of the reactor showed that the Au concentration progressively decreases along the direction of the gas flow. This gradient indicates that the interaction of $(\text{CH}_3)_2\text{Au}(\text{acac})$ with the surface of γ - Al_2O_3 is too strong. Thus, the CVD procedure was modified in order to prevent the uncontrollable decomposition of the organometallic precursor and provide the uniform distribution of the active component over the support. This modified procedure was

used for the preparation of sample 5. First, the support was carefully dehydrated by annealing *in vacuo* ($\sim 10^{-7}$ Torr) at 300–350 °C prior to its contact with vapourised $(\text{CH}_3)_2\text{Au}(\text{acac})$. Second, the deposition was accomplished in a constantly rotating reactor under the quasistationary conditions. The resultant sample was uniformly coloured and the Au concentrations in several probes taken from different places were nearly identical.

According to the TEM studies, sample 4 contained gold particles characterised by a very broad size distribution (from 5 nm to 35 nm), whereas TEM micrographs of sample 5 typically revealed microaggregates of primary $\gamma\text{-Al}_2\text{O}_3$ globules covered with mainly small Au particles of spherical or semispherical shapes with sizes from 2 nm to 4 nm (Fig. 31 *a*), although single larger particles with a diameter 5–10 nm were also present. The size distribution is rather narrow and has a Gaussian shape with a maximum at 2.5–3.0 nm (Fig. 31 *b*).

Figure 31. TEM Image of the Au/ $\gamma\text{-Al}_2\text{O}_3$ catalyst (sample 5) (*a*) and the respective Au particle size distribution (*b*).

The catalyst was prepared by the chemical vapour deposition of $(\text{CH}_3)_2\text{Au}(\text{acac})$ on the $\gamma\text{-Al}_2\text{O}_3$ surface. The mean linear diameter of the Au particles is 3.3 nm.

These Au/ Al_2O_3 catalysts prepared by different synthetic routes were assayed in terms of their catalytic activity towards the CO oxidation. The catalytic studies were performed in a plug-flow reactor at 313 K and ambient pressure. The testing conditions were chosen so as to approach the realistic oxidation conditions in a closed room with ordinary humidity and slightly elevated temperature. The composition of the initial reaction medium (IRM) corresponded to air purified from CO. The results obtained are listed in Table 5.

Under the conditions used, samples 1 and 2 demonstrated high catalytic activities in the CO oxidation. The most active Au/ $\theta\text{-Al}_2\text{O}_3$ catalyst (sample 1) taken in an amount as small as 40–50 mg provided the degree of CO conversion of $\sim 45\%$ at the maximum possible SRM supply rate (400 ml min^{-1}). It was impossible to realise the process for this sample under differential conditions, which resulted in somewhat underestimated reaction rates (see Table 5). The Au/ $\gamma\text{-Al}_2\text{O}_3$ catalyst (sample 2) demonstrated a lower activity probably due to a significantly larger mean size of gold particles in this sample ($\langle d_{\text{vs}} \rangle = 12.5 \text{ nm}$) as compared to sample 1.

Sample 3 did not demonstrate any measurable catalytic activity in the CO oxidation over the temperature range of 313–523 K; in the presence of this catalyst, CO_2 lines were detected in the Raman spectra only when temperature was increased to 773 K (the degree of CO conversion was then $\sim 2\%$). Since the mean size of Au particles ($\langle d_{\text{vs}} \rangle$) in sample 3 is virtually the same as in sample 2 (according to TEM), the observed dramatic difference in the catalytic activity could be attributed to different size distributions of Au particles in these

Table 5. Activities of the Au/ Al_2O_3 catalysts prepared by different methods in the CO oxidation measured in a plug-flow reactor at 313 K.

Sample	$\langle d_{\text{vs}} \rangle^a / \text{nm}$	CO conversion level (%) in		Reaction rate ^b
		1 h	7 h	
1	4.5	89	85	47
2	12.5	19	31	7.4
3	12.0 ^c	< 1	< 1	< 0.05
4	5.6	< 1	< 1	< 0.05
5	3.5	24	55	18.7

Notes. The initial reaction mixture compositions: 1 vol.% CO, 2.2 vol.% H_2O , 20 vol.% O_2 , the rest is N_2 ; the volume rate of the initial reaction mixture supply is 100 ml min^{-1} .

^a Mean volume surface diameter of the Au particles calculated from the TEM data (see Table 4). ^b The unit of measure is $\text{mol CO (mol Au)}^{-1} \text{ s}^{-1}$. ^c The mean particle diameter calculated from the XRD data.

two samples (see Figs 29 *b* and 30 *b*). Sample 2 is characterised by a broad distribution encompassing particles with sizes from 3 nm to 20 nm. Meanwhile, the distribution for sample 3 is much narrower and includes virtually no Au particles smaller than 5 nm. This strongly suggests that in the case of Au/ Al_2O_3 , the specific catalytic activity exhibits the same size effect as was observed earlier for the Au/ TiO_2 , Au/ Co_3O_4 and Au/ Fe_2O_3 systems: the catalytic activity abruptly increases (by several orders of magnitude) with a decrease in the size of Au crystallites down to $d \leq 5 \text{ nm}$.

Studies on the catalytic activity of samples 4 and 5 also demonstrates the size effect. Sample 4 containing only Au particles with a diameter $\geq 5 \text{ nm}$ demonstrated no measurable activity. In contrast, sample 5 composed of mainly small gold particles of $< 5 \text{ nm}$ showed a relatively high activity in the CO oxidation. The starting level of CO conversion in the presence of this catalyst at an Au content of 0.7 mass % was 15%. In three hours, the degree of conversion increased to 35% and remained constant at this level until the end of testing. The apparent activation energy (E_a) of the CO oxidation on the catalyst 5 calculated from the experimental temperature dependence of the reaction rate assuming the Arrhenius-type function is 9.5 kJ mol^{-1} , which is only slightly larger than the respective value of 7 kJ mol^{-1} found by Goodman for model catalysts.¹²⁷ (This again proves the close correspondence between model and real catalytic experiments.)

A change in the electronic state of gold atoms during the preparation of the Au/ $\theta\text{-Al}_2\text{O}_3$ catalysts (sample 1) was studied using Diffuse Reflectance UV-Vis Spectroscopy (DR-UV-Vis).¹⁹⁵ In addition, the plasmon resonance features in the electronic spectra of gold particles with the bulk structure and the electronic spectra of some model Au(III) complexes with the Au–O–Au bonds were simulated theoretically. A colloid suspension of gold containing spherical Au particles with a mean diameter of $\sim 50 \text{ nm}$ was used, as the reference sample, which was prepared by heating of an aqueous HAuCl_4 solution ($0.05 \text{ mg Au ml}^{-1}$) with a 1% solution of sodium citrate. The respective spectra are shown in Fig. 32.¹⁹⁵

The spectrum of an alkalinised HAuCl_4 solution (spectrum 1, Fig. 32) shows an absorption band centred at 48000 cm^{-1} . Such spectra with one weak ligand–metal charge transfer line in the UV range are characteristic of mononuclear complexes $[\text{AuCl}_{4-x}(\text{OH})_x]^-$ with $x = 2$ and 3. According to the literature data, upon treatment of Al_2O_3 with alkalinised HAuCl_4 solutions, the complexes $[\text{AuCl}_2(\text{OH})_2]^-$ and $[\text{AuCl}(\text{OH})_3]^-$ react with the surface OH groups of the support resulting in the immobilisation of the Au(III) ions due to the

Figure 32. Transmission (1) and diffusion reflectance (2, 3) UV-Vis spectra for the Au/ θ -Al₂O₃ catalyst and reference samples; (1) alkalified aqueous solution of HAuCl₄ ([Au] = 0.013 mol litre⁻¹, [OH]/[Au] = 3.8 mol mol⁻¹); (2) θ -Al₂O₃ support after treatment with the HAuCl₄ solution (conditions 1) at 70 °C, thorough washing with water and drying; (3) sample (2) after calcination in air at 400 °C for 4 h (1.5% Au/ θ -Al₂O₃ catalyst). The DR-UV-Vis spectrum of the original θ -Al₂O₃ is shown with a dashed line.

formation of the Al–O–Au bonds. A subsequent thorough washing with warm water leads to the removal of the Au(III) ions weakly bound to the support and the hydrolysis of the Au–Cl bonds in the immobilised complexes. The residual Cl content in samples prepared in this way is < 0.01 mass %, according to X-ray fluorescence analysis.¹⁹⁵

The DR-UV-Vis spectrum of the θ -Al₂O₃ sample treated with an alkalified HAuCl₄ solution reveals a new broad absorption band over 35 000–50 000 cm⁻¹ centred at 44 000 cm⁻¹ (spectrum 2, Fig. 32), which is probably due to chemisorbed Au(III) complexes. The so large width of this band indicates heterogeneous composition of the surface compounds. A shift in the position of the absorption band maximum to lower wavenumber with respect to the spectrum of parent alkalified HAuCl₄ solution can be due to exchange interactions between the Au(III) ions immobilised on the Al₂O₃ surface. The exchange interaction implies that the sorbed Au(III) ions are associated, for instance into ‘islets’ with a high local concentration of grafted complexes with neighbouring metal ions located at a distance of 0.5–1 nm from each other.

In addition to the absorption band at 44 000 cm⁻¹, the DR-UV-Vis spectrum of θ -Al₂O₃ treated with an alkalified HAuCl₄ solution exhibits an additional weak band at 19 000 cm⁻¹ attributed to the plasmon absorption band from gold metal nanoparticles. The appearance of the resonance plasmon line for this sample means that metallic gold is partly formed already upon adsorption or during the washing and/or drying steps. The absorption band at 19 000 cm⁻¹ abruptly increases after annealing of the sample in air at 400 °C and a new band at 25 000–32 000 cm⁻¹ emerges. Since resonance plasmon features cannot be shifted so far to larger wavenumbers, the observation of the band at 25 000–32 000 cm⁻¹ indicates that the Au/ θ -Al₂O₃ sample contains ‘ionic’ species of gold in addition to metal particles.¹⁹⁵

The formation of metal oxide clusters and their co-existence with metallic gold was observed earlier in Au/MgO catalysts manifesting high activity in the low-temperature CO oxidation.^{197, 198} The application of X-ray absorption techniques EXAFS and XANES to probe the chemical state of gold nanoparticles revealed that both cationic and zero-valence (i.e., metallic) gold co-exist in the functioning catalysts and

relative amounts of these two forms depend on the composition of the reaction mixture. Simultaneous measurements of X-ray absorption spectra and the catalytic activity of Au/MgO catalysts in the CO oxidation for reaction media with different reactant ratios made it possible to correlate the reaction rate and relative fractions of the cationic and zero-valence gold. The results of these measurements are shown in Fig. 33. The maximum activity is achieved in the case of Au/MgO catalysts with nearly equal fractions of the ionic and metallic gold.

Figure 33. Catalytic activity of the Au/MgO catalyst in the CO oxidation as a function of surface concentrations of cationic and zero-valence gold in the sample.¹⁹⁷

These results suggest that the activity of the Au/Al₂O₃ catalysts in the low-temperature CO oxidation is due to the associative mechanism of the process similar to that used earlier to rationalise the catalytic action of some metal oxides in this reaction. The associative mechanism of the CO oxidation assumes that a decrease in the apparent activation energy of the catalytic reaction is achieved due to energy-coupled oxidation and reduction of surface oxide metal clusters accompanied by the formation of carbonate structures as key intermediates.

The above data demonstrate a practical potential of the Au/Al₂O₃ catalysts. Indeed, possible areas of application of catalysts providing the low-temperature CO oxidation are extremely broad. These catalysts are of importance for the air purification in closed spaces, solution of the ‘cold start’ problem in the exhaust gas neutralisation, purification of hydrogen from CO for the use in fuel cells based on proton-conducting membranes, etc.

VI. Conclusion

The examples discussed in the present review clearly demonstrate that instrumental techniques for surface studies remain essential for catalytic investigations, since they yield detailed information on the structure of surface sites driving specific catalytic reactions thus helping to establish the structure–activity relationships in heterogeneous catalysts. In parallel, modern trends in surface science require several novel approaches to be included into everyday practice of scientific investigations. In particular, these include:

- *in situ* methods of catalyst characterisation enabling studies exactly under conditions of catalytic reactions (a new term Operando spectroscopy appeared recently to designate this type of experiments);
- techniques for the analysis of nanosized and nanostructured materials (primarily, with a low concentration of an

active component) sensitive to the metal–support interactions (it is the efficient interaction of metal nanoparticles with the support that provides the optimum, from the catalytic perspective size of the active component and its stability against aggregation and deactivation upon sintering);

— methods for the synthesis of nanosized and nanostructured catalysts with a controlled narrow particle size distribution, including both model catalysts on single-crystalline substrates and real catalysts with high specific surface area.

The first approach offers one possible way to address the ‘pressure gap’ problem, whereas two latter approaches address the ‘material gap’ problem. The experimental information on the structure of active sites retrieved by instrumental methods for surface science will be reliable and relevant to specialists in catalysis for the design of highly active and selective catalysts only provided that both these problems are properly addressed. The costs for the development of so expensive direction as surface science are well warranted by the ultimate practical success in the invention of novel advanced catalysts. Essentially, this concerns research efforts that can result in the establishment of a totally new material and technical basis of chemical and petrochemical industry, where 80% of all processes are nowadays catalytic.

Due to the complexity and expensiveness of the surface science instrumentation, further progress in the field is only possible with a wide cooperation of scientists from diverse disciplines (physicists and chemists, theoreticians and experimentalists, surface scientists and catalysis experts), integration of research capabilities of different centres and laboratories, including international collaborations.

The author is grateful to the personnel of the Surface Science Laboratory at the G K Boreskov Institute of Catalysis, Siberian Branch of the Russian Academy of Sciences V V Kaichev, A V Kalinkin, R I Kvon, Yu V Larichev, B L Moroz, A V Pashis, I P Prosvirin, P A Pyryaev, A M Sorokin and M Yu Smirnov as well as to colleagues from other laboratories and foreign colleagues (see references) for the help in the discussion and implementation of experiments bridging surface science and catalysis. The author also thanks the Russian Foundation for Basic Research for the long-term financial support of the work (Project Nos 96-03-33 891, 01-03-32 853, 03-03-89 012-NWO, 06-03-33 020 and 07-03-00 931).

IV. Magnetic resonance imaging of chemical reactions	588
V. Conclusion	595

Abstract. New physicochemical applications of multinuclear magnetic resonance imaging that will determine the development of the method in the near future are considered. These include studies of solids, investigations of mass transfer processes in multiphase systems, studies on *in situ* reactors, heterogeneous hydrogenation with para-hydrogen and spectroscopy of long-lived singlet states. It is noted that in addition to an extension of the range of objects and processes of interest, the magnetic resonance imaging technique itself undergoes considerable changes. The bibliography includes 204 references.

I. Introduction

Magnetic resonance imaging (MRI) formerly referred to as nuclear magnetic resonance (NMR) tomography is known primarily as a method of medical diagnostics. This method is also widely used in biological studies. At the same time, MRI has found increasing and fruitful application in studies of non-living objects, including investigations in chemistry, chemical engineering, materials science, *etc.*^{1–4} Both the fundamentals of MRI and its physicochemical applications were considered in the reviews.^{5–7} In the last five years, this method has gained new applications due to its extensive development, resulting in a considerable expansion of the range of objects and processes studied by MRI. This range includes catalytic reactors and biofilm reactors, fuel cells, microreactors, polymers, drug delivery systems, gas hydrates, rock cores, building materials, film coatings, cultural heritage objects, plants, food products, *etc.* This, in turn, stimulates the further development of MRI technique itself. Efforts of researches in this field of science led

to fundamentally new applications, including those, which have been considered to be impossible or impracticable. In particular, these are MRI of gas transport, single-spin magnetic resonance, NMR spectroscopy and MRI in highly inhomogeneous or very low magnetic fields, MRI of solids and high-temperature processes, the diffusion coefficient and flow rate measurements at time intervals that are substantially longer than the spin relaxation times, and many other.

Unfortunately, these investigations have received little attention in Russia. The present review summarises recent achievements and trends in the development of MRI, including results obtained in recent years at the International Tomography Centre of the Siberian Branch of the Russian Academy of Sciences. In the present review, we do not try to cover the results of all investigations. This is practically impossible taking into account the progress achieved in this field in the last 5–10 years. Our aim is to attract the attention of researchers to this field of science by presenting the most remarkable applications, which apparently will determine the progress in MRI in the nearest future.

II. Multinuclear magnetic resonance imaging of solids

In biomedical applications, the MRI technique is mainly used for investigations of soft tissues and fluid transport (blood and lymph fluid) in living organisms. Until recently, scientific and technical applications of MRI have been limited mainly to investigations of objects containing considerable amounts of liquids. The progress in MRI of gases is hampered mainly by a low density of gases (*i.e.*, a low concentration of nuclear spins) and, as a consequence, low sensitivity and low spatial resolution. As a result, MRI of gases has found limited use although methods for the preparation of hyperpolarised gases with a considerable degree of nuclear spin polarisation have been extensively developed in recent years to overcome limitations associated with low sensitivity. At the same time, in spite of a relatively high density of solid materials, their investigations by MRI also present difficulties due mainly to the characteristic features of magnetic resonance of solids. However, it is evident that the use of MRI for investigations of solid materials would substantially extend the scope of this method.

In the solid phase (unlike in liquids), anisotropic interactions involving nuclear spins are not averaged to zero because of low molecular mobility. This is responsible for a large linewidths in NMR spectra of solids. For example, the line-

widths for quadrupolar nuclei are often > 1 MHz. An exception are soft solids, such as polymers and elastomers, which can often be studied by conventional MRI techniques.^{8,9} For rigid solids, a large linewidths lead to a very fast NMR signal decay, resulting in a substantial decrease in the sensitivity of the technique. Moreover, the NMR signals cannot be detected at all in some cases. In addition, magnetic field gradients, which are far beyond the possibilities of commonly used 'liquid-phase' instruments, may be required to achieve a satisfactory spatial resolution. For example, separate two-dimensional images of powdered alumina and zeolite^{10,11} and one-dimensional projections of ceramic samples¹² were obtained from ^{27}Al NMR signals with the use of magnetic field gradients amplitude of $225\text{--}350\text{ G cm}^{-1}$. However, even such values are beyond the possibilities of modern NMR tomographs.

Several research teams are currently developing approaches to MRI of solids based on solid-state NMR techniques,⁷ such as magic-angle sample spinning,¹³ the use of multiple-pulse sequences,¹⁴ large magnetic field gradients,^{15–18} single point imaging (SPI), single point ramped imaging with T_1 enhancement (SPRITE),^{19–21} continuous wave NMR,²² *etc.* However, the wide application of MRI of solids is substantially hampered by the necessity (actual or implied) of the use of specialised instruments and complex techniques;²³ the vast majority of commercial or homebuilt instruments are oriented towards procedures conventionally used in NMR and MRI of liquids.

It is known that a line broadening in NMR spectra of solids is inhomogeneous, *i.e.*, broadened signals are virtually sets of overlapping signals with a substantially smaller own width. This fact can be used in different ways. For example, the use of long frequency-selective pulses can allow excitation of only a part of the inhomogeneously broadened resonances. In this case, the time of transverse magnetisation decay T_2^* is substantially increased and it becomes possible to use liquid-phase techniques in MRI of solids.^{24,25} The obvious drawback of this approach is that only a small part of nuclear magnetisation is used in experiments, resulting in low sensitivity.

In our studies,^{26–30} we used another approach. Originally, the choice of a solid material ($\gamma\text{-Al}_2\text{O}_3$) and, consequently, the magnetic nucleus (^{27}Al) was determined by our MRI studies of heterogeneous hydrogenation of unsaturated compounds on $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ or $\text{Pd}/\gamma\text{-Al}_2\text{O}_3$ catalysts and by the fact that alumina is a commonly used support for catalysts. However, we found that this approach is also applicable to many magnetic nuclei involved in rigid solid materials. Our investigations were based on a number of concepts well-known in the field of NMR. First, a large difference between homogeneous and inhomogeneous widths of the signals is essentially a large difference between the characteristic decay time of the observed signal T_2^* (the time of transverse magnetisation decay or free induction decay) and the true transverse magnetisation relaxation time T_2 . After the application of the first non-selective radio frequency (RF) pulse, a rapid signal decay with the characteristic time T_2^* is observed. However, the application of the second RF pulse can substantially reverse the decay and refocus magnetisation.¹² Second, the central transition ($1/2 \rightleftharpoons -1/2$) in the spectrum of half-integer quadrupolar nuclei $I = (2n + 1)/2$, $n = 1, 2, \dots$, including ^{27}Al ($I = 5/2$), is much narrower than the satellite transitions.^{18,31} Therefore, the detection of the central band in the spectra of quadrupolar nuclei in many cases poses no big problems,^{32,33} in particular if combined with the phase encoding of the spatial information.

The above approach was used with advantage for two-dimensional imaging of cylindrical alumina pellets and alumina or cordierite monolithic honeycomb supports with ^{27}Al NMR signal detection.^{26,27,29} The images were acquired within ~ 15 min. To demonstrate the potential of this method, a series of composite samples of complex composition con-

taining various materials (Al_2O_3 , V_2O_5 , KMnO_4 , NaHCO_3 , glass, *etc.*) were prepared. Images of the corresponding parts of the composite samples at a spatial resolution of $150\text{--}300\text{ }\mu\text{m}$ were obtained by detecting signals of different nuclei (^{27}Al , ^{23}Na , ^{51}V , ^{55}Mn).^{28–30}

The observation of a signal from a glass tube in images obtained from the ^{27}Al NMR signal is evidence that multi-nuclear MRI shows promise for investigation of glass samples. The studies were based on the detection of NMP signals of ^{27}Al , ^{11}B , ^{23}Na , and ^{29}Si NMR nuclei.^{26,29,30} This can be used, for example, in studies of the macrostructures of catalysts and supports, glass and ceramic materials and the structures of granular layers and containers in which they are located. In particular, the structure of a reactor can be visualised in studies of catalytic processes occurring in the reactor. This, along with studies of transport processes, will allow investigation of the correlation between the structure of the reactor and the processes that take place in it. For this purpose, the MRI technique was used for three-dimensional imaging of model granular layers composed of glass beads (^{23}Na MRI, Fig. 1) or spherical alumina grains (^{27}Al MRI).

Figure 1. Three-dimensional image of the packing of glass beads with a diameter of 3.5 mm in a glass tube with an inner diameter of 4.2 mm . The image was acquired within 9 h by detecting the ^{23}Na NMR signal. The image of the tube has been removed.

The merit of the MRI method is that it not only provides structural information but, which is more important, also gives spatially resolved maps of properties of the objects of interest (velocity, temperature, chemical composition, *etc.*). Hence, the further progress in MRI of solids will be directed towards the use of this method with different image contrast mechanisms. An evident field of application involves studies of the motion of solids and granulated materials.

The development of spatially resolved NMR thermometry is another promising area of investigation. Heat transport processes are of primary importance in the design and use of catalytic reactors. Nuclear magnetic resonance tomography is rather widely applied in thermometry of liquids.^{7,34–37} However, none of the available approaches based on the signal detection of a liquid phase can be used for thermometry of heterogeneous catalytic processes. This is associated with the fact that all parameters used in NMR thermometry (signal intensity, chemical shifts, relaxation times, diffusion coefficients) substantially depend on other factors, for example, on the amount of a liquid in pores. Therefore, it is impossible to relate unambiguously the changes in these parameters to the changes in temperature.

At the same time, the detection of a signal from a solid matrix, which is much less subjected to changes during operation of a reactor, allows the use of MRI for thermometry of reactors. This possibility was documented almost exclusively for soft solids. For example, the pronounced temperature dependence of the longitudinal (spin–lattice) and transverse (spin–spin) nuclear relaxation times (T_1 and T_2 , respectively) was used to construct three-dimensional temper-

ature maps for a *cis*-polybutadiene block, through which cold and hot water was pumped using two pipes,³⁸ and for vulcanisates of butadiene – styrene rubber under dynamic mechanical load.^{8,9,39} Two-dimensional MRI of a KBr crystal,⁴⁰ for which the time T_1 of the ^{81}Br NMR signal shows a pronounced temperature dependence, is an example of thermometry of rigid solids. As mentioned above, alumina is widely used for the preparation of catalysts and supports. Investigations demonstrated that both the time T_1 and the amplitude of the ^{27}Al signal of alumina are characterised by a pronounced temperature dependence.²⁶ In the future, it can be used for the development of procedures for spatially resolved NMR thermometry of solids.

III. Multinuclear magnetic resonance imaging of transport processes

Magnetic resonance imaging has long been advantageously used in investigations of transport processes.⁶ In particular, liquid flow, filtration, dispersion and diffusion in various geometries, including transport in model granular layers,^{41–44} plants,^{45,46} electroosmotic flow,^{47,48} turbulent flows,⁴⁹ etc., were considered in a vast number of publications.

Nowadays, MRI is being increasingly used in studies of structures of bioreactors and transport processes in them. The development of new technologies based on the use of various bioreactors is of importance, for example, in such fields as waste water treatment, food industry, construction of artificial tissues, etc. The MRI technique allows the non-invasive determination of the amount and spatial distribution of a biomass in a reactor and location of inhomogeneities in biofilm structures. For example, studies of the growth of biopolymers based on *Staphylococcus epidermidis* in a capillary bioreactor showed the presence of clusters of biomass, in which channels and cavities were distinguished.⁵⁰ The use of relaxation time contrast made it possible to obtain separate three-dimensional MRI images of water and biopolymers.⁵¹

Another approach to the separate visualisation of water and biofilms was used in the study,⁵² where the differences in the diffusion coefficients were employed. The MRI method was applied also to investigate the structures of methanogenic aggregates from an anaerobic purification system of waste water.⁵³ The contrast of MRI images is substantially enhanced upon absorption of paramagnetic compounds by a biofilm.^{54–56} In model studies, the removal of metal ions (La^{3+} and/or Cu^{2+}) from aqueous solutions with biopolymers based on the bacterium *Citrobacter* sp. was investigated.^{55,56} Considerable attention was focussed on the flow and diffusive transport in bioreactors.^{50,54,57,58} The flow in a new coaxial bioreactor based on hollow fibre permeable membranes was studied.⁵⁹ The relationship between the structure and transport properties of biopolymers was considered in several publications.^{50,58} Mammalian cell-based bioreactors have found increasing use for the production of antibodies, hormones and proteins for therapeutic and clinical application, the tissue growth for transplantation and the design of artificial tissues and organs. The distribution and transport of paramagnetic gadolinium complexes in such reactors were investigated.^{60,61} Aspects of application of MRI in studies of transport and biological activity in biofilms and bioreactors were considered in several reviews (see, for example, Refs 62 and 63).

In recent years, considerable attention has been given to application of MRI in studies of two-phase (liquid – gas) flows in various geometries,⁶⁴ in particular, of gas and liquid trickle flow in model granular beds. In this case, MRI experiments provide information on the residual and dynamic liquid holdup in a reactor, the presence of liquid streamlets in the bed and wetting of the catalyst surface. For example, it was

demonstrated⁶⁵ that the flow pattern can remain unchanged for many hours for a co-current trickle flow of water and air in a model granular bed at constant gas and liquid flow rates. An analysis of the results of investigation was used for the determination of the above-mentioned parameters and their dependence on the liquid flow rate. Changes in the gas flow rate do not lead to substantial changes in the liquid distribution in the layer. However, the initial state of the granular bed was found to have a substantial effect on the gas and liquid distribution in the bed.^{65,66} A study of the dependence of the liquid holdup in the reactor and wetting of the surface of cylindrical alumina pellets in a granular bed on the liquid flow rate⁶⁷ showed that smaller grains are characterised by higher values of these parameters. After the flow is turned on as well as after the temporary interruption of the liquid feed, a few minutes^{64,68} to several hours⁶⁹ are required for the establishment of the stationary liquid and gas distribution in the bed.

Investigations of fast dynamic processes under two-phase flow conditions require fast MR imaging. The imaging at a rate of 10 images per second revealed liquid slugs passing through the imaged slice at a high liquid flow rate.^{64,68} Ultrafast imaging (20 ms for two-dimensional images and 0.3 s for three-dimensional images) allows MRI studies of gas – liquid two-phase flows in the trickle, pulsing and transient flow regimes.^{70,71} Most likely, the pulsing regime begins with the appearance of local fluctuations and is characterised by the co-existence of regions with constant and fluctuating contents of a liquid. The sizes of the regions with an unstable flow increase with the liquid flow rate and finally the regions coalesce. In the transient flow regime, the instability regions in the bed are shifted, which is apparently responsible for a hysteresis in the plot of the pressure drop vs. the liquid flow rate. In the pulsing flow regime, changes in the intensity of most of elements of an MR image are observed. To characterise the periodicity of changes in the local liquid content in the bed, the time autocorrelation function was calculated from these data. A preliminary study of the periodic mode with a modulated liquid feed to the bed was documented.⁷⁰ In spite of changes in the liquid distribution in the bed after the liquid flow rate returns to the starting value, no changes in the wetting of the catalyst and the liquid holdup in the bed were observed.

It should be noted that the character of transport and its quantitative characteristics can be radically changed if the mass transfer is coupled with heat transfer and/or a chemical reaction (see Section IV.2). A comparative study of a two-phase flow of a diesel oil and N_2 in a bed of glass beads or alumina trilobes was carried out under normal conditions and at high temperature and pressure (398 K, 10 atm).⁷² The liquid holdup in the bed was determined from MR images. The results obtained in the trickle flow mode showed a considerable influence of the temperature on the dynamic liquid holdup in the bed, which decreases with temperature.

To study a two-phase flow in channels of honeycomb monolithic supports, for example, in a bubble-train flow with alternating liquid slugs and gas bubbles, it is also necessary to use fast magnetic resonance imaging because, unlike a steady-state pattern in the trickle flow mode, the gas and liquid distribution pattern is continuously changed. The possibility of acquiring 4–8 successive two-dimensional images in ~ 0.6 s was demonstrated in studies of air – water two-phase bubble-train flow in a thin pipe⁷³ and a cordierite monolithic honeycomb support.^{74,75} These experiments allow one to determine the size of gas bubbles and liquid slugs and to follow their motion in time. A fast NMR signal decay provides indirect evidence for liquid recirculation in the case of two-phase bubble-train flow.⁷³ The same approach was used in studies of ascending gas bubbles in channels of a monolith placed in a static liquid.^{64,66,67,76}

Studies of the filtration of liquid–liquid two-phase systems in porous media, for example, of water and silicon oil embedded in glass beads, are presently underway.^{77, 78}

The possibility of investigating gas flow and filtration by the MRI technique has been demonstrated earlier.^{79–82} The results of these studies gave impetus to further progress in MRI techniques as applied to investigations of gas transport. For example, a methane flow and accumulation of solid particles in soot filters of diesel engines was considered.⁸³ A relatively high spatial resolution (100–250 μm) was achieved by increasing the gas pressure to 10 MPa. The measured maps of gas flow velocity showed that the flow distribution through a porous filter wall is relatively uniform along the channel length. The next series of experiments was concerned with the accumulation of small carbon particles, which were introduced into a gas flow, in a filter.

Until recently, it has been believed that the turbulent gas flow in an inhomogeneous magnetic field should lead to fast NMR signal decay and, consequently, this flow cannot be studied by MRI. However, recently it has been demonstrated that this is not true. The maps of flow velocity and turbulent diffusivity for SF_6 flowing at velocities $> 10 \text{ m s}^{-1}$ ($\text{Re} > 10^5$) above a step or about a wing model were reported.⁸⁴ The experimental results are in rather good agreement with calculations by computational fluid dynamics methods.

Even at high pressure, the sensitivity in experiments on MRI of gases remains substantially lower than that of MRI of water. Hence, velocity maps can be obtained only in channels of a rather large diameter and, in contrast to MRI of liquids, cannot be obtained in granular beds. However, studies of gas filtration in porous media are of considerable interest in many fields of science and technology. The use of pulsed field gradient NMR (PFG NMR) for measuring an average propagator (the velocity distribution of molecules) holds promise as an approach to studying gas flow and filtration.^{79, 81, 85} This method was used to obtain average propagators for axial and transverse directions of propane or butane flows in different granular beds.^{86, 87} If the time between gradient pulses (Δ), during which the molecular motion is determined, is short, the Gaussian distribution with a maximum for the zero displacement is observed. A relatively large width of this distribution is associated with a large gas diffusion coefficient. As Δ increases, an extended wing on the side of larger displacements appears in the axial displacement distribution. Then a Gaussian distribution is formed again but with a maximum near the average displacement due to gas flow. The widths of the axial and transverse distributions for large Δ are determined by the corresponding dispersion coefficients, which are substantially larger than the gas diffusion coefficient. In experiments, the dependence of the axial and transverse dispersion coefficients on Δ , the gas flow rate and the grain size in the bed was studied. The Gaussian distribution at large Δ for the axial transport indicates that dead zones are absent in the layer. In the case of gas filtration through a bed of porous particles [for example, of poly(vinyl chloride)],⁸⁷ the axial distribution shows the second peak at zero displacements in the limit of large Δ . This peak corresponds to the gas present in grain pores, which is rather slowly exchanged with the free flowing gas. In addition, the characteristic autocorrelation times of the velocity of gas molecules were experimentally studied for filtration through model granular bed.⁸⁸

In spite of the progress in application of MRI in studies of gas transport, low sensitivity is still the main obstacle to such investigations. Hence, considerable recent attention has been focussed on the production of hyperpolarised gases with a considerable increase (by several orders of magnitude) in nuclear spin polarisation compared to thermal equilibrium polarisation in a spectrometer or tomograph magnet field.⁸⁹ Laser procedures were developed for the continuous genera-

tion of hyperpolarised noble gases (^{129}Xe , ^3He , ^{83}Kr).^{90–92} It is convenient to use these procedures to study gas flow and filtration by MRI.^{80, 93}

The use of hyperpolarised gases, particularly combined with highly sensitive methods for the signal detection (for example, with a superconducting quantum interferometer) allows the detection of NMR signals and MR imaging at very low magnetic fields using extremely small field gradients. For example, experiments⁹⁴ were carried out at a magnetic field of 2.3 mT, which is approximately 3 orders of magnitude lower than those used in most of MRI studies of non-living objects. In the cited study, the filtration of hyperpolarised $^{129}\text{Xe}^*$ through an aerogel and a bed of powdered polypropylene was considered. In the latter case, due to a large chemical shift difference (200 ppm or 5 Hz), bulk xenon and adsorbed xenon were distinguished in spite of a very low magnetic field. Ultra-low frequency magnetic fields allow investigation of samples inside a metal container.⁹⁵ In strong magnetic fields, these investigations are in principle impossible because high-frequency electromagnetic radiation does not penetrate into conducting screens (skin-effect).

In recent years, methods of the so-called remote-detection NMR and MRI have been developed based on the use of continuous generation systems of hyperpolarised gases and their delivery.^{96–99} The remote detection is a new method, in which spatial information is encoded into an NMR signal with the use of radiofrequency pulses and field gradients at the moment when molecules (information carriers) are present in the object of interest, while the signal is detected at a different site. This provides delay for the time of molecule transport from the object to the site of detection. The distance between the object of interest and the site of detection can vary from several millimetres to several metres if the transport time is no longer than the spin relaxation time, which determines the lifetime of the encoded information. An obvious advantage of this approach is that conditions of signal detection can be optimised regardless of the properties and size of the object of interest. Preliminary studies using remote-detection NMR have demonstrated an enhancement of sensitivity and spatial resolution for hyperpolarised $^{129}\text{Xe}^*$ in model objects and real porous materials.^{96, 97} The remote signal detection was applied in MRI of transport in model microreactors.^{98, 99} This made it possible to perform detailed studies on the role of flow, diffusion and mixing processes and reveal dead zones.⁹⁹

The transport of solid granulated materials is used in many industrial processes, including fluidised granular beds, granulation, drying, pneumatic transport, *etc.* Magnetic resonance imaging is widely used for investigating such processes. However, all MRI studies of the transport of solids are based on the detection of the NMR signal of a liquid phase. Hence, liquid-containing solid particles are required. Plant seeds (poppy or mustard) with high oil and moisture content, pharmaceutical pellets with a liquid core, and liquid-saturated porous grains are often used for this purpose.^{4, 6, 100, 101}

Three-dimensional images of a granular bed fluidised with an air stream¹⁰² clearly show low-density regions (as vertical columns) of the particle distribution above each orifice of the gas-distribution plate. Interestingly, these regions were observed at a gas velocity lower than the minimum fluidisation velocity ($U < U_{\text{mf}}$). At $U > U_{\text{mf}}$, these regions coalesce into a single low-density region in the upper part of the bed. The images also clearly show dead zones between adjacent orifices. Mixing of particles in a fluidised bed was studied using two types of particles, which give and do not give NMR signals.¹⁰³ Different modes of fluidisation were examined by recording axial profiles of the particle density distribution, the particle velocity distribution and the effective dispersion coefficient.¹⁰⁴ In somewhat more complex MRI experiments, the contributions of coherent (differences in particle velocity) and incoher-

ent (velocity modulation due to collisions) particle motion to the dispersion coefficients can be distinguished.¹⁰⁵ In particular, the dispersion coefficients for the transverse transport with and without considering the coherent contribution differ by a factor of 3–4; for the axial transport, this difference is substantially smaller. Local information on the particle velocity averaged over the time and an element of an MR image can be obtained by combining MRI sequences and velocity encoding methods.^{102, 105} Velocity distribution maps reflect the upward particle motion in the central part of the bed and downward motion in the near-wall region at a much lower velocity. The transport of a gas used for fluidisation of a granular bed can be studied by MRI. The gas exchange between different phases (gas bubbles and emulsions) was studied and gas velocity distributions at different gas flow rates were obtained with the use of hyperpolarised xenon.^{106, 107}

Magnetic resonance imaging is applied also to study fluidisation of a granular bed in vibrating containers.^{108–111} In addition, the particle transport in Couette flow^{112, 113} and in horizontal rotating cylinders was investigated^{114–117} and filtration of mineral oil-containing Al_2O_3 particles through a bead pack, which serves as a model of a catalytic reactor, was studied.^{85, 118, 119}

The drawback of the above-considered applications of MRI in studies of the transport of solids is that it is necessary to detect the signal of a liquid phase. This largely limits the range of materials and processes, which can be studied by this method. Until recently, the possibility of detecting the NMR signal of a solid phase in such studies has not been considered. The successful use of multinuclear MRI allowed us to study for the first time the motion of solids by the direct detection of the NMR signal of a solid phase. We used³⁰ the MRI method for visualising the rotation of a cylinder filled with an alumina powder. Three-dimensional velocity maps of the two velocity components perpendicular to the cylinder axis were constructed by detecting the ^{27}Al NMR signal. These data are in good agreement with the results of calculations based on the known parameters, *viz.*, the rotation velocity and the diameter of the sample. Propagators for motion of finely grained alumina under the force of gravity were also obtained (Fig. 2).

The further progress in applications of MRI is greatly hampered by the sensitivity of the method. This is also true for the MRI of solids, especially when the signals of nuclei with a low natural abundance of a magnetic isotope or a low magnetogyric ratio are detected. Hence, we made considerable efforts to enhancing the sensitivity of detection of the ^{27}Al NMR signal and signals of other nuclei. One of approaches in

NMR of half-integer quadrupolar nuclei is based on an increase in the level population difference of the central transition as a result of a inversion of satellite transitions by means of adiabatic sweep of the radiofrequency field.¹²⁰ This made it possible to double the intensity of the ^{27}Al NMR signal in MR imaging of a glass tube with a wall thickness of 1.5 mm.³⁰ The use of a narrower spectral band in the signal detection^{19, 121} led to a further increase in the signal-to-noise ratio by a factor of 3.5. Nowadays, we use another approach based on the development and construction of higher-sensitivity resonator-type radio frequency detectors.

Multinuclear MRI can be useful not only in studying the transport of solids but also in investigating the transport of different dissolved compounds. From a methodological viewpoint, this obviates problems associated with the detection of signals of a solid phase because a fast molecular motion in solutions averages anisotropic nuclear spin interactions, resulting in a narrowing of NMR lines by several orders of magnitude. Due to this, all liquid-phase MRI techniques are fully applicable for multinuclear MRI of solutes.

Transport processes of dissolved substances have attracted interest of researchers in different fields of science and technology. For example, the transport of salts in porous building materials is of primary importance. In recent years, multinuclear MRI has found application in studies of such processes.^{122, 123} The design of functional porous materials is often based on impregnation of a porous matrix with various substances. For example, efficient sorbents were prepared by introducing different salts into pores of alumina, silica gel or another porous matrix.¹²⁴ It will be possible in future to characterise both transport processes of dissolved substances in impregnation and drying steps and the final distribution of a solid-phase component introduced into a porous matrix after complete removal of the solvent by combining MRI of dissolved compounds and MRI of solids.^{29, 125, 126}

The transport of dissolved substances is of great importance also in the preparation of supported catalysts by impregnation of a porous support with the corresponding solutions. The diffusive transport rate of substances into a porous support substantially depends on the character of interactions between these substances and the support, the presence of modifying additives in solution, pH of the medium and other factors. In some case, this rate can be very low, but in this case uniform distribution of an active component over a support cannot be achieved. In some cases, a non-uniform distribution of egg-shell, egg-white, *etc.* types are required. In earlier studies, we have found that platinum hexachloride (PtCl_6^{2-}) deposited onto an extended surface of alumina can increase the proton spin relaxation times of liquids filling the pore space of supports.^{127, 128} As a result, MRI images reflecting the macro-distribution of platinum in grains was obtained by detecting signals of a liquid (cyclohexane or water) in grain pores. Analogous experiments were performed for palladium tetrachloride (PdCl_4^{2-}). Moreover, the non-destructive character of MRI allowed, for the first time, the observation of the dynamics of redistribution of adsorbed platinum hexachloride in real time in one grain in the course of competitive adsorption from a solution together with oxalic acid.^{127, 128} Unlike PtCl_6^{2-} and PdCl_4^{2-} , paramagnetic adsorbates lead to a decrease in the spin relaxation times of contacting liquids. This allows the use of MRI in studies of simultaneous adsorption of two active components of different nature (for example, PtCl_6^{2-} and Cu^{2+}) upon simultaneous deposition onto an alumina grain.^{118, 129}

More recently, studies of practical importance were carried out. The corresponding procedures were developed using alumina-supported (Ni/Co)Mo catalysts for hydrodesulfurisation. These catalysts are often prepared with the addition of other components, *viz.*, co-promoters and modifying agents

Figure 2. Particle velocity distribution of finely grained Al_2O_3 in a vertical pipe obtained by detecting the ^{27}Al NMR signal.

(for example, phosphates and citrates). The transport of phosphate in an alumina grain upon impregnation of the latter in an aqueous H_3PO_4 solution was studied in the first step. Magnetic resonance imaging with ^{31}P NMR signal detection provided dynamic visualisation of the phosphate transport in a grain in the course of impregnation.^{125, 126} To confirm the reliability of this method, maps of the spatial distribution of phosphate in the solid phase were recorded after termination of impregnation at various stages of impregnation and the subsequent drying of the granules. This became possible due to the development of the above-considered (see Section II) multi-nuclear MRI of solids. The distribution of phosphate in a dry grain was demonstrated to correlate with the distribution of phosphate in the liquid phase during impregnation. In addition, an investigation with the use of the initially dry grain combined with an alternating detection of ^{31}P (phosphate) and ^1H (water) images demonstrated fast capillary ingress of water from a solution, the penetration of phosphate inside the grain being much slower due to a strong interaction between the phosphate and the surface of alumina pores.

In the next step, the cobalt transport during impregnation of an alumina pellet with an aqueous solution of a cobalt salt was investigated. The dynamics of the process was studied by MR imaging by detecting ^1H NMR signal of water because paramagnetic cobalt ions (Co^{2+}) have a substantial effect on the intensity of the NMR signal of water. The addition of citric acid to an impregnation solution was demonstrated to have a substantial effect on the impregnation process: the cobalt concentration at the periphery of the grain decreases due to a stronger interaction between citric acid and the pore surface and the displacement of cobalt further into the granule (Fig. 3). The influence of the impregnation conditions on the character of cobalt transport and the final distribution of cobalt over the grain of the support was studied in detail. For example, the redistribution of cobalt in the course of impregnation at high and low pH (8 and 1, respectively) of an impregnation solution for a grain with a diameter of 3.5 mm is completed in ~ 2 h. At pH 1, the final distribution has an egg-yolk type. At pH 8, cobalt is uniformly distributed over a granule in spite of the presence of citrate. At intermediate pH (for example, 5), the

impregnation time exceeds 15 h. Images obtained by MRI in studies of the transport of Co^{2+} ions were converted into concentration profiles with the use of calibration curves, *i.e.*, it was demonstrated that quantitative information on transport processes in the course of supported catalysts preparation can be obtained.

In the next step, the transport of molybdenum ($\text{Mo}_7\text{O}_{24}^{6-}$) was studied. Granules were impregnated with an aqueous solution of ammonium heptamolybdate. Diamagnetic molybdenum ions (Mo^{6+}) were found to lead to a substantial increase in the spin relaxation times of water in the pores. This effect is analogous to the effect used earlier in studies of impregnation of support grains with an aqueous solution of H_2PtCl_6 or H_2PdCl_4 (see above). Based on the results of these investigations, approaches were developed for selective visualisation of the regions of grains containing (or not containing) Mo^{6+} , and a procedure was devised for observing the dynamics of molybdenum transport in grains during impregnation. However, it is necessary to use MRI in combination with other physicochemical methods for complete characterisation of such multicomponent systems. For example, spatially resolved optical spectroscopy can be used for determining the nature of ionic metal complexes.^{126, 130}

In the above-described investigations, the transport of a diamagnetic precursor of an active component in grains of a support in the course of the preparation of supported catalysts by impregnation was for the first time monitored by detecting directly the NMR signal of the metal atom. This was exemplified¹²⁵ by the preparation of a $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ catalyst with the observation the dynamics of the process by detecting the ^{195}Pt NMR signal. The approaches developed in the latter study were used for investigating the preparation of catalysts on other supports, for example, for studying the distribution of an active component in different samples of monolithic honeycomb supports both after calcination and in freshly prepared samples.¹³¹ To visualise the spatial distribution of an active component, T_1 -weighted images were generated. Therefore, approaches were devised for the first time to using MRI for the non-destructive control of the preparation of supported catalysts by dynamic visualisation of the distribution of active components and compounds promoting catalytic activity.

Figure 3. Two-dimensional ^1H MRI images reflecting the dynamics of transport of Co^{2+} ions into a $\gamma\text{-Al}_2\text{O}_3$ grain in the course of its impregnation with a solution of 0.2 M $\text{Co}(\text{NO}_3)_2$ and 0.4 M citric acid at pH 1.

The images were acquired by detecting the ^1H NMR signal; the dark ring corresponds to the part of the grain with the highest concentration of Co^{2+} ions; the spatial resolution was $(139 \times 231) \mu\text{m}^2$.

IV. Magnetic resonance imaging of chemical reactions

1. Homogeneous reactions

Under homogeneous conditions, a liquid-phase reaction or related mass-transfer processes can give rise to non-uniform spatial distributions of reactants, products, intermediates and other important parameters. In these cases, MRI can provide useful information on processes occurring in systems. An example is MRI studies of the Belousov–Zhabotinsky (BZ) reaction, metal ion-catalysed oxidation of organic substrates by bromate anions.¹³² A series of interesting MRI investigations were carried out in this field^{133, 134} (see the review⁷). In the last three to four years, after a hiatus, interest in this problem was rekindled. For example, the reaction alternative to the classical BZ reaction, *viz.*, the non-catalytic cyclohexane-1,4-dione + bromate + acid reaction, was studied.¹³⁵ However, since the MR image contrast in all previous studies of the BZ reaction has been based on the periodic change in the oxidation state of metal ions (catalyst), the latter investigation was performed with the addition of manganese ions as a passive indicator of the processes occurring in the system. This allowed investigation of the appearance and evolution of wave structures in this system. The concentrations of the reactants, products and intermediates at different instants of time were determined by NMR monitoring of the reaction, which partially confirmed the reaction mech-

anism proposed earlier. Later,¹³⁶ spatial maps of the concentrations of Mn(II) and Mn(III) ions were obtained directly in the course of the BZ reaction.

The BZ reaction is homogeneous. However, its behaviour can be substantially changed by performing this reaction in thin capillaries or in an inert porous medium. The behaviour of the BZ system in glass bead or quartz sand packs was investigated.^{88, 137, 138} In particular, the concentration wave velocity in a glass bead pack with a bead diameter of 0.5 mm was demonstrated to decrease by a factor of ~ 2.5 after passing through the interface between the bulk liquid and the granular layer filled with the liquid. The wave velocity is proportional to the square root of the diffusion coefficient of an autocatalyst.¹³² The diffusion coefficient in a porous medium decreases by a factor of ε/T (ε is the porosity of the medium and T is the tortuosity of the pore space) compared to the diffusion coefficient in the liquid bulk.¹³⁹ Estimates demonstrated that changes in the concentration wave front velocity after passing through the interface between these phases are associated primarily with this factor.

The concentration wave propagation velocity decreases as the curvature of the front increases.^{140, 141} As the critical curvature is achieved, the formal velocity becomes negative, resulting in the disappearance of wave activity of the medium. The local (on the length scale of individual pores) curvature of the wave front is determined by the pore size in a granular layer. Hence, the propagation of the concentration front can be influenced by varying the grain size. In particular, at fixed concentrations of the key reactants, there is a critical pore size, below which no wave activity is observed. In addition, the wave propagation velocity depends on the bromate anion concentration.¹³² These investigations actually demonstrated that each granular layer is characterised by a particular concentration range, where the wave activity can be observed. For porous materials with small pores, such as alumina, the wave activity was not found at all.

Considerable attention is given to characteristic features of coupling of a non-linear chemical reaction with transport processes in open systems. In particular, very interesting effects are observed in the course of filtration of a BZ reaction medium through inert granular layers. The descending wave velocity (*i.e.*, the wave propagating in the direction of flow) in a porous medium was demonstrated to be substantially larger than the sum of the flow velocity and the wave velocity in the stationary medium, whereas the ascending wave can remain steady-state in a laboratory reference system in a wide range of flow velocities.^{137, 142, 143} Spatially resolved periodic-in-time concentration oscillations were studied¹⁴⁴ by pumping the BZ reaction medium through a glass bead pack. To create constant boundary conditions at the layer inlet, the reaction mixture was introduced from a continuously stirred tank reactor. After the initial transition period, stationary wave structures were observed in the system over a long period of time. Evidently, it is impossible to detect three-dimensional wave structures by optical methods in a non-transparent system.

Since the detailed mechanism of the BZ reaction is rather complex, this unusual behaviour of wave fronts in a granular layer in the presence of a reactant flow remains to be explained.

The concentration wave propagation is observed also in different non-oscillating autocatalytic reactions, which often have a much simpler mechanism than the BZ reaction. In this connection, we performed a series of investigations of such reactions to reveal the common features of coupling of transport processes with a non-linear reaction. For experiments in a reactor containing a stationary granular layer, we chose two autocatalytic systems suitable for MRI studies: oxidation of the Co^{2+} ethylenediaminetetraacetate (EDTA) complex by hydrogen peroxide¹⁴⁵ (OH^- ions act as the autocatalyst)

and oxidation of Fe^{2+} with nitric acid (NO_2^- ions act as the autocatalyst)

In addition to the above-mentioned advantages, an advantage of these systems over the BZ system is that the initiation of chemical waves can easily be controlled. Owing to changes in paramagnetic properties of metal ions in the course of the above transformations, it is easy to acquire MR images with T_1 contrast. For reaction (1), a qualitative pattern for the chemical wave front propagation was obtained. In experiments with reaction (2), the quantitative dependence of the wave propagation velocity on the flow velocity of the reactants through a stationary granular layer was measured. These experiments demonstrated that the wave velocity linearly depends on the flow velocity of reactants, but the slope of the plot differs from unity, *i.e.*, the wave velocity in the moving medium is not a simple sum of the wave velocity in a stationary medium and the flow velocity. For comparison, reaction (2) was performed in a thin capillary. The latter process is characterised by a liquid flow velocity distribution, but the dependence of the wave propagation velocity on the average reactant flow velocity is analogous to that observed for reaction (2) in a reactor with a stationary granular layer. The experiments demonstrated that the wave front propagation can be accompanied by a spontaneous change in velocity from slow to fast and back. This unusual behaviour is apparently attributed to the exothermic character of the chemical reaction and, consequently, to changes in the density of the reaction solution.

In these experiments, considerable efforts were made to develop MRI techniques for studying the chemical wave propagation under different conditions. For example, the chemical wave propagation in polymeric media is of interest as a model, which can be used to study living biological tissues, where different specific transformations can proceed. To perform experiments in polymeric media, we chose oxidation of thiosulfate with chlorite ions

This reaction shows a wave activity at low ($< 0.1 \text{ mol litre}^{-1}$) concentrations of the reactants (autocatalysis by H^+ ions). Isopropylacrylamide gel was used as a polymer matrix. We found that the nuclear spin relaxation times of water vary with pH. For example, the chemical wave propagation in the gel impregnated with the chlorite–thiosulfate reaction solution led to a change in pH by 7 units, resulting in an increase in the relaxation time T_1 by $\sim 200 \text{ ms}$. This allowed us to acquire MR images with pH contrast of the propagating wave front at different instants of time.

The spatially resolved NMR thermometry for visualisation of the chemical wave propagation is another area of methodological development. Since reaction (3) is exothermic, the concentration front propagation can in principle be observed from changes in the local temperature of the medium. Magnetic resonance imaging is rather widely used for measuring the local temperature in different samples.⁷ For systems containing large amounts of water, including living objects, the temperature determination is often based on an almost linear temperature dependence of the chemical shift of a water molecule in a wide temperature range. For the first time, we used MRI thermometry for measuring the local temperature in the course of concentration wave propagation.¹⁴⁶ The reaction was performed in a vertical glass cell with an inner diameter of 9 mm, and two-dimensional images of a 2-mm thick slice were acquired at three-second intervals for central longitudinal or transverse sections. As a result, temperature profiles for this colourless reaction were obtained (Fig. 4). According to the

Figure 4. Temperature profiles obtained in the course of chemical wave propagation in a chlorite – thiosulfate system. Longitudinal sections of the cell are shown; the images were acquired at 25-s intervals; the convective flow is indicated by an arrow.

MRI data, an increase in the temperature of the solution in the course of reaction front propagation was $\sim 8^\circ\text{C}$, which is in good agreement with the results of thermocouple measurements performed separately. The accuracy of MRI measurements of the temperature in these experiments was estimated at 1°C . After the front propagation, the temperature of the solution gradually decreases to the initial level, which is reflected in the temperature profiles. These profiles also demonstrate the presence of convective flows in the cell, resulting from heating of the medium in the vicinity of the reaction front. Therefore, the above-described procedures are applicable to studies of the influence of reactant transport in polymeric media and the temperature on the chemical wave propagation.

