At present, considerable attention is given to studies of the supramolecular structure of membrane – peptide systems. A ‘classical’ object of such studies is peptide Trichogin GA IV. The peptide helix is 1.6 nm long, which is about half the membrane thickness. Most studies were carried out using fluorescent labels.^{102–104} However, this technique has a significant drawback, namely, the labels are too bulky and can be displaced towards the membrane surface along with the peptide.¹⁰³ Therefore, it is interesting to perform corresponding spin label studies because spin labels are much more compact.

The localisation and orientation of peptide Trichogin GA IV in a phospholipid membrane were studied⁶⁷ using the effect of polarity on the parameters of HFI in c.w. EPR spectra. However, molecular motions also contribute to these interactions, thus introducing errors in experimental data. The methods based on ESEEM are free from this drawback.

The ESEEM profile of water concentration in a model phospholipid membrane⁹⁹ was used for the determination of localisation of spin-labelled peptide Trichogin GA IV in this membrane.¹⁰⁵ Three peptide analogues spin-labelled at different positions (1, 4 and 8) were studied.

Figure 6 presents the ESEEM spectra of the three samples. The peak amplitudes obtained should be compared with the amplitudes obtained for the spin labels in lipids measured

Figure 5. Spectral line amplitudes at 2.2 MHz (see Fig. 3) plotted vs. label position in the lipid chain in model phospholipid membranes hydrated with deuterium water. Cholesterol-free DPPC membrane (*a*) and cholesterol-containing DPPC membrane (*b*).

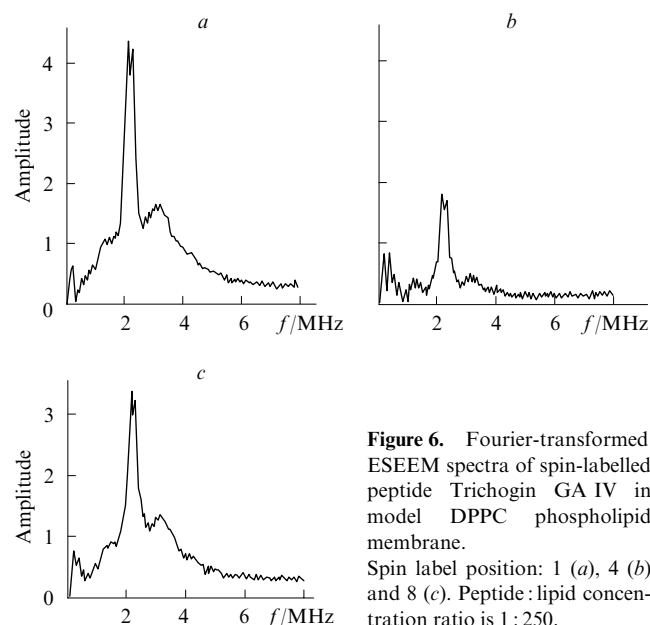

Figure 6. Fourier-transformed ESEEM spectra of spin-labelled peptide Trichogin GA IV in model DPPC phospholipid membrane. Spin label position: 1 (a), 4 (b) and 8 (c). Peptide:lipid concentration ratio is 1 : 250.

under identical conditions (see Fig. 5, data in the absence of cholesterol). A comparison shows that the amplitudes for positions 1 and 8 (4.2 and 3.3 arbitrary units, see Fig. 6) are similar to those for the spin label positions in the lipids that are closer to the membrane surface than position 10 with respect to the polar head, *i.e.*, positions 1 and 8 of the spin labels in the peptide molecule are closer to the membrane surface than the spin label in position 10 in the lipid. At the same time, a comparison of the two types of data showed that position 4 in the peptide molecule is similar to position 10 in the lipid molecule. This suggests that the peptide molecule is oriented parallel to the membrane surface.

This situation is observed at small peptide:lipid concentration ratios (lower than 1 : 100). As this ratio increases to 1 : 20, the saturation changes significantly (Fig. 7), namely, the peak amplitude for the spin-labelled position 1 appreciably decreases. Thus, as the peptide concentration increases, the peptide *N*-terminus moves deeper into the membrane interior and now the orientation of the whole molecule is similar to transmembrane one. As mentioned above, this is accompanied

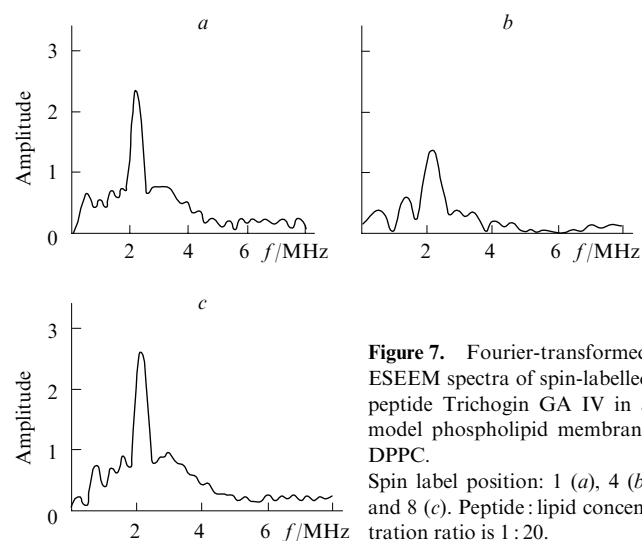

Figure 7. Fourier-transformed ESEEM spectra of spin-labelled peptide Trichogin GA IV in a model phospholipid membrane DPPC. Spin label position: 1 (a), 4 (b) and 8 (c). Peptide:lipid concentration ratio is 1 : 20.

by peptide aggregation into dimers with a broad interspin distance distribution.

Probably, it is these changes in the supramolecular structure of a membrane with embedded peptides that are responsible for the membrane permeability. Probably, the formation of the transmembrane dimer can lead to formation of a channel in the membrane.

A similar approach was employed in a study¹⁰⁶ of localisation of two peptides antibiotics, a natural peptide melittin (26-mer) and a synthetic peptide (15-mer) using model membranes. The spin label was attached to the *N*-termini of the peptides (here, peptides were labelled only in one position¹⁰⁵). Either D₂O-hydrated membranes or H₂O-hydrated membranes containing deuterium-substituted lipids were used. A comparison of the deuterium ESEEM peaks with the peaks of the lipids spin-labelled at different positions showed that the peptide *N*-terminus is on the membrane surface. An increase in the concentration of non-labelled peptides caused a noticeable water penetration into the membrane, which was detected from the increase in the deuterium peaks for the labelled lipids. This suggests that membrane permeability is governed by the peptide concentration.

7. Structural studies of spin-labelled photosynthetic reaction centres

The SDSL and pulsed EPR studies of the supramolecular structure of photosynthetic reaction centres of plants and bacteria began quite recently. In a PELDOR study,¹⁰⁷ the MTSL spin label was attached to a cysteine residue at position 156 of protein *H* in the reaction centre of the bacteria *Rhodobacter sphaeroides* R26. The distance between the spin label and the primary quinone electron acceptor Q_A was found to be 3.05 ± 0.05 nm. The results of measurements were compared with the results of molecular dynamics calculations. It was concluded that the accuracy of measurements is sufficient for detection of structural changes that can be expected upon transfer of an electron.

V. Studies of the dynamics of spin-labelled systems

1. Rotation of methyl groups in nitroxide radicals

The paramagnetic fragment NO in the nitroxide radicals is most often shielded by four methyl groups. Generally, rotation of methyl groups has little effect on the EPR spectral shape; however, in some cases this influence can be significant. Therefore, proper use of EPR spectroscopy in the method of spin labels and probes requires information on the parameters of this motion. Studies of nitroxide radicals aimed at determining the rotational correlation times and the amplitudes of accompanying HFC fluctuations in a wide temperature range have been reported only very recently. They were carried out by the ESEEM method (see above); here the ESEEM effect is due to spontaneous changes in the magnetic parameters of radicals induced by the three-pulse stimulated ESE sequence.^{42–44}

The Fourier transformed stimulated ESE spectra of some nitroxide radicals in glassy toluene, ethanol and water–glycerol (1 : 1) mixture at 77 and 90 K revealed⁴² the appearance of intense peaks in a broad frequency range from 0 to 15 MHz. The peak at 15 MHz, which is due to the interaction with the matrix protons, showed no temperature dependence, whereas the peaks at lower frequencies became much more intense with an increase in *T*. The effect was attributed to rotation of methyl groups. The Fremy salt nitroxide radical contains no methyl groups; a reference experiment with this compound showed no effect.

A study⁴³ of nitroxide radicals in *o*-terphenyl and glycerol in the temperature range 120–260 K also revealed intense peaks that became more intense with increasing *T*. This effect was attributed to relaxation of methyl protons. The nuclear

relaxation rate was determined from the kinetics of peak growth. The rotational correlation time of methyl groups was determined from the relaxation rate using the Redfield theory.²⁰ The Arrhenius parameters of this rotation are as follows: the energy barrier lies in the range 1300–1500 K and the pre-exponent is about 10^{12} s^{-1} .

2. Fast small-amplitude orientation mobility of spin probes in molecular glasses

Spectral transformations with an increase in τ (see Fig. 4) correspond to the model of small-amplitude stochastic librations. In this case, the relaxation anisotropy is determined using expression (4). The results of these calculations and the experimental data are in excellent agreement.²² The whole set of the spectra recorded at different τ was calculated using only one fitting parameter, namely, the product $\langle \alpha^2 \rangle \tau_c$, which is proportional to the relaxation rate $\langle \Delta \omega^2 \rangle \tau_c$.

The c.w. EPR spectra are also consistent with the model of fast small-amplitude motions.¹⁰⁸ Note that c.w. EPR experiments with glassy liquids and other disordered systems are often treated in terms of such motion models as continuous Brownian diffusion in the angular space or discrete rotation by an arbitrary or fixed angle (accounting or ignoring the motion anisotropy).¹⁰⁹ These models assume an infinite molecular motion in the angular space. However, there are data that contradict the infinite character of motion. For instance, if polarised light ‘burns out’ a particular orientation of photosensitive molecules, one can monitor how the spectral ‘hole’ broadens with time.¹¹⁰ These experiments permit immediate measurements of the rate of the infinite angular motion. It was found that the rate determined is many orders of magnitude lower than the rate determined by analysing the EPR spectra of spin probes of similar size. Therefore, the models of infinite motions are inappropriate for the description of the motion in highly viscous media and molecular glasses, often despite good agreement between theory and experiment.¹⁰⁹

The behaviour of the echo-detected EPR spectra with an increase in τ (see Fig. 4) is typical of spin labels and spin probes in disordered media including biosystems. Moreover, it is also characteristic of other types of paramagnetic species that exhibit anisotropic EPR spectra, namely, metal complexes,¹¹¹ semiquinone radicals in high-field EPR¹¹² and molecules in triplet excited states.¹¹³ Thus, it becomes clear that here we deal with some universal basic regularities of the molecular dynamics in such systems. Unusual character of the molecular dynamics in disordered media has long been reported in studies carried out by various physical methods, namely, light scattering,¹¹⁴ single-molecule spectroscopy,¹¹⁵ dielectric relaxation,¹¹⁶ neutron scattering,¹¹⁷ Mössbauer absorption,¹¹⁸ etc. Despite numerous experimental data, the nature of the phenomena is still to be clarified.

Interesting information on the properties of this motion can be obtained using echo-detected EPR spectroscopy. Observation of anisotropic relaxation in echo-detected EPR spectroscopy indicates that orientational motion of the whole molecule occurs in the system. A study of the dynamics of spin probes of different structure and in different glassy solvents¹¹⁹ allowed one to establish with certainty that the motion depends on the nature of the solvent rather than the type of the spin probe. Probes used in these studies were 0.3 to 5 nm in size; therefore, it is clear that it is co-operative molecular dynamics, *i.e.*, the motion occurs by collective rearrangements in the molecular structure, being supramolecular in character. The size of the molecular cluster is a few nanometres. In the case of simple low-molecular-mass glasses the motion is also supramolecular in character.

The principal value of the HFC tensor $\langle A_{ZZ} \rangle$ averaged by fast motions can be determined with ease from c.w. EPR spectra (see Fig. 1). Typical results obtained for molecular

Figure 8. Typical temperature dependences of the spectral splitting $\langle A_{ZZ} \rangle$ (see Fig. 1) obtained for nitroxide spin probes in *o*-terphenyl (a), root-mean-square angles of deviation from equilibrium position obtained from relationship (5) (b) and root-mean-square fluctuations of atomic positions relative to the equilibrium position $\langle x^2 \rangle$ obtained from neutron scattering studies (c). T_d is dynamic transition temperature.

glasses are shown in Fig. 8a. The temperature dependence of $\langle A_{ZZ} \rangle$ is linear at low temperatures and becomes much steeper above a certain temperature. Using these data and relation (5), it is possible to obtain the temperature dependence of $\langle \alpha^2 \rangle$ (Fig. 8b).

3. Dynamic low-temperature transition in disordered media

Neutron scattering^{117, 120} and Mössbauer absorption¹¹⁸ studies of atomic vibrations in molecular disordered (including biological) media (in the latter case the substance under study contains ^{57}Fe ions) revealed a clearly defined transition from harmonic to anharmonic motion on raising the temperature. The effect manifests itself as transition from the linear temperature dependence of the root-mean-square atomic displacement $\langle x^2 \rangle$ (this is characteristic of harmonic motion) to a steeper dependence with an increase in temperature. The transition is only characteristic of the disordered media. A feature of the crystalline state is a linear temperature dependence in the whole temperature range. This transition is

called the dynamic transition; the transition temperature is denoted by T_d (Fig. 8c).

Biosystems have the T_d temperatures lying in the range 200–230 K.¹²⁰ The physiological activity of biosystems manifests itself only above T_d . At present, the nature of this transition and its importance for biosystems have been subjects of intensive studies. Interestingly, these T_d values are similar to the minimum air temperatures on the Earth.

Valuable information on the molecular dynamics can be obtained by echo-detected EPR spectroscopy of spin labels and spin probes. Noteworthy is an analogy between the EPR data and the neutron scattering data shown in Figs 8b and 8c, respectively. Neutron scattering is sensitive to motions at frequencies higher than 10^9 s^{-1} (Mössbauer absorption is sensitive to motions at frequencies higher than 10^7 s^{-1}). These frequencies are of the same order of magnitude as that required for librational narrowing of EPR spectra (10^8 s^{-1}). The characteristic motion amplitudes $\langle x^2 \rangle$ (see Refs 117, 118 and 120) are also similar in magnitude to the $\langle \alpha^2 \rangle$ values shown in Fig. 8b (numerical values of $\langle \alpha^2 \rangle$ expressed in squared radians and of $\langle x^2 \rangle$ expressed in squared Ångströms can be compared with allowance for the fact that the characteristic size of the molecule is $\sim 1 \text{ Å}$). These quantitative relations suggest that different methods deal with the same type of motion.

The applicability of c.w. EPR for measuring $\langle \alpha^2 \rangle$ is limited to non-polar media. In polar media, the measured A_{ZZ} value is additionally affected by the change in the matrix polarity, which may introduce rather large errors. In the case of echo-detected EPR, information on the motion is extracted from the rate of anisotropic relaxation, which is not affected by the polarity of the matrix.

A typical temperature dependence of the characteristic changes in the echo-detected EPR spectra in molecular glasses is shown in Fig. 9. These changes can be characterised by the relative intensity at the centre of the high-field component. At low temperatures, no changes occur, but raising the temperature causes a marked decrease in the intensity, which may be assigned to the dynamic transition.

Figure 9. Typical temperature dependences of characteristic changes in echo-detected EPR spectrum induced by unfreezing of stochastic librations (nitroxide spin probe in *o*-terphenyl); h_1/h_2 is the height ratio of the EPR spectra recorded at different temperatures and normalised to maximum amplitudes; h_2 corresponds to a temperature of 230 K (no spectral changes occur at lower temperatures). The open (1) and solid (2) circles denote data obtained for different nitroxide radicals.

The T_d values determined for molecular glasses (glycerol and *o*-terphenyl) are 195 and 245 K, respectively.^{121, 122} It was found that these temperatures coincide with the T_d values determined for these glasses from neutron scattering data.^{117, 123}

Thus, echo-detected EPR is a sensitive tool for determination of the temperature of the dynamic transition from harmonic to anharmonic (or stochastic) motion. Other important advantages of this technique are the relative, compared to neutron scattering and Mössbauer absorption, accessibility of measurements and the possibility of SDSL studies of different fragments in complex supramolecular systems.

A rather steep decrease in the temperature dependence shown in Fig. 9 prompts that the potential of this motion seems to be temperature dependent and changes its shape above a certain temperature. Different versions are possible, namely, the potential can be essentially anharmonic or it may become a stochastic function of time.

Since the potential is determined by the structure of matter, we can say that the so-called mean order in this structure (correlations in the arrangement of atoms and molecules on the nanometre scale) changes above T_d .

4. Dynamic low-temperature transition in spin-labelled model biomembranes

Echo-detected EPR spectroscopy studies of the dynamics of DPPC lipids spin-labelled at different positions of the lipid chain in model phospholipid membranes with high content of cholesterol (50 mol.%) revealed¹²⁴ a dynamic transition, common to all positions, with T_d lying in the range 200–230 K. This is in agreement with the results obtained in a neutron scattering study.⁹³ A new phenomenon was disclosed in comparing the data for different positions in the spin label, namely, in the membrane interior the dynamic transition spans a wide temperature range and begins at 100–120 K.

A dynamics study of cholestane spin probe (this compound is structurally similar to cholesterol, an important membrane component)¹²⁵ also showed low-temperature motions in the membrane interior.

Different-type dynamics at different distances from the membrane surface and low-temperature motions may appear to be important for understanding the mechanisms of membrane functioning. These data may also be of interest for the development of fundamental concepts of possible mechanisms of biological tissue cryoconservation.

5. Dynamic low-temperature transition in spin-labelled complex biosystems and its interrelation with functional activity

Seed and pollen cells are interesting subjects for studies using the method of spin labels and probes. They show a remarkable ability to be stored for years without loss of vital activity. A possible explanation for this ability involves intracellular glass formation. An echo-detected EPR study of spin probes introduced into the seed and pollen cells revealed a marked anisotropic relaxation at $T > 200 \text{ K}$, which itself indicates glass formation.¹²⁶ These effects depend strongly on the water content in the samples. These studies are important for understanding the processes that govern the storage period of seeds and other biological objects.

Echo-detected EPR was also used to study SDSL reaction centres isolated from the photosynthetic centre of purple bacteria.¹²⁷ These objects are often used in studies of fundamental processes in photosynthesis. Cysteine residues in these centres were labelled with the MTSL spin label. A clearly defined dynamic transition was detected near 200 K. At this temperature, transfer of a photo-induced electron along the electron acceptor chain is blocked,^{128–130} namely, electron back transfer occurs followed by recombination with the

'hole' (radical cation of bacteriochlorophyll dimer) instead of direct electron transfer from the primary quinone acceptor to the secondary one. The nature of the reversal of electron transfer direction is still to be clarified. Moreover, no correlations between this effect and the properties of complex supramolecular structure of the reaction centre were reported so far. The results of echo-detected EPR studies indicate the correlation of this effect with the dynamic transition near 200 K in the system.

6. Dynamic structure of vesicular membranes

The motion of cholestane spin probes in multilayered phospholipid vesicles in the presence of cholesterol was studied by the 2D PELDOR method.⁴⁹ At present, it is accepted that a liquid ordered phase appears in cholesterol-containing membranes in addition to conventional liquid-crystalline phase (which also exists in the absence of cholesterol). The ordered domains are called rafts. The two phases are in equilibrium; their investigations are of considerable interest from the standpoint of research on the membrane operation mechanisms. Visual studies of 2D spectra did allow one to distinguish two phases differing in the rotational diffusion rate and degree of molecular ordering (these parameters were higher in the ordered domains).

VI. Conclusion

The use of pulsed EPR in the method of spin labels and probes have been started quite recently. Spectroscopic methods appeared to be useful in conformational and aggregation studies of large biomolecules, nanostructure of matter, supramolecular structure of multicomponent systems and co-operative orientational dynamics of molecules. In some cases they show a record resolution compared to other physicochemical methods of investigation. For instance, the PELDOR technique is highly sensitive to distance measurements in the nanometre range and provides a 0.1-nm accuracy of measurements at distances of about 3 nm. Echo-detected EPR spectroscopy is a sensitive tool of investigation of small-amplitude stochastic orientational motions (down to amplitudes of 0.1–1°). Using this method, the temperature of dynamic transition from harmonic to anharmonic (or stochastic) motion in disordered molecular media and biosystems can be determined with ease. More and more data reported in the literature indicate that this transition is a crucially important characteristic of living systems.

Pulsed EPR techniques are continuously developed and improved. It is of great importance that the vast majority of the results discussed above were (or could be) obtained using commercially available spectrometers.

Abstract. The experimental and theoretical data concerning the formation of open fulleroid structures (homofullerenes) upon chemical modifications of the fullerene spheroid are generalised. The bibliography includes 88 references.

I. Introduction

Cycloaddition is one of the best studied types of reactions in organic chemistry of fullerenes. The results of detailed studies of cycloaddition reactions involving fullerenes such as the Diels–Alder, 1,3-dipolar, [2+1] and others have been described in numerous publications. In the vast majority of cases, these reactions afford addition products at the fullerene C=C double bond, the so-called [6,6]-closed adducts. As expected for the normal cycloaddition, a π -bond is cleaved and all σ -bonds are maintained in these products. Meanwhile, many examples of the formation of [5,6]-open and [6,6]-open fulleroid structures in parallel, or in addition, to the expected [6,6]-closed adducts are presently available, which implies that it is σ -bonds between the carbon atoms of the fullerene sphere that are cleaved. In some particular cases, open fulleroids can spontaneously isomerise into closed fullerenes and *vice versa*. Various types of the cycloaddition reactions yield fulleroids, and the reasons for the formation of these unexpected structures among reaction products have not yet been completely established. Several authors speculated upon possible reasons for the formation of open adducts, whereas other authors merely described the experimental data obtained. Despite the fact that the formation of open fulleroid structures is undoubtedly of theoretical interest, no systematic review on this topic has been published so far.

II. Reactions of diazo compounds with fullerene

Carbenes are known to readily add to the double bonds C=C to yield cyclopropanes. Diazo compounds are widely used as synthetic precursors of carbenes. However, the thermally induced addition of diazo compounds to C₆₀ fullerene proceeds in a more complex way than the addition of singlet carbenes generated by other methods and affords mixtures of [6,6]-closed (fullerene) and [5,6]-open (fulleroid) isomeric cycloadducts. This is due to two possible mechanisms of the cyclopropane fragment formation in the thermally induced reactions of C₆₀ with diazo compounds: the thermal decomposition of a diazo compound to a carbene followed by its synchronous addition to the [6,6] bond of fullerene giving rise to closed products and the 1,3-dipolar cycloaddition to fullerene followed by the extrusion of nitrogen from the pyrazoline intermediate, which can yield both isomers (Scheme 1).¹

However, thermolysis of 2-diazo-4,5-dicyanoimidazole, which can afford two electrophilic intermediates, *viz.*, carbene-type and zwitter-ionic species stabilised by two electron-withdrawing substituents in the heterocyclic ring in the presence of C₆₀ does not yield isomeric fullerene and fulleroid spiromethanofullerenes (**1** and **2**, respectively),

but rather an adduct **3**.² In our opinion, the radical 1,4-addition is a probable mechanism, since it is quite common in fullerene chemistry,³ whereas no nucleophilic 1,4-addition to

Scheme 1

C_{60} has been described so far in the literature. Furthermore, the conversion of 2-diazo-4,5-dicyanoimidazole into a radical is by far more probable than into an anion, which requires the presence of a reducing agent (Scheme 2).

The thermal attachment of dimethyl diazomethylphosphonate $\text{N}_2\text{CHP}(\text{O})(\text{OMe})_2$ to C_{60} (110 °C, toluene) also yields a mixture of isomeric fullerene and fulleroid cycloadducts in a 3 : 1 ratio.⁴

Pellicciari *et al.*⁵ reported the first addition of carbenoids to C_{60} catalysed by transition metals. In particular, the reaction of C_{60} with alkoxycarbonylcarbenoids generated from diethyl diazomalonate with $\text{Rh}_2(\text{OAc})_4$ as a catalyst provides higher product yields and selectivity as compared to ordinary thermal reactions (Scheme 3, Table 1).

Unstable diazo compounds can be generated *in situ* from stable hydrazones and their derivatives using oxidation of hydrazones, *e.g.*, with MnO_2 .^{6,7} It was suggested^{8,9} that the reaction proceeds through the initial 1,3-dipolar cycloaddition of the diazo compound to C_{60} followed by the extrusion of a nitrogen molecule from the pyrazoline intermediate formed. As a result, a mixture of [6,6]-closed (fullerene) and [5,6]-open (fulleroid) derivatives is obtained. This method was successfully used to introduce methylene bridges containing benzocrown ether fragments⁶ or 3,5-bis[(dimethylamino)methyl]-phenyl (dmmph) group⁷ aimed at studying the complexation properties of new fullerene derivatives. It is of note that the formation of only one of two possible [5,6]-open stereoisomers (**8** and **9**) in addition to [6,6]-closed adduct **7** is feasible for specific asymmetric methanofullerenes, according to calcula-

Scheme 2

Scheme 3

Table 1. Conditions, yields and product ratios for the reaction of C₆₀ with diethyl diazomalonate.

Catalyst	R	Solvent	T/°C	Reaction time/h	Yield (%)	Ratio of isomers		
						4	5	6
—	H	toluene	110	7	35	1	4	2
Rh ₂ (OAc) ₄	H	toluene	20	20	21	14	1	1
Rh ₂ (OAc) ₄	H	1-methylnaphthalene	20	8	42	52	1	—
—	CO ₂ Et	toluene	110	20	10	not determined		
Rh ₂ (OAc) ₄	CO ₂ Et	1-methylnaphthalene	80	32	9	1	—	—

tions. In particular, isomers **8e,f** are feasible, whereas isomers **9e,f** are not.⁶

For all other non-symmetrical methanofullerenes, both [5,6]-open isomers have been isolated. No rationale for this experimental fact has been given.⁶

Initially, the reaction of fullerene with diazo compounds bearing a dmmph group was found⁷ to yield a mixture of [5,6]-open fulleroids and [6,6]-closed methanofullerene in a 9 : 1 ratio.

In addition to the aforementioned oxidation of unsubstituted hydrazones, thermolysis of *N*-tosylhydrazone anions **10** can be employed for the generation of diazo compounds.^{8, 10–16} Their addition also yields a mixture of [6,6]-closed and [5,6]-open isomeric cycloadducts (compounds **11** and **12**, respectively). Conditions of the thermolysis of the corresponding *N*-tosylhydrazone lithium salts in boiling toluene could be tuned so as to enable the preferred formation of fulleroid derivatives. This was accomplished by shortening the reaction time, which favours the formation of a kinetically controlled product.

$R^1 = R^2 = R^3 =$ H (a); $R^1 = R^2 =$ CO₂Et, $R^3 =$ H (b);
 $R^1 = R^3 =$ CO₂Me, $R^2 =$ H (c); $R^1 = R^3 =$ CO₂Et, $R^2 =$ H (d).

The maximum yield of 67% and the maximum isomer ratio of [5,6]-open to [6,6]-closed (13.3 : 1) were achieved for compound **10c** and a reaction time of 25 min. With an increase in the reaction time to 90 min, the yield of monoadducts drops down to 23% and the isomer ratio, to 1.7 : 1. Most probably, such a change in the product ratio is due to the progressive accumulation of the product of thermal rearrangement of the initially formed [5,6]-open isomer into the [6,6]-closed isomer.

In contrast, the reaction of C₆₀ with 4-[bis(4'-*tert*-butylphenyl-4-yl)]benzaldehyde *N*-tosylhydrazone in *o*-dichlorobenzene in the presence of sodium methoxide even at a relatively low temperature (40 °C) yields selectively the thermodynamically more stable [6,6]-closed isomer.¹⁷

The reaction of fullerene C₆₀ with 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl *N*-tosylhydrazone affords only the open isomer in a ~25% yield.¹⁰

The kinetically controlled products, *viz.*, [5,6]-fulleroids, were obtained in the reaction of fullerene with a diazo compound bearing a tetrathiafulvalene substituent¹³ and a diazo compound generated *in situ* from 4-benzoylbutyric acid *N*-tosylhydrazone.¹⁸

An unusual method for the carbene generation has been found in the reaction of C₆₀ with DL-valine and 4,4,5,5-tetramethylimidazoline-2-thione.¹⁹ This reaction yields the respective spiro-fused fulleroid (Scheme 4).

As has been noted above, the reactions of C₆₀ with carbenes afford [6,6]-closed methanofullerenes, whereas those with diazo compounds yield fulleroids (*i.e.*, [5,6]-open isomers). This allows fullerenes to be used as specific probes to distinguish carbenes and diazo compounds. The nature of the adducts formed provides information on the reaction mechanism.²⁰

However, it has to be noted that the thermal reaction of C₆₀ with a dibromo derivative **13**, which involves a carbene intermediate, yields a symmetrical fullerene adduct **14**, dimers formed upon the reaction of two molecules of the carbene intermediate and an isomeric non-symmetrical adduct **15** comprising fullerene and fulleroid fragments in one molecule.²¹ It was shown that the fulleroid **15** was the major reaction product (its yield varies from 5% to 10%), but no explicit ratio between the adducts **14** and **15** was given. According to calculations,²¹ the isomer **15** is more stable than **14** (Scheme 5).

Scheme 4

Scheme 6

from light failed and the starting fulleroid **16** remained quantitatively intact.²⁵

As has been shown by different groups,^{6–8, 13, 18} [5,6]-open fulleroids synthesised in this way undergo a thermal rearrangement into thermodynamically more stable [6,6]-closed isomers. A number of [5,6]-open fulleroids bearing substituents stabilising radical species in the methylene bridge was proven to rearrange into [6,6]-closed fullerenes both in the zero-order (in terms of kinetics) photochemical process and in the high-energy unimolecular route, which involves the disrotatory ring closure into a [5,6]-closed fullerene followed by its rearrangement into the [6,6]-closed isomer *via* biradical intermediates.²² Generally, this process is depicted in Scheme 6 (omitting substituents in the bridge). The energy parameters of various isomers of methanofullerenes and fulleroids calculated by the MNDO method are reported.²³

It has to be stressed that unsubstituted [5,6]-methanofulleroid is not thermally converted into methanofullerene.²⁴ This agrees with the radical mechanism of the rearrangement suggested above, since the formation of a biradical intermediate becomes thermodynamically unfavourable due to the absence of radical-stabilising substituents in the bridge.

The rearrangement of fulleroid **16** into methanofullerene **17** occurs in *o*-dichlorobenzene (*o*-DCB) at 153 °C, but all attempts to perform it in an NMR tube carefully protected

Thus, this rearrangement requires illumination. Indeed, compound **16** is converted into methanofullerene **17** quantitatively upon illumination of its solution with filtered light ($\lambda > 500$ nm, 200 W) for 16 h. Oxygen inhibits the reaction, which supports the suggested biradical mechanism of the isomerisation.

Prato *et al.*²³ also described experiments on the thermal rearrangement of fulleroids into methanofullerenes and presented calculations demonstrating higher thermodynamic

Scheme 5

stability of methanofullerenes. It is of note that the reaction of fullerene with 1-(*p*-methoxyphenyl)diazoethane affords a mixture of [6,6]-closed (**18a**) and two [5,6]-open (**18b,c**) isomers in a 4 : 2 : 1 ratio, whereas the reaction with *p*-methoxyphenyldiazomethane yields only two isomers, *viz.*, [6,6]-closed (**19a**) and one [5,6]-open (**19b**) adducts.

According to calculations for a series of model systems containing fused six- and five-membered rings similar to those in the fullerene molecule (using MMPI, RHF/AM1 and UHF/AM1 methods with the geometry optimisation),⁹ [5,6]-open isomers can become more stable than their [6,6]-closed counterparts with an increase in the degree of convexity.

The known instability of aliphatic diazo compounds makes the control over the process of their addition to C_{60} very difficult, the more so that the reaction occurs in extremely low yields. Zhu *et al.*²⁶ generated diazo compounds *in situ* from a stable precursor, compound **20**, which allowed them to overcome this problem.

Since the addition of KOH to the nitroso compound results in the immediate nitrogen evolution and pyrazoline intermediates have never been observed among the reaction products, it was suggested that the reaction follows the carbene mechanism.

In this case, the [5,6]-open isomer **21** proves thermodynamically more stable. It is formed upon rearrangement of initially formed [6,6]-closed cycloadduct **22** (according to the data from NMR spectra), which was rationalised by the effect

of a bulky aliphatic substituent in the bridge. On the one hand, the sp^2 carbon atoms *i* and *ii* of the fullerene cage in the open adduct are characterised by localised double bonds, which should induce strains in the cyclic structure, according to the Bredt rule. In the closed adduct, these carbon atoms are sp^3 -hybridised and thus the total structural strain is substantially lower. On the other hand, the closed adduct contains a strained cyclopropane fragment, the strain in which is proportional to the steric bulk of the substituent in the methylene bridge. The distance between the carbon atoms *i* and *ii* is larger in the open adduct than in the closed one and thus the strain in the attached molecular fragment is lower. The relative stability of the two isomers, open and closed, is exactly determined by the interplay of these two factors. In the present case, the [5,6]-open adduct is more stable. Zhu *et al.*²⁶ stressed that the adduct isomerisation is strongly affected by solvents. They concluded that temperature, solvent and the nature of substituents are the three key factors governing the formation of a specific isomer. This conclusion on the reasons for a higher stability of open adducts with bulky substituents in the bridge agrees with the aforementioned experimental data²¹ on higher stability of the open isomer with the fullerene molecule serving as the bulky substituent. This explanation, however, contradicts the results of other authors,²⁷ who showed that methanofullerenes bearing substituents of a comparable size [*viz.*, $\text{C(R)CH}_2\cdot\text{C(O)OCH}_2\text{CMe}_2\text{CH}_2\text{OH}$, $R = \text{H, Et, Ph}$] do not rearrange into open fulleroids even upon heating to 200 °C.

Eiermann *et al.*²⁸ reported the electrochemical isomerisation of a [5,6]-open fullerene synthesised by the addition of (*p*-methoxycarbonylphenyl)diazomethane to C_{60} into the respective [6,6]-closed methanofullerene. In this case, the generation of a radical anion **23** favours the isomerisation. The tentative mechanism is shown in Scheme 7.

Scheme 7

$\text{Ar} = 4\text{-MeO}_2\text{CC}_6\text{H}_4$.

As has been mentioned above, there are two possible mechanisms of the cyclopropanation upon thermal reactions of C_{60} with diazo compounds.^{1,9} Wallenborn *et al.*²⁹ theoretically studied the possibility of the formation of methanofullerenes with the thermal extrusion of N_2 from the pyrazoline intermediate. According to *ab initio* calculations (using the B3LYP/6-31G* method) on benzene and pyracene as mimics for the fullerene core, the extrusion of a nitrogen molecule proceeds as a synchronous process with an energy barrier of 15–20 kcal mol^{−1}. The energy of biradical transition states corresponding to potential stepwise mechanism of the reaction is much higher, which makes this mechanism hardly probable.

III. Reactions of azides with fullerene

Aza analogues of carbenes, *i.e.*, nitrenes, which can be generated *in situ* by the thermal decomposition of azides behave similarly in cycloaddition reactions, resulting in [6,6]-closed fulleraziridines. However, it was found³⁰ that the reaction of fullerene with azidoformates **24** yields closed adducts **25** together with an appreciable amount of [5,6]-open isomers **26** (the reactions were accomplished under drastic conditions where azidoformates undergo thermal decomposition to nitrenes). Additionally, fullerooxazolines **27**, which are the thermal rearrangement products of alkoxy carbonyl fulleraziridines, were isolated.

Schick *et al.*³¹ reported the following synthesis. A concentrated solution of fullerene C_{60} in 1-chloronaphthalene was heated at 60 °C in the presence of $N_3CO_2Bu^t$ (1 equiv.); such conditions are typical of the formation of fullerotriazolines. Then the reaction mixture was diluted tenfold with toluene and heated at 120 °C to give a mixture of [5,6]-open and [6,6]-closed adducts (**28** and **29**, respectively) in a ratio 16:3. This result clearly demonstrates the preferred formation of the open fulleroid upon the thermal decomposition of fullerotriazoline **30**. Under the conditions of nitrene generation (*i.e.*, thermal decomposition of N_3CO_2Et), the [6,6]-closed aziridinofullerene is the major reaction product with fullerene.

The reactions with alkyl azides typically afford [5,6]-open adducts, which can further rearrange into more stable [6,6]-closed isomers. Less stable acyl azides preferably yield [6,6]-closed adducts. This can be explained by the fact that the reaction of alkyl azides with fullerene follows the 1,3-dipolar cycloaddition mechanism giving rise to unstable triazolines that further decompose to [5,6]-open adducts. The thermal decomposition of acyl azides proceeds more readily, the resultant nitrenes react with fullerene to yield the [6,6]-closed adducts. Most probably, the nitrene attack occurs to the shortest and most reactive [6,6] bond of fullerene. This conclusion is supported by the fact that the addition of singlet carbenes and silylenes always occurs to the [6,6] bond yielding the respective closed adducts.^{32,33} Nevertheless, the reasons for the formation of [5,6]-open isomers in some reactions of fullerene with oxycarbonylnitrenes remain unclear.³⁴ Banks *et al.*³⁵ formulated two hypotheses. According to one of them,

Scheme 8

R = CH₂CH=CH₂, (CH₂)₂CN.

open adducts are formed directly upon the addition of a singlet nitrene to the [5,6] bond. According to another hypothesis, the addition of the remaining triplet nitrene to fullerene can result in a mixture of [5,6] and [6,6] regioisomers. The former hypothesis is supported by calculations,³⁶ which demonstrated that the [5,6] and [6,6] bonds are comparable in reactivities from both thermodynamic and kinetic viewpoints under the conditions of the nitrene addition to fullerene.

Within the context of investigations into the cycloaddition reactions of isocyanurate-substituted alkyl azides (**31**) to fullerene (Scheme 8), [5,6]-closed isomer **32** has been detected for the first time and convincing spectroscopic evidence for its existence has been gathered: in particular, its ¹³C NMR spectrum revealed two signals assigned to the two sp³-hybridised carbon atoms of the fullerene core.^{37, 38}

The reaction of C₆₀ with 5-(5-azidopentyl)-1,3-diallyl-1*H*,3*H*,5*H*-1,3,5-triazine-2,4,6-trione (*n* = 5) at 100 °C affords in a preparative yield [5,6]-closed isomer **32**, which is successively converted first into [5,6]-open isomer **33** and then into the thermodynamically most stable [6,6]-closed aziridinofullerene **34**. Under more drastic conditions (180 °C), the reaction with 1,3-bis(cyanoethyl)-substituted azide affords closed adduct **34** alongside with the dimerisation product of the intermediate nitrene **35**, which strongly supports the dominance of the nitrene mechanism at high temperature.

The cycloaddition of per-*O*-acetylglycosyl azides to C₆₀ was used³⁹ for the preparation of fullerene glycoconjugates; this reaction yielded a mixture of open stereoisomers **36** and **37** in a ratio 2 : 1.

Compounds with fullerene and porphyrin moieties linked by a polyether linker were synthesised in a similar way.⁴⁰ The cycloaddition of azides was used to introduce a pharmacophore acridine group (known by its activity with respect to DNA) into fullerene.⁴¹ Fulleroid cycloadducts were obtained in all these cases.

Jagerovic *et al.*⁴² considered the dependence of the direction of cycloaddition on the azide structure using aryl and hetaryl azides. It is known that the nitrene addition occurs to the double [6,6] bond to yield closed fulleroaziridines, whereas the initial 1,3-dipolar cycloaddition yields triazoline intermediate, which converts into [5,6]-open π -azafulleroids upon subsequent extrusion of nitrogen. The [6,6]-closed and [5,6]-open cycloadducts are formed from aromatic and heterocyclic

azides **38** and **39**, respectively. However, the authors did not comment this experimental result.

The reaction of C₆₀ with 7-azido-6-fluoroquinoxaline in *o*-DCB at 180 °C yields a mixture of [6,6]-closed (**40**) and [5,6]-open (**41**) isomers with predominance of the former one.⁴³

The structure of [6,6]-closed isomer **40** was reliably established by ¹³C NMR spectroscopy. Unfortunately, the available amount of compound **41** was insufficient for the collection of NMR spectra and thus its assignment to the [5,6]-open isomer was made on the basis of the UV spectrum that revealed no narrow weak band at λ_{max} = 425 nm typical of the closed isomer **40**.

Similar results were obtained for the reaction of fullerene with 2-azido-4,6-diphenylpyrimidine.⁴⁴

Studies of the electrochemical reduction of compounds **40–43** bearing quinoxaline and pyrimidine fragments by means of cyclic voltammetry revealed that they represent first fulleroaziridines that are stronger electron acceptors than the parent fullerene.^{43, 44}

Different products can be obtained in the reaction of fullerene C₆₀ with 2-azido-5-nitropyrimidine, depending on the reaction conditions.^{45, 46} In particular, 4-nitro[60]fullero[1',2':4,5]imidazo[1,2-*b*]pyrimidine (**44**) was obtained upon heating at 100 °C in *o*-DCB; [6,6]-closed 5-nitro-2-[[60]fullereno[1,2-*b*]aziridino]pyrimidine (**45**) was obtained in a 13% yield at 160 °C; and azahomofullerene **46** is formed at a higher temperature (Scheme 9). It is of note that the reaction products do not undergo thermal interconversions.

Scheme 9

The reaction of alkylsulfonyl azides with fullerene yields a mixture of open (**47a,b**) and closed (**48a,b**) adducts, whereas that with arylsulfonyl azides affords exclusively open fulleroids **47c,d**. All open fulleroids synthesised in this way undergo the photochemical rearrangement into [6,6]-closed fulleroaziridines.⁴⁷

R = Me (**a**), Bn (**b**), 4-MeC₆H₄ (**c**), 4-MeOC₆H₄ (**d**).

The possibility of oxidative generation of nitrene from glycylglycine methyl ester enabled the synthesis of a dipeptide with a fulleroid substituent.⁴⁸

Bisazides are added to two fullerene [5,6] bonds giving rise to fulleroid structures. In particular, the reaction of C₆₀ with diethyl diazidomalonate in boiling xylene affords a 1 : 1 adduct representing a bis(aza)fulleroid in a 65% yield.⁴⁹

The bis-addition proceeds regioselectively: it still involves two [5,6] bonds of the same five-membered ring of fullerene even when the azido groups are separated by two or three methylene units.⁵⁰

n = 2, 3.

The reaction of C₆₀ with chiral 1,4-di(*tert*-alkoxy)-2,3-bis(azido)butanes affords the respective chiral bis(aza)fulleroids (2*R*,3*R*)-**49a**, (2*S*,3*S*)-**49a**, (2*R*,3*R*)-**49b** and (2*S*,3*S*)-**49b** in yields of 54%, 49%, 56% and 51%, respectively.⁵¹

R = Me (**a**), Ph (**b**).

It turned out that the regioselective synthesis of aza-homofullerene bisadducts is possible even with monoazides. In particular, the addition of isocyanurate-substituted alkyl azides to fullerene C₆₀ can result in the regioselective formation of diverse azahomofullerene adducts, depending on the bulk and structure of organic substituents.⁵² For instance, in the case of isocyanurate groups with methoxycarbonyl ethyl substituents at the nitrogen atom, an open bisadduct **50** similar to those described above is obtained owing to the azide addition to two [5,6] bonds.

Bisadducts with different structures were unexpectedly formed upon changes in the substituent R at the nitrogen atom in the isocyanurate-substituted alkyl azides virtually independent of the length of the methylene spacer between the azido group and the heterocycle. The structure of adducts **51a,b** was postulated⁵² due to the presence of a signal at

$\delta = 160$ in their ^{13}C NMR spectra, which is typical of carbon atoms bonded to two nitrogen atoms.

$\text{R} = \text{CH}_2\text{CH}=\text{CH}_2$; $n = 2, 3, 5$ (a); $\text{R} = (\text{CH}_2)_2\text{CN}$, $n = 5$ (b).

In our opinion, this single argument is insufficient for the unambiguous determination of the structure that has to be confirmed by X-ray crystallography. The possible pathway to various azahomofullerene bisadducts proposed by the researchers cited is shown in Scheme 10.

The similar bis(aza)fulleroid structure was proposed for fullerene-containing calix[4]arene derivatives (*e.g.*, compounds **52** and **53**) capable of exohedral complex formation with Li^+ , Na^+ and Ag^+ cations. In the [5,6]-open structures formed, one carbon atom of the fullerene part of the adduct is bonded to two nitrogen atoms.^{49, 53}

The reaction of C_{60} with tetrathiafulvalene-substituted methyl azides in *o*-dichlorobenzene with heating in an argon atmosphere for 4 h yields [60]fullero[1,2-*e*]-triazolines stable in the solid state at room temperature; the products include initially formed triazoline **54**, azafulleroid **55** (20%) and traces of fulleroaziridine **56** (Scheme 11).⁵⁴

The mechanism of the reaction involving the 1,3-dipolar cycloaddition of methyl azide to fullerene C_{60} followed by the extrusion of a nitrogen molecule was theoretically substantiated using quantum chemical calculations at the semiempirical level and within the density functional theory.⁵⁵ According to the results obtained, the azide addition occurs to the [6,6] double bond to yield the triazoline intermediate, which is characterised by the energy barrier of $\sim 20 \text{ kcal mol}^{-1}$ and an exothermic effect of $\sim 2 \text{ kcal mol}^{-1}$ (according to B3LYP/6-31G*//AM1 calculations). The subsequent thermal extrusion follows the stepwise mechanism with the cleavage of an N–N single bond followed by the cleavage of a C–N bond with an overall activation energy of $\sim 45 \text{ kcal mol}^{-1}$. The N_2 elimination occurs simultaneously with the formation of a new C–N bond. During this process, the steric influence of the outgoing N_2 molecule prevents the nitrene addition to the [6,6]

Scheme 10

Scheme 11

bond thus enhancing the probability of the addition to the [5,6] bond.

It turned out that substituents at the azafulleroid nitrogen atom strongly affect the rate of the photochemical rearrangement into fulleroaziridines.⁵⁶

In particular, times for the completion of the reaction are 1440 : 1 : > 2160 : 360 for a series of derivatives **57a–d**. Thus, the rates of the photochemical rearrangement differ by a factor

of more than 2000 between the most (**57b**) and least (**57c**) reactive compounds. Photolysis of compounds **57a–d** in air-saturated solutions proceeds much more slowly, which implies intermediacy of the triplet state of the starting azafulleroid.

IV. Reactions of nitrile ylides with fullerene

In all cases described in the early literature, only [6,6]-closed cycloadducts were obtained with fragments of five-membered heterocycles annulated to the fullerene spheroid. Unexpectedly, it was found⁵⁷ that the 1,3-dipolar cycloaddition of nitrile ylides to C_{60} can also yield [5,6]-open fulleroid isomers. Indeed, the cycloaddition of 1-(4-nitrophenyl)-3-phenylnitrile ylide generated *in situ* from *N*-benzyl-4-nitrophenylimidoyl chloride under the action of triethylamine at 130 °C yields [6,6]-closed [60]fullero[1,2-*c*]-5-(4-nitrophenyl)-2-phenyl-2*H*-3,4-dihydropyrrole (**58**) along with a mixture of diastereomeric [5,6]-open fulleroid cycloadducts **59a,b** in a ratio 2 : 1 (Scheme 12). The $\text{C}=\text{N}$ double bond in the open cycloadducts **59** is in the α -position with respect to the unsubstituted phenyl group, whereas it is in the α -position with respect to the nitrophenyl substituent in the [6,6]-closed isomer.

Under milder conditions (toluene, room temperature), this reaction yields another set of cycloadducts with no open

Scheme 12

isomers.⁵⁸ In that case, isomeric compounds **58** and **60** differing in the position of a double bond were isolated.

In our opinion, the nitro group can stabilise the biradical mesomeric form of the ylide, which enables the stepwise addition of the radical form to fullerene yielding open structures in addition to the concerted [6,6]-addition of the dipolar form yielding the closed adduct at high temperature.

V. The formation of fulleroid structures with an open [6,6] bond

The unusual opening of the fullerene sphere has been discovered for the first time⁵⁹ in the reduction of *N*-alkoxycarbonyl[60]fullero[1,2-*b*]-aziridines (**61**) with zinc or magnesium in glacial acetic acid. This reaction yields fulleroids **62** with an open [6,6] bond. In the case of R = Bu^t, the removal of the *tert*-butoxycarbonyl protection with 50% aqueous CF₃CO₂H provides a convenient synthetic route to C₆₀H₂NH (**63**), which is a parent compound of a new class of fulleroids. Under the action of a base (e.g., 1,4-diazabicyclo[2.2.2]octane), compound **63** converts in several minutes into fullero-aziridine **64**.

R = Et, Bu^t, CCl₃CH₂, 9-fluorenylmethyl

This reaction is of general character, compounds **61** bearing diverse substituents (R = Bu^t, Et, CCl₃CH₂ or 9-fluorenylmethyl) can readily be reduced to derivatives **62** in yields of > 90%.

In addition to regioisomeric [6,6]-closed bis(imino)fullerenes, *cis*-1-isomeric bisadducts **65**, which represent the first example of fullerene derivatives with open [6,6]-transannular bonds, were isolated in the bisfunctionalisation of C₆₀ with monoazides (e.g., ethyl and *tert*-butyl azidoformates).⁶⁰

R = Et (a), Bu^t (b).

A relatively regioselective synthesis of compounds **65** was accomplished starting from monoiminofullerenes **66** via highly reactive intermediates **67** generated upon [3 + 2]-cycloaddition with a negatively polarised (R)N atom attached to a positively polarised C(4) atom of the adjacent non-functionalised [6,6] bond. Such a polarisation of bonds in the carbon cages of molecules **66** is supported by calculations using the AM1 method. The thermal extrusion of nitrogen gives rise to biradical intermediates **68**. Due to the localisation of the first addend at the same six-membered ring, normal spin density delocalisation over this ring [*i.e.*, spin density transfer to the C(5) atom] becomes impossible and thus the radical recombination can occur only for the radical site localised at the C(3) atom. Consequently, the formation of 1,2;3,4-bis(imino)[60]-fullerene isomer prevails. The subsequent retro-Diels-Alder reaction (or 2π-2σ isomerisation) results in compounds **65**.

Similar formation of a bisadduct with [6,6]-open transannular bonds was also observed in the reaction of C₆₀ with 2-azido-5-nitropyrimidine.⁶¹

It is of note that this adduct undergoes the electrochemical oxidation more readily than fullerene C_{60} .

It is well known that the reaction of C_{60} with dihalocarbenes (CCl_2 and CBr_2) yields closed [6,6]-dihalomethanofullerenes.^{62–64} Nevertheless, as has been found recently,⁶⁵ [6,6]-difluoromethylene-homo[60]fullerene (**69**) can be synthesised by the reaction of C_{60} with CF_2ClCO_2Na in *o*-DCB in the presence of 18-crown-6.

This open monoadduct is the major reaction product (the yield of pure compound is 19%), whereas polyadducts $C_{60}(CF_2)_n$ ($n = 2, 3$) and minor [5,6]-open isomeric monoadduct are formed as by-products. The structure of the adduct **69** was reliably established by mass spectrometry (MALDI), ^{19}F and ^{13}C NMR, UV and IR spectroscopy and further confirmed by quantum chemical calculations.

VI. The formation of miscellaneous fulleroid structures

The reaction of C_{60} with diazide **70** is also accompanied by the opening of the fullerene sphere. The oxidation of the intermediate yields bislactam **71** with an open carbon cage capable of accommodating foreign small molecules (He or H_2) (Scheme 13).^{66, 67}

The addition of 1,4-bis(2-azidophenyl)buta-1,3-diene to fullerene is accompanied by complex rearrangements of both the fullerene cage and the addend finally resulting in an open derivative with two fused triazole rings.⁶⁸

A fulleroid keto lactam containing an 11-membered ring was synthesised⁶⁹ by the reaction of C_{60} with methoxyethoxymethyl azide.

A fulleroid with an eight-membered ring in the fullerene cage is obtained from the fullerene adduct with 1,3-cyclohexadiene by the photochemical intramolecular [4+4]-cycloaddition followed by the ring opening.^{70, 71}

Fulleroid structures with eight-membered rings in the fullerene cages were synthesised in a similar way by the reaction of C_{60} with nickel-⁷² and palladacyclopentadiene⁷³ derivatives and phthalazine.⁷⁴ The direction of the reaction of C_{60} with phthalazine (**72**) depends on the reaction conditions. In particular, a fulleroid structure **73** with an eight-membered ring in the fullerene cage is formed in 1-chloronaphthalene at 225 °C, whereas the mechanochemical solid-state synthesis yields fullerene dimer **74**. The authors argue that both processes start with the [4+2]-cycloaddition stage.^{74, 75} A tentative mechanism of these reactions for di- and triazines is depicted in Scheme 14.^{74–76} It involves the following principal stages: the [4+2]-cycloaddition of azines to the [6,6] bond of fullerene, the elimination of a nitrogen molecule, the radical [4+4]-cycloaddition⁷⁴ and finally the retro-[2+2+2]-process giving rise to the eight-membered ring.

Similarly, the thermal reaction of C_{60} with a 1,2,4-triazine derivative yields an open fulleroid **75** with an eight-membered ring.⁷⁵

Oxidation of all aforementioned open fulleroids with an eight-membered ring in the cage gives rise to open structures

Scheme 13

Scheme 14

with 12-membered rings^{75–78} (compound **76** can serve as an example). In addition, open structures with 11- and 13-membered rings in the fullerene core were obtained as oxidation products.⁷⁵

The reaction of fulleroperoxide $C_{60}(O)(OOBu^t)_4$ with aluminium chloride yields [5,6]- and [6,6]-oxahomo[60]fullerenes

owing to the oxidative cleavage of the [5,6] and [6,6] bonds in the fullerene cage.⁷⁹

There are experimental data^{80–82} confirming the existence of fluoro derivatives of [6,6]-open oxahomofullerene, in which the oxygen atom is bonded to the fluorinated carbon atoms of the fullerene core.

As has unexpectedly been found, the fluorination of C_{60} with binary fluorides with the general formula $Cs_xPbO_yF_z$ in vacuum at $550\text{ }^{\circ}\text{C}$ yields two stable polyfluorofullerenes $C_{58}F_{18}$ (**77**) and $C_{58}F_{17}CF_3$ (**78**), which represent open structures with a seven-membered ring (Fig. 1).⁸³

The structures of these compounds were established using mass spectrometry and ^{19}F NMR spectroscopy. The authors suggested that the C_{60} molecules lose a carbon atom through the steps of fluorine atom addition to the single C–C and the

Figure 1. The Schlegel diagrams of open fullerene derivatives $C_{58}F_{18}$ (**77**) (a) and $C_{58}F_{17}CF_3$ (**78**) (b). Black circles denote the addition sites of F atoms.

conjugated double C=C bonds followed by elimination of difluorocarbene.

VII. The formation of open homo[70]fullerenes

Chemistry of fullerene C₇₀ is studied in much less detail than that of fullerene C₆₀ due to its lower accessibility. Nevertheless, there are some examples of the formation of open structures derived from fullerene C₇₀.

In contrast to fullerene C₆₀, even monofunctionalisation of C₇₀ gives rise to mixtures of regioisomers due to its lower symmetry and larger differences in the reactivity of bonds. Four [6,6]-closed and four [5,6]-open isomeric adducts are possible.

Ulmer and Mattay⁴⁷ studied the reaction of C₇₀ with sulfonyl azides. It is of note that in this case, in contrast to the analogous reaction with C₆₀, only open adducts are formed. These reactions with azides **79a,b** afford two [5,6]-open isomers **80a,b** (in yields of 9% and 10%, respectively) and **81a,b** (in yields of 6% and 7%, respectively). Meanwhile, the reaction with azide **79c** yields only one fulleroid **80c** (12%).

The reaction of C₇₀ with PhHgCCl₂Br, which produces dichlorocarbene upon heating, affords⁸⁴ three monoadducts (**82**, **83**, **84**) in a ratio of 35:37:29 along with polyadducts. Among the products, the adduct **84** is a [5,6]-open fulleroid.

The reaction of C₆₀ with carbenes yields exclusively [6,6]-closed methanofullerenes, in contrast to the situation with C₇₀.

It is known that it is the [5,6] bond between the atoms C(7) and C(8) of fullerene C₇₀ that is involved in the addition of dehydrobenzene resulting in a [5,6]-closed adduct.⁸⁵ The authors suggested that the reaction of C₇₀ with dichlorocarbene begins with the carbene addition to the [5,6] bond to form a [5,6]-closed methanofullerene, which subsequently undergoes the norcaradiene rearrangement to afford a [5,6]-open fulleroid.

VIII. Theoretical investigations into the possible formation of open adducts in the cycloaddition reactions

The mechanisms of the 1,3-dipolar cycloaddition of diazo-methane, nitrile oxide and nitrene to fullerene C₆₀ have been simulated⁸⁶ by *ab initio* calculations at the B3LYP/6-31G(d,p)//AM1 level. All four possible types of the addition giving rise to [6,6]-closed, [6,6]-open, [5,6]-closed and [5,6]-open adducts have been considered. According to the calculations, the cycloaddition processes resulting in [5,6]-closed and [6,6]-open adducts are endothermic, whereas those resulting in [6,6]-closed and [5,6]-open adducts are exothermic. Among all the aforementioned dipolar ylides, the formation of [6,6]-closed adducts is most favourable from both the kinetic and thermodynamic viewpoints. This process has to follow the concerted mechanism. Qualitatively, this theoretical result can be explained by three factors:

- open structures are more strained than closed ones;
- three and two double bonds in five-membered rings appear in [5,6]-closed and [6,6]-open adducts, respectively, which is energetically unfavourable;
- the [6,6] bonds are characterised by higher electron density than the [5,6] bonds, which enables more efficient overlap of the frontier orbitals upon the [6,6]-addition.

Similar to the case of methanofullerenes and their open isomers, [6,6]-closed aziridinofullerenes are calculated to be more stable than [5,6]-azafulleroids, whereas [6,6]-open and [5,6]-closed isomers should be least stable.^{36, 87, 88}

IX. Conclusion

The literature data summarised in the present review suggest that the presently available experimental results and theoretical studies are insufficient for comprehensive understanding of the mechanisms governing the formation of fulleroids. Furthermore, some experimental facts and rationales for the formation of open structures contradict each other. Nevertheless, certain common regularities behind the cycloaddition processes resulting in open adducts can be revealed, which allows us to make some suggestions on the mechanism of the fulleroid formation.

1. With a high level of confidence it can be assumed that open structures are produced as a result of rearrangement or decomposition of an initially formed closed adduct in the majority of systems studied except for nitrile ylides and a few other nitrenes.

2. Very likely, synchronous addition to the [6,6] bond typically occurs, to yield closed fullerene adducts. This suggestion is supported by both theoretical calculations and numerous experimental data. The available data on the formation of open structures upon the addition of nitrenes, carbenes, diazo compounds, azides and dienes to fullerene suggest that a [6,6]-closed adduct is formed initially but then it is transformed into a fulleroid structure. Nevertheless, some theoretical calculations^{35, 36} point to possible direct addition of nitrenes to the [5,6] bond to yield an open adduct.

3. Open and closed isomers are prone to interconversions, which often do not follow simple structure–stability relationships. In the majority of cases, [6,6]-closed isomers are thermodynamically most stable. Open adducts can transform into closed ones by thermal, photochemical or electrochemical isomerisations; for the opposite process, only thermal rearrangements have been described.

4. Hardly there is a single mechanism explaining the formation of any open structure; several routes to fulleroids can be envisaged.

The first, most common mechanism consists of the thermal decomposition of fulleropyrazolines and fullerotriazolines initially formed upon cycloaddition. The extrusion of a nitrogen molecule proceeds simultaneously with the formation of a new C—X bond, three-membered rings involving a [5,6] bond being preferably formed due to the steric effects of the outgoing nitrogen molecule, *i.e.*, [5,6]-closed adducts are formed. They undergo rapid rearrangements into more stable [5,6]-open fulleroids (Scheme 15).

Scheme 15

An alternative is represented by thermal rearrangements of [6,6]-closed methanofullerenes bearing bulky substituents that induce substantial steric strains in the three-membered ring thus making [5,6]-open isomers thermodynamically more stable. The mechanism of such rearrangements remains unclear.

The third route consists of the formation of [5,6]-open adducts directly as a result of the 1,3-dipolar cycloaddition of specific nitrile ylides to fullerene. Probably, this reaction proceeds as successive addition of nitrile ylide in the biradical form, which gives rise to fulleroids.

There are a number of reactions resulting in the cleavage of a [6,6] bond in the fullerene sphere or even a few σ -bonds at once. These transformations follow different mechanisms that cannot be unified within a single principle. The C—C σ -bonds in a fullerene cage can be cleaved upon the oxidation, reduction or rearrangements.

Processes for obtaining linear block copolymers

T B Zheltonozhskaya, S V Fedorchuk, V G Syromyatnikov

Contents

I. Introduction	731
II. Sequential polymerisation of monomers by the same mechanism	731
III. Combination of different mechanisms of monomer polymerisation	748
IV. Matrix effects in block copolymerisation processes	759

Abstract. The advantages and disadvantages of modern methods of synthesis of linear block copolymers using identical and different mechanisms of monomer polymerisation are considered. The attention is focussed on the synthesis of block copolymers with a controlled molecular structure and narrow molecular-mass distribution. The matrix effects that appear in block copolymerisation due to chemical complementarity of the blocks are considered. The bibliography includes 393 references.

I. Introduction

Block type copolymers include a broad spectrum of heteropolymer compounds comprised of two (A, B), three (A, B, C) and more components. There are linear block copolymers, graft copolymers, star-like block copolymers and block copolymers of complex molecular architecture.¹ During the last fifteen years the synthesis of block copolymers has been considered in reviews and monographs (see, *e.g.*, Refs 2–11). This is due to considerable interest of researchers in such compounds and the development of new polymerisation techniques (first of all, controlled, or ‘pseudoliving’, radical polymerisation¹²) that open new possibilities for macromolecular design. Block copolymers are widely used in nanotechnologies;^{13–19} therefore, obtaining of almost monodisperse products with specified length and position of particular blocks requires improvement of relevant synthetic procedures.

Various methods of synthesis of linear di-, three- and multiblock copolymers of the types A-b-B, A-b-B-b-A, B-b-A-b-B, A-b-B-b-C, [A-b-B]_n, [A-b-B-b-C]_n and gradient (tapered) block copolymers of the A-b-(B-co-A)-b-B type are available at the moment. All of them can be divided into three main groups, namely, (i) sequential polymerisation of monomers by the same mechanism; (ii) monomer polymerisation by some mechanism; and (iii) interaction between reactive end groups of oligomers.

Received 31 January 2007

Uspekhi Khimii 76 (8) 784–820 (2007); translated by A M Raevskiy

This review concerns the first two groups of the methods of synthesis of linear block copolymers and manifestations of the matrix effects in block copolymerisation, where the first block already formed and the growing second block in the macromolecules of di- or triblock copolymers are chemically complementary. In each case we begin with a brief survey of the corresponding polymerisation mechanism and provide references to comprehensive sources.

II. Sequential polymerisation of monomers by the same mechanism

One-stage (or one-pot) synthesis of linear block copolymers is the most preferable method. The approach involves sequential introduction of different monomers into the reaction without changing external conditions (temperature, solvent, *etc.*) and leads to copolymers of necessary composition, with the desired block lengths and narrow molecular mass distribution (MMD). This can be done provided a correct choice of monomers using the ‘living’ ionic, ion-coordinative and ‘pseudoliving’ radical polymerisation.

1. Homogeneous and microheterogeneous radical polymerisation

Sequential free radical polymerisation was the first method used for the synthesis of linear block copolymers. A PMMA-b-PS block copolymer [PMMA is poly(methyl methacrylate) and PS is polystyrene] was synthesised in the early 1940s by adding styrene to PMMA macroradicals.²⁰ The technique was then used for preparation of various block copolymers of the A-b-B and A-b-B-b-A types.²¹ The mechanism, advantages and drawbacks of free radical polymerisation are well known.^{22, 23} The advantages of this block copolymer synthesis were found to be simplicity of practical implementation, high reaction rate and versatility, a great choice of the monomer pairs and weak dependence on the solvent nature and a presence of impurities.^{22, 23} However, poor controllability of the process owing to its high rate and various chain termination reactions leads to broad MMD and compositional inhomogeneity of resulting block copolymers and to the presence of homopolymer impurities. This makes the method unpromising compared to other techniques.

At the same time the advantages of the process (see above) still attract the attention of researchers, as indicated by studies of so-called ‘micellar’ radical polymerisation.^{24–27} At present, this technique is used only in aqueous medium for the synthesis of multiblock copolymers from polyacrylamide (PAA) or

polyacrylic acid (PAAc) and their hydrophobically modified derivatives. However, the one-stage synthesis and some degree of self-control in the system allow one to hope for progress of research in this field. Since only a few reviews of the method are available,^{24, 27} we will dwell on it in more detail.

The main idea of 'micellar' polymerisation, as applied to the synthesis of block copolymers rather than random ones from a mixture of monomers in the presence of radical initiators, is to separate the chemically different monomers in such a fashion that the system be characterised by micro-heterogeneity and no phase separation. This can be done using a mixture of amphiphilic monomers in water in the presence of surfactants (surfactant concentration should be higher than the critical micelle concentration).^{24–31} The mechanism of 'micellar' polymerisation is shown in Fig. 1. One (soluble) monomer is dissolved in the reaction medium and the other (insoluble) monomer is present in the hydrophobic core of surfactant micelles. The introduction of a soluble initiator (potassium or ammonium persulfate) causes polymerisation of the hydrophilic monomer and the hydrophilic block is thus formed. If the growing chain 'meets' a surfactant micelle, polymerisation of the hydrophobic monomer occurs and the hydrophobic block is formed. A multiblock copolymer is a final product.

Figure 1. Schematic representation of micellar radical polymerisation.³² Hydrophilic monomer molecules (1), hydrophobic monomer molecules (2) and surfactant micelles (3).

The authors of the pioneering studies (see, *e.g.*, Ref. 33) assumed that copolymers thus synthesised are comprised of randomly distributed hydrophilic and hydrophobic monomers. However, the properties of these copolymers were different from those of the random copolymers synthesised from the same monomers in a common solvent; therefore, a microblock structure of the copolymers was proposed.³⁰ This hypothesis was confirmed by the results of fluorescence studies of the copolymers containing acrylamide derivatives with styryl or pyrenyl groups as hydrophobic co-monomers.^{34, 35} These studies revealed one of the basic regularities of 'micellar' polymerisation, namely, the higher the hydrophobic monomer to surfactant ratio the longer the hydrophobic blocks.²⁴ The structure of micelles was determined. It was shown that the hydrophilic fragments of hydrophobic monomers are located in the hydrophilic 'corona', which also contains a small amount of hydrophilic monomers.^{24, 34} Hence, it was assumed that chain propagation through addition of hydrophobic monomers begins proceeds in the hydrophilic 'corona' of micelles.

Kinetic studies^{32, 36} of the reaction of acrylamide with *N*-(4-ethylphenyl)acrylamide in the presence of sodium

dodecyl sulfate (SDS) as surfactant revealed some additional features of 'micellar' polymerisation.

Solubilisation of hydrophobic monomers into micelles does not reduce their accessibility to the growing chains formed in the aqueous medium. Hydrophobic monomers are more rapidly added to the propagating chain in the initial steps of the process (the larger the hydrophobic monomer : surfactant ratio the higher the addition rate). This effect was explained by migration of the hydrophobic monomers between micelles that occurs three orders of magnitude faster than the addition of these monomers to the PAA' radical. As a result, during polymerisation of the hydrophobic monomer in one micelle the delivery of this monomer from other micelles is also possible. Therefore, in the initial stages of the process the number of monomer units in the hydrophobic blocks, which determines the lengths of such blocks, can be larger than the average number of hydrophobic monomers in the micelle. As the monomer in the micelles is consumed, the hydrophobic blocks become shorter. The major distinction between 'micellar' polymerisation and conventional emulsion polymerisation consists in the high surfactant to hydrophobic monomer ratio (from 15 : 1 to 70 : 1 by mass, see Ref. 32).

Pioneering studies on 'micellar' polymerisation were carried out using pairs of monomers with hydrophilic acrylamide (AAm) and hydrophobic *N*-mono-substituted AAm. In addition to *N*-(4-ethylphenyl)acrylamide (see the reaction shown above), *N*-benzylacrylamide³⁷ and *N*-octyl-, *N*-decyl- and *N*-dodecylacrylamide were used as hydrophobic co-monomers.³⁸ The hydrophilic/hydrophobic balance in the system was changed using not only insoluble *N*-(*n*-decyl)acrylamide or *N*-[4-(*n*-butyl)phenyl]acrylamide and soluble AAm, but also ionogenic monomers, such as sodium acrylate, sodium 3-acrylamido-3-methylbutanoate and sodium 2-acrylamido-2-methylpropanesulfonate.^{39, 40} Therefore, multiblock copolymers comprised blocks built of random copolymers of AAm with ionogenic co-monomers. Recently, alkyl methacrylates⁴¹ and *N,N*-dialkyl acrylamides^{42, 43} with growing hydrocarbon 'tails' have been used as hydrophobic monomers. Surfactants used in 'micellar' polymerisation include not only anionic SDS and sodium hexadecyl sulfate,^{32, 41–43} but also cationic surfactants, *e.g.*, hexadecyltrimethylammonium bromide.³⁷

2. 'Living' anionic polymerisation

Sequential 'living' anionic polymerisation is the most widely used method of synthesis of linear block copolymers of specified composition, molecular masses of constituent blocks and narrow MMD. Generally, 'living' polymerisation involves no chain termination and chain transfer stages, *i.e.*, the rate constants for these reactions are equal to zero ($k_t = 0$, $k_{tr} = 0$, see Refs 22, 23, 44 and 45). However, the 'living' mechanism is also retained if k_t and k_{tr} are much lower than the rate constant for chain propagation in accordance with the following criteria⁴⁶

$$\frac{k_p}{k_t} \geq \frac{\ln([M]_0/[M]_\infty)}{[I]_0}$$

$$\frac{k_p}{k_{tr}} \geq 10 \frac{[M]_0}{[I]_0} \sim 10 \bar{P}_n.$$

Here $[M]_0$ and $[I]_0$ are the initial concentrations of the monomer and initiator, respectively; $[M]_\infty$ is the concentration of monomer at the end of polymerisation and \bar{P}_n is the degree of polymerisation.

These relations represent two important conditions for 'livingness' of the system and obtaining of polymers with predictable structure and molecular mass. The third condition is fast initiation of the process.²² Exactly in this case the polymer chains are formed and grow simultaneously and the degree of polymerisation rises linearly with the monomer conversion (q)

$$\bar{P}_n = \frac{q[M]_0}{f_i[I]_0},$$

where f_i is the efficiency of initiation. In actual experiments, the condition $k_i = \infty$ (k_i is the rate constant for initiation) is not necessary for control of the molecular mass of a polymer; it is sufficient that inequality $k_i \geq k_p$ be valid.⁴⁶ Obtaining a narrow MMD requires that the following additional conditions be met: (i) equal activity of the growing chains or fast exchange between their active sites; (ii) irreversible chain growth (rate constant for chain propagation should be much higher than the rate constant for depolymerisation). Under these conditions the MMD of the polymer depends only on the degree of polymerisation (according to the Poisson distribution) and the M_w/M_n ratio (*i.e.*, polydispersity index) near to unity.

The 'livingness' of a system may be determined provided that individual or relative rate constants for chain growth, chain termination and chain transfer are known.^{47,48} These principles of retention of the 'living' mechanism mainly concern ionic processes characterised by long lifetimes of active species (this makes it possible to create the fast initiation mode) and by the absence of bimolecular chain termination reactions. Practical implementation of controlled, or 'pseudoliving', radical polymerisation is based on other principles (see below Sections II.5–II.7).

The mechanism of anionic polymerisation and the problems related to the activity of monomers, stability of macro-radicals, choice of initiators, solvents and temperature have been subjects of intensive research and discussion.^{22,23,44,46,49} We remind that anionic polymerisation assumes a nucleophilic attack of carbanion on the double bond of the monomer. Therefore, the monomer which has the most electrophilic double bond and provides greater stabilisation of the negative charge is the most reactive. The nucleophilicity of initiator should be high enough to initiate the process, but not too high to preclude the occurrence of side reactions. The formal criterion for sufficiently high nucleophilicity of the initiator is as follows: the pK_a of corresponding conjugate acid is equal to or higher than the pK_a value of the macroanion.^{22,50} Different forms of active species, namely, ion pairs, separated ion pairs and free ion pairs are in equilibrium. The rate of anionic polymerisation (k_p^-) in the free ion regime increases dramatically⁴⁴

$$k_p^- \approx 10^5 k_p^\pm.$$

To reduce this parameter and thus obtain a narrower MMD, lithium chloride is introduced into the system (this salt shifts the equilibrium from free ions to ion pairs).^{46,51,52}

Solvents used in anionic polymerisation processes include hydrocarbons and ethers. Protic and halogen-containing solvents that favour chain transfer or termination are not used. The 'living' anionic polymerisation requires pure reagents, inert atmosphere and correct choice of temperature conditions. Polymerisation of nonpolar monomers in nonpolar solvents is well controllable at moderate positive temperatures (from 0 to 50 °C). Anionic polymerisation of polar monomers in polar solvents occurs at much higher rates, being controllable at low temperatures (as rule, –78 °C). Chain termination is most often attained by adding methanol.

To obtain a copolymer of specified composition, particular block lengths and narrow MMD by 'living' anionic polymerisation, some additional problems should be solved. The main problem is the relative reactivity of monomers, which determines the possibility or impossibility of initiation of polymerisation of the second (and then third) monomer by macroanions formed in the polymerisation of the first (and the second) monomer.^{22,44,46} To this end, a series of monomers with increasing (electrophilic) reactivity are chosen. The process begins with polymerisation of the least reactive monomer that produces the most reactive macroanion; then increasingly more reactive monomers are added. The second problem is the side reactions occurring upon nucleophilic attack of macroanions on other reactive groups of the second (or third) monomer rather than the double bond. This is true for polymerisation of polar monomers containing hydroxyl, carbonyl, ester, amino and other groups.^{22,46} To prevent the process, the 'living' ends of a preceding block are protected by monomers with bulky groups in α -position (α -methylstyrene, α -diphenylethylene, *etc.*). In addition, only protected derivatives of common functional monomers, in particular, (meth)acrylic acids are employed instead of ordinary functional monomers.^{9,53,54} The protective groups include *tert*-butyl, trimethylsilyl, benzyl, alkoxyalkyl and other groups that are removed by polymer-analogous transformations of the block copolymer.⁹ Sequential anionic polymerisation requires a correct choice of reaction conditions (solvent and temperature) to avoid a heterogeneous process. This is particularly important in the synthesis of block copolymers with thermodynamically incompatible blocks. In this connection we will now consider particular syntheses of block copolymers.

a. Binary nonpolar/nonpolar block copolymers

Nonpolar monomers (styrene, dienes, *etc.*) and their macroanions formed in nonpolar solvents show almost identical reactivity in anionic polymerisation. The similarity of nucleophilicities of the styrene and diene macroanions is confirmed by almost equal pK_a values of conjugate acids (40–42 for styrenes and 43 for dienes).⁴⁶ Therefore, the order in which monomers are introduced is of no concern for the synthesis of corresponding di-, tri- and multiblock copolymers. Copolymers with nonpolar blocks were among the first copolymers synthesised.^{55–57} Among them, copolymers based on polystyrene (PS) and polybutadiene (PB) are best known. These are the first representatives of thermoplastic elastomers⁵⁸ that can absorb radiation.⁵⁹ Di-, tri- and multiblock copolymers of predictable structure and narrow MMD were synthesised by sequential addition of styrene (St) and butadiene (B) (*or vice versa*) in nonpolar solvents (hexane, benzene, *etc.*) in the presence of initiators (organolithium compounds). Moreover, by sequentially introducing (i) one monomer, (ii) an equivalent mixture of two monomers and (iii) the other monomer into the reaction one can obtain the so-called gradient triblock copolymers.^{60–62} Here, the PS and PB blocks are separated by a 'mixed' block characterised by a compositional gradient (transition from pure PS to pure PB) owing to the features of copolymerisation of the monomers.

Scheme 1

b. Binary nonpolar/polar block copolymers

Polar monomers are much more reactive than nonpolar ones in anionic polymerisation in contrast to the reactivity ratio of corresponding macroanions. Therefore, anionic polymerisation of polar and nonpolar monomers only leads to two types of block copolymers, namely, A-b-B and B-b-A-b-B (A is the hydrophobic block, which is formed first). Multiblock copolymers based on such pairs of monomers are synthesised using other techniques, *e.g.*, by the reaction between the end functional groups.

The block copolymers in question first of all include amphiphilic block copolymers based on nonpolar PS, PB and polyisoprene (PI) and on polar poly(ethylene oxide) (PEO). When comparing the nucleophilicities of the St and ethylene oxide (EO) macroanions using the $\text{p}K_{\text{a}}$ values of conjugate acids (41–42 and 16–18, respectively),⁴⁶ it is clear that sequential polymerisation of St and EO should develop very actively. The authors of Ref. 63 were among the first to obtain a PS-b-PEO diblock copolymer by sequential introduction of St and EO into the reactor in the presence of cumyl potassium as initiator.

This copolymer was also synthesised using toluene as solvent and 1-phenylethyl potassium as initiator.⁶⁴ Polymerisation of the first block was carried out at 10 °C. The kinetic curves showed an induction period of about 1 h, which reduced as the temperature increased and upon introduction of tetrahydrofuran (THF). Polymerisation of the second block was conducted at a higher temperature (30 °C); as a result, the EO conversion increased to 92%. To study the self-assembly of block copolymers into micelles, PS-b-PEO copolymers containing intermediate units bearing pyrene, anthracene and phenanthrene groups were synthesised.^{65,66} To improve the controllability of sequential polymerisation of St and EO, in the 1990s it was proposed to carry out the process in a polar solvent (THF) at low temperatures (−78 °C).^{67,68}

PEO-b-PS-b-PEO triblock copolymers were first prepared using sodium naphthalene as initiator and THF as solvent.⁶⁹ An analogous initiator (potassium naphthalene) was used in polymerisation of styrene and ethylene oxide.⁷⁰ However, in a series of other works^{64,71,72} the dimeric or tetrameric adducts

of sodium (potassium) naphthalene with α -methylstyrene were applied as initiators (Scheme 1). It was found that the reactivities of metal naphthalenes in block copolymerisation decrease as follows: potassium naphthalene > sodium naphthalene > lithium naphthalene. The last-named compound is a very poor initiator for the block copolymerisation of styrene and ethylene oxide.⁶⁴

Di- and triblock copolymers based on polydienes and PEO were synthesised by the same method using mono- and bifunctional organopotassium initiators. In this case the lithium initiator was inefficient. For instance, a PB-b-PEO copolymer was obtained in a polar medium (THF) in the presence of cumyl potassium as initiator,⁷³ while a PEO-b-PI-b-PEO triblock copolymer was synthesised by sequential polymerisation of isoprene and EO in THF with potassium naphthalene as initiator.⁷⁴ Polymerisation of the first block was carried out at −40 °C for 6 h and that of the second block was performed at 25 °C for 3 days. Raising the temperature was due to low solubility of PEO in THF.

The copolymers in question also include copolymers with PS, PB or PE (polyethylene) nonpolar blocks and polar blocks of polyalkyl (meth)acrylates and products of their hydrolysis [PAAc and polymethacrylic acid (PMAAc) or their salts]. Note that methacrylates treated as conjugate acids with respect to macroanions formed from them are characterised by $\text{p}K_{\text{a}}$ values of 27–28,⁴⁶ which is much lower than the $\text{p}K_{\text{a}}$ values of styrene and dienes. Therefore, macroanions based on alkyl(meth)acrylates are incapable of initiating anionic polymerisation of nonpolar monomers. The first syntheses of di- and triblock copolymers based on PS and poly(*tert*-butyl acrylate) (PTBA) were reported in the 1990s.⁷⁵ Sequential anionic polymerisation was conducted in THF in the presence of LiCl at −78 °C.

Scheme 2

The block copolymer precursors were then hydrolysed in toluene at 80 °C in the presence of *p*-toluenesulfonic acid as catalyst to obtain the PS-b-PAAc and PAAc-b-PS-b-PAAc polyacid blocks. The synthesis of PS-b-PAAc and PS-b-PMAAc copolymers with controlled molecular structure and narrow MMD following Scheme 2 was simultaneously

reported by three research groups.^{68,76,77} The side reactions characteristic of 'living' PS chains in the polymerisation of (meth)acrylates were avoided by 'capping' the ends of macroanions by 1,1-diphenylethylene^{76,77} or α -methylstyrene.⁶⁸ This synthetic procedure is used to change the hydrophilic/hydrophobic balance in block copolymers; this is a basic technique in the design of micellar structures sensitive to the pH value of the medium and to salt additives.^{78,79} The lengths of the PS and PAAc blocks varied over a rather wide range, but the polydispersity index of the block copolymers was low ($M_w/M_n = 1.05-1.21$).⁸⁰ An alternative procedure of PTBA transformation into PAAc involves prolonged (more than 10 h) hydrolysis in dioxane at 100 °C in the presence of HCl.⁷⁹ PAAc or PMAAc can also be converted to polyacrylates or polymethacrylates by adding alkali.⁷⁹

PE-b-PMAAc and PMAAc-b-PE-b-PMAAc block copolymers were synthesised by sequential anionic polymerisation involving two polymer-analogous reactions.⁸¹ First, anionic polymerisation of butadiene and *tert*-butyl methacrylate (TBMA) in the presence of mono- or bifunctional initiators resulted in PB-b-PTBMA and PTBMA-b-PB-b-PTBMA copolymers. This was followed by hydrogenation of PB using Wilkinson's catalyst and hydrolysis of PTBMA.

Sequential anionic polymerisation of styrene and alkoxyethyl methacrylates, namely, 1-(ethoxy)ethyl methacrylate (EEMA) and 1-(*tert*-butoxy)ethyl methacrylate (TBEMA), was carried out not only at -78 °C and -35 °C, but also at 0 °C.⁸² A well-controlled process resulted in PS-b-PEEMA and PS-b-PTBEMA copolymers of predictable molecular architecture.

Yet another group of copolymers belonging to this class comprises diblock copolymers based on PS or poly(*tert*-butylstyrene) (PTBS) and cationic polyelectrolytes, namely, poly(2-vinylpyridine) (P2VP), poly(4-vinylpyridine) (P4VP), poly[5-(*N,N*-diethylamino)isoprene] and their quaternised derivatives. They are of interest as stabilisers of colloidal dispersions,⁸³ however, the attention was focussed on their micellar structures^{84,85} and films showing microphase separation.⁸⁶ It should be noted that the pK_a values of 2-vinylpyridine and 4-vinylpyridine treated as conjugate acids with respect to corresponding macroanions are much lower (29 and 26, respectively) than the pK_a values of styrene and dienes.⁴⁶ Therefore, polyvinylpyridine macroanions cannot initiate polymerisation of the nonpolar monomers mentioned above. A typical synthetic route to PS-b-P2VP, PS-b-P4VP and PTBS-b-P2VP assumes sequential introduction of nonpolar and polar monomers in THF, the presence of *n*-butyllithium or *sec*-butyllithium as initiator and a low temperature (-78 °C).^{86,87} Yet another initiator, namely, an adduct of *sec*-butyllithium with 1-methylstyrene, was used⁸⁴ to obtain block copolymers with $M_w/M_n = 1.13-1.14$. When needed, the polyvinylpyridine block was treated with methyl iodide in ethanol, which resulted in a strong cationic polyelectrolyte.⁸⁴

Basic monomers, namely, 5-(*N,N*-dialkylamino)isoprenes, have been synthesised quite recently.^{88,89} Two new amphiphilic block copolymers having poly[5-(*N,N*-diethylamino)isoprene] (PDEAI) blocks, PS-b-PDEAI and PDEAI-b-PS-b-PDEAI, were prepared and studied.⁹⁰⁻⁹² The procedure for the synthesis of the triblock copolymer consisting of sequential introduction of diethylaminoisoprene, styrene and again diethylaminoisoprene⁹¹ points to almost equal reactivities of the monomers. The polymerisation was carried out in benzene at 10 °C using *sec*-butyllithium as initiator. The copolymers had narrow MMDs ($M_w/M_n = 1.2-1.4$, $M_n = 1.36 \times 10^4-2.68 \times 10^4$).^{91,92} Quaternisation of the copolymers with dimethyl sulfate gave copolymers having strong cationic polyelectrolyte blocks.

c. Binary polar/polar block copolymers

This group comprises block copolymers based on PEO and poly[alkyl (meth)acrylates]. Comparison of the pK_a values of alkyl (meth)acrylates and oxiranes showed that alkyl (meth)acrylate macroanions should be more reactive than PEO macroanions. Indeed, 'living' poly[alkyl (meth)acrylates] readily initiate the polymerisation of EO.⁹³ However, when using methyl methacrylate (MMA), one can obtain inhomogeneous PMMA-b-PEO copolymers due to side reactions between the 'living' end groups of PEO and the methyl ester groups of PMMA. The monomers can also be introduced in the reverse order. For instance, efficient polymerisation of MMA in THF using PEO disodium alkoxide was reported.⁹⁴ This was explained by the fact that the nucleophilicity of the macroanions is higher than that of the anions at one chain end. Sequential anionic polymerisation of EO and MMA faces two problems.⁹⁵ One of them consists in low solubility of PEO in THF. To avoid the formation of a heterogeneous system, polymerisation of the second block should be carried out at $T > 20$ °C. Under these conditions for polymerisation of MMA the chain termination and chain transfer reactions seem to be unavoidable. The second problem is transesterification between the PEO macroanion and MMA. It was found that by protecting the ester groups of (meth)acrylates with *tert*-butyl groups it is possible to preclude the formation of side products and to obtain copolymers with a desired structure and narrow MMD irrespective of the order of introduction of the monomers. In particular, polymerisation of EO and TBMA in THF at room temperature using cumyl potassium as initiator led not only to diblock copolymers characterised by narrower MMD ($M_w/M_n = 1.4-1.7$) compared to the polymerisation of EO and MMA, but also to multiblock copolymers.⁹⁶ Analogously, sequential anionic polymerisation of the same monomers was used for the synthesis of all possible di- and triblock copolymers, that is, PEO-b-PTBMA, PTBMA-b-PEO, PEO-b-PTBMA-b-PEO and PTBMA-b-PEO-b-PTBMA⁹⁷ with diphenylmethyl potassium and potassium naphthalene as initiators. The synthetic procedure involved polymerisation of TBA at -78 °C; after introduction of ethylene oxide the temperature was raised to 35 °C. Analysis of the reaction products by gel-permeation chromatography and by NMR and IR spectroscopies revealed no side processes and no homopolymers. Quantitative hydrolysis of *tert*-butyl ester groups of PTBMA led to formation of new block copolymers containing PMAAc.

The known non-ionogenic di- and triblock copolymers based on hydrophilic PEO and hydrophobic poly(propylene oxide) (PPO) should be pointed out. They are produced on a large-scale basis under the trademarks 'Proxanols', 'Plurionics' and 'Poloxamers' mainly by sequential anionic polymerisation.²² These amphiphilic block copolymers can form micelles⁹⁸ and complexes with many organic substances^{99,100} including pharmaceuticals.¹⁰¹

A quite interesting group of copolymers is built of PEO and cationic P2VP or P4VP blocks. There are few studies on the synthesis of such compounds, although their micelle-forming properties in aqueous solutions have been a subject of intensive research.¹⁰² Since 2-vinylpyridine and 4-vinylpyridine (VP) are characterised by much higher pK_a values than oxiranes (29 and 26 vs. 16-18, respectively),⁴⁶ one can assume that PVP macroanions will be more reactive than PEO macroanions. This requires that the basic monomer be polymerised first. This order of introduction of the monomers was used in the synthesis of P2VP-b-PEO diblock copolymer.^{102,103} The polymerisation was carried out in THF at -78 °C with cumyl potassium/18-crown-6 ether complex as initiator.¹⁰³ In spite of a narrow MMD of the P2VP blocks, not all 'living' P2VP chain ends initiated the polymerisation of EO. As a result, the

Scheme 3

Scheme 4

Scheme 5

reaction product contained up to 30 mass% of P2VP homopolymer.

Recently, there has been search for new polar hydrophobic polymer blocks to obtain micelle-forming biocompatible and biodegradable materials by copolymerisation with PEO. One of such polymers is poly(ϵ -caprolactone) (PCL). Copolymers PEO-b-PCL that were synthesised and studied recently^{104,105} are promising for the design of macromolecular therapeutic systems.¹⁰⁶ It should be noted that among the monomers listed in Ref. 46, lactones have the lowest $\text{p}K_a$ values in the range from 6 to 8, *i.e.*, their macroanions have the lowest nucleophilicity. Yet another biodegradable hydrophobic polymer is poly-L(or DL)-lactide (PL),¹⁰⁷ which is also widely used as a constituent of block copolymers. For instance, copolymers PEO-b-PL and PL-b-PEO-b-PL were synthesised and studied.^{108,109} However, the synthetic procedure did not involve sequential anionic polymerisation; macroinitiators based on commercially available polyethylene glycol (PEG) ($M_n = 4 \times 10^3$) or PEG monomethyl ether (PEGME, $M_n = 5 \times 10^3$) were employed. The hydroxyl groups of PEG or PEGME were activated by metallic potassium (in THF)¹⁰⁸ or tin 2-ethylhexanoate,¹⁰⁹ converted to mono- or bifunctional initiators and then anionic ring-opening polymerisation of DL- or L-lactide (Scheme 3) was carried out.

Copolymers PEO-b-PL and PL-b-PEO-b-PL were characterised by M_n of $(5.8-19.2) \times 10^3$ and $(6.0-17.4) \times 10^3$, respectively.¹⁰⁹ Analogous triblock copolymers¹⁰⁸ had similar molecular masses; however, the MMD was broad ($M_w/M_n = 3.04-4.21$) due to intermolecular (Scheme 4) and intramolecular (Scheme 5) re-esterification reactions during the polymerisation of D,L-lactide.

By combining sequential anionic polymerisation and polymer-analogous transformations it is possible to form copolymers containing anionic PAAc or PMAAc blocks and non-ionogenic thermally sensitive *N*-mono- or *N,N*-dialkyl-substituted acrylamide blocks.⁹ They are called the double stimuli-responsive copolymers, because the state of the polyacid blocks is determined by the pH value, while the state of the substituted PAA blocks is governed by temperature. The first stage involved block copolymerisation of protected *tert*-butyl acrylate (TBA) with *N,N*-diethylacrylamide (DEAA)⁹ initiated by a mixture of diphenylhexyl lithium with LiCl. The polymerisation of the first block was followed by introducing triethylaluminium into the system. In the second stage the PTBA-b-PDEAA copolymer was hydrolysed to obtain the PAAc-b-PDEAA copolymer. A similar technique was used for the

synthesis of PTBMA-b-PDMAA copolymers [PDMAA is poly(*N,N*-dimethylacrylamide)] with different block lengths.¹¹⁰ First, *tert*-butyl methacrylate was polymerised under the action of an oligostyryllithium adduct with 1,1-diphenylethylene in the presence of LiCl ($T = -30$ °C). Then, the active centres were modified with an excess of diethylzinc at -40 °C, the temperature was reduced to -78 °C, *N,N*-dimethylacrylamide was introduced and the process continued. Block copolymers thus obtained had $M_n = 3.7 \times 10^4$ ($M_w/M_n = 1.33$) and 1.542×10^5 ($M_w/M_n = 1.28$) and contained 48.7 mass % and 14.3 mass % of PDMAA, respectively.

Amphoteric block copolymers, or copolyampholytes, containing acid (PAAc or PMAAc) and basic {poly[*p*-(*N,N*-dimethylamino)styrene] (PDAS), PVP and poly[2-(dimethylamino)alkyl methacrylates]} blocks occupy a special position. They are synthesised by sequential anionic polymerisation of the basic monomers and protected alkyl (meth)acrylates followed by acid hydrolysis of the polyester blocks. Amphoteric diblock copolymers P2VP-b-PMAAc and P2VP-b-PAAc were first obtained¹¹¹ by sequential polymerisation of 2-VP and trimethylsilyl methacrylate (TMSMA) or TBA followed by hydrolysis of the protected ester groups. A P4VP-b-PMAAc copolymer synthesised in a similar fashion was converted to poly(4-vinyl-1-methylpyridinium chloride)-b-PMAAc copolymer by quaternisation of pyridine groups (Scheme 6).^{112,113} When obtaining the PTMSMA-b-PDAS and PTBMA-b-PDMAEMA copolymers {PDMAEMA is poly[2-(dimethylamino)ethyl methacrylate]},^{114,115} the order of introduction of the acid and basic monomers was reversed. Therefore, the macroanions formed by the basic monomers and protected alkyl (meth)acrylates have similar nucleophilicities. Note that the PTBMA-b-PDMAEMA copolymer¹¹⁵ had a desired molecular mass ($M_{n,\text{exp}} = 5.4 \times 10^3$ from gel-permeation chromatography data, *cf.* $M_{n,\text{theor}} = 5.5 \times 10^3$) and a narrow MMD ($M_w/M_n = 1.08$). The initiation efficiency of the polymerisation of 2-(dimethylamino)ethyl methacrylate by PTBMA macroanions was $f_i = 0.92$. Copolyampholytes PMAAc-b-PDMAEMA were also synthesised and studied.¹¹⁶⁻¹¹⁸ A similar synthesis of the di- and triblock copolymers A-b-B, A-b-B-b-A and B-b-A-b-B with poly[2-(dimethylamino)alkyl methacrylate] (alkyl = ethyl, propyl and 1-ethylmethyl) groups as the A component and sodium polymethacrylate as the B component was reported.¹¹⁹ Polymerisation was carried out in THF at -78 °C with diphenylmethyl lithium as initiator and LiCl as regulator.

d. Nonpolar/polar block terpolymers

One of the first reviews concerning the synthesis of linear block terpolymers by sequential anionic polymerisation was reported in 1980.¹²⁰ In the last decade, considerable advances in the design of A-b-B-b-C copolymers with controlled molecular structures were made using this technique. As previously, the key factor in the design of the synthetic procedure is the relative reactivity of monomers and their macroanions.

A few studies on the synthesis of A-b-B-b-C-terpolymers containing two nonpolar blocks have been reported so far. Recently, PS-b-PB-b-PMAAc terpolymers were obtained by hydrolysing PS-b-PB-b-PTBMA terpolymers synthesised by sequential polymerisation of St, butadiene and TBMA.¹²¹ It was found that the presence of a polar (ionogenic) and two nonpolar blocks ('hard' PS and 'soft' PB) in the same macromolecule leads to a specific morphology of triblock copolymer films, which is different from that of diblock copolymer films. To study the morphology of terpolymers with two nonpolar blocks, a PB-b-PS-b-PEO terpolymer was synthesised by sequential polymerisation with *sec*-butyllithium as initiator.¹²² Hydrogenation of the PB block in the presence of Wilkinson's catalyst gave a PE-b-PS-b-PEO terpolymer with two crystallisable end blocks.

Terpolymers having one nonpolar PS or PB block are of much greater interest. The simplest task is to synthesise terpolymers with a side nonpolar block, which in this case is polymerised first and its highly reactive 'living' chain end initiates the polymerisation of a broad spectrum of polar monomers. This method was employed to obtain a PS-b-PMMA-b-PTBA terpolymer.¹²³ The polymerisation of St in cyclohexane was initiated by *sec*-butyllithium. Once formed,

the PS block was 'capped' with α -methylstyrene to avoid side reactions in the polymerisation of MMA. Then, the third monomer was added. Subsequent hydrolysis of TBA units with *p*-toluenesulfonic acid in toluene (at 100 °C for 5 h) afforded the PS-b-PMMA-b-PAAc terpolymer. It was shown that no hydrolysis of MMA units occurs in the polymer-analogous reaction. This polymerisation scheme was implemented in the synthesis of PS-b-PMMA-b-PEEMA terpolymer⁸² with MAAc protected by 1-(ethoxy)ethyl groups as the third monomer. It was possible to introduce the second and third monomers in any order and thus to change the position of the PMAAc ionogenic block formed upon hydrolysis of the protected units. Terpolymers thus obtained had desired compositions and narrow MMDs. PS-b-PMAAc-b-PMMA terpolymers with central ionogenic block and similar chemical structure were also synthesised.¹²⁴ The ability of the A-b-B-b-C terpolymers comprised of one nonpolar, one polar hydrophobic and one polar hydrophilic (ionogenic) block to form specific micellar structures in aqueous and non-aqueous media attracts the attention of researchers. Such block copolymers may be used as nanoreactors and nanocontainers.^{13, 14, 17, 18}

Recently, the synthesis of terpolymers with one nonpolar and two polar hydrophilic blocks by sequential anionic polymerisation has been part of research on novel micellar structures. A number of studies in this field concern the synthesis and investigation of PS-b-P2VP-b-PEO terpolymers with the polybasic central block.^{125–129} Monitoring of changes in the molecular masses and MMDs of the blocks in the course and after the synthesis by gel-permeation chromatography and ¹H NMR spectroscopy gave $M_{n\text{PS}} = 2 \times 10^4$ ($M_w/M_n = 1.07$), $M_{n\text{P2VP}} = 1.4 \times 10^4$ and $M_{n\text{PEO}} = 2.6 \times 10^4$, the polydispersity index of the terpolymer was 1.1 (Ref. 128). The terpolymers formed specific core-shell-corona aqueous micelles.^{127, 130}

A series of studies is devoted to the synthesis of ampholytic block terpolymers. The PS-b-P2VP(P4VP)-b-PMAAc block copolyampholytes were prepared by conventional technique.¹³¹ Sequential polymerisation of St, VP and protected MA gave a precursor of terpolymer and subsequent acid hydrolysis of the protected units resulted in the copolyampholyte. Attempts to synthesise a triblock copolyampholyte with the nonpolar central PS block were reported.^{132, 133} This is a severe problem because P2VP (or P4VP) and protected polymethacrylate macroanions cannot initiate the polymerisation of St. To overcome the difficulty, 5-(*N,N*-dimethylamino)isoprene (DMAI) was used instead of 2-VP (or 4-VP).¹³² The reactivity of DMAI in anionic polymerisation is similar to that of St; therefore, no bifunctional initiator was used in the synthesis of the PDMAI-b-PS-b-PMAAc terpolymer with the central PS block. Sequential polymerisation of the necessary monomers in the reactor afforded a precursor, PDMAI-b-PS-b-PTBMA terpolymer, which was hydrolysed to obtain the PDMAI-b-PS-b-PMAAc copolyampholyte. Another procedure was employed for the synthesis of a copolyampholyte with the side P4VP block.¹³³ In the first stage, a PTBA-based macromonomer with the terminal double bond was prepared. Then, initiation of the macromonomer and anionic polymerisation of St and P4VP (Scheme 7) were carried out.

The process was performed in THF at -78°C using an adduct of *sec*-butyllithium with α -methylstyrene as initiator in the presence of LiCl. The copolyampholyte samples were characterised by narrow MMD ($M_w/M_n = 1.09–1.11$, $M_n = 5.26 \times 10^4–9.86 \times 10^4$).

e. Polar block terpolymers

Presently, a few terpolymers formed by various methacrylates are available. The monomers used are similar in reactivity; therefore, by varying the order of their introduction one can form hydrophilic and hydrophobic blocks at necessary positions. In particular, terpolymers comprised of

x is the number of molecules of the capping agent (α -methylstyrene) added.

poly[2-(perfluorobutyl)ethyl methacrylate], PTBMA and poly[2-(trimethylsilyloxy)ethyl methacrylate] (PTMSOEMA) were synthesised; the monomers were introduced in different order.¹³⁴ Poly[2-(hydroxy)ethyl methacrylate] blocks were prepared by selective hydrolysis of protected PTMSOEMA units. The microphase structure of terpolymer films was studied.¹³⁵

3. Anionic group transfer polymerisation

Anionic group transfer polymerisation (GTP) discovered in 1983 (Ref. 136) is widely used for the synthesis of di- and triblock copolymers based on polyacrylates and polymethacrylates at room temperature or at somewhat higher temperatures. The key condition for practical implementation of a sequential process is to use monomers with similar reactivities. Opinions differ on the mechanism of this kind of polymerisation.^{22, 23, 137–139} Researchers who proposed the GTP technique explained the ‘living’ mechanism of the polymerisation of methacrylates in the presence of initiators (*O*-silyl ketene ketals) and catalysts [strong nucleophiles, *e.g.*, HF_2^- with tris(dimethylamino)sulfonium or tetrabutylammonium counterions] by the formation of intermediate eight-membered ring accompanied by transfer of the trimethylsilyl group.^{22, 46} This is the so-called associative mechanism.

However, more recently yet another (dissociative) mechanism was proposed with allowance for a lower rate of the process compared to the classical anionic polymerisation of methacrylates, a narrower MMD of polymers and nearly identical stereochemical structure of polymers synthesised by both methods (instead of predominant isotacticity expected for GTP).^{140, 141} It assumes that GTP occurs as anionic polymerisation in which a small amount of enolate anions is in equilibrium with the vast majority of silyl ketene ketal end groups.⁴⁶

Owing to this equilibrium the lifetime of the enolate anions is shortened, which favours retardation of GTP compared to the classical anionic polymerisation. The equilibrium (see Scheme 8) and its shift towards a particular type of active centres also provides an explanation for the lower polydispersity of GTP products. Since here the role of counter-ions is played by tris(dimethylamino)sulfonium or tetrabutylammonium cations, solvent-stabilised free anions should act as the chain growth centres.

At present, GTP is treated as classic anionic polymerisation controlled by reversible chain termination (dissociative mechanism) and/or degenerate chain transfer.⁴⁶ Note that direct group transfer polymerisation of AAc and MAAC is also impossible; the PAAc and PMAAC blocks are prepared by GTP of corresponding protected derivatives followed by removal of the protective groups using relevant chemical reactions.⁹ Now we will consider some examples of the GTP-synthesis of block copolymers.

a. Binary block copolymers

Amphiphilic diblock copolymers PMMA-*b*-PMAAC were synthesised¹⁴² using GTP and a polymer-analogous reaction. Sequential polymerisation of MMA and benzyl methacrylate (BMA) was followed by hydrolysis of the protected units. Diblock copolymers PMMA-*b*-PAAc were prepared in a

similar fashion to study the micelle-forming properties.¹⁴³ The AAc units were protected with *tert*-butyl groups. Triblock copolymer PTBMA-*b*-PMMA-*b*-PTBMA was synthesised from the same monomers (MMA and TBMA) by the GTP method.¹⁴⁴ The copolymer with the central hydrophobic block surrounded by hydrophilic blocks was isolated upon hydrolysis of PTBMA.

New diblock copolymers with various basic blocks were synthesised by sequential GTP of 2-(imidazol-1-yl)ethyl methacrylate and DMAEMA at 25 °C using the 1-methoxy-1-trimethylsiloxy-2-methylpropene–tetrabutylammonium benzoate system as initiator.¹⁴⁵ The basic block containing imidazole groups showed high catalytic activity in the hydrolysis of *p*-nitrophenyl acetate. Two more copolymers with the basic blocks, namely, PDMAEMA-*b*-PDEAEMA {PDEAEMA is poly[2-(ethylamino)ethyl methacrylate]} and PDEAEMA-*b*-PMEMA {PMEMA is poly[2-(morpholino)ethyl methacrylate]} were obtained by the GTP technique.^{146, 147}

Diblock copolyampholytes containing PDMAEMA and PMAAc were synthesised by the same method using protected benzyl methacrylate monomer¹⁴⁸ and tetrahydropyranyl methacrylate (THFMA).¹⁴⁹ In the latter case, poly-THFMA blocks were readily hydrolysed at room temperature.

b. Block terpolymers

Model block terpolymers poly[(2-ethylhexyl acrylate)-*b*-PMMA-*b*-PAAc with gradually increasing hydrophilicity of the blocks were synthesised by sequential polymerisation of 2-ethylhexyl acrylate with MMA and TBA followed by hydrolysis of the PTBA block.¹⁵⁰ The GTP technique was used for the synthesis of not only diblock, but also triblock copolyampholytes containing two unlikely charged blocks (PDMAEMA and PMAAc) and a hydrophobic PMMA block.¹⁴⁸ The position of the hydrophobic block strongly affected the micelle-forming properties of the copolyampholytes.¹⁵¹ Triblock copolyampholytes containing the same polymeric components were also obtained using THFMA as the protected monomer and all possible types of introduction of the monomers.¹⁵² Polymerisation was followed by hydrolysis of the PTHFMA block in a weak acid medium.

4. 'Living' cationic polymerisation

'Living' cationic polymerisation makes the design of the chemical structure of block copolymers more versatile, because there exist monomers (isobutylene, alkyl vinyl ethers, *etc.*) that are better polymerised by the cationic mechanism.^{22, 23, 44, 45} Specific features of cationic polymerisation and the stages, kinetics and conditions for carrying out the process have been well documented;^{22, 45, 46} because of this, we will only dwell on the key steps. Cationic polymerisation represents a sequential addition of monomers possessing the properties of nucleophiles and capable of stabilising the positive charge to carbocations.^{22, 23, 45} The development of the process requires that the double bond be the most nucleophilic fragment of the monomer molecule. Traditionally used initiators of 'living' cationic polymerisation include protic acids and products of the interaction of Lewis acids with water, alcohols, ethers and alkyl halides. High reactivity of carbocations predetermines a high rate of chain growth, which makes the process poorly controllable. In addition, β -H atoms become highly mobile; therefore, chain transfer by abstraction of β -protons from the growing carbocations is a typical side reaction occurring in the course of cationic polymerisation of α -olefins.⁴⁶ However, the side reactions can be suppressed by carrying out polymerisation at low temperatures in hydrocarbons and in chlorine- and nitrogen-containing solvents.¹⁵³ Protic solvents and amines that favour chain transfer and chain termination should not be used.

In cationic polymerisation the active centres include the contact and free ion pairs that coexist in equilibrium. The solvent separated ion pairs are not involved in polymerisation processes.⁴⁶ The reactivities of ion pairs and free ions in cationic polymerisation are almost equal ($k_p^\pm \approx k_p^+$), but these species have different lifetimes.^{154, 155} This leads to products of higher polydispersity compared to anionic polymerisation products. An important condition for providing the 'livingness' of the process is reduction of the polymerisation rate. This is achieved by shift of the equilibrium between the active centres towards the contact ion pairs. The growth centres are 'deactivated' by introducing salts (containing the same counterion as the active centre)¹⁵⁶ and nucleophiles (Nu)⁴⁶ that interact with carbocations and form stable ion pairs.

Binding of carbocations to salts or nucleophiles under fast exchange between the active and 'sleeping' centres causes the rate of the process and the polydispersity of macrochains to decrease. Yet another important condition is the reversible character of chain termination. In cationic polymerisation, in the absence of impurities and chain termination agents, the chain growth is mainly ceased owing to collapse of the ion pair,⁴⁶ namely, formation of a covalent bond between the carbocation and counterion (or its fragment²²). However, in some cases the reaction is reversible due to, *e.g.*, the addition of halide ions from the $SnCl_5^-$, $SbCl_6^-$, $SnBr_5^-$, BCl_4^- and BBr_4^- counterions. In such systems, one can hope for controllable character of polymerisation.

The design of a sequential chain in the synthesis of block copolymers using cationic polymerisation has a number of specific features. In particular, the most reactive (most nucleophilic) monomer is most often polymerised first (Scheme 9). This favours fast and quantitative initiation. The polymerisation of the more reactive monomer requires a lower temperature. To activate the polymerisation of the other (less reactive) monomer, the temperature and/or concentration of the co-initiator is increased (Scheme 10).⁴⁶

Scheme 9

Scheme 10

Numerous examples of the synthesis of the A-b-B, A-b-B-b-A, B-b-A-b-B and A-b-B-b-C copolymers by sequential cationic polymerisation are available in the literature. In the early studies, sequential polymerisation of THF and 3,3-bis(chloromethyl)oxetane was carried out.¹⁵⁷ More recently, poly(*p*-methoxystyrene)-*b*-poly(isobutyl vinyl ether) diblock copolymers were prepared.¹⁵⁸ Now we will consider the synthesis of particular block copolymers.

a. Binary nonpolar block copolymers

Studies^{159–162} on the synthesis of block copolymers by sequential cationic polymerisation revealed the possibility of introducing the monomers in the reversed order starting from the less reactive monomer provided that the first block is ‘capped’ with a readily ionisable monomer that cannot be polymerised. This technique was used to obtain almost monodisperse ($M_w/M_n < 1.1$) di- and triblock copolymers containing polyisobutylene (PIB) and poly(1-methylstyrene) (PMS) or other styrene derivatives. Initially, HCl and TiCl_4 were used as initiator and co-initiator, respectively. The polymerisation of IB was followed by ‘capping’ the PIB block with 1,1-diphenylethylene and deactivation of the first Lewis acid (TiCl_4) with titanium isopropoxide or butoxide [$\text{Ti}(\text{OR})_4$]. Then, the second Lewis acid (SnBr_4) was added and the styrene derivative was polymerised. The efficiency of polymerisation initiation of the second monomer approached 100%. At the same time a study on the synthesis of PS-*b*-PMS-*b*-PS copolymers from styrene and *p*-methylstyrene (*p*-MS) characterised by similar reactivities using a bifunctional initiator showed that the resulting triblock copolymer had a narrower MMD ($M_w/M_n = 1.15$) if the more reactive *p*-MS was polymerised first.¹⁶³ When styrene was polymerised first, the product was characterised by $M_w/M_n = 1.34$.

Sequential cationic polymerisation was used for the synthesis of PS-*b*-PIB-*b*-PS triblock copolymers with nonpolar components, which possessed the properties of thermoelastic elastomers.^{164–168}

b. Binary nonpolar/polar block copolymers

Syntheses of block copolymers based on PS, PMS or PB (nonpolar blocks) and on various poly(vinyl ethers) (polar blocks) have been reported. Cationic polymerisation of the following pairs of monomers was studied: *p*-MS–isobutyl vinyl ether (IBVE),¹⁶⁹ St–methyl vinyl ether (MVE), St–chloroethyl vinyl ether (CEVE)¹⁷⁰ and α -MS–CEVE.¹⁷¹ The best results (narrower MMD) were obtained where more reactive monomers, namely, IBVE and MVE, were polymerised first. The technique was used to obtain¹⁷⁰ a PMVE-*b*-PS copolymer with controlled molecular structure and a polydispersity index of 1.33, although the temperature and the Lewis acid concentration were increased in the second stage (see Scheme 9). Polymerisations of the less reactive monomers in the first stage led to mixtures of block copolymers with homopolymers formed by the more reactive monomers in second stage.^{169, 170} Since α -MS and CEVE had almost identical reactivities, their block copolymerisation could be performed in any order.¹⁷¹

Sequential cationic polymerisation starting with the less reactive monomer was employed for the synthesis of PIB-*b*-PMVE copolymers with a very narrow MMD ($M_w/M_n < 1.1$).¹⁷²

c. Binary polar/polar block copolymers

Typical representatives of this group are diblock copolymers based on various polyethers. Copolymers PMVE-*b*-PCVE [poly(cetyl vinyl ether)] having two polyether blocks ($M_n < 3.5 \times 10^3$), a narrow MMD and controllable composition were obtained¹⁷³ using a HI/ZnI_2 mixture as initiator in the early stage of research in this field.¹⁷³ Sequential cationic

polymerisation starting from the most nucleophilic monomer was employed for the synthesis of diblock copolymers comprised of poly(isobutyl vinyl ether) and poly(*p*-methoxystyrene) (PMOS),¹⁶⁹ PMVE and PMOS¹⁷⁴ and poly[*p*-(*tert*-butoxy)-styrene] (PTBOS) and PIBVE.¹⁶⁹ Copolymers PMVE-*b*-PMTEGVE (PMTEGVE is poly(methyltriethylene glycol vinyl ether) were prepared in a similar fashion (Scheme 11)¹⁷⁵ using an adduct of HCl with isobutyl vinyl ether and SnCl_4 as initiating system. The addition of tetrabutylammonium chloride enhanced the ‘livingness’ of the system. Seven samples of copolymers were obtained in a yield of 99 mass % (no homopolymers). They had molecular masses ($M_n = 1.58 \times 10^3 - 1.40 \times 10^4$) similar to theoretical values and narrow MMDs ($M_w/M_n = 1.14 - 1.29$).

Scheme 11

Sequential cationic polymerisation of MVE and ethyl [2-(vinyl)oxyethyl]malonate (EVOEM) to prepare PMVE-*b*-PVOBA diblock copolymers [PVOBA is poly(vinyl-4-butoxy-4-butanoic acid)] (Scheme 12) was reported.¹⁷⁶ Polymerisation of the first block of variable length was followed by introduction of a constant amount of the second monomer and the process was continued. The diblock copolymers thus obtained were involved in two polymer-analogous reactions, namely, alkaline hydrolysis followed by decarboxylation after dialysis. According to size exclusion chromatography and ^1H NMR spectroscopy data, five specimens of PMVE-*b*-PVOBA were characterised by variation of the molecular mass of the first block over a wide range ($M_n = 5.86 \times 10^3 - 3.55 \times 10^4$) and by small variations of the molecular mass of the second block [$M_n = (4.94 - 6.37) \times 10^3$]. The copolymers had narrow MMDs ($M_w/M_n = 1.1 - 1.3$) and served as efficient stabilisers of aqueous and organic iron oxide dispersions.

This polymerisation technique also appeared to be efficient in the synthesis of diblock copolymers based on poly(2-ethyl-2-oxazoline) and poly(L-lactide).¹⁷⁷ Such copolymers attract increasing interest of researchers because they contain two biocompatible blocks.

d. Block terpolymers

The search for new methods of control of the micellar and microphase structures of copolymers predetermines an increase in the number of components in block copolymers, which in turn requires improvement of synthetic procedures. ‘Living’ cationic polymerisation, which is also employed in this case, is of limited use compared to ‘living’ anionic polymerisation. Among the small range of block terpolymers synthesised by this method, mention may be made of model triblock copolymers based on poly(ethyl vinyl ether) (PEVE), PMVE

Scheme 12

and PMTEGVE containing an equal number of each type of monomer units ($N = 20$).¹⁷⁸ These terpolymers attract the attention of researchers owing to combination of a water-insoluble (PEVE), poorly water-soluble (PMTEGVE) and readily water-soluble (PMVE) blocks in the same macromolecule. Interestingly, the terpolymer dissolved in water (less than 1 mass %) possessed the micelle-forming properties only upon addition of a low-molecular-mass salt.

5. 'Pseudoliving' radical polymerisation involving stable radicals

A fundamental problem in polymer chemistry is to develop methods of controlled radical synthesis of polymers. This problem was solved by the end of the XXth century. At present, there are three commonly accepted types of 'pseudoliving' radical process. These are the stable free radical polymerisation (SFRP), atom transfer radical polymerisation (ATRP) and reversible addition–fragmentation transfer (RAFT) radical polymerisation. Mention may also be made of the molecular design *via* interchange to xanthates (MADIX). At the same time all the methods are based on common principles that allow one to carry out a controlled 'pseudoliving' radical process. From the standpoint of control, the drawbacks of free radical polymerisation include (i) high reactivity of radicals and, as a consequence, a very high rate of the process and (ii) bimolecular chain termination reactions. Therefore, it was proposed to 'divide' the overall polymerisation process into a large number of 'short-term' stages by choosing such reversible chain termination reactions (SFRP and ATRP) or chain transfer reactions (RAFT and MADIX) that their equilibrium constants be rather low and provide a long 'sleep' period. Thus, the main idea of 'pseudoliving' radical polymerisation is to provide conditions for reversible chain termination (inhibition) or chain transfer provided that these reversible reactions are faster than the recombination reaction ($k_{\text{in(tr)}} \gg k_t$).^{23, 179–183} Reversible chain termination or chain transfer reactions characterised by low equilibrium constants play the role of a 'valve' that 'opens' the polymerisation process and 'closes' it upon adding a few monomer units. The characteristic features of a 'pseudoliving' radical process include a linear dependence of the molecular mass of the polymer on the monomer conversion and a narrow MMD.^{22, 180–184} The kinetic laws of various types of 'pseudoliving' polymerisation have been comprehensively treated in reviews.^{185, 186} An original method of determi-

nation of the kinetic parameters of controlled radical processes by linearising the polymer chain length distribution was proposed.¹⁸⁷ Presently, all types of 'pseudoliving' polymerisation are widely used in the synthesis of block copolymers; therefore, we will consider the key features of each type separately.

Otsu and Yoshita¹⁸⁸ were the first to report the significance of reversible chain termination in radical polymerisation. In the mid-1980s, the SFRP technique was developed.^{189, 190} The best results were obtained for the polymerisation and copolymerisation of St-based monomers. Reversibility of the process was maintained by the chain termination reaction involving the growing chains and stable nitroxides [*e.g.*, 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO)], which became reversible at $T > 100\text{ }^\circ\text{C}$.

The equilibrium constant for C–O bond cleavage in the polymeric alkoxyamine formed is^{23, 191}

$$K = \frac{k_{-T}}{k_T} = 2.1 \times 10^{-11} \text{ mol litre}^{-1}.$$

Here k_T and k_{-T} are the rate constants for chain termination and re-initiation (TEMPO addition and elimination), respectively. In the presence of TEMPO a controlled radical polymerisation of St is thermally initiated using a conventional radical initiator (*e.g.*, benzoyl peroxide) and low-molecular-mass alkoxyamines (AOA) that are products of the interaction of the initiator, TEMPO and (in some cases) monomer molecule.^{23, 179, 180} The rate of 'pseudoliving' polymerisation of St in the presence of AOA obeys the first-order equation with respect to the monomer concentration

$$-\frac{d[M]}{dt} = k_p K \beta [M],$$

where K is the equilibrium constant and $\beta = [\text{AOA}]/[\text{T}^*]$ is the alkoxyamine:TEMPO concentration ratio (this ratio is a constant for a steady-state process).^{23, 179} In addition, up to $q \sim 90\%$ the process is characterised by a linear dependence of the molecular mass on conversion and by narrow MMD ($1.05 < M_w/M_n < 1.2$)

$$\frac{\bar{M}_w}{\bar{M}_n} = 1 + \frac{2}{tk_{-T}}.$$

A feature of ‘pseudoliving’ polymerisation of styrene is alternation of short ($\sim 10^{-4}$ – 10^{-3} s) addition steps of some monomer molecules to the growing chains and long (~ 40 min) ‘sleep’ periods. In the late stages of SFRP polymerisation the rate of the process decreased and the polydispersity of the product increased because of the decomposition of the polymeric alkoxyamine due to disproportionation reaction between the nitroxide radical and the growing macroradical resulting in hydroxyamine and the polymer with the double bond at the chain end.¹⁸⁶

In addition to TEMPO, stable radicals *N,N*-di(*tert*-butyl)-*N*-oxyl (DBN), *N*-(*tert*-butyl)-*N*-(isopropylphenyl)methyl-*N*-oxyl (TIPNO), *N*-(*tert*-butyl)-*N*-(*tert*-butyldiethylphosphonyl)methyl-*N*-oxyl (DEPN), *etc.* were also used in the SFRP processes.^{185, 186} The structure of the nitroxide radical strongly affects the kinetic parameters of the SFRP process. In particular, the more sterically hindered the nitroxide the easier the C–O bond cleavage in alkoxyamines and the higher the rate constants for their dissociation (k_{-T}) and the equilibrium constants (K). For instance, the polymerisation of styrene in the presence of DEPN was characterised by an equilibrium constant K of 6×10^{-9} mol litre⁻¹ (see Refs 185 and 192), which is two orders of magnitude higher than in the case of TEMPO. This makes it possible to reduce the temperature of the SFRP process.¹⁸⁶

SFRP of acrylic monomers (especially methacrylates) in the presence of TEMPO is complicated by the accumulation of nitroxide in the system, which slow down or even prevent the polymerisation.⁹ The degree of control and the rate of polymerisation of these monomers considerably increase in the presence of sterically hindered nitroxide compounds, such as TIPNO, DBN and DEPN. The reason is a higher dissociation rate of the corresponding alkoxyamines compared to that of the TEMPO-based ones.^{185, 186} In addition, a kinetic study of SFRP of *tert*-butyl acrylate in the presence of DBN showed that the rate of the process increases upon addition of a radical initiator dicumyl peroxide.¹⁹³ No significant MMD broadening occurs in this case. In addition, polymerisation of *n*-butyl acrylate under the action of DEPN occurred even without decomposition of polymeric alkoxyamine and was well controlled.¹⁹² At the same time the polymerisation of methacry-

lates was poorly controlled even using sterically hindered nitroxides because polymeric alkoxyamines tend to undergo disproportionation involving abstraction of a proton from α -methyl group.^{186, 194}

Recently, an interesting avenue of research on *in situ* formation of nitroxide radicals in the polymerisation system emerged.^{195, 196} High-molecular-mass spin adducts are formed in the reactions of chain growth radicals with nitrones and nitroso compounds,^{197–202} triazines,²⁰³ sterically hindered secondary amines,²⁰⁴ a nitrogen monoxide/nitrogen dioxide mixture¹⁹⁶ and other compounds. Controlled syntheses of PS, PMMA, poly(vinyl chloride) (PVC), poly(*N*-vinylpyrrolidone) (PVPD) and copolymers of VPD with MMA in the presence of these stable radicals were carried out at low temperatures (50–120 °C) and at rather high rates.^{196–199, 205} However, inhomogeneous structure of the *in situ* formed nitroxides was reported.¹⁹⁶

A new interesting approach to involvement of inactive monomers (MMA and vinyl acetate (VA) in controlled SFRP process by copolymerisation with an active monomer (St) was proposed.^{194, 206} Yet another procedure for practical implementation of a ‘pseudoliving’ SFRP process in the presence of an alternative stable radical, namely, a product of oxidation of alkyl-9-borobicyclo[3.3.1]nonane, will be considered below (see Section III.1).

a. Binary nonpolar block copolymers

Pioneering studies on SFRP of styrene and its derivatives (under the action of benzoyl peroxide in the presence of TEMPO) aimed at preparing block copolymers date back to the early 1990s.^{184, 207–210} The method was used for the synthesis of A-b-B and A-b-B–b-A type block copolymers.^{211–214} More recently, SFRP was also employed in the synthesis of copolymers with polar blocks.

b. Binary nonpolar/polar block copolymers

Quite interesting copolymers PS-*b*-PPhIMS {PPhIMS is poly-*[p*-(phthalimidomethyl)styrene]} and PS-*b*-PPhIMS-*b*-PS were prepared by the SFRP method.²¹⁵ Initially, the polymerisation of styrene under the action of benzoyl peroxide in the presence of TEMPO resulted in PS bearing a nitroxide end group. Then it was used as macroinitiator of the polymerisation of PhIMS, and diblock copolymers with the same end group were thus synthesised. The third, PS, block was obtained using the diblock copolymer as macroinitiator (Scheme 13).

The molecular masses of the PS blocks increased in proportion to conversion and the M_w/M_n ratio was 1.15–1.25. The number-average molecular masses, M_n , of the copolymers varied between 1.9×10^4 and 3×10^4 . Under the action of hydrazine the phthalimide groups were converted to amino groups and thus di- and triblock copolymers containing basic poly[*p*-(aminomethyl)styrene] blocks were prepared.

Diblock copolymers containing the first PS block and PMMA, poly(ethyl methacrylate) (PEMA), poly(butyl meth-

Scheme 13

acrylate) (PBMA), poly(octyl methacrylate) (POMA), PDMAEMA, poly(vinyl acetate) (PVA) and PDMAA as the second block were synthesised analogously using the same initiator (benzoyl peroxide) in the presence of TEMPO radical at higher temperature ($T = 130\text{ }^{\circ}\text{C}$).²¹⁶ The copolymers were thoroughly characterised by gel permeation chromatography and ^1H NMR spectroscopy. The first stage involved the synthesis of PS blocks with nitroxide group ($M_n = 5 \times 10^2 - 2.6 \times 10^3$), which played the role of macro-initiators in the next step. In all cases, except the polymerisation of DMAEMA and VA, the diblock copolymers were obtained in high yields, the molecular masses increased in proportion to conversion and the polydispersity was $M_w/M_n = 1.2 - 1.5$. The end nitroxide groups were detected for all the copolymers. Interestingly, an earlier attempt²¹⁷ to attain controlled homopolymerisation of DMAA in the presence of TEMPO also failed. Controlled homo- and block copolymerisation of this monomer is only possible in the presence of sterically hindered nitroxides TIPNO.²¹⁸ (Co)polymers thus obtained were characterised by $M_n = 4 \times 10^3 - 4.8 \times 10^4$ and a narrow MMD ($M_w/M_n = 1.10 - 1.21$).

It should be noted that the polydispersity indices of the diblock copolymers obtained by SFRP of PS and poly(meth)acrylates are much higher than those of the identical copolymers synthesised by sequential anionic polymerisation. This is quite natural because the efficiency of nitroxide-bearing PS in SFRP of acrylates is low ($f_i < 0.6$ at 125 °C), being even lower for the polymerisation of methacrylates ($f_i < 0.4$).²¹⁰ Therefore, such diblock copolymers have a broader MMD.

Nitroxide-controlled radical polymerisation was successfully used for the synthesis of diblock copolymers from sodium poly(styrene sulfonate) (PSSNa) and polyvinyl naphthalene²¹⁹ and a copolymer with PS blocks and alternating copolymer of St with maleic anhydride (MA).²²⁰ *N*-(*tert*-Butyl)-*N*-(2-methyl-1-phenylpropyl)-*o*-(1-phenylethyl)hydroxylamine was used instead of TEMPO and the poly(St-alt-MA)-*b*-PS copolymer was synthesised in one step.²²⁰ Styrene and MA were taken in a 9 : 1 ratio; the process began with alternating copolymerisation of styrene with MA, which was followed by homopolymerisation of excess styrene upon consumption of MA. A linear increase in M_n with conversion and a narrow MMD ($M_w/M_n \leq 1.2$) were observed.

c. Binary polar/polar block copolymers

Only a few studies on the synthesis of polar/polar block copolymers using the SFRP technique have been reported so far. In particular, a PTBA-*b*-PDMAA diblock copolymer was obtained by the SFRP method; subsequent hydrolysis of TBA units afforded PAAc blocks.²¹⁸ Studies^{221–223} carried out to selectively modify the microphase structure of polymer films were based on an original idea. Block copolymers containing protected poly(*p*-hydroxystyrene) blocks were synthesised by the SFRP method in the presence of alkoxyamine. To this end, *p*-acetoxystyrene (AOS), *p*-(*tert*-butoxy)styrene (TBOS), *p*-[di(*tert*-butyl)methylsiloxy]styrene and *p*-(tetrahydropyranyloxy)styrene (THPOS) were used. The main goal was not only to improve the polymerisation process using protected monomers, but also to selectively remove the protective groups from particular blocks of the copolymers by a chemical or thermal method, thus affecting the microphase structure of polymer films. In particular, the protective groups were removed from the PAOS blocks by treatment of the films with hydrazine hydrate and from the PTHPOS blocks by heat treatment.

6. Controlled atom transfer radical polymerisation

6. Controlled atom transfer radical polymerisation
Controlled atom transfer radical polymerisation (ATRP) is an alternative to 'pseudoliving' radical polymerisation. The

method developed by two independent research groups in the mid-1990s^{224–229} differs from the SFRP technique in that chain growth is controlled by a reversible termination redox reaction. The growing chain reversibly interacts with a metal (copper^{224, 226} or ruthenium^{227, 228}) halide fragment of a complex with an organic base, donates an electron to the metal and adds the halogen atom. In the case of a copper catalyst the equilibrium is as follows:

Hal = Cl or Br, L is organic ligand; X is substituent.

Since in the course of polymerisation the halogen atom is transferred along the chain, this ‘pseudoliving’ mechanism was named ATRP. The equilibrium constant for chain growth activation is ^{23, 181}

$$K = \frac{k_{\text{Cu}^{\text{I}}}}{k_{\text{Cu}^{\text{II}}}} = \frac{[\text{M}_n^{\cdot}][\text{Cu}^{\text{II}}]}{[\text{M}_n\text{Hal}][\text{Cu}^{\text{I}}]},$$

where $[M_n]$ and $[M_n\text{Hal}]$ are the concentrations of the ‘living’ and ‘sleeping’ radicals. The polymerisation is initiated by low-molecular-mass organic compounds containing a mobile halogen atom, *e.g.*, 1-phenylethyl halides. Most often, complex-forming organic ligands include 2,2′-bipyridyl and its derivatives, namely, 4,4′-di-(hept-1-yl)-2,2′-bipyridyl; 4,4′-di(non-5-yl)-2,2′-bipyridyl (DNBP) and *N,N,N′,N″,N″′*-pentamethyldiethylenetriamine, *N,N,N′,N″,N″′,N″″*-hexamethyltriethylenetetraamine, *etc.*^{181, 186} The reversible termination mode is attained at high temperatures ($T > 100^\circ\text{C}$). However, lower-temperature ATRP were also reported. For instance, the ATRP of styrene, MA and MMA in the presence of $\text{Cu}^{\text{I}}\text{Cl}(\text{Br})$ complexes with sterically hindered DNBP was carried out at 90°C ; the corresponding equilibrium constants K being rather high, namely, $(1-2) \times 10^{-8}$ (Ref. 230), 1.2×10^{-9} (Ref. 231) and 7×10^{-7} (Ref. 232). With nickel and rhodium halide complexes with triphenylphosphine $[\text{NiBr}_2(\text{PPh}_3)_2]$ and $\text{RhBr}(\text{PPh}_3)_3$ as catalysts the temperature of the ATRP polymerisation of MMA was reduced to 75°C ²³³ with retention of MM control and a narrow MMD of PMMA.

The ATRP method has been well documented in monographs and research communications^{12, 181, 186, 234–237} that provide comprehensive treatment of the mechanism of this process and criteria for the choice of each component of the system (monomer, initiator, transition metal, organic ligands and solvent). When carrying out an ATRP process, the initiator, regulator, solvent and other conditions should be chosen for each monomer in such a fashion that the equilibrium constant ($K = 10^{-8 \pm 2}$) and the rate constant for deactivation of radicals ($k_{\text{da}} = 10^{7 \pm 1} \text{ litre mol}^{-1} \text{ s}^{-1}$) be optimum [for reaction (1) $k_{\text{da}} = k_{\text{CuI}}$].²³⁸ The method does its best in the polymerisation of St- and (meth)acrylate-based monomers, but can also be used for polymerisation of acrylamide, (meth)acrylamides and dienes.²³⁸ It should be noted that ATRP polymerisation can be performed not only in organic solvents (most studies),^{232, 239–241} but also in the bulk,²⁴² in emulsion,²⁴³ in suspension²⁴⁴ and even in aqueous solutions.^{245, 246} However, an attempt to use this approach for polymerisation of (meth)acrylamides failed;²⁴⁷ the process was poorly controlled and the resulting polymers were characterised by a broad MMD. Similar results were obtained for ATRP of DMAA, which led to $M_w/M_n > 1.6$ for the resulting PDMAA.^{248, 249} It was shown that ATRP requires the use of protected acid monomers that cannot be coordinated to the

transition metal and thus poison the catalyst.⁹ In addition, the best catalytic systems are obtained using protonated basic ligands, because this precludes strong complexation with the metal.

In contrast to 'living' anionic polymerisation the ATRP technique is quite tolerant to the nature of monomers and solvents. This makes it possible to synthesise the A-b-B-b-A, B-b-A-b-B and A-b-B-b-C type copolymers from polar and nonpolar monomers starting in any order. Each ATRP synthesised polymer has a mobile halogen atom at the chain end. Therefore, it can act as macroinitiator of polymerisation of other monomers under the action of the same catalytic system. Some examples of the use of ATRP for the synthesis of binary and ternary block copolymers are presented below.

a. Binary nonpolar/polar block copolymers

In this group the most popular objects of synthetic studies are di- and triblock copolymers of PS with protected poly(meth)acrylates. As mentioned above, the (meth)acrylic monomers are protected to prevent the poisoning of catalyst. Di- and triblock copolymers of PS with poly(butyl acrylate) (PBA) of well-defined molecular structure were obtained.²⁵⁰ Similar PBA-b-PS copolymers were synthesised in a water-hexane-Brij98 dispersion.²⁵¹ The process was initiated by ethyl-2-bromoisobutyrate and a complex of CuBr with DNBP was used for reversible termination. The block copolymers thus obtained were characterised by $M_n = 1 \times 10^4 - 4 \times 10^4$ and $M_w/M_n = 1.12 - 1.25$. Amphiphilic di- and triblock copolymers of PS with PAAc were obtained as follows:²⁵²⁻²⁵⁶ di- or triblock precursors (with PTBA) were synthesised by ATRP and subsequent acid hydrolysis of the TBA units gave the PAAc blocks. Studies^{252,253} were carried out using methyl 2-bromopropionate as initiator and a complex of CuBr with PDMETA as catalyst. A 'pseudoliving' mechanism of the process with a linear increase in M_n depending on conversion was observed at 60 °C only in polar solvent (acetone).

A similar scheme was also used to obtain block copolymers of PS with PMAAc in other studies;^{257,258} however, the protected monomer was *p*-nitrophenyl methacrylate in the former study and TBMA in the latter.

Examples of successful use of ATRP in the synthesis of highly hydrophobic diblock copolymers based on PS and polyfluorinated polyalkoxystyrenes have been reported.^{259,260} First, polyfluorinated monomers, namely, 2,3,5,6-tetrafluoro-4-(2,2,3,3,3-pentafluoropropoxy)styrene [TF(F₅)S] and 2,3,5,6-tetrafluoro-4-(2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-pentadecafluorooctoxy)styrene [TF(F₁₅)S] were synthesised and their ability to undergo controlled ATRP was checked and confirmed.²⁶⁰ The products synthesised were characterised by a narrow MMD ($M_w/M_n \leq 1.3$). Oligomers with $M_n = 6.5 \times 10^3$ were then used as macroinitiators of the polymerisation of styrene, which resulted in A-b-B type copolymers [poly-TF(F₅)S-b-PS and polyTF(F₁₅)S-b-PS] of well-defined molecular structure and narrow MMD. In addition, the polymerisation in a xylene solution (owing to poor solubility of the fluorinated blocks) was performed using the reverse order of introduction of the monomers and led to B-b-A type copolymers characterised by M_{nPS} of 4×10^3 and 9.7×10^3 , PS content of 36 and 90 mol.%, respectively, and $M_w/M_n \leq 1.37$.

An ATRP synthesised diblock copolymer of poly(4-fluorostyrene) (PFS) and poly(methyl acrylate) (PMA) was converted to PFS-b-PAAc amphiphilic copolymer by hydrolysis of the PMA blocks and used for the synthesis of micellar nanoparticles with cross-linked 'corona' comprised of the PAAc blocks.²⁶¹

b. Binary polar/polar block copolymers

ATRP was used for preparation of amphiphilic diblock copolymers containing hydrophobic PMA or PMMA blocks.

A block copolymer precursor synthesised by sequential polymerisation of MMA with TBMA was selectively hydrolysed,²⁶² which resulted in PMMA-b-PMAAc copolymer. This scheme was also employed in the synthesis of amphiphilic diblock copolymer PAAc-b-PMA²⁶³ with TBA as the protected monomer in the first stage. The micelle-forming properties of the copolymers were the most interesting.

c. Block terpolymers

In recent years, the ATRP method has been used for the synthesis of copolymers containing three chemically different blocks (terpolymers). For instance, not only diblock copolymers, but also terpolymers of composition PTBA-b-PS-b-PMA were synthesised in the study mentioned above.²⁶³ Sequential introduction of TBA, PS and PMA faced no problems, unlike the case of 'living' anionic polymerisation (see Section II.2). The ATRP polymerisation of TBA, MA and styrene led to a PTBA-b-PMA-b-PS terpolymer, which was converted to the PAAc-b-PMA-b-PS terpolymer with increasing block hydrophobicities by hydrolysis of the PTBA block.²⁵² The micelle-forming properties of these compounds and the possibility of nanoparticle formation with a chemically cross-linked 'corona' was studied.

7. 'Pseudoliving' radical polymerisation with reversible chain transfer

The third type of 'pseudoliving' radical polymerisation, namely, reversible addition-fragmentation chain transfer (RAFT) polymerisation was developed in the 1998-1999s.²⁶⁴⁻²⁶⁷ It is characterised by the lowest sensitivity to the nature of monomers, solvents and external polymerisation conditions. The method was even used for controlled synthesis of PAAc ($M_w/M_n = 1.23$) using unprotected AAc [$T = 60$ °C, dimethylformamide (DMF) as solvent and azobis(isobutyronitrile) (AIBN) as initiator].²⁶⁴ A feature of the RAFT polymerisation is the presence of dithioester chain transfer agents (CTA) of the general structure 1-4

which readily react with either the initiator radical (e.g., AIBN) or the growing polymer chain, thus forming a new CTA, or with the macroCTA, and the reactive radical (R^1), which re-initiates the polymerisation:

initiation

where k_d is the rate constant for decomposition of the initiator;

chain growth

addition-fragmentation reaction

where k_{ad} and $k_{-\text{ad}}$ are the rate constants for addition of (macro)CTA molecules to the growing chains and for elimination of the (macro)CTA molecules, respectively, and k_{β} and $k_{-\beta}$ are the rate constants for addition of $(\text{R}^1)^\bullet$ radicals to the macroCTA molecules and for their fragmentation, respectively;

re-initiation/chain growth

chain alignment(degenerative chain transfer)

'Pseudoliving' polymerisation mode provides a reversible chain transfer.^{264, 265, 268} Reversible (degenerative) chain transfer occurs until the MMs of the growing chains become almost equal to one another, thus providing a narrow MMD.

The rate constant for degenerative chain transfer, *i.e.*, the rate constant for radical exchange in the CTA molecules [stage (6)], is defined as follows:

$$C_{\text{ex}} = \frac{k_{\text{ex}}}{k_{\text{p}}} = 0.5 \frac{k_{\text{ad}}}{k_{\text{p}}},$$

where k_{ex} and k_{p} are the rate constant for degenerative chain transfer and the rate constant for chain growth, respectively.^{185, 186} At $C_{\text{ex}} \geq 100$ and at low conversions, the starting CTA is completely transformed into macroCTA following reaction (4) and then the macroCTA participates in degenerative chain transfer following reaction (6). The highest C_{ex} values are characteristic of the RAFT polymerisation of *n*-alkyl acrylates, they are somewhat lower for the polymerisation of styrene and even more lower for that of MMA.²⁶⁹ For instance, the polymerisation of styrene ($T = 40^\circ\text{C}$) and MMA ($T = 60^\circ\text{C}$) under the action of macroCTA (polystyryl dithiobenzoate) was characterised by $C_{\text{ex}} = 6000 \pm 2000$ and 140, respectively.²⁷⁰ The existence of radical intermediates [see stages (4) and (6)] in the RAFT polymerisation of styrene, *n*-butyl acrylate (nBA), *N*-vinylpyrrolidone, VA and other monomers was proved by EPR spectroscopy.^{271, 272} No proof was obtained only for MMA owing to high $k_{-\text{ad}}$ value.²⁷¹ The first CTAs used in the synthesis of PAAc were 1-phenylethyl dithiobenzoate²⁶⁴ and 1-cyanoethyl-2-pyrrolidone-1-carbodithioate.²⁷³

Practical implementation of a RAFT process requires that the rates of radical addition to the $\text{C}=\text{S}$ double bond and subsequent abstraction of reactive radicals be higher than the chain propagation rate. Therefore, the choice of the R^1 and R^2 radicals in the CTA molecule matters. To provide fast radical addition to CTA, the R^2 substituent should act as stabiliser. Usually, this role is played by the phenyl group.²⁶⁸ Rapid abstraction of the R^1 radical requires that R^1 have a rather long lifetime, be active in the re-initiation reaction and be surrounded by bulky groups to avoid recombination. With allowance for these requirements, good results were obtained using a tertiary radical of 4-cyanopentanoic acid.^{268, 273, 274} By appropriately choosing the R^2 substituent one can also eliminate the well-known effect of a strong decrease in the chain propagation rate in the presence of RAFT agents.^{186, 267}

Yet another reaction proposed²⁷⁵ to control radical polymerisation processes is the reaction of chain transfer to dithiocarbonates (xanthates) of general formula represented by structure 2. This type of controlled radical polymerisation was named the 'molecular design *via* interchange to xanthates' (MADIX). Among other CTAs used for reversible chain transfer, mention may be made of trithiocarbonates 3 and dithiocarbamates 4.^{273, 276–278} For instance, dibenzyl and bis(1-phenylethyl) trithiocarbonates provided well-controlled polymerisation of AAc²⁷⁹ and benzyl and cumyl dithiocarbamates provided well-controlled polymerisation of *N*-isopropylacrylamide.²⁷⁷

The number-average MM of a polymer obtained by RAFT polymerisation is given by²⁸⁰

$$\bar{M}_n = q \frac{M_{\text{M}}[\text{M}]_0}{[\text{CTA}]_0 + 2f_{\text{i}}[\text{I}]_0(1 - e^{-k_{\text{at}}t})} + M_{\text{CTA}},$$

where M_{M} and M_{CTA} are, respectively, the molecular masses of the monomer and CTA, and $[\text{M}]_0$ and $[\text{CTA}]_0$ are the initial concentrations of the corresponding reactants. For an ideal RAFT process the number of polymer chains emerged from the initiator molecules should be minimum. In this case the second term in the denominator becomes small compared to $[\text{CTA}]_0$. In addition, the parameter M_{CTA} can be neglected at a high molecular mass of the polymer. Therefore, in most studies on RAFT polymerisation the value \bar{P}_n was estimated from the relationship

$$\bar{P}_n = q \frac{[\text{M}]_0}{[\text{CTA}]_0}.$$

Once synthesised, polymers contain dithioester, xanthate, trithiocarbonate or dithiocarbamate end groups, which permits continuation of controlled radical polymerisation of other monomers to obtain linear block copolymers. The method allows one to carry out controlled synthesis of anionic and cationic polyelectrolytes and polyelectrolyte block copolymers in aqueous medium. Below we present some examples of the synthesis of block copolymers using different versions of the technique. All of them concern diblock copolymers containing at least one polar block.

a. Nonpolar/polar diblock copolymers

These block copolymers were synthesised by the RAFT method. For instance, a PS-*b*-PEA [PEA is poly(ethyl acrylate)] copolymer was obtained by the MADIX technique in emulsion.²⁸¹ By hydrolysis of the ethyl acrylate units it was converted to amphiphilic copolymer PS-*b*-PAAc. A PS-*b*-PEA copolymer ($M_{\text{nPS}} = 2 \times 10^3$, $M_{\text{nPEA}} = 1.95 \times 10^4$; $M_{\text{w}}/M_{\text{n}} \sim 2.0$) was synthesised in a similar fashion and the effect of the degree of hydrolysis of PEA on the character of the micelle-forming properties of the diblock copolymer in aqueous medium was studied.²⁸² A series of poly(St-*alt*-MA)-*b*-PS copolymers with variable length of both blocks [$M_{\text{n}} = (3.11 - 3.52) \times 10^4$] and narrow MMD ($M_{\text{w}}/M_{\text{n}} = 1.09 - 1.16$) was synthesised by the RAFT method.²⁸³

b. Polar (including ionogenic) block copolymers

The RAFT method was used for the synthesis of diblock copolymers involving PAAc and PMAAc, namely, PBA-*b*-PAAc, PMMA-*b*-PMAAc and PBMA-*b*-PMAAc, where PBMA is poly(benzyl methacrylate).²⁶⁵ The polymerisation was carried in DMF with 1-phenylethyl dithiobenzoate as CTA. The copolymers obtained were characterised by low polydispersity. More recently, block copolymers of PAAc with poly(*N*-isopropylacrylamide) (PAAc-*b*-PIPA) were synthesised using 1-cyanoethyl 2-pyrrolidone-1-carbodithioate as

CTA.²⁷³ The first block to synthesise was PAAc, which then played the role of macroCTA in the polymerisation of *N*-isopropylacrylamide. Diblock copolymers with the same components were also obtained with benzyl and cumyl dithiocarbamates as CTA.²⁷⁷ The presence of dithiocarbamate groups at the end is important for subsequent transformation to thiols and conjugation with proteins or pharmaceuticals.

In some studies on the synthesis of polar block copolymers by 'pseudoliving' RAFT polymerisation (see above) and in most related studies to be considered below it was pointed that the best results (narrower MMD) can be obtained if the more rigid block is synthesised first. This indicates an important role of the conformation of the first block in the initiation and growth of the second block. For instance, amphiphilic block copolymers PAAc-*b*-PTBA with well-controlled molecular structure were obtained by polymerisation of acrylic acid followed by the polymerisation of TBA using trithiocarbonate or xanthate as CTA.²⁸⁴ The synthetic route to the block copolymers based on poly(meth)acrylonitrile (PMAN and PMA) involving the RAFT polymerisation starting with the rigid block (PMAN) was patented.²⁸⁵ Chain-transfer agents of general formula $R-S-C(=S)Z$ (R is a mobile group capable of easy elimination by the radical mechanism and Z is a hydrogen or halogen atom or a low-molecular-mass or polymer group) were proposed for the synthesis of linear block copolymers.

Block copolymers having two hydrophilic blocks, PAA and PAAc, were synthesised by the MADIX method using mono- or bifunctional xanthates as CTA.²⁸⁶ The A-*b*-B and A-*b*-B-*b*-A type copolymers were characterised by $M_w/M_n \leq 1.5$.

Interesting studies on the synthesis of polyelectrolyte block copolymers using an improved RAFT technique are available.^{268, 287} The polymerisation was initiated by 4,4'-azobis(4-cyanopentanoic acid) (ABCPA) (**5**), which gave the same tertiary radicals of 4-cyanopentanoic acid upon thermal decomposition as those formed upon abstraction from the CTA molecule [4-cyanopentanoic acid dithiobenzoate (CPADTB) (**6**)] in the course of chain transfer reactions.

This methodology was employed for controlled synthesis of three diblock copolymers containing various polyanionic or polycationic blocks in aqueous solution *via* RAFT. These were PSSNa-*b*-PVBNa based on poly(sodium 4-styrenesulfonate) and poly(sodium 4-vinyl benzoate), PVTMAC-*b*-PDMVBA based on poly(vinyltrimethylammonium chloride) and poly(*N,N*-dimethylvinylbenzylamine) and PNaAAMPS-*b*-PNaAAMB based on poly(sodium 2-acrylamido-2-methylpropane sulfonate) and poly(sodium 3-acrylamido-3-methylbutanoate). The first two copolymers were obtained in two steps.²⁶⁸ The first step (sealed tubes, 70 °C, 8 h) afforded almost monodisperse PSSNa and PVTMAC containing dithioester end groups. The molecular masses of the blocks monotonically increased with conversion. In the second stage (reactor, 70 °C, inert atmosphere, 24 h) both blocks played the role of the macroCTA in 'pseudoliving' radical polymerisation

of sodium vinyl benzoate and *N,N*-dimethylvinylbenzylamine. The copolymer containing polyanionic blocks was characterised by $M_n = 1.86 \times 10^4$ and $M_w/M_n = 1.18$ while the copolymer with polycationic blocks had $M_n = 5.1 \times 10^4$ and $M_w/M_n = 1.37$.

The third copolymer, PNaAAMPS-*b*-PNaAAMB, was synthesised from *N*-substituted acrylamides in two stages using the same reactor²⁸⁷

$\text{X} = \text{SO}_3^- \text{Na}^+ \text{ or } \text{CO}_2^- \text{Na}^+, k = (n + m) \text{ or } (m + n)$.

The monomers were introduced in different order and the overall polymerisation processes were studied, because the polymerisation of acrylamide monomers by the SFRP and ATRP methods is problematic (see above). The polymerisation of the first block (PNaAAMPS or PNaAAMB) was accompanied by a linear increase in M_n with increasing conversion, the reaction being first-order with respect to the monomer concentration; the first-order rate plot showed an induction period (~ 1 h). This was attributed²⁸⁷ to the slow initiation by the initiator used. Unlike the SFRP and ATRP methods for which the polydispersity of products usually decreases with conversion, here the polydispersity M_w/M_n somewhat increased with conversion but remained below 1.3. Because of high viscosities of strong polyelectrolytes in aqueous solutions (this can reduce the reaction rate) in the second stage of polymerisation the concentration of the second monomer was halved. Simultaneously, the duration of the polymerisation of the second block was doubled. The molecular masses M_n of the PNaAAMPS-*b*-PNaAAMB and PNaAAMB-*b*-PNaAAMPS copolymers (6.97×10^4 and 5.79×10^4 , respectively) were in excellent agreement with the theoretical values; the polydispersities M_w/M_n were also low (1.14 and 1.16, respectively).

c. Multiblock copolymers

Prospects for the synthesis of block polyelectrolytes in aqueous solutions offered by the RAFT and MADIX methods are clouded by some circumstances. First, most CTAs are insoluble in water. Second, the synthesis of copolymers containing only one polyelectrolyte block often causes an abrupt increase in the medium viscosity. This complicates the RAFT polymerisation of tri- and multiblock copolymers or makes the process impossible. Therefore, now considerable attention is paid to industrial implementation of this polymerisation technique. In particular, prospects for the synthesis of homopolymers and copolymers using emulsion/mini-emulsion RAFT polymerisation technique were studied.^{288–292} The advantages of the RAFT process under conditions of emulsion/mini-emulsion polymerisation compared to the same process in a homo-

geneous medium consist in a higher chain propagation rate (due to segregation of radicals) and a better processability of products owing to low viscosity in solution at high polymer content. To improve the process, it was proposed to use a train of continuous tank reactors instead of a single reactor.²⁹³ This allows one to achieve higher monomer conversions in smaller reaction volumes and to obtain narrow-MMD multiblock copolymers of specified architecture. Taking the synthesis of gradient multiblock copolymers of St with *n*-butyl acrylate as an example, it was shown that the composition and length of any block can easily be varied by varying the temperature, flow rate in the reactor train and the injection point. The polymerisation was carried out at 72–77 °C with Na₂S₂O₈ as initiator, 1-phenylethyl phenyldithioacetate as CTA and SDS as emulsifier).

8. Other methods

Now we will dwell on yet another, rarely used, method of 'living' polymerisation, namely, sequential anion-coordination polymerisation in the presence of metalloporphyrins, which permits the synthesis of certain block copolymers of specified molecular architecture. It has been comprehensively treated in a review⁴⁶ and concerns controlled room-temperature, ring-opening polymerisation of oxiranes, β -lactones, δ -valerolactones, ϵ -caprolactones, D-lactide, methacrylates and methacrylonitrile. The role of polymerisation initiators and nanoreactors, where a next monomer molecule is added to a growing chain by the anion-coordination mechanism, is played by (5,10,15,20-tetraphenylporphyrinato)aluminium chlorides, (5,10,15,20-tetraphenylporphyrinato)(methyl)aluminium and (5,10,15,20-tetraphenylporphyrinato)(methoxy)aluminium.⁴⁶ The growth centres include aluminium alkoxides for the polymerisation of oxiranes, δ -valerolactones, ϵ -caprolactones and D-lactide; aluminium carboxylate for the polymerisation of β -lactones and aluminium enolate for the polymerisation of methacrylates (see the processes shown in Scheme 14).

Scheme 14

Reversible chain termination reactions of the alcohol or carboxylic acid protons (for the polymerisation of oxiranes and lactones) represent important elements of control of the polymerisation of heterocyclic compounds (see the first and third processes in Scheme 15).^{46, 294}

Scheme 15

The reversible chain termination reactions are much faster compared to chain propagation, namely, $k_t/k_p = 10$ (Ref. 294). Therefore, the polydispersity index of polymers remains very low ($M_w/M_n \approx 1.1$). The number-average degree of polymerisation in these processes is given by the ratio⁴⁶

$$\bar{P}_n = q \frac{[M]_0}{[(\text{TPP})\text{AlHal}] + [\text{H}]},$$

where [H] is the concentration of the compound containing a mobile proton (alcohol or acid). Owing to fast reversible chain termination by the alcohol or acid protons these processes take a few days or weeks until complete consumption of the heterocyclic compounds.⁴⁶ However, they can be accelerated by introducing sterically hindered Lewis acids, e.g., methylaluminium bis[2,6-di(*tert*-butyl)-4-methylphenolate].²⁹⁵

Unlike heterocyclic compounds, (TPP)AlHal do not initiate the polymerisation of methacrylates and methacrylonitrile. Polymerisation of these monomers in the presence of (TPP)AlMe is only possible upon irradiation of the system with visible light (see the last reaction in Scheme 14). These slow processes can also be accelerated by introducing solid Lewis acids, such as methylaluminium bis[2,6-di(*tert*-butyl)phenolate], triphenylphosphine and organoboron compounds.⁴⁶ The Lewis acids are coordinated by the monomer carbonyl groups and enhance their electrophilicity. Successful polymerisation of non-irradiated methacrylates can be performed using more

nucleophilic porphyrins, such as (propylthio)- and (phenylthio)(5,10,15,20-tetraphenylporphyrinato)aluminium with methylaluminium bis[2,6-di(*tert*-butyl)-4-methylphenolate].⁴⁶ In these processes the degree of polymerisation (up to $P_n = 300$) is determined by the ratio

$$P_n = \frac{q[M]_0}{[I]_0},$$

and the MMD is very narrow ($M_w/M_n = 1.05 - 1.2$).⁴⁶

Aluminium porphyrinates were used in the synthesis of diblock copolymers from two oxiranes,^{296, 297} two β -lactones,²⁹⁸ β -lactone and oxirane.²⁹⁸ In the last (mixed) case, β -lactone was polymerised first because aluminium carboxylate at the chain end initiated the polymerisation of oxiranes, whereas the corresponding aluminium alkoxide was incapable of initiating the polymerisation of β -lactone. Diblock copolymers were also obtained by sequential polymerisation of EO and ϵ -caprolactone,⁸³ propylene oxide and D-lactide²⁹⁹ and various methacrylates.³⁰⁰ It should be noted that, in contrast to carbochain polymers, products of polymerisation of heterocycles (in particular, polyethers and polyesters) possess a unique ability to undergo biodegradation.³⁰¹ Therefore, considerable attention has been paid recently to the design of block copolymers containing these specific blocks.^{104 - 109}

III. Combination of different mechanisms of monomer polymerisation

This Section concerns alternative methods of synthesis of block copolymers. Common to all of them is the involvement of different polymerisation techniques in the course of synthesis. This strategy of synthesis of block copolymers is called multimode polymerisation.⁹ The new avenue of research began with a study³⁰² whose authors reported for the first time a transition from 'living' cationic polymerisation of THF to 'living' anionic polymerisation of St. Short after this publication the subject has attracted considerable attention of researchers.^{303, 304} The major impetus to the development of multimode polymerisation techniques came from the need of the synthesis of copolymers from blocks of different chemical nature that are difficult or hard to synthesise by sequential polymerisation of monomers by the same mechanism. The idea of using polymeric products of large-scale synthesis for preparation of block copolymers also played its role. At present, three strategies of multimode polymerisation of linear block copolymers are developed. These are (i) formation of macroinitiators for radical, ionic or other types of polymerisation at the ends of ready polymers; (ii) combination of various mechanisms of controlled ('living' ionic and 'pseudoliving' radical) polymerisation and (iii) use of bifunctional initiators. Consider now each strategy in more detail.

1. Formation of macroinitiators based on ready blocks

Transformation of the end groups of polymers into macroinitiators of polymerisation requires that they bear active

groups of particular chemical nature. In some polymers, such groups are formed in the course of synthesis. An example is provided by PEG containing active hydroxyl groups at the chain ends. In other polymers, especially in practically important polyolefins [PE, polypropylene (PP), PS, poly(4-methylpent-1-ene), *etc.*] the formation of active groups occurs during the synthesis or follows it.^{8, 305}

a. Macroinitiators based on poly(ethylene glycol)

The use of the OH groups of PEG and PEGME to obtain macroinitiators of radical polymerisation and prepare A-b-B, A-b-B-b-A and B-b-A-b-B block copolymers has been a subject of considerable literature (see, *e.g.*, Refs 306 - 310). These problems have been treated in most detail in a review.⁶ There are two main methods of conversion of PEG into macroinitiators. One of them involves direct 'activation' of the OH groups of PEG in the presence of other monomers followed by synthesis of block copolymers. The other technique involves modification of the end groups of PEG, their 'activation' in the presence of monomers and synthesis of di- or triblock copolymers. Now we will consider some examples.

Direct activation of PEG is possible in a redox reaction of formation/breakup of complexes between hydroxyl groups and mixed-valence metal ions (Co^{III} , Ce^{IV} , Mn^{III} , *etc.*).³¹¹ The mechanism of a reaction of isolated OH groups with a Ce^{IV} salt is as follows:^{311, 312}

The lifetime of the intermediate complex varies from tens of seconds to a few hours depending on the structure of the hydroxyl-containing compound.³¹²

Novitskaya and Konkin³⁰⁶ were the first who used reaction (7) for the synthesis of PAN-b-PEO-b-PAN copolymers (PAN is polyacrylonitrile). The starting PEG had a molecular mass of 4.4×10^3 . The PEO content in the resulting triblock copolymer varied from 12% to 20 % by mass. More recently, this technique was employed for the synthesis of PAA-b-PEO-b-PAA, PEO-b-PIPAA, PIPAA-b-PEO-b-PIPAA and PAAC-b-PEO-b-PAAC copolymers with variable molecular mass of the PEO block.^{307, 308} A PMMA-b-PEO-b-PMMA copolymer was synthesised in a similar fashion in the presence of Mn^{III} .³⁰⁹

Yet another method was used for modification of the hydroxyl groups of PEG and formation of thermal macroinitiators, which form free radicals upon a change in temperature. In particular, the reaction of PEG with 4,4-azobis(4-cyanopentanoic acid) gave a polyazo ester, which was used in the synthesis of PEO-b-PAA diblock copolymers (Scheme 16).³¹⁰

The same thermal macroinitiator was obtained as intermediate product in the synthesis of the PEO-b-PS, PEO-b-PMA, PEO-b-PMMA, PEO-b-PVA and PEO-b-PAN copoly-

Scheme 16

mers.³¹³ The reactivities of monomers were compared at the same macroinitiator concentration under identical conditions (60 °C, 24 h). The rates of polymerisation of MA and MMA were higher and, therefore, higher q values and molecular masses of blocks were observed in these cases (q 80%–85% for MA and MMA vs. at most 20% for styrene). This macroinitiator was also obtained³¹⁴ by the interaction of PEG with 4,4-azobis(4-cyanopentanoic acid) anhydride. Then, it was thermally ‘activated’ in the presence of styrene and the PEO-b-PS copolymer was obtained.

A macroinitiator with ester end groups was synthesised in the reaction of PEG ($M_n = 400$) with azobis(cyanopentanoic) acid chloride in the presence of benzoyl chloride or acetyl chloride (Scheme 17)³¹⁵ and used in the polymerisation of St to obtain a liquid block copolymer PEO-b-PS with $M_n = 2.2 \times 10^4 - 2.9 \times 10^4$.

Yet another polyazo ester was synthesised by the interaction of PEG with AIBN in acidic medium (Scheme 18).³¹⁶ Its heating in aqueous acrylonitrile solution caused the formation of polydisperse PEO-b-PAN block copolymer (maximum yield 40 mass % at 85 °C) containing a soluble (6%–12% of PAN) and insoluble (86%–92% of PAN) fractions.

A more complex method³¹⁷ of synthesis of PEG-based macroinitiators of styrene polymerisation involves³¹⁷ the formation of macroazocarbamate in the reaction of PEG with aliphatic diisocyanate and then with 4,4-azobis(4-cyanopen-

tan-1-ol). Heat treatment of the macroazocarbamate in the presence of styrene led to PEO-b-PS copolymer (Scheme 19).

Macroazocarbamate was synthesised analogously using isophorone diisocyanate and initiated polymerisation of MMA.³¹⁸ The final product, a PMMA-b-PEO-b-PMMA copolymer, had $M_w = (2-7) \times 10^5$.

Yet another type of modification of the OH groups of PEG to obtain a PS-b-PEO-b-PS triblock copolymers is shown in Scheme 20.^{319, 320} PEG was mixed with isophorone diisocyanate and then with dihydroperoxides of general formula $\text{HOO}-\text{R}-\text{OOH}$ or with monoperoxide Bu^tOOH . This resulted in yet another thermal macroinitiator, PEO diperoxycarbamate. The final triblock copolymer had a broad MMD and contained the homopolymer due to occurrence of the chain transfer reaction.³¹⁹

Direct ‘activation’ of the OH groups of a PEG-based polyazo ester in the interaction with Ce^{IV} or Mn^{III} followed by thermal initiation was used³²¹ for the synthesis of PMMA-b-PEO-b-PMMA and PMMA-b-PEO-b-PS block copolymers (Scheme 21). A bifunctional polyazo ester was treated with Ce^{IV} or Mn^{III} salts in MMA solution at room temperature. The resulting tetrablock copolymer with the central azo group was heated in the presence of styrene or MMA.

Of course, the block copolymers obtained by radical polymerisation of monomers under the action of PEG-based macroinitiators had broader MMDs compared to the block

Scheme 21

copolymers obtained by controlled sequential polymerisation. Nevertheless, in the former case the number of partners for PEG was larger.

Recently, various transformations of PEG into mono- and bifunctional macroinitiators of anionic ring-opening polymerisation of lactones and lactides to synthesise biodegradable block copolymers^{108,109} (see Section II.2) and studies on the formation of PEG-based macroinitiators of controlled radical polymerisation were reported. For instance, the bromo derivatives of PEG and random copolymers of ethylene glycol and propylene glycol [poly(EG-co-PG)] were used in ATRP of 2,3,4,5,6-pentafluorostyrene (PFSt).^{322,323} PEG chains ($M_n = 2 \times 10^3 - 1 \times 10^4$) and poly(EG-co-PG) ($M_n \sim 1 \times 10^3$, EG content 74 mass %) were converted into macroinitiators by esterification of OH groups with bromoisobutanoic acid bromide. ¹H NMR spectroscopy studies confirmed the limiting degree of functionalisation of the end groups ($F_n = 1$). The ATRP of PFSt at both ends of polyethers afforded triblock copolymers PPFSt-b-PEG-b-PPFSt and PPFSt-b-P(EG-co-PG)-b-PPFSt. The molecular masses of the central blocks increased by 15%–84 % by mass and the polydispersity index M_w/M_n was less than 1.22. The triblock copolymers formed films with well-defined microphase separation and complexes with Li^+ salts.

A unique synthesis of diblock polyelectrolyte PEO-b-P(NaMA) by ATRP in aqueous solution was reported.³²⁴ The polymerisation of NaMA performed with a PEG bromo derivative as macroinitiator and the $\text{Cu}^{\text{I}}\text{Br}-2,2'$ -bipyridyl system as catalyst resulted in a high yield of narrow-MMD copolymer. A feature of the synthesis consisted in an optimal pH value (pH 8–9) that allowed one to maintain a balance between the possible reduction of P(NaMA) chain propagation rate at too high pH and competing protonation of 2,2'-bipyridyl at too low pH.

b. Macroinitiators based on polyolefins

Polyolefins are polymeric materials produced on a large-scale basis. Due to the lack of polar groups they are poorly compatible with inorganic fillers, polar polymers, glass fibre, pigments and metals. An efficient method of improving the compatibility of polyolefins with other materials is the synthesis of polyolefin-based block copolymers containing polar blocks. Therefore, in the last decade researchers undertook considerable efforts to develop methods of functionalisation of polyolefins. These methods were most comprehensively treated in reviews.^{8,305} In the text below we present the most promising techniques used for the synthesis of linear block copolymers. In this connection we will first dwell on the synthesis of polyolefins.

At present, stereoregular polyolefins are synthesised on a large scale using ionic-coordination polymerisation in the presence of heterogeneous or homogeneous Ziegler–Natta catalysts [*e.g.*, $\text{TiCl}_3 + \text{AlR}_n\text{Cl}_{3-n}$ ($n = 1-3$) on MgCl_2 powder].^{22,305} The mechanism of the process is well known.^{22,23} Recently, new homogeneous metallocene and post-metallocene catalysts have been widely used in the field. The major components of the metallocene catalysts are sandwich complexes of Group IV transition metals (Ti, Zr or Hf) with two cyclopentadienyl ligands (**7**). In some cases ligands may be linked by bridging groups involving carbon or silicon atoms.³⁰⁵

Cp_2ZrCl_2 ($\text{Cp} = \eta\text{-C}_5\text{H}_5$)

Complex with unsubstituted ligands

$\text{Cp}_2^*\text{ZrCl}_2$ ($\text{Cp}^* = \eta\text{-C}_5\text{Me}_5$)

Complex with substituted ligands

Active co-catalyst of metallocenes is methylalumoxane (MAO) of general formula $[-\text{Al}(\text{Me})-\text{O}]_n$ with a molecular mass of 8×10^2 to 1.5×10^3 (Ref 305), which is formed upon partial hydrolysis of trimethylaluminium. The post-metallocene catalysts may contain unsubstituted and substituted indene (Ind) or fluorene (Flu) ligands, in particular, $(\text{Ind})_2\text{ZrCl}_2$ and $(\text{Flu})_2\text{ZrCl}_2$, instead of cyclopentadienyls.³⁰⁵ The ability of the ligands to donate electrons to the transition metal increases in the order $\text{Cp} < \text{Ind} < \text{Flu}$.³²⁵ By varying the electronic and steric effects by changing the ligand structure one can control the polymerisation, stereoregularity and the MM of polyolefins, as well as modify their end groups.

To prepare macroinitiators, the end groups of homo- or copolyolefins are functionalised in the course of metallocene-catalysed synthesis of these compounds (to make the products cheaper) using two main procedures involving formation of (i) unsaturated end groups to be chemically modified and (ii) end groups capable of directly initiating block copolymerisation when activated.

The formation of terminal double bonds in polyolefins is due to transfer of β -H atoms or β -alkyl groups (if exist), which occur in the active centres of chain growth (see the reactions shown in Scheme 22) and reduce the molecular mass of the polymer.^{8,305} The first type of transfer resulting in metal hydrides and alkenes (first reaction) was observed in the active centres of neutral or positively charged alkylmetallocenes.³⁰⁵ The second type of transfer (second reaction) was detected in the polymerisation of propylene on heterogeneous metallocene catalysts and in the copolymerisation of propylene with ethylene on $\text{Cp}_2\text{ZrCl}_2 + \text{MAO}$.³⁰⁵ Transfer of β -alkyl (methyl) groups to the transition metal (third reaction) was observed in a study of propylene oligomerisation with Cp_2^*LaMe as catalyst.³²⁶

Scheme 22

β -H transfer to transition metal

β -H transfer to monomer

β -Alkyl transfer to transition metal

The transfer reactions can be controlled with ease by varying the metallocene structure (electronic and steric factors) and conditions of polymerisation (temperature and pressure).³⁰⁵ The more readily the ligands donate electrons to the metal the lower (i) the thermodynamic affinity of the metal to the β -proton in the growing chain and (ii) the probability of β -proton transfer. A similar effect can be attained by increasing the volume and number of substituents in the ligands, because this is accompanied by an increase in steric hindrances to the orientation of a single polymer chain (see the first process in Scheme 22) or to that of a polymer chain and a monomer molecule (see the second process in Scheme 22) in the active

centre that are necessary for β -proton transfer. In addition, reduction of the pressure and temperature causes the transfer rate to decrease; at $T < -20^\circ\text{C}$, the chain transfer reactions can be suppressed at all.

Further modification of unsaturated polyolefin end groups can be done in various fashions.³⁰⁵ One of the most promising methods is to form macroinitiators by, *e.g.*, quantitative ($F_n = 1$) hydroboration of unsaturated end groups using 9-borabicyclo[3.3.1]nonane (9-BBN) (Scheme 23). Alkylborane groups thus obtained are readily oxidised at room temperature and form two radicals.³⁰⁵

Scheme 23

The alkoxy radical is reactive and readily initiates the polymerisation of α -olefins. The borinate radical is more stable, being incapable of initiating polymerisation. In fact, alkyl-9-BBN peroxide, which is in equilibrium with the reactive ($\text{C}-\text{O}^\bullet$) and stable ($\text{B}-\text{O}^\bullet$) radicals, forms an initiating and control system, which can maintain the 'pseudoliving' character of radical polymerisation³²⁶ and is similar to alkoxyamines based on the TEMPO stable radicals in the mechanism of action.

This method of formation of macroinitiators at the ends of unsaturated polyolefins was first used for the synthesis of the following diblock copolymers: PP-b-PMMA and PP-b-PMA,³²⁷ PP-b-PBA, PP-b-PS and PP-b-PVA³²⁸ and PP-b-poly(St-alt-MA).³²⁹ For the first copolymer the 'pseudoliving' polymerisation of MMA is described by Scheme 24.

Scheme 24

In this step, the molecular mass of the polymer increased from 1.3×10^4 (for the starting PP) to 2.9×10^4 (for the PP-b-PMMA copolymer) and the polydispersity index varied insignificantly, from 1.5 to 1.7 (Ref. 327). High efficiency of the initiation with alkylborane groups ($f_i = 1$) was pointed.

Hydroboration of unsaturated polyolefins (isotactic PP) followed by oxidation of the product (Scheme 25) was used to form hydroxyl end groups.³³⁰ Quantitative addition of the borane groups to the double bonds was characterised by lower oxidation efficiency (final value $F_n = 0.7$). The modified PP was activated by dibutyl tin dilaurate [$\text{Bu}_2\text{Sn}(\text{O}_2\text{CC}_{11}\text{H}_{23-n})_2$] and used as macroinitiator of anionic ring-opening polymerisation of ϵ -caprolactone.^{331,332} Based on PP with $M_n = 1.0 \times 10^3$, a PP-b-PCL copolymer with $M_n = 4.6 \times 10^3$ (see Ref. 332) was obtained; the monomer conversion was 70%.

A more complex procedure for conversion of unsaturated polyolefins to macroinitiators by hydroboration (Scheme 26) was also reported.³³³ Treatment of isotactic PP ($M_n = 2.2 \times 10^3$) with a borane/dimethyl sulfide complex led to replacement of all protons by PP chains. Subsequent addition of an organomagnesium reagent resulted in quantitative yield of a macroinitiator of 'living' anionic polymerisation, which was used for the synthesis of PP-b-PMMA block copolymer ($M_n = 2.5 \times 10^3 - 3 \times 10^3$). The 'living' mechanism of polymerisation of the PMMA blocks was confirmed by a linear increase in their molecular mass with time.

Consider two recently developed methods of *in situ* formation of active end groups in polyolefins in the course of metallocene-catalysed synthesis.⁸ They are based on the reaction of chain transfer to specific chain transfer agents (CTA) that do not affect the chain propagation rate. One method uses 9-BBN, while the other uses *p*-methylstyrene as CTA.

In situ modification of polyolefin end groups with 9-BBN appeared to be a complicated task. A proton of the 9-BBN group can be exchanged with ease with alkyl groups of metal alkyls and simultaneously react with unsaturated α -olefins. Therefore, polymerisation of olefins on metallocene catalysts can involve not only chain transfer to 9-BBN, but also side exchange reactions (between borane and aluminium alkyl groups of MAO) and hydroboration of monomers. Nevertheless, these problems were solved and the side reactions avoided.^{8,305} It was shown that the 9-BBN molecules form stable dimers in the conventional nonpolar solvents (hexane, toluene) used for carrying out metallocene-catalysed polymerisation and do not react with olefins. In this case, a perfluoroborate co-initiator, which does not react with most

alkylboranes, was used instead of MAO. This made it possible to develop a rather efficient polymerisation process (Scheme 27) resulting in polyolefins bearing one 9-BBN end group.

A narrow-MMD polymer was obtained³³⁴ by the polymerisation of ethylene in the presence of 9-BBN on the $[\text{Cp}_2\text{ZrMe}]^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$ and $[\text{Cp}_2^*\text{ZrMe}]^+[\text{B}(\text{C}_6\text{F}_5)_4]^-$ catalysts. A linear dependence of $P_n(\text{PE})$ on the monomer: 9-BBN concentration ratio was established:

$$P_n = \frac{k_p[\text{M}]}{k_{tr}[\text{CTA}]}$$

The k_p/k_{tr} ratio determined from the slope of the straight line thus obtained equals 75. The presence of borane end groups in PE was confirmed by NMR spectroscopy. 9-BBN was used as CTA in the synthesis of syndiotactic PS on $[\text{Cp}_2^*\text{TiMe}_2]^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$ catalyst.³³⁵ As the 9-BBN concentration increased, the molecular mass of PS decreased. 9-BBN has almost no effect on the stereotacticity of PS; however, the catalyst activity reduced, which was explained by competitive coordination of St and 9-BBN to the catalyst.

Borane-modified PE and PS were used as macroinitiators of controlled radical polymerisation of MMA and benzyl methacrylate.³³⁴⁻³³⁶ The macroinitiators were 'activated' using the known oxidation reaction of alkyl-9-BBN (see Scheme 23). The kinetics of MMA polymerisation ($T = 25^\circ\text{C}$) under the action of oxidised PE chains (PE: $M_n = 1.94 \times 10^4$ and 4.27×10^4 ; $M_w/M_n = 2.1$ and 2.2 , respectively) was studied.³³⁴ The linear increase in the molecular mass of PMMA with time confirmed the 'pseudoliving' mechanism of radical polymerisation. The resulting PE-b-PMMA copolymers had $M_n = 9.03 \times 10^4$ and 9.76×10^4 and similar MMDs ($M_w/M_n = 2.0$ and 2.9). An analogous picture was observed in a study³³⁵ of MMA and BMA polymerisation under the action of oxidised PS ($M_n = 1.5 \times 10^4$, $M_w/M_n = 2.2$). The molecular masses of the PMMA and PBMA blocks linearly increased with time, which indicated correctness of the polymerisation mechanism proposed. After 24 h, the PS-b-PMMA and PS-b-PBMA copolymers were characterised by M_n of 2.9×10^4 and 3.33×10^4 , respectively.

Yet another example of efficient CTA is provided by *p*-methylstyrene.⁸ Introduction of this compound and molec-

ular hydrogen in metallocene-catalysed polymerisation of olefins led to chain termination and formation of terminal *p*-methylphenyl groups. To make the reaction mechanism efficient and avoid the copolymerisation of olefins with MS, it was proposed to use a sterically hindered metallocene catalyst with bridging ligands. For instance, the problem of chain transfer to MS in the propylene polymerisation in toluene ($T = 30\text{ }^{\circ}\text{C}$) was solved using the *rac*-Me₂Si[2-Me-4-Ph(Ind)]₂ZrCl₂ + MAO system as catalyst.³³⁷ Owing to steric hindrances in the active centre, one *p*-MS molecule added to PP and after that, the polymerisations of all monomers ceased. To cleave the Zr–C bonds and restore the Zr–H bonds responsible for continuation of the polymerisation cycle, hydrogen was added.

The terminal character of *p*-methylphenyl groups was confirmed by ¹H and ¹³C NMR spectroscopies and by the involvement of PP in 'living' anionic polymerisation of styrene.³³⁷ The *p*-methylphenyl groups were 'activated' using the metallation reaction.

The modified PP was suspended in cyclohexane in the presence of excess Bu^sLi at room temperature for 5 h. The product was filtered off and used in the polymerisation of styrene. An increase in the molecular mass of PS with time confirmed the 'living' mechanism of polymerisation. Two samples of the PP-*b*-PS copolymer with $M_n = 5.4 \times 10^4$ and 1.175×10^5 ($M_w/M_n = 2.34$ and 2.25) were prepared (cf. $M_n = 2.59 \times 10^4$ and $M_w/M_n = 2.3$ for the initial modified PP).

The last-named two methods of functionalisation of polyolefins and formation of macroinitiators seem to be the best. They provide a convenient transition from metallocene catalysed polymerisation of the first block to controlled radical or ionic polymerisation of the second block. This offers prospects for attachment of blocks of different chemical nature to the polyolefin blocks and for the design of copolymers of specified molecular structure.

c. Macroinitiators based on another polymers

Polydimethylsiloxane (PDMS) containing flexible hydrophobic chains is produced on a large-scale basis and attracts considerable interest of researchers as a component of block copolymers. The compound is widely used as macroinitiator of polymerisation of various monomers in both the native (with silanol end groups) and end-group-modified forms. Remind that usually PDMS is synthesised on a large-scale basis by anionic polymerisation of cyclic dimethylsiloxanes accompanied by partial polycondensation.²² The modification of SiOH groups in PDMS can be best exemplified by the etherification reaction. PDMS containing one or two silyl ketene acetal groups was used as macroinitiator of GTP of (meth)acrylic acids protected with *tert*-butyl or dimethylsilyl groups.^{338–340} The initiation efficiency was low and therefore the di- and triblock copolymers contained an impurity of the starting PDMS.³³⁸ Hydrolysis of the protected blocks gave amphiphilic copolymers of PDMS and PAAc (or PMAAc) of the A-*b*-B and B-*b*-A-*b*-B types. The copolymers possessed the properties of a surfactant and stabilised the polymerisation dispersions even in supercritical carbon dioxide.^{339,340} PDMS was also used as macroinitiator of 'pseudoliving' radical polymerisation.^{341,342} To this end, halogen derivatives of PDMS were first obtained and the 'pseudoliving' ATRP was carried out.

Recently, yet another method of formation of macroinitiators of radical polymerisation was developed. This is ultrasonic destruction of polymer chains in the presence of monomers. The technique is of particular importance for the synthesis of block copolymers based on natural polymers, *e.g.*, chitosan {poly[β(1–4)-2-amino-2-deoxy-D-glucose]} belonging to polysaccharides.³⁴³ Chitosan is a cationic polyelectrolyte characterised by high reactivity and sorption capacity and also radiation resistance. Ultrasonic destruction of chitosan ($M_v = 1.44 \times 10^5$, frequency 22 kHz, electric current 40 mA, $T = 0\text{ }^{\circ}\text{C}$) in an acetic acid solution in the presence of VPD, AA, acrylonitrile and DMAEMA salt causes the formation of block copolymers containing almost no homopolymers.³⁴³ Only in the case of AAm did the final product contain about 2 mass % of PAA. Clearly, the products of synthesis should be polydisperse with respect to molecular mass and composition. Indeed, ultrasonic destruction of polymers takes some time to complete; the limiting value of the molecular mass is attained at the end of this time interval.³⁴⁴ For chitosan, the limiting molecular mass is 2×10^3 after 15–20 min.³⁴³ As a result, in the initial step of ultrasonic destruction the macroradicals initiating the polymerisation of monomers are longer than in, *e.g.*, 20 min; this is the reason for polydispersity of the product.

2. Combination of 'living' cationic and 'living' anionic polymerisation

Synthetic procedures involving a combination of several types of 'living' ionic and/or 'pseudoliving' radical polymerisation open new prospects for the design of block copolymers; however, this requires considerable experimental efforts. The main problem consists in quantitative conversion of one type of active centres into another type of polymerisation centres. Studies on conversion of 'living' carbocations into 'living' carbanions began in the early 1990s.^{345–353} They were aimed at obtaining block copolymers of nonpolar PIB (elastomer highly resistant to external factors) with rigid poly(meth)acrylate, poly(meth)acrylic acid, polyacrylamide and polyester polar blocks. A number of methods of modification of PIB macrocations were proposed.

Cationic polymerisation of IB was initiated with bifunctional cumyl ether, namely, 1,3-bis(1-methoxyisopropyl)-5-(*tert*-butyl)benzene in the presence of dimethylacetamide and TiCl₄.^{348,349} Therefore, the polymerisation carried out in a methyl chloride–*n*-hexane mixture [40 : 60 (vol.%)] with heating in the last step immediately gave a dichloro derivative of

PIB (Scheme 28),²² Cl-PIB-Cl, which had the expected molecular mass and showed a narrow MMD ($M_n = 6.1 \times 10^4$, $M_w/M_n = 1.15$). In the second stage it was used in the toluene alkylation according to Friedel-Crafts and a ditolyl derivative of PIB was obtained ($F_n = 1$).

In the third stage, MePh-PIB-PhMe was transformed into a 'living' polydianion by the reaction of *sec*-butyllithium (in *n*-hexane) in the presence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) followed by the reaction with 1,1-diphenylethylene in THF. Then, the monomer (MMA) was introduced, the temperature was reduced and PMMA-*b*-PIB-*b*-PMMA copolymers were obtained (see Scheme 28). The copolymers were characterised by $M_{n\text{PMMA}} = 7 \times 10^3 - 1.65 \times 10^4$ and a narrow MMD ($M_w/M_n = 1.23 - 1.30$) and contained almost no homopolymers.³⁴⁹ The PMMA blocks showed a high stereoregularity (content of syndiotactic units was about 75%).

A simpler procedure for quantitative conversion of PIB macrocations to macroanions was also proposed.^{9, 354-356} In the first step cationic polymerisation of IB in a MeCl-*n*-hexane mixture was initiated by TiCl_4 with 2,4,4-trimethyl-2-chloropentane (Scheme 29). 'Living' PIB chains were 'capped' with diphenylethylene, terminated with methanol and diphenylmethoxyl terminal fragments were thus obtained. In the second step they were quantitatively converted to carbanions by the reaction of methoxy groups with alkali metals. Then, the polar monomer (TBMA) was introduced, the temperature was reduced and 'living' anionic polymerisation was carried out. This resulted in PIB-*b*-PTBMA copolymers with controlled molecular mass and a narrow MMD; subsequent hydrolysis gave a block polyacid PIB-*b*-PMAAc (see Scheme 29).

Yet another method of transformation of PIB macrocations into macroanions to obtain PIB-*b*-PTBMA

Scheme 29

(Scheme 30)⁹ differs from the technique considered above in that (i) macroanions are 'capped' with thiophene in the last step of IB polymerisation and (ii) thiophenelithium derivative of PIB ($F_n = 1$) should be synthesised to initiate anionic polymerisation of polar monomers, such as TBMA.

3. Combination of 'living' anionic and 'pseudoliving' radical polymerisation

The discovery of various types of 'pseudoliving' radical polymerisation was followed by intensive use of these techniques in multimode polymerisation. The most promising method of synthesis of block copolymers with controlled molecular structure and low polydispersity is a combination of controlled radical polymerisation and 'living' ionic polymerisation.¹⁸¹ At the same time, attempts to obtain, *e.g.*, PS-*b*-PBA, PS-*b*-PMMA and PS-*b*-PI copolymers with rather broad MMDs by 'pseudoliving' polymerisation (SFRP) following the free radical process have also been reported.³⁵⁷

A specific feature of the multimode process involving a 'pseudoliving' (radical mechanism) and a 'living' (ionic mechanism) polymerisation consists in performing the ionic polymerisation first. The reason is not only the higher temperatures of controlled radical processes, but also easier conversion of ionic active centres into the groups necessary for

initiation and control of 'pseudoliving' radical polymerisation. These groups are different for different types of polymerisation, namely, nitroxides for SFRP, mobile halogen atoms for ATRP, dithioester groups for RAFT and dithiocarbonate (or trithiocarbonate and trithiocarbamate) groups for MADIX.

There are strong proofs of the synthesis of linear block copolymers of well-defined structure and narrow MMD by combining 'living' anionic polymerisation with SFRP or ATRP. A PB-*b*-PS copolymer was synthesised using anionic polymerisation followed by SFRP.^{358,359} The process (see Scheme 31) began with 'living' anionic polymerisation of butadiene in cyclohexane. Termination of PB macroanions to change the polymerisation mechanism was done with an epoxy-functionalised alkoxyamine, namely, 2,2,6,6-tetramethyl-1-(2-glycidyloxy-1-phenylethoxy)piperidine.³⁵⁸ The nitroxide-'capped' PB block had $M_n = 3.84 \times 10^3$ (this is in agreement with the calculated values) and a narrow MMD ($M_w/M_n = 1.02$). High degree of functionalisation of PB ($F_n > 0.95$) was established by ¹H NMR spectroscopy. In the second stage, the nitroxide-'capped' PB served a macroinitiator of 'pseudoliving' polymerisation (SFRP) of styrene in the bulk (see Scheme 31) with the initiation efficiency $f_i = 1$. After 20 h, styrene conversion was 65%. The PB-*b*-PS copolymer was characterised by $M_n = 1.74 \times 10^4$, which was in agreement with the calculated value ($M_n = 1.5 \times 10^4$), and a low polydispersity index ($M_w/M_n = 1.22$).

Considerable literature devoted to combination of 'living' anionic polymerisation with ATRP is available. Now we will dwell on some typical examples. Nonpolar block copolymers PI-*b*-PS were synthesised using a multimode process involving anionic polymerisation and ATRP.³⁶⁰ The synthesis involved not only the polymerisation of particular blocks and transformation of active centres, but also the formation of fluorescent phenanthryl or anthryl linkers between the blocks (Scheme 32) to study the structure and properties of the copolymers. The polymerisation of isoprene in cyclohexane was followed by sequential addition of 1-(9-phenanthryl)- or 1-(2-anthryl)-1-phenylethylene and α, α' -dibromo-*p*-xylene to 'living' PI. The product was isolated and used in 'pseudoliving' radical polymerisation of styrene in the presence of the CuBr-2,2'-bipyridyl system (see Scheme 32). Gel-permeation chromatography and NMR studies revealed good agreement between the experimental [$M_n = (5-45) \times 10^3$] and calculated

Scheme 32

molecular mass and a low polydispersity ($M_w/M_n = 1.1-1.2$) of the PI-*b*-PS copolymers.

A combination of 'living' anionic polymerisation with ATRP was used³⁶¹ for preparation of PS-*b*-P2VP block copolymer containing nonpolar and polar (polybasic) blocks. Anionic polymerisation of St (first stage) in benzene was initiated by Bu^sLi and followed by modification of the PS chain ends to 'cap' them with mobile chlorine atoms (Scheme 33). The product was isolated and dissolved in toluene. The catalyst ($\text{Cu}^{\text{I}}\text{Cl}-2,2'$ -bipyridyl) was introduced followed by the second monomer (2VP) and the mixture was heated to 120°C . Gel-permeation chromatography and NMR data showed that the molecular mass of PS-*b*-PVP was insignificantly different from the calculated MM and that the MMD was also narrow ($M_w/M_n = 1.05-1.14$).

A combination of anionic ring-opening polymerisation with ATRP was used in the synthesis of diblock copolymers containing polar non-ionogenic and polyacid blocks. In particular, anionic ring-opening polymerisation of ϵ -caprolactone (similar to the process shown in Scheme 3) followed by ATRP of TBA resulted in a precursor (PCL-*b*-PTBA copolymer). Subsequent hydrolysis of the PTBA blocks (see the process in Scheme 6) gave a PCL-*b*-PAAc copolymer.³⁶² As another example, copolymers PEO-*b*-PTBA were synthesised by anionic ring-opening polymerisation of EO followed by mod-

ification of the OH groups of PEG with α -halo esters and subsequent ATRP of TBA.³⁶³ The resulting copolymers were then converted to PEO-*b*-PAAc.

Since 'living' ionic and 'pseudoliving' radical polymerisations themselves allow one to synthesise a broad range of binary and ternary block copolymers, combination of the techniques offers additional prospects for the design of block copolymers. In this connection, noteworthy is a study³⁶⁴ on the synthesis of PDMS-*b*-PS-*b*-PDMOMSPA terpolymers {PDMOMSPA is poly[3-(dimethoxymethylsilyl)propyl acrylate]}. An appropriately chosen multimode process involved anionic ring-opening polymerisation of cyclic dimethylsiloxane, transformation of the SiOH groups of PDMS into 2-bromoisobutylsilyl groups and two consecutive ATRPs of styrene and 3-dimethoxymethylsilylpropyl acrylate. The resulting terpolymer was characterised by high affinity to the surface of the silicon plate where it formed a 'brush'-like layer.

4. Combination of 'living' cationic and 'pseudoliving' mechanisms

Controlled synthesis of block copolymers using 'living' cationic and 'pseudoliving' radical (ATRP) polymerisation was first reported in 1997.³⁶⁵ Earlier, 'living' cationic polymerisation to obtain poly(vinyl ethers) was combined with free radical polymerisation of methacrylonitrile³⁶⁶ and benzyl

Scheme 33

methacrylate.³⁶⁷ The lack of control in the second stage led to polydisperse final products containing homopolymers. The authors of study³⁶⁵ synthesised the PS-*b*-PS, PS-*b*-PMA and PS-*b*-PMMA copolymers (with two nonpolar blocks and with nonpolar and polar blocks) of controlled structure and narrow MMD. 'Living' cationic polymerisation of St was carried out using the SnCl₄–1-phenylethyl chloride initiating system in the presence of Bu₄ⁿNCl as nucleophile (Scheme 34).

Scheme 34

The chloro derivative of PS, isolated upon reprecipitation in methanol ($M_n = 2.1 \times 10^3$, $M_w/M_n = 1.17$), served as a macro-initiator of ATRP of styrene, MA and MMA in toluene using the Cu^ICl–4,4'-di(non-5-yl)-2,2'-bipyridyl catalytic system. The molecular masses of the PS-*b*-PS, PS-*b*-PMA and PS-*b*-PMMA copolymers ($M_n = 5.08 \times 10^3$, 6.33×10^3 and 1.109×10^4 , respectively) were in agreement with the calculated values (at $f_i = 1$). This means that the unmodified chloro derivative of PS is a highly efficient macroinitiator of ATRP of styrene and (meth)acrylates. The polydispersity indices of the copolymers were also low ($M_w/M_n = 1.10$, 1.20 and 1.57, respectively).

An important advantage made by the authors of study³⁶⁵ is the one-pot polymerisation of, *e.g.*, the PS-*b*-PMA copolymers. To this end, the chloro derivative of PS was deactivated by methyl methacrylate introduced at -15°C . Then the temperature was increased and the solvent, the Lewis acid and the ester were distilled off, a solution of the catalytic system in toluene and the monomer were added, the temperature was raised to 100°C and ATRP of methyl methacrylate was carried out. One-pot multimode process resulted in the PS-*b*-PMA copolymer characterised by almost the same parameters ($M_n = 6.3 \times 10^3$, $M_w/M_n = 1.21$) as the copolymer obtained *via* isolation of intermediate product.

Similar syntheses of PS-*b*-PIB-*b*-PS and PAOS-*b*-PIB-*b*-PAOS copolymers [PAOS is poly(*p*-acetoxystyrene)] containing three nonpolar blocks, as well as one nonpolar and two polar blocks, were reported.³⁶⁸ Here, 'living' PIB chains propagating along both directions were 'capped' with styrene at both ends. This resulted in a dichloro derivative of PIB, which efficiently initiated ATRP of various monomers (styrene and AOS). This combination of polymerisation processes was also used for the synthesis of block copolymers of PIB with PMAAc.³⁶⁹ 'Living' cationic polymerisation led to mono-chloro and dichloro derivatives of PIB, while ATRP of protected MAAc monomers in the presence of the Cu^ICl(Cu^IBr)–*N,N,N',N',N''*-pentamethyldiethylenetriamine catalytic system followed by acid hydrolysis gave di- and triblock copolymers PIB-*b*-PMAAc and PMAAc-*b*-PIB-*b*-PMAAc. The molecular masses of the blocks varied as follows: $M_{n\text{PIB}} = 2.8 \times 10^3$ – 5.6×10^4 and $M_{n\text{PMAAc}} =$

4.3×10^2 – 1.72×10^3 . Thus, the authors reached the main goal, namely, they synthesised model block copolymers of variable length of the elastomeric and rigid ionic blocks. The mechanical and rheological properties of the block copolymers were determined by aggregation of macrocoils governed by hydrogen and ionic bonds.³⁷⁰

5. Application of bifunctional initiators

Design of selective multifunctional initiators is a new promising approach to implementation of multimode (including one-pot) polymerisation processes. Only a few studies on the subject are available at the moment; however, researchers point to great prospects for this strategy of synthesis of block copolymers. Unlike a simple combination of various polymerisation mechanisms, here the main advantage consists in the possibility of carrying out sequential and concurrent multimode processes that do not include additional chain end functionalisation stages. Puts and Sogah^{371–374} pioneered in formulating the problem and doing research in this field. Initially, the global challenge was to design a universal initiator capable of initiating the most important types of controlled polymerisation processes.³⁷¹ It was assumed that corresponding functional groups of the initiator will act independently. Puts and Sogah greatly succeeded in solving the problem posed. They synthesised a multifunctional initiator 1-[(*tert*-butyl)dimethylsiloxy]-2-[4-[2-(4,5-dihydrooxazol-2-yl)ethyl]-phenyl]-2-(2,2,6,6-tetramethyl-1-piperidineoxy)ethane (**8**).

The compound was designed to allow for the following: (i) alkyl adducts of nitroxides (**1**) can initiate a SFRP process; (ii) C–H bonds (**2**) in α -position to the oxazoline group can form carbanions and initiate 'living' anionic polymerisation;³⁷⁵ (iii) oxazoline ring (**3**) can be a monomer in cationic ring-opening polymerisation;³⁷⁶ (iv) neutral oxazolines are stable to free radicals and ionic reactions; (v) oxazolines are good protective groups for carboxylic acids and can be readily removed;³⁷⁷ (vi) alkylsiloxy group (**4**) can initiate anionic ring-opening polymerisation of heterocycles;³⁷⁸ (vii) by removal of oxazoline protection from CO₂H groups (**3**) and *tert*-butyldimethylsilyl protection from OH groups (**4**) the polymerisation centres can be converted into polycondensation centres.³⁷⁹ Thus, initiator **8** includes four polymerisation centres and allows one to obtain linear, graft and star-like block copolymers. Since only a [poly(2-oxazoline)-*g*-PS] graft copolymer was synthesised using this initiator,³⁷¹ analysis of the synthetic procedure goes beyond the scope of this review.

Then, the multifunctional initiators **9a–d** and tribromoethanol (**10**) were proposed.^{372–374} Using some of them, not only one-pot, but also concurrent multimode syntheses of linear block copolymers were developed. Consider these results in more detail. A bifunctional initiator 1-hydroxy-2-phenyl-2-(2,2,6,6-tetramethylpiperidin-1-yloxy)ethane containing a nitroxide and an OH group (**9a**) was used³⁷⁴ for the synthesis of A-*b*-B and B-*b*-A copolymers from poly(ϵ -caprolactone)

and PS. The role of the order in which the multimode process is carried out (anionic polymerisation of ϵ -caprolactone (CL) followed by 'pseudoliving' SFRP of styrene, or *vice versa*) and the relative reactivities of nitroxide radicals attached to the initiator and to the PCL chain end in the polymerisation of styrene was studied. Anionic ring-opening polymerisation of CL under the action of the OH groups of the initiator in the presence of catalyst $Al(OPr^i)_3$ readily occurred in toluene at 25 °C. However, the nitroxide group of initiator initiated bulk SFRP of styrene only at a high temperature ($T = 125$ °C). Due to significant differences between polymerisation conditions various multimode processes (Scheme 35) involving isolation of intermediate products (**11** or **12**) could be performed with ease. There was no need for additional chain end modification steps. Gel-permeation chromatography and 1H NMR studies revealed full control of the MM of the PCL and PS blocks (linear increase in MM with monomer conversion) irrespective of the order in which they were synthesised; the MMDs of particular blocks and the whole copolymer also remained narrow ($M_w/M_n = 1.07-1.4$). It was found that the nitroxide radicals at the PCL chains are more reactive than those attached to initiator; this manifested itself in acceleration of the polymerisation of styrene in the presence of macroinitiator **11** compared with the homopolymerisation of styrene under the action of the unmodified initiator. In addition, the molecular mass of PS in the block copolymer was controlled up to high values ($M_n = 1.5 \times 10^5$). The authors provided no explanation

for this effect, but the assumption of a change in the medium polarity in the presence of PCL as the sole factor affecting the system under study was ruled out (SFRP of styrene with covalently nonbonded PCL of various molecular mass showed no acceleration of the polymerisation process).

The activity of a simpler commercially available and cheap bifunctional initiator **10** in another multimode process involving 'living' anionic polymerisation and ATRP was checked.³⁷⁴ First, high efficiency of the initiator in (i) anionic ring-opening polymerisation of ϵ -caprolactone [in toluene in the presence of catalytic amounts of $Al(OPr^i)_3$]; (ii) ATRP of styrene (in toluene with $Cu^I Cl-2,2'$ -bipyridyl as catalyst); and (iii) ATRP of MMA in THF in the presence of $NiBr_2(PPh_3)_2$ or $RhBr(PPh_3)_3$ complexes was proved. Then, multimode synthesis of A-b-B and B-b-A copolymers based on PS (or PMMA) and PCL were carried out using the reverse strategy, where polymerisation of CL was followed by polymerisation of styrene (MMA) (see example in Scheme 36). According to 1H NMR data, macroinitiators **13** and **14** and hydroxyl-terminated PS showed high efficiency in polymerisation of the second block ($f_i = 1$). This excluded additional chain-end functionalisation stages from the synthetic procedure. The molecular masses of the PS, PMMA and PCL blocks in the copolymers were in agreement with the calculated values. The polydispersities of particular blocks and the copolymer were also low ($M_w/M_n = 1.21$ and 1.17 for PS-b-PCL with $M_{nPS} = 2.25 \times 10^3$ and $M_{nPS-b-PCL} = 4.45 \times 10^4$, respectively). Taking into account the fact that one end of the diblock copolymer obtained after ATRP of the second block contained chlorine atoms capable of initiating ATRP of the third block, a PCL-b-PBA-b-PMMA copolymer of specified molecular structure was synthesised.³⁷⁴

The possibility of concurrent multimode synthesis of diblock copolymers using bifunctional initiators was first

Scheme 35

Scheme 36

reported by Sogah and co-workers.³⁷³ Using 1-benzoyl-2-[4-(chloromethyl)phenyl]-2-(2,2,6,6-tetramethyl-1-piperidinoxy)-ethane (**9c**) as initiator, the authors carried out concurrent ‘pseudoliving’ SFRP of styrene and ‘living’ cationic polymerisation of 2-phenyl-2-oxazoline (PhOx) (Scheme 37). This unique synthesis was performed in the bulk as follows. The reactor was charged with anhydrous initiator and anhydrous silver triflate (silver trifluoromethanesulfonate, AgOTf), purged with an inert gas, an excess PhOx was added at 25 °C; this resulted in a cationic derivative of the initiator in excess of the monomer. Then, styrene was introduced, the temperature was raised to 125 °C and polymerisation was carried out for 44 h. The rigid block copolymer was cooled, dissolved in CH_2Cl_2 and methanol was added to convert the charged phenyloxazoline group of PPhOx-b-PS to methyl ether group. The AgCl precipitate was filtered off. The PPhOx-b-PS diblock copolymers were characterised by $P_{n \text{ PPhOx}}$ ranging from 29 to 198. The copolymers contained almost no homopolymers (according to gel-permeation chromatography and ^1H NMR spectroscopy data) and had a narrow MMD ($M_w/M_n = 1.27 - 1.40$). Subsequent hydrolysis of the oxazoline units led to copolymers of PEI-b-PS with linear polyethyleneimine (PEI).

Questions posed by Sogah and co-workers.³⁷³ remain unanswered as yet. In particular, the authors confirmed the formation of block copolymers, but gave no proofs of concurrent character of ‘living’ cationic and ‘pseudoliving’ SFRP polymerisation throughout the whole 44 h. An unambiguous answer can be obtained by investigating the kinetics and mechanisms of this and other multimode processes. At the moment, it should be emphasised that this study opens a new avenue of research on polymer synthesis, which involves concurrent and competing polymerisation processes.

IV. Matrix effects in block copolymerisation processes

Now we will consider yet another important aspect, which was ignored for long in studies on the synthesis and properties of block copolymers. Most studies on the subject concern block copolymers whose components are thermodynamically incompatible or show a limited compatibility; macromolecules of such components form ‘supercrystal’ structures in the bulk^{15, 19, 380, 381} and various micellar and vesicular structures

in solution.^{1, 7, 9, 13, 382} However, block copolymers with highly compatible, chemically complementary components are also of considerable interest. Such components can form a system of co-operative noncovalent bonds between blocks, namely, electrostatic bonds, as in ampholytic (or zwitter-ionic) block copolymers,^{112, 113} or hydrogen bonds, as in the block and graft copolymers synthesised from non-ionogenic polymers and polyacids.^{6, 383} This type of block copolymers is treated as intramolecular polymer complexes (IntraPC). They can be used as binders in biotechnology and medicine, membranes, as flocculants and drag reducing agents in the case of turbulent flow.³⁸⁴ Taking into account specific properties of the block and graft copolymers that form IntraPC, the formation of a system of noncovalent bonds between the components in the course of synthesis was hypothesised (in other words, the case in point is manifestation of matrix effects that are well known for polymerisation of monomers in the presence of chemically complementary polymer chains, matrices, in the block and graft copolymerisation).³⁸⁵ The fruitfulness of this hypothesis was first confirmed in the kinetic studies of the synthesis of starch-g-PAA and PVS-g-PAA graft copolymers. Namely, it was shown that the rate of graft copolymerisation of PAA with starch³⁸⁶ and PVS³⁸⁷ substantially increases compared to the rate of homopolymerisation of acrylamide under identical conditions. These results were considered in a review.³⁸⁴

Since investigations of the matrix phenomena in block copolymerisation processes are in the early stage of development, we will dwell on them in more detail. Studies^{388, 389} concern the kinetics of radical block copolymerisation of PAA with different-MM PEG whose terminal groups were activated in the reaction of OH groups with Ce^{IV} ions [see reaction (7)]. Block copolymerisation was carried out in aqueous solution at 25 °C. For comparison, homopolymerisation of AAm initiated with ethanol instead of PEG was performed under similar conditions. Chemical complementarity of PAA and PEG was preliminarily confirmed in the complexation studies of covalently nonbonded polymers³⁹⁰ and a system of H-bonds in the resulting InterPC³⁹¹ in water.

The results of dilatometric studies are presented in Fig. 2. All kinetic curves show an induction period. The authors believed that it is governed by the ‘lifetime’ of the intermediate complex formed by Ce^{IV} ions with the OH groups of PEG. The rate of block copolymerisation of PAA with the lowest-molecular-mass sample (PEG1) and the yield of the PAA-b-

Table 1. Kinetic parameters of block copolymerisation of PAA with PEG of different molecular mass and homopolymerisation of AA.

Polymer	$10^{-4} M_{\text{vPEG}}$	τ/min	$10^5 V_{\text{p}}^{20}/\text{mol dm}^{-3} \text{ s}^{-1}$	$10^5 V_{\text{p}}^{40}/\text{mol dm}^{-3} \text{ s}^{-1}$	$10^5 V_{\text{p}}^{60}/\text{mol dm}^{-3} \text{ s}^{-1}$	q (%)
PAA	—	15.5	1.6	1.02	—	53.5
TBC1	0.1	168.0	0.6 ^a	—	—	14.2
TBC3	0.6	54.9	5.76	5.62	0.16	63.4
TBC4	1.5	31.4	4.62	4.19	0.34	69.5
TBC5	4.0	25.0	15.5	7.92	2.87	80.3

Note. τ_0 is the induction period; V_{p}^{20} , V_{p}^{40} , V_{p}^{60} are the block copolymerisation rates at a monomer conversion, q , of 20%, 40% and 60%, respectively; and q is the monomer conversion after 20 h.

^a Listed is the value for V_{p}^{10} .

**Figure 2.** Conversion for homopolymerisation of AA (1) and block copolymerisation of PAA with PEG with a molecular mass of 1×10^3 (2), 6×10^3 (3), 1.5×10^4 (4) and 4×10^4 (5) at 25 °C plotted vs. time.

PEO-b-PAA1 triblock copolymer (TBC1) were very low, whereas the induction period τ_0 was very long compared to τ_0 for homopolymerisation of AAm (see Fig. 2, curves 1 and 2). Another situation was observed in block copolymerisation of PAA with longer-chain PEG ($M_{\text{v}} > 1 \times 10^3$). Namely, the induction period shortened and the copolymerisation rate and the yield of the final product increased (curves 3–5). This is quantitatively characterised by the data listed in Table 1.

Significant acceleration of the block copolymerisation and an increase in AAm conversion in the synthesis of the TBC3, TBC4 and TBC5 copolymers compared to the synthesis of PAA points to a positive kinetic matrix effect due to the interaction of the PEO blocks (matrices) with the growing daughter PAA blocks that are covalently bonded through a system of hydrogen bonds (see Fig. 2).^{388, 389} The effect became more pronounced with elongation of the PEG block. Indeed, a change in M_{vPEG} from 6×10^3 to 4×10^4 caused the rate of block copolymerisation (V_{p}^{20}) to increase by an order of magnitude compared to the homopolymerisation rate of AAm (see Tabl. 1). This is consistent with the well-known increase in the energy of the interaction between partners and stability of the polycomplex with elongation of polymer chains. Unlike similar matrix processes that occur in water due to formation of a system of H-bonds between the covalently nonbonded matrix and the daughter chain and lead to high compaction of InterPC,³⁹² matrix block copolymerisation of PAA with PEO resulted in water-soluble IntraPC. This is a manifestation of the effect of the third hydrophilic block (PAA), which prevented high hydrophobisation and compaction of macroglobules.

A characteristic feature of the PAA-b-PEO-b-PAA triblock copolymers is a nearly linear increase in the molecular

mass of the PAA blocks (from 4.5×10^4 to 9.07×10^5) with an increase in the molecular mass of the PEO central block.^{388, 389} It was established that the interblock interaction strongly affects both the synthesis and the molecular structure of the block copolymers.

Yet another type of matrix effects was observed³⁹³ in a comparative study of the RAFT polymerisation of monomer mixtures, namely, *N,N*-dimethylacrylamide (DMAA) and 2-(*N*-butyl perfluorooctane-fluorosulfonamido)ethyl acrylate (BPFOFSAEA), in the presence of both low-molecular-mass CTA (3-benzylsulfonylethylthiocarbonylpropionic acid) and a macroCTA obtained by etherification of the low-molecular-mass CTA with PDMS ($M_{\text{n}} = 1.8 \times 10^4$). Polymerisation was carried out under identical conditions at 60 °C. The DMAA content was constant and the content of the second monomer was varied; azobis(isobutyronitrile) was used as initiator. α, α, α -Trifluorotoluene was chosen as the common solvent with allowance for high hydrophobicity of macroCTA. RAFT polymerisation of a mixture of monomers resulted in poly(DMAA-co-BPFOFSAEA) copolymer in the presence of the low-molecular-mass CTA and in poly(DMAA-co-BPFOFSAEA)-b-PDMS-b-poly(DMAA-co-BPFOFSAEA) copolymer in the presence of the macroCTA. In both cases the RAFT process showed some common features, namely, a linear increase in the molecular mass of the polymers with conversion and narrow MMDs for all products ($M_{\text{w}}/M_{\text{n}} = 1.12$ –1.26). However, the compositions of the side blocks in the triblock copolymers were basically different from the compositions of the copolymers obtained in the presence of the low-molecular-mass CTA. Namely, the triblock copolymers contained a large excess of BPFOFSAEA. In fact, the hydrophobic matrix (PDMS block) ‘selected’ the most hydrophobic monomer (BPFOFSAEA) from the mixture, to which it has a higher thermodynamic affinity, this is the reason for the effect observed. Shortening of the induction period in the kinetic curves for the RAFT polymerisation in the presence of macroCTA was also pointed out.

* * *

In this review we considered new methods of synthesis of block copolymers and new aspects of the investigations of the regularities of polymerisation processes, with allowance for chemical complementarity of the blocks formed. This may be useful for further research in this field.

Abstract. Rigid aromatic dendrimers synthesised by convergent, divergent and combined methods are considered. The potential of practical application of rigid aromatic dendrimers is analysed. The bibliography includes 121 references.

I. Introduction

In the last decades, data on dendrimers have been covered in numerous reviews,^{1–28} which suggests continuing interest in this unique class of monodisperse highly branched macromolecules with a highly ordered controllable and regular structure. Unlike conventional polymers, dendrimers incorporate the following three main structural components: the central fragment (core), internal branched units and terminal units (Fig. 1). Two main strategies, divergent and convergent, were developed for the synthesis of dendrimers.

The divergent approach is based on iterative coupling and activation steps starting from the polyfunctional core, the growth of molecules proceeding from the centre to the periphery. In the first step (the growth step), monomers (building blocks) are attached to the core to form first-generation dendrimers (Fig. 2). Monomers (A_nB) containing functional groups of different nature are generally used as building blocks. In these monomers, one group (B) is reactive and can be involved in the reaction, whereas other groups (A_n , their number depends on the nature of the monomer) are deactivated. In the next step (the activation step), the passive groups are activated by deprotection or in other ways, after which these groups are ready to be involved in the growth of dendrimers. Therefore, dendrimers grow layer by layer. Theo-

retical calculations demonstrated that this growth is, however, not infinite.²⁹ The density of the periphery of the molecule increases from generation to generation, and the resulting steric hindrance limits the growth of dendrimers. As a result of steric restrictions, the molecule assumes a nearly spherical shape. The packing density at the periphery achieved in this step is called the De Gennes dense packing.²⁹ According to this model, attempts to grow the subsequent layer should lead to the formation of irregular dendrimers (due to the incomplete substitution of functional groups). This problem is particularly acute for rigid aromatic dendrimers.

The functionalisation of dendrimers in the final step of the molecule formation can be performed with the use of monomers containing the necessary functional groups. The difficulties of controlling the transformations of the functional groups are often considered as a drawback of the divergent approach to the synthesis of dendrimers. Not all functional groups of the growing macromolecule can be involved in the growth of a new layer, which in turn can result in defects in the structure of the final product. This problem can be obviated by using excess of the monomer A_nB , which creates difficulties in the step of purification of the final product. Nevertheless, the divergent approach is a method of choice for the synthesis of high-

generation dendrimers if coupling reactions are selective and efficient.

The convergent approach is also based on the alternation of growth and activation steps. However, the growth of macromolecules occurs from the periphery to the centre, which is achieved due to formation of branched monomers called dendrons, which are attached to the core in the final step of the synthesis. In the first step, a monomer A_nB is attached to the monomer containing peripheral groups of the future dendrimer (the growth step) giving rise to the first-generation dendron (Fig. 3). The activation and coupling of the dendron to the monomer A_nB gives the next-generation dendron. In the

Figure 3. Schematic representation of the synthesis of dendrimers by the convergent method.

last step, the dendrons are attached to the central polyfunctional fragment (core) to form the final dendrimer.

The convergent approach also has advantages and disadvantages. The number of reactive functional groups of each molecule involved in the reaction is small and remains constant regardless of the number of generations and the size of the dendron, thus allowing minimisation of the amount of unconsumed groups. The reaction can be brought to completion using a small excess of the monomer (unlike the divergent method). It is much easier to purify the reaction products synthesised according to the convergent approach, because the reaction mixture contains smaller amounts of by-products. The difference in physical properties of the components of the reaction mixture allows the efficient use of chromatographic purification, thus providing the access to individual macromolecules. However, the convergent approach does not allow the formation of high-generation dendrimers (*i.e.*, dendrimers composed of a large number of layers) because of steric hindrance in the step of coupling of the dendron to the core.¹

An advantage of the convergent method is that it can be used for the preparation of dendrimers containing different functional groups at the periphery of the molecule. To this end, building blocks containing various substituents are used.

Therefore, the divergent approach is the method of choice for the formation of high-molecular-mass monodisperse dendrimers composed of a large number of layers, whereas the convergent approach is suitable when it is necessary to synthesise monodisperse macromolecules containing a small number of layers and different functional groups at the periphery.¹

The potential of the synthesis of macromolecules with different architecture and chemical composition can be extended by combining the divergent and convergent schemes.^{23, 30–33} For example, a versatile procedure for the synthesis of organosilicon dendrimers³¹ is based on the grafting of dendrons, which are prepared according to the convergent scheme onto an oligomeric dendrimer constructed by the divergent method.

In the present review, emphasis is given to rigid dendrimers, because these macromolecules have received little attention in the literature.^{34–38} However, these compounds belong to one of the most interesting classes of dendrimers, are characterised by high chemical and thermal stability and are soluble in conventional organic solvents. Rigid aromatic dendrimers of controlled size hold promise in high-temperature catalysis. In addition, aromatic dendrimers with a π -conjugated system can find use in optoelectronic devices.^{26, 28, 33, 34, 39–41}

II. Rigid aromatic dendrimers synthesised by the convergent method

Polyphenylene dendrimers have been synthesised for the first time^{42, 43} by the convergent method using the Suzuki coupling of substituted phenylboronic acid **1** with aryl bromides.⁴⁴ This was used for the synthesis of dendrimers based on 1,3,5-triphenyl-substituted monomers.

A first-generation dendron was prepared by coupling of 3,5-dibromo-1-(trimethylsilyl)benzene (**2**) with substituted phenylboronic acid **1**. The trimethylsilyl protecting group was removed by treating with boron tribromide followed by hydrolysis, and then activated dendrons **3** were attached to the central fragment, *viz.*, to 1,3,5-tribromobenzene (**4**), giving rise to dendrimer **5**. More branched central fragment **6** was used for the synthesis of dendrimer **7**.⁴³ Monitoring of the reaction of compound **3** with **6** by chromatography demonstrated that the first three bromine atoms are replaced very rapidly, whereas the replacement of other bromine atoms occurs much more slowly due to steric effects. This situation is typical of the convergent synthesis. Due to the presence of a 'rigid' repeating fragment in the dendrimer structure, the shape and size of molecules remain unchanged under different external conditions.

The synthesis of macromolecules based on arylalkyne and phenylacetylene fragments was documented.^{26,45} 4-(*tert*-Butyl)phenyl substituents were used as groups increasing the solubility of the final dendrimer; however, their influence on solubility was extended only up to third-generation dendrimers. Fourth-generation dendrimers with 3,5-di(*tert*-butyl)-phenyl terminal groups proved to be somewhat better soluble.⁴⁶

Poly(phenylacetylene) dendrimers were synthesised using dendrons that have been prepared based on the diethynyl monomer containing a triazene protecting group. This dendron is easily activated for the subsequent coupling reaction by replacing the protecting group by a halogen.⁴⁷

The cross-coupling reaction of first-generation halogen-containing dendron **8** with compound **9** catalysed by a palladium complex afforded second-generation dendron **10**. Due to the rigid defect-free structures of such dendrimers containing conjugated fragments, they possess promising photophysical properties.

Phenylacetylene dendrimers containing Bu^tCO_2 peripheral groups were synthesised by the modified convergent method. Solid-state thermolysis of these systems resulted in the conversion of the Bu^tCO_2 groups into carboxy groups.⁴⁸ Since thermolysis of high-generation dendritic molecules is accompanied by partial cross-linking, an alternative procedure for the synthesis of phenylacetylene dendrimers containing carboxy terminal groups was developed. Dendrimers prepared by this method in high yields (up to 90%) are water-soluble compounds.

A first-generation dendron was synthesised⁴⁹ by coupling of aldehyde **11** with monomer **12** containing two phosphate groups.

Acid hydrolysis leads to the conversion of the acetal group into the aldehyde (compound **13**), which can be involved in the Horner–Wadsworth–Emmons coupling reaction giving rise to second-generation dendron **14**. However, only third-generation dendrons were synthesised by this procedure. The synthesis of the fourth-generation dendron was considered unreasonable because of low yields and long reaction times.

Analogous dendrons were synthesised⁵⁰ by Heck coupling^{51,52} of substituted styrene **15** with 3,5-dibromobenzaldehyde (**16**) followed by the Wittig reaction with methylenetriphenylphosphorane iodide. Unfortunately, dendrons of only three generations could be synthesised by this procedure.

The convergent method was developed⁵³ for the synthesis of polyphenylene-type dendrimers based on the Diels–Alder reaction. This starts with coupling of 4,4'-diethynylbenzil (**17**) with an excess of 2,3,4,5-tetraphenylcyclopentadienone (**18**). 4,4'-Diethynylbenzil is a monomer A₂B-type because it contains two dienophilic ethynyl groups, which can be involved in the Diels–Alder reaction with dienes, and one ethanedione group, which is inactive in the [2+4]-cycloaddition but is helpful for further transformations. Dendron **19** formed in the growth step is converted by the Knoevenagel reaction with diphenylacetone into reactive second-generation dendron **20**. This undergoes the Diels–Alder reaction with the central fragment, *viz.*, tetrakis(4-ethynylphenyl)methane (**21**), to form phenylated rigid second-generation dendrimer **22**. First-, second- and third-generation dendrons were prepared in rather high yields (85%–89%). Nevertheless, all attempts to make the third-generation dendron react failed because steric hindrance did not allow it to undergo condensation with diphenylacetone. However, identical dendrimers of not only

Scheme 1

Scheme 2

(a) $\text{BF}_3 \cdot \text{OEt}_2$, pyrrole, CH_2Cl_2 ; DDQ; (b) BBr_3 , DDQ.

the third, but also the fourth generation can be synthesised using the divergent approach, as will be demonstrated in the next section.

The convergent method was successfully applied to the synthesis of polyphenylene dendrimers containing peripheral substituents of different nature.³⁸ For this purpose, the central fragment, *viz.*, bis(4-ethynylphenyl)bis[4-(triisopropylsilyl)-ethynylphenyl]methane (**23**), with two protected triple bonds was synthesised using a deficient amount of desilylating agents from a tetrasilyl precursor. Then the Diels–Alder reaction with dendrons **24** containing substituents A was carried out. After desilylation, the liberated ethynyl groups were involved in the Diels–Alder reaction with dendrons **25** containing substituents B to give finally dendrimer **26** containing different substituents in one molecule (Scheme 1).

Dendrimers based on porphyrin fragments have attracted interest because of their valuable photophysical properties.^{17, 54–57} For example, rigid polyphenylene dendrimers containing the porphyrin fragment as the central group have recently been synthesised.³⁶ Dendron **27**, which has been prepared by the convergent method using the Suzuki reaction, was coupled with pyrrole. The further demethylation with boron tribromide and oxidation with 2,3-dichloro-5,6-dicyano-*p*-quinone (DDQ) produced dendrimer **28** containing peripheral benzoquinone groups (Scheme 2).

The synthesis of luminescent dendrimers **29** and **30** containing the porphyrin core and carbazole peripheral fragments was documented.⁵⁸ Initially, aldehyde precursors were synthesised by a multistep procedure using the Ullmann reaction or the palladium-catalysed Suzuki reaction. Further condensation with pyrrole was carried out under the Lindsey conditions.^{59, 60}

Due to the presence of large hyperbranched blocks, π -conjugated dendritic molecules possess characteristic three-dimensional architecture, which imparts qualitatively new properties to these molecules compared to linear semiconducting oligomers and polymers.²⁸ π -Conjugated aromatic dendrimers **31a,b** containing stilbene-like groups as bridging fragments were synthesised by the convergent method using the Suzuki

reaction and the Horner–Wadsworth–Emmons reaction.⁶¹ These dendrimers show luminescence in the blue region with high quantum yield, which led the authors to conclude that these compounds can be used as materials for light-emitting diodes.

III. Rigid aromatic dendrimers synthesised by the divergent method

The so-called iptycenes were among the first characterised rigid dendrimers, which were synthesised by the divergent method (using the Diels–Alder reaction).⁶² These unique molecules based on the benzene or iptycene cores (compounds **32** and **33**, respectively) are characterised by high thermal stability.

Very simple but stringent requirements are imposed on the chemical reactions involved in the main cycle including growth and activation of a molecule: the reactions should be unambiguous, enable complete conversion of the substrates and be feasible. One of the most efficient synthetic schemes for the preparation of polyphenylene dendrimers by the divergent method was developed by Müllen and co-workers.^{34, 38, 63–71} This is based on two iterative reactions, *viz.*, the Diels–Alder cycloaddition of tetraphenylcyclopentadienones to substituted ethynyl compounds⁷² (the growth step) and desilylation of tri(isopropylsilyl)-substituted alkynes (the activation step).

The reaction of 3,3',5,5'-tetraethynylbiphenyl (**34**) with cyclopentadienone derivative **35** afforded first-generation dendrimer **36a** containing tri(isopropyl)silyl-substituted ethynyl groups. Activated first-generation dendrimer **36b** with eight ethynyl terminal groups was obtained after removal of tri(isopropyl)silyl protection. The reaction of compound **36b** with cyclopentadienone **35** afforded second-generation dendrimer **37a**. As a result, dendrimer **36a** with a molecular mass of 3119 (220 carbon atoms) was transformed into dendrimer **37a** with a

R = —SiPr_3^i (**a**), — (**b**), H (**c**).

molecular mass of 7606 (548 carbon atoms) by the two-step reaction. In spite of the high molecular masses, compounds **36** and **37** are readily soluble in organic solvents.

Graphite-like highly fused system **38** was prepared by dehydrocyclisation of dendrimer **36c**.

A series of dendritic polyphenylenes were synthesised based on compound **21** as the core using A_2B -type monomer **35** as the building block (Scheme 3). These dendrimers of four generations exhibit good chemical stability, thermal stability and solubility in many organic solvents. In addition, a series of dendrimers were synthesised⁶⁸ using an A_2B block, an A_4B block and various cores [compounds **21**, **34**, 1,3,5-triethynylbenzene (**39**) and 1,2,3,4,5,6-hexakis(4-ethynylphenyl)benzene (**40**)], and their spatial organisation was studied. In the case of an A_2B monomer and cores **21** and **34**, the ability of a dendrimer to grow was demonstrated to be independent of the nature of the core, and the nearly globular shape is achieved only in the fourth generation. On the contrary, the globular shape is achieved very rapidly with the use of an A_4B monomer; however, it is impossible to prepare defect-free dendrimers of generations higher than two.

Alkyl-substituted polyphenylene dendrimers, which are capable of self-assembly on solid surfaces (for example, on graphite), were synthesised^{64, 66, 73} starting from 1,3,5-triethy-

Scheme 3

$$R^1 = n\text{-C}_{12}\text{H}_{25}, \text{H}; R^2 = \text{H}, n\text{-C}_{12}\text{H}_{25}.$$

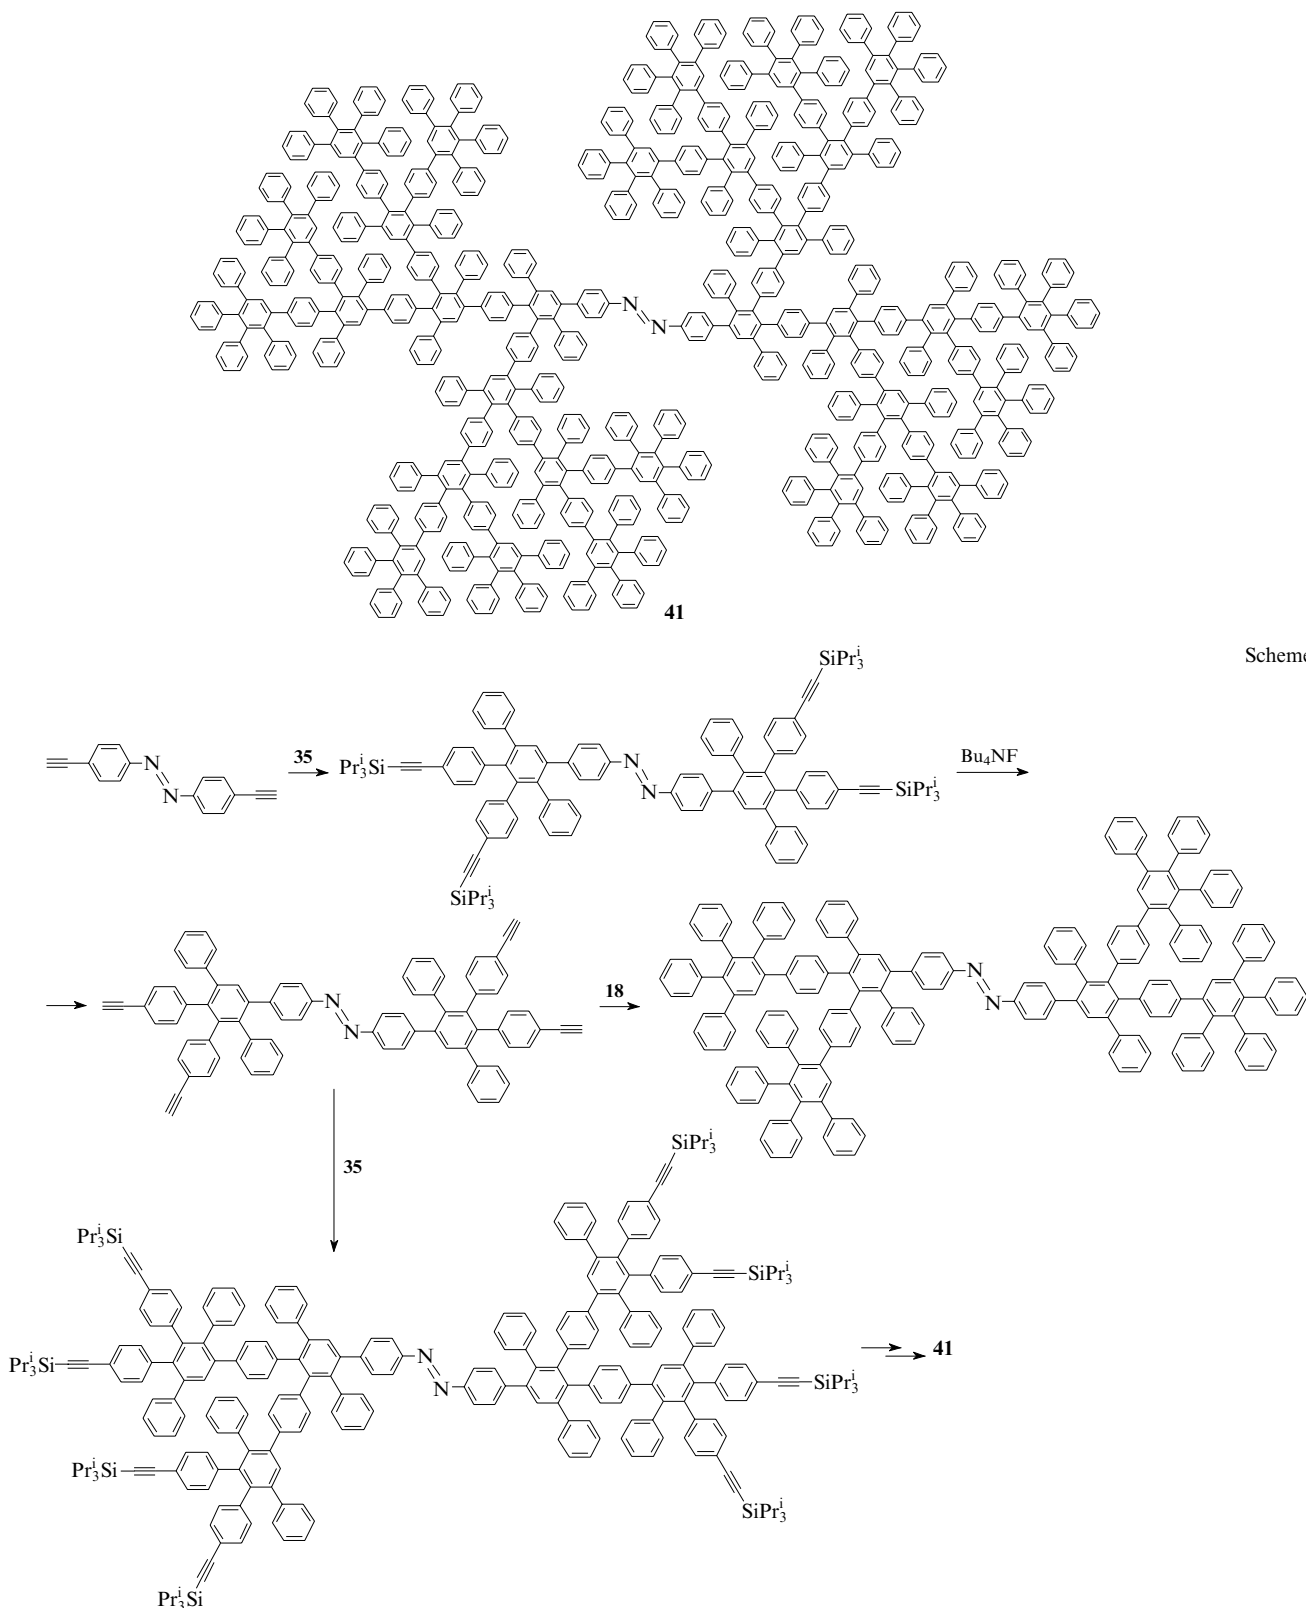

nylbenzene and tetrakis(4-ethynylphenyl)methane (see Scheme 3).

First- and second-generation dendrimers containing the 1,3,5-triethynylbenzene fragment as the core were studied by the molecular dynamics method.⁷⁴ It was demonstrated that only four of six possible conformations of second-generation dendritic molecules are stable, and the dendrimer sizes can vary only within 10%.

A series of dendrimers containing 4, 10 and 22 symmetrically arranged fluorine-substituted aromatic rings were syn-

thesised.⁴³ The surface layers of the molecular structures of dendrimers consist of perfluorinated phenyl groups. Dendrimers are rather thermally stable, monodisperse and readily soluble in organic solvents (THF, CH_2Cl_2 or CHCl_3). In addition, these dendrimers have good electron-conducting properties and chemical stability. Due to the above-mentioned characteristics, these dendrimers are attractive materials for the design of light-emitting diodes.⁷⁵

A series of polyphenylene dendrimers of four generations (compound **41** is a fourth-generation dendrimer) containing

the azobenzene cores were synthesised starting from 4,4'-bis(4-ethynylphenyl)azobenzene (Scheme 4).⁷¹ The resulting dendrimers exhibit reversible photosensitivity under UV-Vis irradiation, which reflects reversible structural changes in the molecule. The influence of the number of the dendrimer generation and the degree of branching of the dendrimers on the kinetic characteristics of photoisomerisation was studied.

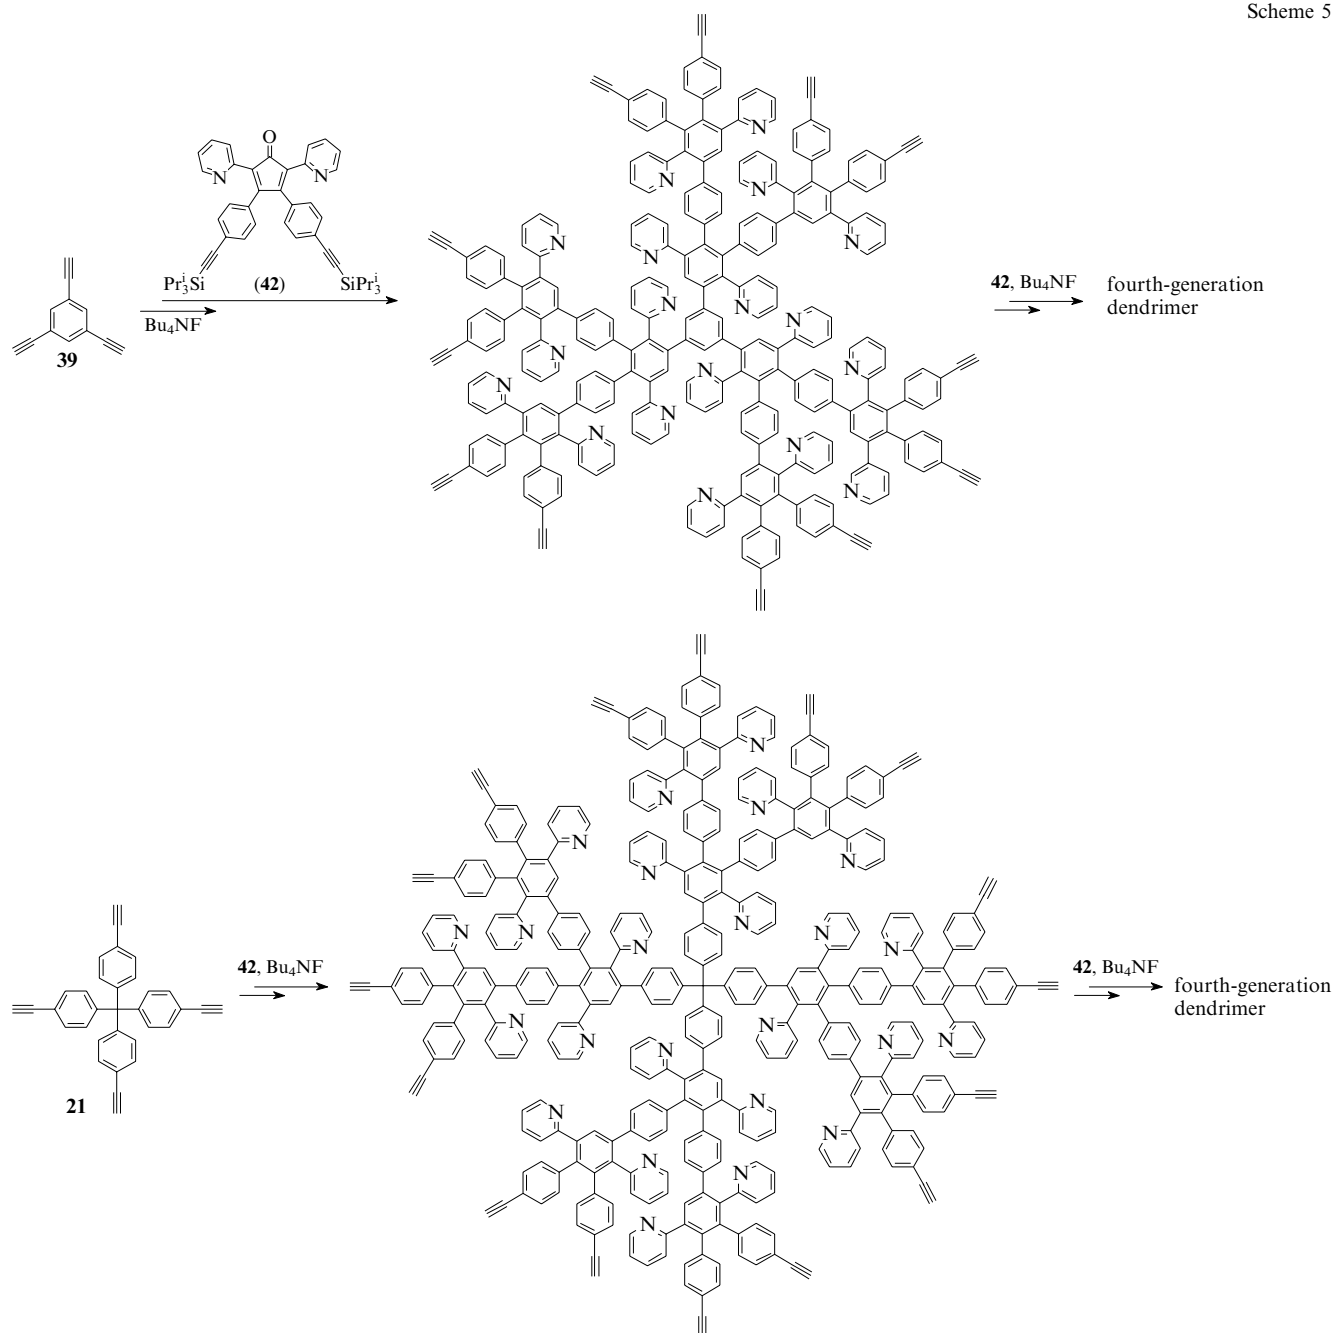

In addition to polyphenylene dendrimers containing different functional groups at the periphery and/or in the centre of the macromolecule, dendrimers with different arrangement and compositions of functional groups in the inner sphere were synthesised. Studies aimed at designing polyphenylene dendrimers based on new pyridine-containing monomers, such as 3,4-bis{4-[tri(isopropyl)silylethynyl]phenyl}-2,5-di(pyridin-2-yl)cyclopenta-2,4-dienone (**42**), 3,4-di(pyridin-2-yl)-2,5-

diphenylcyclopenta-2,4-dienone (**43**) and 2,3,4,5-tetrakis(pyridin-2-yl)cyclopenta-2,4-dienone, have been carried out.^{76–78}

The introduction of pyridine fragments into polyphenylene dendrimers can impart new properties to the latter. The presence of pyridine rings not only at the periphery, but also in the inner sphere of macromolecules extends the potential of functionalisation. Pyridine-containing dendrimers of four generations were prepared using synthetic routes based on the Diels–Alder reaction; however, steric hindrance appears already in the synthesis of the third-generation dendrimer with substituted benzene **40** as the dendrimer core (Scheme 5).

The synthesis of dendrimers of four generations based on core **39** is presented in detail in Scheme 6. In the last step, the third-generation dendrimer containing ethynyl peripheral

Scheme 5

Scheme 5 (continued)

Scheme 6

Scheme 6 (continued)

groups is transformed into the fourth-generation dendrimer containing phenyl peripheral groups.

According to the thermogravimetric analysis, all the dendrimers under study are characterised by rather high thermal stability. Thus, a 10% mass loss in air for second–fourth generation dendrimers was observed at temperatures above 480 °C. According to the differential scanning calorimetry, no phase transitions occur in samples of dendrimers up to the decomposition temperature. The structures of the above-mentioned dendrimers are not destroyed even upon treatment with acids or alkalis over a long period of time. Due to high chemical and thermal stability, the resulting macromolecules are unique compounds among other known dendrimers containing the pyridine or amine (imine) functional groups, and these compounds can be used in corrosive media and/or at high temperatures. In addition, these dendrimers can be used in the design of new hybrid (dendrimer–metal) nanostructured systems having catalytic properties.⁷⁷

The efficient combined divergent/convergent synthesis of new conjugated zero-generation (**44a**) and first-generation (**44b**) dendrimers containing oligo(ethynylthiophene) fragments was documented.³³ This method is based on the iterative Sonogashira and Wittig reactions. The dendrimers prepared in high yields (72%–82%) are readily soluble in organic solvents, which made it possible to study in detail the dependence of their properties on the structure. Due to the ability to absorb light in a very broad frequency range, these dendrimers hold promise for the design of light-absorbing materials analogous to natural substances.

The above-considered results show considerable progress in the synthesis of rigid aromatic dendrimers by both the convergent and divergent methods. It is expected that further investigations will be aimed at extending the range of these dendrimers and searching for fields of their practical application.

IV. Possible areas of application of rigid dendrimers

The development of procedures for the synthesis of versatile dendritic matrices, which can be used for the design of special materials for different fields of application (catalysts, optical materials, magnetic nanoparticles and drug delivery agents), is one of the most interesting and important areas in chemistry of dendrimers. Due to predictable, controlled and highly reproducible molecular sizes, dendrimers are ideal standards for mass spectrometry, electronic and atomic spectroscopy and ultrafiltration. The presence of channels and pores in dendritic macromolecules allows their use for encapsulation and immobilisation of small-molecular-mass guest molecules. The possi-

bility of incorporation of guest molecules into dendrimers has been demonstrated,⁷⁹ which gave impetus to numerous investigations in this field and the design of new composites of dendrimers with guest molecules.^{80, 81} Such host–guest composites can find use in biology, medicine, pharmacology and catalysis.^{14, 23, 82, 83}

The use of dendrimers as host molecules for the encapsulation of guest metal nanoparticles holds considerable promise. Pioneering investigations in this field date back to 1994.⁹ First essential results were published in the late 1990s. The formation of copper nanoparticles in a dendrimeric template was documented.^{84, 85} Reduction of copper ions in the presence of dendrimers gave rise to colloidal solutions stable at room temperature for more than 90 days. The formation of nanoparticles stabilised by a dendrimeric template was confirmed by UV spectroscopy and electron microscopy. Gold nanoparticles in a dendrimeric template were synthesised by an analogous procedure.⁸⁶ It was found that the size of the resulting nanoparticles can be controlled using dendrimers of different generations (from zero to fifth). It was demonstrated that the strategy of the formation of metal nanoparticles inside a dendrimeric nanoreactor can be successfully applied to all transition metals. The introduction of monometallic, bimetallic⁹⁰ and semiconducting⁸⁷ nanoparticles into dendrimers was examined.^{19, 83, 84, 87–93} In this case, dendritic macromolecules are used for efficient stabilisation of supersmall metal particles.

The growing interest in the synthesis of metal nanosized particles in dendrimeric templates was dictated not only by the novelty and simplicity of the procedure, but also by the possible practical applications of nanocomposites, in particular, as catalysts. It was noted⁹⁴ that dendrimers allow combination of advantages of homogeneous and heterogeneous catalysis and can provide the control over the structure and size of catalytic particles. For example, Pd and Pt nanoparticles stabilised by a dendrimeric template are characterised by excellent catalytic activity in hydrogenation of simple (for example, allyl alcohol) and electron-deficient (*N*-isopropylacrylamide) alkenes in an aqueous medium.⁸⁹ Bimetallic nanoparticles synthesised in the presence of dendrimers are also active in the Heck and Suzuki coupling reactions.⁸⁸

The choice of rigid dendrimers as templates for the formation of metal nanoparticles provides better control over the particle growth and morphology. New hybrid (dendrimer–metal) nanostructured systems based on poly(pyridylphenylene) dendrimers, which have catalytic properties, were studied.^{76, 77} The catalytic mono- and bimetallic nanoparticles thus synthesised proved to be rather active catalysts for hydrogenation of the triple bond in acetylenic alcohols.^{95, 96}

Rigid dendritic macromolecules with a strictly defined structure and predictable properties have a high potential for

the design of optical and electronic devices. Conjugated phenylacetylene dendrimers⁹⁷ containing optically pure 4,4',6,6'-tetrabromo-1,1'-bi(2-naphthol) diacetate were among the first rigid dendrimers having optical properties, which hold promise for the design of enantioselective fluorescent sensors. Such optically active dendrimers can also be used in the asymmetric synthesis.

Perfluorinated first- and second-generation polyphenylene dendrimers were investigated as materials for organic light-emitting diodes.⁹⁸ These systems can be used for the design of blue-light-emitting diodes; however, perfluorinated dendrimers are inferior to linear or branched analogues because of a low degree of conjugation of dendrimers (due to the presence of bulky fluorine atoms) and low electron affinity.

The efficiency of natural light-harvesting systems in plants and bacteria performing the visible light harvesting and conversion of visible light energy into chemical energy stimulated many researchers to design analogous artificial systems. Due to the unique features, conjugated dendrimers are attractive materials for such systems. Numerous dendrimers of different architecture with efficient light-harvesting properties have already been synthesised. For example, the synthesis of conjugated phenylacetylene dendrimers and dendrons,^{26, 99–103} phenylenevinylene dendrimers¹⁰⁴ and dendrimers with porphyrin^{105, 106} and perylene groups^{107–109} was documented.

The above-mentioned conjugated dendrimers³³ containing oligo(ethynylthiophene) fragments are highly promising light-absorbing materials due to the efficient inter- and intramolecular energy transfer and a broad absorption spectrum.

Efficient donor–acceptor systems **45** containing the triarylamine core, oligothiophene side branches and peryleneimide terminal groups were studied.¹¹⁰ These systems also showed high photochemical activity. The photochemically stable peryleneimide terminal group acts as an electron acceptor; the

triphenylamine core, as an electron donor. In different solvents (THF, chloroform or toluene), the luminescence quantum yield decreases with an increase in the solvent polarity due apparently to better stabilisation of the donor–acceptor pair.

Porphyrin-containing dendrimers are of interest as synthetic analogues of biological systems.^{16, 111, 112} Porphyrin-type

dendrimers **29** and **30** with carbazole peripheral groups can be used as efficient light-harvesting antennas.⁵⁸ The porphyrin core acts as an energy trap. In addition, porphyrin-containing dendrimers can be involved in various redox reactions.

Multichromophoric system **46** based on rigid polyphenylene dendrimers was studied.¹¹³ The specified spatial arrangement of chromophore groups and their spectroscopic characteristics provide efficient light absorption throughout the visible region and the energy transfer to the central terrylene diimide fragment, which converts this energy into the IR radiation energy.

The growing interest in the synthesis of dendrimers with unique photophysical properties requires a deeper insight into charge transfer mechanism in these systems. Investigations of symmetrical dendritic molecules did not give an unambiguous answer to these questions. Investigations of phenyleneethynylene dendrimers with asymmetric architecture^{100, 101} provided the partial solution to this problem. Intramolecular interactions and the charge transfer mechanism in the systems were considered in more detail.¹⁰³ Phenylethynylene dendrimers exhibit highly efficient energy transfer from dendrons to the core, an increase in the generation number of dendrimers having no negative effect on the fluorescent properties of the system. The fluorescence dynamics was studied for symmetrical and non-symmetrical dendrimers both in the presence and absence of an energy trap. The ~50% energy transfer was found to proceed according to a multistep mechanism. Nevertheless, the process is completed in less than one picosecond.

In recent years, bulky macromolecules bearing charged functional groups and having magnetic properties have attracted growing interest. From this point of view, polyphenylene dendrimers are promising nanoobjects.¹¹⁴ In addition to such advantages as the regular structure and high thermal and chemical stability, polyphenylene dendrimers can stabilise active radical groups with very short lifetimes. In addition to the electronic effects (for example, the resonance effects), dendrimers stabilise radicals due to steric effects by retaining the distance between individual radical groups and preventing them from interacting with each other.^{115, 116} The synthesis of a series of dendrimers containing radicals both at the periphery^{117, 118} and as the core was documented.^{119, 120} In addition, a series of polyphenylene dendrimers (for example, compound **47**) containing definite number of carbonyl groups uniformly distributed in the macromolecular structure were synthesised.

These dendrimers were modified with organolithium reagents with the aim of preparing different types of radicals.¹²¹

V. Conclusion

Polyaromatic dendrimers have various unique properties different from those of aliphatic analogues. The synthesis of such dendrimers is rather simple and unambiguous because monodisperse dendritic molecules are, as a rule, produced in high yields. Due to the rigid molecular shape, the desired arrangement of functional groups in dendrimers can be achieved with the use of appropriate building blocks. This approach facilitates the introduction of functional groups both into the core of dendrimers or dendritic branches and at the periphery. Some of the above-mentioned features, in particular, the presence of numerous functional groups at the periphery, allows the use of dendrimers as nanosupports for catalysts and chromophore groups. Therefore, polyaromatic dendrimers are attractive as objects of investigation for both organic chemists and experts in the fields of materials science and nanotechnology.

Due to a constant shape, rigid dendrimers are used in studies of electron transfer processes between different redox centres. If one centre is located in the core and another centre is present at the periphery of a dendrimer, the distances, which are necessary to overcome for the electron transfer, can be calculated. In addition, dendrimers containing fragments of two different types of fluorescent dyes at the periphery are of interest in studies of energy transfer processes between these dyes (light-harvesting antennas).

The introduction of fluorescent dye labels into dendritic molecules bearing an active receptor allows the use of such systems in biological objects to determine the degree of binding of the receptor to a biological substrate.

Based on the analysis of the published data, it can be concluded that the development of procedures for the synthesis of dendritic systems and a search for new fields of their application are of great importance. Due to the unique properties, dendrimers are interesting objects of investigation for both fundamental science and various fields of applied studies. Virtually defect-free structures of polyaromatic dendrimers hold promise for the design of various materials having optical, catalytic and magnetic properties. Due to high chemical and thermal stability, such dendrimers are particularly attractive materials for the use in corrosive media and/or at high temperatures.

Abstract. Different strategies for the synthesis of symmetrical and unsymmetrical macrocyclic Schiff bases in the absence of metal ions are considered. General methods for performing macrocyclisation under thermodynamic or kinetic control are analysed. The key factors influencing the structure of macrocyclic azomethines are discussed. The bibliography includes 215 references.

Scheme 1

I. Introduction

Schiff bases (azomethines) contain the $\text{RC}=\text{N}$ group and are widely used in organic synthesis, for example, as intermediates in the synthesis of amines. Some azomethines have high biological activities, including antitumour,^{1,2} bactericidal³ or antiviral activity.⁴ Schiff bases containing additional electron-donating groups belong to an important class of heteropolycyclic ligands involved in mono- or polynuclear complexes with metals. Macrocyclic azomethines can trap metal ions with large radii and high coordination numbers, including lanthanides and actinides, in their cavities and form bi- and polynuclear complexes, in which two or more metal atoms are located in one cavity in close proximity to each other and which are characterised by unusual magnetic properties⁵ and catalytic activity.⁶ Some azomethine complexes have non-linear optical properties.⁷ Macrocyclic azomethines are prone to form discotic liquid crystals.⁸ In recent years, it has been demonstrated⁹ that macrocyclic Schiff bases can also recognise and selectively bind anions, thus acting as artificial anionic receptors.

The most general procedure for the synthesis of azomethines is based on acid-catalysed condensation of carbonyl compounds with primary amines discovered by Schiff¹⁰ in 1864. The classical Schiff reaction generally proceeds with high yield (Scheme 1).

Since all steps in this transformation sequence are reversible, the process performed under thermodynamic control affords an equilibrium mixture of products, which can be considered as a dynamic combinatorial library.¹¹ An understanding of the factors determining the equilibrium in this system is of key importance for the achievement of chemoselectivity.

The reactions of dicarbonyl compounds with diamines are much more complicated and can afford a large set of cyclic and acyclic condensation products (Scheme 2). In the first step, one molecule of a dicarbonyl compound reacts with one diamine molecule to give the acyclic [1 + 1]-condensation product **A**, which can then form either the [2 + 1] product **B** with the second molecule of the dicarbonyl compound or the [1 + 2] product **C** with the second diamine molecule. In addition, compound **A** can undergo either cyclisation to give the [2 + 2] macrocycle **D** or polycondensation to form linear oligomers **E** with different molecular mass. In turn, bis-azomethines **B** and **C** can give the macrocyclic [2 + 2]-condensation product **D** in the subsequent reaction with diamine or the dicarbonyl compound, respectively.

The rate-determining step of the reaction depends on the acidity of the medium and it is either the addition of amine at the double bond of the carbonyl group in acidic medium or elimination of the water molecule in neutral medium. Hence, the proton-donor properties of the solvent have a substantial effect on the composition of the products, particularly, in the case of the assembly of large rings or if the starting compounds have complex geometry.

The classical scheme of processes involved in the reaction of diamines with dicarbonyl compounds was reported in several reviews (see, for example, Refs 12 and 13).

In the synthesis of macrocycles, the addition of a template agent is the most efficient way of preventing polycondensation. Systematic studies of the template effect were initiated by Busch and co-workers^{14–17} in the early 1960s. Template agents are generally classified into several types depending on the nature of dominant interactions with the starting compounds (donor-acceptor, electrostatic or hydrophobic interactions, π, π stacking, hydrogen bonding). The principal studies on the template synthesis were covered in sufficient detail in two volumes of *Topics in Current Chemistry*.^{18,19} The anionic template effect was considered in depth in several review articles^{20–22} included in the special issue of *Coordination Chemistry Reviews* and also in reviews.^{23,24} In the last decade, investigations on the synthesis of macrocyclic Schiff bases in the presence of metal ions and the properties of the resulting complexes were summarised in more than ten publications (see, for example, reviews^{13,25–28} and monographs²⁹). The metal template synthesis has been covered in depth in publications by Vigato and co-workers.^{30,31} Recently, Sessler and co-workers³² have published a review on the synthesis of pyrrole-containing macrocyclic Schiff bases by different methods.

The metal template synthesis of macrocyclic Schiff bases has been studied in most detail. However, this method has two substantial drawbacks. First, the reactions with dicarbonyl compounds and diamines as the starting components generally produce symmetrical complexes. Hence, the template synthesis is unsuitable for the preparation of unsymmetrical macrocyclic Schiff bases. Second, metal-free compounds cannot be synthesised by this method. The selective condensation in the presence of a template agent is provided by strong binding of a metal ion in the cavity of the macrocycle. In many cases,

demetallation of complexes can be performed only with the use of simultaneous reduction of imino groups to amino groups.

In the last two decades, considerable efforts were made to develop template-free methods for the synthesis of Schiff bases. In the present review, we analyse main approaches to the synthesis of macrocyclic azomethines by the self-assembly method in the absence of template agents. These data are considered from other points of view and are substantially extended and revised compared to the data published in our earlier review.³³

II. Symmetrical macrocyclic Schiff bases

Symmetrical macrocyclic Schiff bases are generally synthesised by $[n+n]$ -condensation reactions, where $n = 2, 3$ or 4.

Schiff bases prepared from diamines and carbonyl compounds of the aliphatic series are unstable and readily undergo hydrolysis. These macrocyclic ligands are usually synthesised by the template method. On the contrary, azomethines generated from aromatic or heteroaromatic diamines and aliphatic dicarbonyl compounds are rather stable and can be isolated as free ligands. For example, the condensation of acetylacetone with equimolar amount of 2,6-diaminopyridine in methanol in the presence of catalytic amounts of hydrochloric acid affords the corresponding $[2+2]$ macro-cycle **1**.³⁴

The $[2+1]$ -condensation product of acetylacetone with *p*-phenylenediamine, *viz.*, compound **2**, was prepared in high yield in the presence of a large excess of the dicarbonyl compound.³⁵

Even more stable Schiff bases can be synthesised from aliphatic or aromatic diamines and dicarbonyl derivatives of aromatic and heteroaromatic series. These compounds are used in the synthesis of polydentate ligands by self-assembly reactions more often than other reagents.

Aromatic diketones generally react with aliphatic diamines in ethanol in the presence of catalytic amounts of acids to form the corresponding $[2+2]$ -condensation products. For example, the reaction of benzil with 1,3-diaminopropane produces macrocyclic Schiff base **3**.³⁶

This reaction with aromatic diamines proceeds under prolonged reflux and gives not only macrocyclic $[2+2]$ -condensation product **4** but also quinoxaline derivative **5** as a $[1+1]$ -condensation product (Scheme 3).³⁷

The composition of the products synthesised by the reactions of dicarbonyl compounds with diamines is determined by several factors, among which the nature of the starting compounds is of most importance. As a rule, the target products can be prepared in good yields by varying the concentration and the ratio of the reagents, the nature of the solvent, the temperature and the catalyst. The reactions of dicarbonyl

Scheme 3

compounds with aliphatic α,ω -diamines were studied in most detail. For these reactions, the conditions of the synthesis of stoichiometrically controlled condensation products were found.

Two amino groups of aliphatic diamines separated by a hydrocarbon bridge react independently of each other. Hence, the reactions involving these groups cannot, as a rule, be terminated after the formation of acyclic [1 + 1]-condensation products. In the absence of metal salts, most of these reactions produce oligomeric compounds.^{38,39} However, [2 + 2] macrocyclic compounds can be prepared as the major products by carefully choosing the ratio and the concentration of the reactants and the nature of the solvent.⁴⁰

Intermolecular reactions giving oligomers are generally suppressed using high-dilution conditions (the concentration is 10^{-2} – 10^{-3} mol litre⁻¹ or lower) and stoichiometric amounts of the components. The solvent is chosen such that the starting reagents are readily soluble, whereas the target product is poorly soluble. Taking into account the fact that the resulting macrocyclic Schiff bases are less polar than the starting compounds, polar solvents, such as methanol, ethanol and acetonitrile, are the solvents of choice. The reactions can be performed either at room temperature over a long period of time (> 12 h) or by refluxing for 0.5–4 h. Many efficient syntheses of [2 + 2] macrocycles based on aromatic and hetero-aromatic dicarbonyl compounds, which were performed under these conditions, were documented. The composition of the reaction products depends primarily on the nature of the aromatic moiety of dicarbonyl compounds and the presence of substituents in these compounds, whereas the geometry and conformations of the fragments involved in the reaction are insignificant.

The macrocyclisation reactions systematised according to the type of the starting dicarbonyl compounds are considered below.

1. Cyclocondensation of diamines with aromatic dicarbonyl derivatives

The condensation of isophthalaldehyde and terephthalaldehyde with diamines in dilute solutions ($\sim 10^{-2}$ – 10^{-3} mol litre⁻¹) of lower alcohols or acetonitrile affords [2 + 2]-macrocyclic Schiff bases **6a–k**. (Most of macrocyclic compounds based on phthalaldehyde were synthesised by the template method.²⁹)

k	1,3-phenylene	1,4	—	43

X-Ray diffraction studies showed that, in the crystals, such macrocyclic compounds adopt a stair-like conformation with the parallel arrangement of the aromatic rings. The [2 + 2]-condensation product of isophthalaldehyde with 1,3-bis(aminomethyl)benzene, *viz.*, compound **6j**, contains two pairs of mutually parallel aromatic rings, which form a cavity inside the ligand (Fig. 1).⁴⁶ The azomethine groups in this compound are in the *cis,trans* conformation with respect to the aromatic ring.

Unlike acyclic aliphatic diamines, diaminocyclohexanes have a rather rigidly fixed configuration. In *trans*-1,2-diaminocyclohexane, both amino groups are in equatorial positions, and the H₂N–C–C–NH₂ dihedral angle is close to 60°. Because of this, *trans*-1,2-diaminocyclohexane behaves like an almost planar building block, which is prone to form [3 + 3] macrocycles in the reactions with structurally rigid dicarbonyl compounds with the linear arrangement of carbonyl groups.

For example, the reactions of *trans*-(*R,R*)-1,2-diaminocyclohexane with terephthalaldehyde and its derivatives afford [3 + 3]-condensation products **7a–i**. Low yields of some macrocyclic compounds are attributed to the necessity of performing repeated reprecipitation of the resulting compounds to isolate analytically pure samples, although the yields determined from the spectroscopic data are no lower than 80%–85%.

The use of a low-polarity aprotic solvent (dichloromethane) made it possible to perform reactions at high concentrations of the reactants (~ 0.1 mol litre⁻¹) and obviate oligomerisation. According to the results of calculations by the molecular mechanics method, the position of the conformational equilibrium for model compound **8**, which differs from macrocycles **7** by the absence of one azomethine group, is favourable for the closure of the [3 + 3] macrocycle.⁴⁷ Apparently, the cyclic structure is generated from this conformation of the acyclic [3 + 3] precursor.

Figure 1. X-Ray diffraction structure of compound **6j**.⁴⁶ (All structures shown in the figures in the present review were retrieved from the Cambridge Structural Database.)

The X-ray diffraction data for compound **7a** show that the cyclohexane fragments in [3 + 3] azomethine molecules are in one plane, whereas the benzene rings are virtually perpendicular to this plane and form a trihedral prism (Fig. 2).^{47, 51}

A detailed study of this reaction of a series of 2,5-disubstituted terephthalaldehydes showed that their condensation

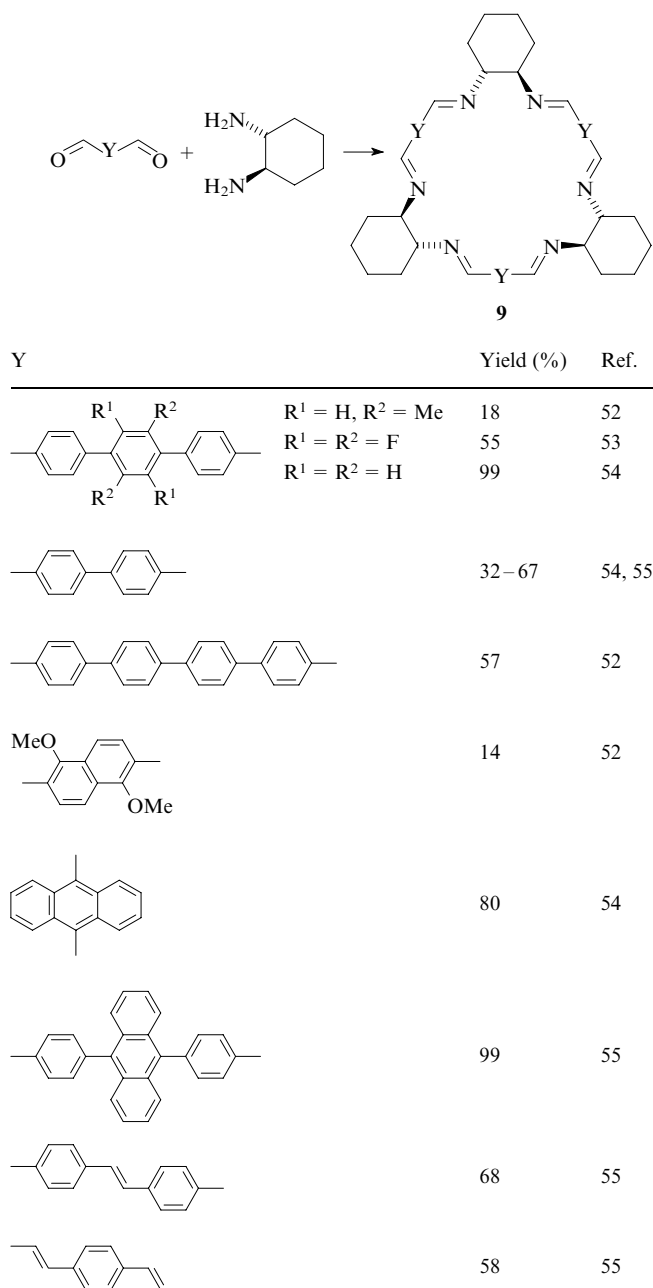

Figure 2. Structure of [3 + 3] azomethine **7a**.⁴⁷

with *trans*-(*R,R*)-1,2-diaminocyclohexane is stereospecific and affords only one of two possible stereoisomeric macrocycles. As a result, only highly symmetrical [3 + 3]-condensation products **7j–n** are formed.⁵⁰

The reaction with *trans*-(*R,R*)-1,2-diaminocyclohexane was successfully extended to other aromatic dicarbonyl compounds containing formyl groups in the *para* positions with respect to each other. For example, [3 + 3] macrocycles **9** were synthesised in yields from moderate to high.

A consideration of the results of macrocyclisation in terms of geometry of the starting compounds (the geometric approach) leads to the conclusion that changes in the mutual orientation of the carbonyl groups in dialdehydes should determine the direction of the process. Actually, the deviation of the angle between the formyl substituents from 180° results in mixtures of cyclic compounds **9** and **10**, [2 + 2] macrocycles being the major reaction products, upon reactions of such dialdehydes with *trans*-(*R,R*)-1,2-diaminocyclohexane.

By contrast, the condensation of substituted isophthalaldehydes, in which the mutual arrangement of the carbonyl groups seemingly hinders the formation of [3 + 3] macrocycles, with *trans*-(*R,R*)-1,2-diaminocyclohexane in concentrated (0.1 mol litre^{−1}) solutions in dichloromethane gives [3 + 3]-macrocyclic azomethines **11a–f** in good yields.

f	Me	H	OTs	59	50

Under these conditions, [3 + 3]-macrocyclic products **11** are formed under kinetic control, but the reaction mixtures contain also [2 + 2] Schiff bases as the products formed under thermodynamic control. The latter were detected in the ESI (electrospray ionisation) mass spectra of the reaction mixtures produced in the synthesis of compounds **11b,c**.⁴⁸ In addition, the [3 + 3]-condensation products can undergo the rearrangement into the corresponding [2 + 2] macrocycles **12b,c** in quantitative yield upon prolonged refluxing (12–72 h) in dichloromethane.⁴⁸

R¹ = Me, R² = H (**b**); R¹ = H, R² = Me (**c**).

This geometric approach does not operate in the reactions of tetramines **13** and **14** with aromatic dicarbonyl compounds. For example, the reactions of diamine **13** with iso- and terephthalaldehydes give [2 + 2]-condensation products **15a** and **15b**, respectively.⁵⁸

However, the reaction of geometrically similar diamine **14** with terephthalaldehyde afforded [3 + 3]-condensation product **17**, whereas isophthalaldehyde gave, as expected, [2 + 2] macrocycle **16a**.⁵⁸ The results of molecular simulation (PM3 method) show that [3 + 3]-condensation product **17** adopts a figure eight-like conformation due to the π, π -stacking interaction between the benzene ring of the terephthalate fragment and the naphthalene system.⁵⁸ Apparently, this interaction determines the reaction pathway.

Stereoisomeric (*R,R*)- and (*S,S*)-1,2-diamino-1,2-diphenylethanes contain two bulky benzene rings serving as conformational anchors. These substituents rather rigidly fix the mutual arrangement of the amino groups. The angle between these groups, like that in *trans*-1,2-diaminocyclohexanes, is close to 60°. Because of this, the reactions of these diamines with dicarbonyl compounds proceed analogously to the reactions of *trans*-1,2-diaminocyclohexanes. For example, the reactions of these diamines with iso- or terephthalaldehyde in dichloromethane at room temperature produce [3 + 3] macrocycles **18**.⁴⁹

An investigation of the behaviour of [3 + 3] macrocycles **18** demonstrated that these compounds are decomposed in chloroform to give oligomeric condensation products. Apparently, [3 + 3] azomethines are generated under kinetic control, whereas oligomers are produced under thermodynamic control. It cannot be ruled out that thermodynamic stability is determined by the solvation effect, *i.e.*, it depends on the nature of the solvent.

The amino groups in *cis*-1,2-diaminocyclohexane are in the equatorial and axial positions. This change in the geometry leads to changes in the reactivity with respect to dicarbonyl compounds. *cis*-1,2-Diaminocyclohexane, unlike the *trans* isomer, reacts with terephthalaldehyde to give a mixture of [2 + 2]- and [3 + 3]-condensation products (mass spectrometric data), with the latter greatly predominating.⁵⁹

Complex mixtures are also produced in the reactions of acyclic 1,2-ethylenediamine.

The field desorption (FD) mass spectrometric study demonstrated⁶⁰ that the reaction of isophthalaldehyde with ethylenediamine in methanol gives a combinatorial library of [1 + 1]-, [2 + 2]-, [3 + 3]- and even [4 + 4]-condensation products.

By contrast, these reactants afford only one reaction product, *viz.*, [2 + 2] macrocycle **6a** (see above), in acetonitrile. Presumably, the use of protic methanol instead of aprotic acetonitrile leads to an increase in the condensation rate and, as a consequence, to a decrease in the selectivity of the reaction.

Dicarbonyl derivatives containing several benzene rings, including those linked to each other through heteroatoms, react analogously to monocyclic compounds. For example, the reactions of bis(2-formylphenyl) chalcogenides **19** (E = Se or Te) with aliphatic diamines in boiling acetonitrile produce the corresponding macrocyclic Schiff bases.^{61, 62}

E = Se, Te; X = (CH₂)_n (n = 3, 6) (yield for E = Se is 61%), CH₂CHMe (71%), (CH₂)₂NH(CH₂)₂ (32%), CH₂(CH₂NHCH₂)₂CH₂ (60%).

2. Cyclocondensation of diamines with pyridine dicarbonyl derivatives

On the whole, pyridine dicarbonyl derivatives are very reactive in nucleophilic addition reactions to the carbonyl group because of the electron-withdrawing character of the pyridine ring, due to which they readily form Schiff bases. However, the selectivity of such reactions is, as a rule, low. Examples of the selective formation of macrocyclic systems from pyridine dicarbonyl derivatives in the absence of template agents are few in number, whereas products of their template condensation in the presence of metal ions are widely known.¹³ As a rule, diformylpyridines react with various diamines in dilute solutions in acetonitrile (more rarely, in methanol) to form [2 + 2] macrocycles **20a–f** in satisfactory yields.

Data on the three-dimensional structures of macrocyclic Schiff bases based on pyridine derivatives are scarce. According to the available data, two pyridine rings in [2 + 2] macrocycle **20f**, which was synthesised from 2,6-diformylpyridine and *trans*-4,5-bis[(1-amino-1,1-diphenyl)methyl]-2,2-dimethyldioxolane, are linked to each other by the π, π -stacking interaction and are spaced by 3.3 Å (Fig. 3).⁶⁶ The azomethine groups of the macrocycle are in the *trans,trans* conformation, resulting in the lipophilic character of the cavity.

Figure 3. Structure of [2 + 2] macrocycle **20f**.⁶⁶

The condensation of *trans*-1,2-diaminocyclohexane with 2,6-diformyl- or 2,6-diacetylpyridine (refluxing in methanol) gives [2 + 2]-macrocyclic Schiff bases **21a,b** in both dilute and concentrated solutions.⁶⁷

R = H (**a**, 68%), Me (**b**, 57%).

The detailed study of this reaction with diformylpyridine and racemic *trans*-diamine demonstrated that this reaction gave a mixture of [2 + 2]- (**21a**) and [4 + 4]-condensation products (**22a**),⁶⁸ which were isolated and characterised by different physicochemical methods, and [3 + 3] macrocycle **23a**, which was detected by the NMR method. No formation of macrocycles diastereomeric with macrocycles **21a**, **22a** and **23a** was observed. The self-organisation of the achiral and racemic starting compounds gives rise to the only stereoisomer even in the case of [4 + 4] macrocyclisation.

The reaction of 2,6-diformylpyridine with *trans*-(R,R)-1,2-diaminocyclohexane also yields a mixture of [2 + 2]-, [3 + 3]- and [4 + 4]-condensation products, with the [3 + 3]-condensation product substantially predominating.⁶⁸

Figure 4. Structure of [2 + 2] macrocycle **21b**.⁶⁷

The structures of [2 + 2] macrocycles **21** containing the *trans*-(*R,R*)-1,2-diaminocyclohexane fragments substantially differ from those of azomethines containing aliphatic diamine fragments because the cyclohexane ring is geometrically more rigid. Macrocycle **21b** adopts a stair-like conformation with the coplanar pyridine rings (Fig. 4).⁶⁷ The pyridine nitrogen atoms are spaced by 3.6 Å due to the fact that all azomethine groups are in the *trans,trans* conformation.

The reactions of *o*-phenylenediamine with pyridine dicarbonyl derivatives in the presence of sulfuric acid also produce macrocycles. Initially, the [2 + 2]-macrocyclic structure has been assigned to the condensation product of 2,6-diacetylpyridine with *o*-phenylenediamine.⁶⁹ However, a more detailed investigation showed that the closure of the macrocycle in this product is followed by intramolecular alkylation at the C=N bond to give product **24**.⁷⁰

In the absence of acids, pyridine dicarbonyl derivatives behave abnormally in the reactions with *o*-phenylenediamines. For example, the reaction of 2,6-diacetylpyridine with *o*-phenylenediamine in ethanol in the absence of acid catalysts affords only [1 + 1]-condensation product **25**, which reacts with neither the dicarbonyl compound nor diamine.⁷⁰

This inertness of bifunctional derivatives can be explained, for example, in terms of the electron-withdrawing properties of the pyridine ring. Since the carbonyl group in the resulting [1 + 1]-Schiff bases **25** is involved in the chain of direct polar conjugation with the amino group, the reactivity of each group substantially decreases.

From this point of view, investigations of the behaviour of 2,6-diformylpyridine *N*-oxide under analogous conditions are of obvious interest. However, the reaction of this compound only with 1,2-ethylenediamine was documented.⁷¹ This reaction proceeds under reflux in methanol and gives [2 + 2] macrocycle **26**.

3. Cyclocondensation of diamines with dicarbonyl derivatives of phenols and their thio analogues

The reactions of diamines with dicarbonyl derivatives of phenols were studied in most detail. Due to the presence of the proton-donating hydroxy group, such dicarbonyl compounds can catalyse self-condensation with diamines. Although the acidity of dicarbonyl derivatives of phenols is not too high (pK_a of salicylaldehyde is 8.37),⁷² the autocatalytic reactions of phenol derivatives with diamines in alcohols proceed easily. The corresponding macrocycles are formed in high yields, although with low selectivity. The reactions of long-chain aliphatic and heteroaliphatic diamines with 4-substituted 2,6-diformylphenols readily proceed in dilute ($\sim 10^{-2}$ mol litre⁻¹) methanolic or ethanolic solutions to give [2 + 2]-macrocyclic Schiff bases **27** in quantitative yields.^{73–79}

As demonstrated above (see Section II.1), dicarbonyl derivatives of phenol ethers react similarly to benzene analogues containing no OR groups. This is the basic difference between derivatives of phenol ethers and phenols. However, the reaction of 2,6-diformylanisoles **28** with ethylenetriamine produces [2 + 2]-macrocyclic Schiff bases **29**.⁸⁰

R = Br, Cl, Me, OMe.

The condensation proceeds more easily if two dicarbonyl fragments are linked to each other by a bridge of an appropriate length to form one molecule. For example, diethylenetriamine reacted with bis-sulfide **30** to give the corresponding macrobicyclic Schiff base, which was reduced to the corresponding polyamine **31** in a total yield of >90%.⁸¹

Under standard conditions (heating in alcohols), dicarbonyl derivatives of phenols do not form macrocyclic Schiff bases in the reactions with ethylene- and propylenediamines.^{41, 43} However, these compounds can be synthesised by performing the reaction in dilute methanolic solutions ($\sim 10^{-2}$ mol litre⁻¹) in the presence of two equivalents of a strong protic acid (HBr). Macrocyclic [2 + 2] Schiff bases **32a–f** thus synthesised were isolated as salts.^{82, 83}

Compound 32	X	R ¹	R ²	Z	A

f	(CH ₂) ₄	Me	H	O	ClO ₄

Figure 5. Molecular structures of doubly protonated macrocycles **32f** (a)⁸⁴ and **32c** (b).⁸⁵

The structures of dications **32a–e** depend on the number of the carbon atoms (n) in aliphatic α,ω -diamines. If $n = 2$ or 4 , the molecules adopt a stair-like conformation. Macrocyclic **32f** [$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{Z} = \text{O}$, $\text{X} = (\text{CH}_2)_4$, $\text{A} = \text{ClO}_4$] formed from 1,4-diaminobutane (Fig. 5a) is an example.⁸⁴ Macrocyclic **32c** containing an odd number of carbon atoms ($n = 3$) adopts a horseshoe conformation because of the close proximity of two aromatic rings of the phenolic fragments located at a distance of 3.6–4.1 Å (Fig. 5b).^{85, 86} Under conditions of acid catalysis, 2,6-bis(aminomethyl)-4-methylphenol reacts with 2,6-diformyl-4-methylphenol to give [2 + 2] macrocycle **33**.⁸⁷

In the reactions with dicarbonyl compounds, thiocarbohydrazide behaves like aliphatic diamines. For example, the condensation of this compound with an equimolar amount of

2,6-diformyl-4-methylphenol in boiling ethanol affords [2 + 2] macrocycle **34**.⁸⁸

The reactions of dicarbonyl derivatives of phenols with 1,2-diaminoalkanes in dichloromethane instead of ethanol produce lower cyclooligomers. As mentioned in the Introduction, the addition of amine at the carbonyl group is the rate-determining step of the reactions giving azomethines in acidic medium. Hence, the use of a less polar aprotic solvent, which prevents dissociation of the hydroxy group of phenol, instead of polar ethanol readily performing the proton solvation is an appropriate solution.

The reaction of 2,6-diformyl-4-methylphenol with (*R,R*)-1,2-diamino-1,2-diphenylethane in dichloromethane at -5°C produced [3 + 3] macrocycle **35**, which was isolated in 99% yield uncontaminated with other azomethines (mass spectrometric data).⁸⁹ The structure of compound **35** is shown in Fig. 6.

By contrast, the reaction of 4-substituted 2,6-diformylphenols with (*S,S*)-1,2-diamino-1,2-diphenylethane in boiling ethanol produces [2 + 2] macrocycles **36a,b**.⁹⁰

R = H (**a**), Bu^t (**b**).

From the above it follows that enantiomerically pure 1,2-diphenylethylenediamines give [3 + 3] macrocycles as the major products under kinetic control and [2 + 2] products under thermodynamic control. An analogous situation is observed

Figure 6. Structure of [3 + 3] macrocycle **35**.⁸⁹

in the reactions of diformylphenols with *trans*-1,2-diaminocyclohexanes even when carried out in alcohols.

For example, the reaction of *trans*-(*R,R*)-1,2-diaminocyclohexane with 2,6-diformyl-4-methylphenol in a concentrated (0.1 mol litre⁻¹) methanolic solution at -5°C or at room temperature produces [3 + 3]-macrocyclic azomethine **37** in quantitative yield.^{57,89,91,92} However, according to the results of the study,⁹⁰ *trans*-(*S,S*)-1,2-diaminocyclohexane reacts with 4-substituted 2,6-diformylphenols under reflux in ethanol for 5 h to give [2 + 2] products **38a,b**. This is circumstantial evidence that the formation of [2 + 2]-condensation products is thermodynamically controlled.

R = H (**a**), Bu^t (**b**).

The structures of the [3 + 3] macrocycles synthesised by the reactions of 1,2-diaminocyclohexane with diformylphenols substantially differ from those obtained in the reactions with diformylbenzenes containing no OH groups (see Fig. 2). In the former case, the molecules adopt a bowl conformation due to which they can be considered as analogues of calix[3]arenes.⁸⁹

The reactions of *o*-phenylenediamine and its derivatives with 2,6-diformylphenols in alcohols easily proceed only in the presence of acids and give salts of [2 + 2] macrocycles **39**, like the reactions with 1,2-ethylenediamine.³⁹

The X-ray diffraction data show that structures of macrocycles **39** are planar, and the hydrogen atoms are localised at the oxygen atoms of the phenolic groups and the nitrogen atoms of the azomethine fragments (Fig. 7).³⁹ Consequently, the macrocycles prepared by the reactions of diformylphenols with aromatic diamines are structurally different from their aliphatic analogues (see above), in which all endocyclic hydrogen atoms are located at the nitrogen atoms of the azomethine groups.

Different, in principle, macrocycles were synthesised by the reactions of 2,6-diformylphenols with *o*-phenylenediamine in the absence of acids. These reactions afford mixtures of [2 + 2]-macrocylic Schiff bases **40**, in which two of four imino groups are reduced, as well as 2,6-bis(benzimidazol-2-yl)phenols **41**.^{74, 93, 94} Macrocylic compound **40** ($R^1 = \text{Me}$, $R^2 = \text{H}$) was synthesised in 60% yield by the reaction of *o*-phenylenediamine with 2,6-diformyl-4-methylphenol in the presence of catalytic amounts of hydrochloric acid (Scheme 4).³⁹

The theoretical investigation of the mechanism of formation of macrocycles **40** by the density functional theory method⁹⁴ demonstrated that the first step of this reaction

Figure 7. Structure of dication **39** ($R^1 = \text{Me}$, $R^2 = \text{H}$).³⁹

(like the reaction of 2,6-diacetylpyridine with *o*-phenylenediamine) gives the [1 + 1]-condensation product, which can be represented as two rotamers **42a** and **42b**.

The most stable conformer **42a** exists in equilibrium with isomer **42b**, whose energy is 3.18 kcal mol⁻¹ lower. In the latter isomer, the distance between the nitrogen atom of the amino group and the carbon atom of the imino group is about 3.5 Å, which is favourable for intramolecular cyclisation.

The resulting benzimidazole **43** is a strong reducing agent. The reaction of **43** with [1 + 1] Schiff base **42a** leads to reduction of the latter to diamine **44**. According to the results of calculation, this process is exothermic (27.3 kcal mol⁻¹).

Scheme 4

Two molecules of diamine **44**, in which the carbonyl and amino groups are separated from each other, are readily involved in the usual Schiff condensation yielding compound **40** ($R^1 = R^2 = H$). This reaction is exothermic ($\Delta H^\circ = -0.12 \text{ kcal mol}^{-1}$, $\Delta G^\circ = -9.15 \text{ kcal mol}^{-1}$).

The X-ray diffraction structure of macrocyclic compound **40** ($R^1 = \text{Bu}^t$, $R^2 = H$) is planar (Fig. 8). In the crystal structure, the molecules are disordered so that the CH_2NH and $\text{CH}=\text{N}$ groups randomly replace each other,

due to which the differences in the lengths of the double and single CN bonds are not observed (the standard $\text{HC}=\text{N}$ and $\text{H}_2\text{C}-\text{N}$ bond lengths are 1.303 and 1.460 Å, respectively).⁹³ Apparently, the crystal structure contains several tautomeric forms, in which the hydrogen atoms are in the vicinity of different nitrogen atoms. In addition, the crystal structure can contain zwitterions, in which all three or four nitrogen atoms are protonated and the negative charges are located on one or two oxygen atoms [the $\text{C}-\text{O}$ bond lengths are 1.33(1) and

Figure 8. X-Ray diffraction structure of macrocycle **40** ($R^1 = \text{Bu}^t$, $R^2 = H$).⁹³

1.34(1) Å and are similar to the standard $\text{C}(\text{sp}^2)-\text{OH}$ and $\text{C}(\text{sp}^2)-\text{O}^-$ bond lengths, respectively].

In the reactions with dicarbonyl compounds, polycyclic aromatic diamines containing amino groups in different aromatic rings behave like aliphatic α,ω -diamines. For example, the condensation of 2,6-diformylphenol in methanol with equimolar amounts of diamino derivatives of biphenyl, diphenylmethane and 1,2-diphenylethane afforded the expected [2 + 2] macrocycles **45**.^{95, 96}

X is absent: $R = \text{Me}$, OMe ; $X = (\text{CH}_2)_n$ ($n = 1, 2$), $R = H$.

Schiff bases that are formed in reactions of diformyl derivatives of polyphenols or their thio analogues with diamines, are of great interest as ligands. Unexpected results were obtained in the reaction with dicarbonyl compounds containing the hydroxy group that undergoes deprotonation, particularly, if the hydroxy and carbonyl groups are in the *ortho* positions with respect to each other. In this case, there are conditions favourable for the formation of strong hydrogen bonds both in the starting dicarbonyl compound and its cyclocondensation products with diamines, resulting in an increase in thermodynamic stability of such compounds. In addition, the absence of the direct polar conjugation between the carbonyl groups in dicarbonyl compounds results in an increase in their reactivity with respect to diamines.

The reaction of diformyl derivative **46** with 1,4-bis(amino-methyl)benzene in THF at room temperature affords [2 + 2]-macrocyclic Schiff base **47**.⁹⁷

The condensation of bis-phenol **48** with 3,6-dioxo-1,8-diaminooctane in a chloroform-methanol mixture under high-dilution conditions affords a mixture of [2 + 2], [3 + 3],

Scheme 5

[4 + 4], [5 + 5], [6 + 6] and even [7 + 7] macrocycles. Some of these products (compounds **49**–**51**) were isolated in the individual state. The high-molecular-mass products were detected by MALDI-TOF mass spectrometry.⁹⁸ It should be noted that the [1 + 1]-condensation product was not found in the mixture (Scheme 5).

The X-ray diffraction data for [2 + 2]-condensation product **49** show that, in the crystal, this macrocycle adopts a twisted, figure eight-like, conformation due to the π, π -stacking interaction between two of four phenol fragments (Fig. 9).⁹⁸ This suggests that the template reaction in which the π, π -stacking plays the organising role is possible, because cycloligomer **49** is produced in the maximum yield.

In the reactions with aliphatic diamines, polyphenols containing the salicylaldehyde fragments linked to each other by

bridges in the *para* position with respect to the hydroxy group show reactivity similar to that of monophenols. For example, the reaction of bis-phenol **52a** with ethylenediamine produces [2 + 2]-macrocyclic Schiff base **53**.⁹⁹

The reactions of bis-phenols **52** with salts of chiral diamines in alcohols in the presence of potassium carbonate under microwave irradiation also afford [2 + 2] macrocycles.¹⁰⁰

Figure 9. X-Ray diffraction structure of [2 + 2] macrocycle **49**.⁹⁸

$R^1 = \text{CH}_2$; $R^2 = \text{H, Br, NO}_2, \text{Bu}^t$; $R^1 = \text{CMe}_2$; $R^2 = \text{H, Br}$;

$R^1 = \text{SO}_2$, $R^2 = \text{H}$; R^1 is absent, $R^2 = \text{H}$;

$R^3-R^4 = (\text{CH}_2)_4, \text{CH}_2\text{NBnCH}_2$; $R^3 = R^4 = \text{CO}_2\text{Bn}$.

The reaction of *trans*-1,4-diaminocyclohexane with a dicarbonyl derivative of bis-phenol **46**, in which the carbonyl groups are fixed by strong hydrogen bonding, produced [2 + 2]-macrocyclic Schiff base **54**.⁹⁷

Because of the absence of direct polar conjugation between the carbonyl groups in dicarbonyl compound **46**, these groups are involved in the reactions with diamines independently of

X is 1,2-phenylene (90%–97%), 1,3-phenylene (58%–64%),
1,4-phenylene (76%–98%), 1,5-naphthylene (90%–97%).

each other, which allows the synthesis of stoichiometrically controlled products. The reaction of 0.1 M solutions of dialdehyde **46** with aromatic diamines (in a ratio of 1 : 1) in THF or DMF at room temperature afforded the corresponding [2 + 2] macrocycles **55**.⁹⁷ The reaction was demonstrated to give initially [1 + 1]-condensation products. The ¹H NMR spectroscopic study showed that these compounds are stabilised (like the final products) by strong hydrogen bonding between the phenolic hydroxy groups and the azomethine nitrogen atoms.⁹⁷

The reactions of dilute (0.04 mol litre⁻¹) methanolic solutions of dialdehyde **46** with an excess of *o*-phenylenediamine or its 4,5-dimethoxy derivative at room temperature yielded acyclic [1 + 2]-condensation products **56**.¹⁰¹

R = H, OMe.

Diamines **56** thus synthesised are very sensitive to atmospheric oxygen and, like the [1 + 1]-condensation products involving 1-R-2,6-diformylphenols (see above), are oxidised to the corresponding benzimidazole derivatives **57**. This process is the major side reaction in the synthesis of these azomethines.¹⁰¹

The X-ray diffraction study showed that two molecules of [1 + 2] azomethine **56** in the unit cell are located so that the nitrogen atoms of the amino groups of one molecule are located close to the carbon atoms of the azomethine fragments of the adjacent molecule.

R = H (71%), OMe (37%).

It was hypothesised that the dimeric structure is retained in solution. Upon prolonged storage of solutions, two molecules of compound **56** undergo condensation to form [2 + 2] macrocyclic Schiff base **58**, which is accompanied by elimination of two *o*-phenylenediamine molecules.¹⁰¹

The condensation of dicarbonyl derivatives of polyphenols with diamines proceeds analogously even if two fragments of salicylaldehyde are linked to each other by a rigid bridge. For example, the reaction of equimolar amounts of dialdehyde **59** with diamines in dilute acetonitrile solution (0.01 mol litre⁻¹) produces [2 + 2]-macrocyclic azomethines **60**.¹⁰²

X = CH₂CH₂, *o*-phenylene.

Important results giving a new insight into the formation of macrocycles were obtained in the study of the reaction of 3,3'-diformyl-2,2'-dihydroxybinaphthyl with (*R,R*)-1,2-diamino-1,2-diphenylethane. For example, dialdehyde having the *R*

configuration forms only oligomers,^{103, 104} whereas the *S* enantiomer undergoes [2 + 2] condensation to give macrocycle **61**.¹⁰⁵

The selective reaction of the *S* enantiomer of dialdehyde with optically pure diamine allowed the resolution of racemic 3,3'-diformylbinaphthyl and the isolation of the pure *S* enantiomer in 50% – 60% yield (with respect to theoretical).¹⁰⁵

Unlike dicarbonyl derivatives of polyphenols, diformylpyrocatechols react with aromatic dialdehydes to form only [3 + 3]-condensation products. Apparently, this is a consequence of the rigid structural preorganisation of the reactants. In some sense, the same factor of self-organisation of macrocycles, which was responsible for the predominant formation of [3 + 3] macrocycles in the reaction of terephthalaldehyde with *trans*-1,2-diaminocyclohexanes (see Section II.1), plays the decisive role.

The reaction of 3,6-diformylpyrocatechol with *o*-phenylenediamines in acetonitrile in the absence of catalysts proceeds in complete agreement with the geometry of the reaction components and affords [3 + 3]-condensation products **62**. The reaction proceeds through the formation of acyclic [1 + 1]- (**63**) and [2 + 2]-condensation products (**64**). In this case, the macrocycles are stabilised by hydrogen bonds, which was demonstrated by ¹H NMR spectroscopy.^{106, 107} Thermodynamically most stable [3 + 3] macrocycle **62** precipitates from the reaction mixture, resulting in the shift of the equilibrium toward the formation of this product (Scheme 6).

Scheme 6

R = H (91%);¹⁰⁶ OC₆H_{13-n} (70%).¹⁰⁷

This reaction in a boiling chloroform–acetonitrile mixture also produces [3 + 3] macrocycles **62**, a much longer reaction time being required for the reactions with long-chain amines [1,2-diamino-4,5-di(hexyloxy)benzene].⁸ In this case, [1 + 1]-, [1 + 2]- and [2 + 1]-condensation products were also detected in the reaction mixture. The position of the equilibrium in this dynamic combinatorial library substantially depends on the reaction conditions. Since [3 + 3] macrocycle **62** is the thermodynamically controlled reaction product, it is formed as the major product upon prolonged refluxing of the reaction mixture. The reaction under kinetic control (low temperature and short reaction time) gives predominantly [1 + 1]-condensation product **63** and at room temperature, [1 + 2]-condensation product **65**. All these compounds were demonstrated⁸ to be intermediates in the reaction affording the [3 + 3] macrocycle.

Other diformylphenols with analogous arrangement of the carbonyl groups are also involved in the reactions with *o*-phenylenediamines. Their reactions with *o*-phenylenediamines in a chloroform–acetonitrile mixture yield [3 + 3]-condensation products (Scheme 7).^{108, 109}

Scheme 7

X-Ray diffraction studies showed that the resulting anti-aromatic 48p-electron macrocycles are non-planar (Fig. 10).^{106, 109} Due to this geometry, the conjugation between the aromatic rings is absent, the antiaromaticity is violated, and these compounds become unstable.

The analogous reaction in commercial chloroform produces [3 + 3] macrocycles **62** along with partially reduced derivatives **66** in low yields (10%–20%). The reduction products

Figure 10. Structure of macrocycle **62** (R = H).¹⁰⁶

were not detected if the reaction was carried out in chloroform purified from traces of moisture and acids.^{8, 110}

n = 4–6.

The mechanism of formation of reduced product **66** is presented in Scheme 8.¹¹⁰ The reaction of [3 + 3] macrocycle **62** with the starting dialdehyde in commercial chloroform affords products of the macrocycle cleavage, including [1 + 1]-condensation product **63**. The latter can undergo intramolecular cyclisation analogous to that described above for phenol derivatives to form benzimidazoline derivative **67**, which is involved in reduction of [3 + 3] macrocycle **62** yielding compound **66**. The transfer of the hydrogen atom to the carbon atom of the imino group occurs from the carbon atom of benzimidazoline, which was confirmed experimentally with the use of an isotope label.¹¹⁰

Scheme 8

Reduction of [3 + 3] macrocycles **62** is accompanied by oxidation of benzimidazoline **67** to benzimidazole **68**, which

Scheme 9

was detected in the reaction mixture along with reduced macrocycle **66** and bis(benzimidazoline) derivative **69**.^{8, 110}

The extension of [3 + 3]-condensation of *o*-phenylenediamines with aromatic 1,4-dialdehydes to naphthalene derivatives resulted in macrocycle **70**, which exists in equilibrium with keto-enamine tautomeric form **71** (Scheme 9).¹¹¹

Tautomerisation of azomethine to the corresponding enamine leads to the removal of antiaromaticity of [3 + 3] macrocyclic Schiff base, the second aromatic ring in naphthalene remaining intact. Studies of model compounds by quantum chemical methods and X-ray diffraction showed¹¹¹ that azomethine derivatives of 1,4-diformyl-2,3-dihydroxynaphthalene, *viz.*, compounds **72** and **73**, unlike their pyrocatechol analogue **74**, exist in the keto-enamine form.

$R^1 = \text{OMe}, R^2 = \text{H}$ (**72**); $R^1 = \text{H}, R^2 = \text{NHBoc}$ (**73**), Boc is *tert*-butoxycarbonyl.

The formation of hydrogen bonds is a powerful driving force for the self-organisation of macrocycles. This is most clearly illustrated by the formation of macrocycles **75** as a result of [6 + 6] condensation of diformylresorcinol with *o*-phenylenediamine (Scheme 10).¹¹²

Scheme 10

$R = \text{OC}_6\text{H}_{13-n}$ (19%), $\text{OC}_5\text{H}_{11-n}$ (25%).

Scheme 11

The fact that the analogous reaction of 2,7-diformyl-3,6-dihydroxynaphthalene was successful suggests that this [6 + 6] macrocyclisation for rigidly preorganised dihydroxydiformyl derivatives of polycyclic aromatic compounds has the general character (Scheme 11).¹¹²

4. Cyclocondensation of diamines with dicarbonyl derivatives of five-membered carbo- and heterocycles

a. 2,5-Diformyl derivatives of furan and thiophene

2,5-Diformylfuran and -thiophene readily react with aliphatic diamines to form [2 + 2]-macrocyclic Schiff bases **76a,b** and **77a–g** if the amino groups are separated by a chain of three or more atoms. Dilute solutions of these compounds in acetonitrile or methanol are used. The behaviour of these dicarbonyl compounds is completely analogous to that of related benzene derivatives (Scheme 12).

The three-dimensional structure of one of these compounds, *viz.*, the reaction product of 2,5-diformylthiophene with 3-oxapentane-1,5-diamine **77e**, was established (Fig. 11).¹¹⁸

Figure 11. Structure of [2 + 2] macrocycle **77e** ($n = 1$).¹¹⁸

Scheme 12

Compound	X	Z	Yield (%)	Ref.
76a	CH_2NHCH_2	O	—	43
76b	$(\text{CH}_2\text{OCH}_2)_n$ ($n = 1-3$)	O	60–70	40
77a	CHOH	S	50–55	113
77b	CH_2NHCH_2	S	—	114
77c	$\text{CH}_2\text{NBu}^t\text{CH}_2$	S	48	115, 116
77d	CH_2SCH_2	S	70	114, 117
77e	$(\text{CH}_2\text{OCH}_2)_n$ ($n = 1-3$)	S	60–70	114, 117
77f	$(\text{CH}_2)_n$ ($n = 1-3$)	S	50–90	117
77g	$(\text{CH}_2)_2\text{NH}(\text{CH}_2)_2$	S	50–90	117

With a geometrically more rigid diamine, *viz.*, *trans*-(*R,R*)-1,2-diaminocyclohexane, more complex processes occur compared to the reactions with flexible aliphatic amines. For example, the reactions of 2,5-diformylthiophene in methanol at room temperature produce [2 + 2] (**78**) and [3 + 3] macrocycles (**79**). Studies by mass spectrometry showed that these products are present in a mixture in equal amounts.¹¹⁹ The replacement of methanol by dichloromethane results in the formation of only one reaction product, *viz.*, [3 + 3] macrocycle **79** (35% yield) (Scheme 13).⁴⁸

Scheme 13

The condensation of 2,5-diformylfuran with *trans*-(*R,R*)-1,2-diaminocyclohexane at room temperature in dichloromethane gives [3 + 3] azomethine **80** in quantitative yield.⁵²

Such different results obtained for related 2,5-diformyl derivatives of furan and thiophene provide conclusive evidence that the formation of [3 + 3] macrocycles depends on the nature of the solvent. In weakly polar dichloromethane, the reactions afford only [3 + 3]-condensation products, whereas a series of products are formed in polar methanol.

b. Diformyl derivatives of pyrrole and compounds with several pyrrole rings

Unlike oxa and thia analogues, α,α' -dicarbonyl derivatives of pyrrole are less reactive toward amines. Hence, the synthesis of pyrrole-containing macrocycles requires the use of a catalyst (acids). A rather few azomethine macrocyclic compounds (for example, compounds **81a–c**) were synthesised by direct reactions of 2,5-diformylpyrrole with aliphatic diamines.

$X = \text{CHOH}$ (**a**, 50%–55%),¹²³ CH_2NHCH_2 (**b**),^{43, 114} CH_2 (**c**, 66%).⁶³

However, not all reactions yield macrocyclic azomethines. For example, the reaction of ethylenediamine with 2,5-diformylpyrrole in ethanol stops at the formation of hemiaminal **82**,

which is the intermediate of the [2 + 2]-condensation reaction.³⁸

The addition of molecular sieves to the reaction mixture favours the completion of the reaction giving rise to macrocycles. Under these conditions, the reactions of diformylpyrrole derivatives with ethylenediamine and propylenediamine produced compounds **81d–f**.¹²⁰

$n = 2$: $R = \text{H}$ (**d**), Me (**e**); $n = 3$, $R = \text{Me}$ (**f**).

Unlike the 2,5 isomers, 3,4-diformylpyrroles react with diamines in the absence of acids and molecular sieves to give [2 + 2] macrocycles **83** in high yields.¹²¹

$R = \text{H}, \text{Me}, \text{Et}$.

The reactions of 3,4-dialkoxy-2,5-diformylpyrroles with hydrazine,[†] which can, in principle, be considered as the simplest diamine, yielded unexpected results. The reactions in

[†] The template synthesis affords the corresponding [2 + 2] macrocycles.

methanol in the presence of HCl afford [4 + 4] macrocycles **84** as the condensation products.¹²²

$R = OC_nH_{2n+1}$ ($n = 1, 6, 10, 14$).

By contrast, the reaction of hydrazine with 5,5'-diformyl-4,4'-dipropyl-2,2'-bipyrrole gives [2 + 2]-condensation product **85**.¹²³

Since aromatic diamines are much less nucleophilic than aliphatic diamines, the reactions of the former with diformyl derivatives of pyrrole proceed only in the presence of acid catalysts. As a rule, the reactions give [2 + 2]-condensation products, *i.e.*, compounds **86a–g**, in good yields.

Compo- und 86	Y	Z	Yield (%)	Ref.
c		OMe	60	126
d	$R^1 = R^2 = H, R^3 = Me$	H	98	127, 128
e	$R^1 = R^2 = H, R^3 = Me$	OMe	66	127
f	$R^1 = Me, R^2 = Et, R^3 = H$	H	91	127
g	$R^1 = R^2 = H, R^3 = Ph$	H	48	128, 129

The reactions of 1,8-diaminoanthracene with diformyl derivatives of the pyrrole series in methanol in the presence of acids also produce [2 + 2]-macrocyclic Schiff bases **87**.^{126, 130}

In the absence of acids, 2,5-diformylpyrrole reacts with *o*-phenylenediamine in ethanol to give only [1 + 1]-condensation product **88**, which is involved in reactions with neither the dicarbonyl compound nor the diamine without additional activation.¹³¹

Since the carbonyl group in the resulting [1 + 1] Schiff base **88** is also involved in the chain of direct polar conjugation with the amino group, both groups become substantially less reactive. Two azomethine molecules in the crystal of **88** are linked to each other to form a stable dimer through four hydrogen bonds between the amino groups and the hydrogen atoms of the pyrrole rings and the oxygen atoms of the carbonyl groups (Fig. 12).¹³¹ The energy of formation of this dimer estimated by quantum chemical calculations in terms of density functional theory¹³¹ is 15.4 kcal mol^{−1}. Apparently, the dimeric structure is retained in solution, which additionally decreases the ability of this azomethine to be involved in further condensation.

c. Diformyl derivatives of pyrazole

Data on macrocyclic azomethine derivatives of five-membered heterocycles containing more than one heteroatoms are scarce. Only several successful syntheses of macrocycles from 3,5-

Figure 12. Structure of the dimer of product **88**.¹³¹

diformylpyrazoles in the absence of metal ions were documented. In alcohols or acetonitrile, the reactions of 1-substituted 3,5-diformylpyrazoles with diamines containing no additional nitrogen atoms produce macrocyclic Schiff bases **89**.^{132, 133}

R = H, Me, Bn; X is *m*-phenylene (30%), CH₂OCH₂ (90%–94%).

Under the same conditions, the reaction of diethylenetriamine or dipropylenetriamine gave pentacyclic products **90** in 80% yield.¹³² Presumably, the reaction initially produces [2 + 2]-macrocyclic azomethine **91**, which undergoes intramolecular cyclisation, *viz.*, the nucleophilic addition of the secondary amino group at the C=N bond.^{132, 133} Most likely, this process is reversible because reduction of Schiff bases **90** to compounds **92** is accompanied by the opening of both imidazolidine rings.^{133, 134}

The intramolecular nucleophilic addition at the C=N bond was observed also in the template condensation of diformyl derivatives of pyrazole with diamines containing additional donor atoms (for example, with 1,3-diamino-2-hydroxypropane, diethylenetriamine, *etc.*).^{135–138} This process was demonstrated to be reversible, and the equilibrium can be shifted by adding ions of various metals or performing transmetallation of the resulting complexes.

R = Me, Bn; *n* = 1, 2.

d. Diformyl derivatives of azulene and ferrocene

The reactions of compounds containing two carbonyl groups in a five-membered carbocycle with diamines have received little study. Only one synthesis of macrocycles by condensation of 1,3-diformylazulene with *trans*-(*R,R*)-1,2-diaminocyclohexane in dichloromethane at room temperature giving rise to a mixture of [2 + 2]- (**93**) and [3 + 3]-condensation products (**94**) in a ratio of 1 : 4 (Scheme 14) was documented.⁴⁸

The reactions of 1,1'-diformylferrocene were studied in more detail. Due to the unique properties, this dicarbonyl organometallic compound is widely studied in supramolecular chemistry. The reactions of 1,1'-diformylferrocene with diamines in acetonitrile or chloroform at concentrations lower than 0.1 mol litre^{−1} generally produce [2 + 2]-macrocyclic Schiff bases **95**.^{139, 140}

X = CM₂CH₂, CH₂CM₂CH₂, CH₂C₆H₄CH₂-3, NHC(Z)NH (Z = O, S).

Scheme 14

The reaction pathway substantially depends on the nature of the diamine. Aliphatic diamines and 1,3-bis(aminomethyl)benzene give [2+2]-cyclocondensation products, whereas 1,4-di(aminomethyl)benzene forms only oligomeric products (Ref. 139).

The carbonyl groups in 1,1'-diformylferrocene are located in different planes and can occupy different positions with respect to each other due to free rotation of the cyclopentadienyl rings. This allows the synthesis of [1+1] macrocycles based on this aldehyde even by the reactions of the latter with lower aliphatic diamines. For example, the reaction of 1,1'-diformylferrocene with 1,3-diaminopropane in ethanol instead of acetonitrile gives [1+1] macrocycle **96** as the major product.¹⁴¹

The reactions of diamines containing amino groups at a longer distance give [1+1] macrocycles as the major products regardless of the nature of the solvent. For example, compound **97** was synthesised by the reaction of 1,1'-diformylferrocene with 1,4-bis(3-aminopropyl)piperazine in a mixture of ethanol and chloroform at a dialdehyde concentration of 6×10^{-3} mol litre⁻¹ (Ref. 139).

Due to ability of two cyclopentadienyl rings in 1,1'-diformylferrocene to rotate about the common axis, the reaction of this compound with *trans*-(*R,R*)-1,2-diaminocyclohexane gave rise to [3+3] azomethine **98**; however, the yield of this product was as low as 13.8%.⁵² Nuclear Overhauser effect (NOE) experiments showed that the cyclopentadienyl rings in each ferrocene moiety of compound **98** in solution are turned round so that the angle between the $\text{C}_{\text{ipso}}-\text{C}(=\text{N})$ bonds is 180°.⁵²

e. Synthesis of cryptands by condensation of diformyl compounds with triamines

Cryptands can be assembled by the Schiff reaction of dicarbonyl compounds with triamines ([3+2] condensation) or of

tricarbonyl compounds with diamines ([2+3] condensation). Only the former reaction has gained wide acceptance.

A unique example of the formation of a cryptand by the latter of condensation type was described in 2001.¹⁴² Compounds **99a,b** were synthesised by the reactions of triformyl derivatives of tripyrromethanes with ethylenediamine or butylenediamine, respectively, in THF.¹⁴²

Regardless of the nature of diformyl compounds, their reactions with polyamines generally produce cryptands. The reactions in dilute solutions ($\sim 2 \times 10^{-2}$ mol litre⁻¹) in different solvents (alcohols or acetonitrile) give [3+2]-condensation products, *viz.*, compounds **100**¹⁴³ and **101a–g**, in moderate or high yields. The cryptands produced in these reactions are structurally similar. Their molecules have a trihedral prismatic shape, the prisms being bound by three aromatic fragments of the dialdehyde and the nitrogen atoms of the polyamine.^{154–157} Figure 13 shows the structure of cryptand **101a** prepared from 2,5-diformylfuran and tris-(2-aminoethyl)amine.¹⁵⁴

Figure 13. Structure of cryptand **101a**.¹⁵⁴

The condensation of 2,6-diformyl-4-methylphenol with 2,6-bis[1,1-bis(aminomethyl)ethyl]pyridine in the presence of

Figure 14. Structure of macrocycle **102**.¹⁵⁹

HBr affords polycycle **102** as the [6 + 3]-condensation product in a yield higher than 90% (Scheme 15).^{158, 159}

Macrocycle **102** contains three [2 + 2] macrocyclic fragments formed by 2,6-diformyl-4-methylphenol and 1,3-propylenediamine, which are linked to each other by pyridine bridges. All three fragments, like free protonated [2 + 2] macrocycles (see Fig. 5b), adopt a horseshoe conformation (Fig. 14).¹⁵⁹

To generalise the results considered in the present section, it should be noted that the following two methods are used most widely for the synthesis of azomethine macrocycles from dicarbonyl compounds and diamines: the condensation of $\sim 10^{-2}$ M solutions of equimolar amounts of the starting compounds in acetonitrile at room temperature and the condensation of more dilute solutions ($\sim 10^{-3}$ M) by refluxing in alcohols. The results of the reactions with aliphatic diamines are determined primarily by the reactant ratio. The synthesis according to most of other procedures affords a library of products. The isolation of individual compounds from this library can be based on low solvation of certain macrocyclic azomethines in low-polarity solvents.

The nature of diamines has the main effect on the ratio of the components. If the amino groups in diamines are separated by a long aliphatic or heteroatomic chain, these groups react independently of each other because they are spatially distant and the conjugation is absent. In reactions with monocyclic dicarbonyl compounds in the absence of acids, diamines in which the amino groups are in rather close proximity (α,β and α,γ diamines), as a rule, form oligomers. In the presence of strong acids (HCl or HBr), these reactions give salts of [2 + 2] macrocycles as the major products.

III. Unsymmetrical macrocyclic Schiff bases

An analysis of the published data shows that the condensation of dicarbonyl compounds with diamines offers great scope for the synthesis of various polydentate Schiff bases. In this class of

compounds, unsymmetrical macrocyclic compounds containing at least two coordination units of different nature (a soft unit for binding late transition metals and a hard unit for binding early transition metals) inside the macrocycle have attracted considerable attention in recent years. Heterobinuclear complexes belonging to this class are of exceptional interest for catalysis. Quantum chemical calculations demonstrated that these complexes can bind low-reactivity compounds (alkenes, carbon monoxide and dioxide, nitrogen and even alkanes) and activate them for further chemical transformations as a result of the concerted push-pull effect of two metals of radically different nature on the substrate molecule.¹⁶⁰ The structures and properties of heterobinuclear complexes were covered in the reviews.^{29, 30, 161}

In the previous sections, we considered several special examples of the synthesis of unsymmetrical macrocyclic Schiff bases. The optimal strategy for the construction of such structures is based on the idea of the fragment assembly involving the [1 + 1] condensation of large bifunctional blocks presynthesised in the previous steps. The diamine and dicarbonyl components are most often synthesised independently, although blocks containing one amino group and one carbonyl group can, in principle, be used. The structure complementarity of the fragments, including their ability to adopt conformations favourable for cyclisation, is the main prerequisite for the last step of the macrocyclic ring closure (Scheme 16).

Scheme 16

The choice of an appropriate solvent capable of stabilising such conformations plays an exceptionally important role. The reactions can proceed both under acid catalysis and in the absence of acids. In some cases, the nature of the anion has a considerable effect on the reaction pathway in the presence of acids, which indicates that anions can act as template agents (see Section IV).

Numerous [1 + 1] condensations of bifunctional blocks with the use of metal ions as template agents were documented. In these reactions, metal ions provide preliminary coordination of the both starting polydentate building blocks by fixing the conformation favourable for cyclisation, which proceeds in the inner coordination sphere of the ion. Its coordination number determines also the size of the resulting ring. In most of the characterised reactions of this type, diamine and one of the presynthesised dicarbonyl precursors were used for the template assembly of macrocyclic Schiff bases. However, many examples of the use of mononuclear metal complexes with a dicarbonyl precursor and a diamine molecule in condensation reactions were documented. In these reactions, the metal ion located in the cavity distant from the reaction centres serves the function of retaining the dicarbonyl fragment in the conformation favourable for cyclisation. Although the carbonyl and amino groups involved in the reaction are not included in the coordination sphere of the metal ion, these transformations are always considered in depth in reviews on the template synthesis.

The assembly of macrocycles based on diamines has found little use because these compounds are difficult to synthesise. Template-free reactions of dicarbonyl compounds with di-

amines giving macrocyclic structures are considered in detail below.

1. Template-free fragment assembly in the absence of acids

As mentioned above, the nature of the solvent has a substantial effect on the [1 + 1] cyclocondensation pathway. The assembly of macrocycles from enlarged blocks is performed in aprotic solvents (acetonitrile, chloroform or dioxane), which rather weakly solvate polar carbonyl and amino groups of the starting compounds without hindering hydrogen bonding between these groups. Hydrogen bonds provide the organisation of the prereaction complex, in which the carbonyl and amino groups of two reactants involved in the reaction are in spatial proximity.

As an example of such condensations, let us refer to the synthesis of oxazamacrocyclic ligands **103**. In the case of *trans*-1,2-diaminocyclohexane, the yields of the products were 89%–95%.

X = (CH₂)₂N(CH₂CH₂NH₂)(CH₂)₂ (n = 1);¹⁶²

X = , n = 0–4.¹⁶³

The reactions of dicarbonyl precursors with aliphatic diamines in chloroform at room temperature under kinetic control produce unsymmetrical compounds **104**.⁷⁵

Z = S, NH; X is absent, CH₂ZCH₂.

The condensation in polar aprotic solvents (chloroform or acetonitrile) also affords [1 + 1] macrocycles (for example, compounds **105a–h**) as the major products if the reactions of aliphatic α,ω -diamines are performed with dicarbonyl derivatives, in which two salicylaldehyde fragments are separated by a flexible oligo(oxyethylene) chain.

$n = 1, 2$.

Compound 105	X	Yield (%)	Ref.
a	(CH ₂) ₂	62–65	164, 165
b	(CH ₂) ₃	42	166
c	(CH ₂) ₂ NMe(CH ₂) ₂	55–60	165, 167
d	(CH ₂) ₂ NH(CH ₂) ₂	60–70	165
e	(CH ₂) ₂ N(CH ₂) ₂	54–59	164
	C ₁₁ H _{23-n}		
f	(CH ₂) ₃ NH(CH ₂) ₃	54–59	164
g	CH ₂ CHCO ₂ H	69–70	164
h	(CH ₂) ₂ CHCO ₂ H	69–70	164

High dilution is yet another prerequisite for the synthesis of [1 + 1]-condensation products. The reactions of dicarbonyl blocks **106**, in which the carbonyl groups located in different parts of the molecules are in spatial proximity, with 1,2-diamines and hydrazine afford [1 + 1]-condensation products **107** in moderate yields only in chloroform at concentrations of 2×10^{-3} mol litre⁻¹ in the presence of molecular sieves. Under these conditions, the condensation is accompanied by dehydrogenation of the macrocyclic system.

Diamine	Z	R	Yield (%)	Ref.
H ₂ N(CH ₂) _n NH ₂ ($n = 2-4$)	S	2,4,6-Me ₃ C ₆ H ₂ (Mes)	—	167
	S	Mes	—	168
	S	Mes	—	168
H ₂ NCH ₂ CH ₂ NH ₂	S	Ph	20	169
	S	Ph	40	169
	S	Mes	50	169
H ₂ N-NH ₂	O	Mes	43	170

The reactions of *o*-phenylenediamine with such dicarbonyl compounds also produce [1 + 1] macrocycles. For example, the reaction of dicarbonyl derivative **106a** with *o*-phenylenediamine in chloroform in the presence of molecular sieves gives the expected [1 + 1] macrocycle **108**.¹⁶⁸

Interestingly, unlike the condensation with aliphatic diamines and hydrazine, the latter reaction is not accompanied by dehydrogenation to form a conjugated system. Apparently, this is associated with the fact that the completely conjugated macrocycle, which could be formed in this transformation, is antiaromatic.

The analogous condensation of compound **106a** with 1,2,4,5-tetraaminobenzene affords [2 + 1]-condensation product **109**.¹⁶⁸

The assembly of macrocyclic Schiff bases can be performed also in methanol under thermodynamic control. For example, [1 + 1] macrocycles **111** were synthesised by the reaction of dicarbonyl compound **110** with 1,2-diaminoalkanes in boiling methanol.^{163, 171}

X = (CH₂)₂,

However, if the dicarbonyl block and diamine are non-complementary, the reactions give, as a rule, mixtures of products. For example, dicarbonyl derivative **112** reacted

with ethylenediamine to form [1 + 1]- and [2 + 2]-condensation products, which were not isolated in the individual state. By contrast, the reactions of this compound with other diamines (1,3-diaminopropane and 1,4-diaminobutane) gave only [1 + 1]-condensation products **113**.¹⁷²

112

113 (~30%)

$n = 3, 4$.

Under prolonged reflux in a methanol–acetonitrile mixture, the dicarbonyl derivative of calixarene (**114**) reacts with diamines to form [1 + 1] macrocycles **115**.¹⁷³

114

115

$X = (CH_2)_n$ ($n = 2$ (56%), 3 (86%), 4 (54%)), 1,2-phenylene (14%), $CH_2C_6H_4CH_2$ -4 (96%)

Enlarged precursor blocks can react with each other to give large rings. For example, salicylaldehyde derivative **110** reacts in boiling ethanol with diamine containing the oxyethylene chain to form [1 + 1] macrocycle **116**.¹⁷⁴

110
116

The reactions of dicarbonyl derivatives of calixarenes with complementary diamines produce [1 + 1] macrocycles **117** in high yields (74%–92%).¹⁷⁵

117

$R = Pr^n, (CH_2)_2OEt$.

Even more complex supramolecular aggregates can be synthesised by condensation of dicarbonyl compounds with per-*O*-methylamino derivatives of α - and β -cyclodextrins.¹⁷⁶ The reaction proceeds at room temperature in acetonitrile in the presence of molecular sieves A4.

The condensation products of 2,6-diformylpyridine with diaminocyclodextrins contain a hemispherical hydrophilic

Figure 15. Structure of modified α -cyclodextrin.¹⁷⁶

cavity bound by a fragment of the dicarbonyl compound (Fig. 15).¹⁷⁶

The use of blocks containing two amino groups for the fragment assembly is limited by the fact that they are less widespread and are difficult to synthesise.

Scheme 17

Z = O, S; R¹, R² = Me, Et; n = 0, 1.

For example, the condensation of compounds **118** with dicarbonyl derivatives of bis-pyrroles (Scheme 17) can be assigned to this type of reactions.[‡]

It should be noted that diamine **119**, which was synthesised by demetallation of the template [1 + 2]-condensation product of 2,6-diformylpyridine with *o*-phenylenediamine,⁶³ does not react with dicarbonyl compounds due to the electron-withdrawing effect of the azomethine fragments conjugated with the amino groups (see Sections II.3 and II.4). However, its reduction product **120**, which is synthesised by refluxing in toluene as a result of redox disproportionation, reacts with 2,5-diformylpyrrole to form an unsymmetrical macrocycle.¹⁷⁷

On the contrary, aromatic diamines acylated at one of the amino groups by dicarboxylic acid readily form macrocycles.

[‡] The data from the graduate study by A M Jasat, University of British Columbia, Vancouver, Canada, 1995.

For example, diamine **121** reacts in an aprotic polar solvent (1,4-dioxane) with various dicarbonyl compounds to give [1 + 1] macrocycles **122a–e**.¹⁷⁸ In this case, the geometry of the starting diamine imposes strict restrictions on the second reaction component (dialdehyde). Diamine **121** is planar, and dicarbonyl compounds, which can adopt planar conformations, are most active in reactions with this diamine resulting in the closure of the macrocycle because only this can give rise to a system containing a long chain of conjugation.

2. Fragment assembly in the presence of protic acids

Numerous syntheses of macrocycles from dicarbonyl compounds and diamines in the presence of protic acids were documented. For example, the reaction with excess acetic acid produced 13-membered azathiacycrown macrocycles **123**.¹⁷⁹ In this case, the acid acts as both the solvent and the acid catalyst.

R = Ph, CH₂Ph; X = (CH₂)_n (n = 3, 4).

In polar protic solvents, which readily solvate amino groups (for example, in methanol), dicarbonyl derivatives of the pyrrole series are involved in condensation only in the presence of strong protic acids. For example, the condensation of dicarbonyl derivatives of the pyrrole series with optically active 2,2'-diamino-1,1'-binaphthyls in methanol in the presence of hydrochloric or trifluoroacetic acid affords macrocycles **124**.¹⁸⁰

Under acid catalysis, dicarbonyl compounds react with weakly nucleophilic diamines, even with 2,3-diaminomaleonitrile, to form macrocycles **125a–i**.

Polypyrrole dialdehyde **126** reacts with hydrazine and 1,3-diaminoguanidine in methanol in the presence of hydrochloric acid to form the corresponding macrocycles **127a,b**.¹⁸⁴

X is absent (**a**), NHC(=NH)NH (**b**).

Macrocycles obtained from polypyrrole derivatives, which are close analogues of extended porphyrins,¹⁸⁵ are of interest for supramolecular chemistry because they contain a cavity inside the macrocycle, which can include substrates of various nature. For example, X-ray diffraction data show that a methanol molecule is fixed in the cavity of compound **125e** by five hydrogen bonds (Fig. 16).¹⁸³ The structures of other inclusion compounds are similar to that described above.¹⁸¹

Figure 16. Structure of the inclusion complex based on macrocycle **125e**.¹⁸³

The strategy of the fragment assembly can be used for the synthesis of three-dimensional structures. The condensation of *meso*-(2-aminophenyl)porphyrin with one or two equivalents

of dialdehyde **128** in the presence of trifluoroacetic acid affords the corresponding three-dimensional polycyclic systems **129** and **130** in moderate yields (30% – 45%) (Scheme 18).¹⁸⁶

Catalysis is required also in the synthesis of heterocyclic analogues of polypyrrole macrocycles, in particular, of pyrazolepyrrole system **131**.¹⁸⁷

Scheme 18

Examples of the successful assembly of macrocycles by condensation of diamines in the presence of protic acids are few in number. For instance, compound **121** reacts with various dicarbonyl derivatives in methanol only in the presence of protic acids to form salts of [1 + 1] macrocycles **122a–c,f** or free Schiff bases **122d,g,h**.^{178, 188} Free macrocyclic azomethines can be isolated by treating the salts with triethylamine. Interestingly, the yield of some macrocycles in these reactions substantially depends on the nature of the acid used in the reaction.

IV. Anion template effect in the synthesis of macrocyclic azomethines

For most of the above-described reactions of dicarbonyl compounds with diamines, the nature of the Brønsted acid anion has no effect on the structure of the reaction products or their yield. However, in 1982 Corey¹⁸⁹ found that the cyclocondensation in the synthesis of the boron-containing antibiotic aplasmomycin efficiently proceeds only in the presence of boric acid. Corey was the first to hypothesise that the borate anion acts in this reaction as the template agent. In 1985, it was found that boric acid serves as a good catalyst for the [2 + 2] condensation of 3,3'-diformyl-2,2'-dihydroxybiphenyl with 1,4-bis(aminomethyl)benzene in methanol. In more recent

years, this approach has been extended to the condensation of this dialdehyde with *o*-phenylenediamine, which allowed the synthesis of macrocycles **132**.

R¹ = H, R² = H, n = 1;¹⁹⁰ R¹ = Bu^t, R² = H, n = 0 (66%);
R² = Me, n = 0 (86%).¹⁹¹

Analogously, boric acid can direct the condensation of other bis-phenol dialdehydes as well. For example, [2 + 2] macrocycles **133** were generated from various diamines in the presence of boric acid.¹⁹²

X = (CH₂)_n (n = 2, 3), , *o*-phenylene.

Apparently, borate with two molecules of the diformyl derivative of bis-phenol is produced as an intermediate in this reaction. Intermediate tetrahedral borate fixes the relative arrangement of the dicarbonyl fragments favourable for the closure of a macrocycle, but renders the oligomerisation impossible. Hence, the role of boric acid as a template agent is limited only to phenol derivatives. This reaction with the use of phenylboronic acid affords boron-containing macrocycles **134**. In this case, the covalent template, *viz.*, phenylboronic

acid, remains in the molecule and forms a macrocycle through ester bonds and additional coordination with the azomethine nitrogen atom.^{193, 194}

$R^1, R^2 = \text{H, Me}; R^3 = \text{H, Me, Ph.}$

The presence of the borate group in amine molecules is favourable for the autotemplate reactions with aldehydes. The reaction of 3-aminophenylboronic acid with substituted salicylaldehydes leads to the autotemplate [3 + 3] macrocyclisation giving rise to compounds **135a–e**.

Compound 135	R^1	R^2	R^3	Yield (%)	Ref.
a	Bu ^t	Bu ^t	H	92	195
b	I	I	H	56	196
c	OH	H	H	57	196
d	H	H	Me	48	197
e	H	H	Ph	65	197

As opposed to the above-described reactions, the reaction of unsubstituted salicylaldehyde with 3-aminophenylboronic acid produces [4 + 4] macrocycle **136**.¹⁹⁷

The possible involvement of acid anions, which are incapable of binding with dicarbonyl compounds or diamines by a strong covalent bond, has long been an open question. Sessler *et al.*¹²⁴ were among the first to find the influence of the nature of anions on the reaction pathway of dicarbonyl compounds with diamines (see Section II.4.b). It appeared that the [2 + 2] cyclisation of 3,4-diethylpyrrole-2,5-dicarbaldehyde with *o*-phenylenediamine produces compound **86a** in quantitative yield only in the presence of nitric acid.

A detailed study of the reaction of 2,2'-diformylbipyrrole with *o*-phenylenediamine in the presence of various acids demonstrated that the reactions of these compounds proceed

$\text{H}^+ = \text{HNO}_3$ (95% yield), H_2SO_4 (84%), HClO_4 (81%), $\text{CF}_3\text{CO}_2\text{H}$ (74%), HCl (47%), HI (37%), $\text{HCl} + \text{Bu}_4\text{NNO}_3$ (> 80%).

in the presence of nitric acid to give product **86b** in a yield of up to 95%, whereas the reactions in the presence of other acids produce the macrocycle in substantially lower yields.¹²⁵

Recently, it has been found that diamide of pyridine-2,6-dicarboxylic acid and *o*-phenylenediamine (**137**) reacts with dialdehydes in the presence of trifluoroacetic or sulfuric acid to form [1 + 1]-condensation products **138a–c**. The reactions in the presence of other acids (HCl, AcOH, HNO₃ or H₃PO₄) afford mixtures of [1 + 1] macrocycles and oligomeric products.

It was demonstrated^{9, 177, 198} that macrocycles containing the dipyrromethane fragment can bind tetrahedral anions. The binding constants of template agents are known to correlate with the molar fraction of the receptor in a dynamic combinatorial library.¹⁹⁹ As mentioned in the Introduction, the synthesis of azomethines from polyfunctional derivatives gives mixtures of products. Therefore, high affinity of receptors for tetrahedral anions accounts for the template function of the latter in the macrocyclisation. However, the role of trifluoroacetic acid remains unclear. This acid can also efficiently

Figure 17. Structure of complex **138c** · H₂SO₄ (for clarity, the hydrogen atoms at the C atoms are omitted).¹⁹⁸

catalyse the macrocyclisation despite that the binding constants of the resulting macrocycles with acetate ions are low.

The structure of the complex of ligand **138c** with sulfuric acid was determined by X-ray diffraction (Fig. 17).¹⁹⁸ As can be seen from Fig. 17, H₂SO₄ occurs in the complex as the dianion; macrocyclic azomethine is present as a derivative doubly protonated at the azomethine nitrogen atoms. This suggests that the synthesis of such systems requires the treatment of the reaction mixture with a base for deprotonation of azomethines.

Further study of the reactions of diamine **137** with dicarbonyl derivatives of the pyrrole series showed that the reaction of compound **137** with 2,2'-diformylbipyrrole (**139**), with carbonyl groups more remote from each other, in methanol in the presence of various acids gives different products.²⁰⁰ Studies by mass spectrometry demonstrated that the reaction in the presence of nitric acid produces only oligomers. Oligomers are also the major products in the reactions catalysed by HCl or HBr, although these reactions produce small amounts of [1 + 1] macrocycles. In the presence of acetic or trifluoroacetic acids, the reaction gives the salt of [2 + 2] macrocycle **140**

Scheme 19

as the major product along with a small amount of oligomers. The salt of [2 + 2] macrocycle **140** containing two H_2SO_4 molecules was isolated without traces of oligomerisation products only in the presence of sulfuric acid as the catalyst.²⁰⁰ This result deserves notice. It indicates that the reaction of **137** with **139** in the presence of tetrahedral anions proceeds according to the template scheme (Scheme 19).

The structure of dihydrate of compound **140**, which was isolated upon the treatment with triethylamine, was determined by X-ray diffraction (Fig. 18).²⁰⁰

Figure 18. X-Ray diffraction structure of macrocycle **140** · 2 H_2O (aromatic and aliphatic H atoms are omitted).²⁰⁰

Macrocycle **140** is quite stable under standard conditions. However, storage of this compound in acetonitrile in the presence of tetrabutylphosphonium hydrosulfate or dihydrophosphate leads to its rearrangement into sulfate of macrocycle **141** in quantitative yield as a result of [3 + 3] condensation.²⁰⁰

Apparently, sulfate of [2 + 2] macrocycle **140** is formed in methanol; sulfate of [3 + 3] macrocycle **141**, in acetonitrile. Evidently, the nature of the solvent has a substantial influence on the formation of macrocycles due to solvation of the anion and macrocyclic products formed in the course of the reaction.

The anion template effect is not the only factor determining the pathway of these reactions giving rise to macrocycles. As demonstrated in Section II, the results of macrocyclisation depend also on π, π -stacking interactions. The formation of macrocycles in $[n + n]$ -template condensations governed by π, π interactions was documented for dicarbonyl derivatives, primarily of benzene and phenol (see Sections II.1 and II.2).

Phenolic azomethines **142a,b** react with 4-*tert*-butyl-2,6-diformylphenol²⁰¹ analogously to related pyridine derivative **137**. However (unlike the anion template reaction of compounds **137** and **139**), the reactions of azomethines **142a,b** with this phenol proceed in the absence of template agents to give [2 + 2] macrocycles **143a,b** without traces of oligomerisation products.²⁰¹ The reaction in the presence of metal ions as the template agent affords a radically different macrocycle, viz., the [1 + 1]-condensation product.²⁰¹

R = H (a), Me (b).

X-Ray diffraction data show that [2 + 2] macrocycle **143a** adopts a figure eight conformation due to pairwise stacking interactions between two phenolic fragments and two *o*-phenylenediamine fragments (Fig. 19).²⁰¹ In addition, this system is stabilised by numerous hydrogen bonds between the phenol hydrogen atoms and the azomethine nitrogen atoms. Evidently, the successful macrocyclisation is attributed to π, π interactions.

From the above it follows that both hydrogen bonds and other weak nonbonding interactions can be efficiently used for controlling the condensation of dicarbonyl compounds with diamines under thermodynamic control. These interactions provide the selective binding of one of the products from the dynamic combinatorial library, thus shifting the equilibrium toward the most stable complex. This phenomenon lies at the basis of an efficient approach to the design of artificial cationic and anionic receptors.

Figure 19. Structure of [2 + 2] macrocycle **143a**.²⁰¹

V. Acyclic condensation products of dicarbonyl compounds with diamines

Investigations of the pathways of formation of acyclic condensation products of dicarbonyl compounds with diamines are of importance primarily in the synthesis of enlarged blocks used in the further fragment assembly of macrocycles. [2 + 1]-Condensation products are of great interest as building blocks for the assembly of unsymmetrical macrocycles by performing their reactions with diamines of different structure. Several successful syntheses of these compounds by the reactions of diformyl derivatives of phenols with aliphatic diamines (the reactant ratio was 2 : 1) were documented. The condensation can be performed in boiling acetonitrile or methanol. Products **144** are formed in nearly quantitative yields.

R = Cl, Me; X = (CH₂)_n (n = 2, 3),²⁰² (CH₂)₂NH(CH₂)₂,
(CH₂)₂S(CH₂)₂,⁷⁵ CH₂(CH₂OCH₂)₂CH₂,²⁰²
(CH₂)₂NHC(O)C(O)NH(CH₂)₂,⁷⁹ NHC(S)NH.⁸⁸

2,6-Diacetyl-4-methylphenol reacts analogously yielding azomethine **145**.²⁰³

The condensation of diformyl derivatives of phenols with tris(2-aminoethyl)amine in a ratio of 3 : 1 in anhydrous acetonitrile affords [3 + 1]-condensation product **146**.^{147, 202, 204, 205} Acyclic condensation product **146** is formed only if the reactants are used in a stoichiometric ratio; otherwise, the macrocyclisation giving cryptands is the main reaction pathway (see Section II.4.e).

The reaction in methanol results not in the triformyl derivative but in its acetal **147**.²⁰⁶

All attempts to perform the stoichiometrically controlled [1 + 2] condensation of dicarbonyl compounds with two equivalents of aliphatic diamines failed. The reactions afford [1 + 2]-condensation products only in the presence of a 50–100-fold excess of diamines. However, attempts to isolate azomethines in the pure form were also unsuccessful because of hydrolytic instability of these compounds. The corresponding stable amines **148** are formed only after reduction of Schiff bases with sodium borohydride.

X = (CH₂)₂ (80%),²⁰⁷ (CH₂)₃ (64%),^{208, 209} (CH₂)₂NH(CH₂)₂.²¹⁰

2,3-Diaminomaleonitrile existing (like *o*-phenylenediamine) in the enediamine form has low basicity and nucleophilicity due to the strong electron-withdrawing effect of two nitrile groups conjugated with the amino groups. The reactions of this compound with dicarbonyl compounds give [1 + 2]-condensation products **149** in high yields.^{211, 212}

After completion of the reaction at the first amino group, the nucleophilicity of the second amino group decreases so that the process is terminated. Regardless of the nature of the dicarbonyl compound and the reactant ratio, diamines **149** were isolated as the only products.

Special procedures were developed for the controlled synthesis of [1 + 2]-condensation products. In these procedures, one of two amino groups in diamines is preliminarily protected. After condensation and reduction of the imine function, the protecting group is removed. For example, the monoacetyl¹⁹⁹ derivative of 1,3-diaminopropane and the monobenzyloxycarbonyl²⁰⁰ derivative of diethylenetriamine gave [1 + 2]-condensation products with diformylpyridine and diformylanisole, respectively, in high yields (the reactants were used in a stoichiometric ratio). The resulting Schiff bases **150** and **151** were immediately (without isolation) reduced to amines followed by deprotection.^{213, 214}

R = (CH₂)₃NHAc.

R = (CH₂)₂NH(CH₂)₂NHCbz (Cbz is benzyloxycarbonyl).

The reactions of 2,6-diformyl-4-R-phenols (R = H or Cl) with a twofold excess of the diamino derivative of calixarene **152** in methanol afford the stoichiometrically controlled [1 + 2]-condensation product **153**.¹⁵² In this case, the aromatic diamine gives the [1 + 2]-condensation product without the formation of the corresponding macrocycle.

R = H, Cl.

To perform the target [1 + 2] condensation of dicarbonyl compounds with *o*-phenylenediamine, one of the amino groups is protected, as in the case of aliphatic diamines (see above). *N*-Acetyl-*o*-phenylenediamine reacts with 4-*tert*-butyl-2,6-diformylphenol in methanol at room temperature to form [1 + 2]-condensation product **154**, which is then reduced with NaBH₄ to yield the corresponding tetramine.²¹⁵

Under analogous conditions (methanol, room temperature), the reaction of *N*-(*tert*-butoxycarbonyl)-*o*-phenylenediamine produces [1 + 2]-Schiff bases **155**.

Y	Z	R	Yield (%)
	COH	Bu ^t	70
	N	H	60

	NH	CMe ₂	69
	O	S	90
	—	—	10

Reduction of the C=N bond in azomethines **155** with NaBH₄ followed by treatment of tetramines **156** with gaseous HCl in dichloromethane afforded salts of acyclic diamines **157**.²¹⁵

Y	Yield of 156 (%)	Yield of 157 (%)
	98	90
	98	75
	95	80
	76	80

These condensations allow the synthesis of diamines and dicarbonyl derivatives containing additional functional groups of different nature. The resulting compounds can be used as building blocks for the construction of more complex macrocycles, which are of interest as polydentate ligands.

VI. Conclusion

The data summarised in the present review show that the condensation of dicarbonyl compounds with diamines under thermodynamic equilibrium conditions gives dynamic combinatorial libraries, which can contain numerous products, due to reversibility of all steps of series-parallel reactions involved in the condensation process. A careful choice of the conditions (the solvent, the concentration and the ratio of the reactants, the temperature and acid catalysis) allows the equilibrium to be shifted toward the target product, and free Schiff bases can be synthesised in good yields in the absence of metal cations, which are traditionally used as template agents. The most complex problem of the formation of unsymmetrical macrocycles can be successfully solved by performing fragment assembly from enlarged building blocks as precursors. In the final step of the synthesis, not only metal ions but also anions can be used as template agents. The latter are particularly efficient in the assembly of macrocycles containing a large number of proton-donor groups capable of hydrogen bonding inside the cavity. Such template condensations provide an approach to the design of artificial anionic and cationic receptors. Polydentate Schiff bases play an important role in coordination and supramolecular chemistry, organic synthesis and various biological and medical applications, resulting in the extensive development of this field of chemistry.

Hypervalent silicon-containing organosilicon derivatives of nitrogen heterocycles

M G Voronkov, O M Trofimova, Yu I Bolgova, N F Chernov

Contents

I. Introduction	825
II. Intramolecular organosilicon complexes of nitrogen heterocycles	826
III. Silatranyl derivatives of nitrogen-containing heterocycles	836

Abstract. The published data on the methods of synthesis, properties and transformations of organosilicon derivatives of nitrogen heterocycles containing a hypervalent silicon atom are generalised and described systematically. The bibliography includes 173 references.

I. Introduction

Most of the known organosilicon compounds contain a tetracoordinate silicon atom. However, the coordination number of silicon can increase to 5 or 6, especially when the silicon atom is surrounded by electronegative substituents. Intermolecular complexes containing a hexacoordinate silicon atom have been known since the early 19th century when Gay-Lussac and Thenard¹ obtained the addition product of ammonia to tetrafluorosilane, $2\text{H}_3\text{N} \cdot \text{SiF}_4$. In the second half of the 20th century, the attention of scientists was attracted by intramolecular complexes of pentacoordinate silicon. Of particular interest among these are silatranes studied in detail by Academician M G Voronkov and his co-workers.^{2–16} Studies on silatranes made a valuable contribution to the theoretical, synthetic, medical and applied chemistry. Organosilicon intramolecular complexes are considered in reviews.^{17–22} These compounds have an unusual molecular structures, high reactivities and specific biological activities.

During the same period, many researchers were interested in organosilicon derivatives of nitrogen heterocycles,^{23–27} which came into use as synthons in organic chemistry for the preparation of biologically active compounds, sorbents, *etc.* It is known that nitrogen-containing rings such as pyrrole, imidazole, pyrazole, pyrimidine, indole, carbazole, *etc.*, form the core of alkaloids, natural and synthetic antibiotics and

other pharmaceuticals. The introduction of an organosilicon substituent containing a hypervalent silicon atom into nitrogen heterocycle molecules changes considerably their electronic structure and reactivity. The most pronounced changes are observed upon introduction of a silatranyl [inductive constants $\sigma_1 = -0.56$,²⁸ $\sigma^* = -3.49$ (Ref. 29)] and silatranylmethyl [$\sigma_1 = -0.36$,³⁰ $\sigma^* = -2.24$ (Ref. 29)] groups exhibiting strong electron-donating inductive effect and having a high dipole moment. This modification of heterocyclic compounds gives rise to new classes of biologically active products promising for medicine and agriculture.

Hypervalent silicon-containing organosilicon derivatives of nitrogen heterocycles can be classified into three groups.

1. Intermolecular complexes of heterocyclic compounds with tetrahalosilanes and organylhalosilanes, for example, complexes of pyridine, picolines, 2,2'- and 4,4'-bipyridines and 1,10-phenanthroline with tetrafluorosilane and organylfluorosilanes which have been described in detail in a review.³¹

2. Heterocyclic compounds in which the silicon atom becomes hypervalent due to intramolecular coordination with endo- (or exo-)cyclic heteroatom N or O.

3. Heterocyclic compounds in which the hypervalent silicon atom is a part of an exocyclic substituent. The main representatives of this group are silatrane derivatives in which the silicon atom is bound to the heterocycle either directly or through a $(\text{CH}_2)_n$, CH_2NR , CH_2S , O or another bridge.

This review deals with organosilicon derivatives of nitrogen heterocycles of the last two groups, except for *N*-(dialkylchlorosilylmethyl)lactams with an $\text{O} \rightarrow \text{Si}$ bond and their derivatives, which were studied in detail by Baukov's group (Russia),^{25,32} and zwitter-ionic spirocyclic $\lambda^5\text{-Si}$ -silicates with an $\text{Si}-\text{C}-\text{N}(\text{Het})$ fragment described by Tacke and co-workers (Germany).^{33–35} Some data concerning compounds of the second and third groups obtained by the authors of the present review have been briefly surveyed before.^{36–38} The organosilicon compounds considered below that contain simultaneously a nitrogen heterocycle and a hypervalent silicon atom are of substantial theoretical interest for organic chemists. The knowledge of the molecular structure and physical properties of these compounds would extend the existing views on both the stereoelectronic structure of the hypervalent silicon derivatives and the specific influence of organosilicon substituents containing a penta- or hexacoordinate Si atom on the character of the heterocycle and its reactivity. In addition, many of these compounds possess high and specific biological activities and are potential pharmaceutical or agricultural agents.

II. Intramolecular organosilicon complexes of nitrogen heterocycles

1. Methods of synthesis

The presence of an organosilicon substituent $\text{YSiX}_n\text{Me}_{3-n}$ ($\text{X} = \text{Cl}, \text{F}$; $n = 1-3$; Y is a hydrocarbon or heteroatomic group) in a nitrogen heterocycle may produce, at a certain molecular structure, a pentacoordinate silicon atom through the donor–acceptor interaction with the endocyclic heteroatom, either nitrogen or oxygen. This is observed, for example, in trifluorosilylmethyl derivatives of 2-mercaptobenzoxazole (1) or 2-mercaptobenzothiazole (2).³⁹

This type of compounds were synthesised by reactions of *S*-trimethoxysilylmethyl derivatives of heterocycles with boron trifluoride etherate. Trifluoro(8-quinolylthiomethyl)- (3) and difluoro(methyl)(8-quinolylthiomethyl)silanes (4) were obtained in a similar way.⁴⁰ However, UV and IR spectroscopic data did not support the assumption about the presence of intramolecular $\text{N} \rightarrow \text{Si}$ donor–acceptor bonds closing six-membered chelate rings in these compounds.

The reaction of *N*-trimethoxysilylalkyl or *N*-dimethoxy(methyl)silylmethyl derivatives of 3,5-dimethylpyrazole and benzimidazole with an excess of boron trifluoride etherate involves not only the replacement of methoxy groups by fluorine atoms but also coordination of nitrogen to the BF_3 molecule to give *B*-trifluoroborazane.^{37, 38}

On treatment with potassium fluoride or carbamide, borazanes lose BF_3 being converted into compounds 5–8.

The reaction of *N*-(trimethoxysilylmethyl)imides of dicarboxylic acids, namely, succinic, glutaric and phthalic acids, with boron trifluoride etherate without a solvent at 35–40 °C afforded intramolecular complexes: *N*-(trifluorosilylmethyl)succinimide (9),^{41–43} -glutarimide (10)^{43, 44} and -phthalimide (11).⁴⁵ In these compounds, the silicon atom is pentacoordinated due to the formation of an additional transannular $\text{O} \rightarrow \text{Si}$ donor–acceptor bond; the presence of this bond was confirmed by X-ray crystallography and multinuclear NMR and IR spectroscopy.^{41, 43–45} These compounds refer to the group of so-called dragonoids.¹³

X = $(\text{CH}_2)_n$ ($n = 2$ (9), 3 (10)), *o*-phenylene (11).

N-(Chlorodimethylsilylmethyl)glutarimide (12) was prepared by the reaction of *N*-(trimethylsilyl)glutarimide with chloro(chloromethyl)dimethylsilane or by the reaction of unsubstituted glutarimide with a mixture of hexamethyldisilazane and chloro(chloromethyl)dimethylsilane.⁴⁶ The presence of a pentacoordinate silicon in compound 12 was demonstrated both in solutions and in crystals

In the case of *N*-(trimethylsilyl)succinimide, the formation of the expected *N*-(chlorodimethylsilylmethyl)succinimide (13) was accompanied by the formation of organosilicon diimide 14, resulting from substitution of the imide fragment for chlorine. According to NMR and X-ray diffraction data, the silicon atom in compound 14 is tetracoordinated.

Hensen and Klebe⁴⁷ demonstrated that the reaction of *O*-lithio-8-hydroxyquinoline with chloro(methyl)silanes $\text{Cl}_n\text{SiMe}_{4-n}$ ($n = 1, 2$) results in substitution of the quinolyloxy group for chlorine to give compounds 15 ($n = 1$) and 16 ($n = 2$) with tetracoordinate silicon atoms.

In an analogous reaction with more chlorinated silanes ($n = 3$ and 4), two chlorine atoms are replaced, because two molecules of lithiated 8-hydroxyquinoline are involved. In the compounds 17 and 18 thus formed, the silicon atom is linked by $\text{N} \rightarrow \text{Si}$ donor–acceptor bonds to both heterocyclic molecules.

It was found⁴⁸ that the silicon coordination polyhedron in (chloro)methyl[bis(8-quinolyloxy)]silane (**17**) is a distorted octahedron.

We proposed a new original method for the synthesis of organosilicon intramolecular complexes of quinoline **19** and **20** containing a pentacoordinate silicon atom by protolytic cleavage of the Si–C bond in trifluoro(phenyl)silane under the action of 8-hydroxy- or 8-mercaptoquinoline:^{38, 49}

Y = O (**19**), S (**20**).

The reaction of trifluoro(phenyl)silane with 8-(trimethylsiloxy)quinoline and its thio analogue occurs as transsilylation with elimination of fluoro(trimethyl)silane to give intramolecular complexes **21** and **22** containing an N → Si donor–acceptor bond.⁴⁹

Y = O (**21**), S (**22**).

Trichloro(phenyl)silane can be used to prepare organosilicon derivatives of nitrogen heterocycles. When made to react with 3 equivalents of 8-hydroxyquinoline in the presence of triethylamine as HCl acceptor, this compound produces complex **23** containing a hexacoordinate silicon atom.⁵⁰

The reaction of pyrrole-2-*N*-(*o*-hydroxyphenyl)carbalimine with dichloro(methyl)phenylsilane results in compound **24**. In this case, the additional coordination of silicon is accomplished through the formation of the donor–acceptor bond with the imine nitrogen.⁵¹

2-(Trimethylsiloxy)methylpyridine reacts with trifluorophenyl- and tetrafluorosilanes to give compounds **25** and **26**, which also contain intramolecular N → Si coordination bonds.⁵²

R = Ph (**25**), F (**26**).

The reaction of lithium methyl(2-pyridylmethyl)amide with SiF₄ in ether gives intramolecular complex **27** with pentacoordinate silicon in 20% yield.⁵³

(a) Et₂O, X = Li; (b) CH₂Cl₂, –25 °C, X = Me₃Si.

Note that compound **27** is also formed on treatment of 2-[methyl(trimethylsilyl)aminomethyl]pyridine with tetrafluorosilane in dichloromethane at –25 °C (yield 62%).⁵³

Lithium trimethylsilyl(6-methylpyridin-2-yl)amide reacts with tetrachlorosilane in ether giving rise to intramolecular complexes **28** or **29**, depending on the reactant molar ratio (1 : 1 or 2 : 1), in good yields.⁵⁴

Compound **28** contains pentacoordinate silicon, while dimer **29** contains a hexacoordinate silicon atom. Dimer **29** is stable on heating to 100 °C, whereas compound **28** decomposes even at 50 °C.

It was found^{55, 56} that reactions of chloromethylsilanes Me_{4–n}SiCl_n (*n* = 2, 3) or HSiCl₃ with 2-[lithiobis(trimethylsilyl)]methylpyridine or its 6-methyl derivative afford compounds **30–35**. These intramolecular complexes contain a pentacoordinate silicon atom incorporated in a four-membered (!) coordination ring through the N → Si bond.

X = H, Y = Z = Cl: R = H (**30**), Me (**31**); X = Me, Y = Z = Cl: R = H (**32**), Me (**33**); X = Y = Me, Z = Cl: R = H (**34**), Me (**35**).

It is noteworthy that no N→Si coordination bond was found in related compounds **36** (X = Y = Z = Me, R = H) and **37** (X = Y = Z = R = Me) obtained from chlorotrimethylsilane.

However, when analogous lithio derivatives of picoline and lutidine containing one trimethylsilyl group are made to react with trichloro(methyl)- or dichloro(dimethyl)-silane, crystalline racemates with tetracoordinate silicon, compounds **38–41**, are formed.⁵⁶

38–41

X = Cl: R = H (**38**), Me (**39**); X = Me: R = H (**40**), Me (**41**).

The metallation of 2-[(trimethylsilyl)phenyl]methylpyridine with *n*-butyllithium in tetrahydrofuran gives a red-coloured solution of complex **A**. Its subsequent reaction with $\text{SiX}_{4-n}\text{Cl}_n$ (X = H, *n* = 3; X = Me, *n* = 1–3) in THF at -78°C leads to compounds **42–45** containing pentacoordinate silicon; the THF solutions of these products are dark-red.⁵⁶

X = H, Y = Z = Cl (**42**); X = Me, Y = Z = Cl (**43**);
X = Y = Me, Z = Cl (**44**); X = Y = Z = Me (**45**).

Intramolecular organosilicon complexes **46–48** were synthesised by the reaction of bis(2-pyridyl)(trimethylsilyl)amine with chloro(halomethyl)methylsilanes $\text{XCH}_2\text{SiMe}_{3-n}\text{Cl}_n$ (X = Cl, Br; *n* = 1–3).⁵⁷ For X = Cl, the reaction proceeds as shown below

n = 1 (**46**), 2 (**47**), 3 (**48**).

Evidently, the reaction starts with quaternisation and isomerisation of the pyridine fragment accompanied by elimination of chlorotrimethylsilane. Formally, the SiMe_3 group is substituted by $\text{CH}_2\text{SiMe}_2\text{Cl}$ (*i.e.*, the reaction occurs as transilylation²⁵) (Scheme 1).

Scheme 1

The compound **B** thus formed isomerises to give pyridinium salt **C**. The silicon atom in intermediates **B** and **C** is tetracoordinated. However, in product **46** containing an N→Si donor–acceptor bond, the silicon atom is pentacoordinated.

As opposed to this mechanism, for X = Br, the pyridinium nitrogen atom becomes the reaction site; therefore, the reaction yields stable pyridinium bromide **49**.⁵⁷

Compound **50** was prepared in a similar way from *N*-trimethylsilyl-2-pyridylamine and chloro(chloromethyl)dimehylsilane.²⁷

The reactions of chloro(chloromethyl)methylsilanes, trichloro(1-chloroethyl)silane and trichloro(chloromethyl)silane with 1-trimethylsilyl-2*H*-1,3,4,6,7,8-hexahydropyrimido[1,2-*a*]pyrimidine have been studied.⁵⁸ These reactions give crystalline intramolecular complexes **51–54** containing a pentacoordinate silicon atom in nearly quantitative yields (88%–94%).

X = H: *n* = 1 (**51**), 2 (**52**), 3 (**53**); X = Me, *n* = 3 (**54**).

Compounds **51–53** were also obtained (yields 86%–92%) from 1-methyl-2*H*-1,3,4,6,7,8-hexahydropyrimido[1,2-*a*]pyrimidine and appropriate chloro(chloromethyl)silanes.⁵⁸

The reactions of substituted 2,6-bis(2-hydroxyethyl)pyridines with dimethyl-, diphenyl- and methylphenyl-dichlorosilanes and with bis(dimethylamino)dimethylsilane yield compounds **55–64**.^{59–63}

$\text{R}^1 = \text{Ph}$; $\text{R}^2 = \text{R}^3 = \text{Me}$ (**55**), Ph (**56**); $\text{R}^2 = \text{Me}$, $\text{R}^3 = \text{Ph}$ (**57**);
 $\text{R}^1 = \text{C}_6\text{H}_4\text{F-4}$; $\text{R}^2 = \text{R}^3 = \text{Me}$ (**58**), Ph (**59**); $\text{R}^2 = \text{Me}$, $\text{R}^3 = \text{Ph}$ (**60**);
 $\text{R}^1 = \text{C}_6\text{H}_4\text{Br-4}$, $\text{R}^2 = \text{R}^3 = \text{Me}$ (**61**);
 $\text{R}^1 = \text{C}_6\text{H}_4\text{Bu}^t\text{-4}$, $\text{R}^2 = \text{R}^3 = \text{Me}$ (**62**);
 R_2^1COH is 2-hydroxyadamantan-2-yl; $\text{R}^2 = \text{R}^3 = \text{Me}$ (**63**), Ph (**64**).

$\text{R} = \text{F}$ (**58**), Br (**61**), Bu^t (**62**).

Compound **63** was the first example of a 1,3-dioxa-7-aza-2-silacyclodecane system incorporating a heterocycle (pyridine) and containing a weak transannular $\text{N} \rightarrow \text{Si}$ coordination bond (length 2.727 Å).⁵⁹ The structure of this compound was confirmed by ^{29}Si NMR spectroscopy [the silicon chemical shift $\delta(^{29}\text{Si})$ was -41.9]. The silicon atom geometry in molecule **63** is much closer to tetrahedral than to trigonal-bipyramidal (see Section II.2.a). The silicon atom in compound **55** also has a geometry intermediate between a tetrahedron and a trigonal bipyramid.⁶⁰

The reaction of *N*-lithio-1,2,3,4-tetrahydro-1,10-phenanthroline with halo(methyl)silanes $\text{Me}_{4-n}\text{SiX}_n$ ($\text{X} = \text{F}, \text{Cl}$; $n = 1-4$) follows the route shown below:^{47, 64}

$\text{X} = \text{Cl}$: $n = 1$ (**65**), 2 (**66**), 3 (**67**); $n = 4$: $\text{X} = \text{F}$ (**68**), Cl (**69**).

According to X-ray diffraction data,^{64–68} and ^{15}N , ^{29}Si (Ref. 69) and ^{19}F (Ref. 70) NMR spectroscopy, the silicon atom in compounds **66–69** is pentacoordinated due to the formation of the intramolecular $\text{N} \rightarrow \text{Si}$ coordination bond. The same is true for the isostructural compound containing an SiF_2Cl group.⁶⁷ Meanwhile, intramolecular $\text{N} \rightarrow \text{Si}$ interaction in 1-trimethylsilyl-1,2,3,4-tetrahydro-1,10-phenanthroline (**65**) is absent or very weak.⁶⁷

Organosilicon intramolecular complex derivatives of phthalocyanine (Pc), naphthalocyanine (Nc), porphyrin, *etc.* containing a hexacoordinated central silicon atom attracted attention of researchers back in the beginning of the second half of the 20th century.^{71, 72} These compounds can be regarded as siliconium(VI) derivatives. Over the period from 1960 to 1965, a dozen of publications were devoted to these compounds, the studies by Joyner *et al.*^{73, 74} being pioneering. In this review we dwell only on the compounds studied over the last two decades.

A key method for the synthesis of phthalocyanino- or naphthalocyanino- λ^6 -siliconium dichlorides is the reaction of silicon tetrachloride with 1,3-diiminoisoindoline.⁷⁵

or 1,3-diiminobenzoisoindoline.⁷⁶

Organosilicon phthalocyanines have received much more attention than phthalocyanino- λ^6 -siliconium dichlorides. Chloroorganylsilyl phthalocyanine derivatives **72–74** were obtained by the reaction of chloroorganylsilanes with 1,3-diiminoisoindoline (yields up to 80%).^{77,78}

**72–74**

R = Me (**72**), Ph (**73**), n-C₈H₁₇ (**74**).

Phthalocyanino- λ^6 -siliconium chlorides can also serve as the starting compounds for the synthesis of organosilicon phthalocyanines. For example, symmetric phthalocyanino- λ^6 -siliconium derivatives **75–84** were prepared from dichloride **70** by the reaction with Grignard reagents.^{78,79}

**75–84**

R¹ = Me (**75**), R²C₆H₄ [R² = H (**76**), 4-Me (**77**), 4-MeO (**78**), 3-CF₃ (**79**)], n-C₈H₁₇ (**80**), R³C \equiv C [R³ = H (**81**), Me (**82**), Bu^t (**83**), Ph (**84**)].

Similarly, chlorine-containing precursors PcSiR¹Cl were converted into unsymmetrical organosilicon phthalocyanine derivatives **85–91**.⁷⁸

Dichloride PcSiCl₂ (**70**) is hydrolysed on treatment with an aqueous solution of pyridine or NaOH to give silanediol

R¹ = Ph: R² = R³C₆H₄ [R³ = 4-Me (**85**), 4-MeO (**86**), 3-CF₃ (**87**)],
R¹ = n-C₈H₁₇: R² = R⁴C₆H₄ [R⁴ = H (**88**), 4-Me (**89**), 4-MeO (**90**), 3-CF₃ (**91**)].

PcSi(OH)₂ (**92**).⁸⁰ The reaction of this product with *tert*-butyl(chloro)dimethylsilane results in siloxy derivative **93**.

The reaction of phthalocyanine **92** with an excess of PcSiCl₂ (**70**) followed by hydrolysis of product **94** (Scheme 2)

Scheme 2

affords $[\text{HOPcSi}]_2\text{O}$ (**95**), which reacts with $\text{Bu}^t\text{Me}_2\text{SiCl}$ in dry pyridine giving rise to compound **96**.⁸⁰

The reaction of chlorotrihexylsilane with $\text{PcSi}(\text{OH})_2$ (**92**) in the presence of tributylamine in dry γ -picoline furnished phthalocyanine $\text{PcSi}[\text{OSi}(\text{n-C}_6\text{H}_{13})_3]_2$ (**97**). An analogous transformation has also been described for naphthalocyanino- λ^6 -siliconium derivative. For example, treatment of dichloride **71** with concentrated H_2SO_4 yields diol $\text{NcSi}(\text{OH})_2$ (**98**), which reacts with $(\text{n-C}_6\text{H}_{13})_3\text{SiCl}$ to be converted into bis(trihexylsiloxynaphthalocyanino)- λ^6 -siliconium $\text{NcSi}[\text{OSi}(\text{n-C}_6\text{H}_{13})_3]_2$ (**99**).⁷⁶

Organosilicon phthalocyanino- λ^6 -siliconium derivatives **100–110** were formed upon reaction of dichloride **70** with appropriate carboxylic acids.⁸¹

$\text{R} = 4\text{-Bu}^t\text{C}_6\text{H}_4$ (**100**), 3-CH=CHSCH=CCH_2 (**101**), $2\text{-MeOC}_6\text{H}_4\text{CH}_2$ (**102**), $3\text{-MeOC}_6\text{H}_4\text{CH}_2$ (**103**), $4\text{-MeOC}_6\text{H}_4\text{CH}_2$ (**104**), $2,5\text{-(MeO)}_2\text{C}_6\text{H}_3\text{CH}_2$ (**105**), $3,4\text{-(MeO)}_2\text{C}_6\text{H}_3$ (**106**), $3,4\text{-(MeO)}_2\text{C}_6\text{H}_3\text{CH}_2$ (**107**), $3,4,5\text{-(MeO)}_3\text{C}_6\text{H}_2\text{CH}_2$ (**108**), $3,4\text{-(MeO)}_2\text{C}_6\text{H}_3(\text{CH}_2)_2$ (**109**), $3,4\text{-(MeO)}_2\text{C}_6\text{H}_3(\text{CH}_2)_3$ (**110**).

At $\text{R} = 4\text{-Bu}^t\text{C}_6\text{H}_4$, compound **100** with a rigid orthogonal arrangement of the aryloxy groups is produced. Bis(3-thienylcarboxylate) **101** is conformationally more flexible. The change in the nature of the aromatic substituent in phthalocyanino- λ^6 -siliconium induces a change in its spectroscopic properties, which are related to the energies of excited states, while elongation of the aliphatic chain causes changes in the luminescence time and the quantum yield.⁸¹

Dichlorosilylphthalocyanine (**70**) reacts with 4-hydroxy-4'-nitroazobenzene in the presence of sodium hydride to give organosilicon bis(azobenzophthalocyanine) **111** with a hexacoordinate central silicon atom. Compound **111** is the first example of azobenzophthalocyanino- λ^6 -siliconium (Scheme 3).⁸² The electrochemical properties of this compound indicate that it is promising for the use in devices such as photoelectric relays.

The synthesis of *Si*-disubstituted phthalocyanino- λ^6 -siliconium derivatives containing two 1,3-bis(dimethylamino)isopropoxy groups (compound **112**)⁸³ or one (**113**) or two (**114**) 1,2,3,4-di-*O*-isopropylidene- α -D-galactopyranose fragments at the central silicon atom was reported.⁸⁴ Organosilicon phthalocyanine derivatives, especially unsymmetrical ones, proved to be highly efficient carcinostatics with respect to

human carcinoma cells HepG2 and were captured by the mouse macrophage J774. The photodynamic activity of these compounds is due to their absorption by cancer cells and efficient generation of singlet oxygen.

The reaction of $\text{PcSi}(\text{OH})_2$ (**92**) with *N,O*-bis(trimethylsilyl)acetamide in the presence of pyridine gives $\text{PcSi}(\text{OSiMe}_3)_2$ (**115**).⁸⁵ Similarly, compounds $\text{Me}_3\text{SiO}(\text{PcSiO})_n\text{SiMe}_3$ ($n = 2\text{--}5$) were prepared from $\text{HO}(\text{PcSiO})_n\text{H}$.

More than 100 papers published during the last 30 years were devoted to the methods of preparation, structure, and properties (chemical, physical, optical and electronic) of organosilicon phthalocyanine polymers and the scope of their applications in advanced fields of engineering and medicine.^{86–94}

Axially disubstituted phthalocyanino- λ^6 -siliconium derivatives with ester groups at the silicon atoms and with phenyl, terphenyl, thienyl, pyrenyl^{95,96} and fullerene⁹⁷ substituents have been synthesised. Electrochemical, absorption and film-forming characteristics of these compounds and dependence of properties on the nature of substituents at the hexacoordinate silicon atom were studied.

Phthalocyanino- λ^6 -siliconium oligomers $\text{R}_3\text{SiO}(\text{SiPcO})_n\text{SiR}_3$ ($n = 2\text{--}4$) comprising two, three or four monomers cross-linked by siloxane bridges have also been described. The spatial and electronic structures of these compounds were investigated by NMR and UV/Vis absorption spectroscopy and by other physical, kinetic and computational methods.^{98–103}

As a conclusion of this Section, consider examples of silicon-containing derivatives of tetra(*p*-tolyl)porphyrin (TTP). The reduction of $\text{Si}(\text{TTP})\text{Cl}_2$ (see Ref. 104) with the $\text{Na/Hg}\text{--THF}$ system afforded tetratolylporphyrino- λ^6 -siliconium $\text{Si}(\text{TTP})(\text{THF})_2$.¹⁰⁵ The reaction of the lithium derivative of TTP with trichlorosilane in dichloromethane at -78°C gave compound **116**.¹⁰⁴ The reactions of compound **116** with SbF_3 (or AgBF_4) and with $\text{Me}_3\text{SiOSO}_2\text{CF}_3$ (or $\text{AgOSO}_2\text{CF}_3$) in CH_2Cl_2 gave difluoride **117** and ditriflate **118** in quantitative yields (Scheme 4).

Scheme 3

Scheme 4

2. Studies of the molecular structure

a. X-Ray diffraction method

The pentacoordinate silicon atom present in organosilicon intramolecular complex derivatives of nitrogen heterocycles containing an endocyclic $N \rightarrow Si$ coordination bond exists in a trigonal-bipyramidal environment. The lengths of the bonds between silicon and two apical ligands for some of these molecules are presented in Table 1.

The $N \rightarrow Si$ dative bond and the $Si-X$ bond ($X = F, Cl, O, N$) usually occupy axial positions. If two or three electronegative atoms are attached to silicon, then the apical position is occupied by the atom with a higher apical activity (the ability to occupy this site and ensure *trans*-coordination of the ligands), which decreases in the sequence $Cl, OCOR > F \approx SR > OR, NR_2 > Ar > Alk > H$.^{108, 109} The position of an atom or an atomic group in this sequence is correlated with their electronegativity and the polarisability of their bonds with silicon.

The displacement of the silicon atom (ΔSi) from the central plane formed by three equatorial ligands toward the axial vertex Z (see Table 1) varies from 0.01 to 0.380 Å.

The compounds of pentacoordinate silicon contain most often a five-membered chelate ring. Compounds with four-membered (**28**,⁵⁴ **30–35**,^{55, 56} **42–44**)⁵⁶ and six-membered (**55–64**)^{59–63} coordination rings are also known.

The variations of the $N \rightarrow Si$ and $Si-Z$ interatomic distances are antiparallel. In molecules **46**, **50**, **51** and **66**, shortening of the $Si-Cl$ bond in the $N \rightarrow Si-Cl$ axial fragment from 3.908 to 2.269 Å is accompanied by elongation of the $Si-N$ bond from 1.766 to 2.028 Å. This is in good agreement with the

Table 1. Bond lengths $N \rightarrow Si$ and $Si-Z$ in the $N \rightarrow Si-Z$ fragment of intramolecular silicon heterocyclic complexes.

Compound	X	Y	Z	$N \rightarrow Si$ /Å	$Si-Z$ /Å	ΔSi /Å	Ref.

^a The $O \rightarrow Si$ bond length is given; ^b bond lengths for two conformers, namely, with an envelope (α) and planar (β) geometries of the six-membered heterocycle are given.

hypervalence theory proposed by Musher¹¹⁰ and developed later by Pestunovich, Sidorkin, and Voronkov.^{14, 15, 111} According to this concept, the axial atoms are bound to the silicon p_z -orbital by a system of three-centre four-electron ($3c-4e$) molecular orbitals.

The equatorial substituents interact with the axial fragment, thus shortening the $N \rightarrow Si$ bond and lengthening the $Si-Cl$ bond.¹⁴ This effect is not very pronounced but evidently significant. However, in molecules **66**, **67** and **69** differing in the number of equatorial chlorine atoms (1, 2 and 3, respectively), the $N \rightarrow Si$ bond length and the axial $Si-Cl$ bond length decrease as the number of chlorine atoms increases (see Table 1).⁶⁸ The equatorial bonds in an ideal trigonal bipyramid (TBP) with the silicon atom in the equatorial plane ($\Delta Si = 0$) are orthogonal to the three-centre MOs. Shortening of the bonds is apparently caused by the electron-withdrawing effect of silicon, which makes the silicon atom approach the axial substituents.

In molecule **51**, the silicon atom is located at the centre of a disordered TBP the axial positions of which are occupied by the heterocycle nitrogen atom and the chlorine atom (the $N-Si-Cl$ angle is 167.9°).⁵⁸ The length of the very short $N \rightarrow Si$ bond (1.852 \AA) is close to a covalent bond length (1.796 \AA), while the length of the very long $Si-Cl$ bond (2.679 \AA) attests to a substantial polarisation.

The two interatomic distances $N-Si$ in 2-[methyl(trifluorosilyl)aminomethyl]pyridine (**27**)⁵³ are non-equivalent, the $N \rightarrow Si$ coordination bond being much longer than the covalent bond. In the TBP of molecule **27**, the pyridine nitrogen atom and the fluorine atom are in the axial positions (the $NSiF$ angle is 178.0°). The $Si-F_{ax}$ bond (1.621 \AA) is longer than $Si-F_{eq}$ (1.603 \AA).

Attention is attracted by the considerable difference between the $O \rightarrow Si$ bond lengths in the *N*-(trifluorosilylmethyl)succinimide (**9**) and -glutarimide (**10**) molecules and that in the *N*-(trifluorosilylmethyl)phthalimide (**11**) molecule, indicating much stronger bonds in the case of compounds **9** and **10** than in compound **11**.^{41, 43–45, 107} This is due to the fact that the five-membered pyrrolidine-2,5-dione ring in the molecule of organosilicon phthalimide derivative **11** is aromatic, as it has a closed six- π -electron shell. Therefore, the nucleophilicity of the carbonyl oxygen atoms in compound **11** is lower than that in non-aromatic molecules **9** and **10**.

The $C=O$ bond incorporated in the five-membered coordination ring of molecules **9–11** (see Table 1) is 0.04 , 0.038 and 0.02 \AA longer than the exocyclic $C=O$ bond (1.202 , 1.202 and 1.210 \AA , respectively) in which the oxygen atom is not coordinated.⁴³ Due to the donor–acceptor bonding of the O and Si atoms in molecules **9–11**, the lengths of the two endocyclic $N-C$ bonds in the heterocycle are different. The $N-C$ bond in compounds **9–11** incorporated in the coordination ring (1.323 , 1.357 and 1.367 \AA , respectively) is much shorter than the $N-C$ bond at the second carbonyl group (1.400 , 1.409 and 1.393 \AA , respectively). These data suggest a higher degree of p, π -conjugation of nitrogen with the carbonyl group incorporated in the coordination heterocycle in molecules **9–11**.

The surrounding of the silicon atom in the 2-diphenyl(methyldichlorosilyl)methylpyridine molecule is nearly tetrahedral, whereas in the 2-[dichlorobis(trimethylsilyl)silylmethyl]pyridine molecule (**30**), the silicon atom of the dichlorosilyl group is located at the centre of the TBP, the $N \rightarrow Si$ bond length being 2.066 \AA .⁵⁵

According to X-ray diffraction^{64–66} and neutron diffraction⁶⁴ data, the lengths of the $N \rightarrow Si$ coordination bonds in 1-trifluoro- and 1-trichlorosilyl-1,2,3,4-tetrahydro-1,10-phenanthroline (**68**) and (**69**) (see Table 1) are much longer than the length of the $Si-N$ valence bond (1.732 and 1.737 \AA , respectively). The replacement of one or two chlorine atoms in molecule **69** by methyl group(s) results in a slight increase in the

$N \rightarrow Si$ distance (see Table 1).⁶⁸ However, when all three Cl atoms are replaced by methyl groups (trimethylsilyl phenanthroline derivative **65**), the $N \rightarrow Si$ donor–acceptor bond is substantially elongated (2.689 \AA). The environment of the silicon atom in molecule **65** can be defined as a highly disordered tetrahedron, unlike that in analogous molecules **68** and **69** where the silicon atom is located at the center of a TBP.⁶⁷

The structures of 2-(trifluorosilylmethyl)thiobenzoxazole (**1**) and -benzothiazole (**2**) resemble each other in many respects. The silicon atom polyhedron is a TBP in both molecules and the lengths of the $N \rightarrow Si$ donor–acceptor bonds are equal to 1.967 and 1.988 \AA , respectively. The $Si-F_{ax}$ bonds in compounds **1** and **2** (1.624 and 1.632 \AA , respectively) are longer than the equatorial $Si-F_{eq}$ bonds (1.594 and 1.589 \AA , respectively).¹⁰⁶

In molecule **28**, the silicon atom is pentacoordinated and has a distorted trigonal-bipyramidal geometry.⁵⁴ The axial positions of the bipyramid are occupied by the $N(Py)$ and Cl atoms (the $NSiCl$ angle is 167.9°). The equatorial $N_{eq}-Si$ valence bond (1.753 \AA) is much shorter than the $N_{ax}-Si$ bond (1.975 \AA), which attests to the presence of $N(Py) \rightarrow Si$ dative interaction.

In the molecule of compound **56**, the axial $N \rightarrow Si-C$ angle is 170° , which implies a distorted TBP.⁶¹ The equatorial $Si-C$ bond is 0.1 \AA shorter than chemically the same axial bond (Table 2), which is a typical feature of this geometry. The $N \rightarrow Si$ bond in **56** is somewhat longer than those in compounds **55** and **63** (by 0.087 and 0.063 \AA , respectively) (see Table 2), which is attributable to a higher positive charge of the silicon atom in the $SiPh_2$ group compared with $SiMe_2$.^{59–61}

In the molecule of compound **61**, which is a bromophenyl analogue of compound **56**, the pentacoordinate silicon atom is at the vertex of a square pyramid. This type of geometry is seldom encountered in hypervalent silicon compounds.⁶² The $N \rightarrow Si$ interatomic distance in molecule **61** (1.950 \AA , see Table 2) is shorter than this distance in any of the studied silatranes (see Section III.2).¹⁵

Unlike compound **56**, the silicon polyhedron in molecules **58** and **60** is a distorted TBP in which the apical positions are occupied by the nitrogen atom and the phenyl group.⁶³ The $N \rightarrow Si$ interatomic distance (see Table 2) is rather long but it is still markedly shorter than the sum of the van der Waals radii of these elements (3.65 \AA). Structural studies of compound **58** have shown^{59, 60} that the $N \rightarrow Si$ distance is somewhat shorter than those found in compounds **55** and **63**.

The silicon atom in molecule **17** has a distorted octahedral geometry. The two bidentate ligands in chloro(methyl)bis-(8-quinolyloxy)silane (**17**) are nearly mutually orthogonal and occur in the *cis*-positions, hence, the silicon atom becomes a chiral centre.⁴⁸ The $Si-O$ bonds form an angle of 168.7° and the $NSiN$ angle is close to right angle (85.3°). The $N \rightarrow Si$ coordination bonds (see Table 2) are much longer than the $N-Si$ covalent bond, *i.e.*, they are the same as in many compounds of penta- and hexacoordinate silicon.

The disordered structure of $Si(TTP)(THF)_2$ has been studied by X-ray diffraction.¹⁰⁴ Four nitrogen atoms and one silicon atom are coplanar, the Si atom being situated in a slightly distorted octahedral environment, while the *meso*-carbon atoms are located above or below the SiN_4 plane. The oxygen atoms of tetrahydrofuran are in axial positions and are bound to silicon by a dative bond.

The silicon atom in the molecule $(TTP)Si(OSO_2CF_3)_2$ (**118**) has a slightly distorted octahedral geometry with triflate groups in the *trans*-position. In this molecule, the porphyrin rings have a corrugated geometry favourable for the incorporation of a small silicon atom. The $O-Si-O$ angle (178°) is nearly linear. The average $Si-N$ distance in molecule **118** is shorter than in molecules **17**⁴⁸ or **115**⁸⁵ (by 0.145 and 0.050 \AA ,

respectively). The molecule [Bu^tMe₂SiO(Pc)Si]₂O (**96**) represents a dimer with PcSi units linked by an oxygen atom.⁸⁰ In the molecule PcSi(OSiMe₃)₂ (**115**), the central silicon atom is located in a distorted octahedral environment. Two symmetrically independent Si(Pc)–O–Si(Me) bond angles are 157.8 and 156.6°.⁸⁵

b. ²⁹Si NMR spectroscopy

In the ²⁹Si NMR spectra of hypervalent silicon compounds, typical upfield shifts of the ²⁹Si signals compared to those of tetracoordinate silicon are observed. The chemical shifts in the ²⁹Si NMR spectra of heterocyclic derivatives of pentacoordinate silicon are summarised in Table 3.

According to ²⁹Si NMR data, the N→Si coordination interaction in Si(V) or Si(VI) organosilicon compound considered here is either missing or very weak if the coordination-induced change in the chemical shift (Δδ) defined as

$$\Delta\delta = \delta[^{29}\text{Si}(\text{V or VI})] - \delta[^{29}\text{Si}(\text{VI})]$$

is close to zero.

Yet another feature of the ²⁹Si NMR spectra of heterocyclic derivatives of hypervalent silicon is the clear-cut temperature dependence of the δ(²⁹Si) value. As temperature decreases, the ²⁹Si signal shifts upfield, indicating an increase in the strength of the N→Si coordination bond. The low-temperature change in δ(²⁹Si) may be caused by two processes taking place on decreasing the temperature:

(1) shift of the equilibrium between the tetra- and pentacoordinate states of silicon toward the latter;

(2) shortening of the N→Si coordination bond in the coordination polyhedron of hypervalent silicon.^{112–114}

Nevertheless, in some cases, the ²⁹Si chemical shift changes in the opposite direction upon decrease in the temperature. For example, in the ²⁹Si NMR spectrum of compound **46**, the chemical shift is –6.2 ppm at 100 °C and –18.4 ppm at –80 °C.⁵⁷ This is due to the equilibrium interconversion of compounds **B** and **C** (see Scheme 1), which decreases the silicon coordination number to 4 *via* the stable iminium chloride **C**.

Attention is attracted by the fact that the pentacoordinate state of Si in *N*-trifluorosilylmethylsuccinimide (**9**), -glutarimide (**10**) and -phthalimide (**11**) in solutions is much less pronounced than in most dragonoids studied by ²⁹Si NMR.^{41–45} The presence of intramolecular O→Si coordination bond in organosilicon derivatives of cyclic imides **9–11** is indicated by lower shielding constants of ¹⁹F nuclei [δ(¹⁹F) = –133.5 (for compound **9**), –134.19 (**10**), –134.6 (**11**)] and the ¹J(²⁹Si–¹⁹F) spin-spin coupling constants [248.8 (for compound **9**), 224.5 (**10**) and 256.3 Hz (**11**)] compared to those for tetracoordinate (chloromethyl)trifluorosilane [δ(¹⁹F) = –143.99, ¹J(²⁹Si–¹⁹F) = 267 Hz]. In the ²⁹Si NMR spectra, the silicon signal [–75.7 (**9**), –94.2 (**10**), –72.0 ppm (**11**)] is shifted upfield relative to that for (chloro-

methyl)trifluorosilane ($\delta = -71.3$) containing a tetracoordinate silicon atom. This difference, which is most pronounced in low-temperature spectra, allows one to detect the enhanced shielding of ^{29}Si nuclei typical of trigonal-bipyramidal silicon derivatives. However, even at $-100\text{ }^\circ\text{C}$, the NMR spectra of compound **11** attest to equivalence of the ^{13}C nuclei of both carbonyl groups [$\delta(^{13}\text{C}) = -168.4$] and the axial and equatorial fluorine atoms. Altogether, this suggests substantial weakening of the $\text{O} \rightarrow \text{Si}$ coordination bond in the organosilicon phthalimide derivative **11** in low-polarity media and fast (on the NMR time scale) transcoordination of silicon from one oxygen atom to another (pendulum effect).⁴⁵ A similar pendulum effect was found in the molecules of *N*-trifluorosilylmethylsuccinimide (**9**), -glutarimide (**10**) and *N*-(dimethylchlorosilylmethyl)glutarimide (**12**).^{41,43,44,46} The substantial difference $\Delta\delta$ (relative to $\text{ClCH}_2\text{SiF}_3$) for compound **10** (-23 ppm) compared to that for compound **9** (-4 ppm) attests to stronger $\text{O} \rightarrow \text{Si}$ interaction in the former.

According to ^{29}Si NMR spectra, compound **30** contains two magnetically non-equivalent trimethylsilyl groups at ambient temperature, which is in line with the sterically more rigid structure in the crystal.⁵⁵ This confirms the assumption that the nitrogen atom in a distorted TBP of molecule **30** is apically bonded to the silicon atom by an intramolecular coordination bond, which closes a four-membered ring. The carbon atom of the 2-substituent in the pyridine ring bears two SiMe_3 groups located in the *cis*- and *trans*-positions with respect to the equatorial H and Cl atoms, respectively.⁵⁵ Unlike this compound, derivative **31** exhibits temperature-dependent ^{29}Si NMR chemical shifts. The lowest-frequency signal of the central silicon atom is observed at $-70\text{ }^\circ\text{C}$. An increase in intensities of the two resonance signals due to the SiMe_3 groups⁵⁵ attests to fast equilibrium between tetra- and pentacoordinate states of the silicon atom at this temperature.

The ^{29}Si chemical shifts of the central silicon atom in compounds **30–35** (see Table 3) with two trimethylsilyl groups at the exocyclic carbon atom are negative.⁵⁶ Meanwhile, in the NMR spectra of isostructural derivatives **42–44** in which one SiMe_3 group has been replaced by phenyl group, the ^{29}Si chemical shifts may be either negative or positive. In the former case, they correspond to a pentacoordinate silicon atom and in the latter case, to a tetracoordinate silicon atom.⁵⁶ The negative ^{29}Si chemical shifts in the spectra of compound **42** indicate that silicon is pentacoordinate. However, in molecules **43** and **44**, it is apparently tetracoordinate. Thus, NMR data imply that the Si atom passes from the tetracoordinate into the

pentacoordinate state. The coordination environment of the central silicon atom depends on the chemical nature and the bulk of the substituents attached. In organosilicon pyridine derivatives **42–44**, silicon is most often pentacoordinate; however, an increase in the bulk of substituents at the central silicon atom results in its tetracoordination.⁵⁶

The presence of a highly basic ligand at the silicon atom in molecules **51** and **52** changes considerably its coordination with respect to that in compounds **46** and **47** containing weakly basic ligands.⁵⁸ Compounds **51–54** contain pentacoordinate silicon in the crystalline state (compounds **53** and **54**, also in solution). In the crystal structure of molecule **51**, the TBP coordination of silicon is highly distorted towards tetrahedral with ionisation of the $\text{Si}-\text{Cl}$ bond (2.679 \AA) as compared with compound **46**. The ratio of structures containing tetra- or pentacoordinate silicon atom in compounds **51–54** in solutions depends on temperature and the solvent nature. An increase in temperature shifts the equilibrium to the pentacoordinate structure and *vice versa* (the entropy effect). The effect of the solvent nature on the ratio of penta- to tetracoordinate Si atoms ($\text{Si}-\text{Cl}$ bond ionisation) correlates with the electron-withdrawing properties of the Si-substituents.⁵⁸

The NMR spectra of organosilicon 1,2,3,4-tetrahydro-1,10-phenanthroline derivatives **65–68** with methyl groups at the central Si atom being replaced by halogen atoms (see Table 3) also show transition from the tetra- to pentacoordinate state of silicon.⁶⁹

The $\delta(^{29}\text{Si})$ value (-217) in the ^{29}Si NMR spectrum of organosilicon tetrakis(4-tolyl)porphyrin derivative (**116**) is indicative of a hexacoordinate state of silicon.¹⁰⁴ The absence of a low-field signal in the ^1H NMR spectrum and the $J_{\text{Si}-\text{H}}$ value in the ^{29}Si NMR spectrum of compound **116** correspond to a *trans*- SiCl_2 group.

A study of the photophysical and voltammetric properties of organosilicon phthalocyanines containing $\text{OSi}(\text{n-C}_6\text{H}_{13})_3$ and $\text{OSiBu}_2(\text{n-C}_{18}\text{H}_{37})$ groups has shown⁷⁶ that they possess the maximum first oxidation potentials due to the highest steric hindrance in their molecules. Meanwhile, the first reduction potential depends little on the spatial structure.

3. Chemical properties

Strange as it may seem, the chemical properties of organosilicon intramolecular complexes of nitrogen heterocycles received relatively little interest from researchers, who paid attention mainly to their synthesis and molecular and stereo-electronic structures. The works devoted to the reactivity of

these compounds were focussed on Si—C and Si—X bond cleavage in organosilicon porphyrin and phthalocyanine complexes (hydrolysis, alcoholysis and halogenolysis).

Organosilicon porphyrin complex **116** containing a central SiCl₂ group reacts with protic solvents.¹⁰⁴ When this compound is treated with methanol, only one chlorine atom is replaced by a methoxy group to give (TTP)Si(OMe)Cl (**119**) (Scheme 5). Hydrolysis of compound **116** results in the loss of the central silicon atom.

When phthalocyanino-λ⁶-siliconium **80** containing two octyl groups reacts with an excess of *N*-bromosuccinimide in benzene (20 °C), the colour of the reaction mixture gradually changes from dark green to deep blue-violet.⁷⁸ According to GLC, the reaction is complete in 2 h giving rise to 1-bromooctane (yield 60%). As a result, both Si—C bonds are cleaved. After being washed with water, methanol, and diethyl ether, the blue-violet precipitate proved to be dihydroxy derivative PcSi(OH)₂ (**92**). Treatment of intermediate **120** with conc. H₂SO₄, NH₄OH and then Et₃SiH in the presence of H₂PtCl₆·6H₂O resulted the phthalocyanine PcSi(OSiEt₃)₂ (**121**). This product results evidently from the reaction of Et₃SiH with diol **92**.

The Si—C bonds in phthalocyanino-λ⁶-siliconium derivatives **76–80** are cleaved by halogens or iodine monochloride even at room temperature.⁷⁸ The Si—C(Octyl) bond in compound **80** cleaves more readily under the action of bromine than under the action of chlorine or iodine. The reactivities of the Si—Ar bonds in organosilicon phthalocyanine complexes **76–80** depend on the nature of the aromatic substituent, decreasing in the sequence 4-MeOC₆H₄ > 4-MeC₆H₄ > Ph ≫ 3-CF₃C₆H₄.

The cleavage of Si—C(Alk) and Si—C(Ar) bonds with iodine chloride occurs in different ways. In the former case, a mixture of chloroalkane and iodoalkane is formed, while in the latter case, aryl iodide is produced.⁷⁸ The Si—C(Alk) bond in phthalocyanino-λ⁶-siliconium derivatives cleaves with greater difficulty than the Si—C(Ar) bond. Halogen induced cleavage of the Si—C(Alk) bond affords alkyl radicals, whereas the Si—C(Ar) bond is cleaved according to the common electrophilic substitution mechanism.

The Si—C bonds in organosilicon Pc complexes **76–80** are cleaved in reactions with CuCl₂ or CuBr₂ (THF, 50 °C) to form the Si—X bond (X = Cl, Br).⁷⁸

76–80

X = Cl, Br.

Organosilicon phthalocyanine complexes **78** and **80** do not react with peroxybenzoic acid.⁷⁸ This fact was attributed to high stability of these complexes with hexacoordinate silicon atom caused by the macrocycle rigidity.

Particular attention is devoted to silicon phthalocyanine polysiloxanes.^{100, 115–117} These polymers are regarded as precursors of conducting polymers. The possibility of the radiation-induced synthesis,¹⁰⁰ the ability to form liquid crystals,¹¹⁶ dark electrical conductivity, electrochemical properties and conduction of microwave radiation were studied in detail for these compounds.

Studies on the chemical properties of hexacoordinate silicon compounds provide valuable information on the mechanisms of Si—C and Si—X bond cleavage and formation. This knowledge helps determining the routes of similar reactions also for Si(VI)-organic complexes with simpler structure.

III. Silatranyl derivatives of nitrogen-containing heterocycles

1. Methods of synthesis

The first representatives of silatranyl derivatives of nitrogen heterocycles, 1-(heterylalkyl)silatrane with the general formula

were synthesised in the 1970s.^{118–124} Since 1993, we have carried out systematic investigations into these compounds.^{36–40}

1-(Heterylalkyl)silatrane are synthesised most often by transesterification of (heterylalkyl)trialkoxysilanes on treatment with tris(2-hydroxyethyl)amine (TEA):^{5, 8, 10, 13, 15}

where Het is the heterocyclic fragment, Y is a hydrocarbon bridge (CH₂)_{*n*} (*n* = 0–3) or a heteroatom (S, O, N) connecting the heterocycle to the silicon atom of the silatranyl group (Sa)

The reaction is carried out in the presence of a basic catalyst (AlkONa, KOH, *etc.*) or without a catalyst, usually with distillation of ethanol.

This method was employed to carry out the first syntheses of 1-[(*N*-azacycloalkyl)alkyl]silatrane **122–130** (yields 70%–79%) in which the Si atom and the heterocycle N atom are linked through one, two or three methylene units. The reactions were carried out in chloroform, benzene or *o*-xylene^{118–121} without a catalyst.

X = (CH₂)_{*n*} [*n* = 2 (**122**), 4 (**123**, **124**), 5 (**125**, **126**), 6 (**127**, **128**)], (CH₂)₂O(CH₂)₂ (**129**, **130**); *m* = 1 (**123**, **125**, **127**, **129**), 2 (**122**), 3 (**124**, **126**, **128**, **130**).

Note that (pyrrolidinomethyl)- (**123**) and (piperidinomethyl)silatrane (**125**) with *m* = 1 have higher melting points than the homologues with *m* = 3 (compounds **124** and **126**, respectively).¹²⁰ However, low-melting (perhydroazepinoalkyl)silatrane (**127**, **128**) do not follow this regularity.

1-(Piperazinoalkyl)silatrane and their *N'*-derivatives (**131–135**) were synthesised by the reaction of the corres-

ponding (piperazinoalkyl)triethoxysilanes with tris(2-hydroxyethyl)amine in boiling xylene in the presence of a catalytic amount of metallic sodium.¹²²

$n = 1$: R = H (**131**), Me (**132**); $n = 3$: R = H (**133**), Me (**134**), Ph (**135**).

The same route was used to convert *N,N'*-bis[3-(triethoxysilyl)propyl]piperazine into 1,4-bis(3-silatranylpropyl)piperazine (**136**) (yield 40%).¹²²

Heating tetrahydroquinoline with (chloromethyl)triethoxysilane in xylene followed by transesterification of the resulting *N*-(triethoxysilylmethyl)tetrahydroquinoline with tris(2-hydroxyethyl)amine affords 1-(tetrahydroquinolinomethyl)silatrane (**137**) in a moderate yield.^{123, 124}

Transesterification of the corresponding (8-quinolylthiomethyl)-, (2-heterylthiomethyl)- and (*N*-heterylalkyl)trimethoxysilanes with tris(2-hydroxyethyl)amine carried out without a solvent or a catalyst resulted in 1-(8-quinolylthiomethyl)- (**138**), 1-(2-heterylthiomethyl)- (**139–141**) and 1-(*N*-heterylalkyl)silatrane (**142–158**) (yields 73%–92%) (Refs 37, 39, 40 and 125).

The reaction of 4-(3-triethoxysilylpropyl)thiomorpholine 1-oxide with tris(2-hydroxyethyl)amine in the presence of a catalytic amount of a saturated methanolic sodium methoxide gives 4-[3-(1-silatranyl)propyl]thiomorpholine 1-oxide (**159**) in 40% yield.¹²⁶ 1-(3-Aminopropyl)silatrane or its 3,7,10-trimethyl derivative reacts with divinyl sulfoxide in ethanol at 45–65 °C to give *N*-[3-(1-silatranyl)propyl] derivatives of thiomorpholine 1-oxide **159**, **160**.¹²⁷

R = H (**159**), Me (**160**).

N-(Trialkoxysilylmethyl)lactams **161** react with tris(2-hydroxyethyl)- or tris(2-hydroxypropyl)amines in boiling xylene in the presence of KOH giving rise to *N*-(silatranylmethyl)lactams **162–168**.¹²⁸

$\text{R}^1 = \text{R}^3 = \text{H}$: $n = 1$ (**162**), 2 (**163**), 3 (**164**);

$\text{R}^1 = \text{H}$, $\text{R}^3 = \text{Me}$: $n = 1$ (**165**), 2 (**166**), 3 (**167**);

$\text{R}^1 = \text{Ph}$, $\text{R}^3 = \text{H}$, $n = 1$ (**168**); $\text{R}^2 = \text{Me}$, Et.

These silatranylactams have also been prepared by a one-pot procedure involving the reaction of *N*-(trimethylsilyl)lactams with (chloromethyl)trimethoxysilane and tris(2-hydroxyethyl)amine without intermediate isolation of *N*-(trimethoxysilyl)methyl derivatives (yields 30%–63%).¹²⁸

Transesterification of *N*-(triethoxysilyl)lactams with tris(2-hydroxyethyl)amine in boiling xylene without a catalyst afforded, 1-[1-(2-oxoperhydroazepino)ethyl]- (**169**) and 1-[1-(2-oxopyrrolidino)ethyl]silatrane (**170**).^{129, 130}

$n = 1$ (**169**), 3 (**170**).

Transesterification of *N*-(trialkoxysilylpropylamino)-methyl derivatives of imidazole, 3,5-dimethylpyrazole, 5-methyl-3-phenylpyrazole and benzotriazole with tris(2-hydroxyethyl)amine or tris(2-hydroxypropyl)amine furnished silatrane derivatives **171–179**.¹³¹

Another synthetic route to compounds **171**, **173–179** is based on anhydrocondensation of the corresponding 1-(3-aminopropyl)silatrane with 1-hydroxymethylated 3,5-dimethylpyrazole, 5-methyl-3-phenylpyrazole, imidazole or benzotriazole in dichloroethane at room temperature.¹³²

The condensation of (3-aminopropyl)triethoxysilane with 2-aminopyridine yielded 2-[3-(triethoxysilyl)propyl]amino-2-pyridine, which was then converted into 2-[3-(1-silatranyl)propyl]aminopyridine (**180**) by transesterification.¹³³

1-(Quinolylaminoalkyl)silatrane **181–184** were synthesised by two routes: transesterification of 4-[3-(triethoxysilyl)propyl]aminoquinolines on treatment with tris(2-hydroxyethyl)amine or by heating of 4-chloroquinoline with 1-(3-aminopropyl)silatrane in diglyme (yields 51%–65%).¹²⁴

When [3-(*N*-heterylamino)propyl]triethoxysilanes are heated with tris(2-hydroxyethyl)amine in benzene or xylene, 1-{3-[(6-chloropyridazin-3-yl)amino]propyl}- (**185**) and 1-{3-[(phthalazin-1-yl)amino]propyl} silatrane (**186**) are formed.¹²¹ Low yields of the products (20%–30%) were attributed to the fact that the triethoxy derivatives were not isolated from the reaction mixture. No increase in the yields of compounds **185** and **186** was achieved by preparing them by the reaction of 1-(3-aminopropyl)silatrane with 3,6-dichloropyridazine or 1-chlorophthalazine in the presence of K₂CO₃:

Silatrane **187–191** containing pyridyloxy or pyridylmethoxy group can be prepared by two methods.^{134, 135} Dehydrocondensation of isomeric pyridylmethanols with 1-hydroxysilatrane in xylene at 130 °C in the presence of 5 mol % Bu^tOK yielded 1-(pyridylmethoxy)silatrane **187–190** (yields 44%–56%). (Note that NaOH, KOH or NaOEt do not catalyse this reaction.)

A more efficient method for the synthesis of 1-(6-methylpyridin-2-ylmethoxy)- (**190**) and 1-(3-pyridyloxy)silatrane (**191**) is based on the reaction of hydroxy(methyl)pyridines with tetraethoxysilane and tris(2-hydroxyethyl)amine in xylene in the presence of 3.5 mol % KOH with distillation of ethanol.¹³⁵

Transesterification of 1-ethoxysilatrane under the action of 2-hydroxypyridine follows an unusual route resulting in 1-silatranyl-2-pyridone (**192**).¹³⁶ This compound is the first silatrane that contains an axial N→Si–N fragment and the mechanism of its formation is the first example of a silatranotropic rearrangement.

The reactions of sodium hetarenethiolates with 1-(chloromethyl)silatrane in DMF furnished (4-hydroxypyrimidin-2-yl)thiomethyl- (**193**), (6-amino-4-hydroxypyrimidin-2-yl)thiomethyl- (**194**), (2-aminopurin-6-yl)thiomethylsilatrane (**195**) and 2-(1-silatranylmethylthio)benzimidazole (**139**), -benzoxazole (**140**) and -benzothiazole (**141**) in 60%–85% yields.¹³⁷

As regards the reactivity toward 1-(chloromethyl)silatrane, sodium hetarenethiolates occupy an intermediate position between EtSNa and Et₂NCS₂Na.

Refluxing of a mixture of 3-substituted 4(5)-(triethoxysilyl)-2-isoxazolines with tris(2-hydroxyethyl)amine in toluene in the presence of NaOH as the catalyst results in silatranes **196–199** in yields of ~70%.^{138, 139} Compounds **196** and **197** can be isolated by recrystallisation from chloroform.

R = Me (**196**, **198**), Ph (**197**, **199**).

2. Studies of the molecular and electronic structures

a. X-Ray diffraction method

The molecular structures of silatranyl derivatives of nitrogen heterocycles in which the Het and Sa groups are linked either by a (CH₂)_n bridge (*n* = 1, 3) or directly have been comprehensively studied by X-ray diffraction.^{11, 12, 15, 18, 22}

Data from numerous X-ray diffraction studies of these compounds indicate that the silatrane cage has a distorted trigonal-bipyramidal structure with a nearly equatorial arrangement of three oxygen atoms and with axial N and C atoms of the (CH₂)_nHet substituent at silicon.

The N→Si–C angle amounts to 174–179°, *i.e.*, it is close to the straight angle in an ideal TBP (180°). The O–Si–O and O–Si–C bond angles are in the ranges of 119.0–119.2 and 95.0–95.8°, respectively. The shift (ΔSi) of the silicon atom from the equatorial plane through three oxygen atoms towards the (CH₂)_nHet substituent is 0.11–0.18 Å. The average length of the Si–O equatorial bond (1.66–1.67 Å) is greater than in organyltrialkoxysilanes containing a tetrahedral silicon atom

[for example, in the MeSi(OMe)₃ molecule, this is 1.63 Å].¹⁴⁰ In the crystalline state, the length of the dative N→Si bond in silatranes is usually in the range of 1.965–2.24 Å, which is much shorter than the sum of the van der Waals radii of the silicon and nitrogen atoms (3.65 Å).

The N→Si interatomic distances in silatranes Het(CH₂)_nSa fall into a rather narrow range (2.09–2.15 Å), being a linear function of the inductive constant σ* of the substituent Het.²⁹ The same range covers the N→Si bond length in the molecules HetSa, which is 2.12 Å. The Si–C bond length in these molecules (1.89–1.94 Å) is much greater than in compounds of tetracoordinate silicon or in silatranes containing a saturated or unsaturated substituent comprising two carbon atoms at the silicon atom (1.77–1.78 Å).¹⁴¹ Since the lengths of the transannular N→Si bond and the Si–C bond in the molecules Het(CH₂)_nSa do not differ much, one should admit that irrespective of the nature, the substituent Het affects the structure of the axial N→Si–C fragment in the same way.

Selected geometric parameters of silatranyl derivatives of nitrogen heterocycles are summarised in Table 4.

The length of the transannular N→Si bond in the *N*-(1-silatranylalkyl)pyrazole molecules Het(CH₂)_nSa for *n* = 1 (compound **144**) is 0.036 Å shorter than that for *n* = 3 (**156**). Conversely, the Si–C bond is 0.026 Å longer for *n* = 1 (compound **144**) than for *n* = 3 (**156**). This is caused by the decrease in the inductive effect of the substituent Het on the Sa group following an increase in the number of methylene groups separating them.¹⁴⁶

In the 8-(1-silatranylmethylthio)quinoline molecule (**138**), the S–CH₂ bond occurs in a nearly ideal crossed position with respect to the silatrane fragment, the SCSiO torsion angle being 179° (Ref. 40). In addition, the *trans*-configuration of the SiCSC bridge is nearly ideal (the torsion angle is 178°). The bridge is approximately in the same plane as the quinoline ring (the CSCC angle is 3°).

In 1-(2-benzothiazolylthiomethyl)silatrane (**141**),¹⁴² the bond lengths of the silatranyl group, except for the Si–C bond length, are similar to the standard values for the XCH₂Sa molecule.¹⁵³ As in other silatranes of this type, the exocyclic Si–C bond is elongated (1.912 Å).¹⁴¹ The geometric parameters of the trigonal-bipyramidal coordination of Si are similar to those established for molecule **138**.⁴⁰ The orientation of the planar benzothiazolylthiomethyl substituent in compound **141** is crossed with respect to the Si–O bonds and also resembles that observed in molecule **138**. The full difference Fourier synthesis shows a clear-cut 0.25 e Å^{–3}-high electron density peak in the line of the transannular N→Si bond at a 0.65 Å distance from the N atom. In the crystals of 1-halosilatranes

Table 4. Geometric parameters of the Het(CH₂R)_nSa molecules (*n* = 0, 1, 3).