2. Heterogeneous reactions

The application of MRI in the *in situ* studies of operating reactors is a relatively new field that made its appearance in the 21st century.¹⁴⁷ Nevertheless, numerous data were obtained during this short period of time. Investigations carried out in the course of a reaction are of great importance because coupling of transport processes with reactions and attendant processes (heat transfer and phase transformation) can fundamentally change the situation.

First *in situ* MRI investigations of heterogeneous catalytic reactions proceeding at high temperature were carried out at the International Tomography Centre of the Siberian Branch of the Russian Academy of Sciences in collaboration with the Institute of Catalysis of the Siberian Branch of the Russian Academy of Sciences. Heterogeneous hydrogenation of unsaturated compounds (α -methylstyrene, heptene, and octene) on supported metal catalysts ($\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ and $\text{Pd}/\gamma\text{-Al}_2\text{O}_3$) were chosen as model reactions

$\text{R}^1 = \text{C}_6\text{H}_5$, $\text{R}^2 = \text{CH}_3$; $\text{R}^2 = \text{H}$: $\text{R}^1 = \text{n-C}_5\text{H}_{11}$, $\text{n-C}_6\text{H}_{13}$.

To perform reactions inside an NMR magnet, a NMR-compatible reactor was designed, which allowed an increase in the temperature of the reaction zone to $\sim 100^\circ\text{C}$ due to external heating by a hot air stream. The reaction zone and the hot-air jacket were placed in an evacuated glass Dewar to prevent overheating of gradient coils of the instrument. The catalyst is placed in the reaction zone; both the liquid reagent which is fed through a capillary and the preheated

hydrogen gas which can be additionally saturated with the reagent vapour are supplied from above.

Early studies^{28, 88, 148–150} addressed the spatial distribution of a liquid phase in a single cylindrical pellet of the 15% $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ catalyst in the course of hydrogenation of α -methylstyrene (AMS). At that time, one two-dimensional image was acquired during ~ 260 s. Nevertheless, this first experiment, where the operation of a model three-phase reactor was directly observed, revealed the presence of considerable concentration gradients of the liquid phase in the catalyst grain under conditions of the simultaneous endothermic evaporation of the liquid reactant and exothermic hydrogenation of its vapour.^{88, 149, 150} Presumably, fast evaporation of the reactant occurs at the interface between the filled and dry parts of the catalyst grain, whereas its vapour is efficiently hydrogenated in the dry part of the grain.

Evidently, to study dynamic processes in a reactor, it was necessary to decrease the MR acquisition time for each image, which is determined primarily by the spin relaxation time of the liquid phase. Hence, subsequent experiments were carried out with grains of the 1 mass % $\text{Pd}/\gamma\text{-Al}_2\text{O}_3$ catalyst containing 0.1 mass % Mn.^{27, 28, 85, 151, 152} This made it possible to acquire two-dimensional images in 34 s. As a result, a number of interesting dynamic processes, such as redistribution of the liquid phase in the granule upon 'ignition' of the catalyst grain, were observed. It is worthy of note that in some experiments, 'ignition' started when the pellet was virtually completely wetted and it led to drying of the grain by more than a half. Most likely, the optimal conditions for the beginning of the process are provided in the near-surface region of the grain, because the temperature directly on the surface is lower due to continuous heat removal by a gaseous reactant flow, while the diffusive transport to inner parts of the grain through pores filled with the liquid is hindered. As a result, 'ignition' begins in the grain at a particular distance from the surface, whereas the near-surface and inner regions of the grain remain filled with the liquid during a much longer period of time. As the liquid reagent is evaporated, the inner wetted region of the grain shrinks, resulting in a decrease in the rate of hydrogen transport to the evaporation – reaction zone. At a particular instant of time, inhibition becomes the main process, the temperature of the grain decreases, and a new cycle of filling of the grain with the liquid begins. Based on these results, a hypothesis can be made that hydrogenation efficiently proceeds in the region under the grain surface, where the optimal balance between the temperature of the grain and the diffusive supply of hydrogen through the pore space is provided.

In longer experiments, numerous grain 'ignitions' giving rise to quasiperiodic oscillations of the liquid that was present in the grain and the back-and-forth motion of the liquid front were observed. These oscillations were observed when the grain was filled with the liquid by more than a half and were accompanied by changes in the amount of the liquid in the grain and its temperature, large gradients of the liquid phase in the grain in the radial direction and the liquid front propagation in a radial direction. The nature of these oscillation is associated with the mutual influence of several processes, such as heat transfer, mass transfer, phase transitions and the chemical reaction itself. This is confirmed by the results of mathematical simulation.¹⁵³

Another type of behaviour is observed when a grain is initially filled with a liquid by less than a half. In this case, the concentration wave propagation along the axis of a cylindrical grain occurs in a plug-like fashion. The largest amount of liquid was detected in the upper part of the grain, where the liquid reactant was delivered. The size of this region and its boundaries continuously oscillated. The remaining part of the grain was filled with a vapour – gas mixture and did not contain the liquid. Evaporation of AMS and the gas-phase reaction led

to temperature oscillations, which were detected in the lower dry part of the grain by a thermocouple located in this region. In the course of oscillations, the instant of time when the largest (smallest) amount of the liquid in the grain was observed did not coincide with the instant of time when the lowest (highest) temperature was detected. In addition, the amounts of the liquid in the upper and lower parts of the grain change out of phase. These observations provide evidence for the delayed feedback between the temperature of the grain and the amount of the liquid in pores.

The oscillating liquid front propagation in a catalyst grain suggests that, under particular conditions, a steady-state reaction can become unstable because of its exothermic character. Subsequent experiments demonstrated considerable sensitivity of the oscillating mode to external conditions. In particular, the existence of oscillations and their periodicity and regularity were found to depend on the activity of the catalyst, the flow rate of liquid AMS and the temperature of the supplied gas.

Experiments with single grains provide information on dynamic processes at a characteristic single-grain size scale. To study processes at larger scales and to investigate interactions and the collective behaviour of grains, experiments were performed with clusters consisting of a small number of spherical catalyst grains with a diameter of 4.2 mm, which form an approximately regular packing containing 3–4 grains in each horizontal layer. Two-dimensional MR images of horizontal sections of the grain packing were obtained. These experiments showed the possibility of ‘ignition’ of individual grains in a layer. These grains can act as microreactors remaining dry after ‘ignition’ due to the efficiency of the reaction in spite of the fact that these grains contact with grains filled with a liquid. In addition, the mutual influence of adjacent grains in the layer was revealed. In particular, it was demonstrated that dry grains can be replenished with the liquid from adjacent wet grains.

In the practice, beds consisting of a huge number of catalyst grains are used. The operation efficiency of a catalytic reactors substantially depends on the liquid phase distribution in a granular bed. It is highly probable that the appearance of hot spots in a bed is also associated with the character of the liquid phase distribution. Hence, it is very important to map the liquid phase distribution in a catalytic reactor for different operation modes. Finally, these investigations will allow establishment of the mechanisms responsible for the development of critical phenomena both at the micro- and macroscale. We carried out a series of investigations of the liquid phase distribution in a granular bed of spherical catalyst grains with a diameter of either 1 or 2–3 mm directly in the course of hydrogenation. In particular, it was found that the liquid phase distribution in a catalyst layer substantially depends on the conditions of reactor start-up. For example, essentially different liquid phase distributions are observed when a liquid reactant is supplied to a dry layer or a layer initially saturated with a liquid.

In subsequent studies, we succeeded in obviating the need for impregnation of catalyst grains with paramagnetic ions to reduce the image acquisition time. Procedures were developed for three-dimensional imaging of the whole catalyst bed with a submillimetre spatial resolution in 20–30 s and for acquiring a set of five two-dimensional sections in 2–3 s each. This, in turn, enabled us to perform the detailed study of the dynamics of the liquid phase redistribution in regular layers of spherical catalyst grains. The results of these investigations confirmed the existence of partially wet catalyst grains over long periods of time, replenishment of dry or partially wet grains with a liquid from adjacent grains and the fluctuating liquid front propagation in partially wet grain (Fig. 5). Evidently, the observation of such effects, which are impossible in a ‘cold’

Figure 5. Liquid phase distribution in a regular bed of a catalyst (1% Pd/ γ -Al₂O₃, catalyst bed diameter is 4.2 mm) directly in the course of octene hydrogenation.

Each image was acquired for 3 s at 0.5–3.5-min intervals; the images show a non-steady-state operation of the reactor; lighter shades of gray correspond to a higher local concentration of the liquid phase.

reactor (in the absence of reaction), is a manifestation of the non-linear coupling of heat and mass transfer processes, phase transformations and a chemical reaction proceeding in the reactor. In the absence of the reaction, the liquid is approximately uniformly distributed as a result of capillary imbibition of the liquid in porous grains. The above-described approaches allow individual imaging of both a liquid phase in porous grains and a liquid filling the space between grains. Experiments demonstrated that the liquid phase transport occurs primarily through film flow over the surface of catalyst grains and showed the possible disturbance of the local phase equilibrium in an exothermic reaction, which creates conditions for the reactor to deviate from a stable operation mode.¹⁵⁴

Images obtained in the above-described experiments reflect the total liquid (both the reactant and the product) distribution. However, NMR is primarily a powerful spectroscopic method. Many available applications are based on a combination of NMR spectroscopy and imaging, which give either spatially localised NMR spectra, *i.e.*, spectra reflecting the local chemical composition, or tomographic images (the spatial distribution of the substance in question). These data are necessary for characterisation of the reactor operation because they provide spatially resolved information on the degree of conversion of the reactants. Undoubtedly, an improvement of combined NMR/MRI techniques for chemical engineering will be one of the main directions of further development in this field.

Unlike high-resolution NMR spectra of bulk solutions, in which the linewidth is often < 1 Hz, NMR spectra of pore-filling liquids are characterised by substantially broader lines. Nevertheless, in room-temperature NMR spectra with a spatial resolution of $2 \times 0.5 \times 0.12$ mm³ of a mixture of AMS and cumene, which fills pores of an alumina grain, the ¹H linewidth is not so large, and at least semiquantitative analysis of the composition of the reaction mixture can be performed.¹⁴⁹ Subsequent experiments were carried out for an operating reactor with a packed bed of catalyst grains with a diameter of 1 mm.¹⁵¹ In three-dimensional experiments (one spectral and two spatial coordinates), NMR spectra were measured for each element of a two-dimensional image. The reactant-to-

product ratios in different regions of the granular layer were determined directly in the course of the reaction by comparing these spectra with the spectra for pure AMS and cumene. The NMR spectrum detected in the upper part, where the liquid reactant is supplied, corresponds to virtually pure AMS; the NMR spectrum detected in the lower part, to the virtually pure product (cumene); the spectrum detected in the middle part corresponds to a mixture of the reactant and the product. Their ratio gradually changes along the height of the layer. In addition, the degree of conversion in the radial direction also varies.

A number of other catalytic reactions (liquid–solid and gas–liquid–solid) were studied by MRI. For example, esterification of methanol and acetic acid giving rise to methyl acetate and water in a reactor with a granular bed composed of small grains of the acidic form of an ion-exchange resin was documented.¹⁵⁵

The spatial pattern of the degree of conversion in a reactor was obtained by combining the spectroscopic and MRI methods. It was found that the concentration of the product along the length of the reactor increases and the degree of conversion decreases as the flow rate increases. The variations of the conversion in the radial direction are as high as $\sim 20\%$. All experiments were carried out under stationary conditions, because the signal acquisition time was long. Later, investigations aimed at revealing correlations between the degree of conversion and the transport characteristics of the reactor with a granular bed were performed.^{68, 156} For example, the plot of the local conversion *vs.* the local rate showed a good correlation between these two parameters in spite of the fact that the degree of conversion is not a local characteristic. An approach used in the studies^{68, 155, 156} is based on the detection of ^1H NMR signals of the OH groups of acetic acid, methanol and water, which coalesce into one broadened line as a result of fast proton exchange. The position of this line in the spectrum depends on the relative concentrations of all three compounds. This approach is limited to a particular class of reactions. A more common approach, which is based on the use of MRI with a spectroscopic resolution, was successfully used¹⁵⁷ for catalytic esterification of propionic acid and butan-1-ol giving rise to butyl propionate and water with the use of an enzyme immobilised on a single calcium alginate grain,

Experiments with the use of one spatial coordinate and one spectroscopic coordinate made it possible to trace the increase in the intensity of the signals of water and butyl propionate and the decrease in the intensity of the signal of butanol in the grain in the course of the reaction.

Multinuclear MRI produces images from not only the ^1H NMR signal but also from signals of other magnetic nuclei. In particular, the ^{13}C nucleus is characterised by a substantially broader range of chemical shifts than the ^1H nucleus, which, in principle, enables one to obtain substantially more accurate quantitative spectral information even in the case of substantial line broadening in NMR spectra. However, since the natural isotopic abundance of ^{13}C is very low (1.1%), the quality of images is poor and, consequently, a long time is required for image acquisition or it is necessary to use isotope-labelled compounds. Nevertheless, such investigations were documented. The competitive transformation of 2-methylbut-2-ene into *tert*-amyl methyl ether and *tert*-amyl alcohol at 40°C catalysed by ion-exchange resin grains ($600\text{--}850\ \mu\text{m}$) in a reactor with a diameter of $15\ \text{mm}$ was studied.¹⁵⁸

Two-dimensional integrated images of a reactor were acquired, and a ^{13}C NMR spectrum was measured for each element. The conversion of 2-methylbut-2-ene into ether and alcohol was found to be gradually increased in the axial direction, the selectivity to ether being retained at $\sim 75\text{--}80\%$. Both the selectivity and the conversion fluctuate in the transverse direction, the variation of the conversion for a fixed axial coordinate being $\sim 15\%$. The equilibrium magnetisation transfer from ^1H to ^{13}C nuclei was used to compensate, in part, for the loss of sensitivity in experiments with a natural isotopic abundance of ^{13}C . However, even in this case, a moderate spatial resolution ($2.5 \times 3.75\ \text{mm}$, without slice selection) was achieved at the acquisition time of one image of 16 h. The ^{13}C NMR signal detection was used also in investigations of hydrogenation and isomerisation of oct-1-ene.¹⁵⁹ To record spectra with a spatial resolution of $2.8\ \text{mm}$ along one coordinate integrated over two other coordinates, more than a quarter of an hour was required.

In spite of considerable difficulties in performing MRI of gases and problems associated with the use of high temperatures in a probe of a microimaging instrument, some research teams designed special apparatus and proceeded to studies of high-temperature gas-phase reactions. For example, to perform MRI studies of combustion processes, a probe with water cooling and a system for removing combustion products was designed.¹⁶⁰ In the experiments, the behaviour of gas streams before and after methane ignition was compared. A stream of the unignited gas was visualised a flow rate of up to $2\ \text{m s}^{-1}$ from an orifice with a diameter of $1\ \text{mm}$. In the presence of flame, an NMR signal gradually disappears at a distance of $\sim 3\ \text{mm}$ from the orifice. The acquisition time of each image was several hours.

One possible way of enhancing the sensitivity in gas-phase MRI experiments is based on the use of hyperpolarised gases (see Section III). In particular, this approach was applied in studies of non-catalytic methane combustion over the surface of a granular layer of partially dehydrated zeolite NaX.¹⁶¹ A mixture of hyperpolarised $^{129}\text{Xe}^*$ and methane was supplied to the layer together with air from the bottom, and the process was studied by recording ^{129}Xe NMR spectra without spatial resolution. Due to very high sensitivity of the ^{129}Xe chemical shift to the environment, the authors succeeded in visualising different regions in the cell, which differ in the concentration of xenon, the composition of the mixture and the temperature. The exchange between these regions in the course of combustion was studied by two-dimensional exchange NMR spectroscopy.

3. Hydrogenation with parahydrogen

Hyperpolarised gases and liquids can be prepared by hydrogenation. Molecular hydrogen (H_2) is a mixture of two spin isomers, *viz.*, orthohydrogen ($o\text{-H}_2$, the total nuclear spin $I = 1$) and parahydrogen ($p\text{-H}_2$, $I = 0$). Only orthohydrogen gives an observable NMR signal due to RF-induced transitions between three spin sublevels. The spin relaxation times of the ^1H NMR signal under normal conditions are rather short ($T_1 = 3\ \text{ms}$, $T_2 = 0.4\ \text{ms}$). However, states with different multiplicities are not mixed in relaxation process, and the time of the ortho–para conversion for hydrogen under normal conditions can be as long as one year. Hence ortho- and parahydrogen can be considered as two different gases, one of which ($p\text{-H}_2$) is generally not involved in NMR experiments because it has the zero nuclear spin.

At room temperature, the $o\text{-H}_2 : p\text{-H}_2$ equilibrium ratio is close to a random value (3 : 1). At lower temperatures, the equilibrium is shifted to $p\text{-H}_2$. At the liquid hydrogen temperature, the equilibrium mixture consists virtually exclusively of $p\text{-H}_2$. At $77\ \text{K}$, the equilibrium ratio is approximately 1 : 1. Taking into account the low rate of spontaneous ortho–para

conversion, normal hydrogen is cooled over a catalyst for ortho–para conversion to achieve the equilibrium. Paramagnetic compounds [FeO(OH), activated carbon, *etc.*] are commonly used as catalysts for this process. An advantage of a low rate of spontaneous conversion is that, after the establishment of the equilibrium at low temperature, hydrogen can be stored at room temperature over a long period of time, no substantial changes in the o-H₂:p-H₂ ratio being observed.

Non-equilibrium mixtures of ortho- and parahydrogen are characterised by the presence of an overall correlation of nuclear spins in an ensemble of molecules. For this correlation to be observed in NMR spectra, it is necessary to break the magnetic equivalence of nuclear spins of two hydrogen atoms. Evidently, this can be achieved by using parahydrogen in hydrogenation, as a result of which two hydrogen atoms in the reaction product are in non-equivalent positions. It is important that two atoms of one hydrogen molecule be added to one substrate molecule, which retains the initial correlation of nuclear spins. In this case, the intensity of the NMR signal of the reaction product increases by a factor of 4×10^4 for a spectrometer with a magnetic field of 7 T and this signal is even more enhanced in weak fields. The spectral manifestation of parahydrogen-induced polarisation depends on the experimental scheme. If hydrogenation is performed directly in an NMR probe, the spectrum shows two antiphase multiplets (the PASADENA effect, parahydrogen and synthesis allow dramatically enhanced nuclear alignment). If the reaction is performed in magnetic field of the Earth followed by the transfer of a sample to a probe of a spectrometer, a net enhancement of two multiplets having opposite signs is observed (ALTADENA, adiabatic longitudinal transport and dissociation engender net alignment).^{162, 163}

During 15 years, hydrogenation with parahydrogen was used primarily in studies of the reaction mechanisms of homogeneous hydrogenation with transition metal complexes (for example, with the Wilkinson and Vaska catalysts). The reaction mechanism implies the formation of a metal dihydride complex as a short-lived intermediate. The use of parahydrogen in hydrogenation allows an increase in the intensity of the NMR signal by several orders of magnitude and, consequently, it is possible to detect ¹H NMR spectra of intermediate dihydride complexes.¹⁶⁴ Parahydrogen-induced polarisation was observed in homogeneous processes involving different Rh, Ir, Ru, Pt and Os complexes. Detailed studies of the kinetics and mechanism of homogeneous hydrogenation reactions involving such complexes were carried out with the use of parahydrogen as a spin label, and in some cases the new intermediate species were detected.^{165–168} As a result of polarisation transfer from protons to other nuclei (¹³C, ³¹P, ¹⁵N, ¹⁹F), a much more detailed spectroscopic information can be obtained.^{169–172}

Interest in the use of parahydrogen for enhancement of the NMR signal was rekindled after the publication of the study,¹⁷³ where hydrogenation with parahydrogen was used for the first time to enhance the signal in MRI. In this study, hydrogenation was followed by polarisation transfer to ¹³C nuclei by varying the external magnetic field. Then the solution was injected into a blood vessel of a laboratory animal and an MR image was recorded. The use of this procedure and its subsequent modifications^{169, 174} allowed the authors to acquire two-dimensional images of a blood vessels (angiograms) from the ¹³C NMR signal of the reaction product in less than 1 s with a natural isotopic abundance of ¹³C.

The presence of a catalyst in solution is a drawback of the approach used in the studies,^{169, 173, 174} which substantially limits its application in studies of living organisms and makes it impossible to perform these investigations in medical purposes. In addition, this fact hampers the development of technical applications of MRI. For example, the construction

of systems with a continuous polarised fluid (liquid or gas) flow for MRI of different objects with the use of homogeneous hydrogenation requires large amounts of an expensive catalyst. In principle, the catalyst can be removed from solution with an appropriate adsorbent.¹⁷⁵ However, the polarisation relaxation time is equal to a few seconds and is additionally decreased in the case of a contact between the product and a porous material.

Up to 2007, data on parahydrogen-induced polarisation in heterogeneous reactions were lacking. It should be noted that polarisation was observed¹⁷⁶ when performing hydrogenation on colloidal (Pd)_x[N(n-C₈H₁₇)₄Cl]_y particles in a liquid. However, it cannot be ruled out that the solution simultaneously contained the dissolved metal complex, which was responsible for the observed polarisation. In addition, the authors of this study mentioned the commonly accepted view that polarisation of the product is impossible in heterogeneous catalytic hydrogenation with parahydrogen. Actually, many industrial hydrogenation catalysts are highly dispersed metal (Pt or Pd) particles deposited on a porous support (for example, Al₂O₃). It is commonly accepted that hydrogenation on these catalysts involves dissociative chemisorption of hydrogen on metal particles, hydrogen migration over the particle surface and spillover onto the support. Under these conditions, the probability that the correlation of nuclear spins of the starting parahydrogen molecule will be retained and that two hydrogen atoms of one H₂ molecule will be present in one product molecule is negligibly small. Hence, until recently, it was believed that parahydrogen-induced polarisation can be observed only in homogeneous catalytic processes with all attendant problems and drawbacks.

In recent years, experts in catalysis have made great efforts to establish bridges between homogeneous and heterogeneous catalytic processes.¹⁷⁷ In many cases, homogeneous catalysts exhibit much higher activity and selectivity; however, the unbeatable advantage of heterogeneous catalysts is that the latter can easily be removed from the reaction mixture. Presently, the latter fact is of key importance not only in view of strengthening of environmental requirements for industrial processes, but also because the catalysts become considerably more expensive as their structure gets progressively more complex. In this connection, a combination of the advantages of homogeneous and heterogeneous catalysis by immobilisation of homogeneous catalysts on an appropriate porous support is one of increasing trends in modern catalysis.^{178, 179} Nowadays, several procedures are available for immobilisation based on formation of hydrogen bonds, ion pairs, covalent attachment to organic or inorganic supports, *etc.* Many of these procedures were used also in the design of new hydrogenation catalysts^{180–185} characterised by high stability, efficiency and selectivity in heterogeneous hydrogenation under mild conditions. It is important that, in many cases, the chemical structure of metal complexes does not undergo substantial changes upon their immobilisation. Consequently, the reaction mechanism presumably remains unchanged upon immobilisation. However, it is difficult to obtain direct evidence for this fact.

Polarisation in heterogeneous hydrogenation with parahydrogen was observed for the first time in the study by Koptug *et al.*¹⁸⁶ (Fig. 6). For this purpose the following three catalysts were used: the Wilkinson catalyst (**1**) immobilised on a styrene–divinylbenzene copolymer (**1**/polymer), the same catalyst immobilised on modified silica gel RhCl(PPh₃)₂PPh₂(CH₂)₂–SiO₂ (**1**/SiO₂) and the immobilised tridentate complex Rh(cod)(sulfos)–SiO₂ (**2**/SiO₂; cod is cycloocta-1,5-diene; sulfos is –O₃S(C₆H₄)CH₂C(CH₂PPh₂)₃). In one series of experiments, hydrogenation was carried out in magnetic field of an NMR spectrometer. For this purpose, a tube with a solution of the substrate (styrene) and the catalyst

Figure 6. Parahydrogen-induced polarisation of nuclear spins in heterogeneous hydrogenation of unsaturated compounds.

(a) ALTADENA for propylene hydrogenation ($R = \text{Me}$) in weak field at $130\text{ }^{\circ}\text{C}$, (b) PASADENA for styrene hydrogenation ($R = \text{Ph}$) in strong field at $60\text{ }^{\circ}\text{C}$. In both cases, equilibrium NMR signals of the reaction product are negligibly small.

($1/\text{SiO}_2$ or $1/\text{polymer}$) was placed in a probe of the spectrometer and heated to $65\text{--}80\text{ }^{\circ}\text{C}$. Both catalysts efficiently hydrogenate styrene to ethylbenzene. In reactions with the use of enriched parahydrogen, both catalysts lead to substantial polarisation of nuclear spins in the reaction product and give rise to the characteristic antiphase structure of multiplets in the NMR spectrum (PASADENA, see Fig. 6b). The NMR spectra of the product, which was prepared by hydrogenation outside a magnet followed by the transfer of the sample to a probe of an NMR spectrometer, show multiplets with net polarisation of opposite signs (ALTADENA). It was also found that after removal of the catalyst from the solution, bubbling with hydrogen did not lead to either the formation of the product or polarisation. These results confirm that polarisation upon hydrogenation with parahydrogen was observed in a heterogeneous process for the first time.

Besides, hydrogenation with parahydrogen was applied for the first time¹⁸⁶ to generate nuclear spin polarisation in gases. For this purpose, catalysts immobilised on a porous support ($1/\text{SiO}_2$ or $2/\text{SiO}_2$) were used. To observe the PASADENA effect, the tube with a dry catalyst was placed in an NMR probe and heated to $80\text{ }^{\circ}\text{C}$. A mixture of propylene and enriched parahydrogen was continuously introduced into a tube through thin capillaries. The nuclear spin polarisation of the reaction product, *viz.*, propane, was determined from NMR spectra. To observe the ALTADENA effect, the reaction was carried out outside a magnet. For this purpose, a mixture of propylene and enriched parahydrogen was continuously purged through a copper tube packed with a catalyst heated to $130\text{ }^{\circ}\text{C}$ and then passed to an NMR probe (see Fig. 6a). The observation of polarisation upon hydrogenation of a gas is

unambiguous evidence for the fact that nuclear spin polarisation can be produced not only in homogeneous but also in heterogeneous processes. Later, polarisation in hydrogenation of propylene with parahydrogen was achieved with the use of the silica gel-immobilised $\text{RhCl}(\text{POMe}_3)_3$ complex.

In further investigations,¹⁸⁷ the possibility of the preparation of a hyperpolarised gas in heterogeneous hydrogenation was used for MR imaging of model objects; NMR tubes with cross-shaped partitions or capillary bundles mounted inside the tubes were used as such objects. As in the earlier experiments,¹⁸⁶ hydrogenation of propylene was performed using a continuous flow of a gas mixture through a heated catalyst. Then the polarised product (propane) was delivered through a system of tubes to the model object, and the MR image was obtained by detecting the NMR signal of the polarised gas. Until recently, the preparation of hyperpolarised gases was limited primarily by laser polarisation of noble gases (see Section III). Therefore, the results of the studies^{186, 187} substantially extended the range of gases, for which the signal-to-noise ratio in MRI experiments can be substantially improved by producing nuclear spin polarisation.

The above-described results are of importance for several reasons. First, the observation of polarisation of the product with the use of parahydrogen is direct evidence for the pair-wise addition of two hydrogen atoms of an H_2 molecule to one substrate molecule. Therefore, these results confirm that the reaction mechanism of hydrogenation by metal complexes remains unchanged upon their immobilisation onto a support. Second, the pair-wise addition is a necessary but not sufficient condition for observation of polarisation. After the formation of the dihydride complex, two hydrogen atoms become non-equivalent and their spin correlation decays due to spin relaxation.¹⁸⁸ Immobilisation of the complex leads to a substantial decrease in molecular mobility, and the spin relaxation times can be substantially shorter than the spin relaxation times of complexes in solution. The observation of polarisation indicates that the lifetime of intermediate dihydride cannot be substantially longer than its spin relaxation time.

The preparation of pure fluids with polarised nuclear spins opens a broad spectrum of new possible applications, particularly, those associated with the NMR signal detection in low and ultra-low magnetic fields,^{189, 190} where the equilibrium differences in the populations of spin energy sublevels are very small. The possibility of creating continuous flows of polarised fluids is particularly attractive. This possibility was exemplified by heterogeneous hydrogenation of propylene. Efficiency of biomedical experiments with parahydrogen-induced polarisation can be increased using solid catalysts. In addition, many studies based on homogeneous hydrogenation with parahydrogen are characterised by an uncertain duration of this process because the termination of bubbling of a solution with parahydrogen does not lead to the immediate termination of the reaction. This substantially complicates the interpretation of the results.^{170, 191} It is important to obtain pure quantum states in experiments with the use of parahydrogen-induced polarisation aimed at designing quantum computers.^{192, 193}

In view of the results of recent investigations, hydrogenation with parahydrogen has yet another important potential application in NMR. Many modern NMR and MRI experiments are based on the creation of particular perturbation of a spin system, which then undergoes evolution over a particular period of time. The evolution is followed by the 'read-out' of the new state of the spin system. This principle provides the basis for the diffusion coefficient and flow rate measurements,^{139, 194} different two-dimensional NMR spectroscopic experiments,¹⁹⁵ *etc.* If the evolution period is substantially longer than the spin relaxation times, the detection of the final state of the spin system does not give useful information on the

processes in question. Hence, until recently, researchers have believed that the maximum evolution time is comparable with the spin–lattice relaxation time (T_1) of the spin system. However, recently it has been demonstrated^{196,197} that this limitation can be overcome by using the unique properties of singlet spin states. Actually, for pairs of equivalent nuclei with spin 1/2, the states with a certain total spin of the pair are the eigenstates of the Hamiltonian: singlet ($I = 0$) and triplet ($I = 1$). This is also the case with a hydrogen molecule (see above). The spinless singlet state is not involved in relaxation processes which affect the NMR spectra, and the interconversion time between states with different total spins can be longer than the spin relaxation times by an order of magnitude or larger.^{196,197} As in the above-considered NMR of parahydrogen, the singlet state of a pair of nuclei is not directly involved in NMR experiments. Hence, to use the unique properties of singlet states, it is necessary to construct a molecular system in which the magnetic equivalence of a pair of nuclei could be ‘switched on’ and ‘switched off’ under the external action on the spin system. So far, the two different ways of performing this switching have been suggested: the physical transfer of a sample from a weak magnetic field to a strong field and back¹⁹⁷ or prolonged RF irradiation of the spin system in a strong field of a spectrometer.¹⁹⁶ For example, the measured lifetime of the singlet state (T_s) of 2,3-dibromothiophene in DMSO- d_6 in weak field was 104 s ($T_1 = 17$ s).¹⁹⁷ For 2-chloroacrylonitrile in DMSO- d_6 , $T_s = 141$ s ($T_1 = 7.8$ s) in the case of continuous RF irradiation.¹⁹⁶

Practical outputs of these investigations hold considerable promise. A substantial increase in the lifetime of spin coherence can be useful in studies of slow transport processes. For example, the use of long-lived singlet states in experiments on measurements of molecular diffusion coefficients (D) by PFG NMR at $T_s = 10 T_1$ allows a decrease of the lower detection limit of D by an order of magnitude, all other factors being the same. An example of the application of this approach was described in the study,¹⁹⁸ where the diffusion coefficients of 2-chloroacrylonitrile in a DMSO- d_6 –D $_2$ O mixture were measured in the temperature range from -46 to $+25$ °C. Long-lived spin states hold promise also in investigations of very slow dynamic processes, such as chemical exchange, conformational transformations, protein and RNA refolding, etc. Two-dimensional exchange spectroscopy with the use of long-lived singlet states was proposed in the study.¹⁹⁹ This study dealt with conformational transformations of monosaccharide, in which all hydrogen atoms, except for two atoms, were replaced by deuterium. The lifetime of the singlet state for this pair of protons was demonstrated to be 37 times longer than T_1 . In an exchange experiment, the mixing time allotted for a conformational change of the molecules was 12 s ($T_1 = 0.7$ s).

The extensive development of the theory of long-lived spin states is presently underway.^{200–204} Evidently, the use of states with lifetimes substantially longer than T_1 also shows promise for imaging applications, particularly, for liquid and gas flows, for example in the remote imaging (see Section III). A combination of the properties of long-lived singlet states and nuclear polarisation produced by hydrogenation with parahydrogen is also promising.^{170,191} The initially produced state of a pair of nuclear spins in the reaction product is singlet, and an additional advantage is that an excess of these states in an ensemble of molecules increases by several orders of magnitude.

V. Conclusion

In recent years, the number of studies in the area of physico-chemical applications of the MRI technique has rapidly increased. In addition to a substantial extension of the range of objects and processes, the MRI technique itself underwent

considerable changes. This stage of investigations is characterised by the development of new applications, which have been considered to be impossible to implement in practice until recently. These are studies of solids without the use of solid-state NMR techniques, investigations of gas transport, studies of high-temperature reactions, etc. In addition, the development of methods of nuclear spin hyperpolarisation and spectroscopy of singlet spin states opens new prospects for the further progress in MRI.

We thank our colleagues engaged in these investigations and particularly our co-authors working at the Borskoy Institute of Catalysis of the Siberian Branch of the Russian Academy of Sciences. The research has been performed with the financial support of the Russian Foundation for Basic Research (Project No. 05-03-32472), the Division of Chemistry and Materials Science of the Russian Academy of Sciences (Project Nos 5.2.3 and 5.1.1), the Siberian Branch of the Russian Academy of Sciences (Integration Grant 11), the Programme for State Support of Leading Scientific Schools of the Russian Federation (Grant NSH-4821.2006.3), the Russian Science Support Foundation (I V Koptug and A A Lysova), the Council on Grants of the President of the Russian Federation (Grant MK-5135.2007.3) and the Global Energy Foundation (A A Lysova).

IV. Magnetic field effects in enzymatic reactions catalysed by horseradish peroxidase	604
V. Conclusion	612

Abstract. The results of spin chemistry studies of the single electron transfer step and the role of spin states of paramagnetic intermediates in the enzymatic oxidation of organic substrates induced by horseradish peroxidase are generalised. Detailed theoretical description of the approach used to analyse the magnetic field effects in enzymatic multispin systems is presented. Prospects for the use of spin chemistry techniques for elucidation of the mechanisms of radical steps of enzymatic processes are considered. The bibliography includes 80 references.

I. Introduction

Spin chemistry methods are used in studies of radical reactions the rates and, often, directions of which depend on the orientation of the electron and nuclear spins of transient radical species and on the strength of external and local magnetic fields. Spin chemistry became an individual avenue of chemical research nearly twenty-five years ago and currently there is no need to introduce it to the reader. The term ‘spin chemistry’ refers to the chemistry of the radical processes mentioned above and to the methods employed. The latter comprise the methods based on the phenomena of chemically induced dynamic electron and nuclear polarisation (CIDEP and CIDNP, respectively), magnetic field effect (MFE), magnetic isotope effect (MIE) and related techniques that have been comprehensively described in a number of reviews and monographs (see, e.g., Refs 1 and 2).

After completion of theoretical description of the magnetic field effects detected in model systems, the last decade was marked by the trend to practical application of this knowledge to the studies of complex chemical and biochemical processes by spin chemistry. This avenue of research seems to be quite

important because elucidation of the structure and properties of short-lived intermediates in chemical reactions belongs to the key problems in modern chemistry. Spin chemistry methods make it possible to study paramagnetic intermediates with lifetimes from a few nanoseconds to a few microseconds, viz., radical ions and neutral free radicals, biradicals, carbenes and carbene analogues and triplet-excited molecules.

The involvement of radical ions, radicals and biradicals in some reactions was only postulated; remarkable examples of successful use of the CIDNP and MFE techniques for elucidation of the mechanisms of these processes have been reported.^{3–5} Of particular interest are recent spin chemistry studies in biology⁶ including investigations of oscillatory enzymatic reactions,⁷ structural features of reversible protein folding,⁸ type of the intermediates in the reactions of B₁₂-dependent enzymes⁹ and simulation of protein–nucleic acid interactions.¹⁰

Recently, the experimental data suggesting that free-radical states initiate processes that damage cell structures, certain proteins and nucleic acids have been accumulated increasingly.¹¹ It is believed that free radicals are responsible for the development of cardiovascular diseases,¹² compromised immune response,¹³ cataract development,¹⁴ development of Parkinson’s disease,¹⁵ schizophrenia,¹⁶ and Alzheimer’s disease,^{15, 17} as well as accelerated ageing and higher risk of cancer.¹⁸ According to modern concepts, destructive changes in living organisms are most probably due to the processes involving reactive oxygen species and oxygen-containing radicals (O₂^{•−}, HO₂[•], HO[•] and ¹O₂) that induce oxidative stress, diseases and senilism.¹⁹ In this connection, a demand arose for spin chemistry studies of reactive paramagnetic intermediates in biological systems.

Paramagnetic species play an important role in some processes that are responsible for normal activity of mammalian cells.²⁰ The involvement of radical species in many biological processes was reviewed.^{21, 22} Enzymatic processes in living systems are sources of various free radicals, in particular, HO₂[•] (Ref. 23). The present review is devoted to reaction mechanisms of horseradish peroxidase (HRP), which is the source of intermediates that react with many free radicals; of note is the appearance of the expression ‘the free-radical chemistry of peroxidase’.²⁴ Peroxidase is present both in mammalian organisms and plants, where it decomposes toxic hydrogen peroxide and can serve as a scavenger of free radicals. It should be noted that at present researchers are far from

knowing all sources of free radicals in the living systems in health and disease.

Taking into account the aforesaid, studies on the elementary processes resulting in emergence of free radicals, in particular, enzymatic reactions, are of considerable interest. The mechanisms of enzymatic reactions are studied by various modern physicochemical methods. Identification of paramagnetic species often faces severe difficulties.²⁵ Problems concerned with detection of free radicals by EPR spectroscopy (low steady-state concentrations of radicals in biological systems) are well known.²⁶ Using the spin trap technique in EPR spectroscopy, one can solve the 'concentration' problem, but some new problems often arise, *e.g.*, the need of suppression of EPR signals corresponding to further transformations of spin traps and stable radicals that formed.²⁶ In addition, when observing the EPR signal of a free radical, it is unclear whether the radical is involved in the process under study or it is the side reaction product. Spin chemistry studies of radical intermediates in biological processes could answer this question. Clearly, enzymatic processes are also promising subjects for spin chemistry studies, because chemical transformations in the active sites of many metal-containing enzymes involve spin-change reactions and interconversions of the intermediates existing in different spin states; it is the oxidation states of such metals as Fe, Cu, Zn, *etc.* that are dealt with. For instance, the catalytic cycle of HRP involves reliably characterised reactive intermediates, the so-called HRP-Compounds the active sites of which contain iron atoms in different oxidation and spin states (high-spin state in native HRP and ferroperoxidase and low-spin state in Compounds I–III).²⁴

N(His) is the nitrogen atom of histidine.

However, until very recently the lack of comprehensive theoretical description of multispin systems precluded the extension of spin chemistry studies of enzymatic processes. Even a few years ago a relevant theoretical description (radical pair theory) was only developed for the cases where reaction products were formed from radical pairs with half-integer spins ($S = 1/2$). Meanwhile, iron-containing intermediates in the high-spin states are paramagnetic intermediates in many biological processes (*e.g.*, in reactions involving iron ions or haem-containing enzymes including HRP and cytochromes). Usually, in such systems a multi-electron atom having several unpaired electrons serves as the radical centre.²⁷ Here, analysis of the MFE requires knowledge of the specific features of the evolution of spin states in multispin systems. At present, intensive experimental research of multispin systems has been carried out taking the processes in radical pairs (RP) induced by the so-called third or fourth spin (usually, the spins of stable radicals or biradicals) as examples.^{28,29} Progress in this field of research, which is in the early stage of development (accumu-

lation of experimental results), was stimulated by the studies^{30,31} in which a novel phenomenon called 'spin catalysis' was discovered.

The magnetic field effects treated in a broad sense, *i.e.*, the effects of external magnetic fields on various processes in living organisms, from migratory orientation of birds to the effect of the so-called magnetic storms on human health, belong to popular subjects of research.³² Since such effects undoubtedly have a complex nature, detection of the changes occurring in the presence of a magnetic field usually provides no information on the mechanisms of generation of the MFE signals and on the magnetic field-sensitive steps of the processes under study.

Mechanistic studies of the magnetic field effect on particular stages of *in vitro* processes using spin chemistry techniques are much more informative. These methods were used for comprehensive treatment of enzymatic processes involving magnetic field sensitive steps with participation of the pairs of paramagnetic species generated in single-electron transfer reactions.^{33–35} Conclusions about the involvement of radical pairs in an enzymatic process are based on a comparison of the experimental and calculated dependences of the rate constants for transformations of paramagnetic intermediates on the magnetic field strength. Such studies were carried out for transformations of reactive paramagnetic intermediates in the catalytic cycle of the oxidation of some HRP substrates in the steady-state^{33–35} and oscillatory regimes.⁷ An important result of these investigations consists of the demonstration of the role of spin states of the paramagnetic intermediates in the catalytic cycle of the enzymatic process.

The magnetic field effects in biological systems were considered in a review,⁶ which also summarised the data on possible biological effects under the action of static and alternating magnetic fields. In the present review, we make an attempt at systematisation and interpretation of the available material concerning theoretical description of the spin and magnetic field effects in multispin enzymatic systems and the results obtained in experimental studies of the dependences of the rates for enzymatic oxidation of organic substrates by horseradish peroxidase on the strength of the external magnetic field.

II. Phenomenological description of the magnetic field and spin effects in enzymatic systems

Reactions the rates and, sometimes, directions of which depend on the orientation of the electron and nuclear spins of the paramagnetic precursors of reaction products are the major subject of spin chemistry studies. An example of such a reaction is shown in Scheme 1.

Scheme 1

A radical pair emerged in, *e.g.*, photochemical or thermal decomposition of a molecule exists in one of the two correlated spin states, namely, in a singlet (S) or a triplet (T) state. The total electron spin of the radicals is equal to zero in the former state and unity in the latter. Usually, the triplet state of the radical pair is non-reactive (or low reactive),¹ and the RP recombination mainly occurs from the singlet state. Magnetic and spin interactions induce transitions between the non-reactive T -state and reactive S -state (the so-called $T \rightarrow S$ -transitions responsible for the change in the fraction of the reactive species). These singlet–triplet transitions represent the

physical essence of the spin and magnetic field effects in chemical processes. The most important magnetic interactions that induce the singlet–triplet transitions and affect their efficiency include the Zeeman interaction of the unpaired electrons in the RP with the external magnetic field, hyperfine coupling (HFC) between the electron spins and the magnetic nuclei (nuclei with a non-zero nuclear spin I) of the radicals and electron exchange interaction between the unpaired electrons in the RP. Figure 1 schematically presents two limiting cases of singlet–triplet mixing. For instance, in weak magnetic fields (Fig. 1 *a*) the hyperfine interaction induces S – T -transitions between all the three triplet Zeeman sublevels (T_0 , T_{+1} and T_{-1}) and the recombining singlet state (HFC-mechanism of singlet–triplet transitions). In strong external magnetic fields that exceed substantially the local magnetic fields due to HFC, a large splitting between the T_{+1} and T_{-1} sublevels leads to the situation where the hyperfine interaction only affects the transitions between the singlet state and one triplet state (T_0). Isotropic hyperfine interaction does not involve the other two triplet states (T_{+1} and T_{-1}) in the S – T -transition (Fig. 1 *b*). Mixing of the S and T_0 states of a radical pair can also be due to the g -factor difference between the radicals (Δg -mechanism of singlet–triplet transitions). Thus, even weak (*e.g.*, Zeeman and hyperfine) magnetic interactions the constants of which are 5–6 orders of magnitude lower than kT can increase the fraction of the reactive state of the radical pair owing to the S – T -transition.

Figure 1. Energy levels of a radical pair and allowed transitions between the S - and T -states in weak (*a*) and strong (*b*) magnetic fields.

The manifestation of singlet–triplet transitions requires that the RP lifetime be rather long. In a condensed medium, this can be attained due to the cage effect. This effect determines two key features of the reactions under study, namely, the relatively long time of contact between partners and the possibility of repeated contacts of the same pair of reactants in the course of diffusion motion. The characteristic cage size (R) and the residence time (τ) of the reactants in the cage are governed by the kinematics of the relative motion, interaction between the reactants and some other properties. For instance, the hyperfine coupling constant between the unpaired electrons and magnetic nuclei (ω , in frequency units) in organic free radicals is of the order of about 10^8 – 10^9 rad s $^{-1}$ and the probability of singlet–triplet transitions on the time scale $\tau \sim 10^{-9}$ – 10^{-10} s is

$$\omega\tau \sim 0.01\text{--}0.1.$$

The probability of S – T -transitions increases with an increase in the viscosity of the solution (as τ increases) or in the reactions involving radical ion pairs (due to the Coulomb interaction between the partner radicals).

The singlet–triplet conversion depends on the orientation of electron and nuclear spins of the partners in the RP and the singlet–triplet conversion rate is affected by the HFC, Δg and external magnetic field. An important consequence is the possibility of manifestation of the magnetic field and spin effects (MIE and CIDNP) in chemical and biochemical reactions.

The MIE is due to the T – S conversion rate difference between the radical pairs containing magnetic nuclei and the RP devoid of such nuclei. The MIE provides the isotopic selectivity in different reaction products. Chemically induced dynamic nuclear polarisation is a manifestation of the α - and β -spin selection in different reaction products. When carrying out the reaction in the probe of an NMR spectrometer, the lines observed in the NMR spectra at the very beginning of the process correspond to the distribution of the spin sublevel population that differs from the Boltzmann (equilibrium) distribution. A detailed description of the spin and magnetic field effects can be found in a monograph.¹

At present, the effect of the external magnetic field and CIDNP were detected for a number of chemical processes, such as single-electron transfer steps in the reactions previously treated as nucleophilic substitution;³ *cis*–*trans*-isomerisation of alkenes including biologically valuable polyenes (retinal and carotenoids);³⁶ donor-acceptor interactions of synthetic analogues of nicotinamide adenine dinucleotide (NADH), namely, 1,4-dihydropyridines containing electron-withdrawing groups^{37–40} and many other processes.

Now we will consider the specific features of manifestation of the magnetic field and spin effects in biochemical systems. In homogeneous solutions, a strong cage effect is most probably due to a high viscosity of the solvent and to the electrostatic interaction between partners in radical ion pairs. Pronounced cage effects are also characteristic of the reactions occurring in molecularly organised media, *e.g.*, liposomes, micelles, ‘guest–host’ inclusion complexes, *etc.* (here, the time spent by radical pairs in the contact zone due to the so-called weak interactions is longer than in non-viscous systems). Weak interactions also include the enzyme–substrate interactions (enzyme–substrate binding) in the active site of enzyme, which is usually considered as the main factor responsible for the high selectivity of enzymatic processes.⁴¹ By analogy with well-studied processes in complexes or micelles,⁴² one can expect that the radical intermediates formed in an enzymatic process will also form quite a long-lived enzyme–substrate complex. Binding of the partners in the active site of enzyme gives grounds to expect manifestations of rather strong electron exchange interaction between paramagnetic species in the enzyme–substrate complexes, which can be detected by spin chemistry techniques.

Now we have to dwell on basic differences between manifestations of the magnetic field and spin effects in homogeneous radical and enzymatic processes. In a radical reaction, the magnetic field effects consist of a change in the ratio of the recombination probability of free radicals to the probability of their escape into the bulk.¹ In enzymatic reactions, where the paramagnetic intermediates are involved in the catalytic cycle, two different spin states of a pair of paramagnetic species (corresponding to recombination and escape to the bulk, see Scheme 1) can characterise different steps in the catalytic cycle. Thus, the magnetic field will affect the ratio of recombination probabilities (or back electron transfer in the case of single-electron transfer) and transition to the next step in the catalytic cycle. As an example, we will consider a model catalytic cycle shown in Scheme 2.

The cycle begins with the formation of an enzyme–substrate complex $[E\cdots SH]$ in which an electron is transferred from the donor (substrate) to acceptor (enzyme) to form the $(P_1 SH^+)$ radical pair in, *e.g.*, the singlet state. Magnetic interactions induce the singlet–triplet conversion; when the RP is in the singlet state, back electron transfer (recombination) and regeneration of the starting enzyme (E) and substrate (SH) are possible. The triplet RP is a precursor of the next stage of the catalytic cycle, which involves the formation of the intermediate P_2 . Thus, this example clearly demonstrated the possibility of the effect of the spin states of paramagnetic

Scheme 2

intermediates on the rates of the processes occurring in the catalytic cycle of the enzyme.

The effect of the magnetic field on an enzymatic process will manifest itself as the dependence of particular steps of the catalytic cycle on the strength of external magnetic field. In this case, the magnetic field effect can be defined as the ratio of the rate constants for the reactions carried out in a magnetic field of specified strength to the corresponding rate constants measured in zero (geomagnetic) field. Analysis of the magnetic field effects detected in enzymatic processes involves measurements of the dependences of the rates of particular steps of the catalytic cycle or the overall process on the strength of the external magnetic field (magnetic field dependence) and a comparison of the experimental and calculated dependences on the magnetic field. In the case of enzymatic processes, the recombination (back electron transfer) probabilities are calculated for a pair of paramagnetic species with specified magnetic resonance parameters (HFC constants, g -factors of radicals, effective electron exchange interaction constant J) with allowance for the lifetimes of the paramagnetic pair and the multiplicity of the initial and recombining states. Now we will consider an approach to the calculation of a recombination probability in multispin systems including enzymes.

III. Theory of the magnetic field and spin effects in enzymatic multispin systems

A model of a multispin system differs from that model used in the radical pair theory in the number of unpaired electrons (> 2). For instance, the spin catalysis³⁰ deal with systems comprising three radicals (triads) or pairs of species with spins $I > 1/2$. Thus, the description of multispin systems requires taking account of possible correlated doublet, quartet, quintet and higher spin states. Recombination probability calculations for such multispin pairs should be carried out with allowance for a large number of subensembles of radical pairs, each corresponding to particular configurations of electron and nuclear spins. The interaction of RP spins with external magnetic fields and the spin–spin interactions induce transitions of a given RP from one subensemble to another. These interactions are described by systems of a large number of coupled kinetic equations. In addition, description of the dynamics of the RP spin state requires the use of quantum mechanics. The density matrix formalism is the most appropriate for simultaneous consideration of the spatial motion and spin dynamics of a radical pair. Now we will calculate the recombination probability in the framework of this method.

If the density matrix, $\rho(\vec{r}, t)$, of a pair of paramagnetic species separated by the distance r depends on r , changes in $\rho(\vec{r}, t)$ with time (t) are governed by three factors, *viz.*, the spin evolution of the unpaired electrons due to the spin–spin interactions and spin interactions with external and local

magnetic fields, the relative motion of reactants and recombination of radicals¹

$$\frac{\partial \rho(\vec{r}, t)}{\partial t} = \left(\frac{\partial \rho}{\partial t} \right)_{\text{spin}} + \left(\frac{\partial \rho}{\partial t} \right)_{\text{motion}} + \left(\frac{\partial \rho}{\partial t} \right)_{\text{recomb}}. \quad (1)$$

This equation is usually written as follows:⁴³

$$\frac{\partial \rho(\vec{r}, t)}{\partial t} = i\hat{L}(\vec{r})\rho(\vec{r}, t) + \hat{R}(\vec{r})\rho(\vec{r}, t) - \hat{U}(\vec{r})\rho(\vec{r}, t), \quad (2)$$

where $\hat{L}(\vec{r}) = \hat{\Omega} + i\hat{R} + \hat{J}(\vec{r})$ is the Liouville operator (Liouvillian), which allows for the coordinate-independent spin evolution due to isotropic HFC and the Zeeman interaction with external magnetic fields ($\hat{\Omega}$), the spin relaxation processes (\hat{R}), and the coordinate-dependent spin evolution induced by the exchange interaction [$\hat{J}(\vec{r})$]. The operator $\hat{U}(\vec{r})$ describes the spin-dependent RP recombination, and its matrix elements characterise the rate of transformation of different components of the density matrix to the reaction product (or products). The functional operator $\hat{R}(\vec{r})$ specifies the motion of reactants, which is usually treated in the framework of classical mechanics.

The probability of RP recombination from a certain spin state at the instant t is given by the corresponding components of the vector $\hat{w}(t)$

$$\hat{w}(t) = \int_0^t \int \hat{U}(\vec{r})\rho(\vec{r}, \tau) d\tau d\vec{r}. \quad (3)$$

Among a large number of methods for solving Eqn (2), the Green function formalism is most often used. The Green functions specify the character of the relative motion of other paramagnetic species in the pair.⁴⁴ This method makes use of a physically substantiated admission that the reaction zone is always a rather narrow region in the space of motion of reactants. In this case, the general matrix expression for the probability of recombination of a pair of paramagnetic species from a certain spin state has the form:⁴³

$$\hat{w} = \hat{U}_0 \hat{g} \left(1 + \hat{U}_0 \hat{g} \right)^{-1} \rho_0, \quad (4)$$

where \hat{U}_0 is the matrix of recombination constants for different spin states (generally, recombination from any electron spin state is possible, but at different rate); \hat{g} is the operator (averaged over the reaction zone) characterising the relative motion and the spin dynamics in the pair. The matrix of this operator is the matrix of characteristic ‘times’. For instance, the matrix element $g_{nm, kk}$ is the mean lifetime of the RP in the spin state $|nm\rangle$ provided that the system initially was in the electron spin state $|kk\rangle$. All elements of this matrix are expressed through the one and only function $g(s)$ characterising the relative motion (changes in the mutual position) in the pair of recombining paramagnetic species.

Carrying out particular calculations often requires knowledge of only certain elements of the matrix \hat{g} , *i.e.*, one or several of characteristic ‘times’. Consider a typical case where the RP can recombine only in a particular electron spin state, *e.g.*, a doublet or singlet state. Let the spin evolution in the RP occur in such a way that no transitions between different recombining states of the radicals occur. Then, the whole ensemble of radical pairs can be divided into subensembles with a particular configuration, $\{m\}$, of nuclear spins in the doublet (or singlet) state. Calculations for each subensemble are performed independently; the recombination probability for a specified subensemble is given by

$$w_m = \frac{U_0 \tau_m}{1 + U_0 \tau_m}, \quad (5)$$

where the quantity τ_m is the mean residence time of the radical pair in the reaction zone in the doublet state with the specified spin configuration $\{m\}$ provided that the pair was born in the reaction zone in the doublet state with the same spin configuration $\{m\}$.

In some cases, transitions between doublet states can play an important role. Suppose that a transition from the doublet state with the nuclear spin configuration $\{m\}$ to the doublet state with the spin configuration $\{m'\}$ is possible. We thus obtain a more general expression compared to Eqn (5)

$$w_m = U_0 \frac{\tau_m + \tau_{mm'} + U_0(\tau_m \tau_{m'} - \tau_{mm'} \tau_{m'm})}{1 + U_0(\tau_m + \tau_{m'}) + U_0^2(\tau_m \tau_{m'} - \tau_{mm'} \tau_{m'm})}. \quad (6)$$

Here $\tau_{mm'}$ is the mean residence time of the RP in the reaction zone in the doublet state with the preset spin configuration $\{m\}$ provided the start is from the doublet state with the preset spin configuration $\{m'\}$. The parameter $\tau_{m'm}$ has a similar meaning.

Further calculations require specifying of the spin Hamiltonian of the RP to describe the spin evolution and choosing an appropriate model for the relative motion to describe the spatial motion of the species. Changes in the mutual position of the species in the enzyme-substrate complex can be described using a rather simple two-position model,⁴⁵ according to which two states of an RP in the cage are possible: (i) radicals contact each other and can recombine and (ii) radicals do not contact each other but can return to the contact state. The state (i) is characterised by the time τ_1 necessary for transition of RP from this state to the state (ii). The state (ii) is characterised by two parameters, namely, the time τ_2 of back transition from the state (ii) to the state (i) and the time τ_c of irreversible decomposition of the RP. The singlet–triplet transitions occur in the state (ii) of the RP.

In the framework of the two-position model, the function $g(s)$ characterising the changes in the mutual position in a pair of recombining paramagnetic species is given by:⁴⁵

$$g(s) = \frac{\tau_p}{n+1} \left(1 + \frac{n}{1+s\tau_c} \right), \quad (7)$$

where n is the number of repeated contacts and $\tau_p = n\tau_1$.

The spin evolution is described using appropriate basis spin states φ_i . For instance, the singlet–triplet basis is suitable for the description of a pair of species with $I = 1/2$. If a pair comprises two species with $I = 1/2$ and 1, the resultant spin state can be doublet or quartet. The spin functions of these states have the form

$$|D\rangle = \begin{cases} \sqrt{\frac{2}{3}}\beta T_{+1} - \sqrt{\frac{1}{3}}\alpha T_0 \\ \sqrt{\frac{2}{3}}\alpha T_{-1} - \sqrt{\frac{1}{3}}\beta T_0 \end{cases}, \quad (8)$$

$$|Q\rangle = \begin{cases} \alpha T_{+1} \\ \sqrt{\frac{1}{3}}\beta T_{+1} + \sqrt{\frac{2}{3}}\alpha T_0 \\ \sqrt{\frac{1}{3}}\alpha T_{-1} + \sqrt{\frac{2}{3}}\beta T_0 \\ \beta T_{-1} \end{cases}.$$

By specifying the spin Hamiltonian of the system it is possible to determine the stationary energy levels (E_i) and the eigenfunctions (wavefunctions) of the system (ψ_i). The stationary wavefunctions in the φ_i basis set are represented by

$$\psi_i = \sum_j (\hat{Q})_{ij} \varphi_j,$$

where $(\hat{Q})_{ij}$ is the matrix that describes transition from the initial spin basis set to the basis of eigenfunctions. The dependence of the wavefunctions on time is as follows:

$$|\psi(t)\rangle = \exp(-i\hat{H}t)|\psi(0)\rangle.$$

Now we will write the density matrix in the basis of the φ_i functions. The action of the operator \hat{Q} on the functions φ_i leads to

$$\begin{aligned} |\varphi(t)\rangle &= \hat{Q}^{-1}|\psi(t)\rangle = \hat{Q}^{-1}\exp(-i\hat{H}t)|\psi(0)\rangle = \\ &= \hat{Q}^{-1}\exp(-i\hat{H}t)\hat{Q}|\varphi(0)\rangle; \end{aligned} \quad (9)$$

since

$$\hat{\rho}(t) = |\varphi(t)\rangle\langle\varphi(t)|,$$

one gets

$$\hat{\rho}(t) = \hat{Q}^{-1}\exp(-i\hat{H}t)\hat{Q}|\varphi(0)\rangle\langle\varphi(0)|\hat{Q}^{-1}\exp(i\hat{H}t)\hat{Q}. \quad (10)$$

For instance, the probability for the RP to exist in a doublet state at any instant is given by:

$$\rho_{DD}(t) = \langle D|\hat{Q}^{-1}\exp(-i\hat{H}t)\hat{Q}|D\rangle\langle D|\hat{Q}^{-1}\exp(i\hat{H}t)\hat{Q}|D\rangle. \quad (11)$$

Here \hat{Q} represents the matrix coefficients; therefore, the expression for $\rho_{DD}(t)$ can be transformed as follows:

$$\begin{aligned} \rho_{DD}(t) &= \sum_i Q_{i1}^4 + \sum_{i,j} Q_{i1}^2 Q_{j1}^2 \exp[-i(E_i - E_j)t] + \\ &+ \sum_{i,j} Q_{i1}^2 Q_{j1}^2 \exp[i(E_i - E_j)t]. \end{aligned} \quad (12)$$

The average lifetime of an RP in a doublet state provided that the RP was born in the same state can be determined from the following expression

$$\begin{aligned} \tau = (\hat{g})_{DD,DD} &= \sum_i Q_{i1}^4 g(0) + \sum_{i,j} Q_{i1}^2 Q_{j1}^2 g[-i(E_i - E_j)] + \\ &+ \sum_{i,j} Q_{i1}^2 Q_{j1}^2 g[i(E_i - E_j)]. \end{aligned} \quad (13)$$

For the two-position model, the equation for τ takes the form

$$\tau = \tau_p \left[\sum_i Q_{i1}^4 + 2 \sum_{i>j} \frac{Q_{i1}^2 Q_{j1}^2}{n+1} \left(\frac{1+n}{1+[(E_i - E_j)\tau_c]^2} \right) \right]. \quad (14)$$

The probability of recombination from the doublet state provided that the RP was formed in the doublet and quartet state, respectively, can be calculated using the following relationships:

$$w^D = \frac{1}{2} \frac{U_0 \tau}{1 + U_0 \tau}, \quad (15)$$

$$w^Q = \frac{1}{4} \frac{U_0(\tau_p - \tau)}{1 + U_0 \tau}. \quad (16)$$

Recombination probability calculations for such systems are exemplified by the reactions catalysed by horseradish

peroxidase containing an iron atom in the active site (see below).

IV. Magnetic field effects in enzymatic reactions catalysed by horseradish peroxidase

1. Modern concepts of the mechanisms of horseradish peroxidase-catalysed oxidation of substrates

Two models for the mechanism of the HRP catalytic cycle are available in the literature, a 'simplified' model²⁷ and a 'chemically realistic' one.²⁴ The former model (Scheme 3) was proposed as a possible mechanism of the oxidation of the natural peroxidase substrate (NADH) in the presence of an initiator (hydrogen peroxide) and involves successive transformation of native HRP (Per^{3+} , Fe^{III}) into reactive paramagnetic HRP intermediates, namely, Compound I containing a haem oxoform π -radical cation ($\text{Fe}^{\text{IV}}=\text{O}^+$) in the active site and Compound II ($\text{Fe}^{\text{IV}}=\text{O}$).

The second model (Scheme 4) was used to describe the NADH oxidation in the absence of H_2O_2 . It is based on the assumption that slow oxidation of NADH with oxygen present in the buffer solution in an acid medium results in the formation of H_2O_2 and that the amount of H_2O_2 formed is sufficient for initiation of the catalytic cycle,⁴⁶ which includes interconversions of native HRP (Per^{3+} , Fe^{III}), Compound I ($\text{Fe}^{\text{IV}}=\text{O}^+$), Compound II ($\text{Fe}^{\text{IV}}=\text{O}$), Compound III ($\text{Fe}^{\text{IV}}-\text{O}-\text{OH}$) and ferropoxidase (Per^{2+} , Fe^{II}).

However, the efficiency of the hypothetical step of H_2O_2 generation casts some doubts. The authors of the present review believe that single-electron transfer between the native HRP and substrate (NADH) is much more probable, because this is a commonly accepted starting point of oxidation in the reactions catalysed by other haem-containing enzymes.^{47, 48} Indeed, according to published data on HRP-catalysed oxidation of substrates,^{49, 50} the binding of a substrate in the active site of enzyme occurs near the haem plane, which permits direct electron transfer from the substrate to the haem. Here, the rate of single-electron transfer from the substrate to the haem in the enzyme-substrate complex should be much higher than the rate of the substrate oxidation by dissolved oxygen (for NADH, $k = 3.0 \times 10^{-6} \text{ s}^{-1}$).²⁴ It should be noted that high probability of single-electron transfer is also due to the donor properties of NADH ($E^0 = -320 \text{ mV}$) and acceptor properties of HRP ($E^0 = -306 \text{ mV}$).⁵¹

However, in spite of these arguments, the concept considering the formation of H_2O_2 as the starting point of the peroxidase-catalysed substrate oxidation still dominates in the literature.^{24, 47} Nevertheless, the aforesaid suggests^{34, 35} that the single-electron transfer step can occur in the $[\text{Per}^{3+} \dots \text{NADH}]$ enzyme-substrate complex. It should be noted that the possibility of electron transfer between HRP and NADH to

give ferropoxidase (Per^{2+}) was discussed in a study of HRP-catalysed oxidation of photoexcited NADH.⁵²

Thus, the possibility of electron transfer between the native HRP and NADH requires experimental proof. Of particular interest are the experimental proofs of the involvement of the $\text{NADH}^{+\cdot}$ radical cation in the enzymatic oxidation processes. Discussion of whether the multistep mechanism involving electron transfer is possible in biological systems

or the oxidation occurs as the hydride transfer remains topical.⁵³ It should be emphasised that the radical steps were proposed for almost all processes involving HRP, that is, hydrogen peroxide utilisation, initiation of polymerisation in the synthesis of plant cell membranes, *etc.*⁴⁷ Meanwhile, only reactive paramagnetic intermediates of the native HRP, *i.e.*, Compounds I–III, were experimentally detected to date.⁴⁶ Since the involvement of paramagnetic intermediates (Per^{3+} , Per^{2+} , Compounds I–III) in the catalytic cycle of HRP can be considered proven (see Schemes 3 and 4), it was quite natural to expect that the use of spin chemistry methods will provide reliable information on hypothetical reactive paramagnetic substrate species generated in these processes.

Further, we briefly outline the methodology of experiments and analysis of the magnetic field effects, which permits reliable establishment of manifestations of the radical steps in the HRP-catalysed oxidation of organic substrates.

2. Methodology of studies on the magnetic field effects in the substrate oxidation catalysed by horseradish peroxidase

To date, detailed magnetic-field-effect-based spin chemistry studies were carried out of the HRP-catalysed oxidation of organic substrates, namely, 2-methyl-1-(trimethylsilyloxy)-prop-1-ene ($\text{Me}_2\text{C}=\text{CHOSiMe}_3$) in the presence of H_2O_2 ,³³ NADH³⁴ and its synthetic analogue, 3,5-di(methoxycarbonyl)-2,3-dimethyl-4-nitrophenyl-1,4-dihydropyridine (nifedipine, NF), in the absence of H_2O_2 .³⁵ In all the three cases, the effective rate constants for transformations of particular intermediates of the catalytic cycle of HRP (Per^{3+} , Per^{2+} , Compounds I–III) were measured using a rapid-scanning stopped-flow spectrophotometer. Since the intermediates listed above show different absorption spectra⁴⁶ (Fig. 2), it is possible to monitor the kinetics of corresponding interconversions. For instance, in the study of $\text{Me}_2\text{C}=\text{CHOSiMe}_3$

Figure 2. Absorption spectra of horseradish peroxidase and peroxidase reactive intermediates.⁴⁷ Compound I (1), Per^{2+} (2), Compound III (3), Compound II (4) and Per^{3+} (5).

oxidation, the changes in the absorbance (A) of the reactive HRP intermediates were detected at 418 nm (maximum absorption of Compounds II and III, see Fig. 2) over a period of 1 s with a time resolution of 1 ms.³³ The time resolution was 16 ms in the NADH oxidation³⁴ and 32 ms in the NF oxidation,³⁵ because the reactions with these substrates took much longer time to complete (up to 500 s). To study the effect of external magnetic field, the mixing cell in which the reaction of the substrate with HRP occurred, was placed between the poles of an electromagnet and the magnetic field strength was varied from 0 to 4500 G. The kinetic traces recorded in each case were compared with the corresponding traces obtained in zero magnetic field (to this end, the residual magnetisation of the electromagnet was compensated up to a value of 0.3 to 0.5 G). The effective rate constants for interconversions of the HRP intermediates were determined using the Levenberg–Marquardt non-linear regression algorithm. The analytical solution to the system of differential equations describing successive transformations of intermediates of the catalytic cycle of HRP with allowance for their molar extinction coefficients at 418 nm^{24,47} was used as the fitting function. The magnetic field effects were detected as the dependence of the ratio of the effective rate constant in a particular magnetic field to the corresponding rate constant determined in terrestrial magnetic field on the strength of the external magnetic field.

3. Analysis of magnetic field effects in the oxidation of 2-methyl-1-(trimethylsilyloxy)prop-1-ene by horseradish peroxidase

The oxidation of $\text{Me}_2\text{C}=\text{CHOSiMe}_3$ by horseradish peroxidase in the presence of hydrogen peroxide³³ was the first example of the substrate oxidation by a haem-containing enzyme, in which the effect of magnetic field on transformations of paramagnetic intermediates was detected.

The kinetic curves (Fig. 3) with allowance for absorption of reactive peroxidase intermediates at 418 nm (see Fig. 2) can be explained by a sequence of conversions of the paramagnetic species. The initial decrease in the absorbance (see Fig. 3, region 1) can be explained by the formation of Compound I (extinction coefficient $\epsilon_{418} = 35 \text{ litre mmol cm}^{-1}$) in the reaction of the native HRP with H_2O_2 . The subsequent reaction of

Figure 3. Kinetic curve of chemical transformations of reactive paramagnetic peroxidase intermediates observed at 418 nm.

Reaction conditions (all concentrations after mixing): 100 mM phosphate buffer (pH 7.4), $[\text{Per}^{3+}] = 4 \mu\text{mol litre}^{-1}$, $[\text{H}_2\text{O}_2] = 0.1 \text{ mmol litre}^{-1}$, [2-methyl-1-(trimethylsilyloxy)prop-1-ene] = $16 \text{ mmol litre}^{-1}$; 25 °C.

Compound I with the first substrate molecule results in Compound II ($\epsilon_{418} = 115 \text{ litre mmol cm}^{-1}$) and, consequently, in an increase in the absorbance (see Fig. 3, region 2). Then Compound II reacts with the second substrate molecule to regenerate the native HRP.

The reaction of HRP with hydrogen peroxide is too fast to be treated correctly under the experimental conditions and at the time resolution mentioned above. In this connection the initial region of the fall-off of the kinetic curve was ignored in the design of the kinetic model for theoretical description of the process. Therefore, changes in the optical absorption can be described, in the framework of the sequence of conversions shown in Scheme 5, using the kinetic model for two successive unimolecular reactions

Since the extinction coefficient of HRP at 418 nm is much lower than that of Compound II (see Fig. 2), the overall function for the description of the experimentally observed kinetics of changes in the optical absorption (A_{418}) is given by:

Scheme 5

Figure 4. Fitting of the experimental kinetic curve using the Levenberg–Marquardt non-linear regression algorithm and analytical solution (18).

Experimental data are shown by open circles and the fitting results are shown by the solid line.

$$A_{418} = [\text{compound II} + \text{Per}^{3+}] \approx \quad (18)$$

$$\approx \frac{[\text{compound I}]_0}{2} \left[1 - \frac{(k_2 - 2k_1) \exp(-k_1 t)}{k_2 - k_1} - \frac{k_1 \exp(-k_2 t)}{k_2 - k_1} \right].$$

To determine the effective rate constants k_1 and k_2 , the analytical solution (18) is used for constructing a corresponding kinetic plot with allowance for the sequence of conversions of reactive paramagnetic intermediates of the peroxidase catalytic cycle (see Scheme 5) using the Levenberg–Marquardt non-linear regression algorithm. Figure 4 illustrates

Figure 5. Magnetic field effect on the rate constants k_1 (a) and k_2 (b) of the oxidation of 2-methyl-1-(trimethylsilyloxy)prop-1-ene catalysed by horseradish peroxidase. Shown are the standard deviations (averaging over three experimental series including 5 or 6 measurements each). Reaction conditions (all concentrations are reported after mixing): 100 mM phosphate buffer (pH 7.4), $[\text{Per}^{3+}] = 4 \mu\text{mol litre}^{-1}$, $[\text{H}_2\text{O}_2] = 0.1 \text{ mmol litre}^{-1}$, $[\text{2-methyl-1-(trimethylsilyloxy)prop-1-ene}] = 16 \text{ mmol litre}^{-1}$; 25 °C.

excellent agreement between the experimental kinetic curve and calculated function (18). The magnetic field effects were calculated as the ratio of the rate constants k_1 and k_2 measured in non-zero external magnetic fields to the corresponding rate constants determined in the zero magnetic field. The magnetic field dependences of the magnetic field effects determined for k_1 and k_2 are shown in Fig. 5. In Section III, we showed that the shape of the magnetic field dependence of the magnetic field effect and positions of extrema are determined by the magnetic resonance parameters of two paramagnetic species.¹ By comparing the experimental magnetic field dependence (see Fig. 5) and the results of calculations using the known semi-classical approximation,⁵⁴ one can determine the magnetic field-sensitive step of the process, namely, the second stage of the catalytic cycle, which involves the interaction of Compound II with the substrate. In this stage, the event of single-electron transfer is followed by the formation of the radical form of Compound II and the radical anion of the enol form of 1-isobutylaldehyde ($\text{Me}_2\text{C}=\text{CHO}^\cdot$). In this case the magnetic field effect is due to the probability difference between back electron transfer in the radical pair in weak and strong magnetic fields. Here, the reversible electron transfer event in the collective triplet state of the RP is accompanied by regeneration of Compound II, whereas the singlet state eventually results in the starting HRP (Per^{3+}) (Scheme 6).

Scheme 6

Thus, manifestation of the magnetic field effect confirms the assumption of involvement of the paramagnetic intermediates in the catalytic cycle of HRP. This also indicates the possibility for a new, non-studied, short-lived radical form of Compound II to exist.^{24, 27, 47}

4. Magnetic field effects in the oxidation of NADH and its synthetic analogues by horseradish peroxidase

a. Enzymatic oxidation of NADH catalysed by horseradish peroxidase

Yet another example of manifestation of the magnetic field effect in the reactions catalysed by HRP is provided by the oxidation of NADH, a natural HRP substrate. In the above discussion of modern concepts of the mechanisms of oxidation of organic substrates catalysed by HRP, mention was made that the initiation step of the catalytic cycle in the absence of hydrogen peroxide requires additional studies. Electron transfer from the donor molecule (NADH) to acceptor (e.g., haem of the active site of HRP) can be a highly probable starting point of the catalytic cycle. The use of spin chemistry methods to prove this assumption seems to be correct.

The oxidation of NADH catalysed by HRP in the absence of H_2O_2 was studied by the stopped-flow spectrophotometric technique (see above). The reactive HRP intermediates (Compounds I, II and III) were also detected at the wavelength of maximum absorption of Compounds II and III (418 nm). Based on the known sequences of interconversions of HRP intermediates⁴⁶ and their molar extinction coefficients²⁴ (see

Figure 6. Kinetic curve of chemical transformations of horseradish peroxidase reactive paramagnetic intermediates observed at 418 nm in the NADH oxidation catalysed by peroxidase.

Reaction conditions (all concentrations after mixing): 100 mM MES buffer, pH 5.6; $[\text{Per}^{3+}] = 1 \mu\text{mol litre}^{-1}$, $[\text{NADH}] = 100 \mu\text{mol litre}^{-1}$; 25 °C.

Fig. 2), the characteristic kinetic curve of this process (Fig. 6) was explained as follows:³⁴ a decrease in absorption in the first step (see Fig. 6, region 1) is associated with the transformation of native HRP ($\epsilon_{418} = 62 \text{ litre mmol}^{-1} \text{ cm}^{-1}$) to ferropoxidase (Per^{2+}) ($\epsilon_{418} = 62 \text{ litre mmol}^{-1} \text{ cm}^{-1}$) upon electron transfer event from the substrate (NADH) to the starting HRP, which results in the formation of the reduced form (Per^{2+}). This is followed by the reactions of ferropoxidase with oxygen dissolved in the buffer solution (Scheme 7), which leads to rapid conversion of Per^{2+} ($k = 5.8 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$) to Compound III ($\epsilon_{418} = 115 \text{ litre mmol}^{-1} \text{ cm}^{-1}$)²⁴ and subsequent increase in absorption (see Fig. 6, region 2). Fast deprotonation of the $\text{NADH}^{+\cdot}$ radical cation ($k = 3.6 \times 10^6 \text{ s}^{-1}$) (Ref. 55) produces the NAD^{\cdot} radical, which reacts with Compound III to give Compound I ($\epsilon = 35 \text{ litre mmol}^{-1} \text{ cm}^{-1}$) (see Scheme 7). This process

Scheme 7

corresponds to the ‘deflection’ region of the kinetic curve (see Fig. 6, region 3). Then, the single-electron reduction of Compound I produces Compound II ($\epsilon_{418} = 115 \text{ litre mmol}^{-1} \text{ cm}^{-1}$), which leads to an increase in the absorption at 418 nm (Fig. 6, region 4).

The initial portion of the kinetic curve of ferropoxidase formation was too fast for quantitative treatment; therefore, the corresponding rate constant was excluded from the theoretical kinetic model. Therefore, in accordance with the proposed sequence of reactions (see Scheme 7), an increase in the absorption (see Fig. 6, regions 2–4) was described using a kinetic model that assumes three unimolecular reactions

Compounds II and III are characterised by equal extinction coefficients that are about three times higher than the molar extinction of Compound I and twice as high as that of Per^{2+} ; therefore, the overall fitting function for the description of the experimental changes in absorbance with time can be written as follows:

$$\begin{aligned} A_{418} &= [\text{compound III}] + [\text{compound II}] + \\ &+ \frac{[\text{compound I}]}{3} + \frac{[\text{Per}^{2+}]}{2} = \\ &= [\text{Per}^{2+}]_0 - \frac{2[\text{compound I}]}{3} - \frac{[\text{Per}^{2+}]}{2}. \end{aligned} \quad (20)$$

The curve calculated using experimental data and the Levenberg–Marquardt non-linear regression algorithm for the overall analytical solution (20) to the system of equations that describe the sequence of reactions in the catalytic cycle of HRP (19) virtually coincides with the experimental kinetic curve shown in Fig. 7. It should be noted that kinetic simulation with allowance for ferropoxidase formation allowed one to obtain the best fit of the experimental and theoretical curves. This made it possible to determine the rate constants k_1 , k_2 and k_3 for the reactions (19).

Yet another proof of occurrence of single-electron transfer between HRP and NADH in the enzymatic oxidation was obtained by analysing the magnetic field dependences of the magnetic field effect detected in this process. The magnetic field effect calculated as the ratio of the effective rate constants in a magnetic field to the corresponding rate constants in the zero magnetic field was found only for the constant k_1 (Fig. 8). The most probable magnetic field sensitive step is electron transfer

Figure 7. Fitting of the experimental kinetic curve for the reaction of peroxidase with NADH using the Levenberg–Marquardt non-linear regression algorithm and analytical solution (20).

Figure 8. Magnetic field effect on the rate constant k_1 of the oxidation of NADH catalysed by horseradish peroxidase.

The error bars show the sum of the instrumental error (3.5%) and the standard error of averaging over three experimental series including 5 or 6 measurements each. Reaction conditions (all concentrations after mixing): 100 mM MES buffer (pH 5.6); $[\text{Per}^{3+}] = 1 \mu\text{mol litre}^{-1}$, $[\text{NADH}] = 100 \mu\text{mol litre}^{-1}$; 25 °C.

between the native HRP and NADH. Subsequent conversion of ferropoxidase in the reaction with oxygen occurs under kinetic control ($k = 6 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$);^{24, 47} therefore, the rate of formation of Compound III will be much lower than the rate of spin conversion in the pair ($\text{Per}^{2+} \text{ O}_2$) and the process will most probably be spin-independent. The interaction of Compound III with the radical NAD^\bullet also cannot be the source of a strong magnetic field effect, if a collision of this radical with the radical NAD^\bullet in the bulk produces the so-called F-pair (strong magnetic field effects are not characteristic of this species).⁵⁶ However, is it possible to consider enzymatic reactions as bulk processes? The issue has not been answered so far. As to the subsequent steps of the catalytic cycle, the interaction of Compound I with NADH produces no RP and the formation of peroxidase as a result of the reaction between Compound II and NADH was not included in the analytical function at all, because this step was not observed on the time scale studied. Thus, we have formulated a hypothesis that the dependence of the rate constant k_1 on the strength of the external magnetic field is due to the effect of the magnetic field on the rate of ferropoxidase formation in the event of single-electron transfer between HRP and NADH.

To check the assumption that the magnetic field effect is formed in the first step of the catalytic cycle, the magnetic field dependence of the magnetic field effect for the paramagnetic pair ($\text{Per}^{2+} \text{ NADH}^{+\bullet}$) was calculated. The RP multiplicity was established in the framework of the theory of crystal field by analysing³⁴ the spin state of the central iron atom in the ferropoxidase haem.⁵⁷

According to modern concepts, the inorganic complex (ferropoxidase, Per^{2+}) can be treated as a stable polyatomic system in which the effect of ligands [porphyrin (N) and histidine (N_{His})] on the central ion Fe(II) is electrostatic in nature. It was established that in a free iron atom five d-states (d_{xy} , d_{xz} , d_{yz} , d_{z^2} and $d_{x^2-y^2}$) with the same energy are split into four groups with different energies in the pyramidal field of ferropoxidase ligands (N and N_{His}), *i.e.*, the quintuply degenerate ^5D -term of free ion is split in the ligand field of the pyramidal complex into four terms, namely, b_1 ($d_{x^2-y^2}$), b_2 (d_{xy}), a doubly degenerate e (d_{xz} , d_{yz}) and a (d_{z^2}).

The electron states of the RP are shown in Scheme 8. Donation of a single electron from NADH to the native HRP

causes the formation of the ($\text{Per}^{2+} \text{ NADH}^{+\bullet}$) RP in the quartet and doublet states. Owing to intersystem crossing, the non-reactive quartet spin state becomes a reactive doublet state. Recombination of the latter (back electron transfer) maintains the possibility of regeneration of the starting HRP and NADH.

Scheme 8

The recombination probability for the RP under study was calculated in the framework of the density matrix formalism for the two-position model. The basics of this approach have been considered above (see Section III). It was assumed³⁴ that the observed quartet–doublet spin evolution of the RP is governed by the electron spin interaction with the constant external magnetic field, isotropic hyperfine interaction between the unpaired electrons and magnetic nuclei in the system and by the exchange interaction between the unpaired electrons, which causes splitting of the RP terms into a doublet and a quartet.

The Hamiltonian of this system of interactions has the form:

$$\hat{H} = \omega_1 \hat{S}_1 + \omega_2 \hat{S}_2 + a \hat{S}_1 \hat{I} + J \hat{S}_1 \hat{S}_2, \quad (21)$$

where $\omega_1 = g_1 \beta \hbar^{-1} H_0$ and $\omega_2 = g_2 \beta \hbar^{-1} H_0$ are the spin precession frequencies of the radicals in the pair of species with the electron spins 1 and 1/2, respectively; the g -factors are $g_1 = 3.25$ (for ferropoxidase)⁵⁸ and $g_2 = 2.003$ (for the substrate radical cation);⁵⁵ $a = 32.9 \text{ G}$ (Ref. 55) is the constant of isotropic hyperfine interaction between the unpaired electron of the radical cation $\text{NADH}^{+\bullet}$ and the magnetic nucleus in this radical cation ($I = 1/2$); and J is the exchange integral between the doublet and quartet terms of the radical pair. It should be noted that in the general case the exchange interaction constant depends on the distance between the radicals (r) and the orientation angles (θ and φ), *i.e.*, $J = f(r, \theta, \varphi)$. For simplicity, only two possible conformational states of the complex $[\text{Per}^{2+} \dots \text{NADH}^{+\bullet}]$ characterised by the quartet–doublet ($Q-D$) evolution with the corresponding exchange integrals J_1 and J_2 varied from 200×10^7 to $300 \times 10^7 \text{ rad s}^{-1}$ were analysed.³⁴ The best agreement between the calculated and experimental dependences on the magnetic field applied was attained at $J_1 = 200 \times 10^7$ and $J_2 = 265 \times 10^7 \text{ rad s}^{-1}$.

The spin Hamiltonian (21) commutes with the projection of the total spin of the electrons and nucleus on the direction of the external magnetic field H_0 , the total projection being equal to

$$\hat{\Sigma}_Z = \hat{S}_{1Z} + \hat{S}_{2Z} + \hat{I}_Z. \quad (22)$$

Because only the states with the same total projection participate in quantum transitions, all spin states of the radical pair

can be divided into the following subensembles: $\Sigma_Z = \pm 2$, $\Sigma_Z = \pm 1$ and $\Sigma_Z = 0$, only the subensembles with the total spin projections equal to $+1$, -1 and 0 contributing to the RP recombination. The behaviour of the stationary energy levels obtained by solving the Schrödinger equation with the Hamiltonian given by expression (21) for the subensembles mentioned above is illustrated in Fig. 9. Recombination probability calculations were carried out for each of the three subensembles. The final recombination probability for the RP ($\text{Per}^{2+} \text{NADH}^{+\bullet}$) was calculated as the sum of the probabilities for each subensemble with allowance for the statistical weights. The recombination probability $W(Q)$ thus calculated for the radical pair ($\text{Per}^{2+} \text{NADH}^{+\bullet}$) born in the quartet state is plotted vs. magnetic field in Fig. 10.

The magnetic field dependence of the recombination probability first calculated for the multispin system was interpreted as follows.³⁴ According to the classical radical pair theory, a radical pair born in the non-reactive quartet state is characterised by a minimum recombination probability in zero magnetic field, which is confirmed by calculations. Further increase in the recombination probability $W(Q)$ in weak magnetic fields corresponds to removal of degeneracy of the Zeeman energy levels on going from the zero to a non-zero magnetic field. Interpretation of the remaining regions of the magnetic field dependence requires consideration of the behaviour of the stationary energy levels of the subensembles with the spin projections equal to $+1$, 0 and -1 (see Fig. 9) in different magnetic fields. A decrease in separation between the energy levels in the range 200–250 G indicates that here one should expect manifestation of specific features of the recombination probability behaviour. Indeed, the theoretical curve (see Fig. 10) shows an extremum at 250 G the position of which unambiguously indicates manifestation of electron exchange interaction (J). The role of J is clearly illustrated in

Figure 9. $Q-D$ transitions in the paramagnetic pair ($\text{Per}^{2+} \text{NADH}^{+\bullet}$) Q . Splitting of stationary energy levels with the total spin projection equal to 0 (a) and -1 (b) in an external magnetic field.

Figure 10. Calculated recombination probability $W(Q)$ for the paramagnetic pair ($\text{Per}^{2+} \text{NADH}^{+\bullet}$) Q plotted vs. the magnetic field induction.

the scheme of the RP terms in the magnetic field (Scheme 9). Effective quartet–doublet mixing is possible in the external magnetic field equal to

$$H_0 = \frac{(3/2)J}{(g_1 + g_2)\beta}.$$

Then, after passage of the local maximum of the magnetic field dependence, the splitting between the energy levels (see Scheme 9, lines 2, 3) increases again due to the Zeeman interaction. As a result, transitions from the quartet state to the doublet state occur at lower rates and the recombination probability decreases (see Fig. 10). Since the frequency of transitions between states is determined by the Larmor frequency difference between the radicals in the pair

$$\omega_{QD} = \omega_1 - \omega_2 = (g_1 - g_2)\beta\hbar^{-1}H_0,$$

the efficiency of transitions between the non-reactive quartet state and reactive doublet state will increase again with an increase in the magnetic field. Therefore, the recombination probability increases in strong magnetic fields (400–1000 G).

The calculated recombination probability characterises the magnetic field effect on the $Q-D$ transition in the radical pair ($\text{Per}^{2+} \text{NADH}^{+\bullet}$), resulting in regeneration of the starting HRP. Therefore, the experimentally detected formation of Compound III in the bimolecular reaction between ferroperoxidase and oxygen molecule with the rate constant k_1 is described by the dependence of $[1 - W(Q)]$ on the magnetic field applied (Fig. 11). A comparison of the calculated (see

Figure 11. Escape probability $[1 - W(Q)]$ calculated for the paramagnetic pair $(\text{Per}^{2+} \text{NADH}^{+\bullet})$ plotted vs. the external magnetic field (simulation of experimental dependence of the rate constant k_1 in the NADH oxidation catalysed by horseradish peroxidase on the external magnetic field).

Figure 12. Kinetic curve of chemical transformations of the peroxidase reactive intermediates observed in the oxidation of nifedipine. Reaction conditions (all concentrations after mixing): 100 mM phosphate buffer (pH 7.0); $[\text{Per}^{3+}] = 1 \mu\text{mol litre}^{-1}$; $[\text{NF}] = 15 \mu\text{mol litre}^{-1}$; 15 vol.% EtOH; 25 °C.

Fig. 11) and experimental (see Fig. 8) magnetic field dependences of the magnetic field effect revealed qualitative agreement between them.

Thus, manifestation of the magnetic field effect, the magnetic field dependence of which is described in the framework of the radical pairs theory, indicates involvement of two paramagnetic species in the NADH oxidation catalysed by HRP. Agreement between the experimental and calculated magnetic field dependences is attained assuming formation of the magnetic field effect in the pair $(\text{Per}^{2+} \text{NADH}^{+\bullet})$. It should be emphasised that the conclusion about the presence of single-electron transfer step in the catalytic cycle of HRP also follows from the analysis of the experimental kinetic curves (see, *e.g.*, Fig. 6).

b. Magnetic field effect in the enzymatic oxidation of nifedipine, a synthetic analogue of NADH

The presence of the single-electron transfer step in the catalytic cycle of HRP was additionally substantiated in the studies of the enzymatic oxidation of nifedipine [3,5-di(methoxycarbonyl)-2,3-dimethyl-4-nitrophenyl-1,4-dihydropyridine], a synthetic analogue of NADH, which were also carried out using the stopped-flow technique.³⁵

The characteristic kinetic curve of the formation and decay of the peroxidase reactive intermediates in the oxidation of NF observed at 418 nm (maximum absorption wavelength of Compounds II and III) is shown in Fig. 12. The kinetic curve was analysed using the approach similar to that described above for the enzymatic oxidation of NADH. It was found that the NF oxidation kinetics can be explained by a sequence of elementary steps³⁵ identical to that proposed³⁴ for the description of the enzymatic NADH oxidation (Scheme 10).

A decrease in the absorbance in the initial portion of the kinetic curve (see Fig. 12, region 1) is associated³⁵ with the formation of ferroperoxidase ($\epsilon_{418} = 62 \text{ litre mmol}^{-1} \text{ cm}^{-1}$) upon electron transfer from NF to the haem iron atom of the enzyme, which also leads to formation of the radical cation $\text{NF}^{+\bullet}$. Further increase in absorbance (see Fig. 12, region 2) occurs during the reaction of ferroperoxidase with the dissolved oxygen to give Compound III ($\epsilon_{418} = 115 \text{ litre mmol}^{-1} \text{ cm}^{-1}$). In the next stage, a neutral nifedipine radical (NF^{\bullet}) formed as a result of deprotonation of the $\text{NF}^{+\bullet}$ radical cation is involved in the reaction. A CIDNP study³⁵ of the transformations of $\text{NF}^{+\bullet}$ in a model process showed that the deprotonation takes a few nanoseconds. The radical thus formed reacts with Compound III, which causes a dramatic

decrease in absorbance (see Fig. 12, region 3) due to the formation of Compound I ($\epsilon_{418} = 35 \text{ litre mmol}^{-1} \text{ cm}^{-1}$). Single-electron reduction of Compound I by the second NF molecule results in the formation of Compound II ($\epsilon_{418} = 115 \text{ litre mmol}^{-1} \text{ cm}^{-1}$); as a result, absorbance increases (see Fig. 12, region 4). No rapid regeneration of the native HRP occurs in the course of the reaction between NF and Compound II; this seems to be due to inactivation of the enzyme in the reactions with radicals.³⁵

At the same time, a comparison of the kinetic curves of the HRP-catalysed oxidation of NADH and NF (*cf.* Figs. 6 and 12) clearly demonstrates significant differences between these processes. For instance, it should be noted that each step of the NF oxidation is much slower than the corresponding step of the reaction of HRP with NADH. This can be explained by several factors, in particular, a lower concentration of NF compared to the NADH concentration (15 and 100 μmol

Scheme 10

litre⁻¹, respectively) and by the use of the phosphate buffer (pH 7.0) instead of the MES buffer (pH 5.6) in which HRP is more reactive.²⁴ The activity of the enzyme is also affected by the addition of EtOH (15%) necessary for solubilisation of NF, because ethanol acts as an inhibitor of HRP.

The effective rate constants for the formation of Compounds III and I were determined by treating the kinetic curves measured at different strengths of external constant magnetic field using the Levenberg–Marquardt non-linear regression algorithm. In this case, the kinetic model for two successive unimolecular stages was considered

and fitting was performed only for the portion of the kinetic curve that describes the kinetics of formation and consumption of Compound III (see Fig. 12,2). It turned out that, similarly to the NADH oxidation, only the rate constant k_1 is magneto-sensitive. The experimental magnetic field dependence of the magnetic field effect (Fig. 13) agrees with the theoretical curve (see Fig. 11) assuming that the magnetic field effect is formed in the pair ($\text{Per}^{2+} \text{NF}^{+\cdot}$) (Scheme 11).

Figure 13. Magnetic field effect on the rate constant k_1 for oxidation of nifedipine catalysed by horseradish peroxidase.

The error bars show the sum of the instrumental error (3.5%) and the standard error of measurements (averaged over three experimental series including 5–6 measurements each). Reaction conditions (all concentrations after mixing): 100 mM phosphate buffer (pH 7.0); $[\text{Per}^{3+}] = 1 \mu\text{mol litre}^{-1}$, $[\text{NF}] = 15 \mu\text{mol litre}^{-1}$; 15 vol.% EtOH; 25 °C.

Thus, we can conclude that, similarly to the case of NADH, back electron transfer in the pair ($\text{Per}^{2+} \text{NF}^{+\cdot}$) occurs in the doublet state of the RP, whereas the quartet spin state is the source of Compound III (see Schemes 8 and 11).

An important conclusion that can be drawn based on the analysis of the magnetic field effects detected in the enzymatic oxidation of the natural substrate of horseradish peroxidase, NADH and its synthetic analogue nifedipine, is as follows. In the absence of hydrogen peroxide, the enzymatic oxidation begins with electron transfer between the native HRP and substrate rather than the reaction with trace amounts of hydrogen peroxide formed as a result of NADH (NF) oxidation by dissolved oxygen, which was earlier considered as the initiation step.^{24, 47}

5. Studies of the magnetic field effect on the NADH oxidation by horseradish peroxidase in an oscillatory reaction

Of particular interest is the oscillatory reaction of NADH with O_2 catalysed by HRP, which has been a subject of intensive studies. The reaction dynamics shows a number of specific features dependent on the reaction conditions.⁵⁹ The peroxidase–oxidase system exhibits bistability (*i.e.*, two different dynamic states can exist under identical experimental conditions).²⁴ Examples are provided by two coexisting stable states⁶⁰ and a stable state that coexists with periodic oscillations.⁶¹

It should be noted that oscillations in an enzymatic system are complex biochemical processes that often involve up to 10–20 coupled elementary reactions associated with either generation or consumption of free radicals. To study the oscillatory oxidation reaction, NADH and oxygen are continuously added to a stirred aqueous buffer solution (pH 5.0–6.5) containing HRP and an initiator (usually, an aromatic compound, such as 4-hydroxybenzoic acid, melatonin or Methylene Blue). Under such conditions one can observe oscillatory processes.^{62, 63} Reaction products include hydrogen peroxide and a number of oxygen-containing free radicals.²⁴ The formation of reactive oxygen species is undesired for cell metabolism due to their destructive properties; additionally, too high concentrations of H_2O_2 cause inactivation of HRP in the reaction of peroxide with Compound I.^{64, 65} A mechanism of inactivation of the enzyme by free-radical species is described⁶⁶ and the role of aromatic initiators in this process was discussed. It was assumed that inactivation is a result of the interaction between reactive oxygen species and the side chains of amino acid molecules and peroxidase sugar residues.⁶⁷ It was shown that reduction of inactivation of the enzyme in the oscillatory system is followed by an increase in the concentration of melatonin, which rapidly reacts with the oxygen radical species formed, *e.g.*, OH^\cdot .

Studies of the effect of external magnetic field on the rate of oscillatory processes are of particular interest. It is quite important to answer the question whether or not does the enzymatic oxidation retain its magnetic field sensitivity in the oscillatory reaction and what is the role of its initiator?

The effect of external magnetic field on the consumption of oxygen in the oscillatory reaction of NADH with O_2 catalysed by horseradish peroxidase was first observed by Olsen *et al.*⁷ The oxygen concentrations in the solution during the reaction in a magnetic field of strength varied from 0 to 4000 G were measured with a Clark-type oxygen electrode. The frequency and amplitude of $[\text{O}_2]$ -oscillations are plotted vs. magnetic field in Fig. 14. The plots exhibit characteristic extrema at about

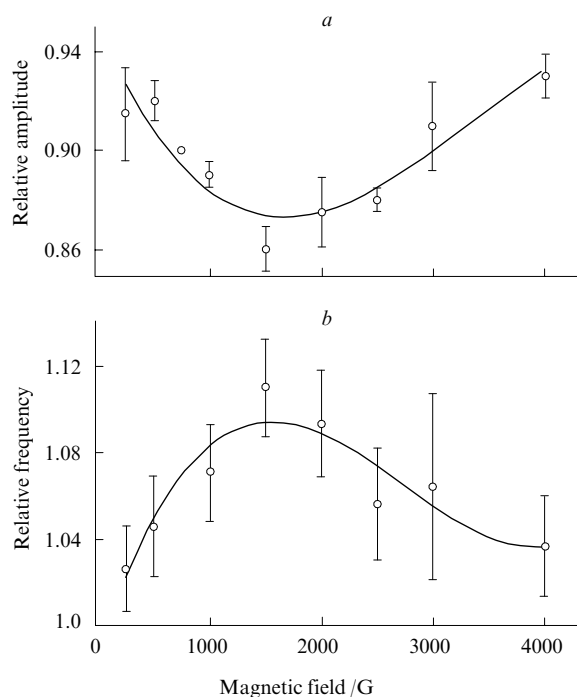

Figure 14. Effect of the magnetic field on the [O₂]-oscillation amplitude (a) and frequency (b).

Figure 15. Effect of the concentrations of peroxidase (a), Methylene Blue (b) and 4-hydroxybenzoic acid (c) on the [O₂]-oscillation amplitude.

1500 G. The magnetic field effect is independent of the pH value, NADH and methylene blue concentrations, being sensitive to the change in the concentrations of HRP and initiator, 4-hydroxybenzoic acid (Fig. 15).⁷ It was assumed that the magnetic field sensitive steps of the oxidase oscillatory reaction can involve radical pairs including Compounds I and II.

The dependence of the magnetic field effects observed on the concentration of phenolic compounds can be explained⁷ by participation of the latter in electron transfer between Compounds I and II in the course of the reactions

Note that the lack of a theoretical magnetic field dependence⁷ precludes drawing unambiguous conclusions about the magnetic field sensitive step of the process. We can only point to significant differences between the magnetic field dependences obtained for the steady-state HRP-catalysed oxidation of organic substrates [Me₂C=CH(OSiMe₃), NADH and NF] (see above) and measured in the course of oscillatory NADH oxidation by peroxidase (*cf.* Figs 5, 8, 13 and 14). These differences can be explained taking into account the fact that in the course of the steady-state substrate oxidation catalysed by HRP the magnetic field effects were detected in particular stages of the catalytic cycle, whereas in the case of oscillatory oxidase reaction⁷ the effect of the magnetic field on the rate of the overall process was studied. The observed dependence of the magnetic field effect on the concentration of phenol⁷ gives grounds to assume the presence of a number of magnetic field sensitive steps in the reaction under study, which can be a possible reason for the differences between the magnetic field dependences (see above).

V. Conclusion

The material presented in this review demonstrates the applicability of spin chemistry methods to studies of paramagnetic species involved in the enzymatic oxidation. Manifestation of the magnetic field effects in enzymatic reactions points to a relationship between the reactivity and spin states of paramagnetic intermediates of the catalytic cycle of HRP. For instance, it was shown that in the absence of hydrogen peroxide the enzymatic oxidation is initiated by electron transfer between the native enzyme and substrate. In addition, observation of the CIDNP effect⁶⁸ in the interaction of photoexcited NADH with horseradish peroxidase not only substantiates the conclusion about the possibility of electron transfer between the peroxidase haem and NADH, but also proves the formation of the radical cation NADH^{•+}, which was postulated in the analysis of the magnetic field effect.³⁴

Agreement between the experimental magnetic field dependences of the magnetic field effects detected in studies of the oxidation catalysed by horseradish peroxidase and the results of calculations in the approximations used in the radical pair theory makes it possible to draw some conclusions on the subtle mechanisms of the processes occurring in the catalytic cycle.

For instance, the molecular dynamics of partners in the enzyme–substrate complex should meet key requirements of the radical pair theory, namely, the rates of electron transfer in

enzymatic processes should be similar to the diffusion rates (otherwise, manifestation of the magnetic field effect is impossible), and the lifetimes of reactive intermediates should not exceed a few microseconds. The calculated magnetic field dependence³⁴ showed the best agreement with experimental data at submicrosecond lifetimes of the pair of paramagnetic species. Since the theoretical model is based on the concept of diffusion of partners, one should assume that reactants to some extent retain their mobilities in the enzymatic processes. In addition, extrema present in the magnetic field dependences at a magnetic fields strength of the order of hundreds of Gauss attest unambiguously to electron exchange interaction between partners in the catalytic cycle of horseradish peroxidase. This is most probably due to the substrate binding in the active site of the enzyme. One can hope that analysis of positions of the extrema in the plots of the magnetic field dependences of the magnetic field effects in the enzymatic oxidation of different substrates in combination with the data obtained by other methods for detection of enzyme–substrate interactions will in the future allow one to formulate criteria for evaluation of binding.

An important result is also the observation of the magnetic field effect in the oscillatory reaction of NADH oxidation by peroxidase. To draw unambiguous conclusions about changes in the processes occurring in the catalytic cycle of peroxidase in the course of oscillatory oxidation in the presence of additional sources of free radicals (Methylene Blue, phenol, *etc.*), one should study the effect of magnetic field on interconversions of HRP-Compounds, as was done for the steady-state oxidation. Differences in the character of the magnetic field dependences of the magnetic field effects detected in particular steps of the steady-state oxidation and in the oscillatory reaction (overall reaction) suggest the presence of non-identified magnetic field-sensitive steps of the oscillatory process.

Summing up, it seems useful to list other enzymatic processes that are most promising for spin chemistry studies in order to establish the mechanisms of elementary reactions. These are first of all the processes involving cytochrome P450 and cytochrome *c* oxidase,⁶⁹ which have well-established paramagnetic intermediates and are structurally similar to the peroxidase Compounds.

Cytochrome P450 plays an important role in enzymatic catalysis by metal-containing enzymes:⁴⁷ it participates in hydroxylation of xenobiotics, such as saturated and unsaturated fatty acids,⁷⁰ steroid hormones,⁷¹ cholesterol,⁷² bile acids⁷³ and prostaglandins.⁷⁴ Despite the fact that the mechanism of substrate oxidation catalysed by cytochrome P450 has been studied for two decades, it is still to be clarified. The catalytic cycle of hydroxylation by cytochrome P450 involves radical steps (Scheme 12).⁴⁷ For instance, it was assumed that

the substrate oxidation starting with the binding by the $\text{Fe}^{\text{IV}}=\text{O}$ group can proceed by either a radical ('radical clock' of norcaradiene and spiro-2,5-octane) or cationic mechanism. This results in different reaction products.⁷⁵

In addition, the state (high-spin or low-spin) of the active site of enzyme in the enzyme–substrate complex and the changes in this spin state upon reduction as a result of single-electron transfer are still unclear.⁴⁸

Spin chemistry methods can be useful in studies of the mechanism of hydroxylation by cytochrome P450. Indeed, by analysing the magnetic field dependences of the effective rates of the interconversions of reactive intermediates in the catalytic cycle of cytochrome and the dependences of the product ratio of substrate oxidation on the strength of external magnetic field it is possible to determine the spin state of iron in the enzyme active site and the spin configurations of the cytochrome reactive intermediates. Analysis of the magnetic field effects also permits monitoring of the effect of electron spins of the cytochrome P450 intermediates on the ratio of the radical and cationic oxidation pathways.

Yet another enzymatic system that can (potentially) be studied by spin chemistry methods is the cytochrome *c*–cytochrome *c* oxidase system. The role of electron-transfer steps in this system has been a subject of considerable discussion.⁷⁶ The case in point is the generation of the chemical potential within a mitochondrion in the respiratory chain, which produces most of the free energy necessary for life processes in aerobic organisms by combining electron transfer and the synthesis of adenosine triphosphate (ATP).⁷⁷ The electron transfer steps involving proteins and highly reactive paramagnetic cytochrome intermediates in the mitochondrial chain is the key to this process. At present, we know that the cytochrome *c*–cytochrome *c* oxidase system contains four cofactors, namely, two copper atoms, a low-spin haem group and a haem group that is a constituent of the protein containing haem iron and copper.⁷⁸ During the reaction, the system adds four electrons in four successive single-electron steps, thus reducing oxygen to water, and at the same time creates a proton gradient across the inner mitochondrial membrane (see Scheme 12). Recently,⁷⁶ the reactive paramagnetic intermediates of cytochrome *c* oxidase were determined spectroscopically. These are peroxide linkers (Compounds P_M and P_R), ferryl intermediate (Compound F), ground state (Compound O), a singly reduced form (Compound E) and a doubly reduced form (Compound R). Interconversions of these species involve single-electron transfer between the paramagnetic intermediates of the enzyme.⁶⁹ Based on the results of structural studies of cytochrome *c*,^{79, 80} possible pathways of electron transfer in the enzyme and a mechanism involving interconversion of cytochrome *c* intermediates were proposed; however, all these assumptions

Scheme 12

require additional proofs. It is desired to prove them in studies of the dynamics of the processes occurring in the cytochrome *c*–cytochrome *c* oxidase system. One can expect that spin chemistry methods, such as the magnetic field effect and chemically induced dynamic nuclear polarisation, will provide the possibility of establishing the role of the electron spin states in different paramagnetic intermediates and obtaining information on the subtle mechanism of functioning of the system of mitochondrial breath, namely, the cytochrome *c*–cytochrome *c* oxidase system.

III. Phenoxy-imine catalysts for olefin polymerisation	627
IV. Conclusion	633

Abstract. The role of catalyst systems in the perfection of polymerisation processes and the improvement of the performance characteristics of polyethylene and other polyolefins is considered. The scope of application of post-metallocene catalysts based on transition metal α -diimine, bis(imino)pyridine and phenoxy imine complexes designed in the last decade is analysed. The structures of complexes depending on the type of ligands are described systematically. The development of research into these catalyst systems is discussed, the optimal structures as regards the activity and selectivity are mentioned, and the mechanism of their action and the prospects for industrial use are demonstrated. The bibliography includes 207 references.

I. Introduction

In the early 21st century, the annual production of polymers exceeded hundred million tons ('*World Polymer Products*' issued by the Chemical Marketing Association, Inc., on September 2005) due to the universal use of these materials in industry and other fields of human activity. Among various classes of polymers, there are leaders in both the amount of production and the width of consumption. For example, the percentage of polyolefins in the total annual production of plastic materials (180–190 million tons) is higher than 50% (105 mil. tons, including ~64 mil tons of polyethylene and ~41 mil tons of polypropylene). Consequently, polyethylene (PE) and polypropylene (PP) are the most widely used polymer materials, whose production increases annually by 3%–7%.

Polyolefins attract great attention of both manufacturers and consumers because these materials are produced from inexpensive and readily available sources and are characterised by an attractive combination of their properties and the ease of processing. The advantages of polyolefins are also their hydrocarbon composition and, consequently, the ease of utilisation by recycling or burning. Polyolefins have wide and various

applications due to rather high melting points [up to 135 °C for polyethylene, ~160 °C for propylene and ~200 °C for poly-(4-methylpentene)] combined with a low weight, transparency, corrosion resistance, rigidity, shock resistance and ability to be modified.

The history of the development of research into polymerisation processes of ethylene, propylene and other α -olefins and the development and commercialisation of polyolefin production processes dates back approximately 70 years. After the first successful technological solutions on procedures for ethylene polymerisation under high pressure, ICI Plc (UK) began commercial production of PE in the late 1930s. More recently, in addition to the autoclave process, a procedure for ethylene polymerisation in tubular reactors was developed and commercialised.¹ These processes hold industrial importance to the present day.

The Nobel Laureates K Ziegler and G Natta laid the scientific foundation for catalytic ethylene and propylene polymerisation at moderate pressure and temperature.^{2–7} These scientists have designed catalysts based on titanium chloride and alkylaluminium compounds, which are commonly known as Ziegler–Natta catalysts. The application of these catalysts and their analogues on the industrial scale took great efforts and years because of difficulties in elucidating the mechanism of action of catalysts, choosing the optimal structures of components of catalyst systems and finding conditions for the preparation of polymers with required properties and performance characteristics.

Montagna and Floyd⁸ suggested a graphical interpretation of the evolution of catalytic olefin polymerisation as an S-shaped step curve (Fig. 1). This curve reflects the relationship between the level of technological solutions and the molecular architecture (structure) control of polymers, on the one hand, and the structural features of polymerisation catalysts and the time of their design, on the other hand. This plot was published in the recent handbook⁹ of polyolefins for characterisation of the steps of perfection of olefin polymerisation processes.

An analysis of the plot presented in Fig. 1 shows that the progress in the control of the polymer structure is always associated with advances in the design of new high-performance and highly selective commercial catalysts.

In the first step of investigations of olefin polymerisation corresponding to the first step in the curve presented in Fig. 1, high-pressure ethylene polymerisation was performed in autoclave reactors. The technology of ethylene polymerisation (1500 atm, 200 °C) by the radical mechanism developed in

Figure 1. Evolution of olefin polymerisation catalysts.