Compound	Bond length/Å			Bond angle/deg			ΔSi/ Å	Ref.
	N→Si	Si–C	Si–O	C–Si–N	C–Si–O	O–Si–O		
138	2.111	1.893	1.667	175.0	95.8	119.0	0.169	40
141	2.100	1.912	1.663	176.7	95.2	119.2	—	142
142	2.089	1.902	1.665	177.9	95.4	119.1	0.16	143, 144
143	2.088	1.898	1.664	176.1	95.6	119.2	0.15	145
144	2.118	1.913	1.663	178.0	—	—	—	146
145	2.095	1.906	1.661	177.4	95.2	119.2	0.15	147
146	2.11	1.910	1.657	176.8	95.2	119.2	0.11–0.12	144, 148
148	2.097	1.897	1.664	177.8	95.4	119.1	0.16	144, 149
149	2.088	1.909	1.667	177.2	95.2	119.2	—	150
151	2.089	1.908	1.658	176.2	95.0	119.2	0.14	151, 152
156	2.154	1.887	1.664	179.7	—	—	—	146
170	2.122	1.909	1.665	177.3	—	—	0.176	129
196	2.119	1.920	1.644	177.5	—	119.0	0.170	139
197	2.118	1.897	1.657	176.1	—	119.0	0.168	139

XSa (X = F, Cl), this delocalised electron density peak, which reflects the strength of the N→Si donor-acceptor interaction, is located at approximately the same distance from the nitrogen atom.¹⁵⁴

It is worthy of note that all carbon–carbon bonds in the pyrrole ring of the *N*-(1-silatranylmethyl)pyrrole molecule (**142**) [especially the C(3)–C(4) bond] are equalised and are shorter than those in unsubstituted pyrrole or *N*-methylpyrrole and in the *N*-(1-silatranylmethyl)indole (**146**) or -carbazole (**148**).^{143, 144, 148, 149} The N–C bond lengths (1.37 Å) are nearly the same as those in pyrrole or *N*-methylpyrrole. The difference between the C(3)–C(4) and C(2)=C(3), C(4)=C(5) bonds in molecule **142** and in pyrrole or *N*-methylpyrrole can be regarded as a measure of electron density delocalisation in the pyrrole ring. The equalisation of all bonds in the pyrrole ring of *N*-(1-silatranylmethyl)pyrrole (**142**) is also indicated by equal bond angles in the pyrrole ring (~108°). These data imply that the pyrrole ring in molecule **142** is more aromatic than in pyrrole or *N*-methylpyrrole, which prompts a comparison of compound **142** with the cyclopentadiene rather than 1-azacyclopentadiene anion. This is also confirmed by quantum-chemical calculations.¹⁵⁵

On going from *N*-(1-silatranylmethyl)pyrrole (**142**) to *N*-(1-silatranylmethyl)indole (**146**) and -carbazole (**148**), equalisation of the bond lengths in the pyrrole heterocycle disappears, indicating a lower aromaticity of the pyrrole fragment in these molecules. Conversely, the average length of the bonds between the benzene-ring carbon atoms in compounds **146** and **148** [1.390 (α), 1.386 (β) and 1.390, 1.393 Å, respectively][†] is smaller than in benzene. This means that the attachment of an *N*-silatranylmethyl group to the indole and carbazole nitrogen atom increases the aromaticity of the benzene rings.^{148, 149}

b. Miscellaneous physicochemical methods

The presence of an intramolecular N→Si bond in *N*-(1-silatranylmethyl)azacycloalkanes **123**–**128** is also supported by ¹H NMR spectra.¹²⁰ Specifically, the proton chemical shifts of the SiCH₂ group in compounds with *m* = 1 (**123**, **125**, **127**) and *m* = 3 (**124**, **126**, **128**) are lower than those in the initial trialkoxysilyl derivatives. The difference between the chemical shifts of the NCH₂- and CH₂O-group protons in derivatives **123**–**128** almost does not depend on the size of the heterocycle, being nearly constant and equal, on average, to 0.97 ppm. This implies transfer of the electronic effect of the substituent (CH₂)_{*n*}N to the whole silatranyl group, *i.e.*, the electronic states of both Si and N atoms are changed. Relying on the change in the chemical shift differences Δδ(SiCH₂) and Δδ(NCH₂) in the spectra of (CH₂)_{*n*}NCH₂Si(OCH₂CH₂)₃N (**123**, **125**, **127**) and (CH₂)_{*n*}NCH₂Si(OR)₃, the extent of the (*p*–*d*)σ interaction in the N→Si–C fragment increases with an increase in the negative inductive effect of the (CH₂)_{*n*}NCH₂ group.

The change in the NMR chemical shifts of the exocyclic NCH₂ protons of the heterocyclic (CH₂)_{*n*}N fragments of silatrane derivatives **123**, **125** and **127** confirms that the basicity of the endocyclic nitrogen atom increases with *n* in the following sequence: 5 < 4 < 6. The basicity of the heterocycle nitrogen atom increases on going from (CH₂)_{*n*}NCH₂Si(OR)₃ to (CH₂)_{*n*}NCH₂Si(OCH₂CH₂)₃N.¹²⁰

The ¹H NMR chemical shifts of solutions of 1-[(*N*-azacycloalkyl)methyl]silatrane (CH₂)_{*n*}NCH₂SiSa (*n* = 4–6) (**123**, **125**, **127**) depend on the nature of the solvent.¹²⁰ On going from

CCl₄ to DCCl₃, hydrogen bonds of the ODCCl₃ and NDCCl₃ types are formed, the latter being stronger. This is confirmed by the frequency shifts Δν(C–D⋯N) and Δν(C–D⋯O) of DCCl₃ in the IR spectra of solutions of compounds **123**, **125** and **127** (~70 and 10 cm^{–1}, respectively). The assumption about hydrogen bonding between chloroform and silatrane molecules in which the oxygen atoms act as donor centres is consistent with the increase in the dipole moments of alkyl-, alkoxy- and aryloxy-silatrane in chloroform¹⁵⁶ compared with those in ethyl acetate or benzene. 1-[(*N*-Azacycloalkyl)methyl]silatrane **123**, **125** and **127** form strong hydrogen bonds with proton donors through the heterocycle nitrogen atom. Meanwhile, no hydrogen bond exists between the deuteriochloroform D atom and silatrane nitrogen since the electron pair of nitrogen is involved in the transannular interaction with silicon and is hence inaccessible.

The ¹H NMR spectra of *N*-(1-silatranylmethyl)lactams contain, apart from the proton signals of the lactam rings and the Si(OCH₂CH₂)₃N group, singlets for the NCH₂Si methylene protons at δ = 2.39–2.98.¹²⁸

In the ¹H NMR spectra of unsubstituted (**187**–**189**) and 6-methyl-substituted (**190**) pyridylmethoxysilatrane, the proton signals for the exocyclic CH₂ group are shifted downfield with respect to these signals in the spectra of initial pyridylmethanols. This is due to interaction of the oxygen atom with silicon of the silatranyl group.¹³⁴

In the ¹⁵N NMR spectra of *N*-(1-silatranylmethyl) derivatives of imidazole (**143**), 3,5-dimethylpyrazole (**144**), 1,2,4-triazole (**145**), 2-methylindole (**147**), benzimidazole (**149**) and phthalimide (**155**), the CH₂Si group has little effect on the chemical shifts of the heterocycle nitrogen with respect to the corresponding *N*-methylazoles.¹⁵⁷ Enhancement of the electron-withdrawing effect of the heterocycle (depending on the number, positions and type of bonding of endocyclic nitrogen atoms) increases the shielding of the ²⁹Si nucleus and deshielding of the ¹⁵N nucleus in the silatrane cage. These dependences of δ(¹⁵N) and δ(²⁹Si) are typical of *Si*-substituted silatrane XCH₂Si.¹⁵

A comparison of the ¹H, ¹³C and ¹⁵N NMR spectra of 1- and 2-substituted (trimethoxysilylmethyl)benzotriazole and 1- (**150**) and 2-(1-silatranylmethyl)benzotriazole (**151**) indicates that the nature of the organosilicon substituent affects only slightly the electron density of the nitrogen atoms, but the nitrogen electron density markedly depends on the substituent position (1 or 2). The difference between the ¹⁵N chemical shifts of 1- (**150**) and 2-isomers (**151**) is more than 100 ppm.^{152, 158}

IR spectroscopy is often used to confirm the structures of silatranyl derivatives of nitrogen heterocycles. The silatrane cage is responsible for the following absorption bands in the IR spectra of compounds Het(CH₂)_{*n*}SiSa (ν): 340–390 (N→Si bond), 730–790 cm^{–1} (CH₂ rocking vibrations), 2870–3000 cm^{–1} (CH₂ stretching vibrations), 1020–1250 cm^{–1} (NC₃ asymmetric stretching vibrations), 750–820, 1040–1180 and 1270–1280 cm^{–1} (Si–O–C skeletal vibrations with predominance of the C–O and Si–C vibrations).¹⁵⁹ The absorption of Si–C vibrations is typical of most silatrane. These are shifted to lower frequencies relative to the corresponding signals observed for tetracoordinate silicon compounds. The bathochromic shift is indicative of a higher positive charge on the silicon atom and polarisation of the Si–C bond. The skeletal vibrations ν(C–C) produce bands at 1020, 940, 1050 cm^{–1}. The two last-mentioned bands are usually doublets.

The mutual influence of the organosilicon substituent and heterocyclic fragment on the exocyclic sulfur atom in 1-silatranylmethylthio derivatives of quinoline **138**, benzoxazole **140** and benzothiazole **141** containing an SCH₂–Sa group in heterocycle positions 8, 2 and 2, respectively, was studied by UV and IR spectroscopy.¹⁶⁰ In the IR spectra of these com-

[†] The unit cell of the *N*-(1-silatranylmethyl)indole (**146**) single crystal contains 4 pairs of crystallographically independent molecules of α- and β-modifications; in the case of *N*-(1-silatranylmethyl)carbazole (**148**), the average bond length for each benzene ring of the carbazole ring is given.

pounds, the absorption bands of the silatrane cage do not depend on the nature of the heterocycle. The UV spectra of compounds **138**, **140** and **141** exhibit a considerable bathochromic shift of the bands corresponding to the heterocycle (quinoline, benzoxazole and benzothiazole) with respect to the absorption spectra of their analogues in which the substituent contains a tetracoordinate silicon atom. This shift is due to high positive inductive effect of the silatranylmethyl group with a pentacoordinate silicon atom.

1- (**150**) and 2-(1-silatranylmethyl)benzotriazoles (**151**) differ in both the number and intensity of UV bands.^{152, 161} The UV spectra of a solution of **150** (benzenoid structure) in MeCN show two absorption peaks at 270–290 and 250–270 nm. Their positions are the same as the positions of peaks in the spectra of unsubstituted and 1-methyl-substituted benzotriazoles. The UV spectrum of a solution of compound **151** (quinonoid structure) contains only one peak at 270–285 nm, like the UV spectra of unsubstituted and 2-methyl and 2-sodium derivatives of benzotriazole.^{152, 161} The benzenoid and quinonoid structures of benzotriazoles **150**, **151** are also manifested in their IR spectra. The spectra of 1-substituted benzotriazole **150** display bands for ring vibrations at 665–670, 1565–1590, 1614–1616 cm⁻¹, while in the case of 2-substituted benzotriazole **151**, these bands occur at 620–630, 1567–1569 cm⁻¹. The IR absorption frequencies of the substituent CH₂Si(OCH₂CH₂)₃N in compounds **150**, **151** almost do not depend on its position (1 or 2).

In the IR spectra of compounds O=S(CH₂CH₂)₂N.(CH₂)₃Si(OCHRCH₂)₃N (R = H, Me) (**159** and **160**), the strong bands at 830 and 1035–1130 cm⁻¹ refer to the Si–O–C groups. This range (1040–1060 cm⁻¹) contains also strong bands for S=O. The medium bands at 489 cm⁻¹ are due to the S=O bending vibrations. The bands at 570–580 cm⁻¹ represent the bending vibrations of the silatrane cage.¹²⁷

In the IR spectra of *N*-(1-silatranylmethyl)lactams (**162**–**167**),¹²⁸ the carbonyl absorption is shifted to longer wavelengths by 20–40 cm⁻¹ relative to that in the spectra of the *N*-(trialkoxysilyl)- and *N*-(trimethylsilyl)methyl derivatives. This effect is enhanced if the silatranyl group bears three methyl groups in positions 3, 7 and 10. For example, in the spectra of compounds **165**–**167**, ν(C=O) is recorded at 1610 cm⁻¹, which is 25–80 cm⁻¹ higher than that for unsubstituted analogues. The lack, in the IR spectra of *N*-(1-silatranylmethyl)lactams, of a band at 1500–1520 cm⁻¹, typical of *Si*-substituted *N*-(dimethylsilylmethyl)lactams with intramolecular O→Si coordination confirms the absence of this coordination bond.

High dipole moments (μ) of silatranes (5–7 D) indicate that the charge transfer from nitrogen to silicon equals 0.1–0.3 e.^{5, 8} In line with this, the dipole moments of (CH₂)_nN(CH₂)_mSi(OCH₂CH₂)₃N (*n* = 4–6; *m* = 1, 3) (**123**–**128**) are in the range of μ = 5.0–5.6 D.¹²⁰ These values are 3.2–3.4 D higher than the dipole moments of the respective (*N*-azacycloalkyl)triethoxysilanes (CH₂)_nN(CH₂)_mSi(OEt)₃ (*n* = 4–6; *m* = 1, 3).

The dipole moments of *N*-(1-silatranylmethyl) derivatives of pyrrole (**142**), indole (**146**), 2-methylindole (**147**) and carbazole (**148**) depend on the structure of the heterocyclic substituent.¹⁴⁴ The dipole moments of the silatranylmethyl derivatives increase in the sequence **148** < **146** < **147** < **142**, which is not the case for *N*-(trimethoxysilylmethyl) derivatives of pyrrole, indole and 2-methylindole, the parent heterocycles (pyrrole, indole, carbazole), 2-methylindole or their *N*-methyl derivatives. This effect is due most likely to specific features of the electronic interaction of the Het and Sa fragments in

compounds **142**, **146**–**148**. The role of their specific spatial structure in solution cannot be ruled out either.

3. Chemical properties

Specific reactivities of 1-(*N*-heterylmethyl)silatranes Het(CH₂)_nSa with polarised Si–C bond are of particular interest.

Indeed, the reaction of 1-(piperidinomethyl)silatrane (**125**) with CCl₄ in benzene gives the corresponding hydrochloride even under daylight [(18–20) 10³ lux].¹⁶² The hydrogen atom is readily split off from the methylene group attached to silicon to give hydrogen chloride, which adds to another molecule **125**. The subsequent behaviour of the Cl₃C[•] radicals and the dehydrogenated initial silatrane as well as the composition and structure of the resulting polymeric products or the exact mechanism of this reaction are still obscure. The induction period of this photochemical process is 0.2 h.

The induction period of a similar reaction with 5-methyl-(*N*-piperidinomethyl)-1-methylquasisilatrane (**200**)

is 96 h at the same luminous intensity. The photochemical reaction of CCl₄ with (CH₂)₅NCH₂Si(OEt)₃ or Et₃N at the luminous intensity of (18–20) × 10³ lux starts only after 120 or 144 h, respectively.

The basicity of nitrogen in 1-(*N*-heterylmethyl)silatranes Het(CH₂)_nSa is much higher than in R₂NCH₂Si(OEt)₃ or in aliphatic amines. This is a result of strong electron-releasing effect of the CH₂Sa^{29, 30} group and n,σ-hyperconjugation in the NCH₂Si fragment.^{162–167}

In molecules such as NCH₂Si(OR)₃, the n,σ-interaction decreasing the nitrogen basicity exists in parallel with the electron-releasing effect of the CH₂Si(OR)₃ group.^{168–170} The enhanced basicity of nitrogen in the NCH₂Sa fragment is also indicated by the ionisation potential (7.46 eV) of the nitrogen lone pair in 1-piperidinomethyl-3,7,10-trimethylsilatrane (**201**),

which is much lower than that in *N*-methylpiperidine (8.30 eV).^{162, 168} The ionisation potentials of the molecules (CH₂)₅NCH₂Si(OEt)₃ and (CH₂)₅NCH₂SiMe(OCH₂CH₂)₂.NMe (**200**) are also increased (7.95 and 8.15 eV, respectively). This is confirmed by equilibrium constants of the phenol complexes with (CH₂)₅NCH₂Si(OCHMeCH₂)₃N (1100 litre mol⁻¹), (CH₂)₅NCH₂Si(OEt)₃ (110 litre mol⁻¹), (CH₂)₅NCH₂SiMe(OCH₂CH₂)₂NMe (**200**) (150 litre mol⁻¹) and Et₃N (52 litre mol⁻¹).^{162, 171} Note that the basicity of the N atom in methylbis(1-silatranylmethyl)amine is even higher. (Pyrrolidinomethyl)- (**123**) and (piperidinoalkyl)silatranes (**125**, **126**) react with methyl iodide in ethanol or toluene to give methiodides **202**–**204** with melting points above 200 °C.¹¹⁸

$m = 1, n = 1$ (**123, 202**);

$m = 2: n = 1$ (**125, 203**), 3 (**126, 204**).

(Silatranylalkyl)tetrahydro-1,4-thiazine 1-oxides react with MeI in a similar way to give quaternary ammonium salts.¹²⁶

The reaction of 1-(8-quinolylthiomethyl)silatrane (**138**) with copper(II), zinc(II) and tin(IV) chlorides in chloroform affords 1 : 1 complexes **205–207**.^{172, 173}

$\text{MCl}_n = \text{CuCl}_2$ (**205**), ZnCl_2 (**206**), SnCl_4 (**207**).

The complex of silatrane **138** with SnCl_4 (**207**) contains a strong $\text{N} \rightarrow \text{Sn}$ donor–acceptor bond. The complex with ZnCl_2 (**206**) has a chelate structure (the zinc atom forms a donor–acceptor bond with nitrogen and sulfur atoms). The reaction product of compound **138** with CuCl_2 , viz., complex **205**, exists in solutions as two species: a complex with the $\text{N} \rightarrow \text{Cu}$ bond and a chelate in which Cu is coordinated to N and S atoms.

1-(8-Quinolylthiomethyl)silatrane (**138**) reacts with an equimolar amount of HCl in ether giving 1 : 1 hydrochloride **208**. When an excess of hydrogen chloride is used, one endocyclic Si–O bond is cleaved in the Sa fragment.^{172, 173}

Note that in the silatrane derivatives of nitrogen heterocycles $\text{Het}(\text{CH}_2)_n\text{Sa}$, the negatively charged oxygen atoms of the silatrane fragment are more prone to form hydrogen bonds than the heterocycle nitrogen atom. In the crystal hydrate of *N*-[1-(1-silatranyl)ethyl]pyrrolidone (**169**), water molecule is connected by $\text{O} \cdots \text{HO}$ hydrogen bonds to the oxygen atom of the silatranyl group.¹³⁰ Unfortunately, the formation of hydrogen bonds by silatrane nitrogen heterocycles has been scarcely studied.

* * *

Silatrane as compounds possessing a cage structure and containing a trace substance, silicon, exert a physiological action on all living organisms, existing at different stages of evolution (from microbes to humans).¹⁶ The biological action

of silatranyl nitrogen heterocycles is due to both the presence of a heterocyclic system and the presence of hypervalent silicon atom in appropriate environment. Unfortunately, the biological activity of 1-(*N*-heterylalkyl)silatrane has not been adequately studied as yet. However, we are confident that in the near future valuable pharmaceutical agents or protection means for agricultural plants will be found among this class of compounds.

IV. Rearrangements of metallasiloxanes	858
V. Metallasiloxanes in catalysis	860
VI. Conclusion	863

Abstract. The current status of the chemistry of metallasiloxanes is surveyed. Synthetic methods affording the metallasiloxane fragments and specific transformations of metallasiloxanes governed by the coordination properties of the metal site are analysed. The emphasis is placed onto the formation of compounds with the metallasiloxane fragments and rearrangements of these fragments. Principles of the design of catalytic systems based on metallasiloxanes, in particular, containing low-coordinated metal sites, are generalised. The bibliography includes 174 references.

I. Introduction

Chemistry of metallasiloxanes (hereinafter, MS), *viz.*, compounds containing a >Si(R)OM fragment, where M is a metal atom, initially emerged as a subfield within chemistry of organosilicon compounds, but then gradually grew into an independent scientific direction. The vast majority of transformations of MS directly involves the SiOM fragment, and the structure of MS is largely governed by the coordination properties of the constituent metal.

Intensive investigations into individual metallasiloxanes started in the 1950s. The major results of these studies are summarised in a number of reviews and monographs.^{1–8} In parallel, oligomeric^{9–11} and polymeric MS containing metallasiloxane fragments in the main organosiloxane chain became a subject of numerous studies. Some of these compounds came into industrial-scale production within literally years of their first synthesis.¹²

The following directions in the chemistry of metallasiloxanes have proven most fruitful over the last 15 years:

— the development of novel methods for the creation of the metallasiloxane fragment, which has led to the discovery of new structural types of MS and extended the range of metal atoms that can be incorporated in the metallasiloxane fragment;

— investigations into highly specific chemical transformations of MS;

— the development of general concepts that describe the formation of the MS structure;

— the elaboration of concepts that rationalise the regularities of rearrangements of metallasiloxane fragments in the structure of MS;

— the application of MS as catalysts in various processes of organic synthesis.

II. Synthetic methods in the chemistry of metallasiloxanes

Methods used to create the metallasiloxane fragment are rather diverse. Some early methods have been modified and are used nowadays.

The reaction of organosilanols with reactive metals, such as alkali metals,¹³ zinc¹⁴ or aluminium,¹⁵ represents one of the historically first methods.

M = K, Na, Zn, Al; *n* is the metal oxidation state.

Presently, this method retains its preparative importance mainly for the synthesis of alkali metal organosilanolates.

The reaction of organosilanols with organometallic compounds is a less common method.^{16–18}

R = Me, Et, Ph; R' = Me, Et; M = Zn, Cd.

Typically, this reaction is accompanied by the liberation of the corresponding hydrocarbon. However, according to recent studies,¹⁹ in some cases hydrocarbon ligands at the metal atom undergo rearrangements (*e.g.*, fulvene converts into cyclopentadienyl giving rise to compound **1**).

Uspekhi Khimii 76 (9) 907–926 (2007); translated by Ya V Zubavichus

R = cyclo-C₆H₁₁; Cp* = η-C₅Me₅,

The heterofunctional condensation is the most common method for the synthesis of MS; this reaction can be accomplished in different ways to afford both individual and oligomeric MS (R, R' and R'' are organic substituents) (Scheme 1).

Scheme 1

X = H: Y = Hal, R'O; X = R': Y = Hal, AcO; X = Ac, Y = Hal.

Z = H, R.

Below we consider only those versions of the heterofunctional condensation that are widely applied in modern studies. A combination X = R'' and Y = Hal (see Scheme 1) is especially suitable for the synthesis of polymeric MS, since the low-molecular-mass condensation product (R''Hal) does not destroy the main chain of the product.²⁰

Organometallic derivatives with Y = OR' should be utilised provided the self-condensation of a silanol R₃SiOH is hindered, for instance:²¹

The heterofunctional condensation of silanols with metal halides (X = H and Y = Hal in Scheme 1) is useful in those cases where a silicon (or metal) atom bears a bulky branched substituent (e.g., isopropyl or *tert*-butyl group).²²

R = Prⁱ, Bu^t.

If the Sn atom bears isopropyl (but not *tert*-butyl) groups, cyclic organostannasiloxanes can undergo polymerisation.

Often, the reaction of organosilanedioles with metal halides results in only partial substitution of organosiloxy groups for the Cl⁻ ions.²³

Derivatives with one or two Cp groups at the metal atom can be obtained provided the Si atom in the starting organosilicon compound bears the Bu^t group; this reaction is impossible with Et or Ph substituents at the silicon atom.²⁴

M = Ti, Zr: Cp' = η-C₅H₄Me; M = Hf, Cp' = η-C₅H₅.

The presence of a bulky branched group at the silicon atom allows the use of organosilaneetriols in addition to diorganosilanedioles in these reactions, since their self-condensation is hindered.²⁵

$$R = 2,6\text{-Pr}_2\text{C}_6\text{H}_3\text{NSiMe}_3.$$

It must be noted that the synthesis of Nb- and Ta-containing MS (for instance, compounds **2a,b**) is accompanied by the formation of metal oxide fragments $M-O-M$,²⁶ which cannot be explained by the heterofunctional condensation mechanism. This fact suggests a rearrangement to occur during the synthesis (this is described in more detail in Section IV).

$$\mathbf{M} = \text{Nb } (\mathbf{a}), \text{Ta } (\mathbf{b}).$$

In some cases, the reaction is additionally complicated by a competing process, *viz.*, organosiloxy group substitution for the π -coordinated ligand.²⁶ Synthesis of compound **3** may serve as an example.

$$\text{Cp}' = \eta\text{-C}_5\text{Me}_4\text{Et}.$$

The strongest shielding effect among organic substituents studied is exerted by the fluorenyl group, which allows complete suppression of the self-condensation of the organosilane-triol upon its reaction with metal alkoxides. The heterofunctional condensation of fluorenyl-substituted organosilane-triols **4a–c**

$$\text{R}^1 = \text{H}; \text{R}^2 = \text{SiMe}_3 \text{ (a), Me (b); R}^1 = \text{Bu}^t, \text{R}^2 = \text{SiMe}_3 \text{ (c).}$$

with titanium alkoxides $\text{Ti}(\text{OR})_4$ yields cage titanasiloxanes **5**.^{27, 28}

Flu is a substituted fluorenyl; R = Et, Prⁱ.

Another relatively rare method for the synthesis of MS, *viz.*, the reaction of organosilanols with metal amides or imides can also be classified as the heterofunctional condensation.^{29–31}

Owing to the presence of bulky substituents at the silicon atom in compound **6**, a novel tricoordinate tungsten compound **7** was synthesised.³⁰

An analogous reaction of metal silylamides with organosilanols yields MS with the disilane bridges Si—Si; the tris(trimethylsilyl)silyl fragment (Me₃Si)₃Si acts as a bulky substituent in this case.^{32, 33}

M	<i>n</i>	L
Co	2	THF, DME, MeCN, PhCN, 2,2'-bipy, 4,4'-bipy, Ph ₃ P
Fe	2	2,2'-bipy, 4,4'-bipy
La	3	THF
Gd	3	THF, MeCN, 4,4'-bipy

The Si—Si bonds in these compounds are highly reactive. They are very sensitive to oxidation and are easily converted into the siloxane fragments Si—O—Si under the action of O₂ (Ref. 32); pyrolysis in the absence of O₂ results in the migration of an O atom, which is accompanied by a rearrangement and formation of the bond Si—M.^{34, 35}

The reaction of alkali metal organosilanolates with polyvalent metal halides (M') is yet another popular version of the heterofunctional condensation; it is commonly referred to as the exchange reaction in the literature.

This reaction is most versatile. It was successfully used to synthesise MS containing Mg, Zn, Al, Ga, Ti, Zr, Fe, Co, Ni, Cu and some other metals,^{8, 11} which substantially extended the range of metal atoms incorporated in the metallasiloxane fragment.^{36–40} The use of bulky organic groups at the silicon atom played the key role in the development of the synthetic potential of this method.

of the metal from the reaction medium in the form of hydroxide. Therefore, for alkali-assisted cleavage of the polysiloxane, definite amount of sodium (not shown in the reaction scheme below), which reacts with the silanol groups, has been added to the reaction medium in addition to alkali to maximally suppress the potential self-condensation of the silanol groups.

Two versions of this reaction have been studied,^{44–49} viz., partial (*a*) and complete (*b*) substitution of the polyvalent metal atoms M' for the silanolate groups SiOM .

For *a*, *b* see text; *n* is the oxidation state of M' ; Vin is vinyl.

The majority of compounds synthesised according to the above scheme irrespective of partial or complete substitution of the silanolate groups have prism-shaped structures (sometimes, skewed prisms) with the cyclosiloxane fragments at the base (compounds **10–14**) (in the structure of compound **11**, the O' atoms belong to coordinated water molecules).

$M = \text{Co (a)}, \text{Mn (b)}, \text{Ni (c)};$

$L = \text{Bu}^n\text{OH}, \text{EtOH}, \text{H}_2\text{O}, \text{Me}_2\text{CO}, \text{CHCl}_3.$

$L = \text{Bu}^n\text{OH}, \text{H}_2\text{O}, \text{Me}_2\text{CO}.$

The cyclic fragments at the base of the prism are expanded from six- to eight-membered rings when lanthanides are introduced into MS^{50–53} (compounds **15**).

$M = \text{Nd}, \text{Gd}, \text{Dy}; L = \text{EtOH}, \text{H}_2\text{O}.$

In some rather rare cases of Cu-containing MS **16a–c** also incorporating alkali metal cations, the cage is characterised by a globular shape.^{54, 55}

Compound 16	M	R	n
a	Na	Et	4
b	Na	Ph	8
c	K	Vin	4

It was possible to convert the prismatic structure into the globular type cage upon prolonged heating of the compound in an organic solvent (butanol or dioxane).⁵⁶

In those case where MS simultaneously contain transition (polyvalent) and alkali metals (in unsubstituted silanolate groups), other transition metals can substitute the alkali metal ions. Here, partial structural transformation of the metal–oxygen part of the cage occurs to yield bimetallic MS **17**, which are also characterised by prismatic structures.^{57–59}

M = Co, Cu, FeOH, FeOMe; L = H₂O, DMSO.

The reaction of Cu-, Co-, Ni- and Mn-containing prismatic MS with acetylacetonate gives rise to a partial removal of the

metal ions from the cage in the form of the respective acetylacetonates.⁶⁰

Substitution of the copper ion for an alkali metal ion in the outer sphere of the globular MS **16c** results in the incorporation of an unusual cation MCl^+ (Ref. 61).

Spirocyclic fragments assembled from the units $\text{M}–\text{O}–\text{M}$ linked to siloxane rings are common to both types of structures (*i.e.*, prismatic and globular). The synthesis of this novel class of the cage MS stimulated chemists to try to rationalise the mechanism of their formation. A suggested general scheme of the formation of such structures postulated the presence of alkali metal silanates in the form of associated silanone derivatives in the reaction medium. These associates rearrange to yield building blocks of the prismatic cages considered above.⁶²

The formation of MS containing unsubstituted organo-silanolate groups can be described in a similar way.

The above method for the synthesis of cage MS has several disadvantages. Thus the yields of target products are low due to the presence of free OH groups in the starting organosiloxane (despite the use of metallic sodium as described above). In addition, no cage MS with small organic substituents at the silicon atoms (*e.g.*, methyl) can be synthesised by this method, since the respective starting siloxanes are insoluble.

The idea of modification of the method for the synthesis of polyhedral MS has been inspired by the above scheme of the cage 'assembly'. It was the first step of the process, *viz.*, the generation of silanolates that has been modified. It was suggested to assemble a cage structure from monomeric units rather than cleave the organosiloxane into separate fragments under the action of a base. The polyvalent metal atoms were thought to act as nuclei that would arrange components of the future polyhedron. Trialkoxyorganosilanes were selected as a source of the monomeric units.^{63–67}

R = Me, Et, Vin, Ph, (CH₂)₃NH₂; R' = Me, Et, Buⁿ;
M = K, Na; M' = Mn, Ni.

The new version provided higher yields in the syntheses of all the above cage structures, this also enabled the synthesis of cage Na,Cu-vinyl-, K,Cu-phenyl- and Na,Cu-methylsiloxanes inaccessible earlier.^{68, 69}

The mechanism of the cage formation considered above was somewhat changed, as applied to trialkoxyorganosilanes. The modified mechanism assumed the generation of metallasiloxane associates **A** followed by the condensation of functional groups at the silicon atom giving rise to spirocyclic fragments around the metal atoms.⁶⁷

R = Me, Vin, Ph; M = K, Na; L = ROH, H₂O.

It must be noted that such a mechanism is equally applicable to the formation of cage MS according to the previous method (*i.e.*, without alkoxyorganosilanes) and seems more preferable, since it does not presume the formation of extremely unstable silanones as intermediates.

The idea of exploiting different reactivities of the fragments Si–O–Si and Si–O–M in polyhedral MS proved to be the most fruitful: the fragment Si–O–Si is sensitive to the action of nucleophilic agents, whereas the fragment Si–O–M is rather susceptible to electrophiles. The reaction of cage MS with Me₃SiCl results in the cleavage of the fragments Si–O–M to yield macrocyclic organosiloxanes, in which the configuration of the starting MS is preserved.^{64, 70, 71} Globular structures are transformed into 12-membered rings with the *cis*–*trans* configuration (*e.g.*, compound **18**; bonds forming a closed macrocycle are shown as thick lines), whereas prismatic structures are transformed into six-membered siloxane rings in the *cis* configuration. The reaction with a mineral acid (H₂S or dilute HCl with cooling) instead of Me₃SiCl yields Si-function-alised stereoregular hydroxycyclosiloxanes **19**.^{66, 72}

(a) is Me₃SiCl (–MCl); (b) is HCl or H₂S (–MCl or M₂S);
X = SiMe₃, H; M = Ni, Mn.

Metal sulfides, which are by-products of the reaction, form nanocomposite aggregates dispersed in the siloxane matrix, which is promising for the design of new materials. Furthermore, the highly reactive hydroxycyclosiloxanes can be regarded as active precursors of structurally organised systems.

Stereoregular organosiloxane rings with smaller sizes, *e.g.* [PhSi(OSiMe₃)O]₄, have been synthesised⁶⁵ in a similar way by the reaction of cyclic organosilanolate [PhSi(ONa)O]₄ with Me₃SiCl.

Presently, it is the only method that makes it possible to synthesise stereoregular cyclosiloxanes with variable sizes. Moreover, it provides wide capabilities for further syntheses. In particular, if the organotrichlorosilane bears functional groups in the organic substituents at the silicon atom, the reaction yields stereoregular cyclosiloxanes, such as (PhSiO)₁₂[OSiMe₂CH₂OCH₂O₂CMe]₁₂, which can be incorporated in polymeric siloxane chains.^{73, 74}

In addition to the methods for the creation of fragments Si–O–M considered above, yet another method is of particular interest. It is based on the cleavage of siloxane chains under the action of metal compounds. For the first time, this reaction has been carried out⁷⁵ with metal halides.

Later, it has been shown^{76–80} that some metal halides as well as alkyl derivatives are capable of cleaving the siloxane bonds in organosiloxane rings.

M = Al, Ga; X = Hal, Alk.

The introduction of tin atoms into MS inverts the roles played by the silicon and tin atoms, *viz.*, the metallasiloxane ring is opened under the action of silicon halides.²²

In the modifications considered above, this reaction is of limited use. However, it became widespread after the discovery of the fact that organometallic compounds can cleave polymeric organosiloxanes. Now that this fact has been reliably established it comes as no surprise. But for a long time, the very idea of a reaction of an organometallic compound with a polymeric organosiloxane seemed a nonsense. An occasional observation gave an impetus to the reconsideration of this issue: MS derivatives were detected upon storage of certain organometallic compounds in a contact with an organosilicon grease (which is often used for a ground joint sealing). In particular, a mixture of Me_2GaCl and Bu^tAsLi_2 in a contact with polydimethylsiloxane $(Me_2SiO)_n$ readily affords polynuclear lithium complex **20** containing neither Ga nor As in a yield of 48%.⁸¹

L = THF.

Similarly, a prolonged storage of a solution of $LiPEt_2$ in diethyl ether at 20 °C in a contact with a silicone polymer gave rise to the formation of Li-containing MS **21** with the hexagonal prismatic structure.⁸²

In the modern version of this method, a diorganosiloxane polymer rather than an individual compound [such as $Me_3SiO \cdot SiMe_3$ or $(Me_2SiO)_4$] is used as the organosilicon component. This allows the introduction (under mild conditions) of the groups Me_2SiO , which are involved in the construction of metallasiloxane cages and can be incorporated as mono-, di- or trisiloxane units. In addition to the metal halides,⁸³ organic derivatives of the main group^{84,85} and transition^{86,87} metals as well as lanthanides^{88,89} can be used as the metal-containing component in this reaction. The structural features of the resultant MS (*e.g.*, **22** and **23**) are considered in detail in the next section.

M = Yb, Tb, Dy, Ho; HPzMe₂ is 3,5-dimethylpyrazole.

We note that in some cases, the reactions of an organometallic compound with a polyorganosiloxane and the respective individual cyclosiloxane yield identical products.⁹⁰

This method is versatile and can be used for the synthesis of alkali metal-containing MS. For instance, the reactions of disiloxanes with organometallic compounds (alkali metal derivatives) (also in the presence of alkoxides) yield mixed silanolates – alkoxides with variable composition.⁹¹

Yet another method for the synthesis of MS consists of the exchange of polyvalent metal ions. Typically, the reaction results in a change in the molecular structure.²¹

This recently discovered transformation stimulated the development of concepts underlying the structure formation in MS (this subject is addressed in more detail in subsequent sections).

Zavin and co-workers^{92, 93} reported a non-traditional method for the formation of metallasiloxane fragments based on the reaction of organochlorosilanes with zinc oxide.

The resultant MS are intermediates in the synthesis of polysiloxanes. Two mechanisms of the transformation were considered.

1. The formation of polymeric zincasiloxane involving bridging coordination bonds:

2. The formation of an intermediate zinc complex with the organosilanone followed by its decomposition:

According to quantum chemical calculations, the former mechanism is more probable from the thermodynamical point of view. This reaction allows the formation of siloxane fragments in a non-hydrolytic way. In particular, completely soluble polymethylsilsesquioxane ($\text{MeSiO}_{1.5}$)_n with a molecular mass as large as ~25 000 has been successfully obtained

from MeSiCl_3 , which was nearly impossible with other methods.

Concluding the section devoted to synthetic methods of MS chemistry we note that the possibility of MS synthesis under conditions of the mechanochemical activation has been demonstrated quite recently; this makes it possible to accomplish a solvent-free process. The reaction of copper acetylacetonate with diphenylsilanediol can serve as an example.⁹⁴

III. The structure of metallasiloxanes

The methods for the synthesis and transformations of MS considered in the previous section are difficult to systematise. On the contrary, the classification of structures of individual MS is rather straightforward. Most conveniently, all the MS synthesised can be divided into three large groups according to the type of the constituent organosilicon fragment:

Similar structures within this classification would fall into the same group. Meanwhile, the general principles of the formation of the coordination sphere of the metal atom remain common for all these groups.

In the vast majority of cases, the coordination sphere of the metal atom is filled by bridging oxygen atoms from the neighbouring fragments $\text{Si}-\text{O}-\text{M}$. The formation of coordination dimers is typical of MS containing monofunctionalised fragments R_3SiO (compounds **24–26**). Similar structures occur for a variety of main group and transition metals,^{21, 29, 95–98} including Ru, Rh and Pd.^{99–104}

In a few cases, coordination tetramers (e.g., compound **27**)^{16, 105} or hexamers (compound **21**) are formed.

L = Me: M = Cd, Zn; L = PPh_3 , M = Cu.

In addition to the oxygen atoms from the $\text{Si}-\text{O}-\text{M}$ groups, highly basic O atoms from the $\text{M}-\text{O}-\text{M}$ groups can be involved in the coordination sphere of the metal atoms [as, for instance, in Nb (**23**) and Pb organosiloxanes (**28**)]¹⁰⁶ as well as anions, usually halides (as in compounds **2** and **3**).

In MS bearing flexible difunctionalised organosilicon fragments $\text{SiR}_2\text{--O--SiR}_2$, the filling of the metal coordination sphere requires the respective change in the molecular conformation. The major driving force of the change, *viz.*, the coordination unsaturation of the metal atom, sometimes makes molecules fold in intricate way. The coordination sphere of the metal atoms involves O atoms of the Si--O--M groups. This can be seen in metallasiloxanes containing aluminium or gallium (compounds **29a–c**),^{76–80} alkali-earth metals (compounds **30a–c**)^{107, 108} or silver (compound **31**).⁸⁷

M = Al: X = Cl (**a**), Br (**b**); M = Ga, X = Cl (**c**).

M = Ca (**a**), Sr (**b**), Ba (**c**); L = Py, tetraglyme.

Trifunctionalised fragments $\text{RSiO}_{1.5}$ give rise to MS with totally different structures, although the basic principle of the metal coordination sphere formation, *viz.*, the involvement of

the O atoms from the fragments Si--O--M and M--O--M and sometimes stabilising Hal^- anions, is preserved. This can be seen in cage structures **12–14**.

It is noteworthy that there are only a few types of the coordination polyhedra of the metal atom; in the majority of cases, the polyhedron is close to either tetrahedron [the coordination number (CN) is 4] or tetragonal bipyramid (CN = 6).

Among ligands that fill the coordination sphere of the metal atom in MS, one ligand takes a special place. This is the silanolate anion, SiO^- . This appears in the structures of MS containing a polyvalent metal and the silanolate groups Si--O--M , where M is an alkali metal. As a result, mixed-metal MS involving metal atoms of different nature (*i.e.*, polyvalent and alkali metals) are formed, the alkali metal atoms being not incorporated in the cage. The existence of anions in these systems was confirmed by electrochemical techniques.¹⁰⁹ The majority of individual crystalline MS obtained so far fall into this type of compounds. They are obtained in high yields (> 90% in some cases)⁶³ and are rather stable and do not change composition upon subsequent recrystallisations. Different structures involving the silanolate anion have been synthesised with a variety of metal atoms. For instance, a series of compounds **32** with Mg,¹¹⁰ Cr,¹¹¹ Co,¹¹² Cu,¹¹³ Gd,¹¹⁴ V,¹¹⁵ and Sn,¹¹⁶ which are characterised by a structure similar to the tetracyclic Al- and Ga-containing MS (*e.g.*, structures **29a–c**), have been synthesised.

M = Mg, Cr, Co, Cu, Gd, V, Sn; R = Me, Ph; L, L' = Py, THF.

Similarly, transition metals, such as Ti,¹¹⁷ Zr,¹¹⁸ Hf¹¹⁹ and Ta¹¹⁶ (compounds **33**), have been successfully incorporated into octahedral MS structures closely related to the Ca, Sr and Ba organosiloxanes (compounds **30a–c**) owing to the silanolate anions.

M = Ti, Zr, Hf, Ta; M' = Na, Li.

MS based on trifunctional fragments $\text{RSiO}_{1.5}$ and containing the silanolate anions are equally numerous. Prismatic Cu, K (**8**), Mn, Co and Cu organosiloxanes (**12a–c**) as well as cubane-like Al¹²⁰ and Ga(In) organosiloxanes¹²¹ (compounds **34**) can be given as examples.

M = Al, Ga, In; M' = Li, Na; R = 2,6-Prⁱ₂C₆H₃NSiMe₃; R' = Me, Et.

Some cage molecules with the silanolate anions specific to this group of compounds have been synthesised, for instance, basket-like Co organosiloxane **35**⁴⁸ and globular structures **16a–c**.

The coordination ability of the silanolate anion is so high that it can replace other ligands in the coordination sphere of the metal atom, in particular, n-donor ligands¹⁰⁵ and the O atoms of the fragments Si–O–M, which are typical ligands for MS.^{97, 122}

M = Al, Fe, Au.

It is worth noting that the O atoms of the fragments Si–O–M can replace n-donor ligands in the coordination sphere of the metal atom both in individual¹⁰² and oligomeric MS.¹²³

R = Ph, Bu^t; M = Co, Ni; n = 3, 4; k ≠ n;

R = Ph, Bu^t; n = 3, 4; k ≠ n.

Therefore, the coordination environment of the metal atom becomes most stable with the introduction of the silanolate anions. For some transition metals (Cr, Co, Cu, V, Ti, Zr and Hf), only MS containing the silanolate anions have been synthesised so far.

Several general regularities not mentioned above that are somewhat hidden by the multitude of structural types of siloxanes can be revealed. First, oxygen atoms located between two silicon atoms, *i.e.*, in the siloxane units Si–O–Si, virtually never enter into the coordination sphere of the metal atom. This can clearly be seen in the structures **20**, **29** and **30**. In sodium diphenylsilanolate **36**, the O atoms of the disiloxane fragments are also located outside the coordination cluster.¹²⁴

A similar situation is observed in the structure of tallasiloxane **22** where metal oxide cubic fragments are linked together into a chain with disiloxane bridges.

This regularity is also strictly obeyed in prismatic structures built up of trifunctionalised fragments RSiO_{1.5} (*e.g.*, compounds **12–14**). This behaviour of the siloxane fragments in MS is due to the ultimately low basicity of the O atom in the unit Si–O–Si. This fact is nearly completely ignored in the literature devoted to MS but it is actually of no surprise. Independently of MS studies, this property of the siloxane bonds has been established for organosiloxanes.¹²⁵ Diorganocyclosiloxanes (Me₂SiO)_n (n = 6–8) cannot be used as crown ethers for the same reason.¹²⁶

Nevertheless, there are examples of structures violating this rule: in complex **37**, the K⁺ cation is coordinated to a seven-membered organosiloxane ring,¹²⁷ in complexes **38** and **39**, the cations Li⁺ are coordinated to five- and six-membered organosiloxane rings, respectively.¹²⁸

These results however should not be interpreted as a manifestation of increased basicity of the O atoms of the fragments Si—O—Si, especially taking into account that the cations are located not exactly in the plane of the ring but rather above it.

Another structural feature of MS nearly completely missed by researchers consists of the formation of metal oxide fragments M—O—M in some cases (*e.g.*, compounds **2**, **3**, **4**, **13**, **23** and **28**). This concerns units linked by σ -bonds rather than coordination interactions. The appearance of such fragments cannot be explained by the schemes of synthesis of these MS and is due to the secondary process, *viz.*, the rearrangement of metallasiloxane chains. It has to be emphasised that no formation of the fragments M—O—M occurs in structures containing the silanolate anions.

IV. Rearrangements of metallasiloxanes

The structural diversity of synthesised MS raised questions on basic principles of their structure formation. The influence exerted by the nature of organic and alkoxy groups at the silicon atom in trialkoxysilanes $\text{RSi}(\text{OR}')_3$ as well as by conditions of synthesis on the selective formation of a certain type of cage (prismatic *vs.* globular) in the synthesis of individual Na,Cu and K,Cu organosiloxanes has been thoroughly studied.⁵⁷

Wide potential of the synthesis of some inaccessible MS provided by the use of bulky R_3SiO groups is now adopted as a specific concept, which considers these groups as an alternative to the cyclopentadienyl ligand due to their rather similar sizes and electron donor properties.¹²⁹

In the majority of studies, the emphasis is placed onto regularities of the synthesis and structural features of the target MS, whereas possible side reactions and post-synthetic transformations of MS have eluded the appropriate consideration for a long time. Nevertheless, from experimental evidence gathered, it gradually became apparent that the as-synthesised compounds partly or sometimes completely rearrange into other compounds with increased or decreased metal content (with respect to the parent compound). Some syntheses ultimately afforded metal-free or silicon-free compounds. Such rearrangements are often accompanied by the formation of metal oxide M—O—M chains (in the reaction equations below, reaction products enriched with silicon are indicated first and those enriched with metal are indicated second).

M = Zn, Hg;

M = Ni, Co;

As has been established upon the extension of the range of compounds under study, similar transformations also occur with oligomeric MS.^{139–144}

In the majority of cases considered in the previous section, the rearrangements are suppressed (typically, due to the presence of stabilising anions). In the absence of suppressing factors, the rearrangements of oligomeric MS can be detected using fractionation. The fractions isolated differ in the metal content, *i.e.*, the M : Si atomic ratio, which gradually decreases from the first fractions to successive ones, rather than in the molecular mass, which is typical of the majority of polymers (Table 1).

In the case of individual MS, the influence of the metal nature (transition *vs.* main group metal) is somewhat masked except for the fact that the synthesis of MS with several transition metals (*viz.*, Cr, Co, Cu, V, Ti, Zr and Hf) was possible only in the presence of the silanolate ions. Meanwhile,

Table 1. Rearrangement products of oligomeric metallasiloxanes.

^a Al : Si; ^b Cu : Si.

this is not required for main group metals. It can be assumed that the syntheses of MS with the transition metals listed above in the absence of the silanolate anions were accompanied by rearrangements to yield products that were of low importance for synthetic chemists. Thus, these results were not reported and the rearrangements eluded the discussion.

In contrast, in the case of oligomeric MS, the influence of the metal nature is more prominent: the rearrangements are manifested more clearly with transition metals. According to the current concepts,^{142, 143} the rearrangements are driven by coordination unsaturation of the metal atoms in siloxane structures. In oligomeric MS, there are three inequivalent types of the oxygen atoms, *viz.*, those present in siloxane, metallasiloxane and metal oxide units:

As has been noted above, the oxygen atoms of the siloxane fragments cannot be involved into the coordination sphere of the metal atom due to their ultimately low basicity. On the contrary, the O atoms of the metallasiloxane (Si—O—M) and metal oxide (M—O—M) units are sufficiently basic and thus readily occupy the coordination sphere of the metal atom.

Thus the driving force of rearrangements consists of the formation of compounds with increased amount of such fragments. They proceed *via* intermediate complexes and further give rise to metal oxide fragments,¹⁴² which cannot be explained by the mechanism of the MS synthesis.

Under certain conditions (primarily, with an appropriate solvent), one of the rearrangement products (either the one enriched with metal or that enriched with silicon) is eliminated from the reaction medium due to its lower solubility. In such cases, the rearrangement can be observed even without fractionation. Two different processes are possible, depending on the composition of the reaction medium, *viz.*, precipitation of poorly soluble crystalline metal-free organosilsesquioxanes (RSiO_{1.5})_n (*e.g.*, compounds **40** and **41**)^{141, 145}

or, alternatively, of poorly soluble fractions enriched with metal. Sometimes, the process results in complete removal of metal in the form of the respective oxide from siloxane chains:¹⁴⁶

In order to gain a deeper insight into the rearrangement of MS, the kinetics of this process was studied using UV spectroscopy. Co-containing oligophenylsiloxanes were selected as the subjects of this study.¹⁴⁷ It was found that the rearrangement obeys the first-order law with a mean apparent reaction rate constant $k_{\text{app}} = (4.5 \pm 0.5) \times 10^{-6} \text{ s}^{-1}$. The first order of the reaction implies that the total rate of the rearrangement is limited by the decomposition of the intermediate complex to yield compounds with increased metal content with respect to the original MS.

According to studies of the MS rearrangement as a function of the number of identical organic groups at the silicon atom,¹⁴⁸ branched structures containing fragments RSiO_{1.5} suppress the rearrangement to a larger extent than linear structures with the fragments R₂SiO. This observation pointed to a possible means to suppress the rearrangement, *viz.*, an increase in the steric hindrance of the molecule with the introduction of sildioxane fragments SiO₂ (Ref. 149).

It has been established¹⁴⁹ that the introduction of sildioxane fragments into oligomeric MS impedes the formation of an intermediate complex, which appears in the course of the rearrangement.

Alternatively, the rearrangement can be suppressed by using bulky aliphatic groups at the silicon atom, which sterically hinder the interchain coordination of MS.¹⁵⁰

R = n-C₉H₁₉, Bu^t.

Conditions accelerating the rearrangement have also been found. It has been established that the presence of a catalytic amount of metal halides promotes rapid rearrangement towards compounds enriched with metal.¹⁴⁹ Presumably, the rearrangement proceeds *via* a six-membered ring intermediate, which is most typical of organosiloxane compounds.

M = Cu, Co; M' = Co, Fe.

The reaction (1) discussed in Section II, in which the Ti atom substitutes the Mg atom in the MS structure, indicates that magnesium can act as an alkali metal as regards the exchange reaction. The electronegativity of Mg (1.2) is close to the respective values for alkali metals (0.91–0.97), which naturally leads to a conclusion that the Mg ion is capable of generating the stabilising silanolate anions in the MS structure. A bimetallic Cu,Ca organosiloxane **42** has been synthesised to verify this suggestion.¹⁵¹ The choice of the alkaline-earth metal was dictated by the fact that calcium, in terms of electronegativity (1.04), is rather more similar to alkali metals and thus a prominent stabilising effect could be expected. Another bimetallic Cu,Cd organosiloxane **43** has been synthesised for comparison¹⁵¹ (for both structures, coordinated solvent molecules are omitted for clarity).

42

43

A comparison of the two structures, **42** and **43**, indicates that the silanolate anions introduced into the structure together with two calcium ions are accommodated in the coordination spheres of four Cu ions. Meanwhile, the cadmium ions, which are characterised by a substantially higher

electronegativity (1.46) as compared to calcium, cannot bring the silanolate ions into the structure. As a result, a stable crystalline structure can be formed only with the assistance of additional coordinated anions (Br^- in the present case).

V. Metallasiloxanes in catalysis

Alkali metal organosilanolates are traditional catalysts of the anionic polymerisation of organocyclosiloxanes aimed at the production of linear organosiloxane polymers.⁸ More recently, it was found that the use of mixed silanolates–alkoxides $\text{K}_4\text{Li}_4(\text{OSiMe}_3)_{6-8}(\text{OBu}^t)_{1-2}$ allows the synthesis of high-molecular-mass organosiloxanes with a low polydispersity.⁹¹

In the majority of cases, the catalytic properties of MS are caused by the nature of the metal atom, which acts as the catalytically active site. As a rule, the siloxy groups play only a secondary role forming a specific environment of the catalytic site. Nevertheless, the involvement of the siloxane matrix becomes decisive in certain cases.

A series of studies have been devoted to the catalytic activity of MS towards the alkene conversion. Catalysts mimicking the Ziegler–Natta catalysts have been developed. In these systems, a transition metal complex is combined with AlR_3 . In particular, it has been demonstrated^{111, 115} that spirocyclic V(IV) and Cr(II) organosiloxanes (compounds **44** and **45**, respectively) combined with AlMe_3 efficiently catalyse the ethylene and propylene polymerisation.

L, L' = Py, THF.

According to an original idea,¹⁵² organosiloxane cage can be used as a support for catalytic sites instead of traditional inorganic silicate matrix. For instance, polyhedral Cr(VI) organosiloxane **46** possesses¹⁵³ as high activity as the classical Philips catalyst (Cr/SiO_2).

R = cyclo- C_6H_{11} .

Modern investigations into the MS-based catalysts of the alkene conversion are dominantly focused on the utilisation of low-coordinate complexes. Several metal triorganosiloxy derivatives (in particular, a tricoordinate tungsten complex **7**) are promising catalysts for the alkene and alkyne activation:

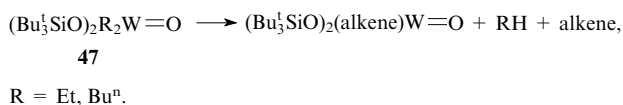

Diorganosiloxyhydridotitanium (promoted with trimethylphosphine) forms an intermediate with ethylene¹⁵⁴ and thus catalyses its conversion into but-1-ene and higher ethylene oligomers.

In specific cases, an alkene is generated upon the conversion of a metal (alkyl)siloxy derivative: for instance, thermolysis of tungsten compound **47** yields alkenes upon β -elimination of the alkyl groups in parallel to alkene complexes.⁴⁰

The advantage of bulky triorganosiloxy substituents at the metal atom is manifested most prominently in studies of catalytic properties of Nb and Ta organosiloxanes. It has to be emphasised that it is with these two metals that Richard Shrock (the 2005 Nobel Prize winner in chemistry) started his search for metathesis catalysts by introducing the *tert*-butoxy groups into the coordination environment of the metal sites in order to impart stability to metallacarbenes generated from them. According to more recent studies,¹⁵⁵ this purpose can alternatively be achieved with *tert*-butylsiloxy groups and it is even more efficient since a larger number of bulky organic groups can be attached to the catalytic site in this case. It has been established¹⁵⁵ that niobium and tantalum triorganosiloxy derivatives add alkenes with the generation of the respective metallacarbenes that catalyse the metathesis reaction.

$\text{M} = \text{Nb}; \text{R} = \text{H, Me, Et, Bu}^t, \text{Ph, 4-MeOC}_6\text{H}_4;$

$\text{M} = \text{Ta}; \text{R} = \text{H, Me, Et, Ph, 4-MeOC}_6\text{H}_4, 4\text{-CF}_3\text{C}_6\text{H}_4.$

$\text{M} = \text{Nb, Ta};$.

Triorganosiloxy-substituted tantalum hydrides represent another type of catalysts. They efficiently bind CO, which

makes them promising catalysts of the Fischer–Tropsch reaction.^{156–159}

Polyhedral Ti^{III} and Ti^{IV} silsesquioxanes, which are characterised by closed (compound **48**) or partly closed (compound **1**) structures,^{160, 161} are used as either homogeneous or heterogeneous alkene epoxidation catalysts.

$\text{R} = \text{cyclo-C}_6\text{H}_{11}.$

Triorganosiloxy derivatives of platinum metals traditionally find wide applications determined by the nature of the metal. The organosiloxy groups increase the stability of these catalysts in the repeated use. Rhodium triorganosiloxy derivative $[\text{Ph}_3\text{SiORh}(\text{CO})_2]_2$ performs as a highly efficient hydroformylation catalyst.¹⁰⁰

Complexes $\text{RMSiPh}_3 \cdot 2\text{L}$ ($\text{M} = \text{Pt or Pd}; \text{R} = \text{Me, Et or Ph}; \text{L}$ is cycloocta-1,5-diene) provide a higher catalytic activity towards the CO hydrogenation than compounds $\text{R}_2\text{M} \cdot 2\text{L}$ or supported catalysts $\text{H}_2\text{PtCl}_6/\text{SiO}_2$ (Ref. 162).

The formation of fragments $\text{Si}-\text{O}-\text{Pd}$ in intermediates is postulated¹⁶³ for the Pd-catalysed cross-coupling processes involving organosilicon reactants.

Oligomeric MS are also applicable in catalysis. It has to be noted that their use as a binder for supported catalysts shows little promise due to the fact that they form most often polymeric systems with a relatively low molecular mass (2000–5000), which are characterised by a low mechanical strength. Nevertheless, studies of their catalytic properties gave rise to interesting and sometimes surprising results.

These compounds were primarily tested in processes of petrochemical synthesis due to their close analogy to inorganic silicates. It has been found that oligomeric MS gradually lose organic substituents being converted into inorganic silicates upon the high-temperature polycondensation, although structural features of the starting MS are preserved. These compounds successfully compete with inorganic silicates with similar compositions, but they possess higher catalytic activities and selectivities in a number of processes, including cracking, halogenation, dehydration, alkylation, *etc.*¹¹

More recently, oligomeric MS found application as catalysts for other reactions where metal silicates were inactive. These include, for instance, the stereoselective oxidation of

hydrocarbons (e.g., 1,4-dimethylcyclohexane) in the presence of oligophenylferrasiloxane.^{164, 165}

Probably, the most important catalytic application of oligomeric MS relates to the halohydrocarbon conversion. A number of large-scale industrial processes are based on these reactions (e.g., the production of polyvinyl chloride, dichloroethane, chlorobenzene, chloroalkanes, etc.). Halohydrocarbons are poor ligands for the majority of metal complexes, which complicates the choice of a proper catalyst. This selection was however made on the basis of the following idea: the most efficient catalysis is expected in those cases where the chain-radical mechanism involving a variable-valence metal atom becomes possible. Transition metals incorporated in the structure of the organosiloxane matrix can change their oxidation state (this is the key step for the catalysis of this type of reactions) remaining within the siloxane cage. Of other advantages of the utilisation of oligomeric MS, their solubility in organic solvents enables their application as homogeneous catalysts. In the case of heterogeneous catalysts, they can be chemically grafted to widely adopted inorganic supports (SiO₂, Al₂O₃ and so on). Furthermore, diverse systems incorporating nearly any transition metals and their combinations in specified ratios are now available. Their properties can be additionally adjusted by varying parameters of the high-temperature condensation processes, which strongly affect surface characteristics of the target catalysts.

Oligomeric Cu, Co and Fe organosiloxanes have been tested¹⁶⁶ as catalysts of the isomerisation of non-symmetric 3,4-dichlorobut-1-ene into symmetric 1,4-dichlorobut-2-ene (it is the key step in the industrial production of chloroprene rubber). The Cu-containing MS manifested the highest activity, which confirmed the current concept assuming the partial reduction of the metal ions in the course of the catalytic reaction: the copper ions undergo the reduction most readily among the compounds studied. Still, the Co- and Fe-containing MS are also of interest, since they provide higher selectivity: no *cis*-1,4-dichlorobut-2-ene is formed in their presence. The major difference of the oligomeric MS from traditional catalysts (i.e., copper naphthenate or halides) consists of their prominent stability: even repeated use (6–10 cycles) does not lead to any significant decrease in activity, whereas traditional catalysts are nearly completely deactivated after the first cycle.

Oligomeric MS have been tested as catalysts in the exchange halogenation processes, which enable the production of halohydrocarbons avoiding the use of halogens as elementary substances.

R = Alk, Ar; Hal = Cl, Br.

In the case of chlorohydrocarbons, a more environmentally friendly industrial process can be implemented using this method. This is especially important for brominated derivatives, since the direct bromination with molecular bromine usually proceeds with difficulty and non-selectively; furthermore, syntheses of bromides are usually multi-step processes.

Detailed investigations^{148, 167, 168} into the exchange halogenation of hydrocarbons, including n-C₁₀H₂₂, n-C₁₂H₂₆, cyclo-C₆H₁₂, *p*-Me₂C₆H₄ and C₆H₅Me, with CCl₄ or CBr₄ (in the presence of a catalytic amount of oligomeric Cu phenylsiloxane) shed light on the mechanism of the process. The reaction follows the radical mechanism: the transfer of the

radical centre along the chain from the [•]CCl₃ radical to the hydrocarbon molecule is shown in the upper half of the scheme, whereas transformations of the catalytic site are shown in the lower half (according to classical view, the catalyst returns to the initial state after the catalytic cycle, which is indicated by the bent arrow). The activity of oligomeric Cu phenylsiloxane remains nearly constant over five catalytic cycles, whereas the standard catalyst CuCl₂·(DMF)_n is deactivated within one cycle.

The above exchange halogenation reaction yields a mixture of monohalogenated derivatives with different locations of the halogen atom. The addition of halohydrocarbons to alkenes proceeds more selectively, since the location of the double bond determines the sites of attachment of the Cl atom and CCl₃ fragment.

Oligomeric monophenyl and diphenyl Cu-containing organosiloxanes have been tested as catalysts in this reaction.¹⁶⁹ The process follows the radical mechanism detailed above. The only difference is that the formation of a radical site is facilitated due to the involvement of the alkene double bond. Structured monophenyl derivatives (i.e., molecules with cage fragments) bearing trifunctional fragments RSiO_{1.5} are characterised¹⁶⁹ by a poorer accessibility of the active site and thus lower catalytic activity with respect to diphenyl derivatives built up of linear fragments.

As has been shown by kinetic studies of the two aforementioned types of halogenation, a substantial fraction of potential catalytic sites is 'switched off' the catalytic process since they are involved into the formation of interchain coordination clusters. The metal atoms tend to complete their coordination spheres by coordinating oxygen atoms from the neighbouring fragments Si—O—M (as has been discussed in previous sections).

As a result, these metal atoms become coordinatively saturated and structurally inaccessible for the interaction with CCl₄. Therefore, the main task is to prevent the formation of the interchain metal oxide clusters. If a metal atom is screened by a ligand, this effectively suppresses the interchain coordination, but does not solve the main problem, since the additional ligand equally hinders the approach of the reactant. A rather easily realisable solution of the problem consists of¹⁵⁰ the use of nonyl instead of phenyl groups at the silicon atoms. According to UV spectroscopy, the Cu ion in the oligononylsiloxane remains coordinatively unsaturated.

Thus, the bulky aliphatic group efficiently suppresses the coordinative interactions between the copper atoms of neighbouring chains by screening the metal sites. In solutions, it

Figure 1. The structure of fragments $(-O)_2RSi-O-Cu-O-SiR(O-)_2$; $R = Ph$ (a), $n-C_9H_{19}$ (b). Contour lines schematically indicate van der Waals surfaces around the molecules.

possesses the mobility of a polymer segment and does not prevent the approach of the organic reactant (CCl_4) to the catalytic site (Fig. 1).

The implementation of this idea gives quite impressive results:¹⁷⁰ the activity of nonyl-containing polymeric Cu MS with respect to the addition of CCl_4 to oct-1-ene is twice larger than that of phenylcuprasiloxanes.

VI. Conclusion

The experimental data considered above clearly demonstrate that metallasiloxanes are very interesting from both theoretical and practical points of view. This explains the multitude of studies devoted to their synthesis and consequent diversity of synthetic approaches to the formation of the fragment $Si-O-M$. The method based on the cleavage of the siloxane bonds with organometallic compounds has been developed to the large extent. The utilisation of bulky aliphatic groups as substituents at the silicon atom has proven its practical usefulness. Many niobium, tantalum, tungsten, *etc.* MS inaccessible earlier have been successfully synthesised, including low-coordinate complexes of these metals.

Metallasiloxanes themselves can be regarded as precursors in the synthesis of siloxanes that cannot be obtained by other methods. In particular, the cleavage of cage MS with electrophilic reagents yields stereoregular organocyclosiloxanes.

From the theoretical point of view, problems related to the structural features of MS are of particular importance, including the factors governing the formation of specific structural types of MS. As has been reliably established to date, the products of many reactions are actually formed due to rearrangements of the initially generated MS. These rearrangements give rise to compounds enriched with either metal or silicon (ultimately, the metal can be completely excluded from the siloxane matrix in the form of the respective oxide). A number of efficient methods for the suppression or *vice versa* facilitation of the rearrangements have been elaborated, depending on the specific goal of the synthesis. Structures stable against the rearrangements emerge in those cases where anions and, primarily, silanolate anions, are involved into the coordination sphere of the transition metal atom.

Spherical fullerene-like organosiloxane molecules can be assembled from cage MS, which can hardly be synthesised by other methods.^{171, 172} According to quantum chemical calculations,^{173, 174} nanotube-like assemblies are also possible for certain combinations of structural parameters.

Figure 2. The structure of metallasiloxane $Cu_{18}O_2(OSiMe_3)_{14}$ (Ref. 138).

Catenane MS should be anticipated in the nearest future. The first representative of this class has already been synthesised:³⁸ it is characterised by an unusual topology built up of two interpenetrating bicyclic fragments (Fig. 2, methyl groups at the Si atoms are omitted for clarity).

Practical applications of metallasiloxanes primarily relates to catalysis. As a rule, the catalytic properties are determined by the nature of the constituent transition metal. Low-coordinate metal (in particular, tungsten) complexes bearing bulky organic substituents at the silicon atom have been attracting much attention from researchers over the recent years.

Oligomeric MS has a huge potential as catalytic systems. Initially, they were considered exclusively as analogues of inorganic silicates for the petrochemical synthesis. But their prominent catalytic activities in other industrially important reactions, in particular, halohydrocarbon conversion and exchange halogenation, have been discovered recently. It has to be emphasised that the type of the siloxane matrix plays equally important role as the nature of the metal in the case of oligomeric MS, since it determines the accessibility of the catalytic site.

The present review is written with a partial financial support from the Grant Council at the President of Russian Federation (the Programme of Federal Support of Young Scientists with the PhD degree, Grant MK-126.2007.3) and Russian Foundation for Basic Research (Project Nos 06-03-32347 and 08-03-00026).

Kinetics of ‘blue’ flames in the gas-phase oxidation and combustion of hydrocarbons and their derivatives

V Ya Basevich, S M Frolov

Contents

I. Introduction	867
II. Cool and blue flames	867
III. Modelling of gas-phase oxidation of acetaldehyde and hydrocarbons C ₁ –C ₇	870
IV. Conclusion	883

Abstract. Experimental and calculated data on the kinetics of ‘blue’ flame observed in the gas-phase oxidation and combustion of hydrocarbons and their derivatives are considered. It is shown that blue flames arise due to the decomposition of hydrogen peroxide that forms in the oxidation of hydrocarbons. They manifest themselves by light emission, are identified by partial heat release (the appearance of a step in the time dependences of temperature and pressure observed in closed-vessel experiments) and propagate as conventional hot flames. The bibliography includes 43 references.

I. Introduction

Oxidation and combustion of hydrocarbons play an important role in chemical engineering, power production in thermal machines of various types and in environmental control. Being started quite long ago, their studies achieved considerable progress only in the second half of the 20th century. By that time, it was reliably stated that slow gas-phase oxidation of hydrocarbons represents a radical-chain reaction with degenerate branches. Kinetic studies of low-temperature oxidation of hydrocarbons have demonstrated its multistage nature. It is assumed that low-temperature oxidation and combustion of hydrocarbons involves the stages of cool, blue and hot flames. All these stages were observed experimentally. Thus cool flames were observed back in 1882 for the hydrocarbon oxidation in heated vessels.¹ Further studies of low-temperature oxidation of hydrocarbons demonstrated that this process represents partial oxidation to afford valuable oxygen-containing products such as alcohols, aldehydes, acids and peroxides. This explains the keen attention drawn to the cool-flame oxidation of hydrocarbons (*e.g.*, see monographs^{2–4} and references therein). However, whereas to date the mechanism of the appearance of cool flame can be considered as understood with a large degree of confidence, the mechanism of the emergence of blue flames is still largely unknown.

Blue flames manifest themselves by light emission and can be identified by a partial heat release (the appearance of a step in curves that describe the time dependences of pressure and temperature in closed-vessel experiments). They can propagate like conventional hot flames. Blue flames were observed in the gas-phase oxidation and combustion of methane, ethane, n-heptane, isooctane and benzene as well as of acetaldehyde and diethyl ether. Experimental and theoretical studies of blue flames observed in the low-temperature oxidation of hydrocarbons and their derivatives are closely associated with the studies of cool flames; hence, the latter will also be briefly considered in this review, especially as both cool and blue flames pertain to low-temperature flames and their separation is a difficult task.

II. Cool and blue flames

It is well known that low-temperature oxidation of hydrocarbons follows the radical-chain mechanism with degenerate branching, where the branching is due to either the decomposition of hydroperoxides formed in the reaction or the interaction of aldehydes formed with oxygen. The main steps of this reaction are as follows:

and *etc.*,

The appearance of cool flame in hydrocarbon oxidation is due to the glow of excited formaldehyde. Blue flame arises as a result of further conversion of hydrocarbons owing to the glow of both excited formaldehyde and formyl radicals. Cool flames are observed at both low and high pressures typical of internal combustion engines (ICE).

The majority of scientists who studied the low-temperature oxidation of hydrocarbons assumed that cool flame arises as a result of explosive decomposition of organic hydroperoxides after their concentration has exceeded a certain critical value (*e.g.*, see Ref. 5). (As a rule, the decomposition is caused by the temperature increase in the course of the reaction). Due to the degenerate branching of the reaction as a result of the hydroperoxide decomposition and also due to the appearance of active species $\cdot\text{OH}$, the process sharply accelerates, heat is released, the temperature and the pressure increase, which leads to the appearance of cool flame.

Figure 1 shows typical kinetic curves of pentane cool-flame oxidation that represent the changes in the overall pressure during the reaction as a result of branching.² Cool flame is identified as a small pressure peak in the $\Delta P(t)$ curve, particularly, at the lowest initial pressure $P_0 = 225$ mm Hg, cool flame appears with a delay $t_i = 120$ s. As the initial pressure increases, the cool-flame delay shortens and the intensity (the pressure peak height) increases. Ultimately, at a pressure $P_0 = 340$ mm Hg, the cool-flame step is followed by hot autoignition, which is accompanied by a strong increase in the pressure (marked by an arrow). This is the so-called two-stage autoignition.

If the cool flame has failed to be transformed into the hot flame so that the reaction mixture is cooled from the vessel walls and also if the initial concentrations of fuel and oxidant have changed insignificantly in the cool flame, the autoignition can be repeated. This is the mechanism of origination of multiple (periodic) cool flames.

Figure 2 shows kinetic curves of cool-flame oxidation of ethyl methyl ketone.⁶ As is seen, cool flames appear twice during the oxidation (1 cf and 2 cf). Figure 3 shows a cool flame region confined by the first cool flame region (light circles) on the one side and a region of hot autoignition (dark

Figure 1. Kinetic curves of cool-flame oxidation of pentane (mixture composition: $\text{n-C}_5\text{H}_{12} + 4\text{O}_2$) for initial temperature $T_0 = 591$ K. Initial pressure P_0 /mm Hg: (1) 225, (2) 250, (3) 280, (4) 320, (5) 330, (6) 340.

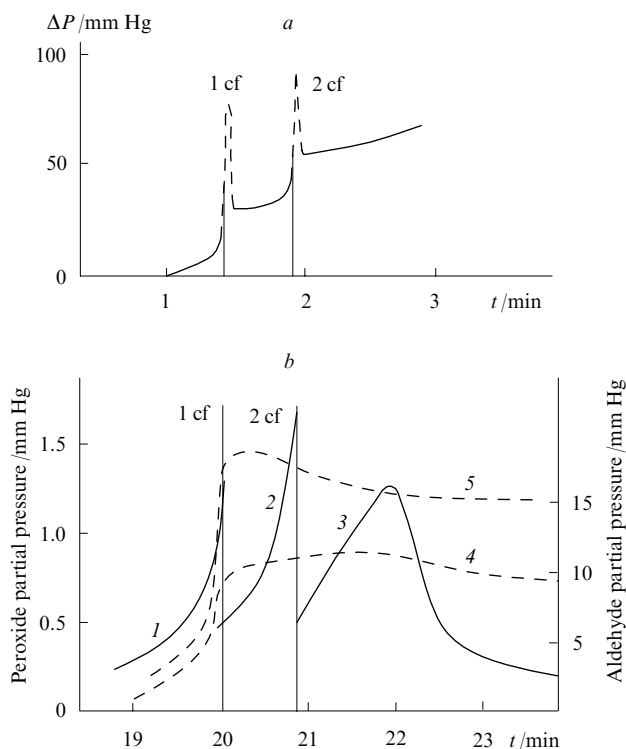

Figure 2. Kinetic curves of cool-flame oxidation of ethyl methyl ketone (mixture composition: $\text{CH}_3\text{COC}_2\text{H}_5 + \text{O}_2$).⁶

(a) Increase in the overall pressure (ΔP); (b) increase in partial pressures of peroxides (curves 1–3), formaldehyde (4) and higher aldehydes (5) in periodic cool flames.

Initial conditions: (a) $P_0 = 32$ kPa, $T_0 = 563$ K (in the presence of acetaldehyde $P_{\text{CH}_3\text{CHO}} = 0.27$ kPa); (b) $P_0 = 40$ kPa, $T_0 = 556$ K.

circles) on the other side in the coordinates 'initial temperature vs. initial pressure'.⁶

As the temperature increases, the formation of peroxides is hindered and, if the concentrations of initial hydrocarbon and oxygen have decreased significantly during the reaction, the oxidation process may be decelerated and even stop but may also continue (depending on conditions) by other reaction channels.

Figure 3. Region of periodic cool flames in equimolar methyl ethyl ketone mixtures with oxygen (numbers within the cool-flame region designate the number of flames).⁶

Figure 4. Logarithms of maximum oxidation rate w_{\max} (solid lines) and delay period τ_p (dash lines) for different temperatures.⁷ Mixture $\text{C}_2\text{H}_6 + 0.5\text{O}_2$; (1) $E = 30.0\text{--}33.6 \text{ kcal mol}^{-1}$, $P_0 = 67 \text{ kPa}$; (2) $E = 55.6 \text{ kcal mol}^{-1}$, $P_0 = 83 \text{ kPa}$.

Cold flames are associated with yet another peculiarity of the oxidation kinetics of hydrocarbons and their derivatives, *viz.*, the presence of a region of the negative temperature coefficient (NTC) in which the reaction rate decreases (or remains unchanged) rather than increases with the increase in temperature (Fig. 4).⁷ This phenomenon is associated with the fact that with the increase in temperature in the course of the reaction (or at an elevated initial temperature), the peroxide formation is hindered and the earlier formed peroxides easily decompose. In this case, the reaction branching that involves peroxides ceases to be dominant and the oxidation continues by other channels, which are not so efficient in the NTC region. As a result, in this temperature range, the rate turns out to be

lower at higher temperatures than at lower temperatures. Below, this phenomenon will be considered in more detail.

The first records of blue flames can be found in the studies by Townend *et al.* (*e.g.*, see Ref. 8 and a monograph² and references therein). They studied cool flames that arise at the ignition of fuel–air mixtures with a heated spiral and observed that the cool flame was followed by the appearance of a second brighter flame that propagated through the vessel. They named this phenomenon blue flame. Blue flames were accompanied by a higher (50–250 °C) warming up of the reaction mixture and brighter glow of excited formaldehyde as compared with cool flames.

Blue flames immediately precede the hot autoignition of hydrocarbons. It is assumed that in blue flame hydrocarbons undergo more extensive transformations as compared with cool flame. In addition to the glow of excited formaldehyde, which is inherent in cool flame, the glow at the wavelength of the formyl radical HC^*O is observed. Figure 5 shows experimental data obtained in the studies of autoignition of isooctane–air mixtures in closed vessels.³ In Fig. 5e, three pressure waves are well distinguishable, namely, the first cool-flame wave, the second blue-flame wave and the third wave of the hot explosion. The blue flame period (second wave) corresponds to the delay (induction period) of the hot explosion. In Fig. 5e, this delay is designated as τ_3 .

One piece of evidence for the multistage mechanism of the low-temperature autoignition of hydrocarbons is the appearance of blue flame in the experiments on the autoignition of 'lean' methane–air and isooctane–air mixtures carried out in ICE at temperatures and pressures near the autoignition point. However, no blue flame was observed in the subsequent experiments in a static bomb at the same temperatures and pressures. The later experiments with ICE also demonstrated the appearance of blue flames in the autoignition region of lean methane–air mixtures and benzene mixtures with oxygen. Hence, it seems that the appearance of blue flames during the autoignition processes in fuel–air mixtures in ICE is reliably ascertained (*e.g.*, see Ref. 3 and references therein).

In contrast to multistage high-temperature autoignition of hydrocarbons, the high-temperature autoignition develops continuously without any intermediate stages and ends with hot flame.

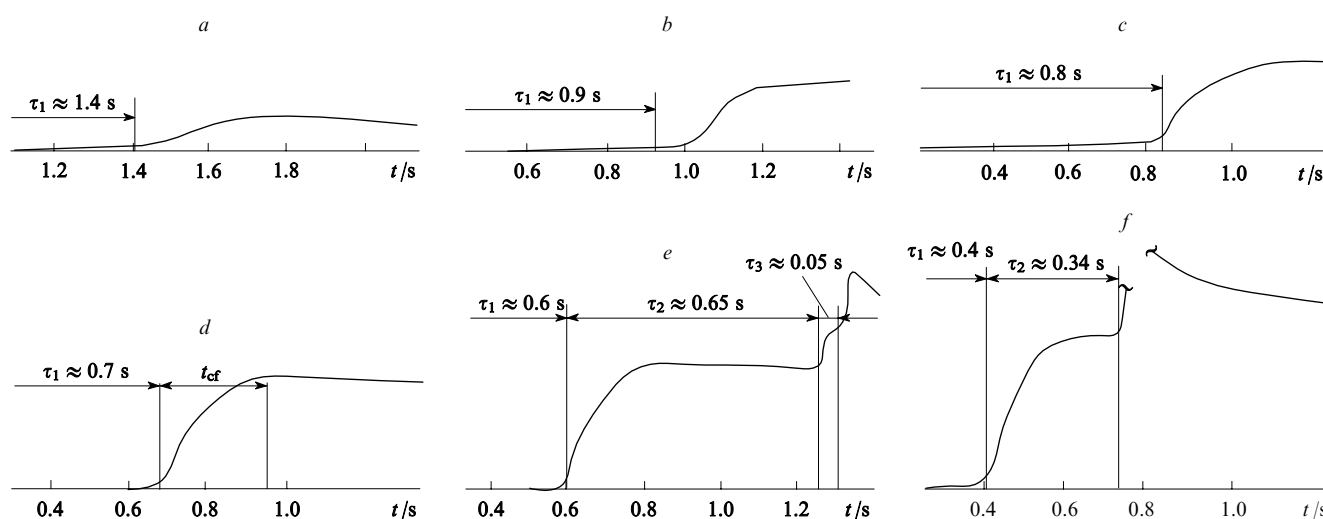

Figure 5. Pressure variation at autoignition of isooctane–air mixtures (stoichiometric ratio $\phi = 1.25$).³ The gain in pressure in the course of the reaction was measured for $T_0 = 643 \text{ K}$ and different initial pressures.

(a) $P_0 = 80 \text{ kPa}$, $P_{\text{ct}}/P_0 = 1.8$; (b) $P_0 = 105 \text{ kPa}$, $P_{\text{ct}}/P_0 = 1.09$; (c) $P_0 = 140 \text{ kPa}$, $P_{\text{ct}}/P_0 = 1.1$; (d) $P_0 = 180 \text{ kPa}$, $P_{\text{ct}}/P_0 = 1.13$; (e) $P_0 = 230 \text{ kPa}$, $P_{\text{ct}}/P_0 \approx 1.14$; (f) $P_0 = 320 \text{ kPa}$, $P_{\text{ct}}/P_0 \approx 1.2$.

Experimental results on the gas-phase oxidation of different hydrocarbons obtained in the mid-20th century are thoroughly described in several monographs.^{2–4}

III. Modelling of gas-phase oxidation of acetaldehyde and hydrocarbons C₁–C₇

For a long time, a concept on the multistage autoignition mechanism of hydrocarbons was not discussed in the literature. The first publications^{9,10} on the oxidation of hydrocarbons at elevated temperatures and pressures, which merely mentioned cool and blue flames but did not establish any new facts, appeared only in the 1980s.

In the long period during which the hydrocarbon oxidation and combustion were studied, numerous kinetic schemes were proposed that described sufficiently comprehensively the oxidation and combustion of particular hydrocarbons, for instance, radical-chain schemes of oxidation and combustion of methane,^{2,4,11,12} ethane,¹³ propane,^{14–16} n-butane,^{17,18} n-pentane,^{19,20} n-heptane,^{21–23} n-octane and isooctane.²⁴ These schemes adequately describe many aspects of hydrocarbon oxidation and combustion, agree with experimental data and allow one to model the corresponding processes. However, if a process can be modelled, then it is sufficiently understood and can be reproduced on the quantitative level. The simultaneous consideration of the known kinetic schemes of oxidation of hydrocarbons and their derivatives allowed the general comprehensive kinetic mechanism of oxidation and combustion of hydrocarbons to be proposed (Table 1 shows such a mechanism for hydrocarbons C₁–C₂; for simplicity, the radical signs in this and the subsequent Table are omitted); however, even incomplete knowledge of all reaction channels and the use of very approximate reaction rate constants often allows one to adequately describe the experimentally observed kinetics of oxidation and combustion using appropriate calculations.

For oxidation of hydrocarbons with ≥ 3 carbon atoms, the cool flames were modelled and the calculations were carried

out that perfectly described the characteristics of these flames.^{14–24} However, none of these studies considered blue flames and the mechanism of their origination. Papers on the modelling of blue flames were absent in the literature, which stimulation us to dwell into this issue.

As was mentioned above, blue flames are experimentally identified by glow and a stepwise gain in pressure observed in closed-vessel experiments. The detection of the blue-flame glow apparently provides little information on the chemical reactions responsible for its appearance; hence, the data on the variations of pressure and, correspondingly, temperature in the course of oxidation attract keen attention for the identification of blue flames. This information can be retrieved from calculations on the simulation of oxidation and combustion processes, which allows one to determine the temperature, the pressure and the concentrations of all products.

Calculations based on kinetic schemes constructed for the low-temperature oxidation of hydrocarbons involve an uncertainty associated with the necessity of taking into account the wall reactions, which are insufficiently studied. For long times and low pressures, the wall reactions can be represented in calculations as unimolecular reactions of the decay of species [reactions (140)–(143)].

1. Acetaldehyde

a. Two regions of the negative temperature coefficient

Acetaldehyde is a convenient subject for studying individual stages of the oxidation processes because its oxidation involves the appearance of intense cool and blue flames. Separate propagation of the latter was even observed at the initial room temperature.

Acetaldehyde oxidation was discussed in many studies (e.g., see monographs^{2–4} and references therein and also a recent paper²⁵); however, none of these publications described blue flames and the more so considered the possibility of their quantitative interpretation.

Kinetic schemes describing the oxidation of hydrocarbons C₁–C₂ were used²⁶ in modelling blue flames at the multistage

^a A is the pre-exponential factor in equation describing the unimolecular (in s^{-1}), bimolecular ($\text{litre mol}^{-1} \text{s}^{-1}$) and trimolecular ($\text{litre}^2 \text{mol}^{-2} \text{s}^{-1}$) reactions.

Figure 6. Regions of propagation of cool and blue flames (region I), only cool flame (II) and normal hot flame (III) in $\text{CH}_3\text{CHO} + \text{O}_2$ mixtures.⁸

Arabic numerals correspond to the conditions (pressure and mixture composition) under which solutions of the problem of propagation of normal hot flame (1, 2), cool flame (3) and combined propagation of cool and blue flame (4) were found.

autoignition of acetaldehyde mixtures with oxygen. Townend *et al.*⁸ have shown that in the induced ignition of 'rich' mixtures of diethyl ether and acetaldehyde with oxygen, one can observe cool and blue flames at reduced (subatmospheric) pressures and ambient or relatively low temperatures (Fig. 6), which involves only insignificant heating in the flames (50–250°) (cited according to Ref. 2). This is why before embarking on the kinetic modelling of blue flame, it is necessary to elucidate whether the region of acetaldehyde autoignition corresponds to the region of propagation of cool and blue flames upon ignition, how these flames are characterised and what are the calculated conditions of their origination. For these purposes, a kinetic scheme of the hydrocarbon C_1 – C_2 oxidation²⁷ supplemented by the data on acetaldehyde oxidation was taken.²⁸ Table 1 shows all the proposed elementary steps of acetaldehyde oxidation.

A homogeneous reaction (*i.e.*, a reaction that simultaneously proceeds in the whole reactor volume) in a closed vessel was modelled. A system of equation describing the material and heat balance in this reaction is as follows:

$$\frac{dn_j}{dt} = \sum_j w_{ij}, \quad (1)$$

$$\rho c_v \frac{dT}{dt} = \sum_j h_{ij} w_{ij} + \frac{\kappa S}{V} (T - T_w), \quad (2)$$

where n_j is the concentration of species; t is the time; T is the temperature; w_{ij} and h_{ij} are the rate and heat of the i th reaction (elementary step) involving the j th species; ρ is the density; c_v is the heat capacity at a constant volume; κ is the coefficient of heat-transfer to the walls of the reaction vessel; S and V are the surface and volume of the reaction vessel or a combustion chamber; T_w is the vessel wall temperature. The first term in Eqn (2) corresponds to the heat release due to the reaction, the second term corresponds to the heat exchange with the wall. The density was calculated using the equation of gas state. The

solution of this equation for the initial conditions $t = 0$, $n_j = [n_j]_0$, $T = T_0$ allows one to describe the kinetics of homogeneous reactions, *i.e.* find the time dependences of the temperature and concentrations of all substances involved in this reaction.

Figure 7 shows the calculated kinetic dependences of temperature (a) and concentrations of starting compounds (b), most important intermediate compounds and radicals

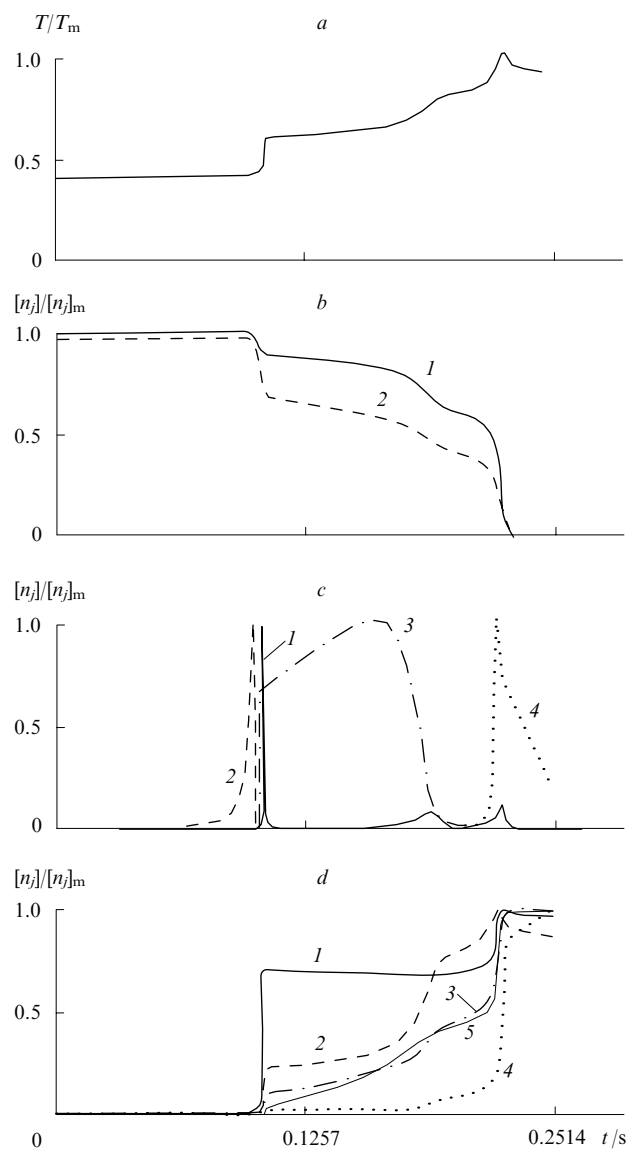

Figure 7. Time profiles of relative temperature (T/T_m , a) and concentrations $[n_j]/[n_j]_m$ (subscript m corresponds to the maximum values) of initial compounds (b), intermediate compounds and radicals (c) and also final products (d) at the autoignition of an acetaldehyde–oxygen mixture.²⁸ Initial conditions: $T_0 = 537$ K, $P_0 = 64.1$ kPa, $[\text{CH}_3\text{CHO}]_0 = 75\%$, $[\text{O}_2]_0 = 25\%$.

(a) T/T_m , $T_m = 1343$ K;

(b) (1) $[\text{CH}_3\text{CHO}]/[\text{CH}_3\text{CHO}]_m$, $[\text{CH}_3\text{CHO}]_m = 0.75$ (here and further, the maximum concentrations are given in volume fractions); (2) $[\text{O}_2]/[\text{O}_2]_m$, $[\text{O}_2]_m = 0.25$;

(d) (1) $[\text{CO}_2]/[\text{CO}_2]_m$, $[\text{CO}_2]_m = 3.67 \times 10^{-2}$; (2) $[\text{H}_2\text{O}]/[\text{H}_2\text{O}]_m$, $[\text{H}_2\text{O}]_m = 1.63 \times 10^{-1}$; (3) $[\text{CO}]/[\text{CO}]_m$, $[\text{CO}]_m = 4.02 \times 10^{-1}$; (4) $[\text{H}_2]/[\text{H}_2]_m$, $[\text{H}_2]_m = 2.33 \times 10^{-1}$; (5) $[\text{CH}_4]/[\text{CH}_4]_m$, $[\text{CH}_4]_m = 8.83 \times 10^{-2}$.

$[\text{CH}_3\text{CO}_3\text{H}, \text{H}_2\text{O}_2, \text{H}, \text{OH}]$ (c) and final products $[\text{CO}_2, \text{CO}, \text{H}_2, \text{H}_2\text{O}, \text{CH}_4]$ (d) on time in the blue flame region for the autoignition of an acetaldehyde mixture ($[\text{CH}_3\text{CHO}]_0 = 75\%$) with oxygen ($[\text{O}_2]_0 = 25\%$). The calculations were carried out for the following initial conditions: $T_0 = 537$ K and $P_0 = 64.1$ kPa. The temperature curve (Fig. 7a) demonstrates three steps, which correspond to the temperature rise in cool, blue and conventional hot flames. The temperature rise in cool flame (at $t \approx 0.1$ s) is explained by a sharp increase in the reaction rate due to branching associated with the decomposition of hydroperoxide $\text{H}_3\text{CO}_3\text{H}$ (hereinafter, the reaction number corresponds to that shown in Table 1).

The same time corresponds to the appearance of a maximum in the $[\text{OH}]/[\text{OH}]_{\text{m}}$ vs. t curve (curve 1 in Fig. 7c).

In cool flame, a great deal of H_2O_2 is formed (curve 3 in Fig. 7c) the concentration of which first increases and then, after a certain period, starts to sharply decrease due to the H_2O_2 decomposition by the reaction

The second temperature jump due to the reaction acceleration as a result of the H_2O_2 decomposition is also accompanied by an increase in the concentration of OH radicals (the second peak in curve 1 in Fig. 7c). It is the chemical processes accompanying this temperature jump that are identified as the blue flame. The identification of blue flame and its mechanism as a local maximum of the reaction rate that arises due to the hydrogen peroxide decomposition was proposed in the study²⁹ dealing with analysis of the kinetics of ethane oxidation. The decomposition reaction of hydrogen peroxide is present in virtually all detailed kinetic schemes of hydrocarbon oxidation. However, before the appearance of the above publication,²⁹ the authors of these schemes never studied blue flames nor analysed their mechanism and the role of hydrogen peroxide decomposition in the appearance of blue flame.

Ultimately, as the reaction mixture is self-heated during the reaction, the conditions arise for the intense reaction branching typical of hot flames

which is accompanied by a new increase in the reaction rate and in the temperature. The concentrations of OH radicals (the third peak in curve 1, Fig. 7c) and hydrogen atoms H (curve 4 in Fig. 7c) increase again and the concentrations of acetaldehyde and oxygen decrease (curves 1 and 2 in Fig. 7b). Figure 7d shows the concentration profiles of several products of acetaldehyde oxidation and combustion, which are formed in the highest yields.

Presumably, the above description of the chemical process of acetaldehyde oxidation reflects the general phenomenological pattern and the essence of the three-stage autoignition of a $\text{CH}_3\text{CHO} + \text{O}_2$ mixture with the formation of cool, blue and hot flames.

Computations made it possible to follow the effect of the initial conditions ($\text{CH}_3\text{CHO} + \text{O}_2$ mixture composition, pressure and temperature) on the form of a $T(t)$ function, which describes most comprehensively the external aspects of a chemical reaction, in the t range from 0 to 0.5 s.²⁶ On the one hand, as the acetaldehyde concentration increases from 75% to 85%, the reaction rate decreases and the $T(t)$ function transforms from three-stage into two-stage due to the disappearance of the hot flame stage. On the other hand, the decrease in the $[\text{CH}_3\text{CHO}]_0$ concentration to 65% increases the reaction rate, and the three-step mechanism remains unchanged. With the

further decrease in the acetaldehyde concentration to 50%, the $T(t)$ function corresponds to a two-stage reaction that involves cool and hot flames. Thus, the form of the $T(t)$ function does not always one to conclude on the presence or absence of different stages during the acetaldehyde oxidation and also on the mechanism of relevant elementary reactions.

As the initial pressure of the gas mixture decreases from 64.1 to 25 kPa and the overall reaction decelerates, the function $T(t)$ transforms from three-stage into two-stage due to the disappearance of the hot-flame stage. At the pressure rise from 64.1 to 100 and 200 kPa, the function $T(t)$ still remains three-stage; however, further increase in the pressure to 400 and then to 1000 kPa results in the reaction acceleration and function $T(t)$ is no step-wise any longer.

The theory of oxidation and combustion of hydrocarbons uses the notion of induction period, which is the time during which the reaction rate increases to explosive without any visible indications. The description of a three-stage process³ involves the concepts of induction periods of cool (τ_1), blue (τ_2) and hot (τ_3) flames, where each period precedes a new increase in the temperature, and also a concept of the overall induction period $\tau_\Sigma = \tau_1 + \tau_2 + \tau_3$. The inflection points in the temperature curve $T(t)$ can be assumed conditionally to correspond to the end of period τ_1 and the beginning of period τ_2 and also the end of period τ_2 and the beginning of τ_3 . The values of τ_1 , τ_2 and τ_3 are largely qualitative estimates. To qualitatively assess the overall induction period τ_Σ , one may assume that it is equal to the time from the beginning of the process to the attainment of the maximum of function $T(t)$.

Basevich *et al.*²⁶ considered the dependence of calculated τ_Σ values on the initial temperature T_0 (Fig. 8). This Figure shows that in the range $T_0 = 500$ –1000 K, the $\tau_\Sigma(T)$ curve has two maxima (at $T_0 = 650$ and 900 K) and two minima (at $T_0 = 537$ and 775 K), *i.e.*, there are two NTC regions ($T_0 = 537$ –650 K and $T_0 = 775$ –900 K) in which the reaction rate decreases with an increase in the temperature.

Figure 8. Dependences of the induction period on the initial temperature for autoignition of acetaldehyde mixtures with air at different temperatures.²⁶

Initial conditions: $P_0 = 64.1$ kPa, $[\text{CH}_3\text{CHO}]_0 = 75\%$.

Figure 9 shows functions $T(t)$ obtained for different initial temperatures corresponding to such extrema in the τ_Σ vs. T_0 curve (see Fig. 8). It is evident that functions $T(t)$ are three-stage for $T_0 = 500$, 537 and 650 K, *i.e.*, in the vicinity of the first minimum (curves 1–3), two-stage without any apparent cool-flame stage for $T_0 = 775$ K (in the vicinity of the second minimum) (curve 4) and monotonically increase without any visible stages for $T_0 = 900$ and 1000 K (curves 5 and 6).

Such a shape of curves is explained by the fact that in the vicinity of the first minimum, three branching reactions occur,

Figure 9. Time dependences of relative temperature for autoignition of acetaldehyde–oxygen mixtures at different initial temperatures.²⁶
 T_0/K : (1) 500, (2) 537, (3) 650, (4) 775, (5) 900, (6) 1000.
 Initial conditions: $P_0 = 64.1$ kPa and $[\text{CH}_3\text{CHO}]_0 = 75\%$.

i.e., three-stage autoignition is observed. Hydroperoxide $\text{CH}_3\text{CO}_3\text{H}$ is formed in the reactions

As the temperature increases (in the temperature range $T_0 = 537\text{--}650$ K), the equilibrium of reaction (135) shifts to the left and active decomposition of CH_3CO radicals by the following reaction begins:

As a result, the hydroperoxide concentration decreases, its decomposition by reaction (–137) does not play a significant role any longer, the rate of acetaldehyde oxidation decreases and the first NTC region appears.

A similar situation takes place in the temperature range $T_0 = 775\text{--}900$ K. At these initial temperatures, a large amount of hydrogen peroxide is formed

As the temperature increases, the equilibrium of reaction (10) shifts to the left. In this temperature range, reactions of consumption of hydrogen atoms start to prevail, the H_2O_2 concentration decreases, the branching of the acetaldehyde oxidation reaction due to the hydrogen peroxide decomposition [reaction (–17)] becomes insignificant and the process decelerates again, which is manifested by the appearance of the second NTC region.

With the further increase in the initial temperature, only one branching reaction remains, namely, the hydrogen atom reaction with oxygen (–2), which is typical of all high-temperature processes of hydrocarbon combustion. Now, function $T(t)$ increases monotonically.

Thus, the existence of two regions of the negative temperature coefficient of the reaction rate was theoretically proved for the first time.²⁶ Their existence was explained by the fact that the temperature range of the formation and decomposition of acetyl hydroperoxide (cool flames) is located much below the temperature range of hydrogen peroxide decomposition (blue flames) so that the cool and blue flames are well separated in time in the acetaldehyde autoignition.

b. Propagation of cool and blue flames

Data on the modelling of the propagation of cool flames through fresh unheated acetaldehyde mixtures with oxygen are available.²⁸ The calculations involved the use of a computer code³⁰ for solving the following system of equations that

describes the one-dimensional stationary propagation of the oxidation and combustion wave to be solved:³¹

$$\frac{\partial}{\partial x} \left[\rho D_j \frac{\partial (n_j/\rho)}{\partial x} \right] - \rho_0 u_n \frac{\partial (n_j/\rho)}{\partial x} + \sum_j w_{ij} = 0, \quad (3)$$

$$\frac{\partial}{\partial x} \left(\lambda \frac{\partial T}{\partial x} \right) - c_p \rho_0 u_n \frac{\partial T}{\partial x} + \sum_{ij} h_{ij} w_{ij} = 0, \quad (4)$$

where x is the coordinate along which the oxidation and combustion wave propagates; ρ , ρ_0 are the currently observed and initial densities, $\rho = \rho_0(T_0/T)(P/P_0)$; D_j is the diffusion coefficient of the j th species of the chemical reaction, $D_j = D_j^*(T/T^*)^{\gamma^2} (P/P^*)$ (the asterisk marks the parameters at normal conditions, $T^* = 293$ K and $P^* = 100$ kPa); u_n is the stationary velocity of wave propagation; λ is the molecular heat conductivity coefficient, $\lambda = \lambda^*(T/T^*)^{\gamma^1}$; c_p is the specific heat, $c_p = c^* + c^{**}T$, where c^* , c^{**} , γ^1 , γ^2 are constants.

The wave propagation velocity was determined based on the condition that the system of equations (3) and (4) has a solution at the following boundary conditions:

$$x \rightarrow -\infty: T \rightarrow T_0, \quad n_j \rightarrow [n_j]_0;$$

$$x \rightarrow +\infty: \frac{dT}{dx} \rightarrow 0, \quad \frac{d(n_j\rho)}{dx} \rightarrow 0.$$

All the necessary coefficients were taken from reference editions.

The problem was solved using the relaxation method where the terms with derivative with respect to time (t) were added artificially to equations (3) and (4). After setting certain initial functions $T(t=0, x)$ and $n_j(t=0, x)$, the calculations were carried on up to a t value at which the temperature and concentration profiles and the u_n value no longer depended on time. As a result, a stationary solution to the non-stationary problem was found. This stationary solution is in fact quasistationary, because the calculations were stopped when the criteria of sufficiently small changes in temperature and concentration with time were fulfilled.

For a conventional 'hot' laminar flame, the stationarity means approaching the thermodynamic equilibrium. For cool and blue flames, there is no thermodynamic equilibrium: there is also no equilibrium in the initial fuel–oxidant mixture, but there exists a quasi-equilibrium that can be retained infinitely long. Apparently, depending on the form of initial functions [mainly depending on the function $T(t=0, x)$ at the right boundary], under conditions close to experimental,⁸ it is possible to find solutions that well describe both cool flame or cool and blue flames, on the one hand [if function $T(t=0, x)$ corresponds to the temperature of cool flame or cool and blue flames], and hot flame, on the other hand [if function $T(t=0, x)$ corresponds to the final equilibrium temperature of combustion].

Calculations²⁸ were carried out for different fuel–oxygen mixtures, the initial temperature $T_0 = 293$ K and several pressures. Profiles of temperature and substance concentrations in the propagating cool flame were reported²⁸ for an equimolar $\text{CH}_3\text{CHO} + \text{O}_2$ mixture at a pressure of 40 kPa (300 mm Hg). For this pressure, the flame propagation velocity was found to be equal to 2.4 cm s^{-1} . In cool flame, the temperature increased from 293 to 772 K. There, nearly 23% of starting reactants were consumed to afford a certain amount of stable products such as H_2 , H_2O , CO , CH_4 , etc. The rapid temperature increase in cool flame corresponds to a considerable increase in the concentration of the OH radical, one of the main active species in this reaction. This jump in the OH concentration coincides with a sharp decrease in the concentration of acetyl hydroperoxide $\text{CH}_3\text{CO}_3\text{H}$. The subsequent

deceleration of the reaction with the decrease in the $[\text{OH}]$ was associated with the decomposition of secondary peroxides $\text{C}_2\text{H}_5\text{O}_2\text{H}$ and $\text{CH}_3\text{O}_2\text{H}$, which are more stable than $\text{CH}_3\text{CO}_3\text{H}$.

The appearance and joint propagation of cool and blue flames in a $\text{CH}_3\text{CHO} + \text{O}_2$ mixture was modelled.³² The first attempts to model blue flames failed due to the instability of the solution. However, this instability was overcome by refining the computation procedure.

The calculations were carried out for $\text{CH}_3\text{CHO} + \text{O}_2$ mixtures with different composition, the initial temperature $T_0 = 293$ K and several pressures. In Fig. 6, the mixture compositions and pressures used in calculations are marked with asterisks. By selecting the initial functions for calculations, it was possible to simulate the flame types observed in experiments.

Let us consider a solution that corresponds to the joint propagation of cool and blue flames during the combustion of the 85% $\text{CH}_3\text{CHO} + 15\%$ O_2 mixture at a pressure of 67 kPa (point 4 in Fig. 6). Figure 10 shows the profiles of the temperature wave (T/T_m , *a*) and the concentration waves ($[n_i]/[n_i]_m$) of initial compounds (*b*), most important intermediate products and radicals (*c*) and final products (*d*), which contain separate zones of cool and blue flames. Under these initial conditions, the velocity of wave propagation was found to be 2.42 cm s^{-1} . Two temperature waves could be distinguished (see Fig. 10*a*). In cool flame, the temperature increased from 293 to 800 K, whereas in blue flame, it increased from 800 to 1267 K. The first temperature wave coincided with the decomposition of acetyl hydroperoxide $\text{CH}_3\text{CO}_3\text{H}$ to form OH radical and demonstrated a local maximum in the decay range. This maximum corresponds to the decomposition of secondary peroxides $\text{C}_2\text{H}_5\text{O}_2\text{H}$ and $\text{CH}_3\text{O}_2\text{H}$, which are somewhat more stable. The second temperature wave is associated with the decomposition of hydrogen peroxide H_2O_2 and HO_2 radicals to form OH radicals [due to the relatively large step of calculations over space, the resulting hydroxyl concentration curve is lumped rather than smooth (curve 4 in Fig. 7*c*)]. The following stable compounds were observed among the combustion products (in the order of decreasing concentration): H_2 , CH_4 , CO , H_2O , C_2H_4 , C_2H_6 , CO_2 , CH_3OH , *etc.* and the following radicals: CH_3 , HO_2 , CH_3O , C_2H_5 , CHO , OH , *etc.* Beyond the combustion zone, $\sim 10\%$ of acetaldehyde and more than 1% of oxygen remain non-consumed.

As was mentioned above, cool flame corresponds to the glow of excited HCHO^* . Apparently, this species is formed by the reaction

As is seen from Fig. 10*c*, the concentration profiles of methoxyl radical CH_3O and hydroxyl OH partly overlap, which corresponds to a certain probability that this reaction occurs in the cool flame zone. According to the same data, the blue flame glow owes its existence to the $(\text{HCO})^*$ radical. Presumably, this radical is formed by the reaction

Concentration profiles of HCHO and OH also overlap in the blue flame reaction zone, which shows that such a reaction can occur in this flame zone with a certain degree of probability.

The acetaldehyde oxidation mechanism assumed in a study²⁸ mentioned above includes none of these reactions, because the appearance of these species and their glow do not affect the main chemical process of heat release. In principle, the HCHO^* glow may be masked by the more intense $(\text{HCO})^*$ glow. The foregoing is nothing but the possible external manifestations of multistage mechanism of the acetaldehyde

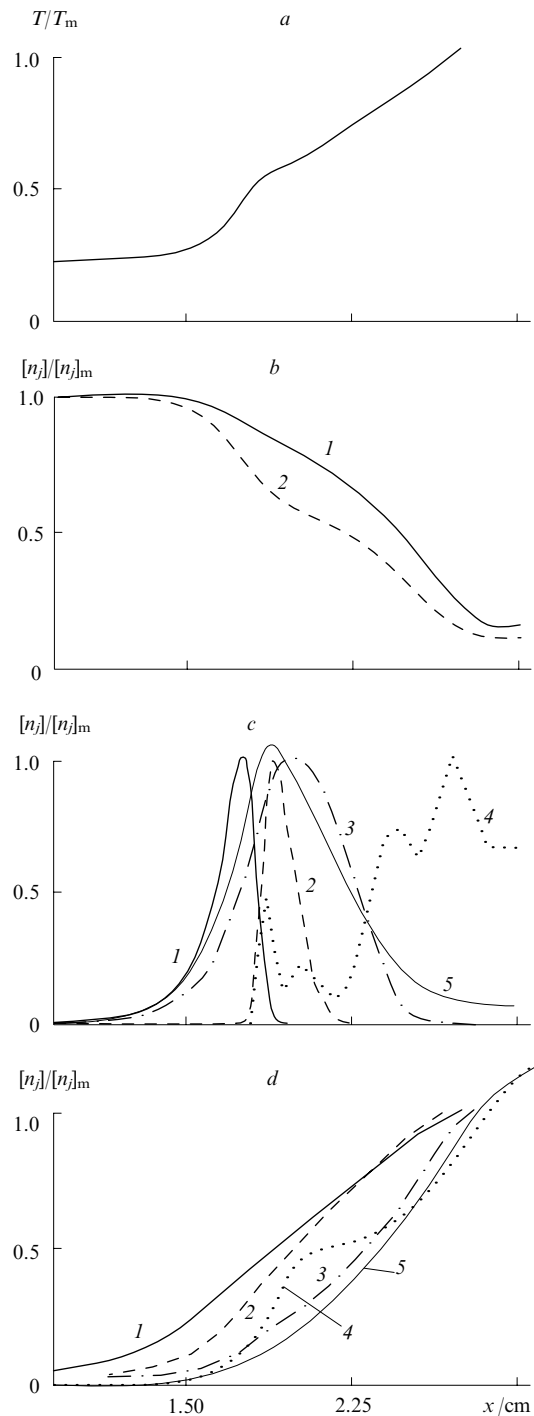

Figure 10. Profiles of relative temperature (T/T_m , *a*) and concentrations $[n_i]/[n_i]_m$ of initial compounds (*b*), most significant intermediate compounds and radicals (*c*) and final products (*d*) in the cool-flame reaction zone.³²

Initial conditions: $[\text{CH}_3\text{CHO}]_0 = 85\%$, $[\text{O}_2]_0 = 15\%$, $T_0 = 293$ K, $P_0 = 67$ kPa (~ 500 Torr).

(*a*) T/T_m , $T_m = 1267$ K;

(*b*) (1) $[\text{CH}_3\text{CHO}]/[\text{CH}_3\text{CHO}]_m$, $[\text{CH}_3\text{CHO}]_m = 0.85$; (2) $[\text{O}_2]/[\text{O}_2]_m$, $[\text{O}_2]_m = 0.15$;

(*c*) (1) $[\text{CH}_3\text{CO}_3\text{H}]/[\text{CH}_3\text{CO}_3\text{H}]_m$, $[\text{CH}_3\text{CO}_3\text{H}]_m = 1.7 \times 10^{-3}$; (2) $[\text{CH}_3\text{O}]/[\text{CH}_3\text{O}]_m$, $[\text{CH}_3\text{O}]_m = 4.5 \times 10^{-5}$; (3) $[\text{H}_2\text{O}_2]/[\text{H}_2\text{O}_2]_m$, $[\text{H}_2\text{O}_2]_m = 8.1 \times 10^{-3}$; (4) $[\text{OH}]/[\text{OH}]_m$, $[\text{OH}]_m = 1.4 \times 10^{-7}$; (5) $[\text{HCHO}]/[\text{HCHO}]_m$, $[\text{HCHO}]_m = 6.0 \times 10^{-3}$;

(*d*) (1) $[\text{H}_2]/[\text{H}_2]_m$, $[\text{H}_2]_m = 0.15$; (2) $[\text{H}_2\text{O}]/[\text{H}_2\text{O}]_m$, $[\text{H}_2\text{O}]_m = 0.0729$; (3) $[\text{CO}]/[\text{CO}]_m$, $[\text{CO}]_m = 0.401$; (4) $[\text{CO}_2]/[\text{CO}_2]_m$, $[\text{CO}_2]_m = 0.024$; (5) $[\text{CH}_4]/[\text{CH}_4]_m$, $[\text{CH}_4]_m = 0.135$.

oxidation and joint propagation of cool and blue flames. The presence of branching reactions in the decomposition of $\text{CH}_3\text{CO}_3\text{H}$ and H_2O_2 also points to the multistage nature of the acetaldehyde oxidation.

It can be stated that when cool and blue flames propagate in fresh unheated $\text{CH}_3\text{CHO} + \text{O}_2$ mixtures, the cool-flame and blue-flame reactions follow the same route as in the appearance of conventional bulk homogeneous cool and blue flames, with a difference that these reactions are initiated by the heat transfer and diffusion and such a double flame propagates over initially unheated mixtures.

The solutions corresponding to the propagating hot flame were not analysed in the mentioned study.²⁸

2. n-Heptane

Well-pronounced blue flame was observed in the combustion of n-heptane. Sokolik and Yantovskii³ experimentally (by recording the pressure) proved the multistage mechanism of the combustion of an n-heptane–air mixture in a closed vessel. The experiment was carried out at the relatively low initial temperature $T_0 = 573$ K and pressure $P_0 = 150$ kPa. The authors observed three pressure waves, namely, the first cool-flame wave, the second blue-flame wave and the third wave corresponding to the hot explosion (Fig. 11). In Fig. 11, the waves of cool and blue flames are united in a single delay τ_2 . This is associated with the fact that the authors have not yet brought forth a concept of multistage autoignition and

Figure 11. Pressure changes at autoignition of an n-heptane–air mixture with stoichiometric ratio $\phi = 1.25$. Initial conditions: $T_0 = 573$ K, $P_0 = 150$ kPa.³

explained the observed pressure jumps based on another idea.

A semi-empirical mechanism of n-heptane oxidation and combustion at the higher initial temperature (700–1300 K) and pressure (1200–10 000 kPa) was proposed and checked in a series of calculations that modelled the autoignition and combustion of n-heptane in propagating flame.³³ Figure 12 shows the autoignition delay times, both experimental and calculated based on the kinetic mechanism of n-heptane autoignition (for the experimental data on the overall autoignition delays $\tau_\Sigma = \tau_1 + \tau_2 + \tau_3$, see Ref. 33). It is evident that the results of calculations adequately agree with experimental data. Modelling of n-heptane oxidation and combustion has shown³⁴ that the proposed³³ kinetic mechanism of this process describes rather adequately the multistage autoignition of n-heptane with the appearance of cool and blue flames. The conditions taken in calculations corresponded to experimental conditions (stoichiometric amounts of n-heptane and air, $P_0 = 1500$ kPa) and the temperature range embraced an interval from 680 to 1000 K (the temperature corresponding to the beginning of high-temperature oxidation). Figure 13 shows the results of calculations. The calculations demonstrated the time dependences (in the range of the overall

Figure 12. Comparison of calculated (line) and measured (points) delays in the ignition of a stoichiometric n-heptane–air mixture at $P_0 = 1500$ kPa.³³

autoignition delay) of the relative temperature (T/T_m) and concentrations ($[n_i]/[n_j]_m$) of key intermediates such as $\text{C}_7\text{H}_{15}\text{O}_2\text{H}$, H_2O_2 , OH and H, which were formed in the autoignition of a stoichiometric n-heptane–air mixture at different initial temperatures. These results show that at $T_0 = 680$ K, the multistage autoignition occurs (curves 4 in Fig. 13 a–d). In the temperature profile (Fig. 13 a), two waves are present. The first wide wave (amplitude of 150°) corresponds to the temperature rise due to the cool flame, the second shorter wave appears at the end of the induction period. Its amplitude is approximately 250° and the temperature reaches as high as ~ 1350 K. This wave corresponds to blue flame. Subsequently, the reaction transforms into hot explosion. The first temperature wave is caused by the reaction acceleration due to the stepwise increase in the concentration of OH radicals formed in the thermal decomposition of hydroperoxide $\text{C}_7\text{H}_{15}\text{O}_2\text{H}$, whereas the second wave is caused by the reaction acceleration with the next sharp increase in the OH concentration due to the thermal decomposition of more stable H_2O_2 molecules. The first slight increase in the concentration of H atoms (curve 4 in Fig. 13 e) is observed at the end of cool flame region, the second is observed in the blue flame region. After the complete decomposition of hydrogen peroxide (the end of the blue flame region), the concentrations of hydroxyl and hydrogen atoms first decrease and then sharply increase due to the branched chain reaction

Due to the vigorous progress of the reaction, the temperature begins to sharply increase and reaches its maximum, i.e., the combustion temperature (is not shown in the Figure).

Figure 13 also shows the time dependences of the relative temperatures and concentrations at higher initial temperatures T_0 : 800 (curve 3), 900 (2) and 1000 K (1). These dependences provide an insight into the dynamics of variations in the temperature and concentrations of the main substances involved in the autoignition on the transition from multistage to single-stage oxidation. As the initial temperature increases to $T_0 = 900$ and 1000 K, the relative concentration of $\text{C}_7\text{H}_{15}\text{O}_2\text{H}$ (Fig. 13 c) decreases by several orders of magnitude and cannot be seen in the plot (shown by arrows), the H_2O_2 concentration decreases less sharply and the concentration of hydrogen atoms is very low during the delay at high initial

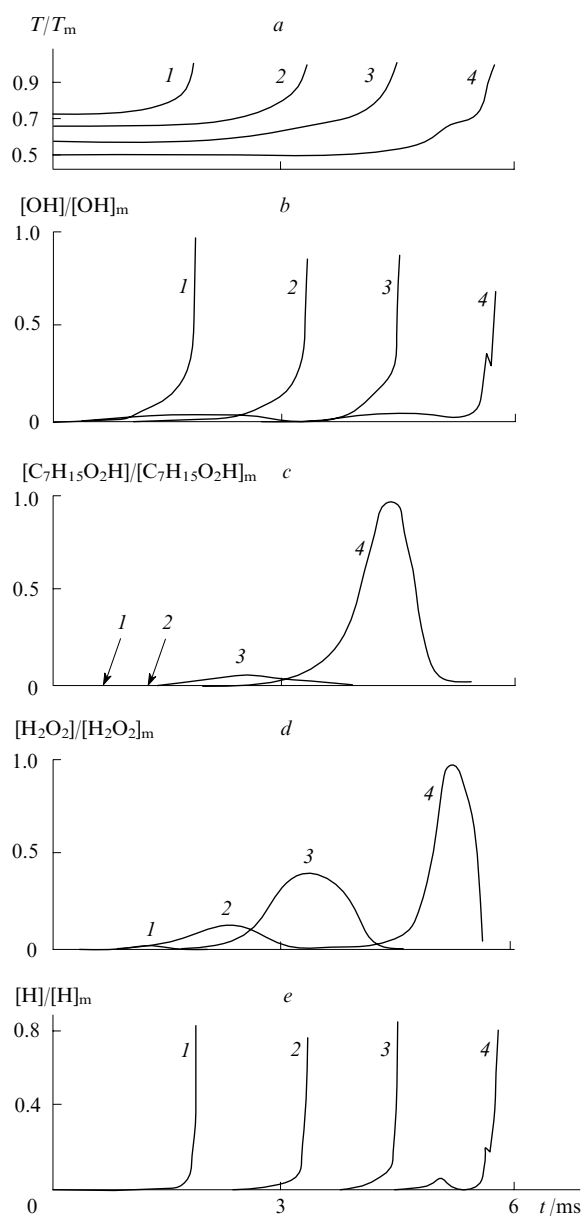

Figure 13. Dependences of relative temperatures (a) and concentrations (b–e) on time for autoignition of a stoichiometric n-heptane–air mixture at $P_0 = 1500$ kPa, $[C_7H_{16}]_0 = 1.87\%$ and different temperatures.³⁴ T_0/K : (1) 1000, (2) 900, (3) 800, (4) 680. (a) T/T_m , $T_m = 1363$ K; (b) $[OH]/[OH]_m$, $[OH]_m = 3.025 \times 10^{-4}$; (c) $[C_7H_{15}O_2H]/[C_7H_{15}O_2H]_m$, $[C_7H_{15}O_2H]_m = 8.176 \times 10^{-5}$; (d) $[H_2O_2]/[H_2O_2]_m$, $[H_2O_2]_m = 8.176 \times 10^{-5}$; (e) $[H]/[H]_m$, $[H]_m = 1.283 \times 10^{-7}$.

temperatures but quickly increases at the hot explosion to a quite considerable value for all temperatures.

Due to the fact that the temperature regions of the formation and decomposition of n-heptyl hydroperoxide are considerably lower than the regions of the formation and decomposition of hydrogen peroxide, the cool and blue flames observed at the n-heptane autoignition are well separated as in the case of acetaldehyde.

3. Propane

No blue flame was observed in the propane combustion. However, in view of similar mechanisms of oxidation and combustion of paraffin hydrocarbons, it can be assumed that propane combustion, like n-heptane combustion, may feature

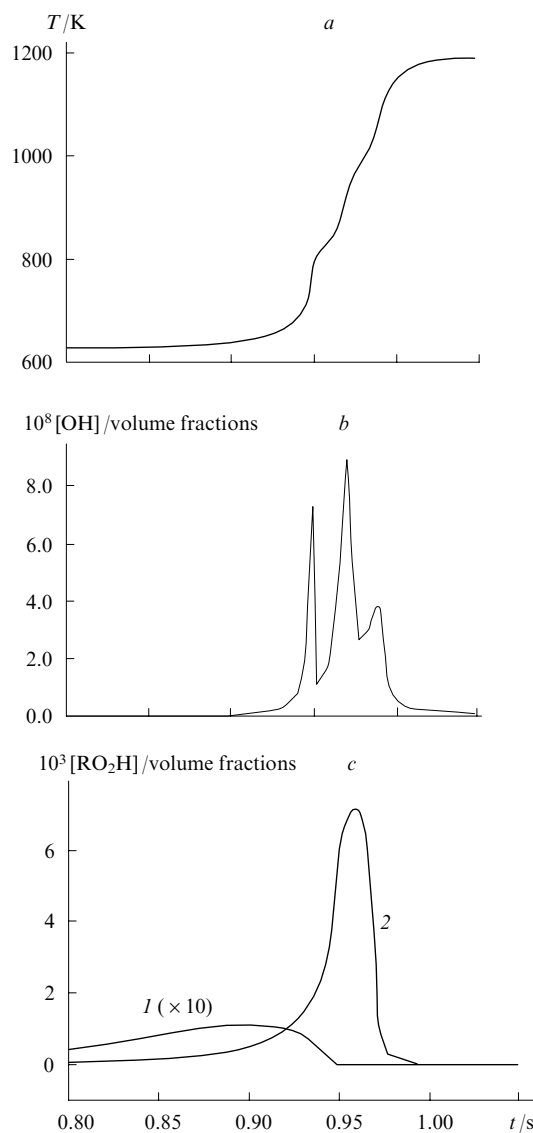

Figure 14. Calculation of autoignition of a propane–air mixture 15.5% C_3H_8 –10.5% O_2 –74% N_2 for initial conditions $T_0 = 625$ K, $P_0 = 550$ kPa.

the appearance of blue flame under appropriate conditions. As follows from the abundant experimental data on the propane oxidation and combustion that can be found in the literature (e.g., see a monograph² and references therein), its oxidation features cool flame, regions of the negative temperature coefficient (NTC) and other phenomena typical of the oxidation of higher hydrocarbons. This is why an attempt was undertaken to theoretically determine the conditions for the appearance of blue flame during low-temperature propane oxidation by modelling. The kinetic mechanism of propane oxidation and combustion was taken from Ref. 16.

Typical calculated temperature vs. time records for the autoignition of a propane–air mixture corresponds to two-stage autoignition, namely, demonstrates delays in the appearance of cool (τ_1) and hot (τ_2) flames (Fig. 14). For example, for $T_0 = 650$ K, the overall delay in the autoignition of a propane (6.5%)–air mixture was ~ 2.48 s (varied from 2.1 to 3.5 s in different experiments). Such a form of hydrocarbon autoignition is typical of low temperatures. Cool flame appears at

the decomposition of propyl hydroperoxide $C_3H_7O_2H$ as a result of chain branching, which leads to a sharp increase in the hydroperoxide concentration and accelerates C_3H_8 oxidation. As all accumulated hydroperoxide is consumed, the reaction decelerates and, in the next period (during the τ_2 delay) hydrogen peroxide H_2O_2 is accumulated. Its decomposition, *i.e.*, the second branching of the reaction, leads to an increase in the reaction rate and, ultimately, to hot explosion (reaction of H with O_2). Immediately before the hot explosion, a local break is observed in the smooth increase of the OH concentration, which, however, does not cause any apparent changes in the temperature growth rate. When richer propane–air mixtures are used, the irregular changes in the OH concentration manifest themselves by the appearance of the second maximum in the $[OH]$ vs. T curve. As a result, the curve demonstrates a break that corresponds to blue flame. Figures 14 *a–c* show the results of calculations of autoignition of a propane–air mixture with the 15.5% C_3H_8 –10.5% O_2 –74% N_2 ratio at $T_0 = 625$ K and $P_0 = 550$ kPa. Three inflections in the $T(t)$ curve and three maxima in the $[OH]$ vs. T curve correspond to the multistage autoignition with the appearance of cool, blue and hot flames.

4. Ethane

Until recently, no blue flame was observed in the ethane oxidation and combustion and even cool flames were discovered not long ago. The analysis of the staged mechanism of the ethane autoignition²⁹ was based on the assumption that its oxidation involves the same reactions as the oxidation of higher hydrocarbons, *i.e.*, the process includes three stages, namely, cool flame, blue flame and hot autoignition. Cool-flame phenomena may be associated with both the ethane oxidation and the oxidation of stable products and radicals that are formed in the later stages and are typical of methane oxidation.

Let us dwell on calculations²⁹ performed using a kinetic mechanism of oxidation of hydrocarbons C_1 – C_2 , which was proposed in Ref. 27 and extended by the introduction of additional reactions necessary for modelling of the cool-flame phenomena at the ethane oxidation (see Table 1). First of all, it was selectively checked whether this model adequately describes certain phenomenological characteristics of the ethane oxidation and combustion in the low and high-temperature ranges. This was necessary because the multistage ethane oxidation was never modelled earlier.

Calculations of the ethane oxidation at low temperatures and moderate pressures (*i.e.*, when the reaction time is long and the diffusion rate is sufficiently high) took into account the following effective wall reactions of the decay of active species:

In calculations, the rate constants k_w used for these reactions were the same and were close to their maximum value in the diffusion approximation. The heat-transfer coefficient was taken equal to $0.126 \text{ J litre}^{-1} \text{ s}^{-1} \text{ K}^{-1}$ in all cases.

The calculations of the low-temperature process were accomplished for different conditions (different mixture compositions, initial temperatures and pressures) described in the experimental study.³⁵ The experiments carried out under these conditions revealed the multiple appearance of one, two or three cool flames, where the number of cool flames increased with the diameter of the reaction vessel. On the qualitative level, the calculations²⁹ adequately described the experimentally observed cool-flame phenomena³⁵ as regards both the

time (minutes) and heating (tens of degrees). Thus at $k_w = 1 \text{ s}^{-1}$, no cool flame was observed at all (this rate constant value corresponds to the highest possible diffusion rate constant under these conditions). For a rate constant $k_w = 0.35 \text{ s}^{-1}$, a single cool flame was observed (manifested by an NTC). Two and three cool flames were observed for $k_w = 0.25 \text{ s}^{-1}$ and $k_w = 0.12 \text{ s}^{-1}$, respectively. For $k_w = 0$ (in the absence of peroxide decay on the wall), the calculations pointed to the autoignition process. The authors of experimental studies³⁵ did not observe the autoignition because they did not deal with pressures above 118 kPa.

Insofar as the calculations described rather adequately the experimental data on cool flames, the next step was the analysis and modelling of the multistage mechanism of ethane combustion under autoignition conditions. Based on the fact that $k_w = 0.353 \text{ s}^{-1}$ at a pressure of 100 kPa and a temperature of 600 K, the authors calculated k_w for other pressures and temperatures. According to calculations, the autoignition begins as soon as a pressure of 150 kPa and a temperature of 560 K ($k_w = 0.23 \text{ s}^{-1}$) are reached (at lower temperatures, no autoignition was observed).

In view of the multistage autoignition mechanism, the authors of calculations considered the combustion of an ethane–oxygen equimolar mixture at $T_0 = 560$ K and $P_0 = 150$ kPa. Under these conditions, a two-stage process is observed, namely, a cool-flame flash occurs with a delay $\tau_1 = 390$ s and is accompanied by a partial energy release and a temperature rise by 104° ; after a time $\tau_2 = 9$ s, hot autoignition occurs so that the overall delay turns out to be $\tau_\Sigma = \tau_1 + \tau_2 = 399$ s. As the temperature is increased from 560 to 600 K, the cool flame delay τ_1 becomes shorter and the flame intensity expressed as a temperature rise (ΔT) becomes lower. Delay τ_2 and overall delay τ_Σ increase.

Note the specific features of the autoignition kinetics in the cool-flame region. According to the analysis, during the induction period that precedes the appearance of cool flame, the accumulation of ethyl hydroperoxide $C_2H_5O_2H$ occurs and the decomposition of the latter leads to the low-temperature branching of the combustion reaction. The branching causes a temperature jump, namely, the cool-flame flash. Methyl hydroperoxide and hydrogen peroxide are also involved in the later stages of ethane combustion. In cool flame, as the temperature increases, the equilibrium in the formation of peroxide radicals $C_2H_5O_2$ shifts to the left (*i.e.*, the formation of $C_2H_5O_2$ radicals is hindered), the reaction is slowed down and the temperature stops to increase. The concentrations of CH_3O and OH radicals in the reaction mixture sharply increase 390 s after the beginning of the reaction. The increase in $[OH]$ reflects the increase in the reaction rate in cool flame. Then, the OH concentration begins to decrease, which entails a decrease in the overall reaction rate after the cool flame.

Based on the shape of kinetic curves obtained with a low resolution, one can infer on a typical two-stage mechanism of autoignition (cool flame and hot autoignition). However, at a higher time resolution, the multistage autoignition can be deduced, *i.e.*, the presence of an additional stage before the hot flame. Thus immediately before the hot autoignition, one can observe an increase in the H_2O_2 concentration and also an increase in the concentrations of C_2H_5O , CH_3O , HO_2 and HCO radicals. This violates the monotonic nature of the first derivative of $T(t)$. At the same time, a new considerable increase in the OH concentration is observed, which points to the acceleration of the ethane oxidation. Modelling makes it possible to find the factor responsible for this acceleration. Thus, if in the middle of the considered time interval, the rate constants of each branching reaction, namely, the rate constants for the decomposition of $C_2H_5O_2H$, CH_3O_2H and H_2O_2 are in turn put to zero, this will not affect the increase in the OH concentration for the case of alkyl peroxides, whereas for

H_2O_2 , this will lead to a decrease in the OH concentration and, hence, to the increase in the reaction rate and the temperature. Hence, one can unambiguously conclude that the reaction branching due to the H_2O_2 decomposition is the main reason for the reaction acceleration. This very increase in the ethane oxidation rate prior to hot flame is defined as the blue flame and allows one to assume the multistage mechanism of the ethane autoignition.

In hot flame (the third stage of autoignition), the chief role in the reaction branching is played by the process

Within the framework of a concept of multistage autoignition of paraffin hydrocarbons, a kinetic scheme of ethane combustion was proposed,²⁹ which contains the following stages: (1) cool-flame stage (reaction branching occurs due to the decomposition of hydroperoxides $\text{C}_2\text{H}_5\text{O}_2\text{H}$, $\text{CH}_3\text{O}_2\text{H}$ and also of a part of H_2O_2), (2) blue-flame stage, which precedes hot autoignition (reaction branching due to the decomposition of hydrogen peroxide) and (3) hot-flame stage (reaction branching due to the reaction of H radicals with oxygen).

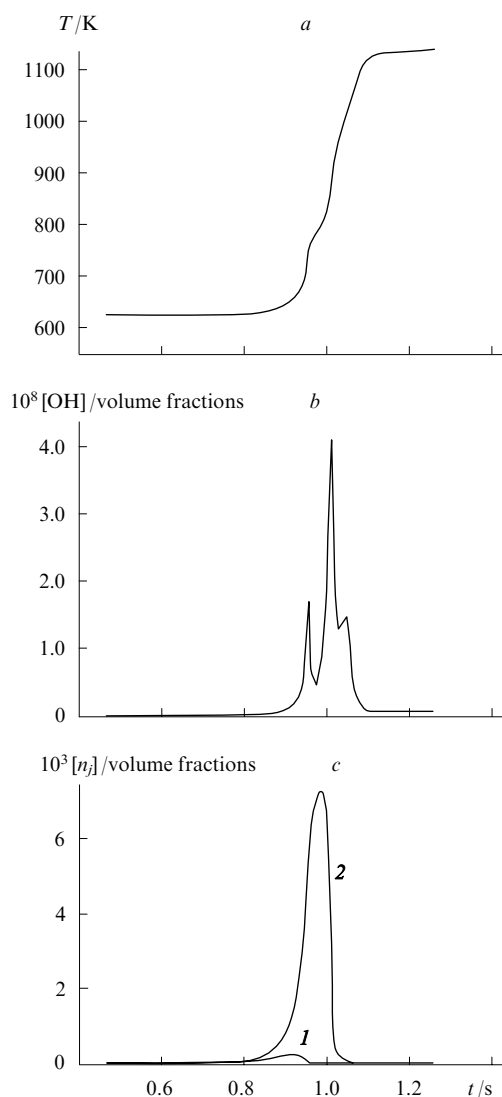

Figure 15. Calculated time dependences of temperature (a) and concentrations [OH] (b), $[\text{C}_2\text{H}_5\text{O}_2\text{H}]$ (c, curve 1) and of H_2O_2 (c, curve 2) for autoignition of an ethane–air mixture 16.5% C_2H_6 –9.5% O_2 –74% N_2 for initial conditions $T_0 = 625$ K and $P_0 = 550$ kPa.

In mixtures richer in ethane, the break of the smooth increase in the concentration [OH] manifests itself by the appearance of the second maximum in the [OH] vs. t curves and a bend in the T vs. t curve, which correspond to blue flame (later calculations¹⁶). As the example, Fig. 15 *a–c* shows the results of calculations of the autoignition of an ethane–air mixture with the composition 16.5% C_2H_6 –9.5% O_2 –74% N_2 for $T_0 = 625$ K at $P_0 = 550$ kPa. Here, as for the propane oxidation, three bends are present in the temperature curve and three maxima appear in the [OH] vs. t curve, which correspond to the multistage autoignition with generation of cool, blue and hot flames.

In the case of ethane, ethyl hydroperoxide plays the chief role in the appearance of cool flames. The closeness of the temperature interval of its decomposition to the temperature interval of hydrogen peroxide decomposition complicates the separation of the cool-flame and blue-flame stages.

5. Methane

The first mention³⁶ of the multistage mechanism of low-temperature oxidation of methane dates back to 1956. In this study, two stages in this process, namely, cool-flame oxidation and autoignition, were observed experimentally.

The first attempt to model the methane autoignition within the framework of a relatively simple kinetic scheme was undertaken in 1982 (Ref. 37) and, although the kinetic scheme used in calculations was developed for modelling of the combustion processes and was supplemented by merely few reactions typical of the low-temperature range of methane oxidation, the results obtained demonstrated the possibility of describing the staged nature of the methane oxidation.

The later calculations employed a kinetic scheme specially developed for the description of low-temperature oxidation of rich methane mixtures.³⁸ Figure 16 shows the results of such calculations.³⁹ As is seen, at the initial temperatures $T_0 < 710$ K, the staged nature of the reaction was not manifested (curve 1). For $T_0 > 758$ K (curves 5–7), ignition occurred (arrows at the ends of curves point to the further increase in the temperature). In the temperature range $T_0 = 728$ –753 K, flashes with incomplete heat release were observed which were followed by reaction inhibition accompanied by a temperature decrease due to the cooling of the reaction mixture by the reactor walls. As a whole, the calculated data corresponded to experimental results described,³⁶ which made it possible to use this kinetic scheme in predicting the behaviour of this reaction under high-pressure conditions

Figure 16. Time dependences of temperature during the oxidation of methane–oxygen mixtures for different initial temperatures.³⁹ Initial conditions: $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $P_0 = 92$ kPa, $\kappa S/V = 6.61 \text{ J cm}^{-3} \text{ s}^{-1} \text{ K}^{-1}$; T_0/K : (1) 710, (2) 728, (3) 748, (4) 753, (5) 758, (6) 768 and (7) 788.

Figure 17. Dependences of (a, b) temperature and (c) concentrations on the reaction time on time scales of (a) seconds and (b, c) microseconds during the oxidation of a methane–oxygen mixture.³⁹

Initial conditions: $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $T_0 = 710 \text{ K}$, $P_0 = 7000 \text{ kPa}$.

(c) (1) $[\text{H}_2\text{O}_2]/[\text{H}_2\text{O}_2]_m$, $[\text{H}_2\text{O}_2]_m = 2.279 \times 10^{-6}$; (2) $[\text{CH}_3\text{O}_2\text{H}]/[\text{CH}_3\text{O}_2\text{H}]_m$, $[\text{CH}_3\text{O}_2\text{H}]_m = 1.412 \times 10^{-8}$; (3) $[\text{HO}_2]/[\text{HO}_2]_m$, $[\text{HO}_2]_m = 1.619 \times 10^{-6}$; (4) $[\text{CH}_3\text{O}_2]/[\text{CH}_3\text{O}_2]_m$, $[\text{CH}_3\text{O}_2]_m = 2.156 \times 10^{-7}$; (5) $[\text{H}]/[\text{H}]_m$, $[\text{H}]_m = 1.420 \times 10^{-8}$.

for which no experimental data could be obtained in static setups.

Calculations were carried out for the mixture 67% CH_4 –33% O_2 at the initial temperature of 710 K and different initial pressures (from 180 to 10 000 kPa). It was found that as the pressure increases, the transition from oxidation to autoignition occurs and the latter is reached in shorter times. Even active heat transfer from the gas to the reactor walls (within reasonable heat transfer coefficients) fails to stop the ignition and reverse the temperature increase, although the heat transfer increases the time the oxidation reaction develops to the autoignition. Figure 17a shows the

typical temperature dependence for the methane oxidation on a time scale of seconds.³⁹ With this resolution, the curve shows no indications of the multistage mechanism. Based on the shape of this curve, the methane oxidation can be assigned to conventional single-stage autoignition processes. However, curve $T(t)$ recorded at a rapid temperature-vs.-time scanning (on a microsecond time scale, Fig. 17b) has a bend, which suggests that the temperature rise to $T = 1400 \text{ K}$ is followed by the reaction retardation with the subsequent hot flash in approximately 15 μs , i.e., the multistage nature of the reaction is evident. In this case, the duration of the first combustion stage was $\sim 4.6 \text{ s}$, and the duration of the second stage was 15 μs (it is very difficult to experimentally observe two stages within such times). The staged nature is evident most clearly in the concentration profiles of hydroperoxides $\text{CH}_3\text{O}_2\text{H}$ and H_2O_2 , and also of radicals HO_2 , CH_3O_2 and H shown on a microsecond scale (see Fig. 17c).

A similar situation was also observed at 750 K and higher, at which the autoignition process that looks as a single-stage process occurs. Calculations of the oxidation of methane–air mixtures were also carried out for the lower oxygen contents, a pressure $P_0 = 10\,000 \text{ kPa}$ and temperatures $T_0 = 683$ –750 K. It was shown that with a decrease in the oxygen content, the indications of the staged mechanism become less pronounced and totally disappear at $[\text{O}_2]_0 = 5\%$.

In the calculations of oxidation processes under high-pressure conditions, the limiting values of reaction rate constants for the infinitely high pressure were taken (the corresponding data can be found in Table 2).

The detection of blue flames in experiments carried out in ICE near the autoignition limits of lean methane–air mixtures served as evidence for the multistage mechanism of hydrocarbon autoignition.⁴⁰

An attempt⁴¹ was made to model blue flames experimentally observed in ICE⁴⁰ by using a kinetic scheme of the process and a computer code that takes into account the piston motion. The analysis of methane oxidation in ICE made it possible to explain the illusory contradiction between the experimental data obtained in ICE⁴⁰ and in a static setup.⁴² Methane oxidation was frozen on the piston back stroke, which makes it possible to establish the initial conditions corresponding to the cessation of the relatively slow initial reaction. In a static bomb, such conditions favourable for the reaction suppression are absent.

For calculations, the same conditions as in the ICE experiments⁴³ were taken (the compression ratio $\varepsilon = 14.7$ for a speed $n = 1000 \text{ rpm}$) (the calculations were carried out according to a kinetic scheme that can be found in Ref. 26 and Table 1). According to calculations, as the compression temperature changes, in the range of low methane concentration, there is a

Table 2. Kinetic parameters of high-pressure oxidation of C_1 – C_2 hydrocarbons.

^a The reaction number corresponds to that in Table 1. ^b The pre-exponential factor A is expressed in s^{-1} for unimolecular reactions, in $\text{litre mol}^{-1} \text{s}^{-1}$ for bimolecular reactions and in $\text{litre}^2 \text{mol}^{-2} \text{s}^{-1}$ for trimolecular reactions.

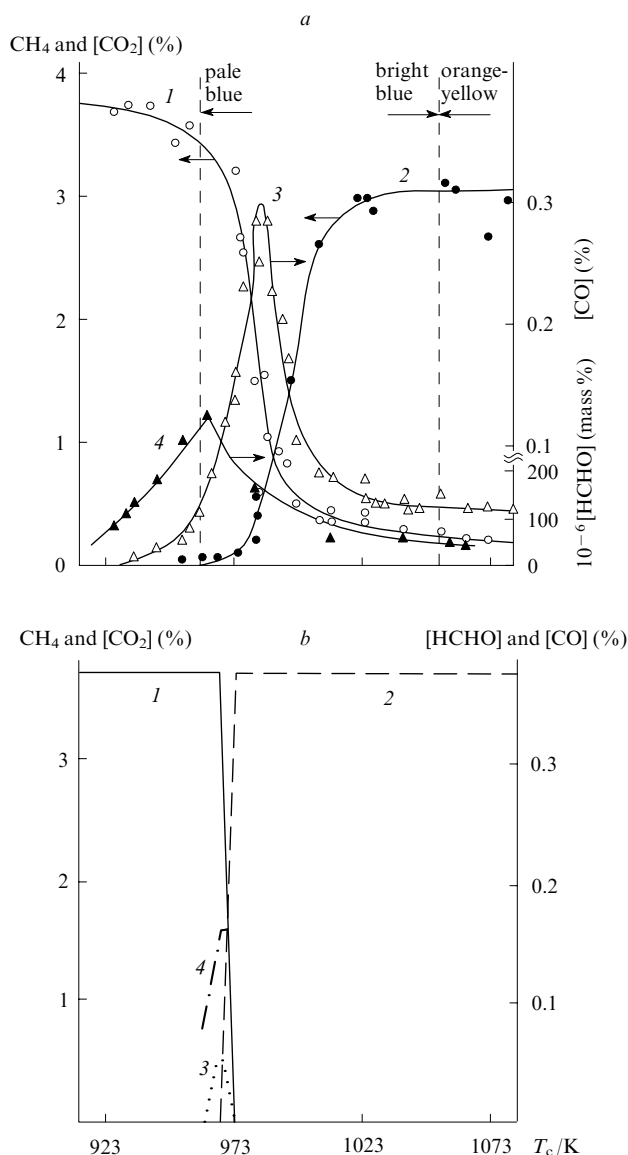

Figure 18. Experimental (a)⁴³ and calculated (b)⁴¹ dependences of relative concentrations of CH₄ (curve 1), CO₂ (2), CO (3) and HCHO (4) on the final compression temperature T_c during the oxidation of a methane–air mixture.

Initial conditions: $[\text{CH}_4]_0 = 3.7\%$, $\varepsilon = 14.7$, $n = 1000$ rpm.

transition from the reaction absence to the complete combustion through the region of incomplete heat release typical of cool and blue flames. In Fig. 18, the dashed lines mark the transition region of the methane incomplete oxidation and combustion, which was experimentally obtained for $[\text{CH}_4]_0 = 3.7\%$. This region extends from 963 to 1053 K, *i.e.*, approximately for 90°. This region revealed experimentally in Ref. 43 was assigned to blue flames. In the calculations (see Fig. 18b) with the same methane concentrations, the blue flame region was merely 1°. As the $[\text{CH}_4]_0$ decreased, the blue flame region extended to 10°. Thus Fig. 19 shows the changes in pressure (curve 1), temperature (curve 2) and concentrations of CH₄, OH, HCHO, CO and CO₂ (curves 3–7) in this transition region. It is evident that methane is partially oxidised to form a certain amount of CO and a very small amount of CO₂. The heat released in the process does not considerably increase the pressure or the temperature.

Figure 19. Diagram of autoignition of a methane–air mixture containing 3.7% CH₄, for $T_c = 968$ K, $\varepsilon = 14.7$, $n = 1000$ rpm. Here, LDP and UDP are the lower (0°) and upper (180°) dead points, CSR are crankshaft rotations.

The reason for the staged mechanism of methane oxidation and the incomplete heat release in the transition region is sequence of poorly separated main branching processes that arise in the decomposition of methyl hydroperoxide and hydrogen peroxide. Thus the analysis of the oxidation kinetics of a lean methane–air mixture under the conditions described in Ref. 43 showed that the branching of active sites takes place mainly due to the reaction

In this case, the OH concentration first increases and then, after the consumption of all accumulated H_2O_2 , starts to decrease. This is why only a part of methane is consumed in the reaction. A hypothetical mathematical experiment in which the rate constant for the H_2O_2 decomposition is set equal to zero in the very beginning shows that virtually no methane can be oxidised under ICE conditions.⁴³ Methyl hydroperoxide $\text{CH}_3\text{O}_2\text{H}$ is the main branching product in the cool-flame oxidation of methane; its decomposition yields hydroxyl

Under the chosen conditions, due to the relatively high initial temperature, only a small amount of $\text{CH}_3\text{O}_2\text{H}$ is formed. Nonetheless, if we set the rate constant for the $\text{CH}_3\text{O}_2\text{H}$ decomposition equal to zero, the methane oxidation is slowed and the yield of products becomes several times lower. Thus, non-separated mixed cool and blue flames were observed in the methane oxidation under these conditions.

All studies devoted to the stepwise mechanism and the pre-flame reactions in the methane oxidation described either cool or blue flames; however, no publications reported on the separate observation of these stages in one experiment. Apparently, it can be concluded that these flames exist only as a united ‘cool-blue flame’ that features the peculiarities of both stages.

Figure 20 shows calculated time dependences of the relative temperature (a) and relative concentrations of hydroxyl (b) and hydroperoxides (c) in the oxidation of rich methane–oxygen mixtures. One can see the regions of the origination of the pre-flame reaction (from 1 to 2.5–3 s) and hot autoignition (at ~ 7.5 s). As seen, the ranges where the temperature rises and the OH concentration increases are situated in the regions

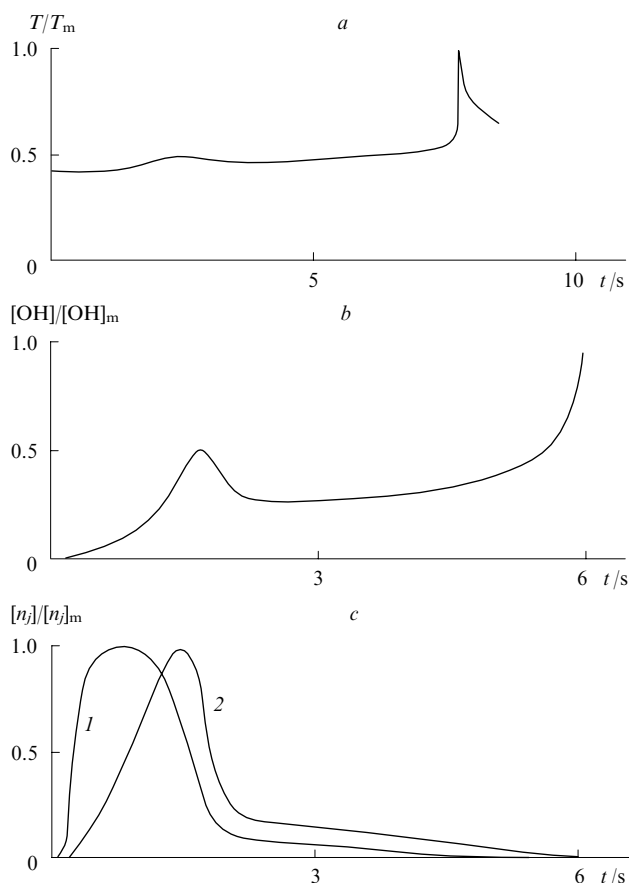

Figure 20. Time dependences of relative temperature T/T_m (a) and relative concentrations of OH (b), $\text{CH}_3\text{O}_2\text{H}$ (c, curve 1) and H_2O_2 (c, curve 2) in the oxidation of a methane-oxygen mixture. Initial conditions: $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $P_0 = 122 \text{ kPa}$, $\kappa S/V = 6.61 \text{ J cm}^{-3} \text{ s}^{-1} \text{ K}^{-1}$, $T_m = 1849 \text{ K}$, $[\text{OH}]_m = 5.43 \times 10^{-9}$, $[\text{CH}_3\text{O}_2\text{H}]_m = 4.19 \times 10^{-5}$, $[\text{H}_2\text{O}_2]_m = 8.60 \times 10^{-2}$.

corresponding to the decomposition of $\text{CH}_3\text{O}_2\text{H}$ (1.3 s) and H_2O_2 (2.6–3 s). Modelling of a process during which the rate constants for the $\text{CH}_3\text{O}_2\text{H}$ and H_2O_2 decomposition decreased one after another has led to a dramatically different pattern of the overall autoignition process, which reflects the effects of both branching reactions on the pre-flame processes. This substantiates a conclusion that the separation of cool and blue flames in the methane oxidation reaction is a difficult and even impossible task and these processes occur simultaneously (with a very short time lag).

IV. Conclusion

Experimental and calculated data obtained based on the detailed kinetic mechanisms of the oxidation of hydrocarbons and their derivatives demonstrate that blue flame arises due to the decomposition of hydrogen peroxide formed in the hydrocarbon oxidation. This is typical of all reactions of oxidation and combustion of hydrocarbons and their derivatives. Blue flame was observed in the gas-phase oxidation and combustion of methane, ethane, n-heptane, isooctane, benzene, acetaldehyde and diethyl ether. Blue flames were clearly observed in the oxidation of acetaldehyde and n-heptane and less clearly in the ethane oxidation. In the methane oxidation, mixed 'cool-blue flame' was observed.

The division of the oxidation process at autoignition into stages is not always possible. Depending on the fuel type, the mixture composition, temperature and pressure, the contribu-

tions of individual stages into the overall oxidation rate can change. These contributions may overlap, which makes impossible their separation. However, the essence of the stepwise mechanism, *i.e.*, the involvement of different reaction groups that make their own contributions to the branching and oxidation, remains unchanged. For example, in the ethane oxidation, the stages corresponding to individual contributions of the $\text{C}_2\text{H}_5\text{O}_2\text{H}$ and $\text{CH}_3\text{O}_2\text{H}$ decomposition reactions could not be separated probably due to their very close kinetic characteristics. In connection with this, it is interesting to analyse the oxidation of heavy paraffin hydrocarbons with the larger number of carbon atoms in molecules for which the kinetic characteristics of the decomposition of the main ($\text{C}_n\text{H}_{2n+1}\text{O}_2\text{H}$) and secondary hydroperoxides are not so similar. At present, when the scientists have at their disposal such fast-response analytical instruments that allow them to study the reactions of hydrocarbon oxidation, the implementation of such a study would be extremely desirable.

Abstract. Methods for the replacement of chlorine atoms in polychloroarenes upon treatment with various reagents are surveyed. Considerable attention is given to catalytic methods and elucidation of the structure–reactivity relationships for polychloroarenes. The bibliography includes 322 references.

I. Introduction

According to the long-term environmental protection strategy of the EU countries, the production and utilisation of environmentally hazardous chemical compounds will be ceased by 2020. Polychlorinated aromatic compounds (polychloroarenes, PCA) are among such compounds. The disposal of toxic PCA produced on the industrial scale, such as first-generation insecticides polychlorobiphenyls and polychlorodioxins formed as their biodegradation products, remains an unsolved problem. Its solution requires information on the reactivity of these compounds, which would suggest promising approaches to their conversion into ecologically safe products or substances with useful properties. Catalytic hydrogenolysis of the C–Cl bond in PCA has been studied in sufficient detail.^{1–8} However, the resulting products are, as a rule, of little practical significance because many hydrogenolysis products can be prepared according to simpler and cheaper procedures. Other reactions of PCA containing from two to six chlorine atoms in the aromatic nuclei have been documented to a lesser extent. Of these reactions, reduction-type processes, including metallation and electron-transfer reactions, as well as reactions with nucleophilic reagents, deserve notice. In addition, the development of procedures for the formation of new C–C and C–heteroatom bonds instead of poorly reactive C–Cl bonds

is a good challenge for processing PCA into practically useful compounds of the aromatic series.

The chemical properties of PCA often differ from those of monochloro derivatives due to the mutual influence of the chlorine atoms. Polychloroarenes are characterised by high acidity of the aromatic protons and high electron affinity. The shift of the first half-wave reduction potential ($E_{1/2}$) to more positive values, on the average, by 0.2–0.3 V, upon the introduction of every next chlorine atom into the aromatic nucleus can serve as the criterion of the electron affinity.^{9, 10} For example, this parameter for hexachlorobenzene is –1.44 V (relative to a saturated calomel electrode), as opposed to monochloroarenes, which are reduced at potentials equal or close to the values of supporting electrolyte discharge. At the same time, a negative charge on the chlorine atoms (for example, in hexachlorobenzene), the small C–Cl bond length (1.7 Å) and the rather large van der Waals radius of the chlorine atoms (1.8 Å) hinder the attack of nucleophiles on the electron-deficient carbon atoms in PCA.

The present review summarises the main reactions of PCA (containing from two to six carbon atoms in the aromatic core) resulting in the replacement of chlorine atoms by other elements. These include:

- (1) nucleophilic substitution reactions,
- (2) reactions accompanied by the C–C bond formation through metallation of PCA,
- (3) transition metal-catalysed cross-coupling reactions.

The only monograph summarising the reactions of PCA was published in 1974.¹¹ The reactions of perchloroalkylarenes that involve the side aliphatic chains with retention of chlorine atoms in the aromatic moieties were considered in a more recent review.¹² In a chapter of a multivolume monograph¹³ devoted to organic halogen-containing compounds, the properties of polyhaloarenes are not considered separately. In this connection, in our opinion, it is reasonable to discuss not only the results of studies published in the last decade, but also the earlier data. The present review includes data on low-chlorinated arenes in particular, because dioxins containing two chlorine atoms in the aromatic nuclei belong to environmentally hazardous compounds. In addition, certain reactions, which have been studied only for arenes containing two or three chlorine atoms, would be useful also for chemical

modifications of highly chlorinated PCA. Since the physico-chemical properties and the structures of polychloroarenes have been covered in detail in the earlier monograph,¹¹ various chemical transformations of these compounds are only considered below.

II. Reactions with S- and Se-nucleophiles

Aromatic thiols, sulfides and their derivatives have found wide use as rubber vulcanisation promoters and modifiers of polymeric compositions. They also serve as intermediates in the synthesis of organic conductors, biologically active compounds and other valuable compounds. The main procedure for their synthesis is based on the nucleophilic substitution of chlorine atoms in chloroaromatic compounds under the action of sulfur-containing nucleophiles.

1. Characterisation of reactions of non-activated polychloroarenes with S- and Se-nucleophiles

Reactions of polychlorobenzenes with sodium alkanethiolates RSNa in hexamethylphosphoramide (HMPA) resulting in high yields of poly(alkylthio)benzenes were documented.^{14–16}

$n = 2–6$; $R = \text{Me, Et, Pr}^i$.

The course of the reactions with sodium ethanethiolate and with sodium methanethiolate especially should be thoroughly controlled^{16,17} because alkylthiobenzenes formed in the first step can undergo dealkylation induced by an excess of sodium alkenethiolate to give alkali metal arenethiolates (see the review¹⁸).

$R = \text{Me, Et}$.

It is more convenient to use Pr^iSNa as the sulfur-containing reagent. Under the reaction conditions, the resulting aryl isopropyl sulfides are stable. After completion of the reaction, these compounds can be transformed into benzenethiols and then into other alkyl aryl sulfides. The latter can be prepared by one-pot reactions with metallic sodium and then with alkylating agents (alkyl iodides or esters). The isopropyl groups can be removed by the reaction with sodium in HMPA or pyridine at $\sim 100^\circ\text{C}$.¹⁹

$n = 2–6$.

Dichlorobenzenes **1a–c**[†] react with sodium alkanethiolates in HMPA to form bis(alkylthio)arenes and their transformation products.¹⁷ For example, the reactions of 1,4-dichlorobenzene (**1c**) with EtSNa and MeSNa afford 1,4-bis(ethylthio)benzene (85%) and 4-(methylthio)benzene-

thiol (52%), respectively, as the major products. The reactions with sodium propane-2-thiolate are not accompanied by S-dealkylation. However, these reactions afford mixtures of mono- and bis(isopropylthio)benzenes. The composition of the products depends on the amount of the reagent. The disubstitution products are the major products in the reactions of Pr^iSNa with 1,3- and 1,4-dichlorobenzenes (**1b,c**); for steric reasons, the reaction with 1,2 isomer **1a** gives 2-chloro(isopropylthio)benzene as the major product even in the presence of an excess of thiolate (Table 1).¹⁵

Table 1. Reactions of isomeric dichlorobenzenes **1a–c** with Pr^iSNa in HMPA at 80°C .¹⁵

Compound	Number of equiv. of Pr^iSNa	Reaction time/h	Products	Yield (%)
1,2- $\text{Cl}_2\text{C}_6\text{H}_4$ (1a)	1	0.5	2- $\text{ClC}_6\text{H}_4\text{SPr}^i$	92
	3	36	2- $\text{ClC}_6\text{H}_4\text{SPr}^i$, 1,2- $(\text{Pr}^i\text{S})_2\text{C}_6\text{H}_4$	68 11
1,3- $\text{Cl}_2\text{C}_6\text{H}_4$ (1b)	1	0.5	3- $\text{ClC}_6\text{H}_4\text{SPr}^i$	60
	3	36	1,3- $(\text{Pr}^i\text{S})_2\text{C}_6\text{H}_4$	5
1,4- $\text{Cl}_2\text{C}_6\text{H}_4$ (1c)	1	0.5	1,4- $(\text{Pr}^i\text{S})_2\text{C}_6\text{H}_4$	56
	3	4	4- $\text{ClC}_6\text{H}_4\text{SPr}^i$, 1,4- $(\text{Pr}^i\text{S})_2\text{C}_6\text{H}_4$	72 7
	3	4	1,4- $(\text{Pr}^i\text{S})_2\text{C}_6\text{H}_4$	96

Thiolate anions react also with highly chlorinated arenes.^{14,17} For example, the reactions of isomeric tri- and tetrachlorobenzenes with an excess of Pr^iSNa in HMPA at 100°C resulted in products of complete substitution of chlorine atoms in yields of up to 95%.¹⁹ The degree of substitution in the reaction with pentachlorobenzene (**2**) can be controlled by varying the temperature. At 0°C , three chlorine atoms are replaced to give compound **3**; at 100°C , five chlorine atoms are replaced to form compound **4**. It should be noted that the removal of the isopropyl groups in dichloroarene **3** with metallic sodium is accompanied by reduction of the $\text{C}–\text{Cl}$ bonds.

The product of the complete replacement of chlorine atoms in hexachlorobenzene (**5**) by Pr^iS groups is formed at room temperature.^{17,20} The increase in the reaction temperature to 100°C results in the elimination of one isopropyl group and the formation of pentakis(isopropylthio)benzenethiol. The reaction of $\text{C}_6(\text{SPr}^i)_6$ with metallic sodium is accompanied by the replacement of one sulfur-containing group by hydrogen.¹⁴

[†] Hereinafter, isomeric PCA have identical numbers but are denoted by different letters.

The reaction of hexachlorobenzene (**5**) with PhCH_2SNa produced hexakis(benzylthio)benzene, whose benzyl groups can be removed under the action of sodium in liquid ammonia.²¹

It should be noted that compounds $\text{C}_6(\text{SAlk})_6$ are produced by nucleophilic substitution only in the case of hexachlorobenzene (**5**). Attempts to obtain this type of compounds by the reactions of copper mercaptides with tetra-, penta- or hexabromobenzenes failed.^{17, 22}

Polychloroarenes were used as the starting compounds for the synthesis of fused heterocycles containing the 1,4-dithiane (**6**, **7**) or 1,3-dithiolane (**8**) fragments.²⁰ Two approaches to the synthesis of these products were developed. One approach is based on the substitution of isopropylthio groups for chlorine atoms in 1,2-dichlorobenzene (**1a**) and 1,3,5-trichlorobenzene (**9a**) followed by the transformation of the resulting compounds into the target heterocycles in six experimental steps. Compounds **6** and **7** are formed in low yields (12% and 8%, respectively, based on the starting chloroarenes).

(a) (1) Pr^iSNa , HMPA, 25 °C, 2 h; (2) Na, 100 °C, 2 h; (3) $\text{BrCH}_2\text{CO}_2\text{Et}$, 50 °C, 2 h; (b) (1) LiAlH_4 , THF; (2) SOCl_2 , PhH, 2 h; (3) MeSO_2SK , EtOH, 18 h; (c) AlCl_3 , MeNO_2 .

Another, more efficient, approach is based on the treatment of the *in situ* generated benzenehexathiolate with dibromoalkanes.²⁰ Reaction products **7** and **8** were synthesised in two steps in satisfactory yields.

The nucleophilic substitution of sulfur for the chlorine atoms was carried out also in other solvents, for example, in DMF,^{23–26} methanol,²⁷ *etc.* Not only alkali metal alkanethiolates, but less nucleophilic alkali metal arenethiolates were also used as the reagents. The reactions of 1,3- and 1,4-dichlorobenzenes (**1b,c**) with potassium benzenethiolate in DMF, dimethylacetamide (DMA), *N*-methylpyrrolidone (NMP), diglyme and ethylene glycol were investigated.^{28, 29} As a rule, both chlorine atoms are replaced in these reactions. The best results (high yields of products) were obtained in DMA and NMP, whereas the reactions in diglyme and ethylene glycol did not virtually take place. Such solvents as water and toluene were used primarily in combination with phase-transfer catalysts (see below).

The substitution of benzene-1,2-dithiolate for the chlorine atoms in 1,2,3,4-tetrachloro- (**10a**) and hexachlorobenzene (**5**) gave polycyclic dithianes **11** and **12**, respectively; however, their yields did not exceed 4%.²⁴

The reaction of 1,2,4,5-tetrachlorobenzene (**10b**) with an excess of $4\text{-ClC}_6\text{H}_4\text{SNa}$ in DMF at 120 °C affords only monosubstitution product **13** due apparently to the insufficiently high nucleophilicity of the 4-chlorobenzenethiolate anion.³⁰

Sodium benzenethiolates (prepared from benzenethiols and NaH) react with 1,2,4-trichlorobenzene (**9b**) in 1,2-dimethoxyethane to give the complete substitution product in 94% yield.³¹ Under these conditions, hexachlorobenzene (**5**) gave hexakis(phenylthio)benzene. 1,3-Dimethylimidazolidin-2-one (**14**) is a solvent of choice for such reactions. In this solvent, the reactions proceed even at room temperature to form hexakis(arylthio)benzenes in high yields.^{32, 33}

Ar = Ph (96%), 4-MeC₆H₄ (91%), 4-Bu^tC₆H₄ (76%), 4-BrC₆H₄ (48%), 2-naphthyl (72%).

Not only mononuclear PCA, but also compounds containing several aromatic rings, react with S-nucleophiles. In polychlorobiphenyls **15**, one chlorine atom at position 4 is generally replaced.²⁷

The substitution product of two chlorine atoms (at positions 4 and 4') was detected only in the case of symmetrical 2,2',4,4',5,5'-hexachlorobiphenyl.

In octachloronaphthalene (**16**), all chlorine atoms can be replaced by sulfur-containing groups in DMF at room temperature.³⁴

In addition to alkane- and arenethiolates, the reactions of PCA were carried out also with other sulfur-containing nucleophiles, including hydrogen sulfide, metal sulfides, isothiurea derivatives, heterocyclic thiones, dimethyl sulfoxide, carbon disulfide and dialkyl sulfides.^{30, 35–39} For example, the reaction of 1,3,5-trichlorobenzene (**9a**) with sodium hydrosulfide produced 3,5-dichlorobenzenethiol (**17**).³⁰

The reaction of 1,4-dichlorobenzene (**1c**) with Na_2S in NMP is of industrial significance as a procedure for the production of poly(1,4-phenylene sulfide). After the completion of the reaction in NMP, small amount of macrocyclic hexamer **18** was isolated from low-molecular-mass fractions.³⁹

The chlorine atoms at positions 1 and 8 in octachloronaphthalene (**16**) were replaced by the disulfide fragment upon refluxing with Na_2S_2 in ethanol.⁴⁰ Fusion of compound **16** with elemental sulfur at 310–320 °C under nitrogen allows the introduction of two disulfide bridges into the molecule.

Carbon disulfide can be used as the S-nucleophile.⁴¹ Oxidation of the reaction product, viz., 2,4-dichlorobenzenethiol (**17**), afforded the corresponding disulfide **19**. Analogously, the reaction of hexachlorobenzene (**5**) with the $\text{CS}_2\text{–Bu}^t\text{OK–DMSO}$ system at 110 °C produced pentachlorobenzenethiol in 72% yield.

The chlorine atom in chloroarenes is replaced by the sulfur atom also in the gas-phase reaction with hydrogen sulfide in a flow reactor at 500–700 °C.^{35, 36} The reaction afforded a complex mixture of products consisting mainly of benzenethiols and diaryl sulfides and was accompanied by the partial dehalogenation of arenes. 1,4-Dichlorobenzene (**1c**) reacts much more easily than chlorobenzene. The yields of 4-chlorobenzenethiol and bis(4-chlorophenyl) sulfide (**20**) are 15% and 56%, respectively. Under these conditions, the reaction of 1,2-dichlorobenzene (**1a**) gives 2-chlorobenzenethiol (30%) and thianthrene **21** (61%); the reaction of 1,2,4-trichlorobenzene (**9b**) produces dichlorobenzenethiol (15%–56%) and 2,7-dichlorothianthrene **22** (26%–45%).

Dialkyl sulfides and dialkyl disulfides can also serve as a source of sulfur at high temperature. 1,4-Dichlorobenzene (**1c**) reacts with diethyl disulfide to form a mixture of 4-chlorobenzenethiol (55%), bis(4-chlorophenyl) sulfide (16%), benzene (9%) and thiophene (14%).³⁸ Presumably, the reaction involves thermal decomposition of dialkyl disulfides accompanied by elimination of hydrogen sulfide, which reacts with PCA. Dialkyl disulfides are reagents of choice for the synthesis of benzenethiols, while hydrogen sulfide, for the synthesis of diaryl sulfides.^{35, 36, 38}

The replacement of chlorine atoms in PCA in the reaction with thiourea under electroreduction conditions in liquid ammonia ($-40\text{ }^{\circ}\text{C}$, with KBr or Bu'OK as the additives) was documented.⁴² The reaction afforded a mixture of sulfur-containing products, *viz.*, ArSH, ArSSAr and ArSAr. The ion-radical $\text{S}_{\text{RN}}1$ mechanism was proposed for this reaction.

Selenation reactions of PCA were less studied. For example, the reaction of PCA with lithium methaneselenolate produces aryl methyl selenides,⁴³ which readily undergo demethylation with an excess of methaneselenolate (analogously to methanethiolates). The resulting areneselenolates can be alkylated with alkyl iodides to give alkyl aryl selenides **23**.⁴⁴ Examples of such products are given in Table 2.

Table 2. Reactions of isomeric dichlorobenzenes **1a–c** with lithium methaneselenolate (4 equiv. MeSeLi, DMF, $120\text{ }^{\circ}\text{C}$) followed by alkylation with RI.⁴³

Compound	Time/h	R	Products 23	Yield (%)
1,2- $\text{C}_6\text{H}_4\text{Cl}_2$ (1a)	16	Me	2- $\text{ClC}_6\text{H}_4\text{SeMe}$	87
1,3- $\text{C}_6\text{H}_4\text{Cl}_2$ (1b)	8	Me	3- $\text{ClC}_6\text{H}_4\text{SeMe}$	86
1,4- $\text{C}_6\text{H}_4\text{Cl}_2$ (1c)	8	Me	4- $\text{ClC}_6\text{H}_4\text{SeMe}$	72
	8	Et	4- $\text{ClC}_6\text{H}_4\text{SeEt}$	81
	8	Pr ⁱ	4- $\text{ClC}_6\text{H}_4\text{SePr}^i$	76

The reaction of hexachlorobenzene (**5**) with sodium benzeneselenolate in HMPA proceeds at room temperature to give hexakis(phenylseleno)benzene.³²

The reaction of 1,2-dichlorobenzene (**1a**) with elemental selenium affords 9,10-diseleno-9,10-dihydroanthracene in moderate yield.⁴⁵

A heterocycle containing the diselenide bridge between positions 1 and 8 of the naphthalene fragment was synthesised by the fusion of perchloronaphthalene (**16**) with selenium at $335\text{--}340\text{ }^{\circ}\text{C}$ in an inert atmosphere.⁴⁰

2. Reactions of activated polychloroarenes with S-nucleophiles

The reactions of PCA containing electron-withdrawing groups in the *ortho* or *para* positions with respect to chlorine atoms generally proceed under milder conditions, in some cases, at room or reduced temperatures. Data on the formation of the reaction products of activated PCA, including compounds **24–29**, with S-nucleophiles are presented in Table 3.^{46–64}

3. Reactions of polychloroarenes with S-nucleophiles under conditions of phase-transfer catalysis

The reactions of PCA with S-nucleophiles can be promoted, in particular, by phase-transfer catalysts (PTC). Crown ethers, ammonium salts and phosphonium salts were used as PTC.^{65,66} Under these conditions, it became possible to perform the reaction of 1,2,4,5-tetrachlorobenzene (**10b**) with an alkanethiol–KOH system in toluene, which does not proceed in the absence of catalysts (Table 4).⁶⁷ The reaction produces 1,4-dialkylthio-2,5-dichlorobenzenes (**30a,b**). The highest yield of the products was achieved with the use of dodecyltricyclohexylphosphonium bromide as the catalyst. The reactions of 1,3,5- and 1,2,4-trichlorobenzenes (**9a,b**) with alkanethiols in the presence of PTC proceed at higher temperatures.

R = $n\text{-C}_7\text{H}_{15}$ (**a**), $n\text{-C}_{12}\text{H}_{25}$ (**b**).

The reactions of dichlorobenzenes require even more drastic conditions ($110\text{ }^{\circ}\text{C}$).⁶⁸ The reactivity of the compounds decreases in the following sequence: 1,2 isomer (**1a**) > 1,3 isomer (**1b**) > 1,4 isomer (**1c**); the reactivity of nucleophiles decreases in the following sequence: primary thiols > tertiary thiols > benzenethiols (Table 5).

The reactions of sodium methanethiolate with dichloro- and trichlorobenzenes in the presence of tetrabutylphosphonium bromide resulted in the replacement of one chlorine atom to yield (methylthio)chlorobenzenes. The latter were transformed into the corresponding disulfides by demethylation and oxidation, for example, as shown below:⁶⁵

3-Chloro-2-(isopropylthio)nitrobenzene was obtained in quantitative yield by the reaction of 2,3-dichloronitrobenzene (**24a**) with the PrⁱSH–KOH system in water in the presence of PTC (the quaternary ammonium salt Adogen 464).⁶⁹

The Bu₄NBr-catalysed reaction of 2,4-dichloro-5-methylacetophenone with *S*-prenylisothiourea allowed the introduction of the prenylthio group into the aromatic nucleus.⁷⁰

III. Reactions with N-nucleophiles

Since amines are much less reactive than S-nucleophiles, the reactions of the former with PCA are performed under more drastic conditions or in the presence of catalysts. In some cases, metal amides are used as aminating agents.

1. Amination of non-activated polychloroarenes

The reaction of 1,4-dichlorobenzene (**1c**) with lithium diisopropylamide at -78°C affords a mixture of isomeric amination products,⁷¹ with 3-chloro-*N,N*-diisopropylaniline predominating. This can be attributed to the fact that the reaction proceeds *via* 4-chlorobenzene.

The reaction of an excess of 1,2-dichlorobenzene (**1a**) with diphenylamine and KOH in the presence of polyethylene glycol dimethyl ether at $160-165^{\circ}\text{C}$ produced *N*-(3-chlorophenyl)-*N,N*-diphenylamine in 53% yield,⁷² which is also evidence for the intermediate formation of 3-chlorobenzene. The reaction of 1,3,5-trichlorobenzene (**9a**) with hydrazine hydrate at $180-200^{\circ}\text{C}$ in pyridine produced 3,5-dichlorophenylhydrazine in 60%–82% yield.⁷³

1,2,4,5-Tetrachlorobenzene (**10b**) reacts with a strong reducing agent, Me₂NCH₂ONa, which is prepared from NaBH₄ and DMF in the presence of Cp₂TiCl₂ (Cp = η -C₅H₅). The complete conversion of the starting compound (GLC data) affords 2,4,5-trichloro-*N,N*-dimethylaniline along with the reduction product.⁷⁴

In the reaction of piperidine with decachlorobiphenyl (**31**), one or two chlorine atoms are replaced.⁷⁵ The degree of conversion depends on the reaction conditions. Thus the monosubstitution at position 4 is achieved upon refluxing in DMF, whereas prolonged heating with an excess of piperidine in an autoclave gives the 4,4'-disubstituted product.

2. Substituent effect on the reactivity and regioselectivity of amination of polychloroarenes

The reactivity of PCA and the pathway of amination depend on the nature and position of the substituent. For example, 2,6-dichlorobenzonitrile (**28a**) reacts with ethylenediamine at 120°C resulting in the replacement of one chlorine atom.⁷⁶ The reaction was performed in the presence of catalytic amounts of P_2S_5 to ensure the attack of ethylenediamine at the nitrile group with the aim of providing the route to the corresponding imidazolidine; however, the electrophilicity of the aromatic C—Cl fragment proved to be higher.

The reaction of perchloroisophthalonitrile (**32**) with ammonia proceeds under milder conditions⁷⁷ to give 3,5,6-trichloro-2,4-dicyanoaniline. In the reaction of compound **32** with an oligopeptide, it is the amino group of the lysine fragment that is involved in the replacement.⁷⁸

In the reactions of dichlorobenzoic acid derivatives **33** and **34a** with amines, one chlorine atom in the *ortho* position with respect to the carboxy group is replaced.^{79–82}

The reactions of polychlorobenzoic esters or amides with amines and hydrazines proceed analogously.⁸² For example, methyl 2,6-dichloro-3-nitrobenzoate reacts with 1 equiv. of alkylamine or hydrazine in aqueous ethanol resulting in the replacement of the chlorine atom at position 2 (82%–97% yields). In the presence of an excess of amine, both chlorine atoms are replaced to give the corresponding products in virtually quantitative yield. In the reactions of 3-aminosulfonyl-2,6-dichlorobenzamides **35** with alkyl- and benzylamines in EtOH, also one or two chlorine atoms are replaced depending on the conditions; in dioxane, the major products result from the replacement of the chlorine atom at position 2.⁸³

R^1	R^2	Yield (%)
H	Bn	62
	Bu ⁿ	86
2-MeC ₆ H ₄	Bn	67
	Bu ⁿ	82
Ph(CH ₂) ₂	EtO(CH ₂) ₂	88

The nitro group is a good activating substituent in the nucleophilic substitution reactions involving PCA.^{84–93} In 2,4-dichloronitrobenzene derivatives **24b**, **25a** and **36**, the chlorine atom in the *ortho* position with respect to the nitro group is replaced.^{85, 86, 88}

$\text{R}^1 = \text{H}$ (**24b**), Me (**36**), Cl (**25a**);
 $\text{R}^2\text{R}^3\text{N} = \text{AlkNH}$, NH_2 , $\text{N}(\text{CH}_2)_4$, N (morpholine).

In the reaction of 3,4,5-trichloronitrobenzene (**25b**) with a heterocyclic amine, the replacement occurs primarily at the chlorine atom in the *para* position with respect to the nitro group.⁹⁴

The reactions of PCA with amines proceed more rapidly at high pressure (0.6–1.0 GPa).⁹⁵ For example, 2,3,5,6-tetrachloronitrobenzene reacts with primary amines under these conditions to form the substitution product of the nitro group; in the reactions with secondary amines, the chlorine atom in the *ortho* position with respect to the nitro group is replaced. In some cases, the reactions afford mixtures of isomeric mono- and diamines. The reactions with diamines produce annelated compounds.

Polychloroarenes containing two nitro groups react at substantially lower temperatures. For example, ammonolysis of 2,4,6-trichloro-1,3-dinitrobenzene (**37**) proceeds at 48 °C and results in the replacement of two chlorine atoms.⁹⁶

In the reactions of 1,2,3,4-tetrachlorodinitrobenzene (**38**) with amines, not only chlorine atoms, but also nitro groups are replaced.⁹⁷ As a rule, primary amines replace one of the nitro groups, whereas secondary amines replace the chlorine atom in the *ortho* position with respect to the nitro group. High yields of the substitution products were achieved in the reactions performed in the two-phase toluene–water system in the presence of tetraalkylammonium salts (for example, Aliquat 336).

Trichlorotrinitrobenzene **39** reacts with hydrazine derivatives at room temperature.⁹⁸ The reaction with acetylhydrazine affords a mixture of monosubstitution products. The reaction with unsubstituted hydrazine is accompanied by dehalogenation and denitration.

The trifluoromethyl group having a strong $-I$ effect also facilitates the replacement of the chlorine atom in PCA. However, its activating effect is weaker than the effect of $-M$ groups. The reactions of trifluoromethyl derivatives of PCA **40a**, **41** and **42a** with amines proceed, as a rule, only at high temperature.^{99–104}

X = H (**40a**), Cl (**41**), NO₂ (**42a**).

Due to the simultaneous presence of the CF₃ and NO₂ groups in chloroarenes **42b** and **43**, the reactions can be performed under milder conditions.^{105, 106}

The relative reactivity of chlorine atoms in PCA depends not only on the activating substituents, but also on the polarisability of the nucleophile.¹⁰⁷ For example, 2,4,6-trichloro-3,5-bis(trifluoromethylsulfonyl)nitrobenzene reacts with sodium azide (a soft nucleophile) in methanol at -80 °C to form a mixture of substitution products. However, harder nucleophiles, such as piperidine and 4-acetylaminobenzene, selectively replace one chlorine atom in the *ortho* position with respect to the nitro group.

3. Catalytic amination of polychloroarenes

Copper salts and oxides catalyse amination of non-activated PCA. The reactions of 1,3-dichloro-substituted tetrafluoro- and 2,4,6-trifluorobenzenes with aqueous ammonia in the presence of CuCl in an autoclave at 140 °C were found to proceed non-selectively to give mixtures of amination and hydrodechlorination products.¹⁰⁸ The reactions of 1,2- and 1,4-dichlorobenzenes (**1a,c**) with ammonia in the presence of copper oxide at 180–240 °C produce the corresponding phenylenediamines.¹⁰⁹

Ultradispersed (nanosized) copper, which is formed *in situ* by the reaction of tris(3,6-dioxaheptyl)amine (TDA-1) with copper salts, proved to be an efficient catalyst for the reaction of *N*-(3-pyridyl)acetamide with dichlorobenzenes **1a,b**.¹¹⁰ The solvent-free reaction was carried out by refluxing the reactants with azeotropic distillation of water.

In some cases, it is reasonable to perform the amination of PCA bearing electron-withdrawing substituents in the presence of copper or its salts as the catalyst. For example, 2,4-dichlorobenzoic acid (**27a**) and its amide (**44**) react with amines in the presence of copper or its salts resulting in the replacement of the *ortho*-chlorine atom with respect to the electron-withdrawing group.^{111–119}

R = H (55%), 4-FC₆H₄ (80%).

In the reaction of valine methyl ester with 3,4-dichloro(trifluoromethyl)benzene (**40a**) catalysed by Cu(I) salts using sonication, the chlorine atom in the *para* position with respect to the CF₃ group is replaced to give the corresponding substitution product in high yield.¹²⁰ Without sonication, the yield is as low as 10%.

4-Aminobenzoic acid in which the nucleophilicity of the amino group is lower than that in aniline reacts with 2,4-dichloro-5-nitrobenzoic acid (**34b**) in boiling DMF in the presence of copper powder to give 2-(4-carboxyanilino)-4-chloro-5-nitrobenzoic acid.¹²¹

Nickel complexes with the 1,1'-bis(diphenylphosphino)ferrocene (dppf), 1,10-phenanthroline (phen) and 2,2'-bipyridyl (bipy) ligands were examined as catalysts for amination of PCA.¹²² Under these conditions, 1-methylpiperazine reacts with 1,3- and 1,4-dichlorobenzenes (**1b,c**), resulting in the replacement of only one chlorine atom.

Amination of PCA (for example, of compounds **9a** and **45a**) with benzophenone imine can be performed with the use of the catalytic Pd₂(dba)₃–dppf system (dba is dibenzylideneacetone).¹²³ After hydrolysis in the final step, the corresponding aniline derivatives are obtained in good yields.

Cross-coupling of 1,2,4,5-tetrachlorobenzene (**10b**) with primary and secondary amines in the presence of Pd(OAc)₂ and ligand **46** according to a developed procedure¹²⁴ afford compounds **47** as a result of the replacement of one chlorine atom.^{125, 126} The reaction is accompanied by reductive dechlorination to dichloroaniline derivatives **48**. Hexachlorobenzene (**5**) does not react with amines under the above-mentioned conditions.

R¹R²N	Yield (%)	
	47	48
(CH₂)₄N	26	10
O(CH₂CH₂)₂N	25	41
BuⁱNH	72	4

Amination of chloroarenes with *trans*-di(μ -acetato)bis{2-[di(*tert*-butyl)phosphino]-2-methylpropyl-C,P}dipalladium (which was prepared by heating Pd(OAc)₂ with Bu₃P in toluene) was covered by the patent.¹²⁷ This method was used for the synthesis of *N*-(4-chlorophenyl)piperidine (59% yield) and 1,4-bis(dibutylamino)benzene (77% yield) by the reactions of 1,4-dichlorobenzene (**1c**) with piperidine or dibutylamine, respectively.

Cross-coupling of 1-bromo-2,6-dichlorobenzene (**49**) with polyamines **50** catalysed by the Pd(dba)₂–BINAP system [BINAP is 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl] proceeds slowly.¹²⁸ However, cyclisation products **51** were prepared by refluxing the reactants in dioxane over a long period of time (50–70 h), the yields being dependent on the length and conformational flexibility of the polyamine chain. The structures of linear by-products **52** provide evidence that the bromine atom is replaced in the first step of the reaction. No cyclisation products are formed in the reaction with the diamino ether H₂N(CH₂CH₂O)₂CH₂CH₂NH₂.

<i>k</i>	<i>m</i>	<i>n</i>	<i>x</i>	Yield (%)

The results of studies on the reactions of mono- and polynuclear chloroarenes in the presence of catalytic systems

containing a source of palladium combined with BINAP,^{129–131} 1-diphenylphosphino-2-(1-methoxyethyl)ferrocene¹³² or tri(*tert*-butyl)phosphine¹³³ may be useful for performing the C–N cross-coupling reactions of PCA.

IV. Reactions with O-nucleophiles

Chlorine atoms in PCA can be replaced by O-nucleophiles to form phenols or their ethers.

1. Reactivity of polychloroarenes towards O-nucleophiles in the presence of bases

Isomeric dichlorobenzenes react with NaOMe in HMPA to form the corresponding chloroanisoles.¹³⁴ In the reactions of 2,6-dichlorotoluene (**45a**) with potassium or sodium methoxides in aprotic solvents, one chlorine atom is replaced.^{135–138} The reaction rate can be increased by addition of copper compounds; however, the resulting aryl methyl ether undergoes partial demethylation.

The reaction of 2,4-dichlorotoluene (**45b**) with KOH in methanol at 200 °C and 30 atm produced 5-chloro-2-methylphenol.¹³⁹ At lower pressure (12 atm), the product was obtained in substantially lower yield (12%).

3-Aminophenol reacts with 1,3,5-trichlorobenzene (**9a**) as the O-nucleophile to give diether **53**.¹⁴⁰ In this reaction, K₂CO₃ or NaOMe was used as the base (B) and HMPA or NMP as the solvent.

The reactions of 1,3,5- (**9a**) and 1,2,4-trichlorobenzenes (**9b**) with BuⁱOK in HMPA¹⁴¹ resulted in the replacement of one chlorine atom to give the corresponding substitution products in low yields. In the case of isomer **9b**, the initially formed ether undergoes dealkylation to give 2,5-dichlorophenol.

Unlike compounds **9a,b**, 1,2,3,5-tetrachlorobenzene (**10c**) undergoes disproportionation under these conditions to form a mixture of 1,2,4,5-tetrachlorobenzene (**10b**), pentachlorobenzene (**2**) and isomeric trichlorobenzenes.¹⁴¹

Hexachlorobenzene (**5**) reacts with potassium *tert*-butoxide in THF¹⁴² or with the $Pr^iOH-NaOH$ system¹⁴³ to give the corresponding alkyl pentachlorophenyl ethers in 67% and 92% yields, respectively. The reaction of decachlorobiphenyl (**31**) with KOH in aqueous methanol (autoclave, 180 °C) or in boiling ethylene glycol produces 4,4'-dihydroxyoctachlorobiphenyl in quantitative yield.¹⁴⁴ In the reaction of decachlorobiphenyl (**31**) with sodium methoxide in a $MeOH$ –pyridine mixture (PyH), one or two chlorine atoms at positions 4 and 4' are replaced depending on the amount of the nucleophile.⁷⁵

The reactions of octachloronaphthalene (**16**) with alkali metal hydroxides and alkoxides were investigated.^{142, 145} Although the reaction conditions are substantially different, it should be noted that the attack of the alkoxide ion occurs predominantly on position 1 of the naphthalene ring; the attack of the hydroxide ion, on position 2. These reactions produce compounds **54a** and **54b**, respectively (Table 6).

Table 6. Reactions of octachloronaphthalene (**16**) with alkali metal derivatives.^{142, 145}

R	Reagent	Solvent	Temperature / °C	Yield (%)	54a : 54b
Me	MeONa	pyridine	115	25 ^a	90 : 10
Me	MeOH, NaOH		~ 100	63	99 : 1
Bu ^t	Bu ^t OK	THF	20	82	85 : 15
H	KOH	DMSO	120	90	30 : 70

^a Disubstituted (25% yield) and trisubstituted (20%) products were also isolated.

Polychlorinated *o*-hydroxylated diphenyl oxides were synthesised by the reactions of polychlorobenzenes with (poly)chloroguaiaacols **55** in the K_2CO_3 –DMF system followed by demethylation of the substitution products with boron tribromide.¹⁴⁶

$m = 0-4; n = 2-5$.

As mentioned above, the presence of an electron-withdrawing substituent in the aromatic ring increases the reactivity of PCA, due to which the reactions with O-nucleophiles can be performed under milder conditions. In these reactions, it is the chlorine atom in the *ortho* position with respect to the electron-withdrawing group that, as a rule, undergoes replacement. For example, the reaction of 2,4-dichlorobenzoic acid (**27a**) with chlorophenols in pyridine in the presence of K_2CO_3 afforded *ortho*-substitution products (in approximately 70% yields).¹⁴⁷ In the reactions of 2,4- (**24b**) and 2,6-dichloronitrobenzenes (**24d**) with hydroxythiophene derivatives in DMSO at 100 °C, the chlorine atom in the *ortho* position with respect to the nitro group is replaced to give the products in 57% and 84% yields, respectively.¹⁴⁸

24b: X = Cl, Y = H;
24d: X = H, Y = Cl

The reactions of 2,5-dichloronitrobenzene (**24c**) with substituted phenols,^{149, 150} including the microwave (MW)-promoted reactions, are characterised by analogous regioselectivity.¹⁵¹

In the reactions of 3,4-dichloronitrobenzene (**24e**)^{152, 153} and 3,4-dichloro-1-trifluoromethylbenzene (**40a**)¹⁵⁴ containing no chlorine atoms in the *ortho* position with respect to the electron-withdrawing group, the attack of O-nucleophiles occurs on the *para* position; for example:

The *para* position in the aromatic ring is more active in hydrolysis of 1-substituted 3,4-dichlorobenzenes. For example, hydrolysis of 3,4-dichloronitrobenzene (**24e**) (15% NaOH in MeOH, 72 °C) affords 2-chloro-4-nitrophenol with the regioselectivity of >99%.¹⁵⁵ The reaction of 3,4-dichlorotrifluoromethylbenzene (**40a**) with the Bu^tOH–KOH system in DMSO at 75 °C produces 2-chloro-4-trifluoromethylphenol in 27% yield.¹⁵⁶ Interestingly, the hydroxy group replaces the Cl atom in the *meta* position with respect to the nitro group in 2,5-dichloronitrobenzene (**24c**) upon hydrolysis of the latter with aqueous NaOH.¹⁵⁷

The reactions of dichloronitrobenzenes **24** with sodium 2,2,2-trifluoroethoxide proceed under more drastic conditions (in DMF or HMPA at 150 °C under N₂).¹⁵⁸ The reactivity of the chlorine atoms increases in the following sequence: *ortho* position > *para* position > *meta* position. For example, under these reaction conditions, the chlorine atom in the *ortho* position with respect to the nitro group is replaced in 2,3- and 2,5-dichloronitrobenzenes (**24a,c**), the reaction of 2,4 isomer **24b** affords a mixture of the *ortho*- and *para*-substituted products in a ratio of 3 : 1, and 3,4 isomer **24e** gives the *para*-substituted product.

The reactions of sodium 2,2,2-trifluoroethoxide with dichlorobenzonitriles proceed analogously to form products in higher yields.

The reactions of trichloroarenes containing electron-withdrawing substituents proceed analogously. For example, the replacement of the chlorine atom in sulfone **56** in the reaction with sodium 2-methoxyethoxide also occurs at the *ortho* position.^{159, 160}

The reactions of dichlorobenzenes containing two or more electron-withdrawing groups with O-nucleophiles were documented.^{161, 162} The product of the replacement at the *para* position with respect to the trifluoromethyl group was prepared in 75% yield by refluxing 3,4-dichloro-2-nitro-6-trifluoromethylbenzene (**42c**) with 3-hydroxybenzoate in acetone in the presence of potassium carbonate. In the reaction of 2,4-dichloro-3,5-dinitrotrifluoromethylbenzene (**43**) with ethyl 3-hydroxybenzoate in acetone at room temperature, the chlorine atom at position 4 is also replaced,¹⁶¹ and the subsequent nitration affords ethyl 5-(3-chloro-2,6-dinitro-4-trifluoromethylphenoxy)-2-nitrobenzoate in a total yield of 83%. 2,6-Dichloro-4-trifluoromethylbenzonitrile (**57**) reacts with HOCH₂CH₂CN and NaCN in acetonitrile at room temperature. In this case, acrylonitrile is eliminated from the initially formed β-cyanoethyl ether to give the corresponding phenol.¹⁶²

Three chlorine atoms are replaced in perchloroisophthalonitrile (**32**) by refluxing it in alcoholic solutions of KOH.¹⁶³

R = Me (79% yield), Et (58%).

Due to high electrophilicity, the chlorine atom at position 2 in 2,4,6-trichloro-1-nitro-3,5-bis(trifluoromethylsulfonyl)benzene (**58**) is replaced by the hydroxy group upon refluxing in methanol even in the absence of bases (apparently, due to the presence of water in methanol).¹⁰⁷ In the reaction of compound

58 with sodium phenoxide in acetonitrile, it is the chlorine atom at position 4 that is replaced.

2. Reactions of polychloroarenes with O-nucleophiles in the presence of catalysts

In some cases, the reactions of PCA with O-nucleophiles are notably promoted by phase-transfer catalysts, metal complex catalysts or enzymes. Let us consider several reactions performed in the presence of phase-transfer catalysts. The reaction of 1,2-dichlorobenzene (**1a**) with the KOH–MeOH system in the presence of 18-crown-6 at 0 °C afforded 2-chloroanisole in 60% yield.¹⁶⁴ 2,4-Dichlorotoluene (**45b**) reacts with KOH in ethylene glycol at 200 °C and 30 atm in the presence of dibenzo-18-crown-6 to give 5-chloro-2-methylphenol in 78% yield.¹³⁹ The reaction of 1,2,3-trichlorobenzene (**9c**) with methanolic KOH at 140 °C in the presence of TDA-1 as the PTC affords a mixture of dichloroanisoles in a total yield of 97%;¹⁶⁴ in the absence of PTC, the yields of the products decrease to 8%.

Hydrolysis of 1,2,4-trichlorobenzene (**9b**) with methanolic NaOH in the presence of poly(ethylene glycol) (PEG 600–800) gives 2,5-dichlorophenol.¹⁶⁵

The replacement of the chlorine atom mainly in the *ortho* position with respect to an electron-withdrawing group is observed also in catalytic reactions. 2,3,4-Trichloronitrobenzene (**25c**) reacts with KOH in DMSO in the presence of tetramethylammonium chloride at 150 °C in an autoclave to form 2,3-dichloro-6-nitrophenol.¹⁶⁶

In addition to PTC, the C–O bond formation in the reactions of PCA is promoted by transition metal compounds. For example, 2,6-dichlorotoluene (**45a**), which is poorly reactive in the absence of catalysts, reacts with sodium *tert*-butoxide in toluene in the presence of the Pd(OAc)₂–Bu₃P system¹⁶⁷ to form 2-(*tert*-butoxy)-6-chlorotoluene. In this reaction, the homodimerisation product of PCA and

2,6-bis(*tert*-butoxy)toluene were isolated as the by-products. The use of the PCy₃ and dppf ligands combined with a palladium salt proved to be less efficient.

Copper compounds are used as catalysts for the C–O cross-coupling involving dichlorobenzenes with electron-withdrawing groups. For example, the reaction of 2,5-dichloroacetophenone (**29a**) with 2,4-dichlorophenol in the presence of CuO resulted in the replacement of the chlorine atom in the *ortho* position of the benzene ring of ketone.¹⁶⁸ In the absence of catalysts (heating of compound **29a** with KOH in xylene), the yield of the product decreases to 82%.¹⁶⁹

In the reactions of 2,5-dichlorobenzoic acid with 3- and 4-chlorophenols (Cu, CuI, NaOMe, MeOH, 200 °C), the chlorine atom at position 2 was replaced to give the products in 78%–82% yield.¹⁷⁰

Enzymatic dimerisation of dichlorotyrosine (**59**) catalysed by horseradish peroxidase (HRP) formally proceeds as the nucleophilic substitution of one chlorine atom to yield an isodityrosine derivative.^{171–173}

V. Reactions with F-nucleophiles

A convenient procedure for the synthesis of fluorine-containing aromatic compounds is based on the replacement of chlorine atoms in PCA under the action of metal fluorides. Considerable data on fluorodechlorination reactions of arenes were covered by patents, which is evidence that this approach is of practical importance. Data on this problem were summarised in the review¹⁷⁴ and monographs.^{175, 176}

1. Reactivity of polychloroarenes in fluorodechlorination

The fact that it is possible, in principle, to transform PCA into polyfluoroarenes was demonstrated for the first time in 1947.¹⁷⁷ The reaction of hexachlorobenzene (**5**) with BrF_3 followed by the successive treatment of the resulting mixture of perhalocyclohexanes $\text{C}_6\text{Br}_2\text{Cl}_4\text{F}_6$ with SbF_5 and zinc dust produced a mixture of chlorofluorobenzenes $\text{C}_6\text{Cl}_n\text{F}_{6-n}$ ($n = 0-6$). Individual reaction products, including hexafluorobenzene (**60**, ~10% yield), were isolated by rectification.

Later, available alkali and alkaline-earth fluorides have been used as fluorination agents. The reactions of non-activated PCA, for example, of 1,3,5-trichlorobenzene (**9a**), with metal fluorides are performed in polar aprotic solvents (sulfolane, DMF, *etc.*) under rather drastic conditions.^{178, 179} The necessity of using high temperatures is determined by low solubility of inorganic fluorides in organic solvents and their ability to form stable weakly nucleophilic hydrates.

The reaction of hexachlorobenzene (**5**) with KF in an autoclave at 460–470 °C for 20 h and then at 490–510 °C for 10 h produced a mixture containing hexafluorobenzene (**60**) and chloropentafluorobenzene (**61**).^{180, 181} At lower temperatures (400–480 °C, 19–35 h), the yield of hexafluorobenzene (**60**) was at most 6%.¹⁸² In the presence of water vapour,¹⁸³ fluorodechlorination is accompanied by the replacement of one chlorine atom with hydrogen to form a large set of polyhalobenzenes, including compounds **60–63** (Scheme 1).

Heating of octachloronaphthalene (**16**) with KF in an autoclave (300–330 °C, 25 h) gave a mixture of products, from which octafluoronaphthalene (24%) was isolated by rectification.¹⁸⁴ According to the data of another study,¹⁸⁵ this reaction at 400 °C, even in the presence of a tenfold excess of KF, afforded heptachloro-1-fluoronaphthalene (**64**) as the major product.

The increase in the temperature to 420 °C resulted in the formation of a mixture of higher fluorodechlorinated products from which 1- and 2-chloro-substituted heptafluoronaphtha-

lenes were isolated in 14.5% and 9.5% yields, respectively. The reaction of octachloride **16** in sulfolane affords a mixture of fluorodechlorination products containing from 1 to 4 fluorine atoms.¹⁸⁶ Individual 2,4,5,7-tetrachloro-1,3,6,8-tetrafluoronaphthalene (**65**) was isolated from the mixture by sublimation.

Polychloroarenes containing additional electron-withdrawing substituents in the aromatic nucleus are more reactive in fluorodechlorination compared to polychlorobenzenes, the reaction often being regioselective. For example, fluorodechlorination of *o*-dichlorobenzenes **24e** and **40a** containing electron-withdrawing groups at position 1 gives 4-fluoro derivatives.^{187–189} The reactions with KF are carried out in aprotic solvents (DMSO, DMF, NMP, sulfolane or DMAA) at 190–250 °C; the products are formed in yields of up to 90%.

EWG = NO_2 (**24e**), CF_3 (**40a**).

The chlorine atom in the *ortho* position with respect to the electron-withdrawing substituent is, as a rule, replaced in 1-nitro-substituted chlorobenzenes **24a**^{190–192} and **25c**.¹⁹³ However, it has been possible to replace the chlorine atoms in the *ortho* and *para* positions by refluxing compound **25c** in DMF in the presence of a mixture of KF and KCl.¹⁹⁴

The cyano group serves as a good activating substituent in polychloroarenes. For example, fluorodechlorination of pentachlorobenzonitrile with KF at 350 °C in an autoclave results in pentafluorobenzonitrile in 70% yield.¹⁹⁵ An analogous

Scheme 1

reaction of tetrachlorophthalonitrile proceeds at 300 °C (the yield of the tetrafluoro derivative is 74%).¹⁹⁶ The reaction of 2,3,4,5-tetrachlorobenzonitrile with KF in sulfolane affords a mixture of fluorodechlorination products, including 2,3,4,5-tetrafluorobenzonitrile.¹⁹⁷ The reaction of tetrachloroisophthalonitrile (**32**) with KF in DMF resulted in the replacement of three chlorine atoms in the *ortho* positions with respect to the cyano groups.^{198–201} All four chlorine atoms in compound **32** can be replaced by performing the reaction in sulfolane.²⁰²

It should be noted that the reaction of 2,4-dichloro-5-fluorobenzoyl fluoride with KF in aprotic solvents gives 2,4,5-trifluorobenzoyl fluoride as the major product.²⁰³

In spite of drastic conditions, PCA containing the labile aldehyde group undergo fluorodechlorination. For example, the reaction of 2,6-dichlorobenzaldehyde (**26c**) with KF in sulfolane at 180 °C affords 2,6-difluorobenzaldehyde in good yield, while the monofluoro derivative is formed as a by-product.¹⁷⁹

2. The means for activation of fluorodechlorination

The use of PTC (quaternary ammonium or phosphonium salts) facilitating the transfer of fluoride anions to an organic phase is one of ways of promoting fluorodechlorination of PCA.²⁰⁴ The use of salts of HF with organic bases, for example, $\text{Ph}_4\text{P}^+(\text{HF}_3)^-$,²⁰⁵ or fluorides with organic cations, such as Me_4NF , as fluorination agents was documented.²⁰⁶

Fluorodechlorination of hexachlorobenzene (**5**) with KF supported on CaF_2 or BaF_2 in the presence of $(\text{Et}_2\text{N})_4\text{PBr}$ as the catalyst at 230 °C in an autoclave affords a mixture of arenes C_6ClF_5 (**61**, 25% yield), $\text{C}_6\text{Cl}_2\text{F}_4$ (**45**) and $\text{C}_6\text{Cl}_3\text{F}_3$ (**62**, 30%).²⁰⁷ Under the above-mentioned conditions, no reaction proceeds in the absence of catalysts. Hexaethylguanidium chloride in combination with crown ethers, diglyme or tetraglyme can be used as PTCs.²⁰⁸ The reaction of hexachlorobenzene (**5**) in the presence of this catalytic system gave a mixture of isomeric products, resulting from the substitution of four chlorine atoms, 1,2,3,5-tetrafluoro derivative **66** being the major product (> 90%).