(1) Low-density PE (non-catalytic radical process); (2) high-density PE and PP (Ziegler–Natta catalysts); (3) gas-phase polymerisation (supported catalysts); (4) preparation of homo- and copolymers with different microstructures (single-site catalysts and metallocenes); (5) copolymerisation of olefins with polar monomers, functionalised polymers and block copolymers (post-metallocene catalysts).

the late 1930s allowed the preparation of polyethylene with a specific structure. Macromolecules of this polymer contain both long-chain and short-chain branches (Fig. 2a). The process equipment was improved to increase the performance and the degree of control over the structure of high-molecular-weight products with the use of a wider range of initiators (in addition to oxygen, peroxides with different structures). This led to an improvement of the properties and an extension of the assortment of PEs.

The second step in the PE production started in 1950s, when the Standard Oil Company (USA) began the commercial production of PE at moderate pressure (~ 40 atm) and temperature of ~ 100 °C in the presence of an alumina-supported molybdenum oxide catalyst.¹⁰ A new class of complex organometallic catalysts discovered by Ziegler and co-workers² in 1953 made a revolution in this technology, resulting in an increase in the efficiency of ethylene polymerisation under moderate pressure. Natta and co-workers^{4–6} developed a procedure for stereospecific propylene polymerisation.

Figure 2. Structures of different types of polyethylene:

(a) Long-chain branches combined with short-chain branches; (b) unbranched polymer; (c) short-chain branches, whose regularity depends on MW; (d) short-chain branches (or the insertion of a comonomer) with a regular distribution in the chain.

There are three factors responsible for the unique technological and industrial advances in the improvement of properties and extension of the scope of application of polyolefins:

— strategy of the control over promising technologies to form materials with improved performance characteristics and an extension of the fields of their rational use;

— permanent perfection of the production processes and the improvement of the structure and properties of polymers, the design of new types of polyolefins;

— dynamism of the development of convenient technologies and the efficiency of introduction of modern technological solutions, which is a prerequisite for the design of materials with new properties and new possibilities of their application.

As mentioned above, the design of new-generation catalysts for olefin polymerisation, in-depth investigations of the mechanism of their action and the determination of conditions for their optimal use were and remain the driving force of the progress in studies in this field. Discoveries of higher-performance catalyst systems always led to the perfection of polyolefin production and new advances in the control of the molecular structures of polymers.

For example, the modification of Ziegler–Natta catalysts by electron-donor additives resulted in an increase in the activity and selectivity of the catalysts by two orders of magnitude.¹¹ The use of such catalysts allowed the simplification of the flow scheme for the polyethylene production (the polymer washing step is excluded) and the improvement of the efficiency of copolymerisation of ethylene with higher α -olefins. As a result, linear low-density polyethylene (LLDPE) was prepared.^{11–23} This polymer consists of linear molecules with short-chain branches (see Fig. 2c), and this is the difference from PE prepared earlier, which has a linear structure without branches and is characterised by a high density (see Fig. 2b).

The design of catalyst systems supported on inorganic adsorbents (SiO_2 , Al_2O_3 or MgCl_2) and, more recently, on polymer supports was an important breakthrough in the perfection of olefin polymerisation catalysts. This gives rise to a new version of the flow scheme, *viz.*, gas-phase polymerisation. The Union Carbide Corporation (USA) was the first to employ this scheme in industry. Later on, this process was used also by other companies [British Petroleum, BASF (Germany), *etc.*]. Studies of the characteristic features of the behaviour of supported catalyst systems, primarily of MgCl_2 -supported catalysts, which were independently performed by the Mitsui Chemical (Japan) and Montedison (Italy) Companies resulted in the design of catalysts allowing the control over the properties and polymer morphology. It appeared that these systems are able to replicate (reproduce the shape) the starting catalyst particles by the resulting polymer particles. This allowed the synthesis of granular polymers directly in a polymerisation reactor.^{11, 23–28}

A new step in the perfection of olefin polymerisation catalysts (1980s) was associated with investigations of so-called ‘metallocene’ catalysts based on coordination organometallic compounds. In these complexes, one or two cyclopentadienyl rings (including substituted rings) form a π bond with the central Group IVB, VB or VIB transition metal atom.^{11, 20, 29–39} A new type of organoaluminium compounds, *viz.*, poly(methylalumoxane) ($[\text{—Al(Me)O—}]_n$, MAO), was used for activation.⁴⁰

In the 25-year metallocene epoch, about 700 patents were granted and more than 10 reviews and monographs devoted to this problem were published (see, for example, Refs 20, 29–31 and 33–39). The following aspects were considered: the evolution of the design of new structures of metallocene complexes, the mechanism of action of catalyst systems based on these complexes with the use of cocatalysts of different nature and the possibility of application of these complexes in

olefin polymerisation and copolymerisation. A detailed analysis of problems associated with the mechanism of olefin polymerisation in the presence of metallocene catalysts and the related publications are beyond the scope of the present review. Let us only note the most important aspects due to which this type of catalysts attracts great interest of researchers.

Metallocene catalyst systems are characterised by a number of important features:

- high activity[†] in ethylene polymerisation (up to 40 tons of PE per gram of transition metal for 1 h);
- the single-site character of the catalysis process;
- the similarity of the constants of copolymerisation of ethylene and higher α -olefins, which provides the uniform incorporation of α -olefins into the polymer chain regardless of the molecular mass of the copolymer (see Fig. 2 d);
- high performance in polymerisation and copolymerisation of a wide range of monomers;
- lower oxophilicity compared to Ziegler–Natta catalysts allowing polymerisation of monomers containing functional groups remote from double bonds.

Judging by numerous predictions, metallocene catalyst systems would replace Ziegler–Natta catalysts in the polyolefin production. However, their introduction occurred much more slowly than expected due primarily to a high price of the components of these catalysts and problems associated with processing of polyolefins.^{41, 42}

To summarise the aforesaid, it can be stated that, in spite of great progress in studies of olefin polymerisation catalysts, a number of problems associated with the technology of these processes remain to be solved. For example, copolymers of ethylene and other olefins with various available comonomers containing polar groups cannot be prepared because of the oxophilic character of the components of metallocene catalyst systems. A search for ways for increasing the performance and selectivity of catalysts and controlling the morphology of the resulting polyolefins as well as the improvement of methods for stereochemical control of the growing chain are still important.

Many research teams were engaged in solving these problems. This gave rise to the subsequent step in the history of evolution of olefin polymerisation processes associated with the design of a radically new generation of catalysts. This step is represented by dashed line 5 at the top of Fig. 1 and corresponds to more perfect catalyst systems characterised by high performance and selectivity, a wider range of conditions (temperature and pressure), the possibility to control the catalytic properties by varying the oxophilicity of the ligand and the ability to control the polymerisation process. These catalysts should solve the problem of copolymerisation of ethylene with polar monomers and should be characterised by high efficiency, accessibility and the safe storage and use. In addition, the use of these catalysts provides the possibility of improving the structural characteristics of polyolefins, thus ensuring better recycling and performance characteristics of polymer materials.

First publications on new catalyst systems meeting the above-mentioned requirements date back only 10 years. Nevertheless, numerous papers, patents and reviews have been published during these years.^{43–52} A new class of high-performance non-metallocene catalyst systems is referred to as ‘post-metallocene catalysts’.[‡]

Most of the studies of olefin polymerisation catalysts published in the last decade are related to systems based on late transition metal complexes with nitrogen-containing ligands (‘the nitrogen skeleton’). These are primarily nickel and palladium diimine complexes as well as iron and cobalt-bis(imino)pyridine complexes (see, for example, Refs 44, 45, 48, 49 and 51). A new type of post-metallocene catalysts based on phenoxy imine complexes of titanium, zirconium, hafnium and some other transition metals has attracted attention more recently.^{47, 50, 52}

In Russia, investigations of post-metallocene catalyst systems started somewhat later. In this connection, the publication of a Russian review devoted to an analysis of the progress in this field will apparently attract interest of researchers concerned with catalytic olefin polymerisation.

II. Catalyst systems based on late transition metal α -diimine and bis(imino)pyridine complexes

1. α -Diimine complexes as catalysts for olefin polymerisation

In 1995, the US research team headed by Brookhart obtained first successful results in the design and application of post-metallocene catalyst systems.^{53–56} The authors demonstrated that ethylene, propylene and hex-1-ene polymerisation can be performed in the presence of nickel or palladium complexes (**1** and **2**, respectively) with bis(arylimine) ligands.

1, 2

M = Ni (**1**), Pd (**2**); R = Me, Prⁱ; X = Cl, Br, Me.

The results of investigations of these systems obtained in the first five years were summarised in the review.⁴⁵ α -Diimine fragments most often contain aryl substituents at the nitrogen atoms and are involved in an aliphatic or complex polyaromatic system (for example, the acenaphthylene system). The general structures of nickel and palladium α -diimine complexes can be represented as follows:

M = Ni, Pd; Hal = Cl, Br; R¹, R², R³ = H, Alk, Ar; R⁴ = H, Alk.

[†] Hereinafter, the activities of catalysts are given in units of (amount of a polymer) [mole (or gramme) of a catalyst]^{−1} h^{−1}.

[‡] The term ‘post-metallocene catalysts’ has been used for the first time in the review by Britovsek *et al.*⁴⁴

A sophisticated analysis of the published data on the synthesis and studies of late transition metal complexes with ligands containing the nitrogen skeleton demonstrated that studies by Brookhart were preceded by earlier investigations in

this field. For example, Yamamoto *et al.* reported⁵⁷ the results of tests of catalysts based on cobalt and iron alkyl complexes with bipyridine ligands (for example, compound **3**), in polymerisation of acrylic acid derivatives, as early as in 1970. It is evident that these catalysts are similar to late transition metal α -diimine complexes.

Later on, it was demonstrated⁵⁷ that bipyridine complexes **3** are characterised by relatively weak coordination of the iron atom by bipyridine ligands. This facilitates side processes, such as β -hydride migration and reductive elimination. The termination of the polymer chain growth leads to fast deactivation of the catalyst⁵⁸ and, consequently, to a decrease in its activity. Because of these drawbacks, researchers have lost interest in this type of complexes.

It should be emphasised that the newly synthesised catalysts based on late transition metal complexes containing ligands with the nitrogen skeleton were covered by numerous patents. In the period from 1994 to 2001, 742 patents were issued (cited from the monograph,⁵¹ p. 59), which is comparable only with the number of patents on the design of metallocene systems.

To perform olefin polymerisation, it is necessary to transform α -diimine complexes into the active form. Methylalumoxane or perfluoroaryl boron compounds (the latter are more suitable for complexes with the central palladium atom) are commonly used as activators (or cocatalysts). Somewhat later, it was demonstrated that simple alkyl derivatives of aluminium can also be used for these purposes.^{59,60}

Depending on the structure of the ligand and the reaction conditions, nickel and palladium α -diimine complexes can exhibit high activity in ethylene polymerisation to give PE with molecular weight (MW) varying in a wide range. For example, the performance of up to 11 (kg PE) mmol⁻¹ h⁻¹ bar⁻¹ was observed for some nickel derivatives,⁵³ PE with MW of up to 1 million was obtained at low temperatures. On the whole, nickel α -diimine complexes provide higher activity of catalysts in ethylene polymerisation and form polymers with higher MW compared to analogous palladium complexes.

Studies of the PE structures showed that new catalyst systems allow the preparation of polymers with short-chain (methyl, ethyl, butyl or longer) branches.

Based on low-temperature NMR spectroscopic data, the branch migration mechanism for ethylene polymerisation in the presence of nickel or palladium α -diimine complexes was suggested (Scheme 1).^{45,61,62} The reactions of the complexes with cocatalysts and coordination with ethylene afford the inactive (latent) cationic form **A** and the polymer chain begins to grow. The formation of the growing linear chain can alternate with β -elimination of a hydride ion and the formation of alkenyl hydride complex **B**, whose transformation gives rise to methyl branching in the growing chain. The formation of the whole macrochain is a result of a combination or alternation of the chain growth and β -elimination of a hydride ion in the alkenyl hydride complex, resulting in the next branching.

According to this mechanism, catalyst systems based on Ni and Pd α -diimine complexes afford polymers with methyl branches. Several successive β -hydride transfer reactions give rise to short-chain ethyl, propyl or other (longer) α -alkyl branches. These catalysts are very promising because they allow the preparation of short-chain branched polyethylenes without the use of comonomers.

For palladium systems, the barrier to ethylene insertion by the migration mechanism was estimated^{53,63} at 17–18 kcal mol⁻¹ (the lowest barrier is observed for the bulkiest imine ligands), whereas this barrier for nickel systems is substantially lower (13–14 kcal mol⁻¹). Therefore, the energy difference of 4–5 kcal mol⁻¹ is consistent with higher activity of nickel complexes observed in experiments.

In the presence of palladium catalysts, the branching of PE is independent of the monomer pressure in the polymerisation process. However, the ethylene pressure influences the polymer morphology. At moderate pressures, polymerisation affords viscous amorphous oils; at high pressures, amorphous rubber-like solids, plastomers (Fig. 3).

In the case of nickel complexes, the degree of branching of PE is always lower than that obtained with the use of palladium analogues, and this degree decreases with increasing ethylene pressure. The sensitivity of the degree of branching of the product to the pressure is a result of a competition between two processes, *viz.*, trapping of ethylene by the active complex and the chain transfer. High pressures are favourable for trapping of ethylene, resulting in a lower degree of branching.

Polymerisation on diimine catalysts giving high-molecular-mass polymers is characterised by a much higher chain growth rate compared to the chain transfer rate. An increase in steric crowding of the axial regions in the square plane of the complex is the key factor responsible for a decrease in the chain transfer rate.⁴⁵ The crystallographic data show that the benzene rings in square-planar palladium α -diimine complexes are located approximately perpendicular to the plane of the square, and the *ortho* substituents are located above and below this plane.

Scheme 1

Figure 3. Branched structures formed upon ethylene polymerisation: plastomers (a) and hyperbranched low-molecular-weight compounds (oils) (b).

Important investigations aimed at optimising the structures of diimine catalyst systems involve variations of the nature of substituents in the ligand and the elucidation of their influence on the characteristics of the resulting polymers. For example, the detailed theoretical investigation of nickel complexes with various diimine ligands was carried out.⁶⁴ An increase in the bulkiness of substituents at the nitrogen atom was demonstrated to play a dual role. First, these groups block the access to the transition metal atom in the axial direction. This destabilises the inactive (latent) state of the catalyst and the chain termination transition state, in which both axial positions are occupied. Second, the aryl rings in nickel complexes, unlike those in palladium analogues, are located in one plane with the diimine fragment, which is favourable for stabilisation of the transition state of ethylene insertion compared to the latent state of the catalyst. An increase in the bulkiness of substituents either at the carbon atoms or in the *ortho* positions of the aryl groups at the nitrogen atoms of diimine results in a more rigid fixation of the plane of the aromatic ring perpendicular to the metal–ligand coordination plane. In this case, *ortho* substituents more efficiently block the axial directions.⁶⁵

In particular, the 2,3-bis(2,6-dimethylphenyl)butanediimine nickel dichloride complex (**1**, R = Me, X = Cl) is one of the most active catalysts in this class.⁶⁶ Ethylene polymerisation on this catalyst activated by MAO affords PE characterised by the number average MW (M_n) in the range of $(1.7–6) \times 10^5$ and a rather narrow molecular weight distribution (MWD) of 2.0–3.5. The degree of branching increases, whereas MW decreases as the temperature of the process is increased. The polymer branching is virtually independent of the Al : Ni molar ratio and the concentration of the catalyst.

Therefore, the main structural feature of ligands in late transition metal α -diimine [as well as bis(imino)pyridine, see below] complexes and catalysts based on these complexes is that the active cationic centre is sterically shielded by bulky *ortho*-substituted aryl groups at the nitrogen atom, resulting in suppression of side processes of chain termination (elimination of the hydrogen atom from the β position and the associative substitution of olefins) during polymerisation. The ability to provide efficient stabilisation of organometallic complexes that are formed in the reactions with monomers is another

important property of these ligands. The electronic structure of ligands is rather flexible because it is determined primarily by the nature of substituents in *N*-aryl groups. These characteristic features were observed in many experimental^{45, 48, 49, 51, 53–58, 67–70} and theoretical^{60, 64, 65, 71, 72} investigations.

Therefore, the activity of α -diimine catalysts based on nickel and palladium complexes in olefin polymerisation was substantially increased by changing the structure of the ligand, to be more precise, by introducing bulky aryl substituents at the *ortho* positions of the phenyl rings at the nitrogen atoms of the imine fragments.⁵¹ Recently, new Ni and Pd complexes with the use of various types of ligand variation were synthesised.^{73–75} For example, complexes having symmetric (**4** and **5**) or non-symmetric (**6**) structures and complexes with heteroaromatic substituents (**7**) were prepared.

M = Ni, Pd; X, Y = Hal, Me; R = Alk.

The activity of catalyst systems based on compounds **4–7** in ethylene polymerisation and MW of polymerisation products appeared to be similar to the corresponding characteristics for complexes, which have been studied earlier by Brookhart. The highest performance was observed for the catalyst based on compound **5**. These systems are characterised by the dependence of the degree of branching of PE and, consequently, of its glass-transition temperature (T_g) on the structure of ligands. For example, complexes **4**, **5** and **7** allow the synthesis of virtually linear PE. In addition, polymerisation in the presence of complex **6** containing unsymmetrical ligands affords PE characterised by a lower degree of branching compared to a polymer prepared with the use of structurally similar Brookhart's complexes. Polymerisation in the presence of catalyst systems based on complexes **7** with peripheral heterocyclic substituents affords polymers with lower MW. It should be noted that an analogous situation is observed for complexes containing other heteroaromatic substituents (for example, indoles, *etc.*) instead of the pyrrole rings.

2. Bis(imino)pyridine complexes as olefin polymerisation catalysts

Several years after the discovery of α -diimine catalysts for olefin polymerisation, Brookhart and co-workers^{45,76,77} in USA and the research group headed by Gibson^{48,78–84} in UK simultaneously and independently published data on the design and examination of iron and cobalt 2,6-bis(aryliminoalkyl)pyridine [hereinafter, referred to as bis(imino)pyridine] complexes.

M = Fe, Co; X = Cl, Br; R¹, R², R³ = H, Alk, Ar; R⁴ = H, Alk.

Iron complexes with R¹ = R³ = Me, Prⁱ or Bu^t, R² = H, R⁴ = Me and X = Cl, Br or NO₃ were the first representatives of this type of compounds.⁷⁷ A short time later, other researchers were also engaged in the synthesis of complexes with *N*-tridentate ligands (see, for example, Ref. 85).

The characteristic structural feature of these complexes is that the metal atom in them has the coordination number 5 and a pseudosquare-pyramidal coordination geometry with the phenyl rings being virtually perpendicular to the plane of the square. High-molecular-weight polyethylene (*M_w* up to 7 × 10⁵) was prepared on these catalysts in high yield upon activation by modified methylalumoxane (MAO) in the presence of ethylene in toluene. As opposed to Ni(II) and Pd(II) diimine catalysts, linear (without branches) PE is formed under analogous conditions even in the presence of bulky ligands in the complexes and at low ethylene pressure. The molecular weight of the polymer varies in a wide range depending on the type of the ligand, the nature of the central metal atom and the concentration of the cocatalyst. As in the above-considered diimine complexes, the bulkiness of the aryl fragments at the imine nitrogen atoms in the ligands in Fe and Co bis(imino)pyridine catalysts plays an important role. Thus, an increase in the bulkiness of the *ortho* substituents also leads to an increase in the activity of the catalyst system.

The mechanism of ethylene polymerisation with the use of catalysts based on Fe(II) bis(imino)pyridine complexes was analysed in detail⁸⁶ using quantum chemical calculations by the density functional theory (DFT) method and in combination with the molecular mechanics method. The calculations were carried out for the active state of the catalysts, *viz.*, for the model (8) and real (9) cationic complexes.

The trapping of ethylene by the cationic metal alkyl complex was demonstrated⁸⁶ to be the rate-determining step of both the chain growth and termination. The mechanism of chain termination involves the β -hydride transfer of the growing chain to the monomer in the active centre as the major process (see Scheme 1). As in the case of α -diimine ligands, the presence of bulky aryl groups containing substituents in the *ortho* positions at the imine nitrogen atom (for example, 2,6-Prⁱ₂C₆H₃) is desirable for the highest performance. In the presence of complexes with such substituents, the chain termination is suppressed and the rate of monomer insertion into the growing chain increases.

The group headed by Brookhart found⁴⁵ that bis(aryl-iminoethyl)pyridine complexes 10–12 containing only one *ortho* substituent in each benzene ring are superactive catalysts for ethylene oligomerisation.

R = Me (10), Et (11), Prⁱ (12).

It should be noted that this fact is consistent with the results of our investigation⁶⁸ of ethylene oligomerisation with the use of substituted diimine complexes.

In the study,⁸³ the dependence of the kinetic activity of bis(imino)pyridine complexes in ethylene polymerisation on their structure (primarily, on the size of substituents in the *ortho* position of the arylimino fragment) was found and the molecular characteristics of PE were determined. These characteristics are also not contradictory to the above-considered data.

Ethylene polymerisation in the presence of iron complexes with various tridentate nitrogen-containing ligands, such as 2,6-bis(aryliminoalkyl)pyridine (13, 14), 2-arylaminoalkyl-6-aryliminoalkylpyridine (15, 16) and 2,6-bis(arylaminoethyl)pyridine (17), and cobalt complex 18 combined with the cocatalyst MAO was investigated.⁸⁴ Compounds containing bis(imine) fragments were demonstrated to have higher catalytic activity than bis(amine) and aminoimine derivatives; complexes with ketimine ligands are more active than complexes with aldimine ligands. Cobalt complex 18 is less active than its iron analogue 15.

M = Fe: R = H (13, 15), Me (14, 16); M = Co, R = H (18).

It was noted that lower activity of amine complexes compared to bis(imino)pyridine analogues is possibly attributed to a relatively weak bond between amine and the iron atom, whose cleavage results in dissociation of the amine fragment. In addition, insufficiently strong conjugation of the ligand environment and the spatial orientation of the amino-aryl substituent, which hinders access of the monomer to the catalyst active site and, correspondingly, the growth of the polymer chain, can also play a particular role.

On the whole, ethylene polymerisation catalysts based on transition metal bis(imino)pyridine complexes are attractive because they are synthetically accessible and inexpensive,⁸⁷ allow the synthesis of products with both narrow and wide MWD and can be activated by various alkyl derivatives of aluminium.^{59,60} The main drawbacks are relatively low thermal stability, which is manifested in a considerable decrease in the catalytic activity of the system as the temperature rises (by a factor of two and nine as the temperature rises to 50 and 70 °C, respectively, compared to the activity at the optimal temperature of 35–40 °C). In addition, an increase in the polymerisation temperature leads to a sharp decrease in the MW of polyethylenes prepared with the use of these catalysts. Attempts to eliminate this drawback were made in several studies.

Our research team made a considerable contribution to the solution of this problem.^{88,89} For example, we demonstrated that the temperature range, where catalysts based on complexes **19–22** containing cycloalkyl substituents in the *ortho* position of the arylimine group exhibit high performance, can be shifted to higher temperatures.

$R^2 = \text{Me}$, $R^1 = \text{cyclo-}C_nH_{2n-1}$ [$n = 5$ (**19**), 6 (**20**), 8 (**21**), 12 (**22**)];
 $R^1 = R^2 = \text{Pr}^i$ (**23**).

Ethylene polymerisation was performed in toluene using the catalyst:activator (MAO) ratio of 1:1500 at ethylene pressure of 0.3 MPa; the reaction time was 1 h.⁸⁹ The curves of the temperature dependence of the activity of catalyst systems based on iron bis(imino)pyridine complexes with cycloalkyl substituents **19–22** and reference complex **23** containing isopropyl substituents at positions 2, 4 and 6 of the arylimine groups are presented in Fig. 4. It can be seen that the activity of catalyst **23** sharply decreases at temperatures higher than 50 °C, whereas the optimal temperatures for cycloalkyl-substituted complexes are higher, this effect being more pronounced as the number of the methylene groups in the ring is increased. The experimental results were confirmed by quantum chemical calculations for the complexes in question.^{88,89}

A generalised analysis of the influence of the structure of transition metal complexes with α -diimine and bis(imino)pyridine ligands on the activity of catalyst systems based on these ligand was performed in the Polymer Research Laboratory of the BASF Company (see the monograph,⁵¹ pp. 59–98). The authors confirmed that the key feature of the ligand

Figure 4. Plot of the activity of complexes **19–23** (curves **1–5**, respectively) vs. the temperature of ethylene polymerisation.⁸⁹

structure of these catalysts is that the active cationic centre is sterically shielded to an extent sufficient to suppress undesirable chain termination processes (primarily, β -hydride elimination and associative substitution of olefins in active complexes). Steric shielding can be provided, for example, by bulky *ortho*-substituted aryl groups bound to the peripheral donor centres (imine nitrogen atoms).

The results of studies of nontraditional substituents at the imine nitrogen atoms of α -diimine and bis(imino)pyridine ligands, for example, of nitrogen-containing heteroaromatic groups, made a substantial contribution to knowledge about the influence of the structure of complexes on their activity. Earlier, when considering the catalytic activity of α -diimine systems containing *N*-pyrrole rings, we have demonstrated that the degree of branching of PE in polymerisation can be changed (decreased or completely suppressed). An similar effect was observed also in the presence of symmetrical (**24–27**) or unsymmetrical (**28**) iron bis(imino)pyridine complexes with peripheral *N*-heterocyclic substituents.⁵¹

A comparison of the polymerisation activity of systems based on complexes **24–28** in ethylene polymerisation with that of the most active classical Brookhart–Gibson catalysts showed that the activity of the former catalyst systems is rather high, but MW of PE prepared with their use is substantially lower. The molecular mass was increased by increasing the bulkiness of the peripheral *N*-azolyl substituents in the catalyst, but this led to a decrease in activity. However, the most substantial difference is that the reaction mechanism changes. Polymerisation with the use of complexes **24–28** affords branched polymeric or oligomeric products, whereas polymerisation with the use of Brookhart–Gibson complexes studied earlier gives linear products.

The above-considered data show that there is a fine equilibrium between the following two processes that occur during ethylene polymerisation catalysed by transition metal bis(imino)pyridine complexes: the monomer insertion resulting in the formation of linear PE and β -hydride elimination with the repeated addition of the isomerised chain giving rise to branched structures. This equilibrium substantially depends on the steric and electronic effects of peripheral substituents in catalytic complexes, whose nature (for example, the introduction of the *N*-azolyl fragment instead of the *N*-phenyl group) determines the mechanism of polymer formation. The chain growth can give rise to either linear or branched structures with the use of both α -diimine and bis(imino)pyridine complexes.

When analysing new complexes containing ligands with the nitrogen skeleton, the recently synthesised oligomeric nickel α -diimine complexes⁹⁰ and iron bis(imino)pyridine complexes⁹¹ deserve note. Unfortunately, the results of examination of these complexes in ethylene polymerisation were not reported in the study cited.⁹⁰ However, in the presence of polyfunctional oligomeric bis(imino)pyridine complexes **29** and **30** (these complexes were synthesised by our group⁹¹) activated by MAO, polyethylenes with high MW were obtained at high temperatures (70–90 °C), *i.e.*, the temperature range of high performance of the catalyst system was extended.

Bis(imino)pyridine complexes not only with the central divalent iron atom but also with other transition metals, such as cobalt, nickel, vanadium, copper, zinc, chromium and manganese, were synthesised. The results of research into the activity of catalyst systems based on various metals were considered.^{92–96} Divalent iron complexes exhibited the highest activity in ethylene polymerisation, whereas Fe(III) complexes proved to have low activity. Divalent cobalt complexes, which were synthesised virtually simultaneously with the iron ana-

logues, are generally substantially less active than the latter. However, Co(II) complexes in the presence of MAO show higher activity in polymerisation of vinyl ethers than the corresponding iron complexes.⁹⁷ Divalent cobalt complexes containing electron-accepting substituents exhibit high activity also in selective dimerisation and oligomerisation of α -olefins.⁹⁸

Vanadium bis(imino)pyridine complexes were documented.⁹⁹ Detailed studies of the influence of the structure of complexes on the properties of the reaction products demonstrated^{100,101} that olefin polymerisation in the presence of vanadium systems gives mainly oligomeric products.

Chromium complexes analogous to iron bis(imino)pyridine complexes have received little study as olefin polymerisation catalysts. As a rule, these complexes exhibit lower activity than the above-considered iron, cobalt and vanadium complexes and often form low-molecular-weight products.^{101,102}

The differences in the behaviour of iron and cobalt 2,6-bis(imino)pyridine complexes activated by modified methylalumoxane in ethylene polymerisation under homogeneous conditions were noted in the recent publication by Kissin *et al.*¹⁰³ Cobalt complexes form virtually single-site catalysts with MMAO, whereas iron complexes give multisite (polyfunctional) catalysts, whose character depends on the Al:Fe ratio, the ethylene pressure, the temperature and the nature of substituents in the ligands.

In recent years, great attention has been given to the mechanism of action of Fe(II) 2,6-bis(imino)pyridine complexes in ethylene polymerisation, including the determination of key intermediates. For example, based on the results of ¹H and ¹³C NMR spectroscopic studies of the structures of intermediates formed in homogeneous systems in the reactions of the complexes with an activator, it was concluded¹⁰⁴ that individual Fe(II) complexes rather than cationic intermediates are active components of the catalyst system. In more recent studies,^{105–108} this conclusion was reviewed and it was hypothesised that neutral complexes in these systems are precursors of active sites for ethylene polymerisation. The schemes of the transformations of these complexes into active sites were proposed. The influence of activators, *viz.*, various alkyl derivatives of aluminium, on both the activity of the Fe(II) 2,6-bis(imino)pyridine complex and the characteristics of the resulting polyethylene (MW, MWD and the molecular structure) was analysed.¹⁰⁸ In this study, data on the number of active sites and the rate constants of chain growth in ethylene polymerisation were obtained.

New views of the mechanism of influence of alkylaluminum cocatalysts AlR_3 ($\text{R} = \text{Et}$, Bu^i or $n\text{-C}_6\text{H}_{13}$) on the activity of iron bis(imino)pyridine complex **31** were reported in the recent publication.¹⁰⁹

It was found that the activity of catalyst systems and the structure, MW and MWD of PE depend on the polymerisation temperature and the $\text{Al}:\text{Fe}$ molar ratio. The analysis of *in situ* UV-Vis spectra suggested the formation of two types of catalytic species, *viz.*, LFeRCl and LFeR_2 (L is 2,6-bis-[1-(2,4,6-trimethylphenylimino)ethyl]pyridine), the predominant formation of which being determined by the $\text{Al}:\text{Fe}$ molar ratio. The LFeR_2 compound has lower activity and favours the formation of low-molecular-mass branched polyethylenes.

It should be noted that catalysts with the nitrogen skeleton, in particular, α -diimine complexes, can be involved in two-component catalyst systems for olefin polymerisation (the method of reactor mixing). These mixtures (provided that the components are compatible and the catalytic activity is not decreased) are synthesised with the aim of changing the structure and molecular characteristics of PE. Reactor mixtures of PE were prepared by combining two catalyst systems, which provide the modification of polymers in the course of the synthesis, with the possibility of controlling their MW and achieving wider MWD.¹¹⁰

The reactor mixtures of PE have been prepared earlier with the use of two-component systems based on Ziegler–Natta catalysts and late transition metal complexes, as well as of metallocene and α -diimine systems.^{111,112}

For these purposes, our research group used two-component heterobimetallic catalyst systems consisting of α -diimine and bis(imino)pyridine complexes.¹¹³ The kinetic features of ethylene polymerisation on methylalumoxane-activated catalysts involving 2,6-bis(imino)pyridyl complexes of iron dichloride **14** and **20** and 1,2-bis(imino)acenaphthyl complexes

$\text{R}^1 = \text{cyclo-C}_6\text{H}_{11}$, $\text{R}^2 = \text{R}^3 = \text{Me}$ (**20**, **32**);

$\text{R}^1 = \text{R}^2 = \text{Pr}^i$, $\text{R}^3 = \text{H}$ (**14**, **33**).

of nickel dibromide **32** and **33** were studied at different ratios of the components in the temperature range of 50–70 °C.

These components were confirmed to be compatible in one reactor, and it was demonstrated that they can be efficiently used (at high rates) to synthesise polyethylene with different MW and short-chain branches. A mixture of complexes **14** and **32** proved to be an optimal combination of the components of a binary catalyst system, which retains high activity and gives rise to branched polyethylenes with satisfactory molecular characteristics.

3. Copolymerisation of ethylene with polar monomers in the presence of catalysts based on α -diimine and bis(imino)pyridine complexes

The structures and low oxophilicity of late transition metal complexes containing ligands with the nitrogen skeleton hold promise for their use as catalysts for copolymerisation of ethylene with polar monomers.

For example, catalyst systems based on palladium α -diimine complexes were successfully used by Brookhart and co-workers^{53,54,56} for copolymerisation of ethylene and propylene with monomers containing functional groups. Methyl acrylate, *tert*-butyl acrylate, methyl vinyl ketone and fluoro-octyl acrylate served as polar comonomers; the process was carried out in the presence of the $[\text{LPdMeCl}] - \text{NaBAR}_4$ systems (L is the α -diimine ligand) using the catalyst in an amount of 0.1 mmol per mole of the monomer in CH_2Cl_2 at 25–35 °C for 18–37 h. High-molecular-mass random polymers, which are amorphous highly branched structures with approximately 100 branches per 1000 carbon atoms, were synthesised. These polymers are characterised by the predominant arrangement of the ester groups at branches or at the ends of the chain (Fig. 5). The glass-transition temperature of these products varies from –67 to –77 °C. The maximum degree of introduction of the comonomer was 12.1%, 0.7%, 1.3% and 5.6% for methyl acrylate, *tert*-butyl acrylate, methyl vinyl ketone and fluoro-octyl acrylate, respectively.

Figure 5. Structure of copolymers of ethylene with acrylates prepared with the use of $\text{Pd}(\alpha\text{-diimine})$ catalysts (X are acrylate groups).

The introduction of functional groups of amines and nitriles into the polymer chain of polyolefins was reported.¹¹⁴ The efficiency of binding of the metal centre of the catalyst to the fragments of the $\text{CH}_2=\text{CH}(\text{CH}_2)_n\text{X}$ monomers ($\text{X} = \text{CN}$, NH_2 or NMe_2), *viz.*, the N -containing polar group and the π -system of the double bond, was compared¹¹⁵ by the density functional theory method. The energies of stabilisation of π - and N -complexes of monomers with Ni(II) - and Pd(II) -based catalysts containing diimine and salicylaldimine ligands were calculated, and the energy diagrams of their decomposition were constructed. It appeared that π coordination of a monomer to metal is more favourable for systems with the central palladium atom, which provides the further growth of the polymer chain. In the presence of nickel catalysts, stronger metal–nitrogen bonds are formed and the latter hinder efficient copolymerisation, which accounts for the lack of success in ethylene copolymerisation with the use of this type of systems.

Chien *et al.*¹¹⁶ successfully performed copolymerisation of ethylene with a series of polar monomers, such as hex-5-en-1-ol, undec-10-enoic acid, methyl vinyl ketone, vinyl acetate and ϵ -caprolactam. The authors modified the catalyst system by activating bis(imino)acenaphthene nickel(II) dihalide with a mixture of methylalumoxane (or diethylaluminium chloride) and dibutylmagnesium.

In the review,¹¹⁷ the optimal structures of nickel and palladium diimine complexes were proposed for copolymerisation of ethylene with polar monomers and the mechanism of formation of copolymers with polar functional groups was analysed based on the results obtained by the research teams headed by Brookhart and Chien. As a result of the electron distribution in the complexes, these palladium catalysts are polar compounds due to which they readily form highly branched PE, and provide the introduction of polar (in particular, acrylate) fragments into the ends of branches in copolymerisation reactions (see Fig. 5).

It should be noted that the possibility of polymerisation of methyl methacrylate in *o*-xylene at 90 °C in the presence of divalent iron complexes with tetradentate nitrogen-containing ligands, for example, with [*N,N'*-diphenyl-*N,N'*-di(quinolin-2-ylmethyl)]-1,2-ethylenediamine (using ethyl 2-bromoisobutyrate as the initiator) was demonstrated for the first time in the recent publication by Seppälä and co-workers.¹¹⁸ In this case, iron complexes catalyse the so-called atom transfer radical polymerisation (ATRP).

4. Supported catalyst systems based on α -diimine and bis(imino)pyridine complexes

As mentioned above, catalyst systems based on α -diimine and bis(imino)pyridine complexes are characterised by relatively low thermal stability and, as a consequence, rapidly lose activity during high-temperature polymerisation. The use of catalysts adsorbed on the surface of inorganic supports is a way to overcome this drawback.¹¹⁹ Experiments with supported catalyst systems demonstrated that they not only have high thermal stability but also allow the synthesis of polymers with substantially higher MW, improve their morphology and density and prevent adsorption of polymers on the walls of the reactor.

Patents^{120, 121} on the preparation of supported α -diimine and bis(imino)pyridine complexes were issued shortly after the discovery of post-metallocene catalysts. These supported catalyst systems were studied in detail.^{122, 123} A comparison of the efficiency of ethylene polymerisation in the presence of the MAO-activated 2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine complex of iron dihalide under homogeneous conditions and in the presence of the SiO₂-supported complex showed¹²³ that the activity of the supported system is 5 times lower. However, the polymer formed on the supported catalyst has higher MW and better morphology.

Our research group¹²⁴ studied the kinetic features of ethylene polymerisation in the suspension and gas-phase modes in the presence of SiO₂-supported 2,6-bis(arylimino)pyridine complexes of iron chloride and 1,2-bis(arylimino)acenaphthyl complexes of nickel bromide containing cycloalkyl substituents in the *ortho* positions of the aryl groups. We prepared supported catalysts under the conditions described in the patents.^{120, 121} It was found that supported catalyst systems based on iron bis(imino)pyridine complexes **19–22** allow a decrease in the amount of the required activator (the optimal Al:Fe ratio is 110). The kinetic characteristics of polymerisation were steady in time (during > 1 h), whereas a sharp decrease in the polymerisation rate during the process was observed for the analogous homogeneous catalyst. For supported systems, the pattern of the dependence of the catalytic activity on the bulkiness of the cycloalkyl substituent in the *ortho* position of the aryl ring also changes. In the latter

case, complex **20** with the cyclohexyl group showed the highest performance, whereas the activity of the corresponding homogeneous analogues increases with increasing bulkiness of the substituent in the series cyclopentyl (**19**) < cyclohexyl (**20**) < cyclooctyl (**21**).

In the presence of substituted 1,2-bis(imino)acenaphthyl complexes of nickel bromide (for example, compound **32**), polymerisation proceeds without the additional (except for the step of catalyst deposition) introduction of a cocatalyst. The kinetic profile of the process is generally similar to that observed with the use of bis(imino)pyridine systems.

In the very recent study by Zakharov and co-workers,¹²⁵ the characteristic features of ethylene polymerisation in the presence of the 2,6-[(2,6-Me₂C₆H₃N=CMe)₂C₅H₃N]FeCl₂ (**34**) complex activated by various alkyl derivatives of aluminium, such as MAO, AlMe₃, AlBu₃¹ and Al(*n*-C₈H₁₇)₃, were investigated. The catalytic behaviour of these systems under homogeneous conditions was compared with that of the systems supported on SiO₂, Al₂O₃ or MgCl₂. The supported catalysts showed high activity, retained stability up to 70–80 °C and gave higher-molecular-mass products. The polymers synthesised with the use of both homogeneous and supported systems were characterised by rather wide MWD. The authors also compared the number of active sites and determined the rate constants for chain growth in the presence of both types of catalysts. It should be noted that these constants for the homogeneous and heterogeneous systems were of the same order in the beginning of the process. However, in the presence of the supported catalysts, these constants remained virtually unchanged with time, whereas they were decreased by a factor of three already within 5 min of polymerisation in the presence of the homogeneous catalysts. The absolute values of the effective rate constants for chain growth¹²⁵ for the homogeneous systems (2.6 × 10⁴ litre mol⁻¹ s⁻¹) are rather similar to those for the supported systems [(1.2–2.4) × 10⁴ litre mol⁻¹ s⁻¹], whereas the numbers of the active sites are substantially different. In the case of the supported systems (0.028–0.032 mol per mole of Fe), this number is lower than that for the homogeneous systems (0.41 mol per mole of Fe). Unfortunately, this fact remained unexplained.

The interaction of the bis(imino)pyridine complex of divalent iron with oxide supports was studied by diffuse reflectance IR spectroscopy.¹²⁶ This study showed that the complex was strongly fixed possibly as a result of interactions of the ligand with several hydroxyl groups on the oxide surface, the geometric arrangement of these groups favours a multisite (according to the nomenclature used by the authors) contact. In aluminium oxide, both hydroxyl groups and Lewis acid sites are located on the surface, which provides stronger binding of the nitrogen-containing ligand to the support.

In the case of formation of supported catalysts on the surface of MgCl₂, the LFeCl₂ complex [L is the bis(imino)pyridine ligand] interacts only with Lewis acid sites of activated magnesium chloride.¹²⁷ Consequently, when choosing the conditions for deposition of the catalyst system, it is necessary to take into account the character of its interaction with the support. A characteristic feature of the behaviour of nickel α -diimine complexes immobilised on MgCl₂ is that the particle shape of the dispersed catalyst system is replicated by the polymer formed on this system.¹²⁸

The scope of action and the elucidation of the optimal conditions for the preparation of SiO₂-supported two-component catalyst systems based on α -diimine and bis(imino)pyridine complexes were described in our study.¹²⁹

Recently, an original procedure for immobilisation of nickel α -diimine complex **35** (Scheme 2) and iron bis(imino)pyridine complex **36** (Scheme 3) on a polymeric support (polystyrene) has been published.¹³⁰ These catalysts were

Scheme 2

DME is dimethoxyethane, AIBN is azobis(isobutyronitrile), (P) is polystyrene.

Scheme 3

called polymerised catalysts. Copolymerisation of an excess of styrene with comonomer complexes in toluene afforded copolymers with low molecular weight (MW \sim 10 000) involving the catalytic complex.

Procedures for the synthesis of the corresponding ligands and complexes containing alkenyl groups, capable of polymerisation, were reported.^{131–134} A procedure was developed for the preparation of an SiO₂-supported polymerised catalyst as spherical particles with a core–shell structure.¹³⁰

The resulting polymerised systems were examined as ethylene polymerisation catalysts in the suspension mode using activation by MMAO. These catalysts showed high activity and gave good results as regards the replication ability in the formation of polymer particles, which confirms the prospects of this field of investigation.

III. Phenoxy-imine catalysts for olefin polymerisation

1. General views

A new generation of post-metallocene catalysts for olefin polymerisation based on transition metal phenoxy-imine[§] complexes was discovered by the research group from the Mitsui Chemical, Inc., Company (Japan) in the framework of the Project 'Ligand-Oriented Catalyst Design' started in the mid-1990s.

[§] The term phenoxy-imine complexes is generally referred to complexes containing salicylaldimine ligands and their analogues.

First patents^{135, 136} and articles (see, for example, Ref. 137) on phenoxy-imine catalyst systems, which were issued less than 10 years ago, marked the beginning of a large series of publications on this problem in different journals.

As the authors noted, the concept of the above-mentioned project was based on the analysis of advances in the design of high-performance single-site olefin polymerisation catalysts and was aimed at searching for systems satisfying the following main criteria:

- catalyst systems should provide an efficient insertion of structurally different olefins, including sterically hindered olefins, as well as polar monomers, into the polymer chain;
- stability of catalysts under standard conditions of the polymerisation process;
- the possibility to control the chain transfer reaction, the achievement of the uniform distribution of the comonomer and stereochemical control of the product;
- extension of the range of the produced polymers by performing copolymerisation with the previously unused monomers.

An important principle of this concept was that olefin polymerisation is accompanied by extensive electron exchange between transition metal and ligands. In this case, it is necessary that the ligands should contain heteroatoms (as a rule, oxygen and/or nitrogen atoms), coordinate metal atoms in a bidentate fashion and have an unsymmetrical structure with mobile electrons (the so-called electron-flexible structure). The ability of transition metals to coordinate olefins and to be introduced into the polymer chain combined with such oriented ligands would provide high activity of the system in

M is metal.

Figure 6. Schematic representation of catalysts discovered based on ligand-oriented catalyst design.⁵²

polymerisation. Figure 6 schematically shows a catalyst system based on ligand-oriented catalyst design.⁵²

It was demonstrated that polydentate electron-flexible unsymmetrical ligands, which are capable of chelating and forming five- or six-membered rings, satisfy the above-mentioned conditions. These are primarily ligands containing phenoxy, pyridine and/or conjugated imine fragments. These ligands are characterised by stability under the reaction conditions, have required electron-donating properties for the efficient olefin insertion and stabilisation of the transition state and contain accessible coordination sites necessary for polymerisation.

However, in my opinion, the authors of this concept, when designing a new class of high-performance phenoxy-imine catalysts, did not give proper attention to studies of the Shell Company on the development of SHOP (Shell Higher Olefin Process) catalysts and improvement of nickel catalyst systems for ethylene oligomerisation and polymerisation.^{138–143}

Initially, the research group headed by Fujita^{135–137} synthesised catalytic complexes with unsymmetrical electron-flexible ligands based on *N*-(*o*-phenoxyphenyl)pyridylaldimine (37, 38) and salicylaldiminate (39–41) derivatives.

37, 38

M = Co (37), Ni (38).

39–41

R = Bu^t, M = Zr (39);
R = H: M = Ti (40), Hf (41).

Studies of the catalytic activity of cobalt complex (37) and nickel complex (38) in MAO-mediated ethylene polymerisation in toluene showed that the former complex is inactive and the latter complex has lower activity than Ni catalysts with α -diimine ligands. Zirconium complex 39 in toluene at 25 °C exhibited activity of 519 (t PE) mol⁻¹ h⁻¹ (the molecular mass of the polymer was $\sim 10^4$), which is 20 times higher than the activity of the metallocene catalyst Cp₂ZrCl₂ (Cp = η -C₅H₅). In addition, this zirconium complex is characterised by rather high stability in a wide temperature range (the activity gradually decreases as the temperature is raised).

Over a rather short period of time, this research group synthesised a large number of structurally different phenoxy-imine complexes containing substituents of different nature both at the imine nitrogen atom and the phenoxy group,^{144, 145} including those with perfluorinated fragments.^{146–149} Conceptually similar derivatives based on nitrogen-containing heterocycles, viz., indolyl-imine¹⁵⁰ and pyrrolyl-imine¹⁵¹ complexes, were also synthesised.

Shortly thereafter, the results of investigations in this field were summarised and systematised, which showed considerable progress in the design of this new class of post-metallocene catalysts.^{52, 149, 152, 153} For example, the classification of different catalysts, which were developed based on the ligand-oriented catalyst design concept, was proposed in the review.⁵² Table 1 summarises the general structures of phenoxy-imine and analogous chelate complexes. It should be noted that not only complexes, in which metal atoms are coordinated by heteroatoms (oxygen and nitrogen), but also titanium phenoxy-cyclopentadienyl complexes with similar properties are referred to this class.^{160, 161}

Many complexes listed in Table 1 proved to be high-performance catalysts for the synthesis of a number of special polymers and copolymers. For example, particular phenoxy-cyclopentadienyl complexes of Group IV transition metals showed high activity in copolymerisation of ethylene with sterically hindered monomers. In the presence of titanium bis(pyrrolyl-imine) complexes, living copolymerisation of ethylene with norbornene giving rise to high-molecular-weight copolymers and block copolymers can be performed at room temperature. The titanium indolyl-imine complex allows living polymerisation of ethylene and propylene and their living block copolymerisation at room temperature.

Among the above-mentioned structures, phenoxy-imine catalysts (or FI catalysts according to the nomenclature by Fujita¹³⁷) are most promising due to high catalytic activity, the possibility of varying substituents in the ligand and the simplicity of the synthesis. These catalysts are considered in more detail below.

The general structure of FI complexes consists of two bidentate unsymmetrical phenoxy-imine ligands coordinated to transition metal.

M = Ti, Zr, Hf, V, Cr, etc.; R¹, R², R³ and R⁴ = Alk, Ar and other groups; X = Hal.

As can be seen in Fig 7, the complexes with $n = m = 2$ can exist in five isomeric forms having an octagonal coordination

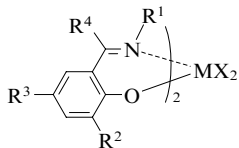

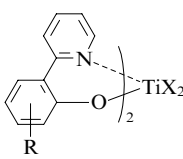

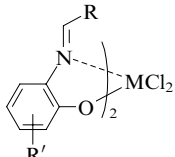

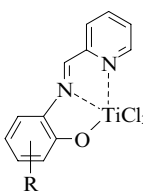

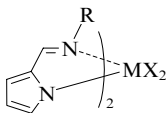

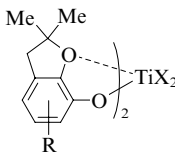

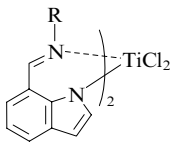

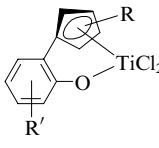

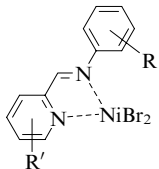

Figure 7. Possible isomeric forms of the octagonal coordination of FI catalysts [the energies of their formation (kJ mol⁻¹) for complex 39 are given in parentheses].⁵²

Table 1. Ligand-oriented olefin polymerisation catalysts.

Complex	Structure	Ref.	Complex	Structure	Ref.
Bis(phenoxy-imine)	 <p>$M = \text{Ti, Zr, Hf, V, Cr, etc.}$</p>	135–137, 144, 145	Bis(phenoxy-pyridine)		158
	 <p>$M = \text{Ti, Zr}$</p>	135–137, 154	Phenoxyimino-pyridine		149
Bis(pyrrolyl-imine)	 <p>$M = \text{Ti, Zr, Hf}$</p>	151, 155, 156	Bis(phenoxy-ether)		149, 159
Bis(indolyl-imine)		150, 157	Phenoxy-cyclopentadienyl		160, 161
Phenylimino-pyridine		149			

(depending on the arrangement of the ligand). According to the ^1H NMR spectroscopic data,⁵² FI catalysts with the central Ti, Zr or Hf atom exist in solution as mixtures of isomers. Quantum chemical calculation (the density functional theory) of the corresponding energies of the formation of isomers showed that isomers **A** and **B** are most often present in solution (see Fig. 7). It should be noted that for some FI complexes the formation of only one isomer is favourable. For example, Zr complex **42** exists predominantly as isomer **B**, whereas Ti complex **43** containing the perfluoroaryl fragment at the imine nitrogen atom exists exclusively as isomer **A**.

The coexistence of different isomeric forms of FI catalysts can be responsible for deviation from the single-site character of the catalyst system formed on their basis.

The structural characteristics and stereochemistry of FI complexes have been extensively studied, including by X-ray diffraction. The geometric parameters of four FI complexes **39** and **44–46**, in which the natures of metal and the substituent in the phenoxy group were varied, were determined.^{52, 162}

$M = \text{Zr: R} = \text{H}$ (**39**), Me (**44**); $M = \text{Ti: R} = \text{H}$ (**45**), Me (**46**).

The X-ray diffraction study demonstrated⁵² that these complexes in the solid state contain the metal centre (Zr or Ti) in a nearly octahedral coordination environment characterised by the space group C_2 with the O, N and Cl atoms being in *trans*, *cis* and *cis* positions, respectively. The bond lengths and bond angles in complexes **39** and **44** and in their homologues **45** and **46** determined by different research groups^{52, 162} are given in Table 2. It can be seen that these results are in good agreement with each other. Small differences in the bond angles are attributed to the presence of the methyl substituent in complexes **45** and **46**.

Table 2. Geometric parameters of FI complexes **39** and **44–46**.

Complex	Bond lengths /Å			Bond angles /deg			Ref.
	M–O	M–N	M–Cl	OMO	NMN	ClMCl	
39	1.985(2)	2.355(2)	2.423(5)	165.5(1)	74.0(1)	100.3(8)	52
44	1.980(3)	2.351(4)	2.428(8)	157.9(9)	84.3(3)	94.6(1)	52
45	1.852(4)	2.236(4)	2.305(2)	171.6(2)	76.4(2)	103.1(1)	162
46	1.844(3)	2.212(5)	2.306(2)	164.0(3)	86.0(3)	94.08(1)	162

The results of quantum chemical calculations⁵² (the density functional theory) for the structures of the precursors of the ethylene-coordinated methyl cationic catalyst, which is generated in the reaction of highly active Zr complex **39** with MAO (the calculated Zr–N bond lengths are given in parentheses), are presented in Scheme 4. The cationic complex has a distorted octahedral coordination, the Zr–N bonds and the polymerisation site being located in one plane. The interaction with a monomer leads to an increase in the length of this bond from 2.232 to 2.337 Å, whereas the Zr–O bond lengths remains unchanged. The change in the Zr–N bond length is indicative of a flexible exchange between the metal atom and the ligands, and the *cis* arrangement of the active site combined with the nature of the ligands is, apparently, responsible for high activity of this FI system [519 (t PE) mol^{−1} h^{−1}].

Scheme 4

New FI catalyst systems synthesised by Fujita and co-workers^{163,164} were studied as ethylene polymerisation catalysts. The authors analysed the dependence of the catalytic activity on the nature of transition metal and the nature and size of substituents at the imine nitrogen atom and in the *ortho* and *para* positions of the phenoxy group. For example, after the replacement of Zr by Ti, Hf, V or Cr in complex **39** combined with the cocatalyst MAO, the catalytic activity was 3, 26, 4 and 1 (t PE) mol^{−1} h^{−1}, respectively.

The first conclusions about the influence of the bulky substituents in the *ortho* position of the phenoxy group and the small substituent at the imine carbon atom were made in the publications.^{163,164} The steric hindrance caused by the bulky substituent adjacent to the oxygen atom of the phenoxy group protects the latter from the electrophilic attack of a Lewis acid, which is present in the polymerisation system, and facilitates the efficient separation of the cationic active species and the anionic species of the cocatalyst. Small substituents in the imine fragment leave sufficient space for the approach of the monomer to the active site of the growing chain. Hence, the presence of the aldimine fragment in the complex provides high activity of the catalyst, whereas ketimine-type FI systems (for example, those containing the substituted RC=N fragment, where R = Me, Et or Ph) are substantially less active.¹⁶⁵

Complexes **47–50** are ethylene polymerisation catalysts of exceptionally high efficiency.

For example, MAO-activated FI system **47** exhibits the surprisingly high activity [6552 (kg PE) mmol^{−1} h^{−1}, 25 °C, MW of the polymer was $\sim 1 \times 10^4$] and is characterised by the record turnover frequency of 64 900 s^{−1} atm^{−1}.⁵² The activities of bis[*N*-(3-cumyl-5-methylsalicylidene)phenylamino]ZrCl₂ (**50**) and bis[*N*-(3-cumyl-5-methylsalicylidene)cyclohexylamino]ZrCl₂ (**48**) are as high as 2 (t PE) mol^{−1} h^{−1} and are increased as the concentration of the catalyst is slightly decreased. For bis[*N*-(3-(2-adamantyl)-5-methylsalicylidene)cyclohexylamino]ZrCl₂ (**49**), the yield of the polymer is 0.7 t min^{−1} (Refs 144 and 145). It was noted^{166,167} that FI complex **42** shows the unusual behaviour, which is manifested in that MWD of the product varies with the temperature. At 0 and 25 °C, the monomodal curve is observed, whereas the curve at 75 °C is bimodal, which was attributed to a change in the ratio between the coordination isomers in the FI system.

Zirconium complexes (for example, **51**), in which the phenyl group at the imine nitrogen atom contains substituents in both *ortho* positions, were also reported.¹⁶⁸ The use of these systems generally results in a decrease in the activity of catalysts. Catalysts **52** are exceptions to the general rule.

In spite of the facts that ketimine complexes are less active than aldimine complexes¹⁶⁵ and that the presence of an *ortho* substituent in the aniline fragment does not lead to an increase in the activity of the system, complexes **52** showed high catalytic activity, and high MW of the resulting polyethylene were achieved.¹⁶⁹

Our research group revealed the relationship between the structure of such catalysts and their activity in ethylene polymerisation using the density functional theory method.¹⁷⁰ The influence of the structure of complexes on the energy effects of the formation of catalytically active species, the formation of π complexes of the catalysts with ethylene, the chain growth and chain transfer and deactivation of the system was analysed for five titanium and zirconium phenoxy-imine complexes. The results of investigation provided an explanation for the different behaviour of Ti and Zr complexes and the dependence of the activity of the catalyst system on the ligand structure.

In the recent study,¹⁷¹ an attempt was made to systematise the results of research into the influence of substituents in phenoxy-imine complexes on their catalytic activity in ethylene polymerisation by analysing FI systems, in which the substituents either at the imine nitrogen atom or in the phenoxy group were varied. An investigation of ten structurally different FI complexes demonstrated that the substituents at the imine nitrogen atom influence not only the activity of the catalyst system but also the temperature range of the efficient catalyst functioning. Sterically hindered substituents in the *ortho* position of the phenoxy group should have the optimal volume; otherwise, the activity of the catalyst system decreases.

In the presence of particular FI catalysts in polymerisation systems, polymerisation can proceed according to the living polymerisation mechanism. Initially, this mechanism was established for structures containing perfluorinated aryl groups at the imine nitrogen atom.^{146–148} For example, living polymerisation of not only ethylene but also of propylene was successfully performed in the presence of complex **43**. In the latter case, syndiotactic polypropylene (SPP) with narrow MWD ($M_w : M_n = 1.11$) was obtained.

Polyethylene was synthesised by living polymerisation with the use of complexes **53–56** combined with MAO [the activity was 43.3 (kg PE) mmol⁻¹ h⁻¹, $M_n = 1.36 \times 10^6$].¹⁴⁷

$R^1 = R^3 = \text{H}, R^2 = \text{F}$ (**53**); $R^1 = R^3 = \text{F}, R^2 = \text{H}$ (**54**);

$R^1 = R^2 = R^3 = \text{F}$ (**55**); $R^1 = R^3 = \text{CF}_3, R^2 = \text{H}$ (**56**).

Quantum chemical molecular orbital calculations demonstrated that the characteristic features of the mechanism of living polymerisation with the use of these systems are associated with the electron-accepting effect of the fluorine atoms, resulting in an increase in the electrophilicity of the metal centre and a decrease in the activation energy for ethylene insertion.

The possibility of living ethylene and propylene polymerisation was demonstrated by Bulychev and co-workers¹⁷² using dinuclear fluorine-containing titanium bis(salicylidene)-imine complexes. According to the results of calculations (the density functional theory), fluorine-substituted phenyl groups at the imine nitrogen atom provide the living polymerisation mechanism. In the course of polymerisation, the fluorine atom in the active state of the catalyst interacts with the hydrogen atom in the β position of the polymer chain thus preventing β hydride transfer.

Living ethylene and propylene polymerisation is successfully used for the preparation of a number of unique block copolymers (both diblock and multiblock copolymers).

We were the first to perform living ethylene polymerisation with the use of non-fluorinated titanium FI systems. For example, it was demonstrated^{162, 173} that ethylene polymerisation on the MAO-activated bis[*N*-(3-(*tert*-butyl)-5-methylsalicylidene)anilinato]TiCl₂ complex (**46**) affords the polymer, whose molecular mass linearly increases with time. After termination of feeding of ethylene and subsequent introduction of hex-1-ene into the polymerisation system, polyethylene–block–poly(hex-1-ene) was obtained. This confirms that polymerisation proceeds according to the living polymerisation mechanism. The detailed analysis of living olefin polymerisation in the presence of various catalyst systems, including phenoxy-imine complexes, was performed in the recent review.¹⁷⁴

2. Influence of activators on catalytic activity and selectivity of FI complexes

The influence of the nature of the cocatalyst on the activity and selectivity of Ziegler–Natta catalysts, as well as of metallocene systems, in olefin polymerisation was considered in-depth in numerous monographs and reviews (see, for example, Refs 8, 12, 16, 17, 22, 36 and 40). Taking into account that FI ligands contain heteroatoms, it could be expected that these complexes would be activated with a larger number of structurally different cocatalysts compared to metallocenes.

Earlier, the successful use of MAO or its modified derivatives as activators of FI complexes has been documented. In addition, the $\text{Bu}_3\text{Al}–\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ systems can serve this purpose.^{144, 175–179} It was found that the mechanism of activation of FI catalysts by this system is based on the formation of amino-ligated complex **57** catalysing polymerisation.

$M = \text{Ti, Zr, Hf, etc.}; R^1, R^2, R^3 = \text{Alk or Ar.}$

The use of FI complexes combined with the $\text{Bu}_3\text{Al}–\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ system in olefin polymerisation results in a decrease in the activity compared to that observed in the presence of MAO; nevertheless, the activity remains at a satisfactory level, MW of the polymers being substantially increased.

Taking into account the specific mechanism of activation, the structure of FI complexes substantially influences the efficiency and selectivity of this type of catalyst systems. For example, polymerisation with the use of FI complex **39** activated with $\text{Bu}_3\text{Al}–\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ at 50 °C affords polyethylene with $\text{MW} \sim 5 \times 10^6$, and the activity of the catalyst was 11 (kg PE) mmol⁻¹ h⁻¹, while the same system combined with MAO exhibited activity of 519 (kg PE) mmol⁻¹ h⁻¹, and MW of the resulting polyethylene was as low as $\sim 1 \times 10^4$. It should be emphasised that the application of the $\text{Bu}_3\text{Al}–\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ system as the activator proved to be very useful.

Magnesium chloride-supported organic derivatives of aluminium, for example, $\text{R}'_n\text{Al}(\text{OR})_{3-n}/\text{MgCl}_2$ (R and $R' = \text{Et or Bu}^t$), were proposed as promising cocatalysts for FI systems. These activating systems simultaneously serve as supports for FI complexes. Earlier attempts^{180, 181} to use these systems

combined with metallocene catalysts have failed. Recently, it has been demonstrated^{182–184} that the efficiency of the use of specially treated MgCl_2 as the cocatalyst for olefin polymerisation is determined by the presence of heteroatoms in FI systems.

The latest advances in research into the FI complex– $\text{R}'_n\text{Al}(\text{OR})_{3-n}/\text{MgCl}_2$ catalyst systems were considered in the publication.¹⁸⁵ For example, the activity of catalyst **49** in ethylene polymerisation in the presence of $\text{R}'_n\text{Al}(\text{OR})_{3-n}/\text{MgCl}_2$ amounts up to 1819 (kg PE) $\text{mmol}^{-1} \text{h}^{-1}$ (50 °C, 0.9 MPa).¹⁸⁵ The use of vanadium-based FI systems in the presence of this type of activators makes it possible to perform polymerisation with high efficiency at high temperatures (75 °C). Modified MgCl_2 serves as the active cocatalyst for living olefin polymerisation with the use of fluorinated FI ligands.¹⁸⁶

Substantial advantages of activators based on modified MgCl_2 are that the polymer morphology is improved (replication of spherical, including ultradisperse, particles of the supported catalyst) and the polymer has a high bulk density and is not deposited on the walls of the reactor.¹⁸⁵ The characteristic features of immobilisation of complexes on modified MgCl_2 and the coordination mode of ligands in supported catalyst systems were reported.^{187, 188}

3. Use of FI catalyst systems for the preparation of non-traditional polyolefins

The use of FI catalysts can allow the preparation of polymers with a nonconventional topology. For example, MAO-mediated complexes **58** and **59** catalyse the formation of low-molecular-mass polyethylenes with terminal vinyl groups (the percentage of vinyl groups at one of the ends of the polymer chain is no lower than 90%).¹⁸⁹ High reactivity of the terminal groups is combined with rather high melting points of these polymers (> 120 °C). Polymerisation in the presence of complex **58** affords a product with the weighted-average molecular weight (M_w) of 2100 and the ratio $M_w : M_n = 1.52$; in the case of compound **59**, $M_w = 3800$ and $M_w : M_n = 1.82$.

$n = 1$ (**58**), 2 (**59**), 3 (**60**), 4 (**61**).

The steric factors rather than the electronic nature of substituents play the key role in the formation of the terminal vinyl groups of the polymers when polymerisation is catalysed by complexes containing lower cycloalkyl (cyclobutyl or cyclopentyl) substituents in the imine fragment. Recently,¹⁹⁰ the structures of zirconium bis(phenoxy)imine complexes **58–61** containing various cycloalkyl groups at the imine nitrogen atom were studied by X-ray diffraction. It was noted that the substituents greatly influence the kinetic behaviour of these complexes in ethylene polymerisation (MAO as the cocatalyst, 25 °C). Complexes **58–61** were demonstrated to have identical coordination geometry irrespective of the number of CH_2 groups in the ring. Nevertheless, the cyclic substituent strongly influences the steric environment of the potential active sites of polymerisation and, consequently, the catalytic activity of complexes **58–61** depends on the bulkiness of the cycloalkyl substituent. Both low- and high-molecular-weight polyethylenes containing unsaturated vinyl groups at the ends of the

polymer chain can be prepared with the use of these phenoxy-imine complexes due to the fact that the β -hydride transfer to monomers prevails over the transfer to the metal centre. This character of the transfer process was confirmed by quantum chemical calculations and experiments on the effect of the ethylene pressure on the polymerisation process. Thus, the influence of substituents in phenoxy-imine complexes on the mechanism of elementary steps of chain transfer in olefin polymerisation was demonstrated for the first time in the study.¹⁹⁰

Polymers containing terminal vinyl groups can find use as macromers for the preparation of copolymers with long-chain branches. Various modifying additives as well as graft and block copolymers can be synthesised by functionalisation of vinyl fragments in these polymers.

Propylene polymerisation catalysed by FI complexes **62** and **63** afforded highly isotactic polypropylene.¹⁷⁹ Isotactic polypropylene (IPP) with $M_w = 172\,000$ and the ratio $M_w : M_n = 2.1$ was synthesised with the use of zirconium complex **62** combined with the $\text{Bu}_3^i\text{Al}-\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ system. This polymer is characterised by a high percentage of *mm* triads[†] (98%) and the relatively high melting point (164 °C). The catalyst based on analogous hafnium complex **63** facilitates the formation of IPP with $M_w = 364\,000$, $M_w : M_n = 3.5$, [*mm*] = 98% and $T_m = 165$ °C.

Syndiotactic polypropylene was synthesised on MAO-activated titanium FI complexes **64** and **65**.^{191, 192} Polymerisation with the use of complex **64** containing the phenyl substituent at the imine nitrogen atom at 1 °C afforded SPP containing 91% of *rr* triads with $T_m = 140$ °C. The replacement of this substituent by the perfluorinated phenyl group (complex **65**) resulted in the formation of SPP with [*rr*] = 94% and $T_m = 156$ °C. Polymerisation in the presence of $\text{Bu}_n^i\text{Al}(\text{OR})_{3-n}/\text{MgCl}_2$ -activated catalyst **65** at 25 °C gave SPP with [*rr*] = 97%, $T_m = 155$ °C and $M_w = 32\,000$. The characteristic features of the formation of SPP were discussed.^{192–196}

It is generally very difficult to synthesise stereo- and regioregular higher α -olefins because of the difficulties in performing stereocontrol of the process (exclusion of 'regio errors'). Another problem is associated with a decrease in the activity of the catalyst because of steric hindrance to the approach of the monomer to the active site. These difficulties were successfully overcome with the use of $\text{Bu}_3^i\text{Al}-\text{Ph}_3\text{CB}(\text{C}_6\text{F}_5)_4$ -activated titanium phenoxy-imine complex **40** as a catalyst for hex-1-ene polymerisation.¹⁷⁶ In this case, atactic (non-regioregular) polyhexene with $M_w = 720\,000$, $M_w : M_n = 1.68$ and the regio error of ~50% was obtained at

[†] Isotactic diads (*m*-diads) are characterised by an identical arrangement of the methyl groups with respect to the plane of the carbon chain of the macromolecules, as opposed to syndiotactic (*r*) diads, in which the methyl groups of propylene are located on the opposite sides of this plane.³⁹

25 °C. Under analogous conditions, polyoctene, poly(4-methylpentene) and other higher polyolefins were prepared. The catalytic activity decreases in the following series of monomers: 4-methylpentene > dodec-1-ene > oct-1-ene > hex-1-ene.

Recently, the advances in the synthesis of isotactic polypropylene have been demonstrated with the use of titanium phenoxy-alimine and -ketimine complexes containing *ortho*-phenoxyhalide substituents.¹⁹⁷

4. Non-standard phenoxy-imine and structurally similar complexes

Group IV metal complexes with tetradentate ligands containing hydrocarbon-bridged phenoxy-imine fragments are of particular interest as high-performance olefin polymerisation catalysts.¹⁹⁸

66–68

$m = 1$, $R = H$, $n = 2$ (**66**);
 $m = 0$; R is 2-adamantyl, $n = 2–6$ (**67**); $R = CH_2Ph$, $n = 4$ or 6 (**68**).

The rigidly organised structure of these complexes is responsible for their high thermal stability and provides stereospecificity in polymerisation reactions. For example, the activity of SiO_2 -supported compound **66** in the presence of MAO is 3.53 (kg PE) $mmol^{-1} h^{-1}$, which is 30 times higher than the activity of an analogous catalyst under homogeneous conditions.¹⁹⁸

The catalytic activity of tetradentate bis(phenoxy-imine) complexes **67** and **68** was studied.^{199–201} These catalysts are characterised by high stability and can function at high temperatures [for example, in the course of solution ethylene polymerisation at 150 °C, the activity of compound **67** was 143 (kg PE) $mmol^{-1} h^{-1}$]. It should be noted that the activity of such catalyst systems increases with the number of CH_2 groups in the bridge between the imine nitrogen atoms.²⁰⁰

Tridentate titanium complexes containing simultaneously the phenoxy-imine and cyclopentadienyl ligands were synthesised;²⁰² however, their activity in ethylene polymerisation appeared to be low. For example, the activity of compound **69** was 15.6 (g PE) $mmol^{-1} h^{-1}$, the molecular weight of the resulting polymer being 1 630 000.

69

In 2005, hybrid titanium (phenoxy-imino-pyrrolyl-imine) complexes **70** and **71** were described.²⁰³ These complexes showed high activity in MAO-mediated ethylene polymerisation. The complexes were prepared by the reaction of the titanium mono(salicylaldimine) complex with the metallated pyrrolylaldimine ligand.

$R = Ph$ (**70**), C_6F_5 (**71**).

Bis(pyrrolyl-imine) complexes of Group IV metals, which are structurally similar to FI systems and were synthesised by Fujita and co-workers,^{204,205} are of great interest in both theoretical and commercial aspects.

$R = Et$, $n-C_6H_{13}$, cyclo- C_6H_{11} , Ph .

Such complexes with the central titanium atom proved to be better ethylene polymerisation catalysts than zirconium complexes. As in the case of phenoxy-imine ligands, methylalumoxane is a more efficient cocatalyst for these compounds than the $Bu_3Al-Ph_3CB(C_6F_5)_4$ system, with MW of the resulting polymers being of the same order of magnitude.

Further investigations^{151,206} demonstrated an interesting possibility of living copolymerisation of ethylene with norbornene in the presence of these systems. This process gives copolymers whose composition is similar to that of alternating copolymers. It should be emphasised that these catalysts are inactive in living homopolymerisation of both norbornene and ethylene. It was found²⁰⁷ that the introduction of substituents into the pyrrolidine ring does not change the activity of the catalyst system.

Pyrrolyl-imine catalysts are very efficient in copolymerisation of ethylene with propylene and α -olefins providing a high degree of comonomer insertion.

A search for and investigation of new structures of phenoxy-imine catalysts and their analogues having unusual and sometimes exotic structures are presently underway. Unfortunately, it is impossible to mention all results obtained by numerous research groups in this important and interesting field of investigation. Nevertheless, the present review hopefully provides insight into the advances and prospects in the design of post-metallocene catalysts for olefin polymerisation.

IV. Conclusion

The fifty-year history of the large-scale production of the most important polymers, *viz.*, polyethylene and polypropylene, which are widely used in various fields of human activity, shows a tremendous role of catalysts in the perfection of the polymerisation process. The use of Ziegler–Natta catalysts, catalyst systems for gas-phase polymerisation and transition metal metallocene complexes made a considerable contribution to the perfection of polyolefin production processes and improvement of their performance characteristics.

The chronology of the design and introduction of new catalysts showed that the search for active and selective catalyst systems for olefin polymerisation is a high-priority field in polymer chemistry. In recent years, the design of these catalysts has become more extensive. It took 30 years to change over Ziegler–Natta catalysts to metallocene catalysts, whereas the last decade witnessed the discovery of a new type of catalysts, *viz.*, transition metal post-metallocene complexes, which hold considerable promise for commercial olefin polymerisation and copolymerisation.

Over a short period of time, the characteristics of post-metallocene polymerisation catalysts, such as activity, selectivity, sensitivity to the reaction conditions, availability, safety and the range of monomers used in polymerisation, became as good as and even better than those of metallocene complexes. The use of these catalysts becomes preferable also from the economical point of view. Post-metallocene systems are characterised by a wide range of activators and supports ensuring their functioning. A wide range of ligands for these systems and prospects for solving the problems of monitoring (NMR method) and controlling the structures of the resulting polymer systems (molecular weight, branching and block structure) substantially extend the scope of their commercial application. The experimentally established possibility of the synthesis of superhigh-molecular-weight polymers and copolymers by the living polymerisation mechanism, the synthesis of block copolymers of different composition, an increase in the percentage of sterically hindered monomers in copolymers and the formation of low-molecular-weight polymers with unsaturated reactive groups are some of the characteristic features of new post-metallocene systems demonstrating their great potentialities. Great prospects for their use are associated also with high performance of heterogeneous complexes, in which modified MgCl_2 serves as the activator and support.

Post-metallocene catalyst systems have been discovered rather recently. Nevertheless, the main aim of investigations of these systems would be expected to be changed, the research into commercial applications of catalysts will be more intensive, interest in the design of new complexes being retained, as well as the mechanism of polymerisation with the use of these catalysts will be refined. The immobilisation of catalyst systems, an increase in the temperature range of their steady activity, the extension of the possibilities to control the structure and performance characteristics of the resulting polymers, simulation of polymerisation processes and tailoring of pilot devices to real industrial conditions will likely receive more attention.

I thank Academician G A Tolstikov and Dr. N I Ivancheva for helpful discussion of some aspects of the present review and Dr S V Myakin for help in preparing this review.

Unsteady catalytic processes and sorption-catalytic technologies

A N Zagoruiko

Contents

I. Introduction	639
II. Theoretical basis and methods for organisation of unsteady-state conditions in catalyst beds	640
III. Catalytic processes that utilise the unsteady states of catalyst	642
IV. Conclusion	650

Abstract. Catalytic processes that occur under conditions of the targeted unsteady state of the catalyst are considered. The highest efficiency of catalytic processes was found to be ensured by a controlled combination of thermal non-stationarity and unsteady composition of the catalyst surface. The processes based on this principle are analysed, in particular, catalytic selective reduction of nitrogen oxides, deep oxidation of volatile organic impurities, production of sulfur by the Claus process and by hydrogen sulfide decomposition, oxidation of sulfur dioxide, methane steam reforming and anaerobic combustion, selective oxidation of hydrocarbons, *etc.* The bibliography includes 234 references.

I. Introduction

Catalytic processes operating under targeted unsteady state conditions receive considerable attention in both the scientific research and industry. The reason for such keen interest lies in the fact that unsteady-state conditions allow one to enhance the efficiency of catalytic technologies, namely, accelerate reactions, enhance their selectivity, increase the yields of the target products, decrease the energy consumption and reduce the operational expenses and the cost of reactors.

None of the known heterogeneous catalysts represent a true unsteady system during its operation. At the very least, this is associated with their inevitable deactivation, which shortens their service life and necessitates their replacement or regeneration once the service life is overrun. Nonetheless, two conceptually opposite approaches are distinguished, namely, a steady-state approach that postulates the time invariability (as far as possible) of all process parameters and the unsteady approach based on the targeted dynamic variation of these parameters. The present review is exclusively devoted to catalytic technologies that employ catalysts under the targeted unsteady-state conditions and demonstrate substantial advantages over analogous stationary processes.

Received 13 September 2006

Uspekhi Khimii 76 (7) 691–706 (2007); translated by T Ya Safonova

In the recent decades, the most significant progress in unsteady catalysis was associated with the reverse-flow processes. The latter are based on concepts of the thermal non-stationarity that arises in a fixed adiabatic catalyst bed as the parameters of the reaction mixture flowed through this bed are modulated. However, it is evident that the progress in this field lies in the development of processes with not only the modulated catalyst temperature but also with the modulated chemical composition of the surface.

The present review considers mainly the gas-phase reactions that occur on the solid catalyst surface. Apparently, the formulated approach can also be applied to multiphase catalytic processes; however, this field is very wide and deserves special consideration.

Insofar as the periodic changes in the catalyst state are directly associated with the sorption, most of processes considered below can be described as sorption-catalytic processes, which implies that it is joint sorption and catalytic processes that occur within one catalyst bed or a single process vessel. This approach does not embrace the combinations of catalytic and sorption processes that are carried out separately and independently in different reactors even within one flow scheme.

In this study, sorption is understood in the general sense, *i.e.*, as the reversible physical adsorption of reactants, their reversible (irreversible) chemisorption associated with chemical reactions and the formation of stable intermediates on the active surface or even as the absorption of reactants in a liquid film of the active component melt.

The first studies of cyclic catalytic processes that involved the periodically modulated catalyst state date back to the 19th century. The analysis of the development of these studies leads to a paradoxical idea that in a certain sense, the first catalytic processes studied were cyclic unsteady processes.

This can be illustrated by several examples. Thus the English chemist Claus^{1,2} studied the reaction of hydrogen sulfide oxidation to sulfur, which opened up the way to the recovery of elemental sulfur from hydrogen sulfide, in fact, first under the adsorption-catalytic conditions (with the adsorption of liquid sulfur on the catalyst). Somewhat earlier, his compatriot Deacon^{3–5} discovered the reaction of hydrogen chloride oxidation with oxygen, which marked the beginning of the catalytic processes for the commercial synthesis of chlorine. Unlike Claus, he did not deal with unsteady technologies but, on the contrary, proposed and carried out a stationary

catalytic process. However, this very fact indicates that the periodic processes preceded his studies.

The same year that his patent was issued,³ the unsteady methane steam reforming in the presence of a sorbent that absorbed CO₂ was described.⁶ This study is considered as the pioneering in the catalytic steam reforming of hydrocarbons.

Many other examples of similar studies carried out since the end of the 19th century to the first half of the 20th century can be mentioned.

Such a development, which, at the first glance, looks paradoxical, however does not lack logics. In their early stage, the studies of the periodical combination of the known chemical reactions could be reduced to the closed reaction cycles, actually, to the stationary catalysis, which, at that time, was of significant interest for practice. Scientific research was also directed towards the stationary catalytic processes as more predictable, reproducible and hence more attractive for their exploration and building up the relevant theories.

Later, with the accumulation of knowledge on the catalytic processes, the limitations inherent in the stationary catalysis and narrowing the freedom of developers of new technologies were revealed. That is why attention was redirected to the 'origins', *i.e.*, the unsteady catalytic processes but with the new insight into the already known phenomena.

Systematic studies of the unsteady phenomena in catalysis date back to the second half of the 20th century. After the first publications on the unsteady modes of operation of catalytic reactors, which appeared in the 1960s,^{7–11} the rapid progress in this field (both experimental^{12–16} and theoretical^{17–20}) was observed.

The studies^{21–29} carried out under supervision of academician G K Boreskov and Yu Sh Matros at the Institute of Catalysis of the Siberian Branch of the Russian Academy of Science have made a considerable contribution into the theory and practice of unsteady catalysis. These studies have given the first physical explanation and substantiation to the observed phenomena, being particularly based on the Boreskov's concept of the changes in the catalyst state under the reaction conditions.

II. Theoretical basis and methods for organisation of unsteady-state conditions in catalyst beds

Any heterogeneous catalytic reaction includes several separate stages that can be associated with successive chemical and sorption processes. Obviously, under steady-state conditions, the rates of these stages are related by rigid balance relationships, which sometimes limit the efficiency of the process.

Under unsteady-state conditions, a set of stages can be represented as separate cycles, which are technologically isolated in the space and/or time. Such conditions make it possible to weaken or violate, at least theoretically, the local balance relationships mentioned above. This eliminates a part of restrictions and opens up additional possibilities for the development of new technologies.

Obviously, the disintegration of reactions into individual cycles implies that the latter form a closed system. In other words, a series of cycles should provide the return of the catalytic system into its original state in order to ensure their repetition. Otherwise, the system cannot be considered as catalytic. Moreover, the closed nature implies the observance of the integral mass and energy balances in the overall process cycle.

The rates of reaction and sorption processes involved in the catalytic cycle and their ratio are determined by the nature of the active catalyst surface and reaction mixture components and also by the external conditions (reaction mixture compo-

sition, temperature, pressure). Hence, the realisation of unsteady-state conditions is associated with the choice of an appropriate catalyst–sorbent and with the cyclic time variations of at least one of external factors.

1. Temperature modulation

The effect of temperature modulation as a source of the unsteady state in catalytic systems was discussed in numerous scientific studies. Their most important result was the development of catalytic reverse-flow processes,^{22, 25, 30, 31} which have found wide use in the industry. Reverse processes involve no direct control over the temperature, and their thermal non-stationarity is caused by the motion of thermal waves in the motionless adiabatic catalyst beds under the conditions of the periodic reversal of the direction of the initial filtrating gas mixture with a low inlet temperature.

Figure 1 shows examples of flow schemes of reverse processes. In the simplest case (Fig. 1 *a*), a system of switching valves changes the flow direction of the reaction mixture in the catalyst bed. In a modified scheme shown in Fig. 1 *b*, the catalyst in the edge parts of the bed is partially replaced by a heat-regenerating material (inert), which is catalytically inactive. Figure 1 *c* shows a multibed scheme (for the sake of simplicity, only two beds are shown) in which the inlet or outlet of both heat and mass (heating/cooling of the flow, inlet/outlet of additional flows and reagents) takes place between the fragments of the catalyst bed. A valve-free version of the reverse process is known, which includes the rotating beds packed with the catalyst and the inert material (Fig. 1 *d*).

Figure 2 shows certain interesting flow schemes in which the thermal non-stationarity in the catalyst beds may be created without the reversal of the reaction flow.²²

It is important to understand that for processes involving the thermal non-stationarity of the catalyst, one faces the problem of the basic approach to the development of such technologies rather than of the unsteady chemical composition of the catalyst.

Figure 1. Flow schemes of reverse processes.

(*a*) A one-bed scheme, (*b*) a scheme inert–catalyst–inert, (*c*) a multibed scheme with intermediate heat exchange and inlet/outlet of flows, (*d*) a scheme with rotating beds; dark arrow shows the direction of rotation of the catalyst bed, light arrows show the directions of the reactant flows. Here and in Fig. 2, solid and dashed arrows show the directions of the reaction flow in different phases of the cycle; C is the catalyst; I is an inert heat-regenerating material; M, Q are the inlet/outlet of reactants and heat, respectively.

Figure 2. Flow scheme of processes with the thermal non-stationarity of catalyst beds (in grey). (a) 'Torus', (b) 'match', (c) 'wings' (the names correspond to those given in Ref. 22).

2. Modulation of the reaction mixture composition

A comprehensive review of the studies on unsteady isothermal modes under forced modulation of the reaction mixture composition is given in Ref. 32. As a rule, the effectiveness of periodic modes is compared with the parameters of equivalent stationary modes in which the reactant concentrations are equal to the cycle-averaged concentrations in the unsteady mode.

In simple reaction mixtures with virtually one reaction route (CO oxidation,^{33–47} hydrogenation of ethylene^{15, 48} and aromatic hydrocarbons,^{49–51} methanation of carbon oxides,^{52–54} syntheses of methanol^{55–57} and ammonia,^{58–63} SO₂ oxidation,^{16, 64} the Claus reaction,⁶⁵ synthesis of ethyl acetate from ethylene and acetic acid,^{66–68} deamination of primary amines and dehydration of alcohols,^{69–72} etc.), the main positive effect of the optimum unsteady mode lies in the increase in the cycle-averaged reaction rate. However, for the majority of simple reaction systems, the rate increase was no more than 1.5–2-fold, which can hardly be considered quantitatively significant. At the same time, it should be noted that for the SO₂ oxidation under isothermal conditions with periodic alteration of the SO₂-containing mixture and air feeding,⁶⁴ the average yield of sulfur trioxide can exceed the equilibrium limit in the equivalent stationary mode.

Modes with periodic modulation of the reactant concentrations in systems with complicated parallel-sequential processes are more interesting.

According to theoretical studies, for the periodic modulation of the mixture composition in a model system of two parallel reactions, the selectivity of the target conversion can change if the reactions have different orders with respect to reactants,¹⁷ whereas in a model system of three sequential reactions in a perfect-mixing reactor, the selectivity with respect to the intermediate product can increase.⁷³ Matros *et al.*^{21–28} carried out a comprehensive systematic analysis of unsteady modes of complex reactions. They have found that the gain in the selectivity of processes carried out in unsteady cyclic modes substantially depends on the reaction mechanism and the type and parameters of unsteady modes. Moreover, they have shown that the adequate description of such systems

requires the use of unsteady kinetic models that take into account the dynamics of adsorption processes and the changes in the catalyst surface state under the reaction conditions.

The possibility of the enhancement of the reaction selectivity and the increase in the yield of the target products and of the reduction of the side-product yields was experimentally demonstrated by the example of several complex processes such as the NO reduction under the action of CO,^{74–80} selective hydrogenation of butadiene⁸¹ and acetylene,^{82, 83} oligomerisation of methane and ethylene,^{84–88} oxidative dimerisation of methane,^{89–92} oxidation of ethylene to ethylene oxide^{93, 94} and propylene to propylene oxide,⁹⁵ oxidative and steam reforming of methane into the synthesis gas,^{96–98} oxidation of propylene to acrolein,^{99–102} anaerobic oxidative dehydrogenation of hydrocarbons (propane to propylene, butane to butene and butadiene, butene to butadiene),^{46, 103–109} oxidation of butane to maleic anhydride, of aromatic hydrocarbons to maleic and phthalic anhydrides, synthesis of aromatic nitriles, the Fischer–Tropsch reaction,³² etc.

For all these reactions, the positive effect was observed only in a limited range of characteristics of unsteady modes (cycle duration, amplitude of concentration oscillations, phase shift in the supply of reactants, etc.). As an example, a system for the catalytic purification of automotive exhausts can be considered. Its peculiarity consists of the fact that the unsteady composition of the original reaction mixture is determined by the specifics of the engine operation. Under the conditions that did not allow one to control the system and optimise the parameters of unsteady modes, both positive and negative effects of the non-stationarity could be observed,^{110–113} and its overall effect was ambiguous.³²

Figure 3 shows flow schemes that makes it possible to realise periodic modulation of the reaction mixture composition and/or the separate delivery of reactants. In the simplest case (Fig. 3a), the modulation of the composition was achieved by the alternating supply of individual reactants or reaction mixtures of different composition. Such a process is basically periodic. To provide the overall continuity in the composition modulation, a scheme that includes two (and more) reactors (Fig. 3b) with the alternating cyclic supply of reactants and the processes with moving or rotating catalyst beds (Figs 3c,d) were used. In the latter case, different reactants are permanently delivered into different reactors and transported in their sorbed state by the catalyst, which permanently travels between the reactors.

3. Chromatographic mode of catalytic reactions

Reactive chromatographic processes with the periodically varied composition of the mixture form a subclass of unsteady processes.^{114–117} They were pioneered by Roginskii back in the early 1960s.^{7–9} In these processes, advantage was taken of the adsorption properties of catalysts, which allow one to carry out chromatographic separation of the reaction mixture simultaneously with chemical transformations. The merits of these technologies include the possibility of separate extraction of individual products and the achievement of superequilibrium degrees of conversion due to the dynamic separation of components in the catalyst bed.

The chromatographic mode is based on the pulsed supply of the reaction mixture (pulsed delivery of reactants into the inert-gas flow or pulsed introduction of one component into the flow of another reactant) and can be implemented in a one-reactor scheme (see Fig. 3a). A multibed scheme with the constant direction of the reaction mixture flow in beds and the periodical shift of the points of the reactant inlet and the product outlet, which provides the permanent circulation of the adsorption and reaction waves in catalyst beds, deserves attention¹¹⁸ (Fig. 4). Such a system, which received the name

A and B are different reactants or mixtures of different composition, C is catalyst.

Simulated Moving Bed Reactor (SMBR), holds much promise for carrying out certain practically important reactions.¹¹⁴

It should be noted that a reactive chromatography process is efficient under the high residence time of the reaction mixture in the reactor, *i.e.*, in case of high loading volume of a catalyst with low specific productivity. Obviously, it is economically more reasonable to use the reactive chromatography only in small-scale processes of fine organic synthesis, where the highly

Figure 4. Flow scheme for a reactive chromatography process with pseudomoving catalyst beds.

The arrow in the centre shows the direction of shift of inlet points of reagents and outlet points of reaction products.

expensive reactants and products determine the high capital and production costs.

4. Periodic pressure modulation

Periodic pressure modulation or the impact of periodic pressure pulses on the reaction system represent an alternative method for the creation of unsteady-state conditions in catalytic reactions. Here, two groups of processes should be distinguished, namely, at low and high frequencies of pressure oscillations.

The first group includes the processes with the cycle duration from several tens of seconds to several minutes. They combine the pressure swing adsorption (PSA) process, which was known since the early 1960s,¹¹⁹ and a catalytic reaction. Such processes are called pressure swing reactions (PSR) processes. Their efficiency was demonstrated in model studies^{120,121} and also by the example of methane steam reforming in the presence of substances that absorb CO₂.¹²²

The second group includes the processes generated by high-frequency pressure pulses (from tenth fractions to several tens and hundreds of Hz). Studies of such processes were surveyed by Silveston and Hudgins.¹²³ Pressure oscillations intensify mass transfer in the catalyst pores, which, on the one hand, can accelerate the reactions in simple reaction systems and, on the other hand, change the selectivities and yields of products and the other parameters in complex systems. Presumably, such pulses can induce oscillations in the reactant concentrations on the catalyst surface, which may affect the reaction rate and selectivity.

Pressure pulses can be generated both by an external source or be induced by mechanical oscillations in catalytic systems. Particularly, as was shown theoretically, the periodic pressure modulation with a frequency of an order of magnitude of several hundreds and thousands of Hz can arise in the channels of a block catalyst as a result of spontaneous turbulisation of the gas flow at the entry of channels in the presence of surface irregularities on the frontal panel of the unit.¹²⁴

III. Catalytic processes that utilise the unsteady states of catalyst

In this Section, attention is focused on the technologies that purposefully utilise the unsteady state of a catalyst. The described processes are based on the combined action of thermal and adsorption unsteady factors.

1. Selective catalytic reduction of nitrogen oxides

As the example of the targeted use of the unsteady state of a catalyst, the NO_x reverse process can be mentioned, which was developed^{30,125,126} at the Institute of Catalysts of the Siberian Branch of the Russian Academy of Sciences based on the principle of the periodic reversal of the reaction mixture flow for the reduction of nitrogen oxides according to the reaction

At the Biysk Oleum Plant, a commercial-scale unit has been developed for the reduction of nitrogen oxides from the exhaust gases of the production of dilute nitric acid. Insofar as ammonia water cannot be evaporated in the 'hot' part of the bed, it was supplied into the central part of the catalyst bed (see Fig. 1 c).

The commercial application of this system showed that this way of ammonia feeding enhances the efficiency of this process above the theoretical estimates. Particularly, the gases were purified from nitrogen oxides to a very high extent and virtually no 'breakthrough' of ammonia was observed.[†]

The detailed kinetic studies of this process and its mathematical simulation^{128–131} have shown that ammonia strongly

sorbs on the catalyst surface and reacts in its chemisorbed state with nitrogen oxides. In the reverse-flow process, ammonia sorbs in the exit part of the bed. Simultaneously, in its entry part, NO_x introduced with the inlet gases react with ammonia sorbed in the previous cycle to form molecular nitrogen. After the flow reversal, this process is repeated. The adsorbed NH_3 is concentrated in the central part of the bed, which virtually totally prevents the loss of ammonia as a result of its desorption from the bed edges. The introduction of ammonia water into the middle part of the bed produces a positive side effect, namely, the direct contact between NH_3 and NO_x becomes possible only in the preheated parts of the reactor, which prevents the formation of explosive ammonium salts in the unit.

2. Deep oxidation of impurities volatile organic compound

Decontamination of exhaust gases of industrial plants from the impurities of volatile organic compounds (VOC), namely, hydrocarbons, alcohols, acids, ethers, esters, aldehydes, ketones, *etc.*, is an important environmental problem.

If the exhausts contain high VOC concentrations, their decontamination may well involve the procedures of extraction and recycling of impurities, which are based on the absorption, adsorption, condensation and membrane processes.³¹ For dilute gases, it is reasonable to use the thermal and catalytic oxidation of VOC with oxygen (usually, atmospheric oxygen) to harmless products, namely, carbon dioxide and water vapour; moreover, in the treatment of low-concentration exhausts, the catalytic reverse-flow processes that provide the autothermal (*i.e.*, without additional supply of energy or fuel) processing of gases with the VOC content from 0.6 to 0.8 g m⁻³ and higher proved to be the method of choice from the economical and environmental viewpoints. Purification of gases with lower VOC contents requires additional energy to be supplied.

Thus, a pressing problem of the treatment of large volumes of vent gases with a very low concentration of harmful impurities (below 0.1 g m⁻³) should be mentioned. This enhances the specific power consumption and increases the cost of decontamination systems. Moreover, such systems should be simple and safe in operation due to the abundance of exhaust sources at different kinds of plants and the quite probable lack of skilled staff.

The decontamination technologies that include the adsorption-catalytic processes meet the criteria mentioned. Their realisation usually requires a simple combination of adsorbents and catalytic reactors, *i.e.*, VOC are first absorbed in a sorbent layer, which is followed by the sorbent regeneration (usually with water vapour or hot air) and the catalytic oxidation of impurities in a separate unit. However, in the framework of this review we are interested in adsorption-catalytic processes based on the VOC adsorption immediately on the surface of a deep-oxidation catalyst at low temperature with periodic regeneration of the catalyst by oxidation of sorbed impurities at elevated temperatures.^{132–141}

Adsorption-catalytic processes exhibit substantial advantages over the conventional catalytic technologies of deep oxidation of VOC, especially in the processing of low-concentration gases. In this case, the use of such processes allows one to avoid permanent heating of gases to be cleaned, which reduces substantially power consumption. Their high technological flexibility makes it possible to decontaminate gases with the initial VOC concentration varying over a wide range and

quickly put units into operation without preliminary heating. Such processes can be implemented within a one-reactor scheme (Fig. 5a) with the periodic elevation of the temperature of the gas to be decontaminated at the reactor inlet in order to initiate the catalyst regeneration.

However, the practical experience and the results of mathematical simulation^{142–145} revealed certain drawbacks of adsorption-catalytic processes. Thus partial desorption of non-oxidised VOC or the products of their incomplete oxidation is possible on heating of the catalyst, which reduces the degree of decontamination and necessitates additional purification of desorbed gases; there is also the risk of the reactor overheating during the regeneration.

These drawbacks can be overcome by the optimisation of flow schemes, operation conditions and parameters of the catalyst-adsorbent. Particularly, one of the ways to minimise desorption losses is the use of a procedure of stepwise heating of the catalyst during its regeneration.¹³⁶ In this version, the gradual heating in the beginning of the regeneration cycle allows one to transform a considerable part of weakly sorbed reactant into its strongly chemisorbed form. However, this approach is effective for a limited number of VOC and, moreover, substantially complicates the regeneration process and makes it more lengthy.

In addition, the losses can be reduced by using relatively coarse-grained catalysts-sorbents (*i.e.*, by creating internal diffusion hindrances for the desorption).¹⁴⁶

The reduction in the efficiency of decontamination due to the desorption of non-oxidised VOC can be avoided by using more sophisticated flow schemes that include, *e.g.*, a post-reactor¹³⁴ (Fig. 5b), which is preliminarily heated before the catalyst regeneration where final oxidation of the desorbed impurities occurs. Yet another version represents an adsorption-catalytic reverse process^{142–144, 147, 148} (Fig. 5c) where the adsorption phase involves the delivery of the original gases into

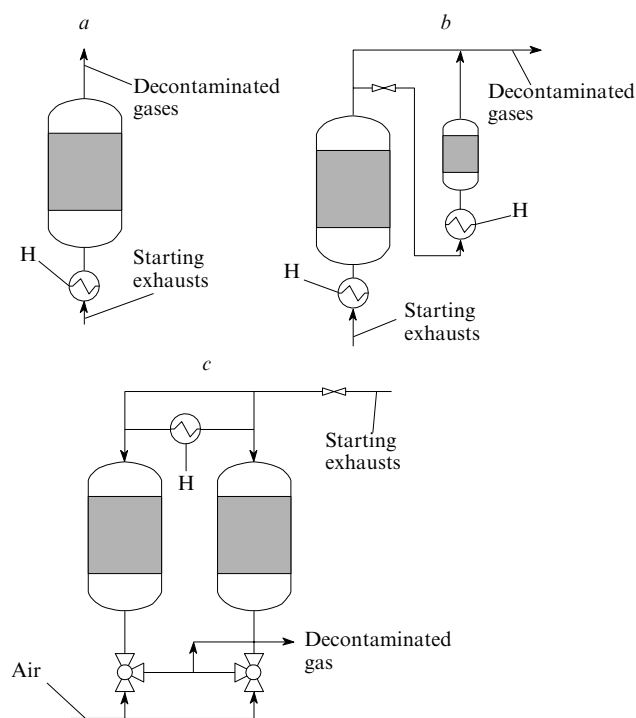

Figure 5. Flow schemes of adsorption-catalytic processes of deep oxidation of VOC.

(a) One-reactor scheme, (b) scheme with additional post-reactor, (c) adsorption-catalytic reverse process. From hereon, H is a heater.

† In other versions of the reverse process (*e.g.*, with the ammonia delivery into the original mixture), the breakthrough caused by the ammonia desorption from the edges of the catalyst bed after the flow reversal posed a serious problem.¹²⁷

two parallel reactors, and the regeneration occurs due to the heating of gases with simultaneous supply of air and periodic changes in the flow direction. In this case, VOC impurities are preferentially sorbed in the catalyst-bed parts adjacent to the point of inlet of the original gases, which allows one to minimise their losses in the desorption. Moreover, the efficient heat regeneration in the mode with the flow reversal makes it possible to considerably reduce the power consumed in the regeneration of the catalyst-sorbent.

It is of note that the developed model of adsorption-catalytic process allows one to cast a fresh glance on the conventional reverse process of deep oxidation of VOC (see Fig. 1*b*). The results of simulation¹⁴⁹ have shown that at moderate temperatures in the inlet of the catalyst bed, before the flow reversal, the admixtures are adsorbed and a substantial part of them is sorbed reversibly. After the reversal of the flow, this part of the bed becomes the outlet and its temperature begins to increase. As a result, a part of sorbed substance can be sorbed to be flown away with the exit gas flow, which substantially decreases the overall degree of decontamination. To avoid this, it is necessary to use sufficiently long beds packed with an inert heat-regenerating material (the choice of this material is also important; in the ideal case, it should have the zero adsorption capacity with respect to VOC), and apply a reasonable strategy of the control over the process (particularly, it is important to choose the correct temperature of flow reversal at the catalyst–inert interface).

Of interest is a flow scheme of an adsorption-catalytic process according to which the catalyst is regenerated by a combustion wave of sorbed VOC that moves towards the gas flow due to the heat conduction of the catalyst bed.^{140, 145} A feature of this mode is that the desorbed substances get into the preheated part of the catalyst bed where they can be efficiently oxidised. However, according to mathematical simulations and experimental studies,¹⁴⁵ the motion of the counter-current heat front is possible only for the low linear filtration rates of the regenerating air. Under these conditions, it is possible to achieve complete conversion of oxygen present in the air flow and, as a consequence, the formation of partial oxidation products, including CO. It was proposed¹⁴⁵ to solve this problem by the installation of an additional post-reactor at the outlet main unit which substantially complicated the scheme and made it more expensive. At the same time, it cannot be ruled out that the use a catalyst-sorbent with a reduced adsorption capacity would be sufficient.

A process is known in which the catalyst regeneration and the oxidation of sorbed VOC occur upon simultaneous increase in the temperature and pressure in the closed space of the reactor-adsorber by delivery of compressed air.¹⁵⁰ The efficiency of this process is due to the fact that no flows at all exit before the end of regeneration and the VOC losses are impossible in principle. However, this process is technologically complicated and requires sufficiently high skill of the staff, which may limit its practical application.

An advantageous version of the adsorption-catalytic processes of VOC oxidation employs a spiral reactor (Fig. 6*a*) consisting of two concentric metal spirals of which one is covered with a thin catalyst layer and the other is coated with a thin sorbent layer.¹⁵¹ The original gas travels along one system of spiral channels to the spiral centre and then along the second system of channels from the centre to the exit. The gas is decontaminated by the adsorption. The periodic regeneration of the sorbent is performed by switching on a heater located in the centre of the spiral. The active heat exchange between the inlet and outlet gases provides the fast heating of the sorbent and the catalyst (due to the heat produced by the heater and

Figure 6. Promising schemes of adsorption-catalytic systems for decontamination of gases from VOC.

(*a*) Spiral adsorber-reactor, (*b*) multidispersed adsorption-catalytic system.

released in the VOC oxidation) with the minimum energy consumption. The high heating rate of the catalyst provides the high efficiency of oxidation of desorbed VOC to harmless products. Due to the complexity of spiral reactors, their practical implementation is hardly possible for high gas flow rates; however, they can be used in compact systems for local decontamination of air.

For the effective decontamination of gases from VOC, a multidispersed adsorption-catalytic system can be used¹⁵² (Fig. 6*b*), which consists of a relatively coarse-grain adsorbent-catalyst with the spaces between the grains filled with a microfibre catalyst. The typical geometric size of catalyst microfibrils ($< 10 \mu\text{m}$) is substantially smaller than the grain size ($> 1 \text{ mm}$); hence, the specific surface of fibres substantially exceeds that of grains. During the regeneration, the catalyst microfibrils are heated in contact with the hot gas flow much more quickly than the grains of the catalyst-sorbent. Correspondingly, VOC desorbed during the regeneration phase come in contact with the preheated catalyst and are efficiently oxidised.

Returning to the second problem of adsorption-catalytic processes of deep oxidation, *i.e.*, the possible overheat of a catalyst above the threshold of its thermal stability, it should be noted that this problem might be solved by the optimisation of the maximum adsorption capacity of the sorbent-catalysts. For example, according to the results of simulations,^{142, 144} this capacity should be from 1 to 2 mass % for the oxidation of aromatic hydrocarbons on the aluminium–chromium–copper catalyst (with the operation temperature limit of 750°C).

In the development of adsorption-catalytic processes, attention was often focused on the elaboration and the use of catalysts and sorbents with the maximum possible adsorption capacity. However, in the general case, the optimum capacity for a process does not coincide with the maximum capacity of the catalyst.

3. Claus sulfur recovery process

The commercial production of elemental sulfur from acid waste gases of certain industrial processes is based on the Claus reaction

This reaction is reversible and exothermic; hence the maximum degree of sulfur recovery from gases is, as a rule, limited by thermodynamic parameters. The catalytic process usually involves several stages. Between the stages, the gases are cooled and the sulfur formed is removed. However, even this does not help in reaching the required degree of sulfur recovery. Obviously, the equilibrium in the Claus reaction can be shifted to the products upon removal of one component of the gas mixture (sulfur or water) directly in the course of reaction.

a. Sulfur condensation and adsorption

According to one version, the Claus reaction is carried out at a temperature below the dew point of sulfur vapour and its condensation occurs directly in the catalyst bed. The transfer of sulfur from the gas to the condensed state can substantially shift equilibrium (2), although this requires the timely cleaning of the catalyst from liquid sulfur by its evaporation. The basics of this approach were formulated by Claus back in the 19th century.^{1,2} Later, the concept of Cold Bed Adsorption was formulated, which gave rise to the development of the commercial CBA¹⁵³ and Sulfreen¹⁵⁴ processes, which are widely used in the modern industrial practice of Claus units tail gas cleanup and make it possible to increase the total degree of sulfur recovery from 96%–98% (the theoretical limit for two- and three-stage stationary Claus units) to 99.5% and higher. For the comprehensive review and the analysis of these technologies, see Ref. 155. It should be noted that sulfur vapour is removed from the gas mixture by both their condensation and the adsorption in the catalyst pores; therefore, the use of the term ‘adsorption-catalytic’ process is justified in this case.

The realisation of such processes requires the use of multi-reactor parallel schemes (see Fig. 3 b) containing, as a rule, two or three reactors in which, in turn, the following stages alternate: reaction/sulfur adsorption, catalyst regeneration (evaporation of sulfur at elevated temperature of the catalyst in a flow of a hydrogen sulfide-containing gas) and reactor cooling.

Moreover, schemes are known in which the catalyst regeneration and the removal of sulfur are carried out using the hot reaction gas delivered from the Claus furnace; as an example, a process¹⁵⁶ in which the unsteady-state conditions in three successive catalyst beds are realised by the periodic shift of the position of the inlet and outlet points of the reaction mixture and, correspondingly, by the change in the succession of catalyst beds the gas flow passes through. Conceptually, this scheme is close to the ‘torus’ scheme (see Fig. 2 a) and also to a scheme with the pseudomoving catalyst beds (see Fig. 4). According to the results of modelling, such a scheme allows up to 99.9% of sulfur to be recovered; moreover, whereas the aforementioned conventional technologies such as Sulfreen serve only for the cleanup of tail gases from stationary Claus units, the proposed scheme is an alternative for the complete combination of the Claus and Sulfreen methods (with virtually the same capital and operational costs as in the Sulfreen process).

b. The Claus reverse processes

Yet another version of processes that include sulfur condensation and evaporation is the Claus reverse process,^{157–165} which due to the periodic reversal of the flow, allows one to carry out

the reaction at a low inlet gas temperature, *i.e.*, under the conditions of sulfur condensation.

Mathematical models of this process have shown^{161–164} that under these conditions, a zone with a temperature above the sulfur dew point is formed in the central part of the catalyst bed. In this zone, the Claus reaction occurs, while in the cooler edge zones, sulfur is condensed and evaporated. In the reverse process, the maximum temperature in the reaction zone that defines the equilibrium yield of sulfur can exceed the sulfur dew point merely by several degrees; as a result, this temperature is substantially lower as compared with the stationary process (the maximum temperature of the latter is determined by both the dew point as the minimum inlet gas temperature and the adiabatic heat of the Claus reaction). This allows one to reach higher degrees of conversion of the starting reactants.

Particularly, the one-stage Claus reverse process, which is carried out by the schemes shown in Fig. 1 a,b, is equivalent to the two-stage stationary process as regards the total degree of sulfur recovery (up to 96%), whereas the reverse process with intermediate heat removal¹⁵⁹ (see Fig. 1 c) is equivalent to the conventional three-stage process with the degree of sulfur recovery approaching 98%. Moreover, the reverse process does not require heat exchangers and the preliminary heating of gases, which makes this technology substantially cheaper.

The one-stage reverse process has the following drawbacks: the degree of sulfur recovery is <96%; a part of sulfur is lost as a result of the incomplete hydrolysis of CS₂ and COS usually present in the reaction gas; sulfur is lost due to the formation of a fog from its vapour. These disadvantages can be overcome by using the Claus ‘double’ reverse process¹⁶⁰ (Fig. 7). The unit includes three reactors, of which the first operates at high temperature of the gas delivered from the Claus furnace (300–400 °C), while the second and third reactors operate at temperatures below the sulfur dew point (120–160 °C). Continuous operation of the second reactor is provided by periodic reversals of the gas flow in the internal circuit, while the catalyst regeneration in the third bed occurs when the order of reactors the gas passes through is changed upon the reversal of the flow direction in the external circuit. High temperature in the first (with respect to the gas flow) reactor favours the efficient hydrolysis of CS₂ and COS and also the efficient regeneration of the catalyst (due to the evaporation of liquid sulfur accumulated in the previous phase of the external cycle). The high overall degree of conversion and also the condensation and adsorption of non-condensed sulfur vapour are

Figure 7. Flow scheme of the Claus ‘double’ reverse process. (1–3) Catalytic reactors, (4, 5) units for sulfur condensation.

favoured by the low temperature in the third reactor (with respect to the gas flow).

According to the results of modelling,¹⁶⁴ the 'double' reverse process provides a high degree of mixture conversion, efficient hydrolysis of COS and CS₂ and elimination of sulfur losses with non-condensed fog (the total level of sulfur extraction was 99.6%–99.8%). This process is advantageous due to the absence of strict requirements to the quick response of switching valves. This is associated with the fact that the switches in the external cycle are rare (about once in a day) and the losses in the switch are insignificant, while the gas breakthroughs in the switches in the internal circle (the characteristic switch frequency is several times per hour) is damped by the protective action of the third bed. The units for the 'double' reverse process do not require complex equipment and thus are very compact.