The inhibition of the subsequent fluorodechlorination of compound **66** is, apparently, attributed to an increase in the concentration of chloride ions with rather high nucleophilicity. The suggestion that the fluorodechlorination is reversible was confirmed in the study,²⁰⁹ where the possibility of transforming $\text{C}_6\text{Cl}_2\text{F}_4$ into trichlorotrifluorobenzene was demonstrated.

The 18-crown-6-catalysed fluorodechlorination of binuclear PCA **16** and **31** with CsF under mild conditions (MeCN , 80 °C)²¹⁰ allows the selective introduction of one fluorine atom at positions 1 and 4, respectively.

Phase-transfer catalysts are successfully used for fluorodechlorination of PCA containing additional electron-withdrawing substituents. In these reactions, the chlorine atoms in the *ortho* and *para* positions with respect to these substituents are generally replaced. For example, the reaction of 2,3-dichloronitrobenzene (**24a**) with KF in xylene in the presence of trimethyl(ethoxypolyoxypropyl)ammonium chloride produced 3-chloro-2-fluoronitrobenzene in 72% yield.²¹¹ Under these conditions, both chlorine atoms are replaced in 2,6-dichlorobenzonitrile (**28a**)²¹² and 2,4-dichloronitrobenzene (**24b**).²¹³ The fluorodechlorination of 2,5-dichloronitrobenzene (**24c**) in the presence of trimethylcetylammmonium bromide at 140–150 °C affords product **67**.^{214, 215} The nitro group is also replaced in the reaction with the use of Ph_4PBr as the PTC.²¹⁶

The reaction of 2,4-dichloro-5-fluorobenzonitrile (**68a**) with KF supported on CaF_2 in the presence of BnEt_3NCl produces a mixture of 2,4,5-trifluoro- and 2-chloro-4,5-difluorobenzonitriles in a total yield of 82%.^{198, 217}

Fluorodechlorination of 3,4-dichlorobenzonitrile (**28b**) with KF in DMSO in the presence of PTCs of the iminium series, such as $(R_2^1N)_2C=N^+=C(NR_2^2)_2Hal^-$, $(R_2^1N)_2C=N^+=P(NR_2^2)_3Hal^-$ or $(R_2^1N)_3P=N^+=P(NR_2^2)_3Hal^-$ ($R^1, R^2 = Alk$), occurs exclusively at position 4 (the yield of the product is 81%–92%).²¹⁸ Polychloroarenes containing chlorine atoms in the *meta* position with respect to an electron-withdrawing substituent are much less reactive. For example, only one chlorine atom is replaced in 3,5-dichloro-4-fluorobenzonitrile (**68b**) or 3,5-dichloro-4-fluoro-1-trifluoromethylbenzene in the reaction with KF in sulfolane in the presence of PTC.²¹⁹

Fluorodechlorination of PCA is promoted by sonication.^{187, 220} For example, the reaction of 3,4-dichloronitrobenzene (**24e**) with KF and *N*-(2-ethylhexyl)-4-(*N,N*-dimethylamino)pyridinium bromide on polystyrene in DMSO promoted by sonication produced 3-chloro-4-fluoronitrobenzene in 95% yield.²²⁰

VI. Reactions with C-nucleophiles

1. Cyanation reactions

The reactions of PCA with copper cyanide produce the corresponding chlorobenzonitriles generally in low yields. For example, the yield of pentachlorobenzonitrile in the reaction of hexachlorobenzene (**5**) with CuCN was only 4%.²²¹ 3,5-Dichloro-2,4,6-trifluorobenzamide and 3,5-dichloro-2,6-difluoro-4-dimethylaminobenzonitrile were synthesised by the reaction of 2,4,6-trichloro-1,3,5-trifluorobenzene (**62**) with CuCN in pyridine and DMF, respectively.²²²

In 5-aminosulfonyl-2,4-dichlorobenzoic acid (**33**), the chlorine atom at position 2 is replaced upon heating with CuCN in DMF to give the derivative of phthalic acid mononitrile.²²³

2,3,4-Trichloronitrobenzene (**25c**) is transformed into 5,6-dichloro-2-nitrobenzonitrile in the reaction with CuCN in the presence of 1 equiv. of DMF.²²⁴

The yield of the cyanation product can be increased in the presence of transition metal complexes as catalysts. For example, the reaction of 1,4-dichlorobenzene (**1c**) with KCN catalysed by Pd or Ni complexes at 100–250 °C produces terephthalonitrile in 87% yield.²²⁵

2. Reactions of polychloroarenes with carbanions

Polychloroarenes activated by the nitro group readily react with anions of CH acids (malonic and cyanoacetic esters, *etc.*) on heating in aprotic solvents. As a rule, it is the halogen atom in the *ortho* position with respect to an electron-withdrawing substituent that is replaced.^{226–228} The reaction with diethyl malonate can serve as an example:

X = Cl, F; $R^1, R^2 = Cl, H$; $R^3 = Cl, H, ArC(O)$.

Methyl (3-chloro-2-nitrophenyl)cyanoacetate was prepared by the reaction of 2,6-dichloronitrobenzene (**24d**) with methyl cyanoacetate in DMF in the presence of K_2CO_3 .^{229, 230}

If a PCA contains no chlorine atoms in the *ortho* position with respect to the activating group, the chlorine atom in the *para* position is replaced. For example, *para*-substitution products were obtained in 80%–85% yields from 3,4-dichloronitrobenzene (**24e**) and 3,4,5-trichloronitrobenzene (**25b**).²²⁸

The reaction of the 2-(cyanomethyl)pyridine anion with hexachlorobenzene (**5**) affords the pyrido[1,2-*a*]indole derivative in nearly quantitative yield.²³¹

The electrochemically generated 2,6-di(*tert*-butyl)-phenolate anion reacts with 1,4-dichlorobenzene (**1c**) as the C-nucleophile.²³²

The reactions of methyl ketone enolates with 1,4-dichlorobenzene (**1c**) in liquid ammonia were studied.²³³ Under photochemical conditions, the ion-radical mechanism operates.

R = Me, Bu^t.

Irradiation of PCA with the light from a mercury lamp (254- or 185-nm) in benzene for 40 h at 25 °C under nitrogen resulted in the replacement of chlorine atoms by phenyl groups, the solvent serving as the source of the latter (Table 7).²³⁴ The reaction, which proceeds apparently by the radical mechanism, is accompanied by partial hydrodechlorination of both the starting arenes and products, particularly, of highly chlorinated compounds.

Table 7. Photochemical transformations of polychloroarenes in benzene.²³⁴

Compounds	Products (yield, %)
1,2-Cl ₂ C ₆ H ₄ (1a)	2-ClC ₆ H ₄ Ph (43) + Ph ₂ (14) + 1,2-Ph ₂ C ₆ H ₄ (1)
1,3-Cl ₂ C ₆ H ₄ (1b)	3-ClC ₆ H ₄ Ph (41) + Ph ₂ (1)
1,4-Cl ₂ C ₆ H ₄ (1c)	4-ClC ₆ H ₄ Ph (26) + Ph ₂ (1)
1,3,5-Cl ₃ C ₆ H ₃ (9a)	3,5-Cl ₂ C ₆ H ₃ Ph (31) + 1,3-Cl ₂ C ₆ H ₄ (1)
1,2,3-Cl ₃ C ₆ H ₃ (9c)	2,5-Cl ₂ C ₆ H ₃ Ph (22) + 3-ClC ₆ H ₄ Ph (3) + 4-ClC ₆ H ₄ Ph (1) + 1,4-Cl ₂ C ₆ H ₄ (1)
1,2,3,4-Cl ₄ C ₆ H ₂ (10a)	2,3,6-Cl ₃ C ₆ H ₂ Ph (21) + 1,2,4-Cl ₃ C ₆ H ₃ (3) + 4-Cl-1,2-Ph ₂ C ₆ H ₃ (2) + 2,5-Cl ₂ C ₆ H ₃ Ph (1) + 3,6-Cl ₂ -1,2-Ph ₂ C ₆ H ₂ (1) + Ph ₂ (1)
1,2,4,5-Cl ₄ C ₆ H ₂ (10b)	2,4,5-Cl ₃ C ₆ H ₂ Ph (9) + 3,4-Cl ₂ C ₆ H ₃ Ph (9) + 1,2,4-Cl ₃ C ₆ H ₃ (2)
1,2,3,5-Cl ₄ C ₆ H ₂ (10c)	2,4,6-Cl ₃ C ₆ H ₂ Ph (7) + 2,3,5-Cl ₃ C ₆ H ₂ Ph (5) + 1,3,5-Cl ₃ C ₆ H ₃ (2)

3. Reactions with anions of heteroorganic compounds

In the reactions of 1,2-dichlorobenzene (**1a**) with lithium diphenylphosphide and diphenylarsenide, one of the chlorine atoms is replaced by a heteroorganic substituent and another chlorine atom is replaced by hydrogen to give the corresponding products in low yields.²³⁵ The hypothesis that this reaction proceeds *via* benzyne was not confirmed, since experiments with furan as a scavenger were unsuccessful.

UV irradiation ($\lambda = 350$ nm) of some PCA in the presence of Me₃SnNa^{236, 237} or Ph₃SnNa²³⁸ in liquid ammonia affords substitution products. The reaction proceeds by the anion-radical mechanism and only under irradiation.

$n = 2, 3$; R = Me, Ph.

1,4-Bis(triphenylstannyl)benzene was obtained in 90% yield by the reaction of 1,4-dichlorobenzene (**1c**) with SnPh₄ in DMSO or acetonitrile under photochemical conditions.²³⁹

VII. Catalytic carbonylation and carboxylation

Catalytic carbonylation of polychloroarenes in the CO–Co₂(CO)₈–NaOH–H₂O system proceeds under UV irradiation (Table 8).²⁴⁰ In some cases, the reaction is accompanied by partial dechlorination (see, for example, the transformation of compound **69**). The selectivity of the reaction is determined by the number and arrangement of substituents in the starting arene.

Table 8. Carbonylation of PCA [conditions: 1) $h\nu$, CO, Co₂(CO)₈, NaOH, H₂O; 2) H⁺] with the 100% conversion of the substrate.²⁴⁰

Compound	Time/h	Products	Yield (%)
1,2-Cl ₂ C ₆ H ₄ (1a)	24	PhCO ₂ H 2-ClC ₆ H ₄ CO ₂ H 1,2-(HO ₂ C) ₂ C ₆ H ₄ PhCl	24 40 2 7
1,3-Cl ₂ C ₆ H ₄ (1b)	20	1,3-(HO ₂ C) ₂ C ₆ H ₄	92
1,4-Cl ₂ C ₆ H ₄ (1c)	20	1,4-(HO ₂ C) ₂ C ₆ H ₄	88
1,3,5-Cl ₃ C ₆ H ₃ (9a)	20	1,3,5-(HO ₂ C) ₃ C ₆ H ₃	86
3,5-Cl ₂ C ₆ H ₃ CO ₂ H (27b)	20	1,3,5-(HO ₂ C) ₃ C ₆ H ₃	89
3,4-Cl ₂ C ₆ H ₃ CO ₂ H (27c)	6	4-ClC ₆ H ₄ CO ₂ H 1,4-(HO ₂ C) ₂ C ₆ H ₄ 2-Cl-C ₆ H ₃ (CO ₂ H) ₂ -1,4 1,2,4-(HO ₂ C) ₃ C ₆ H ₃	15 14 57 11
4,5-Cl ₂ C ₆ H ₂ (CO ₂ H) ₂ -1,2 (69)	24	1,2,4-(HO ₂ C) ₃ C ₆ H ₃ 1,2,4,5-(HO ₂ C) ₄ C ₆ H ₂	53 30

Carbonylation of 1,2-dichlorobenzene (**1a**) affords, along with benzoic and phthalic acids, 2-carboxyphenylglyoxalic acid.²⁴¹

The reaction of polychloroarenes with carbon monoxide in methanol in the presence of MeONa produces methyl arene-polycarboxylates.²⁴² The reaction time varies from 36 to 95 h. Compounds containing vicinal chlorine atoms react much more slowly.

Carbonylation of 1,4-dichloro- (**1c**) and 1,3,5-trichlorobenzenes (**9a**) in EtOH affords ethyl benzenedi- and tricarboxylates.²⁴³

Palladium(0) complexes can be used as catalysts for these reactions.²⁴⁴

dppp is 1,3-bis(diisopropylphosphino)propane.

The use of Pd catalysts in combination with PTC allowed the carbonylation of dichloroarene **70** in the presence of 1-ethyl-5-hydroxypyrazole giving rise to aryl pyrazolyl ketone derivative **71**.¹⁶⁰

dppb is 1,4-bis(diphenylphosphino)butane.

The reactions of PCA with CO₂ proceed less selectively. Electrochemical carboxylation of 3,4-dichloro-1-trifluoromethylbenzene (**40a**) in aprotic polar solvents (Bu₄NBr as the supporting electrolyte, 15 °C, the current density $j = 5-50 \text{ mA cm}^{-2}$) affords 2-chloro-4-trifluoromethylben-

zoic acid as the major product.²⁴⁵ Electrochemical carboxylation of 1,2,4,5-tetrachlorobenzene (**10b**) and hexachlorobenzene (**5**) is accompanied by reductive hydrodechlorination.²⁴⁶

VIII. Catalytic C–C cross-coupling

Aryl chlorides are, as a rule, less reactive than the corresponding bromides and iodides in cross-coupling reactions catalysed by Pd or Ni complexes. The following approaches are used to accelerate these reactions: (1) the introduction of electron-withdrawing groups into the aromatic nucleus, (2) an increase in the nucleophilicity of the cross-counterpart or (3) the use of efficient catalytic systems. In recent years, considerable progress has been achieved in the design of new catalysts, particularly, in combination with sterically hindered phosphine^{247–257} and *N*-heterocyclic^{258–266} ligands. Data on some other types of ligands were reported elsewhere.^{267–272}

1. Reactions of polychloroarenes with organometallic compounds (M = Mg, Al or Zn)

Cross-coupling of PCA, unlike the analogous reactions with monochloroarenes, have been little studied. Most attention was focused on the transition metal complex-catalysed reactions of dichlorobenzenes **1a–c** with the Grignard reagents containing primary or secondary alkyl substituents (the Kumada reaction).^{273–277}

R = Alk, Ph.

The nickel complexes Ni(dppp)Cl₂ [dppp is 1,3-bis(diphenylphosphino)propane] and Ni(dppe)Cl₂ [dppe is 1,2-bis(diphenylphosphino)ethane] are the catalysts of choice allowing the replacement of both chlorine atoms.²⁷³ The high activity of these complexes is attributed to the fact that, after the replacement of the first chlorine atom, the catalyst tends to migrate intramolecularly to the second chlorine atom rather than to escape into solution. This reaction catalysed by the complex Ni(PPh₃)₂Cl₂ with the monodentate phosphine ligand affords products in much lower yields.

The reaction can be terminated after the replacement of one chlorine atom in the case of the complex Ni(triphos)ClPF₆ [triphos is the tridentate ligand *P,P*-bis(2-diphenylphosphinoethyl)phenylphosphine].²⁷⁷ In the cross-coupling reactions of 2,5-dichloro-1-trifluoromethylbenzene (**40b**) and 2,3-dichloroanisole (**72a**) with EtMgBr, the chlorine atom in the *meta* position with respect to the electron-withdrawing substituent is predominantly replaced.²⁷⁷ The selectivity is particularly high in the reaction with compound **72a** (the yields of 2-chloro-3-ethyl- and 3-chloro-2-ethylanisoles are 70% and 4%, respectively).

The reaction can be terminated at the monoalkylation step also in the presence of palladium catalysts [the complex Pd(dppf)Cl₂ is the catalyst of choice] in the dichlorobenzene:Grignard reagent molar ratio of ~2:1.²⁷⁶ In some cases, it is advantageous to add 0.5–1 equiv. (with respect to the catalyst) of the corresponding free ligand. The reactions efficiently proceed in THF at 85–105 °C. The Pd(PPh₃)₄-catalysed reaction of 1,4-dichlorobenzene (**1c**) with MeMgBr affords 4-chlorotoluene as the major product (92%).²⁷⁸

Several cross-coupling reactions of higher chlorinated PCA with the Grignard reagents were documented. The reactions of 1,3,5-trichlorobenzene (**9a**) and 1,2,4,5-tetrachlorobenzene (**10b**) with isopropenylmagnesium bromide in THF in the presence of Ni(dmpe)Cl₂ [dmpe is bis(dimethylphosphino)ethane] resulted in the replacement of two chlorine atoms.²⁷³

The use of the complex $\text{Ni}(\text{dppe})\text{Cl}_2$ allowed the replacement of all chlorine atoms in 1,3,5-trichlorobenzene (**9a**),²⁷⁹ 1,3,5-trialkylbenzenes **73a** being produced in yields of up to 93%.

$\text{Alk} = n\text{-C}_n\text{H}_{2n+1}$ ($n = 6-10$).

Polychloroarenes containing vicinal chlorine atoms are less reactive towards alkylmagnesium bromides. For example, only 'lateral' chlorine atoms are replaced in 1,2,3-trichlorobenzene (**9c**) to give monochlorides **74**. The reaction of 1,2,4-trichlorobenzene (**9b**) affords a mixture of complete substitution products, *viz.*, compounds **73b** (44%), along with dialkylchlorobenzene (22%), the positions of the substituents in the latter remaining unknown.

The reaction of 1,2,4,5-tetrachlorobenzene (**10b**) with *n*-hexylmagnesium bromide in the presence of $\text{Ni}(\text{dppe})\text{Cl}_2$ affords tetrahexylbenzene along with by-products, one of which was identified as 1,2,4-tri(*n*-hexyl)benzene.²⁷⁹

The use of various catalysts allowed the synthesis of 1,3,5-trialkylbenzenes containing different alkyl substituents starting from 1,3,5-trichlorobenzene (**9a**).²⁷⁹ The reaction in THF at -20°C in the presence of $\text{Ni}(\text{acac})_2$ as the catalyst afforded compounds **75** as a result of the replacement of the first

chlorine atom by the group R^1 . The latter compounds were used in the $\text{Ni}(\text{dppe})\text{Cl}_2$ -catalysed reaction with an excess of another alkylmagnesium bromide R^2MgBr . The preparative yields of trialkylbenzenes **76** were achieved only after refluxing in diethyl ether for 7–10 days.

$\text{R}^1, \text{R}^2 = \text{Alk}$.

The reactions of di- (**1a,b**) and trichlorobenzenes (**9a**) with the tricyclic Grignard reagent, *viz.*, tricyclo[4.1.0.0.2,7]hept-1-ylmagnesium bromide (TCH-MgBr), in the presence of $\text{Ni}(\text{dppe})\text{Cl}_2$ were documented.²⁸⁰ The satisfactory yield of the substitution product (53%) was achieved only in the reaction with 1,3-dichlorobenzene (**1b**).

Cross-coupling of tri- and tetrachloroarenes with aromatic Grignard reagents (Table 9) were performed with the use of the catalytic system $\text{Ni}(\text{acac})_2$ –diphenyl[2-(1-hydroxyethyl)phenyl]phosphine (**L**).²⁸¹ Under these conditions, complete substitution of trichlorobenzenes **9a,b,d** and **77** occurred to give the corresponding products in high yields. In the case of 1,2,4,5-tetrachlorobenzene (**10b**), incomplete conversion is accompanied by partial dechlorination.

$\text{X} = \text{H, Cl, OMe}; \text{Y} = \text{H, Ar, OMe}; \text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4$ (Tol);

Table 9. Cross-coupling of tri- and tetrachlorobenzenes with ArMgBr .²⁸¹

Compound	Ar	Time/h	Product	Yield (%)
1,3,5- $\text{Cl}_3\text{C}_6\text{H}_3$ (9a)	Tol	2	1,3,5- $\text{ToI}_3\text{C}_6\text{H}_3$	91
1,2,4- $\text{Cl}_3\text{C}_6\text{H}_3$ (9b)	Ph	48	1,2,4- $\text{Ph}_3\text{C}_6\text{H}_3$	89
1,2,3- $\text{Cl}_3\text{C}_6\text{H}_3$ (9d)	Tol	24	2,6- $\text{ToI}_2\text{C}_6\text{H}_4$	85
1,2,4,5- $\text{Cl}_4\text{C}_6\text{H}_2$ (10b)	Ph	96	1,2,4,5- $\text{Ph}_4\text{C}_6\text{H}_2$	58 ^a
2,4,6- $\text{Cl}_3\text{C}_6\text{H}_2\text{OMe}$ (77)	Tol	20	2,4,6- $\text{ToI}_3\text{C}_6\text{H}_2\text{OMe}$	80

^a By-products: 1-Cl-2,4,5- $\text{Ph}_3\text{C}_6\text{H}_2$ and 1,2,4- $\text{Ph}_3\text{C}_6\text{H}_3$ (2 : 3).

Reactions of PCA with complex organoaluminium compounds were documented.²⁸² For example, compound **24e** containing the nitro group reacts with derivative **78** in the presence of $\text{Pd}(\text{PPh}_3)_4$. The reaction with non-reactive 1,4-dichlorobenzene (**1c**) required the use of a Pd complex with electron-rich phosphine ligands; however, the yield of *p*-xylene was at most 14%.

In the $\text{Pd}(\text{PPh}_3)_4$ -catalysed reactions of 1,2,4,5-tetrachlorobenzene (**10b**) and hexachlorobenzene (**5**) with organozinc compounds (1.6 mol per mole of arene) in boiling THF, one chlorine atom is replaced to give the corresponding products in moderate yields.²⁸³ The conversion of PCA varies from 58% to 89% and is accompanied by side processes, such as homocoupling of the nucleophilic and electrophilic components and reductive dechlorination.

2. Reactions of polychloroarenes with arylboronic acids

Transition metal-catalysed cross-coupling reaction of PCA with arylboronic acids (the Suzuki reaction) can serve as a convenient one-pot procedure for the synthesis of polyarylbenzenes. However, this reaction is far from being always selective. For example, the reaction of 1,2-dichlorobenzene (**1a**) with 4.4 equiv. of $\text{PhB}(\text{OH})_2$ in the presence of the nickel complexes $\text{Ni}(\text{dppf})\text{Cl}_2$ or $\text{Ni}(\text{PPh}_3)_2\text{Cl}_2$ affords a mixture of 2-chlorobiphenyl (**79**) and *o*-terphenyl (**80**).²⁸⁴

[Ni]	Yield (%)	
	79	80
$\text{Ni}(\text{dppf})\text{Cl}_2$	4	69
$\text{Ni}(\text{PPh}_3)_2\text{Cl}_2$	34	28

Cross-coupling of 2,4-dichlorobenzaldehyde (**26b**) with *p*-tolylboronic acid with a nickel catalyst also affords a mixture of compounds, with the *para*-substitution product predominating (the *para* isomer : *ortho* isomer ratio ~ 2 : 1).²⁸⁵ On the contrary, the *ortho* isomer is formed in higher yield with the palladium catalyst $\text{Pd}(\text{dba})_2\text{-L}$ (L = PPh_3 , PCy_3 , dppb or dppf).

The reaction of 1,2-dichlorobenzene (**1a**) with $\text{PhB}(\text{OH})_2$ on a heterogeneous nanocluster catalyst with the composition Cu/Pd/Ru in DMF at 110 °C in the presence of K_2CO_3 as a base affords the monoarylated product in 25% yield.²⁸⁶ In the reaction of 1,4-dichlorobenzene (**1c**) with 4-tolylboronic acid in the presence of the catalytic system $\text{PdCl}_2\text{-PCy}_3\text{-Na}_2\text{CO}_3$ in NMP at 150 °C, also only one chlorine atom is replaced.²⁸⁷

We demonstrated²⁸³ that highly chlorinated PCA, such as C_6Cl_6 (**5**) and $\text{C}_6\text{Cl}_5\text{Ac}$, do not react with phenylboronic acid in the presence of $\text{Pd}(\text{PPh}_3)_4$ under the conditions typical of the reaction of aryl bromides. Unexpectedly, pentachloroiodobenzene also appeared to be inert under these conditions due apparently to steric hindrance of the reactive C–I bond by the adjacent chlorine atoms. The target products were synthesised with the use of modern catalytic systems designed in recent years for the cross-coupling of monochloroarenes, including deactivated compounds. For example, the cross-coupling of $\text{PhB}(\text{OH})_2$ with equimolar amounts of 1,2,4,5-tetrachlorobenzene (**10b**) and hexachlorobenzene (**5**) in the presence of the system $\text{Pd}(\text{dba})_2\text{-Bu}_3\text{P-K}_3\text{PO}_4\text{-PhMe}$ (Ref. 248) gave the

products in 82% and 37% yields, respectively.²⁸³ The Buchwald ligands containing the 2-phosphinobiphenyl fragment, particularly, 2-dicyclohexylphosphino-2'-dimethylaminobiphenyl (**46**),^{125, 126} proved to be very efficient in these reactions.^{247, 252, 253}

The cross-coupling of tri- and tetrachlorobenzenes with arylboronic acids ArB(OH)_2 ($\text{Ar} = \text{Ph}$, 4-MeOC₆H₄ or 4-FC₆H₄) under Buchwald conditions resulted in the complete replacement of the chlorine atoms to give compounds **81–84** in high yields.

Isomers: 1,2,3 (**81a**, 94%); 1,2,4 (**81b**, ~ 100%); 1,3,5 (**81c**, ~ 100%); 1,2,3,4 (**82a**, 88%); 1,2,4,5 (**82b**, 94%).

Attempts to use this procedure for the synthesis of penta-phenylbenzene from C₆HCl₅ (**2**) and for the synthesis of hexaphenylbenzene from C₆Cl₆ (**5**) failed although the target products were detected by GLC-mass spectrometry in amounts up to 10%. After the introduction of four phenyl groups, the replacement of the chlorine atoms by hydrogen in the intermediates Ph₄C₆HCl and Ph₄C₆Cl₂ became the major reaction.

Polychloroarenes containing both electron-donating and electron-withdrawing substituents in the aromatic ring react with phenylboronic acid in the presence of the catalytic system Pd(OAc)₂–ligand. Under these conditions, all chlorine atoms were replaced in 3,4-dichloroanisole (**72b**) and isomeric dichloroacetophenones **29**.¹²⁵

(a) PhB(OH)₂ (2.5 mol), Pd(OAc)₂, **46**, K₃PO₄, PhMe, 90 °C.

The use of palladium *N*-heterocyclic carbene complexes [prepared *in situ* from Pd(OAc)₂ and imidazolium salts]^{283, 288} and the ligand-free method²⁸⁹ for the cross-coupling of 1,2,4,5-tetrachlorobenzene (**10b**) and hexachlorobenzene (**5**) proved to be less efficient.

3. Reactions of polychloroarenes with terminal acetylenes

The reactions of di- and trichlorobenzenes with terminal acetylenes were carried out.^{290–293} The cross-coupling reaction of 1,4-dichlorobenzene (**1c**) with hept-1-yne in the presence of

Pd(PCy₃)₂Cl₂ affords the monosubstitution product in high yield.²⁹⁰

The reaction of isomeric dichlorobenzenes **1a–c** with phenylacetylene in the presence of a pincer palladium complex with additives of ZnCl₂ also gives monosubstitution products.²⁹¹ Their yields depend on the mutual arrangement of the chlorine atoms.

Isomers: 1,2 (36%), 1,3 (19%), 1,4 (80%).

Unexpected results were obtained in the reactions of alkynes with symmetrical tribromotrichloro- (**85**) and trichlorotriiodobenzenes (**86**).^{292, 293} For example, only bromine atoms are replaced in the Sonogashira reaction (75 °C, 30 h) of 1,3,5-tribromo-2,4,6-trichlorobenzene (**85**) with trimethylsilylacetylene. It has become possible to introduce six acetylene groups into the aromatic core only with the use of more reactive alkyne zinc derivatives.

Hal = Br (**85**): R¹ = Me₃Si, X = Cl (62%); R² = Ph, Y = C≡CR² (69%); Hal = I (**86**): R¹ = Ph (33%), R² = Me₃Si (51%), X = Y = C≡CR¹.

2,4,6-Trichloro-1,3,5-triiodobenzene (**86**) reacts with phenylacetylene to form 4,6-dichloro-1,2,3,5-tetrakis(phenylethynyl)benzene. To replace the remaining chlorine atoms, the

reaction with trimethylsilylethynylzinc was carried out at high temperature (90 °C) .

IX. Metallation

1. Grignard reagents based on polychloroarenes: synthesis and reactions with electrophiles

Polychloroarenes react with magnesium to form organomagnesium derivatives. The nature of the solvent is of considerable importance in the synthesis of polychloroarylmagnesium halides. Tetrahydrofuran and other cyclic ethers, such as tetrahydropyran, ethyl tetrahydrofurfuryl ether, 2-ethoxytetrahydropyran and dihydropyran are convenient solvents for this purpose. In these solvents, isomeric 1,3- and 1,4-dichlorobenzenes (**1b,c**) form the Grignard reagents in good yields.^{294, 295} The reaction of 1,2-dichlorobenzene (**1a**) and highly chlorinated PCA give the target products in low yields because of oligomerisation as the side process. An exception is hexachlorobenzene (**5**), which gives C_6Cl_5MgCl in THF in 77% yield.²⁹⁴ In diethyl ether, C_6Cl_5MgCl was prepared by slow (over 2 days) addition of 1,2-dibromoethane to a suspension of an excess of magnesium and hexachlorobenzene (**5**) in diethyl ether (the latter compound is very poorly soluble in diethyl ether).^{296, 297}

The reactions of these organomagnesium derivatives with a series of electrophiles were studied. For example, the reaction of the Grignard reagent prepared from C_6Cl_6 (**5**) with gaseous CO_2 affords pentachlorobenzoic acid in 77% yield,²⁹⁶ whereas the treatment of this Grignard reagent with acetic anhydride affords pentachloroacetophenone in 31% yield. These results are in contradiction with the data of the study,²⁹⁴ where it was noted that C_6Cl_5MgCl does not react with carbon dioxide in THF but reacts with more reactive $SiCl_4$ under analogous conditions.

An α -hydroxy ester was synthesised by the reaction of C_6Cl_5MgCl (**87**) with diisopropyl oxalate in THF (the yield was not reported).²⁹⁸

Decachlorobiphenyl (**31**), like hexachlorobenzene (**5**), forms the Grignard reagents in the reactions carried out in the presence of 1,2-dibromoethane.⁷⁵ The chlorine atoms at positions 4 and 4' are only involved in the reaction giving rise to mono- and dimetallated derivatives, and the latter can be transformed into nona- and octachlorobiphenyls by quenching with water (Scheme 2).

The one-pot synthesis of 3-benzyloxy-5-chlorobenzoic acid from 5-benzyloxy-1,3-dichlorobenzene (**88**) via the Grignard reagent was documented (the conditions and yields were not reported in detail).²⁹⁹

Slow (over 50 h) addition of 1,2-dichlorobenzene (**1a**) to a mixture of metallic magnesium and Me_3SiCl in HMPA at 80–100 °C resulted in 1,2-bis(trimethylsilyl)benzene as the major product.³⁰⁰ The reactions of other PCA containing from two to four chlorine atoms proceed analogously. 2,3,5,6-Tetrakis(trimethylsilyl)cyclohexa-1,3-diene was prepared from compound **1a** in high yield with the use of an excess of reagents at higher temperatures (140–150 °C).³⁰¹

Transmetalation of compound **87** with CuI in THF produces organocopper compound **89**.³⁰² The corresponding biaryls were obtained in moderate yields (~25%) by the cross-coupling of compound **89** with tetra- and pentamethylphenyl iodides.

Organometallic reagents **90** analogous to the Grignard reagents were prepared by the reaction of 1,4-dichlorobenzene (**1c**) with yttrium and samarium.³⁰³ Their subsequent treatment with triphenyltin chloride and water in an acidic medium afforded tetraphenyltin in high yield.

Scheme 2

Ln = Yb, Sm.

Organozinc derivatives of PCA were synthesised by electrolysis of 1,4-dichlorobenzene (**1c**) and 2,5-dichloro-1-trifluoromethylbenzenes (**40b**). The reactions were carried out in an undivided cell with a sacrificial zinc anode in a MeCN–pyridine mixture (9 : 1) in the presence of CoCl_2 and ZnBr_2 as the catalysts.³⁰⁴ The resulting organometallic compounds were transformed into the corresponding iodobenzenes or cross-coupling products with PhI in the presence of $\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$ (Scheme 3).

(a) e^- (2 F mol^{-1}); CoCl_2 (cat), ZnBr_2 (cat), Zn anode, MeCN–PyH (9 : 1); (b) PhI , $\text{Pd}(\text{PPh}_3)_4\text{Cl}_2$; (c) I_2 .

2. Synthesis and reactions of organolithium derivatives of polychloroarenes

Unlike aryl bromides and iodides, monochloroarenes do not, as a rule, react with alkyllithium reagents. However, the mutual activation of chlorine atoms in PCA favours the reactions with these organometallic compounds. For example, hexachlorobenzene (**5**) reacts with Bu^nLi in a THF–hexane mixture at -78°C to form pentachlorophenyllithium (**91**).³⁰⁵ In diethyl ether, this reaction proceeds at -10°C .³⁰⁶

The reaction of hexachlorobenzene (**5**) with an excess of Bu^nLi gives a product, in which two Cl atoms in the *para* positions are replaced.³⁰⁷ Lithiation with *tert*-butyllithium at -125°C allows the replacement of all six Cl atoms. Upon treatment with D_2O , the resulting hexalithium derivative **92** gives benzene- d_6 in quantitative yield.³⁰⁸

In polychloroarenes containing aromatic C–H bonds, the hydrogen atom can selectively be replaced by lithium. For example, the reaction of 1,3,5-trichlorobenzene (**9a**) with Bu^nLi produces symmetrical trilithiotrichlorobenzene,³⁰⁷ whereas the reaction of 1,2,4,5-tetrachlorobenzene (**10b**) results in the replacement of one or two hydrogen atoms depending on the amount of the lithiating reagent.³⁰⁹ The reaction of pentachlorobenzene (**2**) with Bu^nLi also results in the replacement of the H atom by Li.^{307, 309}

Under the lithiation conditions, 1,2,3-trichloro- (**9c**) and 1,2,3,4-tetrachlorobenzenes (**10a**) give mixtures of dechlorination and deprotonation products.³⁰⁷ High chemoselectivity was observed in the reaction with Bu^tLi . Thus treatment of the lithiation products with chlorotrimethylsilane affords the corresponding trimethylsilylarenes containing one less chlorine atom.

X = H (**9c**), Cl (**10a**).

The lithiation of decachlorobiphenyl (**31**), like the reaction with Mg, proceeds regioselectively at positions 4 and 4'.⁷⁵ Quenching of the lithiation products with water affords nona- and octachlorobiphenyls, and their reactions with dimethyl sulfate produce the corresponding 4-methyl- and 4,4'-dimethylperchlorobiphenyls.

Lithium derivatives of PCA are valuable intermediates in the synthesis of various heteroorganic and functionalised arene derivatives.^{125, 306, 310–313} Selected reactions of pentachlorophenyllithium (**91**) with electrophiles with references to the original papers are given below.

Although polychlorophenyllithium derivatives are rather stable (compound **91** is stable in diethyl ether at $-10\text{ }^{\circ}\text{C}$), in some cases these compounds eliminate LiCl to form the corresponding dehydrobenzenes.³¹⁴ For example, the reaction of compound **91** with 1,3,5-tri(*tert*-butyl)benzene affords the cycloaddition product **93**.³⁰⁵ The reactions of $\text{C}_6\text{Cl}_5\text{Li}$ (**91**) with *N*-methylpyrrole³¹⁵ and substituted anthracene proceed³¹⁶ analogously.

2,3,5,6-Tetrachlorophenyllithium (**94**) derived from 1,2,4,5-tetrachlorobenzene (**10b**) can be transformed into 3,4,6-trichlorobenzene, which was detected judging from the formation of the cycloaddition product with *N*-methylpyrrole, *viz.*, compound **95**.³¹⁵

The reactions of 1,3-dichlorobenzene (**1b**) with an excess of ArLi were found³¹⁷ to proceed *via* 3-chlorobenzene, 1,3-dichloro-2-lithiobenzene (**96**) being a precursor of the latter. These reactions afford ultimately *m*-terphenyls **97**. The reaction of compound **1b** with phenyllithium followed by quenching of the reaction mixture with molecular iodine affords the iodo derivative of *m*-terphenyl **98**.

$\text{Ar} = \text{Ph}$ (73%), 4- PhC_6H_4 (65%), 2-MeOC₆H₄ (93%), 4-MeOC₆H₄ (80%).

Compounds **99** and **82b** were prepared analogously from 1,3,5-trichloro- (**9a**) and 1,2,4,5-tetrachlorobenzenes (**10b**), respectively, by the reactions with PhLi .³¹⁷

An efficient procedure for the synthesis of *m*-terphenyls is based on the lithiation of polychlorobenzenes **1b** or **9a** with *n*-butyllithium followed by treatment with ArMgBr . The mechanism of these transformations is analogous to that of the above-described reactions.³¹⁷

1,3-Dichloro-2-lithiobenzene (**96**) gives biphenyl and *m*-terphenyl derivatives as a result of the reaction with 3-chlorobenzene generated *in situ*.³¹⁸ The yield of 2,2',6,6'-tetrachloro-*m*-terphenyl (**100**) was increased to 44% by transforming the lithium derivative into organomagnesium compound **101**, which reacts more smoothly (Scheme 4).³¹⁷

The reactions of 1,2,4,5-tetrabromodichloro- (**102**) and 1,4-dibromotetrachlorobenzenes (**103**) with an excess of PhMgBr also proceed *via* the dihydrobenzene derivative to give 1,2,4,5-tetraphenylbenzene (**82b**).³¹⁹

Hal = Br (**102**, 65%); Cl (**103**, 36%).

* * *

As can be seen from the above data, polychloroarenes can serve as multifunctional synthons for the preparation of various classes of organic and heteroorganic compounds. Nucleophilic aromatic substitution and metallation reactions of PCA have been studied in sufficient detail, whereas transition metal-catalysed cross-coupling reactions have received less attention. A serious progress in the metal complex catalysis achieved in the past years allows the expectation of the development of new efficient methods for transformations of PCA into valuable aromatic compounds. Some of new catalytic systems have been successfully tested in the cross-coupling reactions of dichlorobenzenes and highly chlorinated arenes.

Investigations of the reactivity of PCA are of applied importance. The results of these investigations can substantially contribute to the solution of the problem of chemical utilisation of toxic organochlorine compounds, such as pesticides, waste transformer oil (see, for example, Refs 320–322), dioxins, *etc.*, including the processing of these compounds into new products and materials with practically useful properties.

This review has been written with the financial support of the INTAS (Grant No. 04-82-7271).

VI. Conclusion	928

Abstract. The regular features of the formation of outer-sphere associates of water-soluble calixarenes with metal complexes in solutions and their structure in the solid state are analysed. A comparison with analogous data for other outer-sphere macrocyclic ligands is carried out. Some physicochemical properties of the outer-sphere associates are considered in regards to their potential use for the development of new processes and materials. The bibliography includes 150 references.

I. Introduction

Recent rise of the chemists' interest in transition metal complexes is caused, *inter alia*, by the important role of these complexes in biological processes and their possible application in the design of molecular and nano-devices (conductors,¹ switches,² sensors³ and molecular machines⁴). The transition metal ions are extremely important for living organisms.^{5,6} It is essential that most of 'metals of life' are present in an organism as complexes, that can be divided according to their biological functions into transporters (ionophores), accumulators, activators of inert molecules and bio-catalysts.⁷ The biochemical functioning of metal ions is related mainly to their outer-sphere coordination, which is also important in the design of switching systems based on transition metal complexes.^{1,4} Weak non-covalent interactions are the driving forces of the formation of outer-sphere complexes⁷ and therefore this is most efficient when a cooperative effect takes place. Such effect is especially pronounced in the case of many natural products (DNA molecules, natural ionophores, cyclodextrins) as well as artificial macrocycles. Calixarenes and their derivatives, which are receptors of various ions and molecules, belong to the latter

class of compounds.^{8,9} Calixarene complexes of ions and organic substrates are well documented. However, so far there are no reviews on calixarenes as outer-sphere ligands for metal complexes. The discussion of the chemistry of outer-sphere association of metal complexes with calixarene derivatives and comparison of these compounds with other similar natural and synthetic outer-sphere ligands, including macrocyclic ones, are the main objectives of the present review. The physicochemical properties of the resulting outer-sphere associates (super-complexes) and their potential application in advanced technological processes and design of new materials are also discussed.

II. The driving forces of outer-sphere association of transition metal complexes with various macrocycles, DNA and antibiotics

Many natural receptors, for example, DNA and antibiotics, are not macrocycles. However, their outer-sphere association with transition metal complexes follows the cooperative mechanism of 'host–guest' interactions. Numerous papers are devoted to complexation of DNA with transition metal complexes, many of them were discussed in a review.¹⁰ The interest is caused by the use of coordinatively saturated transition metal complexes for studying the DNA structure. Coordinatively saturated Co^{III} and Ru^{II} octahedral complexes (mainly, polypyridyl complexes) are used for cleavage of DNA molecules and for their direct molecular and/or enantiomeric recognition.^{10–12} It is known that charged phosphate fragments and hydrophobic grooves, formed by nitrogen-containing heterocycles, take part in binding of metal complex to the DNA molecule. Thus, in this case the electrostatic interactions, intermolecular hydrogen bonding and π – π interactions between heterocycles representing the ligands of metal ion and DNA heterocycles are the main driving forces of outer-sphere complex formation.

Some natural antibiotics are also devoid of macrocyclic cavities, but, nevertheless, they possess receptor properties towards transition metal complexes due to the cooperative effect of intermolecular hydrogen bonds and electrostatic interactions in the crown ether-like conformation of their

molecules. Among the natural ionophores, lasalocid A is the most popular receptor of transition metal complexes.^{13, 14}

It is known that lasalocid A is an anionic ionophore capable of effective (outer-sphere) binding of positively charged ammine and amine complexes of transition metals $[Ct^{n+}]$ ($[Co(NH_3)_6]^{3+}$, $[Cr(NH_3)_6]^{3+}$, $[Co(NH_3)_5Cl]^{2+}$, Δ - and Λ - $[Co(en)_3]^{3+}$, $[Pt(NH_3)_6]^{4+}$) to the complexes $[Ct^{n+}][LAS^-]_n$. The lasalocid anion $[LAS^-]$ in the latter surrounds the metal complex and adopts a cyclic pseudo-crown-ether conformation.^{15–18}

Crown ethers represent a class of synthetic macrocyclic receptors modelling some intermolecular interactions ionophore–substrate.^{19–22} The same forces are responsible for binding of metal complexes to crown ethers and ionophores, because the spatially pre-arranged ether oxygen atoms can be involved in both hydrogen bonding and electrostatic interactions. The efficiency of electrostatic interactions of metal complexes with crown ethers is lower than that with ionophores, which results in the increase in the contribution of hydrogen bonding to the total bonding energy. Therefore, the presence of acidic hydrogens in ligands that surround the metal complex is prerequisite for the efficient outer-sphere coordination of metal complexes by crown ethers. Particularly, in the process of formation of outer-sphere complexes of metal ammine and ammine complexes with 18-crown-6 the hydrogen atoms of NH_3 or NH_2 ligands form hydrogen bonds with the oxygen atoms of the crown ether. Complex **1** is an example of such compounds.^{23, 24}

A great number of complexes of crown ethers with transition metal aqua complexes and with metal complexes containing acetonitrile ligands are known. Acetonitrile CH-protons are sufficiently acidic to form hydrogen bonds with the ether oxygen atoms of the macrocycle.²⁴

The structure modifications (*i.e.* introduction of various substituents) and enlargement of the crown-ether ring make possible π – π -interactions with ligands of metal complexes containing aromatic fragments.^{25, 26} Thus both NH_3 ligands take part in hydrogen bonding in the complex of dibenzo-18-crown-6 with $[Pt(bipy)(NH_3)_2]^{2+}$ (bipy is 2,2'-bipyridyl). The large and flexible crown-ether ring adopts a conformation favourable for the interactions of benzo-substituents with the bipy ligands in the inner coordination sphere of this platinum complex. The existence of these interactions was confirmed by

X-ray crystallography and UV-spectroscopy (judging from the presence of charge transfer bands). The recognition of natural siderophore ferrioxamine B ($FeHDFB^+$) by dicyclohexano-18-crown-6 is based upon the ability of the crown-ether ring to bind a primary ammonium group.^{20, 27, 28} However, lasalocid A binds $FeHDFB^+$ in a basic media more efficiently than benzo-18-crown-6 due to the possibility of ionisation and more flexible structure adjustable the structure of the 'guest' molecule. The charge neutralisation occurring simultaneously with hydrogen bonding with the deprotonated hydroxyl group and two ether oxygen atoms of the chain results in more efficient binding than that with the crown-ether oxygen atoms.^{27, 28}

In contrast to crown ethers possessing affinity to positively charged metal complexes, the polyaza-macrocycles in their protonated forms bind anionic complexes. For example, the macrocycles **2a, b** form outer-sphere associates (in the ratio 1:1) in water with transition metal anionic complexes $M(CN)_6^{4-}$, where $M = Fe, Ru, Co$.^{29, 30} In this case, the electrostatic interactions and hydrogen bonding are also the driving forces of formation of outer-sphere complex. The stability of such outer-sphere complexes being determined mainly by the number of protonated nitrogen atoms of the macrocyclic ligand rather than by the type of the metal in the complex anion.

$n = 1$ (**a**), 2 (**b**).

Thus, crown ethers and polyazamacrocycles may be regarded as macrocycles that efficiently bind the charged metal complexes due to electrostatic interactions and hydrogen bonds while hydrophobic interactions in this case are much less important.

Cyclodextrins (CD) is a class of natural macrocycles with a hydrophobic cavity owing to which they form inclusion compounds with metal complexes,^{31, 32} while the presence of hydrophilic outer surface provides good solubility in water.

Cyclodextrins bind neutral and negatively charged species most efficiently, although many examples of the formation of inclusion complexes with positively charged metal complexes are documented.^{32–36} For instance, β -CD binds the oxidised and reduced forms of ferrocenes as well as ferrocenecarboxylate with approximately the same stability constants (10^3 – 10^4) (Ref. 35). Stability of inclusion complexes is determined mainly by the match between the cavity diameter and the hydrophobic fragment size of a 'guest' molecule,^{36–41} although intermolecular hydrogen bonds between a metal complex and hydroxyl groups of cyclodextrin may additionally stabilise the inclusion complexes.⁴² The 1:1 adducts of β - and γ -cyclodextrins with ferrocene are described in Ref. 36, the orientation of ferrocene molecule in β -CD adduct is axial and in γ -CD adduct is equatorial.

Cucurbit[n]urils and calix[n]arenes are the most intensively studied compounds among the synthetic macrocycles. They are widely used as molecular containers for metal complexes and the interest in these compounds increased significantly during the last decade.

The size of internal cavities of cucurbit[*n*]urils with $n = 6-8$ is close to the size of cavities of the molecules of α -, β and γ -CD, respectively.⁴³ However, in contrast to the cyclodextrins, the oxygen atoms of carbonyl groups in cucurbituril portals are more polarised. As a result, the contribution of electrostatic interactions to the total binding energy of the 'host-guest' system is higher than that of CDs and the adducts with positively charged ions are more stable.⁴⁴ The adducts with metal aqua complexes are the most thoroughly studied. They are efficiently bound to carbonyl portals of cucurbiturils and do not form inclusion complexes.⁴⁵⁻⁴⁷ However, the inclusion complexes of cucurbiturils are also known. Particularly, such complexes are formed with a number of solvents and indicators.⁴⁸⁻⁵⁰ The cucurbit[8]uril is more suitable for the formation of inclusion complexes with positively charged metal complexes than cucurbit[6]- and cucurbit[7]urils due to the larger size of the molecular cavity. It was shown⁵¹⁻⁵⁴ that outer-sphere association of cobalt, copper and nickel complexes with ethylenediamine and cyclam results in the formation of inclusion complexes of cucurbit[8]uril.

Calixarenes represent an important class of synthetic receptors, which may exhibit all above-mentioned types of intermolecular interactions.^{8,9} Their spatial structure consists of clearly separated hydrophilic (rim) and hydrophobic (cavity) areas. Besides, the potential of rim modifications and cavity size variations for these molecules is higher than that for cyclodextrins and cucurbiturils.^{8,9} The present review mainly discusses the water-soluble receptors obtained by the introduction of ionised groups into the calixarene matrix, because compounds of this particular class are most comprehensively studied as outer-sphere ligands for charged metal complexes.⁵⁵⁻⁵⁹

For the first time, the possibility of outer-sphere coordination of nickel and copper complexes $[\text{Ni}(\text{H}_2\text{O})_5\text{py}]^{2+}$ and $[\text{Cu}(\text{H}_2\text{O})_4\text{py}_2]^{2+}$ with *p*-sulfonatocalix[4]arene was shown by X-ray analysis.⁵⁵ The pyridine moiety of the metal complexes is located inside the cavity (structures **3a,b**).

Later similar studies were performed for outer-sphere complexes of *p*-sulfonatocalix[4]arene with $[\text{Ni}(\text{phen})_3]^{2+}$ (phen is 1,10-phenanthroline) and $[\text{Co}(\text{diHOSar})]^{3+}$ [sar is 3,6,10,13,16,19-hexaazabicyclo[6.6.6]eicosane, diHOSar = 1,8-(OH)₂sar], and also its thia-analogue with $[\text{Co}(\text{bipy})_3]^{3+}$ (Refs 56-59). The structure of the outer-sphere associate depends on the composition of the solution when the outer-sphere coordination of a labile complex takes place or when free metal ions and ligands are present in the solution alongside with the complex. For example, the above-discussed outer-sphere complexes are not formed in slightly acidic aqueous solutions containing cobalt(II) or nickel(II) salts, pyridine *N*-oxide and *p*-sulfonatocalix[5]arene. Aqua-ions $[\text{Co}(\text{H}_2\text{O})_4]^{2+}$ or $[\text{Ni}(\text{H}_2\text{O})_4]^{2+}$ coordinate sulfo groups of two different calixarene units forming a bridge between them.⁶⁰ The cavities contain pyridine *N*-oxide molecule (L) non-coordinated to the metal.

M = Co, Ni.

Depending on the type of the metal, the system sulfonato-calix[5]arene-lanthanide ion-pyridine *N*-oxide yields, alongside with the complexes of the described type, complexes in which the molecules of pyridine *N*-oxide are coordinated by the metal atoms and complexes of the type **3** where the ligand is located inside the cavity.⁶¹ Thus, gadolinium forms complexes of the first type, while in Eu^{III} , Tb^{III} and Yb^{III} complexes, mixed inner- and outer-sphere coordination was observed. Hence, the presence of several binding centres (the cavity, substituents of the upper and lower rims) allows wide modification of a supra-molecular structure upon variation of the composition of a multi-component solution.⁶² Cucurbiturils also form such ternary complexes in which an organic molecule is incorporated into a macrocyclic cavity and a metal ion is linked to the donor groups of the rim. Particularly, such complexes with sodium ions and some solvents were described for cucurbit[6]uril.⁴⁷

It should be noted that the efficiency of the discussed classes of compounds including the macrocycles as the outer-sphere ligands is determined by cooperative effect of electrostatic and hydrophobic interactions as well as by hydrogen bonding, while the relative contribution of interactions of each type depends on the structure of the outer-sphere ligand. The presence of hydrophobic cavities and hydrophilic rims is a common feature of cyclodextrins, cucurbiturils and calixarenes. For this reason, we will restrict our discussion to the comparative analysis of these macrocycles. However, alongside with the common features, there is also a number of important differences between these compounds. Thus, in contrast to cyclodextrins, cucurbiturils, due to the presence of polar portals, are able to form non-inclusion outer-sphere associates with metal aqua complexes and ternary complexes where the solvent molecules are located inside the cavity and the metal ions are bound by the carbonyl groups of portals. Of numerous calix[*n*]arenes, the water-soluble derivatives, particularly *p*-sulfonatocalix[*n*]arenes, are of special interest as outer-sphere ligands for metal complexes. Such macrocycles can form outer-sphere associates with the charged metal complexes as well as bind metal ions (through inter-sphere coordination by donor groups of upper and lower rims) and, simultaneously ligands (through inclusion to the calixarene cavity). Yet another characteristic of calixarene molecules is their conformational flexibility, which distinguishes them from rigid molecules of cyclodextrins and cucurbiturils. The mobility of aromatic rings of even the most conformationally restricted *p*-sulfonatocalix[4]arenes allows the adjustment of the 'host' cavity to the 'guest' structure. The results of quantum chemical calculations⁶³ show that the inclusion of hydrophobic 'guest' fragment into the cavity of *p*-sulfonatocalix[4]arene decreases the conformational mobility of the cavity-forming rings; the inclusion of aliphatic fragments stabilises the C_{4v} conformation of the complex, the inclusion of aromatic fragments results in the C_{2v} conformation.⁶³ In all the known cases, inclusion of ligand fragments of Cu^{II} , Co^{II} , Co^{III} and Ni^{II} complexes into the cavity of *p*-sulfonatocalix[4]arene and its thia-analogue stabilises the flattened cone conformation (C_{2v}).^{56-59, 64} X-Ray structural analysis of the crystals obtained from the solution of *p*-sulfonatothiacalix[4]arene and tris(bipyridyl) nickel revealed⁶⁴ a conformational transition of the 'host' molecule

from the cone conformation into the so-called partial cone conformation due to the inclusion complex formation. However, it should be noted that the crystal was grown in an autoclave under high temperature and pressure.

III. The thermodynamics of outer-sphere association of water-soluble calixarenes with charged complexes and organic ions in comparison with that of cyclodextrins and cucurbiturils

The data discussed in the previous Section provide a basis for the analysis of similarities and differences in the driving forces of the outer-sphere association of charged complex species with various macrocycles. As the number of papers on the thermodynamics of outer-sphere association of metal complexes with mentioned macrocycles in aqueous solutions is very limited, we compare the formation of complexes of calixarenes, cyclodextrins and cucurbiturils not only with metal complexes, but also with organic cations and neutral molecules. The main difference between cyclodextrins and water-soluble calixarenes is that the formation of cyclodextrin complexes with organic substrates is the entropy-favourable process, while the formation of complexes of water-soluble calix[4]resorcinarenes is entropy-unfavourable process.⁶⁵ In the case of cyclodextrins, the hydrophobic effect caused by water destructure due to the decrease in hydrophobic surface, is dominant and results in the entropy increase.⁶⁶ Meanwhile the multi-centred interactions of a guest molecule with the cyclodextrin cavity are usually not sufficiently effective to be a driving force of the formation of cyclodextrin complexes in aqueous solutions.⁶⁷ As it has already been mentioned, the presence of the polar portals in the cucurbituril molecules significantly increases the contribution of electrostatic interactions in comparison with that in the case of formation of cyclodextrin complexes. For instance, cucurbit[7]uril binds the methylviologen cation (MV^{2+}) more efficiently than β -CD of similar size due to the enthalpy contribution.⁶⁸ Cucurbit[7]uril is also more efficient in binding ferrocene and its alkylammonium derivatives: the corresponding binding constants of β -CD are in the range of 10^3 – 10^4 litre mol⁻¹, while for cucurbit[*n*]urils (*n* = 7, 8) the range is 10^9 – 10^{10} litre mol⁻¹. The value of the constant significantly increases (up to 10^{12} – 10^{13} litre mol⁻¹) for ammonium derivatives of ferrocene.⁶⁹ However, the entropy contribution in the binding of cucurbit[7]uril with MV^{2+} cation is positive, while the entropy changes in the interactions with ferrocene and its ammonium derivative are negative.³⁵ Thus, the presence of polar portals in the cucurbit[7]uril molecules makes the enthalpy contribution in the interactions with positively charged metal complexes favourable. At the same time, the entropy changes depend on a number of factors, the most important being desolvation of the guest species, which in turn is determined by its structure.

The presence of the ionised groups at the rims of water-soluble calix[*n*]arenes and calix[4]resorcinarenes significantly increases the contribution of electrostatic interactions to the total energy of formation of a 'host-guest' complex.⁶⁶ Such

conclusion, for example, was made on the basis of a study of complexation properties of calixarenes **4a–c** and calixarene **4d**, which adopts a partial cone conformation.^{70–72} In particular, it was found that the efficiency of binding of tetramethylammonium cations by calixarene **4b** is an order of magnitude higher than that by calixarene **4c**. A comparison of the complexation ability of calixarenes with amino acids leads to the conclusion that the presence of sulfonate groups in the upper rim of calixarene is necessary for the binding of amino acids.⁷⁰ It should be noted that the binding constant of organic ions also depends on the conformational rigidity of sulfonate groups at the rim of the cyclophane receptor. For example, the binding constant of tetramethylammonium decreases by two orders of magnitude upon transition from calix[4]arene **4a** (Ref. 71) with fixed sulfonate groups in the upper rim of the molecule to sulfonatomethylcalix[4]resorcinarene (**5**)⁷³ with conformationally mobile sulfonate groups.^{70–73}

However, the contribution of the electrostatic interactions to the total energy of formation of inclusion complexes of water-soluble calixarenes and resorcinarenes is considerable, but not decisive. In particular, the analysis of ¹H NMR spectra and thermodynamic characteristics of inclusion complexes of water-soluble sulfonatocalix[4]resorcinarene with a number of organic molecules and ions⁶⁶ reveals that the complexation constant of a non-charged substrate with calixarene is determined mainly by the efficiency of interactions of CH-fragments of the guest molecule with the π -donor cavity of the host molecule. It was shown that the formation of inclusion complexes of water-soluble calix[4]resorcinarenes is an enthalpy-favourable process because CH- π -interactions make a significant contribution to the formation energy. As a result, the higher the CH-acidity of the substrate molecule and the higher the π -donor character of the calixarene cavity, the more efficient the binding.⁶⁶ Later⁷⁴ it was shown that benzene derivatives with electron-withdrawing substituents form more stable inclusion complexes with water-soluble calixarenes than their analogues with electron-donating substituents. This fact also indicates the importance of CH-acidity of the 'guest' molecule in the formation of 'host-guest' complexes. The process of binding of calix[4]arenes **4a** and **4b** with tetramethylammonium and tetramethylanilinium is also enthalpy favourable, while the change in entropy upon complexation is negative.⁷¹ However, when non-inclusion outer-sphere associates are formed, e.g., the associate **6** with a zinc porphyrin

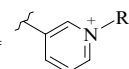

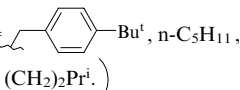

R = H, X = SO₃⁻ (**a**);
R = CH₂CO₂H; X = SO₃⁻ (**b**), (**c**).

R = CH₂CO₂H.

R¹ = (CH₂)₂OEt,
R² = 
R³ = 

complex, the multi-centred interactions between charged rim and the guest molecule require their substantial desolvation. Probably, this is the reason for the positive entropy change in this process.⁷⁵

p-Sulfonatothiocalix[4]arene (**7**) is an analogue of *p*-sulfonatocalix[4]arene in which the methylene bridges are replaced by sulfur atoms.⁷⁶

It was suggested⁷⁷ that thiocalix[4]arene exceeds classical calixarene in its ability to form inclusion complexes due to the larger size of the cavity. However, the later results^{78–80} do not support this suggestion. In particular, a comparison of the values of ΔG , ΔH and ΔS of formation of pyridinium complexes with both receptors revealed that the binding with thiocalix[4]arene is less efficient due to smaller enthalpy contribution.⁷⁹ This was accounted for by the lesser π -donor character of thiocalixarene hydrophobic cavity in comparison with that of classic calixarene, which results in less efficient CH– π -interactions. Hence, thiocalixarene is more selective towards the aromatic fragment of toluene, while calixarene itself binds the methyl group and the aromatic ring with the same probability.⁷⁴

As already mentioned before, the thermodynamic characteristics of inclusion complexes of water-soluble calixarenes with metal complexes are little studied. However, it is natural to assume that the driving forces of the formation of such outer-sphere associates are also electrostatic interactions with the rim and CH– π -interactions with the hydrophobic cavity. The stability and the structure of outer-sphere associates of complexes $[\text{Co}(\text{en})_3]^{3+}$ (**8**), $[\text{Co}(\text{en})_2\text{ox}]^+$ (**9**), $[\text{Co}(\text{L-His})_2]^+$ (**10**), $[\text{Co}(\text{bipy})_3]^{3+}$ (**11**) (en is ethylenediamine, ox is oxalate, L-His is L-histidine) with *p*-sulfonatothiocalix[4]arene and sulfonatomethylcalix[4]resorcinarene (for example, associate **12**) were studied.⁸¹ It was shown that, similarly to the binding of organic cations, the larger the charge of the complex and the more compact its ligands, the higher the stability of outer-sphere associates. For both receptors, the association constant of compound **8** is the highest and the values of the constants decrease in the series **8** > **11** > **10** > **9**. Thus, the substitution of the oxalate anion for one of the en ligands as well as enlargement of the chelate ring on going from en to bipy results in the decrease in the calixarene complexation constant. Moreover, it was shown that the outer-sphere associate **13** containing cation **10** is not an inclusion complex and is formed as a result of multi-centred electrostatic interactions with the rim of the calixarene molecule.

Thus, the following conclusions may be drawn from the analysis of thermodynamic parameters of complexes of cyclodextrins, cucurbiturils and calixarenes with organic and metal-containing substrates:

1. Binding of substrates to cyclodextrins is usually the entropy-favourable process due to a hydrophobic effect, while the 'host–guest' interactions are not efficient enough for a favourable enthalpy contribution. The presence of polar portals in cucurbiturils and charge of rims in calixarenes increases their affinity towards positively charged metal complexes due to more favourable (in comparison with cyclodextrins) enthalpy contribution in the total interaction energy. The enthalpy contribution increases on going from cucurbiturils to water-soluble calixarenes. However, the favourable enthalpy contribution in the formation of 'host–guest' complexes of water-soluble calixarenes is the result of not only significant contribution of electrostatic interactions with charged groups of the rim but also of CH– π interactions with the calixarene cavity.

2. The hydrophobic effect is mainly responsible for the entropy change in the formation of 'host–guest' complexes of cyclodextrins. The entropy change in the cases of cucurbiturils and calixarenes is caused primarily by the guest molecule desolvation and therefore depends on the structure of the molecule as well as on the structure of the 'host–guest' complex.

3. In contrast to cyclodextrins and cucurbiturils, water-soluble calix[4]arenes form outer-sphere associates, where the charged metal complex only covers the charged rim and its ligands are not inserted into the macrocyclic cavity. Obviously, the efficiency of multi-centred electrostatic interactions with the ionised groups of the calixarene rim is responsible for the formation of such complexes of water-soluble calixarenes.

IV. Design of switchable systems on the basis of outer-sphere coordination of charged metal complexes and macrocycles

There is a growing interest in recent years in supramolecular systems in which an external action causes re-orientation of their fragments (components) and/or changes in their physicochemical properties as potential building blocks in the design of the so-called molecular devices and machines.^{82–84} In the present chapter, we discuss the possibility of changing the structure of outer-sphere associates of charged metal complexes and water-soluble macrocycles by varying pH and the electrochemical potential.

1. pH-Switchable systems

Obviously, the presence of ionisable groups in the macrocycle and/or in the guest molecule is a prerequisite for pH-switchable outer-sphere coordination of a metal complex to a macrocycle. Cucurbiturils are devoid of such groups and deprotonation of the hydroxyl groups of cyclodextrins is observed only under strongly basic conditions.⁴⁴ For that reason, the design of pH-switchable systems with these macrocycles is based on the processes of protonation–deprotonation of the guest species. For instance, it was shown⁸⁵ that the binding constants of novocaine with β -cyclodextrin in acidic and neutral media are almost identical in spite of the different degrees of protonation of novocaine (singly and doubly-charged cation, respectively). Only in the basic media, when a neutral form of novocaine is formed, was the fivefold increase in the binding constant was observed. Obviously, cucurbiturils with their additional sources of electrostatic interactions 'host–guest' (the polar portals) are more promising as potential pH-switchable systems than cyclodextrins. The system polyamine–cucurbit[6]uril is one of the first examples of pH-controllable translocation.⁸⁶ pH-In-

duced translocation in this system is caused by different basicity of the nitrogen containing fragments at the opposite ends of the guest molecule.

The protonation of amino groups also drives the polyrotaxane-based molecular machines.^{87, 88}

The carbonyl portals of cucurbiturils may be protonated in highly acidic media;⁴⁴ however, low basicity of the carbonyl groups seriously hinders the application of this process as the source of pH-induced translocation. As it has been mentioned above, the presence of ionised groups at the rim of water-soluble calixarenes results in much stronger dependence of the formation constant of a host–guest complex on the charge of the guest molecule, than in the case of cucurbiturils. However, there were no observations of threading of oxyethyl or polyrotaxane chains through the cavity in the case of water-soluble calix[4]arenes. It was shown⁸⁹ by ¹H NMR study in benzene that triphenylureidocalix[6]arene may form pseudorotaxanes due to the large size and conformational lability of the cavity. However, cyclodextrins and cucurbiturils are more widely used in the design of such molecular machines.

Yet another interesting feature of *p*-sulfonatocalix[4]arenes and their thia-analogues, namely the high acidity of their hydroxyl groups,⁹⁰ should be noted. It is caused by the presence of strong circular intramolecular hydrogen bonds between the phenolic OH-groups at the lower rim of the calixarene cavity. This in turn makes it possible to control the π -donor character of the cavity⁹¹ or the charge at the upper rim⁷³ of calixarenes by pH-induced deprotonation of hydroxyl groups. Alteration of the orientation of non-symmetrical organic cations inside calixarene cavity is one of interesting consequences of the pH dependence of water-soluble calixarene complexation. One of the first examples of pH-regulated relative orientation of a nonsymmetrical ‘guest’ (trimethylanilinium cation, TMA) and ‘host’ (*p*-sulfonatocalix[4]arene) was described.^{91, 92} The formation of inclusion complex in a wide range of pH values was proved on the basis of ¹H and ¹³C NMR spectroscopic data. The calixarene cavity contains mainly the aromatic fragment of TMA at high acidity (pD 0.4), while under neutral conditions (pD 7.3) trimethylammonium group and aromatic moiety are non-specifically bound by the ‘host’ molecule.

The differences in the binding modes may be caused,⁹¹ by changes in the electron-donating properties of an aromatic π -system due to dissociation of hydroxyl groups in the neutral media. The available data⁷¹ show that ditopic TMA is bound selectively through its aromatic fragment to all host molecules having fixed cone conformation and sulfonate groups at the upper rim (compounds **4a,b,d**). At the same time, calixarene **4c** recognises only polar alkylammonium group of TMA. Calixarene **4d**, which adopts a partial cone conformation binds TMA non-selectively like conformationally much more flexible receptor **4a**. Thus, the selectivity of inclusion of more hydrophobic (aromatic) or of more charged (trimethylammonium) fragments is determined by the efficiency of both electrostatic interactions at the rim and CH– π interactions with the calixarene cavity.

In the study of complexation of ditopic *N*-methylpyridinium cation with sulfonatomethylcalix[4]resorcinarene it was found⁷³ that in neutral and slightly acidic media the aromatic fragment is included into the resorcinarene cavity, while deprotonation of calix[4]resorcinarene hydroxyl groups predominantly results in inclusion of the *N*-methyl group into the cavity.

The use of a ditopic guest becomes even more interesting when there is a possibility of comparing the complexation that proceeds under kinetic or thermodynamic control (Fig. 1). Under kinetic conditions, in a multicomponent supramolecular system containing cucurbit[6]uril (CB[6]U), cucurbit[7]uril (CB[7]U), symmetrical cyclohexane-1,4-diammonium cation (**14**) and ditopic adamantyl(alkyl)ammonium ion (Alk = Buⁿ, n-C₆H₁₃, n-C₈H₁₇) (**15**), cation **14** is included into the cavity of cucurbit[7]uril and the alkyl chain of cation **15**, into the cavity of cucurbit[6]uril.⁹³ In equilibrium, the symmetrical cation **14** is included predominantly into the cavity of cucurbit[6]uril and the adamantyl fragment of ditopic cation **15**, into the cavity of cucurbit[7]uril.

Figure 1. Kinetically and thermodynamically controlled complex formation of cucurbit[*n*]urils (*n* = 6, 7) with symmetrical cyclohexane-diammonium cation and ditopic adamantyl(alkyl)ammonium cation.

It is natural to suggest that the switchable complex formation may be based upon ditopic metal complexes, for instance, alkyldimethyl(ferrocenylmethyl)ammonium. It was shown⁹⁴ that the ferrocene fragment of this complex, in accordance with its size, is bound most efficiently to the cavity of β -CD, while the alkyl fragment, of α -CD. Thus, this ditopic ‘guest’ and α - and β -cyclodextrins are the basis for the construction of a multicomponent supramolecular system.

The mutual arrangement of guest and host molecules in the supramolecular complex formed can be changed by varying pH and hence, the charges on various parts of a metal complex. Adeninato-chloro-bis(ethylenediamine)cobalt(III) (**16**) has been chosen as a non-symmetrical guest. This complex undergoes two-stage protonation at the basic nitrogen atoms of adenine heterocycle in neutral and slightly acidic media.

Data from ^1H NMR spectroscopy show that the protonation of the adenine moiety of complex **16** upon decrease in pH from 9 to 6 results in structural changes of outer-sphere associate between *p*-sulfonatothiacalix[4]arene (ST[4]A) and cobalt complex (the structures **17a–c**) (Fig. 2) and in significant increase in its stability constant.⁹⁵ The decrease in pH brings about protonation of both the metal complex and the phenolate rim of *p*-sulfonatothiacalix[4]arene from hexa- to penta-anion. As mentioned above, the increase in π -donor character of the calixarene cavity induced by deprotonation of the phenolic groups results in more efficient $\text{CH}-\pi$ interactions. Therefore, in this case the neutralisation of the adenine fragment due to its protonation rather than the decrease in the π -donor character of the receptor cavity due to the protonation of the phenolate groups is the decisive factor that determines

the 'host–guest' binding constant and the orientation of metal complex relative the macrocycle cavity.

Thus, the presence of ionised and/or ionisable groups at both rims of calix[*n*]arenes is responsible for more efficient pH control of the complexation than in the case of cucurbiturils and cyclodextrins. However, the ability of the calixarene cavity to be 'threaded' by aliphatic and oxyethylene chains is much poorer than that of cyclodextrins and calixarenes, therefore the water-soluble calixarene-based molecular devices and machines should be designed differently.

2. Redox-switchable systems

The electrochemical properties of the inclusion complexes are crucial for the construction of redox-switchable systems. It is known that the redox potential of a redox-active species depends on the character of the solvent and the counter-ions. Naturally the outer-sphere association with macrocycles also should result in the modification of electrochemical properties. In other words, if the outer-sphere environment of a redox-active complex stabilises its reduced or oxidised form, the shift in the electrochemical potential of the pair is observed. Therefore, the larger the difference between the constants of outer-sphere association of macrocycle with reduced and oxidised forms of a metal complex, the larger the shift of the potential. As mentioned above, β -cyclodextrin binds the reduced form of ferrocene more efficiently, which results in a significant shift of potential of the pair $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}$ into the anode region.³³

The opposite shift should be expected for macrocycles that contain polar or ionised groups and therefore form more stable outer-sphere associates with charged metal complexes. Indeed,

Figure 2. Percentage (α) of the adeninatochlorobis(ethylenediamine)-cobalt(III) forms with different degrees of protonation as a function of pH. (1) Form **17a**, (2) form **17b**, (3) form **17c**.

the outer-sphere association with *p*-sulfonatocalix[6]arene results in the cathodic shift of the redox potentials of Fe^{II} (ferrocene) and Co^{III} (cobaltocene) complexes due to stabilisation of oxidised forms with highest positive charge.^{96,97} Outer-sphere interaction of cobalt tris(bipyridyl) with sulfonate derivatives of thiocalix[4]arene and calix[4]resorcinarene⁵⁷ brings about analogous stabilisation of the oxidised form of the complex.

It is natural to expect that cucurbiturils should exhibit properties intermediate between these two extreme cases (sulfocalixarenes and cyclodextrins). Indeed, the inclusion of metal complexes and organic cations into the cavities of cucurbiturils may result in both the anodic and cathodic shifts of the reductive potential of a guest depending on the structure of the latter. Particularly, significant negative (cathodic) shift of the reductive potential of methylviologen ($\text{MV}^{2+}/\text{MV}^+$ and MV^+/MV^0) inserted into the cavity of cucurbit[8]uril indicates that the inclusion complex of the oxidised (charged) form of methylviologen is more stable than that of the reduced form.⁶⁸ However, the inclusion of copper cyclamate⁵⁴ and ferrocene⁶⁹ into the cucurbituril cavity causes a positive (anodic) shift of the potential of the pairs $\text{Cu}^{2+}/\text{Cu}^+$ and $\text{Fe}^{3+}/\text{Fe}^{2+}$. Probably, relative stabilisation of the reduced form in this case indicates a dominant hydrophobic contribution to the energy of host–guest binding. Thus, the cucurbiturils can stabilise preferably both oxidised and reduced forms of a guest molecule. Large cavity of cucurbit[8]uril may include two molecules of a partially reduced form MV^+ , which results in a redox-controlled stoichiometry of the complexation, because the oxidised form MV^{2+} produces a 1 : 1 complex.⁹⁸ Yet another very important difference between the electrochemical properties of inclusion complexes of cyclodextrins and cucurbiturils should be emphasised, namely, the different mechanism of redox processes. In the case of cucurbit[*n*]urils (*n* = 7, 8), the direct electron transfer to methylviologen or from cucurbit[*n*]uril-bound ferrocene takes place, which follows from the fact that the voltammograms recorded at the various scan rates are identical and that the difference in the reduction and oxidation potentials remains the same within the limits of

reversibility.^{68,69} At the same time the oxidation or reduction of cyclodextrin inclusion complexes takes place only upon their dissociation. This results in different cyclic voltammograms recorded at the different scan rates^{93,99} as well as in the increase in the difference of the reduction and oxidation potentials up to 70–80 mV, which is beyond the reversibility limits.

The combination of a redox-active metal complex and various macrocycles is of interest for the design of switchable systems. For example, the design of a molecular machine was based on the predominant inclusion of the oxidised form of cobaltocene into the cavity of sulfocalix[6]arene and of the reduced form, into the cyclodextrin cavity (Fig. 3).⁹⁷

V. Outer-sphere association of metal complexes with macrocycles as a method of modifying physicochemical properties of a supramolecular system

It was shown in the previous Section that it is possible to control the process of inclusion of a metal complex into the cavity of the macrocycles under consideration by an external action (variation of pH or electrochemical potential). The dependence of thermodynamic parameters of the complexation on the charge and structure of the metal complex is the basis for such control. Inclusion of metal complexes into macrocycles also results in changes of their electrochemical properties, which depend on the character of the macrocycle. Therefore, these macrocycles can be regarded as molecular containers, immersion of metal complexes into these containers modifies the physicochemical properties of the complexes. The modification of physicochemical properties of metal complexes induced by their outer-sphere association with macrocycles is discussed in the present Section.

1. Solubility modification

There are hydrophilic and lipophilic areas in molecules of all macrocycles under consideration, which enables modifying the solubility of metal complexes by formation of the corresponding outer-sphere associates. For instance, cyclodextrins and water-soluble calixarenes increase the solubility of water-insoluble species due to their inclusion into the hydrophobic cavity, while the hydrophilic outer surface of the molecule or the hydrophilic rim make the associate formed water-soluble. For this reason the cyclodextrins are used successfully for the transportation of lipophilic metal-containing catalysts into the aqueous phase.⁴¹ In the case of calixarenes, the outer-sphere association with charged metal complexes results in significant decrease in solubility mainly due to neutralisation of the macrocycle rim charge. On the contrary the formation of inclusion complexes of cucurbiturils with charged bis-chelate complexes of transition metals causes the increase in water solubility, while the macrocycle itself is soluble only in highly acidic aqueous media. Binding of charged metal complexes to the macrocycles possessing lipophilic outer surface and hydrophilic inner cavity (antibiotics,¹⁴ crown ethers,¹⁰⁰ calixarenes with hydrophobic substituents¹⁰¹), makes them lipophilic. It should be noted that the selectivity of metal ion–calixarene binding at the chloroform–water interface differs significantly from that in a one-phase system.¹⁰² It is caused by the increase in the contribution of solvation and dissolution energy to free energy of extraction. Similar effect is observed in the extraction of a series of charged copper and cobalt complexes by calix[4]resorcinarene derivatives from aqueous solutions into the chloroform layer.¹⁰¹ Identically measured degrees of extraction of various metal complexes by calix[4]resorcinarene derivatives do not correlate with the corresponding binding constants measured in water–alcohol media. The presence of

Figure 3. A scheme of the complexation of oxidised and reduced forms of cobaltocene with sulfonatocalix[6]arene (SC[6]A) and β-cyclodextrin, respectively.

ionisable groups, for example, hydroxyl groups in calix[4]resorcinarenes and lasalocid, determines the pH-dependence of extraction and transport of the corresponding metal complexes through the chloroform membrane.^{20, 101} We are not going to discuss this area in the present review as there is a number of other reviews on this subject (see, for example, Refs 102 and 103).

The case of calixarene functionalisation is a clear advantage over other macrocycles as it makes possible introduction of substituents required for the efficient binding of the ion to be extracted and the corresponding counter-ion as well as of groups ensuring the required lipophilicity of the extractant or the carrier.¹⁰³ For example, the effective transfer of charged metal complexes was achieved by the introduction of aminomethyl and alkyl (particularly, $n\text{-C}_{11}\text{H}_{23}$) groups in to the calix[4]resorcinarene matrix.¹⁰¹ Macrocycle **18** exists in a zwitter-ionic form due to intramolecular proton transfer from hydroxyl to aminomethyl group and its transportability depends on the presence of both anionic (phenolate) and cationic (ammonium) groups.

At the same time, the cyclodextrins increase the water solubility of lipophilic metal complexes more effectively than calixarenes and cucurbiturils.⁴¹ Probably, the reason is that cucurbiturils are less water-soluble than cyclodextrins while the cavity of calixarenes, in contrast to that of cyclodextrins, is not proper for deep embedding of a guest molecule.

2. Modification of spectral properties of metal complexes

a. NMR spectroscopy

It is known that the inclusion of a fragment of a guest molecule into the receptor cavity results in changes in chemical shifts of its protons in the ^1H NMR spectra.¹⁰⁴ These changes depend on the mutual arrangement of the guest protons in the host cavity and on the structure of the macrocycle. Taking into account the π -donor properties of the calixarene cavity, it is natural to assume that inclusion of a fragment of the inner sphere of the metal complex into the cavity will result in more substantial upfield shift of proton signals than in the case of cyclodextrins or cucurbiturils. From a comparison of single-crystal X-ray data for inclusion complexes of various macrocycles it is possible to conclude that metal complexes are embedded deeper in the cavities of cucurbiturils^{51–53} and cyclodextrins³⁹ than in the cavities of water-soluble calixarenes.^{55–59} However, the changes in the chemical shifts in ^1H NMR spectra are comparable with, or even less than, those in the case of calixarenes.^{35, 41, 51, 57} It should be noted that the calixarene cavity shielding effect provides additional possibilities for studying the structure of host–guest complexes due to more pronounced dependence of the chemical shifts of the guest protons on the position of the molecule in the cavity of the host.^{104–106}

The rate of exchange between free and macrocycle-bound guests is yet another important characteristic of the complexation process. The rate of such exchange for cucurbiturils and cyclodextrins depends on the nature of the guest. Particularly, the slow exchange rate was found for the complex of cucurbit[7]uril with methylviologen ($\sim 10^2 \text{ s}^{-1}$),⁶⁸ while the rate of exchange in the complexes of β -CD with ferrocenecarboxylate, cobaltocene and reduced forms of methylviologen is equal to

$\sim 10^4 \text{ s}^{-1}$. Fast (on the NMR time scale) exchange is typical of inclusion complexes of water-soluble calixarenes with organic cations and charged metal complexes.^{66, 71, 81} However, the exchange slows down significantly upon encapsulation of a guest molecule between two calixarene molecules.^{107–109}

Thus, the NMR spectra of the ‘guest’ and the ‘host’ change upon complexation with all three macrocycles. The shielding effect, which causes the upfield shift of signals of protons of the guest molecule is most pronounced for cucurbiturils (due to the presence of polar portals) and calix[4]arenes (due to the presence of ionised groups at the rim of the molecule and of the π -donating cavity).

b. Electronic absorption spectroscopy

Analysis of the changes in the spectra of metal complexes induced by interactions with macrocycles should be preceded by the analysis of similar changes in indicators because the spectral properties of molecules and ions of the indicators are extremely sensitive to the changes in the micro-environment polarity due to the presence of chromophore groups and an extended π -system. It is for this reason that many indicators are successfully used as probes in the studies of structural and thermodynamic parameters of micellar pseudophases in aqueous solutions.¹¹⁰ Thus the most long-wave absorption bands of some indicators (acridine red, acridine orange, pyronin) exhibit red shift in the formation of inclusion complexes with cyclodextrins and blue shift when placed into the cavity of sulfonated calix[6]arenes in aqueous solutions.¹¹¹ Using the known dependence of the shift of absorption bands of the indicator on the polarity of the solvent,¹¹⁰ one can conclude that the polarity of micro-environment decreases upon inclusion into the cyclodextrin cavity and increases in the cavities of water-soluble calixarenes.¹¹¹ This difference reveals significant dissimilarity between the cavities of these macrocycles. Unfortunately, the low solubility of cucurbiturils in neutral aqueous solutions prevents their comparison with their associates under analogous conditions. A comparison of the inclusion complex formation of β -CD and cucurbituril with a series of indicators in water–formic acid media⁴⁸ showed that the presence of carbonyl portals affects the ‘host–guest’ binding constant, but the changes in spectral characteristics of the indicator molecules upon inclusion into the cucurbituril cavity is analogous to those in the case of cyclodextrin.

The spectral properties of the transition metal complexes also may change as a result of outer-sphere association with macrocycles. It is known that outer-sphere coordination with crown ethers does not alter significantly the spectra of ruthenium amino and diimino complexes,^{112, 113} while the formation of intermolecular hydrogen bonds between hexacyano complexes of the transition metals and protonated polyazamacrocycles results in the shift of the charge transfer band metal–ligand or ligand–metal.¹¹⁴ Similar spectral changes were observed for ruthenium(II) and cobalt(III) tris(bipyridyl) complexes and were caused by intermolecular π – π -interactions with DNA.^{11, 12} Obviously, not merely the presence, but also some preorganisation of the aromatic fragments is required for the stacking interactions in the outer-sphere binding of metal tris(bipyridyl) complexes to macrocycles. For example, the inclusion of a bipyridyl fragment of tris(bipyridyl)cobalt(III) into the cavities of water-soluble calixarenes (sulfonatomethylcalix[4]resorcinarene and *p*-sulfonatocalix[4]arene) virtually does not affect the charge-transfer ligand–metal bands.⁵⁷ It should be noted that the contribution of stacking interactions increases as the conformation mobility of calixarenes increases with the enlargement of macrocycles on going from sulfonatocalix[4]arene to sulfonatocalix[*n*]arenes ($n = 6, 8$).¹¹⁵ The hypsochromic shift of the metal–ligand charge-transfer band observed upon inclusion of tris(bipyridyl)ruthenium(II)

into the cavity of *p*-sulfonatocalix[8]arene may also be explained by the contribution of stacking-interactions.¹¹⁶

The inclusion complex of cucurbit[8]uril with *trans*-dichlorobis(ethylenediamine)cobalt(III) is an example of a complex in which both chelate rings are significantly distorted upon inclusion in the cavity of cucurbit[8]uril.⁵¹ Particularly, one of the chelate rings contracts with the 0.06 Å shortening of the Co–N bonds while the second one expands and the corresponding bonds became 0.05 Å longer. Naturally, such a change in the geometry of the coordination polyhedron results in the variation of the ligand field and is confirmed by the corresponding spectral changes (by shifts and differences in the intensities of the bands of d–d-transitions).

It should be emphasised that the inclusion of Co^{III} bis- and tris(diethyldiamine) complexes into the cavity of water-soluble calixarenes does not affect the spectra in the region of d–d-transitions. This fact is in agreement with the abovementioned conformational mobility of the calixarene cavity, which adjusts itself to the guest molecule during inclusion complex formation.

Octahedral metal trischelates may exist as two chiral isomers (Δ and Λ),¹¹⁷ and spectropolarimetric properties of metal tris(ethylenediamine) complexes are a sensitive instrument for studying conformation of their flexible chelate rings. The conformation of chelate rings in [Co(en)₃]³⁺ in aqueous solution is a superposition of two limiting conformations: *lel* and *ob*. The C–C bond in the former is almost parallel and in the latter, orthogonal to the tris-chelate three-fold axis⁸¹ (Fig. 4). It is known that electrostatic interaction and two- or three-centred intermolecular hydrogen bond are the driving forces of outer-sphere coordination of [Co(en)₃]³⁺ to cyclic and acyclic polyanions.^{118, 119} As a result, the ethylenediamine chelate ring is distorted towards *lel*-conformation in which the NH-protons are the most accessible for the formation of intermolecular hydrogen bond. This, in turn, causes some changes in the CD spectrum of the complex corresponding to the increasing contribution of the *lel*-conformation (Fig. 5).¹²⁰ Interestingly, the outer-sphere association of [Co(en)₃]³⁺ complex with DNA results in changes in the CD spectrum similar to those in the case of association with such simple polyanions as tartrates, in spite of a much more complicated type of interactions.^{10, 121} Outer-sphere interaction with sulfonate derivatives of thiacalixarene and calix[4]resorcinarene results in the opposite effect, *i.e.* in the increase in the main rotational component and in the decrease in the additional component in the CD spectra. This suggests the *lel* → *ob* inversion of the chelate ring. As mentioned above, the CH– π interactions are the main driving force of interactions of hydrocarbon fragments with the hydrophobic cavity of cyclophanes.⁶⁵ Therefore, it is logical to assume that these interactions with the cavities of water-soluble receptors are responsible for the

Figure 4. Limiting *lel*- (a) and *ob*-conformations (b) of ethylenediamine chelate rings in the complex [Co(en)₃]³⁺.

Figure 5. CD spectra of the complex [Co(en)₃]³⁺ without (1) and with outer-sphere coordination with tartrate ions (2) and *p*-sulfonatothiacalix[4]arene (3).

lel → *ob* inversion of the chelate ring as the *ob* conformation provides the best accessibility of CH-protons for the interactions with hydrophobic cavity.

Thus, the chiroptical properties of metal complexes are important for structural as well as chiral recognition and separation of macrocycles. Taking into account successful application of optical and chiroptical properties of cobalt and ruthenium trischelates for DNA recognition, application of chiral trischelates might be potentially useful for the synthesis of enantiomerically pure chiral synthetic macrocycles, such as oxazine derivatives of calix[4]resorcinarenes.¹²²

In conclusion of this Section, it should be noted that the spectral changes of the complexes reflect the types of interactions that emerge during the outer-sphere coordination of the complexes with various macrocycles. Particularly, the inclusion of complexes into rigid cavities of cyclodextrin and cucurbituril results in considerable distortion of the ligand environment of metal ion which, in turn, leads to more significant change in the spectral properties than in the case of non-rigid calixarenes. At the same time, the inclusion of a guest molecule into the calixarene cavity changes its spectral properties in a completely different way. CH– π interactions are typical of the most conformationally rigid *p*-sulfonatocalix[4]arene and its thia-analogue. These interactions cause distortion of the conformation of ethylenediamine chelate ring inside the cavity. The molecule of *p*-sulfonatocalix[8]arene better adjusts itself to the structure of included fragment due to higher conformational mobility. This makes possible, for example, the intermolecular π – π interactions between aromatic fragments of the ligand and one of the aromatic fragments of the 'host' molecule. These interactions cause the shift of metal–ligand or ligand–metal charge-transfer bands.¹¹⁹

c. Luminescent properties

Yet another practically important consequence of the inclusion of a complex into macrocyclic cavity is the change in its luminescent properties. Particularly, a significant increase in the quantum yield of luminescence and the change in the lifetime of the excited state of a lanthanide ion was observed upon inclusion of one of the ligands of the complexes Ln(NTA)₃·H₂O [Ln = Eu, Gd; NTA is 1-(2-naphthoyl)-3,3,3-trifluoroacetone] into the cyclodextrin cavity.^{123, 124} The alteration of photophysical properties of Ru^{II} polypyridyls upon their inclusion into the cavities of cyclodextrins^{125, 126} and into DNA grooves^{127, 128} is thoroughly studied. The increase in luminescence due to restricted deactivation of the emitting transition of Ru^{II} complex by water and oxygen

molecules was observed in both cases. The increase in intensity of luminescence was observed also upon addition of equimolar amount of *p*-sulfonatocalix[8]arene to the solution of tris(bipyridyl) ruthenium(II) in water.¹¹⁶ At the same time, the intensity of fluorescence of an outer-sphere associate of tris(bipyridyl) ruthenium(II) with *p*-sulfonatocalix[4]arene in methanol is considerably lower than that of the free complex. Slight (5 nm) bathochromic shift of the band in the emission spectrum of this associate was also observed.¹²⁹ These effects are presumably caused by interaction of *p*-sulfonatocalix[4]arene (counter-ion) with the dipole of tris(bipyridyl) ruthenium(II) in the excited state and possibly by photoinduced electron transfer as well. However, the possible influence of sulfonatocalix[4]arene on the photoinduced de-chelation caused by thermal transition from the emitting triplet level of bipyridyl to excited d-sublevels^{130, 131} was not taken into account. In turn, the photophysical properties of tris(bipyridyl) ruthenium(II) in aqueous solution are determined to a large extent by the efficiency of photoinduced de-chelation.¹³¹ Unfortunately, so far the number of similar papers on the changes in luminescent properties upon inclusion of complexes into the cucurbituril cavity is small.

3. Modification of reactivity and magnetic properties of metal complexes, stabilisation of unstable forms of complexes

It was already mentioned in Section II that the equilibrium of a complexation of a metal ion with ligands can be shifted upon formation of an outer-sphere associate with a macrocycle. It is very difficult to prove the existence of such stabilisation in solutions, which explains the scarcity of such studies. However, the X-ray studies of associates obtained from aqueous solutions of labile complexes under conditions of equilibrium between the metal ions, ligands and their complexes, show that the stabilisation of such complexes is possible by virtue of outer-sphere association with water-soluble derivatives of calix[*n*]arenes and calix[4]resorcinarenes.^{55, 59, 132} The structure of the complex in a crystal grown from a multicomponent solution is determined by stabilisation effects at both the molecular level (the host–guest interaction with the macrocycle) and the supramolecular level (the crystal packing effects). The selectivity of formation of inclusion complexes of cucurbit[8]uril with respect to the *trans*-isomer of bis(ethylenediamine)cobalt(III) in comparison with the *cis*-isomer is a striking example of the first type of stabilisation effects.⁵¹ Interestingly, the inclusion of the *trans*-isomer into the cavity of a macrocycle increases its thermal stability and inhibits its isomerisation into more thermodynamically stable *cis*-isomer in solutions..

As it has been mentioned in Section V.2.b, the inclusion of a molecule into the cavity of a macrocycle may result in changes in its spectra due to conformational and structural distortions of the chelate rings. The reactivity of the species inside the macrocycle cavity is also changed as a result of the change in the transition state energy upon inclusion complex formation. For example, the formation of a complex of the indicator Phenol Blue with sulfonatocalix[*n*]arenes (*n* = 4, 6, 8) inhibits its deamination in alkaline solutions.¹³³ Similarly, the inclusion of this indicator into the cavity of cucurbituril substantially inhibits its decomposition to *p*-benzoquinone and diamine in acidic media.⁵⁰

The kinetic parameters of redox reactions and the reactions of ligand exchange are the quantitative characteristics of the reactivity of transition metal complexes. There is a number of papers on the catalysis and inhibition of redox reactions, particularly on the changes in the rate of outer-sphere metal-to-metal electron transfer upon outer-sphere binding of one of the transition metal complexes to cyclodextrins, micellar pseudophase, polyazamacrocycles, DNA and polypepti-

des.^{134–141} The analysis of literature shows that there are two main factors determining the effect of outer-sphere association on the redox properties of a complex. The first one is a change in the interaction constant between metal complexes acting as reducing and oxidising agents. If a macrocycle is a counter-ion for one of these complexes, the outer-sphere association decreases the charge of the metal complex. If the oxidising and reducing agents bear opposite charges, inhibition of the redox process upon outer-sphere association of one of the reagents with a macrocycle may be related to the decrease in the constant of ion pair formation between the reactants. On the contrary, if the oxidising and reducing agents bear the same charge, the outer-sphere binding of one of the complexes with the macrocycle may result in more efficient interaction. For instance, it is possible to accelerate the reactions of hexacyanocobaltate and hexacyanoferrate with iodide ion upon outer-sphere association with a protonated polyazamacrocyle.¹¹⁴ Neutralisation of negative charges of the complexes $[\text{Co}(\text{CN})_6]^{3-}$ and $[\text{Fe}(\text{CN})_6]^{3-}$ results in more efficient reaction with iodide ion.

The second factor is the change in electrochemical potential or re-organisation energy. According to the Marcus–Hush theory, this may result in the change in a metal-to-metal electron transfer rate constant. The effect of *p*-sulfonatothiocalix[4]arene on the rate of outer-sphere electron transfer in the system $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}$ where the positively charged Co^{III} complex is included in the cavity of *p*-sulfonatothiocalix[4]arene and negatively charged Fe^{II} complex is not, was studied¹⁴² for the complexes $[\text{Co}(\text{en})_3]^{3+}$, $[\text{Co}(\text{en})_2\text{ox}]^+$, $[\text{Co}(\text{bipy})_3]^{3+}$, $[\text{Co}(\text{L-His})_2]^+$ and $[\text{Fe}(\text{CN})_6]^{4-}$. Kinetic data for the systems of *p*-sulfonatothiocalix[4]arene – $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}$ and for the corresponding binary systems indicate that the outer-sphere association with *p*-sulfonatothiocalix[4]arene results in the decrease in the formation constant of ion pair $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}$. This effect is particularly pronounced for the complex $[\text{Co}(\text{en})_2\text{ox}]^+$ because the inclusion of ethylenediamine chelate ring into the cavity leads to the conformation in which negatively charged oxalate ring is located outside the cavity. This ring prevents the formation of the ion pair with hexacyanoferrate, while the outer-sphere association of *p*-sulfonatothiocalix[4]arene with $[\text{Co}(\text{bipy})_3]^{3+}$ slightly decreases the association constant with hexacyanoferrate. It was noted in Chapter IV that outer-sphere association of tris(bipyridyl) cobalt(II) with *p*-sulfonatothiocalix[4]arene causes the shift of the reduction potential of the $\text{Co}^{\text{III}}/\text{Co}^{\text{II}}$ pair due to stabilisation of the oxidised form.⁵⁷ Irreversible decomposition of other Co^{III} complexes studied upon their reduction prevents obtaining similar data for them. However, it is likely that this effect should be observed for all Co^{III} complexes. According to the Marcus–Hush theory^{143, 144} the cathode shift of potential for the pair $\text{Co}^{\text{III}}/\text{Co}^{\text{II}}$ should cause the decrease in the $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}$ electron transfer constant on going from the binary system $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}$ to the ternary system $\text{Fe}^{\text{II}}-\text{Co}^{\text{III}}-p\text{-sulfonatothiocalix[4]arene}$. However, the values of the electron transfer constants in ternary systems calculated on the basis of experimental data are either close to, or even higher than, those in the binary systems. Therefore, other factors, for instance, the re-organisation energy, affect the value of the electron transfer constant on going from the binary to the ternary system. Interestingly, the increase in the rate constant is observed only in those complexes ($[\text{Co}(\text{en})_3]^{3+}$, $[\text{Co}(\text{en})_2\text{ox}]^+$) where the inclusion of a complex into *p*-sulfonatothiocalix[4]arene cavity results in the distortion of the chelate ring conformation. In conclusion, it should be emphasised that the mechanism of this unusual effect of calixarene on the electron transfer rate is unclear and requires further investigation.

The transition metal complexes are very interesting also due to their magnetic properties. It is known that the spin state of the transition metal complexes and accordingly their mag-

netic properties are determined mainly by the character of ligands in the first coordination sphere. However, there are several interesting examples of the influence of crystal lattice¹⁴⁴ and phase transition^{145, 146} on the spin state of Co^{II} and Fe^{II} complexes, respectively. One can assume that the distortions of the ligand environment due to inclusion of a metal complex into the macrocycle cavity may also cause admixture of the excited spin state of the complex to the ground state. This should result in a change in the spin state and accordingly of the spin transition temperature (high-spin–low-spin or *vice versa*). It is known, for example, that the increase in pressure destabilises the high-spin state and relatively stabilises the low-spin state of tris(ethylenediamine) cobalt(II), because the Co–N bond is longer in the high-spin state of Co^{II} than in the low-spin state.¹⁴⁷ It is of note that the internal pressure in a zeolite cavity exerts a similar effect of destabilisation of the high-spin state of tris(bipyridyl)cobalt(II).^{148–150} One can expect that similar effects will also be observed upon inclusion of metal complexes into cavities of macrocycles, but so far there are no such reports in literature.

VI. Conclusion

The formation of outer-sphere associates of the transition metal complexes with cyclodextrins, cucurbiturils and water-soluble calixarenes has much in common with the formation of the inclusion complexes with organic substrates, which serves as the basis for the development of new recognition methods. At the same time, the inclusion of transition metal complexes into the cavities of macrocycles is most perspective for the modification of their physicochemical properties and for the design of switchable systems as fragments of molecular devices and machines. The analysis of structural and thermodynamic parameters of outer-sphere associates of transition metal complexes with abovementioned macrocycles points to the following properties of water-soluble calix[n]arenes that make them unique as molecular containers for metal complexes.

1. π -Donor character of the calix[n]arene cavity determines both the type of 'host–guest' interactions (CH– π , π – π) and the polarity of microenvironment of a species included into the cavity or its fragment.

2. Due to conformational mobility of the cavity, calix[n]arenes adjust themselves to the structure of the guest molecule so that the type of the host–guest interactions depends on the value of n .

3. Polyfunctionality of calixarenes, in particular, the presence of substituents at the upper and lower rims and of the hydrophobic cavity as an additional binding centre, provides a great variety of complexes that are formed in a multicomponent system 'metal ion–ligand–calixarene'.

4. The predominant contribution of electrostatic interactions into the total Gibbs energy of the complexation of water-soluble calixarenes results in more pronounced dependence of the complexation on pH and on the electrochemical potential.

Thus, the accumulated data show that outer-sphere associates of water-soluble calixarenes with complexes of transition metals are a promising basis for the construction of supramolecular systems the properties of which can be switched by external action.

Abstract. The state of the art in the spectroscopic identification and kinetic analysis of condensed-phase reactions of bivalent germanium derivatives and their dimers is considered. Considerable attention is drawn to the comparison of results obtained by laser flash photolysis and spin chemistry methods. The bibliography includes 95 references.

I. Introduction

At present, the most important direction in chemistry and photochemistry of organometallic derivatives is devoted to the establishment of their reaction mechanisms. The wide use of modern physical research methods [optical, EPR and NMR spectroscopies, Chemically Induced Dynamic Nuclear Polarisation (CIDNP), flash photolysis, time-resolved luminescence, photolysis in cryogenic matrices] made it possible to identify short-lived species in many reactions of organosilicon and organogermanium derivatives. Keen attention of chemists to organometallic compounds containing the 14th Group elements is largely explained by their use in high technologies, first of all, in integrated microelectronics.

Laser flash photolysis and the methods of spin chemistry, namely, photochemically induced dynamic nuclear polarisation and the magnetic effect, play the decisive role in studying reactions that involve short-lived intermediates. The use of photogeneration makes it possible to produce transient species

in high concentrations, record their optical spectra and study the kinetics of their growth and decay.

The literature contains numerous publications devoted to the identification of transient species formed in the condensed-phase photolysis of different silicon and germanium compounds. Among these species, mention should be made of carbene analogues, namely, organylsilylenes and -germylenes, silyl and germyl free radicals and short-lived derivatives of tricoordinate silicon and germanium, namely, substituted silenes and germenes. Thus information on heavy analogues of carbenes can be found in a monograph¹ devoted to the carbene chemistry; results on the synthesis, structure, spectroscopy and reactivity of germylenes and stannylenes are summarised in several reviews^{2–8} and recently published collections^{9,10} of reviews. However, despite the abundance of reference literature on this issue, no comparative analysis of the kinetic data obtained by different spectroscopic techniques and by different authors was carried out.

From our viewpoint, a real assessment of the further development in this field of chemistry requires comparison of the results obtained by laser flash photolysis and CIDNP. Thus, to date, based on the results of spin chemistry methods, the detailed schemes of processes that occur in solutions, involving germylenes and digermenes and including their interconversions, were constructed and the mechanisms for the formation of germanium-containing biradicals were proposed. Note that, although the involvement of the latter in elementary steps was often postulated based on the analysis of reaction products, their presence has never been proved by physical methods with the exception of CIDNP. This is why it seems useful to compare the CIDNP data that contain information on the structure of paramagnetic intermediates (free radicals, carbene analogues, biradicals) as the precursors of products formed, on the one hand, with the kinetic data on the formation and decay of short-lived germanium derivatives obtained in laser flash photolysis techniques, on the other hand.

II. Germylene precursors

In this Section, we describe the organogermanium derivatives that generate diorganylgermylenes under radiation. Cyclic germanium compounds such as $(R^1R^2Ge)_n$ are the efficient sources of germynes.^{1, 11–20} In 1982, the first cyclotrimergermane, hexakis(2,6-dimethylphenyl)cyclotrimergermane (**1a**) was isolated and described.¹⁶ To date, other cyclic tri- and polygermanes were synthesised.

Ar = 2,6-Me₂C₆H₃.

The ring may also include atoms of other elements, *e.g.*, silicon or carbon.²¹

Linear germanes with alkyl and aryl substituents, the analogues of linear hydrocarbons, can also serve as germylene precursors.^{22, 23} The largest group of precursors is formed by germanes of the $R^1R^2GeX_2$ type, where R^1 , R^2 are alkyl or aryl groups and X is a weakly bound heteroatomic substituent.^{3, 24–28}

R^1 , R^2 = Alk, Ar; X = SiMe₃, SePh, N₃, *etc.*

The possibility of generation of germynes from such compounds is often determined by the fact that a heteronuclear bond Ge–E (E = Si, Se, N) is less stable than a homonuclear bond E–E.

Stable digermenes with bulky substituents can serve as efficient sources of germynes. Digermenes with small substituents are short-lived species and are usually cyclised into cyclotetragermanes.

The formation of a germylene from tetraaryldigermene preliminarily synthesised by the photodecomposition of the corresponding trigermane was described.¹⁷

Aryl-substituted digermanes and silylgermanes $R^1R^2_2Ge-GeR^3_3$, $R^1R^2_2Ge-GeR^1R^2_2$ and $R^1R^2_2Ge-SiR^3_3$ (R^1 , R^2 = Ar) were synthesised and studied by laser flash photolysis and matrix-isolation methods.^{29–32} It was demonstrated that this kind of compounds are germylene precursors. Germanium-containing naphthalenes were distinguished as a separate class of precursors with properties similar to those of phenyl-substituted digermanes. Thus for photochemical reactions of 1-(pentamethyldigermanyl)naphthalene (PMDGN) (**2**), the transient species were identified and the composition of final products was determined using the methods of flash and steady-state photolyses.³³

Among the most convenient and frequently used germylene sources, a special place belongs to bicyclic compounds that contain germanium atom(s) in their bridges, namely, 7,7-

dialkyl(diaryl or alkylaryl)-7-germanorbornadienes **3a–e** (see Refs 24, 25 and 34) and 7,8-digermbicyclo[2.2.2]octadienes **4a,b**. The latter serve as precursors of both germynes and digermenes.

$R^1 = R^2$ = Me (**a**), Et (**b**), Buⁿ (**c**), Ph (**d**); R^1 = Me, R^2 = Ph (**e**).

R = Me (**a**), Et (**b**).

Photolysis of 7,7,8,8-tetramethyl-1,4-diphenyl-1,3-benzo-7,8-digermbicyclo[2.2.2]octa-2,5-diene (**4a**) was described for the first time by the authors of Ref. 35. Light-initiated reactions of these compounds were explored^{36, 37} by flash photolysis, matrix isolation and CIDNP methods.

The literature also contains a description of the photodecomposition of thiagermanes, for example, compound **5**, to afford the corresponding germylene and digermene.³⁸

Mes = 2,4,6-Me₃C₆H₂.

Thus, the precursors of reactive transient species of bivalent germanium are rather diverse. The wide choice of molecules with the desired and convenient spectroscopic and photochemical parameters makes it possible to carry out different pulse and steady-state experiments on the determination of properties of primary short-lived products.

III. Generation of transient species in the photolysis of germanium-containing compounds in low-temperature matrices

In chemistry and photochemistry of germanium-containing compounds, the identification of optical spectral bands of germynes and other transient species faces an essential problem associated with the strong dependence of the absorption band peak position (λ_{max}) on the experimental conditions. Moreover, both the method of species generation and the precursor type, on the one hand, and the solvent nature and temperature, on the other hand, are significant. According to modern concepts,⁴ one of the main reasons for this effect could be a trend of germynes towards complexation with Lewis acids and bases. The detection of active species involves either their stabilisation in low-temperature matrices or the use of methods with short detection times (time-resolved methods). Below, we consider the results of studies of short-lived germanium-containing intermediates that appear in the photolysis of different precursors in low-temperature matrices.

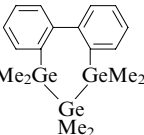

The first matrix-frozen germanium-containing compound subjected to the photolysis was (2,6-Et₂C₆H₃)₂Ge(SiMe₃)₂.¹⁷ The germylene formation was deduced solely from the analysis of final products obtained after the matrix was annealed.

Upon the photolysis (the excitation wavelength λ = 254 nm) of 7,7-dimethyl-1,4,5,6-tetraphenyl-2,3-benzo-7-germanorborna-2,5-diene (Me₂GNB) (**3a**) in 3-methylpentane (3-MP) glasses at 77 K, the optical spectra displayed absorp-

tion bands with maxima at 420 and 317 nm.^{24,25} The first band, which decayed above the matrix melting point, was assigned to dimethylgermylene (Me_2Ge). The second band, which remained in the spectrum after the sample was annealed, was attributed to 1,2,3,4-tetraphenyl-naphthalene (TPN) (**6**).

Photolysis of bis(trimethylsilyl)germane $\text{R}_2\text{Ge}(\text{SiMe}_3)_2$ derivatives ($\text{R} = 2,6\text{-Me}_2\text{C}_6\text{H}_3$, $2,6\text{-Et}_2\text{C}_6\text{H}_3$, $2,4,6\text{-Me}_3\text{C}_6\text{H}_2$) in 3-MP glasses made it possible to record optical spectra for a series of substituted germynes.²⁵ Table 1 shows spectral characteristics of germynes formed from different precursors. It is evident that the absorption maxima of observed bands fall in a range of 400–570 nm. (The nature of an electronic transition corresponding to germylene absorption bands is discussed below). It is noteworthy that the extinction coefficients of bands in low-temperature matrix spectra were not determined due to the absence of internal standards; the quantum yields of germynes described in the cited studies were also absent.

Table 1. Positions of absorption maxima for diorganylgermylenes in a 3-methylpentane matrix ($T = 77\text{ K}$).

Germylene	Precursor	$\lambda_{\text{max}}/\text{nm}$	Ref.
Me_2Ge	$\text{Me}_2\text{Ge}(\text{N}_3)_2$	405	28

	$\text{Ph}_2\text{Ge}(\text{SiMe}_3)_2$	466	25
	$\text{Ph}_2\text{Ge}(\text{GeMe}_3)_2$	462	22
$(4\text{-MeC}_6\text{H}_4)_2\text{Ge}$	$(4\text{-MeC}_6\text{H}_4)_2\text{Ge}(\text{SiMe}_3)_2$	471	25
MesBu^tGe	$\text{MesBu}^t\text{Ge}(\text{SiMe}_3)_2$	508	25
$(2,6\text{-Me}_2\text{C}_6\text{H}_3)_2\text{Ge}$	$(2,6\text{-Me}_2\text{C}_6\text{H}_3)_2\text{Ge}(\text{SiMe}_3)_2$	543	25
$(2,6\text{-Et}_2\text{C}_6\text{H}_3)_2\text{Ge}$	$(2,6\text{-Et}_2\text{C}_6\text{H}_3)_2\text{Ge}(\text{SiMe}_3)_2$	544	25
Mes_2Ge	$\text{Mes}_2\text{Ge}(\text{SiMe}_3)_2$	550	25
$(2,4,6\text{-Pr}_3\text{C}_6\text{H}_2)_2\text{Ge}$	$(2,4,6\text{-Pr}_3\text{C}_6\text{H}_2)_2\text{Ge}(\text{SiMe}_3)_2$	558	25

In 'soft' matrices,[†] germylene molecules even those containing substituents move and gradually undergo dimerisation to digermenes. At liquid nitrogen temperature, this proceeds over tens and hundreds of minutes. Dimerised products exhibit absorption bands at shorter wavelengths. Thus digermene $(\text{Mes}_2\text{Ge})_2$ has an absorption band with the maximum at 406 nm, whereas the corresponding germylene (Mes_2Ge) absorbs at 550 nm (see Table 1). In 'soft' 3-MP–IP matrices, several germylene complexes with organic molecules were synthesised.²⁵ As a rule, complexation substantially shifts the optical absorption bands to shorter wavelengths.

Photolysis of Me_2GNB (**3a**) in a low-temperature toluene- d_8 matrix was observed³⁹ to give rise to an optical

absorption band with the maximum at 420 nm, the same as for many other germanium-containing compounds (see Table 1). However, the authors of this study assigned this band not to a germylene but rather to a biradical $\text{TPN}^{\cdot-}\text{-GeMe}_2$ that appears on the cleavage of merely one $\text{Ge}-\text{C}$ bond. This assumption was based on the absence of noticeable decomposition of germanorbornadiene upon the annealing of the irradiated matrix. According to the authors, on heating of the matrix, the homolysis of the second $\text{Ge}-\text{C}$ bond proceeds much slower than the recombination of the first one. At higher temperatures, the rate constant for the second-bond homolysis may increase to the greater extent than the recombination rate constant. For this reason, in contrast to photolysis in matrices, photolysis in solutions leads to the decomposition of germanorbornadiene **3a**.

The data in Table 1 demonstrate that the position of the absorption band maximum (405–506 nm) in spectra of Me_2Ge formed in low-temperature matrices from different precursors varies over a wide range. One of the reasons for the band shift could be the different geometry of matrix-isolated germynes. As is seen from Table 1, the absorption band maxima of germynes with bulk substituents are shifted up to ~560 nm. As shown below, in such germynes, the $\text{C}-\text{Ge}-\text{C}$ angle is substantially larger due to the repulsion of substituents, which results in the long wavelength shift of the band. Apparently, in low-temperature matrices, too, Me_2Ge species generated from different precursors also have different $\text{C}-\text{Ge}-\text{C}$ angles.

IV. Laser flash photolysis of germanium-containing compounds in solutions. Optical spectra of germynes

Matrix isolation allows one to determine the spectroscopic parameters of reactive species but does not provide any kinetic information on their formation. The time resolution of an order of magnitude of 10 ns, which is typical of laser flash photolysis, offers a possibility for measuring rate constants for the fastest bimolecular reactions. At present, this method is widely used in photochemistry of germanium-containing compounds for studying transient species; this allowed optical spectra to be recorded and different reaction channels to be studied for many germynes.

One of the earliest studies³⁹ was devoted to the lamp flash photolysis of Me_2GNB (**3a**) solutions with 5 μs time resolution. Two absorption bands of transient species with maxima at 380 and 460 nm were observed. Experiments with the addition of dimethylgermylene acceptors into the solution have shown that this species is responsible for the first band. A comparison of absorbances at 380 nm (recorded immediately after the flash) and 320 nm (in 50 ms), *i.e.*, corresponding to the absorption range of TPN (**6**), the second stable product of norbornadiene decomposition, made it possible to determine the extinction coefficient of the dimethylgermylene band ($\epsilon^{380} = 1300\text{ litre mol}^{-1}\text{ cm}^{-1}$). The second band with the maximum at 460 nm in the original spectrum was assigned to germabenzonorcaradiene **7**, the product of the subsequent recovery of the broken $\text{Ge}-\text{C}$ bond.

A later publication³⁴ described the results of laser flash photolysis (248 nm) of compound **3a** in methylcyclohexane

[†] At 77 K, the viscosity of 3-MP mixtures with isopentane (IP) is in the range of $10^{12}\text{--}10^7\text{ Ps (g s}^{-1}\text{ cm}^{-1})$,²⁵ which allows one to call them 'soft'.

with 10 ns time resolution. It was found that upon a laser pulse, two wide bands with maxima at 330 and 490 nm appeared, which were assigned to the triplet–triplet (T–T) absorption of a TPN (**6**) molecule. The same bands appeared when the solutions of tetraphenyl-naphthalene itself were subjected to flash photolysis. In both cases, the spectral bands decayed upon the addition of oxygen into the reaction mixture; moreover, these reactions were characterised by similarly high rate constants (1.5×10^9 litre mol⁻¹ s⁻¹). Note that such rate constants are typical of quenching of triplet states of molecules. Thus, no absorption that could have been assigned to dimethylgermylene was observed. This contradicts both the results of flash photolysis³⁹ and the data on the photolysis of Me₂GNB (**3a**) in low-temperature matrices²⁶ (see Table 1).

It was assumed³⁴ that, upon the germylene elimination, an excited **3a** molecule transforms into an excited TPN (**6**) molecule as a result of dissociation. The transient Me₂Ge was not detected because its lifetime is shorter than several hundreds of nanoseconds. The high quantum yield ($\phi \sim 0.4$) of the conversion

points to the fast (on the picosecond time scale) homolytic cleavage of two Ge–C bonds. In this case, the luminescence with a lifetime of 3 ns observed on the excitation of Me₂GNB (**3a**) can only be attributed to singlet-state ¹(TPN)* luminescence. It should be noted that this explanation is inconsistent with the CIDNP effects observed on the photolysis of compound **3a**, which will be discussed in Section XIII.

An attempt to obtain a spectrum of Ph₂Ge germylene on the flash photolysis (248 nm) of 7,7-diphenyl-7-germanorbornadiene **3d** in hexane was unsuccessful.⁴⁰ Strong T–T absorption of tetraphenyl-naphthalene **6**, which was present in the reaction mixture as an impurity (5%), prevented the detection of the weak germylene signal.

Photodissociation of many other compounds to generate germynes occurred without any complications associated with the formation of excited triplet molecules, in contrast to the case of compounds **3a,e**. Thus laser flash photolysis of aryl-substituted linear trigermynes R₃¹Ge–GeR²R³–GeR₃¹ (R¹–R³ = Me, Ph) led to the appearance of two absorption bands with maxima in the ranges of 320–330 and 420–450 nm in the spectra recorded after the pulse.^{22,23} Both bands decayed with second-order kinetics. The use of double-pulse excitation made it possible to prove that germylene forms upon extrusion from an excited molecule

The analysis of kinetic data has shown that germynes possess long-wavelength absorption bands in the range of 420–450 nm. Short-wavelength bands (320–330 nm) might be associated with digermynes (R₃¹Ge)₂; however, these species have absorption bands in the range of 370–380 nm (see Section XI). Presumably,^{22,23} the homolytic cleavage of the Ge–Ge bond to form digermyl radicals that absorb in the range of 320–330 nm (see Section X) can occur simultaneously with the germylene extrusion. According to the results of laser flash photolysis, the positions of germylene absorption bands (420–450 nm) are well consistent with the results on the trigermine photolysis in low-temperature matrices,^{21,22} which demonstrated similar bands (see Table 1).

Laser flash photolysis (266 nm) of dodecamethylcyclohexagermane (**8**) in cyclohexane¹¹ led to the appearance of an absorption band with the maximum at 450 nm in the optical spectrum.

The decay of this band according to the second-order kinetics (the effective rate constant $k/\epsilon = 2.7 \times 10^7$ cm s⁻¹, where k is the reaction rate constant and ϵ is the extinction coefficient of the band) was accompanied by the appearance of a new band at 370 nm. The first band belongs to dimethylgermylene and the second one belongs to its dimerisation product, namely, digermene (Me₂Ge)₂. Photolysis of compound **8** in a low-temperature 3-MP matrix also resulted in the appearance of a germylene (identified by a band at 430 nm, see Table 1). Apparently, the shift of the band maximum to shorter wavelengths by 20 nm is explained by the changes in the reaction temperature and the solvent nature. Presumably,¹¹ dimethylgermylene is generated from the excited state of the parent molecule without the formation of transient germyl radicals.

On excitation (266 nm) of decamethylcyclopentagermane (**9**) in cyclohexane,¹⁹ an absorption band with the maximum at 490 nm appeared in the spectrum immediately after the laser pulse and then decayed at a rate corresponding to the second-order kinetics ($k/\epsilon = 3.5 \times 10^7$ cm s⁻¹). As it decayed, a new band with the maximum at 370 nm grew and then also decayed by the second-order kinetics ($k/\epsilon = 4.8 \times 10^6$ cm s⁻¹). The former band belonged to dimethylgermylene and the latter corresponded to its dimerisation product (Me₂Ge)₂. Photolysis of compound **9** in a 3-MP matrix led to the appearance of a band with the maximum at 506 nm, which was also assigned to germylene. Thus, for unknown reasons, spectra of germynes formed from cyclopolygermanes **8** (Ref. 11) and **9** (Ref. 19) in cyclohexane solutions demonstrated absorption bands shifted with respect to one another by 40 nm. Moreover, for the germylene formed from compound **9**, the absorption band maximum in the low-temperature matrix shifted to long wavelengths.

Of considerable interest are experiments³³ on subjecting a solution of 1-(pentamethyldigermanyl)naphthalene (**2**) in cyclohexane to laser flash photolysis (308 and 337 nm). Two absorption bands with maxima at 440 and 400 nm appeared in the spectrum immediately after the flash, and a new band at 460 nm appeared in 10 μs. The band at 440 nm assigned to dimethylgermylene decayed with second-order kinetics ($k/\epsilon = 2.5 \times 10^7$ cm s⁻¹), which suggests the formation of a digermene (Me₂Ge)₂. The latter is presumably responsible for the band with the maximum at 400 nm. A comparison of the time of germylene appearance with the compound **2** fluorescence lifetime made it possible to conclude that dimethylgermylene forms from the parent molecule in the excited singlet state. The subsequent appearance of an additional band at 460 nm was explained by the T–T absorption of the parent molecule **2**. However, the 10 μs delay in the appearance of the triplet state ³(PMDGN), which forms from the same excited singlet state ¹(PMDGN) as dimethylgermylene, still remains unexplained.

A spectrum recorded on the laser flash photolysis (248 and 266 nm) of a solution of dimethylphenyl(trimethylsilyl)germane ($\text{PhMe}_2\text{Ge}-\text{SiMe}_3$) in cyclohexane demonstrated a broad absorption band with the maximum at 425 nm, which was explained by the appearance of dimethylgermylene.²⁹

A similar intense absorption band with the maximum at 420 nm (together with two weaker bands at 330 and 490 nm and an additional shoulder in the vicinity of 380 nm) was observed upon a laser flash impact (308 nm) on a solution of dimethylbis(phenylseleno)germane [$\text{Me}_2\text{Ge}(\text{SePh})_2$] in cyclohexane.²⁷ To identify the absorption bands, $\text{Me}_2\text{Ge}(\text{SePh})_2$ was photolysed in 3-MP (77 K) and Ar (21 K) matrices. Upon irradiation (254 nm) of these matrices, similar spectra that contained the same bands as in flash photolysis experiments were observed. A band at 330 nm was assigned to a diphenyl diselenide molecule and the absorption at 490 nm was attributed to the radical PhSe^\bullet formed from this molecule.

Thus, the remaining band (420 nm) might belong to dimethylgermylene. EPR spectra of irradiated matrices showed that the shoulder at 380 nm is related to the appearance of the radical PhSe^\bullet .

Germylene Me_2Ge represents a transient species that formed on the laser flash photolysis (248 nm) of dimethylbis(trimethylsilyl)germane [$\text{Me}_2\text{Ge}(\text{SiMe}_3)_2$] in hexane.¹³ After a flash, absorption bands at 550 and 320 nm were observed. A band at 550 nm decayed according to the second-order kinetics over *ca.* 10 μs with the simultaneous formation of a new band with the maximum at 405 nm. These spectral and kinetic transformations were explained by the following reaction sequence:

According to the data on the photolysis of organylgermanes in low-temperature matrices (see Table 1), the band at 550 nm was assigned to germylene Me_2Ge and the band at 405 nm was assigned to digermene $\text{Me}_2\text{Ge}=\text{GeMe}_2$. A band similar to the former was observed on the photolysis of hexamethylcyclotrigermene (cyclo- Ge_3Me_6 , **1b**).¹³ The absorbance in a band at 405 nm that appeared immediately after the pulse increased in the process. These data are well described by the following reaction scheme:

Flash photolysis (266 nm) of phenyl-substituted digermenes ($\text{Ph}_n\text{Me}_{3-n}\text{Ge}_2$), where $n = 1-3$, in tetrahydrofuran³⁰ also led to the appearance of two absorption bands in the optical spectrum, namely, in ranges of 440–470 and 315–330 nm. The long-wavelength absorption bands of germynes decayed with quasi-first-order kinetics, presumably, in their reaction with THF (for $n = 2$ and 3, the rate constants were 1.1×10^5 and $2.0 \times 10^5 \text{ s}^{-1}$, respectively). The short-

wavelength band assigned to germyl radicals $\text{Ph}_n\text{Me}_{3-n}\text{Ge}^\bullet$ decayed with second-order kinetics with the observed rate constants (k_{obs}) in the range of $(1.9-4.3) \times 10^5 \text{ s}^{-1}$.

The absorption band of germylene Ph_2Ge with the maximum at 445 nm was observed on the flash photolysis (266 nm) of a bis(trimethylsilyl)diphenylgermane [$\text{Ph}_2\text{Ge}(\text{SiMe}_3)_2$] solution in cyclohexane.⁴¹ The absorption decayed with second-order kinetics ($k_{\text{obs}} = 3.7 \times 10^5 \text{ s}^{-1}$) and was accompanied by growth of a new band at 320 nm. The latter corresponds to diphenyldigermene ($\text{Ph}_2\text{Ge}=\text{GePh}_2$) and also decayed with second-order kinetics ($k_{\text{obs}} = 1.5 \times 10^5 \text{ s}^{-1}$).

Studies of solutions of digermene $\text{PhMe}_2\text{GeGeMe}_3$ in cyclohexane revealed the appearance of two absorption bands with maxima at 430 and 320 nm 200 ns after a flash (266 nm).³¹ Presumably, the long wavelength band belongs to a dimethylgermylene formed in the following reactions:

This dimethylgermylene decayed with second order kinetics ($k/\epsilon = 3.2 \times 10^7 \text{ cm s}^{-1}$). The short-wavelength band at 320 nm corresponds to the germyl radical $\text{PhMe}_2\text{Ge}^\bullet$, which also dimerises ($k/\epsilon = 7.0 \times 10^7 \text{ cm s}^{-1}$).

Table 2 shows the positions of absorption band maxima for diorganylgermylenes revealed by the laser flash photolysis. The large number of molecular precursors used and the regular appearance of transient absorption bands in the range of 420–550 nm, and also the detection of similar bands on the photolysis of the same precursors in low-temperature matrices (see Table 1) allows one to conclude that these bands indeed belong to germynes. However, it should be noted that even in the same solvent, the position of a band maximum might considerably shift when a germylene was generated from different precursors. In matrices, the absorption band maxima for Me_2Ge were located in a narrower interval, 420–440 nm (see Table 1); the exception is the data of a study¹⁹ in which a band with the maximum at 506 nm was assigned to dimethylgermylene.

The position of absorption bands in solutions of germylene Me_2Ge (see Table 2) formed from different precursors varies in the interval of 420–470 nm. In this case, too, the position of the dimethylgermylene absorption band maximum (490 nm) given in Ref. 19 does not fit into this interval. Insofar as the majority of studies used cyclohexane as the solvent (see Table 2), the shift of the absorption band of germynes generated from different precursors cannot be explained by the solvent effect.

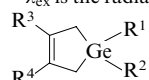

A recently published comprehensive review⁴⁴ on gas-phase reactions of germynes and dimethylstannylene points to a wide scatter of absorption band maxima assigned to dimethylgermylene. Presumably, this suggests that intermediates may have different structures including donor–acceptor complexes of this species.

It should be noted that in recent experiments on the flash photolysis with the better time resolution and the higher sensitivity (experiments with digital signal build-up), the absorption band maxima of germynes were shifted in the long-wavelength direction. It cannot be ruled out that in earlier

studies, the shorter wavelength bands that belonged to digermenes were assigned to germynes due to insufficient resolution times and high recombination rates of intermediates. In the gas phase, the kinetics of reactions of dimethylgermylene formed from different precursors was studied by the absorption in a range of 450–510 nm.⁴⁴ The spectra represented a broad band with the maximum at 476.5 nm, which corresponds to the longest-wavelength absorption band observed for germylene in the liquid phase (see Table 2).

In solutions, germynes are almost always formed in a cage that contains the solvent and the residual precursor. Hence, the formation of germylene complexes with such residues may be assumed as the additional reason for the absorption band shift for germynes generated from different precursors.

In most cases, germynes are dimerised to form digermenes. The value $k/\varepsilon \sim (1-5) \times 10^7 \text{ cm s}^{-1}$ shows that the recombination occurs with a high rate constant. The rate constant for bimolecular recombination (k) is unknown because the extinction coefficient of the germylene band was determined in none of the cited studies. As was mentioned above, the value $\varepsilon^{380} = 1300 \text{ litre mol}^{-1} \text{ cm}^{-1}$ shown in Ref. 39 corresponds to a band with the maximum at 380 nm, which was revealed by the lamp flash photolysis method (time resolution $> 5 \mu\text{s}$). The position of this band strongly differs from those for germynes synthesised in later studies by laser flash photolysis. It is only in the past three years that the attempts were undertaken to determine the extinction coefficients of Me₂Ge and Ph₂Ge species. For dimethylgermylene, $\lambda_{\text{max}} = 470 \text{ nm}$, $\varepsilon = 730 \text{ litre mol}^{-1} \text{ cm}^{-1}$ (Ref. 40) and for diphenylgermylene, $\lambda_{\text{max}} = 500 \text{ nm}$, $\varepsilon = 1850 \text{ litre mol}^{-1} \text{ cm}^{-1}$ (Ref. 43). Therefore, assuming the extinction

coefficient equal to $10^3 \text{ litre mol}^{-1} \text{ cm}^{-1}$, the dimerisation of germynes proceeds with a rate constant in a range of $(1-5) \times 10^{10} \text{ litre mol}^{-1} \text{ cm}^{-1}$. This range virtually coincides with the diffusion rate constant of a bimolecular reaction in hexane [$2.1 \times 10^{10} \text{ litre mol}^{-1} \text{ cm}^{-1}$ (Ref. 40)].

V. Fluorescence of germynes

Photolysis of germanium-containing compounds in low-temperature matrices allows one to obtain not only optical absorption spectra, but also luminescence spectra of transient species. Luminescence of dimethylgermylene was first observed upon photolysis of dodecamethylcyclohexagermane (**8**) in a 3-MP matrix.¹¹ The spectrum represented a broad band with the maximum at 650 nm and was the mirror image of the dimethylgermylene absorption band with the Stokes shift of 7870 cm^{-1} . The fluorescence lifetime was 1–2 ns. Assuming that both the absorption and the fluorescence were due to the transitions between the ground (S_0) and the first excited (S_1) singlet states, the positions of band maxima allow one to determine the energy of the 0–0 transition (2.4 eV). The large Stokes shift was attributed to a considerable increase in the C–Ge–C angle in the first excited singlet state as compared with the ground state.

Fluorescence spectra of certain germynes synthesised from different molecular precursors can be found in Ref. 12. All germynes demonstrated an emission band with the maximum in the range of 620–650 nm (Table 3) and a considerable Stokes shift. Fluorescence excitation spectra coincided with the absorption spectra of these species. The energy of the 0–0 transition of germynes was 2.04–2.43 eV.

Table 3. Fluorescence maxima and the Stokes shift for diorganylgermylenes in 3-MP matrices ($T = 77$ K).

VI. Electronic structure of germynes and the nature of their optical absorption band

Whereas carbenes are characterised by the triplet ground state,^{45,46} the calculations by different quantum chemical methods have shown that the germylene ground state is singlet (Table 4). This was also confirmed by the absence of signals in the EPR spectra of matrices frozen at 77 and 10 K and containing a germylene accumulated on irradiation.¹¹ The singlet–triplet splitting in germynes X_2Ge substantially depends on the nature of substituent X ($\text{X} = \text{H}, \text{Me}, \text{F}, \text{Cl}, \text{Br}$) and lies in the range of 84–355 kJ mol^{-1} ($\sim 1\text{--}4$ eV).⁴⁵ As regards energy, the excited singlet state is higher than the ground state by $> 188\text{--}209$ kJ mol^{-1} .⁴⁶ On germylene excitation, the Ge–X bond distance changes insignificantly; however, the X–Ge–X angle between the bonds substantially increases. The results of quantum chemical calculations of the structure and electronic state energies for carbene heavy analogues including germynes were comprehensively surveyed in several studies.^{8,9} The calculations showed a slight decrease in the E–X bond distance ($\text{E} = \text{C}, \text{Si}, \text{Ge}$) and a substantial increase in the X–E–X angle upon the transition of all carbenes and their analogues into the excited states.

Table 4. Calculated energies ($E/\text{kJ mol}^{-1}$), bond lengths ($r_e/\text{\AA}$) and angles between X–Ge–X bonds (q_e/deg) for the ground ($^1\text{A}_1$) and electronically excited ($^3\text{B}_1$, $^1\text{B}_1$) electronic states of germynes.

		$^1\text{A}_1$	$^3\text{B}_1$	$^1\text{B}_1$	
H_2Ge	E	0	43.5–123.1	182.9–199.3	47–55
	r_e	1.595 ± 0.018	1.543 ± 0.018	1.548 ± 0.005	
	q_e	92.3 ± 1.0	119.1 ± 0.5	122.7 ± 0.6	
Me_2Ge	E	0	57.3–128.3	213.1	45, 47, 53, 56
	r_e	2.022 ± 0.005	2.004 ± 0.004	2.021	
	q_e	97.1 ± 1.6	118.0 ± 0.5	122.0	
Ph_2Ge	E	0	—	—	57
	r_e	2.006	—	—	
	q_e	101.6	—	—	

The optical absorption bands of germynes shown in Tables 1 and 2 are attributed to the electronic transition from the binding $2a_1$ orbital of a germylene X_2Ge (a linear combination of the $4s$ and $4p_z$ orbitals of the germanium atom with the σ orbitals of the substituent X) to the non-bonding $1b_1$ orbital, which is the $4p_y$ orbital of the Ge atom. Presumably, germynes are characterised by the C_{2v} symmetry group. In this group, the $^1\text{A}_1 \rightarrow ^1\text{B}_1$ transition between the terms is permitted as regards the symmetry; however, the orbitals lie in different planes, which decreases their overlap and reduces the transition intensity. Apparently, for this reason the molar extinction coefficient of the germylene band does not substantially exceed 10^3 $\text{litre mol}^{-1} \text{cm}^{-1}$.

VII. Spectroscopy of germylene complexes

The presence of a vacant antibonding $4p_y$ orbital of the germanium atom in germynes makes possible the formation of donor–acceptor complexes of these species with different molecules. Spectroscopic studies of such complexes are often carried out in low-temperature matrices. The UV irradiation of a matrix containing a germanium precursor and a potential complexing agent leads to the accumulation of a germylene. Subsequent annealing and refreezing of the matrix makes it possible to obtain a germylene complex and record its spectrum. This procedure allowed the optical absorption bands of germylene complexes with organic molecules including those containing heteroatoms to be observed.²⁶

For instance, in the spectrum of a 3-MP–IP matrix in the presence of triethylamine, the absorption band of dimesitylgermylene (Mes_2Ge) with the maximum at 550 nm decayed upon annealing and a new band at 414 nm was formed.

Table 5 shows the positions of maxima of new bands that appeared upon the matrix refreezing and belong to germylene complexes. As is seen, the binding of a germylene into a complex shifts the absorption band to shorter wavelengths. Absorption bands of germylene complexes with molecules containing P, N, S and O atoms lie in the range of 306–376 nm. Apparently, this is explained by the interaction of the vacant $4p_y$ orbital of the germylene atom with orbitals of heteroatoms of organic molecules, which changes the energy of the corresponding $n \rightarrow \pi$ transition.^{3,25}

The studied germylene–heteroatomic compound complexes were unstable and dissociated as the matrix temperature increased so that germynes either dimerised to digermenes with the absorption bands in approximately the same spectrum range or were inserted into different bonds. Thus for a 3-MP–IP matrix, a band of the $\text{Bu}_3\text{P} \cdot \text{Ge}(\text{C}_6\text{H}_2\text{Pr}_2-2,4,6)_2$ complex at 334 nm was preserved at 153 K²⁵ but gradually decayed at 173 K with the appearance of the corresponding digermene signal. At 194 K, the lifetime of such a complex was 48 s. The germylene complex with dimethyl sulfide was stable only at 133 K. Certain complexes of this kind decomposed as the matrix melted. As was first observed in Ref. 12, a slight short-wavelength shift (~ 10 nm) of the germylene absorption band accompanies the formation of a germylene complex with aromatic molecules containing π -systems, namely, benzene and naphthalene (see Table 5).

At 77 K, the 3-MP–IP matrix is so ‘soft’ that germynes can diffuse in it. Upon the addition of ethanol into this matrix, the storage of an irradiated sample in it is accompanied by the decay of the germylene absorption band even at 77 K and the growth of a new absorption band with the maximum at 320–367 nm, which belongs to a germylene complex with ethanol (see Table 5).

An argon matrix containing germane (GeH_4) and ozone was studied at 14–18 K.⁵⁸ The analysis of numerous bands in the IR spectrum that appeared on irradiation in different spectral ranges allowed the identification of certain species including germylene complexes with a water molecule. Presumably, the complex was formed in the reaction

The IR spectrum of the complex $\text{H}_2\text{Ge} \cdot \text{OH}_2$ demonstrated absorption bands with frequencies of 1586, 3597, 3687 cm^{-1} , which are close to the vibrational frequencies of a free water molecule in an argon matrix (the matrix contained no water before excitation). Moreover, the H_2Ge fragment of this complex exhibited a triplet signal (1777, 1794, 1814 cm^{-1}) and a low-frequency line (898 cm^{-1}) that corresponded to vibrations of H–Ge–H bonds. A frequency of 1794 cm^{-1} is close to the double frequency of 898 cm^{-1} being its overtone.

Note. Precursors: for Me_2Ge , Me_2GeNB (**3a**)^{25, 26} and $\text{Me}(\text{GeMe}_2)_5\text{Me}$;¹² for Ph_2Ge , Ph_2GeNB (**3d**); for the rest germylenes, $\text{R}_2\text{Ge}(\text{SiMe}_3)_2$.

Moreover, the flash photolysis method allows one to detect germylene complexes with different molecules also in solutions. An optical spectrum of a dimethylgermylene complex with triphenylphosphine represented a broad band with the maximum at 370 nm and the extinction coefficient of 7.5×10^3 litre mol^{-1} cm^{-1} .^{4, 59}

The use of a competitive reaction of dimethylgermylene with CCl_4 made it possible to determine the rate constant of reaction (1), $k = 6.5 \times 10^8$ litre mol^{-1} s^{-1} . The $\text{Me}_2\text{Ge} \cdot \text{PPh}_3$ complex disappeared with the second-order kinetics presumably to form digermene (or a digermene complex with triphenylphosphine) with the rate constant $2k = 1.5 \times 10^9$ litre mol^{-1} s^{-1} . However, from our viewpoint, these results should be checked, because the earlier studies on the lamp flash photolysis of germanorbornadiene with the same time resolution (5 μs)³⁹ failed to correctly identify the transient absorption band at 380 nm.

An absorption band with the maximum at 325 nm was assigned to complexes $\text{R}_2\text{Ge} \cdot \text{NBu}^n\text{H}_2$ ($\text{R} = \text{Me}, \text{Ph}$).⁴³ Complexes $\text{PhMeGe} \cdot \text{NR}_2^1\text{R}^2$ ($\text{NR}_2^1\text{R}^2 = \text{NH}_2\text{Bu}^n$ and NEt_3) were characterised by bands at 330 nm.⁴² The absorption of germylene (PhMeGe) complexes with molecules that contain double bonds [isoprene, 2,3-dimethylbuta-1,3-diene (DMB), 4,4-dimethylpent-1-ene] was shifted to shorter wavelengths ($\lambda_{\text{max}} \sim 275$ nm).⁴² A comparison of these data with the position of absorption bands of complexes in low-temperature matrices (see Table 5) shows that in solutions, the spectrum substantially (by ~ 100 nm) shifts to shorter wavelengths. Provided the interpretation of the absorption band is correct, this shift may be associated with the different geometries of complexes in solutions and low-temperature matrices.

Thus, germylenes efficiently form complexes with organic molecules. In spectra of these complexes, the light absorption bands are substantially shifted as compared with germylene signals. For this reason, in the studies of optical spectra and kinetics of germylene reactions, the potent complexing agents should be removed from the solution. Data on germylene complexes are shown in a review.⁹

VIII. Vibrational spectra of germylenes

On irradiation of germane (GeH_4) isolated in an argon matrix at 4 K with visible and UV light the IR spectrum demonstrated lines that belonged to different photolysis products.⁶⁰ Among numerous signals, the lines of germylenes H_2Ge and D_2Ge with frequencies of 1887, 1864, 920 cm^{-1} and 1329, 1325, 662 cm^{-1} , respectively, were identified. These frequencies correspond to two stretching and one vibrations of $\text{Ge}-\text{H}(\text{D})$ bonds.

An IR spectrum of dimethylgermylene was recorded in a cryogenic (12 K) argon matrix under UV irradiation (254 or 248 nm) of diazodimethylgermane $[\text{Me}_2\text{Ge}(\text{N}_3)_2]$.²⁸ The preliminary irradiation of $\text{Me}_2\text{Ge}(\text{N}_3)_2$ in hydrocarbon matrices at 77 K in the presence of molecules-scavengers of germylenes and the analysis of trapping products showed that diazide is the source of Me_2Ge . In an argon matrix, the majority of bands observed in the IR range belonged to methyl group vibrations; however, in the 600–500 cm^{-1} range, bands corresponding to vibrations of $\text{Ge}-\text{C}$ bonds were observed (Table 6).

Table 6. Vibrational frequencies (ν/cm^{-1}) of argon matrix-isolated Me_2Ge at 12 K and stable $[(\text{Me}_3\text{Si})_2\text{CH}]_2\text{Ge}$ germylene in crystalline state.

	$\nu(\text{Ge}-\text{C})$	613	61	—	—

Quantum chemical calculations of vibrational frequencies of $\text{Ge}-\text{C}$ bonds were carried out^{47, 50, 62–64} for the ground and excited states of two germylenes, namely, H_2Ge and Me_2Ge (Table 7). It was shown^{28, 60} that all frequencies calculated for the ground states of these species are well consistent with those measured in an argon matrix. Modern laser spectroscopic

techniques, namely, Jet-cooled Laser Induced Fluorescence (Jet-cooled LIF) ⁶⁴ and Laser Optogalvanic Spectroscopy (LOS), ⁶⁵ made it possible to experimentally determine the vibrational frequencies of H_2Ge in the ground ⁶⁵ and singlet excited ⁶⁴ states (see Table 7). These results well agree with those obtained by the theoretical CFCI (Corrected Full Configuration Interaction) ⁵⁰ and CI (Configuration Interaction) ⁴⁷ methods and also with the recent quantum-chemical calculations using the CASSCF (Complete Active Space Self-Consistent Field) method. ⁶⁴ The bending vibrational frequency of the

C—Ge—C fragment was twice lower than the stretching vibrational frequency of the Ge—C bond (see Table 7), which is often observed in vibrational spectroscopy. Detailed information on vibrational frequencies of germynes and their complexes can be found in a review. ⁹

IX. Germylene reactions

As was noted above, in the absence of scavenging molecules, germynes disappear in a second-order reaction, *i.e.*, dimerise to form digermenes. A parameter k_{rec}/ϵ , where k_{rec} is the rate constant for bimolecular recombination, usually lies in the range of $(1-3) \times 10^7 \text{ cm s}^{-1}$ (Table 8). Although the exact extinction coefficient of the germylene band was not measured experimentally, it, as noted above, cannot substantially exceed $10^3 \text{ litre mol}^{-1} \text{ cm}^{-1}$, because the recombination constant would otherwise exceed the diffusion rate constant.

Germynes that contain bulky groups as substituents recombine with substantially lower rate constants as compared with dimethylgermylene. For example, k_{rec}/ϵ decreases by more than an order of magnitude (see Table 8) when the methyl group is replaced by an ethyl group and by two orders of magnitude for the butyl group substitution. Thus, the steric factor substantially affects the recombination rate.

Sometimes, germynes disappear in a first-order reaction. Thus the absorption band of diisopropylgermylene (Pr_2^iGe) with the maximum at 560 nm decays with first-order kinetics over 56 ns. ¹⁵ Presumably, Pr_2^iGe isomerises to 2-germapropene $\text{H}_2\text{C}=\text{CMeGeH}_2\text{Pr}^i$ so quickly that the dimerisation has no time to compete with this reaction. It was found ^{31,33} that germynes PhMeGe (the absorption band maximum at 450 nm) and Ph_2Ge (470 nm) disappear over *ca.* 5–10 μs in a first-order reaction (see Table 8) presumably with the solvent, namely, tetrahydrofuran. However, the same germynes were dimerised in cyclohexane. ^{22,23}

Laser flash photolysis studies have demonstrated that germynes quickly react with oxygen. For Me_2Ge , the rate constant for this reaction in cyclohexane lies in the range of

^a In the gas phase.

$(1-2) \times 10^9$ litre mol⁻¹ s⁻¹ for different precursors (Table 9). These values are 10–20 times lower than the diffusion rate constant of the bimolecular reaction in cyclohexane, which is due to the steric effect and the spin prohibitions for the singlet germylene reaction with a triplet oxygen molecule. The steric effect is pronounced for germylenes with bulky substituents,

e.g., Ph₂Ge and Mes₂Ge, which react with oxygen, correspondingly, one- and two-orders-of-magnitude more slowly than dimethylgermylene. Note that the one-order-of-magnitude smaller rate constant obtained for Me₂Ge^{4,39} most probably belongs to the digermene reaction (see Section X).

In a solvent more polar than cyclohexane, namely, tetrahydrofuran, the rate constant decreased by an order of magnitude which was apparently associated with the formation of a Me₂Ge·THF complex that reacted with the oxygen molecule. In the gas phase, the rate constant for the dimethylgermylene reaction with oxygen (4.5×10^{14} cm³ mol⁻¹ s⁻¹ = 2.7×10^7 litre mol⁻¹ s⁻¹)⁴⁴ was two-orders-of-magnitude lower than the constants measured earlier in cyclohexane (see Table 9).

In recently published studies^{40,42,66} on the laser flash photolysis of solutions of germanium-containing compounds, the rate constants for reactions of germylenes Me₂Ge, PhMeGe and Ph₂Ge with oxygen were determined. These constants turned out to be one-order-of-magnitude smaller (see Table 9) than those measured earlier (e.g., see Refs 11, 19, 30–33, 41). These data additionally demonstrated the effect of complexation on the germylene reactivity. The structure of these complexes can be different in each particular case. It is noteworthy that high rate constants were obtained for reactions in cyclohexane, whereas lower rate constants were found in hexane. Probably, in hexane, oxygen forms complexes with solvent molecules, which lessens its diffusion mobility and, correspondingly, reactivity. Moreover, the presence of uncon-

trolled impurities in cyclohexane, which bind germynes and accelerate their loss, is also possible.

One of the tests for the presence of a germylene in photochemical processes included its addition to the double bond of 2,3-dimethylbuta-1,3-diene to form the corresponding germa-cyclopentene. The rate constants for this reaction with Me₂Ge measured on flash photolysis of different molecular precursors lie in a range of $(1.7-4.1) \times 10^7$ litre mol⁻¹ s⁻¹ (Table 10).

Due to the fast reaction of Me₂Ge with the solvent, the rate constant of its reaction with DMB in tetrahydrofuran was not measured. In cyclohexane, the rate constant of the reaction of germynes Et₂Ge and PhMeGe with DMB increased 2- and

5-fold, respectively, as compared with rate constants for Me₂Ge (see Table 10). It should be noted that the rate constants for the reaction of PhMeGe with DMB measured in Refs 22 and 23 were exactly one-order-of-magnitude smaller than that found in Ref. 14 (both experiments were carried out in cyclohexane but used different precursors). For the reaction of Ph₂Ge with DMB in cyclohexane, the data on the rate constant considerably differed from one another, for instance, by a factor of 26 (see Refs 22, 23 and 41). Gas-phase measurements have shown⁴⁴ that in the limit (at high pressures), the rate constant for the addition of Me₂Ge to the double bonds of buta-1,3-diene and 3,3-dimethylbut-1-ene approaches the diffusion limit (1.1×10^{11} cm³ mol⁻¹ s⁻¹ = 6.6×10^9 cm³ mol⁻¹ s⁻¹) and exceeds the rate constant typical of this reaction in cyclohexane by two orders of magnitude (see Table 10). The rate constants for the germylene addition to unsaturated compounds found in recent studies^{40,42,66} exceed the earlier data by two orders of magnitude (see Table 10). Probably, the authors of earlier works observed reactions of digermenes rather than germynes. Thus, the development of instrumentation and methods for the detection of reactions in the liquid phase and also the use of new precursors bring the germylene rate constants measured in solutions closer to those measured in the gas phase.

Carbon tetrachloride is an efficient germylene scavenger. The rate constants for the germylene reaction with CCl₄ are $(1-10) \times 10^8$ litre mol⁻¹ s⁻¹ (Table 11). Studies of ¹H and ¹³C NMR spectra of the reaction products have shown²⁷ that germylene inserts into a CCl₄ molecule at a C-Cl bond.

For this reaction, the data on rate constants also vary depending on the precursor nature. However, the scatter (for the same germylene) is substantially weaker as compared with

germylene reactions with DMB (see Tables 10 and 11). In the gas phase, the rate constant of the reaction of Me_2Ge with CCl_4 was not measured,⁴⁴ because the radiation (193 nm) used in the majority of studies was absorbed by carbon tetrachloride.

Reactions of insertion into $\text{H}-\text{X}$ bonds ($\text{X} = \text{C}, \text{N}, \text{O}, \text{F}, \text{Si}, \text{P}, \text{S}, \text{Cl}$) are typical of carbenes, silylenes and germylenes. According to quantum chemical calculations,^{45, 56, 67–69} the activation energies of such reactions are substantially higher for dimethylgermylene as compared with carbenes and silylenes. Nonetheless, such processes involving germylenes often proceed with high rate constants (Table 12).

X. Optical spectra, vibrational frequencies and kinetics of digermene decay

As was noted above, the annealing of low-temperature matrices containing an accumulated germylene and the flash photogeneration of germylenes in solutions lead in many cases to dimerisation of these species to form digermenes. Table 13 shows the position of absorption bands for certain digermenes formed from different precursors. The data obtained at 293 K pertain to laser flash photolysis experiments. A temperature of 77 K corresponds to experiments that involved annealing and refreezing of irradiated matrices. It is evident that digermene absorption bands are shifted to shorter wavelengths as compared with germylene bands (see Tables 1 and 2). Note that the extinction coefficients of digermene bands also remained unknown. The only extinction coefficient value was determined⁴³ for the $\text{Ph}_2\text{Ge}=\text{GePh}_2$ band with the maximum at 440 nm to be $5970 \text{ litre mol}^{-1} \text{ cm}^{-1}$.

On the photolysis (254 nm) of dimethyldiazidogermane [$\text{Me}_2\text{Ge}(\text{N}_3)_2$] in an argon matrix at 12–18 K, the IR spectrum of dimethylgermylene was recorded²⁹ (see Table 6). Matrix heating to 36 K led to changes in the spectrum, namely, the disappearance of Me_2Ge lines and the appearance of new signals assigned by the authors to tetramethyldigermene (Table 14). Similar results were obtained on the thermolysis of compound **3a** in the crystalline state with the isolation of gaseous products in argon or nitrogen matrices at 5 K.⁷⁰

In certain cases, the digermene absorption decayed with second-order kinetics, which implies the formation of cyclo-

Table 14. Calculated and experimental vibrational frequencies (cm^{-1}) of $\text{Ge}-\text{C}$ and $\text{Ge}-\text{Ge}$ bonds of tetramethyldigermene⁷⁰ recorded in argon (Ar) and nitrogen (N_2) matrices at 5 K.

tetragermanes.¹¹ For this process, only the effective rate constant k/ϵ was determined (Table 15). Insofar as the changes in the absorbances at 450 (germylene) and 370 nm (digermene) were comparable,¹¹ the extinction coefficients of these species are close to one another and apparently equal to $\sim 10^3 \text{ litre mol}^{-1} \text{ cm}^{-1}$. Then, the rate constant for digermene dimerisation is approximately $k \sim 3.9 \times 10^6 \text{ s}^{-1} \sim 4 \times 10^9 \text{ litre mol}^{-1} \text{ cm}^{-1}$, i.e., fairly close to the diffusion limit. A constant that was found³⁷ for the $\text{Me}_2\text{Ge}=\text{GeMe}_2$ dimerisation in cyclohexane with compound **4a** used as the precursor turned out to be nearly six times smaller. Lower recombination rate constants were also found for digermenes containing more bulky substituents (Et and Ph groups) (see Table 15). Note that a digermene with mesityl groups¹³ disappeared with quasi-first-order kinetics ($\tau \sim 300 \mu\text{s}$) by a yet unclear mechanism.

Thus, the performed analysis shows that the dimerisation of, first, germylenes and, then, digermenes may lead to the formation of cyclic germanes. On steady-state photolysis of germanium organic derivatives, the formed germylenes and digermanes may react with cyclic products as the latter are accumulated, which ultimately leads to the appearance of germanium-containing polymers in solutions.

^a Reaction of the first and second orders, k_{eff} is shown in s^{-1} ; ^b first-order reaction, k is shown in s^{-1} .

In addition to their loss in polymerisation, digermenes may disappear in competitive reactions with other molecules. Table 16 shows the rate constants for some of these processes. As seen, oxygen molecules are efficient scavengers of digermenes. However, literature provides the rate constant values for this reaction that differ by three orders of magnitude (see Table 16). Note that germynes react with oxygen and carbon tetrachloride at the rates nearly one-order-of-magnitude higher than digermenes. The reaction of a digermene with 2,3-dimethylbuta-1,3-diene is two-orders-of-magnitude slower than a similar reaction involving a germylene (compare the data in Tables 12 and 16). The rate constant for a digermene reaction with triethylsilane is also substantially lower as compared with a germylene. At the same time, the reactions of methyl-substituted digermenes with alcohols feature the opposite trend. Whereas germynes do not virtually react with alcohols, the rate constants for digermenes approach $\sim 5 \times 10^7 \text{ mol litre}^{-1} \text{ s}^{-1}$. Nonetheless, it can be concluded that by and large, digermenes exhibit considerably lower reactivity as compared with germynes.

XI. Optical spectra of germyl radicals

In addition to the heterolytic cleavage of the Ge—C bond on the photolysis and thermolysis of germanium-containing compounds, the homolytic processes to form germyl radicals may also occur. It was shown²² that the photolysis of tetramethylphenyldigermene $\text{PhMe}_2\text{GeGeHMe}_2$ in a low-temperature 3-MP matrix leads to the appearance of an absorption band with the maximum at 320 nm, which was assigned to a digermyl radical. The band decayed with the matrix melting.

Laser flash photolysis of solutions of peraryltrigermenes $\text{R}_3^1\text{Ge}-\text{GeR}^2\text{R}^3-\text{GeR}_3^1$ ($\text{R}^1-\text{R}^3 = \text{Ar}$) also demonstrated^{22,23} absorption bands with maxima in the range of 320–330 nm, which were attributed to the formation of aryl-substituted digermyl radicals. Extinction coefficients of these bands were not determined. It was shown that the species responsible for this absorption did not react with 2,3-dimethylbuta-1,3-diene but reacted with carbon tetrachloride with high rate constants [$k = (1.3-7.2) \times 10^8 \text{ litre mol}^{-1} \text{ cm}^{-1}$].

Solutions of polygermanes (R_2Ge)_n in cyclohexane were subjected to laser flash photolysis.¹⁴ In addition to germylene absorption (430–460 nm), the spectrum showed bands in the

^a Compound **10e** is

vicinity of 350–370 nm, which were assigned to polygermyl radicals $(R_2Ge)_m^\bullet$. The latter decayed as a result of recombination with effective rate constants in a range $k/\varepsilon = 2.3 \times 10^4$ – 5.1×10^5 litre mol⁻¹ cm⁻¹. It should be noted that the identification of bands assigned to germlyl radicals was complicated by the fact that digermenes exhibit absorption bands in the same spectral range (see Table 13) and disappear in a second-order reaction with very close k/ε parameters (see Table 15).

Laser flash photolysis of aryl-substituted digermenes $(Ph_nMe_{3-n}Ge)_2$ ($n = 1, 2$) led to the formation of germlylenes (absorption band maxima in the range of 440–470 nm) and germlyl radicals $Ph_nMe_{3-n}Ge^\bullet$ (315–330 nm).³⁰ The radicals disappeared through recombination with observed rate constants $k_{obs} = (1.9$ – $4.3) \times 10^5$ s⁻¹. The flash photolysis of a $PhMe_2GeGeMe_3$ solution made it possible to record³¹ the optical spectrum of a germlyl radical $PhMe_2Ge^\bullet$, which represented a band with the maximum at 320 nm. The radical dimerised with $k/\varepsilon = 7.0 \times 10^7$ cm s⁻¹.

Thus, the available data on the laser flash photolysis of germanium-containing compounds show that germlyl and digermlyl radicals absorb in a range of 315–330 nm and disappear in recombination reactions with effective rate constants of the order of magnitude of 10^4 – 10^8 litre mol⁻¹ s⁻¹.

XII. Stable germlylenes

Diorganylgermylenes R_2Ge are usually short-lived reactive species; however, the introduction, into the precursor molecules, of bulky groups R (see Ref. 57) or ligands that are n or π donors able to transfer the electron density to the vacant orbital of the central germanium atom allows one to synthesise long-lived carbene analogues. At present, nearly 30 stable germlylenes are known.⁷² A comprehensive review⁷³ devoted to stable germanium analogues of carbenes, imines and thiones was published.

In certain cases, it is possible to isolate germlylenes in the crystalline form and study their structure. Crystals of stable germlylene $[(Me_3Si)_2CH]_2Ge$ were isolated and its solution in hexane was prepared.⁶¹ A spectrum of this solution demonstrated three light absorption bands with maxima at 414, 302 and 227 nm and extinction coefficients of 970, 1450 and 19 600 litre mol⁻¹ cm⁻¹, respectively. The position of the long-wavelength band (414 nm) well agrees with the absorption maxima of unstable germlylenes synthesised using laser flash photolysis (see Table 2). The extinction coefficient ($\varepsilon \sim 10^3$ litre mol⁻¹ cm⁻¹) assessed based on the recombination parameter for unstable germlylenes $2k_{rec}/\varepsilon$ was also close to the analogous characteristic of the long-wavelength band for $[(Me_3Si)_2CH]_2Ge$.

A sterically hindered stable digermene **12** was synthesised.^{74, 75}

Repulsion of bulky groups led to a substantial increase in the Ge–Ge distance (2.416 Å) in this compound. In solution, as the temperature increased, digermene **12** reversibly dissociated to form two molecules of stable germlylene $\{2,4,6-[(Me_3Si)_2CH]_3C_6H_2\}MesGe$. Compound **12** exhibited

an absorption band with the maximum at 439 nm ($\varepsilon = 2 \times 10^4$ litre mol⁻¹ cm⁻¹), while germlylene $\{2,4,6-[(Me_3Si)_2CH]_3C_6H_2\}MesGe$ had a band at 575 nm ($\varepsilon = 1.6 \times 10^3$ litre mol⁻¹ cm⁻¹). Thermodynamic parameters of the reversible dissociation were $\Delta H = 61.5$ kJ mol⁻¹ and $\Delta S = 177.5$ J mol⁻¹ K⁻¹. The energy of the Ge–Ge bond (61.5 kJ mol⁻¹) was considerably lower[‡] due to the bond stretching as a result of repulsion of bulky substituents.

The extinction coefficient of the long-wavelength band of $MesBu^tGe$ germlylene was also consistent with the estimates for unstable germlylenes. The band itself was shifted to longer wavelengths similarly to the absorption bands of unstable germlylenes containing bulky substituents.

A stable germlylene $(2,4,6-Bu^t_3C_6H_2)_2Ge$ could be stored at -30 °C for several months.⁷⁷ At room temperature, it decomposed in several weeks to evolve 1,3,5-tri(*tert*-butyl)benzene. X-Ray diffraction analysis has shown that the spatial positions of two aryl groups were different and the Ge–C bond distance was 2.053 Å. The C–Ge–C angle was close to 108°, which substantially exceeded the estimates of 91–93° calculated for Me_2Ge (see Table 4). Despite its distorted geometry, germlylene $(2,4,6-Bu^t_3C_6H_2)_2Ge$ in solution exhibited an absorption band with the maximum at 430 nm, the position of which virtually coincided with that of the Me_2Ge band (see Tables 1, 2). A still wider C–Ge–C angle (111.3°) was observed for stable germlylene $(Me_3Si)_3CGeCH(SiMe_3)_2$ (Ref. 78) with Ge–C bond lengths equal to 2.012 and 2.067 Å. Unfortunately, the optical spectrum of this germlylene was not presented in the study.⁷⁸ Note that in germlylene $(2,6-Mes_2C_6H_3)_2Ge$ the C–Ge–C angle was equal to 114.4° and the Ge–C bond distance was 2.033 Å.⁷⁹

A stable cyclic dialkylgermylene, namely, 2,2,5,5-tetrakis(trimethylsilyl)-1-germacyclopentane-1,1-diyl (**13**), which is a monomer in the solid state with the averaged Ge–C bond length of 2.015 Å and the C–Ge–C angle of 91°, was described.⁸⁰

The absorption spectrum revealed a long-wavelength band of germlylene **13** at 450 nm with a small extinction coefficient. Its unstable analogue, 1-germacyclopent-3-ene-1,1-diyl in an argon matrix at 12 K demonstrated a broad absorption band with the maximum in the range of 400–410 nm; the Ge–C bond length was 2.017 Å and the C–Ge–C angle was 88.1° (Ref. 81). Table 17 shows the optical spectral parameters for certain stable germlylenes. It is noteworthy that a stable germlylene $(Bu^t_2N)_2Ge$ exhibits a long-wavelength absorption band with the maximum at 445 nm, the Ge–N bond length of 1.88 Å and the N–Ge–N angle of 111.4° (Ref. 80).

In a recent study,⁴³ the extinction coefficients of long wavelength spectral bands of different short-lived germlylenes were determined (see Table 17). As seen, the coefficients $\varepsilon \sim 1000$ – 2000 litre mol⁻¹ cm⁻¹ fall in the same range as those of stable germlylenes.

[‡] According to quantum chemical calculations,⁷⁶ for an unsubstituted digermene $(H_2Ge=GeH_2)$ the Ge–Ge bond energy is substantially higher (125.6–188.4 kJ mol⁻¹).

XIII. Comparison of the data obtained by chemically induced dynamic nuclear polarisation and laser flash photolysis methods

The analysis of chemically induced dynamic nuclear polarisation effects in thermal and photochemical reactions provides valuable information on the processes involving short-lived (with lifetimes varying from nano- to microsecond scales) radicals and biradicals. CIDNP measurements allow one to find the multiplicities of radical pairs, their precursors and also the reactive states of carbenes and their analogues, *viz.*, silylenes and germylenes.⁸⁵ Note that the nanosecond laser photolysis with the time resolution of an order of magnitude of 10 ns provides no way for the observation of intermediates with lifetimes of several nanoseconds.

Unfortunately, the literature contains no results of photochemical studies of germanium-containing compounds carried out in the pico- and nanosecond time resolution ranges. Apparently, this is associated with the low extinction coefficients of spectral bands of both the parent compounds and the transient species. Moreover, the studies on the photodissociation of germanium derivatives never used the time-resolved IR spectroscopy in the picosecond range. Hence, at present, CIDNP is the only method that allows one to acquire information on the processes involving species with lifetimes of nanoseconds. To date, the literature contains only one review⁸⁶ devoted to the application of spin chemistry methods to studies of short-lived intermediates of photochemical reactions of germanorbornadienes and digermabicyclooctadienes.

CIDNP effects were observed^{87,88} on the thermal decomposition of Me₂GeNB (**3a**). After heating (85 °C) of a chlorobenzene solution of this compound in the presence of benzyl bromide, two germanium-containing products were isolated.

It was assumed that the reaction produces a primary radical pair {PhCH₂· · · · · GeMe₂Br} the recombination of which affords a polarised molecule PhCH₂GeMe₂Br. Elimination of the bromine atom from PhCH₂GeMe₂Br by the radical ·GeMe₂Br results in the extrusion of a second germanium-containing product, Me₂GeBr₂, to the solution bulk. The analysis of CIDNP signs points to the singlet state of the radical pair and, hence, the

singlet ground state of the germylene, which is well consistent with quantum chemical calculations (see Table 4). Note that no CIDNP effects were observed for parent compound **3a** that could be associated with the synchronous cleavage of both Ge–C bonds during the thermal decomposition.

The NMR method was used^{89,90} to study the thermolysis of germanorbornadienes containing different substituents at the germanium atom and in the organic fragment. The authors of a study⁸⁹ assumed that the thermolysis includes two steps with the initial formation of a transient TPN' · · · · · GeR₂ biradical. Insofar as the authors^{89,90} did not study CIDNP effects, their conclusion on the involvement of a biradical in the reaction stemmed from enhanced thermal stability of germanorbornadienes with methyl substituents in the naphthalene fragment.

CIDNP effects were also observed⁹¹ in the photochemical decomposition of compound **3a**. The presence of CIDNP signals for methyl protons of the parent norbornadiene allowed the authors to assume the step-wise cleavage of Ge–C bonds to form a transient biradical. According to the proposed scheme, a singlet biradical produces the parent norbornadiene, whereas the triplet state serves as the source of the other products, namely, 1,2,3,4-tetraphenylnaphthalene (**6**) and dimethylgermylene. 3,3,6,6-Tetramethyl-1-thiacyclohept-4-yne (**11**) served as the dimethylgermylene scavenger. Based on the analysis of CIDNP signs for the dimethylgermylene adduct to the C≡C triple bond in compound **11**, it was concluded that germylene reacts in the triplet state. This was the first study that demonstrated the involvement of triplet dimethylgermylene in a chemical reaction.

Similar results were obtained with CCl₄ molecules used as the dimethylgermylene scavengers.⁸⁶ Photolysis of compound **3a** in a solution containing CCl₄ and C₆D₆ (in a ratio of 1 : 1 or 1 : 3) generated signals from polarised Me₂GeCl₂ and Me₂Cl-GeCCl₃ molecules that were formed from the primary radical pair ClMe₂Ge · · · · · CCl₃, as follows from NMR spectra recorded during the irradiation. The analysis of CIDNP signs showed that the radical pair was formed in the triplet dimethylgermylene reaction with carbon tetrachloride.

However, a later study³⁴ revealed no CIDNP effects for Me₂GNB (**3a**) and TPN (**6**), which allowed its authors to assume a single-step mechanism for the dimethylgermylene generation. In the latter study, an attempt was undertaken to detect transient species in the decomposition of compound **3a** in experiments with laser flash photolysis. It was shown that the excitation of a **3a** molecule leads to the formation of TPN (**6**) in the triplet excited state. Presumably, singlet germanorbornadiene **3a** undergoes one-step dissociation, which is accompanied by the cleavage of both Ge–C bonds over a picosecond time interval. A single TPN (**6**) molecule is formed and quickly converted into the triplet state (S₁ → T₁). Unfortunately, in the latter study,³⁴ no attempt was undertaken to measure the extinction coefficient for triplet–triplet transition band; hence, the relative yield of triplet TPN (**6**) was not determined. Therefore, there is a probability that the formation of TPN in the S₁ state followed by its transition into the

triplet state is not the main channel in the dissociation of Me_2GNB (**3a**).

A thorough analysis of the kinetics of transient absorption changes on the laser flash photolysis of compound **3a** in hexane was accomplished.⁹² A laser flash generated two transient species, which disappeared with substantially different rates. An absorption band in the range of 400–550 nm ($\lambda_{\text{max}} = 480$ nm), which decayed over 300 ns, was assigned to germylene Me_2Ge . Another wide band, which decayed much more slowly (over several microseconds), was assigned to the triplet–triplet absorption of TPN (**6**). This conclusion was substantiated by the measurements of the T–T absorption at the laser flash photolysis of a TPN solution in hexane.

Photodecomposition of germanorbornadiene **3a** may produce TPN (**6**) molecules in the ground (S_0), and excited triplet (T_1) and singlet (S_1) states. The determination of relative yields (γ) of these states requires the knowledge of the extinction coefficient for T–T absorption and the quantum yield of intersystem crossing (ϕ_T for the $S_1 \rightarrow T_1$ process). To determine the extinction coefficient, the T–T energy transfer from a tetraphenylanthracene molecule to anthracene was considered and $\epsilon_{\text{TPN}}^{421} = 12\,700 \text{ litre mol}^{-1} \text{ cm}^{-1}$ was obtained.⁹² Measurements of the laser flash intensity on the photolysis of TPN solutions (excitation to the S_1 state) and the found ϵ_{TPN} value made it possible to determine the quantum yield of intersystem crossing $\phi_T = 0.13$. Note that the $S_1 \rightarrow S_0$ fluorescence quantum yield (ϕ_F) for TPN was found to be 0.09.³⁴ The use of these parameters and the kinetic curves measured on the flash photolysis of compound **3a** allowed the following yields of S_0 and T_1 states of TPN to be estimated: $\gamma_{S_0} = 0.66$ and $\gamma_{T_1} = 0.34$.⁹²

The value $\gamma_{S_0} = 0.66$ can be governed by both the TPN formation immediately in the ground state and the relaxation of the excited S_1 state ($S_1 \rightarrow S_0$). A parameter $\gamma_{T_1} = 0.34$ may also be due to both the direct formation of the triplet state and the intersystem crossing ($S_1 \rightarrow T_1$). According to the analysis, the direct triplet TNP yield on the photodissociation of compound **3a** falls in the range of 0.24–0.34. Thus, the formation of solely S_1 state as was proposed in Ref. 34 cannot provide the appearance of a considerable amount of triplet TNP molecules due to the low quantum yield of the intersystem crossing. A triplet TPN molecule cannot be formed in the photodissociation of a triplet molecule Me_2GNB (**3a**). It was shown³⁴ that the latter mechanism is unlikely because the sensitised photolysis (benzophenone and 9H-xanthen-2-one as triplet sensitizers) generated no transient absorption attributable to the triplet state of germanorbornadiene **3a**.

In the photodissociation of compound **3a** from the S_1 state, the appearance of a triplet TPN molecule can only be explained by the formation of a $^3(\text{TPN} \cdots \text{GeMe}_2)$ biradical with one Ge–C bond cleaved, which can transform from the initial singlet state to the triplet state $^3(\text{TPN} \cdots \text{GeMe}_2)$. In this case, upon the biradical decomposition (the cleavage of the second Ge–C bond), one of components (Me_2Ge or TPN) may find itself in the triplet state. The formation of triplet germylene was confirmed by the analysis of signs of ^1H CIDNP effects on the photolysis of compound **3a** in the presence of electron acceptors.^{90, 91, 93} Unfortunately, the CIDNP method gives no way for making quantitative estimates; hence, the relative yield of $^3(\text{Me}_2\text{Ge})$ species remains uncertain, although it is known to vary from 0% to 66%. The lower limit (0%) is reached in the dissociation of the triplet state $^3(\text{TPN} \cdots \text{GeMe}_2)$ to form the triplet state for only TPN. This is much unlikely because CIDNP confirms the existence of dimethylgermylene in the triplet state.^{86, 91, 93} The upper limit of the triplet Me_2Ge yield is restricted by $\gamma_{\text{Me}_2\text{Ge}} = 1 - \gamma_{T_1} = 0.66$.

Thus, in aggregate, the results of laser flash photolysis and CIDNP studies show that the photodissociation of dimethyl-

germanorborbadiene **3a** and the formation of dimethylgermylene may involve several competitive reactions. The primary process is the excitation of the molecule Me_2GNB (**3a**) into the first singlet excited state.

Insofar as the quantum yield of the photodissociation of compound **3a** is substantially lower than unity ($\phi \sim 0.4$ ³⁴) and fluorescence is virtually absent, the non-radiative relaxation into the ground state plays a considerable role for this molecule. From the excited state, $S_1(\text{Me}_2\text{GNB})$ can dissociate with the cleavage of two Ge–C bonds to form TPN and dimethylgermylene. In turn, TPN can be in either ground or excited singlet states.

The long-wavelength absorption band of compound **3a** lies in the vicinity of ~ 275 nm, which corresponds to the absorbed quantum energy of ~ 4.5 eV. The efficient thermal decomposition of Me_2GNB at approximately 100 °C showed^{87, 88} that the energy of the first Ge–C bond cleavage is 1.0–1.2 eV⁹⁴ (after this process, the break of the second bond consumes far less energy). Hence, the balance energy of ~ 3.3 –3.5 eV is indeed insufficient for the formation of an excited $S_1(\text{TPN})$ molecule, because the maximum of the long-wavelength absorption band of TPN is located at 300 nm [therefore, the energy of $S_1(\text{TPN}) \geq 4.1$ eV].

In the singlet-state dissociation, the appearance of one component (TPN or Me_2Ge) in the triplet state is forbidden in accordance with the total spin conservation law. Though this law does not forbid the simultaneous formation of two species in the triplet state

the probability of such a process is far lower (1 : 9) as compared with the appearance of singlet species. Moreover, in the former case, a problem of energy deficiency also exists, because the stored energy of 3.2–3.5 eV is obviously insufficient for the appearance of $T_1(\text{TPN})$ (with the energy of 2.8–3.0 eV) and $T_1(\text{GeMe}_2)$ (1.2 eV^{45, 53}).

Above, we considered processes in which the photodissociation of Me_2GNB (**3a**) occurred in a single elementary event that included the cleavage of both Ge–C bonds. A reaction with products in singlet states would be more probable. The assumption on the elementary event means that the time lag between the cleavages of the first and second Ge–C bond is much shorter than the time resolution of the experimental method so that the short lifetime of the biradical (the cleavage of the first bond)

does not induce any substantial changes in the yields and electronic states of final products. However, measurements of CIDNP effects^{86, 91, 93} suggest that the biradical lifetime is sufficient for the transition into the triplet state

From this state, the biradical can dissociate to produce one component in the triplet state.

The S–T transition time of a biradical is determined by the intensity of hyperfine interaction (HFI) in radical centres, the difference of *g*-factors and the magnetic field intensity. For parameters characteristic of many radical pairs, the time of transition into the triplet state usually lies in a range of 1–10 ns. The nanosecond laser flash photolysis has the resolution time of 5–10 ns; hence, the optical spectrum of a biradical in both triplet and singlet states is yet unavailable.

The final product, TPN (6) in different electronic states, can appear in at least five of reactions shown above [see reactions (3), (4) and (7)]. The relative share of each channel remains unknown and only the value $\gamma_{\text{T}_1} = 0.34$ shows that the triplet biradical dissociation can contribute about 1/3 of the overall photoreaction yield. The use of the CIDNP method for the detection of reactions (4) and (7) provided evidence for the presence of $\text{T}(\text{GeMe}_2)$ species; however, the individual contribution of each product can be determined only after the determination of its relative yield. Disagreement on the photodissociation mechanism of Me_2GNB that exists in the literature^{34,91,93} can be due to the fact that each channel makes a substantial contribution into the overall yield of photoreaction products. The absence of quantitative measurements of yields led to different conclusions on the mechanism of phototransformations of dimethylgermanorbornadiene **3a**. The comprehensive quantitative characterisation of all processes will be possible only after the determination of the relative yield of dimethylgermylene in the triplet state.

Similar problems arise in the studies on the photochemistry of 7,7,8,8-tetramethyl-1,4-diphenyl-1,3-benzo-7,8-digermabicyclo[2.2.2]octa-1,5-diene (**4a**). This compound was studied by laser flash photolysis³⁷ and CIDNP³⁶ methods. After a laser pulse (in 300 ns), two absorption bands with maxima at 380 and 430 nm were observed in spectra of a cyclohexane solution of compound **4a**. The band at 430 nm, which decayed over 3 μs , was assigned³⁷ to the T–T absorption of diphenylnaphthalene [$\text{T}(\text{DPN})$, $\epsilon^{430} = 3.2 \times 10^4 \text{ litre mol}^{-1} \text{ cm}^{-1}$ (Ref. 95)]. The band at 380 nm, which was assigned to a digermene $\text{Me}_2\text{Ge}=\text{GeMe}_2$ (see Table 13), decayed with second-order kinetics ($k/\epsilon = 6.5 \times 10^5 \text{ cm s}^{-1}$).

Studying the CIDNP effects for methyl-group protons of the parent molecule **4a** and protons of the final product (DPN) made it possible to assume³⁶ that the cleavage of one Ge–C bond to form a singlet biradical $\text{DPN}-\text{Me}_2\text{Ge}^{\bullet}\cdots^{\bullet}\text{GeMe}_2$ is the primary process. The biradical reversible transition into the triplet state and the recovery of the broken bond led to the appearance of CIDNP for protons in parent compound **4a**. Two possible channels were discussed³⁶ for the triplet radical transformation. The first channel was the dissociation of the remaining Ge–C bond to form a digermene and a triplet DPN molecule. The second channel was the dissociation of the Ge–Ge bond to form dimethylgermylene and a triplet biradical ($\text{DPN}^{\bullet}\cdots^{\bullet}\text{GeMe}_2$). The latter could either pass into the singlet state and form a Ge–C bond with the remaining germanium atom (to afford germanorbornadiene) or dissociate to yield the triplet DPN and the second dimethylgermylene species. The analysis of CIDNP effects and the kinetic behaviour of the transient absorption gave no way for making the ultimate choice between these two mechanisms of the triplet 1,6-biradical transformation; however, its involvement in the formation of CIDNP signals is beyond any doubt.

Thus, to be completed, the description of photodissociation of compound **4a**^{36,37} requires the quantitative analysis of the relative yield of diphenylnaphthalene in the triplet and singlet states to be carried out. This information would be helpful in the determination of contributions of different

photodissociation channels for molecule **4a** (biradical dissociation from singlet and triplet states, dissociation without transient biradical formation with simultaneous cleavage of both Ge–C bonds to form a digermene). Insofar as the laser radiation used in Refs 36 and 37 was of different wavelengths (266 and 308 nm, respectively), it cannot be ruled out that the photolysis mechanisms were different. For example, on the excitation of compound **4a** with light with a wavelength of 266 nm, a single photoreaction channel was realised (the digermene $\text{Me}_2\text{Ge}=\text{GeMe}_2$ formation that involved no biradical),³⁷ whereas on the photolysis at longer wavelengths, only one Ge–C bond was cleaved to generate a biradical.³⁶

XIV. Conclusion

The analysis of literature data shows that the light absorption spectrum of dimethylgermylene has a band in the range of 420–490 nm. For this species in the gas phase, the band maximum lied at 480 nm. Apparently, the absorption observed at shorter wavelengths (405–420 nm) belongs to the donor–acceptor germylene complexes. Bands in the range of 370–380 nm are caused by the fast formation of digermenes due to the germylene dimerisation. The absorption of germylenes containing bulky substituents or groups with π -systems is shifted to longer wavelengths (450–550 nm), which is most probably due to widening of the C–Ge–C angle. The shift of germylene absorption bands in the spectra of low-temperature matrices as compared with the solution spectra can be explained by the effects of temperature, the solvent nature and the germylene geometry.

Germylenes usually disappear in dimerisation reactions to form digermenes. Determination of the recombination rate constants requires the knowledge of extinction coefficients of bands in spectra of unstable germylenes. To date, these parameters were measured only for two germylenes, namely, Ph_2Ge and Me_2Ge . The determination of the mentioned values for other germylenes is the burning problem of photochemistry of germanium-containing compounds. Digermenes also disappear in second-order reactions to form cyclic and eventually polymeric structures. Absorption bands of digermenes are shifted to shorter wavelengths by 40–50 nm as compared with germylene bands. For digermenes, the data on the extinction coefficients of bands are also absent. The wide scatter (sometimes up to 2–3 orders of magnitude) of literature data on the reaction rate constants for germylenes synthesised from different precursors presents an important problem. Most probably, the scatter is due to the incorrect assignment of transient absorption bands. Thus the bands earlier assigned to germylenes actually belong to digermenes or germanium-containing radicals. Moreover, this might also be due to the formation of germylene transition complexes with the decomposition products of germanium-containing compounds that appear simultaneously with germylenes.

The majority of studies on the photochemistry of germanium organic derivatives assumed that in the excited states of these molecules, the heterolytic break of Ge–C bonds occurs to form germylenes. However, presumably, in some cases, the competitive homolytic cleavage of a Ge–Ge bond takes place to form germyl radicals. The relative probability of these channels in photoreactions of germanium-containing compounds remains unknown, because for radicals with absorption bands located at still shorter wavelengths, the extinction coefficients are also unknown. The quantum yields of different transient species cannot be determined for the same reason.

The use of the CIDNP method that provides information on the short-lived species unobservable by even the laser flash photolysis method with the nanosecond time resolution is a very interesting trend in photochemistry. A more detailed photolysis mechanism with the formation of transient birad-

icals was first proposed in CIDNP studies of germanium-containing compounds. However, no studies were published to date that contain information on the quantitative relationship between the CIDNP data and the results of laser flash photolysis of germanium derivatives. For this purpose, the resolution time of the laser flash photolysis must be shifted in the pico- and femtosecond ranges. To detect short-lived transient biradicals, it seems promising to use nanosecond photolysis of cooled solutions and low-temperature matrices.

Chirospecific analysis of plant volatiles

A V Tkachev

Contents

I. Introduction	951
II. Chiral gas-liquid chromatography	952
III. Two-dimensional gas-liquid chromatography	956
IV. Preparative enantiomeric resolution	957
V. Identification of enantiomers	958

Abstract. Characteristic features of the analysis of plant volatiles by enantioselective gas (gas-liquid) chromatography and gas chromatography/mass spectrometry are discussed. The most recent advances in the design of enantioselective stationary phases are surveyed. Examples of the preparation of the most efficient phases based on modified cyclodextrins are given. Current knowledge on the successful analytical resolution of different types of plant volatiles (aliphatic and aromatic compounds and mono-, sesqui- and diterpene derivatives) into optical antipodes is systematically described. Chiral stationary phases used for these purposes, temperature conditions and enantiomer separation factors are summarised. Examples of the enantiomeric resolution of fragrance compounds and components of plant extracts, wines and essential oils are given. The bibliography includes 157 references.

I. Introduction

The enantiodifferentiation, *viz.*, the recognition of enantiomers (optical isomers), plays an important role in the functioning of living systems and the appearance of biological activity. Numerous examples concerning differences in biological activity of optical antipodes have been documented. An analysis of the optical purity is of great importance in chemistry of natural compounds, fine organic synthesis, pharmacognosy, drug technology, analytical chemistry and environmental analytical chemistry. Enantioselective gas (gas-liquid) chromatography and GLC-mass spectrometry are the main tools of investigation of enantiomeric composition of natural volatile compounds.

The differences in properties of optical isomers result in the difference in recognition at the molecular level. Many remarkable examples of the recognition of plant volatiles responsible for the characteristic aroma of plants and products of their processing can be given taking into account that the ability to perceive odours is also associated with the molecular recog-

nition of enantiomers as a result of their interaction with olfactory chemoreceptors. For example, the sesquiterpenoid (+)-nootkatone (**1**), which has the bitter taste of grapefruit, has the characteristic grapefruit flavour, which is 2200 times more intense than that of its (–) enantiomer.¹ (–)-Geosmin (**2**) isolated from grape wines has a much stronger flavour (at least ten times stronger) than (+)-geosmin. Grape wines produced from Cabernet Sauvignon grapes contain only (–)-geosmin.² Of four isomeric rose oxides, only (2*S*,4*R*)-rose oxide (**3**) has a pleasant strong rose aroma, whereas other stereoisomers have no flavour. Natural (3*S*,3*aS*,7*aR*)-lactone **4** has a sweat flavour with a coconut undertone, which is 25 million (!) times more intense than that of its (3*R*,3*aR*,7*aS*) isomer.^{3,4} Oct-1-en-3-ol is one of the major components responsible for the mushroom flavour, but only (*R*)-(–) enantiomer **5** has the intense mushroom aroma.⁵ (*R*)-3-Methylthiobutanol (**6**) has the characteristic aroma of potato products, whereas the (*S*) enantiomer has no flavour at all.⁶

The above-considered examples are not arbitrary because the development of methods of enantioselective analysis is to a large extent associated with investigations of fragrant substances; their enantiomeric composition often determines a particular characteristic flavour.

Different plants produce terpenes of different optical purity, whose enantiomeric composition depends on numerous factors. For example, studies on the essential oil of the dill herb *Anethum graveolens* L. showed that the enantiomeric ratio of the major components (dill ether,[†] limonene, α - and β -phellandrenes and carvone) changes with the age of plants and is

[†] The systematic name is (3*S*,3*aS*,7*aS*)-3,6-dimethyl-2,3,3*a*,4,5,7*a*-hexahydrobenzo[*b*]furan.

different in different parts of the plants.⁷ The enantiomeric purity of camphor in essential oils from different plants of the Lamiaceae and Compositae families varies from 0% to 100%, with either the (+) or (−) enantiomer predominating in different plants.^{8,9} As was demonstrated with extracts from roots and seeds of angelica (*Angelica archangelica* L.), the enantiomeric excess of monoterpenes can vary depending on the place of vegetation.¹⁰ An analysis of the enantiomeric composition of the essential oil components allows the determination of the authenticity of essential oils available in the market, for example, of melissa (*Melissa officinalis* L.).^{11,12}

As a rule, sesquiterpene hydrocarbons are present in plant extracts in the optically active form, with a particular enantiomer predominating, whereas derivatives, which are artefacts and are produced in non-enzymatic secondary processes in the course of processing of plant materials, are detected in the optically inactive form (as racemates).¹³

The chirospecific analysis (analysis of the enantiomeric composition of the components) is of great importance in studies of foodstuff, as well as of flavour and fragrance compounds. For example, the quality of grape wines can be determined from the enantiomeric ratio of ethyl lactates.¹⁴ Only one of the enantiomers of octane-1,3-diol and some its derivatives were found in different varieties of apples.¹⁵ With a knowledge of the enantiomeric composition of the strawberry flavour components, it is possible to distinguish between products prepared from strawberry and those flavoured with synthetic strawberry flavourants.¹⁶ (*R*)-3-Mercapto-2-methylpropanol makes a major contribution to the flavour of red grape wines produced from Cabernet Sauvignon and Merlot grapes.¹⁷ Particular enantiomers of branched carboxylic acids are important contributors to the flavour of Parmesan cheese and the characteristic flavour of lamb meat.^{18,19}

Modern methods of chirospecific analysis allowed studies of racemic forms of compounds, which have long been used as fragrance compounds. For example, the characteristic lily flavour was demonstrated to be mainly due to the presence of the (*R*) isomer, which is hundred times more flavouring than the (*S*) isomer.²⁰ Numerous synthetic derivatives of campholenic and fencholenic aldehydes were investigated, which is associated with their unusual wood or sandal flavour.^{21,22} The enantioselective separation of enantiomers of α -ionone, which is an important fragrance compound, by gas chromatography was documented.²³

The analysis of the enantiomeric composition of plant metabolites has numerous applications. This method plays an important role in the determination of the origin of plant extracts and the authenticity of essential oils and flavour and taste components, as well as in the elucidation of the biosynthesis pathways of particular compounds.

Enantiomers of various chemical compounds can be separated by such methods as gas chromatography, high-performance liquid chromatography, capillary electrophoresis, supercritical fluid chromatography, capillary electrochromatography, thin-layer chromatography, *etc.*²⁴ Gas-liquid chromatography (GLC) is most often used for the analysis of the enantiomeric composition of plant volatiles and fragrance compounds.

Enantiomers can be resolved by GLC either directly or indirectly. The indirect approach is based on the preparation of derivatives of the analyte with an enantiomerically pure reagent^{25,26} to transform the enantiomeric pair into the diastereomeric pair and the subsequent separation of the diastereomers by GLC on a usual, *i.e.*, achiral, stationary phase. As an example, let us mention the enantiomeric resolution of (−)-menthol esters and hydroxy acids in the form of *O*-trifluoroacetyl derivatives.²⁷ As a rule, this method is used to analyse polar compounds (alcohols, amines, acids, amino

alcohols, *etc.*), because it is difficult, if at all possible, to study these compounds directly by gas chromatography.

The direct enantiomeric resolution on enantioselective stationary phase columns (chiral GLC) is a much more appealing method. In this case, there is no need to transform analytes into derivatives, and the separation is achieved due to the formation of diastereomeric associates between enantiomers of the analyte and a chiral selector[‡] of the stationary phase.

The history, advances and trends in the development of chiral GLC were covered in the reviews.^{28,29}

II. Chiral gas-liquid chromatography

1. Types of chiral stationary phases

In spite of a large variety of stationary phases used in gas chromatography, there are no universal phases for the separation of all types of compounds. The selectivity of each phase is limited to particular groups of compounds. However, though certain usual achiral stationary phases are suitable for the separation of several groups of organic compounds, no more or less universal chiral stationary phases are presently known.

Enantioselective stationary phases used in chiral GLC can be divided into three groups depending on the character of interactions between the analyte (selectand) and the chiral selector:

- derivatives of optically active amino acids (analytes form hydrogen bonds with the stationary phase);
- optically active metal complexes (analytes form coordination compounds with components of the stationary phase);
- natural and modified cyclodextrins, optically active crown ethers and calixarenes (analytes form inclusion compounds with components of the stationary phase³⁰).

The general methodology, the mechanism of separation, the scope and examples of the use of chiral GLC were considered in detail in the reviews.^{31–34} In the present review, only chiral selectors and stationary phases belonging to the third group, to be more precise, stationary phases based on modified cyclodextrins, will be considered. These stationary phases are most widely used in the analysis of natural volatile compounds, flavour and fragrance compounds, and they are employed in about 90% of examples of the successful enantiomeric resolution.³⁵ In particular, there are reviews on the use of such chiral stationary phases for the analysis of the enantiomeric composition of the components of essential oils and fragrance compounds,^{36–40} fragrant monocyclic monoterpenes⁴¹ and flavour components of cheeses.⁴²

Derivatives of natural amino acids suitable for the application in specific cases⁴³ and polysiloxane-based stationary phases containing optically active metal complexes[§] {for example, 3-(perfluoroacyl)camphorate complexes of metals [Ni(II), Co(II), Mn(II), Rh(I) and Eu(III)], which were used for the enantiomeric resolution of various compounds, including some terpenes³⁴} as chiral selectors are beyond the scope of the present review.

a. Cyclodextrins in enantioselective analysis

Cyclodextrins are cyclic oligomers consisting of α -D-glucopyranosyl residues, which are linked to each other by α -(1 \rightarrow 4) glycosidic bonds. Nowadays, α -, β - and γ -cyclodextrins containing 6, 7 and 8 α -D-glucopyranosyl residues, respectively,

‡ The chiral selector is an enantiomerically pure component of the stationary phase responsible for the recognition of optical isomers.

§ According to the data presented in the review,⁴³ phases containing chiral metal complexes are losing in popularity because of the universal use of cyclodextrin derivatives, as evidenced by a dramatic decrease (almost to zero in 2001–2004) in the number of publications on the use of phases based on chiral metal complexes.

are commercially available. Cyclodextrin molecules have a truncated cone shape. The outer surface of the molecules is hydrophilic, while the inner surface is hydrophobic. Due to this structural feature, cyclodextrins readily form inclusion complexes with organic molecules belonging to different classes of compounds.⁴⁴ It is the ability of cyclodextrins to form inclusion complexes that makes them attractive as agents in various applications[¶] associated with the molecular recognition.⁴⁶

The formation of host–guest complexes is believed to play a major role in the mechanism of recognition of enantiomeric molecules by cyclodextrins and their derivatives.⁴⁷ Complexes of hydrophobic molecules with cyclodextrins are formed through interactions between the substrate (selectand) and the hydrophobic cyclodextrin cavity; the complexation can lead to a change in the conformation of the guest molecule.⁴⁸ As a rule, less polar molecules form more stable complexes than higher-polarity molecules. Since the cavity volumes in α -, β - and γ -cyclodextrins are different, stability of complexes of hydrophobic molecules with a particular cyclodextrin depends on the matching of the size of the guest molecule to the cyclodextrin cavity size.⁴⁵ The formation of such complexes was detected by GLC analysis.⁴⁹

The mechanism of enantiomeric recognition with the use of cyclodextrin stationary phases remains unclear. An analysis of a wide range of model racemic mixtures revealed no relationship between the retention and the thermodynamic characteristics of interactions between selectands and chiral selectors.⁵⁰ However, in spite of the absence of detailed data on the recognition mechanism, cyclodextrin-based stationary phases are used with advantage for the enantiomeric resolution of various compounds. Enantioselective chromatography on cyclodextrin stationary phases plays an important role in the analysis of essential oils for the determination of their quality and authenticity,⁵¹ in the stereochemical analysis of terpenoids, in the determination of the absolute configurations and enantiomeric purity of components of complex natural mixtures,⁵² etc.

b. Chiral stationary phases based on modified cyclodextrins

Cyclodextrins and their simple derivatives have high melting points. Since cyclodextrins used as stationary phases in GLC should exist in the liquid (non-crystalline) state, the analysis should be performed at high temperatures. However, the enantioselectivity of chiral stationary phases, as a rule, sharply decreases with temperature. Hence, cyclodextrins and their simple derivatives are of little use in chiral capillary GLC because these compounds cannot serve as efficient chiral selectors at temperatures at which they are converted into the liquid state.

One way of solving this problem is to dilute high-melting-point cyclodextrin derivatives with polysiloxanes, with the result that the enantioselectivity of resolution is achieved at temperatures lower than the melting points of pure cyclodextrins,⁵³ the nature of polysiloxane having an effect on both the efficiency of the column and its enantioselectivity.^{54–56} However, the use of low-melting-point cyclodextrin derivatives is presently the approach of choice. This field of investigation

originated in 1988 in the research by König and co-workers,^{57–60} who synthesised liquid or wax-like (at room temperature) cyclodextrin derivatives, which had high thermal stability, were well soluble in low-polarity organic solvents and polysiloxanes and exhibited high enantioselectivity in the separation of a wide range of low-molecular-weight compounds. More recently, numerous such derivatives have been synthesised and many of these compounds proved to be very efficient in the enantioselective analysis of volatile plant substances.^{29, 61–66}

Of all available cyclodextrin derivatives, heptakis(2,6-di-*O*-methyl-3-*O*-*n*-pentyl)- (7) and heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyl-dimethylsilyl)- β -cyclodextrins (8) are the most popular chiral selectors, which were employed in most of successful experiments on the separations of terpene compounds and essential oil components.

¶ Due to the ability of cyclodextrins to distinguish positional isomers, functional groups, homologues and enantiomers, these compounds are widely used for the separation of various compounds by different physicochemical methods. In particular, the review⁴⁵ presented data on new applications of cyclodextrins in gel electrophoresis, isotachopheresis, isoelectric focusing, preparative scale electrophoretic techniques, thin-layer chromatography, electrochemically modulated liquid chromatography, microdialysis, the separation on hollow fiber, liquid and composite membranes, foam floatation enrichment, solid- and liquid-phase extraction and counter-current chromatography.

Cyclodextrin derivatives containing the *tert*-butyldimethylsilyl group are of particular interest because these compounds are more easily mixed with various polysiloxanes (the latter are used as diluting agents and have gained wide acceptance in capillary gas chromatography), which facilitates the

preparation of chiral stationary phases. Although the polysiloxane component in these phases is called a diluting agent, it is not absolutely inert in chromatographic experiments. Thus, stationary phases prepared based on the same chiral selector but with the use of various polysiloxane diluting agents show somewhat different enantioselectivity (see, for example, the studies^{55, 56, 67–69}). The temperature of the analysis can be lowered and, as a consequence, the enantioselectivity of separation can be increased with the use of non-polar and low-polarity polysiloxanes as diluting agents for cyclodextrin derivatives.⁷⁰ The enantioselectivity of columns packed with chiral stationary phases depends also on the ratio of the cyclodextrin selector to the diluting agent. For example, for the phases containing 20%, 40% or 60% of octakis(2,6-di-*O*-*n*-pentyl-3-*O*-butanoyl)- γ -cyclodextrin, the maximum selectivity factor (R_s , α)[†] for different enantiomers is achieved with the use of mixtures containing either 60% or 40% of the selector.⁷¹

The enantioselectivity of cyclodextrin phases depends on both the cyclodextrin cavity size and the nature and number of substituents at positions 2, 3 and 6 of α -D-glucopyranosyl residues in the cyclodextrin molecule.^{31, 33} The elution order of enantiomers can change depending on the size of the cyclodextrin molecule.³⁸ For example, the relative retention times of oxygen-containing essential oil components on α -cyclodextrin-based phases are shorter than those on chiral stationary phases based on β -cyclodextrin derivatives.⁷² An investigation of 22 compounds showed that the retention times of analytes measured relative to *n*-undecane depend on their structures. This fact can be used in the preliminary analysis of unknown compounds to assign them to a particular structural group.

The type and position of substituents in cyclodextrin derivatives are apparently of equal importance.^{73, 74} Even small changes in the molecular structure of cyclodextrin derivatives can substantially influence the enantioselectivity of the phase. Consequently, all steps of the synthesis must be carefully controlled to obtain unambiguous results, because the substitution reactions, which are not brought to completion, often produce mixtures of cyclodextrin derivatives.⁷⁵ In addition, to achieve the reproducibility of the results of the subsequent enantioselective analysis, it is necessary to characterise the resulting products in detail.⁷⁶

In spite of the fact that capillary columns for chiral GLC are available in catalogues of many manufacturers and suppliers of gas-chromatographic systems, researchers prepare stationary phases and columns by themselves primarily with the aim of obtaining new, more selective and efficient, columns. Examples of the synthesis of cyclodextrin chiral selectors for chiral GLC are given below.

Mono-2-*O*-alkyl-substituted cyclodextrin derivatives can be synthesised by the treatment of cyclodextrins with dimethyl sulfate, diethyl sulfate or allyl bromide in a 0.37 M aqueous solution of sodium hydroxide.⁷⁷ The products are purified by fractional crystallisation from a water–toluene system followed by column chromatography. In the last step, the products are crystallised from water. 2-*O*-Propylcyclodextrins can be prepared by reduction of the corresponding allyl derivatives.⁷⁷ *O*-Pentyl derivatives of cyclodextrins have gained the widest acceptance.

It should be noted that the influence of the chain length of the alkyl substituent on the enantioselectivity of stationary phases is still debated. For example, the size of the alkyl substituent in 2,3-di-*O*-alkyl-6-*O*-*tert*-butyldimethylsilyl derivatives of cyclodextrins was found to have a substantial effect on the chromatographic characteristics of chiral phases. Accord-

ing to the data published in the study,⁷⁰ heptakis(2,3-di-*O*-ethyl-6-*O*-*tert*-butyldimethylsilyl)- β -cyclodextrin and octakis(2,3-di-*O*-ethyl-6-*O*-*tert*-butyldimethylsilyl)- γ -cyclodextrin are equally efficient in the separation of racemic mixtures of volatile compounds, whereas columns with the corresponding 2,3-di-*O*-methyl derivatives are less suitable for these purposes. The synthesis of cyclodextrin long-chain derivatives has been documented.⁷⁸

c. Optimisation of the selectivity of cyclodextrin chiral selectors

When analysing complex mixtures consisting of chiral compounds of different polarity with different functional groups, it is necessary to use simultaneously several chiral stationary phases with different enantioselectivity to separate all enantiomeric pairs. Several procedures for the preparation of mixed chiral stationary phases have been developed in recent years.^{73, 79–81} The simplest approach is based on the use of a mixture of cyclodextrin derivatives having mutually complementing enantioselectivities. This approach was used with advantage for the simultaneous (in one analysis) enantiomeric resolution of different classes of compounds (monoterpene hydrocarbons, alcohols, ketones and lactones).⁸⁰

Another procedure for optimisation of the properties of chiral cyclodextrin selectors is based on the selective replacement of some functional groups in D-glucopyranose rings. For example, the resolving properties of two cyclodextrins, *viz.*, compound **8** and its 2,3-di-*O*-acetyl analog, were combined in one compound by replacing the 3-*O*-methyl group with the acetyl group in one of the glucopyranosyl groups in compound **8**. The resulting β -cyclodextrin has the resolving properties of individual 2,3-di-*O*-methyl and 2,3-di-*O*-acetyl derivatives.⁷³ Analogously, the useful properties of octakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- and octakis(2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)- γ -cyclodextrins were combined in octakis(3-*O*-acetyl-2-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- and octakis(2-*O*-acetyl-3-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- γ -cyclodextrins.⁷⁹

The enantioselectivity can be increased and more universal columns can be prepared also by mixing two chiral selectors of different nature. The addition of the chiral non-polymeric selector Lipodex E [octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)- γ -cyclodextrin] to an L-valine-based polymer was demonstrated⁸² to give a mixed stationary phase showing good enantioselectivity for a wider range of enantiomeric pairs compared to phases containing these individual chiral selectors, the selectivity factors for all the compounds under study in the enantiomeric resolution on the mixed phase having values averaged over these two phases. For examples, enantiomers of linalool cannot be resolved on a column with an L-valine-base stationary phase ($\alpha = 1.00$), but they can be resolved on a column with the Lipodex E phase ($\alpha = 1.05$). Enantiomers of linalool can also be resolved on the mixed stationary phase. In the latter case, the selectivity factor ($\alpha = 1.02$) is smaller than that on Lipodex E but is larger than that on the L-valine-based phase.