Pilot-plant tests of the Claus reverse process¹⁶⁵ confirmed its feasibility.

c. Adsorption of water vapour

As was noted above, the equilibrium in the Claus reaction can be shifted by the removal of water vapour from the reaction mixture. The Claus process in a combined bed containing catalyst grains and a zeolite sorbent was described.^{166–169} The scheme of this version provides for a two-stage reverse process (see Fig. 1c) with the intermediate heat exchange and the intermediate sulfur removal. The original gas is fed to the reactor at a temperature that exceeds the dew point of sulfur vapour (e.g., at 250 °C). In the first bed, the Claus reaction and the adsorption of water vapour on the sorbent (zeolite) occur simultaneously. The gases that exit from the second bed are first cooled for sulfur condensation and then heated to higher temperature before entering the second bed where the water vapour is desorbed. As the sorbent is saturated with water, the flows in the first bed are reversed and the process is carried out in the same mode.

According to theoretical and experimental studies,^{166–169} removal of water vapour by adsorption provides a substantial shift of the reaction equilibrium and ensures virtually 100% conversion of the mixture even for high initial contents of reactants and the cycle time between reversals of no less than 1 h. However, it was noted¹⁶⁹ that such a scheme has certain drawbacks, particularly, it does not rule out a decrease in the efficiency of the hydrolysis of COS, which may be present in the gases. At the same time, they assumed that these drawbacks can presumably be minimised or eliminated provided the optimum combination of the time-dependent concentration and temperature fields in the catalyst beds will be found.

4. Low-temperature decomposition of hydrogen sulfide

Direct decomposition of H₂S is one of the methods for the production of elemental sulfur from hydrogen sulfide

This method attracts attention due to the possibility of the production of hydrogen (in place of water in the Claus process) in addition to sulfur, which is important in view of the development of hydrogen energetics.

However, all attempts to develop a commercial process of decomposition of hydrogen sulfide faced serious thermodynamic limitations, namely, reaction (3) is reversible and the equilibrium degree of hydrogen sulfide dissociation is virtually zero under ordinary conditions. To achieve the equilibrium H₂S conversion of about 10%, the temperature should be elevated to 700 °C, while its complete dissociation requires temperatures of nearly 2000 °C. It is difficult to carry out such a process; moreover, recombination of sulfur and hydrogen to H₂S during the cooling of the reaction products is probable,

and the elimination of this route would require additional efforts.

In the industry, acidic gases produced upon refining of natural gas and oil and containing, as a rule, considerable amounts of hydrocarbons and carbon oxides in addition to H₂S are the main source of hydrogen sulfide. At high temperatures, there is a high probability for the pyrolysis of these compounds, which may substantially complicate the technology, viz., necessitate the use of rather intricate and expensive equipment for the separation and purification of H₂S before its utilisation.

The use of the adsorption-catalytic process proved to be an effective (and interesting within the framework of this review) way for overcoming the equilibrium limitations of the degree of dissociation of hydrogen sulfide and also for the decrease in the reaction temperature.

The known methods of H₂S decomposition^{170–172} involve hydrogen sulfide chemisorption on the surface of sulfides of transition metals (iron, nickel, cobalt, copper, etc.), which is accompanied by the formation of surface polysulfides of metals and hydrogen, and periodic thermolysis of polysulfides to the original sulfides and sulfur. Chemisorption proceeds at relatively low temperatures (200–550 °C), which, nonetheless, allows one to achieve high degrees of H₂S decomposition. The sorbent is regenerated by heating to 700–800 °C in a gas flow containing no hydrogen or hydrogen sulfide, which results in the release of elemental sulfur.

Startsev *et al.*^{173–176} have shown experimentally that the stage of hydrogen sulfide chemisorption can proceed at a sufficiently high rate even at room temperature, whereas the regeneration occurs at temperatures not exceeding 200–300 °C provided the supported sulfide catalysts or certain catalytically active systems are taken as the chemisorbents.

Figure 8 shows the dynamics of hydrogen evolution in the stage of hydrogen sulfide chemisorption where the gas mixture is fed to the sulfide catalyst bed. In the beginning of the experiment, almost 100% adsorption of hydrogen sulfide was observed; moreover, even at room temperature, considerable amount of hydrogen evolved. If relatively short cycles (<10 min) were used, the process involved no discharge of hydrogen sulfide into the gas phase and the degree of H₂S decomposition was 100%. Periodic regeneration of the catalyst-chemisorbent at moderate temperatures (200 °C) allowed complete recovery of its chemisorption properties. This was confirmed in multiple chemisorption–regeneration cycles.

At the first glance, the possibility of achievement of that high degree of hydrogen sulfide decomposition to sulfur and

Figure 8. Time changes in the outlet concentrations of H₂S (1) and H₂ (2) at the feeding of a gas mixture containing 1 vol.% H₂S to the sulfide catalyst bed. *T* = 20 °C, *P* = 1 atm, contact time is 1 s.

hydrogen at low temperatures contradicts the thermodynamic limitations. This is rationalised as being due to different states of a catalyst in a periodic adsorption-catalytic process, which enables the spatial and temporal separation of the reaction stages and allows one to substantially shift the equilibria.

In the general case, the sequence of stages is as follows:

A simplified scheme includes the transformation of iron sulfide into disulfide in the chemisorption stage

and the reverse transformation in the regeneration stage¹⁴³

Figure 9 shows the equilibrium degrees of conversion of sulfides according to reactions (6) and (7). Reaction (6) is exothermic and virtually irreversible in the low-temperature range. Decomposition of FeS₂ to sulfur proceeds with the absorption of a large amount of heat [which ensures the total endothermic effect in the overall reaction (3)] and is thermodynamically less advantageous (which explains the low equilibrium degree of H₂S dissociation under steady-state conditions at low temperatures).

Figure 9. Equilibrium degrees of conversion of sulfides according to the reactions (7) (1) and (6) (2).

However, the equilibrium degree of sulfide dissociation concerns only steady-state modes of reactions and imposes no direct limitations on the operation of a flow-through reactor with the variable catalyst state. Continuous removal of sulfur vapour from the reaction zone with a flow of a regenerating gas gradually enables complete regeneration of the chemisorbent-catalyst surface. Under these conditions, the equilibrium degree of dissociation determines the regeneration time rather than its maximum degree. It is of fundamental significance that the regeneration occurs in the absence of hydrogen in the gas flow, which eliminates the reverse process, *i.e.*, the H₂S formation.

Obviously, the above description is quite simplified. A much more comprehensive study with involvement of the quantum chemical simulation¹⁷⁶ has shown that the formation of complex compounds comprising hydrogen atoms in addition to the metal and sulfur occurs in the chemisorption of hydrogen sulfide on the surface of a sulfide catalyst.

It should be emphasised that the attainment of super-equilibrium degrees of H₂S dissociation is only possible in a periodic chemisorption-catalytic process with the well-defined separation of the chemisorption and regeneration stages in space and time

The low-temperature decomposition of hydrogen sulfide can be carried out in a multireactor system (see Fig. 3b) with the periodically alternating delivery of a cold gas containing hydrogen sulfide and a heated regeneration gas (*e.g.*, commercial nitrogen, carbon dioxide, natural gas, *etc.*) to each reactor. Such a technology allows one to achieve the 100% conversion of hydrogen sulfide at quite moderate temperatures. At low temperatures, the requirements to construction materials and to the heat removal from the reactor become less severe, in addition, complex sour gases containing hydrogen sulfide can be processed without preliminary extraction and purification of H₂S. Moreover, this reduces the energy consumption due to not only the minimisation of the heat loss as a result of the lower operation temperatures, but also the substantial shift of the heat balance of this reaction. Thus at $T > 600^\circ\text{C}$, the endothermic effect of the sulfur formation as the molecules S₂ was 90 kJ mol⁻¹, while at $T \sim 200^\circ\text{C}$, where S₆ and S₈ are the dominant allotropic forms of sulfur, the effect decreased to 35–40 kJ mol⁻¹. This decrease was caused by strongly exothermic reactions of sulfur molecule growth in the series $\text{S}_2 \rightarrow \text{S}_6 \rightarrow \text{S}_8$.

The chemisorption-catalytic processes are advantageous in a situation where the volume of produced hydrogen is of importance. Particularly, their use is promising in the processing of sour natural gases, *e.g.*, the gas from the Astrakhan gas field, which contains 30% H₂S. The obtained hydrogen can be utilised in fuel cells for the electric power production.

5. Oxidation of sulfur dioxide

Sulfur dioxide oxidation

is a reversible reaction the equilibrium in which can be shifted by adsorption effects. There are two adsorption-catalytic approaches that can substantially enhance the efficiency of the conventional version of this reaction.

a. Water flushing of the catalyst

The first way of shifting the reaction equilibrium is the oxidation of sulfur dioxide at low temperatures in the presence of water vapour. Under such conditions, sulfur trioxide reacts with water to form a sulfuric acid condensate, thus shifting the equilibrium of the target reaction.

The processes of SO₂ oxidation at 35–80 °C on activated carbon (this catalyst was chosen because the conventional vanadium catalysts are inactive at low temperatures) with the initial concentrations of sulfur dioxide of 0.1 vol.%–0.5 vol.% were studied.^{177–179} Under these conditions, the acid formed was condensed and sorbed in the catalyst pores. The catalyst was regenerated by flushing it with water.

The described processes, which were characterised by rather lengthy operation cycles, namely, up to 100–200 min, made it possible to reach very high degrees of sulfur dioxide conversion (the residual concentration of SO₂ in gases was about 50 ppm). However, the use of water flushing leads to the formation of vast amounts of off-grade (low-concentration) acid, which substantially limits the practical application of this technology.

b. Flushing of catalyst beds with air

Yet another method aimed at the shift of the equilibrium to enhance the efficiency of SO₂ oxidation takes advantage of the

adsorption properties of the molten active component of conventional vanadium catalysts.

It was shown¹⁸⁰ that the alternating feeding of the reaction mixture and air to the vanadium catalyst bed can substantially increase the degree of sulfur dioxide conversion. Presumably, flushing of the catalyst bed with air leads to the supersaturation of a film of the molten active component on the catalyst surface with oxygen so that in the next reactant feeding cycle, the oxygen concentration in the melt substantially exceeds its equilibrium value (with respect to the reaction mixture composition); and, hence, the degree of SO₂ conversion can also exceed the equilibrium limit reached in the steady-state mode.

This process can be implemented in a two-reactor scheme (see Fig. 3b) with separate delivery of air and the reaction mixture according to two main versions, namely, with direct flow¹⁸⁰ and counter flow.¹⁸¹ The calculations¹⁸² carried out within the framework of a one-dimensional model of an adiabatic catalyst bed that operates under the plug flow conditions¹⁸³ together with a comprehensive unsteady-state kinetic model of this process,¹⁸⁴ have shown that both versions allow one to reach extremely high degrees of SO₂ conversion (>99.9%). However, the counterflow version provides stable operation of the system in much wider ranges of initial concentrations of sulfur dioxide and inlet gas temperatures and, hence, can be carried out at technologically favourable parameters (cycle duration, catalyst load, initial temperature of gases, *etc.*) in the second stage of the sulfuric acid contacting schemes DC/DA (double contacting/double adsorption). In this case, the total degree of sulfur dioxide conversion in the contact unit can reach 99.999%, which corresponds to the final SO₂ concentration on a level of 50 ppm and meets the most severe environmental requirements. These theoretical conclusions were successfully confirmed by the pilot tests.¹⁴³

6. Steam reforming of methane and CO

The reforming of methane and other hydrocarbons aimed at the production of hydrogen, which is utilised in the syntheses of ammonia and methanol and in the petroleum industry and hydrogen energetics, is among the most important directions of chemical technology.

In these technologies, the most important stages are the methane steam reforming

and the CO steam reforming (water gas shift-reaction)

In both cases, the formation of hydrogen is limited by the equilibrium factors. According to the thermodynamic analysis, the hydrogen yield can be substantially increased if carbon dioxide is removed from the reaction zone. The removal of CO₂ can be accomplished by its adsorption, particularly, on metal oxides, to form carbonates.

Attention is focused on the reaction of methane steam reforming, the equilibrium of which can be shifted due to the absorption of carbon dioxide^{185–193} by various sorbents (CO, MgO, hydrotalcite, dolomite, lithium zirconate, *etc.*). In a single-stage process, hydrogen with the purity grade from 85% to 98% is produced; moreover, the residual mixture mainly contains methane with the minimum amounts of carbon oxides.

Analogous studies have also confirmed the possibility of a substantial shift of the chemical equilibrium in water gas shift reaction by the adsorption of CO₂ on CaO.¹⁹⁴ In this case, hydrogen with the purity grade of 99.5% was formed.

The reverse reaction, namely, the carbon dioxide reduction with hydrogen to CO and water, also deserves mention.¹⁹⁵ In this case, the virtually 100% CO yield was reached due to the adsorption of water on a zeolite sorbent.

It should be stressed that the developments mentioned above were based on a concept of the catalyst steady state, whereas the non-stationarity of the process was entirely attributed to the sorbent effect. Particularly, the well-known steady-state model¹⁹⁶ was used in the simulation of the processes of methane steam reforming. However, the correctness of this approach was not substantiated and is not self-evident.

An interesting scheme was proposed,¹⁹⁷ in which cyclic feeding alternation of steam and the synthesis gas was used in the production of hydrogen on an iron oxide catalyst

This process, which was named the Reformer Sponge Iron Cycle (RESC), can be employed in the production of hydrogen from the natural gas, liquid hydrocarbon fuels and coal gasification products. Similar schemes were proposed recently.^{198, 199}

The production of hydrogen by the catalytic pyrolysis of hydrocarbons with the simultaneous production of valuable types of activated coal is actively studied.^{200–209} In this method, carbon is deposited and accumulated on the catalyst surface, and the processes involved are basically unsteady.

7. Anaerobic oxidation of methane

At present, the processes of cyclic oxidation of methane under anaerobic conditions, where nickel and iron oxides are used as the catalysts, are actively studied.^{210–213} These processes are called Chemical-Looping Combustion (CLC). They are aimed at the deep oxidation, which is achieved by the correct choice of the reaction temperature (1000 °C) and the catalyst composition. Natural gas is passed through a catalyst bed to oxidise hydrocarbons to CO₂ and water vapour; the catalyst is periodically reoxidised with air.

This processes is meant particularly for energy purposes, *e.g.*, for the electric power production. What is its main advantage over the conventional combustion of natural gas consists, is that in the hydrocarbon delivery cycle, the gas mixture at the outlet from the reactor contains only carbon dioxide and water vapour. Due to relative simplicity of water removal from this flow, highly concentrated CO₂ can be produced and extracted later in the pure form and utilised without its emission to the atmosphere. The latter factor is currently the topical problem in view of the Kyoto Protocol requirements. The second advantage of this process is the relatively low temperature in both phases of the cycle, which allows substantial reduction of the emission of nitrogen oxides to the atmosphere.

8. Anaerobic processes of oxidative dehydrogenation of hydrocarbons

The quest for the ways of increasing the selectivity of target reactions in complex reaction systems is among the currently topical problems of catalysis. These reactions include numerous processes of selective catalytic oxidation of hydrocarbons (propane to propylene, butane to butylene and butadiene, *etc.*).

As was shown above, the way of enhancing the selectivity of conversion and the yield of target products as compared with steady-state processes lies in the use of the unsteady state of a catalyst, which can be generated by the cyclic separate feeding of hydrocarbons and the oxidant (air). Oxygen chemisorbed on the catalyst surface acts as the oxidant, whereas

molecular oxygen is not present in the hydrocarbon flow (this explains the term 'anaerobic process').

Reactions of selective oxidation of hydrocarbons with oxygen are, as a rule, exothermic and the selectivity of most of them decreases as the temperature increases. As a consequence, the maximum concentrations of reactants are limited in a steady-state adiabatic process, which has a negative effect on the efficiency. Apparently, the effective coupling of heat and concentration fronts in the catalyst bed is the key problem in the elaboration of selective oxidation processes.

Model studies of parallel adiabatic endothermic reactions have shown^{143, 214–216} that under adiabatic conditions the cyclic feeding of a preheated hydrocarbon into a cold bed of a preliminarily oxidised catalyst leads to substantially lower maximum temperatures as compared with the steady-state process. This is associated with the fact that, in the former case, a considerable portion of heat released in oxidation reactions is consumed for the catalyst heating. The lower temperatures, in turn, favour the higher reaction selectivity. Moreover, this allows one to feed concentrated hydrocarbons into the reactor, which makes it possible to substantially enhance the efficiency of the process.

Model studies also showed the possibility of the existence of a reversed heat front, which, due to the heat conduction of the bed, can move in the catalyst bed counter-currently the reaction gas flow. This allows one to additionally decrease the maximum temperature and enhance the oxidation selectivity.

In the studies^{142, 217} devoted to the processes of selective oxidation of hydrocarbons with the separate delivery of reactants, propane oxidative dehydrogenation to propylene on a vanadium-oxide catalyst was considered. The system of reactions can be written as follows:¹⁰⁴

According to rough estimates, the stage of selective oxidation (8) produces a virtually zero (within the calculation error) heat (about -4.6 kJ per mole of propane), while the total exothermic effect of the overall selective oxidation of propane (116.8 kJ mol⁻¹) is largely due to a sufficiently high exothermic effect in the catalyst reoxidation stage (11), namely, 121.4 kJ per mole of V_2O_4 . At the same time, the stages of deep oxidation of propylene (9) and propane (10) are characterised by pronounced heat evolution (840 kJ mol⁻¹) approximately the same for both these reactions.

Based on these results, a very important conclusion can be drawn, *viz.*, the temperature conditions of the process depend not only on the catalyst activity and selectivity, but also on its thermodynamic properties, particularly, the energy of the bond between chemisorbed oxygen and the surface, which determines the redistribution of the released heat between the stages of catalyst reduction (8)–(10) and reoxidation (11).

According to model studies,²¹⁷ feeding of pure propane with a temperature of 300°C into a cold bed of a preliminarily oxidised catalyst gives rise to a thermal front that travels toward the filtrating gas flow. In the front, due to the virtually zero thermal effect of the main reaction and the insignificant extent of deep oxidation reactions, the catalyst is not heated above the outlet gas temperature.

In addition, such a process can be carried out in a continuous mode with a cyclic separate feeding of cold propane and air in counterflows, *e.g.*, according to the two-reactor scheme (see Fig. 3*b*), into the preliminarily heated catalyst bed. As a result, a stable autothermal unsteady mode is

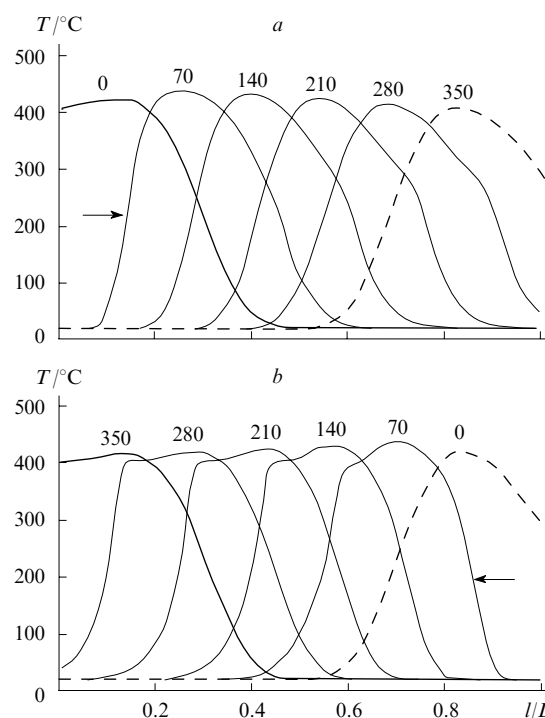

Figure 10. Temperature profiles of a catalyst along the bed length in the established cyclic mode with separate counter-current feeding of propane and air.

(a) Propane feeding cycle (catalyst reduction), (b) air feeding cycle (catalyst reoxidation). Arrows show the direction of the reaction mixture flow, numbers over the curves show time (in s) from the beginning of each cycle. The inlet gas temperature was 20°C in both cycles, the cycle duration was 350 s.

generated in this bed (Fig. 10), which eliminates the necessity of the energy supply and the preheating of reaction flows.

According to estimates, the use of concentrated propane makes it possible to increase the efficiency as compared with steady-state technologies and also noticeably enhance the selectivity of propane oxidation. Among the other advantages of this process, the following factors deserve mention.

1. Technological simplicity and low costs required for its implementation, which is associated with the use of simple and inexpensive reactors with steady-state adiabatic beds of catalyst grains and with the minimum use of the heat-exchange infrastructure.

2. Safety of the process, which is due to the absence of direct contact between hydrocarbons and oxygen.

3. A possibility of utilising air as the oxidant in place of pure oxygen.

4. The possibility of prolongation of the catalyst service life due to the effective suppression of the coke formation in the stage of propane conversion (as a consequence of low temperatures) and to the burning out of coke with oxygen in each cycle of catalyst reoxidation.

The processes under consideration also include the dehydrogenation of paraffins to alkenes, which involves the selective anaerobic oxidation of hydrogen over transition metal oxides and periodic reoxidation of the latter with air,^{218, 219} the partial oxidation of *n*-butane to maleic anhydride²²⁰ (implemented on the commercial scale by DuPont company) and of *o*-xylene to phthalic anhydride²²¹ in moving catalyst beds and also the oxidation of paraffins to alkenes²²² with separate feeding of hydrocarbons and oxygen.

9. Purification of automotive exhaust

The currently topical problems include the problem of 'cold start', which concerns the idle start of an engine when the catalyst temperature is too low.

A solution to this problem lies in the corporation of adsorption traps into the catalytic neutralisers. These traps can adsorb toxic impurities (CO, hydrocarbons, NO_x) and soot particles from the exhaust gases.^{223–226} However, although the sorbed hydrocarbons and soot can be oxidised to the higher or lesser extent, removal of nitrogen oxides poses certain difficulties associated with the fact that these oxides are desorbed during heating of the neutraliser much sooner than the temperature necessary for their efficient reduction is reached.

An original solution to this problem was patented.²²⁷ In essence, the patent describes a procedure for the reversal of flows in a multibed system inert–catalyst–sorber–catalyst–inert, where the reversal is carried out by a mechanical rotation of this system.

At a low temperature, the impurities are accumulated in the sorber located between two catalyst beds. As the temperature increases, the catalyst beds are first to be heated, while the sorber layer is heated later. Thus, the desorption of impurities begins only when the catalyst temperature becomes sufficient for its effective decontamination. This process may be a good illustration of the effective interrelation between the adsorption properties of the system and the dynamics of thermal fields in it.

10. Miscellaneous processes

Among the other processes actively employing the sorption properties of catalysts, the following processes can be singled out:

- direct synthesis of HCN from CO and ammonia with sorption of CO₂ formed on lithium zirconate;¹⁶⁶

- the unsteady Deacon process^{228, 229} of complete oxidation of HCl to elemental chlorine, which includes separate stages, namely, chemisorption of hydrogen chloride on copper oxide to form CuCl₂ and water vapour and the regeneration of the sorber due to the copper chloride oxidation to form CuO and Cl₂;

- a cyclic process of alkene synthesis from methane through transient bromination of methane, which includes the stages of chemisorption of molecular HBr on oxide sorbents used in this process and periodic regeneration of the sorber to form elemental bromine;²³⁰

- synthesis of methanol with removal of the product formed by its absorption with a fine-grain sorber continuously filtered through a fixed catalyst bed;²³¹

- dehydrogenation of cyclohexane to benzene over a metal-hydride catalyst with chemisorption removal of hydrogen;²³²

- unsteady processes of hydrodesulfurisation and hydrodearomatisation of fuels, which take advantage of high adsorption capacity of the catalyst with respect to sulfur compounds^{233, 234} and include reverse processes for hydro-treatment.

All the processes listed above are based on the sorption properties of the catalytic surface and could be carried out in unsteady-state modes with the efficiency enhanced as compared with steady-state processes and particularly afforded superequilibrium yields of the reaction products.

IV. Conclusion

The studies of sorption-catalytic processes described above showed that the purposeful use of sorption (adsorption and chemisorption) properties of heterogeneous catalysts allows one to substantially enhance the efficiency of many catalytic reactions. The highest technological effect can be achieved for

a controlled combination of the thermal non-stationarity with the composition non-stationarity of the catalyst surface.

In the elaboration of a new process, when choosing the main active factor (*e.g.*, concentration modulation), it is necessary to take into account the other factors (dynamic changes in the temperature and the pressure). Otherwise, instead of the expected improvement in the characteristics as compared with steady-state processes, one may obtain a zero and even negative effect.

It should be borne in mind that unsteady catalytic processes are cyclic or periodic, and certain technological efforts may be necessary to ensure their recurrence and, in most cases, the uninterrupted operation of the system as a whole. This complicates practical implementation of such technologies and makes them less attractive; hence, their development is reasonable only if the unsteady-state mode offers substantial advantages over the steady-state processes. Correspondingly, this entails high requirements to the skill of developers and the quality of their service, while the success is determined by the deep insight into the phenomena observed and the use of modern experimental techniques and the methods of comprehensive mathematical simulation.

The diversity of methods for the development of unsteady-state conditions and their combinations is even reflected in the yet unsettled terminology used in the literature. The term 'unsteady catalysis' is often used, although it is too wide and, in certain cases, ambiguous. Insofar as the technologies with modulating catalyst state actively utilise the adsorption phenomena, the term 'sorption-enhanced catalytic processes' is often used. Other popular terms are 'multifunctional processes', which reflects simultaneous occurrence of different types of phenomena (*e.g.*, adsorption and catalysis), and 'chemical looping', which characterises the cyclic nature of processes. The latter are sometimes called (however, not always correctly) the 'reactive chromatographic' processes.

The development of unsteady and adsorption-catalytic processes is a very sophisticated task, which requires that a large number of different factors and their combined action on different-scale levels of the process be understood and taken into account. It should be noted that many relationships typical of steady-state processes do not in principle valid the unsteady catalytic processes.

Particularly, in unsteady processes, even in formally adiabatic catalyst beds, the conditions are realised where the temperature in the bed substantially deviates from the adiabatic value. This difference is determined, in addition to the dynamic effects associated with the regenerative heat exchange and the motion of thermal fronts in the catalyst bed (a property typical of conventional reverse processes with the thermal non-stationarity of the catalyst), by the possible dynamic redistribution of released heat, which occurs in different reaction stages and phases, in both space and time (this is a unique property of systems with the sorption non-stationarity). Depending on the chosen strategy of the realisation of the unsteady mode, the maximum temperature in the process can be either substantially lower (*e.g.*, as in the anaerobic oxidation of hydrocarbons, see Section III.8) or higher (as in the adsorption-catalytic process of VOC oxidation, see Section III.2) than the adiabatic temperature in an equivalent steady-state process.

The use of the sorption capacity of the catalyst allows one to carry out individual reaction stages within certain phases of the technological cycle, which opens up wide prospects for the modulation of the reactant concentrations on the catalyst surface. In many cases, the correct organisation of this process in combination with the temperature factor allows one to overcome the equilibrium limitations and reach higher yields of the target products as compared with analogous steady-state processes.

It is of note that in many cases the parameters of unsteady modes substantially depend on the factors that play a minor role or have an indirect effect on the steady-state technologies. These factors include the bond energy of the reactant with the catalyst surface, the heat capacity of the catalyst, its specific surface, *etc.*

Summarising, the following advantages of the sorption-catalytic technologies over the steady-state methods can be mentioned:

— a decrease in the energy consumption in the processing of low-concentration gases (deep oxidation of VOC);

— an increase in the efficiency of decontamination of exhaust gases (NO_x reduction and purification of automotive exhausts);

— superequilibrium yields of target products in thermodynamically limited reactions (the Claus process, H₂S decomposition, SO₂ oxidation, steam reforming of methane and CO, the Deacon process, *etc.*);

— the enhanced selectivity of partial oxidation processes provided by the use of chemisorbed oxygen as a 'soft' oxidant (oxidation of n-butane to maleic anhydride, o-xylene to phthalic anhydride, paraffins to alkenes, *etc.*).

In many cases, these advantages may include the reduction in the capital costs in the realisation of these processes and also, paradoxical as this may look at the first glance, the simplification of flow schemes and the enhancement of their operation stability.

However, it should be stressed that the aforementioned improvements are achieved only in the case of optimally organised processes. Otherwise, the utilisation of catalyst sorption properties may have a negative effect. Particularly, as was demonstrated above by the example of reactions of deep oxidation of VOC and of the reduction of nitrogen oxides and the oxidation of sulfur dioxide, the sorption-desorption phenomena in a conventional reverse process reduce its efficiency; and, hence, different technological approaches are required in order to achieve positive effects. This is why the key factor of the successful development of sorption-catalytic processes is the correct choice of the process scheme and the search for the optimum strategy for its dynamic control.

The author wants to express his deep gratitude to academician V N Parmon and to A S Noskov, M V Dmitrienko, B S Bal'zhinimaev, V O Strots, P G Tsurul'nikov, A G Okunev, and I A Zolotarskii for valuable discussions and the assistance in the preparation of this publication.

Plant metabolites of the Siberian flora. Chemical transformations and the scope of practical application

E E Shults, V A Raldugin, K P Volcho, N F Salakhutdinov, G A Tolstikov

Contents

I. Introduction	655
II. Results of the resource and structural analytical studies	655
III. Chemical transformations of terpenoids and alkaloids	658
IV. Practical applications of natural compounds and their derivatives	667

Abstract. The results of studies of some terpenoids, alkaloids and phenolic derivatives isolated from Siberian plants are summarised. The structures of the compounds studied are presented and the chemical transformations of the available terpenoids and alkaloids are considered. Examples of practical application of natural compounds and their derivatives are given. The bibliography includes 131 references.

I. Introduction

Natural compounds of plant origin, namely, secondary plant metabolites, are of interest from the scientific and practical standpoints. A fundamental basis for resource studies lies in taxonomy, determination of the chemical composition of plants and elucidation of the structure of particular components. Often, chemical compounds isolated from plants represent novel classes of chemical compounds, which favours the progress in new fields of organic chemistry. At the same time, many plant metabolites and products of their transformations possess practically useful properties, first of all, various biological activities.

At present, a great body of information on plants as sources of valuable compounds has been collected. Many of these compounds can easily be produced in amounts that meet current demands. The development of efficient methods for the isolation of natural compounds in individual form stimulates the design of new pharmaceuticals and agricultural preparations based on them.

Plant metabolites themselves can be the active principles of drugs. For instance, oriental medicine has long used camphor, which was recommended as an inhalation remedy during plague epidemic in the Middle Ages in Europe. A number of individual natural compounds were introduced into medicinal

practice in the 19th century. These are quinine, morphine, strophanthin, *etc.* In the 1950s, drugs based on alkaloids vinblastine and vincristine were introduced into antitumour therapy.

However, at present the search for biologically active compounds is mainly associated with modification of the known plant metabolites aimed at either enhancing the original activity of the chemical compound or obtaining derivatives that exhibit other activities.

For a long time, researchers working at the N N Vorozhtsov Novosibirsk Institute of Organic Chemistry, Siberian Branch of the Russian Academy of Sciences, have been investigating the chemical composition of compounds isolated from forest trees and landscape plants of Siberia and Altai. The resource and structural analytical studies are being carried out to reveal plant producers of valuable metabolites and to develop new methods of processing of plant raw materials to isolate individual compounds that are either used in practice or are of interest for the design of chemical structures with novel properties. The structures of the compounds isolated are determined using all available modern physicochemical methods. In the last two decades, the research carried out at the Institute follows a programme that is aimed, on the one hand, at obtaining basic knowledge on the reactivity of three important classes of plant metabolites, namely, terpenoids, alkaloids and phenolic compounds and, on the other hand, at searching biologically valuable derivatives of these classes of compounds. The ultimate goal of these studies is the development of novel pharmaceuticals and environmentally safe pesticides.

The present review reports on the most important results obtained in the studies of secondary plant metabolites of the Siberian flora.

II. Results of the resource and structural analytical studies

In the 1960s, N N Vorozhtsov, the founder of the Novosibirsk Institute of Organic Chemistry (NIOCh), Siberian Branch of the Russian Academy of Sciences, initiated organisation of the laboratory for wood chemistry. The first two decades of studies headed by V A Pentegova gave a great deal of information on coniferous plants growing in Siberia and Far East (pine, cedar, abies, *etc.*) as unique sources of terpene compounds. Chemical compositions of oleoresins, turpentine and extracts including mono-, sesqui- and diterpenoids from several species of coniferae were determined. The results obtained in these studies

were summarised in a monograph¹ and by right became part of the treasury of knowledge in the domestic and world science of resources and served as the basis of a new research avenue, which is rapidly developed at present.

Particular attention is paid to Siberian plants containing di- and triterpenoids. The interest of chemists and pharmacologists in these compounds is indicated by a number of publications.^{2–7} In addition to terpenoids, researchers at the NIOCh study readily available alkaloids and phenolic metabolites present in some landscape plants. The resource and structural analytical studies of the Siberian flora included search for sources of promising plant metabolites, investigations of variation of the composition of the components depending on the species of plants, identification and structural elucidation of individual compounds and the development of optimum isolation procedures. As a result, researchers at the NIOCh created a database that includes the metabolites characterised by the following major features:

- availability of the plant source;
- efficiency of the isolation procedures;
- chemical structure providing great potential for synthetic modification; and
- putative biological activity.

Here we shall consider a number of compounds that are of interest for further investigations isolation of which from Siberian plants relies on well-developed procedures.

1. Diterpenoids

Undoubtedly, levopimaric acid (**1**), abietic acid (**2**) and their derivative, dehydroabietic acid (**3**) are the most available tricyclic diterpenoids. These compounds are isolated from pine resin and oleoresin, being of interest as substrates for targeted chemical transformations and pharmacological studies.⁸

One of the key components of the extractives of pine needles is a labdane-type diterpenoid isoabienol (**4**). Labdanoids containing a conjugated diene system in the side chain are of interest as the starting compounds for the synthesis of fragrances⁹ and pharmaceuticals.¹⁰ Yet another labdanoid, lambertianic acid (**5**),^{11,12} which can readily be isolated from cedar oleoresin and needles, also exhibits physiological activity. Labdanoids epitorusolol (**6**) and larixol (**7**) can be obtained from oleoresins of the Siberian and Gmelin larch.

Among monocyclic diterpenoids isolated from the oleoresin of Siberian cedar, macrocyclic cembranoid isocembrol (**8**), a structural analogue of metabolites of marine organisms possessing high antitumour activity,¹³ deserves attention.

2. Triterpenoids

As to triterpene compounds, betulin (**9**) isolated from birch bark^{5,14} and glycyrrhizic acid (**10**), a metabolite of licorice⁶ belonging to oleanane-type glycosides, should undoubtedly be ranked first in the availability and pharmacological potential.

From the standpoint of plant physiology, Firs (*Abies* genus) differ from Pines, Spruces and Larches belonging to the same botanical family in production of triterpenoids having a modified lanostane carbon skeleton. One of them, namely, abieslactone (**11**) present in bark of many species of Firs, can readily be isolated from extracts of plant raw materials by crystallisation.^{15, 16} Of particular interest is also an abieslactone derivative **12** with an antitumour activity.¹⁷

Triterpenoids **13–22** produced by Siberian fir (*Abies sibirica* Ledeb.) show structural diversity.^{18–31} These compounds can affect the immune status of agricultural plants, thus enhancing their resistance against fungi.

3. Alkaloids

Classical investigations on alkaloids carried out by researchers from the scientific school headed by academician S Yu Yunusov (Uzbekistan) demonstrate a fruitful combination of the resource, taxonomic, structural analytical and processing studies that enabled the progress in medicinal chemistry and pharmaceutical industry. Despite the fact that most of these studies were carried out using Middle-Asian plant raw materials (see, *e.g.*, a review³²), they played an important role in the studies of Russian alkaloid-containing flora.

The first results of studies on the chemistry, isolation techniques and pharmacological properties of alkaloids from Siberian and Altai plants carried out at the NIOCh clearly demonstrated that the methods and strategies developed by the researchers from Uzbekistan are well applicable for progress in this research avenue. Plants of West Siberia and Gornyi Altai are rich sources of alkaloids many of which also grow in mountain regions of the Middle Asian.

To date, the field and processing investigations made a number of alkaloids including lappaconitine (**23**), methyllicaconitine (**24**), elatine (**25**), songorine (**26**) and berberine (**27**) available for extensive studies.^{33–35} For instance, the pilot plant at the NIOCh can produce several kilogrammes of lappaconitine (**23**) annually.

Lappaconitine (**23**) isolated from *Aconitum septentrionale* Koelle is the active principle of the anti-arrhythmic drug allapinine.³⁶ Alkaloids **24** and **25** isolated from *Delphinium retropilosum* Sambuk³⁴ and *Delphinium elatum* L (Ref. 33), respectively, are agonists of neuronal acetylcholine receptors (N-AChRs);³⁷ the former compound also shows insecticide activity.³⁸ The antiarrhythmic activity of songorine (**26**) produced by *Aconitum barbatum* Pers.³⁵ was reported by research-

chers from Uzbekistan in the 1970s³⁹ and berberine (**27**) isolated from *Berberis sibirica* Pall. is known as choleric and antimalarial agent.⁴⁰

4. Phenolic compounds

Phenolic plant metabolites represent one of the most important classes of natural bioregulators that can have beneficial effect on the vital functions of organisms.^{41–43} Many of them inhibit tumorigenesis and exhibit antiviral (including anti-HIV) and antitubercular activities. Phenolic metabolites of the Siberian flora show a diversity of structural types and have a great resource potential. According to the data obtained by researchers from the Irkutsk Institute of Chemistry, Siberian Branch of the Russian Academy of Sciences,⁴⁴ the total amount of larch wastewood permits large-scale production of phenolic metabolites used as substances for biologically active additives. Recent studies carried out at the NIOCh made many phenolic metabolites available,^{45,46} first of all, the (+)- and (–)-usnic acids (**28**) isolated from lichens.

R = β-Me [(+)-**28**], α-Me [(–)-**28**].

Phenolic compounds also include linear and angular coumarins, which are internal phenol esters. Some Umbelliferae plants produce (+)-pterixin (**29**)⁴⁵ and peucedanin (**30**);⁴⁶ *Myricaria dahurica* is a producer of ellagic acid (**31**), a strong protein kinase inhibitor.⁴⁷

Licorice roots are a source of licoricidine (**32**), which exhibits antiulcer and antitumour activity.⁴⁸ Cedar bark contains readily extractable resveratrol (**33**), pinostilbene (**34**) and their glycoside derivatives, namely, resveratrolsides (**35a**) and pinostilbensides (**35b**).⁴⁹ The therapeutic action of stilbenes **33–35** has been comprehensively reviewed.⁵⁰

R¹ = R² = H (**33**), Me (**34**); R² = Glc: R¹ = H (**35a**), Me (**35b**).

All these phenolic metabolites are considered as promising agents for further modification.

III. Chemical transformations of terpenoids and alkaloids

1. The Diels–Alder (retro-Diels–Alder) reactions

The availability of levopimaric acid (**1**) has made it a subject of synthetic studies. This diterpenoid has two conjugated double bonds and readily reacts with activated alkenes.⁵¹ (Note that the Diels–Alder reaction adducts can be obtained from pine oleoresin containing up to 20% of levopimaric acid). Compound **1** readily reacts with quinone-type dienophiles to give high yields of adducts of unique structures.^{52,53} The effect of the dienophile structure on the selectivity of [4+2]-cycloaddition was studied taking levopimaric acid as an example. It was established that 2,6-disubstituted benzoquinones **36a,b**, 1,2-naphthoquinone and indoloquinones **37a,b** add to diene **1** regioselectively. Regioselectivity of the cycloaddition of asymmetric benzoquinones **36a,b** can be explained by the presence of electron-donor substituents (NHAc, Br) in their molecules; this favours the formation of a hydrogen bond between the carboxyl group and the carbonyl oxygen atom in position 1 of the quinone molecule. In addition, stabilisation of this transition state is also due to the shielding effect of the isopropyl group. Levopimaric acid derivatives **38–40** can be of interest as the starting compounds for the synthesis of pharmacologically valuable products (Scheme 1).

Scheme 1

Of particular interest is the ability of adducts, *i.e.*, bicyclooctadienes, to undergo a retro-diene cleavage. This reaction offers efficient ways for the synthesis of derivatives containing terminal vinyl groups, *e.g.*, 1,4-naphthoquinone (**41**) and pyrrole (**42**).⁵³

(a) 1) CH_2N_2 ; 2) Al_2O_3 , HO^- ; (b) DMF, 150 °C.

(a) 1) H_2O_2 , HO^- , 50 °C; 2) CH_2N_2 ; (b) 260 °C.

Quinopimaric acid (**43**) turned out to be a highly reactive dienophile, which readily reacts with silyloxy- and sulfur-containing butadienes and their aza analogues.⁵⁴ For instance, the reactions of acid **43** with 5-alkoxyoxazoles (the Kondra-

tyeva reagents) result in two compounds, *viz.*, a Diels–Alder adduct **44** and a 1,3-dipolar cycloadduct **45**.⁵⁵ In the latter case, the dipole is likely to be formed upon thermal decomposition of 5-alkoxyoxazole. The results of the reactions of quinopimaric acid (**43**) with alkoxyoxazoles depend on the nature of the solvent. In acetic acid, compounds **44** are the major products (yields 58%–67%), whereas the reactions in an AcOH–MeCN mixture afford adducts **44** (yields 40%–42%) and isoindole derivatives **45** (yields 25%–35%). Further transformations of compound **44** give terpenylazaanthraquinones **46** (Scheme 2).

The behaviour of a morphinan-type alkaloid thebaine (**47**) in the Diels–Alder reaction was studied.⁵⁶ A new group of thebaine derivatives was synthesised, which includes compounds **48**–**54** containing additional carbocyclic and hetero-

cyclic units.^{57–63} Maleimides and maleic anhydride, 2,3-dihydrothiophen-3-one 1,1-dioxide, substituted benzoquinones (or the corresponding hydroquinones in the presence of Ag_2O) and indoloquinones **37a,b** served as the dienophiles. The cycloaddition of thebaine (**47**) to cyclic dienophiles results in 7,8-fused derivatives **46** of 6 α ,14 α -ethnoisomorphinans; the reaction is regioselective in the case of non-symmetric dienophiles.

Scheme 2

R = Me, Et.

R = NHAc, SCH₂X (X = CH₂OH, CO₂H, CO₂Me, CH(NH₂)CH₂OH).

R = H (a), Me (b).

Thebaine (47) reacts with substituted benzoquinones (aqueous dioxane, 20 °C) or with a system hydroquinone–silver oxide (MeOH, 20 °C) to give adducts 51 and subsequent fused hydroquinones 52 (yields 75%–90%). The product ratio varies from 1 : 8 to 1 : 10. Compounds 51 readily isomerise to hydroquinone derivatives 52 under the action of alkaline alumina in CH₂Cl₂ (yields 92%–98%).

Indoloquinone 37a adds to thebaine (47) in aqueous dioxane with simultaneous aromatisation to a dihydro derivative 53a (yield 62%). Regioselectivity of the reaction is probably due to stabilisation of the transition state upon the interaction of the NH group in the pyrrole fragment with the methoxy group in position 6. The reaction of *N*-methylindoloquinone 37b with diene 47 results in products 53b and 54b in a 3 : 2 ratio (overall yield 75%).

A thebaine adduct 50 is prone to skeletal rearrangements with elimination of SO₂.^{57, 60, 61, 64} For the mechanism of this reaction, see Ref. 57. The retro-Diels–Alder cleavage of compound 50 results in a furobenzoazocine derivative 55.^{58, 61, 64}

Here we present some transformations^{62, 63} of adducts 48 and 49, which made it possible to synthesise oripavines (promising psychotropic agents) from natural alkaloids.^{61, 63}

Reactions of morphinandiene 56 with a number of dienophiles were also studied. Taking the Diels–Alder reactions of dienes 47 and 56 as examples, the factors affecting the regio- and stereoselectivity of these processes were studied. It was found that introduction of morphinandiene 56 devoid of the dihydrofuran fragment into the reaction changes the stereochemistry of the cycloaddition. This results in 6β,14β-ethenomorphinans.^{59, 64}

(a) aqueous dioxane; (b) Al₂O₃, CH₂Cl₂, 20 °C.

R = NHAc, SCH₂X [X = CH₂OH, CO₂H, CO₂Me, CH(NH₂)CH₂OH].

2. Diterpenoids in the synthesis of alkaloid-like compounds

Alkaloid-like compounds can be synthesised from structures that can be readily transformed to nitrogen-containing heterocycles. These are, *e.g.*, methyl lambertianate (**57**) and related derivatives.

For instance, terpenocarbolines **59a,b** were synthesised from methyl 16-formyllambertianate (**58**) using the Pictet–Spengler reaction.⁶⁵

RNH₂ is triptamine, X = H; RNH₂ is L-tryptophan, X = CO₂H.

By choosing selective oxidants affecting different fragments of the molecule of lambertianic acid (**5**), it is possible to obtain various oxygen-containing derivatives suitable for further structural modifications. For instance, the oxidation of methyl lambertianate (**57**) followed by aminomethylation involving the furan ring led to *N*-heterocycles **60** and **61** (Scheme 3).^{66, 67}

The synthesis of pyrrolyllabdanoids **62** and **63** from compound **5** has been reported.^{68, 69} In the first stage lambertianic

acid (**5**) is converted to methyl ester **57** under the action of dimethyl sulfate in ethanol; ester **57** is then oxidised using various reagents. Note that compound **62** was isolated as a 1 : 1 mixture of C(8)-epimers.

(a) PhSO₂NHCl, MeOH, 0–5 °C; (b) H₂/Ni-Ra, MeOH, 20 °C; (c) RNH₂, AcOH, H₂O, 90 °C, 15 min. R = Me, Et, cyclo-Pr, Bn.

(a) CrO₃, H₂SO₄, Me₂CO, 0–20 °C; (b) RNH₂, AcOH, 100 °C, 5–8 h. R = Bn, (CH₂)₂Ph, (CH₂)₂C₆H₄OH-4, CH(CO₂H)Et, (CH₂)₃CO₂H.

Synthetic routes to labdane derivatives **64** and **65** containing tricyclic nitrogen-containing fragments starting from lambertianic acid were developed.^{70, 71}

Scheme 3

(a) KMnO₄–MgSO₄, PhH, H₂O, Bu₄NBr, 50 °C; (b) 1) MeNH₂, MeOH; 2) NaBH₄; (c) (CH₂O)_n, CF₃CO₂H, PhH, 80 °C; (d) PCC, CH₂Cl₂, 20 °C; PCC is pyridinium chlorochromate.

(a) $(\text{Me}_2\text{N})_2\text{CH}_2$ or *N*-bis(piperidino)methane, AcCl , CH_2Cl_2 , $0 \rightarrow 20^\circ\text{C}$;
 (b) AlI_3 , PhH , KOH , K_2CO_3 , Me_3BnNCl , 80°C ; (c) PhH , 80°C .
 $\text{R}^1 = \text{R}^2 = \text{Me}$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_5$.

Alkylation of the amino derivative (step *b*) in acetonitrile as a solvent results in products **64** (yields 54%–58%) without isolation of salt. All stages of the synthesis of compound **65** are characterised by good yields (68%–84%), the last step, heterocyclisation, occurs spontaneously.

(a) 1) TsOH , PhH , 80°C ; 2) $\text{Mg}(\text{ClO}_4)_2$, Ac_2O , 20°C ; 3) BnNH_2 , NaBH_4 , $(\text{Pr}^i\text{O})_4\text{Ti}$, $0 \rightarrow 20^\circ\text{C}$; (b) Et_3N , CHCl_3 .

3. Reactions involving metal complex catalysis

The programme of studies on synthetic transformations of some available alkaloids carried out at the NIOCh^{72–79} involves metal complex catalysis as a particular research avenue.

For instance, the aromatic fragment of lappaconitine (**23**) was modified using cross-coupling reactions.^{80, 81} Procedures for lappaconitine bromination and iodination were also developed, which made it possible to obtain the corresponding 5'-halogeno derivatives **66a,b**. Lappaconitine derivatives **67** and **68** containing alkenyl substituents conjugated with the benzene ring were first synthesised by condensation of these halides with ethyl acrylate or 5-vinyl-2-methylpyridine under the Heck reaction conditions.

$\text{Hal} = \text{Br}$ (**66a**), I (**66b**); $\text{R} = \text{EtO}_2\text{C}$ (**67**), Me (**68**);
 dba is dibenzylidene acetone.

Condensation of 5'-iodolappaconitine **66b** with terminal acetylenes, namely, prop-2-yn-1-ol, 2-methylbut-3-yn-2-ol, phenylacetylene and 5-ethynylpyrimidine under the Sonogashira reaction conditions affords lappaconitine derivatives **69–72** containing alkynyl fragments.

$\text{R} = \text{CH}_2\text{OH}$ (**69**), CM_2OH (**70**), Ph (**71**), N -substituted pyrimidine (**72**).

Halogeno derivatives of *endo*-ethenotetrahydrothebaine (**73a,b–75a,b**) and dihydrothebainohydroquinone (**76a,b**) also react with various alkenes in the presence of palladium complex catalysts.^{82, 83} This strategy was used for the synthesis of some C(1)-substituted thebaine derivatives. Succinimido-annulated 1-iodotetrahydrothebaines **73b** are more reactive than pyrrolidine derivatives **74b** in the Heck reaction with ethyl acrylate; the reactions of the former compounds occur under milder conditions and in higher yields.

(a) Br₂ (or ICl), HCO₂H; (b) CH₂=CHCO₂Et, Pd(OAc)₂, P(*o*-Tol)₃,

Et₃N, DMF.

X = Y = O (**73**); X = Y = H₂ (**74**); X = , Y = O (**75**);

Hal = Br (**a**), I (**b**); R = H, Me, Ph, 4-BrC₆H₄.

The effect of the structure of alkenes (acrylates, 2-methyl-5-vinylpyridine, styrene, alkyl vinyl ethers) on the yield of 1-ethenyl-substituted dihydrothebainohydroquinones was studied. It was found that the reaction of 7,8-(1-acetoxy-4-hydroxybenzo)-1-iodo-6,14-*endo*-ethenodihydrothebaine (**76b**) with ethyl vinyl ether results in an arylation product at α -position of the ethyl vinyl ether molecule, but work up of the reaction mixture gives 1-acetyl-7,8-(1-acetoxy-4-hydroxybenzo)-6,14-*endo*-ethenodihydrothebaine (**77b**) as a result of hydrolysis. 1-[(*E*)-Pyridinylethenyl]dihydrothebainohydroquinone **78b** was used in the synthesis of hybrid structures **79b** containing fragments of indolizine- and isoquinoline-type alkaloids (Scheme 4).

Structural modification of thebaine (**47**) and its 7,8-annulated derivatives (e.g., compounds **49** and **52**) using organo-metallic compounds made it possible to synthesise novel morphinan derivatives containing substituents at the C(8) and C(1) atoms. For instance, thebaine adds diazomethane in the presence of copper triflate (0.02–0.04 mol) to give 6 β ,7 β -methylene-6,7-dihydrothebaine (**80**), a carbene addition product of to the C(6)–C(7) bond. A side reaction product, *N,N*-dimethyl-*N*-nor-8 β ,14 β -methylene-8,14-dihydrothebainium trifluoromethanesulfonate (**81**), formed upon addition of two diazomethane molecules to the C(8)–C(14) bond and the tertiary nitrogen atom was also isolated. The structure of

compound **81** was established by spectral data and confirmed by X-ray diffraction analysis.^{84, 85}

We studied the possibility of synthesis of 8 α -substituted derivatives of 14 β -hydroxy-6 β ,7 β -methylenedihydrocodeine. For instance, the oxidation of compound **80** with excess *m*-chloroperoxybenzoic acid (MCPBA) in dichloromethane gives 8 β ,14 β -epoxy-6 β ,7 β -methylene-6,7,8,14-tetrahydrothebaine *N*-oxide (**82**).

The reaction occurs under kinetic control. *N*-Oxide **83** can be isolated from the reaction mixture at a reduced temperature using 0.8 equiv. of the oxidant. The epoxide ring opening in

Scheme 4

(a) Pd(OAc)₂, P(*o*-Tol)₃, Et₃N, DMF; (b) 1) BrCH₂COPh, Et₂O; 2) HC \equiv CCO₂Et, Et₃N, CH₂Cl₂. R¹ = H (**a**), Ac (**b**).

compound **82** under the action of sodium azide in aqueous dioxane gave the 8 α -azido derivative of 6 β ,7 β -methylene-7,8-dihydrocodein-14 β -ol (**84**).⁸⁵

4. Reactions of monoterpenoids in the presence of crystalline aluminosilicate catalysts

Monoterpenoids are widespread in nature. They are produced by Coniferous plants and constitute their oleoresins, turpentine and resins, being also the major components of essential oils extracted from many other plants. Most monoterpenoids are highly reactive compounds and readily undergo various acid-catalysed cyclisation reactions and rearrangements. This often makes selective transformations difficult. For instance, isomerisation and polymerisation reactions occurring upon storage of α -pinene epoxide (**85**) in acid media can result in the formation of more than 200 different products.⁸⁶

It turned out that the problem can be solved by carrying out the process under heterogeneous conditions, namely, on crystalline aluminosilicates (zeolites and clays). The first successful example of the use of aluminosilicates in the chemistry of monoterpenes is provided by the development, in the first half of the 20s century, of a large-scale method for isomerisation of α - (**86**) and β -pinenes (**87**) to camphene (**88**) in the presence of clays.⁸⁷

However, systematic studies of the behaviour of terpenoids on crystalline aluminosilicates began only in the early 1990s.⁸⁸ It was found that the use of zeolites and clays as catalysts of acid transformations of terpenoids made it possible not only to carry out reactions under milder conditions, enhance reaction selectivity, simplify work up of reaction mixtures and solve the acid waste problem, but also often allows the reactions to follow unusual pathways, which cannot be realised under conditions of conventional homogeneous catalysis.

Intramolecular reactions of terpenoids in the presence of aluminosilicate catalysts have been reviewed in detail;^{88–90} therefore, here we only present some examples of intermolecular reactions of monoterpenoids on zeolite and clay supports that were first carried out at the NIOCh. We present the most unusual reactions that demonstrate that the laws of homogeneous catalysis cannot always be directly applied to reactions of labile polyfunctional compounds (including monoterpenoids) in the presence of crystalline aluminosilicate catalysts.

a. Reactions of monoterpenes with carbonyl compounds

Studies of the reactions of some monoterpenes, namely, mircene (**89**), dipentene [(\pm)-limonene] (**90**) and β -pinene (**87**) with aliphatic and aromatic aldehydes in the presence of natural montmorillonite (askanite–bentonite) clay made it possible to develop a simple and efficient method of synthesis of bicyclic ethers **91** with the 3-oxabicyclo[3.3.1]nonane skeleton.^{91,92} The interest in these compounds is due to, *e.g.*,

recently found selectivity of binding to estrogen α - and β -receptors.⁹³ The highest yield of the target product (up to 56%) was attained in the case of β -pinene (**87**).

A possible mechanism of transformations of the three monoterpenes involves the formation of the same intermediate *p*-menthane carbocation **92**, which then interacts with the aldehyde molecule. It should be noted that α -pinene (**86**), which also forms a tertiary carbocation upon protonation, does not react with aldehydes under these conditions. This is apparently due to specific features of adsorption of monoterpenes **86** and **87** on aluminosilicate.

The reaction of dipentene (**90**) with salicylic aldehyde on clay does not stop after the formation of bicyclic ether.⁹⁴ Favourable spatial arrangement of the hydroxyl group in the intermediate carbocation leads to double heterocyclisation resulting in compound **93** with a new tricyclic skeleton.

Reactions of (–)-camphene (**88**) and (+)- α -fenchene (**94**) with acetone in the presence of β -zeolite (H β) mainly give the same enantiomer of tricyclic compound **95**.⁹⁵ The yield and optical activity of the product depend on the solvent used. The best results were obtained for the reaction in CH₂Cl₂ (Scheme 5).

b. Reactions of monoterpene alcohols with aldehydes

Reactions of aldehydes with natural monoterpene alcohols or hydroxymethylated monoterpenes in the presence of aluminosilicate catalysts result in polycyclic ethers. In particular, *trans*-verbenol (**96**) reacts with aldehydes on montmorillonite to give compounds that are structurally similar to products of β -pinene reactions with aldehydes (see Section III.4.a).⁹⁶

Scheme 5

Reactions of *cis*-verbenol and *trans*-verbenol methyl ether (**97**) with aldehydes occur similarly. Therefore, the stereochemistry of the hydroxyl group (including alkylated one) has no effect on the direction of intermolecular reactions; only position of the hydroxyl group in the molecule does matter. Indeed, neither α -pinene (**86**) having no oxygen-containing substituents nor verbenone (**98**) (carbonyl group in position 4)

nor myrtenol (**99**) (hydroxyl group in position 10) react with aldehydes on clays.^{96,97}

Reactions of 3-hydroxymethyl-2-carene (**100**) or 6-hydroxymethylisolimonene (**101**) with salicylaldehyde in the presence of clay gave a tetracyclic compound **102** with a furo[4,3,2-*k*]xanthene skeleton.⁹⁸ The mechanism of formation of this compound involves a number of carbocationic rearrangements (Scheme 6).

At the same time, the reaction of 6-hydroxymethylislimonene (**103**), a double bond regio isomer of compound **101**, with salicylic aldehyde on clay affords product **104** having a 5-oxatricyclo[5.3.1.0^{3,8}]undecene skeleton.⁹⁸ Thus, monoterpenes **103** and **90** containing the same *p*-mentha-1,8-diene

Scheme 6

skeleton react with salicylaldehyde in different manner because they bear different functional groups.

The reaction products of 3-hydroxymethyl-2-carene (**100**) with other aldehydes (α -methylacrolein and butyraldehyde) were also obtained in the presence of clay.⁹⁹ It was found that the direction of these reactions depended on the structure of the aldehyde. For instance, the reaction with α -methylacrolein resulted in indeno[1,7-*bc*]furan **105** as the major product. In the case of Pr^nCHO , the reaction involves the addition of two aldehyde molecules to give 6,10-dioxatricyclo[5.4.0.0^{4,8}]undecane **106** (Scheme 7). Unlike alcohol **100**, attempts to introduce compound **101** into reactions with other aldehydes failed.

Thus, structurally similar, conformationally labile molecules form different products in the presence of montmorillonite clays.

c. Transformations of monoterpenoid epoxides

The behaviour of α -pinene epoxide (**85**) and β -pinene epoxide (**107**) in the presence of crystalline aluminosilicates was studied in detail.^{88, 100} This is associated with both the availability of the starting compounds and the fact that many reaction products (*e.g.*, campholenic aldehyde (**108**), carveol (**109**),

myrtenal (**110**), perillyl alcohol (**111**), *etc.*) are commercially valuable products. The product ratio depends strongly on the nature of the catalysts used (zeolites and clays) and varies over a rather broad range.

Recently,^{97, 101} it has been shown that transformations of verbenol epoxide (**112**) and verbenone epoxide (**113**) in the presence of montmorillonite clays gives different products. Moreover, they significantly differ from the products synthesised using conventional homogeneous catalysts (analogues of campholenic aldehyde). For instance, isomerisation of verbenol epoxide (**112**) results in *trans*-diol **114** as the major product, whereas an analogue of campholenic aldehyde **115** was isolated as the minor product.⁹⁷ Isomerisation of verbenone epoxide (**113**) on clay afforded α -hydroxyketones with the camphane (**116**) and *p*-menthane (**117**) structures, whereas no campholenic-type products were detected.¹⁰¹

Some epoxides of the pinane series undergo intermolecular reactions with aldehydes in the presence of montmorillonite clays. The products formed on clay in the reactions of α -pinene, β -pinene and verbenone epoxides (compounds **85**, **107** and **113**, respectively) with aliphatic aldehydes^{96, 101} have

the 3-oxabicyclo-[3.3.1]nonane skeleton [see reactions of β -pinene (**87**) with aldehydes] with different reactive functional groups.

The reaction of α -pinene epoxide (**85**) with salicylaldehyde⁹⁶ led to unexpected results; namely, an unusual tetracyclic ether **118** was isolated as the only product. The reaction scheme proposed to explain the mechanism of formation of compound **118** involves more than ten stages (Scheme 8).

Reactions of epoxide **112** with aromatic aldehydes in the presence of clay result not only in products of substrate isomerisation, compounds **114** and **115**, but also heterocycle **119**; the product ratio depends on the structure of the aldehyde.⁹⁷ Product **119** has the benzo[1,3-*d*]dioxine skeleton in contrast to the reaction products of other terpenoids with aldehydes (see Section III.4.a), which have the 3-oxabicyclo[3.3.1]nonane skeleton. This can be explained by different reaction mechanisms, namely, heterocyclisation in the last step of formation of compound **119** rather than carbocyclisation in the case of other terpenoids.^{96, 97, 99, 101}

Thus, the use of crystalline aluminosilicate catalysts (clays and zeolites) for performing diverse reactions of monoterpenoids significantly extends the synthetic potential of these compounds and allows easy access to heterocyclic systems that are difficult to obtain. In addition, transformations of terpenoids occur with retention of optical purity under these conditions.^{88, 97, 101}

Note that most reactions presented above do not occur in the presence of conventional homogeneous catalysts. Therefore, the aluminosilicate catalysts not only play the role of the acidic reagent, but also determine the mutual arrangement of the reactants and the site where the cationic centre appears. Because of this, even relatively small changes in the structure of the terpenoid or reagent can cause significant changes in the direction of the reaction.

IV. Practical applications of natural compounds and their derivatives

Studies in the properties of plant metabolites gave practically valuable results. Both natural compounds and their derivatives have found applications in agriculture and medicine.

1. Triterpene acids isolated from fir as the basis for fungicides

Triterpene acids isolated from fir wood green enhance the stability of cotton-plant, crops and vegetables. A mixture of triterpene acids produced in a pilot plant^{102–104} served as the basis for the preparation 'Novosil'. This has passed the Russian Federation State tests and was certified in 1995 as a plant growth regulator.^{105–107} Its positive complex effect on plants consists in an increase in yield by 10%–30%, 2–4-fold enhancement of plant resistance to bacterial and fungal diseases, enhancement of freezing tolerance and drought resistance of plants and acceleration of ripening.¹⁰⁸

2. Pharmacological properties

a. Diterpenoids

Two derivatives of lambertianic acid (**5**), namely, pinusolide (**120**) and a diterpene derivative of γ -aminobutyric acid **121** show pronounced physiological action. Pinusolide, an inducer of apoptosis, is active towards cells of juvenile lymphoblastic and mieloid leukemia,¹⁰⁹ while compound **121** exhibits nootropic activity determined from the rate of dissipation of conditioned passive avoidance reflex and from the degree of the anxiolytic effect.^{110, 111}

Scheme 8

Levopimaric acid is the starting material for the synthesis of dihydroquinopimaric acid (**122**), which shows antiulcer activity, which compares well with modern drugs (*e.g.*, Venter).

b. Triterpenoids

Among triterpene compounds, the most active are betulonic acid derivatives. For instance, betulonic acid-derived dipeptide **123** is a new HIV integrase inhibitor¹¹² and inducer of apoptosis of malignant cells.¹¹³ At present, pre-clinical anti-HIV trials of this preparation are in progress.^{114, 115}

Betulonic acid alanylamide **124** shows antioxidant action and is considered to be a promising corrector of toxic effects in cytostatic chemotherapy.^{116–118}

Glycyrrhizic acid (**10**) has been the subject of considerable attention of researchers for long. A particular manifestation of the physiological activity is the complexation with various drugs, which ensures reduction of the therapeutic dose of the drug.^{119–122}

c. Alkaloids

Modification of diterpene alkaloids made it possible to synthesise novel derivatives of lappaconitine (**23**), which exhibit a much higher anti-arrhythmic activity compared to the well-known drug allapinine.^{123, 124} An example is provided by 5'-bromolappaconitine hydrobromide (**125**). When introduced in a dose equal to one-tenth of the therapeutic dose of allapinine, compound **125** prevents the development of calcium chloride- and adrenaline-induced arrhythmia, being 4.8 times less toxic than allapinine.¹²⁴

A number of highly efficient analgesics possessing no adverse effects typical of morphinans^{63, 125–127} were synthesised from thebaine (**47**). Among the annulated morphinan derivatives, mention may be made of compounds **126–129**.

Compound **126**, in a lipophilic transport form, acts as blocker of pain caused by all types of stimulators. The ED_{50} value was 0.02 mg kg^{-1} for the electric pain stimulation model, 0.07 mg kg^{-1} for the hot-plate model and 0.009 mg kg^{-1} for the acetic acid writhing (AAW) model. These data characterise compound **126** as a μ -receptor agonist.¹²⁶ Compound **127** is a threefold times more efficient pain blocker for the AAW model. The effect of physical and visceral pain control was also observed upon introduction of compound **128**. In the dose corresponding to ED_{50} it only slightly changes the heart rate and has no effect on the bronchomotor tone in cats.¹²⁷ A morphinan derivative **129** shows a prolonged analgesic action on physical pain models.⁶³

* * *

The material presented above shows that intensive development of chemistry of low-molecular-mass plant metabolites is being continued. These compounds are important not only as

representatives of various structural types and information carriers in chemotaxonomic studies, but also as precursors for the synthesis of many valuable products and design of original drugs, cosmetics and agricultural preparations. At present, the available terpenoids and phenolic compounds are first of all used for directed synthesis of complex carbocyclic and heterocyclic structures. Recently, there have been increasing studies on transformations of those alkaloids, which in the native forms are of limited use in medicine owing to high toxicity or pronounced adverse effects. Considerable attention is paid to medicinal chemistry-oriented transformations of the metabolite classes described above (search for novel leader compounds and optimisation of their structures; fragment-oriented ligand design), as reported in recently published reviews, 2, 128–131

Methods for the synthesis of polycyclic nitramines

S V Sysolyatin, G V Sakovich, V N Surmachev

Contents

I. Introduction	673
II. Synthesis of polycyclic nitramines by condensation of amines and their derivatives with formaldehyde	673
III. Synthesis of polycyclic nitramines by condensation of amines and their derivatives with glyoxal	674
IV. Miscellaneous methods for the synthesis of polycyclic nitramines	677

Abstract. Published data on the methods of synthesis of polycyclic nitramines are analysed. The advantages, drawbacks and prospects of two main approaches to the formation of the molecular cage, namely, amine or amide condensation with carbonyl compounds and consecutive formation of the polycyclic cage with introduction of reactive terminal substituents, are discussed. The bibliography includes 64 references.

I. Introduction

Currently, polycyclic nitramines (PCNA) are becoming significant as promising high-energy compounds, which are superior to other explosives in some properties. They have high density, which improves the explosive characteristics without increasing the sensitivity to mechanical action. High content of hydrogen in PCNA (unlike aromatic heterocyclic compounds) results in an increase in the heat of explosive transformation and a decrease in the average molecular mass of the detonation products.

Polycyclic nitramines meet the requirements imposed on promising components of high-energy compositions: they have the optimum oxygen balance, moderate enthalpy of formation and high density.

There are rather few studies devoted to the synthesis of PCNA, most being concerned with the methods of synthesis of 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazatetracyclo-[5.5.-0.0^{3,11}.0^{5,9}]dodecane (hexanitrohexaazaisowurtzitane, CL-20, HNIW).¹ The present review describes systematically the known methods for the synthesis of PCNA, including approaches to the formation of the polycyclic cage and ways of substitution of nitro groups for functional groups at the nitrogen atoms.

The cages of most polycyclic nitramines are synthesised in one step. This way is most convenient for industrial implementation and, as a rule, represents the condensation of amines or amides with carbonyl compounds.

The second stage is introduction of nitro groups. This is accomplished by substituting them for *N*-alkyl and functional (*N*-acyl, *N*-sulfonyl) groups.^{2–6} Nitrolysis of protected secondary amines for the synthesis of cyclic nitramines is fairly well studied.⁷ Of the alkyl substituents, the *tert*-butyl group is replaced most easily. In the series of acyl substituents (CHO, Ac, EtCO, Me₂NCO, ROCO, ArCO), acetyl group is replaced most easily by the nitro group, while the replacement of formyl and propionyl groups requires more drastic conditions. The sulfo group, which undergoes nitrolysis under very mild conditions, is the substituent of choice for the introduction of the nitro group.

Thus, the main problem in PCNA synthesis is construction of a polycyclic cage with *N*-substituents appropriate for substitution of nitro groups. The simplest method for the construction of the hexaazaisowurtzitane cage is condensation of glyoxal with benzylamine or its derivatives. Direct nitrolysis of hexabenzylhexaazaisowurtzitane does not result in HNIW; the major part of investigations on this subject are devoted to the transformation of benzyl groups into substituents suitable for the replacement by the nitro groups.¹

II. Synthesis of polycyclic nitramines by condensation of amines and their derivatives with formaldehyde

The polycyclic cage of nitramines can be formed by condensation of tetramines with formaldehyde. The condensation products are labile compounds, and they are usually converted into the corresponding nitroso derivatives, which are readily nitrated to nitramines.

This method was used to synthesise^{8–10} a number of bicyclic nitramines.

Uspekhi Khimii 76 (7) 724–731 (2007); translated by Z P Bobkova

The reaction of 1,1,2,2-tetrakis(nitramino)ethane (**1**) with formalin gives, instead of the expected 2,4,6,8-tetranitro-2,4,6,8-tetraazabicyclo[3.3.0]octane (**2**), bicyclic compound **3** containing nitrogen and oxygen atoms in the seven-membered heterocycles.¹¹

The cage of bicyclic nitramines can be prepared by aminomethylation of compounds with an active hydrogen atom (the Mannich condensation):^{2, 12}

The reaction of nitraminoethane **1** with formalin and *tert*-butylamine results unexpectedly in elimination of nitramine groups.¹³

The reaction of *N,N'*-dinitrourea with ammonia and formaldehyde gives dinitropentamethylenetetramine **4**, which is the starting compound for the synthesis of octogen.¹⁴ It is assumed that *N,N'*-dinitrourea is hydrolysed to nitramide during the synthesis.

Despite the simplicity and, hence, attractiveness of the PCNA synthesis by condensation of amine derivatives with formaldehyde, it should be noted that compounds with high explosion characteristics cannot be obtained in this way.

III. Synthesis of polycyclic nitramines by condensation of amines and their derivatives with glyoxal

Glyoxal is widely used to prepare nitrogen-containing heterocyclic compounds.^{15, 16} In an aqueous solution of glyoxal, glyoxal hydrate exists in equilibrium with its hydrated oligomeric derivatives.¹⁷

The condensation of glyoxal with primary amines affords mainly 1,2-diaminoethylene glycols **5**, which readily eliminate water being converted into conjugated diimines **6**.^{18, 19}

R = Buⁿ, Buⁱ, Bu^t, cyclo-C₆H₁₁, 4-MeC₆H₄, 4-MeOC₆H₄, 4-HOC₆H₄.

The reactions of glyoxal with primary amides **7** afford products with different degrees of substitution depending on the reactant ratio and reaction conditions.^{20–25}

R = Me, Et, OMe, OEt, OPri, All, Bn, Ph.

Compounds **5** and **6** where R is the benzyl or substituted benzyl group ($R = \text{ArCH}_2$) usually serve as precursors of hexaazaisowurtzitane derivatives **8**.¹

$\text{Ar} = \text{Ph}, \text{XC}_6\text{H}_4$ ($X = 4\text{-Me}, 2\text{-Me}, 4\text{-MeO}, 2\text{-MeO}, 4\text{-Pr}^i, 4\text{-Cl}, 2\text{-Cl}, 2\text{-F}, 2\text{-Br}, 3,4\text{-(MeO)}_2\text{C}_6\text{H}_3$).

Recently, similar hexaazaisowurtzitanes were synthesised²⁶ using other amines (R is furfuryl, allyl, propargyl, 3-pyridylmethyl, cinnamyl, 2-thienylmethyl, 1-naphthylmethyl).

Dimerisation of compound **9** gives rise to piperazine derivative **10**.²⁷

No polycyclic structures are formed in this case.

The reaction of ethylenediamine with glyoxal follows different routes depending on the reactant ratio and reaction conditions. When the molar ratio is 2:1, the reaction gives *trans*-fused tetraazadecalin; its nitration results in 2,5,7,10-tetranitro-2,5,7,10-tetraazabicyclo[4.4.0]decane (**11**).²⁸

The reaction of *N,N'*-dibenzylethylenediamine with glyoxal in 2:1 ratio yields cyclic products containing fused and non-fused heterocycles.²⁹

In the case of 1:1 molar ratio of the reactants, a tricyclic compound is formed in a relatively low yield (< 10%).^{30, 31}

$R = \text{Me}, \text{Pr}^i, \text{Bn}$.

The use of a longer hydrocarbon chain between the amino groups in the diamine results in compounds with non-fused 1,3-diazacycles.³²

Glyoxal reacts with aminoethanols **12** to give oxazabicyclic (**13**) and -tricyclic (**14**) compounds.³³

$R = \text{Me}, \text{Et}, \text{Bu}^n, \text{Ph}$.

The use of *N*-(2-hydroxyethyl)sulfamate in the condensation allows one to obtain the bicyclic cage and easily replace the sulfo group by the nitro group.³⁴

$M = \text{Na}, \text{K}$.

2,2-Diaminohexafluoropropane is a stable compound (unlike diaminomethane); it reacts with glyoxal to afford a bicyclic product, which is nitrated to give bicyclic nitramines.³⁵

Weakly basic diaminofurazan is also readily coupled with glyoxal.^{36, 37} Nitration of the coupling product results in a series of nitro derivatives, including the fully nitrated compound **15**.

The reactions of glyoxal with urea derivatives proceed very easily to afford glycoluril.^{38–41}

$R^1, R^2, R^3, R^4 = H, Me, Et, Ph, CH_2OH$.

Nitration of glycoluril gave a series of its nitro derivatives, among which DINGU and SORGUIL (TENGU) are distinguished as regards explosion characteristics.^{42, 43}

In order to prepare 2,4,6,8-tetranitro-2,4,6,8-tetraazabicyclo[3.3.0]octane, attempts at multicomponent condensation of amines with amides and glyoxal or formaldehyde have been undertaken.^{38, 44} Thus condensation of *N,N'*-dinitromethylenediamine with urea and glyoxal afforded⁴⁵ 2,4,6,8-tetranitro-2,4,6,8-tetraazabicyclo[3.3.0]octan-3-one (**16**).

A series of tricyclic derivatives of urea **17a–e** were synthesised in a similar way.⁴⁶

Compound 17	R^1	R^2	R^3	R^4	R^5	R^6
a	H	H	H	H	H	H
b	NO ₂	H	NO ₂	NO ₂	NO ₂	H
c	NO ₂	H	NO ₂	NO ₂	H	NO ₂
d	NO ₂	NO ₂	NO ₂	NO ₂	H	NO ₂
e	NO ₂	NO ₂	NO ₂	NO ₂	NO ₂	NO ₂

In the search for synthetic routes to bicyclic nitramines, coupling of methylenediamine derivatives with glyoxal was studied. The condensation of *N,N'*-dibenzylidiaminomethane with glyoxal resulted⁴⁷ in a *cis*-fused bicyclic system.

The reaction of *N,N'*-diacyl-4,5-dihydroxyimidazolidine (obtained by condensation of methylenediamide with glyoxal) with dinitramines resulted^{48–51} in a number of bicyclic structures **18–20**. However, attempts to replace the acyl substituents at the nitrogen atoms by the nitro groups failed.

$R = Me, Et$.

The coupling of glyoxal with metal sulfamates deserves special attention. The sulfo group is easily replaced by the nitro group, which makes it the protecting group of choice among those used for the synthesis of polycyclic nitramines. The coupling sulfamates with carbonyl compounds forms not only mono- and bi-, but also tetracyclic products.

The multicomponent condensation of glyoxal with formaldehyde and sulfamates followed by nitration of the bicyclic product with concentrated nitric acid at $-30^\circ C$ affords 2,4,6,8-tetranitro-2,4,6,8-tetraazabicyclo[3.3.0]octane (**21**) (or, at $0^\circ C$, its oxo analogue **22**).⁵²

M = Na, K.

The reaction of glyoxal with sulfamates proceeds in different ways,^{52, 53} depending on the reactant ratio and reaction conditions.

Compound **23** and **24** with the isowurtzitane structure are formed in an acid medium (pH 2.8–4.0) at 50–65 °C. At lower temperature and acidity, salts of 2,3,5,6-tetrahydroxypiperazine-1,4-disulfonic acid (**25**) are mainly formed.

Nitrolysis of sulfonates **23** and **24** with nitric acid–based mixtures proceeds under relatively mild conditions and results in nitramines with the isowurtzitane structure.^{52–54}

Thus, the reactions of amines and their derivatives with glyoxal provide a broad range of PCNA with different structures. Some of them present practical interest and are produced in industry. The main trend of future works would involve the search for economical two-step methods for the synthesis of hexanitrohexaazaisowurtzitane, the most powerful explosive among the PCNA synthesised and the study of application of PCNA and their precursors as biologically active compounds.

IV. Miscellaneous methods for the synthesis of polycyclic nitramines

The following method for the construction of the 3,5,12-triazawurtzitane cage **28** has been proposed:^{56, 57}

R = Me, Et, Prⁿ; R' = Me, Et, Bn, 4-MeOC₆H₄CH₂, 4-Me₂NC₆H₄CH₂.

However, the attempts to carry out substitution at the nitrogen atoms in compound **28** failed.

Nitration of the condensation product of the sulfamate salts with glyoxal (**25**) gave 4,10-dinitro-2,6,8,12-tetraoxa-4,10-diazatetracyclo[5.5.0.0^{3,11}.0^{5,9}]dodecane (**29**).^{53, 54}

This compound can also be prepared in a different way.⁵⁸

Alkylation of ethylenedinitramine with 1,3-diacetyl-4,5-dibromimidazolidin-2-one with subsequent nitrolysis results in bicyclic urea derivative **30**. This compound was also prepared by nitration of the condensation product of ethylenediamine with urea and glyoxal.^{59, 60}

Polycyclic structures called cucurbiturils were prepared by condensation of glycoluril with formaldehyde,⁶¹ and hexacyclic systems were formed upon the reaction of glycoluril, formaldehyde, and diamines.⁶² The attempts to introduce nitro groups in these compounds were unsuccessful.

The reaction of urea with 1,1,3,3-tetraethoxypropane and subsequent nitration yielded 2,4,6,8-tetranitro-2,4,6,8-tetraazabicyclo[3.3.1]nonane-3,7-dione (**31**).⁶⁰

Alkylation of a stannyl derivative of tris(nitramino)cyclohexane was used to synthesise 2,4,10-trinitro-2,4,10-triazaadamantane (**32**).⁵⁶

The possibility of attachment of an amino group at the carbon atom already containing two nitramino groups would give a broad range of PCNA with a tris(nitramino)methane fragment in the molecule, for example, hexanitrohexaazaadamantane. According to calculations, the introduction of terminal amino groups into the PCNA structure would sharply increase the density and explosion characteristic of the compound. Due to the ability of the carboxy group to be replaced by the amino group, the former is a preferable terminal group for the PCNA synthesis.⁶³

The reaction of ethylenediamine with dioxosuccinate, the fixation of the reaction product as the nitrosamine and subsequent nitration with dinitrogen pentoxide in nitric acid gives rise to a bicyclic nitramine containing carboxy groups.⁶³

The methods of synthesis of polycyclic structures by consecutive formation of the molecular skeleton have not been adequately developed as yet, but they are quite promising for the design of diverse PCNA.

* * *

Analysis of published data allows one to distinguish two main methods for the synthesis of PCNA: one-step construction of the polycyclic core of the molecule by condensation of amines and their derivatives with carbonyl compounds and the consecutive formation of the polycyclic cage. Most of PCNA described in the literature were prepared by the former method. The second method is not adequately developed as yet but holds much promise and may yield PCNA of different structures.

The chemistry of high-energy materials, in particular, methods for their synthesis is a topical field of research being actively developed, as indicated by regular publication of new studies (see, for example, the monograph⁶⁴).

IV. Prospects for the use of non-symmetrically substituted phthalocyanines	690

Abstract. The presently known approaches to the synthesis of non-symmetrically substituted phthalocyanines of the A_3B and A_2B_2 types are surveyed. The prospects for the use of these compounds for the synthesis of binuclear and heteronuclear complexes and phthalocyanine oligomers and polymers are demonstrated. The bibliography includes 84 references.

I. Introduction

Phthalocyanines, being synthetic analogues of porphyrins wide spread in nature attract attention of many researchers owing to their prominent chemical and thermal non-stability. Over the last decade, non-symmetrically substituted phthalocyanines bearing different types of substituents came into the focus of interest. These compounds manifest a number of valuable properties enabling their application as advanced materials, in particular in non-linear optics.^{1–12} Non-symmetrically substituted phthalocyanines readily form ordered single layers (*i.e.*, the Langmuir–Blodgett films)^{11–14} and linear polymers.¹⁵ Furthermore, their zinc complexes are promising substrates in the photodynamic anticancer therapy.^{16, 17}

It is of note that the synthesis of non-symmetrical phthalocyanines is a very labourious task, which hinders their studies and practical applications. In the vast majority of cases, non-symmetrically substituted phthalocyanines are synthesised by random cyclisation of phthalogens, which gives rise, naturally, to mixtures of phthalocyanines that are difficult to separate in extremely low yields of the target products.

Non-symmetrically substituted phthalocyanines are of interest from both theoretical and practical standpoints. The presence of different functional substituents in these macrocyclic compounds enables the design of novel supramolecular structures with unique physicochemical properties.^{18–21} That is why the development of methods for the directed synthesis of this class of

compounds is one of the topical directions in the chemistry of phthalocyanines.

In the present review, the emphasis is placed on the methods for the synthesis of non-symmetrically substituted phthalocyanines and their modifications aimed at the introduction of new functional substituents required for the design of bi- and poly-nuclear assemblies of any complexity.

II. Methods for the synthesis of non-symmetrically substituted phthalocyanines

As has been noted above, the directed synthesis of non-symmetrically substituted phthalocyanines remains a challenging problem. The known methods of synthesis do not provide sufficiently high yields^{15–17, 22–41} comparable to those achievable in the synthesis of symmetrical phthalocyanines.

There are two major approaches to the synthesis of non-symmetrically substituted phthalocyanines, *viz.*, the random cyclisation of different phthalonitriles and their synthetic analogues, 1,3-diiminoisindolines,^{15–17, 22–32, 40, 42–50} and the macrocycle ring expansion in subphthalocyanines, *i.e.*, compounds with three rather than four isoindole fragments.^{33–39, 51–56}

1. Methods of synthesis based on the phthalogen random cyclisation

The random cyclisation is presently used the most often for the synthesis of different types of non-symmetrically substituted phthalocyanines, despite its intrinsically low selectivity. Thus the joint cyclisation of two phthalogens **A** and **B** may theoretically afford six products, *viz.*, **AAAA** (A_4), **BBBB** (B_4), **AABB**, **ABAB** (two isomers with the A_2B_2 stoichiometry), **AAAB** (A_3B) and **ABBB** (AB_3) (Scheme 1).

The separation of the resultant random mixture requires the application of sophisticated chromatographic techniques. Due to the high proneness of phthalocyanine molecules to self-aggregation, the isolation of the target product represents a rather difficult problem.^{23, 57} Typically, it can be solved with the use of phthalogens with substituents of different nature. In particular, bulky substituents prevent the self-aggregation and increase the solubility thus facilitating the chromatographic isolation and purification of the target product.^{43, 58, 59}

The yield of a target product is strongly affected by the ratio of the reactants.^{16, 17, 22–27} According to a theoretical analysis, the reaction of phthalogens **A** and **B** with similar reactivities taken in a molar ratio of 3 : 1 yields a mixture containing phthalocyanines A_4 and A_3B in a ratio of 3 : 4.⁵⁸ The total yield of the A_3B products does not exceed 10%–20%. Leznoff and co-workers¹⁷ noted that

Scheme 1

the content of the product A_3B in the reaction mixture can be increased with respect to other possible phthalocyanines by increasing the amount of the phthalogen **A** to 9–10 equivalents. But even in this case, the yield of the target product rarely exceeds 20%.

In the synthesis of the A_2B_2 type phthalocyanines, the formation of two isomers with the identical fragments arranged either next to (**AABB**), or opposite to (**ABAB**), each other is possible.^{15–17, 27, 28, 43–45} These isomers cannot be separated by adsorption chromatography, thus a two-step process has been elaborated¹⁷ for the selective synthesis of the isomer **AABB**.

The reaction of lithium methoxide with phthalonitrile taken in the equimolar ratio in methanol at 40–60 °C yields mainly intermediate **1**. Its subsequent cyclisation with alkoxy-substituted phthalonitriles in *n*-octanol affords complexes **2**.

An alternative approach to the synthesis of structures **AABB** consists of the use of the mixed cyclisation of bis(phthalonitriles) prepared from 3-nitrophthalonitrile and diols with closely arranged OH groups.^{7, 8, 27, 60, 61} Such phthalocyanines synthesised for the first time in the mid 1990s⁶¹ are commonly referred to as side-strapped.

$R = \text{Me}$ (**a**), CH_2Ph (**b**), CHPh_2 (**c**).

$R = \text{Ph}$ (**a**), $4\text{-Bu}^t\text{C}_6\text{H}_4$ (**b**), $4\text{-C}_6\text{H}_4\text{SO}_3\text{Na}$ (**c**).

Since in the starting compound the phthalonitrile groups are located close to each other, the probability of the oligomerisation and formation of binuclear products is rather low, such that non-symmetrically substituted phthalocyanines of the **AABB** type are preferably formed. Nevertheless, the possible formation of a phthalocyanine with two cross-links at the opposite sides is not totally ruled out even in the presence of phthalonitrile.²⁷

Young and Onyebuagu²⁸ proposed a method for the selective synthesis of phthalocyanines **ABAB** based on the cyclisation of 6-nitro-1,3,3-trichloroisindole and substituted 1,3-diiminoisindoline taken in an equimolar ratio.

The target product **4** is formed in 50% yield, which is record high for non-symmetrically substituted phthalocyanines. However, other authors who employed this method^{15,62} observed the formation of the phthalocyanine **AAAB** as a by-product with the total yield of the target phthalocyanine **ABAB** not exceeding 15%–25%. It was also noted⁶³ that the selectivity of the reaction increases with an increase in the bulk of substituents in one of the phthalogens.

Therefore, the random cyclisation as a method for the synthesis of non-symmetrically substituted phthalocyanines provides low selectivity, which weakly depends on the nature and ratio of the starting phthalogens.

The synthesis on a polymer support (**P**) represents a promising modification of the random cyclisation method. This approach involves grafting of a phthalonitrile containing an OH group in a substituent to a polymer, converting the thus modified phthalogen into the respective 1,3-diiminoisindoline analogue followed by its mixed cyclisation with another substituted 1,3-diiminoisindoline.^{40,49}

$\text{Tr}' = \text{CPh}_2\text{C}_6\text{H}_4$;

$\text{R} = \text{Tr}' - \text{P}$ (**a**), **H** (**b**).

An acid treatment of the immobilised phthalocyanine **5a** afforded compound **5b** in 20% yield. The simplicity of the isolation of the target product is an evident advantage of this method — it is sufficient to wash the immobilised phthalocyanine with an appropriate solvent to remove concomitant symmetrical phthalocyanine. Wöhrle and co-workers⁵⁰ proposed to use modified silica gel as a support for the assembly of the target phthalocyanine.

The synthesis on a polymeric support requires that substituents in the starting phthalonitriles should contain suitable reactive groups, which limits the diversity of substituted phthalocyanines that can be synthesised by this method.

2. A method of synthesis based on the ring expansion in subphthalocyanine macrocycles

A rather convenient and elegant method for the synthesis of A_3B -type phthalocyanines has been suggested by Kobayashi *et al.*⁵³ and further developed by Torres and co-workers,^{37,38,51} van Lier and co-workers^{33,54,56} and Wöhrle and co-workers.⁵² These studies showed that energetically strained subphthalocyanines undergo ring opening in the presence of 1,3-diiminoisindolines giving rise to phthalocyanines. In a recent paper, van Lier and co-workers⁵⁶ reported on the synthesis of a number of functionally substituted phthalocyanines **6a–g** by this method. This method provides a substantial advantage over the statistical cyclisation: the reaction selectivity can be finely controlled.

The ring expansion reaction is shown^{64,65} to be of the first order with respect to subphthalocyanine and its selectivity is mainly governed by the nature of substituents in the reactants. The reaction proceeds with the maximum selectivity and the target products are obtained in the maximum yields (>20%) provided that the subphthalocyanine is either non-substituted⁵¹ or bears acceptor substituents,³⁹ whereas the 1,3-diiminoisindoline bears electron-releasing substituents.^{35,38,51,52} Highly reactive 1,3-diiminoisindolines with electron-withdrawing groups yield random mixtures of products.^{36,37}

Compound 6	R ¹	R ²	X	Y	Z
a	H	H	I	H	H
b	H	Bu ^t	I	H	H
c	CH=CHCH=CH	I	H	H	H
d	H	H	H	H	I
e	H	Bu ^t	H	H	I
f	CH=CHCH=CH	H	H	H	I
g	H	H	I	I	H

Mixtures of DMSO with α -chloronaphthalene or *o*-dichlorobenzene are typically used as solvents for the subphthalocyanine ring expansion.^{33–39, 51–54} Dimethyl sulfoxide is the optimum medium for the reaction, but subphthalocyanines are only moderately soluble in DMSO and thus co-solvents are necessary. The use of such solvents as DMF or alcohols results exclusively in the decomposition of subphthalocyanines.³⁹

Torres and co-workers^{37, 38, 66} suggested a mechanism of this reaction. In the first step, an ‘open’ phthalocyanine, which is an intermediate with four isoindole fragments, is formed. Then the intermediate undergoes either ring closure to yield phthalocyanine or fragmentation to a random mixture of products. However, the

mechanism of the attack at subphthalocyanine, which is central, in our opinion, for the selection of optimum conditions for the subphthalocyanine ring expansion, remains largely unexplored.

3. A comparison of the methods for the synthesis of non-symmetrically substituted phthalocyanines

A comparison of yields of non-symmetrically substituted phthalocyanines with the stoichiometry A₃B provided by the subphthalocyanine ring expansion and random cyclisation reveals their similar efficiencies. In both cases, the total yields do not exceed 20%. Thus since the former method requires an additional step of synthesis and purification of subphthalocyanines, the random cyclisation is considered as the method of choice by the majority of researchers despite the laborious isolation of the target products. Furthermore, the random cyclisation of phthalogens with bulky substituents seems to be preferable for the synthesis of A₂B₂-type phthalocyanines.

III. Structure modification of non-symmetrically substituted phthalocyanines

The majority of non-symmetrically substituted phthalocyanines described in the literature bear functional groups, which allow their post-synthetic modifications.^{2–6, 9, 13, 18, 26, 31, 67–70} In particular, a selective method for the synthesis of planar bi- and trinuclear phthalocyanines with the macrocycles linked by ethylene,^{71, 72} ethynyl,^{67, 68, 73} ferrocenediethynyl,^{3, 4} dehydroannulene^{20, 70} or anthraquinone² spacers has been developed. These phthalocyanines are of great potential as new-generation functional materials due to their extended conjugated π -systems providing efficient interactions between the phthalocyanine macrocycles.

1. Structure modification of halogen-substituted phthalocyanines

In the late 1990s, Ali and van Lier⁷⁴ found that zinc 9,16,23-tri(*tert*-butyl)-2-iodophthalocyanine (**7**) readily undergoes the Heck and Stille reactions affording products **8a–e**, **9b,c** and **9a**, respectively, in preparative yields (Scheme 2).

Scheme 2

Later, other cross-coupling products were synthesised²⁶ based on the phthalocyanine **7**. Thus, halogen-substituted phthalocyanines can be regarded as the basic synthetic precursors of both other non-

symmetrically substituted phthalocyanines (with the composition A_3B) and binuclear phthalocyanines.^{2–4, 18, 26, 67–69, 73–75}

Scheme 3

In this way, a fullerene-substituted phthalocyanine (**10**) and a planar binuclear phthalocyanine (**11**) have been prepared. Both compounds manifest unique photophysical properties owing to the efficient intramolecular interaction between the macrocycles.^{70, 73}

The starting phthalocyanine **7** is usually synthesised by co-cyclisation of 4-(*tert*-butyl)phthalonitrile and 4-iodonaphthonitrile,^{26, 73} although an alternative more complex two-step modification of the respective nitro-substituted phthalocyanine has been reported.⁶⁹

Phthalocyanine **12** with two bromine atoms in the *ortho*-position is no less important from the synthetic viewpoint. Its cross-coupling with tributylstannylacetylene yields diethynylphthalocyanine **13**. This compound can also be prepared from the respective diiodo-substituted complex.¹⁸

Starting from phthalocyanine **13**, bi- and trinuclear phthalocyanines **14** and **15** can be synthesised, which can well be regarded as supramolecular structures: the phthalocyanine macrocycles therein are fused through the dehydroannulene spacers (Scheme 3).^{20, 70} This fusion provides even more efficient intramolecular conjugation, which is important for the practical utilisation.

o-Dihalogen-substituted phthalocyanines can be synthesised by co-cyclisation using respective 4,5-dibromo- or 4,5-diiodo-substituted phthalonitriles as one of the phthalogens.^{18, 20, 70}

2. Structure modification of phthalocyanines using the Diels–Alder and Wittig reactions

The Diels–Alder and Wittig reactions are among few classical organic reactions that enable the stereo- and regioselective construction of compounds with specified structures under mild conditions in high yields. The possibility of utilisation of phthalocyanines in these reactions opens broad synthetic prospects.^{71, 72, 76, 77}

The Diels–Alder reaction of non-symmetrically substituted phthalocyanines has been realised for the first time by Hanack and co-workers^{72, 76} aimed at the preparation of linear phthalocyanine-based oligomers and polymers. It was demonstrated first for symmetrically and then for non-symmetrically substituted phthalocyanines (*e.g.*, **16**) that the isobenzofuran fragments in peripheral substituents in phthalocyanine macrocycles readily react as dienophiles with 2,3,4,5-tetraphenylpentadienone as a diene (Scheme 4).

Complex **17** loses CO and tetraphenylbenzene (TPB) molecules upon boiling in toluene yielding an unstable intermediate **18**

Scheme 4

Scheme 5

with a diene structure capable of reacting with dienophiles, *e.g.*, with 1,4-naphthoquinone. Product **19** has to be only aromatised to afford the target phthalocyanine **20**. However, standard reagents used for similar naphthalocyanine substrates (*e.g.*, TsOH) react with phthalocyanines, as a rule, with partial decom-

position of the macrocycles. Therefore, the use of a mild Lewis acid, trimethylsilyl triflate is more appropriate.

The Diels–Alder reaction was also successfully applied to prepare ordered polymeric structures. Non-symmetrically substituted phthalocyanines **ABAB** can be converted into linear polymers (Scheme 5).^{15, 62}

Scheme 6

R is 2-ethylhexyl.

The Wittig reaction necessitates a phthalocyanine to bear at least one aldehyde group. Such phthalocyanines cannot be directly synthesised by the standard method based on the random cyclisation since dicyanobenzaldehydes yield no phthalocyanine products.^{72,77} Therefore, the required aldehyde-functionalised phthalocyanines should be synthesised by a structure modification of other non-symmetrically substituted phthalocyanines (Scheme 6).

Hydrolysis of hydrazone **21** or acetal **22** yields phthalocyanines **23** and **24**, respectively. The starting derivatives **21** and **22** can easily be prepared by the random cyclisation of the corresponding phthalogens.⁷⁷

The Wittig reaction makes it possible not only to modify the structure of non-symmetrically substituted phthalocyanines but also to synthesise planar binuclear phthalocyanines. The structure of the target product in this case is governed by the number of ylide groups in the selected spacer (Scheme 7).

The simple control over the structure of the target products and nearly quantitative yields make this method very useful for both the modification of monophthalocyanines and the preparation of bi- and polynuclear phthalocyanines with a specified spatial orientation of the macrocycles.

The phthalocyanines synthesised by the Diels–Alder or Wittig reactions are characterised by extended conjugated electron systems, which results in bathochromic shifts of the Q band in their UV-Vis absorption spectra.^{71,72,76,77}

3. Functionalisation of nitro-substituted phthalocyanines

A nitro group as an electron-withdrawing substituent activates the aromatic nucleophilic substitution. Furthermore, it can readily be reduced to amino and diazo groups, which can further be involved in the preparation of various alkylation and coupling products.

One possible way to modify nitro groups in non-symmetrically substituted phthalocyanines, *viz.*, the reduction to the amino group, has been mentioned above in the description of the synthesis of moniodo-substituted phthalocyanine **7**. A unique synthesis of planar trinuclear phthalocyanine **25** (Scheme 8) is based on the easy alkylation of the amino group.¹⁹

A similar alkylation reaction has been realised for monohydroxy-substituted phthalocyanine.²¹

Yet another method for the structure modification of mononitrophthalocyanines, *viz.*, the nucleophilic substitution of the nitro group, has been developed^{78,79} for the synthesis of new functionally substituted phthalocyanines, which served as precur-

Scheme 7

Scheme 8

sors of binuclear clamshell phthalocyanines **26a,b**⁸⁰ and a heteronuclear complex phthalocyanine–spacer–subphthalocyanine **27**.^{81, 82}

The *ipso*-substitution of the nitro group is typically accomplished in substrates with strong electron-withdrawing substituents, such as CN groups. Such an approach is used

$\text{R} = \text{Bu}^t$, $\text{R}' = \text{H}$, $\text{M} = \text{Zn}$ (**a**); $\text{R} = \text{R}' = \text{OPr}^n$, $\text{M} = \text{Cu}$ (**b**).

for the synthesis of bis(phthalonitriles)⁸³ and the majority of alkoxy-substituted phthalonitriles.^{27, 84} However, this reaction has not been applied to phthalocyanines so far. The feasibility of the nucleophilic substitution of a nitro group in non-symmetrically substituted phthalocyanines **28a–d** has been demonstrated for the first time and the optimum reaction conditions have been found by our group.⁷⁸ The target complexes **29a–d** containing a benzyl alcohol fragment in a peripheral substituent were isolated in preparative yields.

R = R' = Et (**a**), Buⁿ (**b**), OPrⁿ (**c**); R = Bu^t, R' = H (**d**).

When K₂CO₃ was used as the base, the reaction was completed in 50 h and the products **29a–d** formed in trace concentrations. The use of a stronger base, *viz.*, sodium hydride, made it possible to both accelerate the reaction and increase the yields of the target products **29a–d**. The course of the reaction can conveniently be monitored by means of UV-Vis absorption spectroscopy (Fig. 1). The starting nitrophthalocyanines **28a–d** manifest split Q bands. The products **29a–d** devoid of both electron-releasing and -withdrawing substituents should be characterised by spectra typical of mononuclear metal complexes, which is indeed observed experimentally.

As the nucleophilic substitution reaction proceeds, the splitting of the Q band gradually disappears. Meanwhile, it was found that a prolonged contact of phthalocyanines with a strong base should be avoided, since it results in a gradual decomposition, which was confirmed by control experiments.

A similar reaction of the aromatic nucleophilic *ipso*-substitution was utilised for the synthesis of phthalocyanines **30a–d** containing reactive phthalonitrile fragment.⁷⁸

R = R' = Et (**a**), Buⁿ (**b**), OPrⁿ (**c**); R = Bu^t, R' = H (**d**).

Phthalocyanines **30a–d** are synthetic precursors of non-symmetric binuclear clamshell phthalocyanines. The feasibility of the synthesis of such compounds has been demonstrated with complex **30c** as an example.⁸⁰ The co-cyclisation of phthalocyanine **30c** with substituted phthalonitriles in the presence of copper and zinc acetates afforded binuclear phthalocyanines **26a,b**.

The presence of a benzylic OH group in complexes **29a–d** enables the synthesis of heteronuclear complexes and supramolecular structures. In particular, the reaction of phthalocyanine **29b** with boron μ -chlorohexabutylsubphthalocyanine yields complex **27** involving a phthalocyanine and a subphthalocyanine moieties.

Therefore, the functionalisation of monosubstituted phthalocyanines together with the structure modification of non-symmetrically substituted phthalocyanines considered above make it possible to prepare diverse bi- and polynuclear (including heteronuclear) macrocyclic compounds.

IV. Prospects for the use of non-symmetrically substituted phthalocyanines

Non-symmetrically substituted phthalocyanines attract attention not only from synthetic chemists but also from physicists. Primarily, this concerns complexes of the push–pull type. The

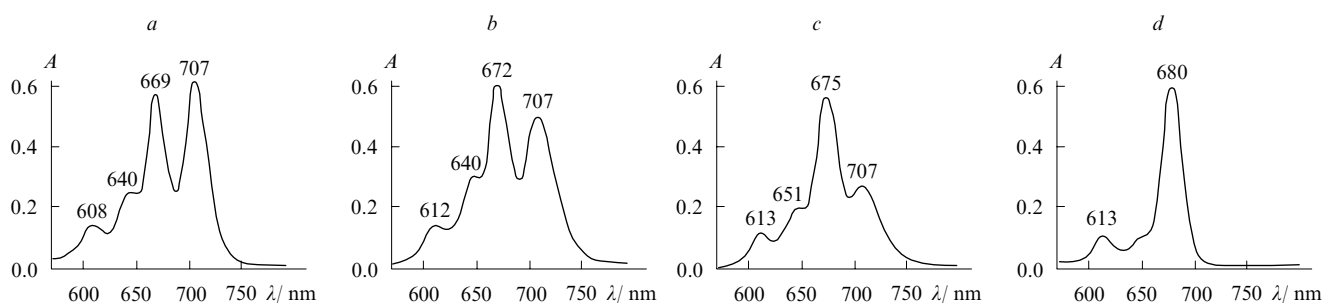

Figure 1. Changes in the UV-Vis absorption spectra (in DMSO) in the course of the nucleophilic substitution of the nitro group in phthalocyanine **28d** in the presence of NaH at 25 °C. Reaction time (min): 5 (**a**), 15 (**b**), 30 (**c**), 45 (**d**).

simultaneous presence of substituents of the opposite character modifies, first of all the spectral properties of these macrocyclic compounds.^{31, 46, 78} In particular, an intramolecular electron transfer from a donating to a withdrawing substituent has been observed in A₃B phthalocyanines.^{11, 14, 47}

Non-symmetrically substituted phthalocyanines possess no inversion centre and thus they are prone to the formation of oriented dipoles upon irradiation with coherent light. They manifest non-linear optical properties and thus can be used for the second harmonic generation.^{11, 12} Furthermore, it was found that these phthalocyanines readily form Langmuir–Blodgett films,^{11–14} which significantly facilitates the above studies.

Recently, the capability of fullerene-substituted A₃B phthalocyanines to separate and accumulate for a long time electric charges in a solid phase has attracted considerable attention. A possible application of such compounds as components of solar cells has already been demonstrated.^{6, 9} The chemical conversion of solar energy was achieved with heteronuclear complexes zinc phthalocyanine–ruthenium(II) tris(bipyridine) **31a–c**.⁵

X = CH=CH (a), NHCO (b), C≡C (c).

Thus, non-symmetrically substituted phthalocyanines are very promising compounds and the progress in the methods for their synthesis will certainly extend fields of their practical utilisation.

* * *

The well-known methods for the formation of a phthalocyanine macrocycle has recently been supplemented with regioselective reactions giving rise to new classes of macrocyclic compounds and unveiling new avenues in the synthesis of supramolecular structures for emerging areas of science and technology. The methods for the synthesis and structure modification of non-symmetrically substituted phthalocyanines are being successfully developed, which makes the macrocyclic compounds accessible for the investigations and practical applications. We hope that the number of structurally diverse non-symmetrically substituted phthalocyanines will expand substantially in the nearest future and some day they will come into practice as advanced functional materials.

Bibliometric analysis of the journal *Uspekhi Khimii* (Russian Chemical Reviews)

I V Zibareva, T N Teplova, O M Nefedov

Scientific journals, which first appeared in the second half of the 17th century (the oldest of the currently existing journals, *Philosophical Transactions of the Royal Society*, has been published since 1665),¹ made a great contribution to the formation and development of science. At that time, scientific journals did not publish review articles, as there was no need in them. However, the subsequent avalanche-like increase in the amount of primary scientific information made impossible 'tracing' of the necessary publications in the rapidly growing number of scientific periodicals. It became necessary to generalise the scientific knowledge either as monographs or as scientific reviews, which are much faster responding and available than monographs. In the early 20th century, special review journals were founded for publishing review articles. In chemistry, these journals were represented by *Chemical Reviews*, *Accounts of Chemical Research*, *Chemical Society Reviews* and so on; in the USSR, the *Uspekhi Khimii* (Russian Chemical Reviews) journal was created for this purpose.

Uspekhi Khimii was founded in 1932 by the decision of the USSR Narkompros (Ministry of Education) for publishing review papers in theoretical and experimental chemistry and chemical engineering that were of great methodological and integrating value. Currently, this is a leading periodical of the Russian Academy of Sciences concerned with chemistry and related sciences. In 2007, *Uspekhi Khimii* marked its 75th birthday. This is a serious age for a journal and a worthy occasion for its bibliometric analysis. The bibliometric (scientometric) methods² using statistical data on publications, references, citation and some other parameters have come in wide use in the second half of the 20th century to characterise the state-of-the-art and the trends in the development of science and to evaluate scientific journals. At present, bibliometric analysis of scientific journals has become routine practice for both foreign and Russian periodicals, including those dealing with chemistry.^{3–10}

Modern bibliometric studies use most often databases (DB) of scientific and technical information as the source of primary data.^{2, 11} Despite the fact that bibliometry is mainly a retrospective descriptive science, systematically described bibliometric data form the quantitative base for analysis. In some cases, this analysis reveals hidden features and trends of a

particular field of research covered by the journal and allows one to formulate proposals for increasing the efficiency and professional image of the journal.

The bibliometric analysis of the journal *Uspekhi Khimii* over the 75-year period of existence was carried out using reliable global DB, viz., Chemical Abstracts (CA) and SCISearch (a version of the Science Citation Index, SCI), i.e., the International Scientific and Technical Network (STN International),¹² through which the journal is perceived by most of the world chemical community (the STN provides the access to the CA DB retrospect down to 1907¹³ and the SCI DB, down to 1974¹⁴). The journal *Uspekhi Khimii* (Russian Chemical Reviews) is included in the core journals list of the authoritative international DB — CA and SCI. It has been abstracted in the CA database from the first issue of 1932; overall, this DB keeps records of 99% of the journal's original publications.

By the search date (February to March 2007), the CA DB has contained 4281 papers of *Uspekhi Khimii* where the publications of 1932–1998 (starting with the first published review 'New problems in the investigation of mineral raw materials' by Academician A E Fersman) were recorded based on the original Russian-language edition *Uspekhi Khimii* (USP), while the 1999–2006 publications were taken from the translated version *Russian Chemical Reviews* (RCR), which has been published since 1960. The SCI database was found to contain 2324 papers published in *Uspekhi Khimii* in 1973–2006.

The joint search through both CA DB and SCI DB resulted in 4403 non-identical publications of the journal for 1932–2006, which is about 90% of the total number of publications (the original and translated versions of a paper were regarded as one publication). The difference between the total number of publications in USP/RCR and their number included in the DBs is due to the fact that from the early years of existence (1932–1950) and up to 1980 the journal published not only submitted papers but also translations of the reviews and survey papers written by most prominent world scientists (J Bernal, L Hammett, C Ingold, K Kohlrusch, E Rutherford, E Schrödinger, G Seaborg and others), which were not abstracted by the DB producers. During the period from 1932 to 1942 the numbers of original and translated articles in the journal were almost equal. Apart from translated articles, the journal also published historical and biographical as well as information articles, in particular, those dealing with the activities of scientific laboratories and institutes of the USSR Academy of Sciences. Figure 1a presents the year-by-year variation of the journal's original publications abstracted in the DB and Fig. 1b shows the same plot for the whole set of journal's publications.

The CA and SCI databases have records of 4766 authors of the journal USP/RCR. The average number of authors per review is two; the average number of reviews per author is less than two. About 75% of authors had only one publication in *Uspekhi Khimii*.