To improve cyclodextrin phases, they are chemically grafted to the polysiloxane backbone, which is, in turn, chemically attached to the inner surface of the column.⁸³ Due to strong retention of the chiral stationary phase, such columns are more durable and are characterised by high stability. In addition, these columns can easily be regenerated by washing with solvents.²⁹ The Chirasil-Dex phase consisting of a cyclodextrin-type selector based on mono-6-*O*-octamethylenepentyl- β -cyclodextrin, which is chemically grafted to polymethylpolysiloxane, is an example of such stationary phases.⁸⁴ This convenient and rather stable phase is widely used for the enantioselective analysis of various compounds.

[†] The selectivity factor is defined as the ratio of the retention times of enantiomers (as a rule, in isothermal conditions).

The Chirasil- γ -Dex phase is constructed analogously and consists of octakis(2,6-di-*O*-*n*-pentyl-3-*O*-butanoyl)- γ -cyclodextrin grafted to polymethylpolysiloxane through the octamethylene spacer.⁷¹

In recent years, efforts have been made to design universal phases for chiral GLC. In particular, combined (hybrid) phases (for example, the Chirasil-Calixval-Dex phase) belong to such phases. The Chirasil-Calixval-Dex phase consists of two chiral selectors, *viz.*, calixarene with pendant L-valine-based diamide groups and polymethylated β -cyclodextrin, chemically grafted to poly(hydromethyl)dimethylpolysiloxane. This combined phase retains the enantioselectivity of each chiral selector and combines their resolving properties. The selectand is bound to this phase both through hydrogen bonds with the calixarene fragments and due to the inclusion into the cyclodextrin cavity. These combined phases provide the separation of both non-polar compounds (hydrocarbons) and polar amino acid derivatives.⁸¹

2. Chromatography conditions

a. Temperature of the analysis

Modern commercially available capillary columns with chiral stationary phases based on substituted cyclodextrins allow operations in the temperature range from 10 to 250 °C, which is sufficient for the analysis of volatile aliphatic, alicyclic and aromatic compounds, mono- and sesquiterpenoids, diterpenes and some most volatile aldehydes, alcohols, ethers and esters of the diterpene series. Thermally labile compounds, for example, furan derivatives, can be separated on cyclodextrin phases by supercritical fluid chromatography at 45 °C and at a carbon dioxide pressure of 200 kg cm⁻².⁸⁵

As shown by numerous examples, the enantioselectivity of cyclodextrin selectors generally increases with decreasing temperature used for the gas chromatographic separation. Hence, to achieve better results, shorter chromatographic columns should be used. In this case, not only the temperature of the analysis can be lowered, thus improving the enantioselectivity of separation, but also the time of the analysis can be reduced.⁶⁸ Examples of the super-fast enantiomeric resolution were documented. For instance, less than 10 s were required to resolve enantiomers of bromochlorofluoromethane on a 50-cm column at ambient temperature (26 °C).⁸⁶

The enantiomeric resolution of the sesquiterpene erythrodiene can be offered as an example of the temperature depend-

ence of enantioselectivity. At 120 °C, the resolution was not achieved, whereas the α factor at 100 °C was 1.027.⁸⁷

b. Detection

Both conventional detection methods developed for achiral chromatography (for example, flame ionisation or chemiluminescence detectors for the determination of small amounts of sulfur-containing compounds⁸⁸) and specific methods based on special properties of optical isomers are used in the gas chromatographic resolution of enantiomeric mixtures. In spite of the fact that the measurement of the angle of rotation of the plane of polarised light is the simplest way of recognising enantiomers, polarimetric detectors have found no use in chiral gas chromatography. This is because the widely accepted separation on capillary columns requires high-sensitivity detectors, while polarimetric detectors are not sufficiently sensitive.

The olfactometric detection is used in studies of fragrance components. After the separation on a column with a chiral

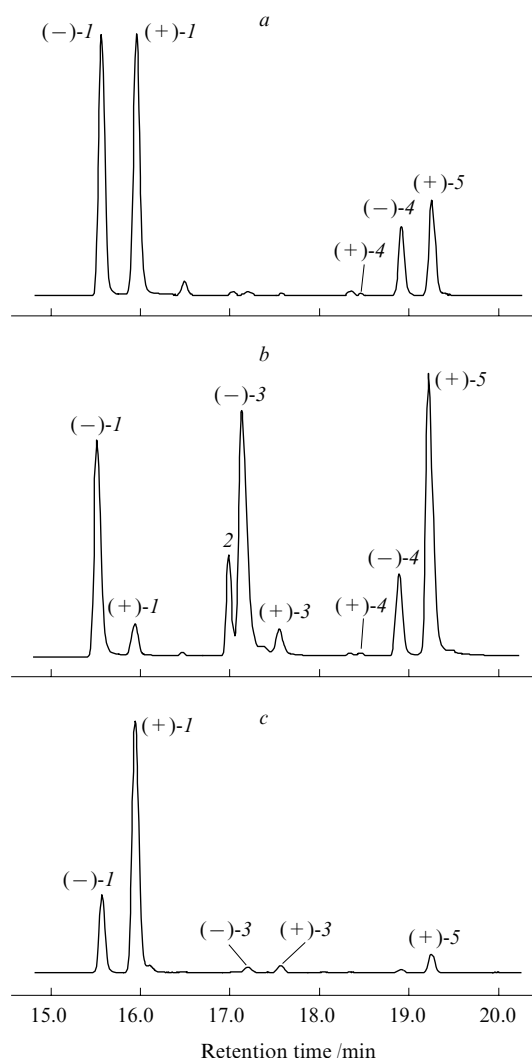

Figure 1. Chromatograms of monoterpene hydrocarbons from oleoresin of the Siberian stone pine (*Pinus sibirica* Du Tour.) (a), the Siberian spruce (*Picea obovata* Ledeb.) (b) and the Scots pine (*Pinus sylvestris* L.) (c) obtained by chiral gas chromatography/mass spectrometry on a 30 m \times 0.25 mm CycloSil-B column (0.25 μ m) at temperatures from 50 to 180 °C (the heating rate was 2 deg min⁻¹).

The peaks of compounds are identified by Arabic numerals: (1) α -pinene, (2) β -myrcene, (3) camphene, (4) β -pinene, (5) 3-carene.

stationary phase, the eluate is divided into two portions. One portion is delivered to a 'usual' (flame ionisation, mass selective, *etc.*) detector, and the odour of another portion of the eluate is evaluated by a human nose *via* a sniffing port.¹⁹ Studies of flavours characteristic of branched carboxylic acids that are present in Parmesan cheese and lamb meat can be referred to as examples.^{18, 19}

The olfactometric detection plays an important role in studies of flavour components of foodstuff because components present in large amounts not nearly always make a decisive contribution to a particular flavour. The analysis of the flavour of freshly squeezed orange juice showed that components that are hardly possible to identify reliably by conventional analysis because of their small amounts, play a great role in the flavour formation, and their true role can be revealed only by the olfactometric detection.⁸⁹

The enantioselective analysis of individual components in mixtures of compounds without their preliminary preparative separation can be performed with the use of mass-spectrometric detectors. However, due to some characteristic features of

mass-spectrometric detectors and the related substantial differences in the detector sensitivity to different groups of compounds, the quantitative analysis by gas chromatography/mass spectrometry presents difficulties. At the same time, the quantitative analysis of the enantiomeric composition of mixtures is very easy to perform by chiral gas chromatography/mass spectrometry, *i.e.*, by the direct method without the use of correction or the sensitivity factors, because enantiomers behave identically in mass spectrometric detectors. The chromatographic peak area ratio of enantiomers is equal to the enantiomeric ratio in the analyte.

Figure 1 shows chromatograms for the separation of mixtures of monoterpene hydrocarbons. It can be seen that pairs of overlapping peaks are absent in the chromatograms, *i.e.*, the separation was successful. The results of the more complex enantiomeric resolution by chromatography in the analysis of multicomponent mixtures containing limonene and β -phellandrene are presented in Fig. 2. These monoterpene hydrocarbons, which are present in many plants, are often found simultaneously and exist as pairs of compounds, which cause complications, because the peaks of these components are unseparable on many columns with widely used nonpolar polysiloxane phases. This pair of monoterpene hydrocarbons was successfully separated on the DB-1701 phase (Fig. 2*a*). However, researchers run into difficulty when attempting to resolve each compound into individual enantiomers on CycloSil-B columns (Fig. 2*b*) because the peak of (–)-limonene coincided with that of (+)- β -phellandrene.

In some cases, when the target components cannot be detected directly (for example in the analysis of labile compounds), their derivatives are synthesised. For instance, to detect (*R*)-3-mercapto-2-methylpropanol in red grape wines, compounds, which are present in the low-temperature vacuum distillation fraction, are subjected to acetylation, and the target compounds are determined as *O,S*-diacetyl derivatives.¹⁷ Enantiomers of some terpene alcohols are resolved as *O*-trifluoroacetyl derivatives.⁶²

III. Two-dimensional gas-liquid chromatography

In the analysis of plant volatiles and food extracts, researchers have, as a rule, to deal with very complex mixtures, which are impossible to separate on modern columns. Considerable progress in studies of such mixtures has been made only with the use of two-dimensional GLC.⁹⁰ This method is based on the successive separation of samples on two different columns. The analyte is delivered to column 1 (the so-called precolumn), where the preliminary separation of components is performed. Then the required fraction of the eluate is taken and divided into two portions. One portion is delivered to detector 1, and another portion is passed to column 2 (the so-called main column), in which the second separation is performed followed by the detection with detector 2. The precolumn is a usual 10–30 m capillary column with a low-polarity polysiloxane phase. This column is used to perform the rough separation of the starting complex mixture and isolate the required (narrow) fraction for the subsequent precision analysis on the main column. The main column is filled with a stationary phase containing a chiral selector, which offers considerable scope for the direct enantioselective analysis of components of complex mixtures of natural compounds.⁸⁷

The direct enantioselective analysis cannot be applied to most of mixtures of sesquiterpene compounds, unlike mixtures of monoterpenoids, because of a high 'density' of components in chromatograms and a large number of overlapping peaks. Only the use of the two-dimensional chromatographic techniques allows the direct analysis of such mixtures. Figure 3 presents the results of analysis of a mixture of sesquiterpene hydrocarbons isolated from oleoresin of the *Abies nephrolepis*

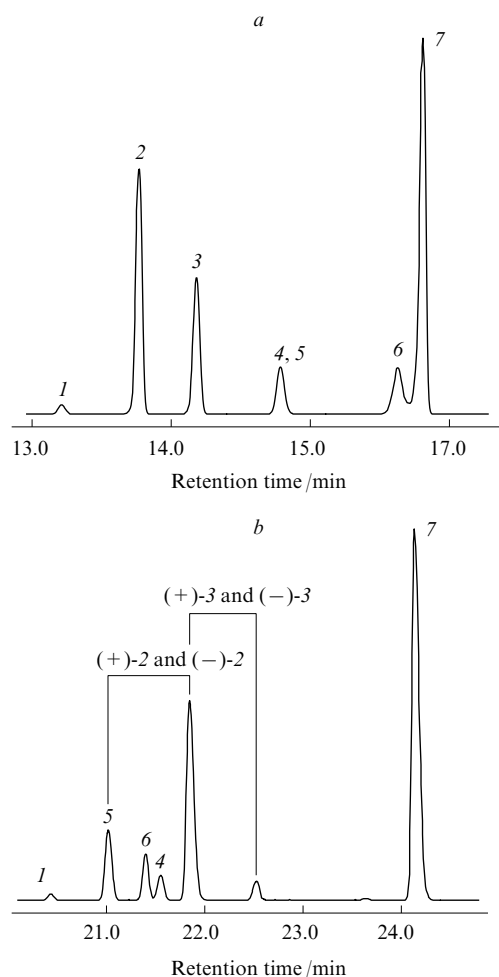

Figure 2. Fragments of chromatograms for the fractions of monoterpene hydrocarbons of essential oil from aerial parts of the *Seseli buchtormense* (Fischer ex Sprengel) W.Koch obtained on DB-1701 (a) and CycloSil-B (b) columns.

(a) 30 m \times 0.25 mm DB-1701 column (0.25 μ m), temperature 50–220 $^{\circ}$ C (the heating rate was 2 deg min^{–1}); (b) 30 m \times 0.25 mm CycloSil-B column (0.25 μ m), temperature 50–180 $^{\circ}$ C (the heating rate was 2 deg min^{–1}). The peaks of compounds are identified by Arabic numerals: (1) α -terpinene, (2) limonene, (3) β -phellandrene, (4) *p*-cymol, (5) *cis*- β -ocimene, (6) *trans*- β -ocimene, (7) γ -terpinene.

Figure 3. Determination of the optical purity of β -bisabolene in a mixture of sesquiterpene hydrocarbons from oleoresin of the *Abies nephrolepis* Maxim. by two-dimensional GLC.

Column 1: CPSil-5, 25 m \times 0.25 mm (0.25 μ m), temperature 50–200 $^{\circ}$ C (the heating rate was 4 deg min $^{-1}$); column 2: 30% heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- β -cyclodextrin in OV-1701 (in the inset), 25 m \times 0.25 mm (0.125 μ m), temperature 50–180 $^{\circ}$ C (the heating rate was 2 deg min $^{-1}$).

followed by the determination of the optical purity of β -bisabolene (**9**) in a complex isomeric mixture.

The first chromatographic separation of a mixture of sesquiterpene hydrocarbons was performed on a column with a polysiloxane phase to isolate a fraction containing β -bisabolene (the retention time varies from 26.60 to 26.70 min). The resolution of this fraction into individual enantiomers was carried out on a column with a β -cyclodextrin-based phase. It should be noted that the direct analysis (using the one-dimensional technique) of the fraction of sesquiterpene hydrocarbons is of no use because the mixture contains, along with β -bisabolene, all other isomeric (*Z*)- α -, (*E*)- α -, (*Z*)- γ - and (*E*)- γ -bisabolenes, which hinder the analysis of enantiomers of β -bisabolene.

There are two radically different arrangements of the precolumn and the main column in two-dimensional chiral GLC (in one or two different thermostats). Manufacturers of gas-chromatographic systems suggest simple solutions for two-dimensional chromatography as instruments in which both columns are placed in a single thermostat. However, this instrumental simplicity, despite a price benefit, offers less possibilities for tuning. In the overwhelming majority of cases, to achieve the most efficient resolution by two-dimensional chiral GLC, the precolumn and the main column with a chiral stationary phase should operate under different temperature conditions, which cannot be provided in instruments, in which both columns are placed in a single thermostat.

A quick technique was developed for the analysis of the enantiomeric composition of mixtures by two-dimensional chiral GLC with the use of a short (1 m) column packed with a cyclodextrin phase. The satisfactory enantiomeric resolution of limonene according to this procedure took only 8 s (!), and the enantiomeric composition of all monoterpene compounds isolated from bergamot oil was determined within 8–9 min.⁹¹

A combination of liquid and gas chromatography (LC-GC) is another efficient combined method for the determination of the enantiomeric composition of mixtures. However, only a few examples of the successful application of this method were documented.⁴⁰

IV. Preparative enantiomeric resolution

The preparative enantiomeric resolution of volatile natural compounds by chiral GLC with the use of cyclodextrin stationary phases is performed on packed columns filled with a solid support coated with modified cyclodextrin as the stationary phase. This method allows the isolation of milligram amounts of individual enantiomers.⁹²

The characteristic feature of preparative chiral GLC is that the best enantiomeric resolution is, as a rule, achieved at the minimum temperatures of the analysis because a lowering of the temperature leads to an increase in the retention times of the components. To decrease the temperature of the analysis, rather short columns and a packing material with a small (compared to usual preparative columns) amount of a stationary phase are used. In addition, the separation is performed at carrier gas flow rates 3–4 times higher than the optimal rates. An increase in the carrier gas flow rate leads to a slight decrease in the efficiency of the column. However, this drawback is compensated, on the whole, by the gain in enantioselectivity of resolution due to lowering of the temperature.

Preparative chiral GLC is generally carried out on a 1.8–2.0-m steel column with a diameter of 4–5 mm filled with a solid support (for example, with the Chromosorb W/HP sorbent with a grain size of 100–120 mesh) coated with a 20%–50% solution of modified cyclodextrin [heptakis(2,6-di-*O*-methyl-3-*O*-*n*-pentyl)- β -cyclodextrin,⁹³ heptakis(2,3-di-*O*-methyl-6-*O*-*n*-hexyl)- β -cyclodextrin,⁹⁴ octakis(2,3-di-*O*-*n*-pentyl-6-*O*-methyl)- γ -cyclodextrin,⁹⁵ octakis(2,6-di-*O*-methyl-3-*O*-*n*-pentyl)- γ -cyclodextrin⁹⁶ or heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- β -cyclodextrin⁹⁶] in polysiloxane [OV-1701,⁹⁷ PS-086⁹⁵ or SE-52 (Ref. 96)] as the stationary phase (2%–6%). The carrier gas flow rate is 200–400 ml min $^{-1}$; the temperature is chosen depending on the nature of the compounds and is varied from 35–45 $^{\circ}$ C (for monoterpene hydrocarbons) to 100–120 $^{\circ}$ C (for sesquiterpenes). The temperature of the chromatographic analysis should be chosen so as to achieve the selectivity factor of ≥ 1.1 . In this case, enantiomers of an optical purity of no less than 90% can be obtained.

Under these conditions, 1–2 mg of racemic compounds can be separated in a single chromatographic run. Milligram amounts of pure enantiomers (up to 97% *ee*) can be obtained by repeated chromatographic steps, these amounts being sufficient for the determination of the sign of optical rotation and, consequently, for the determination of the elution order of enantiomers, as well as for biological assays and pharmacokinetic studies.⁹²

The preparative enantiomeric resolution with the use of capillary columns with a large inner diameter (0.53 mm) and a larger layer thickness of the stationary phase was documented.^{98,99} Such columns provide better resolution compared to packed columns. However, this approach has found little application apparently because of rather complex technical equipment and labour-consuming experiments associated with a low capacity of capillary columns compared to packed columns.

Some plant volatiles exist in the gaseous state. However, no examples of the enantioselective analysis of gaseous plant metabolites have yet been reported, although a procedure for the preparative resolution of chiral gaseous compounds on

cyclodextrin phases at room temperature was elaborated for bromochlorofluoromethane.¹⁰⁰

V. Identification of enantiomers

The reliable assignment of peaks of optical isomers plays a decisive role in chiral chromatography. Since the mechanism of enantiodifferentiation based on interactions of a chiral selector with an enantiomeric pair remains to be elucidated, it is impossible to predict the elution order of enantiomers. Taking into account the fact that the selectivity of columns depends, among other factors, on the chromatographic conditions, it can be concluded that the identification of enantiomers is a complex problem. Generally, at least two model samples are required for the reliable assignment of peaks. One sample should contain both enantiomers (the presence of a racemic mixture is preferable). This sample is used for choosing the optimal chromatographic conditions. Another sample should be enriched in a particular enantiomer with the aim that the elution order of optical isomers can be determined under the optimised conditions.

Many of the most widespread monoterpene compounds are commercially available both as racemic mixtures and individual enantiomers. The situation is more difficult with less widespread compounds. Researchers often have to synthesise such compounds or isolate them from natural mixtures. This is particularly true for sesquiterpene compounds because only a few of them are present in catalogues of manufacturers of chemicals. Moreover, natural sources, from which the target compound can easily be isolated in required amounts, are unknown for many sesquiterpenoids. In this connection, studies aimed at preparing individual sesquiterpenoids or their mixtures of known composition for the use as reference samples in chiral GLC deserve particular notice. For example, the easily available natural sesquiterpene hydrocarbon germacrene D was transformed¹⁰¹ into mixtures of sesquiterpenoids of known composition containing selinane-, cadalene-, eudesmane- and oppositane-type sesquiterpenoids and other

related compounds belonging to the biogenetic tree of germacrane by acid-catalysed, photoinduced or thermally induced rearrangements. However, far not all important sesquiterpenes required as reference compounds can be synthesised from known precursors by rearrangements. Extracts of some lower plants and fungi can be mentioned as sources of 'unusual' enantiomers of plant sesquiterpenoids.⁹⁵

Extensive experimental data on the enantiomeric resolution of plant volatiles, fragrance and flavour compounds by chiral GLC on capillary columns with stationary phases based on chiral selectors are available. Data on the separation factors of enantiomers of various compounds, including plant compounds, were published. In particular, enantiomers were analysed on capillary columns with phases based on octakis(6-*O*-methyl-2,3-di-*O*-*n*-pentyl)- γ -cyclodextrin,¹⁰² heptakis(2,6-di-*O*-methyl-3-*O*-*n*-pentyl)- β -cyclodextrin (Ref. 103) and octakis(3-*O*-butyryl-2,6-di-*O*-*n*-pentyl)- γ -cyclo-dextrin.¹⁰⁴ The enantiomeric separation of octane-1,3-diol, (5*Z*)-octene-1,3-diol, ethyl 3-hydroxyoctanoate and ethyl (5*Z*)-3-hydroxyoctenoate on a column with heptakis(2,3-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)- β -cyclodextrin was documented.^{15, 105} However, the published data summaries are not always useful in practice because they contain no information on the elution order of enantiomers. Data on the resolution of 260 enantiomeric pairs of cyclopropane derivatives were presented in the review,¹⁰⁶ where the selectivity factors were reported without mentioning the conditions of resolution. The successful enantiomeric resolution of γ - and δ -thiolactones of the fatty acid series (C₆, C₈, C₁₀, C₁₂),¹⁰⁷ optical isomers of various natural and synthetic compounds,¹⁰⁸ trifluoroacetates of terpene and nonterpene alcohols⁶² and β - and γ -lactones of the fatty acid series was documented.⁶² However, the elution orders of these enantiomers were also not reported, although the selectivity factors were published.

The aim of the present review was to provide the most detailed information on the chirospecific analysis of plant volatiles. Tables 1–4 summarise data on the enantiomeric resolution of natural plant compounds and selected important

Table 1. Enantiomeric resolution of mono- and sesquiterpenoids and related compounds by chiral GLC on stationary phases containing cyclodextrin derivatives as chiral selectors.

^a The following abbreviations are used: AcF is trifluoroacetyl, Bu is n-butyl, But is butyryl (butanoyl), Pe is n-pentyl and TBS is *tert*-butyldimethylsilyl;

^b determined as trifluoroacetate; ^c enantiomers are not resolved; ^d A 0.162 M solution of α -cyclodextrin in glycerol; ^e 10% β -cyclodextrin in polysiloxane SPB-35; ^f Chirasil- γ -Dex phase: the chiral selector γ -(2,6-Pe-3-But) is grafted to polymethylpolysiloxane through the octamethylene spacer.

Table 2. Enantiomeric resolution of sesquiterpene hydrocarbons by chiral GLC under isothermal conditions on stationary phases containing cyclodextrin derivatives as chiral selectors.

^a The Chirasil- γ -Dex phase: the chiral selector γ -(2,6-Pe-3-But) is grafted to polymethylpolysiloxane through the octamethylene spacer; ^b 6-*tert*-butyldimethylsilyl- β -cyclodextrin in polysiloxane; ^c as pentakis(trifluoroacetyl) derivatives; ^d enantiomers are not resolved.

flavour compounds, such as mono- and sesquiterpenoids and related compounds (Table 1), sesquiterpene hydrocarbons (Table 2), diterpenoids (Table 3) and various aliphatic and alicyclic compounds (Table 4). These data include the types of chiral selectors (modified cyclodextrin), the temperature con-

ditions of chromatography, the selectivity factors and the elution orders of enantiomers.

The following abbreviations are used in the tables to denote chiral cyclodextrin selectors involved in stationary phases: the nature of the starting cyclodextrin (α , β or γ) followed

(in parentheses) by the position and the nature of substituents in modified cyclodextrin molecules. For example, the notation β -(2,6-Me-3-Pe) means that the stationary phase for chiral GLC was prepared based on heptakis(2,6-di-*O*-methyl-3-*O*-*n*-pentyl)- β -cyclodextrin. For the temperature conditions, the following abbreviations are used: 60°(18)–120°(1°)(10)–200°(10°)(5). This means that heating is performed for 18 min at 60 °C followed by the rise of the temperature to 120 °C at a rate of 1 deg min^{−1}, storage at 120 °C for 10 min, the rise of the temperature to 200 °C at a rate of 10 deg min^{−1} and storage at 200 °C for 5 min. For many enantiomeric pairs, the selectivity factors (α) and first-eluted enantiomer are given.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 07-03-00 620-a). I thank N I Tkacheva (N N Vorozhtsov Novosibirsk Institute of Organic Chemistry, Siberian Branch of the Russian Academy of Sciences) for help in the literature search.

V. Thermotropic gel-forming systems for increasing sweep efficiency in water flooding and thermal steam treatment	979

Abstract. Physicochemical methods for enhancing oil recovery from oil fields that are developed using water flooding and thermal steam treatment are considered. The results of pilot testing of processes based on these methods carried out at West Siberian and Chinese oil fields are analysed. The attention is focused on the processes that make use of surfactant blends and alkaline buffer solutions and thermotropic gel-forming systems. The bibliography includes 123 references.

I. Introduction

Currently, Russia is a prominent supplier of hydrocarbon raw materials to the world market. Russia fully satisfies the internal requirements in crude oil and remains simultaneously among the main exporting countries. During the period from 2000 to 2006, crude oil production has steadily increased from 323 to 480 mln t.¹ These are the highest values over the last 20 years. According to data of oil companies, the increase in oil production in Russia due to implementation of enhanced oil recovery (EOR) techniques was ~43–45 mln t per year in 2002–2006.¹

The key method for oil field development in Russia is water flooding used to produce ~95% of crude oil. Most of large oil fields are now at a late stage of development, the current water cut being more than 80%. The flooded reservoir rocks contain residual oil reserves. The newly developed oil fields are characterised, most often, by low rock permeability, high oil viscosity and complex geological structures; therefore, these reserves are difficult to recover. In Russia, the fraction of this type of oil reserves constantly increases. Calculations have shown that an increase in final oil recovery by only 1% would increase the annual production by 20–30 mln t. Therefore, the possibility of increasing oil reserves by enhancing the oil recovery of water-flooded reservoirs appears significant. According to expert estimates, the oil reserves difficult to recover exceed 10¹² tons all over the world, and in mature

economies, these are regarded not only as an inventory for crude oil production, but also as a main source for its intensification in the near future. Effective development of difficult-to-recover oil reserves and further buildup of production requires the design and wide-scale application of new integrated EOR techniques.^{2,3}

II. Trends in the development of enhanced oil recovery methods

In oil field development by water flooding, water is injected into an oil deposit through a network of injection wells. The injection of water makes up for the decrease in the formation pressure caused by oil withdrawal through producing wells. Water flooding is interpreted as displacement of oil from the fractured-porous medium by water with the formation pressure remaining the same and with full compensation of the produced oil volume by the injected water volume. In the initial stage of development, producing wells give anhydrous crude oil and later, a fluid comprising an oil–water mixture. The ratio of the amount of the produced water to the amount of the produced fluid is called water cut.

The oil recovery factor (ORF) is the ratio of the produced oil volume to the initial oil reserves. The development target is one or several oil formations developed together. The ORF value can be represented as the product of oil displacement efficiency (K_d) by the sweep efficiency (K_c) of the target by the given treatment method

$$\text{ORF} = K_d K_c.$$

Even in the favourable case where water has penetrated through 70% of the formation volume ($K_c = 0.7$) and has displaced 70% of oil from the penetrated areas ($K_d = 0.7$), the final ORF would not exceed 50%:

$$\text{ORF} = K_d K_c = 0.7 \times 0.7 = 0.49.$$

Computer simulation of oil field development does not imply explicit use of the coefficients K_d and K_c in design documents. Nevertheless, these values are useful as they allow one to distinguish contributions of K_d and K_c to the ORF.

There are several reasons for incomplete oil recovery on water flooding.^{4–10} They can be divided into three groups. The first group is related to the capillary-porous structure of the reservoir rock and to the enormous overall oil–rock contact

area. The rock surface is always coated with an oil film that is not displaced by water. The film oil can account for 10%–20% of the total oil volume in the reservoir rock. In addition, ~10% of oil remains in the formation as drops entrapped in narrow sections of capillary pores and rock cracks. The displacement of drops is hampered by the capillary pressure gradient, which may be hundreds (or even thousands) times higher than practicable pressure gradients of oil displacement with water. Therefore, the highest K_d value usually does not exceed 0.7. Thus, the first group of reasons is associated with adverse influence of the ion-molecular surface forces at interfaces in the oil–water–rock system.

The second group is related to the difference between oil and water parameters, *viz.*, density and viscosity, resulting in uneven migration of the displacement front of oil by water.

The third group is related to geological and physical heterogeneity of the reservoir (mainly, heterogeneous structure and properties of the reservoir rock at macro- and micro-levels) and is manifested as incomplete sweep of the rock by water flooding, *i.e.*, K_c is < 1 . Finally, this enhances the variance of hydrodynamic and energy and mass exchange processes in the formation.

Enhanced oil recovery can be attained by using physicochemical methods of productive formation treatment, in particular, by introducing chemical reagents, which (*e.g.*, surfactants, solvents, carbon dioxide) eliminate partially or fully the adverse influence of capillary forces. Other materials (polymer solutions, gels, emulsions and foams) change the rheological properties and structure of the filtration flows of the formation fluids (oil, water or emulsions with dissolved gases) and decrease the hydrodynamic anisotropy of the oil formation.

The long experience of using diversified methods for enhancing oil recovery at West Siberia oil fields has shown that methods that increase the sweep efficiency of the injected water are most promising. This is due to the fact that in many deposits progressive increase in the water content in the produced oil (water cut $> 70\%$) is observed even at early stage of development due to the low sweep efficiency ($K_c \approx 0.1–0.2$). Meanwhile, the K_d value for high-permeability, flooded-out formation zones is close to the maximum attainable value, oil displacement by water is close to the frontal drive and $K_c \approx 0.6–0.7$.

The EOR methods that increase K_d (for example, injection of dilute surfactant and polymer solutions) proved to be of low efficiency under field conditions. Meanwhile, the methods that increase K_c (or both coefficients) provided engineering and economic benefits irrespective of the particular impact mechanism.^{11–18} These methods include the following:

- hydrodynamic methods changing the direction of filtration flows (various versions of non-stationary cyclic water flooding);¹⁹

- physicochemical methods for the control of filtration flows: injection of concentrated solutions of surfactants, oil-displacement compositions, cross-linked polymeric and polymer-dispersion systems, viscoelastic and gel-forming systems, gas, emulsions and foam and generation of such systems *in situ*, directly within the oil formation, by using thermotropic gel-forming compositions, organosilicate systems, *etc.*^{5, 8, 9, 20}

From the standpoint of subsurface gas- and hydrodynamics, the problem of coverage of an oil-bearing formation with water flooding is reduced to the control of the filtration flows of formation fluids.²¹ Currently, the predominant view considers EOR methods as efficient means for the control of filtration flows, increase in the sweep efficiency of water-flooding or another active treatment. The same goal is pursued in using hydraulic fracturing of the formation, horizontal drilling and branch wellbore drilling.^{22–24} These methods give rise to a fracture crack network and enhance oil produc-

tion. However, after that, the water cut of producing well fluid rapidly increases. This also suggests using physicochemical methods to control the sweep efficiency and intensify the capillary counter-current impregnation of low-permeability blocks of the fractured reservoir matrix. Physicochemical methods for the control of filtration flows by creating gel barriers in the formation are promising.

The oil remaining in the reservoir after water flooding is called residual. On the basis of expert estimates, the residual oil reserves are classified in the following way:⁴

- oil remaining in low-permeability interlayers and sections not swept by water, 27%;

- oil in stagnant pockets of uniform formations, 19%;

- oil remaining in lenses and at impermeable barriers not exposed by wells, 24%;

- oil retained in capillaries and films, 30%.

Thus, the oil not swept by water flooding due to reservoir heterogeneity accounts for 70% of all residual reserves and represents the main source for enhancing oil recovery. For the production of residual oil, it is important to systematically select the EOR method and to schedule various types of stimulation of producing and injection wells in a definite order with time matching.^{25, 26}

In recent years, the fraction of high-viscosity oils in the total amount of crude oil produced in the world has increased. The reserves of high-viscosity oils exceed ~5 times the recoverable reserves of low- and medium-viscosity oils (according to estimates, 810 and 162 bln t, respectively).²⁷ Large reserves of high-viscosity oils are found in Canada, Venezuela, Mexico, USA, Russia, Kuwait and China.

Of the modern methods for production of high-viscosity oils, thermal steam treatment of formation by stationary or cyclic (huff-and-puff) steam injection is most efficient.^{28–30} Most often, the injected steam has a temperature of 310 to 320 °C at the wellhead and dryness of 70%–80%. The injection pressure usually does not exceed 15–18 MPa. Combustion of 1 t of oil in a steam generation plant gives from 10 to 15 t of steam. The treatment is considered efficient if this gives 1 t of additional produced oil per 3–4 t of steam. The stationary steam injection is accomplished continuously through a network of steam injection wells, while oil is produced through a network of producing wells. The cyclic (huff-and-puff) stimulation consists of three stages: first, steam is injected into producing well, then the well is closed and kept for some period for formation warming up, and after that, oil production is resumed. When oil no longer enters the well, the huff-and-puff cycle is repeated. In this case, the first cycle is most effective, the efficiency of subsequent cycles being lower.

The efficiency of thermal steam treatment can be increased by combining it with physicochemical methods that use gel-forming and oil-displacing compositions. The use of gels increases the sweep efficiency of steam injection, while the use of oil-displacing compositions ensures additional oil recovery. Integrated methods that combine thermal steam and physicochemical treatment of formation are at an early stage of development (the number of these projects is small but they arouse considerable interest).

In 1981, works on enhancing oil recovery by using physicochemical methods were started at the Institute of Petroleum Chemistry of the Siberian Branch of the RAS (IPC SB RAS). A new approach to the development of efficient oil-displacing compositions based on surfactants and alkaline buffer systems has been proposed. A set of original devices and methods for investigation of the physicochemical and rheological properties of the surface and bulk phases in the oil–rock–surfactant solution system have been developed. A promising concept of using the reservoir or injected heat carrier energy for *in situ* generation of oil-displacing fluids, gels and sols directly in the reservoir has been proposed. The physicochemical grounds for

EOR methods making use of gel-forming systems and surfactant compositions were proposed. The principles of selection of oil recovery-enhancing compositions were implemented within the concept considering oil-displacing liquids as physicochemical systems with negative feedback, which maintain self-adjusting properties optimal for oil recovery in the producing formation for a long period of time. In recent years, development of new techniques using inorganic and polymeric gel-forming systems capable of generating gels directly in the formation has been in progress. By using these techniques, it is possible to create diverting barriers and control filtration flows, which would increase oil production and decrease water cut in the producing well product.

The chemical reagents used in industrial oil production should be relatively cheap, environmentally safe and commercially available on a large scale. Their application should not induce irreversible changes in the environmental situation in oil producing regions. The search for new cheap raw material sources for the use in EOR techniques is of special value. In this respect, good promise is given by the joint work of the Institute of Petroleum Chemistry and the Institute of Solid State Chemistry and Mechanochemistry of the Siberian Branch of the RAS dealing with the preparation of soluble compounds from plant stock (cellulose, rice hulls and so on) using mechanochemical treatment and coordinating solvents³¹ and with the use of large-scale industrial products manufactured in Russia, wastes from chemical and petrochemical plants and Kuznetsk Basin coal industry and so on.³²

The specialists of the IPC have developed eight EOR techniques, which are used at West Siberian and other oil deposits. Annually, 150–200 wells are treated according to these techniques. The additional oil production is on average 1–3 th t per treated well and the payback period is 5–10 months. Due to the use of the developed technologies at the West Siberia oil fields, >1.5 mln t of oil were additionally produced during the last 5 years alone. These technologies are cost effective and environmentally safe; they make use of large-scale products available as wastes of various industrial processes in Russia. The pilot tests of gel technologies were successfully carried out in the White Tiger offshore field in South China Sea (Vietnam).

Currently, new technologies for enhancing oil recovery, in particular, for high-viscosity oil fields, are developed. For increasing the efficiency of cyclic steam treatment of high-viscosity oil reservoirs, it was proposed to combine this method with physicochemical methods, in particular, those using polymeric and inorganic gels (for water shutoff) and surfactant compositions and generating, on thermal treatment, carbon dioxide and alkaline buffer system (for decreasing oil viscosity and for additional oil displacement). A set of laboratory studies has been performed. The first field tests of thermotropic gel-forming compositions for water shutoff and surfactant-based oil-displacing compositions were carried out between 2003 and 2006 as applied to cyclic steam treatment of high-viscosity oil reservoirs of the Usinskoye oil field (Komi Republic) and Liaohe and Gaosheng oil fields in China.

III. Compositions of surfactants and alkaline buffer systems used for enhancing oil recovery of low-permeability reservoirs

1. Effect of pH on oil displacement by water

A key factor hampering oil displacement by water is structuring of the adsorption layers in the oil–rock–formation water system. These layers contain tars, asphaltenes, heteroatomic compounds, high-molecular-mass paraffins, mineral colloidal particles.^{33–42} As a result, gel-like layers (films), possibly microemulsions, having high viscosity are formed at the inter-

face. These layers (films) create a structure-mechanical barrier, which accounts for the kinetic stability of the disperse system and prevents thermodynamically favourable processes.⁴³ Therefore, of interest are investigations of boundary layers in the oil–water–surfactant system, especially those carried out by low-frequency vibration methods.^{44–46} These methods allow one to measure rheological parameters of contacting bulky and surface phases under conditions of continuous deformation with small amplitude (this type of deformation occurs in an oil drop or film on filtration through a water-saturated capillary-porous formation material).

For enhancing oil recovery, it is insufficient to ensure low oil–water interfacial tension. The interfacial tension is a thermodynamic value equal to the free energy of the interface; the lower the interfacial tension, the thermodynamically more favourable the oil displacement process.^{47,48} However, thermodynamically favourable process often cannot be accomplished due to its too long duration. In the case we consider, adsorption layers rearrange slowly upon mechanical impact due to the sharp increase in the structural viscosity or, what is the same, due to the appearance of relaxing shear elasticity following a decrease in the layer thickness. Consequently, during water flooding at the formation pressure gradients, the structured adsorption layers behave as non-thixotropic mechanically strong films, which deteriorate filtration of formation fluids and reduce oil recovery.^{33–42,49,50} Thus, to enhance the oil recovery, it is necessary to find practicable ways for destructuring of the adsorption layers and decreasing the interfacial tension.

When aqueous solutions immiscible with oil are used for oil displacement, the interfacial films can be destructured by chemical reagents, namely, by surfactants and/or low-molecular-mass inorganic compounds dissolved in the injected water that are able to destroy hydrogen bonds and weaken hydrophobic interactions between the oil components constituting these films.^{51–55} The surface activity of surfactants should be higher than that of oil components to provide the possibility of displacing them from the adsorption layers. However, surfactants should not form structured interfacial films. None of the commercially manufactured surfactants fully meets these requirements. The properties of the colloidal surfactants used can be improved by adding low-molecular-weight organic co-surfactants and by forming surfactant compositions with low-molecular-mass inorganic chemicals that ensure destructuring (fluidisation) of adsorption layers.

In the oil–water–rock system, the key role in structuring (strengthening) of interfacial layers belongs to hydrogen bonds, although hydrophobic interaction also plays a role at high formation temperatures. The interfacial layers can be destructured most readily and efficiently using alkaline chemicals as parts of oil-displacing compositions to destroy hydrogen bonds and weaken hydrophobic interactions between the oil components of these layers.^{56,57}

The destructuring of interfacial layers by solutions of alkaline reagents is caused by various chemical reactions involving hydroxyl ions, specifically, neutralisation of acid groups (carboxy, phenolic and thiol); saponification of ester bonds; deprotonation of donor heteroatoms (nitrogen, sulfur); association of hydroxyl ions with aromatic fragments of the oil components; and influence on the structure of water and thus on hydrophobic bonding, the conformational mobility of hydrophobic parts of surfactants, *etc.* These reactions involving hydroxyl ions reduce the oil–water interfacial tension (Fig. 1),^{58–60} change the electric double layer,^{61–63} decrease the viscosity of interfacial layers^{58,64} and increase the wettability of the reservoir rock and oil phase by water.^{65–69}

Among all anions, the hydroxyl ion has the highest adsorption potential with respect to the rock oxide minerals in an aqueous medium and the highest mobility and exerts the

Figure 1. Oil interfacial tension for the AV₁ formation of the Sovetskoye (1, 4), D₁ formation of the Romashkinskoye (2, 5) and PK₁₋₂ formation of the Russkoye deposits (3, 6) vs. pH of the aqueous phase of different compositions.⁵

Aqueous solution: (1–3) 0.1 M HCl + NaOH; (4–6) 0.1 M HNO₃ + NH₃.

most pronounced ordering effect on water. In an alkaline solution, the initially hydrophobic sections of the rock become hydrophilic and the thickness of the stable aqueous interlayer between the rock and oil increases. The adsorption of hydroxyl ions increases the surface density of the negative charge of the rock and decreases the number of adsorption sites able to form hydrogen bonds.^{65, 70} This is favourable for improving rock wetting by water and for decreasing adsorption of both anionic and non-ionic surfactants.^{71–75} When surfactants are adsorbed from alkaline solutions onto a negatively charged rock surface, the orientation of surfactant molecules in the adsorption layer is such that the hydrophilic character of the rock does not change. For alkaline solutions of non-ionic and anionic surfactants, a low interfacial tension and neutral wetting in the rock–oil–aqueous phase system can be implemented simultaneously, which is confirmed by the results of testing of selective wetting in a model system with controlled properties of interfaces.^{76–78} This results in high capillary numbers so that the oil-displacing ability of surfactant solutions increases.^{5, 79, 80}

In view of the foregoing, it appears promising to develop compositions containing surfactants and alkaline chemicals and combining the useful features of alkaline water flooding and water flooding using surfactant solutions.^{4, 47, 48, 81, 82} Analysis of the features of oil displacement process by alkaline solutions of surfactants⁵ attests to the presence of an optimal alkalinity range (pH 9.0–10.5) in which the surfactants are chemically stable and have the highest oil-sweeping ability.⁷⁹ In addition, it is in the range of pH 9.0–10.5 that suspensions of clay minerals have the lowest viscosity and adhesion to the reservoir rock,⁸³ which is important for water flooding of low-permeability reservoirs. In this pH range, no noticeable dissolution of rock minerals and precipitation of alkaline-earth metal hydroxides from formation or injected water are observed, whereas at pH > 10.5, calcium and magnesium hydroxides can precipitate and rock minerals dissolve. In highly alkaline media, non-ionic surfactants like hydroxyethylated phenols undergo denaturation resulting in a sharp increase in the critical micelle concentration.⁷¹

Thus, selection of an appropriate alkaline reagent is crucial for the development of effective oil-displacing compositions

based on surfactants. A self-maintained, self-adjusted pH value in the range from 9.0 to 10.5 can be ensured by using buffer systems with maximum buffer capacity in this pH range. In terms of more general views on an oil-displacing composition as a physicochemical system, the presence of an alkaline buffer solution generates a negative feedback and thus imparts the composition with self-adjustment property, *i.e.*, maintenance of its functions in the formation for a long period of time. In physicochemical systems, self-adjustment is necessarily accompanied by a change in the component concentrations and has natural concentration limits within which the parameter characterising the self-adjustment efficiency reaches a maximum. For buffer solutions, the buffer capacity is such a parameter. The condition for maximum capacity is met if the concentrations of the acid (base) and salt composing the buffer system are equal. The thermodynamics of buffer solutions was considered previously.^{84, 85} The effects of dilution, neutral electrolyte and non-electrolyte additives, temperature and pressure on the buffer capacity have been described in detail in a monograph.⁸⁶

Despite the enormous number of substances capable of forming buffer solutions, only some organic and only four inorganic buffer systems are suitable for the required pH range (9 to 10.5): phosphate (tripolyphosphate), silicate, ammonia and borate systems. The tripolyphosphate system can be used to enhance oil recovery of high-permeability reservoirs with low temperature. In the case of low-permeability reservoirs of the West Siberia oil fields, its use is problematic, because sodium tripolyphosphate rapidly hydrolyses above 323 K being converted into trisodium phosphate, which forms insoluble salts with calcium, magnesium and iron ions present in injected and formation waters. The use of silicate systems (specifically, their field preparation) is faced with technical difficulties caused by the tendency of sodium silicate to hydrolytic polycondensation and poor compatibility with oil field brine. It is noteworthy that phosphate and silicate systems are used in the techniques implementing the precipitation and gelation effects for selective isolation of highly permeable zones of the reservoir.

Ammonia, borate and mixed ammonia–borate systems are the systems of choice. They are prepared from ammonia, ammonium nitrate, sodium tetraborate and boric acid. These compounds are rather cheap commercial chemicals manufactured on a large scale.

The use of compositions of non-ionic surfactants with an alkaline reagent at high formation temperatures requires that they contain anionic components, which increase the cloud point of the non-ionic surfactant.⁸⁷ Additionally, in order to enhance the oil-sweeping ability and improve the compatibility with oil field brine and injected water, it is desirable to introduce low-molecular-mass organic compounds that combine the functions of a non-colloidal co-surfactant and a precipitation inhibitor for hydroxides and hardness calcium or magnesium salts. Taking into account the above requirements, a number of compositions based on ionic and non-ionic surfactants (oxyethylated alkylphenols: OP-10, Neonol AF 9-12 and its analogues) were developed and laboratory tested.⁵

2. IPC compositions based on surfactants and alkaline buffer systems

Analysis of the development of physicochemical methods for enhancing oil recovery reveals a clear tendency to impart self-adjustment feature to the oil-displacing fluid, which allow the fluid to maintain its functions in the reservoir rock for a long period of time.⁸⁸ The development of physicochemical principles for selection of surfactant compositions taking into account the thermodynamic and kinetic parameters of the oil–rock–aqueous phase system, which affect the oil displace-

ment from the porous rock, carried out at the IPC SB RAS is based on the concept of an oil-displacing fluid as an above-mentioned physicochemical system with negative feedback. It was proposed that alkaline buffer systems with a highest buffer capacity in the pH range of 9.0–10.5 would be used in the oil-displacing compositions of the IPC series.

Systematic studies of the effect of pH and the ionic strength of aqueous electrolyte solutions on the interfacial tension of oils showed that the pH dependence of the interfacial tension (see Fig. 1) has extreme points: a maximum in the pH range from 4.5 to 5.5 and a minimum at pH 9–10. The maximum is due to the presence of natural surfactants in oil.⁵ These are heteroatomic compounds present as parts of tars and asphaltenes, the most high-molecular-mass oil components. The functional groups of the cationic surfactants present in oil include pyridine, quinoline and other, mainly heterocyclic, basic groups and also tetrapyrrole fragments of oil metal porphyrins. The anionic surfactants present in oil typically contain carboxy, phenolic and thiol functional groups. The decrease in the interfacial tension upon the shift of the aqueous phase pH to the acidic region with respect to the maximum is due to protonation of functional groups of cationic surfactants in the interfacial layer, while that upon the shift of pH to the alkaline region from the maximum is due to neutralisation of the carboxy, phenolic and thiol groups of anionic surfactants. The pH dependences of the interfacial tension for crude oils of West Siberia and the Ural–Volga region are different. In the alkaline region, the interfacial tension decreases substantially for West Siberian crudes, whereas for the sour crudes of the Ural–Volga region, this decrease is slight, which may be attributed to the presence of saturated sulfides having weakly basic properties. For all crudes studied, the interfacial tension varied inversely to the ionic strength of the aqueous phase.

At the oil–aqueous phase interface, the natural surfactants of oil form an amphoteric adsorption layer. The ionisation of the polar ionic groups in the oil natural surfactants in acidic or alkaline medium gives rise to an electric double layer at the interface. The maximum in the dependence of the interfacial tension of oil at the interface with the aqueous phase vs. pH of the aqueous phase corresponds to the isoionic state of the adsorption layer. The maximum pH value corresponds to the isoionic point of the layer (pH_i); it can be calculated as the half-sum of the acid constant indexes (pK_a) of the strongest acidic and basic functional groups in the adsorbed molecules. The strongest acidic groups present in oil surfactants are carboxy groups (pK_a = 5.6), while the strongest basic groups are pyridine (pK_a = 4.6) or quinoline groups (pK_a = 4.9). The calculated pH_i value equal to 5.3 virtually coincides with the experimental pH_i 5.2.

Taking into account the experimental dependences of the interfacial tension on pH and the ionic strength of the aqueous phase, an electrocapillary model of the interfacial layer has been developed.^{5,89} According to this model, the interfacial layer (amphoteric adsorption layer of the natural surfactants present in oil) has the properties of ion exchange membrane. The extremal pattern of dependence of the interfacial tension of oils on pH of the aqueous phase is caused by the presence of an electric double layer arising due to ionisation of the ionisable groups in natural surfactants of oil. The model establishes relationship between the oil composition and the physicochemical parameters of the interfacial layer, which dictates the mechanism of oil displacement by aqueous solutions (due to the change in the interfacial tension, adsorption of the natural surfactants of oil, the composition and concentration of electrolytes in the aqueous phase). In terms of this model, the dependence of the interfacial tension of oil (σ) on the aqueous phase pH is given by the equation

$$\sigma = \sigma_i - b\vartheta^2[-\log(a_{H^+} + KI) - \text{pH}_i]^2 + c\vartheta^4[-\log(a_{H^+} + KI) - \text{pH}_i]^4 - 2.303\Gamma_0 RT \log(1 + K_a I),$$

where σ_i is the interfacial tension in the isoionic point; b is the integral capacity of the electric double layer; $\vartheta = 2.303RT/F$, R is the universal gas constant, T is temperature, F is the Faraday number; a_{H^+} is the proton activity in the aqueous phase; K is the ion exchange constant for the interfacial membrane; I is the ionic strength of the aqueous phase; c is a parameter characterising the dependence of the integral capacity of the electric double layer on its potential; Γ_0 is the limiting adsorption of electrolyte ions in the interfacial layer; K_a is the adsorption constant for electrolyte ions in the interfacial layer.

As an example, Fig. 2 shows the dependences of the interfacial tension on pH, one calculated using the above equation (line) and one experimental (dots) for the crude of the Sovetskoye oil field (AV_{1–2} formation) at the interface with an aqueous electrolyte solution with a constant ionic strength.

Figure 2. Oil interfacial tension vs. pH for the oil of Sovetskoye field (AV_{1–2} formation) at the interface with an aqueous solution of a 1:1 electrolyte with a constant ionic strength $I = 0.1$ mol per kg of water.⁶⁰

On the basis of investigation of the thermodynamic and kinetic parameters of the oil–rock–water–surfactant systems, the most promising IPC compositions involving surfactants and ammonia buffer based on ammonia and ammonium nitrate (cheap commercial products) were proposed for the industrial use at the oil fields of West Siberia. These compositions combine the advantages of alkaline water flooding and water flooding with surfactant solutions.

A distinctive feature of IPC compositions is the fact that they contain constituents of the geochemical nitrogen, carbon or oxygen cycles. This accounts for their environmental acceptability and multifunctionality: the components serve as the nutrition sources for the reservoir microflora, natural indicators (tracer agents) of the filtration flows in the oil accumulation, etc.

Waxy IPC compositions IHN-60 and IHN-100, low-viscosity non-combustible liquids with freezing points ranging from -33 to -55 °C were proposed for winter injection in Northern regions. The use of IPC compositions increases the oil displacement efficiency by 10%–20%. They can be employed over broad ranges of formation temperatures and compositions of formation water and for the development of low-permeability and heterogeneous reservoirs. Upon oil displacement by IPC compositions, the mobility of filtered fluid increases 3–7-fold, which attests to the possibility of appreci-

able increase in the injectivity of injection wells on treatment of the bottomhole formation zone.⁹⁰ The specific loss of the surfactant caused mainly by adsorption on the core material during oil displacement equals 0.2–0.6 mg g⁻¹.

3. Pilot testing of EOR processes using IPC compositions

Two processes making use of IPC compositions have been developed: treatment of the bottomhole zones with small volumes of the compositions; injection of large-volume slugs (portions) of compositions in order to affect the interwell space of the formation.

From 1984 to 2006, treatment of the bottomhole zones of more than 150 injection wells was carried out under different geological conditions in the oil fields of the Tomsk and Tyumen Regions. This process increases the well injectivity 1.5–2.5-fold, decreases the injection pressure by 30%–40%, increases the efficiency of the producing wells that are hydrodynamically connected to injection wells. The duration of the effect is 6 to 16 months. The additional oil production is 20–30 t per t of the injected composition. The technology is cost effective, the payback time being 4–9 months; it is applicable to formations with temperatures of 10–130 °C and permeability of 0.005–0.500 μm², the effect being most pronounced for low-permeable heterogeneous reservoirs of Jurassic and Cretaceous deposits typical of West Siberia.⁵

The pilot testing of technology with injection of large-volume slugs of IPC compositions with controlled alkalinity was carried out from 1985 to 1989 under different geological conditions in the pilot sites of oil fields of West Siberia: AV₁ formation of the Sovetskoye field, YuV₁ formation of the Vakhskoye field, AV₁₋₃, AV₂₋₃, and BV₁₀ formations of the Samotlorskoye field, BV₁₀ formation of the Lor-Yeganskoye field, Yu₁ formation of the Malo-Chernogorskoye field, and AS₄ formation of the Mamontovskoye field (Table 1), and in pilot sites of the V₃ formation of the Severo-Savinoborskoye field (Komi Republic). Altogether > 30 th t of IPC compositions was injected. The slug volume was 0.2%–0.4% of the oil-saturated pore volume of the pilot site formation.^{5, 18}

Analysis of the state of the art of development of the pilot sites resorting to the results of geophysical, hydrodynamic and physicochemical studies showed that IPC compositions improve the water flooding process: the water cut of producing wells decreases, remains constant or increases at a lower rate; the parameters of the bottomhole zone of injection wells and the reservoir (productivity, hydroconductivity, piezoconductivity and permeability) are improved; the dynamic liquid levels in producing wells increase; the residual oil saturation decreases; oil displacement parameters are improved; and the effective formation thickness either increases or remains the same. The injectivity of the injection wells increases, resulting in more intense development. The IPC compositions move

along the formation as a whole entity, being gradually diluted with the formation water. The migration of the composition front is accompanied by a decrease in the water cut of oil, to the utmost, by 30%–40% and a pH increase from 6–7 to 8–10. Some components of the IPC composition can be found in reliably determinable concentrations (0.001%–0.1%) in the producing well product for long periods of time, up to 2–3 years, the highest surfactant and ammonium nitrate concentrations being 0.2%–1.0%. The production of the components from different wells occurs in comparable amounts, which indicates that the formation has been swept throughout the whole pilot site. The diagrams of the space distribution of surfactant and the oil production according to wells are similar, *i.e.*, an increase in the surfactant production is accompanied by an increase in the specific oil production.^{5, 18}

The produced water is less corrosive in the presence of IPC compositions than the injected water. Thus the rate of corrosion of the test samples mounted in the oil-gathering systems in the pilot sites of the Lor-Yeganskoye field was 0.1 mm per year. The IPC compositions present in produced water in concentrations of 0.5% enhance oil dehydration processes.

The engineering and cost efficiency of using IPC compositions at the West Siberia oil fields was evaluated (see Table 1). The increase in the oil recovery was from 2.8% to 27.5% (on average, 8.2%). This technology provides from 9.8 to 68 t (on average, 26.2 t) of oil produced additionally per t of the composition or 183 t of oil per t of the surfactant. A computer model of the process was designed.⁵ The industrial production of the IPC compositions IHN-60 and IHN-100 was organised in Russia (at the CJSC KHIMEKO-GANG and CJSC Polyex plants).

The field tests revealed the stimulating effect of IPC compositions on the development of the reservoir microflora.^{91–93} The components of the ammonia buffer system are involved in the geochemical nitrogen cycle and serve as additional nitrogen nutrition for anaerobic and aerobic bacteria in trophic chains of the microbial biocenosis of the oil-bearing formation. Microbiological studies carried out in injection areas of IPC compositions IHN-60 and IHN-100 into the AV₁ formation of the Sovetskoye oil field, AV₁, AV₂₋₃ and BV₁₀ formations of the Samotlorskoye oil field, YuV₁ formation of the Vakhskoye and BV₁₀ formation of the Lor-Yeganskoye oil fields have shown that the amount of denitrifying and heterotrophic bacteria, including *Pseudomonas* and *Actinomyces*, is much higher than in reference sites. The count of sulfate-reducing bacteria in the produced water in the pilot sites was much lower than that in the injected water or in the produced water in the reference sites. The geochemical activity of the denitrifying bacteria is directed at the oxidation of organic compounds present in oil to give carbon dioxide, bio-surfactants and other substances enhancing the oil recovery.

Table 1. Oil production with the use of IPC compositions on the pilot sites of West Siberia oil fields.¹⁸

Oil field			Oil in place reserves/th t	Amount of the injected IPC composition/th t	Gain in ORF (%)	Additional oil production

IV. Surfactant compositions generating carbon dioxide and an alkaline buffer system in the reservoir

It was noted above that development of high-viscosity oil fields involves thermal treatment techniques. Steam is used most often as the heat carrier. Many researchers have attempted to find chemicals for the addition to steam to improve its action.^{28,30,94} Theoretically, the use of such additives may decrease the temperature of steam condensation, for example, by formation of an azeotropic mixture or water solubility in compressed gases, increase the reservoir permeability for a steam – gas mixture and so on. Carbon dioxide is the additive of choice. The grounds for the beneficial effect of CO₂ are well-known; they include the increase in the reservoir rock permeability for oil, the decrease in the oil viscosity, *i.e.*, a favourable change in the mobility ratio of oil and the aqueous phase, and so on.⁴⁸

For a number of years, the concept of high-viscosity oil formation stimulation by a surfactant-based compositions, which form CO₂ and an ammonia buffer system under the action of formation temperature, has been developed at the IPC SB RAS.^{5,95} Prior to steam injection, a slug of a composition representing an aqueous solution of a blend of non-ionic and anionic surfactants, carbamide and ammonium salts, are introduced into the well. In the oil-bearing formation, carbamide is hydrolysed under the action of high steam temperature to give carbon dioxide and ammonia. Unlike ammonia, carbon dioxide is soluble in oil much better than in water. The partition coefficient for carbon dioxide in the oil – water system in the temperature range of 35–100 °C and the pressure range of 10–40 MPa is between 4 and 10, whereas this value for ammonia does not exceed 6×10^{-4} . Therefore, in the oil – water system, the oil phase is enriched in carbon dioxide and the aqueous phase is enriched in ammonia, which forms, together with the ammonium salt, an alkaline system with the maximum buffer capacity at pH 9.0–10.5, as in IPC compositions. This gives rise to several useful effects. The dissolution of carbon dioxide in oil decreases oil viscosity. In the vapour phase, carbon dioxide and ammonia help to maintain vapor – gas mixture at a temperature below the vapour condensation point; therefore, the efficiency of transfer of oil components by the distillation mechanism increases. Carbon dioxide and ammonia reduce swelling of clay minerals of the reservoir rock and thus help maintaining the initial reservoir permeability. The same role is played by the ammonia buffer system, which is formed upon dissolution of ammonia in an aqueous solution of ammonium salts. In addition, owing to its alkalinity (pH 9–10) and the presence of surfactants, it promotes intensification of the counter-current impregnation of the formation and oil displacement.

1. Kinetics of carbamide hydrolysis in water and surfactant-based compositions

The physicochemical mechanism of action of oil-displacing compositions comprising surfactants and alkaline buffer solutions producing CO₂ *in situ* is based on the kinetics of carbamide (urea) hydrolysis in water and compositions at 80–250 °C.

Carbamide dissolved in water is rather stable up to 80 °C. Above this temperature, it is hydrolysed to give ammonia and carbon dioxide according to the overall reaction

Detailed information about the physicochemical properties of components, phase equilibria and reaction kinetics in the carbamide – water – ammonia – carbon dioxide system have been reported;^{96,97} the kinetics of carbamide hydrolysis has

been described.⁹⁶ The hydrolysis takes place in two steps. The first step is isomerisation of carbamide to ammonium isocyanate

The second step is hydrolysis of ammonium isocyanate to give ammonium carbonate

A kinetic study of carbamide hydrolysis in water and in compositions has shown that the reaction follows the first order kinetics with respect to carbamide in the carbamide concentration range from 0.5% to 20% at 80–100 °C. The average temperature coefficient was 2.4, *i.e.*, the Van't Hoff rule was fulfilled.

For the temperature range of 100–250 °C, the following kinetic parameters were found: the activation energy and the pre-exponential factor for the Arrhenius equation for carbamide hydrolysis in water are 44.6 kJ mol⁻¹ and $4.01 \times 10^4 \text{ h}^{-1}$; for hydrolysis in compositions, $50.8 \pm 1.5 \text{ kJ mol}^{-1}$ and $10.9 \times 10^4 \text{ h}^{-1}$, respectively.⁹⁸ The increase in the activation energy in the latter case is due to the effect of the ammonium salt.

The activation energy for carbamide hydrolysis in the temperature range of 80–100 °C is twice as high as that in the 100–250 °C range. In the 80–250 °C range, the rate-limiting step of the reaction changes, as indicated by a change in the slope of the temperature dependence of the reaction rate constant (Fig. 3). At 80–100 °C, the rate-limiting step is carbamide isomerisation (2), which has a higher activation energy than reaction (3). At 150–250 °C, the rate of carbamide decomposition increases and the solution pH reaches 9–10.5 where reaction (3) becomes the rate-limiting step.

Figure 3. Temperature dependence of the rate constant for hydrolysis of carbamide in a surfactant-based composition at 80–250 °C.⁹⁵ Temperature range /°C: (1) 100–250, (2) 80–100.

As a result of carbamide hydrolysis at 80–250 °C, solutions of carbamide and oil-displacing compositions acquire high buffer capacity with a maximum at pH 9.0–10.5 (Fig. 4).⁹⁸ In water, the rate of carbamide hydrolysis is higher and the time it takes to attain the maximum pH is shorter than in solutions containing ammonium salt; however, the highest buffer capacity is observed only in the presence of the ammonium salt. Indeed, at 100 °C, the highest buffer capacity of the composition is 14.4 g-equiv. litre⁻¹ (pH unit)⁻¹, while that of a carbamide solution is 5.3 g-equiv. litre⁻¹ (pH unit)⁻¹. At 250 °C, the buffer capacities of the composition and carbamide solutions are 22.3 and 7.22 g-equiv. litre⁻¹ (pH unit)⁻¹, respectively. The buffer capacity of compositions is 2–4

Figure 4. Buffer capacity of the surfactant-based composition vs. pH.⁹⁸ (1) Before heating; (2, 3) after heating at 150 °C for 7 and 10 h, respectively.

times higher than that of carbamide solutions in water under the same conditions. Due to the high buffer capacity, 10–100-fold dilution of the hydrolysed composition with water results in only a slight change in pH (0.2–0.5 pH units).

2. Rheological and filtration properties of high-viscosity oil systems with various surfactant compositions generating carbon dioxide and an alkaline buffer system in the oil formation

The alternating thermal steam treatment and physicochemical treatment with surfactant compositions of a high-viscosity oil formation is based on the changes in the rheological properties and a decrease in the viscosity of oil.^{28–30, 48} The features of such alternating treatment were revealed by rheokinetic studies of high-viscosity oils of the Usinskoye and Yaregskoye oil fields in Russia and the Liaohe and Fluarti oil fields in China. The effects of time and temperature of oil autoclaving with compositions on the temperature dependence of oil viscosity during the consecutive heating and cooling were investigated by vibrational and rotational viscometry^{44, 45} in the temperature range of 150–250 °C. For oil:composition ratios varying from 4:1 to 1:1, heating at 150–250 °C for 4–24 h results in a 3–6-fold decrease in oil viscosity in the temperature range of 20–50 °C (Fig. 5). Moreover, the higher the autoclaving temperature the lower the oil viscosity and the broader the composition concentration range in which the viscosity drop takes place. For autoclaving temperature of >200 °C, the viscosity almost does not decrease. The most pronounced decrease in the viscosity of the oils from the Usinskoye and

Figure 5. Temperature dependences of the oil viscosity of the Usinskoye field after maintenance at 200 °C for 6 h with the IHN-KA (1) and NINKA (2) compositions and water (3).⁹⁸

Figure 6. Viscosities of the oil from Usinskoye (1) and Yaregskoye (2) oil fields at 20 °C after maintenance at 150 °C vs. oil to surfactant composition ratio.⁹⁸

Yaregskoye fields occurs at the oil to composition ratio of 2:1 and 4:1, respectively (Fig. 6). As the fraction of the composition heated with oil increases further, the oil viscosity increases due to the formation of high-viscosity emulsions, which was confirmed by ¹H NMR.⁹⁵ These regularities hold most clearly for small shearing stresses corresponding to the filtration conditions of the formation fluids in the reservoir rock and are retained under thermobaric conditions similar to those in the formation, which was confirmed by studies of these systems with a high-pressure viscometer.⁹⁵

Laboratory studies on a high-pressure filtration setup have shown that alternation of steam and composition slugs allows one to enhance oil displacement efficiency compared to thermal steam treatment. The major contribution to the gain in oil displacement efficiency comes from the injection of the first composition slug. A computer model for such process was designed.⁹⁹

3. Pilot-plant testing of the technology using the NINKA compositions

The pilot tests of the technology using surfactant compositions generating *in situ* CO₂ and alkaline buffer system (the NINKA compositions) were carried out in the Permo-Carboniferous high-viscosity oil formation region of the Usinskoye field occurring at a late stage of development. The process was designed to increase the efficiency of thermal steam treatment.^{100, 101} In 2002, injection of 264 m³ of the NINKA composition into three steam injection wells was carried out. The use of this process in long-term steam injection decreases the water cut of the product by 10%–20% and increases the oil production rate by 40% on average with increasing the liquid production rate by 5%–10% on average. The total additional oil production from October 2002 to February 2004 in three pilot sites was 44.3 th t (Table 2) or 14.7 th t of additional oil production per treated well. The process was recommended for use in high-viscosity oil deposits developed using thermal steam treatment.

A promising way is the integrated use of gel-forming and oil-displacing compositions in the high-viscosity oil pool development by means of thermal steam treatment. As a result, it is possible to increase both the sweep efficiency and the oil displacement efficiency with simultaneous intensification of the development.

In 2003, pilot tests of the process involving alternating physicochemical treatment and cyclic steam treatment of the high-viscosity oil pool of the Liaohe field (China) using the NINKA composition were successfully carried out.¹⁰⁰ Thirty and forty tons of the composition and 2.5 th t of steam were injected into each of two wells as several slugs. This provided a

Table 2. Additional oil production from October 2002 to February 2004 for injection of the NINKA composition in the pilot sites of the Usinskoye field.¹⁰⁰

Number of the injection well	Target	Additional oil production /th t	Gain in the month average oil production rate for producing wells (%)

Total		44.3	on average, by 40%

1.8–2.3-fold increase in oil production with respect to steam injection alone, the oil production time increased by 3–5 months; oil viscosity decreased three-fold and the oil pour point decreased from (6–10) to –(4–16) °C. For example, oil production from well 3-2 was 874 t between October 2003 and March 2005, while in the previous cycle with steam injection alone, this was 375 t (Fig. 7). In 2005, the works on using the NINKA composition were continued; injection into five cyclic steam wells was carried out, and monitoring of their operation was completed in 2006. Note that in 2005, repeated injection of the NINKA composition into well 3-2 was carried out (see Fig. 7). Oil production in this cycle was nearly the same as in previous cycle. The alternating injection of steam and the composition is more efficient than steam injection alone.

**Figure 7.** Dynamics of the accumulated oil production from well 3-2 of the Huanxiling region of the Liaohe field (China) in the steam injection cycle in 2001 (1) and the subsequent steam injection cycles with the NINKA composition in 2003 and 2005 (2, 3).¹⁰¹

The pilot tests of using the NINKA composition with thermal steam and cyclic steam treatment of high-viscosity oil pools of Russian and Chinese fields demonstrated the engineering efficiency and environmental safety of the composition.

In China, industrial manufacture of the solid commercial form of the NINKA-1 oil-displacing composition was organized.

V. Thermotropic gel-forming systems for increasing sweep efficiency in water flooding and thermal steam treatment

The increase in the formation sweep efficiency in water flooding is especially topical for oil pools consisting of formations not connected hydrodynamically. In this case, the mechanism of alignment of the displacement front due to capillary and

hydrodynamic cross-flows is not effective. The producing wells are water-flooded even at an early stage of development; it is desirable that the EOR methods that increase the sweep efficiency be used prior to the methods that increase the oil displacement efficiency.

A promising way of solving the problem is gel generation *in situ*. A number of methods for gel generation differing in the type of gel-formation reaction are known. The most widely used reactions are hydrolytic polycondensation ending in the formation of inorganic gels (for example, metal hydroxide and silicic acid gels),^{4,8} the formation of three-dimensional polymeric structures through cross-linking of the macromolecules of natural and synthetic polymers in solutions (polyacrylamide cross-linked by chromium salts, *etc.*),^{8,9,12,13} and solution–gel phase transitions in systems involving polymers with either upper or lower critical solution temperature and water (ethers, cellulose, polyvinyl alcohol, *etc.*).^{102,103}

In the IPC SB RAS, new methods were developed for enhancing oil recovery using thermotropic inorganic and polymeric gel-forming systems that generate gels *in situ* and are designed for increasing sweep efficiency of water flooding or thermal steam treatment.^{95,102–106}

Each oil deposit has its geological and physical characteristics. The composition of oil and the reservoir rock, the oil viscosity, water salinity and the formation temperature and pressure vary over broad ranges. Thus the formation temperature is 8–12 °C in Yakutia oil fields, 20–40 °C in Tatarstan fields, 50–100 °C in West Siberia and 110–170 °C in the South China sea offshore deposits in Vietnam. Water salinity can vary from 0 to 300–400 g litre^{–1}. Therefore, gel-forming systems with controllable properties should be used for enhancing oil recovery.

A study of the physicochemistry and hydrodynamics of the *in situ* gel generation has shown that gel-forming systems are low-viscosity aqueous solutions under surface conditions, while under reservoir conditions, they are converted into gels. Gelation is induced by the thermal energy of the formation or an injected heat carrier, or by the interaction of the injected system with the formation fluids and reservoir rock. The gel formation kinetics and the rheological and filtration characteristics of various types of gels for heterogeneous formations with permeability ranging from 0.01 to 10 μm² were studied. Gel-forming systems with different gel-generation times (ranging from several minutes to several days) in the temperature range of 30–320 °C were proposed. Using these systems, five gel processes for enhancing oil recovery of highly heterogeneous formations were developed at the IPC SB RAS; these processes are used at oil fields of West Siberia and the Komi Republic.^{95,102–107} The environmental safety of reagents accounts for the extensive use of gel processes at oil fields in Russia and abroad.

1. Thermally reversible polymeric gels

A new method for enhancing oil recovery from highly heterogeneous formations based on control of filtration flows and increase in the sweep efficiency by thermally reversible polymeric gels during water flooding has been developed. The gels are formed from polymer solutions with a lower critical solution temperature (LCST).^{103,108,109} The gelation is induced by the thermal energy of the formation or injected heat carrier. Solutions of LCST polymers can form gel *in situ*: at low temperatures, the solutions have low viscosity, while at high temperatures they are converted into gels. The process is reversible: on cooling, the gel is liquefied and becomes again a low-viscosity solution and on repeated heating, the gel is restored. The gelation temperature in the range from 30 to 120 °C and the gelation time can be controlled by inorganic and organic additives, thus adjusting the systems to particular formation conditions, *viz.*, temperature and water salinity. The

gels can be used as effective means for controlling the water influx, preventing gas breakthrough, elimination of gas cones, etc.

At temperatures below LCST, an aqueous solution of the polymer represents a homogeneous system, which splits into two phases above LCST:^{103–109} one phase is a highly dilute and the other phase is a concentrated polymer solution. Due to high viscosity of the latter, decomposition is hindered and non-equilibrium. This gives rise to a microheterogeneous kinetically stable structure, *viz.*, a thermally reversible polymeric gel. In the concentrated phase, a three-dimensional framework is formed, the dilute polymer phase being situated in its cells.

The ability of LCST polymer–water systems to form gels with an increase in temperature allows one to use them in EOR processes aimed at increasing the formation sweep efficiency in water flooding by selective isolation of the swept highly permeable areas of the formation. Cellulose ethers (CE) are the LCST polymers of choice.

The gelation kinetics and rheological characteristics in the CE–aqueous phase system have been studied^{102, 106} in order to establish the possibility of using CE gels under various geological deposit conditions. A typical example of LCST CE is methylcellulose (MC). The properties and structure of MC solutions and gels have been considered in the literature.^{110–114} The temperature dependence of the viscosity of MC solutions passes through a minimum: on heating, the viscosity first gradually decreases from 40–70 to 5–20 MPa s, *i.e.*, 2–14-fold and, after the gelation point has been reached, sharply increases to 100–2000 MPa s (20–100-fold), which is due to a phase transition (Fig. 8). The process is reversible: on cooling, the gel is converted again into a liquid. The temperature where the viscosity is minimum corresponds to the LCST. In cycling (alternation of heating and cooling processes), the rheological parameters of the gel are reproduced.

Figure 8. Viscosities of the aqueous solutions of methylcellulose (1 mass %) vs. temperature at different formation water salinity.⁹⁵ Salinity / g litre⁻¹: (1) 60, (2) 30, (3) 15, (4) 7.5, (5) 0.

The effect of electrolytes and non-electrolytes that change the hydrophobic interactions in the system on phase equilibria and gelation kinetics in MC solutions has been studied experimentally (Fig. 9 and 10). The change in the gelation point of CE solutions is affected most appreciably by anions, the effect being correlated with positions of the anions in the lyotropic series.⁹⁵ The greatest decrease in the LCST is induced by chlorides. The opposite effect, *i.e.*, an increase in the LCST, is exerted by salts with the CNS⁻ anion, and the effect of salts with NO₃⁻ is intermediate: the LCST somewhat increases on a decrease in the gelation point depending on the cation nature. The effect of cations is much less pronounced. For salts with

Figure 9. Effect of the electrolyte nature on the gelation temperature of solutions with a methylcellulose concentration of 1 mass %.⁹⁵ (1) NH₄CNS, (2) NaCNS, (3) KCNS, (4) NH₄NO₃, (5) ZnCl₂, (6) NaNO₃, (7) KNO₃, (8) LiCl, (9) MgCl₂, (10) CaCl₂, (11) KCl, (12) NaCl, (13) AlCl₃.

Figure 10. Effect of the electrolyte nature on the gelation temperature of methylcellulose solutions (1 mass %).⁹⁵ (1) Thiourea, (2) isopropyl alcohol, (3) ethyl alcohol, (4) carbamide, (5) triethanolamine, (6) ethylene glycol, (7) polyglycol, (8) glycerol.

Cl⁻ or CNS⁻ anions, cations play a noticeable role but are unable to change the pattern of anion effect. The most pronounced decrease in the gelation point is induced by 1:1 electrolytes, while the action of 2:1 or 3:1 electrolytes is weaker and almost equivalent. An exception is provided by zinc chloride [a ZnCl₂ concentration above 0.4 mol per kg of water changes the character of effect on the gelation point, which increases (see Fig. 9)] and aluminium chloride (when present in a concentration of >0.8 mol per kg of water). At these concentration, solutions of these chlorides are coordinating solvents. Thiourea, ethyl alcohol and isopropyl alcohol also substantially increase the LCST. The action of electrolyte and non-electrolyte agents is additive.

In view of geological parameters of oil fields, in particular, the formation temperature, salinity of the formation and injected water, it is possible to select gel-forming compositions

optimal for particular conditions to control the filtration flows and increase the sweep efficiency during water flooding.

The rheological measurements carried out using a Haake RheoStress 600 rotational viscometer at temperatures from 20 to 150 °C and pressures of up to 50 atm have shown that joint addition of carbamide and ammonium thiocyanate into CE solutions may give solutions with gelation points of > 100 °C (Fig. 11).¹⁰⁰ The gels retain their rheological characteristics at high temperatures, up to 150–220 °C. In the range of shear rates of $0.5\text{--}5\text{ s}^{-1}$, the gel is a solid-like body exhibiting (judging by the rheological curves) viscoelastic properties. Therefore, gel-forming compositions can be used to control the steam injection profile in cyclic steam wells.

Figure 11. Change in the gelation point of an MC solution upon the addition of ammonium thiocyanate and carbamide (viscosity measurement at a shear rate of 3 s^{-1}).¹⁰⁰

Solution: (1) 1 mass % MC; (2) 1 mass % MC + 5 mass % NH_4CNS ; (3) 1 mass % MC + 20 mass % carbamide; (4) 1 mass % MC + 5 mass % NH_4CNS + 20 mass % carbamide.

The LCST polymer–water systems typically exhibit a temperature hysteresis for the solution–gel phase transition. The hysteresis in the MC–aqueous phase system was studied by determining the gelation point during heating and the liquefaction point during cooling.¹⁰⁰ The effect of additives increasing the gelation point (ethanol, ammonium thiocyanate, thiourea and carbamide) on the hysteresis was studied. The gelation points in these systems were found to almost coincide with the LCST values of polymers found by vibrational viscometry.⁹⁵ The liquefaction point was $30\text{--}50^\circ$ below the gelation point (Fig. 12). The gelation and liquefaction points increase almost linearly with the reagent concentrations, these dependences being parallel for all reagents studied except for carbamide.

The reversibility of the solution–gel phase transition was established experimentally in a study of water filtration through a heterogeneous reservoir model under simulated formation conditions. The studies were carried out in a setup for filtration measurements at a constant water flow rate through the model, which consisted of two parallel columns with different permeabilities to simulate a heterogeneous reservoir. Reservoir rock cores from oil field, various crude oils and formation waters were used in the experiments. After injection of the gel-forming solution into the reservoir model and heating to 60°C , redistribution of the filtration flows took place and was retained on temperature increase up to 220°C . As the temperature was decreased from 220 to 20°C and during the subsequent water filtration, the initial flow distribution was restored.

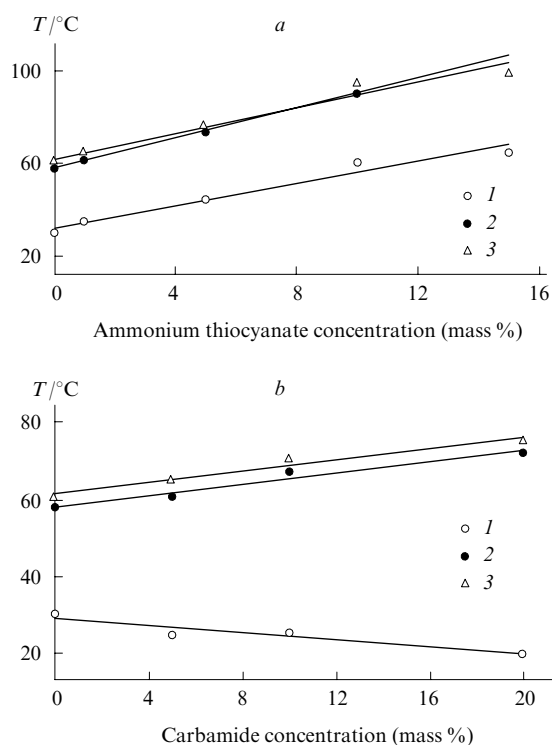

Figure 12. Effect of ammonium thiocyanate (a) and carbamide (b) on gel formation and liquefaction temperatures in solutions with MC concentration of 1 mass %.

$T/^\circ\text{C}$: (1) liquefaction, (2) LCST, (3) gelation.

The gel formation in the reservoir rock results in a selective decrease in the phase permeability of the rock with respect to water (Fig. 13): the pressure gradient for water filtration through the gel is 2–3 times higher than that for oil filtration.¹⁰⁰

The filtration characteristics and the oil-displacing properties of gel-forming compositions based on MC were studied experimentally as applied to heterogeneous reservoirs of West Siberia oil fields.^{115, 116} It was found that injection of a slug of the gel-forming solution into a heterogeneous reservoir model results in redistribution of the filtration flows where the liquid mobility in the highly permeable part sharply decreases, while

Figure 13. Selective increase in the phase permeability for water after the formation of the MC gel in the reservoir rock with a permeability of $11\text{ }\mu\text{m}^2$.

(1) Water injection, (2) oil injection, (3) repeated water injection. The volume of the injected water is determined by the number of pore volumes.

that in the low-permeability part most often remains the same. The redistribution of filtration flows is accompanied by after-sweeping of the residual oil, which is especially pronounced in the case of low-permeability model. Gel-forming compositions have shown high efficiency in increasing the sweep efficiency on heterogeneous reservoir models with interlayer permeability differing by factors of 3–20. Therefore, these compositions were recommended for the control of filtration flows of formation fluids and water shutoff in highly heterogeneous reservoirs. Ammonium thiocyanate and carbamide present in gel-forming compositions are simultaneously trace indicators.

At a temperature of 200 °C under simulated formation conditions, the filtration characteristics and oil displacement efficiency upon physicochemical action of a gel-forming composition on the high-viscosity oil pool were studied. The use of gel-forming composition ensured equalisation of filtration flows due to a decrease in the liquid phase mobility in high-permeability interlayers, which is accompanied by oil after-sweeping from both low- and high-permeability zones of the reservoir model. For example, after injection of the composition into the heterogeneous reservoir model with permeabilities of the columns differing by a factor of 5.4 (0.397 and 2.123 μm^2), redistribution of the filtration flows took place and the ratio of liquid mobilities in the reservoir model changed from 1:4.3 to 50:1. When water was pumped in the opposite direction (simulation of the operation conditions of a cyclic steam well), the filtration pattern was retained. The oil displacement efficiency increased by 12%–13% compared to that observed with steam injection.¹¹⁵

The investigations resulted in the selection of the optimal gel-forming blends for enhancing oil recovery by water influx control during water flooding or thermal treatment of the formation. In particular, gel-forming METKA compositions were developed. A low-viscosity aqueous solution capable of forming gels under formation conditions is injected into the formation at 30–120 °C. A gel screen is formed in the high-permeability formation part into which the main bulk of the composition gets; this results in redistribution of filtration flows. Upon pumping of the METKA composition into injection wells, their input profiles are equalised, water production decreases and the oil production rates of the producing

wells that are hydrodynamically connected to injection wells increase. The METKA compositions are easy to handle; the best water solubility of the polymer is attained in the temperature range of 0–10 °C. The processes are cost effective and environmentally safe and are implemented by means of standard oil field equipment.

Successive large-scale pilot tests of EOR processes based on the use of thermally reversible gels in the West Siberia oil fields were carried out from 1996 to 1997. In 1996, the METKA composition was injected into 11 wells and in 1997, into 47 injection wells (50–100 m^3 per well). In 2–3 months after injection, the producing wells hydrodynamically connected to injection wells showed lower water production and higher oil production rates. This process has been used on an industrial scale at the West Siberia oil fields since 1998 (Lukoil company). An industrial mobile unit for the preparation and injection of the composition was designed (designer the OJSC OTO). Between 1998 and 2003, the METKA composition was injected into 382 wells. The additional oil production amounted to 480 th t ; the payback period was 5–9 months; the process efficiency was on average 1300 t of additionally produced oil per treated well. All reagents are large-scale commercial chemicals.

On combined treatment of both hydrodynamically connected injection wells and producing wells, the process efficiency increases. In 2001, pilot testing of the water shutoff process by simultaneous treatment of the bottomhole zones of the injection and producing wells with gel-forming compositions was carried out in two pilot sites of the AB_1 formation of the Urievskoye oil field.^{107, 117} The injected volume of the composition per well was from 50 to 200 m^3 ; altogether 620 m^3 were injected. This resulted in redistribution of the filtration flows and decrease in water influx, which was manifested in lower water production and higher oil production rates of the producing wells (Fig. 14). The additional oil production was 6542 t over 7 months.

Thermally reversible polymer gels are used in a number of technologies.

A technology for elimination of the behind-the-casing water flow was tested in gas wells of the Myldzhinskoye gas condensate field.¹¹⁸ For example, well No. 133 produced gas

Figure 14. Increase in the oil production (1) and decrease in the water cut (2) for the producing well 1438 after pumping of the gel-forming composition into injection well 1810 (3) and producing well 1438 (4) in the Urievskoye field, formation AV_1 .¹¹⁷

containing formation water; at a gas production rate of 300 th m³ per day, water content was 30 t, which is much higher than the allowable value. After injection of the METKA gel-forming composition together with the installation of a cement bridging, the gas production rate was 430 th m³ per day with only traces of water; the well has operated at such production rate for three years.

In 2002–2003, the Institute of Petroleum Chemistry of the Siberian Branch of the RAS, together with the Institute of Mining of the Siberian Branch of the RAS carried out successful pilot testing of integrated vibroseismic and physicochemical treatment of the BV₈ formation of the Pokachevskoye oil field using the METKA composition.¹⁰⁷

In 2005–2006, processes of increasing the efficiency of cyclic steam treatment of a high-viscosity oil pool using the METKA composition for water shutoff were successfully tested at two wells of the Liaohe deposit (China).¹⁰⁰ After injection of the gel-forming composition, the oil water cut in producing wells decreased and oil production rate increased.

2. Methods for enhancing oil recovery using inorganic gel-forming systems

The ability of the aluminium salt–carbamide–water–surfactant system to generate inorganic gel and CO₂ *in situ* at temperatures 40–320 °C underlies the technology where inorganic gel-forming compositions are used to increase the sweep efficiency of water or steam injection.^{105, 107, 119–121}

The free or bound disperse systems (sols and gels) may be generated in the oil formation by the condensation mechanism, in particular, based on the ‘arising reactants’ (homogeneous precipitation) principle known in analytical chemistry.⁵ Within the framework of this principle, a new physicochemical method for enhancing oil recovery was proposed. A homogeneous aqueous solution containing a gel-forming system is injected into the oil formation. Due to the thermal energy of the formation or an injected heat carrier, one component of the system is gradually hydrolysed, the hydrolysis products inducing a shift of the protolytic equilibrium of another component. This triggers hydrolytic polycondensation of monomer units, and, after a definite period of time, a gel is formed almost instantaneously throughout the whole solution volume. The ‘arising reactants’ principle was implemented in the development of the reported physicochemical EOR method.^{122, 123}

Liquid aluminium salt–carbamide–water–surfactant gel-forming systems are low-viscosity solutions with pH 2.5–3.5. They are able to dissolve carbonate minerals in the reservoir rock and decrease (suppress) clay swelling. The solutions can be prepared using water with any salinity. They are injected into the oil-bearing formation through injection wells using standard equipment.

Carbamide is hydrolysed in the formation to give ammonia and carbon dioxide, which leads to gradual increase in the solution pH. When pH becomes 3.8–4.2, hydrolysis of aluminium ions takes place, and, as a consequence, after some period of time, aluminium hydroxide gel is formed almost instantaneously throughout the whole solution bulk (Figs 15, 16). The time required for gelation depends on the formation temperature and the component ratio in the gel-forming system. After gel generation, the reservoir rock permeability for water decreases 4–35-fold. The greater the initial water saturation and permeability of the reservoir rock the higher the degree of permeability decrease. The static shear stress of the gel is within 3–40 Pa. In the presence of surfactants, wetting of the oil reservoir rock by the gel-forming solution is enhanced and the penetrating and oil-displacing ability of the solution increases. In addition, the surfactant exerts a plasticising action on the aluminium hydroxide gel and can form a foam with carbon dioxide and ammonia evolved upon carbamide hydrolysis.⁵

Figure 15. Change in the pH (1) and shear stress (2) in the aluminium salt–carbamide–water system upon gel formation during maintenance at 97 °C.¹⁰⁷

Figure 16. Viscosity (1–5) and pH (6) change in the aluminium salt–carbamide–water system upon gel formation during maintenance at 150 °C (1, 2), 200 °C (3, 4) and 250 °C (5, 6).¹⁰⁶

The rheological properties of the gel correspond to the properties of a thixotropic pseudoplastic body with the coagulation structure. A distinctive feature of the gel is the permeability for the aqueous phase at shear stresses lower than the static shear stress of the gel itself. Gelation results in redistribution of filtration flows, equalisation of input profiles of injection wells, and a decrease in water cut of the oil from producing wells. Gel-forming systems are designed for the development of oil pools with high formation temperature and heterogeneity, which is typical of West Siberia oil fields and high-viscosity oil pools developed by thermal methods.

In the temperature range of 70–100 °C, the gelation kinetics is determined by the hydrolysis of carbamide, which is much slower than the formation of aluminium hydroxide gel by the coagulation mechanism representing is a cooperative process. The pre-exponential factor ($1.1 \times 10^{12} \text{ s}^{-1}$) in the Arrhenius equation and the activation energy (115 kJ mol^{-1}) for carbamide hydrolysis in the gel-forming solution were estimated. The results are consistent with published values.⁹⁶ However, the activation energy found is lower than the activation energy for carbamide hydrolysis in the absence of aluminium salt (134 kJ mol^{-1}), which is indicative of catalysis by the acid resulting from hydrolysis of the aluminium salt. The effect of temperature on the gelation time (t_g) obeys the Van't

Hoff rule: upon temperature increase by each 10°, the gelation time increases 3.5-fold.

In the temperature range of 100–250 °C the Arrhenius dependence for the solution–gel transition is described analytically by the following regression:

$$\log \frac{1}{t_g} = 0.8322 - 3999.9 \frac{1}{T}.$$

The activation energy and the pre-exponential factor in the Arrhenius equation for the solution–gel transition are equal to 33.3 kJ mol^{−1} and 2.3 s^{−1}, respectively, which is much lower than for the temperature below 100 °C. In addition, in the 100–250 °C range, the effect of temperature on the gelation time does not obey the Van't Hoff rule: an increase in temperature by each 10° results in a 1.2-fold increase in the gelation time. These results provide the conclusion that in the temperature range of 100–250 °C the gelation kinetics in the aluminium salt–carbamide–water system is determined by the coagulation type formation of the aluminium hydroxide gel. The S-shape of the curves shown in Fig. 16 and the low activation energy attest to a cooperative mechanism of the coagulation process similar to the mechanism of phase transition or branching chain reaction.

At 70–100 °C, the gelation time depends on the concentrations and the concentration ratio of aluminium chloride and carbamide in solution; at a temperature above 150 °C this dependence is smoothened down. The lower the carbamide concentration the longer the gel formation. By varying the ratio of the aluminium salt and carbamide, one can control the gelation time, thus adjusting it to a particular formation temperature.^{119, 120}

In the range of 100–250 °C, the gel viscosity depends most appreciably on the aluminium chloride concentration. The effect of the component ratio and temperature is insignificant. The viscosity of solutions with aluminium chloride concentration of 4.0 mass % and 8.0 mass % increases during gel formation by the coagulation mechanism from 1.2–1.6 to 300–3500 MPa s and from 1.8–2.5 to 1800–7500 MPa s, respectively.

On the basis of the results of studies on the gelation kinetics and the rheological characteristics of the aluminium salt–carbamide–water–surfactant systems, gel-forming GALKa compositions and GALKa–surfactant systems were designed. During the period from 1989 to 1995, pilot testing of the EOR technology using inorganic gel-forming GALKa compositions was successfully carried out at West Siberia oil fields; since 1996, this method has been industrially used. This results in redistribution of filtration flows, an increase in the sweep efficiency of water flooding, and, hence, an increase in the ultimate oil recovery by 5%–8%. The additional oil production was 400 to 3000 t per treated well. The pilot testing of gel-processes was successfully carried out at the White Tiger oil field (Vietnam).

In 1996, the IPC SB RAS organised, in cooperation with the OJSC Nefteotdacha, the manufacture of the GALKa composition as a liquid commercial product using aluminium-containing industrial wastes. In 2000, the IPC SB RAS organised, in cooperation with the OJSC AURAT, the manufacture of solid commercial products including the GALKa composition, *viz.*, GALKa–thermogel-S for formation temperatures of 70–320 °C, GALKa–thermogel-U for temperatures of 40–70 °C, GALKa–thermogel-NT for temperatures of 20–40 °C. The advantages of the GALKa–thermogel systems include: controlled gelation temperature, homogeneity and low viscosity of aqueous solutions, low pour points of solutions, and availability of a solid commercial product. This allows them to be used over a broad temperature range (from 20 to 320 °C); they are applicable to low-permeability reservoirs; the composition can be injected into a well by batching directly into the water pipe without preliminary dissolution (this process can be used in the winter season).

The inorganic gels GALKa withstand the temperatures of 300–320 °C; hence, they can be used to increase the sweep efficiency in the thermal steam treatment for the development of high-viscosity oil pools.¹⁰⁷ In 2002, pilot testing of the process using the composition as the commercial solid product was carried out on the thermal steam treatment site PTV-3 of the Permo-Carboniferous pool of the Usinskoye field; 600 m³ of the GALKa–thermogel-S composition were injected into four steam injection wells. The composition showed good field

Figure 17. Monthly oil production (1) and water cut (2) dynamics for 29 wells of the pilot site after injection of the GALKa–thermogel-S composition (3) in the Usinskoye field (observation period from June 2002 to February 2004).¹⁰⁷

Figure 18. Results of the use of the integrated EOR technology including injection of the gel-forming GALKa composition and an oil-displacing composition IHN-100 on the pilot site of the YuV₁ formation of the Las-Yeganskoye field (injection well 9066, producing well 152p).¹⁰⁷ (1) Oil production rate, (2) water cut (%), (3) liquid production rate, (4) injection of compositions.

handling properties and environmental safety. The 29 producing wells of the pilot site produced additionally 33 th t of oil from October 2002 to February 2004. The engineering efficiency amounts to 275 t of additional oil production per t of the solid commercial GALKa – thermogel-S composition. The water production of the producing wells decreased by 3%–45% and the oil production rate increased by 23% on average (Fig. 17); the decrease of the monthly liquid production rate was 19.8% on average.

3. Integrated EOR process using gel-forming and oil-displacing compositions

For enhancing the oil recovery of fields with highly heterogeneous reservoirs at a later stage of development, the isolation of high-permeability watered formations by their blocking should be followed by intensification of liquid filtration in low-permeability formations. This requires an integrated technology: first, a gel-forming composition is used to increase the sweep efficiency of water flooding and then an oil-displacing composition is employed to intensify the development of a low-permeability formation. This combined action on the oil pool allows one to efficiently redistribute the filtration flows of formation fluids and to develop the formations not swept previously by water flooding; this method is efficient for enhancing the oil recovery of low-permeability highly heterogeneous oil pools at both early and late stages of field development.

For the development of oil reserves difficult to recover of the Jurassic deposits of West Siberia, an integrated process was proposed wherein GALKa – thermogel was used as the gel-forming composition and IHN-100 was used as the oil-displacing composition. Unlike the known compositions, these gel-forming and oil-displacing compositions possess complementary physicochemical properties, resulting in synergistic action.

In 2001, pilot testing of the integrated process was carried out in the Las-Yeganskoye field (YuV₁ formation). The GALKa – thermogel-U composition (6, 10 and 18 t) and IHN-100 composition (30, 50 and 48 t) were pumped into injection wells. Analysis of the field data showed that the combined action of these compositions resulted in redistribution of the filtration flows in the formation, involvement of low-permeability interlayers and intensification of their development, which is manifested in lower water cut of the products

and higher oil and liquid production rates from the producing wells hydrodynamically connected to the injection wells (Fig. 18). The additional oil production over the site from January 2001 to October 2002 was 4.4 th t.¹⁰⁷ The process was recommended for industrial use in West Siberia fields.

Currently, development of other integrated methods is in progress, for example, the pulse explosive stimulation of the formation combined with using oil-displacing and gel-forming compositions, physicochemical and microbiological EOR methods.

The development of the physicochemical methods for enhancing oil recovery and increase in the extent of their application may provide, even in the near future, a significant gain in the recoverable reserves and current oil production both on operating and newly explored oil fields in Russia.

Abstract. Theoretical views on the mechanisms of overcoming spin prohibitions in photoprocesses and in enzymatic activation of the O_2 molecule are considered. The electronic structures of various quantum states of this molecule and collision complexes of oxygen with other molecules are given. The patterns of biochemical activation of O_2 through T–S transitions in enzymatic complexes are proposed. It is noted that the enhancement mechanisms for specific exchange interactions in enzymatic complexes have common features with mechanisms of physical photoactivation of oxygen. The bibliography includes 164 references.

I. Introduction

Specific physicochemical properties of the diatomic oxygen molecule are due to incompleteness of the outer π_g -electron shell.^{1–9} Oxygen is paramagnetic⁴ and can both quench and sensitise luminescence of organic compounds,^{1,2} acts as a catalyst of some chemical transformations⁶ and as an oxidant in many processes, in particular, breath, combustion and putrefaction, which occur at different rates and by different mechanisms.^{5–7} Molecular oxygen is basic to life on Earth.⁶ Indeed, it protects living organisms from hard solar radiation, absorbs the most part of UV radiation in upper atmosphere, generates the ozone layer that absorbs softer UV radiation in the stratosphere and, finally, provides the aerobic life with the energy of breath. However, since Lavoisier, who discovered the ability of the oxygen molecule to maintain breath and combustion, there is no clear understanding of the mechanisms of enzymatic activation of O_2 , their relation to the electronic structure and spin of the molecule, to the fine structure of spin multiplet states of oxygen and to other physical (optical and magnetic) properties of this molecule.^{3–21}

The present review is concerned with many aspects of photophysical and biochemical activation of O_2 associated with overcoming spin prohibitions. Photochemistry of singlet

oxygen is only briefly outlined, because it was considered in recent reviews.^{17–21}

Almost all reactions of oxygen molecule with chemically stable diamagnetic compounds are exothermic and require specific activation.^{5–8} Combustion requires initial high-temperature activation of O_2 in the form of ignition (generation of primary radicals),⁸ breath requires biochemical enzymatic activation;⁵ in the case of autooxidation the activation is inefficient and slow.⁶ Exothermicity of the oxidation reactions of organic substances is usually explained by high electronegativity of oxygen and by additional stabilisation of C–O and O–H bonds due to their higher polarity⁶ compared to C–C and C–H bonds. It is believed^{5,6} that, owing to high strength of the O–O bond in the O_2 molecule, the activation energies for reactions involving oxygen are too high for them to proceed at sufficiently high rates under normal conditions. However, the chemical inertness of the oxygen molecule is not due only to high bond energy, but also to spin restrictions.^{3–5,12}

Clearly, aerobic life has appeared and exists due to specific kinetic prohibitions to reactions of paramagnetic oxygen with diamagnetic organic substances.^{3,12} The main source of slowing down of the O_2 reactions is the spin prohibition, namely, the reactants have two unpaired spins (from O_2 molecule; electrons in substrate are paired), while in diamagnetic oxidation products all spins are always paired. The overcoming of this prohibition by introducing (generating) radicals to react with oxygen (burn) is inadmissible to living matter. Enzymes of a living cell find another way to overcome the spin prohibition to reactions of oxygen ‘insertion’ into diamagnetic organic substances. Therefore, establishment of the mechanisms of enzymatic bio-activation of oxygen requires investigations of spin effects.^{3,12}

Nearly three decades ago the author of this review first explained intensity borrowing mechanism of magnetic dipole transitions^{22–24} responsible for the known atmospheric absorption bands of oxygen.¹¹ Calculations of the structure of collision complexes of O_2 with diamagnetic substances^{25–28} and their chemical reactions with account of spin–orbit coupling^{29–33} underlie the theory that made it possible to find the ways of overcoming spin prohibitions in the case of weak intermolecular interactions and in the course of chemical reactions.^{12,29,34–38} Recently, this theory has found numerous supports.^{1,3,35–37,39–43}

This review considers the electronic mechanisms of over-coming spin prohibitions to the reactions of O₂ and oxygen complexes with other molecules including solvent molecules and active sites of enzymes. Processes leading to acceleration of radiative and non-radiative triplet–singlet (T–S) transitions in O₂ molecule induced by collisions in the gas phase and in solution including sensitisation of singlet oxygen are generally termed ‘photophysical activation’. We will also consider mechanisms of singlet oxygen luminescence and quenching, although these processes are in essence deactivation. The possibility of removal of spin prohibition in photophysical processes is treated as the first step towards understanding of biochemical enzymatic reactions of oxygen.^{3,24–37} In the review we also analyse the physical (mainly spectral) and chemical properties of O₂ molecule and the properties of other active forms of oxygen in relation to photosynthesis of atmosphere, combustion, catalysis and bio-oxidation.

II. Mechanisms of triplet – singlet transitions in the oxygen molecule

1. Energy characteristics of pure spin states of the oxygen molecule

Let us consider the ground- and excited-state electronic structure of O₂ molecule and factors determining the probability of T–S-transitions in free the oxygen molecule.

Back in 1848, Faraday weighed various gases with a magnetic balance and established that, unlike many other elements, molecular oxygen is paramagnetic.⁶ An explanation for this amazing fact was reported much later.⁴ Mulliken explained paramagnetism of molecular oxygen by considering the ground-state configuration in which the highest occupied molecular orbital (MO) is a doubly degenerate π_g orbital occupied by two electrons.⁴ In this case the inclusion of a ‘molecular’ analogue of Hund’s rule leads to parallel electron spin orientations in the lowest-energy state. Thus, atmospheric oxygen contains O₂ molecules in the triplet ground state corresponding to the following electronic configuration^{4,22}

$$\Psi = (1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2(3\sigma_g)^2(1\pi_u)^4(1\pi_g)^2. \quad (1)$$

There are four possible quantum states of the molecule with particular values of the spin (S) and orbital (L_z) angular momenta⁴ depending on arrangement of two outer electrons in two degenerate $1\pi_g$ -MOs. Using complex wave functions of MO in the form¹⁵

$$\pi_g^\pm = \psi(r, \theta) e^{\pm i\phi}, \quad (1a)$$

where θ is the angle between the z axis and the radius vector \mathbf{r} , ϕ is the angle of rotation of the radius vector \mathbf{r} about the molecular axis z , these states can be represented by the following qualitative models:

$$\begin{array}{cccc} [\uparrow\uparrow][\uparrow\uparrow] & [\uparrow\downarrow][\uparrow\downarrow] & [\uparrow\uparrow][\downarrow\downarrow] & [\uparrow\downarrow][\downarrow\uparrow] \\ |^3\Sigma_g^- \rangle & |^1\Delta_g \rangle & |^1\Delta_g \rangle & |^1\Sigma_g^+ \rangle \end{array} \quad (2)$$

Here the quantum cells $[\uparrow\uparrow]$ denote degenerate π_g^\pm -orbitals. The respective complex determinant wave functions for the open shells of the states (2) have the form^{4,10}

$$|^3\Sigma_g^- \rangle = \frac{1}{\sqrt{2}} (|\pi^+\pi^-| - |\pi^-\pi^+|), \quad (2a)$$

$$|^1\Delta_g \rangle = |\pi^+\pi^+|,$$

$$|^1\Delta_g \rangle = |\pi^-\pi^-|,$$

$$|^1\Sigma_g^+ \rangle = \frac{1}{\sqrt{2}} (|\pi^+\pi^-| + |\pi^-\pi^+|).$$

Here $|\cdot|$ is the conventional notation of the determinant wave functions,¹⁰ π^+ denotes the α -spin MO (spin-up MO) and π^- denotes the β -spin π_g^\pm -MO (spin-down MO). The functions (2a) are eigenfunctions of the operator of the orbital angular momentum projection (L_z) with the quantum number $\Lambda = 0$ (for the states Σ_g^\pm) and 2 (for the states $^1\Delta_g$)^{4,10–16} in $\hbar = h/2\pi$ units (h is the Planck constant). With allowance for exchange interaction between two π_g -electrons, the triplet state $^3\Sigma_g^-$ has the lowest energy, thus being the ground state; the next is the doubly degenerate singlet state $^1\Delta_g$, while the singlet state $^1\Sigma_g^+$ has the highest energy.^{4,9}

The total spin quantum number (S) in the expression for the eigenfunctions of the operator S^2

$$S^2\Psi = S(S+1)\hbar^2\Psi \quad (3)$$

is equal to zero for singlets and to unity, for triplets.¹⁵ Functions (2a) obey relation (3), their multiplicity (left superscript) is $2S+1$. Qualitative description of energy characteristics of O₂ can be obtained²² using simple semiempirical quantum chemical methods, e.g., INDO.¹⁵ The inclusion of configuration interaction (CI) with the basis set (2) leads to the same splitting between the three states $^3\Sigma_g^-$, $^1\Delta_g$, $^1\Sigma_g^+$, equal to the atomic exchange integral:¹³ $\langle p_x p_y | p_x p_y \rangle = 0.8$ eV. The energies of the singlet states $^1\Delta_g$ and $^1\Sigma_g^+$ calculated relative to the triplet ground-state energy are 0.8 and 1.6 eV, respectively,²² which agrees with experimental data (0.98 and 1.63 eV, respectively).⁹ The agreement is improved by inclusion of configuration interaction and the ... $(1\pi_u)^2(1\pi_g)^4$ configuration, however the pattern of the wave functions remains essentially the same.¹² The following is quite important. Computational quantum chemistry methods usually employ real wave functions for the atomic basis set p_x , p_y and p_z .¹⁵ The singlet states are described by the following combinations of the wave functions:^{10,22}

$$|^1\Delta_g \rangle = ^1\Phi_1 = \frac{1}{\sqrt{2}} (|\pi_x\bar{\pi}_x| - |\pi_y\bar{\pi}_y|), \quad (4)$$

$$|^1\Delta_g \rangle = ^1\Phi_2 = \frac{1}{\sqrt{2}} (|\pi_x\bar{\pi}_y| + |\pi_y\bar{\pi}_x|), \quad (4a)$$

$$|^1\Sigma_g^+ \rangle = ^1\Phi_3 = \frac{1}{\sqrt{2}} (|\pi_x\bar{\pi}_x| + |\pi_y\bar{\pi}_y|), \quad (5)$$

$$|^3\Sigma_g^- \rangle = ^3\Phi_0 = \frac{1}{\sqrt{2}} (|\pi_x\bar{\pi}_y| - |\pi_y\bar{\pi}_x|),$$

where π_x denotes the spin-up (α -spin) $1\pi_{gx}$ -MO and $\bar{\pi}_x$ denotes the spin-down (β -spin) $1\pi_{gx}$ -MO. The real π_g -MO functions in the INDO approximation have a simple form²²

$$\pi_x = \frac{1}{\sqrt{2}} (p_x^A - p_x^B), \quad (6)$$

$$\pi_y = \frac{1}{\sqrt{2}} (p_y^A - p_y^B),$$

where p_x^A denotes the real 2p-AO of the atom A, oriented along the x axis and the symbols ‘A’ and ‘B’ denote the two oxygen atoms. Electrons of the closed shell in Eqns (4) and (5) are omitted because they do not affect the matrix elements of the one-electron operators [dipole moment, angular momentum, spin–orbit coupling (SOC)]. For the triplet ground state $^3\Sigma_g^-$, the form of the determinant functions (2) and (5) remains unchanged, whereas the functions for the singlet states (2) in

the real basis set (6) have another form. This feature should be taken into account¹² in calculations of (i) collision complexes of oxygen molecule with other molecules and (ii) chemical reactions involving this molecule.

The complex functions (1a) and (2) are only convenient in the case of isolated O₂ molecule. By expanding determinants in relationships (5), one can separate the orbital and spin contributions; then the singlet and triplet Σ -states have the form

$$|{}^1\Sigma_g^+\rangle = {}^1\Phi_3 = \frac{1}{\sqrt{2}} [\pi_x(1)\pi_x(2) + \pi_y(2)\pi_y(1)] \frac{1}{\sqrt{2}} [\alpha(1)\beta(2) - \alpha(2)\beta(1)], \quad (5a)$$

$$|{}^3\Sigma_g^-\rangle = {}^3\Phi_0 = \frac{1}{\sqrt{2}} [\pi_x(1)\pi_y(2) - \pi_x(2)\pi_y(1)] \frac{1}{\sqrt{2}} [\alpha(1)\beta(2) + \alpha(2)\beta(1)]. \quad (5b)$$

The '+' and '-' signs at the term ' Σ ' denote mirror symmetry relative to any plane containing the molecular axis, *e.g.*, the *yz* plane. Reflection in this plane causes the π_x -MO to change its sign while the sign of the π_y -MO remains unchanged. Because of this, both components in the orbital part of the wave function (5b) change their signs; *i.e.*, this function is antisymmetrical with respect to reflection in plane, while the wave function (5a) is symmetrical. The same conclusions can be drawn by considering the *xz* plane. As to the complex functions (1a) and (2a), these conclusions are valid for any plane containing the molecular axis,¹⁵ because reflection in plane causes replacement of ϕ by $-\phi$ and, hence, replacement of π^+ by π^- in relation (1a).

Thus, for planar collision complexes of O₂ the real wave functions (5) characterise the key symmetry properties of the low-lying electronic states of this molecule. Selection rules for functions (1) and (2) are also valid for functions (4)–(6). Collision complexes have no inversion point. This formally breaks quantisation of the projection of the orbital angular momentum and in polyatomic molecules the quantum number of the operator L_z is no longer a 'good quantum number'.¹³ However, calculations^{27–31} revealed only minor changes in the structure of the wave functions (4) and (5) and in the energies of corresponding states of collision complexes. Therefore, the collision complexes can be treated using the same notations of terms (4) and (5) as those of free O₂ molecule.

Specific behaviour of O₂ molecule in animated nature is mainly due to the presence of low-energy excited singlet states and the intrinsic magnetic moment (spin) in the ground state (paramagnetism of O₂).^{12, 27} Figure 1 presents the potential curves for certain states of the O₂ molecule, obtained from multiconfiguration self-consistent field (MC SCF) calculations with subsequent inclusion of configuration interaction.^{30, 40} High-energy excited states ${}^3\Sigma_u^-$ and ${}^3\Delta_u$, ${}^3\Sigma_u^+$ responsible for UV emission of oxygen (Herzberg bands) are of great interest for atmosphere photochemistry and gas discharge spectroscopy.^{9, 39–42} When discussing the photochemistry of singlet oxygen (${}^1\Delta_g$), these states are usually left out of consideration, although from the standpoint of spin catalysis theory^{32–34} they should also be taken into account. The triplet state $B^3\Sigma_u^-$ gives an allowed electric dipole transition $B^3\Sigma_u^- \leftarrow X^3\Sigma_g^-$ (Ref. 9) responsible for the Schumann–Runge absorption band. Due to this intense absorption in upper atmosphere, hard solar UV radiation (135–190 nm) does not arrive to the Earth's surface. Since minima on the potential curves for the *B*- and *X*-states are strongly shifted relative to one another

Figure 1. Potential curves for certain quantum states of O₂ molecule obtained from *ab initio* calculations.^{30, 31}

Literary notations of terms used here and in Fig. 2 are common to molecular spectroscopy. Main multiplet states: singlet (*a*, *b*, *c*) and triplet (*A*, *B*).

(see Fig. 1), the vertical transition $B^3\Sigma_u^-/X^3\Sigma_g^-$ leads to dissociation of O_2 molecule. In addition, pre-dissociation of bound vibrational states of the upper term is also possible due to crossing with the potential curves of the Π_u -states.⁹

Various glow phenomena in the night sky including auroral ones are due to decomposition of oxygen molecule to atoms and subsequent recombination of oxygen atoms with the formation of excited O_2 molecules.⁹ In this review, we will leave these interesting phenomena out of consideration. Mention may only be made that theory of forbidden transitions from the $c^1\Sigma_u^-$, $A'^3\Delta_u$ and $A^3\Sigma_u^+$ excited states provides a great body of valuable information on the SOC mechanisms¹² that are important for understanding of the enzymatic activation of oxygen. In addition to the Herzberg bands, red atmospheric bands of oxygen [transition $b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-$ (762 nm)] and IR radiation (transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ at 1270 nm) were detected.⁹ Long optical path in the atmosphere also allows these bands to be clearly defined in absorption (the red band represents a combination of certain Fraunhofer lines) in spite of the forbiddenness and low probability of these transitions.

Until recently, the singlet state of oxygen was of interest only for researchers working in atmosphere optics.^{10,11} In 1976, Krasnovsky¹⁴ first detected luminescence of singlet oxygen ($a^1\Delta_g$) in solution. At present, singlet oxygen is used in technics,^{1,17,18} chemistry^{17–21} and medicine.^{1,19,43} Singlet oxygen molecule $O_2(a^1\Delta_g)$ is known as oxidant in chemical and biological processes, because the spin prohibition is removed and the species is more reactive than the triplet atmospheric oxygen molecule $O_2(X^3\Sigma_g^-)$.^{1–7,19–21} Taking into account four quantum states (2) of oxygen molecule is required for not only understanding of oxygen photochemistry, but also development of theory of the dark chemical reactions,^{12,29,32} in particular, for studies of enzymatic oxidation processes.³⁷

2. Intensities of singlet–triplet transitions in optical spectra of the oxygen molecule

To understand the mechanism of removal of spin prohibitions in chemical reactions involving oxygen, one should consider a theory of intensity of singlet–triplet transitions in isolated O_2 molecule and the effect of solvent on these transitions.^{22–96} Radiative transitions between all states (2) are strictly forbidden in the electric dipole approximation,^{11,43} because all of them have the same parity (gerade symmetry relative to inversion point), whereas the selection rules require a change in parity upon transitions. For electric dipole transitions the projection of the orbital angular momentum on the molecular axis (Λ) should vary by $\Delta\Lambda = \pm 1, 0$. The $^1\Delta - ^1\Sigma^+$ transition is also forbidden due to the selection rule for the projection of the orbital angular momentum ($\Delta\Lambda = 2$). In free O_2 molecule, this transition is detected as a weak quadrupole transition because in the quadrupole approximation the prohibition for $\Delta\Lambda = 2$ is removed.^{12,26} Singlet–triplet transitions between terms (2) are additionally forbidden by the spin selection rule, $\Delta S = 1$. Transition between states (5) is also forbidden by the $\Sigma^- - \Sigma^+$ rule, *i.e.*, we deal with the triple prohibition.

All the prohibitions mentioned above are strict.⁴⁹ The more long-wavelength singlet–triplet transition $^1\Delta_g - ^3\Sigma_g^-$ is additionally forbidden by the selection rule for the orbital angular momentum ($\Delta\Lambda = 2$) and thus characterised by triple prohibition [with respect to spin, parity (gerade–gerade) and orbital angular momentum, that is, $\Delta\Lambda = 2$] in the electric dipole approximation. A diagram of different quantum states (4), (5) and transitions between them for the collision complex of O_2 molecule and a dye is shown in Fig. 2. Both singlet–triplet transitions, $a \rightarrow X$ and $b \rightarrow X$, should be very weak due to the triple prohibition on emission in the dipole approximation.

The potential curves (see Fig. 1) for all the three states (X , a and b) are only slightly shifted relative to one another, the

Figure 2. Scheme of quantum states in a collision complex of O_2 with a dye.

equilibrium internuclear distances (r) being respectively equal to 1.207, 1.216 and 1.227 Å (see Ref. 9). Therefore, only the 0–0 bands corresponding to electronic vibrational transitions between these states are intense in optical spectra.^{9,42,46} The rate constant (k) for spontaneous emission $a \rightarrow X$ obtained by interpolation to zero oxygen pressure (no collisions; intermolecularly unperturbed O_2 molecule) was found to be record-low ($k_{a \rightarrow X} = 2.6 \times 10^{-4} \text{ s}^{-1}$).¹⁷ The $b \rightarrow X$ transition is much more intense ($k_{b \rightarrow X} = 8.9 \times 10^{-2} \text{ s}^{-1}$). The radiative lifetimes¹⁷ of the a and b states are 4600 and 12 s, respectively. The $a \rightarrow X$ and $b \rightarrow X$ transition intensities were first calculated in Ref. 22. In spite of semiempirical character of the wave functions used in the INDO method, the results of calculations²² correctly describe the mechanisms of overcoming spin prohibitions, as was confirmed later by the results of *ab initio* calculations.^{42,50,57} To understand the spin mechanisms of photo- and bio-activation of oxygen, we will consider the key points of the semiempirical theory.²²

Symmetry analysis of the wave functions revealed the possibility of mixing of the singlet and triplet states (5) due to the SOC operator.⁴⁹ For simplicity, we will write this operator in the effective one-electron form^{12,23}

$$H_{so} = \sum_A \zeta_A \sum_i \vec{l}_{i,A} \vec{s}_i = \sum_i \vec{B}_i \vec{s}_i = \sum_i (B_{i,x} s_{i,x} + B_{i,y} s_{i,y} + B_{i,z} s_{i,z}), \quad (7)$$

where ζ_A is the SOC constant for the atom A ($\zeta_O = 153 \text{ cm}^{-1}$), $\vec{l}_{i,A}$ and \vec{s}_i are respectively the operators of the orbital angular momentum and spin angular momentum of the i th electron.¹² The one-electron SOC operator (7) with inclusion of the constants ζ_A determined from atomic spectra gives quite reliable results suitable for explanation of numerous SOC effects in molecules.^{12,13,49} The spin–orbit coupling between the singlet and triplet ($b^1\Sigma_g^+ - X^3\Sigma_{g,0}^-$) states [see relations (5)] is given by²²

$$\begin{aligned} \langle ^3\Sigma_g^- | H_{so} | ^1\Sigma_g^+ \rangle &= \langle ^3\Phi_0 | H_{so}^Z | ^1\Phi_3 \rangle = \\ &= \langle \pi_x | B_z | \pi_y \rangle = -i\zeta_O = -153i \text{ cm}^{-1}. \end{aligned} \quad (8)$$

Equation (5) was written for the triplet state with the zero projection of the total spin on the molecular axis (z axis).²² In the text below this spin sublevel with the quantum number $M_S = 0$ will be designated by $|^3\Sigma_{g,0}^- \rangle$ (for the frame of reference associated with the O_2 molecule) and t_z (if the z axis of the frame of reference in the collision complexes of O_2 with organic reactant molecules matches the line of the O–O bond). The

other two spin sublevels of the triplet state with the quantum numbers $M_S = \pm 1$ in the oxygen molecule are degenerate; we will denote them $|^3\Sigma_{g,1}^- \rangle$. The separation between them and the $M_S = 0$ level equals the zero-field splitting (ZFS) energy,^{9, 22} which for the oxygen molecule is rather high (3.97 cm^{-1} ; cf. a conventional value of 0.1 cm^{-1} for the triplet-excited states of aromatic molecules¹³). The ZFS is due to the dipole–dipole magnetic interaction between two unpaired spins.⁴⁹ In the case of O_2 molecule the SOC also contributes largely to the ZFS at the second-order level of perturbation theory.⁴⁸ Recently, correct *ab initio* calculations of the ZFS energy for oxygen molecule have been reported.⁴⁶ Among previous calculations presented in Refs 47–49, a number of errors are found, whereas semiempirical estimates^{22, 59} appeared to be more reliable.^{13, 46} Seemingly, the results of *ab initio* calculations⁴⁷ are in good agreement with the observed ZFS; however, this is a random coincidence. Indeed, the SOC contribution to ZFS is overestimated (doubled) owing to incorrect value of a factor. Correct calculation of magnetic perturbations in the ZFS is important for understanding of the mechanism of removal of spin prohibition for the singlet–triplet transitions in oxygen.

The matrix element of the operator of the SOC between the $\Sigma^- - \Sigma^+$ triplet and singlet states differs from zero only for the states (5) characterised by the quantum number $M_S = 0$. At the first-order level of perturbation theory, the wave functions of these states are mixed due to SOC²²

$$\Psi_b = |b^1\Sigma_g^+\rangle + c|X^3\Sigma_{g,0}^-\rangle, \quad (9)$$

$$\Psi_{X,0} = |X^3\Sigma_{g,0}^-\rangle - c^*|b^1\Sigma_g^+\rangle, \quad (10)$$

where the mixing coefficient

$$c = \frac{\langle X^3\Sigma_{g,0}^- | H_{\text{so}} | b^1\Sigma_g^+ \rangle}{E(b^1\Sigma_g^+) - E(X^3\Sigma_{g,0}^-)} \quad (11)$$

is small (E is the energy of the corresponding state). With allowance for the semiempirical estimate of the SOC using Eqn (8) and energy difference⁹ in the denominator of Eqn (11) ($13\,195 \text{ cm}^{-1}$), one gets²² $c = -0.0116i$. The small value of the coefficient c provides an excellent substantiation of the applicability of perturbation theory and the wave functions (9) and (10) are characterised by rather high accuracy and correct normalisation. According to *ab initio* calculations,^{42, 50} the SOC matrix element [numerator in Eqn (11)] equals $-178i \text{ cm}^{-1}$, the absolute value of coefficient c being somewhat increased: $|c| = 0.0135$. This coefficient plays a key role in the theory of singlet–triplet transitions of oxygen molecule in the gas phase at low and high pressures and in O_2 solutions in organic compounds and biopolymers.^{22–31}

Let us consider a magnetic dipole transition from the state (9) to the state $|^3\Sigma_{g,1}^- \rangle$ with the quantum number $M_S = \pm 1$. Unlike the spin sublevel $|^3\Sigma_{g,0}^- \rangle$, the $|^3\Sigma_{g,1}^- \rangle$ state is almost ‘pure’, i.e., it contains minor contributions of singlet states. (Actually, it has a small contribution of the $^1\Pi_g$ state, but this is of no concern for the simplified treatment²² of the $b-X$ transition.) The magnetic dipole moment operator

$$\mathbf{M} = \mu_B(\mathbf{L} + 2\mathbf{S}),$$

where μ_B is the Bohr magneton, contains the orbital (\mathbf{L}) and spin (\mathbf{S}) contributions. According to calculations,^{22, 42, 50} the orbital contribution to the moment of the $b^1\Sigma_g^+ - X^3\Sigma_{g,1}^-$ transition is negligible. The major contribution to the $b-X$ transition intensity comes from the spin component²² with the magnetic moment polarisation vector directed perpendicular to the molecular axis. Taking into account expression (9), one has²²

$$\mathbf{M}_{b-X,1} = \mu_B \langle \Psi_b | 2\mathbf{S} | \Psi_{X,1} \rangle = \quad (12)$$

$$= \mu_B \sqrt{2} c \langle X^3\Sigma_{g,0}^- | S_x \pm iS_y | X^3\Sigma_{g,1}^- \rangle = -2\mu_B c.$$

Thus, the $b^1\Sigma_g^+ - X^3\Sigma_{g,1}^-$ transition in the visible region (red atmospheric band of oxygen at 760 nm) in fact ‘borrows’ its intensity from the microwave transition between the spin sublevels $^3\Sigma_{g,0}^- - ^3\Sigma_{g,1}^-$ (magnetic dipole EPR transition induced by the spin operator). The calculated transition moment $\mathbf{M}_{b-X,1} = -0.027 \mu_B$ is almost equal to the value obtained from intensity measurements.⁹ This is a unique example in molecular spectroscopy; here the intensity of an optical electronic transition is determined by the EPR spin current intensity. This provides an explanation for a higher probability of the $b-X$ transition compared to that of the $a-X$ transition. In the latter case there is only a small orbital contribution to the magnetic dipole moment of the transition, due to the SOC-induced mixing of the a , X and $^3, ^1\Pi_g$ states.²² Owing to large energy differences between these states

$$E(^1\Pi_g) - E_X = 78\,000 \text{ cm}^{-1},$$

$$E(^3\Pi_g) - E_a = 48\,000 \text{ cm}^{-1},$$

mixing of the singlets and triplets is negligible and the spin prohibition to the $a-X$ transition remains strict.

One should also consider the probability of the $b-a$ transition, which plays an important role in analysis of the solvent effect on the oxygen spectra. The $b-a$ transition of a free O_2 molecule is responsible for the appearance of a weak Noxon band, which is a quadrupole^{26, 89} with the maximum possible quadrupole moment.²⁶ However, the rate constant for spontaneous emission $b \rightarrow a$ obtained by interpolation to zero pressure is very small ($k_{b \rightarrow a} = 1.7 \times 10^{-3} \text{ s}^{-1}$).⁹ Theoretical studies^{25–28} revealed that this transition should be dramatically enhanced upon collision of O_2 molecule with any diamagnetic molecule. Later on, this conclusion was confirmed experimentally for the gas,³⁹ solid^{51, 52} and liquid phases.^{1, 17, 43, 56}

With allowance for the SOC in the framework of perturbation theory one can explain the intensities of many UV bands of oxygen molecule.^{30, 31, 59, 65, 67, 91–96} In addition to calculations of well-known Herzberg bands,^{9, 30, 49, 65, 67} a reliable explanation was obtained for the intensities of some new bands originated from recently detected new electronic transitions from the metastable state (9), namely, $b^1\Sigma_g^+ - B^3\Sigma_u^-$ and $b^1\Sigma_g^+ - c^1\Sigma_u^-$ (Refs 31, 91–95). The $b^1\Sigma_g^+ - B^3\Sigma_u^-$ transition proceeds by the mechanism of intensity ‘stealing’ from the Schumann–Runge band ($X-B$) due to the SOC (9); the coefficient c [see Eqn (11)] gives a correct order of magnitude^{31, 92} for the electric dipole moment of this transition. The $b^1\Sigma_g^+ - c^1\Sigma_u^-$ transition is also electric dipole in nature; removal of the $\Sigma^- - \Sigma^+$ -type prohibition for the singlet–singlet transition is due to electronic-rotational coupling⁹⁵

$$\begin{aligned} & \left\langle \tilde{c}^1\Sigma_u^- \left| \sum_i \mathbf{er}_i \right| b^1\Sigma_g^+ \right\rangle = \\ & = \sum_n \frac{\langle n^1\Pi_g | B L_+ | b^1\Sigma_g^+ \rangle}{E(b^1\Sigma_g^+) - E(n^1\Pi_g)} \left\langle c^1\Sigma_u^- \left| \sum_i \mathbf{er}_i \right| n^1\Pi_g \right\rangle + \\ & + \sum_k \frac{\langle k^1\Pi_u | B L_+ | c^1\Sigma_u^- \rangle^*}{E(c^1\Sigma_u^-) - E(k^1\Pi_u)} \left\langle k^1\Pi_u \left| \sum_i \mathbf{er}_i \right| b^1\Sigma_g^+ \right\rangle. \end{aligned}$$

Here \mathbf{er}_i is the dipole moment of the i th electron and B is the rotational constant.

Detection⁹⁴ and theoretical identification⁹⁵ of the $b^1\Sigma_g^+ - c^1\Sigma_u^-$ transition bands opens new prospects for atmosphere photochemistry studies. However, no $A^3\Sigma_u^+ - c^1\Sigma_u^-$ electronic transition in the IR region (2400 cm^{-1}) was detected so far, although the corresponding intensity stealing mechanism was developed two decades ago.¹² The magnetic dipole moment of this transition ($M_{A-c} = 0.12\mu_B$) is about five times larger than that of the $b-X$ transition [see Eqn (12)]. The intensity stealing and the spin-prohibition removal mechanisms are very similar to those described by relations (9)–(12); however, this only concerns the $A^3\Sigma_u^+$ and $c^1\Sigma_u^-$ states. The SOC matrix element between these states is equal to the integral (8) while the energy difference in the denominator is very small (2400 cm^{-1}); this is the reason for high extent of intensity stealing from the transitions between spin sublevels of the $A^3\Sigma_u^+$ state (see Refs 12 and 91). The aforesaid is valid for a free O_2 molecule in a highly rarefied gas (upper atmosphere), when collisions can be ignored. Under normal pressure at Earth's surface, collisions with other molecules (O_2 , N_2 , water vapour) significantly affect the intensities of certain absorption bands of oxygen.^{25–43, 51–56}

III. Influence of collisions of oxygen molecule on intensities of forbidden transitions

1. The Noxon transition

Let us consider simple models for collision complexes of O_2 with diamagnetic molecules.^{1, 28, 39, 51, 58, 89, 97–109} Changes in the orbitals of the open π_g -shell of oxygen molecule upon its collision with the nitrogen molecule are shown in Fig. 3. For simplicity, we assume that the collision complex has a planar geometry and lies in the xz plane. All subsequent conclusions are also valid for arbitrary geometry of the complex. The moment of the Noxon transition $a^1\Delta_g - b^1\Sigma_g^+$ of the collision complex radically changes its nature, following the changes in the nature of orbitals of the open π_g -shell. In addition to the pure quadrupole component $\langle^1\Delta_g|Q|^1\Sigma_g^+\rangle$, which is the same for both terms (4) and (4a), the electric dipole component $\langle^1\Delta_g|D|^1\Sigma_g^+\rangle$ appears, which can differ for the two quasi-degenerate components of the singlet state a . The matrix elements of the dipole moment operator

$$D = e \sum_i r_i = \sum_i d_i$$

for the singlet–singlet ($a^1\Delta_g - b^1\Sigma_g^+$) transition [see Eqns (4) and (5)] are equal to the dipole moment difference between two π_g -MOs (see Ref. 28)

$$\langle^1\Phi_1|D|^1\Phi_3\rangle = \langle\pi_x|d|\pi_x\rangle - \langle\pi_y|d|\pi_y\rangle. \quad (13)$$

For the second component of the $a^1\Delta_g$ state [see Eqn. (4a)] the dipole moment of the $a-b$ transition is

$$\langle^1\Phi_2|D|^1\Phi_3\rangle = \langle\pi_y|d|\pi_x\rangle + \langle\pi_x|d|\pi_y\rangle. \quad (14)$$

For the planar collision complex $O_2 + N_2$ (see Fig. 3), the dipole moment difference between two oxygen π_g -MOs differs from zero. Spin-restricted Hartree–Fock⁸⁷ calculations of the triplet ground state of the complex $O_2 + N_2$ (see Fig. 2) revealed significant deformation of the $\pi_{g,x}$ -orbital of the O_2 molecule due to mixing with orbitals of the nitrogen molecule (see Fig. 3b), whereas the $\pi_{g,x}$ -MO remains almost unchanged (see Fig. 3a).^{12, 27} The overlap of the π_x -orbitals of the two molecules (σ -type overlap, see Fig. 3b) is much larger than that of the π_y orbitals (π -type overlap).

The structures of the states (4) and (5) determined with allowance for configuration interaction remain almost unchanged.¹² The dipole moment of the $\pi_{g,x}$ -orbital differs from zero, because it includes quite large contributions of nitrogen atoms; despite small coefficients in the LCAO expansions for these atoms, the dipole moment $\langle\pi_x|d|\pi_x\rangle$ of the $\pi_{g,x}$ -orbital is of great importance because of the long intermolecular distance ($R = 2.8\text{ \AA}$). The moment of the transition (13) reaches a value of 0.1 D, the transition intensity being four orders of magnitude higher than the intensity of the pure quadrupole transition $a^1\Delta_g - b^1\Sigma_g^+$ of free O_2 molecule.¹² This example (see Fig. 3) provides the simplest illustration of the Noxon band (transition $a^1\Delta_g - b^1\Sigma_g^+$) enhancement mechanism in the collision complex due to the appearance of the electric dipole moment of the transition. At arbitrary collision geometry, both terms on the right side of Eqns (13) and (14) differ from zero, but the total intensity of the Noxon band mainly depends on R . The off-diagonal matrix elements of the one-electron operator of the dipole moment between the π_g -orbitals of the open shell of oxygen [see Eqn (14)] depend on the extent of deviation of the collision complex geometry from planar one (see Fig. 3). This is also characteristic of most molecules having more complex structures compared to N_2 . For instance, an oxygen–butadiene collision complex cannot have planes among symmetry elements (only the most probable non-planar π -complex is considered here); in this case the integrals (13) and (14) are commensurable.⁸⁷

The extent of the Noxon band enhancement depends on the polarisability (α_{cp}) of the partner in collision.^{1, 17, 87, 98} This was revealed by the first MINDO/3 calculations with inclusion of configuration interaction for singly and doubly excited configurations.²⁸ Qualitative correlation between the Noxon band enhancement and an increase in the ionisation potential of the partner in collision (molecular polarisability increases as the ionisation potential decreases) was pointed out.¹³ The dipole moment $\langle\pi_x|d|\pi_x\rangle$ of the oxygen $\pi_{g,x}$ -orbital in the complex with nitrogen (see Fig. 3) depends on the contribution of the vacant nitrogen π_g -MO, which is in turn determined by the polarisability of this molecule.^{87, 98} Enhancement of the Noxon band with an increase in the collision-partner polarisability^{28, 87, 98–101} was even better demonstrated in analysis of the results of CI calculations^{12, 97, 98} in the oxygen complexes with helium and hydrogen.

Figure 3. Molecular orbitals, $\pi_{g,y}$ (a) and $\pi_{g,x}$ (b), of O_2 in collision complex of oxygen and nitrogen molecules.

The z axis matches the N_2 molecular axis; the y axis is normal to the xz plane of the complex. White and dark background corresponds to the positive and negative signs of the wave functions.

2. Effect of collisions on intensities of singlet–triplet transitions of oxygen in the visible and near IR optical spectra

Singlet molecular oxygen in the $a^1\Delta_g$ state is produced by photosensitisation of dye solutions.^{1,28} This species plays a key role in some photochemical and photobiological processes.^{53–56} Such diseases as skin cancer and cataract as well as ageing are associated with reactions involving $O_2(a^1\Delta_g)$.^{17–21} Recently, this form of oxygen has been used in organic synthesis, in bleaching, in medicine for treatment of malignant tissues (photodynamic therapy),^{1,18,19} as an air pressure gauge in aerodynamics,^{17,105} as fixing agent in high-spatial and high-temporal resolution microscopes^{56,82,83} and as a microscopic luminescing detector.^{1,17}

Wide use of singlet oxygen is due to unique properties of the singlet–triplet transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$. As mentioned above, this transition of free O_2 molecule (at zero pressure) is characterised by very low emission (rate constant for spontaneous emission is $2.6 \times 10^{-4} \text{ s}^{-1}$).⁹ In compressed gas and in solution the transition probability increases by 3–4 orders of magnitude; luminescence is detected using sensitive photomultipliers.^{14,17,53,56} Such a luminescence was first detected in solutions of biological pigments (photosensitisers of 1O_2) using an improved phosphoroscope under steady-state excitation.^{14,60} Later on, the characteristic narrow band at 1270 nm corresponding to the $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ transition of oxygen molecule in solution was observed in numerous studies using pulsed excitations of photosensitisers.^{1,17,58,61–64,73–77} Good temporal resolution obtained with a germanium detector was reported.^{61–63,75} The quantum yield (Q_a) of luminescence ($a \rightarrow X$ transition) and the lifetime of singlet oxygen (τ_a) in some solutions of saturated hydrocarbons and their halo derivatives were measured.⁶³ Measurements of Q_a in the near IR region are complicated by the lack of appropriate references, because the quantum yield of singlet oxygen (Q_a) should be measured for each solution with a given sensitiser. The radiative rate constant for the $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ transition⁶³

$$k_{a-X} = \frac{Q_a}{\tau_a Q_a}, \quad (15)$$

determined for a series of saturated solvents falls in the range $\sim 0.1–0.2 \text{ s}^{-1}$. The conclusion about independence of k_{a-X} on the solvent is only valid for this series of solutions.⁶³

The author of this review developed^{12,27,28} a simple scheme of stealing the emission intensity of the $a \rightarrow X$ transition of collision complexes of O_2 with diamagnetic molecules starting from calculations of a model complex $O_2 + H_2$. Using a program of configurational interaction calculations^{12,97} for single and double excitations debugged for the modified¹² MINDO/3 method,¹⁵ qualitatively correct description of the spectrum of the complex was obtained and the collision-induced electric dipole moments of transitions were calculated.^{27,28} It was established that the $b-a$ transition of the collision complex acquires a relatively large dipole moment [see Eqn (13)]. As mentioned above, this is characteristic of all collisions of the O_2 molecule with diamagnetic molecules; this also follows from Eqns (13) and (14). In the case of a planar symmetric complex similar to that shown in Fig. 3, relation (13) predicts that the intensity of the $b-a$ transition of the O_2 molecule in the collision complex should dramatically increase due to deformation of the $\pi_{g,x}$ -orbital electron cloud. Even small contributions of the collision-partner (H_2 , N_2 , C_2H_4 , C_6H_6) orbitals induce a large dipole moment of the $b-a$ transition. With allowance for the abnormally strong spin–orbit coupling of the $b^1\Sigma_g^+$ and $X^3\Sigma_{g,0}^-$ states [see Eqn (8)] and for the contribution of the $|b^1\Sigma_g^+\rangle$ state to the wave function $\Psi_{X,0}$ of the ground-state term [see Eqn (10)] one gets that the $a^1\Delta_g \rightarrow X^3\Sigma_{g,0}^-$ transition ‘steals’ the intensity¹² from the $a-b$ transition

$$\langle a^1\Delta_g | D | \Psi_{X,0} \rangle = -c \langle a^1\Delta_g | D | b^1\Sigma_g^+ \rangle. \quad (16)$$

Since the spin–orbit coupling (8) in the oxygen molecule is still the strongest and the coefficient c only depends on the properties of the O_2 molecule, the $|c|$ value in the collision complex remains almost unchanged.^{27,98} The electric dipole moment of the $a^1\Delta_g-b^1\Sigma_g^+$ transition of the collision complex $O_2 + H_2$ at $R = 2.4 \text{ \AA}$ is²⁸

$$\langle a^1\Delta_g | D | b^1\Sigma_g^+ \rangle = 0.0113 \text{ e \AA}.$$

The moment of the $O_2 + H_2$ -collision induced transition $a^1\Delta_g \rightarrow X^3\Sigma_{g,0}^-$ determined using relation (16) is

$$\langle a^1\Delta_g | D | \Psi_{X,0} \rangle = 1.5 \times 10^{-4} \text{ e \AA},$$

which corresponds to an absorption oscillator strength f of 2×10^{-9} and a radiative rate constant of $k_{a-X} = 0.08 \text{ s}^{-1}$. This coincides in order of magnitude with the results obtained by Krasnovsky⁶³ ($k_{a-X} \approx 0.1 \text{ s}^{-1}$). The electron shell of the H_2 molecule provides a simple example of the closed electron shell of the molecule of a saturated compound; therefore, the model for the $O_2 + H_2$ complex chosen here is quite reliable.^{12,28} This was confirmed in calculations of O_2 complexes with other molecules.^{43,53,54,71,84–88,109}

As mentioned above, the Noxon band enhancement depends on the polarisability of the collision partner, which leads to the same dependence for the luminescence band $a^1\Delta_g \rightarrow X^3\Sigma_g^-$. The dependence of the radiative rate constant k_{a-X} on solvent properties has been a subject of discussion initiated by the contradictory results of measurements using different luminescent standards for calibration.^{1,17,35,36,60–64,73–77,101–106} Ogilby *et al.*^{17,77,104} showed that the relative rate constant k_{a-X} changes by an order of magnitude on going from trifluoroethanol to carbon disulfide. These discussions outcompeted a problem of paramount importance, namely, why the intensity of the spin-forbidden transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ increases by 3–4 orders of magnitude upon collisions in solutions, gases and solid matrices compared to the intensities of the transitions of free oxygen molecule.²⁷ The mechanism of stealing the intensity of this transition from the $a^1\Delta_g-b^1\Sigma_g^+$ transition of collision complexes was proposed more than two decades ago;^{12,28} however, until recently^{1,17,43,56} it attracted no attention of specialists in singlet oxygen photophysics. From relation (16) it follows^{12,28} that the ratio of the rate constants for oxygen–solvent collision induced transitions,

$$\begin{aligned} \frac{k_{a-X}}{k_{b-a}} &= \frac{\omega_{a-X}^3 D_{a-X}^2 g_X g_b}{\omega_{b-a} D_{b-a}^2 g_a^2} = \frac{3\omega_{a-X}^3 |c|^2}{4\omega_{b-a}^3} = \\ &= \frac{3(7882 \text{ cm}^{-1})^3 |0.0134i|^2}{4(5239 \text{ cm}^{-1})^3} = 0.00045 \end{aligned} \quad (17)$$

(ω is the transition frequency) should be constant for any solvent, because collisions do not affect mixing of the states (10) and (11) due to SOC. Here, we accounted for equality

$$\langle a^1\Delta_g | D | b^1\Sigma_g^+ \rangle = D_{a-b} = D_{b-a}$$

and used the statistical weights ($g_X = 3$, $g_a = 2$, $g_b = 1$). The matrix element of SOC (11) in oxygen molecule reaches the maximum possible value; its magnitude is large *per se* and does not need an increase through symmetry reduction upon collision. The latter is necessary for the singlet–singlet transition $a^1\Delta_g-b^1\Sigma_g^+$, which is symmetry-forbidden for isolated O_2 molecule in the dipole approximation; this prohibition is

effectively removed in collision complexes. Thus, the spin prohibition to the $a \rightarrow X$ transition is removed due to the SOC in the O_2 molecule itself. This provides an explanation for an increase in the $a \rightarrow X$ transition probability by three and more orders of magnitude in almost any solvent (in proportion to an increase in the $b \rightarrow a$ transition probability).¹²

Pioneering studies^{12,28} in this field were devoted to explanation of the results obtained by Krasnovsky,⁶³ who investigated the luminescence of singlet oxygen in solutions. These studies attracted the attention of researchers who studied the spectra of O_2 in crystals of noble gases^{51,52} and in buffer gas mixtures.³⁹ Considerable enhancement of the $b \rightarrow a$ and $a \rightarrow X$ transitions was found for oxygen present in Ne, Ar, Kr and Xe matrices. The intensity increased with an increase in the atomic number of the noble gas.^{51,52} Gas-phase experiments gave the following values of the ratio (17): 0.00032 (Ne), 0.00037 (Ar), 0.00042 (Kr) and 0.00083 (Xe).³⁹ (The last value for Xe can be easily explained by additional enhancement of the singlet–triplet transition $a \rightarrow X$ due to the effect of the external heavy atom.^{25,98}) Similar values of the ratio (17) confirmed predictions of theoretical studies^{12,27,28,98} while a slight increase in this ratio with the noble gas atomic number was explained by the strengthening of the SOC and by the effect of the external heavy atom.^{24,25}

The ratio of the statistical weights of all states (17) was taken to be unity,⁸⁸ because the collision model chosen assumed only one sublevel of the a and X states is active in transitions. Indeed, only the sublevel (10) of the $X^3\Sigma^-$ state with the quantum number $M_S = 0$ is involved in the formation of the intensity of collision-induced transition $a \rightarrow X$ through ‘mixing’ with the $b^1\Sigma_g^+$ state and stealing of the dipole moment of the Noxon transition [see Eqn (16)]. Both components of the degenerate state $a^1\Delta_g$ can participate in the Noxon band enhancement [see Eqns (13) and (14)]; however, the total intensity corresponds to involvement of only one component (at least for most calculated models for complexes).^{12,27,87,88} Therefore, for the $b \rightarrow a$ transition the statistical weights of the states participating in the transition are equal to unity. Irrespective of the type of the system (gas or solution) and $O_2(a^1\Delta_g)$ generation procedure (gas discharge or sensitisation) both components of the Δ_g state are populated before light emission. Therefore, the statistical weight ratio of the lower-to-upper term for the $a \rightarrow X$ collision-induced transition is 1:2. Thus, the actual ratio of these quantities in relation (17) is 1/2 rather than 3/4 and theory predicts⁸⁸ that

$$\frac{k_{a-X}}{k_{b-a}} = \frac{\omega_{a-X}^3 D_{a-X}^2}{\omega_{b-a} D_{b-a}^2 g_a} = \frac{\omega_{a-X}^3 |c|^2}{2\omega_{b-a}^3} = 0.0003, \quad (17a)$$

which corresponds to the results of measurements in gases,³⁹ solutions^{1,17,64,106} and cryogenic matrices.⁵¹

Analysis of the electronic emission spectrum of NCl molecule in Ar matrix⁶⁸ gave a clear substantiation of the theoretical model (9)–(14), (16). This molecule is a valence-isoelectronic analogue of oxygen molecule; it has a triplet ground state $X^3\Sigma^-$ and the same set of excited singlet states, $a^1\Delta$ and $b^1\Sigma^+$, as the O_2 molecule.⁹ Nitrogen chloride molecule only possesses no inversion symmetry; therefore, electric dipole transitions $b \rightarrow X$ and $a \rightarrow X$ with inclusion of the SOC are allowed.^{12,42} In particular, the $a \rightarrow X,1$ transition is allowed for the sublevels with $M_S = \pm 1$, while transition to the $M_S = 0$ sublevel is forbidden, as well as the corresponding magnetic dipole transitions of free oxygen molecule.¹² The scheme of the $b \rightarrow a$ and $a \rightarrow X$ transition enhancement for the complex with Ar atom in an inert matrix is the same as that proposed for the O_2 collision complexes considered above [see Eqns (9)–(14)]. Only transition to the sublevel with $M_S = 0$ is enhanced, as

follows from relation (16). The NCl molecule is convenient in that the zero-field splitting for sublevels of the $X^3\Sigma^-$ state is clearly seen⁶⁸ in the $a \rightarrow X$ emission spectrum. In addition to the allowed transition $a \rightarrow X,1$ the spectrum of NCl in Ar matrix (1091.2 nm) exhibits a weak band of the $a \rightarrow X,0$ transition (1090.7 nm), which is strictly forbidden for free molecule.⁶⁸ The change in the intensity of this band obeys relation (16) with the coefficient $c = 0.026$ for the NCl molecule (obtained by the author of this review from configurational interaction calculations with inclusion of SOC and with allowance for the measured probability of the $b \rightarrow a$ transition in the Ar matrix).⁶⁸

The intensities of the $a \rightarrow X,0$ transitions of isovalent molecules NBr and NI in solid argon are also in agreement with the model (16). Analysis of the relative intensities in the fine structure of the $a^1\Delta \rightarrow X^3\Sigma^-$ bands of the isoelectronic molecules NCl, NBr and NI in solid argon⁶⁸ confirmed the validity of the intensity borrowing theory for this band [see Eqns (8)–(13)], considered taking oxygen as an example. These data, which were obtained long before the results of direct intensity measurements for the $b \rightarrow a$ and $a \rightarrow X$ transitions of oxygen in solutions,^{17,64} provided strong arguments in favour of correctness of the model (8)–(13), (17a). However, for a decade did these data remain uncalled by researchers who studied photophysics of the singlet state of oxygen in organic and biological systems.^{43,61–64}

In the late 1990s Schmidt *et al.*,^{1,64} and Ogilby¹⁷ carried out direct experimental evaluation of theoretical predictions made using relation (17) for certain solutions. For liquid CCl_4 at room temperature the ratio of the rate constants $k_{a-X} = 1.1 \text{ s}^{-1}$ and $k_{b-a} = 3400 \text{ s}^{-1}$ is 0.000325, which is similar to the value 0.00317 obtained in the argon matrix ($k_{a-X} = 0.013 \text{ s}^{-1}$ and $k_{b-a} = 41 \text{ s}^{-1}$ at 5 K).^{1,51,64,106} In spite of large differences between the rate constants, the ratio (17a) also remains constant for some other solutions.^{17,64} This ratio was measured⁸² for the absorption of singlet and triplet oxygen molecules in deuterated water, where $O_2(a^1\Delta_g)$ has a relatively long lifetime. In all cases including homogeneous mixtures of solvents the $a \rightarrow X$ and $b \rightarrow a$ transition probabilities changed in parallel, as predicted by theory.^{12,27}

Knowledge of the enhancement mechanism of the radiating capacity of singlet oxygen is crucially important for progress in photobiology and medicine. Detection of $O_2(a^1\Delta_g)$ in various biological media is difficult owing to weak intensity and low temporal resolution of the $a \rightarrow X$ phosphorescence signals [this is determined by the radiative rate constant that strongly depends on the structure of (i) biopolymers in the oxygen environment and (ii) entire solution]. Singlet oxygen plays an important role in photobiological processes and photodynamic therapy;^{1,17,18} therefore, one can expect that *in vivo* detection of $O_2(a^1\Delta_g)$ will become a tool of medical practice in the near future. The widely used procedure for $O_2(a^1\Delta_g)$ detection with cryogenic germanium diodes is still far from meeting these requirements. The use of modern photomultipliers for the near IR region (sensitivity of these devices at 1270 nm is ten times higher than that of germanium diodes) allowed the lifetime of $O_2(a^1\Delta_g)$ to be measured ($\tau_\Delta = 40 \text{ ns}$, $Q_\Delta = 0.005$) *in vivo* in rat liver studies.¹ Biological media are highly inhomogeneous and the observed lifetime of singlet oxygen is the average result of various quenching processes. Note that the τ_Δ values are many orders of magnitude smaller than the radiative lifetimes τ_Δ^r determined from the rate constants $k_{a-X} = 1/\tau_\Delta^r$. However, understanding of the mechanisms of intermolecular interactions responsible for the τ_Δ^r values is at least equally important for progress in theory and strategy of $O_2(a^1\Delta_g)$ detection compared to the understanding of quenching mechanisms.

As mentioned above, the rate constant k_{a-X} increases in proportion to the increase in the rate constant k_{b-a} upon

collision of O₂ with the solvent molecule M.[†] The latter constant depends on the difference between the induced dipole moments of two degenerate MOs, $\pi_{g,x}$ and $\pi_{g,y}$ [see Eqn (13)] and, hence, on the polarisability of the solvent molecule α_s . Such an asymmetry of charge transfer to these orbitals of oxygen molecule appears in the case of a ‘planar’ collision, where the O₂ and M molecules lie in the same plane or where the atomic orbitals of the nearest atoms in the O₂ and M molecules overlap to the greatest extent and share the nodal plane. Deviation from this ‘planar’ structure causes mutual cancellation of both terms in relationship (13), but this is accompanied by an increase in the summands in expression (14). All summands in Eqns (13) and (14) depend on the overlap of the O₂ and M molecular orbitals and on the orbital mixing. Intermolecular interaction responsible for an increase in the rate constant k_{a-X} is essentially dispersion interaction,^{12,88} and depends on R^{-6} . The polarisability of the solvent molecule can be expressed through molar refraction:⁶⁴

$$R_m = \frac{4\pi}{3} N_A \alpha_s,$$

where N_A is the Avogadro constant.

If the interaction responsible for acceleration of the $a \rightarrow X$ transition is bimolecular in character, the second-order rate constant

$$k_{a-X}^c = \frac{k_{a-X}}{[S]} \quad (18)$$

should be related to the molar refraction ($[S]$ is the molar concentration of solvent). Actually, linear correlations between $\log k_{a-X}^c$ and $\log R_m$ were observed for a large number of solutions.⁶⁴ The radiative rate constants for $a \rightarrow X$ phosphorescence corresponding to neat liquids are listed in Table 1. The k_{a-X} vary over a wide range from 0.209 s⁻¹ for water to 3.14 s⁻¹ for CS₂.

The first-order rate constants k_{a-X} were calculated assuming^{12,27} that the whole solvent is represented by the nearest collision-partner and the lifetime of such a complex in the solvation shell is sufficiently long to determine the rate constant.

The effect of solvent was also included in other models.^{12,27,54,71,85,86,99} For instance, a loosely bound collision complex O₂ + M was placed in a solvent cavity; the solvent was treated as dielectric continuum (semi-continuum model).⁷¹ Short-range interactions in the O₂ + M pair are fundamentally important for the description of quantum exchange and dispersion interactions responsible for the enhancement of quantum transitions and shifts of energy levels. The semi-continuum model allows for small additional corrections to transition energies, which leads to better agreement between experimental data and results of bathochromic shift calculations[‡] for the $a \rightarrow X$ transition band in solutions; however, the effect of continuum on the emission intensity is negligible.^{54,71} The 0–0 transition band in the gas phase (7882 cm⁻¹, see Ref. 9) is slightly shifted in trifluoroacetic acid (7873 cm⁻¹), the shift being more pronounced in other solvents (e.g., CH₂I₂: 7824 cm⁻¹).¹ A bathochromic shift of the $a \rightarrow X$ transition band within 100 cm⁻¹ was predicted in the first calculations of O₂ + M complexes with M = H₂, C₂H₄, C₆H₆, C₁₀H₈.^{12,103} *Ab initio* calculations⁷¹ gave a 45 cm⁻¹ shift (see Table 3 in Ref. 71) for the 0–0 band of the $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ transition of oxygen in benzene, which is in agreement with experimental

Table 1. Radiative rate constants for singlet–triplet transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ of oxygen molecule in different solvents.^{17,64,76,74,104}

Solvent	k_{a-X}/s^{-1}	$k_{a-X}^c/\text{litre mol}^{-1} \text{s}^{-1}$

data.^{1,54} The calculated dependence of the bathochromic shift of the $a \rightarrow X$ transition band in the collision complex O₂ + Ar on the interparticle distance was reported;⁹⁸ the shift is very small ($\Delta\nu = 2.1 \text{ cm}^{-1}$) near the potential curve minimum ($R = 3.6 \text{ \AA}$) and rapidly increases as R decreases. At $R = 3.25$ and 3 \AA , where the repulsive potential considerably increases, one gets $\Delta\nu = 13.2$ and 39 cm^{-1} , respectively. The continuum model of self-consistent reactive field of the solvent gives poorer results.⁷¹ This model ignores the overlap and orbital mixing between the collision partners, which precludes correct calculations of not only enhancement of the radiating capacity of the $a \rightarrow X$ transition, but also the solvatochromic shift.

Knowledge of the enhancement mechanism of singlet oxygen radiating capacity is also basic to understanding of the nature of solvatochromic shift of the $a-X$ band. In all solutions studied the maximum of the 0–0 phosphorescence band of O₂ (7882.4 cm⁻¹) is shifted by 20–50 cm⁻¹ towards the long-wavelength region, the shift increasing with the solvent polarisability.

Taking into account the fact that the major contribution to the shift of energy levels comes from dispersion interaction, Schmidt^{1,35} proposed a theory of solvatochromic shift of the $a-X$ band. The theory assumes that the shift of the maximum of the 0–0 band ($\Delta\nu$) depends on the polarisability difference between the $a^1\Delta_g$ and $X^3\Sigma_g^-$ states (*i.e.*, on α_Δ and α_Σ)

$$\Delta\nu = -\frac{3\alpha_s}{2d_c^6} \left(\frac{\alpha_\Delta I_\Delta I_s}{I_\Delta + I_s} - \frac{\alpha_\Sigma I_\Sigma I_s}{I_\Sigma + I_s} \right),$$

where I_Σ , I_Δ and I_s are the ionisation potentials of the O₂ and solvent molecules, $d_c = (d_\Sigma + d_s)/2$ is the distance between spherical molecules, d_s is determined from the molar volume of

[†] Notations: M is the solvent molecule involved in the collision complexes and S are other solvent molecules.

[‡] Shift towards long-wavelength region.

the solvent and d_Σ is determined from the van der Waals volume of the O_2 molecule. The solvent polarisability

$$\alpha_s = \frac{3R_m}{4\pi N_A}$$

was determined through the refraction

$$R_m = V_m P_n,$$

where V_m is the molar volume of the solvent,

$$P_n = \frac{n^2 - 1}{n^2 + 2},$$

(n is the refractive index). To explain the bathochromic shift of the $a-X$ band, Schmidt assumed³⁵ that $\alpha_\Delta > \alpha_\Sigma$, as is the case for the excited-state and ground-state polarisabilities. However, the characteristics of the open-shell oxygen molecule [see Eqns (1)–(3)] and the paramagnetic ground state are basically different from those of conventional diamagnetic molecules with closed shells in the ground state. This also concerns the polarisability tensor. For instance, the diagonal elements of this tensor for the x axis are defined as follows:

$$\alpha_{xx} = \sum_n \frac{\langle 0|ex|n\rangle\langle n|ex|0\rangle}{E_n - E_0}, \quad (18a)$$

where ex is the projection of the dipole moment on the x axis; $|n\rangle$ and E_n are respectively the wave function and energy of the n th excited state; the case $|n\rangle = 0$ (not included in the sum) corresponds to the ground state for which the tensor is calculated.¹³ Expressions for other components of the tensor are similar. The excited-state polarisability of a conventional organic molecule should be higher than that of the singlet ground-state, because the energies of transitions between excited states are always lower than the energy of excitation from the closed shell at a sufficiently large number of intense transitions in both cases.

Schmidt's assumption³⁵ $\alpha_\Delta > \alpha_\Sigma$ was rejected based on the results of *ab initio* calculations of O_2 molecule (see Refs 40, 53 and 93), which also cast some doubt⁵³ on his theory of red solvatochromic shift of the $a-X$ band. At all values of the internuclear distance in the O_2 molecule, the polarisability in the $a^1\Delta_g$ state is lower than in the $X^3\Sigma_g^-$ state,⁹⁸ which contradicts the Schmidt hypothesis. Thus, even averaging over vibrational states does not change the conclusion, namely, $\alpha_\Delta < \alpha_\Sigma$. This result can be explained as follows. The polarisability α_Σ of the triplet ground state is mainly determined by the electric dipole moment of the Schumann–Runge transition (D_{SR}^2 , divided by the transition energy), whereas that of the singlet state $a^1\Delta_g$ is determined by the electric dipole moment of the $a^1\Delta_g - ^1\Delta_u$ transition, which is much smaller than D_{SR} (Schumann–Runge transition energy is also lower, especially at $r > 1.23$ Å).^{30, 66} Here the case in point are the components of the tensor α_{zz} , since these transitions are polarised along the molecular axis. It is these transitions that make the major contributions to the average polarisability

$$\alpha_{cp} = \frac{2\alpha_{xx} + \alpha_{zz}}{3}.$$

The perpendicular component is determined by the dipole moments of transitions to the $^1,^3\Pi_u$ states, which are nearly equal for the triplet and singlet transitions. The α_{xx} and α_{zz} values we have obtained are respectively 8.16 and 15.48 a_0^3 for the $X^3\Sigma_g^-$ state and 8.15 and 14.12 a_0^3 , respectively, for the singlet state $a^1\Delta_g$. Here $\alpha_{cp} = 10.6 a_0^3$ for $X^3\Sigma_g^-$ and $\alpha_{cp} = 10.14 a_0^3$ for $a^1\Delta_g$, $\alpha_\Delta - \alpha_\Sigma = -0.46 a_0^3$.

The relation $\alpha_\Delta < \alpha_\Sigma$ is valid for free O_2 molecule in vacuum,⁵³ but will it hold for oxygen in solution? To clarify the issue, we carried out polarisability calculations for collision complexes of O_2 with diamagnetic molecules.⁹⁸ As an example we will consider a collision complex $O_2 + He$, where the He atom serves a model for a simplest closed-shell species.⁹⁸ In this case the average polarisabilities of the triplet and singlet states somewhat increase to $\alpha_{cp} = 11.72 a_0^3$ for $X^3\Sigma_g^-$, $\alpha_{cp} = 12.69 a_0^3$ for $a^1\Delta_g$, i.e., $\alpha_\Delta > \alpha_\Sigma$. The reason consists in the appearance of additional contribution to polarisability due to the induced $a-b$ -transition [see Eqns (13) and (14)] and the contributions of charge transfer transitions for the $a^1\Delta_g$ state. The charge transfer transitions are more intense for the $a^1\Delta_g$ state rather than $X^3\Sigma_g^-$ ground state.^{12, 27, 70} The singlet and triplet charge transfer states are almost degenerate;²⁷ therefore, the energies of the charge transfer transitions from the singlet state $a^1\Delta_g$ are nearly 1 eV lower than those of similar transitions from the triplet ground state $X^3\Sigma_g^-$. The mixing coefficients of the triplet and singlet ground-state wave function (2) with the wave functions of the charge transfer states due to configurational interaction are noticeably larger for the $a^1\Delta_g$ state than for the $X^3\Sigma_g^-$ state,^{12, 27} which predetermines higher intensities of dipole transitions and their greater contribution to polarisability.⁹⁸ The calculated polarisability difference

$$\alpha_\Delta - \alpha_\Sigma = 0.97 a_0^3$$

is in qualitative agreement with the predicted value.³⁵ Using the results of such calculations, one can explain the red solvatochromic shift of the $a-X$ transition band in the framework of the Schmidt theory.

Thermal motion of molecules in solutions is reduced to random jumpwise translational motions from one metastable position to another. O_2 -Type gas molecules are known to exist in solutions in cavities, with rather long lifetimes that are much longer than the jump time. An important contribution to stimulation of the radiative transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ of oxygen molecule comes from asymmetrical intermolecular vibrations in those cavities that are included in modelling as the effect of nearest neighbours only. The inclusion of a few solvent molecules in the nearest solvation shell leads to non-additive enhancement of the $a \rightarrow X$ transition.⁹⁸ Model ternary complexes $O_2 + C_2H_4 + H_2$ were calculated¹⁰⁰ at different collision geometries and co-operative effects of a complex solvation shell on the intensities of the $b \rightarrow a$ and $a \rightarrow X$ transition bands were studied in detail. It was shown that both an increase and a decrease in the probability of the radiative transition $a \rightarrow X$ are possible depending on the mutual position of the collision partners. By and large, calculations^{98, 100} revealed the possibility of co-operative effect of a few solvent molecules on the moment of the $a \rightarrow X$ transition, which explains a large enhancement of singlet oxygen emission in solution compared to that observed in the gas phase.

Fink *et al.*³⁹ studied the intensity of the Noxon band in the microwave discharge spectra of O_2 mixtures with noble and other gases at a reduced pressure. Using a FT IR spectrometer, they obtained a high resolution for the $b \rightarrow a$ transition band at 1.91 μm and found that raising the pressure causes the appearance of a continuum against the background of discrete lines of rotational branches of the $b^1\Sigma_g^+ \rightarrow a^1\Delta_g$ quadrupole transition. The discrete spectrum was assigned³⁹ to unperturbed $O_2(b^1\Sigma_g^+)$ molecule, while the continuum was attributed to collision-induced emission. Metastable molecules $O_2(b^1\Sigma_g^+)$ generated in discharge also give rise to an emission band $b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-$ the intensity of which depends only slightly on collisions.³⁹ This follows from the old semiempirical theory^{12, 25} and is confirmed by *ab initio* calculations,⁸⁷ namely, with allowance for the SOC [see Eqns (9) and (10)] the electric dipole moment of the $b \rightarrow X$ transition is proportional to the dipole moment

Table 2. Radiative rate constants for singlet–singlet transition $b^1\Sigma_g^+ \rightarrow a^1\Delta_g$ of O_2 molecule induced by collisions with various buffer gas molecules.³⁹

Buffer gas	k_{b-a}^c /litre mol ⁻¹ s ⁻¹	R_m /ml mol ⁻¹
He	≤ 0.6	—
Ne	~ 0.6	1.00
N ₂	7.8	4.34
O ₂	9.0	4.00
Ar	10.2	4.13
Kr	21.6	6.22
Xe	46.8	10.10
SF ₆	26.4	11.34
SO ₂	31.8	9.71
PCl ₃	252.0	25.0

Note. Bimolecular constants k_{a-X}^c were determined from the integral intensity ratio of discrete lines and broad bands corresponding to collision-induced transitions. The rate constant for the $b^1\Sigma_g^+ \rightarrow a^1\Delta_g$ transition of free O_2 molecule was taken to be $k_{b-a} = 0.0014$ s⁻¹ (Ref. 39).

difference between the $b^1\Sigma_g^+$ and $X^3\Sigma_g^-$ states. For some calculated collision complexes this difference is negligible and no $b \rightarrow X$ transition enhancement is observed.

Once measured the intensity ratios of the $b \rightarrow X$ and $b \rightarrow a$ transition bands as functions of pressure of various gases, the second-order rate constants for collision-induced singlet–singlet transition $b \rightarrow a$ (Table 2) were determined.³⁹ For neon, one has $k_{b-a}^c = 0.9 \times 10^{-21}$ cm³ s⁻¹, whereas for PCl₃ this rate constant increases by a factor of 467 ($k_{b-a}^c = 42 \times 10^{-20}$ cm³ s⁻¹).³⁹ In Table 2 the rate constants taken from Ref. 39 are given per mole in order to compare with the results of measurements in solutions.¹ The rate constants for quenching of excited $O_2(b^1\Sigma_g^+)$ molecules are 2–3 orders of magnitude higher than the radiative rate constants in the gas phase.^{1,39} In the condensed phase quenching is even more efficient; therefore, luminescence measurements for the $b \rightarrow a$ transition in solutions are difficult.^{1,17,58,64} Chou and Frei⁵⁸ first discovered this emission in CCl₄ solution using triplet benzophenone as sensitizer of the $O_2(b^1\Sigma_g^+)$ state. This result could not be reproduced for long.¹⁰⁶ Taking into account the low rate constant for the Noxon band in free O_2 molecule ($k_{b-a} = 1.4 \times 10^{-3}$ s⁻¹), the observation of a narrow band at 1.92 μ m indicated⁵⁸ a giant enhancement of the $b \rightarrow a$ transition in solution. According to Schmidt *et al.*,^{1,106} the quantum yield of luminescence for the $b \rightarrow a$ transition in CCl₄ solution is 0.00045. Using the observed lifetime of $O_2(b^1\Sigma_g^+)$ molecules, he determined the radiative rate constant for the Noxon band in CCl₄ solution ($k_{b-a} = 3.45 \times 10^3$ s⁻¹); this is six orders of magnitude higher than the rate constant for free O_2 molecule. The calculated moment of the $b \rightarrow a$ transition in the collision complex $O_2 + CCl_4$ depends strongly on the intermolecular distance, being almost independent of collision angles.¹² The average value of R is governed by the molecular velocity in the vicinity of the nearest solvation shell. Assuming that $R_{av} = 2.87$ Å at room temperature, one can obtain the observed enhancement of the $b \rightarrow a$ transition. Tetrachloromethane is not a ‘champion’ with respect to enhancement of the $a \rightarrow X$ and $b \rightarrow a$ transitions in solutions, as follows from calculations^{12,24–28,85–88,98–100} and from the data listed in Table 1.

3. Inclusion of vibrations and vibronic interactions

Enhancement of forbidden transitions in oxygen molecule trapped in a low-temperature inert gas matrix is much less pronounced.^{98–123} Taking into account the symmetry of the nearest environment of an impurity O_2 -centre in the crystal

lattice, one can conclude that the $b \rightarrow a$ transition remains forbidden ignoring lattice vibrations.^{113,123} Transitions become allowed only when assisted by electron–phonon interactions.¹²³ In argon matrix at 5 K, the $b \rightarrow a$ transition is characterised by a radiative lifetime of 24.5 ms, or a rate constant $k_{b-a} = 41$ s⁻¹ (Refs 51 and 52), which is nearly two orders of magnitude lower than in CCl₄ solution. In this matrix the electric dipole moment of the $b \rightarrow a$ transition is induced by each neighbouring argon atom, in the direction from O_2 towards Ar, so the resultant moment of the transition is zero. Thus, enhancement of the $b \rightarrow a$ transition can be due to asymmetrical lattice vibrations. With allowance for nuclear displacements

$$q = R - R_0$$

from the equilibrium position R_0 (change in the intermolecular distance) in the adiabatic approximation, the dipole moment of a vibronic transition $a \rightarrow X$ can be written in the form¹¹³

$$\langle a^1\Delta_g\chi_0 | D | \Psi_{X,0}\chi_v \rangle = -c \left(\frac{\partial D_{b-a}}{\partial q} \right)_{R_0} \langle \chi_0 | q | \chi_v \rangle, \quad (19)$$

where χ_0 and χ_v are the vibrational functions with quantum numbers 0 and v , respectively; for the coefficient c , see Eqn (11). By analogy, for the $b \rightarrow a$ transition one gets

$$\langle b^1\Sigma_g^+\chi_0 | D | a^1\Delta_g\chi_v \rangle = \left(\frac{\partial D_{b-a}}{\partial q} \right)_{R_0} \langle \chi_0 | q | \chi_v \rangle.$$

The equilibrium positions and vibrational functions for the states b , a and X are thought to be the same, which is quite realistic.^{9,98} For many models the calculated moment of the D_{b-a} transition depends strongly on q near the equilibrium complex $O_2 + M$.^{12,98,99,113} The radiative rate constants for the $a \rightarrow X$ and $b \rightarrow a$ transitions determined with allowance for asymmetrical vibrations in the octahedral model of impurity centre $O_2 \cdot Ar_6$ are similar to the observed ones.^{12,51,98}

The 0–0-bands of the $a \rightarrow X$, $b \rightarrow a$ and $b \rightarrow X$ transitions are the most intense because the potential curves for these states are characterised by nearly equal equilibrium distances (see Fig. 1). The Franck–Condon (FC) factors for these bands approach unity, whereas for vibronic overtones they are negligible. For O_2 in the gas phase, even the 0–1 bands have low intensities. In addition to the FC factors, here the dependence of the transition moment on the interatomic distance r should also be taken into account. The magnetic moment of the transition [see expression (12)] rapidly increases with the distance r , because the energy difference in the denominator of Eqn (11) decreases to zero in the limit $r \rightarrow \infty$. The Einstein coefficients for spontaneous emission of this transition determined by integration over r for the magnetic moment of the $b \rightarrow X$ transition of O_2 molecule are equal to 0.0047, 0.0064 and 0.0003 s⁻¹ for the 0–1, 1–0 and 2–0 bands, respectively.⁵⁰ These values are similar to measured ones⁹ and their ratios differ from the FC factor ratios.

Deviations from the FC effects were also obtained for the $a \rightarrow X$ transition.^{12,86} In addition to the 0–0-band of the $a \rightarrow X$ transition (1.27 μ m), Chou and Khan¹¹⁴ found a new, very weak emission band near 1.4 μ m in spectra of chlorine-containing organic solvents ($C_2H_4Cl_2$, $C_3H_5Cl_3$, *etc.*). The band is red-shifted relative to the 0–0-band, the shift being equal to the C–Cl vibrational frequency. Similar weak bands were also detected for other halogen-containing solutions.¹¹⁴ They correspond to the $a \rightarrow X$ transition of O_2 and simultaneous vibrational excitation of the solvent molecule.

Understanding of the nature of these co-operative vibronic transitions is of fundamental importance for theory of singlet state ($a^1\Delta_g$) of oxygen in solutions. Having included these transitions, one can obtain direct substantiation of relations

(11) and (16) and the bimolecular model for oxygen complex with solvent as the primary source of stimulation of emission of the forbidden transition $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ (Ref. 113).

A model for the complex of O_2 with CH_3Cl used in calculations¹¹³ of the transition moment D_{b-a} and its derivative [see Eqn (19)] is shown in Fig. 4. The dipole moment of co-operative vibronic transition $a \rightarrow X$ with simultaneous vibrational excitation of the C–Cl bond in CH_3Cl molecule can be calculated using expression (19) and the standard integral

$$\langle \chi_0 | q | \chi_{v=1} \rangle = \sqrt{\frac{\hbar}{2\mu\omega}},$$

where μ is the reduced mass and ω is the vibration frequency.

Figure 4. Structure of a collision complex $O_2 + CH_3Cl$. C–Cl vibration modulates the intermolecular distance in the equilibrium complex.

Vibrations of the C–Cl bond in the equilibrium complex modulate the intermolecular distance, which in turn strongly affects the moment of the $a \rightarrow X$ electronic transition, induced by intermolecular interactions. The dipole moment of co-operative vibronic transition [see Eqn (19)] was estimated to be equal to 1.42×10^{-5} e Å.¹¹³ This leads to a radiative rate constant of 0.0056 s⁻¹, which is nearly 100 times lower than typical rate constants for the $a \rightarrow X$ transition of the O_2 molecule in related solvents (see Table 1). This estimate is in good agreement with the results reported by Chou and Khan:¹¹⁴ the new emission band is about 100 times less intense than the 0–0-band of the $a \rightarrow X$ transition.

Absorption of thermal IR radiation by homonuclear molecules O_2 and N_2 is strictly forbidden by selection rules. However, weak absorption of IR radiation by air at 6.4 μ m is known. Theory of intensity of vibrational transitions is intimately connected with the theory of enhancement of absorption bands of oxygen in electronic spectra. Geometry optimisation of $O_2 + Ar$ complexes allowed the shifts of the IR bands in different excited states of the O_2 molecule and the corresponding band intensities to be calculated. Of particular importance is the theoretical prediction,⁹⁸ according to which intermolecular interaction affects the $O_2(^5\Pi_g)$ metastable state and its IR absorption spectrum. This state is formed upon recombination of $O(^3P)$ atoms in atmosphere and corresponds to a loosely bound complex or a biradical pair $O(^3P)\cdots O(^3P)$ with a long internuclear distance (2.2 Å). The bond energy (0.12 eV) and vibrational frequency (113 cm⁻¹) of this species are unexpectedly low for diatomic molecule.⁹⁸ Recently,⁹⁴ this associate was detected by the quintet–quintet transition to the ion-pair state. According to calculations of the complex $O_2 + Ar$, it is the $^5\Pi_g$ state that is characterised by the greatest enhancement of IR absorption.⁹⁸ Loosely bound molecules O_2^+ can ‘stick’ to inert gases or aerosol particles, which should manifest itself in the IR spectra. Recombination of $O(^3P)$ atoms also leads to formation of more stable states $^1\Sigma_u^+$, $^3\Delta_u$, $^3\Sigma_u^+$ of O_2^+ molecules; this is accompanied by release of energy and subsequent decomposition of the complex of oxygen with aerosol. Only metastable quintets can readily relax, being at the

same time bound to the third particle (aerosol). Check-up of these predictions seems to be important for remote control in atmospheric photochemistry.

4. Optical effects stimulated by collisions of oxygen and organic dye molecules

Among numerous optical effects,^{1,2} we will consider the enhancement of absorption intensity upon $S_0 \rightarrow T_1$ transition of dye, quenching of dye luminescence and a number of co-operative transitions.^{27, 69–71, 73–88, 98–122} Organic dye molecules typically contain an extended π -conjugation chain and readily excitable π -electrons and have low triplet-state energies and high polarisabilities.^{2, 7} Therefore, the effects of intermolecular interaction manifest themselves most pronouncedly when they influence the optical properties of both oxygen and dye molecules. A collision between excited dye molecule and $O_2(^3\Sigma_g^-)$ produces a short-lived collision complex with a nearly zero equilibrium constant.^{7, 13} Mixing of excited states of the complex and electronic-vibrational relaxation can lead to quenching of fluorescence of the $S_1 \rightarrow S_0$ transition of the dye molecule.^{2, 7, 13}

Here S_0 and S_1 are the ground and excited singlet state of the dye molecule, respectively.

Measurements of the yield of T_1 triplet states of pyrene and anthracene molecules and its perfluoro analogues showed² that quenching of fluorescence proceeds by reaction (20); no energy-transfer products [see Eqn (21)] were detected. It has long been known² that the rate of fluorescence quenching by oxygen varies insignificantly on going from organic molecules [in this case the S_1 – T_1 splitting is such that reaction (21) is exothermic] to molecules for which reaction (21) is highly endothermic. Reaction (22) is spin forbidden. Immediate quenching

is independent of specific features of intermolecular interaction associated with paramagnetism of the oxygen, because there is no need of spin changes in individual molecules; this process should not differ from the quenching by conventional diamagnetic molecules and is therefore of low efficiency. At present, it is commonly accepted that quenching of dye fluorescence by oxygen is mainly due to stimulation of intersystem crossing (ISC) with the transition from the S_1 to the T_1 state.^{1, 2, 13} Theoretical explanation for the high efficiency of ISC (20) is based on quantum chemical calculations of collision complexes.^{27, 70, 71, 103, 109} Now we will give some examples including the results of recent calculations.¹⁰⁷

First, we will consider a collision complex with ethylene as a simplified model. This unsaturated hydrocarbon is not a dye, but has the S_1 - and T_1 -states of the $\pi\pi^*$ -type; calculations of the collision complex of ethylene with oxygen simulate the characteristic features of the intermolecular interaction of O_2 with the π -system. In this model the O_2 molecule is above the ethylene plane at the distance R between the centres of the molecules; the oxygen and carbon atoms form an equilateral trapezoid O–O–C–C similar to that formed by the oxygen and nitrogen atoms in the collision complex $O_2 + N_2$ (see Fig. 3). The complex was calculated¹⁰⁷ using the spin-restricted Hartree–Fock method for open-shell systems with inclusion of configuration interaction in the 6-311G** basis set. The active space of configuration interaction included the most important orbitals of oxygen (from $3\sigma_g$ -MO to vacant

$3\sigma_u$ -MO). Six ethylene orbitals were also included in the CI calculations.¹⁰⁷ The use of extended AO and CI basis sets made it possible to reach¹⁰⁷ a better accuracy compared to that reported earlier,¹⁰⁹ although the models of the complexes were identical.

Comparison of the results obtained by this method (Fig. 5) with the results of calculations of the moments of singlet–singlet transitions¹⁰⁹ showed that extension of the CI basis set leads to enhancement of certain collision-induced transitions. This first of all concerns the 1–4 transition (see Fig. 2), *i.e.*, the co-operative singlet–triplet transition of ethylene with simultaneous excitation of the oxygen $a^1\Delta_g$ state. This transition could be observed in emission as dye phosphorescence whose band is shifted towards the red spectral region by the energy of the $a^1\Delta_g - X^3\Sigma_g^-$ transition.¹⁰⁹ Simultaneously, collisions between oxygen and dye molecules cause quenching of dye phosphorescence; therefore, observation of this co-operative emission is difficult. In principle, it cannot be ruled out that appropriate choice of the dye and the solution concentration will allow one to detect this co-operative emission.

Figure 5. Dipole moments of singlet–singlet transitions (D) induced by collisions between oxygen and ethylene molecules plotted vs. intermolecular distance (R).

Calculations of configuration interaction with the 6-311G** basis set and molecular orbitals using the spin-restricted Hartree–Fock method. Transition (see Fig. 2): 3–1 (1), 1–4 (2), 1–5 (3), 3–2 (4) and 4–5 (5).

The dipole moment of the 1–4 transition rapidly decreases as R increases (see Fig. 5) and becomes the smallest among all dipole moments of the collision induced transitions at $R = 4.2$ Å. It is interesting to compare it with the dipole moment of the 1–5 transition ($a^1\Delta_g - c^1\Sigma_u^-$ transition of oxygen molecule, the frequency of which is similar to the frequency of the Chamberlain band $a^1\Delta_g - A'^3\Delta_u$).⁹⁴ The $a^1\Delta_g - c^1\Sigma_u^-$ transition with intensity strongly enhanced compared to those of the transitions of free oxygen molecule has been revealed in argon matrix;¹⁰⁸ this was explained by strong effect of intermolecular interaction on the electric dipole moment of this transition.^{98, 107, 109} Figure 5 shows that the dipole moment of the 1–5 transition is large even at long intermolecular distances, being the largest among all calculated dipole moments at $R = 4.2$ Å. Enhancement of transitions for oxygen in inert

gas matrix is determined by asymmetrical lattice vibrations relative to O_2 ; it depends on the difference between the distances to nearest neighbours rather than R . Therefore, enhancement of the $a^1\Delta_g - c^1\Sigma_u^-$ transition intensity at long intermolecular distances is of particular importance for explanation of the matrix effect on this transition.¹⁰⁹

Comparison of two transitions, 1–5 and 1–4, shows that the latter becomes more intense at $R < 3.2$ Å (see Fig. 5). It was reported¹⁰⁹ that the dipole moments of the transitions increased not so rapidly, as shown in Fig. 5, as the molecules approached each other. This can be explained by lesser ‘flexibility’ of the 6-31G basis set (see Ref. 97) and poorer inclusion of electron correlation in the configuration interaction method compared to more recent calculations that provide (see Fig. 5) better agreement with experimental data on the radiative lifetimes of emission $c^1\Sigma_u^- \rightarrow a^1\Delta_g$; they also predict a higher probability of the co-operative transition 1–4. This gives grounds to hope that at a sufficiently high concentration of $O_2(a^1\Delta_g)$ in solution this transition can also be detected in absorption.

For the transition $b^1\Sigma_g^+ - a^1\Delta_g$ the component (4) is more active (transition 3–2) than the other quasi-degenerate component (4a) of the $a^1\Delta_g$ state (transition 3–1). This agrees with the results of the simplified analysis of relations (13) and (14) and with Fig. 3. The $b^1\Sigma_g^+ - a^1\Delta_g$ (3–2) transition is relatively intense at long R (3.8–4.2 Å), while at smaller R values the other, shorter-wavelength transitions are enhanced to a much greater extent (see Fig. 5). This is due to an increase in the contributions of charge transfer states to higher-energy terms.¹⁰⁹

Curve 5 in Fig. 5 shows a rapid increase in the probability of the 4–5 transition as the molecules approach each other. This is a co-operative transition from the triplet state to the ground singlet state of ethylene with simultaneous excitation of the oxygen $c^1\Sigma_u^-$ state. At $R = 3$ Å, the dipole moment of this transition is 0.2 D, being commensurable with the dipole moments of the allowed optical transitions.¹³ For many dyes the wavelength of this co-operative transition falls in the visible region; observation of this transition in electric discharge may appear to be useful in studies of the concentration of the $c^1\Sigma_u^-$ states of the oxygen molecule and in the design of new chemical lasers.

The $S_0 - T_1$ transition of ethylene becomes an allowed triplet–triplet transition of the collision complex with oxygen (transition 0–6 in Fig. 2).^{2, 12, 27, 70, 110} Formally, the dipole moment of the transition between the pure configurations, $X^3\Sigma_g^- \times S_0 - X^3\Sigma_g^- \times T_1$, equals to zero; however as configurational interaction causes the triplet states to mix and thus the contributions of charge transfer states and triplet states of the type $X^3\Sigma_g^- \times S_1$ appear, the 0–6 transition is collision induced.^{70, 109} The $S_0 - T_1$ transitions of ethylene were observed upon adding oxygen at high pressure¹¹¹ and in many dye solutions.² The theoretical intensity¹⁰⁹ of the 0–6 transition matches experimental data;¹¹¹ this gives grounds to believe that calculations¹⁰⁹ are suitable for comparative predictions of the probabilities of some other triplet–triplet transitions including co-operative excitations. New intense transitions induced by oxygen–dye collisions were predicted.^{12, 27, 109}

Of particular interest is the singlet–triplet transition 6–7 between two excited states, S_1 and T_1 , of the dye. As the dye molecule contacts the triplet oxygen ($X^3\Sigma_g^-$), this transition not only becomes a dipole-allowed triplet–triplet transition, but also acquires the maximum intensity, which is due to comparatively large contribution of charge transfer states.^{12, 70, 86, 99, 109} Indeed, the S_1 state of the dye has a relatively high energy (1.5–2 eV higher than that of the T_1 state) and stronger mixes with the charge transfer states. In the complex of O_2 with ethylene the dipole moment of the

$X^3\Sigma_g^- \times S_1 - X^3\Sigma_g^- \times T_1$ transition is 0.38 D at an intermolecular distance R of 3.6 Å which is similar to equilibrium one.⁹⁹ Commensurable, although smaller, values were obtained for the O_2 complexes with naphthalene and conventional dyes.¹⁰³ This 'colossal' enhancement of the $S_1 - T_1$ radiative transition, which is forbidden for free dye molecule, provides an explanation for the high rate of quenching of dye fluorescence.²⁷

Analysis of calculations^{99,109} also made it possible to explain the known enhancement of the Herzberg(III) band ($X^3\Sigma_g^- - A'^3\Delta_u$) at high pressure of oxygen or buffer gas and in inert gas matrices.^{9,93,103} High intensity of the Herzberg(III) band and the $c^1\Sigma_u^- - a^1\Delta_g$ transition, as well as co-operative transitions involving the Herzberg state¹⁰⁴ is due to much more efficient mixing of π_u -MOs with the solvent orbitals rather than π_g -orbitals.¹² All features of the interaction between oxygen open shells and solvent molecules are clearly related to enhancement of radiative transitions. Taking account of this fact makes understandable numerous optical effects due to collisions between oxygen and organic dye molecules.^{12,86}

5. Relation between enhancement of radiative transitions and quenching of dye fluorescence

The mechanism of enhancement of collision-induced radiative singlet-triplet transitions of oxygen is intimately related to the acceleration mechanism of non-radiative deactivation of $O_2(a^1\Delta_g)$ (Refs 26, 27, 81) and other quenching processes in the contact complex $O_2 + M$.^{2,13,112-137} Within the framework of the model for dispersion forces the collision induced electric dipole moment of transition of the oxygen molecule can interact with the moments of transitions in solvent. Recall that the dipole-dipole interaction between all virtual transitions in two closely spaced molecules determines the attractive forces acting between them; this interaction is responsible for the dipole-dipole non-radiative energy transfer and (partially) for quenching of singlet oxygen.^{1,2,27,71,115}

An explanation for various types of generation of singlet oxygen due to dipole-dipole energy transfer and CI-calculated transition moments in collision complexes is available.²⁷ Collision-induced dipole moments of $S - T$ -transitions (forbidden in isolated molecules) are mainly due to exchange interaction; therefore, this type of energy transfer can be treated as exchange-resonant one.¹⁰⁷ However, in this case²⁷ its rate should be calculated using the expression for the dipole-dipole interaction between the moments of induced transitions. For instance, quenching of dye fluorescence can be explained by enhancement of non-radiative collision-induced $S_1 - T_1$ -transition with $O_2(X^3\Sigma_g^-)$. Namely, a relatively large dipole moment of the $S_1 - T_1$ -transition (D_{S-T}) induced by collisions between dye and oxygen molecules strongly interacts, by the dipole-dipole mechanism, with the moments of $T_{1,0} - T_{1,v}$ resonant transitions between vibrational sublevels of high-frequency C-H (O-H) vibrations and their overtones of the dye molecule.^{2,27} This also makes understandable the contribution of charge transfer states to the quenching mechanism, because the D_{S-T} strongly depends on them.²⁷ Quenching of T_1 states through energy transfer to singlet oxygen depends on the intensity enhancement of the 0-6 and 1-3 (2-3) transitions and the $a-X$ transition; all of them become dipole-allowed transitions upon collision.²⁷ The applicability of the dipole-dipole mechanism is substantiated by the fact that the distance between the 'emitting' oscillator (induced dipole moment of the $S_1 - T_1$ -transition) and 'absorbing' oscillators (overtones) is noticeably longer than the oscillator size, namely,² both 'dipoles' are at most 0.1 Å long.

The dipole moments of the $S_1 - T_1$ -transitions in the O_2 complexes with ethylene²⁷ and naphthalene,¹⁰³ obtained from MINDO calculations with inclusion of configurational interaction are equal to 0.02 and 0.01 D, respectively, at an

intermolecular distance of 3.2 Å. The D_{S-T} value rapidly increases as the molecules approach each other;^{27,87} however, this is hard to reach in the gas phase under normal pressure. The vector of the dipole D_{S-T} connects the centres of the molecules, being distant from the C-H oscillators. The size and orientations of these oscillators are comparable with analogous parameters of H atom displacements.^{2,86} Theory of non-radiative transitions in the case of non-adiabatic perturbation was considered in Ref. 2. Calculations of the rate of quenching of dye fluorescence by oxygen due to enhancement of non-radiative $S_1 - T_1$ -transition give the rate constants of the order of 10^{13} litre mol⁻¹ s⁻¹, which is much higher than the diffusion constants.²⁷

6. Sensitisation of $O_2(a^1\Delta_g)$ molecule

Singlet oxygen is most often generated using photosensitisation, *i.e.*, energy transfer from excited state of sensitizer to $O_2(^3\Sigma_g^-)$ state. Possible sensitizers include many dyes absorbing visible light, in particular, widely abundant natural compounds, such as chlorophyll, haem, protoporphyrin and other porphyrin derivatives. Therefore, singlet oxygen plays an important role in many photobiological processes.

Excited singlet state of a dye sensitizer (S_1) formed upon absorption of a light quantum is efficiently quenched through oxygen-induced ISC [see Eqn (20)] or due to fast monomolecular transition to the T_1 state. Upon collision with $O_2(^3\Sigma_g^-)$, the long-lived state T_1 generates the quintet, triplet and singlet states of the collision complex. Decomposition of the singlet state into products is spin allowed

Quenching of phosphorescence of tripaflavin adsorbed on silica gel [reaction (23)], was proposed by Kautsky in 1931.^{2,7} Experiments were carried out in a sealed vessel at low concentration of the oxygen added. Quenching was explained by the formation of active oxygen in the singlet state. According to Kautsky's hypothesis, 1O_2 reaches the oppositely lying surface of a silica gel bead containing adsorbed dye and transforms it to the coloured form. This hypothesis was soon forgotten and quenching of the T_1 states of organic molecules was explained by formation of unstable peroxide intermediates (moleoxides).⁷ Only three decades ago Kautsky's ideas were completely substantiated.^{1,2,7} Oxygen efficiently quenches the T_1 states of all organic molecules studied in vapours, liquid solutions, adsorbates and polymers (where diffusion of O_2 is possible).^{1,2} The rate constant for quenching of triplets with oxygen ($k_T^{O_2}$) is about an order of magnitude lower than the rate constant for diffusion (k_d).

Since the quintet, triplet and singlet states of the collision complex are equiprobable, nine collisions on the average produce five quintets, three triplets and one singlet; only in the last-mentioned case reaction (23) is spin-allowed and only in this case singlet oxygen can be generated. Then one has $k_T^{O_2} \leq (1/9)k_d$, which is in agreement with many (not all) experimental data.^{1,2} Complete quenching

can start from the triplet state of the complex;²⁷ it also contributes to $k_T^{O_2}$. Quantum yield measurements confirmed the importance of this quenching channel.¹³¹ Rate constant measurements for quenching of T_1 states of carotenoids gave $k_T^{O_2} \approx 10^9$ litre mol⁻¹ s⁻¹. In this case the formation of $O_2(a^1\Delta_g)$ is impossible, because its energy exceeds that of the T_1 -state,^{1,131} which also points to important role of this channel of complete quenching.

IV. Quenching of the $O_2(a^1\Delta_g)$ molecule

The main mechanism of quenching of singlet oxygen in the gas and liquid phases involves transfer of electronic excitation energy of the $O_2(a^1\Delta_g)$ to the vibrational degree of freedom of the collision partner.^{2, 12, 26, 78, 116–122} In its pure form this mechanism occurs for quenchers with molecules having high oxidation potentials or high energies of triplet-excited states: here the mechanism of charge transfer¹¹⁹ or quenching by transfer of electronic energy to triplet state is impossible.¹ The electronic excitation energy of the $O_2(a^1\Delta_g)$ is transformed to vibrational, rotational or kinetic energy of quencher. Noble gases are the poorest quenchers of singlet oxygen¹ (for argon, the second-order rate constant for quenching is $k_Q^\Delta = 5 \text{ litre mol}^{-1} \text{ s}^{-1}$) because in the gas phase their atoms have no vibrational degrees of freedom and cannot efficiently transform the electronic excitation energy of $O_2(a^1\Delta_g)$ to heat. However such gases as H_2 ($k_Q^\Delta = 2800 \text{ litre mol}^{-1} \text{ s}^{-1}$), NH_3 ($k_Q^\Delta = 2600 \text{ litre mol}^{-1} \text{ s}^{-1}$), C_6H_6 vapour ($k_Q^\Delta = 3200 \text{ litre mol}^{-1} \text{ s}^{-1}$) and water vapour ($k_Q^\Delta = 4900 \text{ litre mol}^{-1} \text{ s}^{-1}$) are the most efficient scavengers.^{1, 118} All hydrides have high-frequency X–H bond vibrations (e.g., $\omega_{\text{sym}} = 2916 \text{ cm}^{-1}$ for CH_4 molecule, $\omega_{\text{asym}} = 3939 \text{ cm}^{-1}$ for H_2O molecule, $\omega_e = 4401 \text{ cm}^{-1}$ for H_2 molecule);^{2, 9} here two or three vibrational quanta are sufficient to absorb the energy of singlet oxygen (7918 cm^{-1}). Molecules containing no C–H or O–H bonds (e.g., CS_2 , CCl_4) are much poorer quenchers of singlet oxygen.^{1, 78}

Initially, lifetime measurements of singlet oxygen in solutions were carried out by indirect chemical methods.^{78, 120–122} By conducting steady-state photo-oxidation of benzofuran in solution with variable concentration of β -carotene, which physically quenches $O_2(a^1\Delta_g)$,¹²² one can determine the product $\tau_\Delta k_Q^\Delta$. Assuming that the rate constant k_Q^Δ for β -carotene is diffusion controlled,¹²⁰ Young *et al.*¹²² determined $\tau_\Delta = 5.5 \text{ }\mu\text{s}$ in methanol.¹²² Later on,^{77, 78, 121} direct lifetime measurements of singlet oxygen in solutions were carried out using pulsed lasers (a greater value was obtained in methanol, $\tau_\Delta = 9.5 \text{ }\mu\text{s}$).^{1, 106} Merkel and Kearns⁷⁸ were the first who noticed significant changes in τ_Δ for different solutions and applied the theory of transfer of the energy of oxygen $a^1\Delta_g$ electronic excitation to solvent vibrations. Later on, these results were repeatedly refined.^{1, 73–77, 101–106, 116–118} According to recent data,^{1, 102} the time τ_Δ varies from $3.1 \text{ }\mu\text{s}$ (H_2O) to 128 ms (CCl_4) and 309 ms ($C_{10}F_{18}$), *i.e.*, within five orders of magnitude.

A number of quantitative theories of $O_2(a^1\Delta_g)$ quenching through transfer of electronic excitation energy to solvent vibrations were put forward.^{1, 26, 78, 116, 118} (This energy transfer is called e–v-deactivation.^{1, 76}) Merkel and Kearns⁷⁸ used the theory of dipole–dipole energy transfer and related τ_Δ to the optical density (OD) of IR absorption of the solvent at the 0–0 and 0–1 vibronic band wavelengths of the $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ transition (1270 and 1592 nm, respectively)

$$\frac{1}{\tau_\Delta} = 0.5(OD_{1270}) + 0.05(OD_{1592}) + \quad (24)$$

+ higher-order corrections.

Rodgers¹¹⁷ measured τ_Δ for a number of solvents and determined the second-order rate constants for quenching of $O_2(a^1\Delta_g)$ by the solvent molecules A ($1/\tau_\Delta = k_{Q,A}^\Delta[A]$); then he measured the τ_Δ values in binary mixtures of solvents A and B and showed the validity of the following equation:

$$\frac{1}{\tau_\Delta} = k_{Q,A}^\Delta[A] + k_{Q,B}^\Delta[B]. \quad (25)$$

The study¹¹⁷ not only appeared to be useful for practical purposes, but also confirmed that quenching of singlet oxygen in the liquid phase is also bimolecular in character. An important contribution of Hurst and Schuster¹¹⁶ consists in thorough choice of solvents. A linear correlation between $1/\tau_\Delta$ and concentration of hydrogen per mole found for a series of aromatic compounds $C_6H_nF_{6-n}$ ($n = 1–5$) made it possible to introduce the second-order rate constants for quenching k_{CH}^Δ per C–H bond (irrespective of the number of fluorine atoms in the molecule). It follows that the quenching ability of the solvent is governed by a certain specific feature of C–H-bonds and that donor–acceptor interactions in these solutions are of no concern (since the fluorobenzenes studied possess the properties of donors). However, this does not mean that the interactions in question are insignificant for quenching of $O_2(a^1\Delta_g)$ in other media (e.g., porphyrin solutions).

The dependences of $1/\tau_\Delta$ on the concentration of C–H bonds and on the OD-containing terms in expression (24) were compared.¹¹⁶ It was found that the dependence on $[CH]$ accounts more correctly for the solvent effect on the quenching rate and that the results of calculations using relation (24) are in poor agreement with experimental values of $1/\tau_\Delta$. Both parameters are interrelated (the higher $[CH]$ the higher OD); however, the optical density of IR absorption explicitly depends on the dipole moment of the transition, so the results¹¹⁶ cast some doubt on the dipole–dipole mechanism of energy transfer. Apparently, the exchange mechanism as well as the dipole–quadrupole one²⁶ also contribute to the quenching through e–v-deactivation.

Hurst and Schuster¹¹⁶ proposed an expression for the second-order rate constant for quenching (k_{XY}^Δ) involving the X–Y bond in the solvent molecule

$$k_{XY}^\Delta = C_\Delta \sum_{mn} F_m F'_n R_{mn}. \quad (26)$$

Here C_Δ is the matrix element of electronic interaction, which includes the type-(11) term and is independent of the solvent; F_m and F'_n are the Franck–Condon factors for the (0– m) vibronic band of the $a \rightarrow X$ transition and for the (0– n) vibrational transition of the X–Y bond, respectively; and the factor R_{mn} characterises the resonance detuning between these two transitions. Table 3 lists a number of rate constants for quenching of singlet oxygen k_{XY}^Δ reported by Hurst and Schuster;¹¹⁶ the data exhibit a large scatter.

Table 3. Second-order rate constants k_{XY}^Δ for quenching of $O_2(a^1\Delta_g)$ involving stretching vibrations of X–Y bonds in the solvent molecule.¹¹⁶

X–Y bond	Wave number / cm^{-1}	k_{XY}^Δ / $\text{litre mol}^{-1} \text{ s}^{-1}$
O–H	3500	2000
O–D	2550	150
C–H	3050	420
C–D	2240	17

Schmidt and Brauer¹¹⁸ studied solvents possessing poor quenching ability, the isotopomer $^{18}O_2$, and improved the Hurst and Schuster theory. For a large number of solvents the measured rate constants for quenching of singlet oxygen are reasonably well described by the relation^{1, 116, 118}

$$k_Q^\Delta = \sum_{XY} N_{XY} k_{XY}^\Delta, \quad (26a)$$

where N_{XY} is the number of X–Y bonds in peripheric regions of the solvent molecule that are accessible to the interaction with molecular oxygen.

Quenching of singlet oxygen can be due to not only the dipole-dipole interaction, but also dipole-quadrupole interactions.^{2,26} The first estimation of the quadrupole moment of the $a-X$ transition showed²⁶ that it is stolen from the quadrupole moment of the spin-allowed $b^1\Sigma_g^+ - a^1\Delta_g$ transition. The stealing mechanism is identical to that described by relation (16) and is due to SOC-induced mixing of the X - and b -states (9) and (10). In addition, the dipole moment operator (D) in relation (16) should be replaced by the quadrupole moment operator (Q). The quadrupole moment of the $a-X$ transition is

$$Q_{a-X} = -cQ_{a-b} = 0.0038 \text{ e } \text{\AA}^2.$$

It contributes negligibly to the radiating capacity¹² but largely to quenching of the $O_2(a^1\Delta_g)$ state through the dipole-quadrupole interaction.²⁶

Collision-induced dipole moment of the $a-X$ transition of oxygen also interacts with the moments of weak overtone IR transitions of solvent and quenches the phosphorescence of O_2 .²⁷ In both cases the rate constant for quenching should depend on the overlap of the emission spectra of singlet oxygen and IR absorption overtones of the solvent. Both predictions are in semiquantitative agreement with the results of indirect measurements $\tau_\Delta^{-2,26,78}$. However, direct (more accurate) measurements of $O_2(a^1\Delta_g)$ lifetime^{116–118} did not confirm this correlation, probably, due to additional (undiscussed) contributions to the quenching mechanism.

As mentioned above, a unique spectral phenomenon, namely, observation of co-operative vibronic emission of singlet oxygen in solutions of halogenated hydrocarbons was explained.^{28,113} The $a-X$ wavelength experienced a bathochromic shift by the energy of the vibrational quantum of the solvent.¹¹⁴ The dipole moment of the $a-X$ transition of oxygen in solution is induced by the collision of O_2 with the solvent molecule (M) and strongly depends on the intermolecular distance (R). Vibrations of the C–Cl bond in the molecule M upon collision of O_2 with the solvent molecule (see Fig. 4) strongly affect the R magnitude and give rise to the derivative of the dipole moment of the $a-X$ transition with respect to R . It is this derivative that determines the probability of co-operative vibronic emission of singlet oxygen accompanied by the bathochromic shift on the C–Cl vibrational frequency.^{28,113} The $a \rightarrow X$ transition of oxygen is accompanied by simultaneous excitation of C–Cl vibrations in the solvent molecule. Calculations of the derivative in Eqn (19) give a correct estimate of the intensity of this synchronised transition in the two molecules.^{28,113} The transition is two orders of magnitude less intense than the $a-X$ transition,²⁸ which agrees with experimental data.¹¹⁴

The theory¹¹³ is important for not only understanding of weak co-operative emission,¹¹⁴ but also explanation of deviations in the rate of $O_2(a^1\Delta_g)$ quenching from the values calculated using the simple theory of inductive-resonant energy transfer to solvent vibrations.^{1,2,26,60,78} The rate of quenching of singlet oxygen is not always related to the overlap integral between the $a \rightarrow X$ emission spectrum and IR absorption spectrum of solvent overtones.^{1,60,78} The frequency of the co-operative vibronic transition differs from the eigenfrequencies of oxygen appearing in Eqn (24), and the moment of this transition efficiently interacts with molecular vibrations of the solvent. In essence, the driving force of energy transfer is reduced to the coupling of the molecular vibrations of the solvent and the motion of electrons in the O_2 molecule with allowance for SOC [see Eqn (11)]. Electronic-vibrational interaction in the contact complex $O_2 + M$ directly relates the electronic wave function of the $O_2(a^1\Delta_g)$ state to the intermolecular and internal vibrations in the molecule M . The intermolecular distance q in expression (19) determines not only the electronic-vibrational contribution to the dipole moment of

the co-operative transition, but also the mixing with the molecular vibrations of the solvent. The intensity of the co-operative transition is very low; however, owing to direct character of energy exchange with the solvent vibrations it can contribute largely to quenching of singlet oxygen. Note that the results obtained using the simple theory of inductive-resonant energy transfer to solvent vibrations show the largest deviation from the experimental data for halogen-containing solvents.²⁶

Yet another important mechanism of quenching of $O_2(a^1\Delta_g)$ is the inclusion of configuration interaction and SOC in the mixing with charge transfer states.¹¹⁵ Unlike the universal mechanism of $e-v$ -deactivation, the charge transfer mechanism manifests itself only for molecules with low oxidation potential ($\leq 1.9 \text{ V vs. s.c.e.}$).¹ It is important to distinguish between this mechanism and actual charge transfer that occurs as the kinetic stage of quenching.^{1,115} We believe that this confusion^{119,121} often occurs in discussing the mechanism of quenching of $O_2(a^1\Delta_g)$. The dependence of the rate constant for quenching ($k_Q^\Delta = 1/\tau_\Delta$) on the ionisation potential (IP) of the quencher was found long ago.^{119–122} Aliphatic amines do not react with $O_2(a^1\Delta_g)$, but efficiently inhibit the oxidation of other compounds possessing high reactivity towards singlet oxygen.^{2,119} Taking into account the increase in $\log k_Q^\Delta$ with a decrease in the amine IP, one can assume¹¹⁹ that the charge transfer configurations (CTC) are mixed with the $a^1\Delta_g$ and $^3\Sigma_g^-$ states and somehow enhance the SOC between them. Explanation for this mechanism (also important for understanding of biochemical activation of oxygen) was reported.¹¹⁵

Now we will write the wave functions of the $a^1\Delta_g$ and $^3\Sigma_g^-$ states in a collision complex with amine molecule in the form^{12,115}

$$^3\Psi_0 = |S_0^3\Sigma_{g,0}^- \rangle = \frac{1}{\sqrt{2}}(|a\bar{a}\pi_x\bar{\pi}_y| - |a\bar{a}\pi_y\bar{\pi}_x|), \quad (27)$$

$$^1\Psi_1 = |S_0^1\Delta_g \rangle = \frac{1}{\sqrt{2}}(|a\bar{a}\pi_x\bar{\pi}_x| - |a\bar{a}\pi_y\bar{\pi}_y|). \quad (28)$$

Here a denotes the highest occupied molecular orbital (HOMO) of the aliphatic amine in the singlet ground state S_0 , i.e., the lone pair orbital of the nitrogen atom. Electrons of inner shells are left out of consideration. Note that the wave function (27) differs from that reported in Ref. 115 in permutation of two MOs and, hence, the sign of the determinant. Charge transfer from amine to the degenerate orbitals, $\pi_{g,x}$ and $\pi_{g,y}$, of the oxygen molecule gives four CTC, namely, two degenerate singlet and two triplet states in the radical pair $\{D^+\cdot O_2^-\}$ produced upon charge transfer (D denotes the electron donor).¹¹⁵ We will consider only those configurations that are important for the explanation of the quenching mechanism,

$$^3\Psi_{ct_y} = |D^+\cdot O_2^-\rangle = \frac{1}{\sqrt{2}}(|\pi_y\bar{a}\pi_x\bar{\pi}_y| - |a\bar{\pi}_y\pi_y\bar{\pi}_x|), \quad (29)$$

$$^1\Psi_{ct_x} = |D^+\cdot O_2^-\rangle = \frac{1}{\sqrt{2}}(|a\bar{\pi}_x\pi_x\bar{\pi}_y| + |\pi_x\bar{a}\pi_y\bar{\pi}_x|). \quad (30)$$

Analysis of intermolecular interaction using the CI method revealed an effective mixing of the triplet configurations (27) and (29) in the collision complex. The singlet states (28) and (30) possess different symmetry with respect to reflection in the O–O–N plane, also being effectively mixed with each other due to CI. Mixing of the second singlet component (4a) with the CTC (30) is impossible. The inclusion of intermolecular interaction in the framework of the CI method gives the $^3\Psi_0 + \varepsilon^3\Psi_{ct_y}$ and $^1\Psi_1 + \delta^1\Psi_{ct_x}$ states which strongly interact

with each other due to SOC.¹¹⁵ The matrix element of the SOC operator between these states includes the integral

$$\varepsilon\delta^* \langle {}^3\Psi_{\text{ct},r} | H_{\text{so}} | {}^1\Psi_{\text{ct},x} \rangle = \frac{\varepsilon\delta^*}{2} \langle \pi_y | B_z | \pi_x \rangle = \frac{\varepsilon\delta^*}{2} \zeta_{\text{O}}, \quad (31)$$

where ε and δ are the admixture coefficients to the $a^1\Delta_{\text{g}}$ and $X^3\Sigma_{\text{g}}^-$ states, respectively.

Relations (27), (29) and (31) include the wave functions of the triplet states with the zero projection of the total spin on the z axis. Comparison with expression (8) shows that the SOC between the CTC (29) and (30) is reduced to the same integral between the degenerate orbitals, $\pi_{\text{g},x}$ and $\pi_{\text{g},y}$, of the oxygen molecule, as that appearing in the matrix element of the SOC between the states (5). Thus, the presence of CTC admixtures always gives rise to the SOC between the $a^1\Delta_{\text{g}}$ and $X^3\Sigma_{\text{g}}^-$ states, which accelerates the non-radiative transition and quenching of singlet oxygen.¹¹⁵ The admixture coefficients ε and δ to the states become significant only for the quencher molecules having low oxidation potentials (≤ 1.9 V v.s. s.c.e.). Otherwise, the CTC energy is too high while the CTC admixture coefficients in Eqn (31) are negligible. According to calculations,^{12, 27, 34, 70, 99, 103} for molecules with ionisation potentials higher than 10.5 eV the ε and δ values are at most 0.01, the integrals (31) being negligible.

Charge transfer configurations (29) and (30) differ in spin and population of the $\pi_{\text{g},x}$ and $\pi_{\text{g},y}$ orbitals. The matrix element of the SOC operator between them can be treated as an electron ‘jump’ from the $\pi_{\text{g},y}$ -MO to the $\pi_{\text{g},x}$ -orbital with a spin flip. This ‘jump’ is identical to rotation of the orbital, *i.e.*, the appearance of an orbital angular momentum or ring current, which induces the magnetic moment interacting with the spin. Since the case in point is the quantum singlet–triplet transition, visual interpretation of this effect is, strictly speaking, inadmissible.¹⁵ However, the simplified ideas of an electron ‘jump’ and orbital rotation are useful in revealing the essence of the mechanism of quenching of singlet oxygen by amines due to admixtures of charge transfer states.

Strengthening of the SOC (to some extent) between the $a^1\Delta_{\text{g}}$ and ${}^3\Sigma_{\text{g}}^-$ states of the O_2 molecule due to CTC contributions always occurs in collision complexes. It is determined by the weight factors of the admixtures ε and δ , which are large only for donor lone electron pairs with low ionisation potential provided a local character of donor–acceptor interaction.¹¹⁵ At present, exact determination of the contributions of different mechanisms to the rate constant for quenching k_{Q}^{A} is impossible owing to the difficulties in the inclusion of vibrational modes of the solvent molecules in the nearest environment of the $\text{O}_2(a^1\Delta_{\text{g}})$ molecule. The concept of admixtures of the charge transfer states [see Eqns (29)–(31)] is fundamentally important for analysis of the mechanisms of biochemical activation of oxygen by oxidases.

V. Biochemical activation of the molecular oxygen

Nearly 100 years ago Academician A N Bach first studied breath from the standpoint of oxygen activation.^{137–139} Based on the concepts of classical chemistry, he assumed the necessity of cleaving a bond in divalent oxygen and release of a chemical valence for addition of other compounds. According to Bach, the corresponding activation energy should be supplied from readily oxidisable unsaturated compounds; O_2 adds to them to give peroxides that degrade under the action of enzymes, and oxygen is transferred to other substrates that are incapable of immediately adding to atmospheric oxygen.¹³⁷ Clearly, at that time it was impossible to allow for specific quantum features of microparticles constituting the molecule, in particular, the spin. The energy of spin-related magnetic interactions is low, however it should be taken into account when studying not only

line splitting in atomic optical spectra and in EPR spectra of radicals,^{13, 38, 46–49, 84, 138, 139} but also the mechanisms of certain chemical reactions.^{12, 37, 140–149} In spite of rapid progress in biochemistry and detailed knowledge of molecular mechanisms of the action of many enzymes, the nature of bio-activation of oxygen is still unclear.^{5, 6, 150, 151} Below we will show that it is the magnetic and exchange spin effects that are often responsible for activation of molecular oxygen by oxidase co-enzymes. The nature of these effects has much in common with the mechanisms considered above when we analysed the photophysical properties of oxygen.

1. Role of spin in chemical reactions involving oxygen

Two unpaired electrons in antibonding π_{g} -MOs are responsible for specific character of the interaction of molecular oxygen with radicals (combustion) and chemically stable diamagnetic compounds (slow oxidation). Two antibonding π_{g} -vacancies make it possible to transform O_2 to O_2^- and O_2^{2-} anions, the formation of the latter being strongly dependent on the presence of electron donors (enzymes) and magnetic perturbations that affect the spin prohibitions.

In 1937, Pauling established that the magnetic moments of hemoproteins decrease as the pH values of solutions increase. The effect was explained by the iron ion spin flip owing to small changes in the coordination of ligands.⁵ The total spin of the Fe^{3+} ion is determined by the number of unpaired electrons in the 3d-shell of the metal. The low-spin state ($S = 3/2$) becomes more stable than the state with $S = 5/2$ as the pH value increases; the transition between these states is induced by the spin–orbit coupling in the 3d-shell of the metal. In weak ligand field the unfilled 3d-shell has degenerate orbitals and the states with different spins have similar energies. Recall that the spin quantum number of one electron ($S = 1/2$) determines the absolute value of the momentum vector

$$\sqrt{S^2} = \sqrt{S(S+1)}\hbar = \frac{\sqrt{3}}{2}\hbar.$$

The summation of electron spins obeys the quantum addition rules,¹⁵ so the total spin of the molecule is zero at ‘antiparallel spins (all spins are paired); such state is called a singlet state. Most chemically stable organic compounds and corresponding oxidation products are diamagnetic, *i.e.*, they have no intrinsic magnetic moment (all spins are paired due to saturation of valences; the total spin of the molecule $S = 0$). Spins can undergo ‘depairing’ when exposed to light; here an electron goes to a vacant MO; according to the Pauli principle, both spins can be parallel (total spin $S = 1$). This excited state is called a triplet state because of three possible orientations of the total spin vector $M_{\text{S}} = \pm\hbar, 0$.

Singlet–triplet transitions are spin-forbidden;¹⁵ this is a strict prohibition, because it can be removed only in the presence of magnetic interactions that are much weaker than electric ones.¹³ The latter determine the energies of chemical bonds and excited states and the pathways of chemical reactions. The spin affects the energy through exchange interaction.¹⁵ A weak SOC slightly mixes the singlet and triplet states of molecules, which gives a nonzero rate of S–T transitions that are observed in the form of phosphorescence and are well known in photochemistry.^{2, 7, 13} Non-radiative S–T transitions also play an important role in the dark reactions, in particular, in catalysis.^{12, 32} Weak SOC acts as a ‘key’ needed to open a ‘heavy door’, that is, the system chooses a pathway of chemical reaction with low activation barrier in the triplet state instead of overcoming a high activation barrier in the singlet state. Recall that the exchange integral appears with different signs in the energies of the S and T states, namely, two radicals form a chemical bond in the S state and repel in the T-state.¹⁵

Unlike most chemically stable organic compounds the O_2 molecule has the triplet ground state. According to Hund's rule, two unpaired electrons in two degenerate $\pi_{g,x}$ and $\pi_{g,y}$ orbitals (configurations π_g^2) have a lower repulsive energy in the triplet state [see Eqn (5b)] compared to the singlet state [see Eqn (5a)]. Because of this oxygen is paramagnetic (it has intrinsic magnetic moment due to spins of two unpaired electrons) and its addition to organic compounds is spin forbidden: starting reactants have the total spin $S = 1$, whereas the oxidation products are diamagnetic ($S = 0$).⁶ Because of spin prohibition, combustion of organic fuels requires activation in the form of high-temperature ignition stage, *i.e.*, generation of primary radicals.^{6–8} Reaction of R^\bullet radical (one unpaired electron, $S = 1/2$, doublet state) with O_2 molecule is spin-allowed, because the starting reactants ($O_2 + R^\bullet$) and product (RO_2^\bullet) have doublet states, which provides the chain character of radical reactions

Here the quantum cell denotes the MO (see above).

Radical RO_2^\bullet can decompose into radicals RO^\bullet and $^\bullet O$, thus making chain branching possible. In radical chain oxidation (combustion) processes the energy is released uncontrollably in the form of heat and light.⁸ Clearly, this mechanism of oxidation with molecular oxygen cannot take place in living cells. However, cells meet their energy needs in the course of metabolic processes using the energy of oxidation of organic compounds under the action of oxygen.⁵ Since cells cannot resist large temperature gradients, they should transform the energy released through oxidation to some kind of chemical energy prior to dissipation in the form of heat. This occurs by combining oxidation with the synthesis of adenosine triphosphate (ATP).^{5, 139} In turn, the cell uses the ATP energy to carry out all endogenic processes, such as chemical syntheses of DNA and proteins, ion transport and mechanical work.¹³⁹ All versatile energy-supplying metabolic processes and reactions occur under subtle enzymatic regulation.⁵ Is it spin-dependent? Despite the fact that to date many reactions of enzymes and metabolic pathways have been studied in detail,^{143–147} the role of spin in biological oxidation of molecular oxygen is still unclear.^{148–158}

2. Cytochrome oxidase

The simplest type of oxygen activation by enzymes containing metal cations involves the formation of intermediate peroxide ions O_2^{2-} . Reduction of O_2 by direct insertion of an electron pair into the filled π_g -orbitals requires spin changes, because the π_g^4 configuration can only be a singlet. Intermediates containing O_2^{2-} are formed in, *e.g.*, cytochromes.^{5, 139} The $Fe^{3+} - O - O - Cu^{2+}$ structure, where the peroxide group is formed from the triplet oxygen and stabilised at its position until introduction of the second electron pair, is quite possible intermediate.¹⁴³ Apparently, electron transfer and formation of O_2^{2-} involves a triplet–singlet quantum transition called spin inversion.^{145, 148} Cytochrome oxidase catalyses four-electron reduction of oxygen molecule to water. No intermediates were detected in the reaction

However, experimental measurements^{5, 158} proved the formation of O_2^{2-} . The reaction centre of cytochrome oxidase includes one haem iron atom and one copper atom. The oxygen molecule binds to the haem Fe^{2+} cation and to Cu^+ ion that donate one electron each to form an O_2^{2-} anion. This provides a way to overcome the major obstacle to oxygen activation, that is, spin inversion (T–S transition).¹⁴⁵ Since the O_2^{2-} dianion has a filled electron shell, the ground state of this species is

totally symmetrical and characterised by the term $|^1\Sigma_g^+ \rangle$. Transfer of two electrons causes the ground-state term, $|X^3\Sigma_g^- \rangle$, of the O_2 molecule to smoothly transform to the term $|^1\Sigma_g^+ \rangle$ of the dianion. The spin–orbit coupling between the states $|^3\Sigma_g^- \rangle$ and $|^1\Sigma_g^+ \rangle$ is symmetry-allowed [see Eqn (8)]; therefore, the reduction

is also symmetry allowed with inclusion of the SOC. Since the SOC integral [see Eqns (8) and (11)] reaches its maximum value owing to symmetry of the oxygen MOs, one can expect that reduction of the oxygen molecule to the dianion should be accelerated due to effective removal of spin prohibition. These qualitative considerations should be complemented by analysis of the structure of the 3d-shells of the metal ions.¹⁴⁸

Transition of the active site of cytochrome oxidase to the singlet state removes spin prohibition to subsequent fast chemical reactions up to formation of stable diamagnetic products.⁵ According to calculations, the spin–orbit coupling that induces the T–S transition involves not only oxygen π_g -MOs, but also electronic changes in the 3d-shell of the iron ion.^{133, 148}

The SOC mechanism can be represented as follows.^{145, 148} Activation upon electron transfer to O_2 first involves excitation of Fe^{2+} ion ($3d \rightarrow 4s$) to form the $1,^3D$ terms. Combination of two triplet states (iron and oxygen) gives the singlet, triplet and quintet states similarly to the case for collision of triplet oxygen and ethylene molecules (states 4 and 6, see Fig. 2). A singlet combination of two triplet states in the initial structure of cytochrome-*c* oxidase is shown in Scheme 1. The T–S transition in this quasi-degenerate pair is formed in the electron shell of the iron ion. The SOC is relatively weak and spin inversion is a relatively slow process. This is the reason for much lower (compared to the expected⁵) reactivity of O_2 towards certain ligands present in cytochromes. The singlet state formed upon T–S transition is shown on the left side of Scheme 1. Transition from this state to the peroxide form O_2^{2-} owing to transfer of two electrons from the metal ions is now spin allowed. This and subsequent processes occur in the singlet states.

Scheme 1

This mechanism of spin inversion occurs in hemerythrin and hemocyanin.¹⁴⁴ Cytochromes containing different protein residues coordinated to the iron ion can include $Fe(II)$ ions in different spin states. Particular cytochromes have iron ions in the triplet ground spin state.¹⁴⁴ In this case reduction of the oxygen molecule to the dianion should occur in accordance with Scheme 1 (see above) with a very high probability without involving SOC.

3. Flavoproteins

Usually,^{5, 139, 148–153} it is assumed that one can overcome the spin prohibition to oxidation of organic substrates with atmospheric oxygen by successive addition of single electrons in the reduction of O_2

Further reactions of diamagnetic hydrogen peroxide are spin allowed. It is assumed⁵ that removal of spin prohibition in

reactions (33)–(35) proceeds as in the case of radical-chain oxidation where the spin prohibition can be removed upon formation of primary radicals. The author of this review found no clear discussion of the issue in biochemical literature (see, e.g., Refs 5, 6, 152 and 153). A fundamental difference between the enzymatic reactions (33)–(35) involving radicals and the radical reactions of the type (32) in chain oxidation processes should be emphasised. In the latter case radicals go to the bulk of gas plasma flame (or in the solution bulk) and do not longer retain the ‘spin memory’ about precursors. All participants of biochemical oxidation reactions (33) and (35), *i.e.*, oxygen and electron transfer agents, are confined within the same active site of enzyme. If an electron is transferred to the oxygen molecule from diamagnetic enzyme, reaction (33) produces a radical ion pair [see Eqn (29)], all spins remain correlated, the ‘spin memory’ is retained and the spin prohibition to subsequent reactions (34) and (35) of a radical ion pair (triplet precursor) thus generated remains valid.

Many researchers believe that the oxygen molecule is very stable and can hardly add one more electron to give a radical anion $O_2^{\cdot-}$; as a consequence, they emphasise that stage (33) is the limiting one.^{5, 139} Further addition of electrons is facilitated and subsequent reduction occurs readily.^{5, 139} The bottleneck of this commonly accepted scheme is that the difficulty of electron addition to O_2 contradicts experimental data, namely, the process is exothermic and occurs with energy release (42 kJ mol^{-1} , see Refs 9 and 55). Enzyme molecules are designed in such a fashion that electron transfer in the respiratory chain be easy.⁵ Indeed, reduced flavoproteins have very low ionisation potentials and are readily oxidisable.¹³⁹ If an O_2 molecule is delivered to the active site of an oxidase and interacts with flavoprotein, there are no physical prerequisites to assume that electron transfer to the oxygen molecule should proceed with difficulty.¹⁴⁹ The obstacle consists in the need of spin flip in the electron transfer stage (33) and formation of a triplet radical ion pair rather than addition of an electron to O_2 .

To clarify the situation, we will consider glucose oxidase as an example.^{3, 37, 148} Reaction (33) in glucose oxidase involves flavine adenine dinucleotide (FAD). Such compounds (flavoproteins) are typical of many co-enzymes; they were discovered in 1932 (‘yellow enzyme’ capable of catalysing the oxidation of nicotinamide nucleotides was isolated from yeasts).⁵ Flavoproteins transfer electrons, as constituents of hydrogen atoms, from organic substrate to the riboflavin component of the enzyme using nicotinamide adenine dinucleotide (NAD^+) and its reduced form ($NADH$).^{5, 139} The structures of these molecules were undoubtedly ‘selected’ by Nature to impart corresponding redox potentials to the co-enzymes.¹⁵⁰ NAD^+ exists in individual form and diffusively moves from one enzyme to another, whereas FAD is tightly bound to protein. Flavoproteins tend to attach H atoms from one substrate and then transfer them to the other (O_2), being added to the same enzyme.⁵ A covalent or hydrogen bond connects FAD to the residue of the polypeptide protein chain; therefore, FAD remains bound to a particular amino acid after proteolysis.

The action of glucose oxidase involves two stages, namely,^{5, 155} glucose oxidation to gluconolactone with reduction of FAD to $FADH_2$ and the reverse cycle, $FADH_2 \rightarrow FAD$, with reduction of O_2 to H_2O_2 . From the standpoint of oxygen activation it is of interest to consider the second stage.

The active site of glucose oxidase from *Aspergillus Niger* has a histidine residue (His516) near the flavin ring of FAD; the distance between the protonated nitrogen atom N^e of histidine and the N(1) atom of $FADH_2$ is about 4 \AA (see Ref. 152). Scheme 2 presents a model for the active site of glucose oxidase. The first phase of the catalytic cycle involves reduction of FAD to $FADH_2$. The initial model A illustrates the O_2 insertion into the active site between the histidine residue of the

protein chain and the N(1) atom; model B illustrates transfer of an electron from $FADH_2$ and formation of a radical pair; and C is the second to the last phase of the catalytic cycle accompanied by the formation of hydrogen peroxide. The last-mentioned stage involves abstraction of a proton from the N(5) atom and its transfer to histidine across the system of H-bonds in the protein and aqueous environments.

Scheme 2

When entering the active site, the O_2 molecule occupies the cavity between these atoms and then transfer of an electron from $FADH_2$ to the oxygen molecule occurs.¹⁴⁸

This results in the formation of a triplet radical pair $\{FADH_2^{\cdot+} \cdots O_2^{\cdot-}\}$ in the active site of glucose oxidase, because the precursor of O_2 is in the triplet state, whereas that of $FADH_2$ is in the singlet state. According to density functional calculations (B3LYP/6-31G*),³ electron transfer is almost thermally neutral (thermal effect of reaction is 0.6 kJ mol^{-1}).

In glucose oxidase, the O_2 molecule is transformed to superoxide ion $O_2^{\cdot-}$ upon addition of an electron, thus being activated.^{3, 148} This slow stage is followed by fast proton transfer from the protonated histidine residue and simultaneous transfer of hydrogen atom from semi-oxidised radical $FADH_2^{\cdot+}$, which results in the formation of hydrogen peroxide.^{148, 150}

4. Electron transfer in glucose oxidase and the spin flip

Now we will return to the key issue, namely, why the electron transfer stage (36) is slow ($k < 10^{-3} \text{ s}^{-1}$). According to calculations, electron transfer to the active site of glucose oxidase should occur spontaneously and rapidly ($k = 10^{-9} \text{ s}^{-1}$), just as O_2 will enter the active site. The O_2 molecule is characterised by a positive electron affinity (0.45 eV), *i.e.*, the addition of an electron is energetically favourable.^{9, 44, 55, 154} Reduced FAD readily donates an electron; indeed, $FADH_2$ has a relatively low ionisation potential.³ The reason is clear. The lowest occupied MO (LUMO) of the FAD molecule is the π^* -orbital of the isoalloxazine ring. In spite of the non-planar structure of this nucleus in $FADH_2$, its highest occupied molecular orbital is similar to the LUMO of the FAD molecule. Both orbitals are mainly localised on the central ring of the flavin nucleus.¹⁵⁰ This confirms a simple MO pattern obtained in the Hückel calculations, namely, the FAD LUMO is identical to the $FADH_2$ HOMO. Namely, the addition of two hydrogen atoms to the N(1) and N(5) atoms

is similar to attachment of two π -electrons to the ring π -system. From this a considerable decrease in the ionisation potential on going from FAD to FADH₂ becomes clear. The electron affinity of the O₂ molecule is much lower than the ionisation potential of FADH₂; however, when O₂ contacts protonated histidine, electron transfer becomes energetically favourable. Electrostatic attraction between the histidine cation and newly formed superoxide O₂^{•−} is the primary driving force of electron transfer and reduction of corresponding activation energy. It also facilitates strengthening of the SOC.

Thus, the active site of glucose oxidase is 'tuned for oxygen activation through electron transfer followed by spin flip according to Scheme 3.

Scheme 3

TE is transfer of an electron.¹⁴⁵

Simultaneous occurrence of reactions (34) and (35) resulting in diamagnetic products requires flip of one spin in the radical pair stage, *i.e.*, a triplet–singlet quantum transition. Such a transition is induced by the spin–orbit coupling, *i.e.*, magnetic interactions due to the orbital and spin motions of electrons (see Scheme 3).³

Spin flip is actually due to relatively strong SOC characteristic of radical pairs including superoxide ions.³ In Scheme 3 the quantum cells denote the HOMOs of both molecules, that is, FADH₂ and O₂. As in the case of quenching of singlet oxygen by amines, where the role of CTC was shown [see Eqns (29), (30)], Scheme 3 presents different orbital structures of the triplet and singlet CTC. The starting triplet radical pair corresponds to a CTC described by Eqn (29), that is, transfer of an electron to the $\pi_{g,y}$ -MO of O₂ molecule, whereas the singlet radical pair corresponds to a CTC described by Eqn (30), namely, transfer of an electron to another degenerate orbital of oxygen, $\pi_{g,x}$. The SOC arises between these CTC and is maximum possible for a system comprised of light (oxygen, nitrogen and carbon) atoms.

Actually, the formation of superoxide is not difficult. Indeed, a triplet radical pair is easily formed just after transfer of H atoms and reduction of FAD to FADH₂. The problem is to carry out a triplet–singlet transition in the radical pair {FADH₂^{•+}...O₂^{•−}} generated in reaction (36), because only the singlet pair can produce peroxide: reactions (34) and (35) involving protonated histidine and radical FADH₂^{•+} proceed concertedly.^{3, 148} Reaction (34) has no effect on electron spins and in reaction (35) the spins remain correlated as in the initial state. Therefore, the initial steps of chemical reactions (34) and (35) should involve a spin flip (T → S transition from the triplet radical pair created upon electron transfer). In accordance with Scheme 3 the SOC integral includes the same components as the integrals (8) and (31)^{3, 37, 148}

$$\langle {}^3\Psi_{\text{ct}_y} | H_{\text{so}}^Z | {}^1\Psi_{\text{ct}_x} \rangle = \langle \pi_y | B_z | \pi_x \rangle = \frac{1}{2} \zeta_{\text{O}} = 76.5 \text{ i cm}^{-1}. \quad (37)$$

The absolute value of this integral equals half the splitting between the ground-state terms $\Omega = 1/2$ and $\Omega = 3/2$ of the superoxide ion $X^2\Pi_g$ (*cf.* experimental value of 160 cm^{−1} (Ref. 9), which is in good agreement with our estimate¹⁵⁴). The rate constant for the triplet–singlet transition can be estimated using the Fermi golden rule¹³

$$k_{\text{T} \rightarrow \text{S}} = \frac{2\pi\rho}{\hbar} |\langle {}^3\Psi_{\text{ct}_y} | H_{\text{so}}^Z | {}^1\Psi_{\text{ct}_x} \rangle|^2 \text{FC}, \quad (38)$$

where FC is the Franck–Condon factor and ρ is the density of final states.

The SOC integral (37) is relatively large; usually,^{12, 13} the matrix elements of the SOC operator for the molecules comprised of the first or second row elements are of the order of 1–10 cm^{−1}. These SOC integrals provide the rate constants for triplet–singlet transitions that are 10⁶–10⁴ times lower than the rate constants for spin-allowed transitions.¹³ The SOC integral (37) provides the rate constant $k_{\text{T} \rightarrow \text{S}}$ that can be compared with the rates of other chemical reactions that are, in principle, possible during existence of the triplet radical pair {FADH₂^{•+}...O₂^{•−}} (back electron transfer, decomposition to new radicals). Despite the fact that the T → S transition in the {FADH₂^{•+}...O₂^{•−}} pair is relatively slow, it is much more efficient than typical T → S transitions in organic molecules and undoubtedly occurs in the active site of glucose oxidase. Subsequent reactions (34) and (35) in the singlet state of the entire flavoprotein system have low activation energies³ and proceed rapidly. Transfer of a proton from the N^ε atom of the histidine fragment [see reaction (34)] is accompanied by proton transfer from the N(1) atom of FADH₂ to give hydrogen peroxide [see reaction (35)] with an the activation energy of only 29 kJ mol^{−1} (see Ref. 3).

Since the SOC integral (37) is only determined by the specific character of O₂^{•−} anion and does not depend on the co-enzyme cation (K), effective T–S transitions in radical pairs {K⁺...O₂^{•−}} should occur in the activation of oxygen by flavoproteins and other oxidases following reactions (33)–(35). This mechanism of the T–S-transition in the radical pair is similar to spin relaxation in the superoxide ion.^{145, 148}

5. Other examples of biochemical activation of oxygen

An important mechanism of enzymatic spin catalysis is characteristic of oxidases containing paramagnetic metal ions.^{37, 145, 149, 156–158} Let us consider the exchange mechanism of acceleration of T → S transitions in radical pairs {K⁺...O₂^{•−}} taking copper amine oxidase as an example. This enzyme contains a bound quinonoid cofactor (topaquinone) near the Cu(II) ion coordinated to the ligands.¹⁴⁹ Consider the limiting stage of the operation of this enzyme, which can also be represented by the common processes (33)–(35). A radical pair {K⁺...O₂^{•−}} in the T-state is formed in the reaction of the type (36). The T → S transition is activated by exchange interactions with the copper ion following the scheme

Exchange interaction with copper ion for the superoxide ion is much stronger than for the co-enzyme (K⁺) radical cation; therefore, the T → S transition of the radical pair is rather fast.³⁷ Measurements of kinetic isotope effects showed that replacement of the ¹⁶O isotope by ¹⁸O significantly slows down the limiting stage of oxygen reduction to peroxide for all enzymes studied.¹⁵² In this case the Franck–Condon factor decreases; therefore, the proposed scheme of enzymatic spin-catalysis^{3, 37, 148–150} provides a complete explanation for all results obtained in the kinetic studies on molecular oxygen activation by the enzymes mentioned above.^{3, 152}

We will complete our comparative analysis of oxygen activation mechanisms taking cytochrome oxidase as an example; this compound catalyses four-electron reduction of O₂ to water in the final reactions of aerobic metabolism.⁵ This is a very important process in the chain of continuous redox reactions involving proton transfer across membranes and creation of chemiosmotic gradient for ATP synthesis.^{139, 157}

Cleavage of the O–O bond in cytochrome oxidase is a related to transfer of electrons and protons across mitochondrial membranes and to the formation of Fe(IV)=O groups in

a complex manner.¹⁵⁸ Note that the O—O bond dissociation, which continuously occurs in upper atmosphere, produces two highly reactive biradicals $O(^3P) + O(^3P)$ having four unpaired electron spins. (The process is spin allowed and can occur in the dark.) These species possess extremely high reactivity, but at low gas concentration the reactivity ‘dissipates’ into recombination, atmospheric emission and particularly, ozone synthesis. The O—O bond dissociation in cytochrome oxidase also causes ‘depairing’ of four spins and could produce two biradicals. Would these biradicals escape from the active site of enzyme to the bulk of proteins, they would ‘burn out’ mitochondria and cytoplasm. It is of great importance to cleave the O—O bond in cytochrome oxidase using the concerted mechanism consistent with other reactions, and thus chemically bind oxygen atoms and simultaneously ‘quench’ the spin. As shown above, in such enzymes chemical reactions are governed by the SOC and weak exchange interactions involving spins of paramagnetic iron and copper ions.⁵ Spin catalysis favours fast and efficient (with small energy expenditure) dissociation of the O—O bond in the oxygen molecule.

Quantum chemistry is a unique tool for understanding of vitally important processes.^{156–160} Similarly to quantum mechanics, which provides explanation for very subtle effects of spin interaction in solids,^{161–164} quantum chemistry makes it possible to study electron-spin dependent properties of living matter.

VI. Conclusion

Removal of spin prohibition on singlet–triplet transitions in oxygen molecule interacting with buffer gas, solvent or co-enzyme molecules in complex biopolymers is in some cases determined by certain common mechanisms. Physical substantiation of the mechanisms of bio-activation of oxygen is impossible if simpler mechanisms of O_2 photo-activation in solutions of organic dyes or upon collisions with other molecules in the gas phase remain unclear. In this review the term ‘photo-activation’ means acceleration of radiative and non-radiative triplet–singlet transitions in oxygen molecule induced by collisions with the solvent molecule, including sensitisation of singlet oxygen.

Analysis of the mechanisms of $O_2(a^1\Delta_g)$ quenching is closely related to these problems, being very important for understanding of the mechanism of bio-activation of oxygen. We considered the electronic structures and energies of various low-lying states of the O_2 molecule and the collision complexes of oxygen with simple (H_2 , N_2 , CH_3Cl , C_2H_4) and more complex molecules (benzene, naphthalene, dyes). The inclusion of specific spin–orbit coupling in the open π_g -shell of oxygen makes it possible to explain the intensities of the T–S transitions of the O_2 molecule and collision complexes. Selective enhancement of the intensity of the $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ radiative transition upon collisions and its quenching in various solvents (M) was explained. The contribution of $M^+ - O_2^-$ charge transfer causes the SOC between the T–S states of oxygen to strengthen, which enhances the quenching of $O_2(a^1\Delta_g)$. Enzymatic activation of oxygen by, e.g., glucose oxidase proceeds by a similar mechanism of T–S-transitions.

The mechanisms of activation and quenching of singlet oxygen involve energy transfer, which depends on exchange interactions, SOC, charge transfer, intra- and intermolecular vibrations. Based on analysis of the physical mechanisms of photo-activation, three types of oxygen activation by oxidase enzymes were proposed. They involve intermediate formation of the superoxide ion, O_2^- , and peroxide ion, O_2^{2-} . Elucidation of O_2 activation mechanisms due to T–S transitions in oxygen-binding enzymatic complexes opens new fields of investigations in biotechnology, namely, research on magnetic biopolymers and the effect of magnetic and microwave fields

on the rate of spin inversion in these complexes,^{13,142} on the yield of O_2^- and OOH radicals and on other important biochemical processes.¹⁶⁰

Nanomaterials for sensors

V E Bochenkov, G B Sergeev

Contents

I. Introduction	1011
II. Physicochemical properties of nanomaterials for sensors	1011
III. Certain application fields of sensors based on nanomaterials	1015
IV. Conclusion	1018

Abstract. Publications of the past five years dealing with nanomaterials used as sensors for determination of gases are analysed. Peculiarities of the production of chemoresistive nanosensors based on semiconducting oxides, carbon nanotubes and polyaniline are outlined. The main application fields of gas sensors are considered. Prospects for the use of quasi-one-dimensional nanomaterials such as nanorods, nanotubes and nanobelts as the materials in sensor units are discussed. The bibliography includes 114 references.

I. Introduction

Nanoscience deals with fundamental problems of natural science on the nanoscale; its results are implemented in nanotechnologies as nanodevices, nanosystems, new substances and nanomaterials.^{1,2}

Nanoparticles are highly reactive; this is why, in the absence of stabilising media, they are studied in high vacuum or at low temperatures. Under conditions of ultralow temperatures, unusual chemical reactions were carried out and different reactivity of metal atoms, clusters and nanoparticles of different sizes was demonstrated.³ The use of low temperatures and the joint condensation of vapours of different compounds led to the development of methods for the cryogenic formation of nanosystems with the gas-sensitive and sensor properties.⁴ Studies in the field of cryochemistry play the important role in the development of nanochemistry.⁵ Nanotechnologies are also beginning to use cryogenic freeze-drying.⁶

Preparation of materials with sensor properties and the development of the corresponding instruments based on these materials is an important problem. After the terrorist act of September 11, 2001, the USA sharply raised financing of the field of nanoscience devoted to sensors and correspondingly reoriented their research policy. New sensor materials are of great social and economic importance. According to the Business Corporation Company, the total sum obtained by the

USA from nanosensors sold in 2004 was ~\$ 190 million. The annual increase in the sale volume of nanomaterial-based sensors is 26% and the total sum from their sale will reach 592 million to 2010. The annual gain in the sale volume was 53% for gas sensors and 32% for biosensors. According to the 'Nanomaterials Research' Journal, the total sale of all types of sensors will reach \$ 2.5 billion in 2010.

The diversity of sensors developed for different fields of science, technology, and industry as well as their properties, preparation techniques and application areas were surveyed in the monograph⁷ and the following review papers:

- control over volatile combustion products in industry,⁸
- analysis of exhaust gases of cars,⁹
- quality inspection of foodstuffs,¹⁰
- peculiarities of using the polyaniline gas sensors,¹¹
- using the plasmon resonance in biosensorics,¹²
- sensors for ammonia detection,¹³
- preparation and chemoresistive properties of nanostructured materials,⁴
- materials for environmental monitoring.¹⁴

In this study, attention is focused on the materials and sensors used in the determination of combustible and toxic gases, volatile organic compounds and in the diagnostics of certain diseases. In our opinion, at present the demand for such sensors is the highest. They are required for the prevention of technological disasters and terrorist attacks, in the environmental protection and the human health care. All these problems are currently central in Russia.

This review considers the problems associated with the use of low temperatures in the synthesis of new gas-sensitive nanomaterials for sensors. Physical and chemical methods of the formation of sensor systems and certain general properties of gas-sensitive materials are discussed. For the most part, chemoresistive sensor materials that change their properties upon adsorption of a particular substance are considered. In contrast to other reviews on the related subjects (*e.g.*, see Refs 4, 15), in the analysis of properties of nanomaterials for sensors special attention is paid to the peculiarities of their synthetic methods of their synthesis, and certain general problems of nanosensors are discussed in relation to the detection of ammonia.

II. Physicochemical properties of nanomaterials for sensors

Nowadays, nanoparticles and nanomaterials are coming into extensive use in the development of sensors.^{4,8–14} However,

recently published monographs on sensors^{16,17} described the use of nanomaterials only briefly and fragmentarily.

Nanomaterials to be used as sensors should exhibit sensitivity, selectivity and stability. The size dependence of nanoparticle properties forms the basis for the development of highly sensitive sensor devices. Certain problems associated with the dependence of the sensitivity of sensors on the size and shape of nanosystems, the ligand type and the response mechanism were considered in several reviews.^{4,15}

In this review, the methods of preparation of gas-sensitive nanomaterials are conditionally divided into physical and chemical. A method used for the formation of nanoheterogeneities in materials at low temperatures, *i.e.*, cryosynthesis, is considered separately.

1. Physical and chemical methods of synthesis of sensor nanomaterials

Physical methods of preparation of gas-sensitive nanomaterials include, *inter alia*, different versions of vacuum deposition that employ the resistive, laser and electron-beam evaporation and magnetron sputtering. As a rule, these methods are used in the preparation of metal-oxide semiconducting nanosystems and metal nanoparticles deposited on different substrates.

Operation of gas sensors is based on the variations in the resistance (conductivity) of chemoresistive materials under the effect of the analysed gas. At present, the majority of sensors for the gas analysis employ semiconducting materials. As a rule, the operation of these materials requires elevated temperatures.

Metal-oxide semiconducting nanomaterials are the most thoroughly studied sensor materials — they were the subject of a considerable number of publications devoted to methods of synthesis^{18–20} and mechanisms of sensor response.^{18,21,22} This is why we do not consider in detail metal-oxide nanomaterials (with the exception of new types of sensors based on nanowires, nanobelts and nanotubes).

Chemical methods of synthesis of sensor nanosystems include their conventional synthesis in solutions and the chemical synthesis in the gas phase. The former is used in the production of materials based on self-assembled nanoparticles of noble metals coated with alkanethiols and in the preparation of gas-sensitive polymeric films. The latter method is actively employed in the synthesis of materials based of carbon nanotubes.

Metal nanoparticles stabilised with organic molecules and the materials based on them are interesting due to their unique properties and the possibility of their application as gas sensors. Metal nanoparticles are stabilised by monolayers of alkanethiol derivatives.^{23,24} The organic coating prevents aggregation of particles and affects their physicochemical properties.²⁵

One of the first studies that employed gold nanoparticles coated with a thin octanethiol film as the sensor[†] units considered the effect of vapours of volatile organic substances on the film conductivity. It was found that the film conductivity remained virtually unchanged under the action of propanol and water vapours and decreased when subjected to action of toluene and trichloroethylene vapours.²⁶ For toluene, the detection limit was several molecules per million. Later, materials sensitive with respect to vapours of polar solvents were synthesised.²⁷ The conductivity in such systems was discussed in terms of two possible mechanisms, namely, the electron tunnelling between metal nuclei and the hopping mechanism of conduction *via* thiol molecules. Changes in the charge distribution in a system with the adsorption of vapours

of volatile substances give rise to the sensor response. Moreover, it was assumed that the swelling of organic matrices upon adsorption of a solvent vapour may influence the film conductivity that is related to the variations in the distance between metal particles.²⁸

When manufacturing chemoresistive thin films based on metal nanoparticles coated with thiol derivatives, it is necessary to know the dependences of the material conductivity on the particle radius, the distance between particles and the dielectric permittivity of the medium. The effect of the distance between nanoparticles of gold and a gold–silver alloy on the conductivity and sensitivity of films was studied.²⁹ For the first time, certain α,ω -dithiols and dicarboxylic acids with different numbers of CH_2 units ($n = 3–18$) were used in addition to decanethiol for the fixation of interparticle distances. It was shown that the sensitivity of samples with respect to vapours of hexane, toluene and benzene depends on the number n of CH_2 units in the spacer chain. This dependence has a sigmoid form, where the largest changes in the sensitivity fall to the n range from 9 to 13.

Conducting polymeric films³⁰ synthesised by chemical methods display the following advantages over metal-oxide sensors: the possibility of operation at room temperature, high sensitivity and short response times. Conducting polymers can be synthesised by chemical and electrochemical reactions, their molecular structure is changed by co-polymerisation or modification of functional groups.³⁰

Attention of scientists was always attracted to the development of the so-called synthetic metals, *i.e.*, conducting materials based on organic compounds. The interest in such compounds increased with the discovery of conduction in polymers.[‡] Different modifications of polyaniline were used most extensively as the sensor materials.

Polyaniline samples can have different shapes and acquire different colours depending on the y value. This makes it difficult to carry out their reproducible synthesis and measure their conductivity. Protonated forms (or salts) of polyaniline have the highest conductivity that reaches $15 \Omega^{-1} \text{cm}^{-1}$ (Ref. 31), which is much lower than the metal conductivity ($10^3 \Omega^{-1} \text{cm}^{-1}$).

The methods of preparation of polyaniline films, the mechanism and features of their modification with different inorganic and organic compounds were analysed.¹¹ Their modification involved the use of acids (HA), where $\text{A} = \text{Cl}, \text{HSO}_4, \text{ClO}_4$. The sensitivity of modified polyaniline films placed, *e.g.*, in the ammonia atmosphere changed as a result of protonation and deprotonation.^{32,33}

[†] Nowadays, solutions containing alkanethiol-stabilised gold and silver nanoparticles can be purchased from suppliers of chemicals.

[‡] For this discovery, A J Heeger, A D MacDiarmid and H Shirakawa were awarded the Nobel Prize-2000 in chemistry.

Table 1. Sensitivity of polyaniline films with respect to different gases depending on the preparation method.

NO ₂	H ₂ S	SO ₂
Spin-coating		
++ (4 ppm)	+++ (4 ppm)	++ (2 ppm)
Thermal deposition		
++ (2 ppm)	+(10 ppm) irreversible	+(10 ppm)

Note. In parentheses, the gas concentration is shown. Symbols +, ++ and +++ designate the relative value of response.

Table 1 shows the sensitivity of non-modified polyaniline films synthesised by different methods with respect to different gases.

It was noted³⁴ that polyaniline is insensitive with respect to carbon dioxide or methane; the same paper reports the results of studies of the polyaniline film conductivity (in nitrogen atmosphere, at room temperature) as a function of its thickness and the method of preparation. The conductivity of polyaniline synthesised by thermal evaporation was $10^{-10} \Omega^{-1} \text{ cm}^{-1}$. This was higher as compared with samples synthesised by the spin-coating method. The higher conductivity of films obtained by the thermal deposition was associated with the predominant presence of *N*-phenyl-*p*-phenylenediamine blocks in the sample. The other method produced a mixture of *N*-phenyl-*p*-phenylenediamine and quinonediimine blocks, which interrupted the sequence of conjugated double bonds. It was demonstrated³⁵ that polyaniline films containing polyvinyl alcohol may be used in the analysis for carbon dioxide. Composites based on polyaniline and copper particles were used in the analysis for chloroform.³⁶

Incorporation of palladium particles into polyaniline was accomplished.³⁷ Examination of the ability of different surfaces to change the conductivity of deposited polyaniline films has shown that the deposition rate of polyaniline on a hydrophobic surface was higher as compared with hydrophilic films. Similar dependences were obtained^{38,39} for thiol-modified silicon and gold surfaces, respectively. The conductivity of films on hydrophobic surface was higher; however, the adhesion of films to hydrophilic surfaces was stronger. The use of polyaniline as the material chemoresistive towards different gases faces the problems associated with stability, selectivity and response times that are typical of all gas sensors.

Carbon nanotubes are the promising material for gas sensors. They are synthesised by several methods, which can be classified into two groups associated with the use of either high or moderate temperatures. The former group includes the methods that employ arc discharge, the second group comprises the catalytic chemical vapour deposition.⁴⁰

One of the first gas sensors based on carbon nanotubes could detect low concentrations of NO₂ and NH₃ at room temperature.⁴¹ This result served as an impetus for the further experimental^{42,43} and theoretical^{43,44} studies of the sensitivity of carbon nanotubes with respect to gases. Particularly, it was shown⁴⁵ that materials synthesised upon the deposition of carbon nanotubes on tin(IV) oxide substrates were chemoresistive with respect to NO₂. For multi-walled carbon nanotubes with external diameters of ~30 nm, a linear dependence of their response on the ammonia concentration in the range of 5–200 ppm at 25 °C was revealed.⁴² The response time was 3 min; however, to recover its performance, a sensor should be annealed at 250 °C for 6 h.

To enhance the sensitivity of carbon nanotubes, their surface was modified with metal particles,^{46,47} covalently bound functional groups, polymers and even DNA mole-

cules.⁴⁸ This provided an increase in the selective adsorption of particles of a certain kind due to their interaction with functional groups or as a result of acceleration of catalytic processes on the surface of metal nanoparticles. Carbon nanotubes modified with palladium nanoparticles exhibited sensitivity with respect to hydrogen for its content in the range from 50 to 10 000 ppm at room temperature.⁴⁹

Single-walled nanotubes functionalised with poly(*m*-aminobenzenesulfonic acid) demonstrated the detection limit at a level of 5 ppm (Ref. 50). The use of a polyaniline coating allowed the record-breaking detection limit for ammonia of 50 ppb to be reached.⁵¹

In the gas detection, it was proposed^{52,53} to use carbon nanotubes as the anode in ionisation detectors. Due to the high field intensity, vertically aligned carbon nanotubes allowed the breakdown potential to be substantially reduced. This made it possible to use such detectors in portable gas analysers and gas chromatographs. The advance in the synthesis of vertical carbon nanotube forests promotes the development in this field.⁵⁴

2. Cryosynthesis

The use of low temperatures in the production of nanostructured materials is first of all associated with the possibility of limiting the diffusion mobility of particles and, as a consequence, decreasing the sizes of growing aggregates.

Cryochemical technologies were successfully employed in the preparation of small-size particles⁶ that can be used in the production of gas-sensitive materials. Thus samples of nanograin tin(IV) oxide synthesised by chemical deposition followed by cryogenic freeze-drying were chemoresistive with respect to carbon monoxide.⁵⁵

Based on fundamental studies in the field of low-temperature chemistry,⁵⁶ a new approach to the synthesis of nanostructured gas-sensitive materials has been developed, namely, the low temperature deposition of metal vapour in vacuum followed by oxidation.⁵⁷

Figure 1 illustrates the essence of this method, which consists of the vacuum condensation of metal vapour on a substrate kept at a temperature from 80 to 300 K. Cooling of the substrate considerably decreases the diffusion mobility in the deposition. As a result, columnar structures can be formed in the moment of condensation as a result of the attraction of the approaching atoms to the already deposited clusters. The subsequent controlled annealing destroys the structure to afford spherical particles on the oxide substrate non-wettable by the metal.

The introduction of oxygen makes it possible to form materials with certain nanostructures and chemical compositions, particularly, with nanograins of the core-shell structure that are connected with bridges. The control over the deposition parameters such as the rate and the temperatures of the substrate and the evaporator allows one to govern the structure of synthesised condensates and chemically modify the surface of grains. Low-temperature deposition made it possible to synthesise lead nanoparticles sensitive with respect to ammonia and water vapours.^{58,59} From our viewpoint, the sensitivity of such systems is due to the formation of a percolation structure of lead nanoparticles with the size of ~50 nm coated with semiconducting oxides. Oxide bridges between the metal particles are responsible for the overall conductivity of the material and the manifestation of the chemoresistive effect.

The chemoresistive properties of materials also depend on the changes in their microstructure and porosity. This was taken into account in a method of low-temperature co-condensation with an additional component (e.g., an inert gas), which is removed from the system on annealing. Thus the structure of thin lead films was affected by its co-condensation with carbon dioxide.⁶⁰ It was shown that the roughness of the

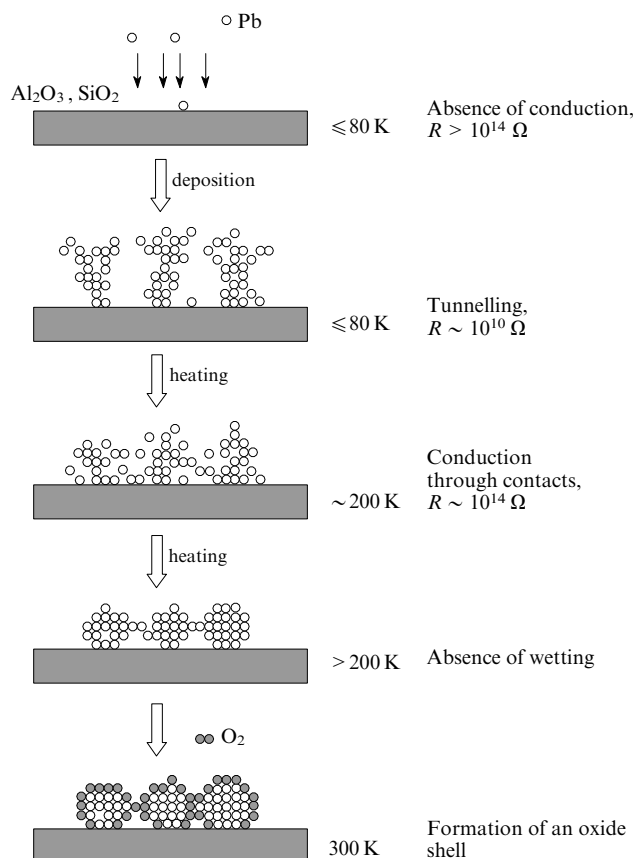

Figure 1. A model of cryogenic formation of gas-sensitive metal condensates on non-wettable substrates.⁵⁷

resulting films was higher as compared with lead films untreated with carbon dioxide. The noted fact allows one to consider the co-condensation – annealing method as promising for the preparation of materials with well-developed surface areas.

3. Sensitivity and selectivity

The sensitivity of semiconducting nanomaterials is determined by two basic factors, namely, the ratio of the surface area (S) to the volume (V) and the ratio of the Debye screening length (L_D) to the effective radius of conducting channels (R). All other conditions being the same, the larger the S/V and L_D/R ratios the higher the material sensitivity.

Numerous studies of thin nanostructured SnO_2 films showed that the sensitivity of samples with respect to detected gases dramatically increased as the grain size decreased to several nanometers.^{61–64} A systematic analysis of the size dependence of the sensitivity of SnO_2 samples can be found in Ref. 65. Problems of the selectivity of nanostructured gas-sensitive materials and the possibility of their use in the analysis of multicomponent gas mixtures.⁶⁶

A conventional method aimed at the enhancement of sensitivity and selectivity of semiconducting metal-oxide nanomaterials consists of doping samples with metal nanoparticles, *e.g.*, palladium,⁶⁷ platinum,⁶⁸ gold,^{69,70} silver.^{65,71} Thus the deposition of palladium nanoparticles on the surface of tin dioxide nanowires led to the increase in the sensitivity of such a system with respect to oxygen and hydrogen. This is explained by the increase in the concentration of O^- anions due to the acceleration of dissociation of oxygen molecules on palladium particles.⁷² In turn, the size of dopant nanoparticles also affects the sensitivity of nanomaterials with respect to gases. It was

shown that with a decrease in the size of silver particles deposited on tin dioxide particles, the sensitivity of this system with respect to ethanol vapours increased.⁷³

Recently, to enhance the sensitivity of chemoresistive materials, quasi-one-dimensional nanomaterials such as nanowires, nanorods and nanobelts came into use in addition to films.^{15,74–77} To a certain degree, this was associated with the development and investigation of such structures.^{78,79} Their use allows one to substantially lower the detection limits, because as compared with films, the conductivity of a one-dimensional nanosample responds to a smaller amount of the adsorbate.

As an example, we consider the mechanism of the sensor response of silver oxide nanowires to ammonia and hydrogen chloride vapours (Fig. 2).

Figure 2. Scheme of a presumed mechanism of the Ag_2O response to ammonia and hydrogen chloride at room temperature.⁸⁰

The proposed mechanism takes into account that, at room temperature, the oxide surface is coated by hydroxyl groups.⁸⁰ With the adsorption of ammonia and amines, these groups are deprotonated to form a negatively charged surface layer, which prevents the transport of electrons and favours an increase in the wire resistance. The effect of acid vapour leads to protonation of surface hydroxyl groups and, as a consequence, reduces the resistance.

A comparison of properties of nanowires and thin granulated films formed by silver particles connected with oxide bridges has evidenced the higher sensitivity of nanowires.⁸¹ A qualitative model explaining this effect is shown in Fig. 3.

The adsorption of ammonia molecules increases the resistance of contacts between silver nanoparticles. For films, a change in the resistance of several contacts merely changes the route of electron transport (Fig. 3*a*). For nanowires, ‘blocking’ of a single contact can substantially decrease the conductivity of the whole wire (Fig. 3*b*). Thus, the adsorption of the same amount of substance will induce a greater change in the nanowire conductivity as compared with a thin film, which is the case in practice. It was shown^{82–84} that tin dioxide nanowires exhibit sensitivity with respect to low concentrations of CO.

New types of nanomaterials for sensors were discussed in a review.⁸⁵

Sensitivity of sensors can additionally be increased by designing one-dimensional objects connected with bridges that control the conductivity of the whole nanosystem. A comparative study of how straight SnO_2 nanowires ~ 100 nm thick and segmented nanowires with a diameter of ~ 500 nm formed by segments ~ 80 nm long and 10 nm thick respond to the addition of 0.4 ppm hydrogen have shown that the signal was higher for segmented wires although their

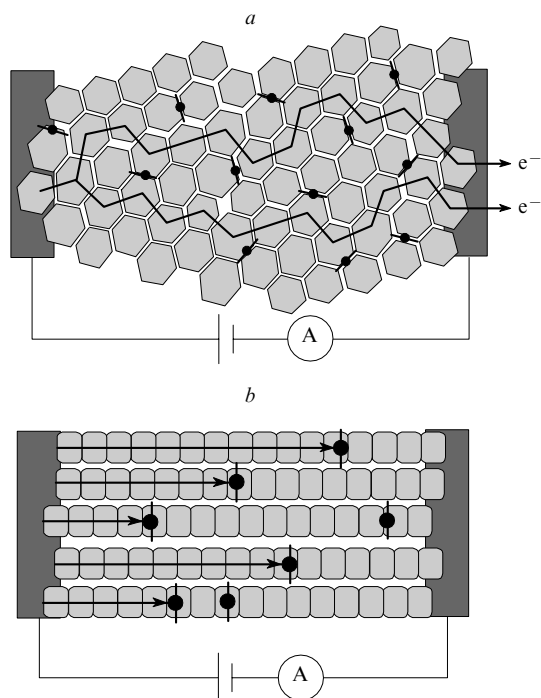

Figure 3. Model illustrating the changes in conductivity upon adsorption of ammonia on oxidised surface of silver particles (a) thin films and (b) nanowires.⁸¹

average radius several times exceeded that of straight nanowires.⁸⁶

Highly ordered arrays of core-shell nanoparticles with metal cores and semiconductor shells was proposed as a new type of sensor materials.⁸⁷

The increase in the sensitivity and selectivity of sensor nanosystems is the prime objective of scientists. The application field of sensors (especially oxide-based) can be extended by lowering the working temperature of gas-sensitive materials to room temperature. One of the ways to solve this problem may be the use of metal oxides in the form of quasi-one-dimensional materials. From our viewpoint, the development of systems with the higher selectivity should be based on the targeted synthesis of ligands capable of the selective interaction with the determined gases.

III. Certain application fields of sensors based on nanomaterials

Chemoresistive sensors are used in different fields of science and technology and in industry for the control over technological processes and the contents of toxic substances in air, water and soil. Below, certain fields of practical application of sensors are considered by the example of ammonia and several other gases and volatile organic substances. Attention is focused on the use of sensors in medicine.

1. Environmental monitoring

The environmental air and water contain large (and permanently growing) amounts of different impurities with wide concentration ranges. This stimulates the search for new versions of the use of metal oxides, which form the basis of conventional sensor materials. For example, a system comprising SnO_2 , ZnO , WO_3 , CuO and In_2O_3 was proposed for flow-through determinations of CH_4 , CO , NO , NO_2 , NH_3 , SO_2 and H_2S at temperatures in the range of 200–400 °C.⁸⁸

The environmental monitoring requires the knowledge of temperature dependence of the sensitivity with respect to the determined gas. The effect of temperature on the sensitivity of thin tin dioxide films manufactured by electron beam evaporation was explored for the determination of different concentrations of hydrogen, carbon oxide and ethylene, and the kinetics of their response was simulated.⁸⁹ It was shown that the minimum sensitivity and temperature are related to the energies of adsorption (E_{ads}) and activation (E_a). Being dependent on the nature of a gas, the adsorption energy determines the strength of its bonding with the oxide surface, whereas the activation energy determines a barrier that should be overcome to induce the surface oxidation. In turn, the quantities E_{ads} and E_a depend on the concentration of the analysed gas.

A cheap and relatively sensitive sensor for hydrogen was developed based on palladium nanowires deposited on the surface of highly oriented pyrolytic graphite.⁹⁰ The sensor operates at room temperature; its conductivity is two orders of magnitude higher in the presence of hydrogen than in its absence.

New sensors for ammonia and amines were developed. A new sensor based on V_2O_5 nanowires with extremely high sensitivity with respect to amines was described.⁹¹ The high conductivity of wires makes it possible to use this sensor at room temperature. The limiting sensitivity, which was defined as a concentration at which the signal exceeds the noise by a factor of three, was <30 ppb for *tert*-butylamine. Sensitivity with respect to amines increased linearly as the humidity of the carrier gas increased to 60%. The conductivity depended on the position of the amine contact with vanadium wires. The selectivity of the sensor was determined by comparing its response to amine, ammonia, propanol and toluene following 5-min contacts. The highest sensitivity was exhibited towards ammonia and amine.

In air, sulfuric and nitric acids react with ammonia to form particles of ammonium sulfate and nitrate. These particles serve as nuclei for the formation of aerosols and smog in air over large cities. With the appearance of smog, the air temperature decreases due to the sunlight screening.

The ammonia content in air is usually 10–100 ppb and falls to several molecules per billion over the ocean. In the vicinity of livestock farms, the ammonia concentration can reach 10 ppm (Ref. 92). To determine ammonia in the atmosphere, response times of about a minute are sufficient; air is delivered to the sensitive material by jet systems.

A different situation is observed in the determination of ammonia in exhaust gases of vehicles or in air-conditioned passenger compartments. The ammonia content in exhaust gases should be determined at a level of ~8 ppm (Ref. 93). To prevent the appearance of odour in the passenger compartment, the ammonia concentration should be detectable at a level of no higher than 50 ppm with the sensor response time of several seconds.

Exhaust gases of engines operating on diesel oil contain high concentrations of NO and NO_2 (NO_x).^{94,95} The amount of toxic nitrogen oxides can be reduced by their selective catalytic reduction⁹⁶

The reaction is carried out by the injection of a controlled amount of ammonia into the exhaust system. In this process, the ammonia sensor should measure its concentrations of an order of magnitude of several molecules per million, have the response time within 1 minute and operate at elevated temperatures.⁹⁴

Sensors based on zinc oxide nanorods with palladium particles deposited on the surface have demonstrated high

sensitivity with respect to hydrogen.⁹⁷ In a nitrogen flow with the hydrogen concentration varied from 10 to 500 ppm, the sensor determined concentrations < 10 ppm, was easily recoverable and did not respond to the presence of oxygen.

Nanorods of molybdenum oxide with the diameter from 50 to 300 nm and the length of 2–4 μm were used in sensors for the detection of carbon monoxide and ethanol at 200 °C. Carbon oxide was determined in amounts < 30 ppm (Ref. 98).

2. Sensors in chemical industry

The use of sensors in chemical industry is discussed by the example of ammonia. Ammonia is synthesised from molecular nitrogen and hydrogen at high temperatures and pressures in

the presence of catalysts. For the most part, it is used in the production of fertilisers and in certain chemical processes; large amounts of ammonia are still used in refrigerating units for foodstuff storage at temperatures below 0 °C.^{99,100} At ammonia utilising plants, its leakage is possible; this is why such plants should be equipped with appropriate detection systems that allow one to prevent environmental contamination with ammonia. The maximum allowable amount of ammonia in the surrounding air should not exceed 20 ppm. Such a concentration is allowed to hold for a long time; for its detection, sensors with the response times of an order of magnitude of one minute may be used. The ammonia production is a high-temperature process; hence, sensors should withstand temperatures of up to 500 °C.

In recent years, keen attention has been paid to the development of new sensors for ammonia. Sensors based on silver oxide microwires were developed.⁸⁰ Nanowires of zinc oxide were prepared and their sensitivity with respect to ammonia at room temperature was studied (using quartz crystal microbalance).¹⁰¹ The nanowires were synthesised by evaporation of zinc granules at 900 °C in air and then deposited onto the quartz crystal surface. It was found that with the increase in the thickness of layers, the absolute magnitude of response towards ammonia linearly increased. Samples were sensitive to ammonia in the concentration range from 40 to 1000 ppm. The response time was ~5 s. Sensors based on ZnO nanowires were stable and provided reproducible results.

Semiconducting oxides underlie the majority of sensors for ammonia used in the chemical industry. In such sensors, the signal is determined by the conductivity variations caused by the reaction of negatively charged oxygen species (O^- , O^{2-}) with the reducing gas on the sensor surface. To enhance the selectivity of oxide sensors, different doping additives were used, particularly, transition metals.

Figure 4 illustrates the dependence of the sensitivity of tungsten oxide with respect to NH_3 and NO on the addition of different metals.¹⁰² These data were obtained at 350 °C in the analysis of exhaust gases of vehicles. The sensor systems, which in addition to SnO_2 , employed WO_3 doped with gold and MoO_3 , were capable of detecting ammonia in the concentration range from 1 to 1000 ppm.¹⁰³ Such sensors were used in the detection of ammonia losses in refrigerating units¹⁰⁴ and in the combustion of gases.⁸⁸

Sensors for the determination of hydrogen, methane, carbon monoxide and hydrogen sulfide were developed by the deposition of metal particles with different catalytic activity on the surface of carbon nanotubes. The selective determination of these gases involved the use of a pattern-recognition method.⁴⁷

3. Sensors in biology and medicine

Nowadays, active studies are carried out aimed at the use of nanoparticles in biology and medicine. The problems to be solved in these fields of knowledge are closely interrelated; this is why they are often considered together. For biological and medicinal applications, nanoparticles that as a rule have hydrophobic stabilising shells should be transferred to aqueous solutions where the hydrophobic ligands are replaced by hydrophilic. For this purpose, it is necessary to use molecules that contain several functional groups of which some groups can be used for stabilisation of nanoparticles and the other should promote their modification and functionalisation.

As such molecules, amphiphilic polymeric molecules that are capable of transferring virtually any particle into aqueous media are used.¹⁰⁵ Their relative drawback is associated with the increase in the nanoparticle volume due to the formation of several stabilising layers. At the same time, the diversity of amphiphilic polymers makes it possible to introduce different

Figure 4. The effect of the introduction of 1 mass % of different dopants on the sensitivity of a gas sensor based on tungsten oxide with respect to ammonia and nitrogen monoxide.¹⁰² S is sensor response, R_a and R_g are the sample resistance in air and in the analysed gas atmosphere, respectively.

functional groups into shells of nanoparticles, bind the latter with bioactive molecules and use them as sensors.

When using nanoparticles, attention should be paid to the toxicity of nanosystems. Substances utilised in biology and medicine even if safe on the microlevel can become toxic on the nanoscale. Bearing this in mind, it is important to study the particle–cell interactions.² The adverse effect of nanoparticles on a cell can manifest itself as follows:

- a nanoparticle may oxidise the cell membrane; finding itself in the cell environment, a nanoparticle can behave as a toxic chemical that causes apoptosis,⁸ *i.e.*, the cell death;
- a nanoparticle captured by the cell membrane or adsorbed on its surface can become the reason for the impaired cell functions;
- a toxic effect can appear in the interaction of nanoparticles of different shapes (*e.g.*, spherical and fibre) in a cell.

Studies of the properties of CdSe nanoparticles and the CdSe/ZnS nanosystem have shown that the toxicity depends on the nanoparticle size, its surface coverage and the nature of functional groups bound with its surface.¹⁰⁶ Toxicity of CdSe particles was found in yet another study.¹⁰⁷

Studies on the use of different types of quantum dots[¶] as the markers for cells, tissues, bacteria and viruses are actively progressing. As compared with organic dyes, quantum dots exhibit the higher photostability and sensitivity.

The ambiguity of views of scientists on the toxicity of nanoparticles does not reduce the number of publications on the use of these materials as the sensitive tags for sensors. Nanocrystals and especially quantum dots are the convenient markers that are unsusceptible to light bleaching and sufficiently biocompatible. Moreover, in cell fission, nanoparticles get to both new cells preventing the loss of the label. Particles CdS that exhibit fluorescence properties were grown on magnetic FePt nanoparticles. Such nanoformations can be delivered to any internal organ to follow the state of the latter.

For the same purpose, hybri nanoparticles and quantum dots covered with phospholipid bilayers (phospholipids are also parts of the membrane) were used.¹⁰⁸ Such nanosystems exhibit good luminescence properties, biocompatibility and can be used in the monitoring of cell transformations. For example, similar particles were introduced into frog's embryonal cells, which allowed scientists to follow the foetus development.[†]

Metal nanoparticles can be used in enhancing the sensitivity of a sensor for the determination of DNA. Thus detection of 5–10 DNA chains¹⁰⁹ involved the use of magnetic iron oxide nanoparticles and citrate-stabilised gold nanoparticles, which allowed the DNA detection with sufficiently high sensitivity. Figure 5 illustrates this process. In addition to using two metals, silver-coated electrodes were employed for the amplification of the signal from gold-modified DNA. Such a trick increased the light scattering (outlet signal), which allowed 10 chains or 500 zeptomoles ($1 \text{ zmol litre}^{-1} = 10^{-21} \text{ mol litre}^{-1}$) to be detected. This method requires neither the use of enzymes nor great times and is relatively cheap. It also allows one to distinguish DNA molecules containing individual bases with the sensitivity of up to $10^{-18} \text{ mol litre}^{-1}$. The elaborated method was used in the detection of anthrax DNA.

§ Apoptosis is a phenomenon of programmed cell death accompanied by the appearance of typical cytological evidence (apoptosis markers) and molecular processes.

¶ Quantum dots are crystals of, as a rule, nanosize inorganic semiconductors that exhibit unique physical and chemical properties untypical of the same substances on the macroscale. Quantum dots may be bound to biological molecules by chemical bonds.

† In contrast to other studies, no mention was made on the toxicity of CdSe.¹⁰⁸

The development of the similarly fast and high-sensitive sensors is the burning problem for the prevention of terrorist attacks.

The requirements imposed upon the selectivity, precision and reliability of methods for the determination of clinically important metabolites as the indicators of the state of human health are gradually becoming more stringent. New versions of the detection of compounds associated with different diseases are being actively developed. One of such methods was used in the creatinine determination.¹¹⁰ Creatinine, a common urine component, is also present in blood and muscles. Blood of a healthy person contains creatinine at a level of 35–140 $\mu\text{mol litre}^{-1}$. In kidney diseases or their transplantation, the creatinine concentration in blood serum and plasma may reach 1 mmol litre^{-1} .

Figure 6 illustrates the operation of a sensor by the example of creatinine determination. The main components of this system include the enzyme creatinase deaminase and a polyacrylamide hydrogel that contains spheres of polystyrene latex with diameter of 120 nm.

Under the action of the enzyme, creatinine is quickly hydrolysed to form hydroxide ion OH^- . In the second stage, 2-nitrophenol is added to the system by titration, which changes pH of the medium. Phenol deprotonation leads to hydrogel swelling due to an increase in the phenol solubility. As

Figure 6. Illustration of operation of a sensor for creatinine.¹¹⁰

a result, with the increase in the creatinine concentration, the luminescence lines shift to lower energies, *i.e.*, the bathochromic shift is observed.

The spectral sensitivity of a sensor allows one to reliably determine creatinine concentrations in the range of $0.1 - 1 \text{ mmol litre}^{-1}$. With the aim of simplifying the creatinine determination, coloured calibration charts were proposed.¹¹⁰ Such charts will allow patients to obtain information without using special instruments, which is of vital importance for those suffering kidney diseases.

The approach developed for the creatinine determination was used in designing a sensor for glucose.¹¹¹ Clinical tests have shown that such a sensor makes it possible to determine up to $0.15 \text{ mmol litre}^{-1}$ glucose in solutions at 37°C . The elaboration of such sensors is of great importance for diabetic patients.

Inhalation of air containing high ammonia concentrations can lead to pulmonary edema; once the ammonia concentration reaches $5000 - 10\,000 \text{ ppm}$, death occurs in $5 - 10 \text{ min}$. Prolonged exposure in an atmosphere containing small ammonia concentration does not harm the health. This is due to the fact that ammonia is not accumulated in organisms. It is the metabolite of proteins and nucleic acids. Ammonia is removed from organisms with urine in the form of urea and ammonium salts. A small amount of ammonia is secreted by sweat glands.

In certain diseases, the organism contains an enhanced amount of ammonia, which can be found by the analysis of the exhaled air.¹¹² Such a test makes it possible to quickly diagnose stomach ulcer induced by the presence of bacteria *Helicobacter pylori*¹¹³ or the urea imbalance inherent of kidney diseases. As little as several cubic centimetres of exhaled air are sufficient for the analysis with gas-sensitive sensors.¹¹⁴

Diagnosing of *Helicobacter pylori* is based on the urea conversion to ammonia and bicarbonate. Laying aside the complex processes that involve bacteria and lead to the ammonia synthesis, it should be noted that such analyses require sensors capable of the detection of $< 50 \text{ ppb}$ ammonia in the exhaled air in the presence of carbon dioxide in concentrations up to 3% .¹¹² The response time of such sensors should not exceed several minutes. To date, this problem is still unsolved. This example of the ammonia determination for the identification of *Helicobacter pylori* demonstrates all the complexity of problems faced by a designer of sensors for diagnosing diseases.

IV. Conclusion

The analysis of studies published in the recent years allows one to draw several general conclusions on the synthesis and application of nanomaterials in the development of new gas sensors. Two trends are clear, *viz.*, the development of sensors to be employed at room temperature and the use of new quasi-one-dimensional nanostructures (such as nanotubes, nanorods, nanobelts, nanowires, *etc.*) as the sensors.

Studies of size effects typical of substances in the nanostate should stimulate the further investigations of the sensor activity that depends on the surface-to-volume ratio, porosity, sample size and possible reactions with different oxygen forms on the sensor surface.

The use of quasi-one-dimensional materials and the production of hybrid systems require the refinement of mechanisms of the sensor sensitivity. Understanding of these mechanisms determines the successful use of new sensor materials. The following general requirements can be imposed upon virtually all sensor materials: the high sensitivity, selectivity, stability and safety. The other requirements to sensors differ depending on application fields and conditions. The development of nanoscience opens up new directions in the use of sensors, particularly, in the analysis of operation, identification, and safe performance of instruments and materials produced by nanotechnologies.

This review was written at partial financial support of the Russian Foundation for Basic Research (Project No 05-03-32 293) and the Grant of President of the Russian Federation for young Russian scientists, namely, candidates of sciences and their supervisors, (No. MK-4996.2006.3).

Abstract. The state of the art of studies on combustion of organophosphorus compounds (OPC) is presented. The chemical processes occurring in flames upon introduction of OPC additives, the mechanisms of OPC transformations and effect on the combustion rate and the structure and propagation limits of hydrogen and hydrocarbon flames are considered. The key results of experimental and theoretical studies and simulation of the combustion chemistry of hydrogen and hydrocarbon mixed and diffusion flames with and without OPC are described. The mechanism of flame promotion and inhibition by OPC is analysed. The prospects of practical applications of phosphorus compounds as flame promoters and suppressants are evaluated. The toxicity and environmental impact of OPC are discussed. The bibliography includes 124 references.

I. Introduction

The chemistry of phosphorus compounds is very extensive and diversified. Phosphorus and its compounds are common in nature ranging from Earth crust minerals to living organisms where phosphorus is vitally important.

The first mention on the investigation into combustion of phosphorus dates back to the 17th century. In 1680, R Boyle¹ burned phosphorus in air and obtained white vapour, which turned into a white powder on cooling. On treating this powder with water, he obtained a liquid with acid properties. Later in has been found that during combustion of phosphorus and its compounds, a large number of phosphorus-containing species are present in the flame. The mechanism of phosphine combustion proposed in 1993 included about 20 phosphorus oxides and phosphorus-containing acids.² The existence of numerous phosphorus derivatives in the flames attest to a

complex chemical mechanism of transformations of phosphorus and its compounds.

The interest in the combustion chemistry of organophosphorus compounds (OPC) first arose in relation to the problem of destruction of chemical weapons (first of all, nerve agents), which present a serious hazard for both the environment and human life. The combustion of war gases in furnaces formed the basis of an advanced process for the destruction of chemical agent stockpiles. This process was implemented in the USA in the Johnston atoll.^{3,4} At that stage, researchers were mainly interested in the mechanism of destruction of complex organophosphorus molecules that simulate chemical agents in a flame.

The term ‘destruction’ is used to mean the transformation of a compound upon reactions with other flame components or upon pyrolysis rather than its thermal decomposition. The intermediate and final products of OPC destruction in the flame were identified using dimethyl methylphosphonate [DMMP, $CH_3PO(OCH_3)_2$], trimethyl phosphate [TMP, $(CH_3O)_3PO$] and diisopropyl methylphosphonate [DIMP, $CH_3PO(iso-OC_3H_7)_2$] as models. On the basis of obtained results, reactions of H and OH radicals with OPC molecules were proposed, their rate constants were estimated and a number of kinetic mechanisms of OPC combustion were developed. Subsequently, OPC aroused interest as compounds able to retard (inhibit) combustion.

For many years, halo-substituted, mainly bromo-substituted hydrocarbons (halons) such as CF_3Br have been employed as flame suppressants. However, after these compounds were found to deplete the Earth ozone screen, the production of environmentally hazardous halons ceased in industrially developed countries in conformity with the Montreal convention (1990).⁵ Environmentally safe halons like CF_3H and C_2F_5H had low flame suppression efficiency compared to bromine-containing halons; therefore, search for a substitute for halons among other classes of compounds was started. The search led to the OPC family having good prospects as combustion inhibitors.^{6–8}

It is noteworthy that OPC do not merely dilute flames (thermophysical flame suppression effect), but rather change the concentration of the most reactive atoms and radicals in the flame, first of all, H, O and OH (chemical suppression of flame by additives), thus having considerable effect on combustion parameters even at low additive concentration (0.03 vol.%).

Received 4 April 2007

Uspekhi Khimii 76 (11) 1094–1121 (2007); translated by Z P Bobkova

The purpose of this review is to generalise the data on the chemistry and mechanism of OPC transformations in the flames and non-thermal plasma published in the last decades. The review considers in detail the mechanisms of flame promotion, inhibition and suppression by OPC additives. The specific features of inhibition processes for different types of flames are analysed and the dependences of the efficiency of these processes on their conditions (pressure, fuel type, and fuel excess or deficiency) were found. The unique properties of OPC (in particular, physicochemical and toxicological) that distinguish them from other inhibitors were revealed, the effect of OPC on the Earth ozone layer was estimated. On the basis of all the available published data, the prospects for practical applications of phosphorus-containing inhibitors were evaluated.

II. Methods and approaches to investigation of the combustion mechanism of organophosphorus compounds

The chemistry of combustion of organophosphorus compounds has been studied using special experimental and computational methods. Since these processes occur under extreme conditions, many of these methods are actually unique and often poorly known; therefore, below they are described in brief.

1. Experimental methods for investigation of combustion mechanism of organophosphorus compounds

a. Study of the chemical structure of flames by molecular-beam mass spectrometry

The understanding of the essence of chemical kinetic processes taking place in the flames requires knowledge of gas composition in the flames and distribution of combustion product concentrations over the combustion zone. The identification of compounds in the flames and measurement of their concentrations and concentration profiles are usually performed by probe sampling followed by mass spectrometric^{9, 10} or optical spectroscopic analysis. Each of the procedures has its advantages; they have repeatedly been used in the research of flames.

Some species found in the flames (atoms, free radicals and ions) are too reactive and unstable to be sampled and analysed by conventional methods; therefore, the sample was introduced into the ionisation chamber of a mass spectrometer as a molecular beam in which molecules did not collide with either one another or the vacuum chamber walls. The profiled probe nozzle and a large pressure differential promote efficient freezing of reactions that occur in the flame, so that quite a robust sample enters the analyser.

Probe molecular beam mass spectrometry (MBMS) is now the only method to detect all species present in the flame (including reactive species), measure their concentrations and spatial distribution, *i.e.*, determine the chemical structure of the flame.¹¹ However, this method requires additional measures for the separation of substances having similar mass spectra. One of such measures is selective (or so-called soft) ionisation of species in the sample by photoionisation^{12, 13} or electron impact.^{14, 15} For this purpose, a setup with an advanced ion source with a small energy scatter of electrons (± 0.25 eV) corresponding to thermal scatter was designed at the Institute of Chemical Kinetic and Combustion of the Siberian Branch of the RAS.

Owing to soft ionisation, analysis can be carried out at low ionisation energies close to the ionisation potentials of atoms, radicals and molecules and thus it serves for mitigation (or elimination) of molecular ion fragmentation upon electron impact and, hence, facilitates identification of compounds based on their mass spectra.^{14, 15} Table 1 presents ionisation

Table 1. Ionisation potentials and ionisation electron energies for major components of the flame with OPC additives.

Compound or species	<i>m/z</i>	Ionisation potential/eV	Ionisation electron energy in the experiment /eV
PO	47	8.3 ± 0.3	12.8
PO ₂	63	11.0 ± 0.5	12.8
HOPO	64	10.7 ± 0.3	12.8
HOPO ₂	80	12.4 ± 0.2	14.5
(HO) ₃ PO	98	11.5 ± 0.5	17.5
(CH ₃ O) ₂ (CH ₃)PO	124	9.9 ± 0.5	20.0
(CH ₃ O) ₃ PO	140	9.9 ± 0.5	20.0
H	1	13.3 ± 0.5	16.2
O	16	13.6 ± 0.2	16.2
OH	17	13.2 ± 0.2	16.2

potentials and ionisation voltages (ionisation energies, IE) used to measure the major components of flames with OPC additives: atoms, free radicals and key phosphorus-containing compounds. The ionisation potentials of compounds such as PO, PO₂, HOPO, HOPO₂ and (HO)₃PO were determined by measuring the ionisation efficiency curves upon direct sampling of flames with OPC additives. The relative error of measurement of the concentrations of stable compounds in the flame by this method is $< 10\%$, that for radicals is $< 30\% - 50\%$. The perturbing effect of the sampler during flame probing is an important aspect influencing correct interpretation of the experimental results. In recent years, a number of experimental and computational studies dealing with the flame perturbation by the probe were published (see, for example, Refs 16, 17). The results obtained in these studies substantiate the efficiency of using the experimental temperature profile for simulation of the concentration profiles of compounds in the flame.

b. Measurement of flame temperature using thermocouples

The temperature distribution across the combustion zone is usually measured by microthermocouples [Pt/(Pt + 10% Rh) and so on] with different diameters. For preventing catalytic processes, the thermocouple surface is coated by SiO₂ or ceramics.¹⁸ The emission corrections were estimated by the Kaskan formula¹⁹ or excluded by using compensation measurements.²⁰ The agreement between the temperature and concentration profiles across the zone was attained by shifting the concentration profiles with respect to the temperature profile.²¹ The error of temperature measurement usually did not exceed ± 30 K.

c. Methods of measurement of normal flame propagation speed

Several methods exist for measuring of the normal propagation speed of the flame front in laminar pre-mixed gas mixtures. One method is based on the use of the Mache–Hebra burner,²² which provides the contour of the visible image of the flame as a regular cone. The accuracy of measurement of the flame speed by this method is $\pm 5\%$. This method for flame propagation speed measurement is very convenient due to its simplicity and availability but is considered to be least accurate.

The technique of zero heat flux to the burner, which has found wide use in recent years, is more accurate.^{23, 24} This method makes use of a flat burner consisting of a copper disc with evenly distributed holes and the side surface cooled by tap water. The radial temperature distribution over the burner surface is measured by insertion of thermocouples into its holes at different distances from the burner centre. When temperature is evenly distributed over the burner disc surface, a heat flux from the flame to the burner is absent, the flame existing

under nearly adiabatic conditions. This means that the flow rate of the combustible mixture is equal to the free distribution speed of the flame.

The method of measurement of the normal speed of flame propagation using a constant volume bomb also deserves attention.²⁵ This measurement requires a special high-pressure chamber, as ignition of the combustible mixture results in substantial pressure rise in a closed vessel.

d. Methods of determination of the minimum quenching concentrations of flame suppressants

The minimum quenching concentration (MQC) is a concentration of a substance in the flame such that the flame is quenched when this concentration has been attained. This is an important characteristics for evaluating the prospects of using a particular compound as a flame suppressant. A standard method for determining the MQCs of flame suppressants^{26, 27} is the cup burner method. It consists of suppression of the diffusion methane–air or n-heptane–air flame by introducing flame suppressant vapour into the air stream.²⁷ Poorly volatile (liquid) compounds are injected into the air stream by means of a nebulizer. Air is heated to enhance evaporation rate of the aerosol of the liquid compound. Yet another, alternative method for determination of MQC is the ‘cylinder’ method described by Baratov *et al.*^{28, 29} Whereas the cup burner method implements a scenario of extinguishing a local ignition source by an air stream with admixed flame suppressants, the ‘cylinder’ method is based on a fire extinguishing scenario in an indoor area.

One more method, the fire chamber method, is used to determine the MQC of flame suppressants under nearly natural conditions. These measurements require a large amount of flame suppressant; therefore, this method cannot be used for screening.

A special setup was designed to study the quenching efficiency of a turbulent[†] flame upon short-term supply of a flame suppressant.³⁰ Using this setup, the dependence of MQC on the supply time of the flame suppressant and the fuel volumetric flow rate was studied. For the study of turbulent flame quenching by poorly volatile liquid OPC, a setup similar to that described previously³⁰ was manufactured.³¹ Both simulate aircraft engine fire extinguishing. Liquid flame suppressants were supplied by a highly dispersed aerosol generator (particle size < 1 µm) of an original design.³¹

2. Numerical simulation and quantum chemical calculations

a. Simulation software

The chemistry of OPC combustion is often studied by numerical simulation, which allows one to calculate the propagation speed and the chemical and thermal structures of multicomponent laminar and diffusion flames. Model calculations use thermochemical and transport characteristics of flame components, detailed chemical mechanism of the combustion process as a set of elementary steps with indicated rate constants for each step. These calculations were carried out using PREMIX and CHEMKIN softwares.^{32, 33} The PREMIX programme calculates (for a unidimensional case) the flame propagation speed and the temperature and component concentration profiles in a freely propagating flame or a flame stabilised on a flat burner. The CHEMKIN-II programme and later versions CHEMKIN-III and CHEMKIN-IV softwares choose the required thermochemical, kinetic and transport characteristics of flame components from the databases included in the program package. All calculations are based on solution of the energy conservation equation with allowance for diffusion.

[†] A turbulent flame site above a tank with liquid fuel is most difficult for extinguishing, especially if the tank is located behind a wedge-like barrier.

One can also use the HCT programme (Hydrodynamics, Chemistry and Transport)³⁴ developed at the Lawrence Livermore National Laboratory (USA) and the OPPDIF programme,³⁵ which is a part of the CHEMKIN package. The latter programme was used to calculate the temperature and component concentration profiles, the radial and axial constituents of the flow velocities along the burner axis in the diffusion flame stabilised at the counterflow of the fuel and the oxidant (the Potter burner^{36, 37}).

b. Kinetic mechanisms

Although the kinetic models of hydrogen and hydrocarbon combustion bear only an indirect relation to the OPC combustion chemistry, the results of simulation of the structure or propagation speed of OPC-doped flames still depend appreciably on the selected mechanism for hydrogen and hydrocarbons. In this connection, we considered it necessary to present brief information on the most often encountered mechanisms of combustion of these compounds.

The rate constants for reactions that describe the hydrogen combustion process have been reported.^{38–40} The H₂ combustion was studied in detail by Dixon-Lewis *et al.*,⁴¹ Tsang and Hampson⁴² and Yetter *et al.*⁴³ A kinetic scheme of hydrogen combustion that includes 40 most important elementary steps involving 8 species has been described.⁴⁴ Although this process has been well studied, a large number of models that differ from one another in both the set of reactions and the rate constants for these reactions can be found in the literature. The latest model of hydrogen oxidation under atmospheric pressure was developed in 2004.⁴⁵

Hydrocarbon flames can be simulated using the GRI-Mech mechanism⁴⁶ describing the combustion of natural gas in the presence of nitrogen. A version of this mechanism, namely, GRI-Mech 3.0 comprises 325 reactions involving 53 components (including argon). One more, Konnov's mechanism⁴⁷ includes 1207 reactions involving 127 components. This is used to describe the combustion of hydrocarbons (≤C₃) and their derivatives. The last-mentioned mechanism was successfully used to calculate the speed of free propagation of propane–air flames.⁴⁷ The results are in good agreement with experimental results.^{48, 49} The kinetic mechanism of propane combustion proposed by Conaire *et al.*⁵⁰ and upgraded by Curran *et al.*⁵¹ was used to describe the structure of propane–oxygen flames with OPC additives stabilised on a flat burner⁵² and to calculate the propagation speed of propane–air flames.⁵³ The mechanism includes 469 steps which involve 77 components.

c. Quantum chemical calculations

The thermochemistry of phosphorus-containing compounds has little been studied until recently. Only recently, was this field of OPC chemistry developed owing to quantum chemical calculations,^{54–56} which became much more precise. This is especially important, as phosphorus oxides are unavailable as commercial chemicals due to their low stability. Table 2 presents the formation enthalpies of PO, PO₂, PO₃, HOPO, HOPO₂, (HO)₂PO, HPO, HPO₂, P₂O₃, P₂O₄ and P₂O₅(gas). Not only thermochemical parameters of OPC (enthalpy, entropy), but also the rate constants for some key reactions of phosphorus-containing species with atoms (H, O, C, N) and radicals were calculated.^{52, 53}

As shown below, these calculations identify more precisely the previously developed kinetic mechanisms and provide better agreement between the experimental data and the results of simulation of the flame propagation speed and chemical structure.

A considerable contribution to the development of OPC combustion mechanism and the kinetic model of the process was made by theoretical works carried out at the Lawrence

Table 2. Formation enthalpies ($\Delta H_f^\circ/\text{kJ mol}^{-1}$) of phosphorus-containing compounds calculated by various methods.

Compound	BAC-MP4 (Ref. 54)	CBS (Ref. 56)	BAC-G2 (Ref. 52)	G3X2 (Ref. 55)
PO	−12.6	−33	−37	−38

HPO ₂	−406		−425	
P ₂ O ₃	−616		−658	
P ₂ O ₄	−855		−908	
P ₂ O ₅	−1072		−1135	

Livermore National Laboratory (USA). The OPC combustion model proposed at this laboratory was based on quantum chemical calculations of the thermochemical properties of phosphorus-containing molecules and transition states and reaction rate constants. This approach is more substantiated from the kinetic standpoint as compared with mere variation of the rate constants, as was done in the early investigations. The thermochemical data (enthalpy, entropy and heat capacity) were calculated for 25 compounds of pentavalent phosphorus in which the phosphorus atom is bound to hydrogen, carbon, nitrogen or sulfur atoms.

3. Integrated approach to elucidation of the combustion mechanism of organophosphorus compounds

An efficient approach to investigation of the OPC combustion chemistry is a comparison of experimental and simulated data. The larger the number of combustion characteristics being compared (propagation speed and chemical structure of the flame, propagation limits, minimum quenching concentrations and so on) the more thorough the verification of the proposed kinetic model and the more reliable the model. A problem of many (almost all) kinetic mechanisms is that they have been validated against a limited number of data.

It is noteworthy that the combustion mechanism depends on the stoichiometric composition of the fuel mixture. In the fuel-rich flames, the processes are complicated due to the formation of heavy hydrocarbons, soot precursors. These flames are most often difficult to study, and general hydrocarbon combustion models often poorly predict the characteristics of these flames.

The most thorough verification for any mechanism is a comparison of the calculated and measured flame structures, first of all, a comparison of the concentration profiles of atoms, radicals and other unstable species. This approach was used to study the chemistry of OPC combustion and especially to study the mechanism of inhibition of hydrocarbon flames by TMP.

III. The mechanism of destruction of organophosphorus compounds in the flame

The first soft ionisation MBMS study⁵⁷ devoted to the OPC transformations in the flames (1994) reported the mass spectra of samples taken from the flame and the intensity profiles for ion peaks with m/z corresponding to the initial compounds and intermediate and final products of TMP and tributyl phosphate (TBP) combustion in a hydrogen–oxygen flame at a pressure of 80 Torr. When measuring the TMP and TBP concentration in the flame, it was shown that OPC in a low-pressure hydrogen–oxygen flame are consumed faster than the major flame components (H₂ and O₂). Systematic research into the mechanism of destruction of DMMP, TMP, DIMP, and some other OPC was carried out in the subsequent studies.

1. Mechanism of destruction of dimethyl methylphosphonate

In a study of the structure of a hydrogen–oxygen flame doped with DMMP at 47 and 76 Torr, key intermediates of DMMP destruction with masses of 110 and 94 were detected and identified as methyl methylphosphonate and methylphosphonic acid, respectively. The final phosphorus-containing products of DMMP combustion with m/z 47, 63, 64 and 80 were identified as (PO), (PO₂), (HOPO) and (HOPO₂).^{14, 58, 59}

a. Intensity profiles of the mass peaks of the starting dimethyl methylphosphonate and the intermediate and final products of its destruction

In order to analyse the possible intermediates of DMMP destruction, mass spectra of samples taken from the H₂/O₂/Ar flame ($P = 47$ Torr) doped with 0.2 vol.% DMMP were recorded. The flame samples were taken at distances of ≤ 4 mm from the burner (within the DMMP destruction zone in the flame).¹⁴ The ion peaks with m/z 79, 80, 81, 93, 94, 95, 96, 98, 109, 110 were found in the mass spectra of the samples. The contributions of the fragment ions resulting from ionisation of the DMMP molecule to these peaks were eliminated using a mass spectrum of DMMP recorded in an argon flow. Note that the mass spectrum of DMMP recorded in this way does not contain ion peaks with m/z 110 or 80.

Figure 1 shows the intensity profiles of the peaks of DMMP with m/z 124 and ions with m/z 110, 94 and 80 (with subtracting the contributions of fragment ion peaks) depending on the distance (l) from the burner surface to the probe at $P = 43$ Torr and IE = 12.1 eV. The intensity profiles of ion peaks with m/z 110, 94 and 80 pass through maxima; the intensity maxima of the peaks with m/z 110 and 80 are located at a 1.5 mm distance from the burner, while that for the peak with m/z 94 is at a 2.5 mm distance from the burner. Figure 2 shows the intensity profiles of the peaks of DMMP and ions with m/z 95, 96, 98 and 110 (with subtracting the small contributions of fragment ion peaks) depending on the distance l for $P = 47$ Torr and IE = 20 eV. The presence of maxima in the intensity curves for ion peaks with m/z 80, 94, 95, 96, 98 and 110 indicates that these peaks may correspond to intermediates.

Figure 1. Intensity profiles of ion peaks with m/z 80 (curve 1), 94 (2), 110 (3) and 124 (4) in the H₂/O₂/Ar flame with 0.2 vol.% DMMP at $P = 43$ Torr and IE = 12.1 eV.¹⁴

There are two intermediates with the mass 110: dimethyl phosphonate [HPO(OCH₃)₂] and methyl methylphosphonate [HOPO(OCH₃)(CH₃)]. Under electron impact, both com-

Figure 2. Intensity profiles of the peaks of initial DMMP (curve 1) and ions with m/z 110 (curve 2), 98 (3), 96 (4) and 95 (5) in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with 0.2 vol.% DMMP at $P = 47$ Torr and $\text{IE} = 20$ eV.¹⁴

pounds give species with masses of 95 and 80;⁶⁰ therefore, ion peaks with m/z 95 and 80 correspond to intermediate fragment compounds (presumably, decomposition products of methyl methylphosphonate¹⁴). The peak with m/z 96 corresponds to methylphosphonic acid $[(\text{HO})_2\text{PO}(\text{CH}_3)]$. The intensity of the ion peak with m/z 81 is approximately twice as high as the intensity of the m/z 98 peak, and the behaviour of the intensity curve of the m/z 81 peak fully reproduces that for the ion peak with m/z 98. The ion with mass 81 may thus be a fragment ion of a compound with mass 98 (this compound was identified as orthophosphoric acid). The ion with mass 94 was identified as the $\text{PO}_2(\text{OCH}_3)$ molecular ion. The ion peaks with m/z 79, 93 and 109 correspond to the fragment ions formed upon bombardment of DMMP with electrons. The mass spectra of samples taken from flames were also found to contain peaks corresponding to species with m/z 28 (CO), 44 (CO_2), 47 (PO), 63 (PO_2) and 64 (HOPO).

The intensity profiles of ion peaks with m/z 47, 63, 64, 80 and 98 recorded for flames doped by 0.2 vol.% DMMP at $P = 47$ Torr are presented in Fig. 3. The ion peak with mass 80 has a maximum at a ~ 1 mm distance from the burner surface. It was found that different substances are responsible for contributions to the ion peak with m/z 80 at different distances from the burner surface. Thus analysis of the curve of DMMP ionisation efficiency has shown that the peak with m/z 80 recorded in the flame at a 1 mm distance from the burner surface has the appearance potential $AP = 11.5 \pm 0.3$ eV, while the ion peak with the same mass detected at a distance of 7–10 mm has $AP = 13.5 \pm 0.5$ eV. Analysis of the mass spectra⁶⁰ of the presumed intermediate product, *viz.*, methyl methylphosphonate (mass 110), indicates that it is fragmented upon electron impact to give an ion with mass 80. Thus, at distances of up to 3 mm (where the ion with m/z 110 was detected as an intermediate), the major contribution to the intensity of the peak with m/z 80 is due to the methyl methylphosphonate fragment ion. At distances $l > 3$ –4 mm from the burner surface (*i.e.*, in the final products of DMMP destruction), the molecular ion of HOPO_2 with the same mass appears in the flame.

Analysis of the concentration profiles of intermediates recorded in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame doped with 0.2 vol.% DMMP suggests the following sequence of DMMP transformations in the flames (possible compounds corresponding to these masses are given in brackets):

Figure 3. Intensity profiles of ion peaks with m/z 47 (PO, curve 1), 63 (PO_2 , curve 2), 64 (HOPO, curve 3), 80 (curve 4), 98 $[(\text{HO})_3\text{PO}]$, curve 5] and 124 (DMMP, curve 6) in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with 0.2 vol.% DMMP at $P = 47$ Torr and $\text{IE} = 13.4$ eV.¹⁴

For interpreting the obtained experimental results, the possible fragmentation routes of DMMP (subsequently, also TMP) in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame were analysed. The following types of reactions were considered:

- (i) unimolecular decomposition and four-centre reactions;
- (ii) bimolecular elimination of H, CH_3 and OCH_3 from the DMMP molecule by H, O and OH radicals and the substitution of alkyl and alkoxy groups;
- (iii) bi- and trimolecular recombination reactions.

The enthalpies of the reactions were calculated using the enthalpies of formation of some OPC estimated by Melius.[‡] On the basis of these data, a detailed kinetic mechanism of DMMP destruction in the flame was proposed.⁵⁸ Subsequently, this mechanism was upgraded (reactions from the mechanism proposed by Twarowski^{61–63} were also included).

b. The Twarowski mechanism

An important step towards the understanding of the mechanism of OPC effect on flames was made after they were found to be applicable for increasing the efficiency of a ramjet fueled by hydrogen. It was found that combustion of hydrogen at high altitudes and, hence, at low pressures gives H and OH radicals in super equilibrium concentrations in the combustion chamber. These radicals have no time to recombine in the combustion chamber and are carried away to atmosphere, resulting in a loss in the engine power. For increasing the completeness of combustion, it was proposed to add phosphine to the fuel; this additive ensured an additional kinetic channel of recombination of H and OH radicals to give water. Twarowski^{2, 61–63} carried out a series of studies dealing with the effect of phosphine additive on the H and OH radical recombination rate in the flame. On measuring the variation of the concentrations of OH radicals formed upon combustion of a diffusion hydrogen–oxygen flame in the presence of phosphine vapour by laser-induced fluorescence, Twarowski²

[‡] Private communication (1996, the Lawrence Livermore National Laboratory, USA).

assumed that recombination of OH radicals is catalysed by phosphorus oxides and phosphorus-containing acids: PO, PO₂, HOPO and HOPO₂. He proposed a mechanism for catalytic recombination of H and OH radicals with participation of these phosphorus compounds; in more recent works,^{61–63} he supplemented this mechanism by new reactions with modified rate constants.

c. Analysis of the destruction mechanism

In a study¹⁴ devoted to determination of the general mechanism of OPC transformations in the flame, it was shown that destruction of OPC takes place through replacement of CH₃ and CH₃O groups by H and OH radicals. The full spectrum of the final phosphorus-containing products of OPC combustion was also identified. The obtained results served as the prerequisite for the design of other models for OPC destruction in flames on the basis of detailed kinetics and calculations of structures and propagation velocities of OPC-doped flames.

An essential contribution to the study of chemistry and mechanism of OPC destruction in flames was made by Werner and Cool,¹³ who investigated the chemical structure of rich hydrogen–oxygen flames doped with 0.1 vol.% DMMP.[§] On the basis of the obtained results, they developed a kinetic model for DMMP destruction in the flames. Using soft UV ionisation MBMS, they identified a number of intermediates of DMMP destruction in the flame such as (CH₃)PO₂ (78), (CH₃O)PO (78), (CH₃)(CH₃O)(OCH₂)PO (123), (HO)₂PO(CH₃) (94) and HOPO(CH₃)(OCH₃) (110) (the values in parentheses are the molecular masses of the products). It was shown experimentally¹³ that the destruction occurs upon the reaction of DMMP molecule with H and OH radicals (mainly, with replacement of alkyl and alkoxy substituents by OH groups).

Werner and Cool¹³ also calculated the rate constant for the thermal decomposition of DMMP. According to their data, the activation energy of the reaction of DMMP with OH equals 365 kJ mol^{−1}, indicating a negligibly low contribution of DMMP pyrolysis during combustion. On the basis of their own experimental results¹³ and earlier data¹⁴ and resorting to quantum chemical calculation data obtained by Melius, Werner and Cool¹³ proposed the first detailed mechanism of DMMP destruction in the flame. Using this mechanism, the flame structure was simulated and the results were compared with the experiment. Unfortunately, the researchers did not measure the concentrations of final and intermediate phosphorus-containing combustion products (including stable ones); therefore, the concentration intensity profiles across the combustion zone were equated (in the maximum) to the maximum concentrations of these compounds found by simulation. This somewhat decreases the significance of the work,¹³ as the lack of quantitative experimental results did not allow them to verify whether the model can correctly predict the distribution of combustion product concentrations across the flame zone.

The knowledge of the presence of the above-listed compounds in DMMP-doped flames was used by some researchers to design their own models for DMMP destruction in the flames and to calculate the chemical structure and the free propagation speed of a flame with DMMP additive (see, for example, Refs 64 and 65).

Quantitative measurement of the concentrations of combustion products was the next step towards the understanding of the OPC combustion chemistry.⁶⁶ Thus the proposed mechanisms of OPC destruction were verified by comparing the simulation data with experimental results on the flame structure, and this allowed the researchers to perfect the mechanisms. Since direct calibration of a MBMS unit used to

study the OPC transformations in the flame with respect to PO, PO₂, HOPO or HOPO₂ is impossible due to their instability and, hence, the lack of these compounds, their calibration coefficients were determined from the phosphorus material balance in the flame. Metaphosphoric acid HOPO₂, which exists as the crystals (P₂O₅)_x(H₂O)_y, where $x:y \approx 1:1$, can be considered an exception. However, the extremely low saturated vapour pressure of this acid precludes direct calibration of the unit with respect to this compound.

The calibration factors of phosphorus oxides and phosphorus-containing acids were determined by measuring the intensities of peaks of ions with m/z 40 (Ar), 47 (PO), 63 (PO₂), 64 (HOPO) and 80 (HOPO₂), *i.e.*, the final products of DMMP and TMP combustion in hydrogen–oxygen flames with different composition. The introduction of knowingly larger number of equations than variables into the set of phosphorus balance equations (the set of equations was overdetermined) owing to the large number of peak intensity measurements in the flames with different composition increased the calculation accuracy. The calculated calibration coefficients were used to determine the concentration profiles for PO, PO₂, HOPO and HOPO₂ in a hydrogen–oxygen flame with OPC additive.

The structure simulation of burner-stabilised flames used, as the input data, the temperature profiles measured by a thermocouple with a junction located near the probe orifice. Simulation of the structure of the H₂/O₂/Ar flames in the presence of DMMP⁵⁸ in terms of the Twarowski mechanism² demonstrated that with reaction rate constants proposed by Twarowski, the model predicts incorrectly the concentrations of these components. Analysis of the sensitivity of the rate constants of reactions comprised in the Twarowski kinetic mechanism (Table 3) to the concentrations of phosphorus oxides and phosphorus-containing acids showed that agreement between the simulation and measurement results can be attained by increasing the rate constants for trimolecular reactions 3, 5, 10 and 13 and simultaneously decreasing the rate constants for bimolecular reactions 2, 4, 7, 8, 9, 11, 12 and 14. Such changes in the rate constants resulted in an increase in the calculated HOPO₂ concentration and a decrease in the PO concentration. As a result, the concentration ratio [HOPO]/[PO₂] approached the experimental value.

Previously, incorporation of a number of primary steps giving rise to HOPO(CH₃)(OCH₃) (m/z 110), HOPO(OCH₃)₂ (126), HOP(CH₃)(OCH₃)₂ (125) and PO(CH₃)(OCH₃)(OCH₂) (123) into the DMMP destruction mechanism has been proposed.^{13,14} In the study considered,⁵⁸ reactions involving HOP(CH₃)(OCH₃)₂ (m/z 125) were not included in the final DMMP destruction model, as sensitivity analysis of the consumption rate of DMMP revealed a negligibly low influence of these steps on the kinetics of DMMP consumption. The measurements also showed that only HOPO(CH₃)(OCH₃) was present in the flame in considerable amounts, while HOPO(OCH₃)₂ and PO(CH₃)(OCH₃)(OCH₂) were not detected at all. Thus, the following route of DMMP destruction in the flame was proposed:⁵⁸

The assumption that the reactions of DMMP with hydroxyl yield preferably methyl methylphosphonate rather than dimethyl phosphate is supported by the fact that the C–O bond energy is lower than the C–P bond energy. The mechanism of DMMP destruction proposed by

[§] The same authors published a special study dealing with determination of the ionisation potentials of compounds (CH₃)PO₂ and (CH₃O)PO₂.¹²

^a The dimensionality of the pre-exponential factor A in the equation for the rate constant is s^{-1} for a unimolecular reaction, $\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$ for a bimolecular reaction and $\text{cm}^6 \text{mol}^{-2} \text{s}^{-1}$ for a trimolecular reaction.

Korobeinichev *et al.*⁵⁸ is presented in Scheme 1 (the corresponding reaction enthalpies are given in brackets).

The proposed mechanism of DMMP destruction in the flame was used to calculate the structure of a flame doped with 0.2 vol.% DMMP and the results of calculations were com-

Scheme 1

pared with the results of measurements. The agreement was satisfactory for almost all flame components. The concentration profiles of the following intermediates of DMMP destruction in the flame were reported:⁵⁸ methyl metaphosphate ($(\text{CH}_3\text{O})\text{PO}_2$), methyl methylphosphonate, methylphosphonic acid and orthophosphoric acid.

No direct calibration of an MBMS unit with respect to intermediate organophosphorus products of DMMP destruction was carried out, as these compounds are lacking, unstable or non-volatile (as, for example, methylphosphonic acid), and calibration with respect to orthophosphoric acid proved to be impossible, because this acid decomposed above 100 °C to give water and pyrophosphoric acid. Therefore, the calibration coefficients of the intermediate organophosphorus compounds in the flame were found using the procedure of equating the maximum measured and calculated concentrations, as this was done before (see Ref. 13).

It should be borne in mind that PO , PO_2 , HOPO and HOPO_2 are formed in the flame at high temperature, while after cooling, the composition of combustion products may change appreciably (apparently, various phosphorus-containing acids may form).

2. Mechanism of trimethyl phosphate destruction

The mechanism of destruction of TMP in the flame, unlike that of DMMP, has been studied in detail.^{15, 58, 64, 67–69} Mass spectra of the samples taken from the $\text{H}_2/\text{O}_2/\text{Ar}$ flame doped with TMP exhibited peaks for the intermediate and final products of TMP destruction with m/z 80, 95, 96, 109, 110, 111, 112 and 126. The intensity profiles of some of these peaks and the TMP peak with m/z 140, recorded with $\text{IE} = 21$ eV, are presented in Fig. 4. Since the ion peak with m/z 126 is missing from the mass spectrum of TMP and its intensity profile passes through a maximum, this peak may be related to an intermediate of TMP destruction identified as dimethyl phosphate $\text{HOPO}(\text{OCH}_3)_2$ (DMP).

Figure 4. Intensity profiles of peaks of initial TMP (m/z 140) (curve 1) and ions with m/z 126 (2), 110 (3), 109 (4) and 80 (5) in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with 0.2 vol.% TMP at $P = 47$ Torr, $\text{IE} = 21$ eV.¹⁴

The mass spectra of tri- and dimethyl phosphates exhibit ion peaks with m/z 80, 95, 96, 109, 110, 111 and 112. Figures 5 and 6 present the intensity profiles of these peaks in the flame with subtracting the contributions of TMP and DMP. It can be seen from Fig. 6 that the profile of the ion peak with m/z 110 has three maxima, the third one being feebly pronounced and may be the result of overlap of two curves with maxima at

Figure 5. Intensity profiles of ion peaks with m/z 96 (curve 1), 95 (2), 111 (3), 112 (4) with allowance for contributions of TMP and DMP fragment ions at $P = 47$ Torr in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with 0.2 vol.% TMP.

Figure 6. Intensity profiles of ion peaks with m/z 110 (curve 1), 109 (2), 80 (3) with allowance for contributions of TMP and DMP fragment ions at $P = 47$ Torr in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with 0.2 vol.% TMP.¹⁴

$l = 1.1$ and 1.9 mm. The ion with m/z 110 can be identified either as the molecular ion of dimethyl phosphonate $\text{HPO}(\text{OCH}_3)_2$ or dimethyl phosphite $\text{HOP}(\text{OCH}_3)_2$ or as the fragment ion formed from monomethyl phosphate $(\text{HO})_2\text{PO}(\text{OCH}_3)$ (molecular mass 112). It can be seen from Figs 5 and 6 that the maximum of the ion peak with m/z 112 coincides with the third maximum of the m/z 110 peak. This prompted the conclusion that the third maximum of the m/z 110 peak corresponds to monomethyl phosphite, while the first one is due to dimethyl phosphite. The second maximum has not yet been interpreted. The peaks with m/z 80 and 109 were attributed to fragment ions formed from monomethyl phosphate and dimethyl phosphite. The ion peak with m/z 96 belongs apparently to monomethyl phosphite (the m/z 95 peak is due to a product of its fragmentation). The intensity profiles of ion peaks with m/z 47 (PO), 63 (PO_2), 64 (HOPO) and 80 (HOPO_2) in the flames with TMP and DMMP additives follow the same pattern.

On the basis of these data, possible reactions for TMP destruction in the flame were proposed. The kinetic model of TMP destruction based on these studies was verified in relation to different flames. The concentration profiles of the organophosphorus products of TMP destruction were constructed by

carrying out direct calibrations of an MBMS unit with respect to TMP, DMP and dimethyl phosphite.⁶⁴ Pure monomethyl phosphate was not obtained; therefore, its concentration was estimated from the phosphorus material balance for the flames. Apart from the transformation steps of TMP and the intermediate products of its combustion, which logically follow from analysis of the composition of the combustion products, the reactions of TMP with the OH radical were also considered. It was found that this reaction does not give dimethyl phosphate and methyl alcohol, as was considered previously, but gives water and organophosphorus radical resulting from elimination of the H atom from a TMP molecule.⁷⁰

$$(\Delta H_{298}^\circ = -79.09 \text{ kJ mol}^{-1}).$$

The rate constant for this reaction was measured at a temperature of 300 K, and no activation energy was determined.⁷⁰ This was taken to be equal to the activation energy of a similar reaction of DMMP with OH,¹³ i.e., 16.7 kJ mol⁻¹. The pre-exponential factor in the Arrhenius equation was calculated proceeding from the accepted activation energy and the measured rate constant.⁷⁰ Thus, this reaction was included in the mechanism as a possible primary step of TMP destruction in the flame.

The mechanism of TMP destruction is presented in Scheme 2.^{58, 64} It is of interest to carry out the integral analysis of the transformation routes of TMP and some products of its incomplete destruction to elucidate the role of each step. Analysis showed that the ($\cdot\text{CH}_2\text{O}$)(CH₃O)₂PO radical formation is a key step (consuming more than 70% of TMP), the

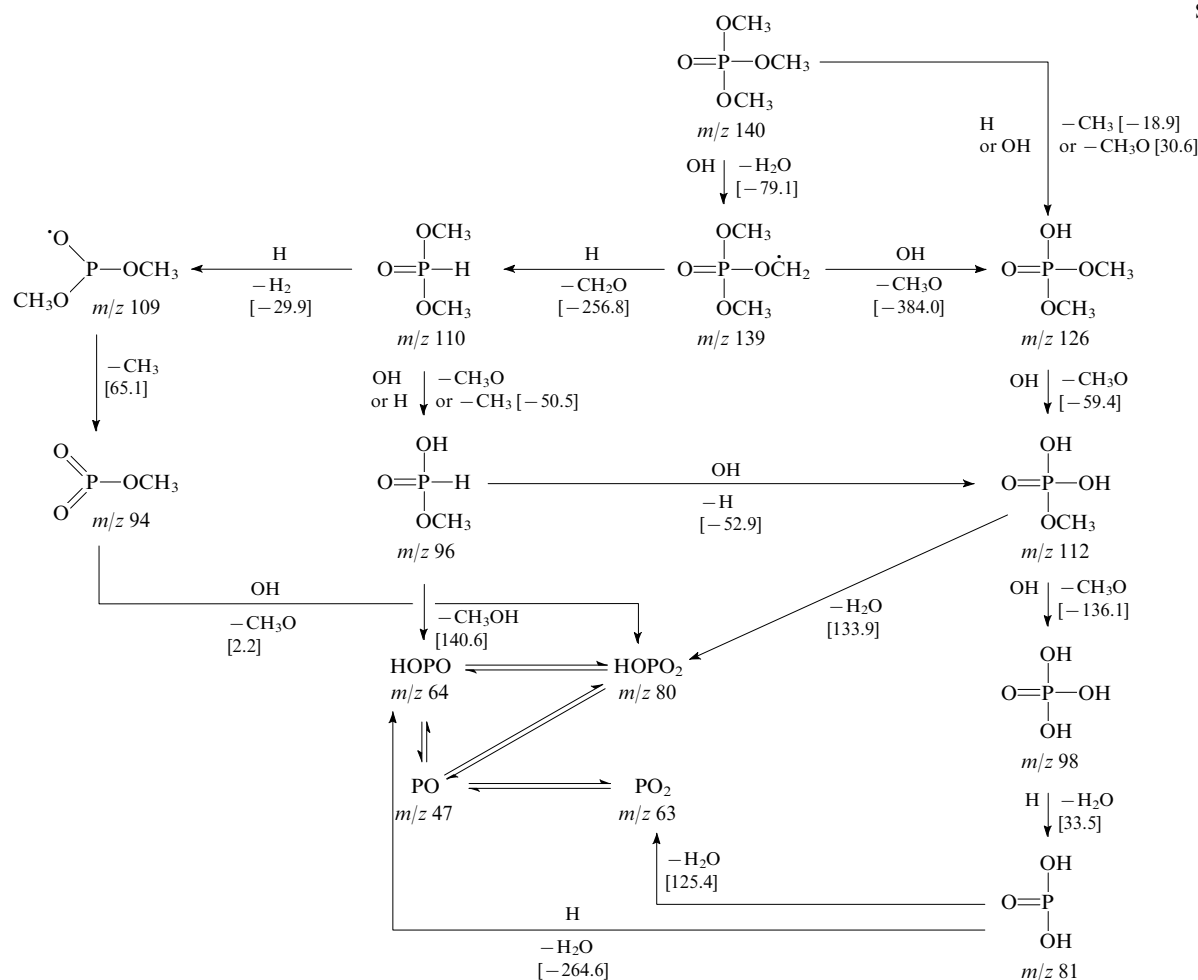

main bulk of products being formed *via* this step. The proposed mechanism of TMP destruction was used to model the structure of the H₂/O₂/Ar flame with a TMP additive.

Figure 7 presents the measured and calculated concentration profiles for TMP and intermediate organophosphorus products of its decomposition in the H₂/O₂/Ar flame at low temperature. It can be seen from comparison of the calculated and experimental data that, despite certain discrepancies, the proposed⁵⁸ model predicts with a satisfactory accuracy the concentration profiles of intermediate organophosphorus products of the destruction of the starting compound. Figure 8 shows the calculated and measured concentration profiles of the final phosphorus-containing products of TMP combustion, namely, PO, PO₂, HOPO, HOPO₂ and (HO)₃PO. Satisfactory agreement between the simulated and experimental results was obtained. [The experimental and simulated results for stable substances (H₂, O₂, H₂O) are compared in Section IV.]

It follows from the series of studies devoted to the OPC combustion chemistry that predicting the concentration profiles of the combustion products PO, PO₂, HOPO and HOPO₂ using the kinetic model is the most complicated task, but these concentration profiles, in addition to the concentration profiles of the H and O atoms and OH radicals, allow one to find whether the mechanism correctly describes the OPC combustion, which is especially important for the description of OPC as combustion inhibitors (or promoters).

Original mechanisms for DMMP and TMP destruction in the flames based on quantum chemical calculations of thermochemical data and on the estimation of rate constants for separate steps were proposed almost simultaneously by two

research groups.^{52, 54} (Glaude *et al.*⁵⁴ took into account all the possible intermediates of destruction of these OPC.) The developed mechanisms were used to simulate the structure of the low-pressure hydrogen–oxygen flame doped with 0.2 vol.% DMMP or TMP. A comparison of the calculation results⁵⁴ with earlier experimental results^{64, 69} demonstrated

good agreement between them as regards both the concentrations of stable components in the flame (H_2 , O_2 and H_2O) and the concentrations of PO, PO_2 , HOPO, HOPO_2 and $(\text{HO})_3\text{PO}$, which is the most difficult-to-attain fitting criterion. At that time, the developed mechanism was the most complete (it included 202 reactions involving 41 phosphorus compounds). This mechanism served as the basis for the development of the mechanism of inhibition of methane and propane flames by OPC additives under atmospheric pressure (see below).

3. Mechanism of destruction of diisopropyl methylphosphonate and sarin

The chemistry of DIMP combustion in the H_2/O_2 flame at low pressure has been studied.⁷¹ Diisopropyl methylphosphonate decomposes rather readily, unlike TMP or DMMP, when heated in an inert gas flow; therefore the thermal decomposition reactions were included in the mechanism of DIMP destruction in the flame. The kinetics and the products of DIMP pyrolysis in a flow type reactor were studied by Zegers and Fisher;⁷² the results are presented below.

$$k = 10^{12} \exp\left(\frac{-153.4 \pm 20}{RT}\right) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

While estimating the contribution of thermal decomposition of DIMP to the overall destruction rate of the substance in the flame, it was concluded⁷² that thermal decomposition plays a minor role in the total mechanism of DIMP destruction. As in the case of other OPC, the major steps of DIMP destruction include the reactions of the OPC molecule with the H atom and OH radical, resulting in replacement or elimination of the CH_3 and $\text{C}_3\text{H}_7\text{O}$ groups, respectively.

By analogy with the DIMP destruction steps, Korobeinichev *et al.*⁷¹ proposed also the possible steps of sarin destruction. They carried out altogether 10 reactions and calculated the heats of reactions based on the Melius thermochemical data (the Lawrence Livermore National Laboratory).

The rate constants for unimolecular decomposition of dimethyl ethylphosphonate, triethyl phosphate and DIMP were calculated.⁵⁴ The correctness of calculations was verified by comparing the simulation data with the experimental results on the pyrolysis of the above-mentioned OPC in a flow type reactor.

As a continuation of their research, the same group⁷³ developed the destruction mechanisms for a number of fluorinated OPC and TMP, DMMP, DIMP and sarin. The hierarchical schemes of reactions were based on previously proposed mechanisms of OPC destruction using the principle of chemical bond additivity. The kinetic models of combustion of the above-listed OPC and sarin were used in the calculations predicting their consumption rates during the combustion of natural gas (94% of methane and 6% of ethane) with air in a perfect-mixing reactor.[¶] A comparison of the dependences of concentrations of various OPC in the combustion on temperature and residence time has shown that TMP and DMMP consumption follow identical kinetics; the same is true for DIMP and sarin. The researchers concluded that only DIMP is a true mimic of sarin.

Scheme 3 shows simplified patterns of the thermal destruction of DIMP and sarin at high temperature in a perfect-mixing

¶ This process simulates disposal of these compounds by incineration in a furnace.

reactor. It is noteworthy that both DIMP and sarin destruction mechanisms include not only thermal decomposition steps. A full mechanism of sarin combustion that includes 24 steps most of which are reactions of sarin with H and OH radicals has been reported.⁷³

Comparative analysis of the mechanisms of destruction of various OPC carried out by the researchers cited has shown that the six-centred elimination of C_3H_6 present in the destruction mechanisms of DIMP and sarin is responsible for their higher reactivity compared to that of TMP or DMMP. This means that C—C bonds are most susceptible to cleavage in the OPC molecule.

It is noteworthy that the conclusions drawn⁷³ are at variance with the conclusions of an earlier publication.⁷¹ As noted above, experimental study and numerical simulation of the DIMP destruction mechanism in the low-pressure hydrogen—oxygen flame⁷¹ led to the conclusion that the thermal decomposition of DIMP gives a minor contribution to the overall destruction rate. Apparently, these discrepancies can be interpreted in the following way. The concentrations of H, O and OH atoms and radicals in the hydrogen—oxygen flame at low pressure are very high (according to a publication,⁷⁴ the $\text{H} + \text{O} + \text{OH}$ molar concentration is about 10%). This suggests that the role of thermal decomposition of even thermally unstable compounds is negligibly low against the high rate of DIMP consumption in reactions with the H, O and OH radicals. In hydrocarbon flames, the total molar concentration of active species was reported⁷⁵ to be two orders of magnitude lower. In this case, the role of thermal decomposition markedly increases.

4. Mechanism of destruction of organophosphorus compounds in a non-thermal plasma

The mechanisms of OPC destruction in the flame and non-thermal plasma have much in common. Therefore, it is pertinent to consider briefly the works devoted to the chemistry of OPC destruction in corona discharge plasma. From the practical standpoint, the non-thermal plasma attracts attention of researchers as a medium for effective destruction of toxic or hazardous compounds in low concentrations.

The identification of the OPC destruction products in a non-thermal plasma^{76–78} made it possible to propose the mechanism of their destruction. Among the stable intermediate products of DMMP destruction in the corona discharge plasma, methyl methylphosphonate and monomethyl phosphate were detected; methylphosphonic and orthophosphoric

acids were formed as the final products of DMMP destruction. The same species are also the final products of DIMP destruction, whereas isopropyl methylphosphonate is an intermediate product. The destruction of TMP yields dimethyl and monomethyl phosphates (intermediates) and orthophosphoric acid (final product).

Thus, in a non-thermal plasma, DMMP, DIMP and TMP undergo the following transformations:

The identification of the OPC decomposition products in a non-thermal plasma showed that they are the same as many OPC destruction products in the flame. Apparently, in a corona discharge, as in the flame, the alkoxy and alkyl groups are replaced successively by H or OH. Two possible mechanisms of OPC destruction in the nonthermal plasma, radical and ionic ones, have been described. According to the radical mechanism, OPC destruction occurs upon the reaction of the atoms and radicals formed in the discharge with OPC, similarly to the situation in the flame. The discussion of the ionic mechanism in the OPC destruction in the nonthermal plasma is beyond the scope of this review. It should be noted that no unambiguous evidence supporting either of these two mechanisms is currently available.

IV. Mechanism of promotion and inhibition of the H_2/O_2 flames by addition of organophosphorus compounds

Korobeinichev *et al.*^{14, 57, 64} first demonstrated experimentally that the addition of 0.2 vol.% OPC to the $\text{H}_2/\text{O}_2/\text{Ar}$ flames at low pressure results in an increase in the final temperature of the flame and the degree of combustion and in a decrease in the combustion zone width. Figure 9 shows the measured and calculated (at a 15 mm distance from the burner) final temperatures of the $\text{H}_2/\text{O}_2/\text{Ar}$ flame stabilised on a flat burner at 47 Torr, depending on the initial concentration of the TMP additive.⁷⁹ Under these conditions, the increase in temperature

Figure 9. Maximum temperature of the $\text{H}_2/\text{O}_2/\text{Ar}$ flame stabilised on a flat burner at a pressure of 47 Torr vs. TMP concentration.⁷⁹ The continuous line shows the calculated values; the light dots are experimental values and the dark dots show the change in the adiabatic equilibrium temperature.

of the stabilised flame is not related to lower heat loss in the burner, as is usually the case upon the addition of inhibitors; conversely, on the addition of TMP, the flame temperature increases simultaneously with the increase in the temperature gradient at the burner surface, *i.e.*, with an increase in the heat loss. Thus, the increase in the flame temperature with an increase in the TMP concentration is due not to the introduction of additional fuel into the flame but to more complete combustion of the fuel already present as a result of the ability of OPC combustion products to catalyse recombination of the H and OH radicals to give water, *i.e.*, to promote combustion.

The experimental and simulation results are in satisfactory agreement, which confirms the consistency of the kinetic model. For comparison, Fig. 9 shows also the equilibrium temperatures of the adiabatic flames with the same composition. The difference between the adiabatic flames and flames stabilised on a flat burner (cooled) is that in the latter case, a large portion of heat is absorbed by the burner.

Figure 10 shows the concentration profiles of the stable components H_2 , O_2 and H_2O in the $H_2/O_2/Ar$ flame stabilised on a flat burner at a reduced pressure of 47 Torr without additives or with 0.2 vol.% TMP.⁶⁶ The narrowing of the combustion zone (the final composition of the combustion products is attained at a shorter distance from the burner surface) and fuller combustion of the H_2 and O_2 components attest to a promoting effect of TMP on the flame.

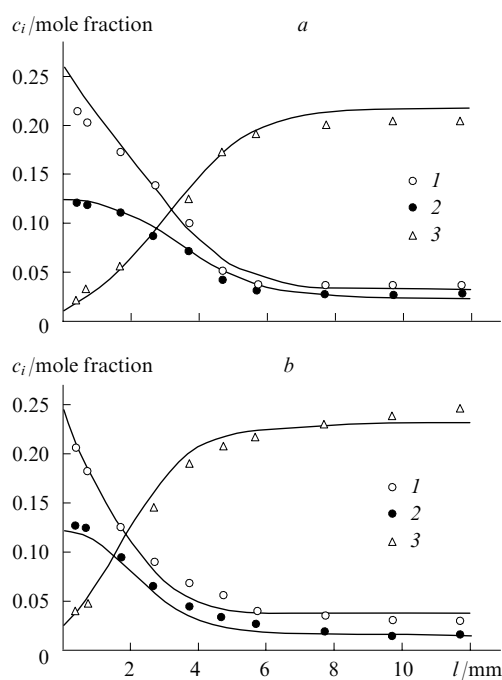

Figure 10. Concentration (c_i) profiles of stable components H_2 (1), O_2 (2) and H_2O (3) in the $H_2/O_2/Ar$ flame stabilised on a flat burner at $P = 47$ Torr without additives (a) and with 0.2 vol.% TMP (b).⁶⁶ The dots show experimental values and the lines correspond to simulation results.

The observed promoting effect was confirmed by comparing experimental data with simulation results obtained using the mechanism proposed by Glaude *et al.*⁵⁴ The promoting effect of OPC increases with an increase in the concentration and reaches a maximum at an OPC concentration of ~ 0.6 vol.%. This can be seen from the computational data presented in Fig. 11, which shows the dependence of the free propagation speed of the hydrogen–oxygen flame on the additive concentration at a reduced pressure (47 Torr). In the

Figure 11. Normal propagation speed of the H_2/O_2 flames vs. the concentration of TMP additive at pressures of 47 (curve 1) and 760 Torr (curve 2).

TMP concentration range from 0 vol.% to 0.6 vol.%, this additive acts as a promoter. On further increase in the TMP concentration, the flame propagation speed decreases. At a pressure of 760 Torr (1 atm), OPC acts only as an inhibitor.

The effect of OPC on the concentration of the H, O and OH radicals in the flame is shown in Fig. 12, which gives the calculated and measured concentrations of these radicals in the $H_2/O_2/Ar$ flame without additives and with 0.2 vol.% TMP.⁶⁶ The introduction of OPC results in a decrease in the concentration of hydrogen and oxygen atoms and an increase in the hydroxyl concentration. It can be seen

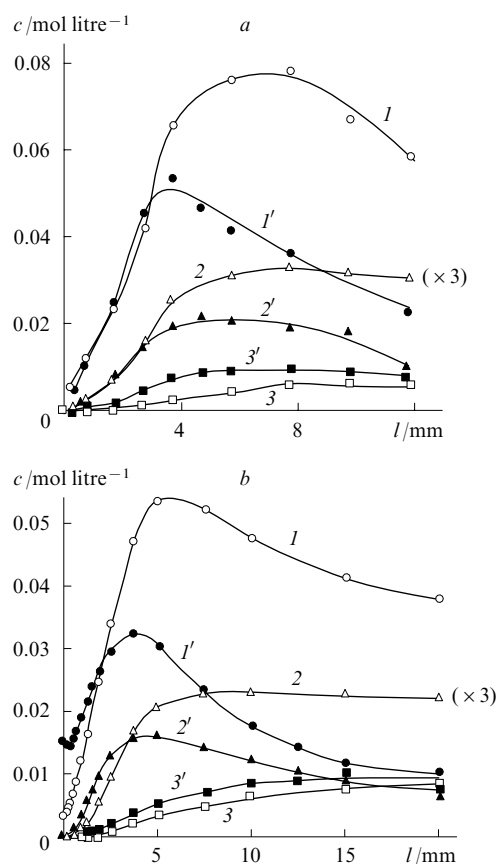

Figure 12. Concentration profiles of radicals H (curves 1, 1'), O (2, 2') and OH (3, 3') in the $H_2/O_2/Ar$ flame stabilised on a flat burner at $P = 47$ Torr without an additive (light dots) and with 0.2 vol.% TMP (black dots).⁶⁶ (a) experimental data, (b) simulation results.

from comparison of the concentration profiles that the computation and experimental results are in satisfactory agreement. The effect of OPC on the concentrations of H, O, and OH radicals is an important feature of these compounds, which accounts for their possible practical application as combustion inhibitors and flame suppressants.

It was shown⁶⁹ that the addition of OPC to a methane–oxygen flame at a pressure of 0.1 bar decreases the flame propagation speed. Thus, OPC are combustion promoters only for low-pressure hydrogen flames. Note that an increase in the propagation speed of flames with an increase in the concentration of the inhibitor (bromoethane, dibromotetrafluoroethane, bromine, diethylamine, methane, and methanol) in lean and rich hydrogen–air flames at high pressures was described previously.⁸⁰ However, the mechanism of this effect is different and is related, in the authors' opinion, to the fact that active additives can function as additional fuel or oxidant.

The additional heat release caused by combustion of the additive (at a definite concentration) can counterbalance its inhibiting action. However, the action of OPC is due to a kinetic rather than thermophysical effect. The H and OH radical recombination in the flame catalysed by OPC destruction products is yet another channel for water formation

which provides heat release. The evolved heat increases the temperature and accelerates recombination of active species, despite the decrease in their concentration in the flame.

A detailed interpretation of the promoting effect of OPC based on the analysis of the kinetic model of OPC destruction (see Ref. 58) has been proposed.^{79, 81} The calculations of the quadratic branching rate

for the combustion zone of a hydrogen–oxygen flame at low pressure showed that the rate of this reaction considerably increases with an increase in the TMP concentration and reaches a maximum at $c_{\text{TMP}} = 0.5 \text{ vol.}\% - 0.6 \text{ vol.}\%$. This increase in the reaction rate is mainly due to an increase in the flame temperature[†] as a result of increase in the recombination rate of H, O and OH atoms and radicals. The quadratic branching rate stops to grow following an increase in the TMP concentration where the flame temperature reaches an equilibrium.

A comparison of contributions of various reactions to the flame propagation speed demonstrated that with an increase in the TMP concentration, the contribution of branching exceeds considerably the contributions of reactions (2)–(5) contained in the hydrogen oxidation mechanism (Fig. 13).

The increase in the branching rate with an increase in the TMP concentration and saturation of this effect as the flame temperature approaches the equilibrium value is shown in Fig. 14. Among reactions involving phosphorus-containing

[†] The rate of branching reaction, which is proportional to the product of H atom concentration by the rate constant for the reaction, increases with an increase in the TMP concentration owing to the fact that the reaction rate constant grows (with an increase in temperature) faster than the H concentration drops.

Figure 13. Sensitivity coefficients $[u(k)/u(k/5)]$ of reactions (1)–(5) taking place in the flame comprising 26% H_2 + 13% O_2 + 61% Ar at $P = 47.5$ Torr and $T_0 = 370$ K for different TMP concentrations;⁸¹ $u(k)$ is the flame propagation speed calculated with the standard rate constant for the reaction; $u(k/5)$ is the rate calculated with the rate constant decreased fivefold.

Figure 14. Rate constant for quadratic branching $\text{H} + \text{O}_2 = \text{OH} + \text{O}$ as a function of temperature of the flame comprising 26% H_2 + 13% O_2 + 61% Ar without additives (curve 1) and with TMP (curves 2–5) added in different concentrations at $P = 47.5$ Torr and $T_0 = 370$ K.⁸¹ c_{TMP} (%): 0.1 (2), 0.4 (3), 0.8 (4), 1.0 (5).

compounds to which the flame propagation speed is most sensitive (according to Ref. 81), the following reactions should first be noted:

These reactions result in chain termination and play an important role in the catalytic radical recombination cycle. The calculation of the sensitivity coefficients of the flame propagation speed to the reaction rate constants for flames with different OPC concentrations has shown that in the additive concentration range from 0 vol.% to 0.5 vol.%, these coefficients are positive, *i.e.*, recombination reactions increase the flame propagation speed. When the TMP concentration is $> 0.5 \text{ vol.}\%$, the coefficients are negative and decrease with an increase in the OPC concentration in the flame, *i.e.*, the

Figure 15. Sensitivity coefficients of key reactions (6)–(10) taking place in the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with participation of OPC for different TMP concentrations.⁸¹

hydrogen combustion is retarded. Thus, transition from promotion to inhibition with the same reactions being responsible for this attests to unique properties of phosphorus compounds. Figure 15 presents the sensitivity coefficients (ξ) for the key reactions that take place in the flame and involve phosphorus-containing compounds at different TMP concentrations. The sensitivity coefficients were determined from the relation

$$\xi = \frac{u(k) - u(k/5)}{u(k)} 100\%,$$

where $u(k)$ is the free propagation speed of the $\text{H}_2/\text{O}_2/\text{Ar}$ flame with a TMP additive at a pressure of 47.5 Torr; $u(k/5)$ is the free propagation speed of the flame calculated using the reaction rate constant reduced fivefold.

Under atmospheric pressure, the concentration of active species in the flame is two orders of magnitude lower than under reduced pressure, and the temperature of the adiabatic flame is close to thermodynamic equilibrium; therefore, even a minor additive of phosphorus compounds results only in flame inhibition.

The chemistry of combustion of sulfur and nitrogen compounds is similar to the phosphorus combustion chemistry. The inhibiting action of SO_2 on the hydrogen–oxygen flame stabilised on a flat burner has been studied.⁸² The reactions

which play the key role in the inhibition mechanism and form the inhibition cycle, are similar to the reactions of phosphorus oxides and phosphorus-containing acids. However, the inhibiting efficiency of sulfur compounds is much lower compared to phosphorus. This can be attributed to the lower rates of catalytic reactions.

A computational theoretic analysis of the effect of nitrogen oxide admixture on the ignition delay in a hydrogen–air mixture has been carried out.⁸³ The calculations showed that at temperatures above 1200 K, the addition of NO to a hydrogen–air mixture somewhat decreases the ignition delay, *i.e.*, NO functions as a promoter. However, at lower temperature, the ignition delay increases, *i.e.*, the NO admixture functions as an inhibitor. The researchers believe that the effect of nitrogen oxide on the hydrogen oxidation kinetics is due to its ability to catalyse radical recombination

These reactions are analogous to those presented for OPC.

V. Studies of the mechanism of inhibition and quenching of hydrocarbon flames by organophosphorus additives

1. Premixed laminar flames

a. The structure of flames with organophosphorus additives

The work of Hastie and Bonnell,⁶ who studied the effect of the classical inhibitor CF_3Br and of TMP on the methane–oxygen and hydrogen–oxygen flames of various types and compositions by molecular-beam mass spectrometry and optical methods, should be considered the pioneering study dealing with the effect of OPC on the combustion processes under atmospheric pressure. The visual monitoring of the height of the flame cone stabilised on the Bunsen burner allowed them to draw the first conclusion that the introduction of a TMP additive resulted in a decrease in the normal free propagation speed of the methane–oxygen flame, *i.e.*, they demonstrated that TMP is a combustion inhibitor. Hastie and Bonnell⁶ were the first to propose a series of reactions involving phosphorus compounds (phosphorus oxides and phosphorus-containing acids), which described recombination of H and OH radicals. This was actually the first interpretation of the mechanism of flame inhibition by OPC.

Numerous experimental data collected by these researchers are unique and highly important. The key result of their studies is the discovery of the change in the concentrations of H, O and OH radicals upon the introduction of TMP into the flame. Hastie and Bonnell⁶ obtained the first experimental proof for the existence of a relationship between the addition of TMP and the decrease in the concentration of active species in the flame. They measured the intensity profiles for ion peaks of PO, PO_2 and HPO_2 in the mass spectra. Noteworthy also is Hastie's contribution to the molecular-beam mass spectrometry studies of the behaviour of PO, PO_2 and HOPO_2 in the flames.⁸⁴ However, his paper⁸⁴ presents no consistent quantitative experimental data that could be compared with simulation results to verify the proposed inhibition mechanism. This study seems not to be completed as yet, because the results

were presented only in a report⁶ and were not published in refereed editions.

Korobeinichev *et al.*⁸⁵ measured experimentally the concentration profiles of phosphorus oxides and phosphorus-containing acids in the methane–oxygen flames with TMP additive at a pressure of 1 atm and determined the dependences of the flame propagation speed on the additive concentration. A comparison of the results thus obtained with the data of simulation of the flame structure and propagation speed in terms of the mechanism proposed for the low-pressure flame⁵⁸ showed a discrepancy between the simulation and experimental results. Analysis of the sensitivity of flame propagation speeds to the change in the rate constants for PO-, PO₂-, HOPO- and HOPO₂-involving reactions and the effect of these reactions on the concentrations of phosphorus-containing products in the flame prompted the necessity of changing the pre-exponential factor in the expression for the rate constants for some key steps in the mechanism proposed by Korobeinichev *et al.*⁵⁸

Considerable progress in the understanding of processes that take place in the flames with OPC additives was attained owing to quantum chemical calculations,⁵⁵ which resulted in upgrading of the Twarowski mechanism of flame inhibition by organophosphorus compounds. By computation of the potential energy surfaces for the transformations

which were earlier regarded as elementary steps,⁵⁴ Mackie *et al.*⁵⁵ demonstrated that actually these reactions occur in two steps:

The subsequent calculation of the potential energy surfaces using more advanced methods^{52, 53} demonstrated that these reactions may include even more steps:

According to the calculation,⁵³ the rate constant for the latter reaction at a temperature of 1500 K was 10 times higher than the value proposed previously.⁵⁴ Figure 16 shows the potential energy surfaces for the possible paths of the HOPO₂ + H reaction. On the basis of quantum chemical calculations of the rate constants for some reactions and calculation of the thermochemical properties of phosphorus-containing molecules and transition states, the most complete and currently substantiated mechanism of flame inhibition by OPC additives under atmospheric pressure was developed at the Lawrence Livermore National Laboratory.⁸⁶ This mechanism includes

Figure 16. Potential surfaces of the possible transformation paths of the system HOPO₂ + H (paths a–d) and the reaction products of HOPO₂ with H.⁵³

The enthalpies of formation (in kcal mol^{–1}) for compounds and transition states are given.

210 steps involving 43 compounds. Apart from the above-considered steps, the steps involving compounds like P₂O_n and reactions of phosphorus oxides with alkyl radicals such as CH₃ and C₂H₅ were also included. The subsequent analysis showed that these steps do not have a significant effect on the results of flame simulation over a wide range of equivalence ratio. Thus, this mechanism can be considered even somewhat excessive.

The mechanism of flame inhibition by OPC additives can conventionally be divided into two parts. The first part includes destruction of OPC (TMP and DMMP) to ‘light’ phosphorus-containing compounds like H_xP_yO_z; the second one includes reactions of H_xP_yO_z with the H, O and OH radicals, which ensure their removal from the flame through their catalytic recombination. This part of the mechanism is crucial in the description of flame inhibition phenomena by OPC additives. Table 4 presents the reactions from the second part of the mechanism and the corresponding rate constants. The notes to the Table outline the methods used to estimate the rate constants.

Note that Jayaweera *et al.*⁵³ made considerable advances not only in the development of the proper mechanism but in the in-depth understanding of processes taking place in the flames with OPC additives. They estimated the efficiency of action of inhibitors on the premixed flames using two parameters: the change in the concentrations of the H and OH radicals and the flame propagation speed. Both parameters were discussed for lean and rich flames with equivalence ratio $\phi = 0.8$ and 1.3, respectively.

It was mentioned above that the addition of OPC inhibits flame propagation by accelerating the recombination of H and OH radicals; therefore, the distribution of concentrations of

^a The rate constant was taken from Ref. 62 (the expression for the rate constant was converted into the Arrhenius form). ^b The efficiency coefficients for a third body M (H₂O or H₂) are referred to N₂ (the efficiency factor of H₂O is 16, that of H₂ is 2.5). ^c The pre-exponential factor present in the equation for the rate constant for forward reaction was calculated using the pre-exponential factor from the equation for the rate constant for the reverse reaction taking into account partial equilibrium. The activation energy of the forward reaction CH₃OH + H = CH₃O + H₂ (elimination of the hydrogen atom) was equal to zero according to calculations. Estimated by Glaude *et al.*⁵⁴ ^d The proposed mechanism includes several reactions with identical initial compounds and products but following different channels (for example, elimination and addition reactions). ^e The rate constant was adjusted to the temperature range of 300–2400 K and *P* = 1 atm (see the text). ^f Estimated by Glaude *et al.*⁵⁴ ^g The pre-exponential factor of the forward reaction was taken from reaction CH₃OH + O = CH₃O + OH.⁸⁷ The activation energy of the forward reaction was calculated from the activation energy of reverse reaction taking into account the partial equilibrium. The activation energy of reverse reaction is equal to zero (from the Evans–Polanyi diagramme⁸⁸). ^h According to calculation, the rate constant for reaction (22) is the same as that for H₂O + OH = H₂O + OH, estimated by Glaude *et al.*⁵⁴ ⁱ Calculated by analogy with the reaction CO + HO₂ = CO₂ + OH (Ref. 42). Estimated by Glaude *et al.*⁵⁴ ^j Calculated by analogy with the reaction C₂H₅OH + HO₂ = C₂H₅O + H₂O₂ (Ref. 89). Estimated by Glaude *et al.*⁵⁴ ^k Based on Walker's recommendation for the reactions RH + O₂ = R + HO₂ (Ref. 90). Estimated by Glaude *et al.*⁵⁴ ^l Calculated by analogy with the reaction CH₃OH + CH₃ = CH₃O + CH₄ (Ref. 91). Estimated by Glaude *et al.*⁵⁴ ^m Addition of the H atoms to the O atom in PO₂. Rate constant calculated by Twarowski and increased threefold.⁶⁵ ⁿ By analogy with the reaction ROH + OH = RO + H₂O (Ref. 92). The activation energy was taken to be equal to the bond energy H–C (tertiary carbon atom), which corresponds approximately to the H–O bond energy in HOPO. ^o Calculated on the basis of the radical recombination rate. ^p Based on the reaction NO + HO₂ = NO₂ + OH (Ref. 93). Estimated by Glaude *et al.*⁵⁴ ^q Calculated on the basis of compact transition state with a zero activation barrier. ^r By analogy with the reaction CH₃ + NO₂ = CH₃NO₂ (Ref. 94). ^s By analogy with the reaction CH₃ + NO₂ = CH₃ONO (Ref. 95). ^t The Mackie addition reaction,⁵⁵ the pre-exponential factor was decreased. ^u Addition of an H atom to the P atom in PO₂. It is assumed that 1% of all reaction products is HPO₂. ^v Addition of the H atoms to the P atom in PO₂. It is assumed that virtually the whole reaction gives HOPO. The rate constant was taken from Ref. 65. ^w The rate constant was calculated from the BAC MP4 data. The *cis* transition state was used.^{96,97}

these two radicals over the flame zone with and without OPC is an important characteristics. As follows from computation results,⁵³ DMMP decreases considerably the concentrations of these radicals in both types of flame; the concentration of the H radical decreases faster in the rich flame than in the lean flame. On the basis of foregoing, the authors concluded that there is a difference between the inhibition efficiency of lean and rich flames by OPC [the inhibition efficiency is the difference between the flame propagation speed without an additive (u_0) and with DMMP additive (u) normalised to the flame propagation speed without DMMP: $(u_0 - u)/u_0$]. The experimental and computation results were used to plot the dependence of the inhibition efficiency on the equivalence ratio (ϕ). This value proved to be very sensitive to the accuracy of measurement of the combustion rate.[‡] The mechanism of flame inhibition by OPC additives developed at the Livermore National Laboratory describes well the dependence of the inhibition efficiency on the equivalence ratio.

According to simulation data,⁹⁸ the efficiency of flame propagation inhibition by the addition of DMMP increases monotonically with an increase in the equivalence ratio from 0.8 to 1.3. However, when experimenting with rich and lean flames, Jayaweera *et al.*⁵³ did not find any significant difference between the DMMP action on these flames, and only calculations did show a slight difference in the inhibition efficiency. To gain an understanding of how OPC inhibit lean and rich flames, the inhibition cycles of these flames were studied in detail.⁵³ Using PREMIX software,⁹⁹ the authors simulated the concentration profiles of OPC involved in the recombination of H and OH radicals in freely propagating propane–air flame with DMMP additive at $P = 1$ atm and calculated the profiles for the formation rates of PO_2 in lean and rich flames (Fig. 17 *a* and *b*, respectively). It follows from the obtained data that the major reaction of PO_2 formation in both types of flames is as follows:

This path to PO_2 is reasonable for a lean flame characterised by high concentrations of OH radicals but for a rich flame characterised by high concentrations of H radicals, it was more reasonable to assume that reaction (10) would be the major path to PO_2 .

However, it was found that reaction (10) makes a minor contribution to the formation of PO_2 due to its high activation energy (11 kcal mol⁻¹) [for comparison, the activation energy of reaction (11) equals 1.5 kcal mol⁻¹]. The major path of PO_2 consumption in both flames is reaction (7). Reactions (7) and (11) form together the catalytic cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ in which the H and OH radicals recombine to give H_2O .

The sensitivity coefficients (ξ) of reactions (6)–(11) to the concentrations of H atoms were analysed⁵³ to determine those having the most pronounced effect on the concentration of hydrogen atoms and to identify the key inhibitor. The sensitivity coefficients of particular reactions to the concentrations of H atoms were determined as derivatives of the mass fractions of H atoms with respect to the pre-exponential factor present in the equation for the rate constant (Fig. 18). A negative sensitivity coefficient means that an increase in the reaction rate results in a decrease in the H atom concentration, *i.e.*, inhibition, while a positive coefficient means that an increase in the reaction rate results in an increase in the H atom concentration. Only reactions involving compounds like H_xPO_y were taken into account. It was noted⁵³ that the sensitivity coefficient of key reaction (1) to the H atom

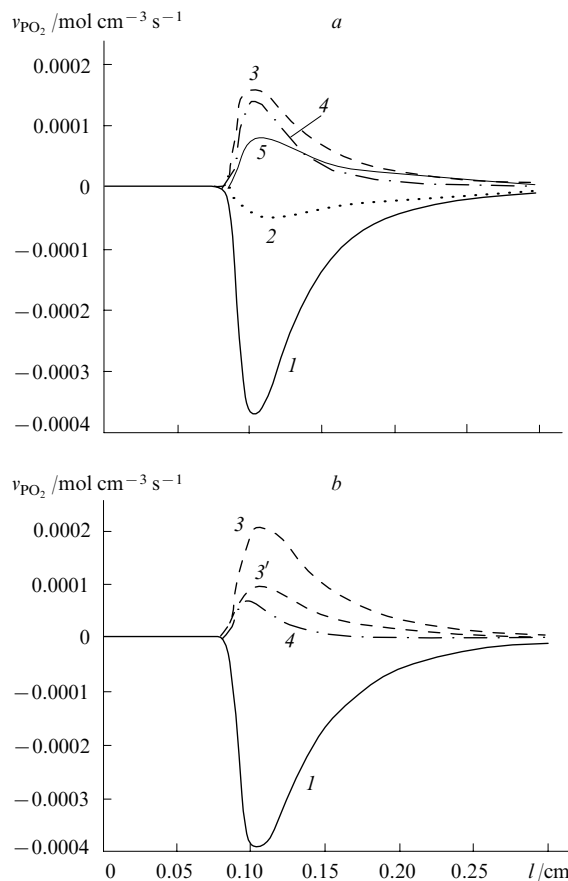

Figure 17. Rates of PO_2 formation and consumption (v_{PO_2}) along reactions (6)–(9) and (11) in lean (*a*) and rich (*b*) flames.⁵³ (1, 2) PO_2 consumption by reactions (7) and (6), respectively, (3–5) PO_2 formation by reactions (11), (8) and (9), respectively (3, through H elimination, 3', through adduct formation).

concentration markedly exceeds in magnitude the sensitivity coefficients of other reactions.

It was found⁵³ that the highest sensitivity of reactions involving H_xPO_y to the H atom concentration in the flame is observed in the post-flame zone. Reaction (7) and, for lean flames, also reaction (9) are most sensitive to the H atom concentration (the rate constant for the latter reaction increases owing to the appearance of a new reaction channel, which was described above).

A curious fact is the increase in the rate of reaction (6) in the lean flame upon an increase in the concentration of H atoms (in the rich flame, the sensitivity of this reaction to the concentration of H atoms is insignificant). The authors believe⁵³ that the sign of the sensitivity coefficient of reaction (6) to the concentration of H atoms changes owing to the fact that the concentrations of H and OH radicals in the cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ decrease faster than in the cycle $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$. The formation of HOPO_2 by reaction (6) results in a decrease in the PO_2 concentration and a decrease in the rate of reaction (7); as a consequence, smaller amounts of H and OH radicals recombine. This suggests that HOPO is a better catalyst than HOPO_2 . In a lean flame where the HOPO_2 concentration is higher than in a rich flame, a lower inhibition efficiency should be expected. The data of calculation of the relative change in the flame propagation speed (see below) also demonstrate that phosphorus inhibits flame less efficiently in lean mixtures than in rich mixtures.

[‡] Note that the accuracy of measurements of propagation speeds of rich flames is relatively low. This hampers comparison of the experimental and calculation data.

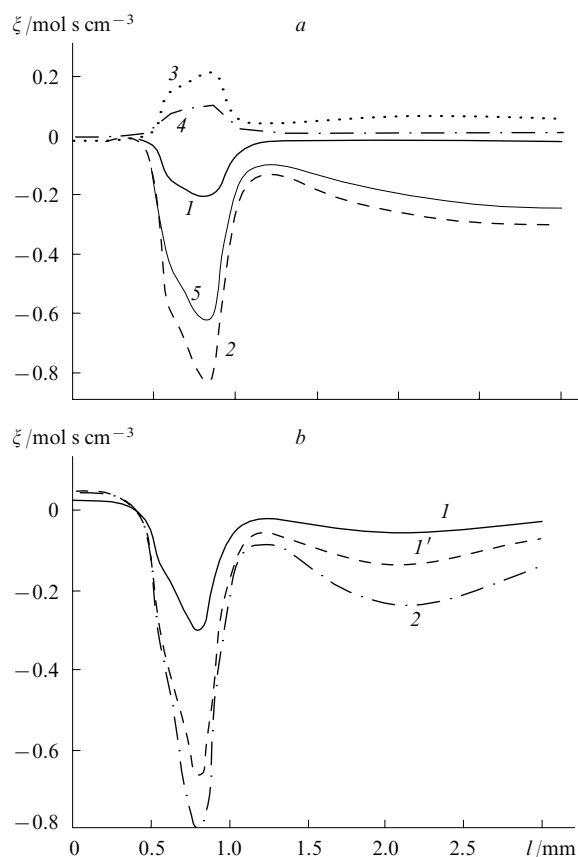

Figure 18. Sensitivity of reactions involving H_3PO_3 taking place in lean (a) and rich (b) flames to H atom concentration:⁵³ (1, 1') reactions (11) (1, through adduct formation, 1', through H atom elimination); (2) reactions (7); (3) reactions (6); (4) reactions (12); (5) reactions (9).

The sensitivity of other reactions was interpreted⁵³ proceeding from the fact that recombination of the H and OH atoms is more efficient in the catalytic cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ than in the cycle $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$. The increase in the rate constants of reactions that direct the reaction stream along the more efficient cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ leads to a decrease in the concentrations of the H and OH radicals (flame inhibition), while the increase in the rate constants for reactions that direct the reaction stream through the cycle $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$ decreases the overall recombination rate of the H and OH radicals and, hence, increases their concentration in the flame.

The reaction

that directs the reaction stream along the less efficient cycle accelerates the formation of the H and OH radicals. The same is true for reaction (6). Both reactions have positive sensitivity coefficients to the concentrations of H atoms. Meanwhile, an increase in the rate constant for reaction (9) returns the reaction stream to the more efficient cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ and inhibits the formation of the H and OH radicals. The transformation paths of the initial components and final and intermediate products in lean and rich flames are sketched in Figs 19 a,b, respectively [only reactions with the rates of $> 2 \times 10^{-6} \text{ mol cm}^{-3} \text{ s}^{-1}$, which make the greatest contributions to the formation and consumption of the H and OH radicals (given in brackets⁸), are given].

§ The reaction rates are given for the distance of 1.07 mm from the burner surface where the PO_2 formation rate is maximum.

Figure 19. Transformation paths of PO_2 in lean (a) and rich (b) flames.⁵³

It can be seen from Fig. 19 that $\text{HOPO} \rightleftharpoons \text{PO}_2$ (cycle A) and $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$ (cycle B) are the key inhibition cycles. In both cycles, phosphorus compounds act as catalysts of recombination of H and OH radicals to give H_2O . Reaction (12) also takes place being a part of a large cycle. MacDonald *et al.*¹⁰⁰ observed also the recombination of two H atoms with participation of PO_2 and HOPO in diffusion flames. Analysis has shown that recombinations $\text{H} + \text{OH}$ and $\text{H} + \text{O}$ predominate over the reaction $\text{H} + \text{H}$.

To understand how the two inhibition cycles change with the variation of the equivalence ratio, the extent of oxidation of key phosphorus-containing compounds in lean and rich flames were studied. It could be expected (as was actually shown⁵²) that in a lean flame, compounds with a higher oxidation state (for example, HOPO_2) would be present in higher concentrations than compounds with lower oxidation state (for example, HOPO). The opposite is true for a rich flame: the HOPO concentration is higher than the HOPO_2 concentration. The concentration of HPO is insignificant in both types of flame and has no influence on the reaction rates. As a result of the difference between the HOPO and HOPO_2 concentrations, *i.e.*, depending on the equivalence ratio, the directions of the reaction streams change. In both types of flame, the cycle $\text{HOPO} \rightleftharpoons \text{PO}_2$ is more efficient but in the rich flame where the HOPO concentration is higher than in the lean flame, it is 30% more efficient than the cycle $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$. In a rich flame, the species PO plays a significant role in the inhibition, while in lean flame, PO_3 is such a species. In the lean flame, the cycle $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$ is approximately 5 times as significant as in the rich flame owing to the much higher concentration of HOPO_2 . For this reason, the inhibition path involving $(\text{HO})_2\text{PO}$ becomes important.

It should be noted that, although the inhibition efficiencies of the flame involving the catalytic cycles $\text{HOPO}_2 \rightleftharpoons \text{PO}_2$ and $\text{HOPO} \rightleftharpoons \text{PO}_2$ are different in lean and rich flames, their total efficiency is comparable in these two cases, *i.e.*, phosphorus ‘finds’ the most efficient route for flame inhibition. Thus, the ability of phosphorus compound to inhibit flame is unique.

Yet another interesting issue is that the reactions of flame inhibition by phosphorus-containing compounds are most efficient in rather high-temperature regions of the flame at $T > 1600$ K (this corresponds to a distance of 0.9 mm from the burner surface). This is due to the fact that at $T < 1300$ K, the concentrations of all key phosphorus-containing radicals are low (the temperature of 1300 K, which was taken as the reference point, corresponds to consumption of a half of DMMP). The compound $(\text{HO})_2\text{PO}$ formed in the beginning of the combustion zone, which is also an inhibitor, is consumed at higher temperature.

The authors⁵³ pointed to a certain similarity between OPC and the ‘ideal’ inhibitor described by Rumminger *et al.*,¹⁰¹ who showed, using a stoichiometric methane–air flame as an example, that at 1 atm an efficient inhibitor starts to operate at $T > 1700$ K and does not lose activity at least up to 2150 K. In the opinion of the researchers cited,¹⁰¹ the inhibitor that is active at low temperatures is inefficient. This conclusion is based on numerical calculations of the flame propagation speed and structure and on the calculation of the rate of formation and consumption of radicals over the flame zone. Calculations¹⁰¹ showed that inhibition is most efficient in the case where the maximum chain termination rate in catalytic recombination of H and OH radicals involving the inhibitor coincides with the maximum concentrations of these radicals. Analysis of the model has shown that spatial coincidence of the maximum rates of formation of H atoms according to the quadratic chain branching reaction (1) with the maximum rate of consumption of H atoms in catalytic recombination is the actual criterion.

The studies,^{75,102} which partly confirm the conclusions drawn by Jayaweera *et al.*,⁵³ are devoted to the structure of methane–oxygen flames with TMP additives stabilised on a flat burner under atmospheric pressure. Figures 20 *a–d* show the concentration profiles of the H and OH radicals in lean

($\phi = 0.8$, Fig. 20 *a,b*) and rich ($\phi = 1.2$, Fig. 20 *c,d*) flames without an additive and with 0.22 vol.% TMP. Note that in the study cited,¹⁰² the concentration profiles of the hydrogen atom in the flame under atmospheric pressure were measured for the first time. It was found that the introduction of the inhibitor results in a sharper decrease in the concentrations of H and OH radicals in a rich flame compared to the lean flame; the most pronounced decrease in the concentrations of H and OH radicals occurs in the zone of chemical reactions rather than in the zone of formation of the final combustion products (which is consistent with the simulation results⁵³).

It was found^{75,102} that the concentrations of radicals and key phosphorus-containing compounds in the zone of combustion products in inhibited flames under atmospheric pressure are close to equilibrium values. A comparison of experimental data with the results of calculation of the flame structure using the inhibition mechanism⁵³ shows that in the case of lean flames they are in satisfactory agreement. For rich hydrocarbon flames, the agreement is less satisfactory, which is apparently due to the fact that the inhibition mechanism of rich flames needs to be further developed. This is also indicated by the results of another work¹⁰³ dealing with the structure of rich and stoichiometric methane–oxygen flames without additives and with ~ 0.05 vol.% DMMP at a pressure of 660–670 Torr. The experimental procedure used in the study cited¹⁰³ included microprobe sampling of the flame followed by analysis of gaseous products by FT IR spectroscopy. Although the sampling procedure used precluded measurement of the concentrations of labile components, the researchers measured the concentration profiles for formaldehyde, methanol, all C_2 hydrocarbons and the oxides CO and CO_2 in the flame.

It was found that the addition of DMMP into rich flame results in an almost sevenfold increase in the concentration of methanol and a twofold increase in the concentration of acetylene, the ethylene concentration being somewhat decreased. Since the transformation of the CH_3 radical into CH_3OH requires an oxygen atom, while the transformation of CH_3 into C_2 hydrocarbons requires only CH_3 , the increase in the CH_3OH concentration may be indicative of the change in the concentration of oxygen atoms in the flame upon the introduction of an inhibitor.

The simulation of the flame structure¹⁰³ using two different inhibition mechanisms by OPC additives proposed by Glaude *et al.*^{54,65} showed that neither of these mechanisms predicts correctly the variation of the concentrations of CH_2O , CH_3OH and C_2 hydrocarbons caused by introduction of the inhibitor. The disagreement between the experimental and simulation results indicates that none of the models used in calculations takes into account the most important processes of the chemistry of inhibition of rich flames by OPC. Thus, a mechanism of inhibition of rich flames by OPC additives that would take into account the reactions of phosphorus-containing products with carbon-containing flame components has not been developed so far, which is due to some extent to the lack of understanding of the chemistry of hydrocarbon combustion under conditions of excess fuel and to the lack of the model describing the combustion of rich flames.

b. Propagation speed of flames with organophosphorus additives

The dependence of the speed of free propagation of a 4:96 propane–air flame on the concentration of the OPC additive at an initial temperature of 95 °C has been studied.¹⁰⁴ The results of measurements of flame burning velocities with addition of nineteen OPC, including fluorinated OPC, are summarised in Fig. 21. The calculation results for TMP are also presented. The compounds demonstrated similar efficiencies (to within the error of measurements).¹⁰⁴ The OPC used and their boiling points are summarised in Table 5.

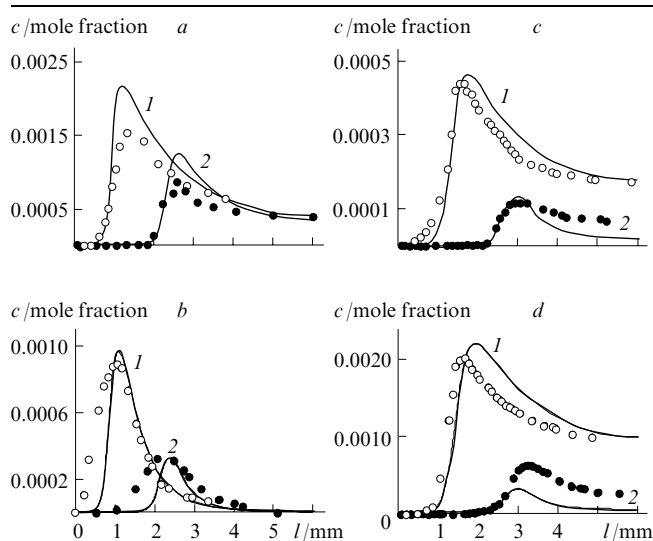

Figure 20. Concentration profiles of H (*b, d*) and OH (*a, c*) radicals in lean (*a, b*) and rich (*c, d*) flames without additives (light dots and curves 1) and with 0.22 vol.% TMP (dark dots and curves 2).¹⁰²

The dots show experimental values and the lines correspond to simulation results.

Figure 21. Propagation speed of the $C_3H_8/O_2/N_2$ flame vs. inhibitor concentration (c_{in}).¹⁰⁴ The inhibitors were a number of OPC (presented in Table 5) and CF_3Br . The dots show experimental values and the lines correspond to simulation results with addition of TMP.

The decrease in the normal propagation speed of the flame upon injection of an inhibitor is due to two factors: chemical (radical decay) and thermal (dilution of the flame with the inhibitor and introduction of additional fuel). The contributions of each factor were identified by analysing the curve for the flame propagation speed vs. the limiting concentration of the inhibitor.¹⁰⁵ (This method has been already successfully used to compare the chemical efficiencies of the additives.¹⁰⁶) After introduction of OPC in low concentrations ($<0.3\%–0.4\%$) into the flame, the decay of radicals in recombination reactions involving these OPC becomes the major factor responsible for the decrease in the combustion rate. Therefore, all compounds show similar efficiencies (see Fig. 21), which almost do not depend on their chemical structure and are determined by the presence of a phosphorus atom in their molecules.

Table 5. Flame suppressants and their boiling points.

Number of the compound	OPC	Boiling point / °C	Pressure / Torr
1	$(CH_3O)_3PO$ (TMP)	180	760
2	$(C_2H_5O)_3PO$	215	760

The effect of TMP (0.06 vol.%) on the propagation speed of methane–air flames at a mixture temperature of $35^\circ C$ has been studied as a function of the composition of the mixture (the ϕ value varied from 0.75 to 1.45).⁷⁵ The flame propagation speed was measured by measuring the heat flux to the burner^{23,24} and calculated in terms of the mechanism of flame inhibition by phosphorus compounds described by Jayaweera *et al.*^{53,86} and two mechanisms of methane oxidation, namely, the GRI⁴⁶ and the Curran^{50,51} mechanisms (Fig. 22).

Figure 22. Propagation speed of methane–air flames with 0.06 vol.% TMP vs. ϕ .⁷⁵ The dots show experimental values, the continuous line corresponds to simulation results in terms of the GRI mechanism,⁴⁶ and the dashed line corresponds to simulation in terms of the Curran mechanism.^{50,51}

The calculated flame propagation speeds depended on the selected mechanism of methane oxidation; none of the mechanisms used provided a satisfactory description for the measured dependence of the combustion rate on the equivalence ratio over the whole range (this is one more piece of evidence pointing to imperfection of the proposed multistage kinetic models for hydrocarbon combustion).

Figure 23 shows the efficiency of flame inhibition (E_f) vs. ϕ . The value

$$E_f = \frac{u_0 - u}{u_0}$$

was determined from the experimental and simulated data. All curves (both those calculated from experimental data and those obtained by simulation) had a maximum at $\phi = 1.1–1.3$. The calculation data predict an increase in the inhibition efficiency in the range $\phi = 0.7–1.2$, which is attrib-

Figure 23. Inhibition efficiency (E_f) vs. ϕ .¹⁰⁴ The dots show experimental values, the continuous line corresponds to simulation results in terms of the GRI mechanism,⁴⁶ and the dashed line corresponds to simulation in terms of the Curran mechanism.^{50,51}

utable to higher efficiency of the cycle $\text{PO}_2 \rightleftharpoons \text{HOPO}$ compared to $\text{PO}_2 \rightleftharpoons \text{HOPO}_2$. The inhibition efficiency calculated from experimental data is almost invariable over this range of ϕ . The decrease in the inhibition efficiency in rich flames was attributed⁷⁴ to incomplete destruction of phosphorus-containing products of TMP destruction into active inhibitors, *viz.*, phosphorus oxides and phosphorus-containing acids. The results indicate that further studies of the OPC combustion chemistry are required in order to elucidate the inhibition mechanism of flames with a large excess of fuel.

2. Diffusion flames formed at the counterflows of the fuel and the oxidant

Diffusion flames have aroused enhanced interest in recent years. The diffusion flame formed at the counterflows of the fuel and the oxidant is a convenient investigation object for the following reasons. This flame is stabilised in space between the nozzles at a certain distance from them under nearly adiabatic conditions. Although the diffusion flame is two-dimensional, the simulation of its structure can be reduced to a one-dimensional problem, which is implemented in the readily available OPDIFF programme.³⁵ This allows one to compare experimental data on the flame structure with simulation results and make counterflow flames a convenient investigation object in the OPC combustion chemistry.

Consider the series of papers^{36,37,107} devoted to the effect of OPC on diffusion flames stabilised on the Potter burner with fuel and oxidant counterflows. Diffusion flames are 'stretched'. An important parameter of such flames is the stretch ratio (a , s^{-1}), which is calculated from the relation

$$a = \frac{2V}{L} \left(1 + \frac{V_f}{V_{\text{ox}}} \sqrt{\frac{\rho_f}{\rho_{\text{ox}}}} \right),$$

where V is the gas linear velocity, L is the distance between the nozzles, ρ is the density (the subscripts f and ox refer to the fuel and the oxidant, respectively). The stretch ratio is actually inversely proportional to the residence time of the reaction mixture in the flame. This value is also called the velocity gradient (the change in the gas flow velocity in the space between two nozzles).

Typical stretch ratio values for counterflow flames are 100 to 800 s^{-1} . The higher the fuel and oxidant feed rates, the greater the flame stretch ratio. Finally, at a certain stretch ratio (quenching stretch ratio), the flame is quenched. The inhibitor (flame suppressant) decreases the stretch ratio needed to quench the flame; therefore, the efficiency of flame suppressants can be conveniently determined from the dependence of the quenching stretch ratio of a flame on the flame suppressant concentration.

The parameter E_q calculated from the formula

$$E_q = \frac{a_{q0} - a_q}{a_{q0}},$$

where a_{q0} is the quenching stretch ratio for a pure flame, a_q in the quenching stretch ratio for an inhibited flame, has been proposed¹⁰⁰ for comparison of the efficiency of counterflow flame quenching by various inhibitors. The subscript q (quenching) implies that all parameters correspond to the instant of quenching. It was found that DMMP and TMP are 2–4 times more efficient suppressants than CF_3Br .^{7,63,108,109} The introduction of a phosphorus-containing compound (1500 ppm) decreases the quenching stretch ratio of the flame by 35%. The injection of the additive into the oxidant flow in a diffusion methane – air flame was found to be 2–4 times more efficient than injection into the fuel flow (in this case, a region with excess fuel is formed on the fuel injection side in the

diffusion flames).¹⁰⁹ This is attributable to low inhibition efficiency of rich flames ($\phi > 1.2$) by phosphorus compounds.⁷⁵

The efficiency of quenching of the counterflow $\text{CH}_4/\text{O}_2 - \text{O}_2/\text{N}_2$ flame (0.2/0.8–0.4/0.6) by fourteen OPC and CF_3Br was studied (Fig. 24, the OPC numbering is the same as in Table 5).¹⁰⁴ The additives were injected into the oxidant flow whose temperature was 100°C . The plots for the quenching stretch ratio *vs.* the inhibitor concentration were compared with the quenching stretch ratios obtained with one of the most effective inhibitors, *viz.*, iron pentacarbonyl $\text{Fe}(\text{CO})_5$ (curve 2 in Fig. 24).¹¹⁰

Figure 24. Quenching stretch ratio (E_q) of counterflow flames *vs.* initial concentration of the inhibitor (c_{in}).¹⁰⁴ Inhibitor: OPC (compound numbering is the same as in Table 5), CF_3Br (curve 1), $\text{Fe}(\text{CO})_5$ (curve 2); (3) calculation results for TMP.

According to the measurement results, at $c_{\text{in}} < 0.1$ vol.%, all of the OPC had equal efficiency, which was 7 times higher than that of CF_3Br but 3 times lower than that of iron pentacarbonyl. These results indicate that the efficiency of OPC depends on the concentrations of phosphorus oxides and phosphorus acids and hardly depends on the structure of the initial molecule. The quenching stretch ratios (curve 3 in Fig. 24) for the flames with 0.12 vol.% and 0.25 vol.% TMP (designated by * in Fig. 24) calculated in terms of the mechanism of inhibition by OPC proposed by Korobeinichev *et al.*^{58,85} were compared with the experimental data. It was found experimentally that the quenching stretch ratio decreases by 10% and 20% in the presence of 0.12 vol.% and 0.25 vol.% TMP, respectively. The values predicted by numerical simulation are 9.4% and 18.8%. Thus, the results of measurements are in good agreement with the computation data.

The chemical structure of counterflow flames (diffusion or premixed) was studied by laser-induced fluorescence^{7,8,111,112} and probe mass spectrometry techniques.^{113–115} The molecular-beam mass spectrometry was first applied to probing of a counterflow diffusion flame by Marinov *et al.*¹¹⁶ The concentration profiles of stable components and phosphorus compounds were obtained and the concentration profile of the OH radical in the flame without additives and with 0.12 vol.% TMP was measured.^{113–118}

Analysis of the concentration profiles of phosphorus oxides and phosphorus acids shows that the composition of these compounds in the 'lean' region of the diffusion flame (where excess oxygen is present) is the same as their composition in a lean premixed flame in which HOPO_2 predominates.^{75,102} In the 'rich' region of the diffusion flame, the

HOPO is the main phosphorus-containing component, which is typical of rich premixed flames.^{75, 102} The numerical calculation of the flame temperature and comparison of the obtained data with the results of measurements have shown that the temperature measurement by a thermocouple arranged on the burner axis gives results that best coincide with the computation results.

The flame structure was also calculated upon simulation in terms of the mechanism of inhibition by OPC.^{53, 85} The calculated concentration profiles describe experimental data with a satisfactory accuracy; however, the experimental concentration profiles of compounds in the flame are somewhat broadened compared to calculated profiles, which is due to imperfection of the model used in the OPPDIF programme (the model neglects the edge effects).

3. Air co-flow diffusion flames

The studies of air co-flow diffusion flames were aimed first of all at determining the minimum quenching concentrations of flame suppressants by the cup burner method. Studies of OPC containing no fluorine atoms showed that they are combustible and useless as flame suppressant; therefore, fluorine-substituted OPC were chosen. The MQC values for fluorine-containing organophosphorus inhibitors were measured by the cup burner method independently by Russian³¹ and American¹¹⁹ research groups. In both cases, almost identical cup burners were used, the flame suppressant was supplied through a nebulizer, and the only difference was in the air flow temperature: in one study,¹¹⁹ the measurements were carried out at 55 °C and in the other study,³¹ at 75 °C. In the latter work,³¹ five fluorine-containing OPC and CF₃Br were additionally studied (note that organofluorine compounds proved to be less effective than OPC). The measured MQC values are summarised in Table 6. The minimum quenching concentrations are usually expressed as volume fractions or percent, but for practical purposes it is required to know the mass MQC. Analysis of the data presented in Table 6 shows that many fluorine-containing OPC are capable of flame quenching when present in low volume concentrations; however, owing to high molecular masses, their weight consumption exceeds that of

Table 6. Minimum quenching concentrations of fluorine-substituted OPC and CF₃Br.³¹

Compound	Minimum quenching concentration	
	vol. %	g m ⁻³
[(CF ₃) ₂ CHO] ₂ PO(C ₂ H ₅)	2.0 ± 0.2	366
[(CF ₃) ₂ CHO] ₃ P	2.2 ± 0.2	523
(CF ₃ CH ₂ O) ₂ PO(CF ₃)	2.3 ± 0.2	322
(CF ₃ CH ₂ O) ₃ P	2.6 ± 0.2 (3.1) ^a	381
(CF ₃ CH ₂ O) ₂ PO[OCH(CF ₃) ₂]	no quenching at 3% concentration	—

(CF ₃ CH ₂ O) ₂ P(CF ₃)	3.0 ^a	400
(CH ₃ O)PO(CF ₃) ₂	4.6 ^a	443
(CF ₃ CH ₂ O)P(CF ₃) ₂	1.8 ^a	215
(CF ₃ CH ₂ O)PO(CF ₃) ₂	no quenching at 5% concentration (see ^a)	—
CF ₃ Br	4.6	306

^a Data from Ref. 119.

less effective CF₃Br. Unfortunately, it was impossible to extinguish the flame with (CF₃)₃PO, which has low molecular mass,¹¹⁹ apparently due to its combustibility.

The results of cup burner experiments give not only the MQC values, but also the dependence of the quenching concentration of one flame suppressant (often an inert diluent, for example, CO₂) on the quenching concentration of the other one, often an active agent. Figure 25 shows the dependences of the quenching concentration of CO₂ on the quenching concentration of fluorine-containing OPC, organofluorine compounds and CF₃Br. It can be seen from the presented data that despite the different MQC values, all phosphorus-containing flame suppressants have similar efficiencies (when present in concentration of ~0.5%). Note that the quenching concentration of CO₂ ceases to decrease with an increase in the quenching concentration of some OPC [for example, (CF₃CH₂O)₂(C₂H₅)PO], which is indicative of combustibility of these compounds under these conditions (the heat evolved upon their combustion counterbalances the inhibitory effect).

British researchers^{120, 121} used an advanced flame ionisation detector (FID) of a chromatograph to study quenching of air co-flow diffusion flames (hydrogen–air and methane–air) by flame suppressants. They tested a large number of OPC. When methane–air flame was used, the MQC values of flame suppressants determined by this and by the cup burner techniques coincided with satisfactory accuracy. The advantage of the FID method^{120, 121} is the possibility of using a small amount of a flame suppressant for determining its MQC. Despite the encouraging results and the simple design, the FID method has not yet found extensive use.

Figure 25. Quenching concentration of CO₂ vs. quenching concentration (*c_{RS}*) of fluorine-substituted OPC (curves 1–9), organofluorine compounds (curves 10–13) and CF₃Br (curve 14).³¹

Compounds: (1) (CF₃CH₂O)₂PO(C₂H₅), (2) [(CF₃)₂CHO]₂PO(C₂H₅), (3) (CF₃CH₂O)₂PO[OCH(CF₃)₂], (4) (CF₃CH₂O)PO[OCH(CF₃)₂]₂, (5) [(CF₃)₂CHO]₂PO(CH₃), (6) [(CF₃)₂CHO]₂PO(CF₃), (7) (CF₃CH₂O)₃P, (8) (CF₃CH₂O)₂PO(CF₃), (9) [(CF₃)₂CHO]₃P, (10) HCF₂CF₂CH₂OCF₂CHF₂CF₃, (11) CF₃CF₂CF₂OCH₂CF₃, (12) (CF₃)₂C=CFCF₂CF₃, (13) (CF₃)₂CFCF=CFCF₃, (14) CF₃Br.

4. Turbulent flames

The efficiency of quenching turbulent flames by short-term injection of (CF₃CH₂O)₃P and CF₃Br into the air stream was determined³¹ on a test bench analogous to that described in

Table 7. Parameters GWP and HGWP calculated for different time ranges characterising the effect of OPC on climatic changes.

Compound	HGWP				GWP			
	20 years	100 years	500 years	∞	20 years	100 years	500 years	∞
$P_3N_3F_6$	0.1	43.5	12.9	4.0	6.9×10^{-3}	2.8×10^{-3}	2.5×10^{-3}	0
$(CF_3CH_2O)_3P$	7.56×10^{-4}	3.1×10^{-4}	2.74×10^{-4}	2.71×10^{-4}	4.8	0.43	0.426	0.426

Ref. 30. A study of the temperature dependence of the MQC of the phosphite $(CF_3CH_2O)_3P$ in the air temperature range of 35 to 86 °C showed³¹ that at $T < 60$ °C some of the flame suppressant occurs as an aerosol and some as vapour; therefore MQC is the sum of concentrations. When $T > 60$ °C, MQC corresponds only to the concentration of flame suppressant vapour.

For $T = 75$ °C, the MQC measured for the turbulent flame equals 4 vol.%, which is approximately 1.5 times higher than the concentration measured for the diffusion flame by the cup burner technique. The difference may be related to either the loss of $(CF_3CH_2O)_3P$ during its supply to the flame or to the fact that quenching of the turbulent flame differs appreciably from quenching of the laminar flame. No such difference was observed in determination of the MQC of CF_3Br ;³¹ however, the coincidence of its MQC values may be accidental.

It was impossible to determine the MQC of trimethyl phosphite,³¹ because after the flame quenching, the mixture of TMP vapour with air and combustion products self-ignited.[¶] It was found that at an air temperature of 90 °C and a TMP concentration of 8.5 vol.%, no repeated ignition of TMP vapour takes place; however, this quenching concentration can hardly be considered minimum.

VI. Toxicity and environmental impact of organophosphorus compounds

1. Determination of toxicity

In order to evaluate the prospects of using OPC as flame suppressants, the toxicity of a number of OPC was studied. For example, the toxicities of TMP, DMMP, DEMP, tris(2,2,2-trifluoroethyl) phosphate, trimethyl phosphite and tris(2,2,2-trifluoroethyl) phosphite were assessed.¹²³ The toxicological parameters were measured for laboratory mice upon intragastric administration of the tested compounds in various doses. Dimethyl and diethyl methylphosphonates were dissolved in water prior to the measurements and $(CF_3CH_2O)_3PO$, which is almost insoluble in water, was used as an emulsion in olive oil. Each test series was carried out for 4–8 mice.

The toxicity (LD_{50}) of the OPC upon intragastric administration was relatively low ranging from 0.27 to 10.5 ± 0.09 ml per kg of live weight.¹²³ DMMP was least toxic, while tris(2,2,2-trifluoroethyl) phosphite was the most toxic. No action of these compounds to skin or mucous membranes was observed.

The toxicity of tris(2,2,2-trifluoroethyl) phosphite vapour upon inhalation was also assessed. The concentration of tris(2,2,2-trifluoroethyl) phosphite vapour at 25 °C is 0.4 vol.% (59 mg litre⁻¹). This concentration was not lethal for mice, which have spent 15 min in a chamber with atmosphere saturated with the phosphite vapour. They all survived for 5 weeks. However, when the temperature in the chamber was raised to 30–35 °C and the OPC concentration increased to 0.68 vol.% (100 mg litre⁻¹), one mice died within 15 min

after inhalation of $(CF_3CH_2O)_3P$ vapour and the other four mice died after 2 days. The animal death was due to lung damage. Although the toxicological parameters (LC_{50}) of the tris(2,2,2-trifluoroethyl) phosphite vapour could not be determined, it is obvious that the vapour toxicity is much higher than that of intragastrically administered liquid compound.

2. Environmental impact of organophosphorus compounds

When assessing the impact of various compounds on the environment, two key factors are considered first of all: their impact on the Earth ozone layer and the contribution to the global warming. The impact on the ozone layer is determined by the dimensionless parameter ODP (ozone depletion potential). Trichlorofluoromethane was used as the reference, its ODP being taken to be unity. The efficient flame suppressant CF_3Br (halon 13B1) the production of which was forbidden by the Montreal Convention efficiently depletes the ozone layer, its ODP being 10.

The effect of $(CF_3CH_2O)_3P$ as a representative of OPC on the environment was studied at the laboratory of the Chemical Physics of Atmosphere of the Institute of Energy Problems of Chemical Physics of the RAS.¹²⁴ The calculations showed that ODP of this OPC can be considered to be zero. The presence of $(CF_3CH_2O)_3P$ in the atmosphere in a practically infinite amount does not deplete the ozone layer. According to calculation data, the existence time of $(CF_3CH_2O)_3P$ in the atmosphere is 0.019 years.

The contributions of compounds to the global warming (enhancement of the greenhouse effect) are characterised by two dimensionless parameters, the main parameter GWP (Global Warming Potential) and additional parameter HGWP (Halocarbon Global Warming Potential), which is calculated with respect to the GWP of trichlorofluoromethane. The GWP and HGWP parameters are calculated for particular time intervals. The GWP of carbon dioxide for the interval $t = \infty$ is taken to be unity. The GWP and HGWP values for two OPC, *viz.*, phosphazene $P_3N_3F_6$ and tris(2,2,2-trifluoroethyl) phosphite, were calculated.¹²⁴ The calculation results are presented in Table 7. The data indicate that these OPC do not possess properties of greenhouse gases and have almost no impact on the Earth climate warming.

* * *

The information summarised in this review shows that considerable progress in the understanding of OPC combustion chemistry has been achieved in the last decade. However, a number of problems still remain unsolved. First of all, this refers to the chemistry of combustion of rich hydrocarbon flames. No data on the combustion chemistry and the mechanism of inhibition of atmospheric hydrogen–oxygen flames, especially rich ones, by organophosphorus compounds are available either, although they are much simpler as regards possible combustion intermediates and final products than hydrocarbon flames.

This review was written with the financial support of the Russian Foundation for Basic Research (Project No. 07-03-11 005-ano).

[¶] Previously, it has been shown¹²² that TMP vapour burns at elevated temperature.

Non-metallocene rare-earth organometallic derivatives: synthesis, structure and application in the catalysis of transformations of unsaturated substrates[†]

A A Trifonov

Contents

I. Introduction	1049
II. Neutral alkyl and aryl complexes	1050
III. Cationic alkyl complexes	1062
IV. Hydride complexes	1064
V. Non-metallocene rare-earth organometallic derivatives in catalysis of transformations of unsaturated substrates	1065

Abstract. The review summarises advances in the post-metallocene chemistry of rare-earth organometallic compounds. The synthesis, structures and reactivities of complexes containing metal–carbon and metal–hydrogen bonds and stabilised by N-, P- or O-donor ligands are considered. The catalytic activities of these compounds in alkene polymerisation, hydroamination, hydrosilylation and hydroboration are discussed. The bibliography includes 139 references.

I. Introduction

Organic derivatives of rare-earth metals (rare-earth elements, REE) have a unique combination of properties and are of considerable interest as catalysts for different reactions. Due to large ionic radii of rare-earth elements^{1,2} combined with Lewis acidity and the presence of unoccupied 5d and 6s orbitals (for Ln^{3+} ions), these compounds have a pronounced tendency to form complexes and exhibit high coordination numbers.³ An insignificant contribution of the covalent component to rare-earth metal–ligand interactions removes restrictions associated with the compatibility of the orbitals in symmetry. This can give rise to radically new types of compounds the reactivity of which differs from that of d element derivatives. Due to the similarity of the redox and chemical properties of rare-earth elements combined with a substantial variation in the ionic radii in the series of these compounds (from 0.885 Å for Sc to 1.172 Å for La),² there is a unique possibility for optimising the reactivity of metal complexes by constructing the metal coordination sphere and choosing the appropriate radius of the central atom in accordance with specific features of the catalysed reaction. The fact that metallocene-type rare-earth metal alkyl and hydride complexes are efficient catalysts (or their precursors) for hydrogenation,^{4–7} polymerisation,^{8–10} hydrosilylation,¹¹ hydroboration,^{12,13} hydroamination^{14–16} and hydrophosphination^{17–19} of alkenes clearly demonstrates that these compounds have a high catalytic potential.

Since rare-earth metals are electropositive and the metal–ligand interactions in their organic derivatives are predominantly ionic in character, ligands capable of forming stable anions were traditionally used in this field of chemistry. This is why cyclopentadienyl complexes have prevailed among known organic derivatives of REE until recent years.²⁰ The stability and reactivity of rare-earth organometallic compounds are largely determined by the degree of steric saturation of their coordination spheres with the result that certain requirements are imposed on the ligands. The latter should be rather bulky and fill the metal coordination sphere at low coordination numbers of metal atoms, resulting in the kinetic stability of metal complexes. The synthesis of complexes soluble in non-polar non-coordinating solvents is an important problem, the solution of which would allow the synthesis of derivatives containing no coordinated Lewis bases and bearing the central atoms with low coordination numbers. This would lead to an increase in the catalytic activity of complexes as a result of the exclusion of the competition between the Lewis base and the substrate for a site in the metal coordination sphere.

In recent years, the trend has been toward the design of new non-cyclopentadienyl ligand systems allowing for stabilisation of rare-earth metal alkyl[‡] and hydride complexes.^{21–23} The aims of the replacement of ligands are to enhance stability of REE derivatives with retention of high catalytic activity, to increase the catalyst tolerance to functional groups of monomers, to extend the scope of the design and control of the geometry of the metal coordination sphere in complexes and to control the catalytic activity of metal complexes and the selectivity of the reactions. At the same time, studies of the influence of the coordination environment of rare-earth metal atoms on the reactivities of M–C and M–H bonds and the catalytic activity of compounds are of considerable interest. A comparison of the catalytic activities of rare-earth metal complexes containing anionic non-carbocyclic-type ligands with those of metallocene-type analogues would allow the determination of the relationship between the properties of metal complexes (structure, effective positive charges on metal

[†] Dedicated to Academician G A Abakumov on the occasion of his 70th birthday.

[‡] Hereinafter, the term alkyl complexes is used in reference to complexes containing alkyl or substituted alkyl ligands (for example, CH_2SiMe_3 , etc.).

atoms and Lewis acidity) and their activity in the catalysis of transformations of alkenes.

The present review summarises methods for the synthesis, structures, reactivities and catalytic activities of rare-earth metal complexes (alkyl, cationic alkyl, hydride, *etc.*) stabilised by N-, O- or P-donor ligands.

II. Neutral alkyl and aryl complexes

1. Monoalkyl and -aryl complexes

a. Complexes with monoanionic N-containing ligands

The bidentate amidinate anions $[R^1C(NR^2)_2]^-$ are among the first non-cyclopentadienyl ligands, which have been successfully used for stabilisation of rare-earth metal alkyl complexes. The monomeric yttrium derivatives $L_2YR(THF)$ [$L = PhC(NSiMe_3)_2$, $R = CH_2Ph$ (**1**)] and L_2YR [$L = PhC(NSiMe_3)_2$, $R = CH(SiMe_3)_2$ (**2**), $L = p\text{-MeOC}_6\text{H}_4C(NSiMe_3)_2$; $R = CH(SiMe_3)_2$ (**3**)] were synthesised.²⁴

Complexes **1–3** are thermally stable in deuteriocyclohexane or deuteriobenzene. No evidence of the H/D exchange, metallation of the solvent or thermal decomposition of the complexes was observed upon heating of these solutions at 100 °C for several hours. The X-ray diffraction study of complex **3** showed that this complex is monomeric. The steric parameters of the amidinate fragments are similar to those of the pentamethylcyclopentadienyl ligands, whereas their electronic properties are substantially different. Based on semi-empirical INDO/1 calculations for the model $[HC(NH)_2]_2YMe$ and $(\eta^5\text{-Cp})_2YMe$ complexes, it was concluded that the higher electron-withdrawing ability of amidinate ligands results in an increase in the positive charge on the

yttrium atom in bis(amidinate) derivatives compared to metallocene-type analogues. The charge separation for the $Y-C$ bond in the $[HC(NH)_2]_2YMe$ and $(\eta^5\text{-Cp})_2YMe$ complexes is 1.06 and 0.75e, respectively, *i.e.*, the bond in the former compound is much more polar. In the authors' opinion, the larger positive charge on the yttrium atom in $[HC(NH)_2]_2YMe$ leads to a larger orbital contraction, thus hindering interactions between the metal and the substrate (for example, H_2) and resulting in the absence of the H/D exchange and in lower hydrogenolysis rates compared to cyclopentadienyl derivatives.²⁴

Compound **2** reacts with terminal alkynes to form dimeric acetylide complexes **4** and activates C–H bonds in acetonitrile to give dimeric complex **5** (Scheme 1). The reaction of

Scheme 1

complex **1** affords, in addition to C–H bond activation product **5**, compounds **6** and **7** as a result of the insertion at the nitrogen–carbon double bond. The reaction of compound **2** with pyridine involves the metallation of the pyridine ring at the α position with respect to the nitrogen atom to give complex **8**. The reaction of compound **1** affords the addition product at the double bond of the heterocycle (compound **9**). The hydrogenolysis of compounds **1** and **2** gives rise to dimeric hydride **10** (see Scheme 1).^{25,26}

Alkyl and aryl derivatives of scandium stabilised by amidinate ions $\{[\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScR}, \text{R} = \text{CH}_2\text{SiMe}_3 \text{ (11), Mes; } [\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScMe}(\text{THF})\}$ were synthesised by the exchange reaction of the chloride complex $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScCl}(\text{THF})$ with the corresponding alkyllithium reagents.²⁷ The reactions of complex **11** with $\text{Me}_3\text{SiC}\equiv\text{CH}$ and H_2 produce monomeric acetylenide $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Sc}(\text{C}\equiv\text{CSiMe}_3)$ and dimeric hydride $\{[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Sc}(\mu\text{-H})\}_2$ (**11a**), respectively.

The tetrasubstituted guanidinate ligands $[\text{R}_2\text{NC}(\text{NR}')_2]^-$, like the amidinate anions, are N,N-chelating singly charged ligands and are of interest because of the simplicity of their synthesis, the diversity of coordination abilities and the ease of modifications of their electronic and steric characteristics.²⁸ Monomeric alkyl derivatives of yttrium with diisopropyl-substituted guanidinate ligands $[(\text{Me}_3\text{Si})_2\text{NC}(\text{NPr}^i)_2]_2\text{YR}$ [$\text{R} = \text{Bu}^t$ or $\text{CH}(\text{SiMe}_3)_2$] were synthesised and structurally characterised.²⁹ These compounds contain no coordinated Lewis bases, resulting in low coordination numbers of the central atom. Bulkier dicyclohexyl-substituted guanidinate ligands were also successfully used for the synthesis of alkyl and aryl derivatives of yttrium and samarium, *viz.*, L_2YBu^t (**12**), $\text{L}_2\text{YPh}(\text{THF})$ ³⁰ and $\text{L}_2\text{SmCH}(\text{SiMe}_3)_2$ ³¹ [$\text{L} = (\text{Me}_3\text{Si})_2\text{NC}(\text{NCy})_2$, Cy is cyclohexyl]. It should be noted that the yttrium atom in complex **12** is coordinatively saturated, resulting in the agostic interaction between the metal atom and two methyl groups of the *tert*-butyl substituent, which is responsible for short Y–C contacts and substantial deviations of the bond angles at the central carbon atom of the Bu^t group from the tetrahedral value.³⁰ X-Ray diffraction and ¹³C NMR spectroscopic studies showed that agostic interactions exist not only in the crystalline state, but also in deuterobenzene.

Monoanionic bidentate pyrrolocarbaldiminate ligands (L) were successfully used in the synthesis of yttrium (**13**) and samarium (**14a,b**) complexes by the reactions of chlorides $\text{L}_2\text{LnCl}(\text{THF})$ ($\text{Ln} = \text{Y}$ or Sm) with the corresponding alkyllithium reagents in toluene.³² Attempts to synthesise the methyl derivative of yttrium according to an analogous procedure failed. The monomeric structure of complex **14a** and the bidentate coordination of the ligands L were confirmed by X-ray diffraction.

Ar = 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$; R = CH_2SiMe_3 (a), Me (b).

A tridentate amidinate ligand containing an additional donor group in the side chain was used for the synthesis of the corresponding benzyl derivatives of yttrium **15**.³³ The X-ray diffraction study showed that in the crystalline state, only one of the amino groups of the amidinate ligands is coordinated to the metal atom.

L = $\text{PhC}(\text{NSiMe}_3)\text{N}(\text{CH}_2)_3\text{NMe}_2$.

The monoanionic tridentate hydridotris(3-*tert*-butyl-5-methylpyrazolyl)borate ligand (TPB-Me, Bu^t) belongs to a few ligand systems allowing the synthesis of organometallic derivatives of divalent ytterbium (**16a,b**).

R = CH_2SiMe_3 , $n = 1$ (a); R = $\text{CH}(\text{SiMe}_3)_2$, $n = 0$ (b).

Complex **16b** was studied by X-ray diffraction, which confirmed its monomeric structure. This compound readily reacts with phenylacetylene to form the corresponding acetylenide $\text{LYb}(\text{C}\equiv\text{CPh})$.³⁴

Complexes with dianionic N-containing ligands

Diamide ligands, which differ in the number of donor groups, as well as in the nature and length of the bridge between the functional groups, are among the most widely used ligands in chemistry of rare-earth non-cyclopentadienyl ligands. The sterically rigid dianionic ligand 2,2'-bis(*tert*-butyldimethylsilylamido)-6,6'-dimethylbiphenyl (DADMB) was used for the synthesis of alkyl derivatives of yttrium. The coordination of this ligand to the metal atom gives rise to the seven-membered metallacycle. Compounds **17a,b** were synthesised by the exchange reactions of the starting chloride $(\text{DADMB})\text{YCl}(\text{THF})_2$ with MeLi and $(\text{Me}_3\text{Si})_2\text{CHLi}$, respectively (Scheme 2). Analogous ethyl and *n*-hexyl complexes **17c,d** were prepared by the addition of hydride **18** at the double bonds of ethylene and hex-1-ene, respectively, in THF.³⁵ The structure of compound **17c** was established by X-ray diffraction.

Scheme 2

tion. This study demonstrated that complex **17c** is monomeric, and the yttrium atom is additionally coordinated by two THF molecules.

The use of a sterically less rigid ligand (L), in which two amide groups are linked by the propylene bridge, allowed the synthesis of more strained six-membered metallacyclic derivatives of yttrium. The reactions of iodo derivative **19** with PhCH₂K and (Me₃Si)₂CHK afforded complexes **20a,b**; their structures were established by X-ray diffraction.^{36,37} Both complexes proved to be rather stable in deuterobenzene at room temperature and are inert to hex-1-ene and ethylene.

R = CH₂Ph, *n* = 2 (a); R = CH(SiMe₃)₂, *n* = 1 (b).

Diamino-substituted pyridines and benzenes (LH₂), which can act as bi- and tridentate ligands, were used for the synthesis of scandium, yttrium and lutetium derivatives by the elimination of tetramethylsilane from the tris(trimethylsilylmethyl) derivatives Ln(CH₂SiMe₃)₃(THF)₂ (Ln = Sc, Y or Lu) in the reactions with LH₂.

The monomeric complexes (BDPPpyr)LnCH₂SiMe₃.(THF)_{*n*} (*n* = 1, Ln = Sc or Lu; *n* = 2, Ln = Y) proved to be

rather stable at room temperature in hexane; their stability was found to decrease with increasing ionic radius of the metal atom. Derivatives of the sterically less hindered pyridine-containing analogue BMespyr, for example, (BMespyr).LnCH₂SiMe₃(THF)_{*n*} (*n* = 1, Ln = Sc; *n* = 2, Ln = Lu), appeared to be less stable under analogous conditions (hexane, 20 °C), the yttrium compound being unstable to an extent that attempts to isolate this compound at room temperature failed. Alkyl derivatives (BDPPoxyl)LnCH₂SiMe₃(THF) (Ln = Sc, Lu or Y) were synthesised in good yields with the use of diamino-substituted benzene BDPPoxyl, which, unlike pyridine-containing ligands, cannot be intramolecularly stabilised by the coordination of the nitrogen atom to metal but which contains the bulky isopropyl substituents in the aniline fragments.³⁸

An unusual approach to the synthesis of trimethylsilylmethyl derivative of neodymium **21** containing the tridentate 2,6-diiminopyridine ligand was proposed.³⁹ The partial alkylation of the starting NdCl₃(THF)₃ with RLi (R = CH₂SiMe₃) is followed by the reaction with diimine **22** or lithium salt **23** depending on the Nd : R ratio (1 : 4 or 1 : 2, respectively). The dianion is formed as a result of C–H bond activation in the methyl groups at the imine carbon atoms of the 2,6-diiminopyridine fragment of 2,6-(2,6-Pr₂C₆H₃N=CMe)₂C₅H₃N. The structure of complex **21** was established by X-ray diffraction.

Ar = 2,6-Pr₂C₆H₃.

Ar = 2,6-Pr₂C₆H₃.