Received 6 June 2007

Uspekhi Khimii 76 (8) 747–751 (2007); translated by Z P Bobkova

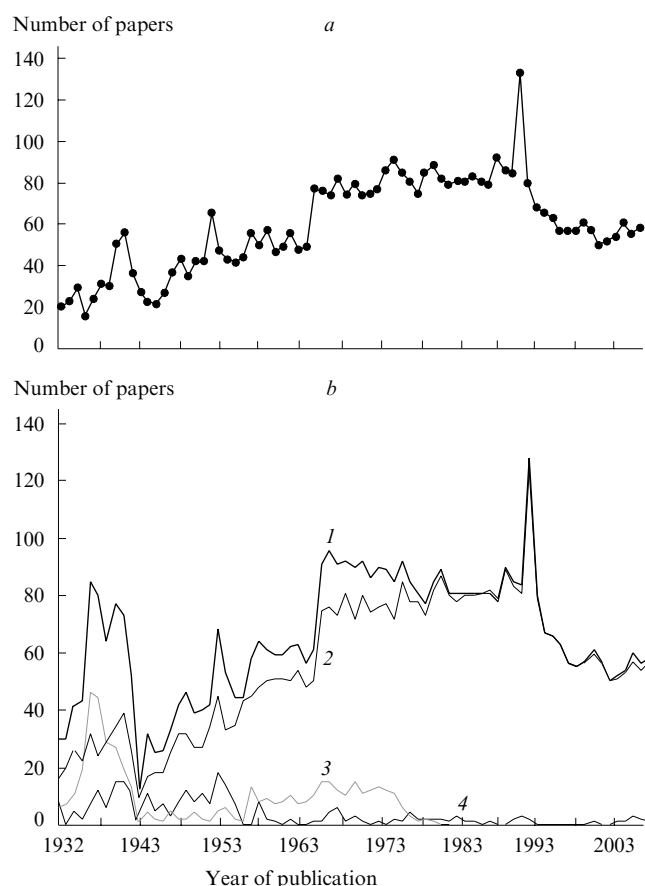

Figure 1. Year-by-year variation of the journal publications abstracted in the CA DB (a) and found by examining all journal issues (b). (1) Total number of papers, (2) original reviews, (3) translated papers, (4) other.

The small difference between the curve shown in Fig. 1 a and curve 2 in Fig. 1 b is due to the fact that not all of the original papers published in *Uspekhi Khimii* were abstracted in the DB.

The authors' addresses kept in the DBs can be used to investigate their geographic and departmental distributions. The CA database cites the addresses for all authors. Table 1 summarises the institutions the employees of which appear most often in the journal (based on the data for 1978–2006), and Table 2 presents the departmental affiliations of the authors. It can be seen that the Academy of Sciences predominates among the departments and Moscow predominates among the cities.

Subject classification and controlled terminology of the CA DB allow one to characterise, although roughly, the main subject matter of journal publications. In the CA database, every abstract is placed in a particular subject section corresponding to the publication contents. The primary (1907) 30 sections were transformed in 1962–1967 into 80 subject sections, which were combined in 1974 into five gross categories: Biochemistry (BIO, sections 1–20), Organic chemistry (ORG, sections 21–34), Macromolecular chemistry (MAC, sections 35–46), Applied Chemistry and Chemical Engineering (APP, sections 47–64) and Physical, Inorganic and Analytical Chemistry (PIA, sections 65–80).¹⁵

The distributions of journal publications according to the CA DB subject sections and categories are presented in Fig. 2 (the publications of 1932–1966 were assigned to the currently existing categories taking into account the known prehistory of the sections¹⁵). These results indicate, in particular, that organic and physical chemistry prevail among branches of chemistry. Up to the mid-1960s, the attention has been

Research Institutes	379	142
Other	16	18

focussed on the physical, inorganic and analytical chemistry, and in subsequent years, on organic chemistry (in the last decade, *Uspekhi Khimii* published many reviews on the chemical foundations of materials science). Since the mid-1960, the quantitative relations between the subjects distinguished in Fig. 2 for decade periods have been generally retained.

Analogous data for the journal *Chemical Reviews*⁵ published by the American Chemical Society demonstrate that the majority of papers in this journal are also concerned with organic and physical chemistry. However, in recent years *Chemical Reviews* have published increasing number of reviews related to biological and biomedical sciences.⁵

The renown of any scientific journal is evaluated, among other factors, based on the amount of citation of papers

Figure 2. Distribution of *Uspekhi Khimii* (Russian Chemical Reviews) publications among the subject sections of the CA DB. (1) ORG, (2) PIA, (3) MAC, (4) BIO, (5) APP.

published in this journal by other periodicals; this is reflected, in particular, by the impact factor (IF) of the journal. In terms of this parameter, *Uspekhi Khimii* has held the first or second position among all Russian scientific journals during the last 10 years. According to the Journal Citation Reports (JCR) DB, in 1996–2006 the impact factor of the journal varied from 0.983 (in 1997) to 2.392 (in 2004) (Fig. 3).^{16,17}

The citation search for the journal publications was carried out by two standard procedures:^{6–10} (i) using special search terms created on the basis of journal publications found; (ii) using full and abbreviated names of original (USP) and translated (RCR) versions of the journal. According to the SCI DB, 4403 publications of the journal were cited 66 350 times in 1974–2006; the original version was cited 47 827 times, while the English-translated one (since 1960) was cited 18 523 times.

Figure 3. Impact factor of the journal *Uspekhi Khimii* for 1996–2006 (no data for 2002 are available).

According to the CA DB, 4403 publications of the journal were cited 22 857 times in 1996–2006; of these, the original version was cited 12 303 times, while the English-language one, 10 556 times. A comparison of the list of publications in USP/RCR with the obtained list of references to these publications revealed journal's papers not included in the DB and, hence, not found during the primary search. This is due to the facts that *Uspekhi Khimii* published translated reviews from other journals not covered by the DB and that the original papers references to which contained mistakes in the digital part (year, volume, the first page), precluding their unambiguous identification, were also missing from the DB. The subsequent discussion takes into account only unambiguously identified original publications in USP/RCR. As a result, the number of citations of these identified publications in the SCI DB in 1974–2006 amounted to 61 540, while that in the CA DB was 22 401. Table 3 presents 15 most cited journal publications in the period of 1993–2006 according to the SCI

and CA DBs and Table 4 shows the most cited publications of the journal (more than 150 citations) for 1974–2006 (according to the SCI DB data) with indication of the journal version that is cited.

It can be seen from Table 3 that the numbers of citations according to the SCI DB and CA DB do not coincide, but nevertheless, they allow one to evaluate the popularity of a particular paper. (It should, however, be borne in mind that the amount of citation does not say anything about other features of the papers, *i.e.*, the originality and reliability, information value and the contribution to the scientific progress.¹⁸) It follows from Table 4 that both Russian- and English-language versions of the journal are cited. When comparing the citation data with data on downloading of full papers from the journal's Internet site (Table 5, statistical data from the

journal's DB), one can see that the request rate for the electronic versions of the papers does not correlate with the citation rate. Note that of the 17 publications presented in Table 5, nine are related to nanomaterials.

Analysis of the citation dynamics makes sense for comparing rather long periods of time, for example, 10-year periods of publications and 12-year citation periods. Table 6 presents the citation data for these periods, which demonstrate that the number of citations of journal publications for corresponding 12-year periods was only 40%–50% of the total number of citations by the search instant (the end of 2006). Thus it follows that the reviews published by *Uspekhi Khimii* (Russian Chemical Reviews) remain topical for long.

The reviews published in *Uspekhi Khimii* (Russian Chemical Reviews) are often cited by both Russian and foreign

Table 7 presents quantitative data on citation of reviews published by USP/RCR by Russian and foreign periodicals. The journal self-citation is low: from 3.4% to 3.9%.

In conclusion, we would like to note that in recent years, owing to crucial changes in the editorial policy of the journal Uspekhi Khimii (Russian Chemical Reviews), transfer of the whole body of preparatory work for the edition of Russian- and English-language versions to the editorial office and recruiting highly skilled research personnel from the chemical institutes of the Russian Academy of Sciences for participation in editorial work, it became possible to increase the quality of selection of reviews and preparation for publication, to improve the appearance of the journal and attain almost simultaneous publication of the Russian and English versions.

The range of the journal authors and the staff of the Editorial Board headed by Academician O M Nefedov since 1995 were substantially extended; the international Advisory Board was founded. The journal started to practice the publication of invited reviews and subject-related issues devoted to topical trends of chemical science as well as the publication of special issues composed of reviews by leading scientists of particular centres of chemical science such as the Siberian Branch of the RAS, Moscow, St Petersburg and Kiev Universities, the Institute of Problems of Chemical Physics of the RAS and other.

Currently, both versions of the journal (Uspekhi Khimii and Russian Chemical Reviews) appear as both printed and electronic editions. Since 1995, the following information about the journal is available free on the Internet (<http://www.uspkhim.ru>): general information, subscription terms, the contents of the journal for a year and brief abstracts of all papers. In 2004, in cooperation with the British company Turpion Ltd (a partner in publishing English version of the journal), the electronic archive of the English version starting with the first issue (1960) was composed and an up-to-date integrated system for preparation, publication and distribution of the electronic version of the journal with the on-line submission and refereeing options was elaborated. By now, the first stage of composing the electronic archive of the Russian version of the journal for 1990–2006 has been completed.

All this helps to maintain the subscribers' and readers' interest in the journal and to ensure its high rating.

Abstract. Various pulsed EPR in the method of spin labels and probes based on electron spin echo spectroscopy (spin echo envelope modulation through electron–nuclear interactions, electron–electron double resonance, echo detected EPR, *etc.*) are considered. These methods provide information on the conformations of complex biomolecules, nanostructure of matter, depth of water penetration into biological membranes, supramolecular structure of multicomponent systems (membrane–peptide, *etc.*), co-operative orientational dynamics of molecules and dynamic low-temperature transitions in disordered molecular media and biosystems. The bibliography includes 130 references.

I. Introduction

The method of spin labels and probes has been widely used in physicochemical and biophysical studies since the 1970s.^{1–3} Spin probes are stable paramagnetic molecules (usually, nitroxyl radicals^{4,5}) that are introduced into the system under study as a minor additive. Spin labels represent nitroxide radicals covalently bound to macromolecules. The method of spin labels and probes is used in studies of the local structure of molecules and molecular dynamics, for identification of particular functional groups, measurement of oxygen concentration and proton content, determination of polarity, acceleration of nuclear spin relaxation in MRI studies and for solving some other problems.[†]

The method makes use of unpaired electrons present in radicals, which permits utilisation of electron paramagnetic resonance (EPR) spectroscopy. Despite the fact that EPR spectroscopy emerged more than six decades ago, the state-of-the-art in this field is characterised by continuous progress and improvement of various experimental techniques. Quite recently, pulsed EPR spin label–spin probe studies began using, in particular, pulsed electron–electron double resonance (PELDOR), electron spin echo envelope modulation

(ESEEM), pulsed electron–nuclear resonance, echo-detected EPR, *etc.* All of them are based on the ESE technique.^{6,7}

Pulsed EPR spectroscopy significantly extended the potential of the method of spin labels and probes. It allows one to investigate the nanostructure of matter including large biomolecules, supramolecular structure of complex systems, *e.g.*, membranes and their peptide components as well as co-operative small-amplitude orientational motions of molecules in disordered media and biological liquids.

There are a number of reviews^{8–15} concerning particular aspects of pulsed EPR spin label–spin probe studies. The main goal of this review was to briefly outline the fields of application of the method, to summarise the results of recent investigations and to highlight new experimental techniques.

II. EPR spectroscopy of nitroxide radicals — the fundamentals

1. Nitroxide radicals. Site-directed spin labelling technique

Nitroxide radicals are stable paramagnetic molecules containing a paramagnetic NO fragment bearing an unpaired electron.^{4,5} This fragment is surrounded by the shielding substituents (usually, methyl groups). To date, a few hundreds of nitroxide radicals have been synthesised. A few simple examples are given below:

The so-called site-directed spin labelling (SDSL) technique appeared to be of particular importance for obtaining information on the molecular level.^{16–18} The method involves attachment of a spin label to the molecular fragment of interest in a complex biomolecule or supramolecular system. In protein studies, a cysteine residue in the amino acid sequence is most often labelled using a methanethiosulfonate spin label, namely,

[†] According to the IUPAC Compendium of Chemical Terminology (2nd Edition, 1997), the use of the prevailing terms ‘nitroxyl radicals’ and ‘nitroxides’ as a class name for ‘aminoxyl radicals’ is not desirable.

(1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl)methyl methanethio-sulfonate (MTSL). Artificial protein analogues containing this residue are also studied. It is possible to label some other amino acid residues, *e.g.*, lysine, aminoisobutyric acid, *etc.* Small spin-labelled peptides containing less than 50 amino acids and bearing spin labels at desired positions of the amino acid sequence can directly be synthesised. Not only peptides and proteins, but also other biomolecules (*e.g.*, lipids) can be site-directed spin labelled.

2. EPR spectra of nitroxide radicals. Electron – nuclear interactions. The effects of motion

In the framework of the first-order perturbation theory, the X-band (wavelength about 3 cm, frequency ~ 10 GHz) EPR condition for nitroxide radicals can be quite correctly approximated by¹⁹

$$g(\theta, \varphi)\beta B + a(\theta, \varphi)M = \hbar\omega, \quad (1)$$

where

$$g(\theta, \varphi) = g_{XX} \sin^2 \theta \cos^2 \varphi + g_{YY} \sin^2 \theta \sin^2 \varphi + g_{ZZ} \cos^2 \theta,$$

$$a(\theta, \varphi) = \sqrt{A_{XX}^2 \sin^2 \theta \cos^2 \varphi + A_{YY}^2 \sin^2 \theta \sin^2 \varphi + A_{ZZ}^2 \cos^2 \theta},$$

β is the Bohr magneton; B is the magnetic field induction; M is the nuclear spin projection on the quantisation axis; \hbar is the Planck constant; ω is the frequency of the alternating magnetic field; g_{XX} , g_{YY} and g_{ZZ} are the principal values of the g -tensor; and A_{XX} , A_{YY} and A_{ZZ} are the principal values of the hyperfine coupling tensor. Usually, the molecular system of coordinates is used, in which the X axis is aligned with the N–O bond and the Z axis is normal to the plane in which the \geq N–O fragment is situated. The angles θ and φ define the direction of the magnetic field in the spherical system of coordinates. Typical values of the components of the magnetic tensors of nitroxide radicals are as follows: $g_{XX} \approx 2.0090$, $g_{YY} \approx 2.0060$, $g_{ZZ} \approx 2.0025$, $A_{XX}/g_e\beta \approx A_{YY}/g_e\beta \approx 5$ G, $A_{ZZ}/g_e\beta \approx 35$ G (g_e is the g -factor of free electron). In the case of high-field

EPR, Eqn (1) should be augmented with a term corresponding to the Zeeman interaction between atomic nuclei.

The overall shift of the resonance due to unresolved hyperfine coupling (HFC) of the unpaired electron with other nuclei in the radical and matrix is about 3 G. In the c.w. EPR spectrum, these couplings remain unresolved due to superposition of many lines with small splittings; it should be noted that signals from radicals characterised by different $g(\theta, \varphi)$ values may appear in the same spectral region.

The c.w. EPR technique involves sweep of the field B under continuous action of alternating microwave field at a constant frequency ω . Figure 1 shows a typical shape of the EPR spectrum of a nitroxide radical. Usually, the first derivative of the absorption lineshape with respect to the magnetic field is measured. The parallel and perpendicular orientations of the molecule are also shown; this can be done assuming axial symmetry of the magnetic tensors (see above) and ignoring unresolved hyperfine coupling.

Orientalional motions cause averaging of magnetic interactions. In the X-band, the characteristic frequency variation due to different molecular orientations is $\sim 10^9$ rad s⁻¹. Therefore, in the case of fast motions of the whole molecule at frequencies much higher than 10^9 rad s⁻¹ the EPR spectrum should exhibit three lines of equal intensity corresponding to three projections of the nitrogen spin on the direction of the external magnetic field. Here, the g -tensor and the HFC tensor are averaged to the scalar values equal to 1/3 of the spurs of the tensors.

Biological and other supramolecular systems are usually characterised by slow molecular motions at frequencies lower than 10^9 rad s⁻¹. As a consequence, no complete averaging occurs; therefore, the results obtained in conventional c.w. EPR experiments are often ambiguous. Pulsed methods based on the ESE technique are sensitive to motion even under glass transition conditions.

3. Electron – electron dipole – dipole interactions between radicals

At present, the dipole–dipole (d–d) interaction between electron spins in spin labels is widely used in studies of the nanostructure of spin-labelled systems. This interaction is of the order of $g_e^2\beta^2/r^3$ in magnitude, where r is the distance between two radicals. Pulsed EPR methods based on the ESE technique are highly sensitive to d–d-interaction. The characteristic times of transverse relaxation in organic solids are about 10^{-6} s and thus the upper bound of the measured distances is nearly 5 to 7 nm. The lower bound obtained from the ‘dead time’ of an instrument ($\sim 10^{-7}$ s) is close to 1.5 nm. The advantage of ESE spectroscopy consists of high accuracy of measurements in this range of distances. At $r \sim 3$ nm, the error is at most 0.1 nm.^{8–10} This is a record spatial resolution among all known physical methods, which allows one to reveal subtle effects in the nanostructure of matter that cannot be disclosed by other methods. It should also be noted that ESE studies do not require special treatment of samples (*e.g.*, crystallisation, high degree of purification, *etc.*)

The Hamiltonian of magnetic dipole–dipole interactions between the magnetic moments of two electrons has the form

$$H_d = g_1 g_2 \beta^2 \frac{r^2 \mathbf{S}_1 \mathbf{S}_2 - (\mathbf{S}_1 \mathbf{r})(\mathbf{S}_2 \mathbf{r})}{r^5}, \quad (2)$$

where g_1 and g_2 are the g -factors of two particles; \mathbf{S}_1 , \mathbf{S}_2 are the spin operators; \mathbf{r} is the radius vector connecting the particles. Almost all long-chain biradicals can be studied in the point dipole approximation, which assumes that the spin density of the unpaired electron is localised at some point.¹⁰

When studying nitroxide biradicals, one can use the perturbation theory, which treats the Hamiltonian (2) as a small

Figure 1. EPR spectrum of a nitroxide radical.

The lower curve represents the EPR spectrum as the first derivative of the absorption lineshape with respect to the magnetic field. Dashed lines denote particular components of HFC; for each component, approximate positions of the parallel and perpendicular orientations are shown. The inset specifies the molecular system of coordinates. The splitting between the outermost peaks in the lower curve approximately equals the doubled A_{ZZ} principal value of the HFC tensor [averaged value is $\langle A_{ZZ} \rangle$ in the presence of librations].

perturbation compared to expression (1). In the case of weak d–d-interactions, where

$$\varepsilon_d \ll |g_1 - g_2|\beta B$$

(this is always valid at $r > 0.15$ nm), the transition frequencies for each of the two spins are given by¹⁰

$$\omega_{1,2} = \frac{g_{1,2}\beta}{\hbar}B \pm \frac{1}{2}\varepsilon_d, \quad (3)$$

where

$$\varepsilon_d = \frac{g_1 g_2 \beta^2}{r^3 \hbar} (1 - 3 \cos^2 \Theta),$$

(Θ is the angle between the direction of the external magnetic field and the line connecting two radicals). The sign \pm means that for each spin the resonance is shifted due to the d–d-interaction with the partner spin depending on the projection of the latter on the direction of the external magnetic field.

Considering pulsed EPR methods, expression (3) leads to temporal dependences of the type $\cos(\varepsilon_d t)$ (see below).¹⁰ The Fourier-transformed EPR spectrum exhibits a doublet at the frequencies $\pm \varepsilon_d$. In a polyoriented system, the frequency (ω)-dependent intensities of the dipolar doublet lines are averaged over all spatial orientations of the pair. At

$$\omega_{\perp} = \pm \frac{g_1 g_2 \beta^2}{r^3 \hbar},$$

singularities appear ($\Theta = \pi/2$, perpendicular orientation of the pair). Often, only the singularity due to the relatively low intensity of other lines can be observed experimentally. Its position permits immediate determination of the distance r .

4. Electron spin echo of nitroxide radicals

Excitation of transitions between spin energy levels by intensive microwave pulses causes the appearance of a free induction signal, *i.e.*, an oscillating macroscopic transverse magnetisation.^{6,7} Optimum conditions for observation of the free induction signal are attained by applying a pulse that causes a $\pi/2$ (90°) flip of the magnetisation vector. Typical microwave pulse durations in ESE spectrometers are 10 to 100 ns. Signal decay is due to the scatter of precession frequencies (this determines the shape of the EPR spectrum).

The resolution of ESE spectrometers is limited by the characteristic time of transient processes in the cavity upon application of microwave pulses (usually, it is of the order of 100 ns),^{6,7} which is called the ‘dead’ time. In the case of nitroxide radicals, the nonzero ‘dead’ time makes observation of the free induction signal impossible owing to fast signal decay. The free induction signal can only be observed after some hardware improvements aimed at shortening the ‘dead time’, *e.g.*, on going to the Ku-band (resonance frequency 17 GHz, not to be confused with the Q-band!) and to elevated temperatures (this is required for line narrowing).

Two pulses applied with a time delay cause the appearance of an echo signal (see Fig. 2a). The time delay after the second pulse equals the time delay between two pulses, τ . The optimum flip angle of the magnetisation vector upon application of the second pulse is π . The formal notation for the pulse sequence and the echo signal is given below:

$$\pi/2 - \tau - \pi - \tau - \text{echo}.$$

The mechanism of the appearance of the echo signal is as follows. The second pulse follows the first one after the time delay τ and changes the phase of spin precession in the plane normal to the external magnetic field. Now the precessing spins

Figure 2. Electron spin echo pulse sequences.

Basic two-pulse sequence (a), three-pulse stimulated echo sequence (b) and two-frequency double resonance (PELDOR) (c). PELDOR experimental conditions: detection at the A spin frequency and an additional pump pulse at the B spin frequency. Dashed lines show an additional refocusing pulse and echo (see text).

have the same velocities but different initial phases. At the instant τ after the second pulse, refocussing occurs (all spins have the same phase) and the echo signal appears (then, defocussing will occur again). The echo signal decays with increase in τ due to spin relaxation.

Yet another method for ESE detection is the three-pulse stimulated echo pulse sequence (Fig. 2b)

$$\pi/2 - \tau - \pi/2 - T - \pi/2 - \tau - \text{echo}.$$

The first pulse creates a precessing transverse magnetisation and the second pulse creates the projection of the magnetisation vector on the Z axis (longitudinal magnetisation), which retains its magnitude during the time T in the absence of relaxation. This pulse creates a nuclear coherence, *i.e.*, the system is described by a non-stationary superposition of various electron–nuclear states upon application of the second pulse. The third pulse again creates the transverse magnetisation, which refocusses at the instant

$$t = 2\tau + T,$$

i.e., the echo signal appears.

A feature of the ESE studies of nitroxide radicals consists in incomplete (or selective) excitation of the EPR spectrum by microwave pulses. In most experiments, the pulse amplitudes reach 3–5 G, whereas the overall width of the EPR spectrum is of the order of 70–80 G. In some cases (*e.g.*, in studies of spectral diffusion, *i.e.*, stochastic fluctuations of the resonance frequency due to orientational motion), this feature is of crucial importance.

If orientational motions cause fluctuations of the resonance frequencies with the root-mean-square $\langle \Delta\omega^2 \rangle$ and the correlation time τ_c , theory predicts that at

$$\langle \Delta\omega^2 \rangle \tau_c^2 \ll 1,$$

the relaxation rate is given by $\langle \Delta\omega^2 \rangle \tau_c$.²⁰ The $\Delta\omega$ value can be estimated with ease from Eqn (1). For simplicity, suppose an axial symmetry

$$g_{XX} = g_{YY} = g_{\perp}, A_{XX} = A_{YY} = A_{\perp}.$$

Let us denote

$$g_{zz} = g_{\parallel}, A_{zz} = A_{\parallel}.$$

In the case of small-amplitude motions the angle θ fluctuates by $\Delta\theta$. Then, in a constant magnetic field B , expansion of the resonance frequency fluctuations $\Delta\omega$ in terms of $\Delta\theta$ has the form²¹

$$\Delta\omega = 2 \sin \theta \cos \theta \times \left[(g_{\perp} - g_{\parallel}) \frac{\beta B}{\hbar} + M \frac{A_{\perp}^2 - A_{\parallel}^2}{2\hbar \sqrt{A_{\perp}^2 \sin^2 \theta + A_{\parallel}^2 \cos^2 \theta}} \right] \Delta\theta. \quad (4)$$

At $\theta = 0, \pi$ and $\pi/2$, the $\Delta\omega$ value equals zero, *i.e.*, spin relaxation near the canonical orientations (parallel and perpendicular) should be slow.

Fast small-amplitude orientational motions also manifest themselves in c.w. EPR spectra, because they cause partial averaging of anisotropic magnetic interactions. In the case of orientational motion about an axis lying in the XY plane of the molecular system of coordinates, the parameter A_{\parallel} is averaged²²

$$\langle A_{\parallel} \rangle = A_{\parallel} - (A_{\parallel} - A_{\perp}) \langle \alpha^2 \rangle, \quad (5)$$

where the angular deviation, α , from the equilibrium position is related to $\Delta\theta$ as follows: $\Delta\theta = \alpha \sin \phi$. The parameter $\langle A_{\parallel} \rangle$ can be measured with ease from the splitting between the outermost peaks in the EPR spectrum (see Fig. 1).

III. Pulsed EPR techniques

1. ESEEM through electron – nuclear interactions

If an electron spin interacts with a nuclear spin, application of microwave pulses at the EPR resonance frequency causes simultaneous excitation of both allowed and forbidden spin transitions (without and with nuclear spin flip, respectively) in a solid.^{6,7} Interference of the resonance frequencies of these transitions upon ESE decay induces beats (oscillations) of the signal, which are called electron – nuclear modulation or the electron spin echo envelope modulation (ESEEM) effect.^{6,7} A few examples of the ESEEM effect are shown in Fig. 3 *a*, which corresponds to the interaction between the unpaired electron of the spin label and deuterons from the surrounding heavy water. The Fourier-transformed frequency spectrum of the beats exhibits peaks (see Fig. 3 *b*), the positions of which are determined by the electron – nuclear interactions. In the case of interactions with the nearest nuclei in the matrix, these peaks are centred around the resonance (Larmor) frequency of a given nucleus in the magnetic field of the ESE spectrometer (2.2 MHz for deuterons). These peaks cannot be resolved in c.w. EPR experiments (see above).

The ESEEM through electron – nuclear interactions represents a convenient tool of structural studies in the nearest environment of spin labels; it can be used for identification of the types of the nuclei in the nearest environment and determination of their spatial arrangement relative to the unpaired electron.

This approach has long been used in pulsed EPR spectroscopy, where it can be considered classical. Most related methodological problems have been solved to date. The fundamentals of the ESEEM technique have been comprehensively treated in monographs.^{6,7} Recently, this method has found increasing application in studies of the local environment of spin labels.

Figure 3. Typical signal oscillations (ESEEM) induced by electron – nuclear interactions (*a*) and Fourier-transformed frequency spectrum (*b*) of a spin label in D_2O -containing matrix.

From original experimental ESEEM a smooth non-oscillating function (result of averaging) was subtracted; the resulting $V_n(T)$ signal is normalised to this function at $T = 0$. F_c denotes the Fourier transform amplitude.

2. Pulsed electron – electron double resonance in studies of d – d-interactions between radicals

As mentioned above, the d – d-interaction between radicals is now widely used in studies of the nanostructure of spin-labelled systems. Most of them are carried out by pulsed double electron – electron resonance (PELDOR).^{8–10,13} The method was proposed in the 1980s.^{23,24} It allows one to determine the distances between radicals on the nanometre scale, draw conclusions on the conformations of doubly spin-labelled biomolecules and estimate the size of the aggregate (cluster) of spin-labelled molecules in the case of their aggregation (clusterisation).

In the PELDOR experiments the echo signal appears upon application of a conventional two-pulse sequence and an additional 180° pump pulse at the other resonance frequency (Fig. 2 *c*). The spins responsible for the appearance of the echo signal are called A spins while their partner spins (in our case, they are influenced by the additional pulse) are called B spins. The phase of the A spins at $t = 2\tau$ equals

$$\varphi_A = \pi \pm \varepsilon_d T$$

(the ‘plus’ or ‘minus’ sign depends on the projection of the B spin).

The echo signal is proportional to $\cos(\varepsilon_d T)$, which means that the signal is modulated at the frequency ε_d as the time T changes. Note that here modulation is due to electron – electron rather than electron – nuclear interactions (see above). The Fourier transform of the modulated ESE decay in a polyoriented system leads to the appearance of a peak at the singularity frequency

$$\omega_{\perp} = \pm \frac{g_1 g_2 \beta^2}{r^3 \hbar}.$$

The separation between spin labels can be determined from the position of this peak.

The effect of finite pulse duration (theory assumes infinitely short pulses) can be eliminated using an additional refocussing pulse.¹³

Pulsed ELDOR technique also allows study on clusterisation of spin-labelled molecules. Actually, the pump pulse excites only a fraction, P_B , of the partner spins of a given A spin. If a cluster comprises N particles and the probability of simultaneous excitation of more than one B spin is low (*i.e.*, $P_B N \ll 1$), the ESE signal is given by⁸

$$V(T) = [1 - P_B \langle 1 - \cos(\varepsilon_d T) \rangle]^{N-1}. \quad (6)$$

It follows that at $t \rightarrow \infty$ the $V(T)$ value tends to the limiting value equal to $(1 - P_B)^{N-1}$. This asymptotic value can experimentally be measured with ease and thus one can estimate the number of particles, N , in the cluster.

The same effect can be attained not only by irradiating B spins at the other resonance frequency, but also by changing the magnetic field in a pulsed (jumpwise) manner. This experimental technique was practically implemented in the X-band²⁵ and W-band²⁶ EPR experiments. The A spins are excited using the three-pulse stimulated echo sequence. In the time between the second and third pulses, the magnetic field is changed in a jumpwise manner and a 180° pump pulse is applied. Due to shift of the resonance, this pulse affects only the B spins. The approach assumes the time delay τ between the first and second pulses to be varied. Here, electron–nuclear modulation also appears in addition to modulation through electron–electron interactions. The two mechanisms can be distinguished by separating the overall decay signal into the decay signal observed in the presence and in the absence of pump (no pump pulse). These mechanisms are independent of each other and should therefore contribute multiplicatively to the observed envelope modulation.

The advantage of the field-step PELDOR over the two-frequency PELDOR technique consists in the possibility of using a scanning pump²⁵ owing to an increase in the proportion of spins P_B to be excited, which leads to an increase in the modulation depth. A drawback of the technique is the effect of transverse relaxation on the echo decay observed.

Various methodological aspects of the PELDOR technique have been considered in a number of recent studies. Mention may be made of the problem of correct inclusion of the spin label structure and binding to a biomolecule in modelling the structure of the biomolecule from PELDOR data.²⁷ Methodological aspects concerned with extraction of information from PELDOR data and optimisation of experimental design have been considered.^{28–30} A comparative PELDOR study of biradicals in two (X and S) EPR bands was carried out.³¹ Since the electron–nuclear modulation depends on the particular microwave band while the electron–electron modulation is independent of it, the approach can be employed to determine the contribution of the electron–electron modulation. It was reported³² that the quality of information extracted from the PELDOR frequency spectra can be improved using isotopic substitution, namely, by replacing (i) ^{14}N atom by ^{15}N atom and (ii) hydrogen atom by deuterium atom in one radical of the pair. Here, the 2D version of the four-pulse PELDOR was proposed as the experimental technique. The potential of PELDOR studies of biradicals in the high-frequency EPR band (frequencies higher than 95 GHz) was discussed.³³ Orientational selectivity effects due to high spectral resolution were demonstrated.

3. Miscellaneous methods of investigation of d–d-interactions

Complications in PELDOR experiments (need for an additional source of microwave radiation, a special cavity, *etc.*) gave an impetus to the development of miscellaneous experimental techniques for studying d–d-interactions.

The ‘2 + 1’ method³⁴ is similar to the PELDOR technique except for the fact that all pulses are applied at the same resonance frequency. The pulse sequence is as follows:

$$\text{pulse 1} - T - \text{pulse } (+1) - (\tau - T) - \text{pulse 2} - \tau - \text{echo}.$$

The echo signal is created by two pulses (pulse 1 and pulse 2); an additional pulse (it is this pulse that is called +1) is necessary to achieve alternation of the d–d-interaction. Experiments involve variation of the time T at constant τ . A drawback of the ‘2 + 1’ method is that it is not free from electron–nuclear ESEEM. Moreover, the dipole–dipole interaction alternates under the action of not only pulse +1, but also the second pulse. Correct allowance for interference between these two effects is not always possible. As a result, information on the d–d-interaction can be significantly distorted.

Method based on double-quantum coherence. Using an appropriately designed pulse sequence, it is possible to excite a double-quantum coherence in the spin level system of a biradical.³⁵ A commonly used pulse sequence for this experiment includes four pulses. Three of them ($\pi/2$ pulses) create a stimulated echo signal. An additional π pulse is applied at the midpoint of the time interval between the second and third pulses. The contribution of the double-quantum coherence is selected using the pulse phase cycling from one series to another. Experiments involve variation of the time τ ; the signal is modulated at the ε_d frequency.

In order to avoid the loss of signal during the ‘dead’ time, an additional refocussing (fifth) pulse is applied. One can also use the six-pulse sequence, in which the double-quantum coherence is created by three rather than two pulses.

$$\pi/2 - \tau/2 - \pi - \tau/2 - \pi/2.$$

The advantage of this approach consists in the absence of the interference effects characteristic of the ‘2 + 1’ method. However, in this case the electron–nuclear ESEEM occurs too.³⁶ The drawbacks of the double-quantum coherence technique also include the large number of phase change cycles (a total of sixty-four cycles), which can introduce an additional error, and high demands to experimental equipment, namely, the amplitudes of microwave pulses should be higher than the pulse amplitudes for commercially available spectrometers. Finally, the phenomenon is characterised by a rather complicated theoretical description and the lack of a clear picture. Nevertheless, a number of double-quantum coherence studies of the d–d-interaction of spin probes are available in the literature. Methodological aspects of application of the method have been considered.³⁷ ESEEM suppression techniques were also proposed.³⁸

A method based on the solid-state NMR pulse sequences³⁹ is based on the known ‘solid echo’ and Jeener–Broekaert pulse sequences. The ‘solid echo’ pulse sequence is as follows:

$$(\pi/2)_x - \tau - (\pi/2)_y - \tau - \text{echo}.$$

Compared to the double-quantum coherence method, here the experimental design is much simpler (smaller number of phase change cycles is required). However, theoretical description remains complicated and no clear representation of the phenomenon is available.

The aforesaid suggests that at present PELDOR is the most convenient method of investigation of d–d-interactions. It provides a clear picture of the phenomenon and essentially simplified theoretical description and is almost free from the ESEEM effects. These advantages were demonstrated in a comparative double-quantum coherence and PELDOR study³⁶ of a doubly spin-labelled protein with a label-to-label separation of 3.55 nm.

4. Relaxation-induced enhancement of electron–electron ESEEM induced by in d–d-interaction

The drawback of all the methods described above including PELDOR is low portion of excited spins (at most 10%–15%) due to a large width of the EPR spectra of nitroxide radicals compared to the amplitude of microwave pulses; as a consequence, the ESEEM effect is weak. This drawback becomes particularly pronounced on going to high-field EPR. An approach⁴⁰ based on the use of spin–lattice (longitudinal) relaxation in the spin pair makes it possible to overcome these difficulties. The Larmor frequency of the resonance A spin coupled with an off-resonance B spin

$$\omega_A^* = \omega_A + m_B \varepsilon_d,$$

where m_B is the B spin projection, can be changed by B spin flips induced by longitudinal relaxation. In this case the probability for an odd number of the B spin flips to occur during the time interval T is $0.5[1 - \exp(-T/T_1)]$, where T_1 is the longitudinal relaxation time. With scanning τ , the stimulated ESE is modulated at the dipolar frequency ε_d . The modulation amplitude increases with the ‘evolution’ period T . Relaxation-induced dipolar modulation enhancement (RIDME) was observed experimentally.⁴⁰ The RIDME method is free from the drawbacks associated with the low portion of excited spins, because up to 50% of all off-resonance spins can be involved in dipolar modulation. Therefore, RIDME is a quite promising method of high-field ESE studies, as was shown by, *e.g.*, a 130-GHz (4.4 T) ESE.⁴¹

5. ESEEM modulation due to spontaneous intramolecular motions and nuclear spin relaxation

Modulation phenomena in conventional ESE methods are due to coherent dynamic effects caused by simultaneous excitation of two and more transitions in the EPR spectrum under the action of microwave pulses. In the case of RIDME, the ESE modulation is due to spontaneous changes in the magnetic parameters of radicals under the action of the pulse sequence. However, spontaneous changes can also be induced by intramolecular motions⁴² and nuclear spin relaxation in the nearest environment.⁴³ Such effects are studied using the three-pulse stimulated echo sequence. It includes scanning the time delay τ between the first and second pulses at the fixed time delay T between the second and third pulses. The ESEEM is due to a spontaneous change in the Larmor precession frequency of electron spin in the course of system evolution between the pulses during the time T , induced by longitudinal nuclear spin relaxation in the nearest environment. The longer the time T the more probable the event. Manifestation of spontaneous processes in the ESEEM have been considered in a review.⁴⁴

6. Pulsed high-field/high-frequency EPR

High-field (high-frequency) EPR is observed in magnetic fields higher than 3 T (frequencies higher than 95 GHz). Continuous-wave high-field/high-frequency EPR has long been used in studies of spin-labelled systems. The main advantage of the technique consists of orientation selectivity due to the g -factor anisotropy, which permits investigation of particular (dif-

ferent) orientations of spin probes and spin labels. Therefore, research on polyoriented systems provides information identical to that obtained in studies of oriented single crystals. Recently, a number of pulsed high-field/high-frequency EPR studies of the molecular structure and dynamics of spin-labelled systems have been reported (see, *e.g.*, Refs 26, 33, 41, 45, 46). High-field/high-frequency EPR spectrometers are commercially available.

7. Echo-detected EPR in studies of orientational dynamics

In echo-detected EPR, the echo signal is recorded as the function of the magnetic field at different times τ (2D experiment).²¹ Different resonance fields correspond to different orientations of the radical relative to the external magnetic field direction (see Fig. 1); therefore, the method allows one to obtain information on the orientational dependence of the relaxation rate or relaxation anisotropy. The relaxation anisotropy is related to the mechanism and rate of motion.

For convenience, a number of echo-detected EPR spectra are recorded at different τ normalised to the same magnetic field corresponding to the spectral maximum and then plotted together as shown in Fig. 4. This allows one to exclude the magnetic field independent isotropic relaxation governed by some processes not related to motions and to clarify the character of the relaxation anisotropy. For instance, Fig. 4 shows that relaxation near the spectral edges (they correspond to the parallel orientation of the molecule, see Fig. 1) is slower.

Figure 4. Typical echo-detected spectra recorded at different time intervals τ between pulses and normalised to the maximum intensity. The thin solid line denotes the results of calculations using the model of fast small-amplitude motions (see text).

Echo-detected EPR of spin probes is sensitive to fast small-amplitude stochastic motions of the spin probe and spin label molecules near equilibrium positions. Such orientational motions are called stochastic librations; they are only characteristic of disordered molecular (including biological) media. The technique is sensitive to very small motion amplitudes (down to $0.1-1^\circ$).⁴⁷ Note that stochastic motions are different from dynamic orientational oscillations that are characteristic of any phase state of matter.

8. Two-dimensional pulsed electron–electron double resonance in studies of orientational dynamics

The pulse sequence of 2D pulsed electron–electron double resonance^{12, 48, 49} is the same as the PELDOR pulsed sequence. The difference is that here the free induction signal appeared after application of the last pulse is measured. The Fourier transform is performed over two times, the time T and the time

delay after the last pulse in the pulse sequence. The 2D spectra allow one to differentiate the homogeneous broadening due to the motion and the inhomogeneous broadening caused by microscopic ordering, *i.e.*, to obtain information on structural dynamic heterogeneity of the system. In this case, observation of the free induction signal requires the use of short-‘dead-time’ instruments, *e.g.*, Ku-band EPR spectrometers (17 GHz). Line narrowing can be attained at elevated temperatures.

9. Pulsed double electron – nuclear resonance

In addition to ESEEM EPR, electron – nuclear interactions can be studied by c.w. electron – nuclear double resonance (ENDOR) and by pulsed ENDOR according to Mims and Davies. A comparative study⁵⁰ of the interaction of spin labels with ³¹P nuclear spins carried out by different experimental techniques showed that the most reliable data can be obtained using the Mims pulsed ENDOR method, which allows small splittings (to 0.03 MHz; this corresponds to a distance of 1 nm) to be measured. In studies of spin-labelled lipids in a completely hydrated membrane these measurements permit determination of the tilt angles of lipid chains with respect to the membrane plane.

High-field pulsed ENDOR/EPR studies are also possible.⁵¹ Orientation selectivity allows one to obtain more detailed information on the structure of the nearest environment of the molecule under study. This method was used to study the geometry of complexes of spin probes with solvent molecules (*e.g.*, complexes of 5-doxylosteoric acid with deuterated alcohols).⁵¹

10. ‘Saturation – recovery’ technique in time-resolved EPR

Time-resolved EPR⁵² is not a pulsed technique, because the EPR signal is detected using c.w. microwave field. Considering relaxation time measurements, the ‘saturation – recovery’ technique occupies an intermediate position between the pulsed and c.w. EPR, because it combines pulsed saturation of the EPR spectrum (usually, the saturation pulse is a few microseconds long) and continuous recording of the EPR signal. The method was employed to study acceleration of the spin label relaxation in biosystems induced by the fluctuating magnetic dipole – dipole interaction with the neighbouring metal ion. The results obtained were used for estimating the distance in a pair spin label – ion.^{53–55}

The ‘saturation – recovery’ technique is used for the determination of local concentrations of molecular oxygen (so-called oximetry) in biological objects.⁵⁶ It is based on acceleration of spin label relaxation by collisions with molecular oxygen.

EPR has an advantage over than the ESE spectroscopy-based techniques, when the ESE (or free induction) signal cannot be observed due to the problems related to the ‘dead’ time of the spectrometer and short relaxation times. However, the technique is not free from drawbacks including a lower temporal resolution, a complex and ambiguous theoretical description and lower functionality.

There are some interesting applications of time-resolved EPR spectroscopy for solving spin chemistry problems. An example is provided by spin polarisation transfer to the spin label in the molecule of a model hexapeptide from photo-excited chromophore located in the same molecule.⁵⁷ Yet another example is the effect of spin labels on the formation of spin polarisation in spin-correlated radical pairs generated upon photoexcitation of photosynthetic reaction centres in plants.⁵⁸ The results obtained may be useful in studies of electron transfer in these systems. Pulsed EPR spectroscopy also seems to be useful in this case.

IV. Structural studies of spin-labelled systems

1. Conformations of long-chain biradicals and doubly spin-labelled biomolecules

Different conformations of a molecule have different length. Therefore, the conformational structure of biradicals or doubly spin-labelled biomolecules can be determined by measuring the distances between two unpaired electrons in them. Details of relevant measuring techniques including PELDOR and some other methods have been reviewed (see, *e.g.*, Refs 8–10). Now we will discuss the state-of-the-art in the field and recent literature.

Long-chain biradicals can adopt a large number of possible conformations; therefore, one should consider a distance distribution function of paramagnetic fragments. If the distance distribution is expected to be rather narrow, its width can be directly estimated from the ESEEM decay. In particular, a magnetic field jump PELDOR study of two long-chain (~2 nm long) biradicals (a rigid-chain and a flexible one) was reported.²⁵ The distance distribution width estimated from the ESEEM decay for the flexible biradical was found to be about 0.3 nm.

Conformations of a biradical containing two nitroxide fragments separated by a chain comprising from 8 to 20 methylene groups ($n = 8, \dots, 20$) were studied by the PELDOR method.^{59,60} A large scatter of distances between the two radicals was expected. The data extracted from the frequency spectra were compared with the results of calculations of (i) fully stretched *trans*-conformation (limiting case) and (ii) conformational statistics at a specified temperature. The results of distance measurements and conformational statistics calculations coincided within the limits of experimental error. At $n = 10$ and $r = 2.1$ nm (average distance), the distribution function width at half-height was 0.5 nm.

The PELDOR technique permits measurements of spin – spin interactions not only in nitroxide biradicals, but also in biradicals containing a paramagnetic metal ion as the spin partner.⁶¹

Doubly spin-labelled peptides can also be studied in a similar manner. If the spin labels are separated by a short distance (< 1.5 nm), c.w. EPR spectroscopy is employed.⁶² If the label – label distance exceeds 1.5 nm, pulsed EPR techniques should be used.

PELDOR studies of conformations of a doubly spin-labelled peptide Trichogin GA IV in organic glasses are available.^{63–65} This linear peptide isolated from the fungus *Trichoderma longibrachiatum* is a rich source of aminoisobutyric (Aib) acid

(n-Oct is n-octanoyl and Lol is leucinol). Trichogin GA IV possesses antibacterial and antifungal properties. Such peptides can create ionic channels in membranes, thus making them permeable, which may cause cell death. A distinctive feature of Trichogin GA IV is that its molecule is short. It comprises only 10 amino acids, which is much smaller than the membrane thickness; therefore, the mechanism of membrane permeability is unclear as yet.

The Aib residues are replaced by structurally similar nitroxide spin labels (TOAC) in the course of chemical synthesis.⁶⁶

For convenience, the peptide terminal groups could be replaced by other residues. This does not change the membrane-modifying properties of the peptides.⁶⁷ The peptides synthesised were doubly labelled at positions 1 and 4, 4 and 8 or 1 and 8. The first two types of biradicals can be studied by c.w. EPR spectroscopy, whereas the third type can only be studied by pulsed EPR methods due to long spin–spin separations.

Conformations of doubly spin-labelled peptide were studied at 77 K in different glass-forming solvents (methanol, ethanol, trifluoroethanol) and in chloroform–DMSO mixtures with different component ratios.^{63,64} PELDOR studies in all matrices revealed modulation effects at different oscillation frequencies. The distances between the spin labels in positions 1 and 8 vary from 1.53 (in trifluoroethanol) to 2.18 nm (in ethanol). It was concluded that the peptide adopts the 3_{10} -helical conformation in trifluoroethanol and the 2_7 -helical conformation in other matrices.

Conformation of spin-labelled Trichogin-1,8 in biological membranes was studied.^{68,69} The distance distribution function in egg L- α -phosphatidylcholine membranes exhibits two maxima at 1.3 and 1.8 nm.⁶⁸ The authors suggested that the peptide conformations represent combinations of the α -helical conformation, 3_{10} -helical conformation and more stretched conformations. Similar results were obtained for this peptide in model phospholipid membranes.⁶⁹

PELDOR studies of doubly-nitroxide-labelled RNA were reported.^{70–72} The label–label distances were found to lie between 2 and 5 nm. The results of measurements were in agreement with the results of molecular dynamics calculations. Based on the results obtained, the conformations of the biomolecules were determined.

Changes in the conformation of a protein (BtuB) upon binding to a substrate (TonB) in a membrane have been a subject of a joint SDSL–PELDOR study.⁷³ The protein binds and carries vitamin B₁₂ across the outer membrane of Gram-negative bacteria such as *Escherichia coli*. The protein was doubly spin labelled. In the absence of the substrate, the results of measurements showed a narrow interspin distance distribution for the number of pairs (number of pairs from r to $r + dr$). In the presence of the substrate, the distance distributions broadened. This indicates a substrate-induced transition of the protein from the ordered to disordered state.

Singly labelled Na⁺/H⁺ regulators, namely, NhaA from *Escherichia coli* were studied.⁷⁴ Residues situated in domains undergoing pH-dependent structural changes were chosen for site-directed spin labelling. PELDOR experiments revealed modulation of the echo signal, which showed that NhaA exists in the dimeric form. The modulation depth reversibly decreased with the decrease in the pH value, thus indicating an increase in the distance in the dimer. Relation between these results and the mechanism of NhaA activity was considered.

The structure of different-size [2]catenanes was studied by the PELDOR method.⁷⁵ Each of the two macrocycles was spin labelled. The molecular conformation distribution and size were evaluated by comparing the experimental data and theoretical estimates.

The arrangement of the b -subunits in the holo-enzyme F₀F₁-ATP synthase from *E. coli* was investigated by the SDSL and PELDOR methods.⁷⁶ Based on the interspin distances, parallel orientation of two helices and other structural features were revealed.

A double-quantum coherence study of model peptide helices was carried out.⁷⁷ The intramolecular distances were determined and the folding of the helices was studied.

The possibility of SDSL and PELDOR studies of the global structure of nucleic acids was considered.⁷⁸ Spin labelled duplexes of DNA dodecamers with known structure were used as model systems. The distances measured by PELDOR

(2 to 4 nm) were in agreement with those obtained from NMR data.

2. Peptide aggregation in molecular glasses and biomembranes

There are reasons to assume that peptide aggregation in biomembranes significantly affects their functional properties, e.g., formation of ionic channels. The sizes of peptide aggregates are on the nanometre scale, which points to the possibility of using the PELDOR method.

To clarify possible mechanisms of peptide aggregation in biomembranes, peptides in simpler model systems were studied. The results of the PELDOR studies of aggregation of spin-labelled peptide Trichogin GA IV in organic molecular glasses were considered in detail in reviews.^{8,10,14} No aggregation was observed in polar media, whereas in glasses of low polarity the number of molecules in aggregates (N) varied from 3.1 to 4.3 depending on the type of the system. For spin-labelled Trichogin dimers (two molecules covalently bound in 'head-to-tail' fashion) in a chloroform–toluene mixture, the number N varies from 2 to 3 and the interspin distance varies from 3.0 to 4.5 nm.⁷⁹ As the concentration increases, the formation of tetramers occurs.⁸⁰

A PELDOR study of aggregation of spin-labelled zervamycin IIA (fungal hexadecapeptide) in a glassy toluene–methanol mixture at 77 K revealed the presence of aggregates with antiparallel orientation of the peptide molecules.⁸¹

Aggregation of spin-labelled peptide alamethicin in polar and non-polar molecular glasses was studied.⁸² The peptide molecule contains 20 amino acid residues.

Act-Aib-Pro-Aib-Ala-Aib-Ala-Glu-Aib-Val-Aib-Gly-

-Leu-Aib-Pro-Val-Aib-Glu-Gln-Phol.

The compound possesses the properties of an antibiotic. Samples spin-labelled at position 16 by replacing the amino-isobutyric acid residue by the TOAC spin label were studied. No aggregation was observed in the polar glass, in contrast to the glass of low polarity (chloroform–toluene mixture). It was found that the number of molecules in the aggregate is rather large and varies from 6 to 8.

Aggregation of spin-labelled peptides Trichogin GA IV in biological membranes was studied.^{68,69} At a concentration of 2.2 mol.%, the peptide is uniformly distributed in egg L- α -phosphatidylcholine membrane.⁶⁸ The addition of cholesterol (up to 16.5 mol.%) led to an increase in the local peptide concentration. No peptide aggregation occurred at low peptide concentration in model phospholipid membranes (peptide:lipid ratio lower than 1:100).⁶⁹ An increase in the peptide concentration in the model phospholipid membranes to a peptide:lipid ratio of 1:20 caused the formation of dimeric aggregates with an average interspin distance of nearly 2.5 nm.

Peptide aggregation with an increase in the peptide concentration seems to be of fundamental importance for the appearance of membrane channels. A unique advantage of the PELDOR technique consists in the possibility of determining the number and characteristic size of molecules in aggregates.

3. Nanostructure of ionomers

Ionomers are polymers bearing ionic end groups.^{83,84} The ionomer structure comprises ionic clusters a few nanometres in size. The intercluster distance is of the same order of magnitude. These parameters of the nanostructure of ionomers based on a polyisoprene/polystyrene copolymer were estimated in a PELDOR study using ionic spin probes.^{85–87} The surface of ion clusters is accessible to such probes. The characteristic interparticle distance in the cluster was about

2 nm and the characteristic cluster – cluster distance was nearly 5 nm. The results obtained were considered in more detail in reviews.^{10, 13}

4. Detection of structural transformations in materials

The mechanism of formation of mesoporous materials (MCM-41 and SBA-15) from the starting micellar compounds in the presence of spin probes was studied by the method of ESEEM through electron – nuclear interactions.^{88–91} In different stages of the reaction the sample was cooled to 77 K and the ESEEM through the interaction of the spin-probe unpaired electron with deuterium present in the starting compounds was recorded. A number of stages of the formation of the materials were observed and interpreted.

5. Profile of water penetration into biomembranes

The depth of water penetration into a biomembrane is an important characteristic that governs transport of polar and charged particles across membranes and the energy characteristics of protein embedding in them.^{92–95} The content of water in the local environment of the spin label was measured using the ESEEM effect due to hyperfine interaction of the spin-label unpaired electron with deuterium nuclei in the molecules of heavy water used for hydration of membranes.^{96–99} The use of heavy water is due to the fact that, first, the amplitude of deuterium modulation much exceeds that of proton modulation. Second, this allows the contribution of the protons of biomolecules to the ESEEM effect to be separated. Using the SDSL technique, one can determine the local concentration of water in the nearest environment of the spin label by the ESEEM method. The estimated spatial resolution of the method was about 0.5 nm.

Studies were carried out using either lipids spin-labelled at different positions of the aliphatic chain in DL- α -dipalmitoyl phosphatidylcholine (DPPC) model phospholipid membranes^{96, 99} or spin probes based on *p*-doxylstearic acid ($n = 5, 7, 12, 16$) in multilayered egg phosphatidylcholine liposomes.^{97, 98} The experimental techniques employed were two-pulse echo^{96–98} and stimulated echo,⁹⁹ the latter being much more accurate.

The experimental temporal oscillations of stimulated ESEEM signals and the corresponding cosine-Fourier-transformed spectra are similar to those shown in Fig. 3. The

spectrum exhibits a narrow line and a broad background component (see Fig. 3 *b*). According to theoretical analysis,⁹⁹ the narrow line is due to the interaction with free water, whereas the broad component arises from the interaction with bound water that forms a complex with the nitroxide radical. For samples labelled at different positions of the lipid chain, the amplitudes (spectral density) of the deuterium line are appreciably different. In Fig. 5 this amplitude is plotted vs. label position (amplitudes of the narrow line and broad component appeared to be in proportion to each other). As the label ‘moves’ into membrane’s interior, the amplitude (and, hence, water concentration) decreases. In the presence of cholesterol, the concentration of water near the membrane surface is higher and decreases much more abruptly on ‘moving’ into the membrane interior. The drop occurs near the C(8) atom in the lipid chain. The smooth decrease in the absence of cholesterol can be explained by ‘entanglement’ of lipid chains (cholesterol favours ordering of lipid molecules).

The results mentioned above were also considered in a review.¹⁰⁰

6. Localisation of peptides and other biomolecules in membranes

A series of spin probes, namely, *p*-doxylstearic acid ($n = 5, 7, 10, 12, 16$) in DPPC and dihexadecyl prosthate (DHP) vesicles were studied by the ESEEM method.¹⁰¹ The ESEEM effect was induced by the interaction between the unpaired electron in the doxyl group and ³¹P nuclei of the polar heads of the lipid vesicles. Based on the results obtained, one can draw conclusions about localisation of the spin probe relative to the membrane surface. It was found that the spin probe penetrates about 0.5 nm into the DHP vesicles.