Diamido-pyridine- and diamido-amine-type tridentate dianionic ligands (LH₂) have also found use in recent years. For example, five-coordinate scandium alkyl and aryl complexes **24a–d**, **25a,b**, **26** (Scheme 3) and **27** were synthesised starting

Scheme 3

from anhydrous chloride ScCl_3 by two successive exchange reactions or by the protolysis of the corresponding $\text{R}_3\text{Sc}(\text{THF})_2$ derivatives ($\text{R} = \text{CH}_2\text{SiMe}_3$ or Ph) with an equimolar amount of a neutral ligand.^{40–42}

The X-ray diffraction study showed that five-coordinate compounds **24c** and **27** are monomeric, whereas the four-coordinate complex $[(\text{MeC}(2\text{-C}_5\text{H}_4\text{N})(\text{CH}_2\text{NC}_6\text{H}_4\text{Me-4})_2)_2\text{ScCH}_2\text{SiMe}_3]_2$, which contains no coordinated THF molecules, has (in the crystalline state) the dimeric structure due to the presence of two bridging amide groups.

Yttrium complexes **28a–c** with σ -bonded aryl ligands containing an additional donor group were synthesised⁴³ by the elimination of arene in the reactions of the corresponding amines with the triaryl derivative. Compound **28a** decomposes at 25 °C, whereas complexes **28b,c** are much more stable.

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**a**); $\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Et}$ (**b**), Cl (**c**).

Alkyl complexes with tetradentate dianionic ligands are represented by bis(amidinate) (**29**)⁴⁴ and aminotropone imine (**30**)⁴⁵ derivatives.

c. Complexes with dianionic N-containing macrocyclic ligands

Rare-earth metal complexes with macrocyclic ligands have attracted attention due mainly to their luminescence and magnetic properties.⁴⁶ However, examples of the use of N-containing macrocyclic ligands as the stabilising coordination environment for alkyl derivatives of rare-earth elements are scarce. The doubly deprotonated octaethylporphyrin (OEP) macrocycle was successfully used for the synthesis of alkyl derivatives of yttrium (**31a**), lutetium (**31b**)⁴⁷ and scandium (**31c–e**).⁴⁸ Complexes **31a,b** were synthesised in 70%–80%

yields by the reactions of octaethylporphyrin (OEP) H_2 with the $\text{Ln}[\text{CH}(\text{SiMe}_3)_2]_3$ derivatives ($\text{Ln} = \text{Y}$ or Lu) involving elimination of alkane and by the exchange reactions of the corresponding phenoxides $(\text{OEP})\text{Ln}(\text{OC}_6\text{H}_3\text{Bu}_2^1\text{-2,6})$ ($\text{Ln} = \text{Y}$ or Lu) with $(\text{Me}_3\text{Si})_2\text{CHLi}$. The resulting compounds proved to be thermally rather stable and withstand heating in toluene at 60 °C for 6 h. The structure of complex **31b** was established by X-ray diffraction. The coordination sphere of the lutetium atom can be described as a square pyramid formed by the coordinated slightly curved OEP ligand and the $\text{CH}(\text{SiMe}_3)_2$ group. Scandium compounds **31c–e** were prepared by the reactions of chloride $(\text{OEP})\text{ScCl}$ with the corresponding alkyl-lithium reagents. According to the X-ray diffraction study, complexes **31c,d** are structurally similar to lutetium complex **31b**.

$\text{Ln} = \text{Y}$, $\text{R} = \text{CH}(\text{SiMe}_3)_2$ (**a**); $\text{Ln} = \text{Lu}$, $\text{R} = \text{CH}(\text{SiMe}_3)_2$ (**b**);

$\text{Ln} = \text{Sc}$: $\text{R} = \text{Me}$ (**c**), CH_2SiMe_3 (**d**), $\text{CH}(\text{SiMe}_3)_2$ (**e**).

Derivatives **31a,b** readily react with $\text{HOC}_6\text{H}_3\text{Bu}_2^1\text{-2,6}$, $\text{Bu}^t\text{C}\equiv\text{CH}$ and H_2O to give monomeric phenoxide $(\text{OEP})\text{Ln}(\text{OC}_6\text{H}_3\text{Bu}_2^1\text{-2,6})$, dimeric acetylide $[(\text{OEP})\text{Ln}(\mu\text{-C}\equiv\text{CBu}^t)]_2$ and dimeric hydroxide $[(\text{OEP})\text{Ln}(\mu\text{-OH})]_2$, respectively. Unlike compounds **2** and **17a,b**, complexes **31a,b** do not react with hydrogen even under a pressure of 25 atm (25 °C).⁴⁷ Scandium derivatives **31c–e** readily bind at the $\text{C}=\text{O}$ double bond of carbon monoxide and at the $\text{C}=\text{N}$ double bond of xylil isocyanate; however, the reactions afford inseparable mixtures of products. The reactions of methyl derivative **31c** with CO_2 and acetone also readily proceed at room temperature to give, respectively, the acetate and *tert*-butoxide complexes.⁴⁸

trans-*N,N*-Dimethylated porphyrinogen (PORF) was used as a convenient polydentate ligand, which allowed the synthesis of monomeric alkyl complexes of trivalent samarium **32a,b** containing no coordinated solvent molecules, halide ions or alkali metals.⁴⁹

The divalent samarium derivative $(\text{PORF})\text{Sm}(\text{THF})_2$ was used as the starting compound. The oxidation of this compound with *tert*-butyl chloride followed by the treatment with the corresponding derivative RLi afforded complexes **32a,b**,

their structures were confirmed by X-ray diffraction (the ethyl groups are omitted for simplicity).

Unlike metallocene-type samarium methyl complexes, complex **32a** appeared to be rather inert. This compound does not activate C–H bonds in benzene, alkenes or diethyl ether.

d. Complexes with monoanionic N,O-containing amide ligands

Bidentate monoanionic amide ligands containing an additional donor group, [Me₂Si(NBu^t)(OBu^t)][−] (L), have been proposed for the first time as an alternative to cyclopentadienyl ligands.^{50, 51} The monomeric five-coordinate yttrium complex L₂YCH(SiMe₃)₂ (**33**) was synthesised by the exchange reaction of chloride L₂Y(μ-Cl)₂Li(THF)₂ with (Me₃Si)₂CHLi. Compound **33** reacts with hydrogen in THF to give unstable hydride [L₂Y(μ-H)]₂, which was characterised in solution by ¹H and ¹³C NMR spectroscopy. The reactions of complex **33** with alkynes RC≡CH (R = Me₃Si or Bu^t) are accompanied by the Y–C and Y–N bond cleavage to form acetylenides (RC≡C)₃Y; however, PhC≡CH undergoes polymerisation in this reaction. The reaction of derivative **33** with excess of MeC≡N is accompanied by the C–H bond activation and elimination of bis(trimethylsilyl)methane. The subsequent insertion of one equivalent of MeC≡N at the Y–C bond and the 1,3-proton shift give rise to complex **34** (Scheme 4). The C–H bond activation was observed also in the reactions of complex **33** with pyridine, methylpyridine and ethylpyridine. The X-ray diffraction study of complexes **33** and **34** showed that this ligand system is bulkier than the η⁵-C₅Me₅ ligand.

e. Complexes with dianionic N,O-containing diamide ligands

The tridentate dianionic ligand containing two oxygen-bridged amido-containing fragments, [2-Bu^tNC₆H₄)₂O]^{2−}, was used⁵²

for the synthesis of five-coordinate yttrium complex **35**. The structure of the latter was determined by X-ray diffraction.

Doubly deprotonated 4,13-diaza-18-crown-6 (DAC) proved to be suitable coordination environment for the synthesis of the yttrium derivative (DAC)YCH₂SiMe₃ (**36**).^{53, 54}

The reaction of complex **36** with phenylacetylene produces an equilibrium mixture of butatrienediyl {[(DAC)Y]₂Y. (μ-PhC=C=C=CPh)} and dimeric acetylenide {[(DAC)Y(μ-C≡CPh)]₂} complexes.

f. Complexes with monoanionic N,P-containing amide ligands

Being soft Lewis bases, neutral phosphines are considered as unsuitable ligands for coordination to hard rare-earth metal ions.⁵⁵ The coordination of the phosphine groups to rare-earth metal atoms was achieved with the use of the monoanionic amide ligand [N(SiMe₂CH₂PMe₂)₂][−] containing two PMe₂ fragments in the side chains (Scheme 5).

The exchange reaction involving yttrium or lutetium chloro complexes (**37**) and phenyllithium or benzylpotassium produced^{56, 57} the corresponding derivatives **38a–c**. An attempt to synthesise⁵⁸ allyl derivatives of yttrium by the reaction of complex **37a** with AlIMgCl led to the replacement of one of the amide ligands to form compound **39**, rather than to the expected substitution of the chlorine atom. Complexes **38a–c** are thermally unstable and are involved in cyclometallation at the methylene group to give metallacyclic derivative **40**.⁵⁹

Scheme 4

Scheme 5

g. Complexes with dianionic N,P-containing amide ligands

The macrocyclic dianionic bis(amidophosphine) ligand $[\text{PhP}(\text{CH}_2\text{SiMe}_2\text{NSiMe}_2\text{CH}_2)_2\text{PPh}]^{2-}$ (P_2N_2) was used for the synthesis of rare-earth metal alkyl and aryl complexes. The reactions of $[(\text{P}_2\text{N}_2)\text{Ln}(\mu\text{-Cl})_2]$ (Ln = Y (**41**), Ho, Yb or Lu) with $(\text{Me}_3\text{Si})_2\text{CHLi}$ and $\text{Me}_3\text{SiCH}_2\text{Li}$ in toluene produce the corresponding derivatives $(\text{P}_2\text{N}_2)\text{LnR}$ [Ln = Y, R = $\text{CH}(\text{SiMe}_3)_2$, CH_2SiMe_3 (**42**); Ln = Ho, R = CH_2SiMe_3 ; Ln = Yb, R = CH_2SiMe_3 ; Ln = Lu, R = CH_2SiMe_3], whereas the arylation of these complexes strongly depends on the ionic radius of the metal atom.^{60, 61} For example, the reactions of Y and Ho complexes with phenyllithium and biphenyllithium are accompanied by the dimerisation of aryl radicals to form the dinuclear complexes $[(\text{P}_2\text{N}_2)_2\text{Ln}]_2 \cdot (\mu\text{-}\eta^6\text{:}\eta^6\text{-Ph}_2)$ [Ln = Y (**43**) or Ho] and $[(\text{P}_2\text{N}_2)_2\text{Y}]_2[\mu\text{-}\eta^6\text{:}\eta^6\text{-(C}_6\text{H}_4\text{-Ph-}p)_2]$ containing the biphenyl or quaterphenyl dianion, respectively (Scheme 6).

Scheme 6

The slow transformation of complex **42** into dimer **43** in benzene at room temperature accompanied by elimination of tetramethylsilane was observed. For ytterbium having a

smaller ionic radius, the phenyl derivative $(\text{P}_2\text{N}_2)_2\text{YbPh}$ was isolated and characterised by X-ray diffraction. The presence of THF appeared to be the decisive factor for the suppression of the dimerisation of the aryl radicals. For example, the yttrium aryl complex was isolated as the adduct with THF, $(\text{P}_2\text{N}_2)\text{Y}(\text{C}_6\text{H}_4\text{Me-4})(\text{THF})$, in the reaction of $[(\text{P}_2\text{N}_2)\text{Y} \cdot (\mu\text{-Cl})_2]$ with *p*-tolyllithium in a toluene–THF mixture.⁶¹

h. Complexes with monoanionic alkoxide ligands

The five-coordinate neodymium alkyl complex $\text{L}_2\text{Nd} \cdot (\text{CH}_2\text{SiMe}_3)(\text{THF})_2$ (**44**) containing two sterically hindered phenoxide ligands L was obtained in a mixture with the derivative $\text{LNd}(\text{CH}_2\text{SiMe}_3)_2$ by the reaction of neodymium tris(phenoxide) with the corresponding magnesium derivative in a toluene–THF mixture.⁶² The structure of complex **44** was confirmed by X-ray diffraction.

Yttrium compound **45a** and ytterbium compound **45b** with the Danip ligand containing two *o*-anisole fragments were synthesised by the successive exchange reactions of LnCl_3 with one equivalent of $(\text{Danip})\text{Li}$ and two equivalents of $\text{KOC}_6\text{H}_3\text{Pr}_2\text{-2,6}$ in THF.⁶³ In complex **45b**, the ytterbium coordination sphere involves one carbon atom and two oxygen atoms of the 2,6-di(*o*-anisyl)phenyl fragment and two oxygen atoms of the 2,6-diisopropylphenoxide ligands, *i.e.*, the coordination number is 5. The compound of yttrium having a larger ionic radius⁶⁴ was isolated as the adduct with THF (**45a**); the coordination number of the metal atom in this adduct is 6.

Ln = Y, *n* = 1 (a); Ln = Yb, *n* = 0 (b).

i. Complexes with dianionic alkoxide ligands

Derivatives containing biphenyl-2,2'-diolate and 1,1'-binaphthyl-2,2'-diolate anions represent complexes with dianionic alkoxide ligands. Compounds **46** and **47** were synthesised for the first time⁶⁵ by the reaction of substituted biphenyldiol or binaphthyldiol with the $\text{La}[\text{CH}(\text{SiMe}_3)_2]_3$ complex (Scheme 7).

The reaction of complex **47** with CO is accompanied by the insertion of the latter at the La–C bond followed by the 1,2-

Scheme 7

migration of the SiMe_3 group to form enolate $[1,1'-(2\text{-OC}_{10}\text{H}_5\text{.SiPh}_3\text{-3})_2]\text{La}[\text{OC}(\text{SiMe}_3)=\text{CHSiMe}_3]$.⁶⁵

An analogous approach was used for the preparation of rare-earth metal alkyl and aryl complexes containing the enantiomerically pure (*R*)-Biphen⁶⁶ and (*R*)-Binol- SiAr_3 ligands.^{67,68}

Complex **48** was isolated⁶⁶ as the dimer formed by two bridging aryloxy groups. The treatment of this complex with excess THF leads to dissociation of the dimer and the formation of adduct **49**.⁶⁶

The Binol- SiAr_3 derivatives are monomeric.^{67,68} Compounds **50** and **51** can be given as examples.

$\text{Ln} = \text{Sc, Y, Lu}$; $\text{Ar} = \text{Ph, 3,5-Me}_2\text{C}_6\text{H}_3$.

$\text{Ar} = \text{Ph, 3,5-Me}_2\text{C}_6\text{H}_3$.

j. Complexes with monoanionic N,O-alkoxide ligands

Among bidentate N,O-alkoxide ligands, salicylaldiminate ligands are most widely used in the synthesis of alkyl derivatives. The elimination of substituted alkane in the reactions of 2-iminomethylphenols with trialkyl derivatives was demonstrated^{69–71} to be a convenient procedure for the preparation of such complexes, whereas the exchange reactions do not produce the target compounds in good yield. The reactions of the $\text{Ln}(\text{CH}_2\text{SiMe}_2\text{R})_3(\text{THF})_n$ compounds ($\text{Ln} = \text{Sc}$ or Y ; $\text{R} = \text{Me}$ or Ph ; $n = 1$ or 2) with two equivalents of 2-iminomethylphenol LH afford complexes **52a–k** in high yields.^{69–71}

Compound 52	Ln	Ar	R	n
a	Sc	Ph	Ph	1
b	Y	Ph	Ph	2
c	Sc	2- $\text{Pr}^i\text{C}_6\text{H}_4$	Ph	1
d	Y	2- $\text{Pr}^i\text{C}_6\text{H}_4$	Ph	1
e	Sc	Mes	Me	0
f	Y	Mes	Ph	1
g	Y	Mes	Me	0
h	Sc	2,6- $\text{Pr}_2\text{C}_6\text{H}_3$	Me	0
i	Sc	2,6- $\text{Pr}_2\text{C}_6\text{H}_3$	Ph	0
j	Y	2,6- $\text{Pr}_2\text{C}_6\text{H}_3$	Ph	0
k	Y	2,6- $\text{Pr}_2\text{C}_6\text{H}_3$	Me	0

Thermal stability of the reaction products substantially depends on the bulkiness of the substituent at the nitrogen atom. The complexes with the substituents $\text{Ar} = \text{Ph, 2-Pr}^i\text{C}_6\text{H}_4$ or Mes are unstable and slowly decompose in the temperature range from -20 to $+20$ °C, in the case of $\text{Ar} = \text{Ph}$ or $2\text{-Pr}^i\text{C}_6\text{H}_4$ the decomposition being accompanied by the migration of the $\text{CH}_2\text{SiMe}_2\text{R}$ group to the aldimine carbon atom (structure **A**), whereas the *ortho*-methyl substituents of the aryl group are metallated in the case of $\text{Ar} = \text{Mes}$ (structure **B**).⁷⁰

On the contrary, five-coordinate derivatives of the bulkiest ligand with $\text{Ar} = 2,6\text{-Pr}_i^2\text{C}_6\text{H}_3$ (compounds **52h–k**) are characterised by high thermal stability and decompose in the toluene solvent only upon prolonged heating at 140°C . This reaction is accompanied by metallation of one methyl group of the isopropyl substituent.⁷¹

The reaction of the trialkyl complex $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})$ with iminomethylphenol 2-($\text{CyN}=\text{CH}$)-6- $\text{Bu}^t\text{C}_6\text{H}_3\text{OH}$ (LH) produced the monoalkyl yttrium derivative $\text{L}_2\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$ even when the starting compounds were taken in equimolar amounts.⁷²

k. Complexes with dianionic N,O-alkoxide ligands

In recent years, sterically hindered polydentate bis(phenoxide) ligands containing additional donor groups capable of coordinating to metal atoms have found wide use in the chemistry of rare-earth organometallic compounds. The reaction of $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$ with bis(phenol) **53** was demonstrated⁷³ to proceed selectively to give six-coordinate yttrium complex **54** in good yield.

The X-ray diffraction and NMR spectroscopic data provide evidence that the methoxy group is coordinated to the metal atom in complex **54** both in the crystalline state and in nonpolar solvents. It should be noted that complex **54** is inactive in the ethylene polymerisation.

An analogous approach was used⁷⁴ for the synthesis of scandium complex **55** with the bis(phenoxide) ligand containing the tertiary amine and pyridine groups.

Erbium and ytterbium complexes (**56a,b**) with the related bis(phenoxide) ligand containing two amino groups were synthesised from metal trichlorides by the successive exchange reactions. The structure of compound **56b** was established by X-ray diffraction.⁷⁵

$\text{Ln} = \text{Er (a)}, \text{Yb (b)}$.

Yttrium alkyl complex **57** stabilised by the substituted tetradentate N,N' -ethylenebis(salicylaldimine) ligand was also prepared by the exchange reaction; however, the bis(dimethylsilyl)amide fragment was used in the latter case as the leaving group.⁷⁶

2. Heterobimetallic alkyl complexes

a. Complexes with monoanionic N-containing ligands

Monoanionic monodentate amide ligands have found little use in the synthesis of alkyl derivatives of rare-earth elements. The sterically hindered N -(2,6-diisopropylphenyl)trimethylsilylamide ligand was used⁷⁷ for the first time for the preparation of the bis(arylamido) chloride complexes $[\text{N}(\text{C}_6\text{H}_3\text{Pr}_i^2-2,6)(\text{SiMe}_3)_2\text{LnCl}(\text{THF})]$ ($\text{Ln} = \text{Nd}$ or Yb). The reactions of these compounds with methyl lithium (in a molar ratio of 1 : 2) in a toluene–diethyl ether mixture produce ate complexes **58a,b**.⁷⁸ The X-ray diffraction study showed that only one of

two methyl groups serves as a bridge between the lanthanide and lithium atoms.

Ln = Nd (a), Yb (b).

Ate complexes containing monoanionic bidentate amidinate and guanidinate ligands, $L_2Ln(\mu-Me)_2Li(TMEDA)$ [$L = PhC(NSiMe_3)_2$, $Ln = Y$ (**59a**);²⁶ $L = (Me_3Si)_2NC(NPr^i)_2$, $Ln = Y$,²⁹ Nd (**59b**), Yb (**59c**);^{79, 80} $L = (Me_3Si)_2NC(NCy)_2$, $Ln = Y$,³⁰ TMEDA is N,N,N',N' -tetramethylethylenediamine], were synthesised by the reactions of the corresponding chlorides $[L_2Ln(\mu-Cl)]_2$ or $L_2Ln(\mu-Cl)_2Li(B)_n$ ($B = THF$, DME or Et_2O) with two equivalents of MeLi in the presence of excess TMEDA. The reaction of complex **59a** with $Bu^tC\equiv CH$ afforded the corresponding heterobimetallic acetylenide $L_2Y(\mu-C\equiv CBu^t)_2Li(TMEDA)$.

b. Complexes with dianionic amide ligands and N-containing macrocycles

The synthesis of derivatives of the dianionic tridentate 2,6-diiminopyridine ligand, in which the neodymium and lithium atoms are linked by two bridging methyl ligands or one methyl ligand and one chloride ligand, respectively, $[2,6-(2,6-Pr^i_2C_6H_3NC(=CH_2))_2C_5H_3N]Nd(\mu-Me)(\mu-X)[Li(THF)_2]$ ($X = Me$ or Cl), was documented.³⁹

The octaethylporphyrin derivative of yttrium (OEP)Y. $(\mu-Me)_2Li(OEt_2)$, which was synthesised^{47, 81} by the reaction of phenoxide (OEP)Y($OC_6H_3Bu^t_{2-6}$) with MeLi (in a ratio of 1:2), belongs to heterobimetallic alkyl complexes with dianionic N-containing ligands.

Trivalent samarium methyl and vinyl complexes **60a,b** with the octaethylcalix-tetrapyrrole ligand (Et_8 -calix-pyrrole) were synthesised⁸² by the reactions of chloride (Et_8 -calix-pyrrole). $SmCl[Li_2(THF)_3]$ with the corresponding lithium reagents RLi ($R = Me$, $CH_2=CH$). The alkylation of the dinuclear complex $(Et_8$ -calix-pyrrole) $Sm_2\{(\mu-Cl)_2[Li(THF)_2]\}_2$ affords tetramethyl complex **61**.⁸³ (The ethyl groups in structures **60** and **61** are omitted for clarity.)

R = Me (a), $CH_2=CH$ (b)

c. Complexes with dianionic N,O-containing diamide ligands

The tetradentate ligand, in which two 2-amino-4-methylpyridine (Ap) fragments are linked by the siloxane bridge $O(SiMe_2)_2$, was used⁸⁴ for the synthesis of heterobimetallic yttrium complex **62**.

In the study of the reaction of the Sm^{III} bis(trimethylsilyl)-amide complex containing the *trans*-dioxaporphyrinogen ligand (PORFO) with amide $NaN(SiMe_3)_2$,⁸⁵ the process was found to be accompanied by activation of one C—H bond of the trimethylsilylamide group and produces metallacyclic γ -alkylamide complex **63** (the ethyl groups are omitted).

d. Complexes with alkyl- and aryloxy ligands

The reaction of $Sm(OC_6H_3Pr^i_{2-6})_3$ with three equivalents of Me_3SiCH_2Li in toluene produced heterobimetallic trinuclear samarium complex **64**,⁸⁶ in which the metal atom is coordinated by one terminal CH_2SiMe_3 group, one bridging CH_2SiMe_3 group and three bridging aryloxy ligands (coordination number of Sm is 5).

Bimetallic four-coordinate yttrium complex **65** was synthesised⁸⁷ by two successive exchange reactions of YCl_3 with two equivalents of $(\text{Me}_3\text{Si})_2\text{CHLi}$ and two equivalents of LiOBu^t . The structures of complexes **64** and **65** were established by X-ray diffraction. The coordination environment of the yttrium atom can be described as a distorted tetrahedron formed by two terminal $\text{CH}(\text{SiMe}_3)_2$ groups and two bridging *tert*-butoxide groups. The formation of yttrium ate complex **66**, which is a separated ion pair, was observed⁸⁸ in the reaction of YCl_3 with $\text{Me}_3\text{SiCH}_2\text{Li}$ and $\text{LiOC}_6\text{H}_3\text{Pr}_2^1\text{-2,6}$ (in a ratio of 1 : 2 : 2). The analogous reaction of the lutetium complex also produced ionic complex **67** consisting of the discrete cation and anion; however, this complex does not contain LiCl . It should be noted that complex **66** contains the unusual $[\text{Li}(\text{THF})_3]_2\text{Cl}]^+$ cation.

The formation of the heterodinuclear complex $\text{Li}[\text{Y}(\text{OSiBu}^t\text{Ar}_2)(\text{OC}_6\text{H}_3\text{Bu}_2^1\text{-2,6})(\text{CH}_2\text{SiMe}_3)_2]$ ($\text{Ar} = \text{C}_6\text{H}_4$, CH_2NMe_2) by the reaction of the derivative $\text{Y}(\text{OSiBu}^t\text{Ar}_2)(\text{OC}_6\text{H}_3\text{Bu}_2^1\text{-2,6})_2$ with two equivalents of $\text{Me}_3\text{SiCH}_2\text{Li}$ was documented.⁸⁹

e. Adducts of rare-earth metal complexes with trialkylaluminium

Due to the catalytic activity of the Ziegler–Natta systems based on rare-earth metal complexes in the alkene and diene polymerisation, considerable attention has been given to the reactions of their tris(amides) and tris(alkoxides) with various trialkyl derivatives of aluminium. These reactions produce heterobimetallic complexes containing the $\text{Ln}-\text{C}$ bond. The reaction of $\text{Nd}(\text{NPr}_2)_3(\text{THF})$ with 3 equivalents of AlMe_3 was found⁹⁰ to be accompanied by the $\text{Nd}-\text{C}$ bond formation to give the heterobimetallic trinuclear complex with three bridging methyl groups, $\text{Nd}(\text{NPr}_2)[(\mu\text{-Me})\text{AlMe}_2][(\mu\text{-Me})_2\text{AlMe}_2]$. The seven-coordinate neodymium complex $[\{\text{Me}_2\text{Al}(\mu\text{-Me})\}_2\text{Nd}(\mu_3\text{-NPh})(\mu\text{-Me})\text{AlMe}_2]$ containing the μ_3 -imide ligand was synthesised⁹¹ by the reaction of $[\text{Nd}(\text{NPh})_3(\text{KCl})_3]$ with Al_2Me_6 . Four sites in the neodymium coordination sphere are occupied by two chelating anions $[(\mu\text{-Me})\text{AlMe}_2]^-$, and three sites are occupied by the tridentate group $(\mu_3\text{-NPh})(\mu\text{-Me})\text{AlMe}$. The yttrium octaethylporphyrin complex $(\text{OEP})\text{Y}$.

$(\mu\text{-Me})_2\text{AlMe}_2$ was synthesised^{47, 81} by the reaction of 2 equivalents of AlMe_3 with $(\text{OEP})\text{Y}(\mu\text{-Me})_2\text{Li}(\text{OEt}_2)$.

Studies of the reactions of lanthanide aryloxides with AlR_3 showed that they can produce adducts of different composition depending on the bulkiness of the ArO group and the ionic radius of the lanthanide atom. For example, the reaction of $\text{Ln}(\text{OC}_6\text{H}_3\text{Pr}_2^1\text{-2,6})_3$ with AlR_3 (in a ratio of 1 : 4) produced the trinuclear complexes $\text{Ln}(\text{OC}_6\text{H}_3\text{Pr}_2^1\text{-2,6})[(\mu\text{-OC}_6\text{H}_3\text{Pr}_2^1\text{-2,6})\cdot(\mu\text{-R})\text{AlR}_2]_2$ [$\text{Ln} = \text{La}$ or Sm ; $\text{R} = \text{Me}$ or Et ;^{92, 93} $\text{Ln} = \text{Y}$, $\text{R} = \text{Me}$ (Ref. 94)]. Lanthanum aryloxide containing the bulkier 2,6-di-(*tert*-butyl)phenoxide groups OAr ($\text{Ar} = \text{C}_6\text{H}_3\text{Bu}_2^1\text{-2,6}$ or $\text{C}_6\text{H}_2\text{Bu}_2^1\text{-2,6-Me-4}$) reacts with AlMe_3 to form the dinuclear complex $\text{La}(\text{OAr})_3(\text{AlMe}_3)$.⁹⁴ The reactions of aryloxides of rare-earth metals having a smaller ionic radius produce the monotetramethylaluminate complexes $\text{Ln}(\text{OAr})_2\cdot[(\mu\text{-Me})_2\text{AlMe}_2]$ ($\text{Ln} = \text{Y}$ or Lu ; $\text{Ar} = \text{C}_6\text{H}_3\text{Bu}_2^1\text{-2,6}$, $\text{C}_6\text{H}_2\text{Bu}_2^1\text{-2,6-Me-4}$ or $\text{C}_6\text{H}_2\text{Bu}_3^1\text{-2,4,6}$).⁹⁴ The reaction of the trinuclear complex $\text{Y}_3(\text{OBu}^t)_7\text{Cl}_2(\text{THF})_2$ with AlMe_3 in hexane afforded⁹⁵ bimetallic complexes, in which the yttrium and aluminium atoms are linked by the bridging methyl ligands $\text{Y}[(\mu\text{-OBu}^t)(\mu\text{-Me})\text{AlMe}_2]_3$ or $(\text{Bu}^t\text{O})(\text{THF})\text{Y}[(\mu\text{-OBu}^t)(\mu\text{-Me})\cdot\text{AlMe}_2]_2$. The mono- and bis(tetraalkylaluminate) complexes $[\text{Me}_2\text{Al}(\text{O}_2\text{CC}_6\text{H}_2\text{Pr}_3^1\text{-2,4,6})_2\text{Ln}[(\mu\text{-Me})_2\text{AlMe}_2]]$ and $\{\text{Ln}(\text{O}_2\text{CC}_6\text{H}_2\text{Bu}_3^1\text{-2,4,6})[(\mu\text{-Me})_2\text{AlMe}_2]_2\}_2$ were synthesised^{96, 97} by the alkylation of rare-earth carboxylates $[\text{Ln}(\text{O}_2\text{CC}_6\text{H}_2\text{R}_3\text{-2,4,6})_3]_n$ ($\text{R} = \text{Me}$, Pr^i or Bu^t ; $\text{Ln} = \text{Y}$, La or Nd) with trialkylaluminium AlR_3 ($\text{R} = \text{Me}$ or Et).

3. Dialkyl and diaryl complexes

Rare-earth metal dialkyl complexes have attracted increasing attention as the starting compounds for the synthesis of cationic alkyl derivatives serving as active alkene polymerisation and co-polymerisation catalysts.^{98, 99} Half-sandwich dialkyl complexes were considered in special sections of recent reviews.^{100, 101}

a. Complexes with monoanionic N-containing ligands

The synthesis, structures and reactivities of yttrium, scandium and lanthanide dialkyl complexes (**68a–f**) stabilised by bulky benzamidinate ligands were documented.^{102, 103} The complexes were synthesised by elimination of tetramethylsilane in the reactions of amidine with the trialkyl compounds $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$. Derivatives of metals having a smaller ionic radius contain one coordinated THF molecule (compounds **68b, f**), whereas the coordination number of the central atom in complexes of metals with larger ionic radii (**68a, c–e**) increases to 6 as a result of coordination of an additional THF molecule.

$\text{Ln} = \text{Y}$ (**a**), Sc (**b**), La (**c**), Nd (**d**), Gd (**e**), Lu (**f**); $n = 1$ (**b, f**), 2 (**a, c–e**).

Yttrium dialkyl complex **69** can also be prepared by the exchange reaction with a less bulky tridentate amidinate ligand containing an additional amino group in the substituent.³³ An

attempt to apply this procedure to the synthesis of the dibenzyl derivative led to the formation of ate complex **70**, in which the Y and Li atoms have the coordination numbers 6 and 4, respectively. Therefore, a decrease in the volume of the σ -bonded ligand (CH_2Ph instead of $\text{CH}(\text{SiMe}_3)_2$) leads to substantial changes in the coordination environment of the Y atom. Thus, the amidinate ligands are coordinated only by two N atoms, whereas the nitrogen atom of the amino group is coordinated to the lithium ion.

$\text{L} = \text{PhC}(\text{NSiMe}_3)\text{N}(\text{CH}_2)_2\text{NMe}_2$.

A bidentate anilido-imine ligand was used¹⁰⁴ for the synthesis of yttrium dialkyl complexes **71a,b**.

A series of lanthanide dialkyl complexes **72** containing the chiral bidentate bis(oxazoline) ligands (Box) were synthesised *in situ* by elimination of alkane from the corresponding derivatives $\text{Ln}[\text{CH}(\text{SiMe}_3)_2]_3$ in the reactions with BoxH. The lutetium complex was isolated from the reaction mixture and its structure was established by X-ray diffraction.¹⁰⁵

β -Diketiminato ligands have found wide use in the synthesis of four-coordinate scandium dialkyl complexes. The $[\text{ArNC}(\text{R}^1)\text{CHC}(\text{R}^1)\text{NAr}]\text{ScR}_2^2(\text{THF})_n$ complexes (**73a–i**) ($\text{Ar} = 2,6\text{-Pr}_2^i\text{C}_6\text{H}_3$) were synthesised^{106,107} by the alkylation of the corresponding dichlorides $[\text{ArNC}(\text{R}^1)\text{CHC}(\text{R}^1)\text{NAr}]\text{ScCl}_2(\text{THF})_n$ ($n = 0$ or 1).

Compound 73	R ¹	R ²	Compound 73	R ¹	R ²
a	Me	Me	f	Me	CH_2Bu^t
b	Me	CH_2Ph	g	Bu^t	CH_2Bu^t
c	Bu^t	Me	h	Me	CH_2SiMe_3
d	Bu^t	Et	i	Bu^t	CH_2SiMe_3
e	Bu^t	CH_2Ph			

It should be noted that only derivative **73a** ($\text{R}^1 = \text{R}^2 = \text{Me}$) contains one coordinated THF molecule. For derivatives bearing larger substituents R^1 and R^2 , $n = 0$. This synthetic approach allows the preparation of the mixed alkyl derivatives $[\text{ArNC}(\text{Bu}^t)\text{CHC}(\text{Bu}^t)\text{NAr}]\text{ScMe}(\text{CH}_2\text{SiMe}_3)$ and dialkyl derivatives containing no coordinated Lewis bases. The high potential of these ligands in stabilisation of rare-earth organometallic compounds is demonstrated by the fact that even diethyl derivatives, which are generally very unstable because of the tendency to undergo β -hydride elimination, can be isolated in the presence of β -diketiminato ligands. The structures of complexes **73a,c,e,h,i** were established by X-ray diffraction. The dimeric dimethyl complex $[\{\text{ArNC}(\text{Me})\text{CHC}(\text{Me})\text{NAr}\}\text{ScMe}_2]_2$ is involved in the disproportionation with dichloride $[\{\text{ArNC}(\text{Me})\text{CHC}(\text{Me})\text{NAr}\}\text{ScCl}_2]_2$ to give the alkyl chloride derivative $[\{\text{ArNC}(\text{Me})\text{CHC}(\text{Me})\text{NAr}\}\text{ScClMe}]_2$.¹⁰⁸ The reactions of complexes **73h,i** with $\text{Bu}^n\text{P}=\text{Te}$ are accompanied by the insertion of the tellurium atom at the $\text{Ln}-\text{C}$ bond to form the corresponding tellurolates $[\text{ArNC}(\text{Me})\text{CHC}(\text{Me})\text{NAr}]\text{Sc}(\text{TeCH}_2\text{SiMe}_3)_2$.¹⁰⁹

The synthesis and structure of lutetium complex **74** containing the tridentate anilido-pyridine-imine ligand were documented.¹¹⁰

Recently, monoanionic tetradentate amide ligands have been designed^{111,112} and used in the synthesis of yttrium (**75a,b**) and lanthanum (**75c**) dialkyl complexes. It should be noted that the use of a ligand in which the 1,4,7-triazacyclononane and amide fragments are dimethylene-bridged allows the isolation of the lanthanum dialkyl complex. In the case of the ligand containing the shorter silylene (SiMe_2) bridge, the reaction is accompanied by the metallation of one methyl group resulting in the formation of dimer **76**.

$\text{Ln} = \text{Y}$; $\text{R} = \text{Me}$ (**a**), Pr^i (**b**); $\text{Ln} = \text{La}$, $\text{R} = \text{Me}$ (**c**).

The monoanionic tetradentate ligands $[(\text{Me}_2\text{NCH}_2\text{CH}_2)_2\text{N}-\text{X}-\text{NBu}^t]^-$ [$\text{X} = (\text{CH}_2)_2$ (L^1) or SiMe_2 (L^2)], in which three neutral amine fragments are not linked together to form a rigid ring, were used¹¹³ for the synthesis of yttrium derivatives. The reaction of L^1H with $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$ produces complex **77**, whereas the reaction of this starting compound with L^2H is accompanied by the rapid metallation of one methyl group to form metal-lacyclic product **78**. The C–H bond activation was observed also upon storage of compound **77** in deuterobenzene at room temperature for 8 h resulting in the formation of compound **79**.

The synthesis of yttrium dialkyl and diphenyl complexes containing the dimethyl tris(pyrazolyl)borate ligands TPB-Me_2 and $(\text{TPB-Me}_2)\text{YR}_2(\text{THF})$ ($\text{R} = \text{Me}$, Bu^t , CH_2SiMe_3 or Ph) was documented.¹¹⁴ Unfortunately, these compounds were characterised only by spectroscopic methods and elemental analysis.

The deprotonation of aza-18-crown-6 (MAC) with the yttrium derivative $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$ affords complex **80** in which the metal atom is located in the centre of the cavity of the hexadentate macrocyclic ligand, and the CH_2SiMe_3 groups are in axial positions.¹¹⁵

b. Complexes with monoanionic O-containing ligands

The only dialkyl derivative containing an aryloxy ligand is known. An X-ray diffraction study showed⁸⁷ that compound **81** exists as a monomer in the crystalline state.

c. Complexes with monoanionic N,O-containing aryloxy ligands

Salicylaldimine ligands containing substituents of different bulkiness in the aromatic rings of the phenol and imine fragments were used for the synthesis of scandium and yttrium dialkyl complexes. The reactions of equimolar amounts of the $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$ compounds ($\text{Ln} = \text{Sc}$ or Y) with the 2-($\text{MesN}=\text{CH}$)-6- $\text{Bu}^t\text{C}_6\text{H}_3\text{OH}$ (L^1H) ligand produce trigonal-bipyramidal five-coordinate complexes **82a,b**. Scandium compound **82a** is stable in a toluene solution at room temperature, whereas yttrium analogue **82b** undergoes disproportionation to form the homoligand complex L_3Y . The scandium derivative $\text{L}^2\text{Sc}(\text{CH}_2\text{SiMe}_3)_2(\text{THF})$ was isolated also in the reaction with the iminomethylphenol 2-($\text{CyN}=\text{CH}$)-6- $\text{Bu}^t\text{C}_6\text{H}_3\text{OH}$ (L^2H).⁷² The reaction of L^2H with the yttrium compound produces the six-coordinate complex $\text{L}_2^2\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$ containing two phenoxy-imine ligands and one CH_2SiMe_3 group regardless of the reactant molar ratio.

Ln = Sc (**a**), Y (**b**).

The related ligand with the bulkier diisopropylphenyl substituent at the nitrogen atom, 2-(2,6-Prⁱ₂C₆H₃N=CH)-6-Bu^tC₆H₃OH (L³H), was used in the study.⁷¹ An analogous synthetic approach allowed the synthesis of the yttrium alkyl complexes L³Y(CH₂SiMe₂R)₂(THF)_n (R = Me or Ph; n = 1 or 2); however, a mixture of products was obtained in the case of the scandium complex.

Phenols containing the 1,3,5-triazacyclononane fragment as the substituent were used¹¹⁶ as polydentate ligands in the synthesis of scandium derivatives **83**.

R¹ = CH₂SiMe₃; R² = Me, Prⁱ; R¹ = Ph, R² = Me.

d. Complexes with monoanionic N,P-containing amide ligands

A series of scandium dialkyl complexes **84a–c** containing the amidodiphosphine ligand were synthesised¹¹⁷ by the exchange reaction of the dichloride [N(SiMe₂CH₂PPRⁱ₂)₂]ScCl₂(THF) with 2 equivalents of the corresponding alkyllithium reagents. An X-ray diffraction study of compounds **84b,c** showed that the complexes are monomeric in the crystalline state and have a distorted trigonal-bipyramidal structure. In the cited study, the reactions of complexes **84** with CO, H₂, CH₃I, nitriles, isocyanides and silanes were investigated; however, all these reactions are accompanied by decomposition of the starting compound and give complex mixtures of products.

R = Me (**a**), Et (**b**), CH₂SiMe₃ (**c**).

III. Cationic alkyl complexes

The first cationic rare-earth metal complex containing the substituted alkyl group, [La(η⁵-C₅Me₅){CH(SiMe₃)₂}.(THF)_n]⁺[BPh₄][−], was synthesised in 1992.¹¹⁸ This class of

compounds has attracted considerable interest after the discovery¹¹⁹ of the catalytic activity of cationic scandium complexes in the ethylene polymerisation.

Cationic complexes **85a–f** with bulky benzamidinate ligands were synthesised^{102,103} by the reactions of the corresponding dialkyl derivatives with the Brønsted acid [PhNMe₂H]⁺[BPh₄][−] in THF. The structures of compounds **85a–e** were established by X-ray diffraction.

Ln = Sc, n = 2 (**a**); Ln = Y, n = 3 (**b**); Ln = La, n = 4 (**c**);

Ln = Nd, n = 4 (**d**); Ln = Gd, n = 4 (**e**); Ln = Lu, n = 3 (**f**).

Cationic derivatives can also be prepared by the transfer of one organic ligand, which is coordinated to the metal atom through the M–C σ-bond, to a strong electrophile. For example, the reaction of the scandium dibenzyl complex containing the β-diketiminato ligand with the Lewis acid B(C₆F₅)₃ produces cationic compound **86**.¹⁰⁶ Unlike complexes **85a–f**, compound **86** exists as a contact ion pair, in which the aromatic ring of the benzyl group is η⁶-coordinated to the metal atom.

Ar = 2,6-Prⁱ₂C₆H₃.

The reactions of rare-earth metal dialkyl complexes with Lewis acids can produce different cationic complexes depending on the reactant ratio (Scheme 8), as was exemplified¹²⁰ by scandium dimethyl complex **73c** containing the β-diketiminato ligand with the bulkier *tert*-butyl substituents at the imine carbon atoms.

For example, the reaction of **73c** with B(C₆F₅)₃ in a molar ratio of 1 : 0.5 affords dinuclear cationic complex **87**, in which two metal atoms are linked by the bridging methyl group. This complex is unstable and decomposes with the evolution of methane. If the reactants are used in a ratio of 1 : 1, the reaction produces monomeric compound **88** existing as an ion pair in which the counterions are linked together by the bridging methyl ligand and by a weak interaction between the scandium atom and the fluorine atom in the *ortho* position of one of the C₆F₅ rings. This compound is stable in the solid state at −30 °C; however, in solution it undergoes decomposition accompanied by the evolution of methane and the metallation of the isopropyl group. ¹H NMR spectroscopic studies showed that the ion pair is not dissociated in solution. The treatment of complex **73c** with two equivalents of B(C₆F₅)₃ affords doubly charged cationic derivative **89**.

Scheme 8

Cationic scandium alkyl complex **90**, which exists as a solvent-separated ion pair and contains the bromobenzene molecule η^6 -coordinated to the metal atom in the cationic moiety, was synthesised¹²¹ by the reaction of [ArNC(Me).CHC(Me)NAr]ScMe₂ with [Ph₃C][B(C₆F₅)₄] in bromobenzene. In the reactions of complex **90** with arenes having a higher basicity (C₆H₆, C₆H₅Me or C₆H₃Me₃) compared to bromobenzene, the arenes replace the PhBr molecule in the metal coordination sphere.

The reactions of the scandium dialkyl complexes [ArNC(R¹)CHC(R¹)NAr]ScR₂ (R¹ = Me or Bu^t; R² = Me, CH₂SiMe₃ or CH₂Bu^t) with B(C₆F₅)₃ and B(C₆F₅)(BPF) (BPF is perfluorinated biphenyl-2,2'-diyl, C₁₂F₈), the properties of the resulting cationic complexes and the dynamics of the constituent contact ion pairs were described.¹²² It was found that cationic derivatives of less bulky β -diketiminate ligands containing methyl substituents at the imine carbon atoms are less stable, and the migration of one C₆F₅ group from the boron atom to the metal atom is observed in a toluene solution (Scheme 9). For complexes containing Bu^t-substituted β -diketiminate ligands, this migration is not typical. At room temperature, these compounds are rather stable. However, the metallation of the methyl group of the isopropyl fragment occurs at high temperatures (308–323 K).

Scheme 9

Cationic yttrium organometallic derivatives **91** containing the anilido-imine ligand were synthesised as a result of the migration of one CH₂SiMe₂R group (R = Me or Ph) in complexes **92** to B(C₆F₅)₃.¹⁰⁴

It was demonstrated¹¹⁰ that the reactions of compounds containing two M–C bonds with Lewis acids can have a more complex mechanism. For example, the reaction of lutetium complex **74** with B(C₆F₅)₃ in THF is accompanied by elimination of one methyl group from the SiMe₃ fragment to form a new Si–C bond, resulting in the formation of the fragment CH₂SiMe₂CH₂SiMe₃ in complex **93**.¹¹⁰

The fact that the reaction of B(C₆F₅)₃ with complex **80** in THF produces the cationic derivative [(MAC)YCH₂SiMe₃].

$[\text{B}(\text{C}_6\text{F}_5)_3\text{CH}_2\text{SiMe}_3]$ was confirmed by multinuclear NMR spectroscopy. This compound is very unstable at room temperature and decomposes within a few minutes to give tetramethylsilane.¹¹⁵

It was found¹¹³ that the protonation in the reactions of the Brønsted acid $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ with complexes **77** and **79** proceeds differently (at the $\text{Y}-\text{CH}_2\text{SiMe}_3$ or $\text{Y}-\text{CH}_2\text{N}$ bond for compounds **77** and **79**, respectively) but gives the same cationic derivative **94**.

(a) $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$.

IV. Hydride complexes

Metallocene-type rare-earth metal hydride complexes exhibit unique reactivity¹²³ and still remain among the most promising catalysts. Most of the known rare-earth metal hydride complexes are dimeric.^{3, 123} The only reliably characterised monomeric hydride $[\text{1,3,4-Bu}_3\text{C}_5\text{H}_2]_2\text{CeH}$ containing the bulky cyclopentadienyl ligands was described as late as in 2005.¹²⁴ Hydride complexes are most often synthesised by the $\text{Ln}-\text{C}$ σ -bond cleavage with molecular hydrogen^{125, 126} or phenylsilane.¹²⁷

The development of post-metallocene chemistry of rare-earth metal hydride complexes has started in recent years. Benzamidinate complex **10**, which was prepared by the hydrogenolysis of compound **2** at 3 atm and 40 °C in benzene (see Scheme 1), was the first and, for many years, the only hydride complex containing no cyclopentadienyl ligands.

Complex **10** is rather stable in hydrocarbon solvents up to 100 °C; however, it reacts with the $\text{C}-\text{O}$ bond of THF and also binds to the $\text{C}-\text{N}$ bonds of acetonitrile and pyridine to form the $\{[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Y}(\mu-\text{N}=\text{C}(\text{H})\text{Me})_2$ and $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Y}(\text{py})$ compounds, respectively. The reaction of compound **10** with α -picoline is accompanied by the $\text{C}-\text{H}$ bond activation to give the $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Y}(\eta^2-(\text{C},\text{N})-2-\text{CH}_2\text{NC}_5\text{H}_4)$ complex.²⁶ The reaction of complex **10** with acetylene is accompanied by hydrogen elimination to form dimeric acetylenide $\{[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Y}(\mu-\text{C}\equiv\text{CH})_2\}$. The scandium analogue $\{[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Sc}(\mu-\text{H})_2$ (**11a**) was synthesised²⁷ by the reaction of the corresponding alkyl complex **11** with H_2 (benzene or hexane, 1 atm, 20 °C). The $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScMe}(\text{THF})$ and $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScMes}$ compounds react with H_2 to give hydride **11a** only at high temperature (70 °C). Complex **11a** is stable in deuteriobenzene; no evidence of decomposition was observed even upon heating at 60 °C overnight. Compound **11a** is not involved in the exchange reaction with D_2 . The dimeric structure of this

complex is rather stable, and dissociation was not observed even after the treatment with THF. The addition of complex **11a** at the triple bond of tolane affords the $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{ScC}(\text{Ph})=\text{CHPh}$ compound.

Lutetium hydride $\{[(\text{Me}_3\text{Si})_2\text{NC}(\text{NPr}^i)_2]_2\text{Lu}(\mu-\text{H})_2$ (**95**) stabilised by the guanidinate ligands and containing no coordinated Lewis bases was synthesised¹²⁸ by the reaction of the $[(\text{Me}_3\text{Si})_2\text{NC}(\text{NPr}^i)_2]_2\text{LuCH}_2\text{SiMe}_3$ complex with PhSiH_3 (in a ratio of 1 : 1) in hexane. This compound differs from other bis(guanidinate)-type derivatives by the asymmetric coordination of the guanidinate ligands in two $[(\text{Me}_3\text{Si})_2\text{NC}(\text{NPr}^i)_2]_2\text{Lu}$ fragments.

Yttrium alkyl complexes **17a,b** readily react with phenylsilane in benzene at room temperature to form hydride **18**. This hydride can also be prepared by the hydrogenolysis of compounds **17a,b** under high pressure at room temperature in deuterobenzene. The exchange of the hydride ligands for deuterium from the solvent was observed upon storage of hydride **18** in THF-d_8 . In THF, complex **18** binds to the $\text{C}=\text{C}$ bonds of ethylene and hex-1-ene to give the corresponding alkyl complexes (see Scheme 2).

It was reported³⁷ that the hydrogenolysis of the $[2,6-\text{Pr}^i_2\text{C}_6\text{H}_3\text{N}(\text{CH}_2)_2\text{NC}_6\text{H}_3\text{Pr}^i_2-2,6]\text{YCH}(\text{SiMe}_3)_2(\text{THF})$ complex in toluene under an H_2 pressure of 1.5 atm proceeds very slowly. The hydrogenation of the $\text{Y}-\text{C}$ bonds was accompanied by the insertion of H_2 at one of the two $\text{Y}-\text{N}$ bonds of two diamide ligands to form the trinuclear $[\text{Y}_3\{2,6-\text{Pr}^i_2\text{C}_6\text{H}_3\text{NH}(\text{CH}_2)_2\text{NC}_6\text{H}_3\text{Pr}^i_2-2,6\}_2\{2,6-\text{Pr}^i_2\text{C}_6\text{H}_3\text{N}(\text{CH}_2)_2\text{N}(\text{C}_6\text{H}_3\text{Pr}^i_2-2,6\}(\mu-\text{H})_3(\mu_3-\text{H})_2(\text{THF})]$ complex.

The μ_3 -bridging coordination of the hydride ligand linking together the samarium atom and two lithium atoms was observed⁸² also in hydride complex **96** containing the calixpyrrole ligand. Complex **96** can be synthesised from methyl derivative **60a** by either the hydrogenolysis in THF at room temperature or the treatment with phenylsilane.

The $\text{Sm}-\text{H}$ distance in complex **96** is 2.25(7) Å, which is substantially larger than the bond lengths in known dimeric metallocene-type samarium hydrides (2.05 Å).¹²⁹ Complex **96** is stable in THF at room temperature for several weeks or at 60 °C for several hours. Compound **96** rapidly reacts with ethylene at room temperature and under atmospheric pressure to form the vinyl derivative accompanied by hydrogen elimination.

Heterobimetallic five-coordinate hydride complex **97** was prepared in 10% yield by the treatment of samarium methyl complex **61** with phenylsilane in THF at room temperature. The structure of complex **97** was established by X-ray diffraction. The complex contains two $\text{LiOCH}=\text{CH}_2$ fragments, which are formed, apparently, as a result of the cleavage of the THF molecule under the action of two MeLi molecules.⁸³ The second hydride-containing product, $(\text{Et}_3\text{-calix-pyrrole})\cdot\text{Sm}(\text{H})\text{Li}_2(\text{THF})_6$, was also isolated from the reaction mixture; however, the latter product was not reliably characterised.

The only hydride complex of lanthanides in the oxidation state +2 (compound **98**) was described. This complex was synthesised¹³⁰ with the use of the tris(pyrazolyl)borate ligands (TPB-Me,Bu^t) as the stabilising coordination environment.

The hydrogenolysis of alkyl complexes **52h–k** stabilised by the salicylaldiminate ligands **L** was found^{69,71} to proceed differently depending on the nature of the metal. For example, the hydride compound that is formed in the case of scandium immediately binds to the C=N bond of one of the ligands **L**, whereas dimeric hydride **99** was isolated in the case of yttrium. The latter complex is inert to ethylene.

The reaction of complex **34** with hydrogen was demonstrated to produce centrosymmetric dimeric hydride $[\{\text{Me}_2\text{Si}(\text{NBu}^t)(\text{OBu}^t)\}_2\text{Y}(\mu\text{-H})_2]$, which was detected⁵⁰ in the

reaction mixture by ¹H NMR spectroscopy. However, attempts to isolate the hydride complex failed because this complex undergoes disproportionation in solution to give the $[\text{Me}_2\text{Si}(\text{NBu}^t)(\text{OBu}^t)]_3\text{Y}$ compound.

The reactions of complexes **84b,c** with hydrogen are accompanied by elimination of the corresponding alkanes; however, hydrides were not detected in the reaction mixtures, and the ³¹P NMR spectra provided evidence for the presence of a complex mixture of products.¹¹⁷

An attempt to synthesise the yttrium dihydride complex by the reaction of the dimethyl derivative (TPB-Me₂)YMe₂(THF) with H₂ under a pressure of 8 atm at 0 °C led to the formation of a thermally unstable complex, which was characterised by IR spectroscopy.¹¹⁴

V. Non-metallocene rare-earth organometallic derivatives in catalysis of transformations of unsaturated substrates

1. Catalysis of alkene and diene polymerisation

Yttrium dihydride complex **10** catalyses the ethylene polymerisation under a pressure of 4 atm at 65 °C in deuteriobenzene.^{25,26} An increase in the monomer pressure to 70 atm improves the efficiency of the reaction, but the activity, on the whole, remains low $[4 \text{ (g PE) (mmol catalyst)}^{-1} \text{ h}^{-1}]$. The resulting polyethylene has a molecular mass $M_w = 2.399 \times 10^5$, $M_n = 4.63 \times 10^4$ and a high polydispersity ($M_w/M_n = 5.2$). It should be noted that no yttrium organometallic derivatives, except for complex **10**, were detected in the reaction mixture by ¹H NMR spectroscopy. Yttrium benzyl complex **1** also initiates the ethylene polymerisation, but the activity of this complex is even lower than that of hydride **10**. Both complexes do not catalyse the propylene and hex-1-ene polymerisation. No traces of oligomerisation products or allyl complexes were found even at 80 °C. Scandium analogue **11a** proved to be²⁷ virtually inactive in the ethylene and propylene polymerisation.

Yttrium dialkyl complex **68a** with the bulky amidinate ligand initiates the ethylene polymerisation in the presence of the activator $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ at 50 °C and a monomer pressure of 5 atm at a high rate.¹⁰² After a polymerisation time of 5 min, the molecular mass M_w of the polymer was 4.3×10^5 ; after 30 min, M_w was 1.211×10^6 , the polydispersity being very low ($M_w/M_n = 1.2$). Calculations demonstrated that there is one yttrium centre per 1.1 polymer chain in the course of polymerisation, which is indicative of the living polymerisation and a low probability of the chain transfer through β -elimination. It was noted that the efficiency of the catalyst decreases with time. The catalyst efficiency was $1037 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$ at a reaction time of 5 min, and it was only $400 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$ after 30 min. It should be noted that the six-coordinate analogue of compound **68a** containing an additional THF molecule in the metal coordination sphere is absolutely inactive in the ethylene polymerisation under analogous conditions. However, the addition of partially hydrogenated AlBu_3 (TIBAO) to a mixture of compound **68a** and $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ results in the formation of catalytic systems active in the ethylene polymerisation [the efficiency is $2670 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$, $M_w/M_n = 2.1$]. In the presence of TIBAO, M_w of the polymer is somewhat lower and the polydispersity is higher (~ 2) than the corresponding characteristics in the absence of this additive.

The catalytic activity of dialkyl amidinate complexes **68b–f** in the ethylene polymerisation in the presence of $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ and TIBAO at 30 °C and a monomer pressure of 5 atm was investigated.¹⁰³ It was found that the catalytic activity of the systems substantially depends on the ionic radius of the metal atom. Scandium having the smallest

ionic radius among the rare-earth elements, as does lanthanum having the largest ionic radius, show low activities. The activities of about $3000 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$ were observed for metals having intermediate ionic radii (Y and Gd). The polyethylene prepared in the presence of these catalysts is characterised by a high molecular mass ($M_w = 1.5 \times 10^6$) and the polydispersity $M_w/M_n \approx 2$. The conclusion was drawn that the main mechanism of the chain transfer in this system involves the transfer of the alkyl radical to the Al atom. It should be noted that the lutetium complex having a small ionic radius showed a moderate activity [$342 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$] and gave rise to the product with a low polydispersity ($M_w/M_n = 1.4$), which is indicative of the absence of the chain transfer, as opposed to systems with complexes of metals with larger ionic radii.

Lutetium hydride **95** stabilised by guanidinate ligands catalyses¹²⁸ the ethylene polymerisation; however, its efficiency is low. Complex **95** belongs to a few rare-earth metal derivatives initiating the propylene polymerisation [the activity was $3.9 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$]. Compound **95** is also efficient in the styrene polymerisation at room temperature and allows the preparation of polymers with a high molecular mass $M_w = 1.25 \times 10^6$ and a rather low polydispersity $M_w/M_n = 1.54$.

Heterobimetallic bis(guanidinato)alkyl complexes **59b,c** initiate the styrene polymerisation⁷⁹ in the temperature range of $70\text{--}100^\circ\text{C}$. It should be noted that the reaction does not proceed at 55°C ; at 100°C , the yield of the polymer is substantially lower, which was accounted for by the deactivation of the catalysts at high temperatures. The polystyrene samples have molecular masses in a range of $(1.72\text{--}5.89) \times 10^4$ and rather low polydispersities (~ 2), which increase with temperature. Studies of the microstructures of the resulting polymer samples showed that they are predominantly atactic. However, the macromolecules contain from 53% (70°C) to 28% (85°C) of syndiotactic fragments depending on the polymerisation temperature.

In spite of numerous investigations on the synthesis of rare-earth metal complexes with β -diketiminate ligands, data on their catalytic activity are scarce. Scandium dimethyl complex **73c** showed high catalytic activity in the ethylene polymerisation [$300\text{--}1200 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$] in the presence of $\text{B}(\text{C}_6\text{F}_5)_3$ or $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$ as the activator and poly-(methylalumoxane) (MAO) as the cocatalyst at 50°C .¹²⁰ This complex allows the preparation of polyethylene with a high molecular mass [$(0.851\text{--}1.866) \times 10^6$] and a rather narrow molecular mass distribution (MMD) ($M_w/M_n = 1.7\text{--}2.2$). The use of an analogous complex containing Cl ligands instead of Me groups in the presence of MAO leads to a decrease in the catalytic activity of the system to $9.9 \times 10^4 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$ (polyethylene has $M_w = 1.357 \times 10^6$, $M_w/M_n = 2.2$).

Yttrium alkyl and hydride complexes **17a,b** and **18** containing the dianionic ligand DADB proved to be poorly active in the ethylene polymerisation.³⁵

A study of yttrium dialkyl complexes stabilised by the monoanionic tetradentate N-donor ligands (L) in the ethylene polymerisation showed¹¹¹ that the nature of the ligand has a decisive effect on the catalytic activity of the complexes generated in the $\text{LY}(\text{CH}_2\text{SiMe}_3)_2\text{--}[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ systems. For example, complexes **75a,b** containing the 1,4,7-triazacyclononane ligand proved¹¹¹ to be active catalysts for the ethylene polymerisation in the presence of $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ (toluene, $30\text{--}80^\circ\text{C}$, 5 atm). Their efficiency was $(0.70\text{--}1.79) \times 10^3 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$. The polyethylene samples had a high polydispersity ($M_w/M_n = 4.0\text{--}6.0$). In addition, catalysts lost 5%–30% of the initial activity during a rather short period of time (10–15 min). Unlike complexes **75a,b**, compound **77**, in which the yttrium

atom is in an analogous coordination environment but which contains the structurally different N,N-donor ligand, is inert to ethylene in the presence of $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ as the activator. In the presence of $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$ as the activator, which does not form the free Lewis base PhNMe_2 in the reactions with dialkyl complexes, complex **77** catalyses the ethylene polymerisation (toluene, 50°C , 5 atm) but it loses catalytic activity during 4 min.¹¹³

Yttrium dialkyl and diaryl complexes containing the dimethyl tris(pyrzoly)borate ligands (TPB-Me_2) or $(\text{TPB-Me}_2)\text{YR}_2(\text{THF})$ ($\text{R} = \text{Me}$, Bu^t , CH_2SiMe_3 or Ph) catalyse the ethylene polymerisation giving a linear polymer with a high molecular mass (up to 2×10^6) and a high polydispersity (2.50–4.14).¹¹⁴ The complex with $\text{R} = \text{Bu}^t$ proved to be more active (the total turnover number was 1932).

Yttrium dialkyl complex **81** initiates the ethylene polymerisation but it is inert to propylene and butadiene.⁸⁷

The treatment of neodymium alkoxide $\text{Nd}_3(\mu_3\text{-OBU}^t)_2 \cdot (\mu_2\text{-OBU}^t)_3(\text{OBU}^t)_4(\text{THF})_2$ (Refs 62 and 131) with dialkylmagnesium compounds affords systems, which can catalyse the ethylene polymerisation. The polymerisation at 0°C and a monomer pressure of 1 atm in the presence of these catalysts and phenylsilane or H_2 gives low-molecular-mass polyolefins [the activity is $5\text{--}20 \text{ (kg PE) mol}^{-1} \text{ h}^{-1} \text{ atm}^{-1}$].¹³¹

Complexes **32a,b**,⁴⁹ **35** (Ref. 52) and **54** (Ref. 73) proved to be inactive as initiators for the ethylene polymerisation.

The heterobimetallic diiminopyridine complex $[\text{2,6-}\{\text{2,6-Pr}^i\text{C}_6\text{H}_3\text{NC}(\text{=CH}_2)\}_2\text{C}_5\text{H}_3\text{N}\}\text{Nd}(\mu\text{-Me})(\mu\text{-Cl})[\text{Li}(\text{THF})_2]$ containing the bridging methyl and chloride ligands, which link together the neodymium and lithium atoms, proved to be a highly efficient catalyst for the synthesis of *cis*-polybutadiene, whereas the activity of the fully methylated analogue (containing the Me group instead of the Cl atom) was unexpectedly much lower.³⁹

The catalytic system, which was prepared by the treatment of neodymium alkoxide $\text{Nd}_3(\text{OBU}^t)_9(\text{THF})_2$ with dialkylmagnesium reagents, proved to be inefficient in the butadiene polymerisation, whereas systems based on tris(phenoxides) $\text{Nd}(\text{OC}_6\text{H}_4\text{Bu}^t\text{-2,6-Me-4})_3(\text{THF})_n$ ($n = 0$ or 1) are suitable for the living polymerisation of butadiene and the preparation of polymers with a low polydispersity ($M_w/M_n = 1.3$) containing up to 95% of *trans* units.¹³² These systems allow also the synthesis of butadiene–styrene copolymers with a molecular mass M_n up to 5×10^4 and a styrene content of 3%–15%.

2. Catalysis of polymerisation of polar monomers

a. Acrylic monomers

Yttrium and samarium alkyl complexes **13** and **14a,b** were studied³² as initiators for the methyl methacrylate (MMA) polymerisation. Compounds **13** and **14a** exhibit high catalytic activity and isospecificity in both the block and solution polymerisation of MMA. Compound **14a** showed good results as regards the stereoregularity of polymer products in a wide temperature range (from -40 to $+65^\circ\text{C}$); however, the isotacticity of poly(methyl methacrylate) (PMMA) samples somewhat decreases with temperature. The block copolymerisation initiated by complex **14a** affords a isotactic polymer with a very high molecular mass ($M_n = 1.41 \times 10^6$) and a low polydispersity ($M_w/M_n = 1.31$). Yttrium complex **13** provided much lower selectivity but the molecular mass distribution remained rather narrow (1.24–1.98). It should be noted that methyl complex **14b** appeared to be absolutely inactive in the MMA polymerisation.

The scandium complex $(\text{BDPPpyr})\text{ScCH}_2\text{SiMe}_3(\text{THF})$ with the tridentate diamino-substituted pyridine ligand (see Section II.1.b) catalyses³⁸ the MMA polymerisation at 40°C in toluene at a high rate to give PMMA with molecular masses $M_w = 1.29 \times 10^5$, $M_n = 8.1 \times 10^4$ and a low polydispersity ($M_w/M_n = 1.6$). Analogous yttrium and lutetium complexes

with large ionic radii exhibited very low activity, whereas derivatives of other ligands examined in the study³⁸ proved to be inactive.

Heterobimetallic neodymium and ytterbium complexes **58a,b** initiate the MMA polymerisation⁷⁸ at good rates even at $-78\text{ }^{\circ}\text{C}$. The PMMA samples have predominantly syndiotactic structures, high molecular masses ($>10^4$) and polydispersities varying from 1.61 to 1.93.

Neodymium bis(guanidinate) complex **59b** proved to be an efficient catalyst for the MMA polymerisation at $40\text{ }^{\circ}\text{C}$. The resulting polymer⁸⁰ had a molecular mass of 10.8×10^4 and a polydispersity of 2.16.

The use of the $\text{Nd}_3(\mu_3\text{-O}^t\text{Bu})(\mu_2\text{-O}^t\text{Bu})_3(\text{O}^t\text{Bu})_4 \cdot (\text{THF})_2 - (\text{n-C}_6\text{H}_{13})_2\text{Mg}$ systems allows the synthesis of polyethylene–PMMA block-copolymers.¹³¹ The $\text{Nd}(\text{OC}_6\text{H}_2 \cdot \text{Bu}^t\text{-2,6-Me-4})_3(\text{THF})$ and $\text{Nd}(\text{OC}_6\text{H}_2\text{Bu}^t\text{-2,6-Me-4})_3 - (\text{n-C}_6\text{H}_{13})_2\text{Mg}$ systems¹³² catalyse copolymerisation of butadiene with glycidyl methacrylate, resulting in the formation of block polymers.

b. ϵ -Caprolactone and lactides

Bis(guanidinate) complexes **59b,c** are efficient catalysts for the ϵ -caprolactone polymerisation.⁸⁰ In the case of neodymium complex **59b**, the conversion achieved 100% at $20\text{ }^{\circ}\text{C}$ during 15 min even at the monomer: initiator ratio of 1000:1; ytterbium derivative **59c** proved to be somewhat less active. The resulting polymer has a high molecular mass [$M_n = (7.44\text{--}11.03) \times 10^4$] but a rather wide MMD ($M_w/M_n = 1.92\text{--}2.96$).

Yttrium alkyl complexes **66** and **81** and lutetium alkyl complex **67** containing the phenoxide ligands were demonstrated⁸⁷ to initiate ϵ -caprolactone polymerisation. However, data on the activity of the catalysts and the properties of the polymers were not reported.

The use of scandium complex **82a** with the phenoxy-imine ligand allows the polymerisation of ϵ -caprolactone with a quantitative conversion at $0\text{ }^{\circ}\text{C}$ during 1 min. The molecular mass of the polymer was 7.1×10^4 , and the polydispersity was 2.9.⁷² Complex **56b** exhibited somewhat lower activity;⁷⁵ however, the resulting polyester had a much lower polydispersity ($M_w/M_n = 1.49$) and a lower molecular mass ($M_n = 5.05 \times 10^4$). Related bis(phenoxide) complex **54** initiates the living polymerisation of racemic lactide at a high rate, which gives predominantly a heterotactic polymer.¹³³

3. Catalytic C–C bond formation (dimerisation of alkynes)

An investigation of the catalytic activity of yttrium complexes **1**, **2** and **10** in the dimerisation of terminal alkynes showed²⁶ that, as opposed to systems with metallocene-type catalysts,^{134,135} the reaction pathway in the presence of these complexes substantially depends on the size of the substituent at the triple bond of the substrate. For example, dimerisation of alkynes $\text{RC}\equiv\text{CH}$ with small substituents ($\text{R} = \text{H}$, Me or Pr^{*t*}) was not observed even upon prolonged heating ($80\text{ }^{\circ}\text{C}$), whereas alkynes with bulky substituents ($\text{R} = \text{Ph}$, SiMe_3 or Bu^t) do undergo dimerisation under analogous conditions. It should be noted that the rate of alkyne dimerisation catalysed by amidinate complexes **1**, **2** and **10** is much lower than that in the presence of bis(cyclopentadienyl)-type complexes.¹³⁴ The regioselectivity of the reaction depends also on the nature of alkyne. Thus, the $\text{PhC}\equiv\text{CH}$ and $\text{Bu}^t\text{C}\equiv\text{CH}$ compounds undergo the selective head-to-tail dimerisation to form 2,4-disubstituted but-1-en-3-yne **100**, whereas the reverse selectivity is observed for $\text{Me}_3\text{SiC}\equiv\text{CH}$, and the reaction affords exclusively the 1,4-substituted head-to-head addition product, viz., *trans*- $\text{Me}_3\text{SiC}(\text{H})=\text{C}(\text{H})\text{C}\equiv\text{CSiMe}_3$ (**101**).

The cationic complex $[\text{LLa}(\text{CH}_2\text{SiMe}_3)]^+[\text{B}(\text{C}_6\text{F}_5)_4]^-$, which was prepared by the reaction of $[\text{PhNMe}_2\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ with the $\text{LLa}(\text{CH}_2\text{SiMe}_3)_2$ complex (**75c**), was used *in situ* in the catalysis of the phenylacetylene dimerisation. At $50\text{ }^{\circ}\text{C}$, the reaction proceeds at a high rate and a very high selectivity to give *cis*-1,4-diphenylbut-1-en-3-yne in 99% yield.¹¹²

4. Catalytic C–N bond formation (hydroamination of alkenes)

The catalytic hydroamination of alkenes and alkynes resulting in the addition of amines at multiple bonds of unsaturated substrates is a very convenient, efficient and environmentally safe procedure for the synthesis of nitrogen-containing compounds.^{14, 136, 137} Organic rare-earth metal derivatives are among the most promising catalysts for the hydroamination–cyclisation of unsaturated compounds with unactivated double bonds proceeding under mild conditions at a high rate and a high enantioselectivity, which allows the synthesis of nitrogen-containing heterocyclic, including biologically active, compounds.^{15, 16}

Lanthanum alkyl complexes **48** and **49** containing the chiral Biphen ligand proved to be efficient catalysts for the hydroamination–cyclisation of 2,2'-dimethylpent-4-enylamine and hex-5-enylamine at room temperature, the activity of monomeric complex **49** being almost twice as high as that of dimer **48**.⁶⁶

Unfortunately, the enantioselectivity of complexes **48** and **49** is low, and the reactions produce racemic mixtures of heterocycles. The use of the Binol-SiAr₃ ligands with the bulky Ar₃Si substituents at positions 3 and 3' (complexes **50** and **51**) allows not only the retention of high activity in the hydroamination, but also a substantial enhancement of the enantioselectivity of the reaction (to 95%).^{67, 68} In the presence of these complexes, the cyclisation of aminopentenes proceeds at a high rate even at room temperature, whereas the reaction of aminohexenes requires high temperature ($60\text{--}100\text{ }^{\circ}\text{C}$). The catalytic activity of these complexes increases with increasing ionic radius of metal. Compound **51** catalyses the hydroamination of styrene with propylamine at $60\text{ }^{\circ}\text{C}$, the addition being anti-Markovnikov.⁶⁸

Yttrium complexes **28a–c** also exhibited high activity in the catalysis of the hydroamination–cyclisation of various aminoalkenes and aminoalkynes.⁴³ The electron-withdrawing effect of the dichlorophenyl substituents (compound **28c**) enhances the stability of the catalyst to degradation as a result of protonolysis, which is manifested in its high activity in the cyclisation of pent-4-enylamine and 5-phenylpent-4-enylamine. The double cyclisation of 2-allyl-2-methylpent-4-enylamine can be performed at $60\text{ }^{\circ}\text{C}$ with the use of complexes **28a** and **28c**; this reaction affords 2,4,6-trimethyl-1-azabicyclo[2.2.1]heptane as a mixture of *endo,endo* and *exo,exo* isomers.

The use of scandium organometallic complexes with salicylaldimine and β -ketimine ligands for the initiation of the hydroamination–cyclisation of aminoalkynes and aminoalkenes was documented.¹³⁸ In the cited study, the first cationic system (compound **88**) initiating the intramolecular hydroamination was described.

Complexes **52i**, **73c** and **52l** ($L = \text{Sn}$, $\text{Ar} = \text{Mes}$, $R = \text{Ph}$) catalyse the hydroamination–cyclisation of 5-phenylpent-4-ynylamine (25 °C for complexes **52i**, **l** and 65 °C for complex **73c**) giving substituted pyrrolidine in quantitative yield. However, these complexes are inactive in the catalysis of the intermolecular hydroamination of hex-1-yne with aliphatic amines. Complex **52i** containing ligands with the bulky diisopropylphenyl substituent at the imine nitrogen atom is inactive in the hydroamination of 2,2-diphenylpent-4-enylamine. However, the use of a less bulky ligand containing the mesityl substituent (complex **52l**) results in the appearance of the catalytic activity; the complete conversion is achieved at 65 °C for 2 h. β -Diketimine complex **73c** catalyses the hydroamination of 2,2-diphenylpent-4-enylamine at room temperature but at a low rate. The activity of the catalyst was increased by a factor of ~ 60 and the amount of the catalyst charge was halved with the use of cationic derivative **88**. The use of this cationic complex makes it also possible to perform the cyclisation of aminoalkenes, which is, as a rule, a more complex process compared to aminopentenes.

5. Catalytic C–Si bond formation (hydrosilylation of alkenes)

Yttrium methyl and hydride complexes **17a** and **18** can catalyse the formation of ethylphenylsilane from ethylene and PhSiH_3 at room temperature and an ethylene pressure of 0.35 atm.¹³⁹ The hydrosilylation of hex-1-ene, styrene and norbornene with PhSiH_3 proceeds in the presence of complex **17a**, whereas cyclohexene, α -methylstyrene and *trans*-stilbene are not involved in this reaction. In the presence of this complex, secondary silane PhMeSiH_2 is involved in the addition reaction only with hex-1-ene and styrene. It should be noted that aliphatic alkenes give predominantly anti-Markovnikov addition products, whereas the hydrosilylation of styrene affords benzyldisilane derivatives as the major products. Complex **17a** containing the enantiomerically pure (*S*)-biphenyl ligand showed a high enantioselectivity in the catalysis of the hydrosilylation of norbornene with phenylsilane (*ee* 90.4%).

Lanthanum complexes **48** and **49** (Ref. 66) catalyse the hydrosilylation of hex-1-ene, styrene and norbornene with ethylphenylsilane at 60 °C, the catalytic activity of monomeric complex **49** is, as a rule, lower than the activity of dimeric complex **48** containing no coordinated THF molecules. The hydrosilylation of styrene proceeds at a high rate and a high selectivity to give predominantly the Markovnikov addition product. Unexpectedly, the rates of hydrosilylation of hex-1-ene and norbornene appeared to be substantially lower than that of styrene. Both reactions are stereoselective and give exclusively the 1,2-addition product and the *exo* adduct for hex-1-ene and norbornene, respectively.

6. Catalytic C–B bond formation (hydroboration of alkenes)

Yttrium bis(amidinate) complexes **1**, **2** and **10** (Refs 12 and 26) catalyse the hydroboration of hex-1-ene with catecholborane. However, the activity of these complexes is substantially lower than that of the $(\eta^5\text{-C}_5\text{Me}_5)_2\text{LaCH}(\text{SiMe}_3)_2$ complex.¹³ In all reactions, the catalyst deactivation was observed, which is apparently due to the reaction of catecholborane with the benzamidinate ligands. The catalytic activity of complexes **1**, **2** and **10** is substantially higher than that of metallocene-type yttrium catalysts.

* * *

The data summarised in the present review clearly show that the last decade witnessed considerable advances in the search for new ligand systems alternative to the cyclopentadienyl ligand and capable of stabilising highly reactive rare-earth organometallic derivatives. The progress achieved in this field confirms great possibilities for manipulating the reactivity of rare-earth metal complexes containing M–C and M–H bonds by the design of ligand systems and the coordination sphere of the central atom and a considerable potential of these compounds in the catalysis of various transformations of unsaturated substrates. The further progress in the catalytic applications of rare-earth organometallic compounds would be expected to be determined by advances in the chemistry of their hydride and cationic complexes.

Synthesis of polymers with protogenic groups by polymer-analogous transformations

A L Rusanov, E A Solodova, E G Bulycheva, M Abadie, V Voitekunas

Contents

I. Introduction	1071
II. Transformations of metallated polymers	1071
III. Transformations of polymers without preliminary metallation	1077

Abstract. The progress in the synthesis of polymers containing sulfonic and phosphonic acid groups by polymer-analogous transformations is analysed. Two key methods for the introduction of these groups are considered, namely, metallation of the original polymers followed by functionalisation and modification of reactive fragments of macromolecular chains. Special concern is focused on the properties of polymeric materials obtained. The bibliography includes 71 references.

I. Introduction

Permanently growing interest in fuel cells and their key components, proton-conducting membranes,^{1–10} is the challenge for the search for new methods of the synthesis of polymeric electrolytes containing protogenic (sulfonic and phosphonic acid) groups. Despite significant progress in the creation of proton-conducting membranes based on basic polymer–acid complexes,¹¹ the membranes based on solid polymeric electrolytes in which the protogenic groups are linked to macromolecules by covalent bonds are the most interesting. These systems are usually prepared by functionalisation (for example, sulfonation or phosphorylation) of polymeric compounds or by polymerisation of monomers containing sulfonic and phosphonic acid groups.^{1–10}

Each approach has its advantages and drawbacks. Thus, many aromatic polymers can readily be sulfonated at fragments with the highest electron density. However, sulfonic groups located at these positions can be substituted under the action of H^+ , which decreases hydrolytic stability of sulfonated polymers in highly acidic media. The synthesis of polymers from monomers containing protogenic groups is complicated due to reduced reactivity and labourious procedure for purification of the starting compounds.

Uspekhi Khimii 76 (11) 1145–1156 (2007); translated by M G Esernitskaya

Currently, an alternative approach to the synthesis of polymers containing sulfonic and phosphonic acid groups is being developed, namely, polymer-analogous transformations of compounds containing protogenic groups in an explicit or latent form. In the present review, progress in development of this promising field of polymer chemistry is analysed.

II. Transformations of metallated polymers

Introduction of sulfonic acid groups into macromolecules usually includes preliminary metallation of polymers followed by the treatment of polyanions with compounds containing sulfonic acid groups in an explicit or latent form. Most researchers apply this method for the preparation of sulfonylated polyamides and polybenzimidazoles.

1. Polyamides and polybenzimidazoles containing sulfonic and phosphoric acid groups

Metallation of aromatic polyamides, primarily poly(*p*-phenyleneterephthalamide) (PPPTA), is discussed by Takayanagi *et al.*^{12–22} and by other researchers.^{23–27} Treatment of PPPTA with sodium hydride in DMSO results in deprotonation of the amide groups of PPPTA to yield polyanion **1**.

Subsequent reaction of polyanion **1** with propane 1,3-sultone gives a copolymer of *p*-phenyleneterephthalamide and 3-(*p*-phenyleneterephthalamido)propanesulfonic acid (Scheme 1).²⁸

Transformation of poly(2,2'-*m*-phenylene-5,5'-dibenzimidazole) **2** was carried out in a similar way.^{29–36} The corresponding polyanion **3** was prepared by the reaction of the initial polymer with lithium hydride in dimethylacetamide (DMA) (Scheme 2). The final reaction product is polybenz-

Scheme 1

Scheme 2

imidazole (PBI) containing propanesulfonic acid residues (PBI-PS).

Polymers with butanesulfonic acid (PBI-BS) and methylpropanesulfonic acid (PBI-MPS) residues were synthesised from polybenzimidazole and butane 1,4-sultone and butane 2,4-sultone, respectively, using the same procedure.

The degree of substitution (α) of sulfoalkyl groups for the hydrogen atoms at the nitrogen atom in polybenzamide was estimated from the ^1H NMR and elemental analysis data; α appeared to depend on the reactant ratio. For instance, α reaches 60% at a propane-1,3-sultone:PBI ratio equal to 5. PBI modified with these groups are better soluble in polar organic solvents (for example, in DMA or DMSO) than the initial polymers, solubility also depending on the α value.

Introduction of sulfoalkyl substituents into aromatic macromolecules gives heat-resistant proton conducting polymeric electrolytes having electrochemical characteristics that can be controlled by changing the amount of protogenic groups and the length of alkyl chains. These polymers exhibit good moisture absorption and proton conductivity, close to those observed for sulfonic groups, but they retain such important characteristics as heat resistance, chemical stability, and mechanical strength.

Heat resistance of PPPTA and PBI, as well as of their sulfoalkyl derivatives have been compared in a number of publications (see, for example, Ref. 32). It was found that no destruction of PPPTA occurs in a nitrogen atmosphere up to 550 °C, whereas fast mass loss (up to 50% of the initial mass) starts at 600 °C. Polymers modified with sulfopropyl side groups ($\alpha = 66\%$) are stable to 400 °C; at 800 °C 40% of the initial mass is retained.

Heat resistance of anhydrous copolymer PBI-PS was studied by thermogravimetric analysis (TGA) in a nitrogen atmosphere.⁵ Destruction of PBI-PS occurred in the temperature range of 400–450 °C, that is, at significantly lower temperatures than that of the initial PBI.

In spite of the fact that for copolymer PBI-PS, destruction temperature decreases to 400 °C with increasing α , it is nevertheless higher than destruction temperature for perfluorinated polymeric electrolytes (280 °C).

Elemental analysis and FTIR studies of destruction of copolymer PBI-PS showed that the sulfur content and the

intensity of the S–O absorption band decrease following heating of the samples at the temperature above 400 °C for 1 h. This result is similar to that obtained by Gieselmann and Reynolds,³² who have found that destruction of PBI-PS was connected with desulfonation processes. Destruction temperatures for sulfonated aromatic polymeric electrolytes lie within the range of 200–350 °C. Thus, polybenzimidazoles containing sulfoalkyl groups are more heat resistant. Heat resistance of sulfoalkyl polymers is the result of strong chemical bond between alkyl and sulfonic acid groups. Introduction of sulfoalkyl groups into the polymer with the use of alkane sultones is one of the most common methods for the synthesis of heat-resistant proton-conducting polymeric electrolytes.

Arenesulfonic acid fragments can also be introduced into aromatic condensation polymers. Thus polyanions **1** and **3** prepared from PPPTA and poly(2,2'-*m*-phenylene-5,5'-dibenzimidazole), respectively, readily react with *p*-bromomethylbenzenesulfonic acid (Scheme 3).^{28–36}

The peripheral sulfoalkyl substituent is detached from the polymeric chain under more drastic conditions than the sulfopropyl group, this being independent of the polymer type.

The above-considered polymers were studied by TGA in inert and oxidative (in the presence of oxygen) environments.³³ The initial PBI is a heat-resistant polymer: in an inert atmosphere, the mass loss begins at 650 °C, 5% mass loss is observed at 700 °C and at 800 °C, > 80% of the initial mass is retained. Mass loss for substituted polymers in an inert environment starts at lower temperatures, as could be expected upon introduction of substituents non-conjugated with the polymer backbones. Destruction of poly(2,2'-*m*-phenylene-1,1'-(4-sulfoalkyl)-5,5'-dibenzimidazole) with $\alpha = 22\%$ starts at 480 °C, while that with $\alpha = 54\%$ starts at 450 °C. After elimination of all substituents from the polymer, the process slows down; at 800 °C, 50%–60% of the initial mass is retained.

In dry air, the mass loss of polybenzimidazole starts at 520 °C, whereas its destruction in an inert environment starts at a temperature about 100 °C lower. Substituted PBI demonstrate insignificant difference in destruction temperatures in oxidative environments. The main difference in the behaviour of polymers in air and in a nitrogen atmosphere is that in air the mass losses are markedly higher, but the amount of the residual

Scheme 3

coke at high temperatures is much less. This effect originates first from the lower stability of PBI in dry air and only then from the influence of substituents.

Introduction of sulfoaryl and sulfoalkyl groups into aromatic polymers increases moisture absorption, in other words, polymers become more hygroscopic. Moisture absorption of polymers is defined as a change in the polymer mass prior and after hydration and depends on the relative humidity of the medium. Equilibrium moisture absorption for the copolymer PBI-PS increases with an increase in relative air humidity and degree of sulfoalkylation. For example, moisture absorption of PBI-PS with $\alpha = 73.1\%$ is $11.3 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$ (see[†]) at a relative humidity of 90% and room temperature, whereas polymeric membrane Nafion 117 (perfluorinated polymer containing a small amount of sulfonate groups) has a moisture absorption of $11.0 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$ under the same conditions. Moisture absorption values for copolymers PBI-BS and PBI-MPS at a relative air humidity of 90% are 19.5 and $27.5 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$, respectively. These high dehumidification values for sulfoalkylated PBI result from a larger length and branching of alkyl chains. This seems to be associated with larger flexibility of long alkyl chains and larger water amount capable of being absorbed in cavities formed by branched substituents.

Studies of proton conductivity of polymers under consideration show that hydrated copolymers PBI-PS demonstrate high proton conductivity at room temperature. Conductivity of PBI-PS containing $3.1 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$ reaches $10^{-5} \text{ S cm}^{-1}$ at 80°C and somewhat decreases at higher temperatures due to moderate (about 10 mass %) loss of water. Conductivity of the PBI-PS film containing $> 5.2 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$ increases with increase in temperature and reaches a value of $10^{-3} \text{ S cm}^{-1}$ at temperatures above 100°C . The PBI-PS film containing more water [moisture absorption $11.3 \text{ mol H}_2\text{O (g-mol SO}_3\text{H)}^{-1}$] also demonstrates high proton conductivity ($\sim 10^{-3} \text{ S cm}^{-1}$).

Moisture absorption values for membranes prepared from copolymers PBI-PS at a relative air humidity of 90% are comparable with that for Nafion.

Proton conductivity of the membrane Nafion reaches $10^{-3} \text{ S cm}^{-1}$ at room temperature, but it decreases at temper-

atures $> 100^\circ\text{C}$ due to a loss of absorbed moisture.³⁷ In contrast, high proton conductivity of hydrated PBI-PS is retained at temperatures above 100°C . High values of moisture absorption and proton conductivity for copolymers PBI-PS at elevated temperatures are associated with peculiar behaviour and physical state of absorbed water.

The above results give reasons to conclude that sulfoalkyl aromatic polymeric electrolytes possess sufficient heat resistance to be used in fuel elements at 80°C , that is, at the temperature that is optimal for the work of membranes based on perfluorinated polymeric electrolytes.

Study of proton conductivity of sulfoalkylated PBI at various relative humidity values showed³⁸ that conductivity increases with an increase in degree of substitution. Sulfoalkylated polybenzimidazole with $\alpha = 75\%$ demonstrates high conductivity (about $10^{-2} \text{ S cm}^{-1}$) at 40°C and 100% relative humidity.

Phosphoalkylated polymer was obtained by metallation of PBI 2 followed by introduction of the phosphoethyl groups.⁵

N-Substitution of the benzimidazole ring occurs readily. However, the polymer formed is insoluble in organic solvents, probably, due to self-aggregation of the phosphonate groups in the course of substitution. Phosphoethylated PBI demonstrates high proton conductivity ($10^{-3} \text{ S cm}^{-1}$) even in the form of a pellet. Thus, it can be stated that introduction of polar phosphonic acid groups is an efficient method for the preparation of novel proton-conducting polymeric electrolytes.

[†] Hereinafter moisture absorption is expressed as moles of H_2O per 1 g-mol of SO_3H .

2. Poly(ether sulfones) containing sulfonic and phosphoric acid groups

Metallation of polymers was also used for the introduction of protogenic groups into poly(ether sulfone)s (PES).^{39–41} Synthesis of sulfonated PES based on commercially produced poly(ether sulfone) Udel (**4**) was reported.³⁹ The process includes lithiation of the polymer, treatment of the product with sulfur dioxide, oxidation of lithium sulfinates formed to lithium sulfonate, and transformation of the latter into corresponding polysulfonic acid under the action of HCl.

This approach allows the introduction of sulfonic acid groups into positions that determine high hydrolytic stability of the target polymers.³⁹

Sulfonated PES prepared in this way exhibit ion exchange capacity of $(0.5–3.2) \times 10^{-3}$ g-mol SO_3H per 1 g of polymer. Membranes based on these polymers are characterised by high conductivity and hydrolytic stability in 1 N HCl and in water at temperatures up to $80^\circ C$.

In continuation of this study, partial oxidation of lithium sulfinates groups of PES formed to lithium sulfonate groups was carried out,⁴⁰ and the residual lithium sulfinates groups were alkylated with α,ω -diiodoalkanes. This alkylation gave cross-linked polymers, which were transformed into the acidic form by the action of 1 N HCl.

Membranes from polymers obtained in this way with optimum degree of cross-linking and the length of alkylene cross-linking bridges demonstrate low ionic resistance and high heat resistance.

Lithiation of PES is also used for the preparation of sulfophenylated systems.⁴¹ In this case, a metallated polymer

reacts with cyclic anhydride of 2-sulfobenzoic acid, which followed by ion exchange under the action of 0.5 N HCl.

The values of proton conductivity for these polymeric membranes determined by impedance spectroscopy at $60^\circ C$ are $(14–32) \times 10^{-3}$ S cm^{-1} , which, in principle, demonstrates a possibility to use them as promising proton-conducting materials. For a detailed description of electrochemical characteristics of membranes obtained, see Ref. 42.

PES with short alkyl chains in sulfoalkyl substituents have been synthesised.⁴³ In this case, the polymers containing lithium sulfinates groups reacted with sodium ω -bromoalkane-sulfonates and butane-1,4-sultone (Scheme 4).

Thermogravimetric analysis of PES-based membranes containing sulfoethyl, -propyl, and -butyl groups showed that these materials are stable up to $300^\circ C$ in a nitrogen atmosphere. Calorimetry studies show that these modified polymers absorb more moisture [moisture absorption values are from 11 to 14 mol H_2O (g-mol SO_3H) $^{-1}$]. The proton conductivity value for membranes containing 0.9 sulfopropyl substituents per elementary unit of poly(ether sulfone) is 77 mS cm^{-1} at $70^\circ C$.

Lithiated PES were used for the preparation of phosphorylated polymers. In particular, the synthesis of poly(ether sulfones) containing phosphonate groups in the *ortho*-positions relative to sulfo groups of the macromolecular backbone is reported⁴⁴ which is based on $S_nP(V)$ nucleophilic substitution.⁴⁵ The reaction of metallated PES **4** with dialkyl and diaryl phosphochloridates occurs without catalysts.

According to Guiver *et al.*,⁴⁶ lithiation and subsequent reaction of polyanions with electrophiles do not lead to destruction of macromolecules of poly(ether sulfones).

Polymer containing $P(O)(OH)$ groups bound to the benzene ring through a difluoromethylene bridge was prepared by the following route: lithiation of PES **4**, its transformation into iodobenzoyl derivative, phosphorylation of the intermediate

Scheme 4

NMP is *N*-methylpyrrolidone.

under the action of diethyl (bromodifluoromethyl)phosphonate in the presence of zinc and dealkylation of the polymer formed with bromotrimethylsilane.⁴⁷ This polymer exhibits enhanced acidity.

(a) Zn, BrCF₂P(O)(OEt)₂, CuBr, DMF, sonication, 25 °C;
(b) 1) BrSiMe₃, CHCl₃, 40 °C; 2) 5% 1 M HCl in MeOH.

Proton conductivity of membranes based on this polysulfone reached 5 mS cm⁻¹ at 100 °C; according to TGA, destruction started at ~230 °C and was accompanied by the cleavage of the C–P bond.⁴⁷

A more convenient approach to phosphorylated PES is based on lithiation of the brominated polymer **5**,⁴⁸ because substitution of lithium for the halogen atom occurs easier than for the hydrogen atom. The synthesis of phosphorylated PES

after the stages of bromination and lithiation of the initial polymer **4** includes the reaction of the intermediate with diphenyl phosphochloridate followed by hydrolysis of the phenoxy groups.

In this case, the degree of phosphorylation reached 50%.

3. Poly(aryloxyposphazenes) with phosphonic acid groups

Cyclic (**6**) and polymeric phosphazenes (**7**) containing *p*-bromophenoxy side groups are used for the synthesis of phosphorylated poly(aryloxyposphazenes). Compounds **6** and **7** were treated with butyllithium and then with diethyl phosphochloridate.^{49, 50}

Poly(aryloxyphosphazenes) functionalised by phenylphosphonic acid are formed⁵¹ from the polymers **7** in accordance

with Scheme 5. *tert*-Butyllithium is added to a solution of poly(aryloxyphosphazenes) **7** with different numbers of brominated benzene rings in THF at -75°C , lithium phenoxide intermediates obtained are treated with diphenyl phosphochloridate. Subsequent alkaline hydrolysis and treatment with an acid give polymers with phenylphosphonate groups.

Attempts to phosphorylate lithiated polymers by gradual addition of diphenyl phosphochloridate to the reaction mixture resulted in precipitation of the polymer and formation of an insoluble product. If the reagent was added quickly, a soluble polymer was obtained. ^{31}P NMR studies showed that in the latter case, intramolecular reaction of diphenyl phosphonate groups with the lithium phenoxide fragments of the same polymeric chains takes place, thus promoting the formation of the phosphorus-containing 'bridge' between two aryloxide side groups.

Scheme 5

Phosphorylation of polymers *via* lithium phenoxide intermediates usually occurs with 50% conversion of bromophenoxy substituents into diphenyl phosphonates. The overall amount of lithium phenoxide intermediates that react with diphenyl phosphochloridate is about 70%; however, only half of the metallated groups is converted into the diphenyl phosphonate groups. According to elemental analysis, more than 90% of the bromine atoms of the initial polymer were lithiated. Thus, it is side reactions of reactive lithium phenoxide intermediates formed upon reaction with diphenyl phosphochloridate that is the limiting factor of the overall transformation rather than incomplete lithiation. These results are in accord with the data obtained for diethyl chlorophosphate.⁵⁰

Hydrolysis of phenyl esters was performed by treatment of a polymer solution in THF with 1.0 N NaOH for 24 h. In the course of the reaction, the polymer precipitates from the solution, after that hydrolysis continues, but to an insignificant extent. No changes in the molecular mass of the polymer were observed, thus proving the known fact that polyphosphazene macromolecules are stable against basic hydrolysis.

The advantage of this method for the synthesis consists of the possibility of varying the polymer composition by changing the ratio of the initial side aryloxy groups, degree of lithiation and the degree of hydrolysis of the ester groups.

The polymers obtained were tested as membranes for fuel elements.^{52,53} These membranes are characterised by a low

coefficient of methanol diffusion. This coefficient for membranes based on phosphorylated polymers appeared to be 12 times smaller than that for membrane Nafion 117 and 6 times smaller than that for membrane made of cross-linked sulfonated polyphosphazenes.^{52,53} Ion-exchange capacity values for membranes from phosphorylated polymers are in the range of $(1.17-1.47) \times 10^{-3}$ equiv g⁻¹, proton conductivity values lie in the range of $10^{-2}-10^{-1}$ S cm⁻¹. Thus, membranes under consideration exceed in some characteristics the analogues based on sulfonated polyphosphazenes.^{52,53}

III. Transformations of polymers without preliminary metallation

Along with the introduction of protogenic groups into metallated polymers, the method based on transformations of reactive groups of macromolecular chains without preliminary metallation is also widespread.⁵⁴⁻⁶⁴ Bromine and fluorine atoms, NH fragment of the benzimidazole ring, and carboxy groups could be distinguished as reactive groups in polymers.

Bromination⁵⁴ of aromatic polyethers **8** obtained from bis(propylcarbamate) derivatives of mono- and dibromotetra-phenylhydroquinone (Scheme 6) was among the first attempts to use substitution of bromine atoms in polymers for the introduction of phosphonic acid groups.

Treatment of polymers **8** with diethyl phosphite in the presence of triethylamine and tetrakis(triphenylphosphine)-palladium as a catalyst results in polymers containing diethyl phosphonate groups. Dealkylation of the latter is performed with an excess of bromotrimethylsilane in CCl₄. Bis(trimethylsilylated) intermediate is hydrolysed with HCl in methanol. The target polymers are well soluble in DMSO; flexible and strong films were cast from these solutions. Thermal, chemical and hydrophilic properties of the films suggest that they can be used as polymeric electrolyte membranes for fuel elements.⁵⁴

Brominated poly(ether sulfones) can be transformed into phosphorylated polymeric systems using Pd-catalysed formation of the P-C bond. Bromination of PES **9** followed by

Scheme 6

X = Y = Z = H; X = Br, Y = (EtO)₂P(O), Z = P(O)(OH)₂.

phosphorylation of the bromine-containing product is described.⁵⁵

(a) $(\text{EtO})_2\text{P}(\text{O})\text{H}$, Et_3N , $\text{Pd}(\text{Ph}_3\text{P})_4$ or $\text{Pd}(\text{dba})_2$.

Complexes of $\text{Pd}(0)$ with triphenylphosphine and dibenzylideneacetone (dba) were used as catalysts for phosphorylation. Triethylamine was added to the reaction mixture to bind the evolving HBr . It is known^{56, 57} that the molar ratio of the components and the reaction temperature markedly influence the yield, therefore, the effect of all these parameters on phosphorylation of polymers was comprehensively studied.

In particular, it was shown that an increase in temperature from 90 to 120 °C results in an increase in degree of phosphorylation, whereas further temperature increase to 140 °C causes destruction of the polymer. The Pd catalyst was found to be more active in the absence of triphenylphosphine ligands. The highest degree of phosphorylation ($\alpha = 88\%$) was achieved with diphenyl oxide as a solvent. The optimum aryl bromide : diethyl phosphite : triethylamine ratio was found to be 1 : 22 : 4, which is close to the values reported.⁵⁸

Transformation of brominated PES into phosphorylated PES also occurs in the presence of nickel catalysts. The reaction of brominated PES **10** with tris(trimethylsilyl) phosphite (TMSP) catalysed by NiCl_2 is reported.⁵⁹ Subsequent methanolysis results in removal of the trimethylsilyl groups to give phosphorylated product.

(a) NiCl_2 , TMSP, PhOPh , 200 °C; (b) MeOH .

The polymers obtained are soluble in *N*-methylpyrrolidone as such or in the presence of 2 vol.% – 5 vol.% concentrated HCl . According to TGA, destruction of polymers with arylphosphonic groups starts at temperatures > 325 °C, whereas similar polymer with sulfonic acid groups decomposes at temperatures > 200 °C. Depending on the degree of acidic group substitution, proton conductivity values for PES with arylphosphonate groups at 25 °C are $1.2\text{--}8.7\text{ mS cm}^{-1}$, which is less than proton conductivity of the polymer with sulfonic acid groups (20 mS cm^{-1}).

Polyaryloxyphosphazenes **11** containing bromomethyl groups are phosphorylated under the action of sodium organophosphites, in particular, sodium dibutyl phosphite.⁵⁰ The reaction proceeds in THF at 25 °C and results in the product in a quantitative yield. Studies of the routes for transformation of the ester fragments into phosphonic acid fragments are in progress.

N-Substituted polybenzimidazoles containing the $\text{P}(\text{O})(\text{OH})$ groups bound to the benzimidazole rings through the ethylene bridge were prepared by the reaction of polybenzimidazoles **12** with diethyl vinylphosphonate.⁶⁰

Currently, hetero- and carbocyclic polymers with activated fluorine atoms in aromatic rings have attracted significant

Scheme 7

attention. These polymers can undergo aromatic nucleophilic substitution with various nucleophiles, for example, with phenols containing acidic groups.^{59–62} In particular, *p*-fluorophenyl-substituted polyquinoxalines **13** were involved into the reactions with phenol- and naphtholsulfonic acids.^{61–64} The reaction was carried out in NMP in the presence of potassium carbonate (Scheme 7). The polymers obtained in this way are well soluble in *m*-cresol, NMP, and possess film-forming properties.

Similar approach was used by Ghassemi and McGrath,⁶⁴ who performed the reaction of fluorinated polybenzophenone **14** with sodium *p*-phenolsulfonate. According to the ¹⁹F and ¹³C NMR data, about 50% of all fluorine atoms are substituted under these conditions. The authors believe that a relatively low degree of substitution is associated with deactivating effect of the sulfonate group on the phenoxide fragment. Another factor affecting the degree of transformation is partial precipitation of the sulfonated polymer.

Poly[(4-carboxy)phenoxy]phenylquinoxalines **15** were synthesised by the treatment of *p*-fluorophenyl-substituted poly-

quinoxalines **13** by *p*-hydroxybenzoic acid under the conditions of aromatic nucleophilic substitution (NMP, K₂CO₃).⁶³

Y is O, CH₂, SO₂ or none;

(a) n HO-C₆H₄-CO₂H, NMP, K₂CO₃; (b) CF₃CO₂H.

Then poly[(4-carboxy)phenoxy]phenylquinoxalines **15** were involved into the reactions with 8-aminonaphth-1-ol-3,6-disulfonic acid and 1,8-diaminonaphthalene-3,6-disulfonic acid (Scheme 8)⁶² in polyphosphoric acid. High-molecular-mass polymers containing naphthoxazine- and pyrimidinedisulfonic acid substituents were formed as products.

Scheme 8

This approach to the creation of polymers with sulfonic acid groups has a general character. Any polymers containing carboxy groups or their derivatives can be involved in the reaction. Moreover, introduction of two sulfonic acid groups into the same aromatic ring of the substituent leads not only to increasing proton conductivity of the membrane, but also to an increase in its heat resistance, because in this case sulfonic acid groups stabilise one another.

* * *

The method for the synthesis of polymers by polymer-analogous transformations, which has been recently developed, is a promising approach to polymers with protogenic, sulfonic and phosphonic acid groups. It is remarkable that this method is especially efficient for the preparation of polymers with phosphonic acid groups, because the latter show higher heat resistance and hydrolytic stability than sulfonic acid groups.⁶⁵ This method allows preparation of polymers containing protogenic groups not only in backbones the of macromolecules, but also in peripheral fragments, which, according to Refs 66–71, favours the increase in the resistance of these polymers against high temperatures, oxidation, and hydrolysis. Stability of polymers is a factor determining potentialities of this method for creation of novel proton-conducting membranes with valuable properties.

V. Conclusion	1090

Abstract. The results of experimental and theoretical approaches to the study of some stable and unstable chemical species in low-temperature noble gas matrices are considered. The characteristic features of matrix effects manifested in the spectra of the SH radicals in krypton matrices are discussed. The structure and the spectra of HArF in argon matrices and the structure and dynamics of the intermolecular complexes HXeOH with water are analysed. The bibliography includes 55 references.

I. Introduction

Cryochemistry is concerned with the structure and properties of substances at low temperatures.¹ Using methods of cryochemistry, it is possible to obtain and stabilise chemically unstable species and compounds; to this end, the species are isolated from one another in inert matrices (most often, in solid noble gases) at temperatures that preclude thermal diffusion. Matrix-isolated chemical species are traditionally studied using various spectroscopic methods.² (The term ‘chemical species’ usually refers to any molecular system: atoms, molecules, ions, radicals or intermolecular complexes.)

In recent years, studies dealing with matrix-isolated species have been carried out in a number of laboratories all over the world. One trend of such studies is the synthesis of chemical compounds of noble gases.^{3–5} One more important trend is the study of photodissociation of small molecules in solid noble gas matrices.⁶ These two trends are closely interrelated,

because, on the one hand, the synthesis of inert gas compounds always includes the step of photolysis and, on the other hand, studies of compounds formed upon insertion of chemical species into a noble gas matrix provide important information concerning the dynamics of a photochemical process.^{7,8}

Identification of matrix-isolated species based on their low-temperature vibrational and/or electronic spectra is a challenge. The solution of this problem requires advanced experimental equipment, reliable procedures, experienced researchers and often good fortune. Molecular modelling techniques based on quantum theory form an essential part of these studies.

This review presents several examples of experimental and theoretical studies of stable and unstable chemical species isolated in low-temperature noble gas matrices: SH radicals in krypton matrices, HArF species in argon matrices and intermolecular complexes HXeOH in water clusters. These studies have recently been carried out at the Departments of Chemistry of the M V Lomonosov Moscow State University and the University of Helsinki.

II. Matrix effects in the spectroscopy of SH radicals in krypton matrices

The interest in the photochemistry of SH radicals, close analogues of OH radicals, is due first of all to the topicality of studies of photochemical processes taking place in the atmosphere.⁹ Free OH and SH radicals are investigated most often by spectroscopic methods. The spectra of the SH radical in the gas phase and in the van der Waals clusters SH·Rg (Rg is a noble gas: Ne, Ar, Kr) have been reported.¹⁰ However, spectroscopic studies in condensed media, in particular, in low-temperature noble gas matrices, are required to obtain a more comprehensive picture of the properties of this species. Yet another reason for the interest in matrix-isolated SH radicals is related to noble gas chemistry. For example, upon annealing of a xenon matrix containing SH and H species, the formation of the HXeSH molecule was detected.¹¹

The luminescence spectra of SH corresponding to the transition between the ground ($X^2\Pi$) and the first excited ($A^2\Sigma^+$) states

were recorded in various low-temperature matrices.¹² (In the interpretation of these spectra, differences between OH and SH radicals were taken into account.) However, the spectra

recorded in a krypton matrix differed from the spectra recorded in other matrices.¹³ Detailed investigation of the luminescence spectra of SH in krypton led to a conclusion that the specific behaviour of the species isolated in a solid matrix is a result of a change in the electronically excited state of the species caused by the interaction with the matrix Kr atoms.^{14,15} Thus, in this case, we are dealing with the so-called 'matrix effect'.

Figure 1 shows the characteristic luminescence spectrum of SH radicals in solid krypton at 7.5 K.¹³ The SH species were generated by photolysis of H₂S induced by an excimer laser ($\lambda = 193$ nm) mainly according to the reaction

After electronic excitation of the photolysis products, the luminescence spectra were recorded on a Spec 270M spectrophotometer with a resolution of 0.3 nm. A specific feature of the spectra is the presence of two peaks, at 375 (hereinafter referred to as peak *I*) and 413 nm (peak *II*) corresponding to excited states of the molecule with different lifetimes. It was found experimentally that peaks *I* and *II* refer to the transition between the first excited $A^2\Sigma^+$ ($v' = 0$) and the ground $X^2\Pi$ (v'') electronic states of the SH radical. By processing the kinetic data, the lifetimes of the states for both peaks were estimated as 350 (peak *I*) and 750 ns (peak *II*).

On the basis of the results of spectroscopic studies, it was suggested that the presence of two peaks in the SH luminescence spectra in a krypton matrix is due to different trapping sites of this radical by the matrix.¹³ Molecular modelling of the dynamics of the SH radical in solid krypton made it possible to substantiate this statement and identify the trapping sites.

The general strategy of modelling of matrix effects is as follows. A heterogeneous cluster of a specified size representing

Figure 1. Experimental luminescence spectra of the SH radical in a krypton matrix at short (30 ns, curve 1) and long (1300 ns, 2) delay times and their difference (3). [Curve 3 shows the dependence of the short-lived component *I* on the wavelength; two bands can clearly be seen, which correspond to 0–0 and 0–1 transitions separated by a distance (~ 2500 cm⁻¹) comparable with the SH vibration frequency in the ground electronic state.]

a fragment of the inert gas crystal lattice (face-centred cubic, fcc) with a cavity accommodating the SH species is used as the model. Construction of the potential energy surface (PES) of such heterocluster is a challenge. Combination of *ab initio* and semiempirical quantum chemistry methods is most reasonable. The former are used to describe the structure and dynamics of the embedded molecule, while the latter are used to calculate the interactions of the embedded molecule with the matrix atoms. On the basis of the chosen interaction potentials, characteristics of this heterocluster system are calculated, and the results of calculations serve as the basis for interpretation of experimental data.

The behaviour of the SH radical in krypton matrices has been simulated.¹⁴ The potential energy surfaces of the heteroclusters SH@Kr_{*n*} ($n \leq 56$) correlated with either ground [SH($X^2\Pi$) + *n* Kr] or excited [SH($A^2\Sigma^+$) + *n* Kr] states of the system were constructed by combining an *ab initio* quantum chemical method to describe the SH species and the semiempirical method using diatomic fragments in molecules (diatomics-in-molecules, DIM) for SH interaction potentials ($X^2\Pi$ or $A^2\Sigma^+$) with the Kr atoms¹⁶ and Kr...Kr pair interaction potentials. The DIM method (see, for example, Ref. 17) is, on the one hand, an extension of the pair interaction potentials algorithm and, on the other hand, this is a semiempirical version of the valence bond theory, which allows effective inclusion of energy contributions of diatomic fragments in various electronic states to the total energy of a polyatomic molecular system.

The reliability of the potential energy surfaces of the triatomic complex SH...Kr in the ground and electronically excited states calculated by the DIM method was verified by thorough comparison of these surfaces with empirical approximations¹⁰ of the SH($X^2\Pi$)...Kr and SH($A^2\Sigma^+$)...Kr surfaces derived from high-resolution spectroscopy data of the van der Waals clusters. According to these results,¹⁰ in the ground electronic state the triatomic complex is weakly bound, the energy of its dissociation into SH in the ground state $X^2\Pi$ and a Kr atom in the ¹S state is about 100 cm⁻¹. The equilibrium geometry structure of the complex is linear with a distance (R_e) from the SH centre of mass to the Kr atom equal to 4.28 Å and an S–H bond length of 1.35 Å. The PES of the SH($A^2\Sigma^+$) + Kr(¹S) system in the electronically excited state has two minima separated by a saddle point. The deepest minimum with the energy of 1706 cm⁻¹ corresponds to linear SH...Kr with $R_e = 3.26$ Å and $\theta = 0^\circ$ (θ is the angle formed by the S–H bond and the straight line from the centre of mass of the SH radical to the Kr atom), while the other minimum (with the energy of ~ 1400 cm⁻¹) corresponds to the position of the krypton atom near the SH radical on the side of the sulfur atom (Kr...SH) with $R_e = 2.6$ Å and $\theta = 180^\circ$. The saddle point is characterised by $R_e = 4.02$ Å and $\theta = 64^\circ$. Substantial differences in the interaction energies of the krypton atom with the SH radical occurring in the electronically excited state in different parts of the krypton matrix are responsible for the features of low-temperature spectra of SH, namely, the presence of two peaks in the luminescence spectrum (see Fig. 1). Figure 2 shows the plots for the DIM-calculated potentials of the ground (*a*) and excited (*b*) states of the triatomic complex.

It is noteworthy that representing the interaction potentials of species in the SH@Kr_{*n*} clusters in terms of the DIM approximation calculated for each group of three atoms SHKr_{*i*} ($i = 1, \dots, n$) and the Kr_{*i*} – Kr_{*j*} pair potentials allows one to estimate the energies and forces acting on atoms and use them for calculating the molecular dynamic (MD) trajectories of species.

Firsov *et al.*¹⁵ simulated the spectrum of the SH radical in the krypton matrix corresponding to the electronic transition $A^2\Sigma^+$ ($v' = 0$) \rightarrow $X^2\Pi$ (v'') using a version of mixed quantum

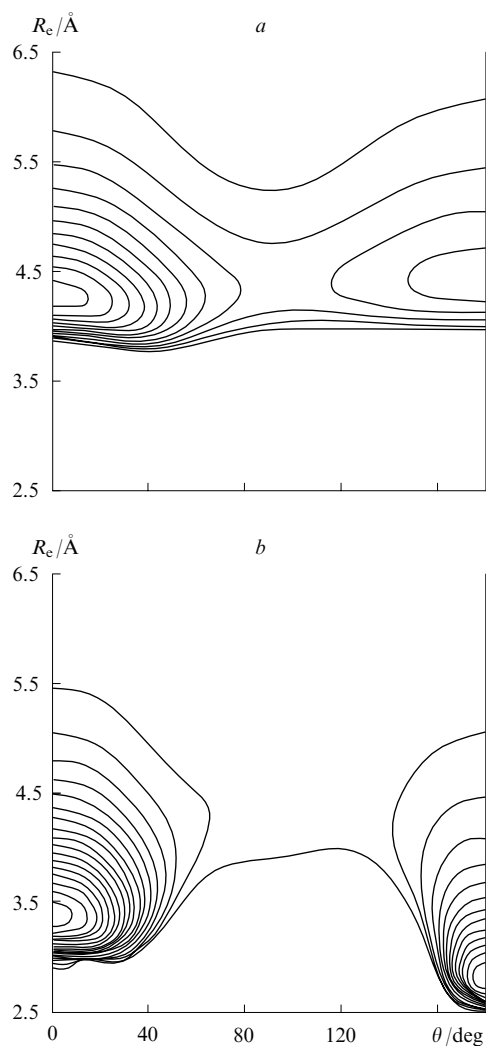

Figure 2. Potential energy surfaces of the ground (*a*) and electronically excited (*b*) states of the triatomic complex SH...Kr. The contour lines for the ground state are drawn every 10 cm^{−1}, those for the excited state are drawn every 100 cm^{−1}.

and classical molecular dynamics.[†] In this approximation, the SH radical with a random orientation of the S–H bond was placed on a random site in the central part of the fcc lattice composed of 256 Kr atoms (the lattice parameter was 5.67 Å). Then the Kr atoms located closely to S or H atom were removed; as the closeness criterion, distances of 2.9 Å on the side of sulfur and of 2.5 Å on the side of hydrogen were used. Then MD trajectories were calculated in two stages. In the first stage, which was 1 ps long, the system temperature was maintained at 7 K by correcting (scaling) the species velocities on the PES of the ground state of the SH(*X*²@)Kr_{*n*} cluster. In the second stage, the calculation was carried out for the PES of the excited state of the SH(*A*²Σ⁺)@Kr_{*n*} cluster with the system energy being maintained constant. The second stage of about 10 ps long was split into 20 000 steps. Every 10 steps (2000 times over the trajectory), the electron transition wavelengths and intensities (the Franck–Condon factors), radial distribution functions and particle lifetimes (τ) were found by the numerical solution of the one-dimensional Schrödinger equa-

tion along the variable corresponding to the S–H distance, and the positions of the Kr atoms located most closely to the S and H atoms were recorded for subsequent averaging. After the calculation, the average spectrum over the trajectory, the average lifetime and the average radial distribution function were estimated and the probability map for the Kr atoms to occur in various positions near the H atom was constructed. The lifetime was estimated from the formula¹⁹ for each discrete vibrational state of the electronically excited state:

$$\tau_{v''}^{-1} = \frac{4}{3c^2} \langle v' | \Delta U^3 D^2 | v' \rangle, \quad (1)$$

where c is the velocity of light, v' is the wave function of the lower vibrational level of the electronically excited state, ΔU is the energy difference between the ground and electronically excited states, D is the transition dipole moment of the SH radical from the ground to excited state. For calculation of the corresponding matrix elements, it was necessary to calculate the dependence of the transition dipole moment between the electronic states on the internuclear distance in SH.

Analysis of the calculated trajectories and spectra led to the conclusion that both peaks observed in the experiments (*I* and *II*, see Fig. 1) refer to two different trapping sites of the SH radical by the krypton cluster. The peak with a lower wavelength (peak *I*) corresponds to the trajectories along which the SH radical freely moves within the krypton cluster. The peak at greater wavelength (peak *II*) refers to the trajectories characterised by the formation of the triatomic complex SH...Kr, *i.e.*, the radical is bound to one atom of the Kr lattice. The calculated lifetimes of SH excited states for both types of trajectories also correlate with experimental characteristics of the luminescence spectra (Table 1).

Table 1. Experimental and theoretical characteristics of peaks in the luminescence spectra of the SH radical in the Kr matrix.

Characteristics	Peak <i>I</i>		Peak <i>II</i>	
	experiment	calculation	experiment	calculation
Peak position/nm	375	340–350	413	390–400
Lifetime/ns	350	550–600	750	800–840
Features of MD trajectories	—	free rotation of SH in Kr	—	complex SH...Kr

A more comprehensive picture of the spatial distribution of Kr atoms around the SH radical is provided by Fig. 3. Different colour intensity shows the configuration space areas corresponding to different positions of the inert gas atom located most closely (this is determined in every integration step) to the hydrogen atom. The maps are constructed in a relative coordinate system in which the H atom is always located in the origin of coordinates and the x -axis is directed along the S→H bond. The results validate the assumption concerning the presence of different trapping sites of the SH molecule by the krypton matrix, which is reflected in the observed experimental spectra.

In addition to providing new information on the spectroscopy of SH radicals, Refs 14 and 15 considerably contributed to the investigations into structure and dynamics of solids doped with small molecules. These studies demonstrate the possibility of observing and interpreting the trapping sites of a molecule occurring in the electronically excited state in a low-temperature krypton matrix. Previously, such effects in cryochemistry have not been reported.

[†] This method was first applied to describe the spectra of the Cl₂ molecule in solid neon.¹⁸

Figure 3. Distribution of the probability density for the occurrence of Kr atoms around the SH radical in the SH@Kr_n clusters; (a) trajectories describing free rotation of SH in the Kr matrix (peak I in the luminescence spectrum of matrix isolated SH radicals); (b) trajectories that tend to give SH · Kr complexes (peak II).

III. Structure and spectra of the HArF molecule in argon matrices

As a continuation of molecular dynamics studies for interstitial compounds in low-temperature noble gas matrices, the trapping sites of the exotic HArF molecule in the ground electronic state by an argon matrix were determined. The HArF species discovered in 2000 is the first electrically neutral chemical compound of argon.^{3–5} It is formed upon photodissociation of HF in solid argon at 7 K followed by matrix annealing at temperatures up to ~20 K:

Initially, the formation of this compound was established by IR spectroscopy.^{3–5} Subsequently, it has been shown¹⁴ that IR spectroscopy provides knowledge also on the molecular structure and dynamics in a doped matrix.

Figure 4 shows the spectra of HArF in solid argon in the region of H–Ar stretching vibrations. Curves 1 and 2 were recorded at different matrix annealing temperatures, 20 and 33 K. The characteristic triplet of the spectral lines (1965.7, 1969.4 and 1972.3 cm^{–1}) is observed only for low annealing temperature and completely disappears at higher temperature. The doublet shifted towards larger wavenumbers (2016.3 and 2020.8 cm^{–1}) predominates, conversely, at higher annealing temperatures up to matrix destruction at 40 K. On the basis of the obtained experimental results, it was hypothesised that the triplet of the spectral lines corresponds to a thermally unstable trapping site of HArF in the argon matrix, while the doublet shifted to the blue spectral region is due to another, more stable (or thermally relaxed) trapping site of the HArF molecule in the solid argon matrix.^{20–22} The use of molecular modelling

Figure 4. Spectra of the HArF molecule in solid argon recorded at matrix annealing temperatures of 20 (1) and 33 K (2). The measurements were carried out at 7 K.

confirmed this assumption and identified the trapping sites of the guest species.^{23–25}

An original hybrid procedure for calculation of the PES of HArF@Ar_n heteroclusters ($n = 363$ or 364) has been reported.²³ The energy of the embedded molecule (HArF) and its first and second derivatives with respect to nuclear coordinates were calculated by the high-precision *ab initio* method MP2/6-311++G(2d,2p) using PC GAMESS software.²⁶ The interactions of argon atoms with one another were described by pair potentials well parametrised to many properties of this gas.²⁷ The interaction of HArF with each atom of the matrix was calculated in the DIM approximation taking into account contributions of ionic and neutral pair potentials. This calculation algorithm proved to be useful for modelling the properties of the HF@Ar_n clusters.²⁸ This combined procedure, that is, quantum mechanics with diatomics-in-molecules approximation (QM/DIM), was also successfully tested in the simulation of the spectra of gas-phase mixed Ar_n(HCl)_m and Ar_n(HF)_m clusters.²⁹

The calculated PES for the HArF@Ar_n system was used to find the stationary points on the surface and calculate the harmonic vibration frequencies. The atom sites in the fcc lattice of the argon matrix served as the initial coordinates. Figure 5 shows two optimised structures corresponding to the trapping sites of the HArF molecule by solid argon. According to the calculation results, the structure presented in Fig. 5a refers to a thermally unstable trapping site; it is responsible for characteristic spectral bands at 1970 cm^{–1} (see Fig. 4). The structure shown in Fig. 5b was assigned to the stable trapping site characterised by bands at 2120 cm^{–1}.

This assignment was based on the following computation data. First, the H–Ar vibrations in the unstable structure (see Fig. 5a) are responsible for a triplet of harmonic frequencies of 2203, 2204 and 2207 cm^{–1} (depending on the vacancy position in the lattice), and the harmonic frequency of 2246 cm^{–1} assigned to the stable structure (see Fig. 5b) is shifted to the blue region by almost the same distance as in the experimental spectrum. Second, the energy of the unstable structure is

Figure 5. First solvation shells of two possible structures formed upon trapping of the HArF molecule by solid argon. Trapping site: (a) unstable, (b) stable.

4–5 kJ mol^{−1} higher than that of the stable structure and with the possibility of matrix relaxation (*i.e.*, at higher temperature), the structure with lower energy should predominate, which was actually observed in experiments. Thus, the trapping sites of the HArF molecule by solid argon can be considered to be established. However, the thermal relaxation mechanism of the unstable configuration still remains unknown, which requires further theoretical analysis.

IV. Structure and dynamics of HXeOH in water clusters

Matrix cryochemistry methods are widely used at the University of Helsinki to study the properties of chemical compounds containing noble gas atoms.^{3–5} In particular, the HXeOH species formed upon laser irradiation of a low-temperature water–xenon mixture followed by matrix annealing was detected experimentally.^{30–32} The metastable species HXeOH is responsible for a local minimum in the PES of the Xe + H₂O system, whereas the complex Xe · H₂O is the major compound (having the lowest energy). It was suggested that complexes of HXeOH with water molecules may exist. This was of interest, in particular, in relation to the geochemical problem of xenon deficiency.^{33, 34}

Figure 6*a,b* shows the IR spectra of a water molecule in solid xenon near the bending mode of the H₂O molecule. It can be seen that the spectra of the Xe + H₂O system with a low water content (see Fig. 6*a*) vary with an increase in the H₂O concentration (see Fig. 6*b*). After photolysis at 193 nm, which results in decomposition of the water molecule in the xenon matrix, and matrix annealing, which increases the mobility of the active species, the spectra exhibit the bands for HXeOH (at 1578 cm^{−1}) and two additional peaks designated in curve 3 by C₁ and C₂ (see Fig. 6*b*). It was suggested that these peaks correspond to H–Xe vibrations in the complexes HXeOH · H₂O and HXeOH · (H₂O)₂, respectively. Later this hypothesis was confirmed in a theoretical study³⁵ dealing with molecular modelling of the intermolecular complexes of HXeOH with water. Previously, similar complexes of noble gas hydrides with nitrogen have been observed experimentally (for example, HArF · N₂ in Ref. 36) and studied by computational chemistry.³⁷

The first stage of modelling included the use³⁵ of the combined quantum and molecular mechanics (QM/MM) method, specifically, the embedded species (HXeOH) was described by quantum chemistry methods and the surrounding water molecules were described by molecular mechanics in the effective fragment (EF) potential approximation.³⁸ The calculations were carried out using PC GAMESS software.²⁶ The computation showed that water molecules of a specified

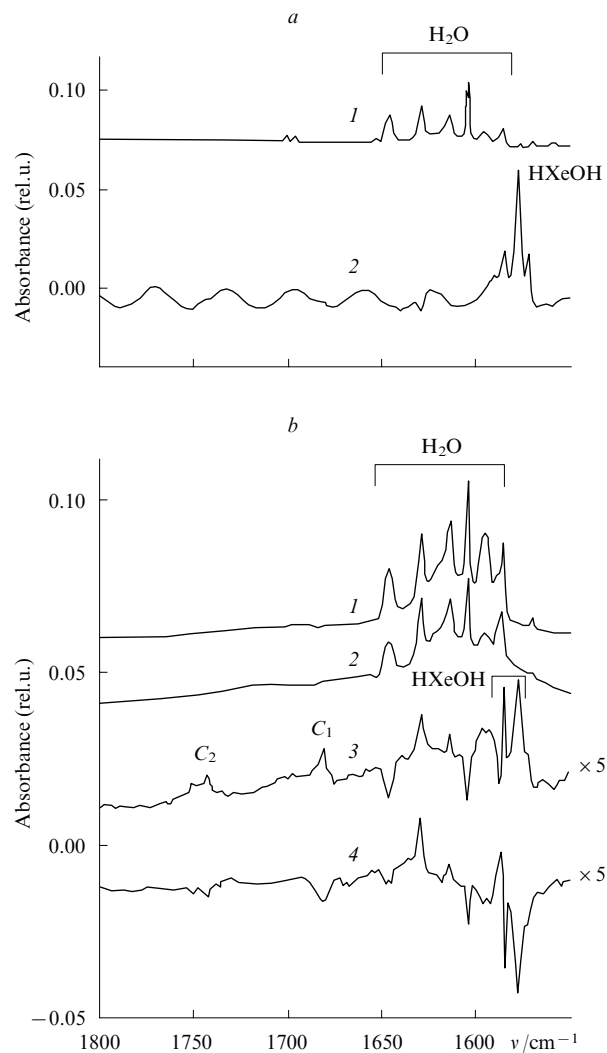

Figure 6. IR spectra of water in solid xenon recorded at low (a) and higher (b) concentrations of water; (a): (1) spectrum recorded after condensation, (2) after matrix annealing; (b): (1) spectrum recorded after condensation; (2) after photolysis; (3) after matrix annealing; (4) after short-term photolysis of the annealed matrix.

geometry configuration (*i.e.*, effective fragments) can form cages that completely trap HXeOH. However, these local minima in the PES proved to be artifacts of this computational procedure; on passing to a higher modelling level (by quantum chemistry techniques), the clusters containing > 3 water molecules were destroyed. In particular, the use of MP2 method with aug-cc-pVTZ basis functions on the oxygen and hydrogen atoms, Stuttgart pseudopotential³⁹ and the appropriate basis set (6s6p1d)/[4s4p1d] on xenon resulted in configurations of the local and global minima in the PES of the HXeOH complexes containing from one to three water molecules. Thus, it was established that the PES local minima correspond to the bound states of the HXeOH · (H₂O)_n systems (*n* = 0–3). Figure 7 shows the calculated equilibrium structures for the complexes HXeOH · (H₂O)_n. These complexes may decompose through potential barriers ranging from 0.4 (for *n* = 3) to 39.6 kcal mol^{−1} (*n* = 0) to give xenon complexes with water clusters: Xe · (H₂O)_{n+1}, which account for the PES global minima.

Table 2 summarises the computation results for the parameters of the HXeOH · (H₂O)_n complexes.

Figure 7. Equilibrium geometry configurations of the complexes $\text{HXeOH} \cdot (\text{H}_2\text{O})_n$ for $n = 0$ (a), 1 (b), 2 (c), 3 (d) corresponding to the local minima in PES. The distances are given in Å.

[For the HXeOH molecule (a) the results of various *ab initio* calculations taken from Ref. 32 are given in brackets.³²]

The use of a conventional scaling procedure for the vibration frequencies calculated in the harmonic approximation permits direct comparison of the theoretically calculated frequencies and experimental positions of bands in the vibrational spectrum. If a scaling factor has been selected (e.g., 0.88 based on the H–Xe stretching band in the HXeOH molecule), the theoretical estimates of the bands for the complexes $\text{HXeOH} \cdot \text{H}_2\text{O}$ and $\text{HXeOH} \cdot (\text{H}_2\text{O})_2$ (1669 and 1735 cm^{-1} , respectively) are in good agreement with experimental data (1681 and 1742 cm^{-1}). Thus, peaks C_1 and C_2 in the spectra of matrix isolated species (see Fig. 6b) are due to the HXeOH complexes with one and two water molecules. In the spectra of systems containing hydrogen bonds, the signals are shifted to the blue (short-wavelength) region with respect to the initial spectrum. Currently, such systems are under vigorous research.⁴⁰ In the case of HXeOH , the blue shift of the H–Xe frequency is attributable to additional charge transfer between the HXe and OH fragments induced by complexation with a water molecule.

Interesting results were obtained in the modelling of decomposition pathways of the $\text{HXeOH} \cdot (\text{H}_2\text{O})_n$ complexes, i.e., upon system transition from local to global minima along the reaction coordinate. To this end, configurations of the transition states as saddle points with the only vibration frequency were found. On both sides from these points, minimum energy paths to the reactant and product valleys were constructed. Figure 8 shows the calculated energy profile corresponding to decomposition of the $\text{HXeOH} \cdot (\text{H}_2\text{O})_2$ complex. The local minimum in the beginning of the reaction path

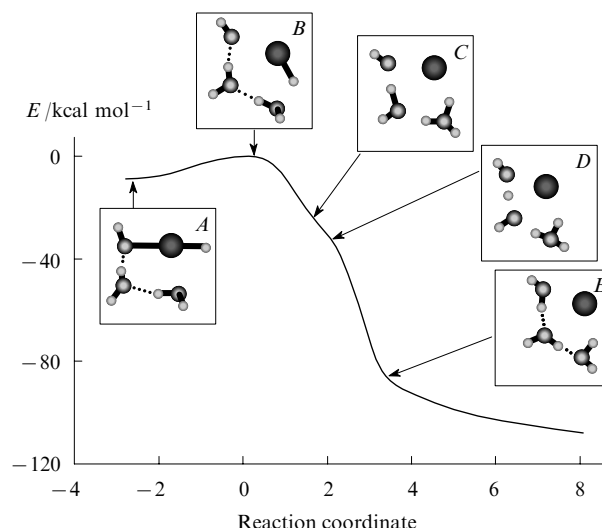

Figure 8. MP2 calculated decomposition pathway of the complex $\text{HXeOH} \cdot (\text{H}_2\text{O})_2 \rightarrow \text{Xe} \cdot (\text{H}_2\text{O})_3$. The insets show configurations of the metastable state of the initial complex (A), transition state (B), reaction product (E) and two intermediate structures along the proton transfer path (C and D).

corresponds to the metastable state of the $\text{HXeOH} \cdot (\text{H}_2\text{O})_2$ complex (A), transition state B is shown on the top of the barrier and the decomposition product $\text{Xe} \cdot (\text{H}_2\text{O})_3$ (E) occurs at the end of the path. Intermediate structures C and D illustrate the proton migration along the hydrogen bond system. As the system moves from left to right, immediately after transition state B has been reached, the proton from the XeH^+ fragment migrates to the nearest water molecule (structure C). The proton from the resulting H_3O^+ species migrates to the next water molecule from which one more proton moves to the hydroxyl ion OH^- (structure D).

This mechanism of proton transfer along the oriented chains of water molecules illustrates the molecular scheme usually referred to as water (or proton) conductor.

V. Conclusion

Despite the obvious priority of experimental works in modern chemistry and physics, the contribution of computer molecular modelling of the physicochemical properties of compounds has become rather weighty in recent years. This is due to fast progress in the computer technology, development of new effective theoretical approaches to this problem and the accumulated experience in the study of particular systems. The examples of solution of complicated problems dealing with structure determination of unstable chemical species, HArF and HXeOH , isolated in low-temperature inert gas matrices demonstrate the advantages of combined effort of experimentalists and theorists. We focused on the theoretical aspect of the studies dealing with the structures, spectra and transformation dynamics of noble gas compounds, because the experimental studies of these compounds have been the subject of recent comprehensive reviews.^{4,5}

The examples we considered are fairly typical, although they represent only a minor portion of the studies of matrix-isolated species by combinations of spectroscopic and molecular modelling methods. Consider briefly other achievements in this field of chemistry. Thus Frenking and co-workers^{41,42} predicted the structure of the stable neutral noble gas compound HeBeO using quantum chemical calculations before the experimental proof for the existence of HArF molecule was

Table 2. Calculated parameters of the $\text{HXeOH} \cdot (\text{H}_2\text{O})_n$ complexes.

Parameter	$n = 0$	$n = 1$	$n = 2$	$n = 3$
Harmonic frequencies of Xe–H vibrations/ cm^{-1}	1790	1897	1972	2066
(relative intensities of the IR bands)	(1.00)	(0.77)	(0.58)	(0.15)
Energies of complexes (kcal mol^{-1}) with respect to the $\text{Xe} + (n+1) \text{H}_2\text{O}$ system	109.5	98.7	87.7	76.4

obtained.³ Significant for further development of this field of science are also studies by Feldman *et al.*^{43–46} and Misochko *et al.*,^{47–49} who analysed active species in noble gas matrices using both experimental and theoretical approaches. Chaban and co-workers^{50–52} performed a number of important theoretical investigations of noble gas compounds, and the review by Gerber⁵³ presents a detailed discussion of the works on the structure and dynamics of these compounds. The review by McDowell³⁷ covers both published and author's results of quantum chemical calculations of molecules containing noble gas atoms. Finally, special mention should be made of two theoretical works^{54,55} predicting the possibility of existence of biomolecules with an inserted xenon atom on the basis of quantum chemical calculations.

Low-temperature matrix isolation has been developed as an experimental technique that allowed investigation of the properties of stable and unstable molecules isolated as fully as possible from the influence of other species. However, the progress in the instrumental equipment enabled detection of the interaction of matrix isolated compounds with the matrix material. The obtained experimental data are of interest for the development of the theory of intermolecular interactions; however, interpretation of the experimental results requires much effort.

Modern *ab initio* quantum chemistry methods provide virtually exact description of the structures and spectra of small (comprising up to 10 atoms) molecules in vacuum, *i.e.*, under conditions where they are separated from other species. Accurate calculations for intermolecular complexes, especially weakly bound complexes with noble gas atoms, are very difficult. The studies discussed in this review used the approach in which the theoretical problem was split into two levels: a matrix-isolated species was modelled by *ab initio* quantum chemistry methods, while its interaction with the matrix species was described by well parametrised semiempirical potentials, in particular, by diatomics-in-molecules potentials. Direct comparison of the calculation results obtained by this combined approach with experimental results often demonstrates the success of this strategy.

Apparently, the future development of the modelling techniques for matrix-isolated species would be related to more active use of molecular dynamics combined with *ab initio* quantum chemical calculations. This would allow direct calculation of the temperature dependences of spectra of matrix isolated species.

The authors are grateful to co-authors of their publications A A Granovskii, D A Firsov, M Pettersson, E Isoniemi, H Tanskanen and A Lignell for fruitful discussion during the research and to Professor G B Sergeev for steady interest and attention to our work. This review was written with partial financial support of the Federal Target Science and Technology Programme of the RF (Project No. 2006-RF-112.0/001/052) and of the Academy of Sciences of Finland (Project CoE CMS).

III. Obtaining rate coefficients at very low temperatures	1096
IV. Recent results on the carbon chemistry at very low temperatures	1097
V. Perspectives	1102

Abstract. The review describes briefly the chemistry of interstellar clouds and focusses on how bimolecular neutral–neutral reactions may influence its evolution. Experimental techniques that give information on the reactivity and the dynamics of these processes are presented with a special attention to the CRESU (Cinétique de Réaction en Ecoulement Supersonique Uniforme) technique, which is the only one able to deliver rate coefficients at very low temperatures for reactions between two neutral partners. Recent advances concerning the reactivity of carbon-bearing molecules are described in more detail with a special attention to the reaction kinetics of C_2 and C_4H with small stable hydrocarbons. The bibliography includes 161 references.

I. Introduction

For many years, the field of gas phase reaction kinetics involving neutral partners has been restricted to experimental studies which were carried out essentially at temperatures greater or equal to room temperature. The interest in the chemistry of the Earth stratosphere that arose in the early 1970s stimulated the adaptation of experimental equipment to extend the study of kinetics down to 200 K. This led to a significant increase, although still limited, in the number of available rate coefficients at sub-ambient temperatures.^{1–3} For reasons that will be explained further, only in some very specific cases experimental data had been obtained down to 77 K.^{4–7} In the last twenty years, however, the development and adjustment of new technologies opened the possibility of exploring much colder temperature areas leading to a significant amount of reaction rate constant measurements down to 13 K.^{8,9} Although some experiments were also carried out at 7 K,⁸ these dealt with inelastic collisions and focussed on energy transfer processes only. In the solid state, it is worth mentioning however that this record was beaten and an

abundant research field on autowave chemical transformations near 4 K has been developed within the last 20 years.^{10–13}

From the fundamental point of view, the new obtained data in the gas phase were like a revolution for chemical physics science as they revealed that the Arrhenius equation does not hold for a large number of neutral–neutral reactions including those for which a saturated molecule was involved. Barrierless reactions, indeed, were found to be much more frequent than suspected. Furthermore, these new experiments stimulated the development of new theories of reactive collisions.^{14–31} A comparison between experiment and theory at such low energies (let us remember that 13 K corresponds to about 1 meV) was actually a decisive test of the quality of potential energy surfaces required for a correct description of chemical processes. A large number of theoretical studies was then undertaken in order to reproduce the experiments but till now, most of these works were carried out on a case-by-case basis (see for example^{14, 18, 24, 26}) and no general trends are presently known to quantify the effectiveness of a chemical process at very low temperature although some very recent attempts are shedding interesting light in this difficult task.^{9, 21, 30–32}

Beside these fundamental considerations, studying reactivity at temperatures as low as 10 K is of major importance for the understanding of a large number of (very) cold natural environments in which a rich chemistry is taking place. Whereas the mean surface temperature of the Earth is presently about 288 K, much lower temperatures can be found as, for example, in the area of Verkhoyansk in Siberia (Russia) where the thermometer can go down to 200 K. In our own atmosphere, recent observations indicate that the temperature at the mesopause can be lower than 150 K at high latitudes.³³ Thanks to the development of space missions, ground telescopes and satellites, new horizons were revealed to our knowledge and demonstrated the existence of even colder extraterrestrial environments. The atmosphere of Giant Planets or their satellites is only several tens of a Kelvin: 70 K at the tropopause of the now well known Saturn's satellite Titan,³⁴ 50 K in the atmosphere of Neptune³⁵ or Pluto.³⁶ In the coma of comets, temperatures ranging from 10 K to 200 K³⁷ have been determined according to the distance to the Sun and the position with respect to the nucleus. Beyond the solar system, we penetrate in the so-called interstellar medium, an apparently empty space which separates stars from each other. This very tenuous environment (mean density ~ 1 atom cm^{-3}) is actually quite heterogeneous containing for example very

diluted (< 0.01 atom cm^{-3}) and hot ($\sim 10^6$ K) areas, remnants of super novae explosions where atoms have lost several of their electrons and much colder (10 K) and denser (10^4 molecules cm^{-3}) zones where an amazingly rich chemistry is now identified. The latter are called molecular clouds (or dark clouds) because most of the molecules identified in the interstellar medium were discovered in these dense enough media so that the UV light coming from neighbouring stars cannot penetrate deep inside.³⁸ To date, thanks to radioastronomy and satellites such as ISO (Infrared Space Observatory) or orbiting telescopes such as HST (Hubble Space Telescope), about 150 different molecules have been identified in the interstellar medium (230 including isotopomers).^{39, 40} This number is permanently growing and the development of the ALMA interferometer in Chile and the future space telescope Herschel (launching July 31st, 2008) will certainly considerably enrich the list. A compilation of the presently known molecules in the interstellar and circumstellar media is presented in Table 1 which also includes the year of the first detection of each molecule. More details, and particularly the references announcing the first discovery of each species, can be found at the website held by Woon.³⁹ How such a variety of molecules, among which a large number are organic, can be produced and survive in such harsh environments is a fundamental question that gave birth to a new field in astronomy about 40 years ago: astrochemistry.

In the present review, I will essentially focus the discussion on interstellar molecular clouds and experimental techniques that could be employed for the study of gas phase neutral–neutral reaction kinetics at very low temperature.

II. Neutral–neutral reactions in interstellar chemistry

Understanding how stars and their associated planetary system form is one of the major challenges of modern astrophysics. It is now largely accepted that molecular clouds are the cradle of stars which are generated by local gravitational collapses inside the cloud leading to a strong pressure increase which eventually will start thermonuclear reactions. In this frame, molecules play a critical role in the dynamical stability of the cloud and act as a cooling reservoir.⁴¹ Inelastic collisions with other species, and more particularly H_2 , which is by far the more abundant molecule, enable conversion of kinetic energy into radio or mm radiations which eventually can escape from the cloud which is optically thin in this wavelength range. As a consequence of molecular cooling, the thermal pressure inside the cloud is reduced and eventually will not be able to counterbalance gravitation any more leading to the collapse of the cloud.⁴²

It is then essential to clearly understand the fate of interstellar molecules. With this objective in mind, astronomers started to develop gas phase photochemical models of interstellar clouds in the mid-seventies.^{43–48} Their aim was to reproduce the observed abundances of these molecules taking into account all chemical and physical processes that were expected to play a role in their formation and destruction. Knowledge of a large number of parameters was required including the photon and cosmic ray fluxes coming from outside the cloud, the rate constants for reactive and inelastic collisions and the branching ratios of reactions. The most elaborated interstellar models are presently taking into account about 400 species (neutral and charged) and 4000 processes.^{49, 50} It is worth mentioning here that the most recent models are now starting to include gas surface processes, as the presence of important molecules such as H_2 cannot be explained by chemical schemes simply based on gas phase chemistry. The physical conditions reigning in molecular clouds (low temperatures, low pressures) restrict however the

Table 2. Classes of chemical reactions that are included in chemical models of interstellar clouds.

	$\text{AB} + \text{e}^- \rightarrow \text{A}^- + \text{B}$

chemistry to two-body, exothermic and barrierless processes. The different families of reactions that are considered in interstellar models are listed in Table 2.

Chemistry is initiated by ionisation of molecular and atomic hydrogen, helium and carbon atoms by the VUV radiation of stars in the outer part of the cloud and cosmic rays in its inner part, which is opaque to VUV photons. A series of ion–atom (H) and ion–molecule (H_2) reactions lead to the production of bigger polyatomic ion molecules, which eventually will recombine dissociatively thus producing neutral molecules. These can also be generated by radiative association processes and neutral–neutral reactions, which is the scope of this paper. Then, although detected cations in the interstellar medium represent only about 10% of the presently known species, they play a central role in the increase of chemical complexity. Very recently, it is worth stressing that the first negative ion molecules C_8H^- (Refs 51, 52), C_6H^- (Ref. 53) and C_4H^- (Ref. 54) have been discovered in the molecular envelope of IRC + 10 216 and in the dense molecular cloud TMC-1, which will certainly focus the interest of modellers on the anion chemistry in a very close future.

For about twenty years and up to the early nineties, interstellar cloud chemistry was thought to be essentially driven by ion–molecule reactions because, due to the strong attractive forces between an ion and the permanent or induced dipole on the neutral reagent, these processes were generally barrierless and very fast ($> 10^{-9}$ $\text{cm}^3 \text{ s}^{-1}$ molecules $^{-1}$). On the other hand, for many years, neutral–neutral reactions were expected to be inefficient at the very low temperature of molecular clouds as they were thought to proceed with positive activation energy barrier (E_a). The temperature dependence of the rate coefficient k was then usually described by the Arrhenius equation $k = k_0 \exp(-E_a/k_B T)$ which leads to insignificantly small rate coefficients at temperature of *ca* 10 K. Only a few radical–radical reactions such as $\text{O} + \text{OH} \rightarrow \text{O}_2 + \text{H}$ were considered in models because this class of processes could be expected to have no barrier.⁴⁷ Furthermore, at that time very few data were available at temperatures below 200 K because experimental techniques were not suited for this kind of measurements (see below). In the early nineties, as

explained further, the adaptation of the CRESU technique to the study of radical–neutral reactions shed a new light on the field and demonstrated that a large number of these processes, and more particularly those involving a saturated molecular partner, can be very efficient at temperatures as low as 13 K. This discovery was carefully considered by interstellar cloud modellers who then published dedicated articles analysing the impact of these new views.^{49,55,56} The number of neutral–neutral processes included in models was significantly increased and rate coefficients were re-evaluated on the bases of the new experimental data (initially concerning the reactivity of the CN and CH radicals). The main consequence of this upgrading was to reduce the rate of formation of complex species because of a prompt destruction of small radicals which initiate the chemical scheme leading to complex molecules.⁵⁵

Although a significant number of binary neutral–neutral reactions have been studied at very low temperatures now, much more data are still required. In the following section I will discuss the main difficulties faced by this kind of studies and I will show how the CRESU technique can resolve a large part of them.

III. Obtaining rate coefficients at very low temperatures

As mentioned previously, for a long time low temperature experimental rate coefficients were not available. Modellers had then to estimate or evaluate these parameters and therefore the results of simulations of the interstellar cloud chemistry were subject to very large uncertainties although they were able to reproduce some general aspects. To obtain low temperature data, one common practice (still in use nowadays) was to extrapolate the temperature dependence of a reaction for which rate coefficients were measured at room temperature and higher. As illustrated in Figure 1a and 1b, this can lead to dramatic errors at temperatures as low as 20 K. In this example, the reaction $\text{CN} + \text{C}_2\text{H}_6$ was initially studied by Herbert *et al.*⁵⁷ in the temperature range 297–694 K. Data are shown in Fig. 1a on an Arrhenius plot and seem to fit an Arrhenius dependence with modest activation energy. Figure 1b shows the attempt to extrapolate these measurements down to interstellar temperatures. As it can be seen, the extrapolated rate coefficient decreases impressively by almost 7 orders of magnitude from room temperature down to 20 K. However, experimental results obtained by Sims *et al.*⁵⁸ one year after the study by Herbert *et al.* show that the rate coefficient behaviour changes completely since a minimum was reached at about 200 K and then the rate starts again to increase leading to a difference of 6 orders of magnitude at 25 K between experiment and extrapolation. Fortunately, all situations are not as critical as this one, but this example clearly indicates that experimental data are definitely required to strongly and correctly constrain interstellar cloud models.

It is then necessary to generate a cool environment in which reaction kinetics could be studied. The simplest idea is to cryogenically cool down a slow-flow reactor cell. In that case, however, one is immediately faced with the decay of the saturated vapour pressure of gases when the temperature is reduced and, as a consequence, condensation to the refrigerated walls of the cooled vessel. The solution to prevent condensation is to limit the total concentration of the reagents in the cell to keep them at partial pressures that are below their vapour pressure at the wall temperature. However, the concentration must be high enough to perform kinetic experiments, and only gases with a significant vapour pressure at the wall temperature are then suitable. This method therefore becomes more and more limited at temperatures lower than 200 K and was never applied below the liquid nitrogen temper-

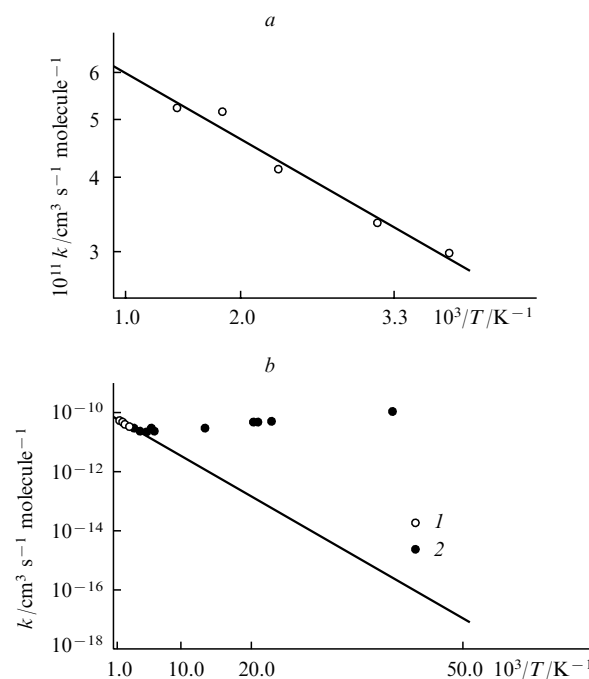

Figure 1. Arrhenius plot of the rate constant for the reaction $\text{CN} + \text{C}_2\text{H}_6$ in the temperature range 297–694 K (a)⁵⁷ and Arrhenius plot of the rate constant for the reaction $\text{CN} + \text{C}_2\text{H}_6$ in the temperature range 25–694 K (b) (1),⁵⁷ (2).⁵⁸ The straight line is an Arrhenius extrapolation to low temperature of the data obtained by Herbert *et al.* at temperature greater than 297 K.

ature of 77 K. At this temperature, only a few experiments have been conducted for a limited number of reactions involving gases such as CO (Refs 6, 7) and H_2 (Refs 4, 5) which have high enough vapour pressures at such temperatures. More details and references in relation to these techniques can be found in Ref. 3.

Generating low temperatures can also be achieved using supersonic expansions. The fundamentals of the technique here is to convert part of the internal energy of a quasi static flow into kinetic energy. There are several kinds of supersonic expansions.

The simplest is the so-called free jet, which is formed by expanding a gas from a high-pressure reservoir (typically ~ 1 bar) into a high-vacuum chamber through a small orifice or a nozzle. The temperatures obtained with this method can be extremely low down to 0.1 K but cannot generally exceed 20 K. The density is typically less than 10^{15} cm^{-3} in most of the useable areas of the jet.^{59,60} However, the expansion is inhomogeneous, with strong spatial density and temperature gradients.^{61,62} As the expansion evolves the collision frequency decreases and therefore the different temperature moments (translation, rotation and vibration) cannot reach equilibrium.⁶³ The gradients of temperature and density, the low frequency of collisions and the short useable area of the jet make it difficult to perform kinetic experiments in these free-jet expansions although some ion–molecule reactions have been studied⁶⁰ because for this class of processes the long-range electrostatic forces are strong enough to attract together reagents travelling with virtually no translational velocity. Nevertheless, free jet expansions are widely employed in spectroscopy⁶⁴ for which problems of disequilibrium in the flow are not important.

A molecular beam is an extension of the free jet technique as it is obtained by extracting the centreline beam of the free jet by skimming and pumping away the excess gas. The skimming

action prevents supersonic waves from spreading back into the gas and increasing the translational temperature, and at the same time, enables one to obtain a well-collimated flow with a narrow velocity distribution. Molecular beams are very useful in studies of collisional dynamics.^{65,66} As the frequency of collisions is very small in a molecular beam, data are obtained from experiments in which two collimated reagent beams intersect at fixed angle in a scattering region where single reactive or inelastic collisions occur between the components of the beams.^{65–72} The species of each beam are characterised by a well-defined velocity and usually also internal quantum states. By varying the velocity of the molecular beams and their intersection angle, differential cross sections (product angular and velocity distributions) can be measured at different collisional energies. The technique provides valuable information on the nature of the products of the reaction and its mechanism.⁷² Most of these so-called crossed molecular beam machines, however, work with beams at right angle and therefore the usual collisional energies are rather high with respect to those encountered in the molecular rich interstellar medium. Some devices are designed to vary the beam intersection angle which enables some reduction in the relative collision energy.^{73–77} The lowest collision energy presently available was obtained by Naulin and Costes⁷⁶ who can make experiments using an apparatus for which the intersection angle can be varied from 90° down to 22°, the latter corresponding to a collision energy of 0.35 kJ mol^{−1} (*i.e.* ~30 K). In this experiment, relative total cross sections (also referred as excitation function in the literature) can be integrated assuming a Maxwell distribution of relative velocities at temperature T and a Boltzmann distribution of reactant internal energies to extract a thermal rate coefficient, $k(T)$. This, however, is a relative value and has to be normalised using data obtained from other techniques. More interestingly, the technique provides the temperature dependence of the calculated rate coefficient which can be directly compared with other experimental methods.^{76,78}

Absolute rate coefficients can be obtained as a function of temperature using ‘collimated’ supersonic flows generated by the isentropic expansion of a buffer gas through an axisymmetric convergent–divergent Laval nozzle.⁷⁹ At the exit of the nozzle, the supersonic flow, typically 10 to 20 mm in diameter, moves with a bulk velocity which is parallel to the axis of the nozzle and uniform for several tens of centimetres which is also the case for temperature, pressure and hence density. The diffusion velocity is always negligible with respect to the bulk velocity, thus avoiding the major problem of condensation associated with the use of cryogenically cooled cells. As a consequence, in such expansions, heavily supersaturated conditions prevail and as a matter of example condensable species such as water, ammonia⁸⁰ or even polycyclic aromatic hydrocarbons^{81,82} can be maintained in the gas phase at very low temperatures. In contrast to free jet expansions and molecular beams where the concept of temperature is not really valid, the relatively high gas density (10^{16} – 10^{17} molecule cm^{−3}) in the uniform supersonic flow ensures that frequent collisions take place during the expansion and subsequent flow, maintaining thermal equilibrium. It is worth stressing here that the temperature of the supersonic flow is not a tuneable parameter as it is constrained by the divergent profile of the Laval nozzle which is specifically designed to obtain a given temperature and pressure in the supersonic flow.[†] Hence, a series of Laval nozzles are required to match

the range of temperature that needs to be explored. Clearly, uniform supersonic flows are ideal chemical reactors.^{8,79,83}

Uniform supersonic flows were initially developed in a continuous flow version for the study of ion–molecule reactions by Rowe and co-workers⁷⁹ in the early eighties in the laboratoire d’Aérothermique in Meudon (France). The technique was christened as CRESU, a French acronym meaning Cinétique de Réaction en Ecoulement Supersonique Uniforme which can be translated in English by Reaction Kinetics in a Uniform Supersonic Flow. About ten years later, the methodology was adapted to the study of neutral–neutral reactions⁸³ at the Université de Rennes 1 (France) and in the mid-nineties mimicked at the University of Birmingham (United Kingdom).⁸⁴

The typical temperatures than can be achieved are usually in the range 15–300 K.^{8,9} However, the reservoir of the nozzle and the nozzle itself can be pre-cooled using for example liquid nitrogen. In these conditions, supersonic flows with a temperature as low as 7 K (see Refs 85, 86) can be achieved. The choice of the reactant, however, is then limited to those having a vapour pressure high enough to avoid condensation on the walls of the reservoir of the nozzle in which the flow is almost stagnant.

With respect to the determination of rate coefficients, a limitation of the CRESU technique lies in the supersonic nature of the flow which restricts the available hydrodynamic time to a few hundreds of microseconds. As a consequence, only rate coefficients greater than 5×10^{-13} cm³ s^{−1} molecule^{−1} can usually be measured. Another aspect that is worth mentioning concerns the size of the apparatus. The supersonic flow is made of an inner isentropic core embedded into a boundary layer resulting from the viscosity of the gas. Minimising this boundary layer (and hence optimising the length of the supersonic flow) requires introducing large gas flow rates into the reservoir (typically 50 standard litres per minute). Since Laval nozzles are usually designed to obtain a low pressure into the supersonic flow (typically a fraction of a mbar) in order to avoid possible clustering, large pumping capacities are necessary for the apparatus (typically 25 000 m³ h^{−1}). The size of pumps directly determines the size of the chamber which is 3 m long and 50 cm in diameter.

If pressures of about 1 mbar are however acceptable in the supersonic flow for the study of a given process, then a significant reduction in pumping capacities can be accepted as it is the case for the mini-CRESU that has been constructed in the Université de Bordeaux 1 by Costes and co-workers.⁸⁷ This apparatus however cannot reproduce temperatures lower than 50 K in the supersonic flow because of its limited pumping capacities. In order to reduce the cost required for the development of a CRESU continuous supersonic flow, another alternative can be to pulse the supersonic flow so that large flow rates are only introduced during a few milliseconds and therefore pumping capacities are significantly diminished. The pulsed CRESU technique was first developed at the University of Arizona (USA) by Smith and co-workers⁸⁸ and it is now also in use at the University of Berkeley (USA) in Leone’s group⁸⁹ and at the University of Goettingen (Germany) in Troe’s team.^{90–92} Another apparatus is under development at the University of Leeds (United Kingdom) in Pilling’s group. Due to their small pumping capacities, the pulsed CRESU supersonic flows are limited to temperatures greater than 50 K.

Table 3 lists the two-body neutral–neutral reactions that were experimentally studied using the continuous or pulsed version of the CRESU method.

IV. Recent results on the carbon chemistry at very low temperatures

In this section, I will discuss recent results that were obtained concerning the reactivity of neutral carbon-bearing radicals,

[†] It is worth mentioning here that originally, Laval nozzles were developed in the aeronautics area for their ability in maintaining a collimated gas at their exit. They are used as exhausts for the burnt gases of rockets because their design optimises the thrust when the spacecraft takes off.

Table 3. Bimolecular reactions studied using the continuous and pulsed versions of the CRESU apparatus.

^a T_{\min} is the minimum temperature at which the experiment has been carried out. ^b For these reactions, the binary nature is not firmly established. ^c Personal unpublished data.

and more particularly C₂ and C₄H, in the presence of hydrocarbon reactants. One of the main motivations for these studies lay in the involvement of these species in the photochemical cycle of diacetylene C₄H₂ in the atmosphere of Titan, a molecule considered to be an important step through the production of polyacetylene polymers and eventually the observed hazes.¹²² Furthermore, both radicals have been identified in the interstellar medium^{123–129} as well and can contribute to the production of more complex molecules by reacting with other hydrocarbons.

Rate coefficients were measured using the continuous CRESU apparatus available in Rennes in the temperature

range 24–300 K for reactions involving C₂ (Refs 111, 113) and 39–300 K for those concerning C₄H.¹¹² The CRESU supersonic flow was associated to laser techniques to produce and detect the radicals *in situ* using the time resolved Pulsed Laser Photolysis–Laser Induced Fluorescence (PLP-LIF) technique. The fundamentals of the method have been described in detail elsewhere⁸³ and therefore a brief summary will be presented here focussing only on the specificities connected to the present studies. The PLP-LIF technique uses two pulsed lasers which are combined and co-propagate along the axis of the supersonic flow as it can be shown in Fig. 2. The first laser produces a homogeneous concentration of the

desired radical by photolysis of a suitable precursor. Then, after a variable and controlled time delay, the radical is excited to an upper electronic state by a tuneable laser acting as a probe and its fluorescence is collected by means of an optically fast telescope – mirror combination mounted within the main vacuum chamber in which it is set at right angle of the supersonic flow. Photons are then directed onto a fixed photomultiplier tube through an interference filter. Production and detection conditions for $C_2(X^1\Sigma_g^+)$, $C_2(a^3\Pi_u)$ and $C_4H(\tilde{B}^2\Pi_i)$ are specified in Table 4.

For a given concentration of the reactant, the rate of loss of the radical along the flow axis is observed by scanning the delay time between the pulses from the photolysis and probe lasers using a delay generator. As the time delay between lasers increases the fluorescence signal decreases because radicals have been consumed in the reaction during their transit along the flow. A typical trace of the LIF decay can be seen in Fig 3 as well as the exponential fit which allows one to determine a first-order rate coefficient. Plotting this rate as a function of the reactant concentration, which can be varied by means of flow controllers, leads to a straight line whose slope gives the requested second-order rate coefficient. A typical second-order plot is shown in Fig. 4 as an illustration. It is worth

stressing that this kind of study only scans the destruction of the reagent radical, hence no information can be extracted about the nature of the products and the branching ratios when several exit channels are open.

The C_2 radical is a peculiar molecule in the sense that its first excited electronic state $a^3\Pi_u$ ($v = 0$) is only separated from the ground state $X^1\Sigma_g^+$ ($v = 0$) by 610 cm^{-1} ($\sim 880\text{ K}$).¹³⁰ In our experimental protocol,⁹⁷ photolysis of the precursor tetrachloroethylene at 193 nm produces mainly the triplet state which then can relax to the ground state when suitable conditions exist in the flow. Using He, Ar or N_2 as the buffer gas of the supersonic flow results in the presence of both states out of Boltzmann equilibrium in the flow. This is an uncomfortable situation for the study of the reactivity of the singlet state because introducing a reagent may result in a partial relaxation of the triplet state to the ground state in characteristic times of the same order of magnitude than the reaction of the ground state with that reagent. The LIF signal of the ground state will then be sustained by this source involving the measurement of an underestimated rate coefficient. To get rid of this complex situation, molecular oxygen was introduced in the reservoir of the nozzle at a fixed flow rate in addition to the studied reagent. We have demonstrated in a previous work⁹⁷

Figure 3. Decay of $C_2(X^1\Sigma_g^+)$ LIF signal at 36 K in the presence of C_2H_2 ($[C_2H_2] = 3.8 \times 10^{13}$ molecules cm^{-3}) and He buffer gas ($[He] = 5.3 \times 10^{16}$ atoms cm^{-3}), fit to a single exponential function.

that O_2 was an efficient scavenger for the triplet state in the temperature range 50–200 K and therefore in this range, experiments were carried out with the singlet ground state only present in the reactor. At temperatures below 50 K, a mixture of both states was, however, present and consequences will be discussed in a further paragraph. At room temperature, oxygen was also introduced to generate an equilibrated population of triplet and singlet states before reaction with the reagent took place. The study of the removal of the triplet state was obviously made without introducing oxygen.

As mentioned in Table 4, the ground state was detected using the Mulliken bands at *ca.* 231 nm whereas the triplet state was identified through the Swan bands at about 516 nm. Five hydrocarbons were studied: CH_4 , C_2H_2 , C_2H_4 , C_2H_6 and C_3H_8 . The whole results are presented in Figs 5 to 9 where data are gathered by reactant for both singlet and triplet states. In the case of CH_4 , the triplet state however is non reactive and therefore Fig. 5 contains data for the singlet state only.

As it can be observed, the reactivity of the triplet state is always lower than that of the ground state. The former is poorly removed by saturated hydrocarbons. For C_2H_6 measurements were only carried out at 200 K and 300 K because the process was not efficient enough at lower temperatures to be measurable by the CRESU apparatus. It seems however that destruction of $C_2(a^3\Pi_u)$ increases with the complexity of the hydrocarbon because measurement for propane showed a

Figure 4. Plot for the removal of $C_2(X^1\Sigma_g^+)$ by C_2H_2 at 36 K in He, yielding a value for the second-order rate coefficient of $k = 4.7 \times 10^{-10}$ cm^3 s^{-1} molecule $^{-1}$.

Figure 5. Second-order rate coefficients k for the removal of $C_2(X^1\Sigma_g^+)$ by CH_4 measured as a function of the temperature.

rate coefficient that is one order of magnitude greater than for C_2H_6 . At the lowest temperature of the experiment however the rate coefficient was also unquantifiable. Although measurable, the removal of the triplet state with propane was still an order of magnitude lower than the reactivity of the singlet state. For unsaturated hydrocarbons, the triplet state is significantly more destroyed, but still in a less efficient way than the singlet state (about a factor of 2 to 3). Finally, it is important to stress that it is not possible in this experiment to discriminate between the pure reactivity and the possible relaxation of the triplet state to the ground state. It is then more appropriate to talk about the total removal of the triplet state rather than about the reactivity with reactants. More details can be found in Ref. 113.

With respect to the singlet ground state, the determined rate coefficients were always found to be very fast over the whole temperature range (greater than 10^{-10} cm^3 s^{-1} molecule $^{-1}$) except for methane for which the rate coefficient was measured to be about constant and at least one order of magnitude lower than for C_2 - and C_3 -based hydrocarbons. The temperature dependence is usually rather weak although a shallow maximum can be identified at about 50–70 K. Values are very close to the collisional limit and this is more particularly true for C_2H_2 and C_2H_4 .

Figure 6. Second-order rate coefficients k for the removal of $C_2(X^1\Sigma_g^+)$ (1) and $C_2(a^3\Pi_u)$ (2) by C_2H_2 measured as a function of the temperature.

Figure 7. Second-order rate coefficients k for the removal of $C_2(X^1\Sigma_g^+)$ (1) and $C_2(a^3\Pi_u)$ (2) by C_2H_4 measured as a function of the temperature.

Concerning data obtained for the singlet state at temperatures below 50 K the analysis shows that the removal of the singlet state by the three saturated hydrocarbons only results from pure reactivity with these species because the removal of the triplet state is very small or immeasurable below 50 K. For unsaturated hydrocarbons the situation is more complex because the removal of the triplet and the singlet states are found to be very fast. Then the observed decay of the rate coefficient below 50 K could come from underestimated values of the rate coefficient due to relaxation of the triplet state. Since this latter process cannot be clearly evaluated, we prefer to maintain a cautious analysis and claim that these results are lower-limit rate coefficients for the reactivity of $C_2(X^1\Sigma_g^+)$ with C_2H_2 and C_2H_4 . It is worth stressing however that this behaviour was already observed at low temperature for several reactions as for example those involving boron⁷⁸ or silicon^{101,114} atoms with hydrocarbons. As for the reaction $B + C_2H_2$,⁷⁸ a very small activation barrier can also be responsible for the observed decay.

More details concerning these studies can be found elsewhere¹¹¹ and more particularly a discussion concerning the possible consequences of these high rate coefficients for the photochemistry of Titan and Giant Planets. Briefly, these results show that reactions of C_2 with C_2H_2 , C_2H_4 and C_2H_6 are significant destruction routes of the dicarbon radical which are presently not taken into account in the photochemical models of the atmospheres of these bodies. Moreover, in the

Figure 8. Second-order rate coefficients k for the removal of $C_2(X^1\Sigma_g^+)$ (1) and $C_2(a^3\Pi_u)$ (2) by C_2H_6 measured as a function of the temperature.

Figure 9. Second-order rate coefficients k for the removal of $C_2(X^1\Sigma_g^+)$ (1) and $C_2(a^3\Pi_u)$ (2) by C_3H_8 measured as a function of the temperature.

chemistry of circumstellar envelopes,¹³¹ the reactivity of C_2 with C_2H_2 , which is a potential source of C_4H , has been recently updated using our new measurements because the rate coefficient which was in use was underestimated by at least a factor of four⁵⁰ (and associated website <http://www.udfa.net/>). Reactions with C_2H_4 and CH_4 which were absent in the chemical scheme have also been added.

Finally, it is interesting to note that the kinetic behaviour of $C_2(X^1\Sigma_g^+)$ with C_2H_2 , C_2H_4 , C_2H_6 and C_3H_8 is quite similar to that observed for CH with the same reactants¹¹⁰ indicating that the reactive mechanisms might be similar *i.e.*, insertion or addition of the radical followed by a hydrogen elimination. Regarding to the products, little information can be found in the literature. The reaction of the ground state of C_2 with CH_4 is expected to proceed *via* insertion of C_2 in the C–H bond.^{132,133} Kaiser *et al.*^{134,135} performed crossed molecular beam experiments to study the dynamics of $C_2(X^1\Sigma_g^+)$ and $C_2(a^3\Pi_u)$ with C_2H_2 (see Ref. 135) and C_2H_4 (see Ref. 134) at collision energies in the range 14.7–28.9 kJ mol^{−1} (*i.e.* ~1100–2300 K) and combined them with *ab initio* electronic structure calculations. They concluded that one exit channel was available and leads to 1 hydrogen atom elimination.

The C_4H radical is produced in the laboratory by photodissociation of diacetylene, C_4H_2 , using UV or VUV light. One of the major difficulties concerning the study of the reactivity of this radical with hydrocarbons lies in the synthesis of diacetylene which cannot be bought from private companies. This very unstable molecule was made in our laboratory from the dehydrochlorination of 1,4-dichloro-2-butyne ($C_4H_4Cl_2$). It was then stored into a 20-litre glass vessel buffered with helium under a total pressure of 1.2 bar. This mixture was then introduced in the reservoir of the Laval nozzle using a micro-metric valve. The C_4H radical was produced by photolysis of C_4H_2 using an excimer laser working at 248 nm. The pencil of radicals generated all along the flow axis was detected by LIF exciting a $^2\Sigma^+ \rightarrow ^2\Sigma^+$ vibronic band of the $\tilde{B}^2\Pi_i - \tilde{X}^2\Sigma^+$ electronic system at a wavelength of *ca.* 408 nm. Fluorescence was collected with a photomultiplier tube through a low-pass glass filter (see Table 4).

Twelve hydrocarbons were studied including CH_4 , C_2H_2 , C_2H_4 , C_2H_6 , C_3H_4 (propyne and propadiene), C_3H_6 , C_3H_8 , C_4H_6 (butyne and butadiene), C_4H_8 and C_4H_{10} . This work was limited to temperatures greater than 39 K because below that value rotational relaxation of C_4H was not fast enough to be completed within the available hydrodynamic time of the experiment. A sample of our results limited to CH_4 , C_2H_2 , C_2H_4 , C_2H_6 , C_3H_4 (propyne) and C_3H_8 is presented in Figures 10 and 11. In all cases, reactivity increases when the temperature is lowered and, as for C_2 , the rate coefficient reaches a

shallow maximum before starting to slightly decrease in some cases. It is worth noting that the rate coefficient increases with the number of carbon atoms in the molecule when considering the reagents by family (alkanes, alkenes, alkynes and dienes). As for $C_2(X^1\Sigma_g^+)$, the rate coefficients are very fast and close to the collision limit indicating that these processes are certainly barrierless. More details concerning these measurements can be found elsewhere.¹¹²

Among the studied hydrocarbons, six have been detected in the atmosphere of Titan (CH_4 , C_2H_2 , C_2H_4 , C_2H_6 , C_3H_4 : propyne and C_3H_8). In photochemical models of this Saturn's moon, only reactions of C_4H with the first four reagents are taken into account probably because the abundance of propyne and propane are too small. We have compared our measurements with the values of the rate coefficients included in these models^{136–140} and realised that the chosen rates were always underestimated, sometimes by more than one order of magnitude. The closest estimations were proposed in a recent model by Wilson and Atreya¹⁴⁰ who used rate coefficients comparable with those measured recently for reactions of C_2H with CH_4 , C_2H_2 , C_2H_4 and C_2H_6 (see references in Table 3). These aspects clearly show that the photochemical models should be revised. In particular, these new experimental data may affect the formation of polyaromatic polymers which are

one possible route for the production of the thick haze that is present in the upper atmosphere of Titan.^{122, 141}

At this stage of our knowledge, it is rather interesting to start comparisons of the known rate coefficients that were measured within the last 15 years at very low temperature. More particularly, some stable reagents have now been studied in the presence of a large number of differing radicals. Concerning carbon-based species the reactivity of acetylene has been studied in flow gases containing radicals such as $C(^3P)$, CH , C_2 , C_2H and C_4H (see references in Table 3). The temperature evolution of the rate coefficients for these five reactions is presented in Fig. 12a and 12b. As it can be seen, rates are all fast and present temperature dependences that are rather similar. These observations may help in the estimation of rate coefficients for which the measurement is not experimentally possible and may suggest new theoretical routes to explore.

V. Perspectives

Although a lot of studies have been carried out on the experimental determination of rate coefficients at very low temperature within the last 15 years, there is still a considerable amount of work to be achieved. Beside carbon chemistry, there are several directions that are of particular interest.

Most of the present available studies concern small systems *i.e.*, atomic radicals or simple molecular radicals and reagents (see Table 3). There are still several aspects that remain unexplored however. As a matter of example, the chemistry of sulfur is completely unknown at very low temperature although molecules such as SO or SO_2 are routinely used to trace shock areas in the interstellar medium.^{142, 143} The reac-

tivity of sulfur atoms is certainly of interest in the production of more complex sulfur-bearing molecules. The chemistry of metastable atoms is also important in our atmosphere and in planetary atmospheres as well. Only a few data concerning the reactivity of $O(^1D)$ are available at temperatures close to 200 K.^{144–146} Extension to the lower temperatures of Titan should be valuable as well as determining rate coefficients for other atoms such as $N(^2D)$, $C(^1D)$ or $S(^1D)$. A much more difficult task resides on the experimental study of radical–radical reactions because in that case one of the partners must be produced in a large and well-defined quantity (typically 10^{13} molecules cm^{-3}) so that the characteristic time of the reaction is small enough to be measured by experimental setups such as supersonic flows. It is worth mentioning here the very recent study concerning $O + OH$ which was conducted at temperatures as low as 39 K.⁹³ Future work may focus on reactions such as $N + OH$, $O + CN$, $O + CH$ or a simpler one $N + NO$ which are all of particular interest in interstellar chemistry.

Another important aspect that modern astrophysics revealed is the complexity of the existing interstellar molecules as illustrated by Table 1. It is important to understand how this complexity may be generated and to which level it can be brought. Although polycyclic aromatic hydrocarbons have not yet been directly observed in the interstellar medium, it is now largely accepted that they are mostly present. Their reactivity with other molecules is then of particular interest because insertion mechanisms could contribute to the building up of new species containing an increasing number of aromatic cycles. The study of dimerisation and eventually nucleation of PAHs can also give new insights in the generation of nanoparticles by extension of interstellar dust. Finally, reactions of simple stable C_2 , C_3 and C_4 -based hydrocarbons with radicals should also be completed although it is rather well documented now.

Measuring rate coefficients, although being of crucial importance, is only a partial answer to the understanding of a chemical process. Obviously, the identification of the products and the quantification of the branching ratios are vital as well. This aspect is much more difficult with the available experimental techniques dedicated worldwide to the investigation of gas phase kinetics. Although products can be identified by several methods such as LIF or mass spectrometry, the determination of their concentration is usually not possible. Some recent works are noteworthy however. Reactions for which only one exit channel is open can be used as references to determine the quantity of products of another process. This idea was used by the group of Seakins in Leeds (UK)^{147, 148} and Loison in Bordeaux (France)^{149–153} to obtain the branching ratio of channels containing hydrogen atoms. Calibration reactions such as

can be used whereas H atoms are detected by VUV-LIF. These studies however are only available at room temperature and it would be worth to extend them at interstellar temperatures. The development of infrared lasers opens new possibilities for the determination of branching ratios. Multipass cells can be coupled to infrared light to detect molecular radicals by absorption techniques and quantify their concentration. Using this method, Herschberger and co-workers^{154–159} obtained a significant amount of results at room temperature and above. One of the major problems here lies in the vibrational population of the produced molecules which may not be in equilibrium and therefore relaxation processes could inter-

fere in the measurements. This was solved by the authors using SF_6 as a buffer gas,¹⁶⁰ a technique which is inapplicable to CRESU supersonic flows because of potential polymerisation of large concentrations of SF_6 during the expansion. A more promising technique lies on the photoionisation of products at threshold using VUV light and collection of the ions by a time-of-flight mass spectrometer. VUV can be generated by wave mixing laser techniques. This however is rather limited because of the restricted accordability of the generated light. Furthermore, the quantity of photons is generally rather small. A more appropriate tool for this kind of study is light produced from a synchrotron. Recent works have been undertaken at room temperature coupling a slow flow cell reactor to the ALS synchrotron in Berkeley.¹⁶¹ By scanning the VUV light it is possible to detect products according to their ionisation potential which allows one to separate isomers. Provided that ionisation cross sections are known, the concentration of the products can be extracted from the experiment. Using a reduced version of the CRESU apparatus, it could be possible to couple it to a synchrotron (SOLEIL in France) and then make this kind of experiments at low temperatures.

Another challenge of experimental gas kinetics would be to be able to study the reactivity of molecules at even colder temperatures. The CRESU technique is well designed for this kind of task although the continuous version will request considerable pumping capacities to reach temperatures as low as a few Kelvin. Let's remind that the technique is presently limited to temperatures greater than 15 K for a reservoir kept at room temperature. Using a pulsed version of the CRESU apparatus coupled to the pumping capacities which are available in Rennes will make it possible however to obtain temperatures lower than 5 K reducing by a factor of 3 the present limit. This idea is in development in our lab and would open new horizons. More particularly it would allow one to compare theory and experiments in these extreme conditions. Indeed, theoretical predictions indicate that peculiar behaviours of the rate coefficients below 10 K should occur. As a matter of example, capture theories are expecting a maximum of the rate coefficient close to that temperature and then a significant decrease for colder conditions.

As it can be seen through these pages, the field of gas kinetics at low temperature is very active and has still unexplored areas. The development of new technologies however should allow experimentalists to push the limits even further and exciting results are expected in the future.

The present work was made possible thanks to the very efficient collaboration of my colleagues in Rennes: C Berteloite, P Birza, S Le Picard, A Páramo, B R Rowe, I R Sims and D Travers. I am particularly grateful to B R Rowe and I W M Smith, whose association made possible the development and success of the studies of neutral–neutral reactions at very low temperatures. The work is funded through two French national programmes: Physique et Chimie du Milieu Interstellaire (PCMI) et Planétologie (PNP); the European commission through the 'Molecular Universe' network; the Region of Brittany and Rennes Metropole to which I express my deep thanks.

Tunnelling chemical reactions of hydrogen isotopes in quantum solids

V V Khmelenko, E P Bernard, S Vasiliev, D M Lee

Contents

I. Introduction	1107
II. Historical background	1107
III. Studies of exchange tunnelling reactions of hydrogen isotopes in clusters forming impurity – helium solids	1109
IV. Studies of H atoms in solid H ₂ films at ultralow temperatures	1117
V. Conclusions and future work	1120

Abstract. The kinetics of tunnelling reactions of hydrogen isotopes in solid molecular nanoclusters immersed in superfluid helium and the changes in the environment of the atoms during the course of these reactions are reviewed. Results of pulsed electron spin resonance show that a very large fraction (50%–60%) of the stabilised atoms reside on the surfaces of the nanoclusters. The results of studies of the recombination and the exotic behaviour of hydrogen atoms in a solid molecular hydrogen matrix at ultralow temperatures (0.15–0.9 K) are also discussed. The bibliography includes 68 references.

I. Introduction

In this paper we review recent experimental and, briefly, theoretical studies of quantum chemical reactions of atomic hydrogen isotopes in solid molecular matrices at low and ultralow temperatures. We put our main emphasis on the experimental work utilising the magnetic resonance methods of electron spin resonance (ESR), nuclear magnetic resonance (NMR) and electron – nuclear double resonance (ENDOR).

We begin in Section II with a brief historical background of the research on the physical processes and chemical reactions which occur with atomic hydrogen isotopes trapped inside solid hydrogen and/or deuterium molecular matrices. In Section III, we present in more detail a description of the experimental procedure for the preparation of the nanoclusters in superfluid helium and the ESR methods (9 GHz continuous

wave and pulsed spectrometers) used for these studies. We also discuss the studies of the kinetics of exchange tunnelling reactions of hydrogen isotopes at $T \sim 1.35$ K in nanoclusters of impurity – helium (Im – He) solids. The changes of the environment of the atoms during the course of these reactions and the trapping sites of atoms in nanoclusters are also reviewed. In Section IV we discuss the experimental techniques for studies of H atoms in solid H₂ films at ultralow (0.15–0.9 K) temperatures. We present the results of studies of the recombination and the exotic behaviour of H atoms in thin (~ 50 nm) H₂ films in this temperature range. Section V contains a summary, some conclusions and future prospects for investigations of tunnelling reactions of hydrogen isotopes.

II. Historical background

Studies of hydrogen atoms trapped in solid molecular matrices have a long history, starting in the mid-1950s. Jen *et al.*,^{1,2} Wall *et al.*,³ and Pietter *et al.*⁴ performed the first investigations of H atoms in solid H₂. The main motivation for these studies was the achievement of high concentrations of stabilised H atoms for possible application as a rocket fuel. An advantage as compared to existing chemical fuels would be realised only if concentrations of H atoms in solid H₂ of order 7.5% could be achieved.⁵ Various methods were employed for producing H atoms, such as electron and γ -ray bombardment of solid H₂, deposition of the products of electrical discharges in gaseous H₂ on cold surfaces, and the addition of low concentrations of radioactive T₂ to solid H₂. Electron spin resonance (ESR) was used to measure the H atom concentrations. It was found that the average concentrations of H atoms were very small (less than 0.01%). This fact made impossible any practical applications of H – H₂ solid mixtures. Moreover, the amounts of H atoms were found to decrease gradually due to their recombination:

A revival of interest in this system occurred only after three decades because it provided a unique opportunity to study the processes of quantum physical diffusion and quantum tunnelling reactions. The influence of isotopic effects on these processes could also be studied. According to the idea of Andreev and Lifshits,⁶ at low enough temperatures, any impurity inside a crystal becomes delocalised and may freely move within certain energy bands in a fashion similar to the

conduction of electrons in metals. This proposal was followed by detailed theoretical studies by Kagan *et al.*⁷ They suggested a phonon assisted mechanism for the physical diffusion of H atoms through the potential barriers in H₂ crystal lattices. The dependence of the recombination rate of H atoms in solid H₂ on temperature according to this mechanism was determined to be linear, as given by

$$k_H(T) = AT.$$

At the same time Ivliev *et al.*⁸ experimentally studied the diffusion of H atoms in solid H₂. The main method for studying the process of quantum diffusion was to measure the rate of recombination of the atoms. However, before recombining, the atoms need to approach each other within a lattice constant. At close enough spacing between the atoms, they distort the lattice potential, and their motion may become severely impeded by the energy level mismatch between the neighbouring sites. Therefore, such 'recombinational' diffusion appears to be much slower than the actual spatial diffusion in an ideal crystal. The studies of the latter still remain an important and challenging task in this research field. It was found that at temperatures above 4.3 K the recombination rate of H atoms follows the Arrhenius law,

$$k_H(T) \sim \exp\left(-\frac{E_a}{kT}\right),$$

where $E_a \sim 103$ K and k is the Boltzmann constant. However, in the temperature range 1.3–4.2 K a linear dependence of k_H on temperature was observed. The latter result was explained by the quantum diffusion mechanism discussed by Kagan *et al.*⁷ From the measurements of the concentration of H atoms in these experiments it was possible to calculate the absolute rate constants and the value of the coefficient A in the formula $k_H(T) = AT$, which was found to be equal to $(2 \pm 1) \times 10^{-24} \text{ cm}^3 \text{ s}^{-1} \text{ K}^{-1}$. These results suggested that the physical quantum diffusion of H atoms in solid H₂ was an important process leading to recombination. In contrast, the Nagoya group led by Miyazaki⁹ and the Chernogolovka group led by Gordon¹⁰ suggested that the dominant process for the migration of H atoms in solid H₂ is the tunnelling exchange chemical reaction:

which provides a chemical diffusion mechanism for the motion of the H atoms from one trapping site to another. Matrix isolated H atoms are confined to potential wells in a molecular H₂ matrix. These wells are not infinitely deep so it is possible for the H atom to tunnel *via* chemical reactions (1) through the matrix. For substitutional sites, tunnelling would correspond to a change in position of the atom by one lattice spacing, so the position of the atom and the neighbouring molecule are interchanged. This process could be repeated many times, thus providing a mechanism for an atom to move through the matrix. The barrier for this reaction is known¹¹ to be 4600 K, which is significantly larger than that for the physical diffusion of H atoms in solid H₂ (~ 100 K). On the other hand the potential barrier for exchange tunnelling is significantly narrower. Takayanagi *et al.*¹² performed theoretical calculations of rate constants for exchange tunnelling reactions of hydrogen isotopes. The theoretical prediction gives a very fast rate constant for reaction (1). Additionally, recent measurements of the recombination rates at different pressures up to 13 MPa show the independence of k_H on pressure.¹³ This important finding could not be explained by physical diffusion, which should be suppressed with increasing pressure, thus supporting the hypothesis of chemical exchange tunnelling of H atoms.

The exchange chemical reaction:

is expected to be much slower because of the larger mass. The experimental results obtained by studying D atom recombination decay are in good qualitative agreement with theoretical predictions by Takayanagi *et al.*¹² Experimental studies of D atoms in bulk D₂ solids were performed by Sharnoff and Pound,¹⁴ Iskovskikh *et al.*¹⁵ and Miyazaki *et al.*^{16–18} Deuterium atoms in D₂ nanoclusters were studied by Gordon *et al.*^{10,19} and Bernard *et al.*^{20,21} Iskovskikh *et al.* found that thermally activated diffusion is responsible for recombination of atoms at temperatures higher than 7 K, but at lower temperatures the two-phonon quantum physical diffusion of D atoms was suggested.¹⁵ The latter mechanism explained the temperature dependence obtained for the rate constant, $k_D \sim T^9$. In contrast, Miyazaki *et al.*^{16,17} and Gordon *et al.*¹⁰ considered that the migration of D atoms through D₂ crystals occurred due to the tunnelling exchange chemical reactions similar to the case of H atoms in solid H₂.

Two important tunnelling exchange reactions that have also been studied experimentally are:

Exchange tunnelling reactions between atoms and molecules of hydrogen isotopes in solid mixtures were discovered by Gordon *et al.*¹⁰ during studies of the stabilisation of nanoclusters containing H and D atoms produced by injection of a gaseous mixture into superfluid ⁴He (at $T \sim 1.8$ K) after it had passed through a radiofrequency (RF) discharge. They found a large enhancement of the concentration of hydrogen atoms in hydrogen–deuterium solid samples so obtained, as compared with the content of hydrogen atoms in the initial gas jets. For example, for a gas content ratio $[\text{H}_2]/[\text{D}_2]$ equal to unity, they observed only ESR signals from hydrogen atoms, indicating an absence of D atoms. Considering all possible exchange chemical reactions between atoms and molecules of hydrogen isotopes, they concluded that due to differences in the zero-point energies of H₂, HD and D₂ molecules, only reactions (1)–(4) and reactions

can occur, leading to a depletion of D atoms and a growth in the H atom population. Reactions:

are endothermic and cannot proceed at the temperature of experiment. As a result of reactions (1)–(6), which occur at these temperatures mainly by tunnelling, H atoms tend to migrate through the matrix until they are surrounded by a shell of deuterium molecules or they recombine with other H atoms.

A few month later, Ivliev *et al.*²² in Moscow and Tsuruta *et al.*⁹ in Nagoya, Japan, using different experimental approaches, studied the evolution of concentrations of hydrogen and deuterium atoms in solid molecular hydrogen–deuterium mixtures, providing direct confirmation of exchange tunnelling reactions at low temperatures. The Nagoya group performed comprehensive quantitative studies of atoms in solid molecular matrices of hydrogen isotopes. They studied the rates of different tunnelling reactions,^{9,16–18,23} the influence of *o*-H₂ in solid H₂ on the rate constant for reactions of H atoms,^{24–26} the temperature effect on the reaction of atoms²⁷ and the trapping sites of the atoms in molecular matrices.^{28–32}

These results were summarised in the monograph edited by Miyazaki.³³

Ivanov *et al.*³⁴ have modeled the temperature dependence of the rate constant for tunnelling reaction (4) in the solid phase. Their model describes the rate constant K at lowest temperatures by the formula

$$\ln k = \ln k_0 + C_4 T^4 + C_5 T^5 + C_6 T^6 + C_8 T^8.$$

The coefficients in this formula were obtained from comparison with the experimental measurements of rate constants in the temperature range 2.6–6.5 K by Miyazaki *et al.*²⁷ The formula predicted that at the lowest temperatures $\ln k$ would be almost independent of temperature. Further studies of this reaction in the solid phase at lower temperatures would be desirable.

The exchange reactions between atoms and molecules of hydrogen isotopes have also been studied in cross beam experiments in gas phase at room temperature. Zhang and Miller³⁵ performed theoretical calculations of the rate constants for these reactions and obtained very good agreement with the experimental results.

During the past five years, the kinetics of exchange tunnelling reactions have been studied at Cornell in samples created by the method that originated in Chernogolovka.^{36,37} The gel-like solids created in superfluid helium are now known as impurity–helium solids or alternatively as impurity–helium condensates.^{38,39} Impurity–helium solids are highly porous gel-like nanomaterials consisting of interconnecting clusters of impurities with a characteristic size 5–9 nm and an average density over the entire sample volume as low as 10^{20} atoms (molecules) cm^{-3} . Each cluster contains approximately 10^4 atoms and molecules. This means that the concentration of the clusters in the impurity–helium solids is of order 10^{16} cm^{-3} . Tunnelling exchange reactions between atoms and molecules of hydrogen isotopes could then be investigated in the collection of nanoclusters and the results could be compared with those obtained earlier in bulk solids. Reactions among chemically active atoms and molecules within nanoclusters are predicted to be more efficient and selective than analogous reactions in bulk material.⁴⁰

Although most studies of H atoms in solid H_2 were performed at temperatures above 1 K, Webeler⁴¹ studied the recombination heating in solid H_2 containing 0.03% radioactive T_2 in the temperature range $0.16 \text{ K} \leq T \leq 0.8 \text{ K}$. The β -decay led to the dissociation of H_2 molecules, thus providing a population of H atoms. Results show an increase of H atom concentration with time, followed by spontaneous decay. Lowering the temperature led to an increase in the energy release from the recombination of H atoms during spontaneous decay. The first studies of recombination rates of H atoms in solid H_2 in the temperature range 0.15–0.9 K were performed very recently by Ahokas *et al.*⁴² A high-field ESR spectrometer,⁴³ in combination with a ^3He – ^4He dilution refrigerator cryostat, was employed in these investigations.

III. Studies of exchange tunnelling reactions of hydrogen isotopes in clusters forming impurity–helium solids

1. A setup for studies of tunnelling reactions in nanoclusters

The experimental setup for investigating exchange tunnelling chemical reactions in nanoclusters at low temperatures at Cornell University is described in more detail elsewhere.⁴⁴ The experiments were performed in a specially designed Janis cryostat with a variable temperature insert (VTI), which is a thermally insulated chamber, separated from the main 4 K helium bath. A needle valve connects the main helium bath of

the cryostat to the VTI. Continuously pumping the VTI while supplying helium from the main bath permits long-term investigations of impurity–helium solids well below the lambda temperature (2.17 K) of liquid helium. The lower part of the cryostat was placed between the pole pieces of a homogeneous Varian electromagnet for CW and pulsed ESR investigations. Impurity–helium solids with stabilised H and D atoms for ESR investigations were prepared *in situ* in the Janis cryostat. The homemade insert for formation and investigation of atoms contained in Im–He solids is shown in Fig. 1. For sample preparation, a gas mixture of H_2 and/or D_2 and He was transported from a room temperature gas handling system to the cryogenic region. To provide H and D atoms *via* dissociation of the gas molecules, high-power radio-frequency ($f \sim 50 \text{ MHz}$, $P \sim 70 \text{ W}$) was applied to electrodes around the quartz capillary carrying the mixed gases. The resulting jet of helium gas with a small fraction (1%–4%) of impurity atoms and molecules emerging from the quartz capillary was directed onto the surface of superfluid ^4He

Figure 1. Low temperature insert used in the ESR investigation of Im–He solids.⁴⁴ The quartz beaker is lowered into ESR resonant cavity for measurements after sample preparation.

contained in a small beaker suspended above the VTI helium bath. The addition of helium gas increased the efficiency of dissociations of impurity molecules in the discharge due to interactions between the impurity and metastable He atoms and also retarded agglomeration of impurity atoms and molecules in the gas jet. The jet penetrated the surface of the liquid helium and a macroscopic snow-like translucent material was created. This material fell down through the liquid ^4He to form a porous solid at the bottom of the beaker. A fountain pump connected to the bottom of the helium bath in the VTI maintained a constant liquid helium level in the beaker. The temperature during sample preparation was 1.5 K. At the top of the beaker was a funnel that caught the sample as it condensed below the helium surface, which was 2 cm below the end of the quartz capillary. A set of teflon blades scraped the sample from the funnel while the beaker was rotated so that the sample could fall to the bottom of the cylindrical part of the beaker. A jet with a flux of $\sim 5 \times 10^{19}$ atoms and molecules per second yielded $\sim 0.3\text{--}0.4\text{ cm}^3$ of sample in 10 minutes.

In independent X-ray scattering studies of the $\text{D}_2\text{--He}$ and $\text{D}_2\text{--Ne--He}$ samples, it was shown that these samples consisted of nanoclusters of D_2 molecules, each surrounded by thin layers of solid helium.^{20,21} The typical deuterium cluster size is estimated to be $\sim 5\text{--}9\text{ nm}$. These nanoclusters assemble into a porous gel-like structure. From the comparison of the intensity of the D_2 cluster peak with the intensity of the scattering from liquid helium, the molecular deuterium densities in these samples were found to be of order 10^{20} cm^{-3} . It was difficult to carry out structural studies of $\text{H}_2\text{--He}$ solids because solid hydrogen tends to float to the surface of the collection beaker filled with superfluid helium. Actual studies of hydrogen clusters in this research were performed with $\text{H}_2\text{--Ne--He}$ solids prepared with a mixture of hydrogen and neon make-up gas. The heavier neon clusters allowed the mixture to accumulate in the sample cell. An X-ray investigation of similar $\text{D}_2\text{--Ne--He}$ solids provided evidence that neon and deuterium existed in separate clusters in the sample. The result justifies the assumption that H_2 and Ne mainly occurred in separate nanoclusters in these experiments.

After sample preparation, the beaker containing the sample was lowered into the ESR cavity, which was situated at the bottom of the cryostat in the homogeneous field region of the Varian 7800 electromagnet. The volume occupied by the sample inside the cavity was 0.35 cm^3 . The homemade cylindrical cavity was operated in the TE_{011} mode. The cavity has an axial hole to provide access for the sample to be introduced. Two different inserts were used in the experiments, one for detection of CW ESR signals by an X-band homodyne spectrometer and the other for detection of electron spin echo signals by a pulsed X-band homodyne spectrometer. Only the microwave cavities were different in these inserts. A high quality factor cavity ($Q \sim 3000$) was used in the CW ESR experiments, while in the pulsed ESR experiments a low quality factor cavity ($Q \sim 700$) was employed to avoid a long cavity ring-down time. CW and pulsed ESR signals were obtained for samples immersed in liquid helium at temperatures $\sim 1.35\text{ K}$. CW ESR signals were recorded by using a continuous wave reflection homodyne spectrometer (Varian E-4) operating near 9.1 GHz. Derivatives of the ESR absorption lines were detected at $\sim 0.32\text{ T}$ by lock-in amplification using an additional small amplitude modulation field oscillating at 100 kHz. Atomic concentrations were measured by comparing the intensity of the atomic signals with the intensity of a signal from a small ruby crystal that was used as a secondary standard. The ruby crystal was attached permanently to the bottom of the microwave cavity. The calibration of the absolute value of the number of spins in the ruby crystal was made by using a standard organic diphenyl-picrylhydrazyl (DPPH) sample with a known number $\sim 2.4 \times 10^{17}$ of spins. The measurements

were carried out at $T = 1.35\text{ K}$. A nuclear magnetic resonance (NMR) magnetometer was used for precise measurements of the applied magnetic field.

For pulsed ESR studies of atoms in Im--He solids, a special homodyne detection spectrometer was designed.⁴⁵ The spectrometer operates in the X-band region with a microwave frequency of 8930 MHz. Figure 2 shows a simplified block scheme of the pulsed ESR spectrometer. A 12-channel programmable pulse generator, operating at a 125-MHz clock frequency, provides logic signals to the P–I–N diode switch, bi-phase modulator, oscilloscope trigger and traveling wave tube (TWT) grid modulator. Microwaves from the tunable oscillator are amplified and split into pulse and reference paths. The pulses are amplified by a 1 kW, 50 dB TWT amplifier operating in the saturated regime. The amplified pulses pass through a circulator before transitioning to a 20 cm length of stainless steel coax at the entrance to the cryostat. (A similar arrangement was used in the CW spectrometer). This prevents excessive heat conduction into the cryostat. A low loss coax traverses the remaining 107 cm to the resonant cavity at the bottom of the cryostat, which is situated between the poles of the Varian electromagnet. Echo signals return through the same cabling to the circulator, which routes them to a low noise amplifier (LNA) that is protected by a diode limiter from the powerful microwave pulses. After amplification, a quadrature mixer provides homodyne detection by referencing the echo signals to the microwave oscillator. The resulting in-phase and quadrature signals are sampled by a digital oscilloscope and transferred *via* GPIB to a computer. The spectrometer design differs from other machines used to acquire electron spin echo data at cryogenic temperatures in three significant ways.⁴⁶ First, space constraints in our cryostat require the use of a coax rather than a waveguide connection to our cavity-type resonator. Second, our resonant cavity is a modified CW ESR

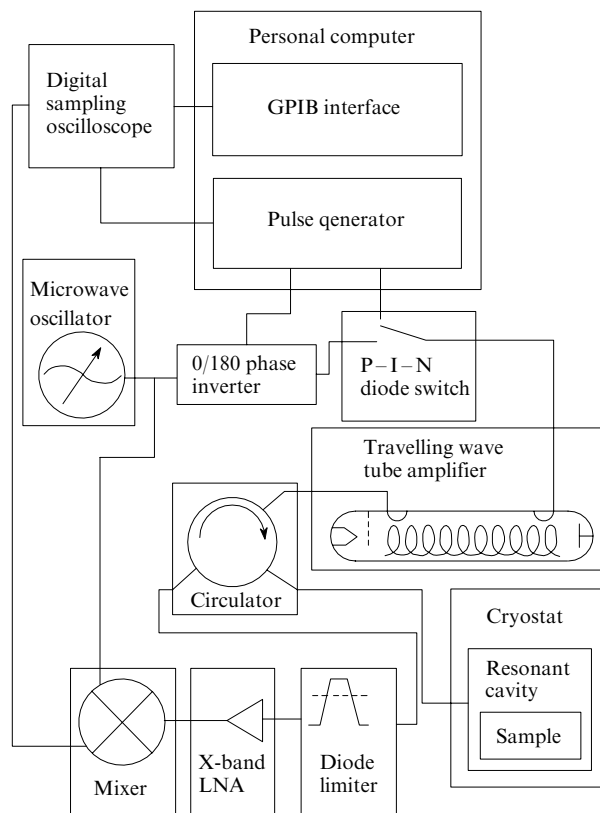

Figure 2. Block diagram of pulsed ESR spectrometer.

quartz-filled cavity designed to admit a funnel containing Im–He solid samples. To facilitate broadband excitation by short pulses, a chromium coated quartz ring is bonded with epoxy to thin fingers protruding from a brass pedestal. Adjusting the pedestal position then adjusts the Q factor of the cavity; we have found a Q of ~ 700 to be effective for detecting electron spin echo envelope modulation (ESEEM) due to deuterium nuclei. Further details of this method will be provided in a later section. For this apparatus, a 90° pulse has duration 40 ns. Finally, the spectrometer output is sampled by a sampling oscilloscope, not a boxcar integrator. Integrating a narrow section of the echo peak recovers standard boxcar ESEEM data. Alternatively, for two-pulse ESEEM experiments the echo can be sectioned in time and the phase correction algorithm of Astashkin *et al.* applied.⁴⁷ This corrects for the fact that the phase of the modulation harmonics varies within each echo, and therefore allows the entire echo to contribute to the signal, thus improving the signal/noise ratio.

2. CW ESR studies of tunnelling exchange reactions of hydrogen isotopes in clusters forming impurity–helium solids

The Im–He solids formed by injection of hydrogen isotopes into He II are of special interest due to their potential to manifest various quantum phenomena. The observation of tunnelling exchange chemical reactions between atoms and molecules of hydrogen isotopes at low temperatures in Im–He solids represents an important example of such a quantum phenomenon. Investigations of tunnelling reactions in Im–He solids were first performed by the Chernogolovka group.^{10, 19} By using the CW ESR method, they studied the efficiency of the stabilisation of hydrogen and deuterium atoms in Im–He solids using hydrogen–neon–helium, deuterium–helium, or hydrogen–deuterium–helium gas mixtures. In contrast with earlier work, it was found that maximum local concentrations of H and D atoms as high as 1% could be easily achieved in Im–He solids. However, they were not able to study the time evolution of the concentration of stabilised atoms.

Recently, studies of the kinetics of tunnelling exchange reactions between atoms and molecules of hydrogen isotopes in nanoclusters have been performed by the Cornell group.^{44, 48–51} The X-band CW ESR method was used in these studies. This method allows a determination of the time dependence of the hydrogen and deuterium atom concentrations during the tunnelling exchange reaction and it also provides information concerning changes in the environment of these atoms as the reactions proceed.

Initially the kinetics of tunnelling reactions were studied in each of the two pure hydrogen isotopes. The main features of the atomic hydrogen and atomic deuterium spectra recorded from a sample with initial gas mixtures in the ratios $\text{H}_2:\text{Ne}:\text{He} = 1:4:100$ and $\text{D}_2:\text{He} = 1:20$ are shown in Fig. 3. The hydrogen ESR lines are accompanied by two satellite lines, one on either side of the main line. The satellite lines are assigned to forbidden transitions involving an electron spin flip and a simultaneous spin flip of a proton on a neighbouring ortho-hydrogen molecule. Each of the ESR signals of H atoms was fitted with a sum of three Gaussians (one central line plus two symmetric satellites). From these fits the ratio of the intensities of the satellite and main lines is found to be 0.2. The splittings observed between the main and satellite lines (4.5 ± 0.1 G) are consistent with a proton spin flip in the 3 kG field. Because of the small nuclear magnetic moment of the deuteron, the corresponding splitting for electron spin–deuteron spin interactions is only 0.7 G. This is unobservable in these experiments because the ESR linewidths of the main lines are about 2 G and thus the small satellite lines are hidden by the broad main lines.

In the mixed samples, which contain both H and D atoms, the observation of satellite lines provides strong evidence that a

Figure 3. CW ESR derivative signals of atomic hydrogen in Im–He solid prepared from $\text{H}_2:\text{Ne}:\text{He} = 1:4:100$ gas mixture (a) and of atomic deuterium in Im–He solid prepared from a $\text{D}_2:\text{He} = 1:20$ gas mixture (b). ESR spectra were obtained at $T = 1.35$ K.

large fraction of the hydrogen and deuterium atoms are found in clusters of molecular hydrogen and/or molecular HD. In other words, they are not isolated as individual atoms separated by layers of solid helium. Therefore the solid samples provide a unique opportunity to carry out quantitative studies of the kinetics of tunnelling reactions of hydrogen isotopes in nanoclusters. The results of such experiments can then be compared with analogous studies performed in bulk solid mixtures of hydrogen isotopes. Different behaviour can be expected as a result of the large surface areas of the clusters.

According to Trammel *et al.*⁵² the intensity ratio between the satellite lines and their respective main lines is proportional to the number of protons surrounding a stabilised atom and is strongly dependent on their positions:

$$\frac{I_{\text{sat}}}{I_{\text{main}}} = \frac{3}{20} \left(g_e \frac{\beta_e}{H_0} \right)^2 \langle r^{-6} \rangle N. \quad (9)$$

In the above equation g_e is the electron g factor, β_e is the Bohr magneton, H_0 is the applied magnetic field, r is the distance from an atom to a proton belonging to a neighbouring molecule, and N is the number of these protons. If a reasonable assumption can be made for the number of protons in molecules surrounding the atom, then the average distance between the atom and molecules can be found. Moreover, from the time dependence of this ratio during the course of the chemical reactions, it is possible to obtain the changes in the number of ortho-hydrogen molecules surrounding the atoms.

The time dependence at $T = 1.35$ K of the average concentration of H atoms in a $\text{H}-\text{H}_2-\text{Ne}-\text{He}$ sample and that of D atoms in a $\text{D}-\text{D}_2-\text{He}$ sample are displayed in Fig. 4. The addition of neon was required in the former sample because, unlike the D_2-He sample, the H_2-He solid does not sink to the bottom of the cell, due to its small density. As mentioned earlier, the tunnelling exchange reactions drive the migration of isolated atoms. The relatively fast migration of a hydrogen atom due to the tunnelling reaction (1) leads to recombination with another H atom ($\text{H} + \text{H} \rightarrow \text{H}_2$), and thus explains the

Figure 4. Time dependence of concentrations of atomic deuterium prepared from a D_2 :He = 1:20 gas mixture (1) and atomic hydrogen prepared from H_2 :Ne:He = 1:4:100 gas mixture (2) in Im-He solids stored at $T = 1.35$ K.⁴⁹

rapid decay of the number of hydrogen atoms in the sample at $T = 1.35$ K.

The equation

$$\frac{dn}{dt} = -2k_H(T)n^2. \quad (10)$$

describes the decrease of the concentration of H atoms (n) with time (t) when the temperature of the sample is kept constant.¹⁵ The experimental dependence of the variable $1/n$ on t should thus be linear, with the slope equal to $2k_H(T)$. The characteristic time (the half life) for the concentration to drop by 50% is

$$\tau_{1/2} = [2k_H(T)n_{H,loc}]^{-1}, \quad (11)$$

where $n_{H,loc}$ is the initial local concentration of H atoms. The average concentration of H atoms at the beginning of the measurements is $n_{H,av} = 10^{15} \text{ cm}^{-3}$ according to Fig. 4. As indicated earlier the H_2 clusters and Ne clusters form separately. We shall make the reasonable assumption that the density of H_2 molecules in the H- H_2 -Ne-He samples is roughly similar to the density of D_2 in D_2 -He samples,²¹ which is equal to $\sim 10^{20} \text{ cm}^{-3}$. This is more than two orders of magnitude lower than the density of the solid molecular hydrogen, which is equal to $2.4 \times 10^{22} \text{ cm}^{-3}$. This means that the local concentration of H atoms in the clusters constituting the sample is two orders magnitude larger than the average concentration, giving $n_{H,loc} = 10^{17} \text{ cm}^{-3}$. The decay time of H atoms, $\tau_{1/2}$, shown in Fig. 4 is 150 ± 20 min. From Eqn (11), the rate constant for recombination of H atoms in solid H_2 was found to be $k_H(1.35) = 5.5 \times 10^{-22} \text{ cm}^3 \text{ s}^{-1}$. This value is much larger than those obtained in bulk H_2 solids by the Nagoya group,¹⁸ $k_H(1.9-4.2) = (4.4-5.9) \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$, and the Moscow group,^{8,15} $k_H(1.35) = 2.7 \times 10^{-24} \text{ cm}^3 \text{ s}^{-1}$. This result may be due to a higher mobility of H atoms on the surfaces of the clusters or due to an inhomogeneous distribution of H atoms within the clusters.

The significantly slower decay of D atoms is attributed to the much slower migration of deuterium atoms through molecular deuterium due to the reaction (2). The same Eqn (10) describes the decrease of the concentration of D atoms with time. The initial local concentration of D atoms, $n_{D,loc}$, is equal to $6.25 \times 10^{19} \text{ cm}^{-3}$ and the characteristic decay time of D atoms is 2500 ± 500 min. From the relation

$$k_D = \frac{1}{2} \tau_{1/2} n_{D,loc},$$

it is found that

$$k_D(1.35 \text{ K}) = 5 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}.$$

This value is in qualitative agreement with value $k_D(4.2) = 4 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$, obtained by Iskovskikh *et al.*¹⁵ in solid D_2 at $T = 4.2$ K, but significantly larger than value $k_D = 3.3 \times 10^{-27} \text{ cm}^3 \text{ s}^{-1}$ obtained by Miyazaki *et al.*¹⁷

A completely different behaviour of hydrogen and deuterium atoms was observed in impurity-helium solids containing hydrogen and deuterium atoms along with hydrogen and deuterium molecules.⁴⁹ The main features of atomic hydrogen and deuterium spectra recorded from a sample with an initial gas mixture in the ratio $H_2:D_2:He = 1:4:100$ are shown in Fig. 5. Both the deuterium and the hydrogen ESR lines are

Figure 5. CW ESR derivative signal from Im-He sample prepared from gas mixture $H_2:D_2:He = 1:4:100$ (a). 'H' marks the allowed ESR transitions between the hyperfine levels of atomic H; 'D' indicates the hyperfine transitions of atomic D, and 'F' indicates the forbidden ESR transition of H atoms. Typical derivative signals for low field hyperfine line of hydrogen atoms (b) and deuterium atoms (c) show, at an expanded scale, both the allowed and the accompanying satellite lines. The lines in figures (b) and (c) represent simulations of the signals as the sum of three Gaussians.⁴⁹

accompanied by two satellite lines symmetrically positioned about the main line. The satellite lines are assigned to forbidden transitions involving an electron spin flip and a simultaneous spin flip of a proton on a neighbouring HD or on an ortho-hydrogen molecule. The forbidden transition associated with the hyperfine levels of H atoms is also shown.

A large number of different initial gas mixtures were used for preparation of $\text{H}_2\text{--D}_2\text{--He}$ solids.^{44,49} Immediately after preparation of all Im–He solids, a large enhancement of the H atom concentration relative to that of D atoms was observed, as compared to the ratio of H_2 to D_2 in the original gas mixtures. The fraction of H and D atoms as a function of the relative H_2 concentration in the condensed $\text{H}_2\text{--D}_2$ gas mixtures is shown in Fig. 6. The enhancement of the H atom concentrations at the earliest stage of sample preparation is attributed to the fast exchange tunnelling reaction (3), which leads to a large reduction in the number of D atoms and a corresponding increase in the number of H atoms with a time constant of order 1 min. During this reaction, most of the H_2 molecules that have neighbouring D atoms in the sample are converted into HD molecules. The rate constant for this reaction is calculated theoretically to be $3.56 \times 10^{-25} \text{ cm}^3 \text{ s}^{-1}$ (Ref. 12). Recently, this tunnelling reaction was studied experimentally by Kumada⁵³ in bulk HD--D_2 and $\text{D}_2\text{--H}_2$ solid mixtures in the temperature range between 4 and 8 K. The reactions were initiated by UV photolysis of DI molecules doped in these solids for 30 s, followed by measuring the time variation of the ESR intensities of H and D atoms. The ESR intensity of D atoms produced by photolysis decreases but that of H atoms increases with time. The variation of the concentrations of the D and H atoms with time can be described in terms of a fast and a slow processes. The fast process, which was essentially complete within 300 s after photolysis, is assigned to the reaction (3). The rate constant for this reaction was determined to be $(2.9 \pm 0.3) \times 10^{-25} \text{ cm}^3 \text{ s}^{-1}$ in solid HD--H_2 and $(5.0 \pm 1.1) \times 10^{-25} \text{ cm}^3 \text{ s}^{-1}$ in solid $\text{D}_2\text{--H}_2$ mixtures at $T = 4.1 \text{ K}$, which is very close to the theoretical calculations by Takayanagi *et al.*¹² These results provide very strong evidence favouring the role of tunnelling exchange reactions in the solid hydrogen isotopes.

Figure 6. The dependence of the fractional concentrations of H (1) and D (2) atoms in the $\text{HD--D}_2\text{--He}$ samples as a function of H_2 content in the $\text{H}_2\text{--D}_2$ gas mixtures used for sample preparation. For each point the concentrations were determined just after sample preparation.

For the case of Im–He solids, the time dependence of the concentration of H and D atoms on a longer time scale (2–40 h) showed a further increase in the concentration of H

atoms. The simultaneous presence of deuterium and hydrogen molecules in the make up gas allows us to form impurity helium solids containing hydrogen atoms and deuterium atoms as well as hydrogen, deuterium, and hydrogen deuteride molecules. In Fig. 7a–c we show the results obtained at Cornell, which dramatically illustrate the time dependence of the hydrogen and deuterium atom concentrations for different initial make-up gas mixtures.⁴⁹ In spite of the higher concentration of D_2 compared with that of H_2 in the sample produced from the initial gaseous mixture $\text{H}_2:\text{D}_2:\text{He} = 1:2:60$, the concentration of deuterium atoms is about two orders of magnitude smaller than the hydrogen atom concentration and it decays more rapidly (Fig. 7a). These results are in sharp contrast to the Cornell studies of $\text{H}_2\text{--Ne--He}$ impurity solids, with no deuterium present, in which the decay of hydrogen atoms due to recombination was much more rapid. This can be explained by the presence of many D_2 and HD molecules in the sample, which lead to anomalously slow diffusion of the H atoms through the clusters, and by the partial replenishment of hydrogen atoms through the chemical reactions (3) and (4).

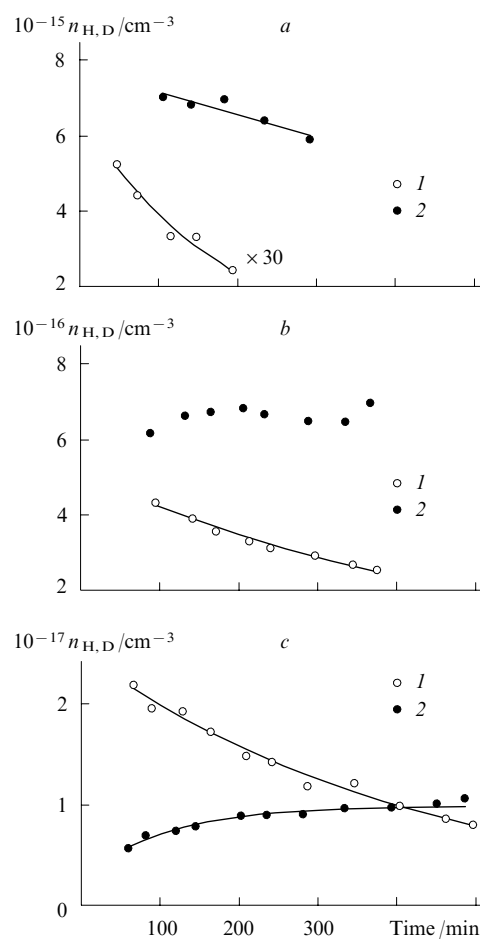

Figure 7. Time dependence of concentrations of atomic deuterium (1) and atomic hydrogen (2) in different Im–He solids at $T = 1.35 \text{ K}$.⁴⁹ $\text{H}_2:\text{D}_2:\text{He}$ mixture: 1:2:60 (a), 1:4:100 (b), 1:8:180 (c).

Furthermore, these reactions also explain the faster decrease of the deuterium atom concentration as compared with that in the $\text{D--D}_2\text{--He}$ sample (see Fig. 4). In Fig. 7b the population of hydrogen atoms remains almost constant, meaning that the production is almost in balance with recombinational decay in the sample produced from an $\text{H}_2:\text{D}_2:\text{He} = 1:4:100$ mixture. In Fig. 7c the population of hydrogen

atoms actually shows an increase that is driven by the chemical reactions as time evolves. The large initial supply of deuterium molecules in the gas mixture $\text{H}_2:\text{D}_2:\text{He} = 1:8:180$ means that a copious supply of deuterium atoms is available in the sample, leading to a higher production of hydrogen atoms.

The exchange tunnelling reactions can be used to produce very large concentrations of atomic hydrogen in these mixed solids. In the Cornell studies samples obtained from a variety of initial gas mixtures have been investigated in order to determine the one which yields the highest hydrogen atom concentration.⁴⁴ The experimental plot shown in Fig. 8 gives the H and D average concentrations after a storage time ~ 500 min following initial sample preparation. The largest concentration, of order $(7.5 \pm 3.0) \times 10^{17} \text{ cm}^{-3}$, was obtained by using the gas mixture $\text{H}_2:\text{D}_2:\text{He} = 1:4:100$.

Figure 8. The dependence of the average concentrations of H atoms (1) and D atoms (2) in Im-He solids on the fraction of hydrogen gas in the make up gas mixture.⁴⁴ For each point the concentrations were determined after a waiting period of 500 minutes following sample collection.

The very long term stability of the sample obtained from this gas mixture at a temperature of $T = 1.35 \text{ K}$ has also been studied in these investigations.⁵¹ The time dependence of the logarithm of the average concentrations of H and D atoms in the sample produced from an initial gas mixture $\text{H}_2:\text{D}_2:\text{He} = 1:4:100$ is displayed in Fig. 9. The concentration of H atoms remained constant throughout the 40-h experiment. During the same period of time, the concentration of D atoms decreased from its initial value of 10^{17} cm^{-3} by 2.5 orders of magnitude. The reaction (4) continued to eliminate D atoms and generate H atoms in the $\text{HD}-\text{D}_2-\text{He}$ solid during the long-term experiment. From the decay rate of the D atoms, one can estimate a rate constant, $k_{\text{D-HD}}$, for this reaction from the equation

$$\frac{d[\text{D}]}{dt} = -k_{\text{D-HD}}[\text{HD}][\text{D}].$$

The decay time of D atoms was determined from the slope of the line presented in Fig. 9; $k_{\text{D-HD}} = 2.9 \times 10^4 \text{ s}$. Assuming the impurity cluster density is close to that of solid D_2 , one finds an initial HD concentration equal to $9.3 \times 10^{21} \text{ cm}^{-3}$ and a rate constant $k_{\text{D-HD}} = 3.6 \times 10^{-27} \text{ cm}^3 \text{ s}^{-1}$, which agrees with the value found by Kumada *et al.*²⁷ in bulk samples.

The time dependence of the ratio of the satellite line to the main line for hydrogen and deuterium atoms was studied for a $\text{HD}-\text{D}_2-\text{He}$ sample, while the tunnelling reaction (4) was occurring. The time dependence of these ratios for H and D

Figure 9. Time dependence of the logarithms of the average concentration of H atoms (1) and D atoms (2) in $\text{HD}-\text{D}_2-\text{He}$ solids immersed in superfluid helium at $T = 1.35 \text{ K}$.⁵¹ Sample was prepared from $\text{H}_2:\text{D}_2:\text{He} = 1:4:100$ gas mixture.

atoms is shown in Fig. 10. It was found that for H atoms, the ratio is equal to 0.11 and this value remains essentially constant during the course of the reaction. Thus, by Eqn (9), the average number of HD molecules surrounding H atoms in the sample does not change during the experiment. Due to the tunnelling reaction (5), a hydrogen atom might migrate to the next site in the solid matrix and possibly meet another hydrogen atom, which could lead to recombination and decay of the hydrogen atom concentration. However, this process is predicted to be ~ 200 times slower than the diffusion of H through H_2 by tunnelling.¹² The observed stability of hydrogen atoms in the sample being discussed is not yet completely understood. Additional studies of the immediate environment of the stabilised atoms are needed for further elucidation of the nature of the tunnelling reactions.

Figure 10. Time dependence of the ratio of the intensities of the satellite and the main lines (B) for hydrogen atoms (1) and deuterium atoms (2) in $\text{HD}-\text{D}_2-\text{He}$ solids stored at $T = 1.35 \text{ K}$.⁵¹

In contrast, for D atoms the ratio was reduced from 0.2 to 0.14 in 14 h, showing that the number of HD molecules surrounding D atoms is decreased by 30%. The D atoms consume HD and release H atoms. The rate process is complicated by the fact that the D atoms exist in a variety of sites having between zero and twelve neighbouring HD molecules. The population of these sites initially follows a binomial distribution, with 40% of the neighbours of the D atoms being

HD and the remainder being D₂. The lifetime of a D atom in a given site is inversely proportional to the number of HD neighbours, so that over time the distribution of sites becomes skewed toward D atoms occupying sites with fewer HD nearest neighbours that show smaller satellite line ratios.

3. Pulsed ESR studies of H and D atoms in clusters forming Im–He solids

The CW method suffers from a high degree of inhomogeneous line broadening due to the neighbouring nuclei and atomic radicals. As we mentioned earlier, this broadening obscures the observation of satellite lines associated with transitions involving the spin flip of an electron and a simultaneous spin flip of a deuteron on a neighbouring HD or D₂ molecule. The standard pulsed ESR method of echo refocusing provides a means to study these weak couplings within inhomogeneously broadened systems. As discussed earlier, a homemade pulsed homodyne X-band spectrometer, designed for the study of atoms in Im–He solids, was used in the experiments at Cornell.⁴⁵ A primary echo sequence of 90°–τ–180°–τ–echo with a 90° pulse length of 40 ns was used. To obtain the dependence of the amplitude of spin echo signals on the time between subsequent pulse pairs, τ was varied from 460 ns to 12 μs, while the recovery time *t* between successive pulse sequences was held constant at 400 ms. The method of ESEEM proved to be a powerful technique for observing spin flips on neighbouring deuterons. The first experiments were performed on D–D₂–He samples prepared from a gas mixture with a ratio D₂:He = 1:20. Figure 11 displays the experimental electron spin echo amplitude vs. τ, giving the ESEEM trace along with the simulated one for the low field hyperfine line of

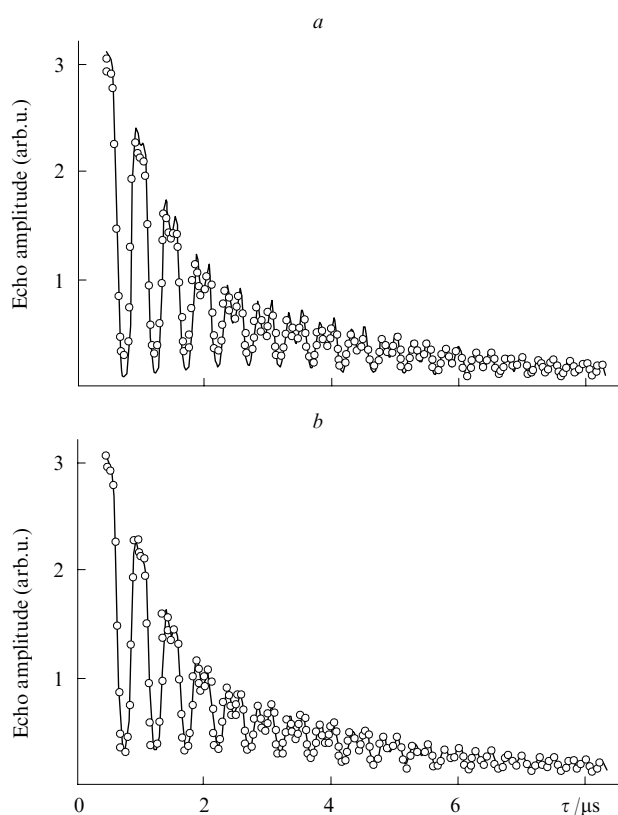

Figure 11. Two-pulse ESEEM trace of the low field hyperfine line of D in D₂–He sample.⁵⁴ (a) The circles show every fourth data point. The line shows the best fit of the bulk population model. (b) The circles show every fourth data point. The line shows the best fit of the two population (bulk and surface) model $E(\tau)$.

the D atom. The echo signal intensity decreased monotonically and was strongly modulated by the first and second harmonics of the Larmor frequency of deuterons in the molecules near the D atoms. The applied magnetic field couples to the deuterons much more strongly than the field due to the electron spins, so the applied magnetic field determines the ~2 MHz Larmor frequency of the deuterons. The amplitude of the modulation depends on the number of deuterons surrounding the D atoms and their proximity to those atoms. The amplitude of modulation is also proportional to $I(I+1)$, where *I* is the nuclear spin quantum number of the molecule interacting with the D atom. Therefore the amplitude of modulation of ESEEM signals for atoms surrounded by D₂ molecules with *I* = 2 and *I* = 1 should be much larger than for the case of atoms surrounded by protons (as a constituent of HD) with *I* = 1/2. This difference is especially pronounced at low temperatures because the ground state of D₂ is predominantly of the *I* = 2 form and conversion to the ground state occurs rapidly in the vicinity of the unpaired electron spins of the hydrogen and deuterium atoms. The ESEEM signal associated with the proton moment has not been observed in our experiments.

For analysis of the experimental ESEEM data the model used initially was that developed by Kumada *et al.*³¹ to study D atoms in bulk D₂. They simulated their ESEEM signals with the standard theoretical results for orientationally disordered crystalline systems.⁵⁵ This model assumes that all possible orientations of the face centred cubic (fcc) deuterium crystal axis with respect to the applied magnetic field are equally represented within the sample. The Hamiltonian includes terms representing electron–nuclear interactions through dipolar magnetic coupling and an isotropic superhyperfine coupling due to the contact interaction of the electronic wave function with the nuclear wave function of the nearest neighbouring molecules. No internuclear couplings are included; as a result, the echo modulation due to the presence of several nuclei surrounding the electron spin is simply the product of the modulation due to each individual nucleus.

The echo signal as a function of the interpulse time τ was modeled as:

$$E(\tau) = E_{\text{dec}}(\tau)E_{\text{b}}(\tau),$$

$$E_{\text{b}}(\tau) = \prod_{i=1}^5 \langle E_i(\tau) \rangle_{\theta}^{N_i},$$

$$E_{\text{dec}}(\tau) = Ae^{-\tau/T_2},$$

where $E_{\text{dec}}(\tau)$ contains the characteristic exponential decay time T_2 of the electron spin echo and $E_{\text{b}}(\tau)$ represents the modulation of the echo due to the N_i molecules populating the closest five coordination shells $i = 1-5$ around the electron spin. The modulation functions $E_i(\tau)$ due to each individual molecule are averaged over all orientations before they are multiplied. This unphysical feature of the model is computationally expedient and causes only slight changes in the predicted echo signals for systems with weak electron–nuclear couplings such as hydrogen or deuterium atoms substitutionally positioned within a deuterium matrix.⁵⁶

At liquid helium temperatures D₂ can exist in ortho- and para-states corresponding respectively to the *J* = 0 and *J* = 1 rotational states of the molecule. The para state is 85 K more energetic than the ortho-state but its conversion to the ortho-state is highly forbidden. Deuterons are bosons, so the product of the spatial and spin wave functions of the deuterons must be symmetric under particle exchange. The allowed molecular spin states are then *I* = 0 and *I* = 2 for ortho-deuterium and *I* = 1 for para-deuterium. The energy difference between the *I* = 0 and *I* = 2 states is extremely small compared to the

thermal energy, so the populations of the states are determined by their degeneracy. As there are five orientations of the $I = 2$ state and one orientation of the $I = 0$ state, 5/6 of the ortho-deuterium molecules are in the $I = 2$ spin state, while 1/6 of the ortho-deuterium molecules are in $I = 0$ spin state. The para-to-ortho relaxation of deuterium is catalysed by the magnetic field gradients produced by paramagnetic species, so that all of the deuterium molecules in the nearby coordination shells around a D atom can be assumed to be of the ortho-form. As the $I = 0$ molecules are not magnetically active, the number of molecules in each coordination shell must be adjusted accordingly. For example, for an atom substitutionally positioned in D_2 fcc, the first shell of twelve nearest neighbours is modelled with ten spin-2 particles, each possessing the Larmor frequency of the deuteron.

Ponti⁵⁷ has shown that Chebyshev polynomials of the second kind relate the ESEEM modulation function due to a particle of any spin to the modulation function that would result if that particle were spin 1/2. Specifically,

$$E_i(\tau) = \frac{1}{2I+1} U_{2I}[V_i(\tau)],$$

where U_n is the n th Chebyshev polynomial of the second kind and $V_i(\tau)$ is the spin 1/2 modulation function. Finally, the explicit form of $V_i(\tau)$ is

$$V_i(\tau) = \frac{K}{2} \left[1 - \cos(\omega_\alpha \tau) \right] \left[1 - \cos(\omega_\beta \tau) \right],$$

$$K = \left(\frac{B\omega_L}{\omega_\alpha \omega_\beta} \right)^2,$$

$$B = 3g_n \beta_n g_e \beta_e \frac{\cos \theta \sin \theta}{\hbar(r_i)^3},$$

$$\omega_L = g_n \beta_n H_0,$$

$$\omega_\alpha = \left[\left(\frac{A}{2} + \omega_L \right)^2 + \left(\frac{B}{2} \right)^2 \right]^{1/2},$$

$$\omega_\beta = \left[\left(\frac{A}{2} - \omega_L \right)^2 + \left(\frac{B}{2} \right)^2 \right]^{1/2},$$

$$A = g_n \beta_n g_e \beta_e \frac{3 \cos^2 \theta - 1}{\hbar(r_i)^3} + 2\pi a_{\text{sup}},$$

where r_i is the distance from the electron to coordination shell i , θ is the angle between the applied field H_0 and the vector pointing from the radical to the molecule, g_e and g_n are the g -factors of the electron and nuclear spins, β_e and β_n are the Bohr and nuclear magnetons, and a_{sup} is the isotropic superhyperfine coupling.

Kumada *et al.*³¹ fitted a_{sup} and r_i to their data obtained from pure irradiated solid deuterium for two sets of N_i and r_i . One set corresponded to the environment around substitutional sites in the D_2 fcc lattice and the other set corresponded to the environment around interstitial sites. The predicted modulation functions were radically different (the interstitial sites have much deeper modulation due to the smaller nearest neighbour distances) and it was immediately clear that the D atoms reside in the substitutional sites. Numerical fitting gave $r_i = 3.6$ Å, corresponding to the nearest neighbour spacing of the unstrained molecular lattice, and $a_{\text{sup}} = 70$ kHz.

Applying the above model to our Im–He solid gave poor agreement with the data obtained for the D– D_2 –He sample

as presented in Fig. 11 *a*. For Im–He solids it is reasonable to suggest that atoms are stabilised not only inside molecular clusters, but also on the surfaces of these clusters. Following this suggestion, the experimental ESEEM data were fitted with two decaying exponentials multiplied with two oscillatory modulation terms:

$$E(\tau) = A \left[Q e^{-\tau/T_{2Q}} + (1-Q) e^{-\tau/T_{2L}} \right] \left[b E_b(\tau) + (1-b) E_s(\tau) \right],$$

where A , Q , T_{2Q} and T_{2L} parameterise the echo decay and b weights the modulation functions E_b and E_s .⁵⁴ The function E_b simulates the ESEEM signal of D atoms within the solid clusters by assuming they are substituted into an fcc lattice composed of D_2 molecules. The modulation signal E_b produced by atoms positioned within deuterium nanoclusters was identical to that described above for atoms substituted in bulk deuterium. The function E_s is produced by the same model, but with the population of each coordination shell around the atom reduced by one-half. This simulates D atoms at the surfaces of the clusters in contact with the helium. We fixed r_i and a_{sup} to the values found to describe bulk deuterium so that our modulation function contained only one free parameter, the ratio of atoms within the deuterium nanoclusters to atoms at the cluster–helium interface. The functional form of the echo decay was found empirically to fit the data well with a small number of parameters. Notably, modelling the data with separate decay functions for the bulk and surface terms results does not improve the fits.

As a result of applying the modified model, the two-pulse ESEEM measurements presented in Fig. 11 *b* were well described by fits that placed 50%–60% of the deuterium atoms at the interface between the molecular deuterium nanoclusters and the superfluid liquid helium.⁵⁴ The rest of the atoms occupy substitutional sites within the nanoclusters. These pulsed ESR measurements provide the first direct indication that a large fraction of the atomic radicals within impurity–helium solids reside on the cluster–helium interfaces, as first suggested by Gordon.⁵⁸ This result implies that some mechanism causes the deuterium atoms to preferentially occupy the nanocluster surfaces, whereas a random substitution of the deuterium molecules of the clusters would only place 10%–20% of the atoms at the cluster–helium interface, depending on the cluster size.

The measurements of ESEEM signals by pulsed ESR provide complementary information about deuterons surrounding H and D atoms in solid mixtures of hydrogen isotopes that cannot be provided by CW ESR due to the small deuteron magnetic moment. The ESEEM signal associated with ESR studies of H atoms in a HD– D_2 –He solid produced from an initial gaseous mixture $H_2:D_2:He = 1:4:100$ is shown in Fig. 12 *a*. For the analysis of the ESEEM data, the model applied for D– D_2 –He solid was modified to account for the presence of D_2 and HD molecules surrounding the atoms, with the ratio of HD and D_2 molecules allowed to vary as a fitting parameter. The fraction of atoms at the surface was assumed to be 55%, the same as was found in the D_2 –He solid.⁵⁴ The best fit in a model calculation of the ESEEM signal of the H atoms, which is represented as a solid line in Fig. 12 *a*, was obtained for a configuration in which ten deuterium and two HD molecules surrounded the H atoms.⁵⁹ The ESEEM signals for H atoms recorded at the beginning of the experiment and 6 hours later were identical, showing that the number of D_2 and HD molecules surrounding the H atoms did not change as the reaction proceeded. This result was in agreement with previously described CW experiments in which the satellite amplitudes remained unchanged throughout the experiment.⁵¹

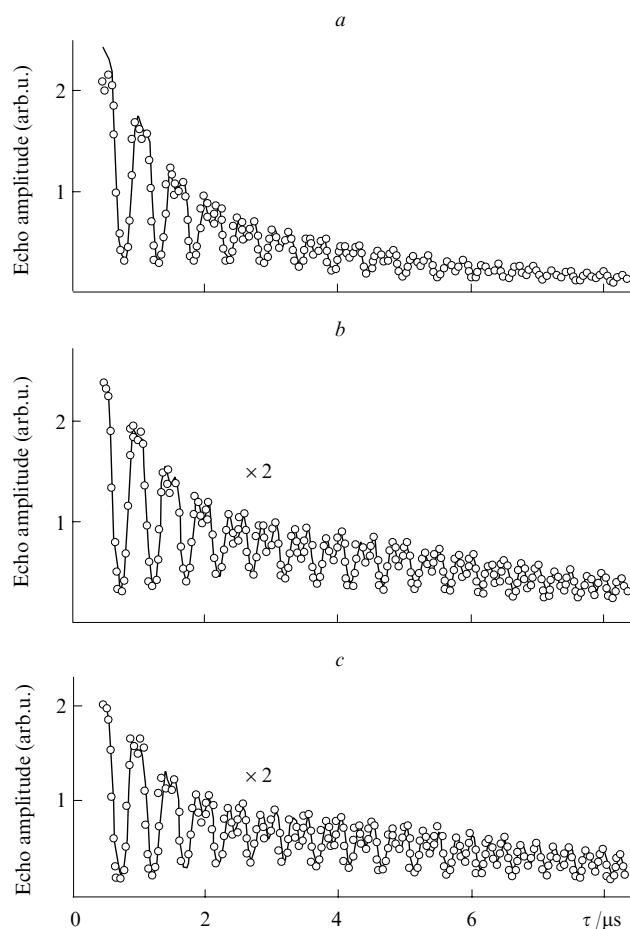

Figure 12. Two pulse ESEEM signals (circles) for the H and D atoms in HD–D₂–He solid at 1.35 K taken at 8.93 GHz: (a) low field hyperfine component of H atoms at 2910.1 G; (b, c) low field hyperfine components for D atoms at 3105.5 G at the beginning of the experiment and six hours later, respectively. Solid lines are the best fits of model calculations to the experimental data (see text).⁵⁹

The ESEEM data for D atoms show that their number decreases over the course of the tunnelling reaction (see Figs 12 *b* and 12 *c*). Modelling of the ESEEM signals for D atoms in the HD–D₂–He solid obtained at the beginning of the experiment (solid line in Fig. 12 *b*) shows that nine D₂ and three HD molecules surrounded a typical D atom within the bulk of the cluster. The same model shows that six hours later (see Fig. 12 *c*) ten D₂ and two HD molecules surrounded a typical D atom. This result is also in good agreement with the results obtained from CW ESR measurements discussed earlier, which suggested that the number of protons (and thus the number of HD molecules) surrounding the D atoms decreases by about 30% in the first six hours following the formation of the sample obtained from the H₂:D₂:He = 1:4:100 gas mixture.

In conclusion, the CW and pulsed ESR methods provide complementary information about the trapping sites and the changing environment of atoms participating in low temperature tunnelling reactions. This information is particularly important for elucidation of the mechanisms of tunnelling reactions of hydrogen atoms.

IV. Studies of H atoms in solid H₂ films at ultralow temperatures

The methods for creating systems of matrix isolated hydrogen atoms mentioned above led to the formation of highly inhomogeneous solids with many defects. In all of these methods one gets quite irregular solids, where the diffusion of the atoms is mediated by inhomogeneities of the crystalline field.

A novel method of ultra-slow deposition of films of solid H₂ with embedded hydrogen atoms has been recently discovered in experiments with spin polarised atomic hydrogen gas.⁴² It is well known that spin-polarised atomic hydrogen gas can be stabilised at temperatures approaching absolute zero (see Ref. 60 and references therein). Atoms are stabilised by applying a strong magnetic field and lining the walls of the experimental cell with a superfluid helium film, thus preventing adsorption of the atoms. The schematic of a typical experimental setup for studies of spin-polarised H gas (H↓) is presented in Fig. 13. Atomic hydrogen gas is produced in a cryogenic radiofrequency dissociator, and the high field-seeking fraction (H↓) is pulled into the sample cell located in a 4.6 T magnetic field. The typical flux of atoms entering the sample chamber (SC) (see also Fig. 14 *a*) is $\sim 2 \times 10^{13} \text{ s}^{-1}$. With the continuously operating dissociator, bulk gas densities up to $2 \times 10^{15} \text{ cm}^{-3}$ can be accumulated in the SC at a temperature of $\sim 350 \text{ mK}$. H↓ atoms of both lowest hyperfine states *a* and *b* (Fig. 14 *b*) are accumulated in equal amounts. The H↓ samples were not perfectly stable against recombination of the atoms into H₂ even in very strong ($> 10 \text{ T}$) magnetic fields due to the unavoidable three-body recombination channel. The molecules resulting from recombination stick to the walls of the experimental chamber and slowly form a layer of solid H₂. This layer in the experiments with H↓ helps to reduce the decay rate of the sample due to one-body nuclear relaxation. A typical rate for solid H₂ film growth is very slow, 0.5–1 molecular layer per hour, which is mainly limited by the efficiency of the radiofrequency dissociator.

Figure 13. Block diagram of the setup for investigations of H atoms in solid H₂ at ultralow temperatures. The label MC denotes the mixing chamber of the ³He–⁴He dilution refrigerator.

Figure 14. Schematic drawing of the sample cell (a); hyperfine level diagram for hydrogen atom in a strong magnetic field (b).⁴²

(a) Fabry–Perot ESR resonator (1), helical NMR resonator (2), Mylar foil (3), quartz microbalance crystal (4). (b) Arrows denote electron and nuclear spin projections. The values of the angles θ are determined from the equation $\tan 2\theta = a/[h(\gamma_e + \gamma_p)H]$, where a is the hyperfine constant, H is the magnetic field and γ_e , γ_p are the electron and proton gyromagnetic ratios, respectively.

It has been found that H atoms are captured inside the solid H_2 films covering the SC walls.⁴² The mechanism of this process is not known. One of the possibilities is that the molecules appear in the gas phase in one of the highest rovibrational states⁶¹ and may transfer their energy to the atoms in binary collisions. The energy acquired by the atom in such an event can exceed the potential barrier for the atoms to penetrate into the helium film (~ 40 K), and therefore the atom can punch through the film and stick to the solid H_2 . It has been verified that the atoms do not appear in the sample cell as a result of diffusion from the dissociator along the solid H_2 film covering the surface of the fill line. Closing the hydraulic valve at the cell bottom stopped the growth of the atomic ESR signal. Although very slow, this method of deposition of films of H_2 with embedded H atoms has a number of advantages in comparison with the traditional methods of creating such systems employed earlier. The system is absolutely free of any possible impurities, since no other gas, except H_2 can exist at temperatures below 1 K. Although some small admixtures ($< 10^{-4}$) of spin-polarised deuterium can be generated in the dissociator, they cannot reach the sample cell passing through the 0.5 m long filling line, since the recombination rates for D are $> 10^3$ times larger than for H. Another advantage of this method is that the deposition rate and

average energy flux into the system is so slow that one may expect to obtain solid crystals with the least amount of internal crystalline defects, thus making this system very close to ideal for studies of quantum diffusion and tunnelling chemical reactions.

Due to the strong magnetic fields needed for the stabilisation of H_2 , high frequency (128 GHz) ESR and 910 MHz NMR and ENDOR methods were used to characterise the samples. The H_2 films containing H atoms were situated on the surface of the Mylar foil and on the lower spherical mirror (see Fig. 14 a), both located at antinodes of the Fabry–Perot resonator (FPR) operating in the TEM_{005} mode (see Refs 43 and 60 for more details of the experimental setup).

The ESR spectrum of H atoms in solid H_2 in the applied magnetic field of 4.6 T basically consists of two lines separated by 507 G due to the hyperfine interaction. In Fig. 15 (upper trace) the ESR spectra of the lower field line of H atoms in solid H_2 are presented together with the corresponding line originating from the atoms of the gas phase above the film obtained at $T \sim 350$ mK. Special shim coils were used to minimise the magnetic field inhomogeneity, or *vice versa*, to increase the gradient and resolve the absorption lines originating from the atoms located on the Mylar foil and the lower mirror. Integrals of these lines were equal to each other, which indicates a homogeneous film coating over the sample cell walls. Having the possibility to resolve the lines from the free atoms in the gas phase and the matrix isolated ones, one can obtain useful information about the influence of the crystal environment on the g -factor and the hyperfine constants. The ESR lines of H atoms in solid H_2 were found to be shifted by ~ 0.28 G towards the centre of the spectrum compared with those of free atoms (see Fig. 15) with the magnitude of the shift being the same for both ESR lines. Therefore, the atoms in the solid have the same value of the g -factor and a somewhat reduced hyperfine interaction.

Figure 15. ESR spectra of the H_2 gas and of H atoms in the solid H_2 matrix observed in the measurements: upper left trace is small H_2 density $\sim 2 \times 10^{13} \text{ cm}^{-3}$ (left peak) together with the H in solid H_2 line (right peak); bottom traces are H in solid H_2 spectrum.⁴² Note that the $a-d$ transition signal is larger than the $b-c$ transition signal.

To manipulate the populations of the states a and b , nuclear spin transitions were induced by applying resonant excitation to the helical 910 MHz resonator (HR) located on the side of the FPR (see Fig. 14 a). Due to the small number of atoms in the sample and the poor sensitivity of NMR, it is not possible to detect the NMR absorption directly. However, one can detect it through the change of the ESR signal associated with the change of the populations of hyperfine states. For observation of such double resonance spectra, the allowed

electron $b \rightarrow c$ transition was saturated with high excitation power while the ESR sweep was stopped in the middle of the H in H_2 line. Then a radiofrequency signal was applied to the helical NMR resonator (HR) with its frequency swept through the position of the nuclear $a \rightarrow b$ transition (near 909 MHz). The power absorbed by the ESR is increased once the nuclear resonance condition is reached, since the atoms are transferred from the a to the b state (Fig. 16). The position of the ENDOR line relative to that of the free atoms gives the value of the hyperfine constant change $-1320(10)$ kHz. This reduction of the hyperfine constant with respect to the free atoms implies that the atoms are situated in substitutional sites. In this case the effects of van-der-Waals attraction to the neighbouring molecules dominate over the Pauli repulsion.⁶² A similar conclusion has been made in the ENDOR studies of Nagoya group³⁰ for the H in H_2 samples obtained by a different method. A remarkable feature of the ENDOR spectra observed in the films of H in H_2 created by the slow deposition method⁴² is the unusually small width of the NMR transition (~ 15 kHz). This provides good evidence of the high quality of the H_2 crystals obtained by this method.

Figure 16. ENDOR spectrum of hydrogen atoms in solid H_2 .⁴²

Another interesting feature found in the experiments with the H in H_2 films⁴² was the very high stability of the atoms to recombination (Fig. 17) at temperatures below 150 mK. For this temperature range no decay of H atoms was detected over a period of at least two weeks. A slow decrease of H atom concentration has been observed at 300 mK and 480 mK. Figure 18 shows the values of the recombination rate constants obtained in these experiments compared with the previous higher temperature results and with the theoretical predictions. It has been found that for temperatures below 0.9 K the recombination rate constants, $k_H(300 \text{ mK}) = 1.5 \times 10^{-25} \text{ cm}^{-3} \text{ s}^{-1}$ and $k_H(480 \text{ mK}) = 3 \times 10^{-25} \text{ cm}^{-3} \text{ s}^{-1}$ are much smaller than predicted theoretically^{7,63} and found in previous experiments⁸ at $1.35 < T < 4.2$ K. However, at the highest temperatures (900 mK) used in the studies of the H in H_2 films⁴² the rate constant increased substantially and came into close agreement with extrapolation of the previous results. The vanishingly small recombination at the lowest temperatures makes it promising to achieve extremely low temperatures for this metastable system in future experiments, since recombination heating would not be a factor.

Populations of the lower hyperfine states can be manipulated by saturation of the ESR or NMR transitions. Saturating the $b \rightarrow c$ transition leads to the pumping of the atoms from the state b to a (via the Overhauser effect) through the relaxation of

Figure 17. Decay of H in H_2 sample at different temperatures.⁴² T/mK : (1) 150 (lower time scale), (2) 300, (3) 480, (4) 900 (all upper time scale).

Figure 18. Temperature dependence of logarithm of rate constant for recombination of H atoms in solid H_2 : our experimental results at $T < 1$ K (1), experimental results⁸ for the temperature range $1.3 < T < 4.2$ K (2) and theoretical prediction for $T < 1$ K (3).⁷

the partially forbidden $a \rightarrow c$ transition. The relaxation time of the $a \rightarrow c$ transition of H atoms inside H_2 films is about 3 s. Using the Overhauser effect, one can transfer the entire population to the a state within several seconds. Then the a and b populations can again be equalised by applying resonance power to the $a \rightarrow b$ transition. Recovery of the population ratio n_a/n_b or the polarisation

$$p = \frac{n_a - n_b}{n_a + n_b}$$

to the equilibrium value is controlled by the nuclear relaxation process which turns out to be very slow, $t_{b \rightarrow a} \sim 60\text{--}80$ h at 150 mK (Fig. 19). A most intriguing observation in the experiment of Ref. 42 was the non-Boltzmann population of the hyperfine states b and a in the steady state. The populations ratio is typically characterised by the value of nuclear polarisation. The value of $p(t \rightarrow \infty) = 0.5(1)$ observed at $T = 150$ mK was much larger than $p \approx 0.14$ dictated by the Boltzmann statistics with $n_a/n_b = \exp(E_{a-b}/T)$, with $E_{a-b} \approx 43$ mK being the energy difference between the a and b states. The

Figure 19. Evolution of the nuclear polarisation $p = (n_a - n_b)/(n_a + n_b)$ at $T = 150$ mK after saturation of the $b-c$ transition (1) and after partial saturation of the $a-b$ transition (2). The horizontal dashed line marks the nuclear polarisation corresponding to a thermal (Boltzmann) ratio $n_a/n_b = \exp(E_{a-b}/T)$ with $T = 150$ mK.⁴²

non-equilibrium population ratio observed in these experiments can be explained by the possible formation of a Bose–Einstein condensate (BEC) in the ensemble of atoms. This cannot occur if the atoms are evenly distributed over the crystal because the average density is not high enough to reach quantum degeneracy. If however, there are regions in the crystal with much higher local concentrations, the condensation may happen there and the system should then consist of two kinds of atoms, those in the high concentration regions and those in the rest of the crystal.

A powerful concentrating mechanism such as the phase separation seen in solid ^3He – ^4He mixtures^{64,65} and potentially in ortho-para solid H_2 mixtures^{66,67} is required to reach a concentration of $\sim 5 \times 10^{20} \text{ cm}^{-3}$, which corresponds to a BEC onset temperature of 0.2 K for H atoms with effective mass $3.5 m_{\text{H}}$ as calculated from the experimental n_a/n_b population ratio. Diffusion of the H atoms *via* exchange tunnelling can be considered as a motion of ‘quasivacancies’, leading to a broad energy band and low effective mass.⁶⁸ One might imagine that the H atom rich phase exists in small bubbles or layers surrounded by the H atom starved phase.

V. Conclusions and future work

Impurity–helium solids are highly porous gel-like nanomaterials consisting of interconnecting clusters of impurities with a characteristic size 5–9 nm and an average density over the entire sample volume as low as 10^{20} atoms (molecules) cm^{-3} . In fact, Im–He solids are a collection of nanoclusters. One cubic centimeter of a typical Im–He sample contains a large number ($\sim 10^{16}$) of clusters, each consisting of $\sim 10^4$ molecules and 10–100 or more stabilised atoms. Therefore, it is possible to study simultaneously a large collection of nanoreactors, in which low temperature chemical reactions can be investigated.

The kinetics of exchange tunnelling reactions of hydrogen isotopes were studied in nanoclusters immersed in superfluid helium at $T = 1.35$ K. The rate constants for different reactions have been determined and the changes of the environments of hydrogen and deuterium atoms in the course of these reactions have been studied. The rate constants for reactions (2) and (4) in nanoclusters were found to be similar to those obtained in bulk solids. In contrast, the rate constant for the reaction (1) in nanoclusters is an order of magnitude higher as compared to that obtained in bulk solid hydrogen. Possibly the recombination of H atoms occurs primarily on the surfaces of

the nanoclusters. The analysis of the pulsed ESR data shows that 50%–60% of all stabilised atoms reside on the surfaces of the nanoclusters.

Reactions between hydrogen atom isotopes might be studied at even lower temperatures. This would shed more light on the details of tunnelling processes in chemical reactions occurring in the solid phase. The study of Im–He solids at ultralow (10–20 mK) temperatures should be pursued. Obviously, such a program will encounter major technological challenges to adapt methods of preparation of Im–He solids with high concentrations of stabilised atoms to the restrictions existing in a dilution refrigerator cryostat. Nevertheless, such investigations could show great promise. Cooling down the H– H_2 –He samples with high concentrations of stabilised H atoms to the temperature region of 10–20 mK could lead to the observation of Bose–Einstein condensation of H atoms.

Another approach to studies of the kinetics of recombination of H atoms in H_2 solids at ultralow temperatures was demonstrated. The technique usually used for studies of spin-polarised hydrogen gas also provided the opportunity to prepare and investigate H atoms in thin molecular films of solid H_2 . For the first time, the recombination rates of H atoms in solid H_2 were studied in the temperature range 0.15–0.9 K. It was found that recombination rate constants are significantly smaller at these temperatures than was predicted theoretically. Moreover, at $T = 0.15$ K, H atoms were very stable during two weeks of observations. At this temperature the population of the lowest hyperfine state of atomic hydrogen was found to be much larger than that expected from the Boltzmann distribution. A possible explanation for this observation is achievement of the Bose–Einstein condensation of H atoms in solid H_2 . This might be possible if regions of high local concentration of H atoms can be created in solid H_2 . Additional studies of the temperature dependence of the populations of the lowest energy levels of H atoms are necessary to confirm whether BEC is actually occurring in this system. Alternative explanations should also be explored in future experiments and theoretical work.

We would like to thank the National Science Foundation (Grant No. DMR-0504683), NASA (Grant No. NAG3-2871) and CRDF (Grant No. RUP1-2841-CG-06) for support prior to and during the preparation of this review. We also are grateful to the Academy of Finland (Grant No. 206109) and the Wihuri Foundation for supporting the research program at Turku University. One of us (D M Lee) would like to thank the Aspen Center for physics, which provided a forum for interesting discussions. The authors take this opportunity to express their gratitude to R Boltnev, S Kiselev, P Borbat, J Freed, E Müller, V Kiryukhin, J Jarvinen, J Ahokas and E Vehmanen for stimulating and useful discussions.

VI. Conclusion	1134

Abstract. Specific features of cryochemical reactions of transition metal atoms, small clusters, complexes and nanoparticles are considered. New phenomena that arise in nano- and subnanoscale systems at low temperatures are analysed. It is shown that the competition between self-assembly processes of metal atoms and reactions of metal aggregates of different size with organic and inorganic reagents determines the chemical nature and properties of the intermediate and final products. Special attention is paid to the analysis of size effects caused by the dependence of the reactivity of metal clusters and nanoparticles on the number of constituent atoms. Prospects for the use of competitive cryochemical reactions are discussed. The bibliography includes 185 references.

I. Introduction

Recent progress in cryochemistry was largely associated with the development of methods for synthesis and stabilisation of atoms, small clusters and nanoparticles incorporating from just a few metal atoms to hundreds and thousands.^{1–5} At present, studies of these systems form the basis of a new direction of chemistry, namely, cryonanochemistry. In cryonanochemistry, attention is focused on the size effects associated with the dependence of the reactivity of clusters and nanoparticles on the number of constituting atoms.¹ Atoms and clusters that emerge in the thermal evaporation of metals in vacuum are much more reactive than bulk metals.⁵ At low

temperatures, these high-energy and extremely reactive particles undergo consecutive and competitive chemical reactions with different organic and inorganic molecules. Low-temperature covalent and non-covalent interactions lead to the formation of new chemical compounds of metals in the zero or lower oxidation states and to the stabilisation of unstable structures and labile coordinatively unsaturated complexes, radicals and unusual molecules. Such systems are of interest for coordination chemistry, chemistry of clusters and organometallic compounds, atmosphere and space chemistry. They may also be used in the development of new metal-containing nanomaterials and in the elaboration of new nanotechnologies.

This review analyses the experimental and theoretical data on competitive cryochemical reactions of metal atoms and small clusters in condensed media, namely, in solid matrices of inert gases (in the presence of one or two active reagents) and in low-temperature co-condensates containing reactive components, for the metals of the first, second and third transition rows. Special sections are devoted to thermal transformations of metastable mono- and polynuclear lanthanide complexes and to chemical reactions of silver and gold atoms, clusters and nanoparticles as the systems most promising for nanochemical and nanocatalytic applications. Attention is focused on the kinetic analysis of competitive chemical reactions that involve metal particles of different sizes and shapes with different ligands. Processes of formation and stabilisation of nanoparticles in low-temperature matrices and co-condensates are considered; mechanisms of their reactions with certain organic and inorganic reagents are discussed and manifestations of size effects typical of reactions of these small-scale chemical entities are analysed. In this review, almost no attention is paid to the problems associated with the development of a new promising research direction, *viz.*, spectroscopic studies of metal clusters and their reactions in solid hydrogen matrices and liquid helium nanodroplets as condensed quantum systems. This is explained by the fact that these problems are of their own, independent importance.

The authors of this review are united by long-term collaboration within the framework of INTAS projects. The material of this review was partly presented as the plenary lectures at the VIth International Conference on Low Temperature Chemistry (Chernogolovka, 2006).

II. Size effects in reactions of atoms and small clusters of transition metals (Sc, Ti, Cr, Fe, Co, Ni, Cu) with organic and inorganic molecules in inert matrices at low temperatures

Reactions of transition metal atoms and clusters with organic and inorganic molecules attract keen attention. Indeed, such processes model the reactions of molecules of various reagents with the active sites on the metal catalyst surface, which allows study of unusual chemical processes including the activation of small molecules such as carbon dioxide and nitrogen.^{6–8} Coordination of CO₂ to metal sites is the key stage of its catalytic and electrochemical reduction.^{9–11} The method of matrix spectroscopy makes it possible to identify intermediate products of various reactions and elucidate the mechanism of metal coordination with ligand molecules.

The reactions of atoms of the 1st transition series elements (Sc, Ti, Cr, Fe, Co, Ni, Cu) with carbon dioxide were studied systematically by matrix Fourier transform IR spectroscopy (FT IR) using isotopically labelled molecules ¹³CO₂ and C¹⁸O₂.^{12–15} The obtained results together with density functional theory calculations made it possible to determine the equilibrium parameters of formed complexes and elucidate the coordination type of a metal. It was shown that in a carbon dioxide matrix at 10 K, metal atoms of the first transition rows (Fe, Co, Ni and Cu) form 1 : 1 complexes with CO₂ molecules. In these complexes, the coordination of these molecules to metal atoms was of the ‘side-on’ ($\eta^2_{O,O}$) type for nickel, the ‘end-on’ ($\eta^1_{C,O}$) type for copper and the C type (η^1_C) for iron (Fig. 1). The energy of a bond formed by a nickel atom with CO₂ was 17.5 kcal mol^{–1}, which is comparable with the binding energies of this atom in its complexes with similar molecules, namely Ni(C₂H₄), Ni(C₂H₄)₂ and NiCO.^{16–20} On the other hand, atoms of elements situated in the beginning of this period (Ti, V and Cr) effectively inserted into C–O bonds of CO₂ molecules to form oxocarbonyl derivatives (O)M(CO)(CO₂). According to calculations, the insertion of a titanium atom into a C–O bond of the CO₂ molecule proceeded virtually without activation and the thermodynamic stability of a (O)Ti(CO) molecule substantially exceeded the stability of possible complexes Ti(CO₂) (Fig. 2). The interaction of a titanium atom with the second CO₂ molecule resulted in the formation of an even more stable (O)Ti(CO)(CO₂) complex [$D_e(\text{CO}_2) = 28 \text{ kcal mol}^{-1}$, D_e is the energy of ligand bonding] in which the CO₂ molecule turned out to be in the ‘side-on’ coordination with respect to the titanium atom and the fragments (O)Ti(CO) and Ti(CO₂) were located in perpendicular planes.

Figure 1. Types of complexes formed in the reaction of transition metals with CO₂.

Type: (a) $\eta^2_{O,O}$, (b) $\eta^1_{C,O}$, (c) η^1_C , (d) η^1_O .

Figure 2. Possible structures of complexes formed in the titanium reaction with CO₂.¹²

(I–VI) are the types of structures corresponding to different steps of optimisation.

It was found²¹ that excited titanium atoms insert into C–H bonds of ethylene molecules in argon matrices at 10 K upon irradiation of samples with light with a wavelength > 400 nm. The TT IR method using isotopically labelled ethylene molecules ¹²C₂H₄, ¹³C₂H₄, C₂D₄, CH₂CD₂ and natural titanium isotopes revealed the formation of compounds containing Ti–C bonds, namely, titanacyclopentene H₂Ti(C₂H₂) and vinyltitanium monohydride. The appearance of monoligand titanium π -complexes Ti(C₂H₄) was not confirmed experimentally, although model calculations carried out within the framework of the density functional theory (DFT) predicted the presence of strong bonding in this case. Titanium hydrides and carbonyls were obtained in the co-condensation of metal atoms with ligand molecules at superlow temperatures in inert matrices.^{22–25}

In argon-diluted systems at low temperatures (10–30 K), virtually no interaction of atoms of the metal group under consideration with CO₂ was observed. The competitive interaction of nickel simultaneously with two ligands (N₂ and CO₂) in dilute argon matrices led to an unexpected result, the cooperative effect of co-ligands.¹² The binding of CO₂ molecules into a complex was substantially intensified when N₂ molecules were added to the argon matrix. The preliminary coordination of a nitrogen molecule into transient Ni(N₂) species induced the hybridisation of 4s and 3d orbitals of the nickel atom, which intensified the Ni → CO₂ charge transfer in a mixed-ligand complex Ni(CO₂)(N₂) as compared with a monoligand Ni(CO₂) complex. The obtained data are well described by a model ‘electron donation L → M/back donation M → L’ (the Chatt–Dewar–Duncanson model), which was used for the description of these systems.^{26–28} A comparison of potential energy curves of these interactions have shown that the binding energy of a nickel atom with the CO₂ molecule is 17.5 kcal mol^{–1}, whereas the binding energy of a Ni(N₂) complex with the CO₂ molecule is almost twice as high, namely, 32 kcal mol^{–1}.

A reaction of copper with molecular nitrogen was studied in nitrogen and argon matrices by the FT IR and UV-Vis spectroscopic techniques.²⁹ In argon matrices with a constant ratio metal : matrix = 1 : 1000, the aggregation of metal atoms was determined by the nitrogen content. The Cu₂ : Cu ratio in a nitrogen matrix was larger than in an argon matrix and decreased upon dilution with argon. The co-condensation led to the formation of two complexes of copper dimers with the ‘end-on’ coordination of ligands, namely, mono- [Cu₂(N₂)]

and bisligand $[\text{Cu}_2(\text{N}_2)_2]$ complexes with binding energies of 7.9 and 12.8 kcal mol⁻¹, respectively.

No complexes were formed in argon-diluted systems with a ratio $\text{N}_2:\text{Ar} < 0.5$ that contained infinitesimal amounts of copper aggregates.²⁹ The interaction of copper atoms with nitrogen molecules started with the addition of a second ligand, CO, into the system. This was manifested by the formation of mixed complexes of copper atoms $\text{Cu}(\text{N}_2)\text{CO}$ for which the energies of ligand bonding [$D_e(\text{Cu}-\text{CO}) = 17.2$ and $D_e(\text{Cu}-\text{N}_2) = 7.5$ kcal mol⁻¹] were substantially higher as compared with the corresponding monoligand complexes, namely, 9.5 kcal mol⁻¹ for $\text{Cu}-\text{CO}$ and -0.1 kcal mol⁻¹ for $\text{Cu}-\text{N}_2$. The strong polarisation of 4s orbitals in a dimer Cu_2 substantially weakened the σ -repulsion between the lone electron pair of a ligand and the $4s^1 3d^{10}$ electron shells of a copper atom in Cu_2L complexes. Thus, in the systems under consideration, dimeric nitrogen complexes $\text{Cu}_2(\text{N}_2)$ were preferentially formed.

Co-condensation of thermally evaporated copper atoms with carbon dioxide and an excess of argon afforded no reaction products. Co-condensation of copper vapour with an excess of carbon dioxide in the absence of matrix components led to the formation of 'end-on' monoligand complexes.¹² Density functional theory calculations using the 'Gaussian 03' computational package and the B3LYP functional were aimed at the comparison of reactivities of Cu atoms and Cu_2 dimers with respect to carbon dioxide and carbon disulfide.^{30–32} The potential energy surface of the $\text{Cu}-\text{CO}_2$ system demonstrated a single minimum, which corresponded to the OCuCO insertion product with a potential barrier of 63 kcal mol⁻¹ (Fig. 3). At the same time, a copper dimer Cu_2 in the singlet state underwent an activationless transformation into an 'end-on' complex $\text{Cu}_2(\text{OCO})$ with the energy 2.1 kcal mol⁻¹ lower than that of the starting reactants Cu_2 and CO_2 . Based on the performed calculations, several insertion products into the C–O bond of carbon dioxide were proposed as other putative intermediate products (Fig. 4). As in the case of copper reaction with nitrogen molecules, the reactivity of a copper dimer turned out to be higher than that of a copper atom.

Figure 3. Potential energy variations in the $\text{Cu} + \text{CO}_2$ reaction and the structure of an intermediate product corresponding to the energy minimum (bond distances are shown in Å).³¹ TS is the transition state.

A series of $\text{Fe}_x(\text{N}_2)_y$ complexes were obtained in the reaction of mass-selected iron clusters with an excess of molecular nitrogen.³³ An IR spectroscopic study coupled with the Fourier analysis using isotopically labelled ligand molecules and the results of DFT simulations have shown 'end-on' $\text{Fe}(\text{N}_2)_5$ complexes to be the main reaction products of iron atoms with nitrogen molecules. Furthermore, cluster complexes $\text{Fe}_2(\text{N}_2)_x$ and $\text{Fe}_3(\text{N}_2)_x$ were observed. The early formation of $\text{Fe}_2(\text{N}_2)_x$ complexes ($x = 1–5$) in argon matrices was revealed by UV-Vis and IR spectroscopic techniques.³⁴ As in the case of copper, the ratio between the matrix-stabilised metal atoms and clusters $\text{Fe}:\text{Fe}_x$ was determined by the content of additionally introduced nitrogen. The maximum content of Fe_2 dimers was observed for the 0.05% nitrogen concentration in the argon matrix. For the higher nitrogen concentrations, iron dimers efficiently reacted with nitrogen

Figure 4. Potential energy variations in the reaction of a copper dimer Cu_2 (singlet state) with CO_2 and the structure of intermediate products corresponding to the energy minima (bond distances are shown in Å, angles are shown in degrees).^{31, 32}

Figure 5. IR spectra of co-condensates of vapour of heat-evaporated iron and molecular nitrogen ($T = 12$ K, $\text{Fe}:\text{N}_2 = 1:1000$).³⁴ Complex $\text{Fe}_2(\text{N}_2)_2$ exists in two forms, namely, 'end-on' and 'side-on'.

molecules to form diverse complexes with different coordination types (Fig. 5).

Co-condensation of nitrogen with certain metallocenes $\text{M}(\text{Cp})_2$ ($\text{Cp} = \eta^5\text{-C}_5\text{H}_5$; $\text{M} = \text{Fe}, \text{Co}, \text{Ni}, \text{Mn}, \text{V}$) at 12–20 K afforded mixed-ligand complexes in which a nitrogen molecule was coordinated to a metal atom.^{35–37} The reaction of iron porphyrin complexes with NO produced nitrosyl adducts of porphyrins that may be considered as a heme model.³⁸

Co-condensates of transition metal vapours and aromatic hydrocarbons represent very reactive systems that produced mono- and bisarene complexes of transition metals and clusters and their more intricate complexes.³⁹ The reactions of chromium atoms and small clusters with benzene in argon matrices at 12 K were studied by FT IR, UV-Vis and resonance Raman spectroscopic methods.³⁹ The following chromium compounds were identified: $\text{Cr}(\text{C}_6\text{H}_6)$, $\text{Cr}(\text{C}_6\text{H}_6)_2$, Cr_2 , $\text{Cr}_2(\text{C}_6\text{H}_6)$, $\text{Cr}_2(\text{C}_6\text{H}_6)_2$ and $\text{Cr}_3(\text{C}_6\text{H}_6)$. The use of selective photoexcitation of certain species allowed the authors to carry out a series of competitive chemical reactions of chromium atoms and dimers and their complexes

Exothermic reactions at low and ultralow temperatures (1.3–30 K) can also occur in the space on cosmic dust particles under the action of radiation.^{40–47} The reactions of transition metals with polycyclic aromatic hydrocarbons are of undeniable interest for astrochemistry and astrophysics. It was assumed that such reaction products might be a source of

certain unidentified radiation types observed in the interplanetary space.⁴⁸

The possibility of these reactions was demonstrated by the FT IR spectroscopy in reactions of iron with pyrene and coronene in argon matrices at 4–10 K as an example.⁴⁹ It was found that pyrene forms unstable complexes with iron atoms, whereas coronene preferentially reacts with Fe_2 dimers to form mono- and bisligand complexes $\text{Fe}_2(\text{C}_{24}\text{H}_{12})_n$, where $n = 1$ or 2. These complexes were thermally stable up to 40 K and resistant to irradiation in the near UV and visible ranges (200–700 nm). Iron aggregates were easily formed in argon matrices with an increase in the metal concentration and exhibited the higher electron affinity (0.9 eV for Fe_2) as compared with an iron atom (0.15 eV); this explains the higher stability of their complexes. It is interesting that Fe_2 and Fe_3 clusters readily formed complexes with nitrogen molecules in binary $\text{Fe}-\text{N}_2$ systems, whereas no coronene complexes were detected in ternary $\text{Fe}-\text{coronene}-\text{N}_2$ co-condensates. This can serve as an indirect confirmation of the fact that coronene preferentially reacts with iron dimers. It is noteworthy that no coronene complexes were observed for nickel and titanium that do not form any aggregates under similar conditions.

III. Formation of metal nanoparticles in active matrices

The interaction of metal atoms with active ligand molecules in low-temperature co-condensates can be described as a sequence of competitive processes of aggregation of metal atoms and reactions of metal aggregates containing different numbers of nuclei with ligand molecules (Scheme 1).

Scheme 1

M is metal, L is ligand

The active-matrix molecules can play the role of ligands and form donor–acceptor or charge-transfer complexes with atoms and clusters. Depending on the temperature of the system and the concentrations of metal atoms and clusters, this may lead to the formation of mono- or polynuclear complexes and of nano- or subnanosized metal particles solvated with matrix molecules. Silver and copper feature the formation of different-sized clusters and nanoparticles in which a metal formally exists in the zero-valent state. Studying particles of different sizes makes it possible to follow the formation of the electronic and crystal structures of metals.

Silver and copper clusters and nanoparticles are easily formed at low temperature by the condensation of their vapours with the excess of an inert component,⁵⁰ thermo- and photo-aggregation of atoms⁵¹ and by mass-spectral selection of clusters followed by their condensation in inert matrices.² Nanoparticles can be stabilised at room temperature provided the metal vapour is co-condensed with certain organic substances that are capable of specific non-covalent interactions and can form donor–acceptor complexes with transition metal atoms, clusters and nanoparticles.⁵²

Metal particles measuring up to 10 nm were synthesised by low-temperature co-condensation of vapour of silver, copper, gold and other transition metals with acetone, ethanol, tol-

uene, trimethylamine, dimethylformamide, dimethyl sulfoxide and other compounds.⁵ Heating of the co-condensate to room temperature afforded colloid solutions of nanoparticles with different stability that could be sputtered on different surfaces to form film coatings of various thickness.^{52, 53}

Acrylic acid (AA), methyl acrylate (MA) and dimethylaminomethyl acrylate were also used for the stabilisation of silver nanoparticles.^{54, 55} Low-temperature co-condensation of the metal vapour with MA followed by heating of the system to room temperature afforded stable silver organosols with 15 nm particles. Co-condensation with lead vapour produced bimetallic particles measuring < 5 nm. The transition from binary Ag/MA and Pb/MA systems to the ternary Ag/Pb/MA system was accompanied by non-additive changes in the properties. Polymerisation of MA was inhibited by lead and initiated by silver and the competition of these processes led to the formation of smaller bimetallic particles.⁵⁴ Co-condensation of silver vapour with 2-methylaminoethyl methacrylate afforded silver particles with diameters of 15–20 nm and their aggregates. Such cryochemical methods made it possible to synthesise silver particles dispersed in water, acetone and toluene, which were stabilised in the presence of poly(2-methylaminoethyl methacrylate).⁵⁵

A method of stabilisation of copper nanoparticles in polyethylene was developed.⁵⁶ According to EXAFS and electron microscope studies, the average size of stabilised particles (copper nanocrystals) was 17 nm. A highly dispersed phase was formed upon decomposition of copper diacetate.

Low-temperature co-condensation of vapour of silver and copper and of Cd, Pb, Sn, Mn, Sm, Zn with the *p*-xylylene monomer, which undergoes easy polymerisation even at 100–120 K, was used in the synthesis of nanosized metal particles encapsulated in polymeric films.^{57–59} The particle size determined by the transmission electron microscopy was 3–8 nm. The resulting films exhibited sensor and chemoresistive properties with respect to water and ammonia vapour.^{60, 61}

Copper nanoparticles incorporated into poly(*p*-xylylene) in the course of low-temperature co-condensation of components were observed to exhibit high catalytic activity with respect to isomerisation of chlorine-containing compounds.^{62, 63} The activity of these particles was two orders of magnitude higher than that of highly dispersed copper supported on silica gel.

Cryoformation of nanosized silver and copper particles in mesogenic alkylcyanobiphenyl matrices was studied in detail.^{64–68} In co-condensates of silver and copper vapour with alkylcyanobiphenyl molecules at 80–90 K, low-temperature complexes of metal atoms were revealed.^{69, 70} IR spectra of co-condensates demonstrated two new bands in the range of stretching vibrations. The characteristic bands of the CN group were shifted by –150 and –200 cm^{–1}, which pointed to the formation of silver and copper π -complexes with the cyanobiphenyl fragments of the matrix molecules. Indeed, the electron density shift from the binding orbital and the partial population of the antibonding orbital of the ligand should lead to loosening of the multiple bond in the complex, *i.e.*, to a decrease in the vibration frequency of the corresponding bond in the π -complex. Spectra of Ag/5CB and Ag/5CB/C₁₀H₂₂ (5CB is 4-*n*-pentyl-4'-cyanobiphenyl) co-condensates also exhibited new bands in the range of 650–660 cm^{–1}, which were attributed to the metal–ligand vibrations in π -complexes. The formation of π -complexes was confirmed by quantum chemical calculations performed for 4-*n*-pentyl-4'-cyanobiphenyl and its central cyanobiphenyl fragment.^{71, 72} The structure of this complex includes two cyanobiphenyl fragments antiparallel to one another and a silver atom sandwiched between the CN fragment of ligand 1 and the centre of a benzene ring of ligand 2 (Fig. 6). In the ground state, the complex may acquire two electronic configurations, namely, a

Figure 6. The structure of a bisligand silver complex with alkylcyanobiphenyl ligands Ag(5CB)₂; (1, 2) see text.

neutral complex Ag(5CB)₂ and a charge-transfer complex Ag⁺(5CB)₂[–]. For an interligand distance of 4.4 Å (the charge-transfer complex configuration), the calculated vibration frequency shifts of the C≡N bond in this complex as compared with this bond in the ligand molecule were –150 and –175 cm^{–1}, which were consistent with the experimentally observed values of –150 and –200 cm^{–1} for Ag/5CB films at 90 K.

EPR spectra of Ag/5CB samples contained a doublet of doublets (*A* and *B*, low-field and high-field spectrum components) with *g*-factors of 2.001, 2.003 and hyperfine coupling (HFC) constants of 48.5 and 55.7 mT, respectively (Fig. 7).⁷⁰ The analysis of literature data^{73, 74} suggests that the appearance of components *A* and *B* in the EPR spectrum is the result of the formation of π -complexes of silver atoms (¹⁰⁷Ag and ¹⁰⁹Ag) with cyanobiphenyl molecules. A comparison of HFC constants of silver atoms in the obtained samples with those of atoms stabilised in an inert hydrocarbon matrix (63.22 and 72.75 mT for ¹⁰⁷Ag and ¹⁰⁹Ag, respectively) allowed assessment of the spin density on the Ag atom as 0.89. This value is typical of π -complexes with metal atoms and points to the partial donation of the electron density from occupied orbitals of a metal atom to the antibonding π^* -molecular orbital of a ligand.

Figure 7. EPR spectrum of an Ag/5CB co-condensate at 80 K.⁶⁸

In EPR spectra of Cu/5CB co-condensates, an anisotropic quartet signal of a cyanobiphenyl complex of a copper atom was detected ($J = 3/2$).^{66, 75} Spin-resonance parameters of complexes were as follows: $g_{xx} = g_{yy} = 2.007$, $g_{zz} = 1.981$, $A_{iso} = 19$ mT; HFC on ⁶³Cu and ⁶⁵Cu isotopes were unresolved due to the close *g*-factors of their nuclei. The relatively low HFC constants for copper together with the highly anisotropic signal suggested that the highest occupied molecular orbital in a complex that contained a lone localised electron was of the hybrid nature and that the electron density

was shifted from a metal atom to ligand molecules. The spin density on the metal atom did not exceed 0.1.

The EPR spectra of co-condensates also revealed a central signal *C* (see Fig. 7) with a *g*-factor close to that of a free electron (2.003). The signal could be caused by the conducting electrons spin resonance (CESR) from a set of nanosized metal clusters and their complexes stabilised in the 5CB matrix. Similar signals were also observed for sufficiently concentrated silver and copper co-condensates with saturated hydrocarbons and inert gases.^{76,77} This signal represented a superposition of several isotropic lines of Lorentzian shape. The *g*-factor and the widths of signal line depended on the size of metal particles due to the difference in the spin–lattice relaxation times (*T*₁). Taking into account the presence of experimental *g*-factor shifts, the average size of metal particles stabilised in cyanobiphenyl matrices at 90–120 K was assumed to be 1–2 nm. An increase in the Ag to 5CB ratio led to the domination of processes of silver aggregation in the system, which substantially decreased the yield of this complex. On heating of co-condensates from 90 to 150 K, the relative intensity of doublet lines of silver complexes (quartet lines for copper complexes) decreased and the relative intensity of the central component increased, which pointed to the thermal decomposition of metastable complexes and the increase in the concentration of nanosized metal clusters due to the spontaneous aggregation of metal atoms that emerge in the system.

Studies of electron absorption spectra for the Ag/5CB and Ag/5CB/decane systems confirmed the results obtained by IR and EPR spectroscopic techniques. UV-Vis spectra of Ag/5CB co-condensates at 80 K (Fig. 8, curve 1) revealed a structured absorption band of a silver complex with a peak at 360 nm, which corresponded to light-yellow co-condensate films. Quantum chemical simulation of excited states of this complex pointed to the presence of several intense charge-transfer transitions metal–ligand and ligand–ligand in the range of 360–400 nm.⁷⁸ The absorption at 360 nm disappeared as the co-condensate film was annealed to 200–300 K. A broad band with the peak at 420 nm that appeared at these temperatures (see Fig. 8, curves 2, 3) was probably due to the absorption of surface plasmons of nanosized silver particles⁷⁹ formed as a result of aggregation of silver atoms and small clusters during the thermal decomposition of the complex. According to the data of transmission electron spectroscopy, depending on the phase state of the Ag/5CB system, two types of particles were formed, namely, globular with the average diameter of 15 nm and anisotropic rod-like particles ~200 nm long. The increase in the metal concentration and aggregation in an orientation-

Figure 8. Optical spectra of silver co-condensates with 4-n-pentyl-4'-cyanobiphenyl at different temperatures.⁶⁹
T/K: (1) 80, (2) 200, (3) 300.

ordered mesophase favoured the formation of rod-like metal particles.^{80,81}

Thus, metal complexes appear in the course of low-temperature co-condensation of metal vapour and reactive organic components containing functional complexing groups. Annealing of this system leads to the thermally induced decomposition of unstable complexes and the matrix-controlled aggregation of metal atoms and small clusters of different sizes and shapes. The chemical nature and properties of the resulting reaction products are determined by the competition between self-assembling processes and the reactions of different-sized metal aggregates with molecules of reagents added to the system.

IV. Thermal transformations of metastable complexes of lanthanide atoms and clusters

As was shown above, cryochemical synthesis allows one to obtain new compounds and complexes for a series of d-metals in unusual oxidation states and with unusual coordination of ligand molecules. Competitive cryochemical reactions of lanthanide atoms with certain organic and inorganic ligands also lead to unusual products, where both the changes in the oxidation state and the formation of complexes between zero-valent lanthanides and CO, ethylene, tri(*tert*-butyl)benzene and its derivatives can be expected.^{81–84}

The majority of reactions of lanthanide atoms lead to the changes in the metal oxidation state. Their reactions with oxygen were studied by the example of cerium, praseodymium, terbium and europium. Europium formed several oxides and peroxides with different compositions, namely, EuO₂, Eu₂O₄, Eu₂O₃, EuO₂·Eu₂O₂.⁸⁵ Cerium, praseodymium and terbium produced mixtures of oxides LnO and peroxides LnO₂.⁸⁶ The reaction of gadolinium with chlorine in argon matrices afforded GdCl₃. In the case of holmium, this reaction produced a mixture of comparable amounts of metal dichloride and trichloride and the monochloride HoCl; for ytterbium, a mixture of dichloride and trichloride was formed. Europium formed a mixture of dichloride and trichloride, where the former prevailed. No formation of europium monochloride was detected. All the products were identified by IR spectroscopy.⁸⁷ Under similar conditions, reactions of holmium and europium with bromine and iodine were carried out. It was shown that with bromine, both lanthanides produce di- and tribromides in comparable amounts. Their reaction with iodine also afforded di- and triiodides, where diiodide dominated for europium and triiodide prevailed for holmium. IR spectra of iodine co-condensates with holmium and europium also contained bands that could be assigned to polymeric iodides.⁸⁸

The reaction of samarium with alkyl halides was studied under conditions of matrix isolation in the temperature range of 12–30 K.⁸⁹ IR spectroscopic data revealed the formation of methane in this reaction. Under conditions of matrix isolation, a reaction of samarium with CO₂ was studied.^{89,90} Based on the IR and UV spectroscopic data, the reaction sequence shown in Scheme 2 was proposed.

Scheme 2

Straight lines mean that the corresponding reaction occurs at the condensation temperature (12 K); curved lines correspond to the reaction on heating (30 K)

The reactions of samarium with alcohols (ROH) were studied.^{91–94} These reactions afforded the corresponding hydrocarbons RH and samarium alkoxides $\text{Sm}(\text{OR})_x(\text{OH})_{3-x}$. The reaction products contained insignificant amounts of doubled alkanes R–R, which pointed to the radical mechanism of this process. In the first stage, samarium atom was inserted into the C–O bond of an alcohol molecule to form RSmOH and trivalent samarium alkoxide $\text{Sm}(\text{OR})_3$. For isopropyl alcohol, a cluster compound $\text{Sm}_5\text{O}(\text{OR})_{13}$ could also be formed.⁹⁴ The composition of this compound was revealed by elemental analysis and NMR spectroscopy.

Cryocondensation of samarium with acetone followed by annealing of the co-condensate and hydrolysis led to a set of saturated and unsaturated hydrocarbons and alcohols, namely, $\text{CH}_3\text{CH}=\text{CH}_2$, C_3H_8 , $(\text{CH}_3)_2\text{CHCH}(\text{CH}_3)_2$, $(\text{CH}_3)_2\text{C}=\text{C}(\text{CH}_3)_2$, $(\text{CH}_3)_2\text{CHOH}$ and samarium hydroxide.⁹⁵ A samarium cryocolloid produced in the co-condensation of samarium atoms with an unsaturated hydrocarbon reacted with acetone and the co-condensate was heated to its melting point. Co-condensation of metals with acetylacetone also produced samarium, holmium, erbium and dysprosium acetylacetonates.⁹⁶ Furthermore, the co-condensation of samarium, acetylacetone and dimethyl sulfoxide afforded a samarium acetylacetonate adduct to dimethyl sulfoxide.⁹⁶

Co-condensation of lanthanide atoms with substituted diazabutadiene $\text{Bu}^t\text{N}=\text{CHCH}=\text{NBu}^t$ (Bu^tDAB) led to the formation of a chelate complex containing three ligand molecules (Scheme 3).^{97,98}

$\text{Ln} = \text{Y}, \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}, \text{Ho}, \text{Yb}$.

The structure of the samarium complex was studied by X-ray diffraction analysis. It was shown that five-membered rings $\text{Sm}-\text{N}-\text{C}-\text{C}-\text{N}-\text{Sm}$ are virtually planar, deviating by 0.051 \AA from the plane. The $\text{C}=\text{N}$ bond distance was $1.35(3) \text{ \AA}$, which is much longer as compared with the free ligand [$1.283(6) \text{ \AA}$]. This may be due to the electron density transfer from a metal atom to the lowest unoccupied molecular orbitals (LUMO) of the ligand to form Ln^{2+} and Ln^{3+} ions. This is why it is more correct to represent the samarium complex and analogous compounds of the lanthanides as the complexes formed by trivalent metals with radical anions, *i.e.*, $[\text{Ln}^{3+}(\text{Bu}^t\text{DAB}^{\cdot-})_3]$. The analogous ytterbium compound $[\text{Yb}^{3+}(\text{Bu}^t\text{DAB}^{\cdot-})_3]$ had a magnetic moment of $5.9 \mu_{\text{B}}$ in the solid state at room temperature and $2.4 \mu_{\text{B}}$ at $T < 100 \text{ K}$. A model was proposed according to which this compound exists in two forms, namely, as $[\text{Yb}^{3+}(\text{Bu}^t\text{DAB}^{\cdot-})_3]$ at temperatures above 100 K and $[\text{Yb}^{2+}(\text{Bu}^t\text{DAB}^{\cdot-})_2(\text{Bu}^t\text{DAB})]$ at lower temperatures. The calculated magnetic moments of these species were 5.5 and $2.45 \mu_{\text{B}}$, respectively, which was consistent with the experimental data. Erbium, neodymium and samarium co-condensation with buta-1,3-diene produced analogous products, namely, $\text{Ln}(\text{C}_4\text{H}_6)_3$.⁹⁹ The introduction of dimethylbutadiene into this reaction resulted in the formation of complexes with the composition $\text{Ln}[(\text{CH}_3)_2\text{C}_4\text{H}_4]_2$. The magnetic susceptibility measurements have shown that

in all the cases, the degree of oxidation of lanthanide atoms was $3+$.

Co-condensation of samarium, erbium and ytterbium vapours with hydrocarbons containing double bonds, namely, ethylene, propylene and allene, led to the formation of products that afforded a mixture of saturated and unsaturated hydrocarbons from C_1 to C_6 upon hydrolysis. This suggests that the reaction mechanism is rather complex and involves the insertion of lanthanide atoms into the C–C bond to form a ring

or a chain $\text{Ln}-\text{C}-\text{C}-\text{Ln}$.¹⁰⁰

Low-temperature reactions of ytterbium, erbium and samarium with terminal alkynes afforded products with absorptions in the range of $2020\text{--}2060 \text{ cm}^{-1}$ (triple bond vibrations), namely, $(\text{YbC}_9\text{H}_{14})_n$, $(\text{ErC}_{12}\text{H}_{19})_n$ and $(\text{SmC}_{12}\text{H}_{19})_n$.¹⁰¹ Co-condensation of samarium atoms with hexane gave rise to the evolution of hydrogen; hydrolysis of the co-condensate produced hex-1-yne and insignificant amounts of destruction products.¹⁰² Experimental data suggest the following reaction sequence:

$\text{R} = n\text{-C}_4\text{H}_9$.

Co-condensation of samarium vapour with 1-bromopentane at 80 K afforded green films. On heating, a mixture of saturated and unsaturated hydrocarbons, namely, pentane, decane and pentene, was obtained. Results of EPR studies gave grounds for assuming the radical mechanism of this process.¹⁰³

At present, several reactions of lanthanide atoms and clusters are known to involve no changes in oxidation state. It was assumed that for efficient complexation a lanthanide atom should acquire the $4f^{n-1}5d^16s^2$ configuration as a result of the transition of one f electron to the d shell.¹⁰² The energy of excitation of an f electron to the d sublevel is of crucial importance for this process. Figure 9 illustrates the dependence of this energy on the degree of population of the f shell. The interaction of lanthanide atoms with CO molecules was studied for a series of metals, namely, Pr, Nd, Sm, Eu, Gd, Ho and Yb, in an argon matrix at $10\text{--}40 \text{ K}$ using the electronic and IR spectroscopic methods.^{104–106} In the majority of cases, carbonyls $\text{Ln}(\text{CO})_x$ were formed ($x = 1\text{--}6$). Heating of the

Figure 9. Calculated excitation energy $[f^n s^2] \rightarrow [f^{n-1} d^1 s^2]$ as a function of the degree of population of the f orbital of a non-excited lanthanide atom.⁸²

system to 15–40 K transformed the lower carbonyls to the higher, $\text{Ln}(\text{CO})_6$. In a range >40 K, carbonyls of all metals underwent destruction, where the destruction temperature corresponded to the matrix melting point. The distinguishing feature of samarium and europium is that they did not form carbonyls at $x = 1-3$ for Sm and $x = 1, 3$ for Eu. It should be mentioned that the decomposition temperature of the higher samarium carbonyl (30 K) was lower as compared with the higher europium carbonyl (40 K), which is in conflict with their excitation energies (see Fig. 9). Gadolinium carbonyl that has a d electron in the ground state also proved to be unstable. The most stable carbonyls were formed by metals with the larger number of d-electrons, *e.g.*, by Cr, Mn, Fe, Co, Ni.

Reactions with ethylene were studied in detail for europium and samarium atoms and clusters in argon matrices and also for samarium co-condensates with ethylene.^{89,107} It was found that two complexes, $\text{Ln}(\text{C}_2\text{H}_4)$ and $\text{Ln}(\text{C}_2\text{H}_4)_2$, are formed. On gentle heating, the monoligand complex was transformed to the biligand complex. Taking into account the presence of free samarium atoms even in non-dilute ethylene, it can be assumed that the formation of a $\text{Ln}\cdot\text{L}$ complex and its subsequent transformation to $\text{Ln}\cdot 2\text{L}$ are limited by the rotational diffusion. The decomposition temperature of the higher europium complex (~ 60 K) exceeded that of the higher samarium complex (~ 40 K). The structure of the monoligand samarium complex with ethylene was studied.¹⁰⁷ It was assumed that this complex is stabilised due to weak direct interaction of half-occupied metal f orbitals with σ and π orbitals of their ligand.

Reactions of lanthanides with aromatic ligands, namely, 1,3,5-tri(*tert*-butyl)benzene (TTB), 2,4,6-tri(*tert*-butyl)pyridine (TTPy) and 2,4,6-tri(*tert*-butyl)phosphorine (TTP), were studied in their co-condensates in the temperature range of 80–373 K.^{82,83,108,109} The structure of a single crystal of the gadolinium TTB complex was determined by X-ray diffraction analysis. The molecules of the complex had a sandwich structure with a metal atom located between two benzene rings in the staggered conformation. The LUMO energy of heteroaromatic ligands is lower than the LUMO energy of benzene, which leads to the stronger interaction of ligands with the metal d orbitals. As a result, on going to analogous heteroaromatic complexes of lanthanides, the bond becomes stronger and the decomposition temperature increases (Table 1). The bond strength in lanthanide complexes with aromatic ligands increased with the decrease in the metal atom radius, the reduction of the energy of f electron excitation and the lowering of the LUMO energy of the ligand.^{82,109}

Samarium complexes with 4-n-pentyl-4'-cyanobiphenyl were detected in an argon matrix at 6–10 K and in Sm co-condensates with 5CB at 80–240 K.^{110,111} The formation of

such complexes was revealed by the appearance of new absorption bands in the IR spectra, namely, a triplet band at 2170 cm^{-1} (complex I) and 2060 cm^{-1} (complex II) (Fig. 10). The bands were shifted to lower frequencies as compared with vibrations of the CN group of the ligand (2230 cm^{-1}). This made it possible to assign new bands to CN vibrations in π -complexes. Splitting of a band at 2170 cm^{-1} to three components can be associated with the stabilisation of different complex configurations in a low-temperature argon matrix and also with different local environment. The activation energy of the formation of complexes was close to zero, which confirmed their formation at 6–10 K. The first complex was formed at 6–10 K in a molar ratio $\text{Sm}:5\text{CB}:\text{Ar} = 1:33:10\,000$. At such dilution, the aggregation of metal atoms was absent, and the complex was formed from samarium atoms. The composition was determined by a modified method of multiple ratios in a series of experiments on the joint condensation of samarium and 5CB with a 100–1000-fold excess of decane. The stoichiometric composition was $\text{M}\cdot 2\text{L}$ for complex I and $\text{M}\cdot\text{L}$ for complex II. Bearing in mind the tendency of lanthanide atoms for the formation of bisligand sandwich complexes and the susceptibility of cyanobiphenyl molecules to dimerisation at low temperatures,¹¹² the second complex was also considered as a bisligand binuclear $2\text{M}\cdot 2\text{L}$ complex.

In the temperature range of 80–95 K, samarium co-condensates with 4-n-pentyl-4'-cyanobiphenyl in a molar ratio $\text{M}:\text{L} = 1:10$ contained only the complex $\text{M}\cdot 2\text{L}$.^{113,114} As the sample was heated to 210 K, the absorption band of the complex $\text{M}\cdot 2\text{L}$ disappeared and a band of the complex $2\text{M}\cdot 2\text{L}$ emerged. Heating above 210 K led to the decomposition of both complexes. The complex $\text{M}\cdot 2\text{L}$ absorbed in the visible range at 400 nm, while the complex $2\text{M}\cdot 2\text{L}$ absorbed at 420 nm. The UV spectrum of the $\text{Sm}/5\text{CB}$ co-condensate contained an absorption band of the complex $\text{M}\cdot 2\text{L}$ at 400 nm at 95 K. As the temperature increased, a shoulder at 420 nm appeared, which corresponded to the complex $2\text{M}\cdot 2\text{L}$. Electronic spectra of co-condensates demonstrated a broad long-wavelength absorption band with a peak at

~ 600 nm, which can be assigned to the absorption of metal nanoparticles. An increase in the length of the hydrocarbon substituent chain in the ligand molecule had no effect on the stability of complexes. On going from 5CB to its heteroaromatic analogue, 4-n-pentyl-4'-cyanophenylpyridine (5Py), the stability of complexes increased.¹¹⁴ The IR spectrum of the co-condensate at liquid nitrogen temperature contained a single band at 2150 cm⁻¹, which corresponded to the complex Sm·2(5Py). As the temperature increased to 230 K, a new band at 2100 cm⁻¹ appeared (Sm·5Py). The thermal decomposition of complexes occurred above 230 K, *i.e.*, 20 K higher as compared with the Sm/5CB system. This can be associated with the stronger metal–ligand bonding in complexes Sm·5Py. On going from samarium to europium, the thermal stability of the complex Ln(5CB)₂ also increased.

Model calculations of structures of complexes were carried out in terms of the density functional theory with the B3LYP exchange-correlation potential using the NWChem programme.^{115, 116} Only the ligand part involved in the complexation was considered. The optimised structures had the form of sandwiches (Fig. 11). The most stable state was reached at multiplicity 10 for complex *I* and multiplicity 15 for complex *II*; the binding energies were 10.6 and 31.3 kcal mol⁻¹, respectively. Multiplicity substantially affected the values of a torsion angle between the benzene ring planes of one ligand (φ_1), an angle between benzene ring planes of two ligands (φ_2) and an angle formed by axes of ligands (φ_3). In the complexation, the stretching frequency of the cyanobiphenyl CN group in both complexes shifted to lower values, which was consistent with the experimental data.

Figure 11. Optimised structures of complexes M(CB)₂ (*I*) and M₂(CB)₂ (*II*).¹¹⁵

The equilibrium structures and complexes formed by europium atoms and their dimers with non-substituted cyanophenylpyridyl ligands were simulated using quantum chemical methods.¹¹⁷ For mononuclear complexes, the competition between two mechanisms of metal atom coordination was observed, namely, between the formation of sandwich π -complexes, which is caused by the interaction with π orbitals of the ligand, and the σ -coordination to the nitrogen atom of the pyridine ring. Sandwich structures of alkylcyanophenylpyridyl ligands were stabilised as a result of intermolecular N...H contacts between the nitrogen atom of the cyano group and the terminal hydrogen atom of the ethyl group. The higher thermal stability of the binuclear complex was demonstrated.

As the temperature of Sm/5CB and Sm/5Py co-condensates increased from 183 to 223 K, simultaneous decay of SmL₂ signals and growth of Sm₂L₂ signals were observed in the IR spectra (Fig. 12). This pointed to the transformation of mononuclear complexes ML₂ to binuclear complexes M₂L₂.^{118, 119} The following kinetic scheme, which includes the competition between processes of metal atom aggregation and their interaction with ligand molecules, was proposed:

Figure 12. IR spectrum of a Sm/5CB co-condensate at different temperatures.¹¹¹

T/K: (1) 8, (2) 163, (3) 183, (4) 203, (5) 223, (6) 243, (7) 273.

The consumption of a complex ML₂ at this temperature did not reach zero but stopped at a certain degree of transformation, which is typical of multistep chemical reactions in the solid phase.¹²⁰ As the temperature increased, the degree of transformation increased. The effective activation energies were 17.5 and 18.5 kJ mol⁻¹ for 5CB and 5Py, respectively. The results of experimental and theoretical studies^{113–119} have demonstrated the importance of taking into account the competitive reactions of metal atoms and aggregates when analysing the thermal transformations of complexes in low-temperature co-condensates.

V. Competitive reactions of silver and gold particles of different sizes and shapes with model reagents

Studies of competitive chemical reactions of metal particles in different degrees of aggregation with model chemical reagents attracted special attention.^{121, 122}

Competitive reactions of silver and copper atoms and clusters, which were stabilised in a nanostructured 4-n-pentyl-4'-cyanobiphenyl matrix, with carbon tetrachloride as a model reagent, were studied by EPR and UV-Vis spectroscopic techniques.^{122–125} EPR spectra of ternary co-condensates of silver with carbon tetrachloride and 4-n-pentyl-4'-cyanobiphenyl, which contained CCl₄ in a concentration varying from 0 mol % to 10 mol % with respect to cyanobiphenyl, were studied at 80–300 K. For systems with [CCl₄]:[5CB] ≤ 0.03, only doublet signals of π -complexes formed by silver atoms with cyanobiphenyl ligands Ag(5CB)₂

were observed. The addition of carbon tetrachloride to the system led to the formation of several paramagnetic products of competitive reactions of silver atoms and clusters with 5CB matrix molecules and added CCl_4 . Heating-cooling cycling of samples and computer simulations of spectra corresponding to different temperatures and different component concentrations made it possible to reveal several paramagnetic species, namely, nanosized metal particles, a σ -complex of a silver atom with two ligands (5CB and CCl_4) and an adduct of trichloromethyl radical to silver chloride $\text{AgCl}-\text{CCl}_3$ (Ref. 125).

Annealing of co-condensates at 90–200 K changed relative intensities of signals under consideration. Figure 13 shows the temperature dependences of yields of paramagnetic products formed in the reactions of silver atoms and nanosized clusters with carbon tetrachloride and matrix (5CB) molecules for co-condensates with different ratios of reagents (Ag, CCl_4 and 5CB). In the temperature range of 90–120 K, the doublet signals of a π -complex formed by silver atoms with 5CB matrix molecules, which could be detected in systems with low CCl_4 concentrations, were observed to decay. This was caused by the thermal decomposition of the π -complex. Simultaneously, for samples with low carbon tetrachloride concentrations, an increase in the intensity of signals of silver nanoclusters was observed (see Fig. 13 *a*). At the same time, samples with higher CCl_4 concentrations demonstrated no increase in intensity of signals of silver nanoclusters (see Fig. 13 *b*).

These changes were attributed to the reactions of silver atoms, which emerge in the decomposition of π -complexes, with carbon tetrachloride and metal clusters formed in the system. At substantially lower CCl_4 concentrations, the

decomposition of π -complexes was accompanied by the preferential aggregation of atoms to form nanosized silver clusters, which were stabilised in the matrix up to a temperature corresponding to the system restructuring, *i.e.*, 210–230 K. It is noteworthy that the CESR signals of nanosized silver clusters were more symmetric for ternary co-condensates $\text{Ag}/5\text{CB}/\text{CCl}_4$ as compared with the binary $\text{Ag}/5\text{CB}$ system. This may serve as evidence for the narrowing of the size distribution of metal clusters. Apparently, the observed effect was caused by the fact that the least stable and most reactive clusters were the first to react; the most stable and highly symmetrical icosahedral clusters (Ag_{13} , Ag_{55} , *etc.*) were stabilised in the 5CB matrix and accumulated at this temperature. Thus, at low temperatures, the role of active species in the reaction with CCl_4 was played by silver atoms; on heating of the co-condensate, the nanosized clusters, which were formed in the aggregation of the silver atoms emerged in the thermal decomposition of complexes, also became reactive.

Gold is conventionally classified with the most stable and least reactive metals the surface of which is inert with respect to chemisorption of molecules of most gases.¹²⁶ Gold is the only transition metal that does not have a stable oxide (its most stable oxide, Au_2O_3 , is actually metastable). Gold exhibits the maximum electronegativity among all metals, being only slightly more positive as compared with typical non-metals such as sulfur or iodine; gold has the record-breaking electron affinity (2.31 eV) and ionisation potential (9.22 eV).¹²⁷

In the past decade, gold particles measuring <5 nm attracted attention due to their unique catalytic properties.^{128–133} It was shown that gold clusters and nanoparticles are efficient catalysts in low-temperature CO oxidation,^{131, 132} selective propene oxidation to propene oxide,¹³⁴ NO reduction,¹³⁵ selective hydrogenation of acetylene and butadiene,¹³⁶ reduction of nitrogen oxides,¹³⁷ hydrochlorination of acetylene to vinyl chloride,^{138, 139} vinyl acetate synthesis¹⁴⁰ and some other reactions.^{141, 142}

Low-temperature (10 K) co-condensation of gold atoms with a CO and O_2 mixture (1 : 1) was found to produce gold(II) carbonyl peroxyformate. The latter underwent decomposition to two CO_2 molecules when heated to 30–40 K.¹⁴³ Thus, it can be concluded that the carbon monoxide oxidation to dioxide CO_2 is catalysed by individual gold atoms.

It was stated that Au_2 dimers react with CO, NH_3 and ethylene.¹⁴⁴ In contrast to silver and copper dimers, gold dimers reacted with molecular hydrogen, which may be associated with the relativistic nature of gold. This determines the contraction of s orbitals to make the resulting Au–H bond more stable.

Using a mass-selection technique and jet reactors, the molecular adsorption of different molecules on neutral and charged gold clusters Au_x , Au_x^- , Au_x^+ ($x = 2–20$) was studied.^{145–147} For anionic clusters involving up to 20 atoms, a ‘saw-tooth’ size dependence of oxygen adsorption with a clearly pronounced even-odd alternation was observed.^{147, 148} Clusters containing even numbers of atoms readily adsorbed oxygen, whereas those with odd number of atoms were inert. This effect was due to the strong alternation of the electron affinity with the varied cluster size. The higher electron affinity for clusters with odd numbers of atoms¹⁴⁶ prevented the adsorption of oxygen molecules that occurs due to the electron density transfer from a gold cluster to the antibonding π^* orbital of the oxygen molecule.¹⁴⁸ Gold species with the number of atoms > 20 were far less reactive.

The chemisorption of carbon monoxide on anionic gold clusters led to preferential formation of mono- and dicarbonyl clusters with odd numbers of gold atoms, namely, Au_5CO , Au_{11}CO , Au_{15}CO , $\text{Au}_{15}(\text{CO})_2$.^{149, 150} Even the long-term exposure of this system at high CO concentrations did not lead to the formation of higher carbonyls. This agrees with the

Figure 13. Temperature dependences of relative intensities of paramagnetic signals of the reaction products of silver atoms and clusters with carbon tetrachloride and matrix (5CB) molecules for co-condensates with reactant ratios (a) $\text{Ag} : \text{CCl}_4 : 5\text{CB} = 1 : 3 : 100$ and (b) $1 : 10 : 100$.¹²⁵ (1) $\text{Ag}(5\text{CB})_2$, (2) ClAgCCl_3 , (3) Ag_x , (4) $\text{Ag}(5\text{CB})\text{CCl}_4$.

earlier data on the CO adsorption on the surface of gold single crystals for which the adsorption curves reached saturation at small surface coverages. It is interesting that a single-atom gold anion did not virtually react with CO, whereas one or two CO molecules reacted with dimeric (Au_2^-) and trimeric (Au_3^-) gold anions to preferentially afford $\text{Au}_3(\text{CO})_2$ dicarbonyl in a stable 8-electron configuration.¹⁵¹ This also involved a shift of s and d orbitals of a gold atom as a manifestation of the relativistic effects.

Studies of oxygen and CO chemisorption play an important role for efficient CO oxidation to CO_2 . Co-chemisorption of oxygen and CO was successfully performed on anions of gold dimers (Au_2^-) and trimers (Au_3^-); no adsorption was observed on monomeric anions Au^- (see Ref. 152). No formation of gold carbonyls was detected in the reaction with oxygen that proceeded an order of magnitude faster than the CO adsorption. Among intermediate products, $\text{Au}_3(\text{CO})\text{O}_2$ and $\text{Au}_3(\text{CO})(\text{O}_2)$ were detected, which confirmed the co-adsorption. The initial CO adsorption on Au_6^- clusters led to the formation of several carbonyls $\text{Au}_6(\text{CO})_n$. Subsequent treatment of these clusters with oxygen resulted in the ligand substitution to form $\text{Au}_6(\text{CO})_{n-1}\text{O}_2^-$, where one CO molecule underwent oxidation to CO_2 . For gold clusters, the reaction rate exceeded that observed on common gold catalysts by at least two orders of magnitude. The disadvantage of using such small particles concerns the impossibility of recycling this catalytic system.¹⁵³

The reaction of gold dimer anion Au_2^- with CO and O_2 led to the formation of Au_2O_2^- and $\text{Au}_2(\text{CO})\text{O}_2^-$; the final system contained also Au_2^- species.¹⁵⁴ The following scheme of oxidation was assumed:

Density functional theory calculations pointed to a possibility of the existence of an intermediate species $\text{Au}_2(\text{CO})\text{O}_2^-$ both as the product of CO insertion into the O—O bond (Fig. 14a) and in the form of gold dimer peroxyformate (Fig. 14b), which opens up a virtually activationless route of Au_2O_2^- reaction with CO.^{153, 154}

Figure 14. Reaction products of CO and O_2 with gold clusters (bond distances are shown in Å); (a, b) see text.¹⁵⁴

Fourier-transform mass spectrometry and ion-cyclotron resonance studies of the O_2 and CO co-chemisorption on gold nanoclusters have unambiguously demonstrated that the preliminary treatment with CO considerably accelerated the reaction of the cluster with O_2 . This pointed to the cooperative

effect of two ligands on the CO oxidation.¹⁵⁵ In this process, both the reaction with Au_n^- gold anions and the oxidation of preliminarily formed carbonyl complexes $\text{Au}_n(\text{CO})_m$ were size-sensitive. Carbon dioxide was the product of both reactions.

The presence of water vapour had a considerable effect on the reactivity of gold clusters Au_n . As compared with the original clusters, the hydroxylated Au_nOH^- clusters formed upon oxidation exhibited the inverse reactivity, namely, clusters with an even number n were inert and those with an odd numbers easily chemisorbed oxygen.¹⁵⁶

The reactivity of Au_n^+ ($n = 1-12$) clusters in their reactions with H_2S was studied.¹⁵⁷ Cations Au^+ and Au_2^+ were virtually inert; among larger species, clusters with even n were more reactive. The reaction led to the liberation of hydrogen and formation of sulfur-containing products. Cationic clusters with the number of gold atoms up to 10 efficiently chemisorbed hydrogen.

The reactivity of large gold clusters ($n \geq 10$) depended on their structure and shape.^{158, 159} Modelling of structures of nanosized gold clusters both anionic and neutral has shown¹⁶⁰⁻¹⁶² that due to the contribution of relativistic factors, gold species (containing up to 13 atoms) had the shape of a plane or a plate. Moreover, the ionisation potential, the electron affinity, the difference in energies of the highest occupied and the lowest unoccupied molecular orbitals, and the ability to selectively chemisorb molecules of O_2 , CO, etc. are all the size-dependent quantities that exhibit the typical alternation for clusters containing even and odd numbers of metal atoms.^{163, 164} For planar gold species, substantial anisotropy of polarisability was observed.¹⁶⁵ In the lateral direction, the polarisability was high (close to that of metals), whereas in the normal direction, the polarisability value approached that of semiconducting silicon. The theoretical prediction of structures for species with $n = 30-10000$ has demonstrated the possibility of formation of different types of disordered,¹⁶⁶ edged cuboctahedral and icosahedral clusters¹⁶⁷⁻¹⁶⁹ that could be transformed to one another¹⁷⁰ due to small difference in stabilisation energies.¹⁶⁶

In catalysis, nanosized gold clusters and particles deposited on metal-oxide supports were used.¹⁷¹⁻¹⁷⁴ Several studies were devoted to the formation of gold nanoparticles in the vapour deposition from the gas phase to afford two- and three-dimensional aggregates.¹⁷⁵⁻¹⁷⁷ It was shown that the activity of deposited nanodispersed gold particles is largely determined by the interaction of metal particles with the substrate, the presence of adsorbed and covalently bound functional groups, the electron-donating or -withdrawing properties of the surface, the size of deposited particles and the presence of low-coordinated gold atoms in their structure as well as by the degree of charge transfer in the chemisorption of a reagent molecule.¹⁷⁸⁻¹⁸⁰ A strong size effect was observed in the CO oxidation to CO_2 on the exposure of a $\text{CO}:\text{O}_2 = 1:5$ mixture over deposited Au/TiO₂ clusters at room temperature. The maximum activity was observed for gold particles measuring 2.8–3.2 nm (Fig. 15). This was associated with the transformation of particles that exhibit non-metal properties into particles with metallic properties.¹⁸¹ A detailed analysis of the effect of the size and the shape of gold particles deposited on different substrates was performed.¹⁸² The properties of deposited gold nanoparticles were observed to widely deviate from those of bulk gold samples, e.g., the activity deviated by more than an order of magnitude.^{183, 184} Highly symmetric (with a fifth-order symmetry axis) gold clusters with ‘magic’ numbers of atoms, namely, 13, 55, 147, etc., proved to be more stable and less reactive. Thus an Au_{55} cluster ($d = 1.4$ nm) was unsusceptible to oxidation under the action of oxygen plasma, whereas smaller clusters (< 1 nm) underwent oxidation under these conditions.¹⁸⁵

Figure 15. Activity of gold particles deposited on TiO₂ by (1) vacuum condensation and (2) chemical deposition as a function of their size.¹²⁹

VI. Conclusion

This survey of the literature data and of the results obtained by the authors of this review shows that the methods of cryochemistry and nanochemistry make it possible to carry out and control self-assembling processes of metal atoms to form nano- and subnanosized aggregates, perform competitive chemical reactions of atoms, small clusters and nanosized particles of transition metals with different organic and inorganic substances, study the kinetics of cryochemical process and simulate their individual stages, and acquire information on the mechanisms of uncommon chemical reactions in low-temperature co-condensates.

At present, effective low-temperature methods are being developed aimed at the stabilisation of small clusters and nanosized metal particles in the matrices formed by inert gases and certain organic and inorganic substances and on the surfaces of different substrates and at carrying out selective chemical reactions of particles of different sizes and shapes with reagents added to the systems. The accumulation of data on the reactions of nanosized particles of different metals for a wide range of temperatures in the gas phase and in condensed systems, namely, liquid and solid co-condensates, as well as their kinetic analysis will allow one to reveal the fundamental trends in the manifestation of size effects in nanochemistry of metals and the periodicity in the variation of reactivity of these particles. This information together with the comparative analysis of characteristics of ligand-free and ligand-stabilised clusters makes it possible to separate the effect of the metal core size and the stabilising effect of the ligand shell and the effects of the phase state of the system and its temperature. This approach coupled with the quantum chemical modelling of the studied systems will allow one to pass from documentation of separate cases of the dependence of the particle reactivity on the number of the constituent atoms to the development of the general kinetic theory that would relate the particle size in the studied substances to their chemical properties. Cryonanochemistry is used in the elaboration of new methods for the synthesis of nanostructured materials with unique optical, magnetic, electrophysical and mechanical characteristics.

It is also necessary to mention certain general problems that challenge modern cryonanochemistry. First of all, this is the development of methods of synthesis of metal particles with

controlled sizes and narrow size distributions in the range of 1–5 nm. The synthesis of highly reactive nanoparticles requires the elaboration of special effective methods for their stabilisation.

Second, it is necessary to develop methods for carrying out highly selective catalytic, photochemical and thermal processes based on competitive reactions of small metal particles to be used as the basis in the production of nanodevices and nanomaterials. The quest for promising applications is associated with the development of methods for the formation of ordered ensembles of metal particles of definite sizes and shapes incorporated into the structured matrices based on polymers, liquid crystals, carbonaceous and biological systems. The use of low temperatures offers a possibility of the direct introduction of metal atoms and clusters into organic and inorganic matrices without using additional chemical reagents and solvents. This can result in the development of environmentally clean and safe methods for the synthesis of nanostructured materials.

Third, the carrying out of cryonanochemical processes and the synthesis of nanoparticles and nanostructured materials to be used in practice should be accompanied by scaling of synthetic methods to obtain the required macroamounts of target products and by the development of procedures for maintaining long-term stability of their physical and chemical properties.

Wide prospects are opened up for the use of cryochemical methods in the production of metal-containing nanostructures on cooled surfaces of organic, inorganic and polymeric substances. The use of low temperatures and the controlled condensation of reagent vapour allow one to synthesise and stabilise particles measuring 1 nm and smaller. Such hybrid materials may find their application in catalysis and as chemical sensors.

Of undeniable interest is the development of multifunctional hybrid nanosystems based on chemically modified metal particles and biologically active substances, which includes the development of new systems for medicinal diagnostics and the target delivery of medicinal drugs.

Abstract. Results of investigations of organic azide photochemistry in inert gas matrices and the most important spectroscopic studies of the last decade, which formed the basis for the modern views on the photochemistry of azides, are analysed. The unique potential of the matrix isolation technique for the reliable identification of reaction intermediates is demonstrated. The bibliography includes 226 references.

I. Introduction

The term ‘matrix isolation’ was introduced by Pimentel^{1,2} and Porter³ in 1954 to describe the technique in which the substrate in a mixture with an inert gas is deposited onto a rather cold surface providing rapid freezing of the mixture. This gives rise to solid samples in which (in the ideal case) each substrate molecule is surrounded by one or several layers of the inert gas and is thus isolated from other substrate molecules. Argon, neon, nitrogen, their mixtures and xenon are most commonly used as inert gases. The technical details of the method and its numerous applications have been considered in a series of monographs and reviews.^{4–10}

In the course of time, the term ‘matrix isolation’ came to be applied in a more general sense, encompassing a range of techniques where substrate (guest) molecules are trapped in a solid inert material (host). Crystals, zeolites, polymers, *etc.* can serve as such materials. Numerous studies of reaction intermediates were carried out in frozen glassy organic solvents. This method of investigation is also sometimes referred to as the matrix isolation. However, in the present review the term matrix isolation will be used only in its original sense.

Two presently available methods for the detection and investigation of reaction intermediates are based on either time-resolved spectroscopic techniques or the stabilisation of intermediates in different matrices at low temperatures and

their studies by conventional spectroscopic methods. In the former case, not only spectroscopic but also kinetic data can be obtained. In the latter case, the structures of possible intermediates can be more reliably predicted due to more detailed spectroscopic information. The use of the matrix isolation techniques is particularly promising in combination with IR spectroscopy of intermediates, because well-resolved IR spectra with a linewidth of $\sim 1\text{--}3\text{ cm}^{-1}$ can be recorded in inert gas matrices at very low temperatures even for rather complex species in a very wide spectral range.

In early studies on the matrix isolation, the assignment of bands in IR spectra of intermediates was based primarily on the record of the characteristic absorption bands with a wide use of the isotopic substitution, reactions of primary intermediates, *etc.* The interpretation of experimental IR and electronic absorption spectra was greatly simplified due to the development of accurate theoretical methods for their calculation. For example, good agreement between calculated and experimental IR spectra can be achieved with the use of the density functional theory (DFT). The hybrid B3LYP method^{11,12} with the 6-31G* basis set is most widely used for this purpose. In these calculations, the vibrational frequencies are somewhat overestimated, which is accounted for by introducing the correction coefficient of 0.9614.¹³

The positions of maxima in electronic absorption spectra and the oscillator strengths for transitions can also be calculated by quantum chemical methods with good accuracy. The CASSCF/CASPT2 approach,^{14,15} which is implemented, for example, in the MOLCAS programme package,¹⁶ provides the most accurate results. The time-dependent DFT method^{17,18} also gives reliable results, particularly, for systems with closed-shell electronic configurations.

The aim of the present review is to analyse the role of the matrix isolation technique in revealing the mechanisms of photolysis of certain classes of organic azides. Organic azides have found use as photoresists in lithography,¹⁹ in the design of conducting polymers,²⁰ organic synthesis,²¹ photoaffinity labelling of biopolymers²² and covalent labelling of the polymer surface.^{23–25} Numerous spectroscopic studies of the intermediates of the organic azides photolysis were performed in the gas phase, in low-temperature glasses and inert gas matrices, and in solutions using time-resolved methods. The results of early studies were summarised in reviews (see, for

Uspekhi Khimii 76 (12) 1218–1240 (2007); translated by T N Safonova

example, Refs 26–31). The data obtained by the matrix isolation technique were considered in reviews.^{32, 33}

In the last decade, there has been dramatic progress in the understanding of the mechanisms of photochemical transformations of alkyl, acyl and aryl azides. The successful use of time-resolved spectroscopic methods for the detection of singlet aryl nitrenes (primary photolysis products of aryl azides) and high-level quantum chemical calculations for the analysis of the spectra and reactivity of these compounds provided a detailed understanding of the complex mechanism of the phototransformations of aryl azides.^{34–37} A considerable progress in the elucidation of the unusual nature of singlet acyl nitrenes was achieved due to the use of the matrix isolation technique combined with high-level quantum chemical calculations.^{38–40}

In the present review, the results of studies on photochemistry of alkyl, aryl and acyl azides in inert gas matrices are analysed. The most interesting recent data obtained with the use of time-resolved methods and the most important spectroscopic and theoretical results underlying the modern views on the photochemistry of azides are considered.

II. Detection and properties of the simplest nitrene NH

Singlet nitrenes are the primary photolysis products of most of azides.^{36, 37} Almost all nitrenes exist in the triplet ground state.^{29–31, 35–37} (Acyl nitrenes considered in Section IV are exceptions.)

The imino radical NH generated in the photolysis,^{41–46} thermolysis⁴⁷ or the multiphoton dissociation^{48, 49} of hydrazoic acid is the simplest nitrene.

Pimentel and co-workers⁵⁰ were the first to study the photolysis of HN₃ by the matrix isolation technique. The IR spectrum of the photolysis products was recorded in an argon and nitrogen matrices, and a series of lines in the spectrum were assigned to nitrene NH and the radical NH₂. This publication was followed by a number of investigations of matrix-isolated nitrene NH and its deuterium-substituted analogue (ND) both in the triplet ground state $^3\Sigma^-$ and the excited metastable state $^1\Delta$ by UV and luminescence spectroscopy.^{51–55} The spectroscopic characteristics and the relaxation of the lowest excited singlet state of nitrene NH (or ND) ($^1\Delta$) in Ne, Ar, Kr and Xe matrices were studied in detail.^{54, 55} The diagram of the lowest energy levels of the NH radical (Fig. 1) can be constructed based on the results of spectroscopic investigations in matrices^{54, 55} and in the gas phase.^{41–46}

Figure 1. Energy level diagram for nitrene NH based on experimental data.^{41–46, 54, 55}

Figure 2. Molecular orbitals of nitrene NH. (The 1σ orbital, the $1s$ atomic orbital of the nitrogen atom, is omitted.)

A knowledge of the electronic structure and the spectra of the simplest nitrene is very useful in the analysis of more complex nitrenes formed by the photolysis of alkyl, acyl and aryl azides. In the NH species, the molecular orbital (MO) corresponding to the N–H bond (2σ) and the MO of the nitrogen lone pair (3σ) are occupied by electron pairs (Fig. 2). Two valence electrons should be distributed between two degenerate antibonding MO, π_x and π_y . This electronic configuration gives rise to three lowest electronic states (terms) of NH, $^3\Sigma^-$, $^1\Delta$ and $^1\Sigma^+$; the triplet state $^3\Sigma^-$ is the ground state (Fig. 3). This figure gives also components of the doubly degenerate lowest singlet state $^1\Delta$ with the closed- and open-shell electronic configurations and the electronic state $^1\Sigma^+$. Two configurations, which are mixed in the lowest singlet state $^1\Delta$ with a minus sign, are mixed with a plus sign in the state $^1\Sigma^+$. It can easily be demonstrated that in this state the probability of finding two non-bonding electrons at a single point in the space is much higher compared to the state $^1\Delta$ and consequently the energy of the state $^1\Sigma^+$ is substantially higher.

Figure 3. Schematic representation of the electronic states of nitrene NH: one of three spin components of the lowest triplet state $^3\Sigma^-$, two components of the lowest singlet state $^1\Delta$ (having the closed- and open-shell electronic configurations) and the second singlet state $^1\Sigma^+$.

The electronic absorption spectra of NH both in the triplet ground state ($^3\Sigma^-$) and the lowest singlet state ($^1\Delta$) show intense lines in the near-UV region with maxima at 336 and 324 nm, respectively.^{41, 46} Both transitions are associated with the electron excitation from the lone pair (3σ) to the π orbital occupied by one electron (π_x or π_y in Fig. 2). This transition is

observed also in the electronic absorption spectra of other organic nitrenes (see Sections III and V).

III. Photochemical transformations of alkyl azides

Photolysis of alkyl azides, including those in which the azido group is bound to the tertiary carbon atom, in solution at room temperature affords the corresponding imines or their further transformations products in quantitative yields.^{56,57} No reaction products of alkyl nitrenes with solvents or active additives could be detected.⁵⁷

The photochemistry of the simplest alkyl azide, *viz.*, methyl azide, was studied in sufficient detail,^{57–60} including the use of the matrix isolation technique.^{61,62} According to the IR spectroscopic data, the photolysis of methyl azide and its different isotopically substituted analogues in Ar, N₂ and CO₂ matrices at 4 and 14 K gives methyleneimine as the only product.^{61,62} It cannot be ruled out that singlet methylnitrene is the primary species formed in the photolysis of methyl azide; however, this species readily undergoes isomerisation to methanimine even at cryogenic temperatures and has no time to relax to the triplet ground state.

In subsequent studies, emphasis was given to the matrix photochemistry of alkyl azides in which the azide group is bound to the tertiary carbon atom. The absence of the α -H atom gave promise that the rate of isomerisation of singlet alkyl nitrene to imine would be lower, thus making possible the relaxation of singlet alkyl nitrene to the triplet ground state. The photolysis of *tert*-butyl azide in a nitrogen matrix was performed at 12 K.⁶³ Imine **1** was detected by IR spectroscopy as the only reaction product.

The formation of strained bridgehead imines was observed in the photolysis of matrix-isolated bridgehead azides, for example, of adamantyl, bicyclo[2.2.2]octyl, bicyclo[3.2.1]heptyl and norbornyl azides.^{64–68} The matrix photochemistry of 1-azidoadamantane (**2**)⁶⁷ and 1-azidonorbornane (**3**)⁶⁸ was studied in most detail.

The low-temperature photolysis of azide **2** in argon and nitrogen matrices, 3-methylpentane glasses, a polyethylene matrix and the solid state afforded strained imine **4**, which was characterised by IR, electronic absorption, Raman and circular dichroism spectra, along with trace amounts of triplet 1-adamantyl nitrene **3**(**5**), which was identified from the ESR spectrum at 8210 G ($E = 0$, $|D/hc| = 1.69 \text{ cm}^{-1}$) and based on the reaction with CO.⁶⁷ Heating of the matrices (for example, to 36 K in the case of an argon matrix) led to dimerisation of imine **4**.

1-Azidonorbornane (**3**) was irradiated in an argon or polyethylene matrix at 12 K using monochromatic radiation with different wavelengths, and the reaction products were identified by IR, UV and ESR spectroscopy method, as well as based on the reaction with methanol or CO.⁶⁸ The photolysis of azide **3** is a more complex process compared to the photolysis of

azide **2**. Three types of imines (**6a**, **b** and **7**) and trace amounts of triplet nitrene **8** were detected.⁶⁸ Imines **6** and **7** are light-sensitive, undergo interconversions and are decomposed to unidentified products.

Triplet nitrene **8** was identified based on the ESR signal at 8124 G ($E = 0$, $|D/hc| = 1.65 \text{ cm}^{-1}$), the narrow band in the electronic absorption spectrum at 298 nm and its reaction with CO in an argon matrix at 36 K.⁶⁸

Since the photolysis of alkyl azides in solution, low-temperature glasses and inert gas matrices affords the corresponding imines as the major primary products, it was hypothesised⁵⁷ that the elimination of molecular nitrogen from alkyl azides in the excited singlet state and the formation of imine are concerted processes and occur without the involvement of singlet alkyl nitrene as an intermediate. This hypothesis has been neither confirmed nor denied experimentally.

Since the irradiation of alkyl azides in inert gas matrices and low-temperature glasses affords triplet alkyl nitrenes only in trace amounts, the sensitised photolysis was proposed as a method for the detection of these species.^{58,69,70} More recently, a series of alkyl nitrenes have been generated by intramolecular sensitisation,^{71–73} including that in an argon matrix.⁷³ For example, the irradiation of α -azidoacetophenone (**9**) and its derivatives gives benzoyl radical (**10**) (through the α -C–C bond cleavage) and triplet nitrene **11**. In solution at room temperature, the main reaction involves the C–C bond cleavage.⁷³ In an argon matrix, only nitrene **11** was detected at 12 K based on the absorption band in the near-UV region with a maximum at 280 nm.⁷³

As mentioned above, the photochemistry of methyl azide was studied in most detail. Triplet methylnitrene was detected in numerous studies both in the condensed phase by the triplet sensitisation^{58,60} and in the gas phase in the corona discharge.^{74–77} The zero-field splitting parameters ($|D/hc| = 1.595 \text{ cm}^{-1}$), which have been initially determined^{58,60} based on the results of experiments in low-temperature glasses, were doubted.⁷⁵ The commonly accepted value $|D/hc| = 1.720 \text{ cm}^{-1}$ was determined by gas-phase spectroscopy.⁷⁸

The electronic absorption spectrum^{79–82} and the luminescence spectrum^{74–77,78–82} of triplet methylnitrene were recorded many times. The 0–0 transition in its electronic absorption spectrum is observed at 316.9 nm in a nitrogen matrix⁸⁰ and at 314.3 nm in the gas phase,⁸¹ which is close to the maximum observed in the electronic absorption spectrum of the NH radical (336 nm).^{41,42} The singlet–triplet splitting in methylnitrene ($\Delta E_{\text{ST}} = 1.352 \pm 0.011 \text{ eV}$ or $130.7 \pm 1.3 \text{ kJ mol}^{-1}$) was determined from the photoelectron spectrum of the CH_3N^- anion.⁸³ This parameter appeared to

be somewhat smaller than that for the NH radical (1.561 eV, see Fig. 1).

Therefore, it is impossible to decide between two probable mechanisms of photolysis of methyl azide based on the published data. According to one mechanism, singlet methylnitrene is formed as the primary intermediate, but its lifetime, even in cryogenic matrices, is too short (due to the isomerisation to methyleneimine) for the relaxation of this species to the triplet ground state. According to another mechanism, the elimination of molecular nitrogen from methyl azide in the excited singlet state and the formation of imine are concerted and proceed without the involvement of singlet nitrene as an intermediate. To understand whether $^1[\text{CH}_3\text{N}]$ is the real intermediate, *i.e.*, whether it is characterised by a minimum on the potential energy surface (PES), the properties of this species were calculated by quantum chemical methods.^{84–93}

Based on the results of earlier studies,^{84–88} it was concluded that no minima on the PES correspond to singlet methylnitrene. However, these calculations were carried out at a low level of theory with the use of small basis sets. Because of this, quantum chemical calculations were repeated in 1990s.^{89–93}

As in the case of the NH radical, the components of the lowest singlet state with the closed- and open-shell electronic configurations in singlet methylnitrene having the C_{3v} symmetry form the doubly degenerate state 1E . The latter undergoes a Jahn–Teller distortion to give the states $^1A'$ and $^1A''$ (C_s symmetry) with the energy difference smaller than 0.04 kJ mol^{−1}.^{86,93} The isomerisation of $^1[\text{CH}_3\text{N}]$ in the state $^1A'$ was studied⁸⁹ at the TC-CISD+Q level of theory (the configuration interaction with single and double excitations based on two-configuration wavefunctions) with a rather large basis set (TZ2P+f). The maximum with a barrier height of ~ 4 kJ mol^{−1} was found on the PES. Nevertheless, the authors of this study suggested that lowering of the symmetry of the system and a more accurate account of the electronic correlation would lead to the disappearance of the barrier in accordance with the results of earlier calculations.^{85,86}

In 2000, a new attempt was made⁹³ to establish the presence of a barrier between the positions $^1[\text{CH}_3\text{N}]$ and $\text{H}_2\text{C}=\text{NH}$ on the PES. The calculations were carried out by the CASSCF(12/11) and CASPT2 methods with the cc-pVDZ and cc-pVTZ basis sets. As in the earlier study,⁸⁹ the maximum on the PES was found, and its energy appeared to be higher than that of the reagent by ~ 2 kJ mol^{−1} (CASSCF calculations) and 16 kJ mol^{−1} (CASPT2 calculations). An analysis of vibrations calculated by the CASSCF(12/11) method showed that the maximum with the C_s symmetry corresponds to the true transition state. Since the electronic correlation is generally overestimated by the CASPT2 method, it was suggested that the barrier height for the isomerisation of $^1[\text{CH}_3\text{N}]$ to $\text{H}_2\text{C}=\text{NH}$ is in the range of 11 ± 4 kJ mol^{−1}.⁹³ Since the reaction is highly exothermic ($\Delta H = -348$ kJ mol^{−1}, the CASPT2 method), the transition state is early, the C–H bond in this state is elongated by only 0.01 Å, and the C–N bond is shortened by 0.016 Å.⁹³ Therefore, according to the results of calculations at the highest levels of theory, singlet methylnitrene does correspond to a minimum on the PES, but its formation was not detected even by femtosecond spectroscopy.⁵⁹

Recently, the photolysis of trifluoromethyl azide (**12**) has been studied⁹⁴ by IR and UV spectroscopy in an argon matrix at 12 K and by the ESR method in polycrystalline pentane. After irradiation of a solution of azide **12** in polycrystalline pentane at 6–10 K with light with a wavelength of 254 nm, the ESR signal centered at 8620 G was observed. This signal was assigned to triplet trifluoromethylnitrene (**13**). The parameters

Figure 4. Difference electronic absorption spectra recorded after irradiation of trifluoromethyl azide in an argon matrix at 12 K for 5 (1), 25 (2) and 45 min (3).⁹⁴

The positions and relative intensities of the absorption bands in the spectra of triplet nitrene **13** (positive peak) and azide **12** (negative peak) calculated at the TD-B3LYP/6-31G* level of theory are indicated by vertical bars.

of this spectrum ($|D/hc| = 1.736$ cm^{−1}) are similar to those for nitrenes $^3(\text{NH})$ ($|D/hc| = 1.863$ cm^{−1})⁹⁵ and $^3(\text{CH}_3\text{N})$ ($|D/hc| = 1.720$ cm^{−1}).⁷⁸

Upon irradiation of azide **12** in an argon matrix at 12 K with a wavelength of 254 nm, its absorption ($\lambda_{\text{max}} = 257$ nm) decreased and an intense absorption band with a pronounced vibrational structure ($\lambda_{\text{max}} = 342, 347.5$ and 354 nm) appeared (Fig. 4).⁹⁴ The latter band was assigned to triplet nitrene **13** based on the similarity to the spectrum of $^3(\text{CH}_3\text{N})$ and agreement with the results of calculations. The IR spectrum showed new bands, one of which (1185 cm^{−1}) was assigned to nitrene $^3(\text{13})$; a series of bands (929, 1015, 1379 and 1735 cm^{−1}) were assigned to perfluoromethyleneimine (**14**) (Fig. 5). A comparison of the experimental and calculated IR spectra shows that nitrene $^3(\text{13})$ and imine **14** are produced in comparable amounts. The formation of $^3(\text{NCF}_3)$ upon irradiation of azide **12** is indicative of the formation of singlet nitrene $^1(\text{13})$ as an intermediate, and a minimum on the PES corresponds to this species.

According to the results of CASSCF (8,8)/6-31G* calculations, the isomerisation of $^1[\text{NCF}_3]$ to imine **14** is exothermic ($\Delta H = -193$ kJ mol^{−1}).⁹⁴ However, it is substantially less exothermic than the presumed isomerisation of singlet methylnitrene ($\Delta H = -348$ kJ mol^{−1}),⁹³ which is indicative of the presence of a much higher barrier to the isomerisation of nitrene $^1(\text{13})$ compared to methylnitrene.

Figure 5. IR difference spectrum recorded after irradiation of azide **12** in an argon matrix at 12 K for 25 min (*I*). The IR spectra of triplet nitrene **13** (*2*) and imine **14** (*3*) calculated at the B3LYP/6-31G* level of theory (the calibration factor is 0.97) (data of the author of the present review).

IV. Photochemical transformations of acyl azides

The thermal rearrangement of acyl azides RC(O)N_3 (the Curtius rearrangement) giving isocyanates in quantitative yields at 60–80 °C has been known over the years and has been studied in detail.^{39, 96–99}

R = Alk, Ar.

The photolysis of acyl azides in solution affords two types of products, *viz.*, isocyanates (the photo-Curtius rearrangement) and products derived from capture of the carbonyl nitrenes $[\text{RC(O)N}]$ by solvent molecules.⁹⁸ For example, the thermolysis of pivaloyl azide $[\text{Bu}^t\text{C(O)N}_3]$ in cyclohexane produces the corresponding isocyanate in 99.4% yield.^{100, 101} The photolysis of $\text{Bu}^t\text{C(O)N}_3$ gives isocyanate in a yield of only 40% both in inert solvents and alkenes, which react with acylnitrenes to form the corresponding aziridines.^{100, 101} The photolysis of benzoyl azide and a series of its derivatives in both inert solvents and solvents giving adducts with acylnitrenes affords isocyanates in similar yields (40%–50%).^{102, 103}

Based on these facts, it was concluded that isocyanates and acylnitrenes are independently formed in the photolysis of acyl azides and that acylnitrenes do not undergo isomerisation to isocyanates.^{98, 100–103}

R = Alk, Ar.

The photolysis and thermolysis of alkoxy carbonyl and aryloxy carbonyl azides $[\text{ROC(O)N}_3]$ afford mainly products derived from the corresponding nitrenes $[\text{ROC(O)N}]$ as precursors.⁹⁸ The yields of isocyanates and their transformation products are generally low.

Ethoxycarbonyl azide **15** has received the most attention in the literature. The analysis of the reaction products led to the conclusion that the thermolysis of azide **15** affords ethoxycarbonylnitrene (**16**) in the singlet state, which stereospecifically reacts with alkenes to give the corresponding aziridines (Scheme 1) and undergoes the relaxation to the triplet ground state $^3(\text{16})$.^{98, 104, 105} Triplet nitrene $^3(\text{16})$ also reacts with alkenes, but this reaction is not stereospecific (apparently, the reaction proceeds *via* the intermediate biradical) (see Scheme 1).⁹⁸

Scheme 1

R = Alk, Ar.

In the photolysis of azide **15**, the yield of the products generated in the reaction of nitrenes was ~70%.^{104, 105} The analysis of aziridines showed that singlet $^1(\text{16})$ and triplet $^3(\text{16})$ nitrenes are simultaneously formed in the primary process in a ratio of 2 : 1.^{98, 105} Singlet nitrene $^1(\text{16})$ is also inserted into the C–H bonds of alkanes and O–H bonds of alcohols and is captured by alkynes and benzene to form azepine.⁹⁸

The triplet nature of the ground state of nitrene **16** was confirmed by the observation of the ESR spectrum in low-temperature glasses ($|D/hc| = 1.603 \text{ cm}^{-1}$, $|E/hc| = 0.0215 \text{ cm}^{-1}$).⁶⁰ A similar spectrum ($|D/hc| = 1.65 \text{ cm}^{-1}$, $|E/hc| = 0.024 \text{ cm}^{-1}$) was recorded for triplet (4-acetylphenoxy)carbonylnitrene.^{106, 107}

Recently, the photochemistry of azide **15** has been studied¹⁰⁸ by laser flash photolysis ($\lambda_{\text{ex}} = 266 \text{ nm}$) in Freon ($\text{CF}_2\text{ClCFCl}_2$) at room temperature. The formation of at least two intermediates, *viz.*, triplet nitrene **16** ($\lambda_{\text{max}} = 400 \text{ nm}$, the lifetime was $\tau = 1.5 \text{ }\mu\text{s}$) and ethoxycarbonyl radical **17** ($\lambda_{\text{max}} = 333 \text{ nm}$, $\tau = 0.4 \text{ }\mu\text{s}$), was observed. Triplet nitrene **16** reacted with tetramethylethylene ($k = 3 \times 10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$) and triethylsilane ($k = 1 \times 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$).¹⁰⁸

The photolysis of (4-acetylphenoxy)carbonyl azide was also studied.^{106, 107} Only the reaction products of the corre-

sponding nitrene were found, whereas isocyanate and its transformation products were not detected.¹⁰⁷

The photochemistry of methoxycarbonyl azide (**18**) and its deuterium derivative was studied in inert gas matrices at 4 and 10 K.^{109, 110} The IR spectrum of the reaction products shows characteristic lines assigned to methoxy isocyanate (**19**) and its further transformations products, *viz.*, formaldehyde and isocyanic acid.

Triplet methoxycarbonylnitrene was not detected.¹¹⁰ This is apparently due to the photochemical transformation of the latter into isocyanate.

Thus, the photochemical reactions of azides $\text{ROC}(\text{O})\text{N}_3$ ($\text{R} = \text{Alk}$ or Ar) have not been adequately studied, and it is necessary to study these reactions in more detail by the matrix isolation technique. However, the analysis of the reaction products showed that the photolysis and thermolysis of these azides produce the corresponding nitrenes having the triplet ground state^{60, 106–108} in high yields.^{98, 101, 102, 104–108}

As was mentioned in the beginning of this Section, the photolysis of acyl azides $\text{RC}(\text{O})\text{N}_3$ ($\text{R} = \text{Alk}$ or Ar) affords isocyanates in rather high yields.⁹⁸ The ESR spectra of acylnitrenes in the triplet state were not observed after the photolysis of azides $\text{RC}(\text{O})\text{N}_3$, as opposed to the photolysis of azides $\text{ROC}(\text{O})\text{N}_3$. The characteristic features of the photolysis of carbonyl azides were revealed and the unusual properties of the corresponding nitrenes were explained with the use of the matrix isolation techniques^{38, 40} combined with the results of quantum chemical calculations.^{38–40, 99, 111, 112}

Among acyl azides, benzoyl azide (**20**) has received most attention.^{38–40, 102, 103, 113–116} In early studies,^{102, 103, 113–116} the photolysis of this compound was demonstrated to give the photo-Curtius rearrangement product (phenyl isocyanate **21**, ~40% yield) along with the reaction products of singlet benzoylnitrene (**22**) with alkenes, sulfides, *etc.* The direct and triplet-sensitised photolysis of benzoyl azide in alkenes affords the same products characteristic of the reactions of nitrene **1**(**22**).^{115, 116} No ESR spectra of triplet benzoylnitrene were observed upon the photolysis of benzoyl azide in glassy solvents.^{60, 70}

To reveal the multiplicity of the ground state of aroylnitrenes, the photochemistry of 2-naphthoyl azide (**23**) and a series of acetyl and nitro derivatives of benzoyl azide was studied in detail,^{106, 107, 117, 118} including investigations by the laser flash photolysis technique. As in the case of benzoyl azide, the corresponding isocyanate (~50%) and the reaction products of singlet 2-naphthoylnitrene (**24**) with alkenes and cyclohexane (~45%) were detected upon irradiation of azide **23**. The triplet sensitisation also affords products typical of the reactions of nitrene **1**(**24**).¹⁰⁶ The ESR spectrum of triplet nitrene **24** was not observed. Analogous results were obtained in studies of the photolysis of acetyl and nitro derivatives of benzoyl azide. Although the authors failed to detect singlet aroylnitrenes by spectroscopic methods, their data leave little doubt that the ground state of aroylnitrenes is singlet.^{106, 107, 117, 118} However, this unusual fact remained unexplained.

To understand why aroylnitrenes can have the singlet ground state, we calculated the singlet–triplet splitting (ΔE_{ST}) for nitrenes **22** and **24** by the B3LYP method.¹¹¹ The calculated ΔE_{ST} is small (~21 kJ mol⁻¹); however, according to the calculations, the triplet state is the ground state. Recall

that $\Delta E_{\text{ST}} = 150.6$ kJ mol⁻¹ for the simplest nitrene NH and 130.7 kJ mol⁻¹ for CH₃N. The significant stabilisation of the singlet state compared to the triplet state in aroylnitrenes is attributed to the special bonding between the nitrogen and oxygen atoms, due to which the structure of the singlet nitrenoid species is intermediate between the nitrene and oxazirine structures.¹¹¹

Having understood the nature of the singlet nitrenoid species, we studied the photolysis of benzoyl azide by the matrix isolation technique with the aim of detecting this species by spectroscopic methods.³⁸ After irradiation for 2 min in an argon matrix with light with the wavelength of 254 nm, the electronic absorption spectrum of azide **20** disappeared and a new band with a maximum at 300 nm appeared (Fig. 6, spectrum 1). Simultaneously, absorption bands of azide **20** virtually completely disappeared in the IR spectrum, and new bands appeared, among which the intense absorption at ~2270 cm⁻¹ was assigned to phenyl isocyanate.³⁸ The subsequent irradiation with light with the wavelength of 313 nm led to the disappearance of the absorption band in the UV spectrum (see Fig. 6, spectrum 2). At the same time, the intensity of some bands in the IR spectrum substantially decreased, whereas the intensity of other bands increased (Fig. 7, spectrum 1).

Thus, the photolysis of benzoyl azide affords at least two products. One of these products is characterised by absorption with a maximum at ~300 nm and it is transformed into another product upon irradiation with light with the wavelength of 313 nm. Most of the lines in the experimental IR spectrum recorded 8 min after irradiation are in good agreement with the calculated spectrum of isocyanate (see Fig. 7, spectrum 2), except for one rather intense band at 1193 cm⁻¹, which is absent in the calculated spectrum.³⁸ The results of our investigations^{38, 40} were reproduced in the study,¹¹⁹ and the previously unidentified band was assigned to phenyl cyanate (**25**) produced in a small amount. Therefore, isocyanate **21** and trace amounts of cyanate **25** are the final products.^{40, 119}

Figure 6. Difference electronic absorption spectra recorded upon irradiation of compound **20** at 254 nm for 2 min in an argon matrix at 12 K (**1**) and of the same sample irradiated at 313 nm for 8 min (**2**).³⁸ The positions and relative intensities of the absorption bands of nitrene **1**(**22**) calculated at the CASSCF/CASPT2 level of theory are indicated by vertical bars.

Figure 7. IR difference spectrum of the photolysis products of benzoyl azide upon irradiation with light with $\lambda = 254$ nm for 2 min followed by irradiation for 8 min with light with $\lambda = 313$ nm in an argon matrix at 12 K (*I*).

Positions and relative intensities of the bands in the IR absorption spectrum of isocyanate **21** (**2**) and nitrene $^1(\mathbf{22})$ (**3**) calculated at the B3LYP/6-31G(d) level (the correction factor is 0.97).^{38, 40}

The band in the electronic absorption spectrum at 300 nm (see Fig. 6, spectrum *I*) belongs to the singlet nitrenoid species $^1(\mathbf{22})$, which has the structure intermediate between the nitrene and oxazirine structures. According to CASSCF/CASPT2 calculations, two most intense transitions in the optical absorption spectrum of the species $^1(\mathbf{22})$ have maxima at 306 and 290 nm (see Fig. 6). In addition, the calculated spectrum shows a band corresponding to the transition to the first excited state with a maximum at 513 nm and a very low intensity. This band is associated with the electron excitation from the allyl-type π orbital to the σ^* orbital of a very weak N–O bond.

The calculated IR spectrum of the species $^1(\mathbf{22})$ is also in excellent agreement with the experimental IR spectrum of an intermediate species having an absorption maximum at 300 nm (see Fig. 7, spectrum *I*, negative peaks).

The ratio of the yields of **21** and $^1(\mathbf{22})$ in the primary process is estimated as 64 : 36 from the initial slope of the kinetic curves of the formation of these products upon irradiation ($\lambda = 254$ nm).³⁸

Thus, the use of the matrix isolation techniques combined with quantum chemical calculations provided an insight into the unusual nature of singlet aroylnitrenes.

It should be noted that the calculations of the properties of the simplest acylnitrenes HC(O)N and HOC(O)N were carried out in numerous studies.^{38–40, 99, 111, 112, 120–127} In early studies,^{120–124} quantum chemical calculations were performed at a rather low level of theory, and, as a consequence, the results of these calculations are inconsistent with the modern views of the electronic and geometric structures of acylnitrenes. In 1999,

the potential energy surfaces for the model systems CHNO¹²⁵ and CH₂NO¹²⁶ were studied in detail by the high-level G2, CASSCF, CASPT2 and QCISD(T) methods. Numerous local minima and transition states between these minima were found, and structures of triplet formylnitrene and singlet cyclic oxazirine with a very long N–O bond (1.73 Å) were located. According to calculations by the G2 method, the energy of the singlet species is lower than that of the triplet species by 12 kJ mol^{−1}.¹²⁶ In turn, according to CASPT2/cc-pVTZ and QCISD(T)/cc-pVTZ calculations (with the CASSCF/cc-pVTZ geometry), the energy of the triplet state is lower than that of the singlet state by 16 and 3 kJ mol^{−1}, respectively.¹²⁶ It is known^{127–129} that the CASPT2 method underestimates the energy of systems with open-shell electronic configurations (in the case under consideration, of the triplet state) compared to those with closed-shell electronic configurations (the singlet species) by 13–17 kJ mol^{−1}. Our calculations by the CCSD(T) method with an extrapolation to the infinite basis-set limit³⁸ predicted that the singlet state lies 3 kJ mol^{−1} lower in energy than the triplet state. For acetylnitrene [MeC(O)N], according to the recent calculations by the high-level CBS-QB3 method, the singlet state is lower in energy than the triplet state by ~ 17 kJ mol^{−1} (Ref. 39).

In addition, the energy of the singlet species calculated by the B3LYP method was demonstrated^{38–40} to be substantially overestimated (by ~ 38 kJ mol^{−1}) compared to the energy of the triplet nitrene. Hence, the energy of the singlet nitrenoid species $^1(\mathbf{22})$ should be ~ 17 kJ mol^{−1} lower than that of the triplet species $^3(\mathbf{22})$, which is consistent with its detection in an argon matrix.

The CCSD(T) calculations with an extrapolation to the infinite basis-set limit for the simplest nitrene HOC(O)N⁴⁰ showed that the triplet state for both the *syn* and *anti* rotamers is the ground state, and the singlet nitrenoid species lies higher in energy by 26 and 16 kJ mol^{−1}, respectively. For methoxycarbonylnitrene, the ground state is also the triplet. According to CBS-QB3 calculations, the singlet state is higher in energy by 23.8 kJ mol^{−1} (Ref. 39).

The singlet–triplet splittings for nitrenes ROC(O)N and RC(O)N are different due to the weaker bonding between the nitrogen and oxygen atoms in the $^1A'$ state of the former, which manifests itself in lengthening of the N–O bond. It is unlikely that the oxygen atom of the alkoxy or aryloxy group can hinder the σ bonding between the nitrogen and oxygen atoms in the CON fragment. Presumably, the π bonding between these atoms is weaker due to an extension of the π system in the presence of the OR group.

The commonly accepted view (presented in many handbooks and reviews^{21, 22, 26–33}) is that the addition at double bonds and the insertion into the C–H, O–H and N–H bonds are typical of singlet nitrenes. However, these reaction products were detected only for acylnitrenes and, as will be demonstrated in the next section, for perfluoro-substituted phenylnitrenes. However, these singlet nitrenes do not belong to ‘usual’ nitrenes. The electronic and geometric structures of these nitrenoid species are characteristic of oxazirines, although the N–O bond in these species (1.7–1.8 Å) is substantially longer than the typical single bond (~ 1.5 Å).

The calculations demonstrated^{39, 40} that the above-considered reactions (the addition at double bonds and the insertion into the bonds) of nitrenoid species with an unusual structure proceed with a low or even zero activation energy. Recently, the temperature dependence of the rate constant for the reaction of nitrene $^1(\mathbf{22})$ with hex-1-ene in Freon has been experimentally studied.³⁹ It appeared that the rate of this reaction is virtually temperature independent, and even a small negative activation energy ($E_a = -0.25$ kJ mol^{−1}) was measured.

V. Photochemical transformations of aryl azides

As mentioned in the Introduction, considerable progress in understanding the photochemical transformations of aryl azides was achieved in the last decade. This is mainly due to the fact that the primary products of their photolysis, *viz.*, singlet arylnitrenes, were detected and their reactivity was studied.^{34–37} The spectroscopic and kinetic data were analysed using high-level quantum chemical calculations (CASSCF/CASPT2).^{34–37} Combined theoretical and experimental studies of the properties of phenylnitrene and its simple derivatives were covered in reviews.^{34, 36} The kinetic and spectroscopic properties of short-lived (~ 100 ps – 100 ns) singlet arylnitrenes were examined in detail.^{35, 37} However, investigations by the matrix isolation techniques have received little attention. In addition, a series of very recent studies^{130–133} dealt with the photolysis of aryl and heteroaryl azides by the matrix isolation techniques, which provided deeper insight into the characteristic features of these processes.

1. Photochemistry of phenyl azide

The photochemistry of the simplest aryl azide, *viz.*, phenyl azide, has attracted most attention. For many years, only polymeric tars have been detected upon the photolysis and thermolysis of this compound.^{21, 27} However, the thermolysis¹³⁴ and photolysis¹³⁵ of phenyl azide in the presence of aniline or diethylamine (DEA) afforded the corresponding azepines **26** in high yield (no lower than 70%). It was postulated that the thermolysis and photolysis of phenyl azide lead to the elimination of molecular nitrogen and the formation of the $[C_6H_5N]$ intermediate.^{134, 135}

$R^1 = R^2 = Et$; $R^1 = H$, $R^2 = Ph$.

It was hypothesised that either benzoazirine (**27**) or cyclic ketene imine (1-azacyclohepta-1,2,4,6-tetraene or 1,2-didehydroazepine, **28**) is a species reacting with amines.^{134, 135} It was not ruled out that singlet phenylnitrene (**29**) can be the precursor of these compounds.

An analysis of the photolysis products of phenyl azide under different conditions is indicative of the formation of all the above-mentioned intermediates. At lower concentrations of solutions of phenyl azide, tarring decreases and the reaction produces azobenzene.^{136, 137} This indicates that singlet intermediates [compounds **27** and/or **28**] serve as a reservoir for triplet nitrenes $^3(29)$, which either undergo dimerisation or react with the starting azide to give azobenzene as the final product. Unfortunately, the formation of azobenzene was not studied by direct methods, for example, by the laser flash photolysis.

In 1962, the ESR spectrum of triplet nitrene $^3(29)$ was recorded in a glassy matrix at 77 K ($|D/hc| = 0.998$ cm⁻¹), and the triplet state of this nitrene was demonstrated to be the ground state.⁶⁹ Shortly thereafter, the low-temperature electronic absorption spectrum of nitrene $^3(29)$ was recorded in a glassy matrix.¹³⁸ More recent studies¹³⁹ showed that this

nitrene readily undergoes isomerisation to ketene imine **28** upon irradiation.

It was hypothesised that the nucleophilic addition of amines to benzoazirine **27** affords substituted 3*H*-azepines **26** as the major products.^{134, 140–142} The transient absorption spectrum observed in experiments on the laser flash photolysis was also assigned to compound **27**.^{140–142}

The situation changed when ketene imine **28** was detected upon the photolysis of phenyl azide in an argon matrix.¹⁴³ The irradiation of phenyl azide in an argon matrix at 8 K with light at $\lambda > 360$ nm (or $\lambda > 216$ nm) led to the formation of a product giving an intense band in the IR spectrum at 1895 cm⁻¹ characteristic of heterocumulene structures ($-N=C=C-$).

It appeared that ketene imine **28** is unstable upon further irradiation ($\lambda > 360$ nm); however, the formation of benzoazirine **27** was not observed.¹⁴³ In a more thorough investigation¹⁴⁴ of the photolysis of phenyl azide and its ¹⁵N-labelled analogue in argon and neon matrices at 12 K, at least 40 new bands were found in the IR spectrum, and 11 bands were assigned to compound **28**.¹⁴⁴ The assignment of the other bands was not made; however, the authors hypothesised that these bands belong to photolysis products of ketene imine. In addition, the ESR spectrum characteristic of nitrene $^3(29)$ ($|D/hc| = 1.027$ cm⁻¹, $E = 0$ cm⁻¹) was observed upon irradiation ($\lambda > 216$ nm) of phenyl azide in an argon matrix at 12 K.¹⁴⁵

Detailed study of the photolysis products of phenyl azide in organic solvents in a wide temperature range (77–293 K) combined with the measurements of their electronic absorption and luminescence spectra led to the conclusion¹³⁹ that triplet nitrene **29** is the major product at 77 K.

Studies by time-resolved IR spectroscopy and the laser flash photolysis convincingly demonstrated^{146, 147} that ketene imine **28** ($\lambda_{max} \approx 350$ nm, $\nu_{max} = 1889$ cm⁻¹) is the intermediate detected in time-resolved experiments at room temperature. This ketene imine reacts with DEA to give intermediate 1*H*-azepine, which is transformed into 3*H*-azepine (**26**) as the final product.^{146, 147}

Thus, the results obtained in solutions and inert gas matrices differ substantially from those obtained in low-temperature glasses. In glasses, triplet nitrene **29** is formed as the major product, whereas ketene imine **28** is the major reaction product in solution at room temperature and in inert gas matrices at ~ 10 K. Two hypotheses were put forward to explain this contradiction.¹³⁹ According to one hypothesis, the secondary photolysis of nitrene $^3(29)$ proceeds in inert gas matrices to give ketene imine **28**. According to another hypothesis, the primary intermediate, *viz.*, vibrationally excited singlet nitrene $^1(29)$, has no time to relax to the ground vibrational state and undergoes rapid isomerisation to ketene imine.

To find an explanation for this contradiction, new investigations of the photolysis of phenyl azide in the inert gas matrices and low-temperature glasses were carried out.^{148, 149} The irradiation in nitrogen or argon matrices at 12 K with light with the wavelength of 334 nm afforded compound **28** in a small amount, whereas another species was generated as the major product. The IR spectrum of the latter was assigned to nitrene $^3(29)$.¹⁴⁸ The irradiation of nitrene $^3(29)$ with long-wavelength light (485 nm or > 450 nm) caused its transformation into ketene imine **28**, which, in turn, could be transformed into nitrene $^3(29)$ under irradiation with light with $\lambda = 334$ nm. The ratio between the concentrations of the nitrene and the ketene imine in the initial steps of irradiation ($\lambda = 334$ nm) was found¹⁴⁸ to be $\sim 4:1$ in all matrices (nitrogen, argon and glassy 2-methylbutane). It was hypothesised¹⁴⁸ that ketene imine **28** is generated from the vibrationally or electronically excited state of singlet nitrene $^1(29)$.

Figure 8. Electronic absorption spectra of the starting phenyl azide in an argon matrix (with an addition of 10% nitrogen for the improvement of the optical properties) at 12 K (1) and of a sample after irradiation: $\lambda = 254$ nm, 10 min (2); visible light ($\lambda > 455$ nm), 15 min (3); UV irradiation ($\lambda = 334$ nm), 130 min (4).

The influence of the nature of the matrix (Ar, CH₄ or 3-methylpentane) on the photolysis of phenyl azide was studied¹⁴⁹ but the irradiation was performed with shorter-wavelength light ($\lambda = 280 \pm 5$ nm). A conclusion was reached that the formation of nitrene **3**(**29**) is more preferable in CH₄ and 3-methylpentane matrices than in an argon matrix. This effect was attributed to the faster relaxation of vibrationally excited singlet nitrene **1**(**29**) in polyatomic solvents compared to that in a one-atom argon matrix.

The spectra, which we recorded upon irradiation of phenyl azide in an argon matrix, are given as examples in Figs 8 and 9. The short-wavelength irradiation ($\lambda = 254$ nm) affords a mixture of nitrene **3**(**29**), which gives a well-resolved spectrum at 290–320 and 430–480 nm, and ketene imine **28** with a characteristic broad band at $\lambda_{\text{max}} = 340$ nm (Fig. 8, spectrum 2). The further irradiation with visible light ($\lambda > 455$ nm, 15 min) leads to the virtually complete disappearance of the absorption of nitrene **3**(**29**) and an increase in the intensity of the absorption of ketene imine **28** (Fig. 8, spectrum 3). The subsequent irradiation with light with $\lambda = 334$ nm leads to an increase in the intensity of the absorption of nitrene **3**(**29**) (Fig. 8, spectrum 4).

As can be seen from Fig. 9, all lines in the experimental IR spectra of the photolysis products can be assigned to nitrene **3**(**29**) and ketene imine **28**, and there is a good agreement between the calculated and experimental IR spectra of both intermediates. It can also be seen from this Figure that nitrene **3**(**29**) is transformed into ketene imine upon irradiation with visible light (spectrum 1), whereas the irradiation with UV light causes the transformation of ketene imine **28** into nitrene **3**(**29**).

Assuming that the photolysis affords only products **27** and **3**(**29**), which is consistent with the observed IR spectrum, the individual electronic absorption spectra of these compounds can be obtained (Fig. 10). The calculated electronic absorption spectra of these intermediates are in good agreement with experimental data. It should be noted that transitions of an electron of the lone pair to the π -type singly occupied molecular orbital (SOMO) ($\lambda_{\text{calc}} = 289$ nm) and the p_x -type SOMO lying in the plane of the ring ($\lambda_{\text{calc}} = 287$ nm) make a considerable contribution to the absorption band of triplet phenyl-nitrene at 270–320 nm. The spectra of the simplest nitrenes **3**(NH) ($\lambda_{\text{max}} = 336$ nm)^{41,42} and **3**(CH₃N) (316.9 nm) are also associated with analogous transitions.⁸⁰

Figure 9. IR difference spectra of preirradiated ($\lambda = 254$ nm, 10 min) matrix-isolated phenyl azide (an argon matrix with 10% nitrogen, 12 K) after irradiation with visible light ($\lambda > 455$ nm) for 15 min (1) and after UV irradiation ($\lambda = 334$ nm) for 130 min (2).

The IR spectra of ketene imine **28** (3) and triplet nitrene **29** (4) calculated at the B3LYP/6-31G* level of theory (the correction factor is 0.9614).

As opposed to the results of the study,¹⁴⁸ according to which irradiation of phenyl azide at 334 nm affords compounds **3**(**29**) and **28** as the primary products in a ratio of 4 : 1, our investigation showed that the irradiation with shorter-wavelength light ($\lambda = 254$ nm) gives primary products in a yield of $\sim 0.5 : 1$, i.e., the formation of ketene imine **28** is more preferable. This fact indicates that the latter is actually formed in the course of isomerisation of vibrationally excited singlet nitrene **29** and is consistent with the results of the recent studies

Figure 10. Electronic absorption spectra of triplet nitrene **29** (1) and ketene imine **28** (2). The calculated positions and relative intensities of the absorption bands of nitrene **3**(**29**) [solid bars, CASSCF(12,12)/CASPT2//CASSCF(8,8)/6-31G* calculations]¹⁵⁰ and ketene imine **28** (dotted bars, B3LYP/6-31+G* calculations) are indicated by vertical bars.

on the photolysis of phenyl azide and a series of its derivatives in solution at room temperature by femtosecond electronic absorption spectroscopy^{151–154} and femtosecond IR spectroscopy.¹⁵⁵ It was found that the N–N bond dissociation in aryl azides under study proceeds on the femtosecond time scale (*ca.* 100–500 fs).^{151–154} For example, the time of formation of singlet biphenyl-4-yl nitrene in the photodissociation of biphenyl-4-yl azide ($\lambda_{\text{ex}} = 266$ nm) in acetonitrile is ~ 100 fs, and the time of formation of the corresponding nitrene from biphenyl-2-yl azide is 280 ± 150 fs.^{152, 153} The resulting singlet aryl nitrenes [including nitrene **1(29)**] are vibrationally excited, and the shorter the wavelength of the photoexcitation the larger the excess of vibrational energy. The vibrational relaxation in acetonitrile proceeds within 10 ps (for singlet biphenyl-4-yl nitrene^{152, 153} and 3,5-dichlorobiphenyl-2-yl nitrene in cyclohexane,¹⁵¹ the relaxation time is 11 ps).

The theoretical analysis¹⁵³ of the PES section along the reaction coordinate corresponding to the elimination of molecular nitrogen for the ground (S_0) and two excited singlet states (S_1 and S_2) of aryl azides suggests that the first excited state (S_1) is apparently dissociative. The second excited state (S_2) is the bound state, and its geometry is similar to that of the state S_0 . Upon absorption of UV irradiation, the excitation to the state S_2 takes place. The time of formation of vibrationally excited singlet aryl nitrene (< 500 fs) corresponds to the time of internal conversion into the dissociative state S_1 . It was also found¹⁵³ that the surfaces for S_1 and S_0 intersect each other. Consequently, the S_1 state of aryl nitrenes can be deactivated to the ground state. This explains why, in spite of a high rate of formation of aryl nitrenes, the quantum yield of photodissociation can be substantially smaller than unity; for example, the quantum yield for phenyl nitrene is close to 0.5 and is temperature independent (300 and 77 K).³¹

Singlet aryl nitrene [for example, **1(29)**], which is formed upon dissociation of aryl azide, has a considerable excess of vibrational energy and can easily overcome the potential barrier. Actually, studies by femtosecond time-resolved IR spectroscopy showed that a part of ketene imine **28** is very rapidly formed in acetonitrile at room temperature (also in the vibrationally excited state).¹⁵⁵ The formation of ketene imine and its vibrational relaxation proceed on the time scale of 10–50 ps. Unfortunately, attempts to separate these two processes and determine the time of formation of ketene imine failed.¹⁵⁵

Although the hypothesis about the possible involvement of vibrationally excited singlet phenyl nitrene **1(29)**[#] in the isomerisation was made^{139, 148} many years ago, it was confirmed only very recently.¹⁵⁵ However, the isomerisation of nitrene **1(29)**[#] to ketene imine **28** competes with its vibrational relaxation to the ground vibrational state **1(29)**, in which this species also undergoes the thermally activated isomerisation to form ketene imine **28**.^{34–37}

In 1997, the spectrum of singlet nitrene **1(29)** ($\lambda_{\text{max}} = 350$ nm, Fig. 11) with a lifetime of ~ 1 ns at room temperature was recorded for the first time.^{156, 157} The kinetics of transformations of this species was studied in detail in a wide temperature range (170–270 K), which allowed the simultaneous determination of the rate constant of its intersystem crossing to the triplet ground state and the activation parameters of the isomerisation (A and E_a).¹⁵⁰ The observed rate constant (k_{obs}) decreases as the temperature is lowered to ~ 170 K, and then reaches the constant value of $\sim 3.2 \times 10^6 \text{ s}^{-1}$, which was assigned¹⁵⁰ to the rate constant of the intersystem crossing (k_{isc}) of singlet nitrene **29** to the triplet ground state. The temperature dependence of the rate constant of isomerisation $k_R = k_{\text{obs}} - k_{\text{isc}}$ obeys the Arrhenius law (Fig. 12). The activation energies ($E_a = 23.4 \pm 1.3 \text{ kJ mol}^{-1}$) and the preexponential factors ($A = 10^{13.1 \pm 0.3} \text{ s}^{-1}$) were determined.¹⁵⁰

Figure 11. Electronic absorption spectra recorded after the laser excitation (266 nm, 35 ps) of phenyl azide in pentane: after 2 ns at 233 K (1) and after 10 ns at 295 K (2).^{150, 156}

The calculated positions and relative intensities of transitions in nitrene **1(29)** [at the CASSCF(12,12)/CASPT2 level of theory with the geometry calculated at the CASSCF(8,8)/6-31G* level]¹⁵⁰ are indicated by vertical bars.

The rate constants of the intersystem crossing estimated from the data obtained in solution [$(3.2 \pm 0.3) \times 10^6 \text{ s}^{-1}$]¹⁵⁰ and in glassy methylcyclohexane at 77 K [$(3.8 \pm 0.3) \times 10^6 \text{ s}^{-1}$]¹⁵⁸ have similar values, thus confirming the hypothesis that the constant k_{isc} is temperature independent.¹⁵⁰

Figure 12. Temperature dependences of the observed rate constant for the decay of singlet nitrene **1(29)** (k_{obs}) (1) and the rate constant for the isomerisation k_R ($k_R = k_{\text{obs}} - k_{\text{isc}}$) (2) in the Arrhenius coordinates.¹⁵⁰ The inset shows the temperature dependence of the rate constant k_{obs} .

Figure 13. Occupation of the orbitals in nitrene **29** by non-bonding electrons and the bond lengths (in Å) for the lowest states calculated at the CASSCF/6-31G* level.¹²⁹

It has long been commonly accepted that singlet phenylnitrene, like other singlet arylnitrenes, has a closed-shell electronic configuration (1A_1).^{21, 26–30} However, relatively recently it has been shown that the lowest singlet state of nitrene **29** (1A_2) has an open-shell electronic configuration, *i.e.*, two electrons with opposite spins occupy two different orbitals, *viz.*, the π -type orbital and the p_x orbital located on the nitrogen atom and lying in the ring plane.^{159–161} The excited singlet state 1A_1 lies higher in energy by ~ 60 kJ mol⁻¹ (Ref. 162). The orbital populations and the bond lengths for three lowest spin states of nitrene **29** are shown in Fig. 13.

The singlet–triplet splittings ($\Delta E_{ST} = 73–76$ kJ mol⁻¹) calculated at high levels of theory^{129, 160, 161, 163} are in good agreement with the experimental values estimated by photoelectron spectroscopy (75 ± 8 kJ mol⁻¹)¹⁶² and photoionisation spectroscopy (77 ± 3 kJ mol⁻¹).¹⁶⁴

In 1997, quantum chemical calculations at the CASSCF/CASPT2 level of theory showed that the isomerisation of nitrene **1(29)** to ketene imine **28** proceeds in two steps.¹²⁹ In the first rate-limiting step, the nitrene undergoes isomerisation to azirine **27**. The second step involves the three-membered ring opening to form compound **28**.

The barrier for the cyclisation reaction evaluated at the CASPT2 level is 39 kJ mol⁻¹ (Ref. 129). However, this method generally overestimates the stabilisation of systems having an open-shell electronic configuration compared to species containing paired electrons¹²⁷ [for an analogous system, the error was 14 kJ mol⁻¹ (Ref. 129)]. Taking into account this error, the barrier for the cyclisation of nitrene **1(29)** is 25 kJ mol⁻¹, which is in excellent agreement with the measured activation energy of isomerisation (23.4 ± 1.4 kJ mol⁻¹).¹⁵⁰

According to calculations,¹²⁹ the barrier for the second step (**27** \rightarrow **28**) is as low as 13 kJ mol⁻¹ (Fig. 14). This result is consistent with the fact that azirine **27** was not detected in time-resolved experiments.^{139, 146, 147, 150, 156, 157} Although the lifetime of this intermediate is very short, the formation of the reaction product of this species with ethanethiol, *viz.*, the

Figure 14. Energetics of the isomerisation of singlet phenylnitrene **1(29)** calculated at the CASPT2(8,8)/6-311G(2d,p)//CASSCF/6-31G(d) level.¹²⁹ TS is the transition state.

corresponding *ortho*-substituted aniline (in 39% yield), in the photolysis of phenyl azide in ethanethiol was documented.¹⁶⁵

The mechanism of photolysis of phenyl azide taking into account the results of the very recent studies^{150, 155–158} is presented in Scheme 2.

The above-considered data can be briefly summarised as follows. The photodissociation of phenyl azide proceeds on the femtosecond time scale (< 500 fs) to form singlet phenylnitrene in the vibrationally excited state **1(29)[#]**. The vibrational relaxation of the latter competes with the isomerisation to azepine, which is also formed in the vibrationally excited state. Singlet phenylnitrene in the ground vibrational state **1(29)** can undergo relaxation to the triplet ground state $3(29)$ (the intersystem crossing, ISC) or, by overcoming the barrier, transformed into benzoazirine **27**, which, in turn, is transformed into azepine **28**. At room temperature, the isomerisation is the major process. The contribution of the intersystem crossing increases as the temperature is lowered; it becomes the major process at temperatures below 170 K.

2. Photochemistry of phenyl azide derivatives

The photochemistry of simple derivatives of phenyl azide has been studied in sufficient detail, including investigations by the matrix isolation technique.^{144, 166–170} The spectroscopy and kinetics of the reactions of substituted singlet phenylnitrenes in solution in a wide temperature range (150–300 K) have been investigated recently.^{151, 158, 171–178} The influence of substituents was considered in detail in the reviews.^{35, 37} It should be noted that the influence of substituents on the rate constant for the cyclisation of phenylnitrene to azirine is not very significant. For example, the presence of two methyl substituents in the *ortho* position with respect to the nitrogen atom leads to an increase in the reaction barrier due to the steric effect and an increase in the lifetime of nitrene at room temperature by approximately an order of magnitude.¹⁷³ Such substituents as the cyano and phenyl groups in the *para* position also increase the lifetime by approximately an order of magnitude.^{176, 178}

The introduction of two fluorine atoms at the *ortho* position with respect to the nitrogen atom has the maximum effect on the rate constant for the cyclisation.^{175, 177} For

Scheme 2

ISC is the intersystem crossing; \rightsquigarrow is the vibrational relaxation.

example, the lifetime of singlet 2,6-difluorophenylnitrene at room temperature increases by two orders of magnitude. This is due to the high electronegativity of the fluorine atom.^{37, 177} Due to rather long lifetimes, polyfluorinated singlet arylnitrenes can be involved in bimolecular reactions, including the insertion into C–H bonds and the addition at double bonds.^{179–185} Hence, polyfluorinated aryl azides are the most promising reagents for photoaffinity labelling of biopolymers^{186–192} and covalent modification of the surface of polymer coatings.^{23–25}

The introduction of substituents can lead also to changes in the relative reaction rates of the two-step isomerisation of singlet nitrene to the corresponding ketene imine. For example, the second step (the ring opening) is the rate-limiting step for biphenyl-2-yl nitrene and 2,4,6-tri-(*tert*-butyl)phenyl nitrene, and it is possible to detect the derivative of azirine **27**.^{158, 178} All these effects have been analysed in detail earlier³⁷ and are beyond the scope of the present review.

In the study,¹⁴⁴ the photolysis of phenyl azide was investigated (along with the photolysis of ten its *para* and *meta* derivatives containing F, Cl, CN, Me or MeO substituents) in nitrogen and argon matrices. In all cases, the IR spectra of the photolysis products in the matrices at 12 K show the most intense band (or a series of bands) at 1890–1906 cm^{−1}. Consequently, it was concluded that the corresponding ketene imine derivatives **28** are the major products in all reactions.

Unlike the photolysis of *para*- and *meta*-methyl derivatives of phenyl azide,¹⁴⁴ the photolysis of 2,6-dimethylphenyl azide (**30**) in a nitrogen matrix at 12 K affords the corresponding triplet nitrene ³(**31**) as the major product. In the presence of CO, the latter gives 2,6-dimethylphenyl isocyanate (**32**).¹⁶⁷ Insignificant amounts of the corresponding ketene imine **33** were found upon UV irradiation of triplet nitrene.

Analogous results were obtained¹⁶⁶ in the study of the photolysis of perfluorophenyl azide (**34a**) in a nitrogen matrix. The major primary product, *viz.*, perfluorophenyl nitrene (**35a**) in the triplet state, was involved in the photochemical reaction with CO to give the corresponding isocyanate. Azirine and ketene imine were not found.¹⁶⁶

More recently, it was confirmed¹⁶⁸ that the photolysis of perfluorophenyl azide (**34a**) and 2,6-difluorophenyl azide (**34b**) in an argon matrix affords the corresponding triplet nitrenes **35a,b** as the major products. However, as opposed to the previous study,¹⁶⁶ the irradiation of nitrenes ³(**35a,b**) with visible light ($\lambda = 444$ nm) was found to give the corresponding azirines **36a,b**. This process is reversible, and the irradiation of azirines **36** with light with $\lambda = 366$ nm leads to their transformation into the corresponding triplet nitrenes **35**.¹⁶⁸

R = F (a), H (b).

In the very recent past, the photolysis of azide **34b** in an argon matrix at 12 K has been more thoroughly studied by IR and electronic absorption spectroscopy combined with quantum chemical calculations.¹⁶⁹ As opposed to the earlier studies,^{166, 168} the interconversions of benzazirine **36b** and ketene imine **37b** were also observed. The complete scheme of the

phototransformations of azide **34b** can be represented as follows.

The formation not only of the corresponding triplet nitrene and ketene imine but also of azirine was observed¹⁷⁰ in the photolysis of *p*-azidoaniline (**38**) in an argon matrix at 12 K. The irradiation of triplet nitrene **39** was found to give not only ketene imine **40** but also azirine **41**, which, in turn, disappears upon irradiation at 313 nm.

Therefore, the photolysis of phenyl azide and a series of its *meta* and *para* derivatives in nitrogen and argon matrices at ~ 10 K affords the corresponding ketene imines in high yield. The latter are, most likely, generated from vibrationally excited singlet nitrene, as well as in the course of the secondary photolysis of the corresponding triplet nitrenes.

The photolysis of phenyl azide derivatives containing two substituents in the *ortho* position (azides **30** and **34a,b**) or a strong electron-donating substituent in the *para* position (azide **38**) gives the corresponding triplet nitrene, $^3(31)$, $^3(35)$ or $^3(39)$, as the only primary photolysis product.^{166–170, 193} This result correlates with a substantial increase in the barrier for the cyclisation of the corresponding singlet nitrenes [$^1(31)$, $^1(35)$ or $^1(39)$] to azirines.^{37, 194} In some cases, azirines (**36a,b** and **41**) were detected. According to calculations,^{37, 177, 194} the barriers for the isomerisation of the latter azirines to the corresponding ketene imines (**37a,b** and **40**) are rather high.

3. Photochemistry of polycyclic aryl azides

As in the case of phenyl azide and its derivatives, the formation of polycyclic aryl nitrenes in the triplet ground state giving characteristic ESR spectra was observed upon irradiation of polycyclic aryl azides in glassy matrices at 77 K.^{60, 195–198} The photochemistry of 1- and 2-naphthyl azides was studied in most detail, including investigations by the matrix isolation technique.^{131, 198, 199}

The photolysis of 2-naphthyl azide (**42**) in solution in the presence of diethylamine affords the corresponding diamino derivative **43** in high yield.²⁰⁰

However, the photolysis of 1-naphthyl azide (**44**) in the presence of DEA gives mainly azanaphthalene²⁰⁰ along with small amounts of 1-aminonaphthalene²⁰⁰ and diamino derivative **45**.²⁰¹ The yield of compound **45** increases as the temperature decreases.²⁰¹

The formation of products **43** and **45** suggests that the corresponding tricyclic azirines are involved as intermediates of the photolysis of azides **42** and **44**. The spectrum of the products recorded in the photolysis ($\lambda > 330$ nm) of these azides in nitrogen and argon matrices at 12 K showed characteristic bands, which can be assigned to the corresponding azirines and ketene imines.¹⁹⁹ In the case of azide **44**, the band that appeared at 1730 cm^{-1} was assigned to tricyclic azirines **46** and(or) **47**. Upon prolonged photolysis, the spectrum showed bands at 1926 and 1912 cm^{-1} assigned to the corresponding dihydroazepines **48** and(or) **49**. Analogously, bands with maxima at 1708 , 1723 and 1736 cm^{-1} were initially observed in the IR spectrum recorded in the photolysis of azide **42**; these bands can be assigned to azirines **50** and(or) **51**. The secondary photolysis was accompanied by the appearance of bands at 1911 and 1923 cm^{-1} assigned to dihydroazepines **52** and(or) **53** (Scheme 3). Unfortunately, it was impossible to make a more precise assignment at that time.

Scheme 3

As mentioned above, the development of more precise methods for calculations of IR and electronic absorption spectra of possible products allowed a more reliable and comprehensive analysis of the results obtained by the matrix isolation technique. Recently, the photolysis of azides **42** and **44** in an argon matrix has been reinvestigated,¹³² and the new assignment of the bands in experimental electronic absorption and IR spectra was carried out based on detailed theoretical calculations. In the experimental IR and electronic absorption spectra, bands of triplet nitrenes **54** and **55**, azirines **46** and **50**, ketene imines **49** and **53** (Figs 15 and 16) and cyclic ylides **56** and **57** were identified.

Detailed calculations of PES, on which interconversions of the species under consideration proceed (see Figs 15 and 16), were performed in the study.¹³² According to the calculations, singlet nitrene ¹(**55**) undergoes cyclisation to form exclusively azirine **46**, whereas nitrene ¹(**54**) gives azirine **50**. Azirines **47** and **51**, being highly energetic, are not formed.

The photolysis of 1- and 2-naphthyl azides with light with $\lambda = 313$ nm initially affords singlet nitrenes ¹(**55**) and ¹(**54**), whose relaxation to the triplet ground state competes with the cyclisation to azirines **46** and **50**. The latter are generated also in the secondary photolysis of triplet nitrenes ³(**55**) and ³(**54**).¹³⁴ The prolonged irradiation of the triplet nitrenes can lead to their transformations into cyclic ketene imines **49** and **53**, respectively, which have been observed earlier.¹⁹⁹

The photolysis of azirines **46** and **50** affords new previously unknown isomers **56** and **57** instead of the expected ketene imines **48** and **52**. These compounds can formally be assigned to cyclic nitrile ylides the existence of which has been predicted.²⁰²

Recently, the photolysis of naphthyl azides has been studied in solution at room temperature by IR spectroscopy with a time resolution of ~ 200 ns and by the laser flash photolysis technique in glassy 3-methylpentane at 77 K.²⁰³ Upon the laser excitation of azide **44** at 77 K, singlet nitrene ¹(**55**) was found, and this compound relaxed to the triplet ground state ³(**55**) with a rate constant of $k_{isc} = (1.1 \pm 0.1) \times 10^7$ s⁻¹. In turn, azirine **46** having a lifetime of 3.2 ± 0.6 μ s in acetonitrile at room temperature was detected by time-resolved IR spectroscopy.²⁰³ The rate constant of the reaction of **46** with DEA was estimated at $\sim 1.4 \times 10^5$ litre mol⁻¹ s⁻¹. The low rate constant is consistent with low yields of diamine **45** in steady-state experiments.

As opposed to the photolysis of azide **44**, no intermediates having absorption at > 320 nm were observed upon the laser excitation of azide **42** in glasses at 77 K. Under steady-state conditions, the formation of triplet nitrene **54** was also not observed. These data are in contradiction with the fact that triplet nitrene **54** was obtained as the major primary photolysis product of azide **42** in an argon matrix.¹³² Two explanations were given for this contradiction.²⁰³ First, nitrene ³(**54**) could be the product of the secondary photolysis of azirine **50** in an argon matrix. According to an alternative hypothesis, $k_R \gg k_{isc}$ for singlet nitrene ¹(**54**) at 77 K, but $k_{isc} \gg k_R$ at 12 K (k_R is the rate constant for the cyclisation of singlet nitrene, and k_{isc} is the rate constant for the intersystem crossing to the triplet ground state). For the fulfillment of these conditions, the barrier for the cyclisation of nitrene ¹(**54**) (E_a)

Figure 15. Relative energies of isomers of 1-naphthyl nitrene and the transition states of their transformations.¹³²

The CASPT2//CASSCF(12,12)/6-31G* calculations relative to the energy of ¹(**55**) (italic) and the B3LYP/6-311 + G(2d,p)//B3LYP/6-31G* calculations relative to the energy of ³(**55**) and taking into account the singlet–triplet splitting for nitrene **55** calculated at the CASPT2 level (normal font). In all cases, the zero-point energy was taken into account. Structure **47** corresponds to the transition state in the DFT calculations and a shallow minimum in the CASSCF calculations.

The CASPT2//CASSCF(12,12)/6-31G* calculations relative to the energy of ¹(54) (italic) and the B3LYP/6-311 + G(2d,p)//B3LYP/6-31G* calculations relative to the energy of ³(54) and taking into account the singlet – triplet splitting for nitrene 54 calculated at the CASPT2 level (normal font). In all cases, the zero-point energy was taken into account.

should be in the range of $1.26 < E_a < 8.80 \text{ kJ mol}^{-1}$, which is consistent with the calculated data (see Fig. 16).¹³²

Azirine **50** was also detected as the photolysis product of 2-naphthyl azide in acetonitrile at room temperature by time-resolved IR spectroscopy. The lifetime of this compound appeared to be substantially longer ($150 \pm 10 \text{ }\mu\text{s}$) than that of azirine **46**, which is consistent with the theoretical calculations (see Figs 15 and 16).²⁰³ The rate constant of the reaction of azirine **50** with DEA ($\sim 2.5 \times 10^5 \text{ litre mol}^{-1} \text{ s}^{-1}$) is almost twice as high as that for azirine **46** ($\sim 1.4 \times 10^5 \text{ litre mol}^{-1} \text{ s}^{-1}$). The substantially higher yield of diamine **43** is attributed to the longer lifetime of azirine **50** compared to azirine **46**.

The photolysis ($\lambda = 308$ and 313 nm) of phenanthren-9-yl azide in an argon matrix has been studied recently,¹⁹⁸ and the corresponding azirine was detected. Under irradiation, the latter (like 1- and 2-naphthyl azides, see Figs 15 and 16) was transformed into the corresponding cyclic ylide. The ESR spectrum of triplet phenanthren-9-yl nitrene was also observed. The following scheme of the phototransformations of this azide was proposed.

Therefore, the difference in the photochemistry of phenyl azide (and its simple derivatives) and polycyclic aryl azides (1- and 2-naphthyl azides, phenanthren-9-yl azide, *etc.*) is associated mainly with the differences in the thermodynamics of the isomerisation of the corresponding singlet aryl nitrenes. As can be seen from the PES for the transformations of singlet phenyl nitrene ¹(29) (and a series of its derivatives),^{35, 37} ketene imine is thermodynamically more favourable than azirine (see Fig. 14, $\Delta H = -10.5 \text{ kJ mol}^{-1}$). This is why ketene imine is involved in the reactions with nucleophiles. The introduction of one more phenyl ring into the molecule substantially stabilises one of isomeric azirines and destabilises another isomer (see Figs 15 and 16). For energy reasons, only one azirine can be formed, the isomerisation of which to the corresponding ketene imine is thermodynamically impossible. As a result, the photolysis of naphthyl azides and some other polycyclic azides in the presence of amines affords the corresponding diamines.^{200, 201}

VI. Reactions of triplet nitrenes with oxygen

As mentioned in Section V.2, triplet aryl nitrenes can react with a CO molecule either upon slight heating of a matrix or under the photochemical conditions.^{166, 167} The present Section deals with reactions of nitrenes in the triplet ground state with

molecular oxygen. For aryl nitrenes, this reaction was studied primarily in glasses at 77 K (Refs 159 and 204–207) and in solutions at room temperature by the flash photolysis technique.^{159, 206–212} The reactions of triplet *p*-aminophenyl nitrene **3**(**39**) with oxygen was studied by the matrix isolation technique.¹⁷⁰ This reaction was studied also for the simplest triplet nitrene ³(NH) in the gas phase^{213, 214} and in xenon and argon matrices.²¹⁵

The NO[•] and HO[•] radicals are generated as the major reaction products of the ³(NH) species with molecular oxygen in the gas phase.^{213, 214} Based on the results of quantum chemical calculations,^{214, 216} it was hypothesised that the primary event affords imine peroxide HNOO; the isomerisation of the latter (the 1,3-hydrogen shift) gives rise to hydroperoxynitrene HOON, which is rapidly decomposes to radicals.

The IR spectrum of imine peroxide and its ¹⁸O-isotopically substituted analogue was recorded in the course of the photolysis of HN₃ followed by heating of an oxygen-containing xenon matrix.²¹⁵ After irradiation of an HN₃–O₂–Xe mixture (in a ratio of 1 : 5 : 550), *cis*- and *trans*-HONO, NH₂OH, N₂H₂ and ³(NH) were obtained. After heating of the preirradiated sample to 50 K followed by cooling to 12 K, a group of lines in the IR spectrum (3132.2, 3120.5 and 3109.8 cm^{–1}) assigned to nitrene ³(NH) completely disappeared and five new intense lines assigned to imine peroxide HNOO appeared.

Analogous results were obtained upon irradiation of HN₃ in an O₂-containing argon matrix. However, in this case, HNOO is formed without heating upon storage of a sample at 12 K for several hours. Based on a comparison of the calculated and experimental IR spectra, it was concluded that only one isomer (most likely, *trans*-HNOO) is formed.²¹⁵ Unfortunately, the electronic absorption spectra were not measured in the study.²¹⁵ However, it is evident that HNOO has absorption in the visible spectral region, because the irradiation with light with 400–600 nm led to the disappearance of peroxide and the appearance of an additional amount of nitrous acid (HONO).

The reaction of triplet aryl nitrenes with oxygen has received much more attention. It has long been believed that the corresponding nitro compounds (ArNO₂) are the major oxygen-containing photolysis products of aryl azides (ArN₃) in the presence of oxygen.^{193, 204, 217–219} Later, the formation of small amounts of nitroso compounds (ArNO)^{220, 221} and azoxy compounds that are formed apparently, by the reaction of triplet aryl nitrenes with ArNO has been documented.^{137, 218}

It was stated²²² that PhNO is the primary photolysis product of phenyl azide in acetonitrile in the presence of oxygen, and only this compound is formed at a low concentration (10^{–4} mol litre^{–1}) of the irradiated solution. Nitrobenzene becomes the major reaction product upon irradiation of a concentrated (~10^{–2} mol litre^{–1}) solution of phenyl azide.²²²

More recently, it has been shown^{159, 206, 207} that the corresponding nitro and nitroso compounds are the primary photolysis products of *p*-amino-, *p*-nitro- and *p*-methylphenyl azides. It should be noted that in these studies, small volumes of solutions containing azides at low concentrations (~10^{–4} mol litre^{–1}) were irradiated, thus excluding the secondary phototransformations of the initially formed products. The photolysis of all azides under study in alkanes affords nitro compounds in higher yields.

In the case of *p*-azidoaniline, the influence of the medium on the ratio of the yields of *p*-nitro- to *p*-nitrosoanilines was investigated, and this ratio was demonstrated to decrease on going from hexane (2.4) to acetonitrile (0.53).^{205, 206} Recently, the kinetics of the consumption of phenyl azide and the accumulation of the photolysis products in acetonitrile (2.5 × 10^{–4} mol litre^{–1}) has been studied.²¹⁰ It was demonstrated that during irradiation of phenyl azide, the concentration of PhNO₂ monotonically increased, and the concentration of PhNO first increased and then decreased virtually to zero, the yield of PhNO being substantially higher than that of PhNO₂ in the initial step of irradiation, as in the irradiation of *p*-azidoaniline.^{206, 207}

Heating of glassy matrices containing triplet aryl nitrenes and dissolved O₂ to temperatures, at which the mobility of the latter substantially increases (90–110 K), affords diamagnetic adducts giving an intense absorption band in the near-UV or visible spectral region.^{159, 204–207} The structures of aryl nitroso oxides were assigned to these adducts.

In the pioneering study,²⁰⁴ emphasis was given to diazide **58**, photolysis of which can afford triplet nitrene **3**(**59**) and dinitrene **3**(**60**). Upon prolonged storage of the irradiated sample, both diamagnetic and paramagnetic products were obtained, and both these products were assigned to adducts of mononitrene **3**(**59**) with oxygen. In the study,²⁰⁴ based on the fact that the intensity of the ESR spectrum assigned to dinitrene **60** remains unchanged, it was stated that dinitrene does not react with O₂. However, the accuracy of the ESR method is low. Hence, these results cannot completely exclude the formation of adducts **61** and **62**, among which paramagnetic compounds can be present (Scheme 4).

Although the assignment of the paramagnetic species to the adduct of mononitrene **59** with oxygen was erroneous,²⁰⁴ it has long been commonly accepted that the reaction of triplet aryl nitrenes produces both diamagnetic aryl nitroso oxides and paramagnetic aryliminodioxo biradicals.

Recently, the reaction of triplet *p*-aminophenyl nitrene **3**(**39**) with oxygen in a matrix consisting of 86% argon, 10% N₂ and 4% O₂ has been studied.¹⁷⁰ The irradiation of azide **38** in this matrix with light with λ = 254 nm, as well as in the absence of O₂, gave triplet nitrene **39** (Fig. 17, spectrum 1). After slow heating of the matrix to 30 K followed by the storage at this temperature for 5 min and the subsequent cooling to 12 K, the intensity of the bands of nitrene **3**(**39**) in the electronic absorption spectrum slightly decreased, a band characteristic of aryl nitroso oxides appeared in the visible spectral region at λ_{max} = 445 nm (Fig. 17, spectrum 2), and

Scheme 4

Figure 17. Difference electronic absorption spectra recorded in an argon matrix containing 4% O₂ at 12 K after irradiation of azide **38** with light at $\lambda = 254$ nm (*1*), after annealing of a sample at 30 K (*2*) and after irradiation with light at $\lambda > 515$ nm for 5 min (*3*).¹⁷⁰

Figure 18. IR difference spectra recorded after annealing of a preirradiated sample of azide **38** at 30 K (*1*) and after irradiation with light at $\lambda > 515$ nm for 5 min (*2*).¹⁷⁰ The signals of *p*-nitroaniline are marked with asterisks.

the IR spectrum showed a series of new bands (Fig. 18, spectrum *1*). It should be noted that the reaction of nitrene **3**(**39**) with oxygen has been studied earlier in a glassy mixture of tetrahydrofuran and toluene (1 : 1) at 95 K; the formation of the adduct giving a band at $\lambda_{\text{max}} = 495$ nm was observed.^{207, 208}

The irradiation of a sample with visible light ($\lambda > 515$ nm) leads to the disappearance of the absorption band of nitroso oxide **63** and the appearance of a new band in the near-UV region at $\lambda_{\text{max}} = 326$ nm (Fig. 17, spectrum *3*) and a series of bands in the IR spectrum (Fig. 18, spectrum *2*), which are identical to the bands in the IR spectrum of *p*-nitroaniline (**64**) (marked with asterisks in Fig. 18).

It appeared¹⁷⁰ that two isomers of nitroso oxide (*cis*- and *trans*-**63**) are formed. One of them disappears after irradiation for 30 s ($\lambda > 515$ nm) being transformed into *p*-nitroaniline. This isomer is characterised by a long-wavelength band at $\lambda_{\text{max}} = 460$ nm (Fig. 19, spectrum *1*) and a series of bands in the IR spectrum (Fig. 20, spectrum *1*, the negative differential

Figure 19. Difference electronic absorption spectra recorded in an argon matrix at 12 K after irradiation of the adduct of triplet nitrene **39** with O₂ with light at $\lambda > 515$ nm for 30 s (*1*) and after additional irradiation for 5 min (*2*).

The positions and relative intensities of electron transitions in the spectrum of the *trans* isomer of nitroso oxide **63** (black bars) and its *cis* isomer (gray bars) calculated at the CASSCF/CASPT2 level with the geometry optimised at the CASSCF level¹⁷⁰ are indicated by vertical bars.

absorption). Another isomer, the absorption spectrum of which is shifted to shorter wavelengths ($\lambda_{\text{max}} = 425$ nm), is also transformed into *p*-nitroaniline upon further irradiation (see Figs 19 and 20, difference spectra *2*).¹⁷⁰

The validity of the assignment of the adducts of nitrene **3**(**39**) with oxygen to the *cis* and *trans* isomers of nitroso oxide **63** was confirmed by a good agreement between the experimental and calculated electronic absorption spectra (see Fig. 19) and IR spectra (see Fig. 20). The agreement between the calculated and experimental electronic absorption spectra is much poorer when the geometry calculated by the density functional theory is used.¹⁷⁰ The agreement between the IR spectra calculated by the DFT method and the experimental spectra of the *cis* and *trans* isomers of nitroso oxide **63** is

Figure 20. IR difference spectra recorded in an argon matrix at 12 K after irradiation of the adduct of triplet nitrene **39** with O₂ with light at $\lambda > 515$ nm for 30 s (*1*) and after additional irradiation for 5 min (*2*). IR spectra of the *cis* isomer of nitroso oxide **63** (*3*) and its *trans* isomer (*4*) calculated at the B3LYP/6-31G* level (the correction factor is 0.9614).¹⁷⁰

satisfactory (see Fig. 20) but it is noticeably poorer than that for triplet nitrene **39**. Hence, it is incorrect to describe nitroso oxides by single-determinant wavefunctions. For example, the contribution of the ground state configuration to the wave function of the *cis* and *trans* isomers of nitroso oxide **63** estimated at the CASSCF level of theory is $\sim 82\%$, and the contribution of the doubly excited configurations is $\sim 18\%$.¹⁷⁰

However, the population numbers of the CASSCF natural orbitals only slightly differ from 0 and 2 (the largest deviation is 0.13 for HOMO and LUMO), and this fact contradicts the statement^{220, 221, 223} that arylnitroso oxides are essentially biradical in character.

The use of low-intensity monochromatic radiation allows the observation of interconversions of the *cis* and *trans* isomers of compound **63** along with their transformation into *p*-nitroaniline (Scheme 5).

Scheme 5

It is commonly accepted^{2204, 210, 212, 220, 221, 224, 225} that the photolysis of arylnitroso oxides (ArNOO) affords cyclic dioxaziridines **65**, which are transformed into nitro compounds through the ring opening. Actually, intermediate species were observed²²⁴ in the photolysis of a series of nitroso oxides of stilbene and *p*-biphenyl in glassy tetrahydrofuran at 77 K. These species were transformed into the corresponding nitro derivatives in the dark at a rate constant of $3 \times 10^{-3} \text{ s}^{-1}$. It was hypothesised that these species can be assigned to the corresponding dioxaziridines **65**. Unfortunately, we failed to detect intermediate species in the photolysis of nitroso oxide **63**.¹⁷⁰

The formation of nitroso oxides in cryogenic matrices is evidence for a low activation energy of the reaction of triplet nitrenes with molecular oxygen. The rate constants for this reaction were measured for triplet phenylnitrene,²¹⁰ a series of its derivatives^{159, 206, 207} and pyren-1-yl nitrene.¹⁹³ It appeared that the rate constant is substantially lower than the diffusion limit and is in a range of $(0.8-8) \times 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$ for all aryl nitrenes under study. For phenylnitrene, the temperature dependence of the rate constant was studied and the activation parameters were estimated ($A = 10^{9.6 \pm 0.4} \text{ litre mol}^{-1} \text{ s}^{-1}$ and $E_a = 18 \pm 2 \text{ kJ mol}^{-1}$).²¹⁰

Numerous attempts were made to calculate the thermodynamics of the reaction of triplet nitrenes with oxygen.^{170, 207, 216, 224-226} The results obtained^{170, 226} with the use of the CBS-QB3 approach, which is one of the most accurate multi-level techniques, are presented in Fig. 21. According to

Figure 21. Relative enthalpies (at 0 K) of species involved in the formation and transformations of phenyl- (**1**, X = H) and *p*-aminophenyl nitroso oxides (**2**, X = NH₂) calculated by the CBS-QB3 method.^{170, 226}

the Wigner rule, the reaction of triplet nitrene with a triplet oxygen molecule can, in principle, produce nitroso oxide both in the singlet and triplet states. The reaction giving nitroso oxides in the triplet state is virtually thermoneutral and, according to calculations,²²⁶ its activation energy is rather high ($45-55 \text{ kJ mol}^{-1}$). The reaction producing arylnitroso oxides in the singlet ground state is exothermic ($\Delta H \approx -80 \text{ kJ mol}^{-1}$). However, the transition state on the singlet PES was not located.²²⁶

The mechanism of the transformation of arylnitroso oxides into the final nitro and nitro compounds remains obscure. Only in the case of arylnitroso oxide **63**, the flash photolysis study showed that the decay kinetics of this compound is described by the second-order reaction with a rate constant close to the diffusion limit.^{206, 208} The electronic absorption spectrum of the intermediate, the precursor of the final products (ArNO and ArNO₂), was recorded, and the structure of dimeric peroxide **66** was assigned to this intermediate. The formation of the final nitro and nitroso compounds from this intermediate can easily be conceived.

The decay kinetics of all other nitroso oxides under study (PhNOO and its *p*-Me, *p*-NO₂, *p*-Br, *p*-OMe and *p*-NMe₂ derivatives) is not described by the second-order reaction and is either exponential or biexponential.^{159, 207, 209-212} The biexponential character of the decay kinetic curves is associated with the formation of the *cis* and *trans* isomers of arylnitroso oxides having different reactivities.^{211, 212}

It was hypothesised that thermal transformations of arylnitroso oxides (like photochemical transformations) proceed through the formation of intermediate dioxaziridine **65**.^{209-214, 225} However, this reaction cannot explain the for-

mation of ArNO. The assumption of the possible formation of ArNO in the reaction of aryl azide in the triplet excited state $^3(\text{ArN}_3)^*$ with oxygen is invalid because the dissociation of the azido group in the singlet excited state of aryl azides proceeds on a hundred femtosecond time scale.^{152–155} The intersystem crossing to the triplet state cannot proceed on such a short time scale.

The possibility of the formation of ArNO in the reaction with solvents cannot be ruled out. For example, the irradiation of phenyl azide in the presence of O₂ in acetonitrile with 10% benzene additive was found^{220, 221} to give phenol in 15% yield. The irradiation of phenyl azide in acetonitrile in the presence of 10% toluene afforded kresol (in 12% yield) and benzaldehyde (in 5% yield). The addition of cyclohexane to the solution resulted in the isolation of cyclohexanone (5%) and cyclohexanol (17%).

Thus, both the simplest triplet nitrene $^3(\text{NH})$ and triplet aryl nitrenes react with molecular oxygen in cryogenic matrices to form the corresponding nitroso oxides. In the case of imino peroxide HNOO, only the *trans* isomer was detected, whereas the formation of both the *cis* and *trans* isomers was observed for aryl nitroso oxides. Nitrous acid (HONO) is formed in the course of photolysis of imino peroxide HNOO. Upon irradiation of aryl nitroso oxides (ArNOO), the reversible *cis*–*trans* isomerisation and the irreversible transformation into the nitro compounds (ArNO₂) were observed. The formation of intermediates, viz., dioxaziridines, in the course of photolysis was not reliably confirmed. The mechanism of dark transformations of aryl nitroso oxides into the final nitro and nitroso compounds was not ultimately established as well.

VII. Conclusion

Before the modern physicochemical methods were developed, knowledge about intermediate species could be obtained solely based on the analysis of the reaction products. Only in the mid-20th century, when two powerful tools of investigation (the flash photolysis and matrix isolation techniques) were devised, the direct observation and studies of the properties of the reaction intermediates became possible. Considerable progress has been achieved in the development of the flash photolysis techniques allowing experiments to be performed with femtosecond and even attosecond time resolution. Although the progress in the matrix isolation techniques is less impressive, it remains one of the main methods of obtaining the most complete spectroscopic information on the reaction intermediates, which allows their reliable identification. The matrix isolation technique is particularly promising in combination with IR spectroscopy of intermediates, because well-resolved IR spectra with a linewidth of $\sim 1 \text{ cm}^{-1}$ can be recorded in a very wide spectral range in inert gas matrices at very low temperatures ($\sim 10 \text{ K}$). In the last decade, the procedure of the assignment of bands in the experimental electronic absorption and IR spectra of intermediates has been substantially simplified and it has become more reliable due to the development of rather precise theoretical calculation methods.

Investigations of the photolysis of azides by the matrix isolation technique made a considerable contribution to the elucidation of the rather complex mechanism of this important photochemical reaction. For example, the detection of ketene imine in the course of photolysis of phenyl azide in an argon matrix had a considerable effect on the interpretation of the results obtained by alternative methods, including the flash photolysis technique. The hypothesis about the possibility of the formation and isomerisation of singlet aryl nitrenes in the vibrationally excited state, which has been made for the first time to interpret the results obtained in cryogenic matrices, has been confirmed very recently in femtosecond studies.^{151–155} In very recent years, the use of the matrix isolation technique

combined with high-level quantum chemical calculations allowed the elucidation of the unusual nature of singlet acyl nitrenes,^{38–40} which are promising for the photoaffinity labelling of biopolymers, and provided an insight into the detailed mechanism of photolysis of polycyclic aryl azides.¹³²

My studies included in the present review were carried out with the financial support of the Russian Foundation for Basic Research (Project Nos 95-03-08920, 98-03-32021 and 01-03-32864), the Ministry of Education of the Russian Federation (Grant E02-5.0-27), the Division of Chemistry and Materials Science of the Russian Academy of Sciences, the US National Science Foundation (Grants CHE-8814950 and CHE-9613861) and the Swiss National Science Foundation (SCOPES2000, Grant No. 7SUPJ062336).
